## Getting Started

## 1

Product Description ..... 1-2
Key Features ..... 1-2
Organizing Data
Create Categorical Arrays ..... 2-3
Create Nominal Arrays ..... 2-3
Create Ordinal Arrays ..... 2-5
Change Category Labels ..... 2-8
Reorder Category Levels ..... 2-10
Reorder Category Levels in Ordinal Arrays ..... 2-10
Reorder Category Levels in Nominal Arrays ..... 2-11
Categorize Numeric Data ..... 2-15
Merge Category Levels ..... 2-18
Add and Drop Category Levels ..... 2-20
Plot Data Grouped by Category ..... 2-24
Test Differences Between Category Means ..... 2-28
Summary Statistics Grouped by Category ..... 2-37
2
Sort Ordinal Arrays ..... 2-39
Categorical Arrays ..... 2-41
What Are Categorical Arrays? ..... 2-41
Categorical Array Conversion ..... 2-41
Advantages of Using Categorical Arrays ..... 2-43
Manipulate Category Levels ..... 2-43
Analysis Using Categorical Arrays ..... 2-43
Reduce Memory Requirements ..... 2-44
Index and Search Using Categorical Arrays ..... 2-46
Grouping Variables ..... 2-51
What Are Grouping Variables? ..... 2-51
Group Definition ..... 2-52
Analysis Using Grouping Variables ..... 2-52
Missing Group Values ..... 2-53
Dummy Indicator Variables ..... 2-55
What Are Dummy Variables? ..... 2-55
Creating Dummy Variables ..... 2-56
Regression with Categorical Covariates ..... 2-59
Create a Dataset Array from Workspace Variables ..... 2-65
Create a Dataset Array from a Numeric Array ..... 2-65
Create Dataset Array from Heterogeneous Workspace Variables ..... 2-68
Create a Dataset Array from a File ..... 2-71
Create a Dataset Array from a Tab-Delimited Text File ..... 2-71
Create a Dataset Array from a Comma-Separated Text File ..... 2-74
Create a Dataset Array from an Excel File ..... 2-77
Add and Delete Observations ..... 2-79
Add and Delete Variables ..... 2-83
Access Data in Dataset Array Variables ..... 2-87
Select Subsets of Observations ..... 2-93
Sort Observations in Dataset Arrays ..... 2-97
Merge Dataset Arrays ..... 2-101
Stack or Unstack Dataset Arrays ..... 2-106
Calculations on Dataset Arrays ..... 2-111
Export Dataset Arrays ..... 2-115
Clean Messy and Missing Data ..... 2-117
Dataset Arrays in the Variables Editor ..... 2-122
Open Dataset Arrays in the Variables Editor ..... 2-122
Modify Variable and Observation Names ..... 2-123
Reorder or Delete Variables ..... 2-125
Add New Data ..... 2-127
Sort Observations ..... 2-129
Select a Subset of Data ..... 2-130
Create Plots ..... 2-133
Dataset Arrays ..... 2-135
What Are Dataset Arrays? ..... 2-135
Dataset Array Conversion ..... 2-135
Dataset Array Properties ..... 2-136
Index and Search Dataset Arrays ..... 2-138
Descriptive Statistics
3
Introduction to Descriptive Statistics ..... 3-2
Measures of Central Tendency ..... 3-3
Measures of Dispersion ..... 3-5
Quantiles and Percentiles ..... 3-7
Exploratory Analysis of Data ..... 3-11
Resampling Statistics ..... 3-16
Bootstrap ..... 3-16
Jackknife ..... 3-19
Parallel Computing Support for Resampling Methods ..... 3-20
Data with Missing Values ..... 3-21
Statistical Visualization
4
Introduction to Statistical Visualization ..... 4-2
Scatter Plots ..... 4-3
Box Plots ..... 4-6
Distribution Plots ..... 4-8
Normal Probability Plots ..... 4-8
Quantile-Quantile Plots ..... 4-10
Cumulative Distribution Plots ..... 4-12
Other Probability Plots ..... 4-14
Using Probability Distributions ..... 5-2
Supported Distributions ..... 5-3
Parametric Distributions ..... 5-4
Nonparametric Distributions ..... 5-9
Working with Distributions Through GUIs ..... 5-10
Exploring Distributions ..... 5-10
Modeling Data Using the Distribution Fitting Tool ..... 5-12
Custom Distributions Using Distribution Fitting Tool ..... 5-49
Visually Exploring Random Number Generation ..... 5-50
Statistics Toolbox Distribution Functions ..... 5-53
Probability Density Functions ..... 5-53
Cumulative Distribution Functions ..... 5-63
Inverse Cumulative Distribution Functions ..... 5-67
Distribution Statistics Functions ..... 5-69
Distribution Fitting Functions ..... 5-71
Negative Log-Likelihood Functions ..... 5-78
Random Number Generators ..... 5-81
Using Probability Distribution Objects ..... 5-85
Using Distribution Objects ..... 5-85
What are Objects? ..... 5-86
Creating Distribution Objects ..... 5-89
Object-Supported Distributions ..... 5-90
Performing Calculations Using Distribution Objects ..... 5-91
Capturing Results Using Distribution Objects ..... 5-98
Probability Distributions Used for Multivariate Modeling ..... 5-100
Gaussian Mixture Models ..... 5-100
Copulas: Generate Correlated Samples ..... 5-108

## Random Number Generation

## 6

Generating Random Data ..... 6-2
Random Number Generation Functions ..... 6-3
Common Generation Methods ..... 6-5
Direct Methods ..... 6-5
Inversion Methods ..... 6-7
Acceptance-Rejection Methods ..... 6-9
Representing Sampling Distributions Using Markov Chain Samplers ..... 6-13
Using the Metropolis-Hastings Algorithm ..... 6-13
Using Slice Sampling ..... 6-14
Generating Quasi-Random Numbers ..... 6-15
Quasi-Random Sequences ..... 6-15
Quasi-Random Point Sets ..... 6-16
Quasi-Random Streams ..... 6-23
Generating Data Using Flexible Families of Distributions ..... 6-25
Pearson and Johnson Systems ..... 6-25
Generating Data Using the Pearson System ..... 6-26
Generating Data Using the Johnson System ..... 6-28
Hypothesis Tests
7
Introduction to Hypothesis Tests ..... 7-2
Hypothesis Test Terminology ..... 7-3
Hypothesis Test Assumptions ..... 7-5
Hypothesis Testing ..... 7-7
Available Hypothesis Tests ..... 7-13
Analysis of Variance
8
Introduction to Analysis of Variance ..... 8-2
ANOVA ..... 8-3
One-Way ANOVA ..... 8-3
Two-Way ANOVA ..... 8-9
N-Way ANOVA ..... 8-12
Other ANOVA Models ..... 8-26
Analysis of Covariance ..... 8-27
Nonparametric Methods ..... 8-35
MANOVA ..... 8-39
Introduction to MANOVA ..... 8-39
ANOVA with Multiple Responses ..... 8-39
Parametric Regression Analysis
9
Parametric Regression Analysis ..... 9-2
What Is Parametric Regression? ..... 9-2
Choose a Regression Function ..... 9-2
Update Legacy Code with New Fitting Methods ..... 9-3
What Are Linear Regression Models? ..... 9-7
Linear Regression ..... 9-11
Prepare Data ..... 9-11
Choose a Fitting Method ..... 9-13
Choose a Model or Range of Models ..... 9-14
Fit Model to Data ..... 9-20
Examine Quality and Adjust the Fitted Model ..... 9-20
Predict or Simulate Responses to New Data ..... 9-39
Share Fitted Models ..... 9-42
Linear Regression Workflow ..... 9-43
Regression Using Dataset Arrays ..... 9-50
Linear Regression with Interaction Effects ..... 9-53
Interpret Linear Regression Results ..... 9-63
Linear Regression Output and Diagnostic Statistics ..... 9-71
Summary of Measures ..... 9-71
Cook's Distance ..... 9-72
Coefficient Confidence Intervals ..... 9-75
Coefficient Covariance ..... 9-77
Coefficient of Determination (R-Squared) ..... 9-78
Delete-1 Change in Covariance (covratio) ..... 9-81
Delete-1 Scaled Difference in Coefficient Estimates (Dfbetas) ..... 9-84
Delete-1 Scaled Change in Fitted Values (Dffits) ..... 9-86
Delete-1 Variance (S2_i) ..... 9-88
Durbin-Watson Test ..... 9-90
F-statistic ..... 9-92
Hat Matrix ..... 9-95
Leverage ..... 9-96
Residuals ..... 9-99
t-statistic ..... 9-107
Stepwise Regression ..... 9-111
Stepwise Regression to Select Appropriate Models ..... 9-111
Compare large and small stepwise models ..... 9-111
Robust Regression - Reduce Outlier Effects ..... 9-116
What Is Robust Regression? ..... 9-116
Robust Regression versus Standard Least-Squares Fit ..... 9-116
Ridge Regression ..... 9-119
Introduction to Ridge Regression ..... 9-119
Ridge Regression ..... 9-119
Lasso and Elastic Net ..... 9-123
What Are Lasso and Elastic Net? ..... 9-123
Lasso Regularization ..... 9-123
Lasso and Elastic Net with Cross Validation ..... 9-126
Wide Data via Lasso and Parallel Computing ..... 9-129
Lasso and Elastic Net Details ..... 9-134
References ..... 9-136
Partial Least Squares ..... 9-137
Introduction to Partial Least Squares ..... 9-137
Partial Least Squares ..... 9-138
Generalized Linear Models ..... 9-143
What Are Generalized Linear Models? ..... 9-143
Prepare Data ..... 9-144
Choose Generalized Linear Model and Link Function ..... 9-146
Choose Fitting Method and Model ..... 9-150
Fit Model to Data ..... 9-155
Examine Quality and Adjust the Fitted Model ..... 9-156
Predict or Simulate Responses to New Data ..... 9-168
Share Fitted Models ..... 9-171
Generalized Linear Model Workflow ..... 9-173
Lasso Regularization of Generalized Linear Models ..... 9-178
What is Generalized Linear Model Lasso Regularization? ..... 9-178
Regularize Poisson Regression ..... 9-178
Regularize Logistic Regression ..... 9-182
Regularize Wide Data in Parallel ..... 9-189
Generalized Linear Model Lasso and Elastic Net ..... 9-195
References ..... 9-197
Nonlinear Regression ..... 9-198
What Are Parametric Nonlinear Regression Models? ..... 9-198
Prepare Data ..... 9-199
Represent the Nonlinear Model ..... 9-200
Choose Initial Vector beta0 ..... 9-203
Fit Nonlinear Model to Data ..... 9-203
Examine Quality and Adjust the Fitted Model ..... 9-204
Predict or Simulate Responses to New Data ..... 9-208
Nonlinear Regression Workflow ..... 9-212
Mixed-Effects Models ..... 9-219
Introduction to Mixed-Effects Models ..... 9-219
Mixed-Effects Model Hierarchy ..... 9-220
Specifying Mixed-Effects Models ..... 9-221
Specifying Covariate Models ..... 9-224
Choosing nlmefit or nlmefitsa ..... 9-226
Using Output Functions with Mixed-Effects Models ..... 9-229
Mixed-Effects Models Using nlmefit and nlmefitsa ..... 9-234
Examining Residuals for Model Verification ..... 9-249
Pitfalls in Fitting Nonlinear Models by Transforming to Linearity ..... 9-255
Generalized Linear Models
10
Multinomial Models for Nominal Responses ..... 10-2
Multinomial Models for Ordinal Responses ..... 10-5
Hierarchical Multinomial Models ..... 10-9
Survival Analysis
11
What Is Survival Analysis? ..... 11-2
Introduction ..... 11-2
Censoring ..... 11-2
Data ..... 11-3
Survivor Function ..... 11-5
Hazard Function ..... 11-7
Kaplan-Meier Method ..... 11-11
Hazard and Survivor Functions for Different Groups ..... 11-19
Survivor Functions for Two Groups ..... 11-26
Cox Proportional Hazards Regression ..... 11-31
Cox Proportional Hazards Model for Censored Data ..... 11-34
Multivariate Methods
12
Introduction to Multivariate Methods ..... 12-2
Multivariate Linear Regression ..... 12-3
Multivariate Linear Regression Model ..... 12-3
Solving Multivariate Regression Problems ..... 12-4
Estimation of Multivariate Regression Models ..... 12-6
Least Squares Estimation ..... 12-6
Maximum Likelihood Estimation ..... 12-10
Missing Response Data ..... 12-12
Set Up Multivariate Regression Problems ..... 12-16
Response Matrix ..... 12-16
Design Matrices ..... 12-21
Common Multivariate Regression Problems ..... 12-22
Multivariate General Linear Model ..... 12-30
Fixed Effects Panel Model with Concurrent Correlation ..... 12-35
Longitudinal Analysis ..... 12-43
Multidimensional Scaling ..... 12-50
Introduction to Multidimensional Scaling ..... 12-50
Classical Multidimensional Scaling ..... 12-50
Nonclassical Multidimensional Scaling ..... 12-55
Nonmetric Multidimensional Scaling ..... 12-57
Procrustes Analysis ..... 12-61
Compare Landmark Data ..... 12-61
Data Input ..... 12-61
Preprocess Data for Accurate Results ..... 12-62
Compare Handwritten Shapes ..... 12-63
Feature Selection ..... 12-70
Introduction to Feature Selection ..... 12-70
Sequential Feature Selection ..... 12-70
Feature Transformation ..... 12-75
Introduction to Feature Transformation ..... 12-75
Nonnegative Matrix Factorization ..... 12-75
Principal Component Analysis (PCA) ..... 12-78
Quality of Life in U.S. Cities ..... 12-80
Factor Analysis ..... 12-92
Partial Least Squares Regression and Principal Components Regression ..... 12-102
Cluster Analysis
13
Introduction to Cluster Analysis ..... 13-2
Hierarchical Clustering ..... 13-3
Introduction to Hierarchical Clustering ..... 13-3
Algorithm Description ..... 13-3
Similarity Measures ..... 13-4
Linkages ..... 13-6
Dendrograms ..... 13-8
Verify the Cluster Tree ..... 13-10
Create Clusters ..... 13-16
k-Means Clustering ..... 13-21
Introduction to k-Means Clustering ..... 13-21
Create Clusters and Determine Separation ..... 13-22
Determine the Correct Number of Clusters ..... 13-23
Avoid Local Minima ..... 13-26
Gaussian Mixture Models ..... 13-28
Introduction to Gaussian Mixture Models ..... 13-28
Cluster with Gaussian Mixtures ..... 13-28
Parametric Classification
14
Parametric Classification ..... 14-2
Discriminant Analysis ..... 14-3
What Is Discriminant Analysis? ..... 14-3
Create Discriminant Analysis Classifiers ..... 14-3
Creating a Classifier Using ClassificationDiscriminant.fit ..... 14-4
How the predict Method Classifies ..... 14-6
Create and Visualize a Discriminant Analysis Classifier ..... 14-9
Improve a Discriminant Analysis Classifier ..... 14-14
Regularize a Discriminant Analysis Classifier ..... 14-22
Examine the Gaussian Mixture Assumption ..... 14-29
Bibliography ..... 14-35
Naive Bayes Classification ..... 14-36
Supported Distributions ..... 14-36
Performance Curves ..... 14-39
Introduction to Performance Curves ..... 14-39
What are ROC Curves? ..... 14-39
Evaluate Classifier Performance Using perfcurve ..... 14-39
Supervised Learning (Machine Learning) Workflow and Algorithms ..... 15-2
Steps in Supervised Learning (Machine Learning) ..... 15-2
Characteristics of Algorithms ..... 15-7
Classification Using Nearest Neighbors ..... 15-9
Pairwise Distance ..... 15-9
$k$-Nearest Neighbor Search and Radius Search ..... 15-12
$K$-Nearest Neighbor Classification for Supervised Learning ..... 15-25
Construct a KNN Classifier ..... 15-25
Examine the Quality of a KNN Classifier ..... 15-26
Predict Classification Based on a KNN Classifier ..... 15-27
Modify a KNN Classifier ..... 15-27
Classification Trees and Regression Trees ..... 15-30
What Are Classification Trees and Regression Trees? ..... 15-30
Creating a Classification Tree ..... 15-31
Creating a Regression Tree ..... 15-31
Viewing a Tree ..... 15-32
How the Fit Methods Create Trees ..... 15-35
Predicting Responses With Classification and Regression Trees ..... 15-37
Improving Classification Trees and Regression Trees ..... 15-37
Alternative: classregtree ..... 15-47
Splitting Categorical Predictors ..... 15-55
Challenges in Splitting Multilevel Predictors ..... 15-55
Pull Left By Purity ..... 15-56
Principle Component-Based Partitioning ..... 15-56
One Versus All By Class ..... 15-57
Ensemble Methods ..... 15-58
Framework for Ensemble Learning ..... 15-58
Basic Ensemble Examples ..... 15-68
Test Ensemble Quality ..... 15-70
Classification with Imbalanced Data ..... 15-76
Classification: Imbalanced Data or Unequal Misclassification Costs ..... 15-82
Classification with Many Categorical Levels ..... 15-90
Surrogate Splits ..... 15-94
LPBoost and TotalBoost for Small Ensembles ..... 15-97
Ensemble Regularization ..... 15-102
Tuning RobustBoost ..... 15-114
Random Subspace Classification ..... 15-118
TreeBagger Examples ..... 15-124
Ensemble Algorithms ..... 15-145
Support Vector Machines (SVM) ..... 15-161
Understanding Support Vector Machines ..... 15-161
Using Support Vector Machines ..... 15-167
Nonlinear Classifier with Gaussian Kernel ..... 15-169
SVM Classification with Cross Validation ..... 15-173
Bibliography ..... 15-182
Markov Models
16
Introduction to Markov Models ..... 16-2
Markov Chains ..... 16-3
Hidden Markov Models (HMM) ..... 16-5
Introduction to Hidden Markov Models (HMM) ..... 16-5
Analyzing Hidden Markov Models ..... 16-7
Design of Experiments
17
Design of Experiments ..... 17-2
Full Factorial Designs ..... 17-3
Multilevel Designs ..... 17-3
Two-Level Designs ..... 17-4
Fractional Factorial Designs ..... 17-5
Introduction to Fractional Factorial Designs ..... 17-5
Plackett-Burman Designs ..... 17-5
General Fractional Designs ..... 17-6
Response Surface Designs ..... 17-9
Introduction to Response Surface Designs ..... 17-9
Central Composite Designs ..... 17-9
Box-Behnken Designs ..... 17-13
D-Optimal Designs ..... 17-15
Introduction to D-Optimal Designs ..... 17-15
Generate D-Optimal Designs ..... 17-16
Augment D-Optimal Designs ..... 17-19
Specify Fixed Covariate Factors ..... 17-20
Specify Categorical Factors ..... 17-21
Specify Candidate Sets ..... 17-21
Statistical Process Control
18
Introduction to Statistical Process Control ..... 18-2
Control Charts ..... 18-3
Capability Studies ..... 18-6
Quick Start Parallel Computing for Statistics Toolbox ..... 19-2
What Is Parallel Statistics Functionality? ..... 19-2
How To Compute in Parallel ..... 19-3
Parallel Treebagger ..... 19-5
Concepts of Parallel Computing in Statistics Toolbox ..... 19-7
Subtleties in Parallel Computing ..... 19-7
Vocabulary for Parallel Computation ..... 19-7
When to Run Statistical Functions in Parallel ..... 19-8
Why Run in Parallel? ..... 19-8
Factors Affecting Speed ..... 19-8
Factors Affecting Results ..... 19-9
Working with parfor ..... 19-10
How Statistical Functions Use parfor ..... 19-10
Characteristics of parfor ..... 19-11
Reproducibility in Parallel Statistical Computations ..... 19-13
Issues and Considerations in Reproducing Parallel Computations ..... 19-13
Running Reproducible Parallel Computations ..... 19-14
Parallel Statistical Computation Using Random Numbers ..... 19-15
Examples of Parallel Statistical Functions ..... 19-19
Parallel Jackknife ..... 19-19
Parallel Cross Validation ..... 19-20
Parallel Bootstrap ..... 19-21

## Functions - Alphabetical List

Burr Type XII Distribution ..... B-12
Definition ..... B-12
Background ..... B-13
Parameters ..... B-14
Fit a Burr Distribution and Draw the cdf ..... B-15
Compare Lognormal and Burr pdfs ..... B-17
Burr pdf for Various Parameters ..... B-19
Survival and Hazard Functions of Burr Distribution ..... B-20
Divergence of Parameter Estimates ..... B-22
See Also ..... B-24
Chi-Square Distribution ..... B-25
Definition ..... B-25
Background ..... B-25
Example ..... B-26
See Also ..... B-26
Copulas ..... B-27
Custom Distributions ..... B-28
Exponential Distribution ..... B-29
Definition ..... B-29
Background ..... B-29
Parameters ..... B-29
Example ..... B-30
See Also ..... B-31
Extreme Value Distribution ..... B-32
Definition ..... B-32
Background ..... B-32
Parameters ..... B-34
Example ..... B-35
See Also ..... B-37
F Distribution ..... B-38
Definition ..... B-38
Background ..... B-38
Example ..... B-39
See Also ..... B-39
Gamma Distribution ..... B-40
Definition ..... B-40
Background ..... B-40
Parameters ..... B-41
Example ..... B-42
See Also ..... B-42
Gaussian Distribution ..... B-43
Gaussian Mixture Distributions ..... B-44
Generalized Extreme Value Distribution ..... B-45
Definition ..... B-45
Background ..... B-45
Parameters ..... B-46
Example ..... B-47
See Also ..... B-49
Generalized Pareto Distribution ..... B-50
Definition ..... B-50
Background ..... B-50
Parameters ..... B-51
Example ..... B-52
See Also ..... B-53
Geometric Distribution ..... B-54
Definition ..... B-54
Background ..... B-54
Example ..... B-54
See Also ..... B-55
Hypergeometric Distribution ..... B-56
Definition ..... B-56
Background ..... B-56
Example ..... B-57
See Also ..... B-57
Inverse Gaussian Distribution ..... B-58
Definition ..... B-58
Background ..... B-58
Parameters ..... B-58
See Also ..... B-58
Inverse Wishart Distribution ..... B-59
Definition ..... B-59
Background ..... B-59
Example ..... B-59
See Also ..... B-60
Johnson System ..... B-61
Logistic Distribution ..... B-62
Definition ..... B-62
Background ..... B-62
Parameters ..... B-62
See Also ..... B-62
Loglogistic Distribution ..... B-63
Definition ..... B-63
Parameters ..... B-63
See Also ..... B-63
Lognormal Distribution ..... B-64
Definition ..... B-64
Background ..... B-64
Example ..... B-65
See Also ..... B-66
Multinomial Distribution ..... B-67
Definition ..... B-67
Background ..... B-67
Example ..... B-67

## Getting Started

## Product Description <br> Perform statistical modeling and analysis

Statistics Toolbox ${ }^{\mathrm{TM}}$ provides algorithms and tools for organizing, analyzing, and modeling data. You can use regression or classification for predictive modeling, generate random numbers for Monte Carlo simulations, use statistical plots for exploratory data analysis, and perform hypothesis tests.

For analyzing multidimensional data, Statistics Toolbox includes algorithms that let you identify key variables that impact your model with sequential feature selection, transform your data with principal component analysis, apply regularization and shrinkage, or use partial least-squares regression.

Statistics Toolbox includes specialized data types for organizing and accessing heterogeneous data. Dataset arrays store numeric data, text, and metadata in a single data container. Built-in methods enable you to merge datasets using a common key (join), calculate summary statistics on grouped data, and convert between tall and wide data representations. Categorical arrays provide a memory-efficient data container for storing information drawn from a finite, discrete set of categories.

## Key Features

- Statistical arrays for storing heterogeneous and categorical data
- Regression techniques, including linear, nonlinear, robust, and ridge, and nonlinear mixed-effects models
- Classification algorithms, including boosted and bagged decision trees, k-Nearest Neighbor, and linear discriminant analysis
- Analysis of variance (ANOVA)
- Probability distributions, including copulas and Gaussian mixtures
- Random number generation
- Hypothesis testing
- Design of experiments and statistical process control

## Create Categorical Arrays

In this section...<br>"Create Nominal Arrays" on page 2-3<br>"Create Ordinal Arrays" on page 2-5

## Create Nominal Arrays

This example shows how to create nominal arrays using nominal.

## Load sample data.

load('fisheriris')
The variable species is a 150 -by- 1 cell array of strings containing the species name for each observation. The unique species types are setosa, versicolor, and virginica.
unique(species)
ans $=$
'setosa'
'versicolor'
'virginica'

## Create a nominal array.

Convert species to a nominal array using the categories occurring in the data.

```
speciesNom = nominal(species);
class(speciesNom)
ans =
```

nominal

The nominal array, speciesNom, has three levels corresponding to the three unique species. The levels of a categorical array are the set of possible values that its elements can take.

```
getlevels(speciesNom)
ans =
    setosa versicolor virginica
```

A categorical array can have more levels than actually appear in the data. For example, a categorical array named AllSizes might have levels small, medium, and large, but you might only have observations that are medium and large in your data. To see which levels of a categorical array are actually present in the data, use unique, for instance, unique(AllSizes).

Each level has a label, which is a string used to name the level. By default, nominal labels the category levels with the values occurring in the data. For speciesNom, these labels are the species types.

```
getlabels(speciesNom)
```

ans $=$
'setosa' 'versicolor' 'virginica'

## Specify your own category labels.

You can specify your own labels for each category level. You can specify labels when you create the nominal array, or by using setlabels.
speciesNom2 = nominal(species,\{'seto','vers','virg'\});
getlabels(speciesNom2)
ans =

```
    'seto' 'vers' 'virg'
```

Verify that the new labels correspond to the original labels in speciesNom.
isequal(speciesNom=='setosa',speciesNom2=='seto')
ans =

The logical value 1 indicates that the two labels, 'setosa' and 'seto', correspond to the same observations.

## Create Ordinal Arrays

This example shows how to create ordinal arrays using ordinal.

## Load sample data.

```
AllSizes = {'medium','large','small','small','medium',...
    'large','medium','small'};
```

The created variable, AllSizes, is a cell array of strings containing size measurements on eight objects.

## Create an ordinal array.

Create an ordinal array with category levels and labels corresponding to the values in the cell array (the default levels and labels).

```
sizeOrd = ordinal(AllSizes);
getlevels(sizeOrd)
ans =
    large medium small
getlabels(sizeOrd)
ans =
    'large' 'medium' 'small'
```

By default, ordinal uses the original strings as category labels. The default order of the categories is ascending alphabetical order.

Suppose that you want to include additional levels for the ordinal array, xsmall and xlarge, even though they do not occur in the original data. To specify additional levels, use the third input argument to ordinal.

```
sizeOrd2 = ordinal(AllSizes,{},...
    {'xsmall','small','medium','large','xlarge'});
```

```
getlevels(sizeOrd2)
ans =
    xsmall small medium large xlarge
```

To see which levels are actually present in the data, use unique.

```
unique(sizeOrd2)
ans =
    small medium large
```

## Specify the category order.

Convert AllSizes to an ordinal array with categories small < medium < large. Generally, an ordinal array is distinct from a nominal array because there is a natural ordering for levels of an ordinal array. You can use the third input argument to ordinal to specify the ascending order of the levels. Here, the order of the levels is smallest to largest.

```
sizeOrd = ordinal(AllSizes,{},{'small','medium','large'});
getlevels(sizeOrd)
ans =
    small medium large
```

The second input argument for ordinal is a list of labels for the category levels. When you use braces \{\} for the level labels, ordinal uses the labels specified in the third input argument (the labels come from the levels present in the data if only one input argument is used).

Verify that the first object (with size medium) is smaller than the second object (with size large).

```
sizeOrd(1) < sizeOrd(2)
```

ans =

1

The logical value 1 indicates that the inequality holds.

```
See Also nominal | ordinal | getlabels | getlevels | unique | isequal |

Concepts
- "Categorical Arrays" on page 2-41
- "Advantages of Using Categorical Arrays" on page 2-43
```

## Change Category Labels

This example shows how to change the labels for category levels in categorical arrays using setlabels. You also have the option to specify labels when creating a categorical array.

## Load sample data.

load('carsmall')
The variable Cylinders contains the number of cylinders in 100 sample cars.

```
unique(Cylinders)
```

ans =

4
6
8

The sample has $4-, 6$-, and 8 -cylinder cars.

## Create an ordinal array.

Convert Cylinders to a nominal array with the default category labels (taken from the values in the data).

```
cyl = ordinal(Cylinders);
```

getlabels(cyl)
ans =
'4' '6' '8'
ordinal created labels using the integer values in Cylinders, but you should provide labels for numeric data.

## Change category labels.

Relabel the categories in cyl to Four, Six, and Eight.
cyl = setlabels(cyl ,\{'Four','Six','Eight'\});

```
getlabels(cyl)
ans =
    'Four' 'Six' 'Eight'
```

Alternatively, you can specify category labels when you create a categorical array using the second input argument.

```
cyl2 = ordinal(Cylinders,{'Four','Six','Eight'});
getlabels(cyl2)
```

ans =
'Four' 'Six' 'Eight'
See Also ordinal | getlabels | setlabels |
Related - "Reorder Category Levels" on page 2-10Examples

- "Add and Drop Category Levels" on page 2-20
- "Index and Search Using Categorical Arrays" on page 2-46
Concepts- "Categorical Arrays" on page 2-41- "Advantages of Using Categorical Arrays" on page 2-43

## Reorder Category Levels

In this section...<br>"Reorder Category Levels in Ordinal Arrays" on page 2-10<br>"Reorder Category Levels in Nominal Arrays" on page 2-11

## Reorder Category Levels in Ordinal Arrays

This example shows how to reorder the category levels in an ordinal array using reorderlevels.

## Load sample data.

```
AllSizes = {'medium','large','small','small','medium',...
    'large','medium','small'};
```

The created variable, AllSizes, is a cell array of strings containing size measurements on eight objects.

## Create an ordinal array.

Convert AllSizes to an ordinal array without specifying the order of the category levels.

```
size = ordinal(size);
getlevels(size)
ans =
    large medium small
```

By default, the categories are ordered by their labels in ascending alphabetical order, large < medium < small. For example, check whether or not the first object (which has size medium) is smaller than the second object (which has size large).

```
size(1) < size(2)
```

ans $=$

## 0

The logical value 0 indicates that the medium object is not smaller than the large object.

## Reorder category levels.

Reorder the category levels so that small < medium < large.

```
size = reorderlevels(size,{'small','medium','large'});
getlevels(size)
ans =
    small medium large
```

Verify that the first object is now smaller than the second object.
size(1) < size(2)
ans =

1
The logical value 1 indicates that the expected inequality now holds.

## Reorder Category Levels in Nominal Arrays

This example shows how to reorder the category levels in nominal arrays using reorderlevels. By definition, nominal array categories have no natural ordering. However, you might want to change the order of levels for display or analysis purposes. For example, when fitting a regression model with categorical covariates, LinearModel.fit uses the first level of a nominal independent variable as the reference category.

## Load sample data.

load('hospital')
The dataset array, hospital, contains variables measured on 100 sample patients. The variable Weight contains the weight of each patient. The
variable Sex is a nominal variable containing the gender, Male or Female, for each patient.
getlevels(hospital.Sex)
ans =

## Female <br> Male

By default, the order of the nominal categories is in ascending alphabetical order of the labels.

Plot data grouped by category level.
Draw box plots of weight, grouped by gender.
figure()
boxplot(hospital.Weight, hospital.Sex)
title('Weight by Gender')

Weight by Gender

The box plots appear in the same alphabetical order returned by getlevels.

## Change the category order.

Change the order of the category levels.

```
hospital.Sex = reorderlevels(hospital.Sex,{'Male','Female'});
getlevels(hospital.Sex)
ans =
    Male Female
```

The levels are in the newly specified order. Draw box plots of weight by gender.

```
figure()
boxplot(hospital.Weight,hospital.Sex)
title('Weight by Gender')
```

Weight by Gender

The order of the box plots corresponds to the new level order.

```
See Also nominal | ordinal | getlevels | LinearModel.fit | reorderlevels |

- "Advantages of Using Categorical Arrays" on page 2-43
```

## Categorize Numeric Data

This example shows how to categorize numeric data into a categorical ordinal array using ordinal. This is useful for discretizing continuous data.

## Load sample data.

load('hospital')
The dataset array, hospital, contains variables measured on a sample of patients. Compute the minimum, median, and maximum of the variable Age.
quantile(hospital.Age, [0,.5,1])
ans =
$25 \quad 39 \quad 50$

The variable Age has the ages of each patient, ranging from 25 to 50 .

## Convert a numeric array to an ordinal array.

Group patients into the age categories Under 30, 30-39, Over 40.

```
hospital.AgeCat = ordinal(hospital.Age,{'Under 30','30-39','Over 40'},...
    [],[25,30,40,50]);
getlevels(hospital.AgeCat)
ans =
Under 30 30-39 Over 40
```

The last input argument to ordinal has the endpoints for the categories. The first category begins at age 25 , the second at age 30 , and so on. The last category contains ages 40 and above, so begins at 40 and ends at 50 (the maximum age in the data set). To specify three categories, you must specify four endpoints (the last endpoint is the upper bound of the last category).

Display the age and age category for the second patient.
hospital.Age(2)
hospital.AgeCat(2)
ans =

```
Over 40
```

When you discretize a numeric array into categories, the categorical array loses all information about the actual numeric values. In this example, AgeCat is not numeric, and you cannot recover the raw data values from it.

## Categorize a numeric array into quartiles.

The variable Weight has weight measurements for the sample patients. Categorize the patient weights into four categories, by quartile.

```
p = 0:.25:1;
breaks = quantile(hospital.Weight,p);
hospital.WeightQ = ordinal(hospital.Weight,{'Q1','Q2','Q3','Q4'},...
    [],breaks);
getlevels(hospital.WeightQ)
ans =
    Q1 Q2 Q3 Q4
```

Display the weight and weight quartile for the second patient.
hospital.Weight(2)
ans =

163
hospital.WeightQ(2)
ans =

## Summary statistics grouped by category levels.

Compute the mean systolic and diastolic blood pressure for each age and weight category.
grpstats(hospital, \{'AgeCat', 'WeightQ'\},'mean', 'DataVars', 'BloodPressure') ans =

|  | AgeCat | WeightQ | GroupCount | mean_BloodPressure |  |
| :--- | :--- | :--- | ---: | ---: | ---: |
| Under 30_Q1 | Under 30 | Q1 | 6 | 123.17 | 79.667 |
| Under 30_Q2 | Under 30 | Q2 | 3 | 120.33 | 79.667 |
| Under 30_Q3 | Under 30 | Q3 | 2 | 127.5 | 86.5 |
| Under 30_Q4 | Under 30 | Q4 | 4 | 122 | 78 |
| 30-39_Q1 | $30-39$ | Q1 | 12 | 121.75 | 81.75 |
| 30-39_Q2 | $30-39$ | Q2 | 9 | 119.56 | 82.556 |
| 30-39_Q3 | $30-39$ | Q3 | 9 | 121 | 83.222 |
| 30-39_Q4 | 30-39 | Q4 | 11 | 125.55 | 87.273 |
| Over 40_Q1 | Over 40 | Q1 | 7 | 122.14 | 84.714 |
| Over 40_Q2 | Over 40 | Q2 | 13 | 123.38 | 79.385 |
| Over 40_Q3 | Over 40 | Q3 | 14 | 123.07 | 84.643 |
| Over 40_Q4 | Over 40 | Q4 | 10 | 124.6 | 85.1 |

The variable BloodPressure is a matrix with two columns. The first column is systolic blood pressure, and the second column is diastolic blood pressure. The group in the sample with the highest mean diastolic blood pressure, 87.273, is aged 30-39 and in the highest weight quartile, 30-39_Q4.

Examples

Concepts

- "Merge Category Levels" on page 2-18
- "Plot Data Grouped by Category" on page 2-24
- "Index and Search Using Categorical Arrays" on page 2-46
- "Categorical Arrays" on page 2-41
- "Advantages of Using Categorical Arrays" on page 2-43

## Merge Category Levels

This example shows how to merge categories in a categorical array using mergelevels. This is useful for collapsing categories with few observations.

## Load sample data.

load('carsmall')

## Create a nominal array.

The variable Origin is a character array containing the country of origin for 100 sample cars. Convert Origin to a nominal array.

```
Origin = nominal(Origin);
```

getlevels(Origin)
ans =

France Germany Italy Japan Sweden USA
There are six unique countries of origin in the data.
tabulate(Origin)

| Value | Count | Percent |
| ---: | ---: | ---: |
| France | 4 | $4.00 \%$ |
| Germany | 9 | $9.00 \%$ |
| Italy | 1 | $1.00 \%$ |
| Japan | 15 | $15.00 \%$ |
| Sweden | 2 | $2.00 \%$ |
| USA | 69 | $69.00 \%$ |

There are relatively few observations in each European country.

## Merge categories.

Merge the categories France, Germany, Italy, and Sweden into one category called Europe.

```
Origin = mergelevels(Origin,{'France','Germany','Italy','Sweden'},...
    'Europe');
```

```
getlevels(Origin)
ans =
    Japan USA Europe
```

The variable Origin now has only three category levels.
tabulate(Origin)

| Value | Count | Percent |
| ---: | ---: | ---: |
| Japan | 15 | $15.00 \%$ |
| USA | 69 | $69.00 \%$ |
| Europe | 16 | $16.00 \%$ |

The category Europe has the $16 \%$ of observations that were previously distributed across four countries.

## Add and Drop Category Levels

This example shows how to add and drop levels from a categorical array.

## Load sample data.

load('examgrades')
The array grades contains exam scores from 0 to 100 on five exams for a sample of 120 students.

## Create an ordinal array.

Assign letter grades to each student for each test using these categories.

| Grade Range | Letter Grade |
| :--- | :--- |
| 100 | A + |
| $90-99$ | A |
| $80-89$ | B |
| $70-79$ | C |
| $60-69$ | D |

```
letter = ordinal(grades,{'D','C','B','A','A+'},[],...
```

    [60,70,80,90, 100, 100]);
    getlevels(letter)
ans =
$\begin{array}{lllll}\text { D } & \text { C } & \text { B } & \text { A } & \text { A+ }\end{array}$

There are five grade categories, in the specified order D $<\mathrm{C}<\mathrm{B}<\mathrm{A}<\mathrm{A}+$.

## Check for undefined categories.

Check whether or not there are any exam scores that do not fall into the five letter categories.
any(isundefined(letter))

| 1 | 0 | 1 | 1 | 0 |
| :--- | :--- | :--- | :--- | :--- |

Recall that there are five exam scores for each student. The previous command returns a logical value for each of the five exams, indicating whether there are any scores that are <undefined>. There are scores for the first, third, and fourth exams that are <undefined>, that is, missing a category level. You can find the exam scores that do not have a letter grade using the isundefined logical condition.
grades(isundefined(letter))
ans =

55
59
58
59
54
57
56
59
59
50
59
52

The exam scores that are in the 50 s do not have a letter grade.

## Add a new category.

Put all scores that are <undefined> into a new category labeled D-.
letter(isundefined(letter)) = 'D-';
Warning: Categorical level 'D-' being added.
> In categorical.subsasgn at 55
getlevels(letter)
$\begin{array}{llllll}\text { D } & \text { C } & \text { B } & \text { A } & \text { A+ }\end{array}$
The ordinal variable, letter, has a new category added to the end. Reorder the categories so that D- L .
letter = reorderlevels(letter,\{'D-','D','C','B','A','A+'\}); getlevels(letter)
ans =
$\begin{array}{clllll}\text { D- D } & \text { C } & \text { B } & \text { A } & \text { A+ }\end{array}$

Now that all exam scores have a letter grade, count how many students received a higher letter grade on the second test than on the first test.

```
sum(letter(:,2) > letter(:,1))
ans =
```

    32
    Thirty-two students improved their letter grade between the first two exams.

## Drop a category.

Count the number of A+ scores in each of the five exams.

```
sum(letter=='A+')
ans =
    0 0 0 0 0
```

There are no A+ scores on any of the five exams. Drop the category A+ from the ordinal variable, letter.

```
letter = droplevels(letter,'A+');
```

getlevels(letter)
ans $=$
D- D C

$\square$
B ..... ACategory A+ is no longer in the ordinal variable, letter.
See Also ordinal | isundefined | reorderlevels | droplevels |
Related - "Create Categorical Arrays" on page 2-3Examples- "Reorder Category Levels" on page 2-10- "Merge Category Levels" on page 2-18- "Index and Search Using Categorical Arrays" on page 2-46
Concepts - "Categorical Arrays" on page 2-41- "Advantages of Using Categorical Arrays" on page 2-43

## Plot Data Grouped by Category

This example shows how to plot data grouped by the levels of a categorical variable.

## Load sample data.

load('carsmall')
The variable Acceleration contains acceleration measurements on 100 sample cars. The variable Origin is a character array containing the country of origin for each car.

## Create a nominal array.

Convert Origin to a nominal array.
Origin = nominal(Origin); getlevels(Origin)
ans =
France Germany Italy Japan Sweden USA

There are six unique countries of origin in the sample. By default, nominal orders the countries in ascending alphabetical order.

## Plot data grouped by category.

Draw box plots for Acceleration, grouped by Origin.

```
figure()
boxplot(Acceleration,Origin)
title('Acceleration, Grouped by Country of Origin')
```

The box plots appear in the same order as the categorical levels (use reorderlevels to change the order of the categories).

Few observations have Italy as the country of origin. Tabulate the number of sample cars from each country.
tabulate(Origin)

| Value | Count | Percent |
| ---: | ---: | ---: |
| France | 4 | $4.00 \%$ |
| Germany | 9 | $9.00 \%$ |
| Italy | 1 | $1.00 \%$ |
| Japan | 15 | $15.00 \%$ |
| Sweden | 2 | $2.00 \%$ |
| USA | 69 | $69.00 \%$ |

Only one car is made in Italy.
Drop a category.

Delete the Italian car from the sample.

```
Acceleration2 = Acceleration(Origin~='Italy');
Origin2 = Origin(Origin~='Italy');
tabulate(Origin2)
```

This output shows that even though the car from Italy is no longer in the sample, the nominal variable, Origin2, still has the category Italy.

```
getlevels(Origin2)
```

ans =

France Germany Italy Japan Sweden USA
Note that this is intentional-the levels of a categorical array do not necessarily coincide with the values. Use droplevels to remove the Italy category.

```
tabulate(Origin2)
    Value Count Percent
    France 4 4.04%
    Germany 9 9.09%
        Italy 0 0.00%
        Japan 15 15.15%
    Sweden 2 2.02%
        USA 69 69.70%
Origin2 = droplevels(Origin2,'Italy');
tabulate(Origin2)
tabulate(Origin2)
    Value Count Percent
    France 4 4.04%
    Germany 9 9.09%
    Japan 15 15.15%
    Sweden 2 2.02%
        USA 69 69.70%
```

The Italy category is no longer in the nominal array, Origin2.
Draw box plots of Acceleration2, grouped by Origin2.

```
figure()
boxplot(Acceleration2,Origin2)
title('Acceleration, Grouped by Country of Origin')
```

Acceleration, Grouped by Country of Origin

The plot no longer includes the car from Italy.

## Test Differences Between Category Means

This example shows how to test for significant differences between category (group) means using a $t$-test, two-way ANOVA (analysis of variance), and ANOCOVA (analysis of covariance) analysis.

The goal is determining if the expected miles per gallon for a car depends on the decade in which it was manufactured, or the location where it was manufactured.

## Load sample data.

load('carsmall')
The variable MPG has miles per gallon measurements on a sample of 100 cars. The variables Model_Year and Origin contain the model year and country of origin for each car.

Create a factor for the decade of manufacture.
The first factor of interest is the decade of manufacture. There are three manufacturing years in the data.
unique(Model_Year)
ans =
70
76
82
Create an ordinal array named Decade. Merge the observations from years 70 and 76 into a category labeled 1970s, and put the observations from 82 into a category labeled 1980s.

Decade = ordinal(Model_Year,\{'1970s','1980s'\},[],[70 77 82]); getlevels(Decade)
ans =

1970s 1980s

## Conduct a two-sample t-test for equal group means.

Draw a box plot of miles per gallon, grouped by the decade of manufacture.

```
figure()
boxplot(MPG, Decade)
title('Miles per Gallon, Grouped by Decade of Manufacture')
```

Miles per Gallon, Grouped by Decade of Manufacture

The box plot suggests that miles per gallon is higher in cars manufactured during the 1980s compared to the 1970s. Compute the mean and variance of miles per gallon for each decade.
[xbar,s2,grp] = grpstats(MPG,Decade,\{'mean','var','gname'\})
xbar $=$
19.7857
31.7097
35.1429
29.0796
grp $=$
'1970s'
'1980s'
This output shows that the mean miles per gallon in the 1980s was 31.71 , compared to 19.79 in the 1970s. The variances in the two groups are similar.

Conduct a two-sample $t$-test, assuming equal variances, to test for a significant difference between the group means. The hypothesis is

```
    H0}:\mp@subsup{\mu}{70}{}=\mp@subsup{\mu}{80}{
    HA}:\mp@subsup{\mu}{70}{}\not=\mp@subsup{\mu}{80}{}
MPG70 = MPG(Decade=='1970s');
MPG80 = MPG(Decade=='1980s');
[h,p] = ttest2(MPG70,MPG80)
h =
    1
p =
    3.4809e-15
```

The logical value 1 indicates the null hypothesis is rejected at the default 0.05 significance level. The p-value for the test is very small. There is sufficient evidence that the mean miles per gallon in the 1980s differs from the mean miles per gallon in the 1970s.

## Create a factor for the location of manufacture.

The second factor of interest is the location of manufacture. First, convert Origin to a nominal array.

```
Location = nominal(Origin);
tabulate(Location)
tabulate(Location)
        Value Count Percent
        France 4 4.00%
    Germany 9 9.00%
        Italy 1 1.00%
        Japan 15 15.00%
    Sweden 2 2.00%
        USA 69 69.00%
```

There are six different countries of manufacture. The European countries have relatively few observations. Combine the categories France, Germany, Italy, and Sweden into a new category named Europe.

```
Location = mergelevels(Location,{'France','Germany','Italy','Sweden'},...
```

    Europe');
    tabulate(Location)

| Value | Count | Percent |
| ---: | ---: | ---: |
| Japan | 15 | $15.00 \%$ |
| USA | 69 | $69.00 \%$ |
| Europe | 16 | $\mathbf{1 6 . 0 0 \%}$ |

Compute the mean miles per gallon, grouped by the location of manufacture.

```
[xbar,grp] = grpstats(MPG,Location,{'mean','gname'})
```

xbar $=$
31.8000
21.1328
26.6667
grp =

```
'Japan'
'USA'
'Europe'
```

This result shows that average miles per gallon is lowest for the sample of cars manufactured in the U.S.

## Conduct two-way ANOVA.

Conduct a two-way ANOVA to test for differences in expected miles per gallon between factor levels for Decade and Location.

The statistical model is

$$
M P G_{i j}=\mu+\alpha_{i}+\beta_{j}+\varepsilon_{i j}, \quad i=1,2 ; j=1,2,3,
$$

where $M P G_{i j}$ is the response, miles per gallon, for cars made in decade $i$ at location $j$. The treatment effects for the first factor, decade of manufacture, are the $\alpha_{i}$ terms (constrained to sum to zero). The treatment effects for the second factor, location of manufacture, are the $\beta_{j}$ terms (constrained to sum to zero). The $\varepsilon_{i j}$ are uncorrelated, normally distributed noise terms.

The hypotheses to test are equality of decade effects,

$$
\begin{aligned}
& H_{0}: \alpha_{1}=\alpha_{2}=0 \\
& H_{A}: \text { at least one } \alpha_{i} \neq 0,
\end{aligned}
$$

and equality of location effects,

$$
\begin{aligned}
& H_{0}: \beta_{1}=\beta_{2}=\beta_{3}=0 \\
& H_{A}: \text { at least one } \beta_{j} \neq 0 .
\end{aligned}
$$

You can conduct a multiple-factor ANOVA using anovan.

```
anovan(MPG,{Decade,Location},'varnames',{'Decade','Location'});
```

This output shows the results of the two-way ANOVA. The p-value for testing the equality of decade effects is $2.88503 e-18$, so the null hypothesis is rejected at the 0.05 significance level. The p-value for testing the equality of location effects is $7.40416 \mathrm{e}-10$, so this null hypothesis is also rejected.

## Conduct ANOCOVA analysis.

A potential confounder in this analysis is car weight. Cars with greater weight are expected to have lower gas mileage. Include the variable Weight as a continuous covariate in the ANOVA; that is, conduct an ANOCOVA analysis.

Assuming parallel lines, the statistical model is

$$
M P G_{i j k}=\mu+\alpha_{i}+\beta_{j}+\gamma \text { Weight }_{i j k}+\varepsilon_{i j k}, i=1,2 ; j=1,2,3 ; k=1, \ldots, 100
$$

The difference between this model and the two-way ANOVA model is the inclusion of the continuous predictor, Weight $t_{i j k}$, the weight for the $k$ th car, which was made in the $i$ th decade and in the $j$ th location. The slope parameter is $\gamma$.

Add the continuous covariate as a third group in the second anovan input argument. Use the name-value pair argument Continuous to specify that Weight (the third group) is continuous.

```
anovan(MPG,{Decade,Location,Weight},'Continuous',3,...
    'varnames',{'Decade','Location','Weight'});
```

| -1) Figure 2: N-Way ANOVA |  |  |  |  | $\square$ | 回 | 3 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| File Edit | View Insert | Tools | Desktop | Window |  |  | v |
| Analysis of Variance |  |  |  |  |  |  |  |
| Source | Sum Sq. | d.f. | Mean Sq. | F | Prob |  | * |
| Decade | 729.63 | 1 | 729.63 | 83.16 | 0 |  |  |
| Location | 40.67 | 2 | 20.34 | 2.32 | 0.10 |  |  |
| Weight | 1131.51 | 1 | 1131.51 | 128.96 | 0 |  |  |
| Error | 780.88 | 89 | 8.77 |  |  |  |  |
| Total | 6005.28 | 93 |  |  |  |  | $\checkmark$ |
| Constrained (Type III) sums of squares. |  |  |  |  |  |  |  |

This output shows that when car weight is considered, there is insufficient evidence of a manufacturing location effect ( $p$-value $=0.1044$ ).

You can use the interactive aoctool to explore this result.
aoctool(Weight,MPG,Location);
This command opens three dialog boxes. In the ANOCOVA Prediction Plot dialog box, select the Separate Means model.

This output shows that when you do not include Weight in the model, there are fairly large differences in the expected miles per gallon among the three manufacturing locations. Note that here the model does not adjust for the decade of manufacturing.

Now, select the Parallel Lines model.

When you include Weight in the model, the difference in expected miles per gallon among the three manufacturing locations is much smaller.

## Summary Statistics Grouped by Category

This example shows how to compute summary statistics grouped by levels of a categorical variable. You can compute group summary statistics for a numeric array or a dataset array using grpstats.

## Load sample data.

load('hospital')
The dataset array, hospital, has 7 variables (columns) and 100 observations (rows).

## Compute summary statistics by category.

The variable Sex is a nominal array with two levels, Male and Female. Compute the minimum and maximum weights for each gender.

```
stats = grpstats(hospital,'Sex',{'min','max'},'DataVars','Weight')
stats =
Female
    Sex GroupCount
min_Weight
max_Weight
Female
Male Male 47 158 202
1 1 1
147
```

The dataset array, stats, has observations corresponding to the levels of the variable Sex. The variable min_Weight contains the minimum weight for each group, and the variable max_Weight contains the maximum weight for each group.

## Compute summary statistics by multiple categories.

The variable Smoker is a logical array with value 1 for smokers and value 0 for nonsmokers. Compute the minimum and maximum weights for each gender and smoking combination.

```
stats = grpstats(hospital,{'Sex','Smoker'},{'min','max'},...
    'DataVars','Weight')
stats =
```

|  | Sex | Smoker | GroupCount | min_Weight | max_Weight |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Female_0 | Female | false | 40 | 111 | 147 |
| Female_1 | Female | true | 13 | 115 | 146 |
| Male_0 | Male | false | 26 | 158 | 194 |
| Male_1 | Male | true | 21 | 164 | 202 |

The dataset array, stats, has an observation row for each combination of levels of Sex and Smoker in the original data.

## Sort Ordinal Arrays

This example shows how to determine sorting order for ordinal arrays.

## Load sample data.

```
AllSizes = {'medium','large','small','small','medium',...
    'large','medium','small'};
```

The created variable, AllSizes, is a cell array of strings containing size measurements on eight objects.

## Create an ordinal array.

Convert AllSizes to an ordinal array with levels small < medium < large.

```
AllSizes = ordinal(AllSizes,{},{'small','medium','large'});
getlevels(AllSizes)
ans =
    small medium large
```

## Sort the ordinal array.

When you sort ordinal arrays, the sorted observations are in the same order as the category levels.
sizeSort = sort(AllSizes);
sizeSort(:)
ans =
small
small
small
medium
medium
medium
large
large

The sorted ordinal array, sizeSort, contains the observations ordered from small to large.

## Categorical Arrays

In this section...<br>"What Are Categorical Arrays?" on page 2-41<br>"Categorical Array Conversion" on page 2-41

## What Are Categorical Arrays?

Categorical arrays are Statistics Toolbox data types for storing categorical values. Categorical arrays store data that have a finite set of discrete levels, which might or might not have a natural order. There are two types of categorical arrays:

- ordinal arrays store categorical values with ordered levels. For example, an ordinal variable might have levels \{small, medium, large\}.
- nominal arrays store categorical values with unordered levels. For example, a nominal variable might have levels \{red, blue, green\}.

In experimental design, these variables are often called factors, with ordered or unordered factor levels.

Categorical arrays are convenient and memory efficient containers for storing categorical variables. In addition to storing information about which category each observation belongs to, categorical arrays store descriptive metadata including category labels and order.

Categorical arrays have associated methods that streamline common tasks such as merging categories, adding or dropping levels, and changing level labels.

## Categorical Array Conversion

You can easily convert to and from categorical arrays. To create a nominal or ordinal array, use nominal or ordinal, respectively. You can convert these data types to categorical arrays:

- Numeric array
- Logical array
- Character array
- Cell array of strings

## See Also ordinal | nominal |

## Advantages of Using Categorical Arrays

In this section...<br>"Manipulate Category Levels" on page 2-43<br>"Analysis Using Categorical Arrays" on page 2-43<br>"Reduce Memory Requirements" on page 2-44

## Manipulate Category Levels

When working with categorical variables and their levels, you'll encounter some typical challenges. This table summarizes the functions you can use with categorical arrays to manipulate category levels. For additional functions, type methods nominal or methods ordinal at the command line, or see the nominal and ordinal reference pages.

| Task | Function |
| :--- | :--- |
| Add new category levels | addlevels |
| Drop category levels | droplevels |
| Combine category levels | mergelevels |
| Reorder category levels | reorderlevels |
| Count the number of observations in each category | levelcounts |
| Change the label or name of category levels | setlabels |
| Create an interaction factor | times |
| Find observations that are not in a defined category | isundefined |

## Analysis Using Categorical Arrays

You can use categorical arrays in a variety of statistical analyses. For example, you might want to compute descriptive statistics for data grouped by the category levels, conduct statistical tests on differences between category means, or perform regression analysis using categorical predictors.

Statistics Toolbox functions that accept a grouping variable as an input argument accept categorical arrays. This includes descriptive functions such as:

- grpstats
- gscatter
- boxplot
- gplotmatrix

You can also use categorical arrays as input arguments to analysis functions and methods based on models, such as:

- anovan
- LinearModel.fit
- GeneralizedLinearModel.fit
- NonLinearModel.fit

When you use a categorical array as a predictor in these functions, the fitting function automatically recognizes the categorical predictor, and constructs appropriate dummy indicator variables for analysis. Alternatively, you can construct your own dummy indicator variables using dummyvar.

## Reduce Memory Requirements

The levels of categorical variables are often defined as text strings, which can be costly to store and manipulate in a cell array of strings or char array. Categorical arrays separately store category membership and category labels, greatly reducing the amount of memory required to store the variable.

For example, load some sample data:
load('fisheriris')
The variable species is a cell array of strings requiring 19,300 bytes of memory.

Convert species to a nominal array:

```
species = nominal(species);
```

| Workspac |  |  |
| :---: | :---: | :---: |
| Name ${ }^{\text {- }}$ | Bytes | Value |
| \#meas | 4800 | <150x4 double> |
| (4) species | 790 | <150x1 nominal> |

There is a $95 \%$ reduction in memory required to store the variable.

## Index and Search Using Categorical Arrays

It is often useful to index and search data by its category, or group. If you store categories as string labels inside a cell array of strings or char array, it can be difficult to index and search the categories. When using categorical arrays, you can easily:

- Index elements from particular categories. For both nominal and ordinal arrays, you can use the logical operators $==$ and $\sim=$ to index the observations that are in, or not in, a particular category. For ordinal arrays, which have an encoded order, you can also use inequalities, >, >=, <, and $<=$, to find observations in categories above or below a particular category.
- Search for members of a category. In addition to the logical operator $==$, you can use ismember to find observations in a particular group.
- Find elements that are not in a defined category. Categorical arrays indicate which elements do not belong to a defined category by <undefined>. You can use isundefined to find observations missing a category.
- Delete observations that are in a particular category. You can use logical operators to include or exclude observations from particular categories. Even if you remove all observations from a category, the category level remains defined unless you remove it using droplevels.

The following brief examples illustrate several indexing and searching methods.

## Load sample data.

load('carsmall')
Convert the char array, Origin, to a nominal array. This variable contains the country of origin, or manufacture, for each sample car.

Origin = nominal(Origin);

## Search for observations in a category.

Determine if there any cars in the sample that were manufactured in Canada.

```
any(Origin=='Canada')
ans =
    0
```

There are no sample cars manufactured in Canada. List the countries that are levels of Origin.

```
getlevels(Origin)
```

ans =
France Germany Italy Japan Sweden USA

## Index elements that are in a particular category.

Plot a histogram of the acceleration measurements for cars made in the U.S.

```
figure()
hist(Acceleration(Origin=='USA'))
title('Acceleration of Cars Made in the USA')
```

## Delete observations that are in a particular category.

Delete all cars made in Sweden from Origin.

Origin = Origin(Origin~='Sweden'); any(ismember(Origin,'Sweden'))
ans =

0
The cars made in Sweden are deleted from Origin, but Sweden is still a level of Origin.
getlevels(Origin)
ans =

Remove Sweden from the levels of Origin.
Origin = droplevels(Origin,'Sweden');
getlevels(Origin)
ans =
France Germany Italy Japan USA

## Check for observations not in a defined category.

Get the indices for the cars made in France.

```
ix = find(Origin=='France')
ix =
```

    11
    27
    39
    61
    There are four cars from France. Remove France from the levels of Origin.

```
Origin = droplevels(Origin,'France');
```

Warning: OLDLEVELS contains categorical levels that were present in the
input array A. As a result, the output array B contains array elements
that have undefined levels.
> In categorical.droplevels at 52

The warning indicates that you are dropping a category level that has elements in it. These observations are no longer in a defined category, indicated by <undefined>.

```
Origin(ix)
ans =
    <undefined>
    <undefined>
    <undefined>
```

```
You can use isundefined to search for observations with an undefined category.
find(isundefined(Origin))
ans =
    1 1
    27
    39
    6 1
```

These indices correspond to the observations that were in category France, before that category was dropped from Origin.

## Grouping Variables

In this section...<br>"What Are Grouping Variables?" on page 2-51<br>"Group Definition" on page 2-52<br>"Analysis Using Grouping Variables" on page 2-52<br>"Missing Group Values" on page 2-53

## What Are Grouping Variables?

Grouping variables are utility variables used to group, or categorize, observations. Grouping variables are useful for summarizing or visualizing data by group. A grouping variable can be any of these data types:

- Numeric vector
- Logical vector
- String array (also called character arrays)
- Cell array of strings
- Categorical vector

A grouping variable must have the same number of observations (rows) as the dataset array or numeric array you are grouping. Observations that have the same grouping variable value belong to the same group.

For example, the following variables comprise the same groups. Each grouping variable divides five observations into two groups. The first group contains the first and fourth observations. The other three observations are in the second group.

| Data Type | Grouping Variable |
| :--- | :--- |
| Numeric vector | $\left[\begin{array}{lllll}1 & 2 & 2 & 1 & 2\end{array}\right]$ |
| Logical vector | $\left[\begin{array}{lllll}0 & 1 & 1 & 0 & 1\end{array}\right]$ |

| Data Type | Grouping Variable |
| :--- | :--- |
| Cell array of strings | \{'Male ', 'Female ', 'Female ' , 'Male ', 'Female ' \} |
| Categorical vector | Male Female Female Male Female |

Grouping variables with string labels give each group a meaningful name. A categorical array is an efficient and flexible choice of grouping variable.

## Group Definition

Typically, there are as many groups as unique values in the grouping variable. However, categorical arrays can have levels that are not represented in the data. The groups and the order of the groups depend on the data type of the grouping variable. Suppose G is a grouping variable.

- If G is a numeric or logical vector, then the groups correspond to the distinct values in $G$, in the sorted order of the unique values.
- If $G$ is a string array or cell array of strings, then the groups correspond to the distinct strings in $G$, in the order of their first appearance.
- If G is a categorical vector, then the groups correspond to the unique category levels in $G$, in the order returned by getlevels.

Some functions, such as grpstats, accept multiple grouping variables specified as a cell array of grouping variables, for example, $\{G 1, G 2, G 3\}$. In this case, the groups are defined by the unique combinations of values in the grouping variables. The order is decided first by the order of the first grouping variable, then by the order of the second grouping variable, and so on.

## Analysis Using Grouping Variables

This table lists common tasks you might want to perform using grouping variables.

| Grouping Task | Function Accepting Grouping <br> Variable |
| :--- | :--- |
| Draw side-by-side boxplots for data <br> in different groups. | boxplot |
| Draw a scatter plot with markers <br> colored by group. | gscatter |
| Draw a scatter plot matrix with <br> markers colored by group. | gplotmatrix |
| Compute summary statistics by <br> group. | grpstats |
| Test for differences between group <br> means. | anovan |
| Create an index vector from a <br> grouping variable. | grp2idx |

## Missing Group Values

Grouping variables can have missing values provided you include a valid indicator.

| Grouping Variable Data Type | Missing Value Indicator |
| :--- | :--- |
| Numeric vector | NaN |
| Logical vector | (Cannot be missing) |
| String array | Row of spaces |
| Cell array of strings | ' ' |
| Categorical vector | <undefined> |

## Dummy Indicator Variables

In this section...<br>"What Are Dummy Variables?" on page 2-55<br>"Creating Dummy Variables" on page 2-56

## What Are Dummy Variables?

When performing regression analysis, it is common to include both continuous and categorical (quantitative and qualitative) predictor variables. When including a categorical independent variable, it is important not to input the variable as a numeric array. Numeric arrays have both order and magnitude. A categorical variable might have order (for example, an ordinal variable), but it does not have magnitude. Using a numeric array implies a known "distance" between the categories.

The appropriate way to include categorical predictors is as dummy indicator variables. An indicator variable has values 0 and 1. A categorical variable with $c$ categories can be represented by $c-1$ indicator variables.

For example, suppose you have a categorical variable with levels \{Small, Medium, Large\}. You can represent this variable using two dummy variables, as shown in this figure.

|  | $X_{1}$ | $X_{2}$ |
| :--- | :---: | :---: |
| Small | 0 | 0 |
| Medium | 1 | 0 |
| Reference |  |  |
| Large | 0 | 1 | Group

In this example, $X_{1}$ is a dummy variable that has value 1 for the Medium group, and 0 otherwise. $X_{2}$ is a dummy variable that has value 1 for the Large group, and 0 otherwise. Together, these two variables represent the three categories. Observations in the Small group have 0s for both dummy variables.

The category represented by all 0 s is the reference group. When you include the dummy variables in a regression model, the coefficients of the dummy variables are interpreted with respect to the reference group.

## Creating Dummy Variables

## Automatic Creation of Dummy Variables

The regression fitting functions, LinearModel.fit, GeneralizedLinearModel.fit, and NonLinearModel.fit, recognize categorical array inputs as categorical predictors. That is, if you input your categorical predictor as a nominal or ordinal array, the fitting function automatically creates the required dummy variables. The first level returned by getlevels is the reference group. To use a different reference group, use reorderlevels to change the level order.

If there are $c$ unique levels in the categorical array, then the fitting function estimates $c-1$ regression coefficients for the categorical predictor.

Note The fitting functions use every level of the categorical array returned by getlevels, even if there are levels with no observations. To remove levels from the categorical array, use droplevels.

## Manual Creation of Dummy Variables

If you prefer to create your own dummy variable design matrix, use dummyvar. This function accepts a numeric or categorical column vector, and returns a matrix of indicator variables. The dummy variable design matrix has a column for every group, and a row for every observation.

For example,

```
gender = nominal({'Male';'Female';'Female';'Male';'Female'});
```

```
dv = dummyvar(gender)
dv =
\begin{tabular}{ll}
0 & 1 \\
1 & 0 \\
1 & 0 \\
0 & 1 \\
1 & 0
\end{tabular}
```

There are five rows corresponding to the number of rows in gender, and two columns for the unique groups, Female and Male. Column order corresponds to the order of the levels in gender. For nominal arrays, the default order is ascending alphabetical.

To use these dummy variables in a regression model, you must either delete a column (to create a reference group), or fit a regression model with no intercept term. For the gender example, only one dummy variable is needed to represent two genders. Notice what happens if you add an intercept term to the complete design matrix, dv .

```
X = [ones(5,1) dv]
X =
    1 0 1
    1 1 0
    1 1 0
    1 0 1
    1 1 0
rank(X)
ans =
    2
```

The design matrix with an intercept term is not of full rank, and is not invertible. Because of this linear dependence, use only $c-1$ indicator variables to represent a categorical variable with $c$ categories in a regression model with an intercept term.

## Regression with Categorical Covariates

This example shows how to perform a regression with categorical covariates using categorical arrays and LinearModel.fit.

## Load sample data.

load('carsmall')

The variable MPG contains measurements on the miles per gallon of 100 sample cars. The model year of each car is in the variable Model_Year, and Weight contains the weight of each car.

Plot grouped data.
Draw a scatter plot of MPG against Weight, grouped by model year.
figure()
gscatter (Weight, MPG, Model_Year, 'bgr', 'x.o')
title('MPG vs. Weight, Grouped by Model Year')

The grouping variable, Model_Year, has three unique values, 70, 76, and 82, corresponding to model years 1970, 1976, and 1982.

## Create dataset and nominal arrays.

Create a dataset array that contains the variables MPG, Weight, and Model_Year.
cars = dataset(MPG,Weight,Model_Year);
Convert the variable Model_Year to a nominal array.
cars.Model_Year = nominal(cars.Model_Year);

## Fit a regression model.

Fit a regression model using LinearModel.fit with MPG as the dependent variable, and Weight and Model_Year as the independent variables. Because Model_Year is a categorical covariate with three levels, it should enter the model as two indicator variables.

The scatter plot suggests that the slope of MPG against Weight might differ for each model year. To assess this, include weight-year interaction terms.

The proposed model is

$$
E(M P G)=\beta_{0}+\beta_{1} \text { Weight }+\beta_{2} I[1976]+\beta_{3} I[1982]+\beta_{4} \text { Weight } \times I[1976]+\beta_{5} \text { Weight } \times I[198
$$

where $I[1976]$ and $I[1982]$ indicate the model years 1976 and 1982, respectively. In this model, 1970 is the reference year.

```
fit = LinearModel.fit(cars,'MPG~Weight*Model_Year')
fit =
```

Linear regression model:
MPG ~ 1 + Weight*Model_Year
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | ---: |
| (Intercept) | 37.399 | 2.1466 | 17.423 | 2.8607 |
| Weight | -0.0058437 | 0.00061765 | -9.4612 | 4.6077 |
| Model_Year_76 | 4.6903 | 2.8538 | 1.6435 | 0.1 |
| Model_Year_82 | 21.051 | 4.157 | 5.0641 | 2.2364 |
| Weight:Model_Year_76 | -0.00082009 | 0.00085468 | -0.95953 | 0.3 |
| Weight:Model_Year_82 | -0.0050551 | 0.0015636 | -3.2329 | 0.001 |

```
Number of observations: 94, Error degrees of freedom: 88
Root Mean Squared Error: 2.79
R-squared: 0.886, Adjusted R-Squared 0.88
F-statistic vs. constant model: 137, p-value = 5.79e-40
```

The regression output shows:

- LinearModel.fit recognizes Model_Year as a nominal variable, and constructs the required indicator (dummy) variables. By default, the first level, 70, is the reference group (use reorderlevels to change the reference group).
- The model specification, MPG~Weight*Model_Year, specifies the first-order terms for Weight and Model_Year, and all interactions.
- The model $R^{2}=0.886$, meaning the variation in miles per gallon is reduced by $88.6 \%$ when you consider weight, model year, and their interactions.
- The fitted model is

$$
M \hat{P} G=37.4-0.006 \text { Weight }+4.7 I[1976]+21.1 I[1982]-0.0008 \text { Weight } \times I[1976]-0.005
$$

Thus, the estimated regression equations for the model years are as follows.

| Model Year | Predicted MPG Against Weight |
| :--- | :---: |
| 1970 | $M \hat{P} G=37.4-0.006$ Weight |
| 1976 | $M \hat{P} G=(37.4+4.7)-(0.006+0.0008)$ Weight |
| 1982 | $M \hat{P} G=(37.4+21.1)-(0.006+0.005)$ Weight |

The relationship between MPG and Weight has an increasingly negative slope as the model year increases.

## Plot fitted regression lines.

Plot the data and fitted regression lines.

```
w = linspace(min(Weight),max(Weight));
figure()
gscatter(Weight,MPG,Model_Year,'bgr','x.o')
line(w,feval(fit,w,'70'),'Color','b','LineWidth',2)
line(w,feval(fit,w,'76'),'Color','g','LineWidth',2)
line(w,feval(fit,w,'82'),'Color','r','LineWidth',2)
title('Fitted Regression Lines by Model Year')
```

## Test for different slopes.

Test for significant differences between the slopes. This is equivalent to testing the hypothesis

```
    H0}:\mp@subsup{\beta}{4}{}=\mp@subsup{\beta}{5}{}=
    HA:\beta
anova(fit)
ans =
```

|  | SumSq | DF | MeanSq | F | pValue |
| :--- | :--- | ---: | ---: | ---: | ---: |
| Weight | 2050.2 | 1 | 2050.2 | 263.87 | $3.2055 \mathrm{e}-28$ |
| Model_Year | 807.69 | 2 | 403.84 | 51.976 | $1.2494 \mathrm{e}-15$ |
| Weight: Model_Year | 81.219 | 2 | 40.609 | 5.2266 | 0.0071637 |
| Error | 683.74 | 88 | 7.7698 |  |  |

This output shows that the $p$-value for the test is 0.0072 (from the interaction row, Weight:Model_Year), so the null hypothesis is rejected at the 0.05 significance level. The value of the test statistic is 5.2266 . The numerator degrees of freedom for the test is 2 , which is the number of coefficients in the null hypothesis.

There is sufficient evidence that the slopes are not equal for all three model years.

## Create a Dataset Array from Workspace Variables

```
In this section...
"Create a Dataset Array from a Numeric Array" on page 2-65
"Create Dataset Array from Heterogeneous Workspace Variables" on page
2-68
```

## Create a Dataset Array from a Numeric Array

This example shows how to create a dataset array from a numeric array existing in the MATLAB ${ }^{\circledR}$ workspace.

## Load sample data.

load('fisheriris')

Two variables load into the workspace: meas, a 150-by-4 numeric array, and species, a 150-by- 1 cell array of strings containing species labels.

## Create a dataset array.

Use mat2dataset to convert the numeric array, meas, into a dataset array.

```
ds = mat2dataset(meas);
ds(1:10,:)
ans =
\begin{tabular}{llll} 
meas1 & meas2 & meas3 & meas4 \\
5.1 & 3.5 & 1.4 & 0.2 \\
4.9 & 3 & 1.4 & 0.2 \\
4.7 & 3.2 & 1.3 & 0.2 \\
4.6 & 3.1 & 1.5 & 0.2 \\
5 & 3.6 & 1.4 & 0.2 \\
5.4 & 3.9 & 1.7 & 0.4 \\
4.6 & 3.4 & 1.4 & 0.3 \\
5 & 3.4 & 1.5 & 0.2 \\
4.4 & 2.9 & 1.4 & 0.2 \\
4.9 & 3.1 & 1.5 & 0.1
\end{tabular}
```

The array, meas, has four columns, so the dataset array, ds, has four variables. The default variable names are the array name, meas, with column numbers appended.

You can specify your own variable or observation names using the name-value pair arguments VarNames and ObsNames, respectively.

If you use dataset to convert a numeric array to a dataset array, by default, the resulting dataset array has one variable that is an array instead of separate variables for each column.

## Examine the dataset array.

Return the size of the dataset array, ds.

```
size(ds)
ans =
    150 4
```

The dataset array, ds, is the same size as the numeric array, meas. Variable names and observation names do not factor into the size of a dataset array.

Return the metadata properties of the dataset array, ds.

```
ds.Properties
ans =
    Description: '
    VarDescription: {}
        Units: {}
        DimNames: {'Observations' 'Variables'}
        UserData: []
        ObsNames: {}
        VarNames: {'meas1' 'meas2' 'meas3' 'meas4'}
```

You can also access the properties individually. For example, you can retrieve the variable names and store them in a new variable, names.

```
names = ds.Properties.VarNames
names =
    'meas1' 'meas2' 'meas3' 'meas4'
```

## Access data in a dataset array variable.

You can use variable names with dot indexing to access the data in a dataset array. For example, find the minimum value in the first variable, meas1.
min(ds.meas1)
ans $=$
4.3000

## Modify the dataset array.

The four variables in ds are actually measurements of sepal length, sepal width, petal length, and petal width. Modify the variable names to be more descriptive.

```
ds.Properties.VarNames = {'SLength','SWidth','PLength','PWidth'};
```

Additionally, you can add a description for the dataset array.

```
ds.Properties.Description = 'Fisher iris data';
ds.Properties
ans =
    Description: 'Fisher iris data'
    VarDescription: {}
        Units: {}
        DimNames: {'Observations' 'Variables'}
        UserData: []
        ObsNames: {}
        VarNames: {'SLength' 'SWidth' 'PLength' 'PWidth'}
```

The dataset array properties are updated with the new variable names and description.

## Add a variable to the dataset array.

The variable species is a cell array of strings containing species labels. Add species to the dataset array, ds, as a nominal array named Species. Display the first five observations in the dataset array.

```
ds.Species = nominal(species);
ds(1:5,:)
ans =
\begin{tabular}{lllll} 
SLength & SWidth & PLength & PWidth & Species \\
5.1 & 3.5 & 1.4 & 0.2 & setosa \\
4.9 & 3 & 1.4 & 0.2 & setosa \\
4.7 & 3.2 & 1.3 & 0.2 & setosa \\
4.6 & 3.1 & 1.5 & 0.2 & setosa \\
5 & 3.6 & 1.4 & 0.2 & setosa
\end{tabular}
```

The dataset array, ds, now has the fifth variable, Species.

## Create Dataset Array from Heterogeneous Workspace Variables

This example shows how to create a dataset array from heterogeneous variables existing in the MATLAB workspace.

## Load sample data.

load('carsmall')

## Create a dataset array.

Create a dataset array from a subset of the workspace variables.

```
ds = dataset(Origin,Acceleration,Cylinders,MPG);
ds.Properties.VarNames(:)
ans =
    'Origin'
    'Acceleration'
```

```
Cylinders'
'MPG '
```

When creating the dataset array, you do not need to enter variable names. dataset automatically uses the name of each workspace variable.

Notice that the dataset array, ds, contains a collection of variables with heterogeneous data types. Origin is a character array, and the other variables are numeric.

## Examine a dataset array.

Display the first five observations in the dataset array.

| ds $(1: 5,:)$ |  |  |  |
| :--- | :--- | :--- | :--- |
| ans $=$ |  |  |  |
|  |  |  |  |
|  |  |  |  |
| Origin | Acceleration | Cylinders | MPG |
| USA | 12 | 8 | 18 |
| USA | 11.5 | 8 | 15 |
| USA | 11 | 8 | 18 |
| USA | 12 | 8 | 16 |
| USA | 10.5 | 8 | 17 |

You can use datasetfun to return the data type of each variable in ds.

```
varclass = datasetfun(@class,ds,'UniformOutput',false);
varclass(:)
ans =
    'char'
    'double'
    'double'
    'double'
```

You can get additional information about the variables using summary (ds).

## Modify a dataset array.

Cylinders is a numeric variable that has values 4, 6, and 8 for the number of cylinders. Convert Cylinders to a nominal array with levels four, six, and eight.
ds.Cylinders = nominal(ds.Cylinders,\{'four','six','eight'\});

Display the country of origin and number of cylinders for the first 15 cars.

```
ds(1:15,{'Origin','Cylinders'})
ans =
\begin{tabular}{ll} 
Origin & Cylinders \\
USA & eight \\
USA & eight \\
USA & eight \\
USA & eight \\
USA & eight \\
USA & eight \\
USA & eight \\
USA & eight \\
USA & eight \\
USA & eight \\
France & four \\
USA & eight \\
USA & eight \\
USA & eight \\
USA & eight
\end{tabular}
```

The variable Cylinders has a new data type.

## Create a Dataset Array from a File

In this section...<br>"Create a Dataset Array from a Tab-Delimited Text File" on page 2-71<br>"Create a Dataset Array from a Comma-Separated Text File" on page 2-74<br>"Create a Dataset Array from an Excel File" on page 2-77

## Create a Dataset Array from a Tab-Delimited Text File

This example shows how to create a dataset array from the contents of a tab-delimited text file.

## Create a dataset array using default settings.

Navigate to the folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Import the text file hospitalSmall.txt as a dataset array using the default settings.

```
ds = dataset('File','hospitalSmall.txt')
ds =
```

| name | sex | age | wgt | smoke |
| :--- | :--- | :--- | :--- | :--- |
| 'SMITH' | 'm' | 38 | 176 | 1 |
| 'JOHNSON' | 'm' | 43 | 163 | 0 |
| 'WILLIAMS' | ' f ' | 38 | 131 | 0 |
| 'JONES' | ' f ' | 40 | 133 | 0 |
| 'BROWN' | 'f' | 49 | 119 | 0 |
| 'DAVIS' | 'f' | 46 | 142 | 0 |
| 'MILLER' | 'f' | 33 | 142 | 1 |
| 'WILSON' | 'm' | 40 | 180 | 0 |
| 'MOORE' | 'm' | 28 | 183 | 0 |
| 'TAYLOR' | 'f' | 31 | 132 | 0 |
| 'ANDERSON' | 'f' | 45 | 128 | 0 |
| 'THOMAS' | 'f' | 42 | 137 | 0 |

| 'JACKSON ' | 'm' | 25 | 174 | 0 |
| :--- | :--- | :--- | :--- | :--- |
| 'WHITE' | $' m{ }^{\prime}$ | 39 | 202 | 1 |

By default, dataset uses the first row of the text file for variable names. If the first row does not contain variable names, you can specify the optional name-value pair argument 'ReadVarNames', false to change the default behavior.

The dataset array contains heterogeneous variables. The variables id, name, and sex are cell arrays of strings, and the other variables are numeric. You can see the data type and other descriptive statistics for each variable by using summary to summarize the dataset array.

```
summary(ds)
```

name: [14x1 cell string]
sex: [14x1 cell string]
age: [14x1 double]

| min | 1 st quartile | median | 3rd quartile | max |
| :--- | :--- | :--- | :--- | :--- |
| 25 | 33 | 39.5 | 43 | 49 |

wgt: [14x1 double]

| min | 1st quartile | median | 3rd quartile | max |
| :--- | :--- | :--- | :--- | :--- |
| 119 | 132 | 142 | 176 | 202 |

smoke: [14x1 double]

| min | 1st quartile | median | 3rd quartile | max |
| :--- | :--- | :--- | :--- | :--- |
| 0 | 0 | 0 | 0 | 1 |

## Import observation names.

Import the text file again, this time specifying that the first column contains observation names.

```
ds = dataset('File','hospitalSmall.txt','ReadObsNames',true)
```

ds =

|  | sex | age | wgt | smoke |
| :---: | :---: | :---: | :---: | :---: |
| SMITH | 'm' | 38 | 176 | 1 |
| JOHNSON | 'm' | 43 | 163 | 0 |
| WILLIAMS | 'f' | 38 | 131 | 0 |
| JONES | 'f' | 40 | 133 | 0 |
| BROWN | 'f' | 49 | 119 | 0 |
| DAVIS | 'f' | 46 | 142 | 0 |
| MILLER | 'f' | 33 | 142 | 1 |
| WILSON | 'm' | 40 | 180 | 0 |
| MOORE | 'm' | 28 | 183 | 0 |
| TAYLOR | 'f' | 31 | 132 | 0 |
| ANDERSON | 'f' | 45 | 128 | 0 |
| THOMAS | 'f' | 42 | 137 | 0 |
| JACKSON | 'm' | 25 | 174 | 0 |
| WHITE | 'm' | 39 | 202 | 1 |

The elements of the first column in the text file, last names, are now observation names. Observation names and row names are dataset array properties.

```
ds.Properties
```

ans =
Description: ''
VarDescription: \{\}
Units: \{\}
DimNames: \{'name' 'Variables'\}
UserData: []
ObsNames: \{14x1 cell\}
VarNames: \{'sex' 'age' 'wgt' 'smoke'\}

You can always add or change the observation names of an existing dataset array by modifying the property ObsNames.

Notice that the DimNames property has name as the descriptor of the observation (row) dimension. dataset got this name from the first row of the first column in the text file.

```
Change the first element of DimNames to LastName.
ds.Properties.DimNames{1} = 'LastName';
ds.Properties
ans =
    Description:
    VarDescription: {}
            Units: {}
        DimNames: {'LastName' 'Variables'}
        UserData: []
        ObsNames: {14x1 cell}
        VarNames: {'sex' 'age' 'wgt' 'smoke'}
```

You can use observation names to index into a dataset array. For example, return the data for the patient with last name BROWN.
ds('BROWN',:)
ans =

|  | sex | age | wgt | smoke |
| :--- | :--- | :--- | :--- | :--- |
| BROWN | 'f' | 49 | 119 | 0 |

Observation names must be unique.

## Create a Dataset Array from a Comma-Separated Text File

This example shows how to create a dataset array from the contents of a comma-separated text file.

## Create a dataset array.

Navigate to the folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Import the file hospitalSmall.csv as a dataset array, specifying the comma-delimited format.

```
ds = dataset('File','hospitalSmall.csv','Delimiter',',')
ds =
```

| id | name | sex | age | wgt | smoke |
| :--- | :--- | :--- | :--- | :--- | :--- |
| 'YPL-320' | 'SMITH' | 'm' | 38 | 176 | 1 |
| 'GLI-532' | 'JOHNSON' | 'm' | 43 | 163 | 0 |
| 'PNI-258' | 'WILLIAMS' | 'f' | 38 | 131 | 0 |
| 'MIJ-579' | 'JONES' | 'f' | 40 | 133 | 0 |
| 'XLK-030' | 'BROWN' | 'f' | 49 | 119 | 0 |
| 'TFP-518' | 'DAVIS' | 'f' | 46 | 142 | 0 |
| 'LPD-746' | 'MILLER' | 'f' | 33 | 142 | 1 |
| 'ATA-945' | 'WILSON' | 'm' | 40 | 180 | 0 |
| 'VNL-702' | 'MOORE' | 'm' | 28 | 183 | 0 |
| 'LQW-768' | 'TAYLOR' | 'f' | 31 | 132 | 0 |
| 'QFY-472' | 'ANDERSON' | 'f' | 45 | 128 | 0 |
| 'UJG-627' | 'THOMAS' | 'f' | 42 | 137 | 0 |
| 'XUE-826' | 'JACKSON' | 'm' | 25 | 174 | 0 |
| 'TRW-072' | 'WHITE' | 'm' | 39 | 202 | 1 |

By default, dataset uses the first row in the text file as variable names.

## Add observation names.

Use the unique identifiers in the variable id as observation names. Then, delete the variable id from the dataset array.

```
ds.Properties.ObsNames = ds.id;
ds.id = []
ds =
```

|  | name | sex | age | wgt | smoke |
| :--- | :--- | :--- | :--- | :--- | :--- |
| YPL-320 | 'SMITH' | 'm' | 38 | 176 | 1 |
| GLI-532 | 'JOHNSON' | 'm' | 43 | 163 | 0 |
| PNI-258 | 'WILLIAMS' | 'f' | 38 | 131 | 0 |
| MIJ-579 | 'JONES' | 'f' | 40 | 133 | 0 |
| XLK-030 | 'BROWN' | 'f' | 49 | 119 | 0 |

| TFP-518 | 'DAVIS' | 'f' | 46 | 142 | 0 |
| :--- | :--- | :--- | :--- | :--- | :--- |
| LPD-746 | 'MILLER' | 'f' | 33 | 142 | 1 |
| ATA-945 | 'WILSON' | 'm' | 40 | 180 | 0 |
| VNL-702 | 'MOORE' | 'm' | 28 | 183 | 0 |
| LQW-768 | 'TAYLOR' | 'f' | 31 | 132 | 0 |
| QFY-472 | 'ANDERSON' | 'f' | 45 | 128 | 0 |
| UJG-627 | 'THOMAS' | 'f' | 42 | 137 | 0 |
| XUE-826 | 'JACKSON' | 'm' | 25 | 174 | 0 |
| TRW-072 | 'WHITE' | 'm' | 39 | 202 | 1 |

## Delete observations.

Delete any patients with the last name BROWN. You can use strcmp to match the string 'BROWN ' with the elements of the variable containing last names, name.

```
toDelete = strcmp(ds.name,'BROWN');
```

ds(toDelete,:) = []
ds =

|  | name | sex | age | wgt | smoke |
| :--- | :--- | :--- | :--- | :--- | :--- |
| YPL-320 | 'SMITH' | 'm' | 38 | 176 | 1 |
| GLI-532 | 'JOHNSON' | 'm' | 43 | 163 | 0 |
| PNI-258 | 'WILLIAMS' | 'f' | 38 | 131 | 0 |
| MIJ-579 | 'JONES' | ' f ' | 40 | 133 | 0 |
| TFP-518 | 'DAVIS' | $' \mathrm{f} '$ | 46 | 142 | 0 |
| LPD-746 | 'MILLER' | 'f' | 33 | 142 | 1 |
| ATA-945 | 'WILSON' | 'm' | 40 | 180 | 0 |
| VNL-702 | 'MOORE' | 'm' | 28 | 183 | 0 |
| LQW-768 | 'TAYLOR' | 'f' | 31 | 132 | 0 |
| QFY-472 | 'ANDERSON' | 'f' | 45 | 128 | 0 |
| UJG-627 | 'THOMAS' | 'f' | 42 | 137 | 0 |
| XUE-826 | 'JACKSON' | 'm' | 25 | 174 | 0 |
| TRW-072 | 'WHITE' | 'm' | 39 | 202 | 1 |

One patient having last name BROWN is deleted from the dataset array. The array now has 13 observations:

```
size(ds)
```

135
Note that the row and column corresponding to variable and observation names, respectively, are not included in the size of a dataset array.

## Create a Dataset Array from an Excel File

This example shows how to create a dataset array from the contents of an Excel ${ }^{\circledR}$ spreadsheet file.

## Create a dataset array.

Navigate to the folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Import the data from the first worksheet in the file hospitalSmall.xlsx, specifying that the data file is an Excel spreadsheet.

```
ds = dataset('XLSFile','hospitalSmall.xlsx')
```

ds =

| id | name | sex | age | wgt | smoke |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 'YPL-320' | 'SMITH ' | 'm' | 38 | 176 | 1 |
| 'GLI-532' | 'JOHNSON ' | 'm' | 43 | 163 | 0 |
| 'PNI-258' | 'WILLIAMS' | 'f' | 38 | 131 | 0 |
| 'MIJ-579' | 'JONES' | 'f' | 40 | 133 | 0 |
| 'XLK-030' | 'BROWN' | 'f' | 49 | 119 | 0 |
| 'TFP-518' | 'DAVIS' | 'f' | 46 | 142 | 0 |
| 'LPD-746' | 'MILLER ' | 'f' | 33 | 142 | 1 |
| 'ATA-945' | 'WILSON ' | 'm' | 40 | 180 | 0 |
| 'VNL-702' | 'MOORE' | 'm' | 28 | 183 | 0 |
| ' LQW-768' | 'TAYLOR ' | 'f' | 31 | 132 | 0 |
| 'QFY-472' | ' ANDERSON ${ }^{\prime}$ | 'f' | 45 | 128 | 0 |

| ' TRW-072' | 'WHITE' | 'm' | 39 | 202 | 1 |

By default, dataset creates variable names using the contents of the first row in the spreadsheet.

## Specify which worksheet to import.

Import the data from the second worksheet into a new dataset array.
ds2 = dataset('XLSFile','hospitalSmall.xlsx','Sheet',2)
ds2 =

| id | name | sex | age | wgt | smoke |
| :--- | :--- | :--- | :--- | :--- | :--- |
| 'TRW-072' | 'WHITE' | 'm' | 39 | 202 | 1 |

## Add and Delete Observations

This example shows how to add and delete observations in a dataset array. You can also edit dataset arrays using the Variables editor.

## Load sample data.

Navigate to the folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Import the data from the first worksheet in hospitalSmall.xlsx into a dataset array.

```
ds = dataset('XLSFile','hospitalSmall.xlsx');
size(ds)
ans =
    14 6
```

The dataset array, ds, has 14 observations (rows) and 6 variables (columns).

## Add observations by concatenation.

The second worksheet in hospitalSmall.xlsx has additional patient data. Append the observations in this spreadsheet to the end of ds.

```
ds2 = dataset('XLSFile','hospitalSmall.xlsx','Sheet',2);
dsNew = [ds;ds2];
size(dsNew)
ans =
    22 6
```

The dataset array dsNew has 22 observations. In order to vertically concatenate two dataset arrays, both arrays must have the same number of variables, with the same variable names.

## Add observations from a cell array.

If you want to append new observations stored in a cell array, first convert the cell array to a dataset array, and then concatenate the dataset arrays.

```
cellObs = {'id','name','sex','age','wgt','smoke';
    'YQR-965','BAKER','M',36,160,0;
    'LFG-497','WALL' ,'F',28,125,1;
    'KSD-003','REED' ,'M',32,187,0};
dsNew = [dsNew;cell2dataset(cellObs)];
size(dsNew)
ans =
    25 6
```

## Add observations from a structure.

You can also append new observations stored in a structure. Convert the structure to a dataset array, and then concatenate the dataset arrays.

```
structObs(1,1).id = 'GHK-842';
structObs(1,1).name = 'GEORGE';
structObs(1,1).sex = 'M';
structObs(1,1).age = 45;
structObs(1,1).wgt = 182;
structObs(1,1).smoke = 1;
structObs(2,1).id = 'QRH-308';
structObs(2,1).name = 'BAILEY';
structObs(2,1).sex = 'F';
structObs(2,1).age = 29;
structObs(2,1).wgt = 120;
structObs(2,1).smoke = 0;
dsNew = [dsNew;struct2dataset(structObs)];
size(dsNew)
ans =
    27 6
```

## Delete duplicate observations.

Use unique to delete any observations in a dataset array that are duplicated.

```
dsNew = unique(dsNew);
```

size(dsNew)
ans =
216
One duplicated observation is deleted.

## Delete observations by observation number.

Delete observations 18, 20, and 21 from the dataset array.

```
dsNew([18,20,21],:) = [];
```

size(dsNew)
ans =

186
The dataset array has only 18 observations now.

## Delete observations by observation name.

First, specify the variable of identifiers, id, as observation names. Then, delete the variable id from dsNew. You can use the observation name to index observations.

```
dsNew.Properties.ObsNames = dsNew.id;
dsNew.id = [];
dsNew('KOQ-996',:) = [];
size(dsNew)
ans =
    17 5
```

The dataset array now has one less observation and one less variable.

## Search for observations to delete.

You can also search for observations in the dataset array. For example, delete observations for any patients with the last name WILLIAMS.

```
toDelete = strcmp(dsNew.name,'WILLIAMS');
dsNew(toDelete,:) = [];
size(dsNew)
ans =
16 5
```

The dataset array now has one less observation.

## See Also

dataset | cell2dataset | struct2dataset

Concepts - "Dataset Arrays" on page 2-135

## Add and Delete Variables

This example shows how to add and delete variables in a dataset array. You can also edit dataset arrays using the Variables editor.

## Load sample data.

Navigate to the folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Import the data from the first worksheet in hospitalSmall.xlsx into a dataset array.

```
ds = dataset('XLSFile','hospitalSmall.xlsx');
size(ds)
ans =
    14 6
```

The dataset array, ds, has 14 observations (rows) and 6 variables (columns).

## Add variables by concatenating dataset arrays.

The worksheet Heights in hospitalSmall.xlsx has heights for the patients on the first worksheet. Concatenate the data in this spreadsheet with ds.

```
ds2 = dataset('XLSFile','hospitalSmall.xlsx','Sheet','Heights');
ds = [ds ds2];
size(ds)
ans =
    14 7
```

The dataset array now has seven variables. You can only horizontally concatenate dataset arrays with observations in the same position, or with the same observation names.
ds.Properties.VarNames \{end\}
hgt
The name of the last variable in ds is hgt, which dataset read from the first row of the imported spreadsheet.

## Delete variables by variable name.

First, specify the unique identifiers in the variable id as observation names. Then, delete the variable id from the dataset array.

```
ds.Properties.ObsNames = ds.id;
ds.id = [];
size(ds)
ans =
    14 6
```

The dataset array now has six variables. List the variable names.

```
ds.Properties.VarNames(:)
ans =
    'name'
    'sex'
    'age'
    'wgt'
    'smoke'
    'hgt'
```

There is no longer a variable called id.

## Add a new variable by name.

Add a new variable, bmi-which contains the body mass index (BMI) for each patient-to the dataset array. BMI is a function of height and weight. Display the last name, gender, and BMI for each patient.
ds.bmi $=$ ds.wgt*703./ds.hgt.^2;

```
ds(:,{'name','sex','bmi'})
ans =
\begin{tabular}{|c|c|c|c|}
\hline & name & sex & bmi \\
\hline YPL-320 & 'SMITH' & 'm' & 24.544 \\
\hline GLI-532 & 'JOHNSON' & 'm' & 24.068 \\
\hline PNI-258 & 'WILLIAMS' & 'f' & 23.958 \\
\hline MIJ - 579 & JONES' & 'f' & 25.127 \\
\hline XLK-030 & BROWN ' & 'f' & 21.078 \\
\hline TFP-518 & DAVIS' & 'f' & 27.729 \\
\hline LPD-746 & 'MILLER' & 'f' & 26.828 \\
\hline ATA-945 & 'WILSON' & 'm' & 24.41 \\
\hline VNL-702 & 'MOORE' & 'm' & 27.822 \\
\hline LQW-768 & TAYLOR ' & 'f' & 22.655 \\
\hline QFY - 472 & 'ANDERSON' & 'f' & 23.409 \\
\hline UJG-627 & THOMAS' & 'f' & 25.883 \\
\hline XUE-826 & 'JACKSON' & 'm' & 24.265 \\
\hline TRW-072 & 'WHITE' & 'm' & 29.827 \\
\hline
\end{tabular}
```

The operators ./ and .^ in the calculation of BMI indicate element-wise division and exponentiation, respectively.

## Delete variables by variable number.

Delete the variable wgt, the fourth variable in the dataset array.

```
ds(:,4) = [];
ds.Properties.VarNames(:)
ans =
    'name'
    'sex'
    'age'
    'smoke'
    'hgt'
    'bmi'
```

The variable wgt is deleted from the dataset array.

Concepts • "Dataset Arrays" on page 2-135

## Access Data in Dataset Array Variables

This example shows how to work with dataset array variables and their data.

## Access variables by name.

You can access variable data, or select a subset of variables, by using variable (column) names and dot indexing. Load a sample dataset array.
load('hospital')
The dataset array has 7 variables (columns) and 100 observations (rows). You can double-click hospital in the Workspace window to view the dataset array in the Variables editor.

Display the names of the variables in hospital.
hospital.Properties.VarNames(:)
ans =
'LastName'
'Sex'
'Age'
'Weight'
'Smoker'
'BloodPressure'
'Trials'

Plot a histogram of the data in the variable Weight.
figure()
hist(hospital.Weight)

The histogram shows that the weight distribution is bimodal. Draw box plots of Weight grouped by the values in Sex (Male and Female). That is, use the variable Sex as a grouping variable.

```
figure()
boxplot(hospital.Weight,hospital.Sex)
```

The box plot suggests that gender accounts for the bimodality in weight.

## Select a subset of variables.

Create a new dataset array with only the variables LastName, Sex, and Weight. You can access the variables by name or column number.

```
ds1 = hospital(:,{'LastName','Sex','Weight'});
ds2 = hospital(:,[1,2,4]);
```

The dataset arrays ds1 and ds2 are equivalent. Use parentheses ( ) when indexing dataset arrays to preserve the data type; that is, to create a dataset array from a subset of a dataset array. You can also use the Variables editor to create a new dataset array from a subset of variables and observations.

## Convert the variable data type.

Convert the data type of the variable Smoker from logical to nominal with labels No and Yes.

```
class(hospital.Smoker)
ans =
logical
hospital.Smoker = nominal(hospital.Smoker,{'No','Yes'});
class(hospital.Smoker)
ans =
nominal
Display the first }10\mathrm{ elements of Smoker.
hospital.Smoker(1:10)
ans =
    Yes
No
No
No
No
No
    Yes
    No
    No
    No
```

If you want to change the level labels in a nominal array, use setlabels.

## Add variables.

The variable BloodPressure is a 100-by-2 array. The first column corresponds to systolic blood pressure, and the second column to diastolic blood pressure. Separate this array into two new variables, SysPressure and DiaPressure.

```
size(hospital.BloodPressure)
```

ans =

```
hospital.SysPressure = hospital.BloodPressure(:,1);
hospital.DiaPressure = hospital.BloodPressure(:,2);
hospital.Properties.VarNames(:)
ans =
    'LastName'
    'Sex'
    'Age'
    'Weight'
    'Smoker'
    'BloodPressure'
    'Trials'
    'SysPressure'
    'DiaPressure'
```

The dataset array, hospital, has two new variables.

## Search for variables by name.

Use regexp to find variables in hospital with the string 'Pressure ' in their name. Create a new dataset array containing only these variables.

```
bp = regexp(hospital.Properties.VarNames,'Pressure');
bpIdx = cellfun(@isempty,bp);
bpData = hospital(:,~bpIdx);
bpData.Properties.VarNames(:)
ans =
    'BloodPressure'
    'SysPressure'
    'DiaPressure'
```

The new dataset array, bpData, contains only the blood pressure variables.

## Delete variables.

Delete the variable BloodPressure from the dataset array, hospital.

```
hospital.BloodPressure = [];
hospital.Properties.VarNames(:)
ans =
    'LastName
            'Sex'
            'Age'
            'Weight'
            'Smoker'
            'Trials'
                    SysPressure'
                    DiaPressure'
```

The variable BloodPressure is no longer in the dataset array.

## See Also dataset

## Select Subsets of Observations

This example shows how to select an observation or subset of observations from a dataset array.

## Index observations by name.

Load the sample dataset array, hospital. Dataset arrays can have observation (row) names. This array has observation names corresponding to unique patient identifiers.

```
load('hospital')
hospital.Properties.ObsNames(1:10)
ans =
    'YPL-320'
    'GLI-532'
    'PNI - 258'
    'MIJ-579'
    'XLK-030'
    'TFP-518'
    'LPD-746'
    'ATA-945'
    'VNL - 702'
    ' LQW-768'
```

These are the first 10 observation names. You can use them to index into the dataset array. For example, extract the last name, sex, and age for the patient with identifier XLK-030.
hospital('XLK-030', \{'LastName','Sex','Age'\})
ans $=$

|  | LastName | Sex | Age |
| :---: | :--- | :--- | :--- |
| XLK-030 | 'BROWN' | Female | 49 |

## Index a subset of observations by number.

Create a new dataset array containing the first 50 patients.

```
ds50 = hospital(1:50,:);
size(ds50)
ans =
    50 7
```

## Search observations using a logical condition.

Create a new dataset array containing only male patients. To find the male patients, use a logical condition to search the variable containing gender information.

```
dsMale = hospital(hospital.Sex=='Male',:);
dsMale(1:10,{'LastName','Sex'})
ans =
\begin{tabular}{lll} 
& LastName & Sex \\
YPL-320 & 'SMITH' & Male \\
GLI-532 & 'JOHNSON' & Male \\
ATA-945 & 'WILSON' & Male \\
VNL-702 & 'MOORE' & Male \\
XUE-826 & 'JACKSON' & Male \\
TRW-072 & 'WHITE' & Male \\
KOQ-996 & 'MARTIN' & Male \\
YUZ-646 & 'THOMPSON' & Male \\
KPW-846 & 'MARTINEZ' & Male \\
XBA-581 & 'ROBINSON' & Male
\end{tabular}
```

You can use multiple conditions to search the dataset array. For example, create a new dataset array containing only female patients older than 40.

```
dsFemale = hospital(hospital.Sex=='Female' & hospital.Age > 40,:);
dsFemale(1:10,{'LastName','Sex','Age'})
ans =
\begin{tabular}{llll} 
& LastName & Sex & Age \\
XLK-030 & 'BROWN' & Female & 49 \\
TFP-518 & 'DAVIS' & Female & 46
\end{tabular}
```

| QFY-472 | 'ANDERSON ' | Female | 45 |
| :--- | :--- | :--- | :--- |
| UJG-627 | 'THOMAS' | Female | 42 |
| BKD-785 | 'CLARK' | Female | 48 |
| VWL-936 | 'LEWIS' | Female | 41 |
| AAX-056 | 'LEE' | Female | 44 |
| AFK-336 | 'WRIGHT' | Female | 45 |
| KKL-155 | 'ADAMS' | Female | 48 |
| RBA-579 | 'SANCHEZ' | Female | 44 |

## Select a random subset of observations.

Create a new dataset array containing a random subset of 20 patients from the dataset array hospital.

```
rng('default') % For reproducibility
dsRandom = hospital(randsample(length(hospital), 20),:);
dsRandom.Properties.ObsNames
```

```
ans =
```

    'DAU-529'
    'AGR-528'
    ' RB0-332 '
    'Q00-305 '
    ' RVS-253'

    'MEZ-469'
    'UDS-151'
    'MIJ-579'
    'DGC-290'
    
## Delete observations by name.

Delete the data for the patient with observation name HVR-372.
hospital('HVR-372',:) = []; size(hospital)
ans =
$99 \quad 7$

The dataset array has one less observation.
See Also dataset I
Related - "Add and Delete Observations" on page 2-79
Examples

- "Clean Messy and Missing Data" on page 2-117
- "Dataset Arrays in the Variables Editor" on page 2-122
- "Sort Observations in Dataset Arrays" on page 2-97
- "Index and Search Dataset Arrays" on page 2-138

Concepts - "Dataset Arrays" on page 2-135

## Sort Observations in Dataset Arrays

This example shows how to sort observations (rows) in a dataset array using the command line. You can also sort rows using the Variables editor.

## Sort observations by the values of a single variable.

Load the sample dataset array, hospital. Sort the observations by the values in Age, in ascending order.

```
load('hospital')
dsAgeUp = sortrows(hospital,'Age');
dsAgeUp(1:10,{'LastName','Age'})
ans =
LastName Age
XUE-826 'JACKSON' 25
FZR-250 'HALL' 25
PUE-347 'YOUNG' 25
LIM-480 'HILL' 25
SCQ-914 'JAMES' 25
REV-997 'ALEXANDER' 25
XBR-291 'GARCIA' 27
VNL-702 'MOORE' 28
DTT-578 'WALKER' 28
XAX-646 'COOPER' 28
```

The youngest patients are age 25 .
Sort the observations by Age in descending order.

```
dsAgeDown = sortrows(hospital,'Age','descend');
dsAgeDown(1:10,{'LastName','Age'})
ans =
\begin{tabular}{lll} 
& LastName & Age \\
XBA-581 & 'ROBINSON' & 50 \\
DAU-529 & 'REED' & 50 \\
XLK-030 & 'BROWN' & 49
\end{tabular}
```

| FLJ-908 | 'STEWART' | 49 |
| :--- | :--- | :--- |
| GGU-691 | 'HUGHES' | 49 |
| MEZ-469 | 'GRIFFIN ' | 49 |
| KOQ-996 | 'MARTIN' | 48 |
| BKD-785 | 'CLARK' | 48 |
| KKL-155 | 'ADAMS' | 48 |
| NSK-403 | 'RAMIREZ' | 48 |

The oldest patients are age 50.

## Sort observations by the values of two variables.

Sort the observations in hospital by Age, and then by LastName.

```
dsName = sortrows(hospital,{'Age','LastName'});
dsName(1:10,{'LastName','Age'})
ans =
```

|  | LastName | Age |
| :--- | :--- | :--- |
| REV-997 | 'ALEXANDER' | 25 |
| FZR-250 | 'HALL' | 25 |
| LIM-480 | 'HILL' | 25 |
| XUE-826 | 'JACKSON' | 25 |
| SCQ-914 | 'JAMES' | 25 |
| PUE-347 | 'YOUNG' | 25 |
| XBR-291 | 'GARCIA' | 27 |
| XAX-646 | 'COOPER' | 28 |
| QEQ-082 | 'COX' | 28 |
| NSU-424 | 'JENKINS' | 28 |

Now the names are sorted alphabetically within increasing age groups.

Sort the observations in hospital by Age in an increasing order, and then by Weight in a decreasing order.

```
dsWeight = sortrows(hospital,{'Age','Weight'},{'ascend','descend'});
```

dsWeight(1:10, \{'LastName', 'Age', 'Weight'\})
ans =

|  | LastName | Age | Weight |
| :--- | :--- | :--- | :--- |
| FZR-250 | 'HALL' | 25 | 189 |
| SCQ-914 | 'JAMES' | 25 | 186 |
| XUE-826 | 'JACKSON' | 25 | 174 |
| REV-997 | 'ALEXANDER' | 25 | 171 |
| LIM-480 | 'HILL' | 25 | 138 |
| PUE-347 | 'YOUNG' | 25 | 114 |
| XBR-291 | 'GARCIA' | 27 | 131 |
| NSU-424 | 'JENKINS' | 28 | 189 |
| VNL-702 | 'MOORE' | 28 | 183 |
| XAX-646 | 'COOPER' | 28 | 127 |

This shows that the maximum weight among patients that are age 25 is 189 lbs.

## Sort observations by observation name.

Sort the observations in hospital by the observation names.

```
dsObs = sortrows(hospital,'obsnames');
dsObs(1:10,{'LastName','Age'})
ans =
```

|  | LastName | Age |
| :--- | :--- | :--- |
| AAX-056 | 'LEE' | 44 |
| AFB-271 | 'PEREZ' | 44 |
| AFK-336 | 'WRIGHT' | 45 |
| AGR-528 | 'SIMMONS' | 45 |
| ATA-945 | 'WILSON' | 40 |
| BEZ-311 | 'DIAZ' | 45 |
| BKD-785 | 'CLARK' | 48 |
| DAU-529 | 'REED' | 50 |
| DGC-290 | 'BUTLER' | 38 |
| DTT-578 | 'WALKER' | 28 |

The observations are sorted by observation name in ascending alphabetical order.

## Merge Dataset Arrays

This example shows how to merge dataset arrays using join.

## Load sample data.

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Import the data from the first worksheet in hospitalSmall.xlsx into a dataset array, then keep only a few of the variables.

```
ds1 = dataset('XLSFile','hospitalSmall.xlsx');
ds1 = ds1(:,{'id','name','sex','age'})
ds1 =
id
    'YPL-320'
    'GLI -532'
'PNI-258'
    'MIJ-579'
    'XLK-030' 'BROWN' 'f' 49
    'TFP-518' 'DAVIS' 'f' 46
    'LPD-746' 'MILLER' 'f' 33
    'ATA-945' 'WILSON' 'm' 40
    'VNL-702' 'MOORE' 'm' 28
    'LQW-768' 'TAYLOR' 'f' 31
    'QFY-472' 'ANDERSON' 'f' 45
    'UJG-627' 'THOMAS' 'f' 42
    'XUE-826' 'JACKSON' 'm' 
    'TRW-072' 'WHITE' 'm' 39
        name
sex age
'SMITH' 'm'
38
    'JOHNSON '
'm'
    'WILLIAMS
```

The dataset array, ds1, has 14 observations (rows) and 4 variables (columns).
Import the data from the worksheet Heights2 in hospitalSmall.xlsx.
ds2 = dataset('XLSFile','hospitalSmall.xlsx','Sheet','Heights2')
ds2 =

```
id hgt
'LPD-746' 61
'PNI-258' 62
'XUE-826' 71
'ATA-945' 72
'XLK-030' 63
```

ds2 has height measurements for a subset of five individuals from the first dataset array, ds1.

## Merge only the matching subset of observations.

Use join to merge the two dataset arrays, ds1 and ds2, keeping only the subset of observations that are in ds2.

JoinSmall = join(ds2,ds1)

JoinSmall =

| id | hgt | name | sex | age |
| :--- | :--- | :--- | :--- | :--- |
| 'LPD-746' | 61 | 'MILLER' | 'f' | 33 |
| 'PNI-258' | 62 | 'WILLIAMS' | 'f' | 38 |
| 'XUE-826' | 71 | 'JACKSON' | 'm' | 25 |
| 'ATA-945' | 72 | 'WILSON' | 'm' | 40 |
| 'XLK-030' | 63 | 'BROWN' | 'f' | 49 |

In JoinSmall, the variable id only appears once. This is because it is the key variable-the variable that links observations between the two dataset arrays-and has the same variable name in both ds1 and ds2.

## Include incomplete observations in the merge.

Merge ds1 and ds2 keeping all observations in the larger ds1.

```
joinAll = join(ds2,ds1,'type','rightouter','mergekeys',true)
joinAll =
```

id hgt name sex age

| 'ATA-945' | 72 | 'WILSON ' | 'm' | 40 |
| :---: | :---: | :---: | :---: | :---: |
| 'GLI-532' | NaN | 'JOHNSON ' | 'm' | 43 |
| 'LPD-746' | 61 | 'MILLER ' | 'f' | 33 |
| 'LQW-768' | NaN | 'TAYLOR ' | 'f' | 31 |
| 'MIJ-579' | NaN | 'JONES' | 'f' | 40 |
| 'PNI-258' | 62 | 'WILLIAMS' | 'f' | 38 |
| 'QFY-472' | NaN | 'ANDERSON ${ }^{\prime}$ | 'f' | 45 |
| 'TFP-518' | NaN | 'DAVIS' | 'f' | 46 |
| 'TRW-072' | NaN | 'WHITE' | 'm' | 39 |
| ' UJG-627' | NaN | 'THOMAS ' | 'f' | 42 |
| 'VNL-702' | NaN | 'MOORE ' | 'm' | 28 |
| 'XLK-030' | 63 | 'BROWN ' | 'f' | 49 |
| ' XUE-826' | 71 | 'JACKSON ' | 'm' | 25 |
| 'YPL-320' | NaN | 'SMITH' | 'm' | 38 |

Each observation in ds1 without corresponding height measurements in ds2 has height value NaN. Also, because there is no id value in ds2 for each observation in ds1, you need to merge the keys using the option 'MergeKeys', true. This merges the key variable, id.

## Merge dataset arrays with different key variable names.

When using join, it is not necessary for the key variable to have the same name in the dataset arrays to be merged. Import the data from the worksheet named Heights3 in hospitalSmall.xlsx.

```
ds3 = dataset('XLSFile','hospitalSmall.xlsx','Sheet','Heights3')
ds3 =
```

identifier hgt
'GLI-532' 69
'QFY-472' 62
'MIJ-579' 61
'VNL-702' 68
'XLK-030' 63
'LPD-746' 61
'TFP-518' 60
'YPL-320' 71
'ATA-945' 72
'LQW-768' 64

```
'PNI-258'62
```

' UJG-627' ..... 61
' XUE-826' ..... 71
TRW-072' ..... 69
ds3 has height measurements for each observation in ds1. This dataset array has the same patient identifiers as ds1, but they are under the variable name identifier, instead of id (and in a different order).

You can easily change the variable name of the key variable in ds3 by setting d3. Properties.VarNames or using the Variables editor, but it is not required to perform a merge. Instead, you can specify the name of the key variable in each dataset array using LeftKeys and RightKeys.

```
joinDiff = join(ds3,ds1,'LeftKeys','identifier','RightKeys','id')
```

joinDiff =

| identifier | hgt | name | sex | age |
| :---: | :---: | :---: | :---: | :---: |
| 'GLI-532' | 69 | 'JOHNSON ' | 'm' | 43 |
| 'QFY-472' | 62 | 'ANDERSON ' | 'f' | 45 |
| 'MIJ-579' | 61 | 'JONES' | 'f' | 40 |
| 'VNL-702' | 68 | 'MOORE ' | 'm' | 28 |
| 'XLK-030' | 63 | 'BROWN ' | 'f' | 49 |
| 'LPD-746' | 61 | 'MILLER ' | 'f' | 33 |
| 'TFP-518' | 60 | 'DAVIS' | 'f' | 46 |
| 'YPL-320' | 71 | 'SMITH' | 'm' | 38 |
| 'ATA-945' | 72 | 'WILSON' | 'm' | 40 |
| 'LQW-768' | 64 | 'TAYLOR' | 'f' | 31 |
| 'PNI-258' | 62 | 'WILLIAMS' | 'f' | 38 |
| 'UJG-627' | 61 | ' THOMAS ${ }^{\prime}$ | 'f' | 42 |
| 'XUE-826' | 71 | 'JACKSON' | 'm' | 25 |
| 'TRW-072' | 69 | 'WHITE' | 'm' | 39 |

The merged dataset array, joinDiff, has the same key variable order and name as the first dataset array input to join, ds3.

## See Also <br> dataset | join |

## Stack or Unstack Dataset Arrays

This example shows how to reformat dataset arrays between wide and tall (or long) format using stack and unstack.

## Load sample data.

Navigate to the folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Import the data from the comma-separated text file testScores.csv.

```
ds = dataset('File','testScores.csv','Delimiter',',')
ds =
```

| LastName | Sex | Test1 | Test2 | Test3 | Test4 |
| :--- | :--- | :--- | :--- | :--- | :--- |
| 'HOWARD' | 'male' | 90 | 87 | 93 | 92 |
| 'WARD' | 'male' | 87 | 85 | 83 | 90 |
| 'TORRES' | 'male' | 86 | 85 | 88 | 86 |
| 'PETERSON' | 'female' | 75 | 80 | 72 | 77 |
| 'GRAY' | 'female' | 89 | 86 | 87 | 90 |
| 'RAMIREZ' | 'female' | 96 | 92 | 98 | 95 |
| 'JAMES' | 'male' | 78 | 75 | 77 | 77 |
| 'WATSON' | 'female' | 91 | 94 | 92 | 90 |
| 'BROOKS' | 'female' | 86 | 83 | 85 | 89 |
| 'KELLY' | 'male' | 79 | 76 | 82 | 80 |

Each of the 10 students has 4 test scores, displayed here in wide format.
With the data in this format, you can, for example, calculate the average test score for each student. The test scores are in columns 3 to 6 .

```
ds.TestAve = mean(double(ds(:,3:6)),2);
ds(:,{'LastName','Sex','TestAve'})
ans =
LastName
    Sex
    TestAve
```

| 'HOWARD' | 'male' | 90.5 |
| :--- | :--- | ---: |
| 'WARD' | 'male' | 86.25 |
| 'TORRES' | 'male' | 86.25 |
| 'PETERSON' | 'female' | 76 |
| 'GRAY' | 'female' | 88 |
| 'RAMIREZ' | 'female' | 95.25 |
| 'JAMES' | 'male' | 76.75 |
| 'WATSON' | 'female' | 91.75 |
| 'BROOKS' | 'female' | 85.75 |
| 'KELLY' | 'male' | 79.25 |

A new variable with average test scores is added to the dataset array, ds.

## Reformat the dataset array into tall format.

Stack the test score variables into a new variable, Scores.

```
dsTall = stack(ds,{'Test1','Test2','Test3','Test4'},...
    'newDataVarName','Scores')
dsTall =
```

| LastName | Sex | TestAve | Scores_Indicator | Scores |
| :--- | :--- | :---: | :--- | :--- |
| 'HOWARD' | 'male' | 90.5 | Test1 | 90 |
| 'HOWARD' | 'male' | 90.5 | Test2 | 87 |
| 'HOWARD' | 'male' | 90.5 | Test3 | 93 |
| 'HOWARD' | 'male' | 90.5 | Test4 | 92 |
| 'WARD' | 'male' | 86.25 | Test1 | 87 |
| 'WARD' | 'male' | 86.25 | Test2 | 85 |
| 'WARD' | 'male' | 86.25 | Test3 | 83 |
| 'WARD' | 'male' | 86.25 | Test4 | 90 |
| 'TORRES' | 'male' | 86.25 | Test1 | 86 |
| 'TORRES' | 'male' | 86.25 | Test2 | 85 |
| 'TORRES' | 'male' | 86.25 | Test3 | 88 |
| 'TORRES' | 'male' | 86.25 | Test4 | 86 |
| 'PETERSON' | 'female' | 76 | Test1 | 75 |
| 'PETERSON' | 'female' | 76 | Test2 | 80 |
| 'PETERSON' | 'female' | 76 | Test3 | 72 |
| 'PETERSON' | 'female' | 76 | Test4 | 77 |
| 'GRAY' | 'female' | 88 | Test1 | 89 |
| 'GRAY' | 'female' | 88 | Test2 | 86 |

| 'GRAY' | 'female' | 88 | Test3 | 87 |
| :--- | :--- | :--- | :--- | :--- |
| 'GRAY' | 'female' | 88 | Test4 | 90 |
| 'RAMIREZ' | 'female' | 95.25 | Test1 | 96 |
| 'RAMIREZ' | 'female' | 95.25 | Test2 | 92 |
| 'RAMIREZ' | 'female' | 95.25 | Test3 | 98 |
| 'RAMIREZ' | 'female' | 95.25 | Test4 | 95 |
| 'JAMES' | 'male' | 76.75 | Test1 | 78 |
| 'JAMES' | 'male' | 76.75 | Test2 | 75 |
| 'JAMES' | 'male' | 76.75 | Test3 | 77 |
| 'JAMES' | 'male' | 76.75 | Test4 | 77 |
| 'WATSON' | 'female' | 91.75 | Test1 | 91 |
| 'WATSON' | 'female' | 91.75 | Test2 | 94 |
| 'WATSON' | 'female' | 91.75 | Test3 | 92 |
| 'WATSON' | 'female' | 91.75 | Test4 | 90 |
| 'BROOKS' | 'female' | 85.75 | Test1 | 86 |
| 'BROOKS' | 'female' | 85.75 | Test2 | 83 |
| 'BROOKS' | 'female' | 85.75 | Test3 | 85 |
| 'BROOKS' | 'female' | 85.75 | Test4 | 89 |
| 'KELLY' | 'male' | 79.25 | Test1 | 79 |
| 'KELLY' | 'male' | 79.25 | Test2 | 76 |
| 'KELLY' | 'male' | 79.25 | Test3 | 82 |
| 'KELLY' | 'male' | 79.25 | Test4 | 80 |

The original test variable names, Test1, Test2, Test3, and Test4, appear as levels in the combined test scores indicator variable, Scores_Indicator.

With the data in this format, you can use Scores_Indicator as a grouping variable, and draw box plots of test scores grouped by test.
figure()
boxplot(dsTall.Scores,dsTall.Scores_Indicator)

## Reformat the dataset array into wide format.

Reformat dsTall back into its original wide format.

```
dsWide = unstack(dsTall,'Scores','Scores_Indicator');
dsWide(:,{'LastName','Test1','Test2','Test3','Test4'})
```

ans =

| LastName | Test1 | Test2 | Test3 | Test4 |
| :--- | :--- | :--- | :--- | :--- |
| 'HOWARD' | 90 | 87 | 93 | 92 |
| 'WARD' | 87 | 85 | 83 | 90 |
| 'TORRES' | 86 | 85 | 88 | 86 |
| ' PETERSON ' $^{\text {'GRAY' }}$ | 75 | 80 | 72 | 77 |
| ' RAMIREZ' $^{\text {'JAMES' }}$ | 89 | 86 | 87 | 90 |
| 'WATSON ' | 96 | 92 | 98 | 95 |

| 'BROOKS' | 86 | 83 | 85 | 89 |
| :--- | :--- | :--- | :--- | :--- |
| 'KELLY' | 79 | 76 | 82 | 80 |

The dataset array is back in wide format. unstack reassigns the levels of the indicator variable, Scores_Indicator, as variable names in the unstacked dataset array.

## See Also dataset | double | stack | unstack |

## Calculations on Dataset Arrays

This example shows how to perform calculations on dataset arrays.

## Load sample data.

Navigate to the folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Import the data from the comma-separated text file testScores.csv.

```
ds = dataset('File','testScores.csv','Delimiter',',')
ds =
```

| LastName | Sex | Test1 | Test2 | Test3 | Test4 |
| :--- | :--- | :--- | :--- | :--- | :--- |
| 'HOWARD' | 'male' | 90 | 87 | 93 | 92 |
| 'WARD' | 'male' | 87 | 85 | 83 | 90 |
| 'TORRES' | 'male' | 86 | 85 | 88 | 86 |
| 'PETERSON' | 'female' | 75 | 80 | 72 | 77 |
| 'GRAY' | 'female' | 89 | 86 | 87 | 90 |
| 'RAMIREZ' | 'female' | 96 | 92 | 98 | 95 |
| 'JAMES' | 'male' | 78 | 75 | 77 | 77 |
| 'WATSON' | 'female' | 91 | 94 | 92 | 90 |
| 'BROOKS' | 'female' | 86 | 83 | 85 | 89 |
| 'KELLY' | 'male' | 79 | 76 | 82 | 80 |

There are 4 test scores for each of 10 students, in wide format.

## Average dataset array variables.

Compute the average (mean) test score for each student in the dataset array, and store it in a new variable, TestAvg. Test scores are in columns 3 to 6.

Use double to convert the specified dataset array variables into a numeric array. Then, calculate the mean across the second dimension (across columns) to get the test average for each student.

```
ds.TestAvg = mean(double(ds(:,3:6)),2);
```

```
ds(:,{'LastName','TestAvg'})
ans =
\begin{tabular}{lr} 
LastName & TestAvg \\
'HOWARD' & 90.5 \\
'WARD' & 86.25 \\
'TORRES' & 86.25 \\
' \(^{\prime}\) PETERSON ' & 76 \\
'GRAY' & 88 \\
'RAMIREZ' & 95.25 \\
'JAMES' & 76.75 \\
'WATSON ' & 91.75 \\
'BROOKS' & 85.75 \\
'KELLY' & 79.25
\end{tabular}
```

## Summarize the dataset array using a grouping variable.

Compute the mean and maximum average test scores for each gender.

```
stats = grpstats(ds,'Sex',{'mean','max'},'DataVars','TestAvg')
stats =
\begin{tabular}{lllcc} 
& Sex & GroupCount & mean_TestAvg & max_TestAvg \\
male & 'male' & 5 & 83.8 & 90.5 \\
female & 'female' & 5 & 87.35 & 95.25
\end{tabular}
```

This returns a new dataset array containing the specified summary statistics for each level of the grouping variable, Sex.

## Replace data values.

The denominator for each test score is 100. Convert the test score denominator to 25 .

```
scores = double(ds(:,3:6));
newScores = scores*25/100;
ds = replacedata(ds,newScores,3:6)
ds =
```

| LastName | Sex | Test1 | Test2 | Test3 | Test4 |
| :--- | :--- | ---: | ---: | ---: | ---: |
| 'HOWARD' | 'male' | 22.5 | 21.75 | 23.25 | 23 |
| 'WARD' | 'male' | 21.75 | 21.25 | 20.75 | 22.5 |
| 'TORRES' | 'male' | 21.5 | 21.25 | 22 | 21.5 |
| 'PETERSON' | 'female' | 18.75 | 20 | 18 | 19.25 |
| 'GRAY' | 'female' | 22.25 | 21.5 | 21.75 | 22.5 |
| 'RAMIREZ' | 'female' | 24 | 23 | 24.5 | 23.75 |
| 'JAMES' | 'male' | 19.5 | 18.75 | 19.25 | 19.25 |
| 'WATSON' | 'female' | 22.75 | 23.5 | 23 | 22.5 |
| 'BROOKS' | 'female' | 21.5 | 20.75 | 21.25 | 22.25 |
| 'KELLY' | 'male' | 19.75 | 19 | 20.5 | 20 |

The first two lines of code extract the test data and perform the desired calculation. Then, replacedata inserts the new test scores back into the dataset array.

The variable of test score averages, TestAvg, is now the final score for each student. Change the variable name to Final.

```
ds.Properties.VarNames{end} = 'Final';
ds
ds =
```

| LastName | Sex | Test1 | Test2 | Test3 | Test4 |
| :--- | :--- | ---: | ---: | ---: | ---: |
| 'HOWARD' | 'male' | 22.5 | 21.75 | 23.25 | 23 |
| 'WARD' | 'male' | 21.75 | 21.25 | 20.75 | 22.5 |
| 'TORRES' | 'male' | 21.5 | 21.25 | 22 | 21.5 |
| 'PETERSON' | 'female' | 18.75 | 20 | 18 | 19.25 |
| 'GRAY' | 'female' | 22.25 | 21.5 | 21.75 | 22.5 |
| 'RAMIREZ' | 'female' | 24 | 23 | 24.5 | 23.75 |
| 'JAMES' | 'male' | 19.5 | 18.75 | 19.25 | 19.25 |
| 'WATSON' | 'female' | 22.75 | 23.5 | 23 | 22.5 |
| 'BROOKS' | 'female' | 21.5 | 20.75 | 21.25 | 22.25 |
| 'KELLY' | 'male' | 19.75 | 19 | 20.5 | 20 |

## Export Dataset Arrays

This example shows how to export a dataset array from the MATLAB workspace to a text or spreadsheet file.

## Load sample data.

load('hospital')
The dataset array has 100 observations and 7 variables.

## Export to a text file.

Export the dataset array, hospital, to a text file named hospital.txt. By default, export writes to a tab-delimited text file with the same name as the dataset array, appended by .txt.

```
export(hospital)
```

This creates the file hospital.txt in the current working folder, if it does not previously exist. If the file already exists in the current working folder, export overwrites the existing file.

By default, variable names are in the first line of the text file. Observation names, if present, are in the first column.

Now, export hospital with variable names suppressed to a text file named NoLabels.txt.
export(hospital,'File','NoLabels.txt','WriteVarNames',false)
There are no variable names in the first line of the created text file, NoLabels.txt.

## Export to a comma-delimited format.

Export hospital to a comma-delimited text file, hospital.csv.
export(hospital,'File','hospital.csv','Delimiter',',')

## Export to an Excel spreadsheet.

Export hospital to an Excel spreadsheet named hospital.xlsx.
export(hospital,'XLSFile','hospital.xlsx')

By default, the first row of hospital.xlsx has variable names, and the first column has observation names.

## See Also

dataset | export |

## Clean Messy and Missing Data

This example shows how to find, clean, and delete observations with missing data in a dataset array.

## Load sample data.

Navigate to the folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Import the data from the spreadsheet messy.xlsx.

```
messyData = dataset('XLSFile','messy.xlsx')
messyData =
```

| var1 | var2 | var3 | var4 | var5 |
| :---: | :---: | :---: | :---: | :---: |
| 'afe1' | '3' | 'yes' | '3' | 3 |
| 'egh3' | '.' | 'no' | '7' | 7 |
| 'wth4' | '3' | 'yes' | '3' | 3 |
| 'atn2' | '23' | 'no' | '23' | 23 |
| 'arg1' | '5' | 'yes' | '5' | 5 |
| 'jre3' | '34.6' | 'yes' | '34.6' | 34.6 |
| 'wen9' | '234' | 'yes' | '234' | 234 |
| 'ple2' | '2' | 'no' | '2' | 2 |
| 'dbo8' | '5' | 'no' | '5' | 5 |
| 'oii4' | '5' | 'yes' | '5' | 5 |
| 'wnk3' | '245' | 'yes' | '245' | 245 |
| 'abk6' | '563' | 11 | '563' | 563 |
| 'pnj5' | '463' | ' $\mathrm{no}{ }^{\prime}$ | '463' | 463 |
| 'wnn3' | '6' | 'no' | '6' | 6 |
| 'oks9' | '23' | 'yes' | '23' | 23 |
| 'wba3' | '1 | 'yes' | ' $\mathrm{NaN}{ }^{\prime}$ | 14 |
| 'pkn4 ${ }^{\prime}$ | '2' | ' $\mathrm{no}{ }^{\prime}$ | '2' | 2 |
| ' adw3' | '22' | 'no' | '22' | 22 |
| 'poj2' | '-99' | 'yes' | '-99' | -99 |
| 'bas8' | '23' | 'no' | '23' | 23 |
| 'gry5' | 'NA' | 'yes' | 'NaN ' | 21 |

When you import data from a spreadsheet, dataset reads any variables with nonnumeric elements as a cell array of strings. This is why the variable var2 is a cell array of strings. When importing data from a text file, you have more flexibility to specify which nonnumeric expressions to treat as missing using the option TreatAsEmpty.

There are many different missing data indicators in messy.xlsx, such as:

- Empty cells
- A period (.)
- NA
- NaN
- -99

## Find observations with missing values.

Display the subset of observations that have at least one missing value using ismissing.

```
ix = ismissing(messyData,'NumericTreatAsMissing',-99,...
```

    'StringTreatAsMissing', \{'NaN','.', 'NA'\});
    messyData(any(ix, 2),:)
ans =

| var1 | var2 | var3 | var4 | var5 |
| :--- | :--- | :--- | :--- | ---: |
| 'egh3' | '.' | 'no' | '7' | 7 |
| 'abk6' | '563' | $' 1$ | '563' | 563 |
| 'wba3' | '' | 'yes' | 'NaN' | 14 |
| 'poj2' | '-99' | 'yes' | '-99' | -99 |
| 'gry5' | 'NA' | 'yes' | 'NaN' | 21 |

By default, ismissing recognizes the following missing value indicators:

- NaN for numeric arrays
- ' ' for string arrays
- <undefined> for categorical arrays

Use the NumericTreatAsMissing and StringTreatAsMissing options to specify other values to treat as missing.

## Convert string arrays to double arrays.

You can convert the string variables that should be numeric using str2double.
messyData.var2 = str2double(messyData.var2); messyData.var4 = str2double(messyData.var4)

```
messyData =
```

| var1 | var2 | var3 | var4 | var5 |
| :--- | ---: | :--- | ---: | ---: |
| 'afe1' | 3 | 'yes' | 3 | 3 |
| 'egh3' | NaN | 'no' | 7 | 7 |
| 'wth4' | 3 | 'yes' | 3 | 3 |
| 'atn2' | 23 | 'no' | 23 | 23 |
| 'arg1' | 5 | 'yes' | 5 | 5 |
| 'jre3' | 34.6 | 'yes' | 34.6 | 34.6 |
| 'wen9' | 234 | 'yes' | 234 | 234 |
| 'ple2' | 2 | 'no' | 2 | 2 |
| 'dbo8' | 5 | 'no' | 5 | 5 |
| 'oii4' | 5 | 'yes' | 5 | 5 |
| 'wnk3' | 245 | 'yes' | 245 | 245 |
| 'abk6' | 563 | '' | 563 | 563 |
| 'pnj5' | 463 | 'no' | 463 | 463 |
| 'wnn3' | 6 | 'no' | 6 | 6 |
| 'oks9' | 23 | 'yes' | 23 | 23 |
| 'wba3' | NaN | 'yes' | NaN | 14 |
| 'pkn4' | 2 | 'no' | 2 | 2 |
| 'adw3' | 22 | 'no' | 22 | 22 |
| 'poj2' | -99 | 'yes' | -99 | -99 |
| 'bas8' | 23 | 'no' | 23 | 23 |
| 'gry5' | NaN | 'yes' | NaN | 21 |

Now, var2 and var4 are numeric arrays. During the conversion, str2double replaces the nonnumeric elements of the variables var2 and var4 with the value NaN. However, there are no changes to the numeric missing value indicator, -99.

When applying the same function to many dataset array variables, it can sometimes be more convenient to use datasetfun. For example, to convert both var2 and var4 to numeric arrays simultaneously, you can use:

```
messyData(:,[2,4]) = datasetfun(@str2double,messyData,'DataVars',[2,4],...
    'DatasetOutput',true);
```

## Replace missing value indicators.

Clean the data so that the missing values indicated by the code -99 have the standard MATLAB numeric missing value indicator, NaN .

```
messyData = replaceWithMissing(messyData,'NumericValues',-99)
```

| messyData $=$ |  |  |  |  |
| :---: | ---: | :--- | ---: | ---: |
|  |  |  |  |  |
| var1 | var2 | var3 | var4 | var5 |
| 'afe1' | 3 | 'yes' | 3 | 3 |
| 'egh3' | NaN | 'no' | 7 | 7 |
| 'wth4' | 3 | 'yes' | 3 | 3 |
| 'atn2' | 23 | 'no' | 23 | 23 |
| 'arg1' | 5 | 'yes' | 5 | 5 |
| 'jre3' | 34.6 | 'yes' | 34.6 | 34.6 |
| 'wen9' | 234 | 'yes' | 234 | 234 |
| 'ple2' | 2 | 'no' | 2 | 2 |
| 'dbo8' | 5 | 'no' | 5 | 5 |
| 'oii4' | 5 | 'yes' | 5 | 5 |
| 'wnk3' | 245 | 'yes' | 245 | 245 |
| 'abk6' | 563 | '' | 563 | 563 |
| 'pnj5' | 463 | 'no' | 463 | 463 |
| 'wnn3' | 6 | 'no' | 6 | 6 |
| 'oks9' | 23 | 'yes' | 23 | 23 |
| 'wba3' | NaN | 'yes' | NaN | 14 |
| 'pkn4' | 2 | 'no' | 2 | 2 |
| 'adw3' | 22 | 'no' | 22 | 22 |
| 'poj2' | NaN | 'yes' | NaN | NaN |
| 'bas8' | 23 | 'no' | 23 | 23 |
| 'gry5' | NaN | 'yes' | NaN | 21 |

Create a dataset array with complete observations.

Create a new dataset array that contains only the complete observations-those without missing data.

```
ix = ismissing(messyData);
completeData = messyData(~any(ix,2),:)
completeData =
```

| var1 | var2 | var3 | var4 | var5 |
| :--- | ---: | :--- | ---: | ---: |
| 'afe1' | 3 | 'yes' | 3 | 3 |
| 'wth4' | 3 | 'yes' | 3 | 3 |
| 'atn2' | 23 | 'no' | 23 | 23 |
| 'arg1' | 5 | 'yes' | 5 | 5 |
| 'jre3' | 34.6 | 'yes' | 34.6 | 34.6 |
| 'wen9' | 234 | 'yes' | 234 | 234 |
| 'ple2' | 2 | 'no' | 2 | 2 |
| 'dbo8' | 5 | 'no' | 5 | 5 |
| 'oii4' | 5 | 'yes' | 5 | 5 |
| 'wnk3' | 245 | 'yes' | 245 | 245 |
| 'pnj5' | 463 | 'no' | 463 | 463 |
| 'wnn3' | 6 | 'no' | 6 | 6 |
| 'oks9' | 23 | 'yes' | 23 | 23 |
| 'pkn4' | 2 | 'no' | 2 | 2 |
| 'adw3' | 22 | 'no' | 22 | 22 |
| 'bas8' | 23 | 'no' | 23 | 23 |

## Open Dataset Arrays in the Variables Editor

The MATLAB Variables editor provides a convenient interface for viewing, modifying, and plotting dataset arrays.

First, load the sample data set, hospital.
load('hospital')
The dataset array, hospital, is created in the MATLAB workspace.

| Workspace |  |
| :--- | :--- |
| Name $\_$ | Value |
| atc | Description | | 'Simulated hospital data' |
| :--- |
| <100x7 dataset> |

The dataset array has 100 observations and 7 variables.
To open hospital in the Variables editor, click Open Variable, and select hospital.

The Variables editor opens, displaying the contents of the dataset array (only the first 10 observations are shown here).

| 囲 hospital < $100 \times 7$ dataset> |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\begin{gathered} 1 \\ \text { LastName } \end{gathered}$ | $\begin{gathered} 2 \\ \operatorname{Sex} \end{gathered}$ | $\begin{gathered} 3 \\ \text { Age } \end{gathered}$ | $\begin{gathered} 4 \\ \text { Weight } \end{gathered}$ | $\begin{gathered} 5 \\ \text { Smoker } \end{gathered}$ | BloodP |  |
| 1 YPL-320 | 'SMITH' | Male | 38 | 176 | 1 | 124 | 9318 |
| 2 GLI-532 | 'JOHNSON' | Male | 43 | 163 | 0 | 109 | 77 [11, |
| 3 PNI-258 | 'WILLIAMS' | Female | 38 | 131 | 0 | 125 | 83 [] |
| 4 MU-579 | 'JONES' | Female | 40 | 133 | 0 | 117 | $75[6,1$ |
| 5 XLK-030 | 'BROWN' | Female | 49 | 119 | 0 | 122 | 80 [14, |
| 6 TFP-518 | 'DAVIS' | Female | 46 | 142 | 0 | 121 | 7019 |
| 7 LPD-746 | 'MILLER' | Female | 33 | 142 | 1 | 130 | 8813 |
| 8 ATA-945 | 'WILSON' | Male | 40 | 180 | 0 | 115 | 82 [] |
| 9 VNL-702 | 'MOORE' | Male | 28 | 183 | 0 | 115 | 782 |
| 10 LQW-768 | 'TAYLOR' | Female | 31 | 132 | 0 | 118 | 8611 |

In the Variables editor, you can see the names of the seven variables along the top row, and the observations names down the first column.

## Modify Variable and Observation Names

You can modify variable and observation names by double-clicking a name, and then typing new text.

|  | 1 | 2 |
| :---: | :---: | :---: |
|  | LastName | Gender |
| 1 YPL-320 | 'SMITH' | Male |
| 2 GLI-532 | 'JOHNSON' | Male |
| 3 PNI-258 | 'WILLIAMS' | Female |
| 4 MU-579 | 'JONES' | Female |
| 5 XLK-030 | 'BROWN' | Female |

All changes made in the Variables editor are also sent to the command line.

```
Command Window
    >> hospital.Properties.VarNames{2} = 'Gender';
fx >>
```

The sixth variable in the data set, BloodPressure, is a numeric array with two columns. The first column shows systolic blood pressure, and the second column shows diastolic blood pressure. Click the arrow that appears on the right side of the variable name cell to see the units and description of the variable. You can type directly in the units and description fields to modify the text. The variable data type and size are shown under the variable description.

| 6 | - 78 | 9 |
| :---: | :---: | :---: |
| BloodPressure | Trials |  |
| 124 | foll Ascending |  |
| 109 | a |  |
| 125 | UNITS |  |
| 117 | mm Hg |  |
| 122 | DESCRIPTION |  |
| 121 | Systolic/Diastolic |  |
| 130 | , |  |
| 115 | <100×2 double> | : |
| 115 | $70 \%$ |  |

## Reorder or Delete Variables

You can reorder variables in a dataset array using the Variables editor. Hover over the left side of a variable name cell until a four-headed arrow appears.

After the arrow appears, click and drag the variable column to a new location.

The command for the variable reordering appears in the command line.

```
Command Window
    >> hospital = hospital(:,[1:4 6 5 end]);
fx >>
```

You can delete a variable in the Variables editor by selecting the variable column, right-clicking, and selecting Delete Column Variable(s).

The command for the variable deletion appears in the command line.

## Command Window

```
    >> hospital(:,'Weight') = [];
fx >>
```

## Add New Data

You can enter new data values directly into the Variables editor. For example, you can add a new patient observation to the hospital data set. To enter a new last name, add a string to the end of the variable LastName.

| 100 ZZB-405 | 'HAYES' | Male | 48 | 114 | 86 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| 101 | 'JONES' |  |  |  |  |
| 102 | hs |  |  |  |  |

The variable Gender is a nominal array. The levels of the categorical variable appear in a drop-down list when you double-click a cell in the Gender column.

You can choose one of the levels previously used, or create a new level by selecting New Item.

| 100 ZZB-405 | 'HAYES' | Male |  |
| :--- | :--- | :--- | :--- | :--- |
| 101 Obs101 | 'JONES' | Female |  |
| 102 |  | Female |  |
| 103 |  | Male |  |
| 104 |  | New item |  |
| 105 |  |  |  |

You can continue to add data for the remaining variables.
To change the observation name, click the observation name and type the new name.

| 100 ZZB-405 | 'HAYES' | Male | 48 |
| :--- | :--- | :--- | :--- |
| 101 Obsi01 I | JONES' | Female | 45 |
| 102 |  |  |  |

The commands for entering the new data appear at the command line.

```
Command Window
    >> hospital.LastName{101} = 'JONES';
    Warning: Observations with default values added to dataset
    variables.
    > In dataset.subsasgn at 584
    >> hospital.Sex(101) = 'Female';
    >> hospital.Age(101) = 45;
    >> hospital.BloodPressure(101,2) = 85;
    >> hospital.BloodPressure(101,1) = 120;
    >> hospital.Properties.ObsNames{101} = 'QPO-187';
fx >>
```

Notice the warning that appears after the first assignment. When you enter the first piece of data in the new observation row-here, the last name-default values are assigned to all other variables. Default assignments are:

- 0 for numeric variables
- <undefined> for categorical variables
- [] for cell arrays

You can also copy and paste data from one dataset array to another using the Variables editor.

## Sort Observations

You can use the Variables editor to sort dataset array observations by the values of one or more variables. To sort by gender, for example, select the variable Gender. Then click Sort, and choose to sort rows by ascending or descending values of the selected variable.

When sorting by variables that are cell arrays of strings or of nominal data type, observations are sorted alphabetically. For ordinal variables, rows are sorted by the ordering of the levels. For example, when the observations of hospital are sorted by the values in Gender, the females are grouped together, followed by the males.

| \# hospital < $100 \times 6$ dataset> |  |  |  |
| :---: | :---: | :---: | :---: |
|  | 1 <br> LastName | 2 Gender | $\begin{gathered} 3 \\ \text { Age } \end{gathered}$ |
| 1 PNI-258 | 'WILLIAMS' | Female | 38 |
| 2 ML-579 | 'JONES' | Female | 40 |
| 3 XLK-030 | 'BROWN' | Female | 49 |
| 4 TFP-518 | 'DAVIS' | Female | 46 |
| 5 LPD-746 | 'MILLER' | Female | 33 |
| 6 LQW-768 | 'TAYLOR' | Female | 31 |
| 7 QFY-472 | 'ANDERSON' | Female | 45 |
| 8 UJG-627 | 'THOMAS' | Female | 42 |
| 9 ELG-976 | 'HARRIS' | Female | 36 |
| 10 XBR-291 | 'GARCIA' | Female | 27 |

To sort by the values of multiple variables, press Ctrl while you select multiple variables.

When you use the Variables editor to sort rows, it is the same as calling sortrows. You can see this at the command line after executing the sorting.

## Command Window

```
    >> hospital = sortrows(hospital,'Gender','ascend');
fx
```

## Select a Subset of Data

You can select a subset of data from a dataset array in the Variables editor, and create a new dataset array from the selection. For example, to create a dataset array containing only the variables LastName and Age:

1 Hold Ctrl while you click the variables LastName and Age.
2 Right-click, and select New Variable from Selection > New Dataset Array.

| \＃hospital＜ $100 \times 6$ dataset＞ |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\begin{gathered} 1 \\ \text { LastName } \end{gathered}$ | $\begin{gathered} 2 \\ \text { Gender } \end{gathered}$ | $\begin{gathered} 3 \\ \text { Age } \end{gathered}$ | 4BloodPressure |  |  | $\begin{gathered} 6 \\ \text { Trials } \end{gathered}$ |  |
|  |  |  |  |  |  | Smoker |  |  |
| 1 PNI－258 | ＇WILLIAMS＇ | Female |  | Cut |  |  | Ctrl + X |  |
| $2 \mathrm{ML}-579$ | ＇JONES＇ | Female |  | Copy |  |  | Ctrl + C |  |
| 3 XLK－030 | ＇BROWN＇ | Female |  | Paste |  |  | Ctrl＋V |  |
| 4 TFP－518 | ＇DAVIS＇ | Female |  | 膭 Paste as New Column Variable（s）to the left <br> 膭 Paste as New Column Variable（s）to the right |  |  |  |  |
| 5 LPD－746 | ＇MILLER＇ | Female |  |  |  |  |  |  |  |  |
| 6 LQW－768 | ＇TAYLOR＇ | Female |  |  |  |  |  |  |  |  |
| 7 QFY－472 | ＇ANDERSON＇ | Female |  | 賏 Delete Column Variable（s） |  |  |  | 4］ |
| 8 UJG－627 | ＇THOMAS＇ | Female |  | Sort Ascending |  |  |  |  |
| 9 ELG－976 | ＇HARRIS＇ | Female |  |  |  |  |  |  |
| 10 XBR－291 | ＇GARCIA＇ | Female |  | Sort Descending |  |  |  |  |
| 11 BKD－785 | ＇CLARK＇ | Female |  | New Variable from Selection |  |  |  |  |
| 12 JHV－416 | ＇RODRIGUEZ＇ | Female | ग | 123 | 19 |  | 011 |  |
| 13 VWL－936 | ＇LEWIS＇ | Female | 41 | 114 | 88 |  | 08 |  |
| 14 AAX－056 | ＇LEE＇ | Female | 44 | 128 | 90 |  | 1 ［］ |  |
| 15 DTT－578 | ＇WALKER＇ | Female | 28 | 129 | 96 |  | 17 |  |

The new dataset array appears in the Workspace window with the name LastName．The Command Window shows the commands that execute the selection．

You can use the same steps to select any subset of data．To select observations according to some logical condition，you can use a combination of sorting and selecting．For example，to create a new dataset array containing only males aged 45 and older：

1 Sort the observations of hospital by the values in Gender and Age， descending．

2 Select the male observations with age 45 and older．

| 囲 hospital < $100 \times 6$ dataset> |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\begin{gathered} 1 \\ \text { LastName } \end{gathered}$ | $\begin{gathered} 2 \\ \text { Gender } \end{gathered}$ | $\begin{gathered} 3 \\ \text { Age } \end{gathered}$ | $\begin{gathered} 4 \\ \text { BloodPressure } \end{gathered}$ |  | 5 <br> Smoker | $\begin{gathered} 6 \\ \text { Trials } \end{gathered}$ |
| 1 XBA-581 | 'ROBINSON' | Male | 50 | 125 | 76 |  | [20,26,30] |
| 2 DAU-529 | 'REED' | Male | 50 | 129 | 89 |  | 122 |
| 3 FL-908 | 'STEWART' | Male | 49 | 129 | 95 |  | 115 |
| 4 MEZ-469 | 'GRIFFIN' | Male | 49 | 119 | 74 |  | 09 |
| 5 KOQ-996 | 'MARTIN' | Male | 48 | 130 | 92 |  | 1 [13,15,21,27] |
| 6 FCD-425 | 'GONZALES' | Male | 48 | 123 | 79 |  | [] |
| 7 ZZB-405 | 'HAYES' | Male | 48 | 114 | 86 |  | 028 |
| 8 YYV-570 | 'SCOTT' | Male | 47 | 127 | 84 |  | 08 |
| 9 VDZ-577 | 'PHILLIPS' | Male | 45 | 117 | 89 |  | 0 [10,15,17,19] |
| 10 WCJ-997 | 'BELL' | Male | 45 | 138 | 82 |  | 17 |
| 11 AGR-528 | 'SIMMONS' | Male | 45 | 124 | 77 |  | [8,18,25] |
| 12 BEZ-311 | 'DIAZ' | Male | 45 | 136 | 93 |  | 1 [] |
| 13 MSL-692 | 'GREEN' | Male | 44 | 121 | 92 |  | [] |

3 Right-click, and select New Variables from Selection > New Dataset Array. The new dataset array, LastName1, is created in the Workspace window.

| Workspace | (1) | Command Window |
| :---: | :---: | :---: |
| Name - | Value | >> hospital = sortrows (hospital, \{'Gender', |
| abc Description | 'Simulated hospital data' | >> LastName1 $=$ hospital (1:12,1:6); |
| H LastName | <100x2 dataset> | $f_{\text {x }} \times>$ |
| \# LastNamel | <12x6 dataset> |  |
| \# hospital | <100x6 dataset> |  |

4 You can rename the dataset array in the Workspace window.

| Workspace |  |
| :--- | :--- |
| Name $\triangle$ | Value |
| abc | Description |$\quad$ 'Simulated hospital data'

## Create Plots

You can plot data from a dataset array using plotting options in the Variables editor. Available plot choices depend on the data types of variables to be plotted.

For example, if you select the variable Age, you can see in the Plots tab some plotting options that are appropriate for a univariate, numeric variable.

Sometimes, there are plot options for multiple variables, depending on their data types. For example, if you select both Age and Gender, you can draw box plots of age, grouped by gender.

## Dataset Arrays

In this section...<br>"What Are Dataset Arrays?" on page 2-135<br>"Dataset Array Conversion" on page 2-135<br>"Dataset Array Properties" on page 2-136

## What Are Dataset Arrays?

Statistics Toolbox has dataset arrays for storing variables with heterogeneous data types. For example, you can combine numeric data, logical data, cell arrays of strings, and categorical arrays in one dataset array variable.

Within a dataset array, each variable (column) must be one homogeneous data type, but the different variables can be of heterogeneous data types. A dataset array is usually interpreted as a set of variables measured on many units of observation. That is, each row in a dataset array corresponds to an observation, and each column to a variable. In this sense, a dataset array organizes data like a typical spreadsheet.

Dataset arrays are a unique data type, with a corresponding set of valid operations. Even if a dataset array contains only numeric variables, you cannot operate on the dataset array like a numeric variable. The valid operations for dataset arrays are the methods of the dataset class.

## Dataset Array Conversion

You can create a dataset array by combining variables that exist in the MATLAB workspace, or directly importing data from a file, such as a text file or spreadsheet. This table summarizes the functions you can use to create dataset arrays.

| Data Source | Conversion to Dataset Array |
| :--- | :--- |
| Data from a file | dataset |
| Heterogeneous collection of <br> workspace variables | dataset |

| Data Source | Conversion to Dataset Array |
| :--- | :--- |
| Numeric array | mat2dataset |
| Cell array | cell2dataset |
| Structure array | struct2dataset |

You can export dataset arrays to text or spreadsheet files using export. To convert a dataset array to a cell array or structure array, use dataset2cell or dataset2struct.

## Dataset Array Properties

In addition to storing data in a dataset array, you can store metadata such as:

- Variable and observation names
- Data descriptions
- Units of measurement
- Variable descriptions

This information is stored as dataset array properties. For a dataset array named ds, you can view the dataset array metadata by entering ds. Properties at the command line. You can access a specific property, such as variable names-property VarNames-using ds.Properties.VarNames. You can both retrieve and modify property values using this syntax.

Variable and observation names are included in the display of a dataset array. Variable names display across the top row, and observation names, if present, appear in the first column. Note that variable and observation names do not affect the size of a dataset array.

```
See Also dataset | export | dataset2cell | dataset2struct | mat2dataset | cell2dataset | struct2dataset
```

- "Export Dataset Arrays" on page 2-115
- "Dataset Arrays in the Variables Editor" on page 2-122
- "Index and Search Dataset Arrays" on page 2-138

## Index and Search Dataset Arrays

There are many ways to index into dataset arrays. For example, for a dataset array, ds, you can:

- Use () to create a new dataset array from a subset of ds. For example, ds1 $=\mathrm{ds}(1: 5,:)$ creates a new dataset array, ds1, consisting of the first five rows of ds. Metadata, including variable and observation names, transfers to the new dataset array.
- Use variable names with dot notation to index individual variables in a dataset array. For example, ds. Height indexes the variable named Height.
- Use observation names to index individual observations in a dataset array. For example, ds('Obs1',:) gives data for the observation named Obs1.
- Use observation or variable numbers. For example, ds (: , [1, 3,5]) gives the data in the first, third, and fifth variables (columns) of ds.
- Use logical indexing to search for observations in ds that satisfy a logical condition. For example, ds(ds.Gender=='Male', :) gives the observations in ds where the variable named Gender, a nominal array, has the value Male.
- Use ismissing to find missing data in the dataset array.

The following brief examples illustrate several indexing and searching methods.

## Load sample data.

```
load('hospital')
```

size(hospital)
ans =
$100 \quad 7$

The dataset array has 100 observations and 7 variables.

## Index the variable by name.

Return the minimum age in the dataset array.

```
min(hospital.Age)
ans =
    25
Delete the variable Trials.
hospital.Trials = [];
size(hospital)
ans =
    100 6
Index the observation by name.
```

Display measurements on the first five variables for the observation named PUE-347.
hospital('PUE-347',1:5)
ans =

```
PUE-347 'YOUNG'
```

| Sex | Age Weight |  |
| :--- | :--- | :--- |
| Female | 25 | 114 |

Smoker
false

## Index variables by number.

Create a new dataset array containing the first four variables of hospital.

```
dsNew = hospital(:,1:4);
```

dsNew.Properties.VarNames(:)
ans $=$
'LastName'
'Sex'
'Age'
'Weight'
Index observations by number.

```
Delete the last 10 observations.
hospital(end-9:end,:) = [];
size(hospital)
ans =
    90 7
```

## Search for observations by logical condition.

Create a new dataset array containing only females who smoke.

```
dsFS = hospital(hospital.Sex=='Female' & hospital.Smoker==true,:);
dsFS(:,{'LastName','Sex','Smoker'})
ans =
```

## Introduction to Descriptive Statistics

You may need to summarize large, complex data sets-both numerically and visually-to convey their essence to the data analyst and to allow for further processing.

## Measures of Central Tendency

Measures of central tendency locate a distribution of data along an appropriate scale.

The following table lists the functions that calculate the measures of central tendency.

| Function Name | Description |
| :--- | :--- |
| geomean | Geometric mean |
| harmmean | Harmonic mean |
| mean | Arithmetic average |
| median | 50 th percentile |
| mode | Most frequent value |
| trimmean | Trimmed mean |

The average is a simple and popular estimate of location. If the data sample comes from a normal distribution, then the sample mean is also optimal (minimum variance unbiased estimator (MVUE) of $\mu$ ).

Unfortunately, outliers, data entry errors, or glitches exist in almost all real data. The sample mean is sensitive to these problems. One bad data value can move the average away from the center of the rest of the data by an arbitrarily large distance.

The median and trimmed mean are two measures that are resistant (robust) to outliers. The median is the 50th percentile of the sample, which will only change slightly if you add a large perturbation to any value. The idea behind the trimmed mean is to ignore a small percentage of the highest and lowest values of a sample when determining the center of the sample.

The geometric mean and harmonic mean, like the average, are not robust to outliers. They are useful when the sample is distributed lognormal or heavily skewed.

The following example shows the behavior of the measures of location for a sample with one outlier.

```
x = [ones(1,6) 100]
x =
    1
locate = [geomean(x) harmmean(x) mean(x) median(x)...
    trimmean(x,25)]
locate =
    1.9307 1.1647 15.1429 1.0000 1.0000
```

You can see that the mean is far from any data value because of the influence of the outlier. The median and trimmed mean ignore the outlying value and describe the location of the rest of the data values.

## Measures of Dispersion

The purpose of measures of dispersion is to find out how spread out the data values are on the number line. Another term for these statistics is measures of spread.

The table gives the function names and descriptions.

| Function <br> Name | Description |
| :--- | :--- |
| iqr | Interquartile range |
| mad | Mean absolute deviation |
| moment | Central moment of all orders |
| range | Range |
| std | Standard deviation |
| var | Variance |

The range (the difference between the maximum and minimum values) is the simplest measure of spread. But if there is an outlier in the data, it will be the minimum or maximum value. Thus, the range is not robust to outliers.

The standard deviation and the variance are popular measures of spread that are optimal for normally distributed samples. The sample variance is the minimum variance unbiased estimator (MVUE) of the normal parameter $\sigma^{2}$. The standard deviation is the square root of the variance and has the desirable property of being in the same units as the data. That is, if the data is in meters, the standard deviation is in meters as well. The variance is in meters ${ }^{2}$, which is more difficult to interpret.

Neither the standard deviation nor the variance is robust to outliers. A data value that is separate from the body of the data can increase the value of the statistics by an arbitrarily large amount.

The mean absolute deviation (MAD) is also sensitive to outliers. But the MAD does not move quite as much as the standard deviation or variance in response to bad data.

The interquartile range (IQR) is the difference between the 75th and 25th percentile of the data. Since only the middle $50 \%$ of the data affects this measure, it is robust to outliers.

The following example shows the behavior of the measures of dispersion for a sample with one outlier.

```
x = [ones(1,6) 100]
x =
    1
stats = [iqr(x) mad(x) range(x) std(x)]
stats =
    0 24.2449 99.0000 37.4185
```

## Quantiles and Percentiles

This section explains how the Statistics Toolbox functions quantile and prctile compute quantiles and percentiles.

The prctile function calculates the percentiles in a similar way as quantile calculates quantiles. The following steps in the computation of quantiles are also true for percentiles, given the fact that, for the same data sample, the quantile at the value Q is the same as the percentile at the value $\mathrm{P}=100^{*} \mathrm{Q}$.

1 quantile initially assigns the sorted values in X to the $(0.5 / n),(1.5 / n), \ldots$, ( $n-0.5] / n$ ) quantiles. For example:

- For a data vector of six elements such as $\{6,3,2,10,8,1\}$, the sorted elements $\{1,2,3,6,8,10\}$ respectively correspond to the (0.5/6), (1.5/6), (2.5/6), (3.5/6), (4.5/6), and (5.5/6) quantiles.
- For a data vector of five elements such as $\{2,10,5,9,13\}$, the sorted elements $\{2,5,9,10,13\}$ respectively correspond to the $0.1,0.3,0.5$, 0.7 , and 0.9 quantiles.

The following figure illustrates this approach for data vector $X=\{2,10,5$, $9,13\}$. The first observation corresponds to the cumulative probability $1 / 5=$ 0.2 , the second observation corresponds to the cumulative probability $2 / 5$ $=0.4$, and so on. The step function in this figure shows these cumulative probabilities. quantile instead places the observations in midpoints, such that the first corresponds to $0.5 / 5=0.1$, the second corresponds to $1.5 / 5=$ 0.3 , and so on, and then connects these midpoints. The red lines in the following figure connect the midpoints.

## Assigning Observations to Quantiles

By wwitching the axes, as the next figure, you can see the values of the variable $X$ that correspond to the p quantiles.

## Quantiles of $\boldsymbol{X}$

2 quantile finds any quantiles between the data values using linear interpolation.

Linear interpolation uses linear polynomials to approximate a function $\mathrm{f}(x)$ and construct new data points within the range of a known set of data points. Algebraically, given the data points $\left(x_{1}, y_{1}\right)$ and $\left(x_{2}, y_{2}\right)$, where $y_{1}=$ $\mathrm{f}\left(x_{1}\right)$ and $y_{2}=\mathrm{f}\left(x_{2}\right)$, linear interpolation finds $y=\mathrm{f}(x)$ for a given $x$ between $x_{1}$ and $x_{2}$ as follows:

$$
y=f(x)=y_{1}+\frac{\left(x-x_{1}\right)}{\left(x_{2}-x_{1}\right)}\left(y_{2}-y_{1}\right) .
$$

Similarly, if the $1.5 / n$ quantile is $y_{1.5 / n}$ and the $2.5 / n$ quantile is $y_{2.5 / n}$, then linear interpolation finds the $2.3 / n$ quantile $y_{2.3 / n}$ as

$$
y_{\frac{2.3}{n}}=y_{\frac{1.5}{n}}+\frac{\left(\frac{2.3}{n}-\frac{1.5}{n}\right)}{\left(\frac{2.5}{n}-\frac{1.5}{n}\right)}\left(y_{\frac{2.5}{n}}-y_{\frac{1.5}{n}}\right)
$$

3 quantile assigns the first and last values of $X$ to the quantiles for probabilities less than ( $0.5 / n$ ) and greater than ( $[n-0.5] / n$ ), respectively.

quantile | prctile | median

## Exploratory Analysis of Data

This example shows how to explore the distribution of data using descriptive statistics.

## Generate sample data.

rng('default') \% for reproducibility
$x=[$ normrnd $(4,1,1,100)$ normrnd $(6,0.5,1,200)]$;
Create a histogram of data with normal density fit.
histfit(x)

The distribution of the data seems left skewed and normal distribution does not look like a good fit to this distribution.

## Obtain a normal probability plot.

probplot('normal', x)

Probability plot for Normal distribution

This probability plot also clearly shows the deviation of data from normality.

## Compute quantiles of data.

```
p = 0:0.25:1;
y = quantile(x,p);
```

$z=[p ; y]$
z =

| 0 | 0.2500 | 0.5000 | 0.7500 | 1.0000 |
| ---: | ---: | ---: | ---: | ---: |
| 1.0557 | 4.7375 | 5.6872 | 6.1526 | 7.5784 |

Plot a box plot.
A box plot helps to visualize the statistics.
boxplot(x)

You can also see the $0.25,0.5$, and 0.75 quantiles in the box plot. The long lower tail and plus signs also show the lack of symmetry in the sample values.

## Compute the mean and median of data.

```
y = [mean(x) median(x)]
y =
```

The mean and median values seem close to each other, but a mean smaller than the median usually flags left skewness of the data.

## Compute the skewness and kurtosis of data.

```
y = [skewness(x) kurtosis(x)]
```

$y=$

$$
-1.0417 \quad 3.5895
$$

A negative skewness value means the data is left skewed. The data has a larger peakedness than a normal distribution because the kurtosis value is greater than 3.

## Check for outliers.

Compute the z-scores.
Z = zscore(x);
Find the z -scores that are greater than 3 or less than -3 .
find(abs(Z)>3);
ans $=$
335

The 3rd and 35th observations might be outliers.

## Resampling Statistics

In this section...<br>"Bootstrap" on page 3-16<br>"Jackknife" on page 3-19<br>"Parallel Computing Support for Resampling Methods" on page 3-20

## Bootstrap

The bootstrap procedure involves choosing random samples with replacement from a data set and analyzing each sample the same way. Sampling with replacement means that each observation is selected separately at random from the original dataset. So a particular data point from the original data set could appear multiple times in a given bootstrap sample. The number of elements in each bootstrap sample equals the number of elements in the original data set. The range of sample estimates you obtain enables you to establish the uncertainty of the quantity you are estimating.

This example from Efron and Tibshirani [33] compares Law School Admission Test (LSAT) scores and subsequent law school grade point average (GPA) for a sample of 15 law schools.
load lawdata
plot(lsat,gpa,'+')
lsline

The least-squares fit line indicates that higher LSAT scores go with higher law school GPAs. But how certain is this conclusion? The plot provides some intuition, but nothing quantitative.

You can calculate the correlation coefficient of the variables using the corr function.

```
rhohat = corr(lsat,gpa)
rhohat =
    0.7764
```

Now you have a number describing the positive connection between LSAT and GPA; though it may seem large, you still do not know if it is statistically significant.

Using the bootstrp function you can resample the lsat and gpa vectors as many times as you like and consider the variation in the resulting correlation coefficients.

Here is an example.

```
rhos1000 = bootstrp(1000,'corr',lsat,gpa);
```

This command resamples the lsat and gpa vectors 1000 times and computes the corr function on each sample. Here is a histogram of the result.

```
hist(rhos1000,30)
set(get(gca,'Children'),'FaceColor',[.8 .8 1])
```

Nearly all the estimates lie on the interval [0.4 1.0].

It is often desirable to construct a confidence interval for a parameter estimate in statistical inferences. Using the bootci function, you can use bootstrapping to obtain a confidence interval. The confidence interval for the lsat and gpa data is computed as:
ci $=$ bootci(5000,@corr,lsat,gpa)
ci $=$
0.3313
0.9427

Therefore, a $95 \%$ confidence interval for the correlation coefficient between LSAT and GPA is [0.33 0.94]. This is strong quantitative evidence that LSAT and subsequent GPA are positively correlated. Moreover, this evidence does not require any strong assumptions about the probability distribution of the correlation coefficient.

Although the bootci function computes the Bias Corrected and accelerated ( BCa ) interval as the default type, it is also able to compute various other types of bootstrap confidence intervals, such as the studentized bootstrap confidence interval.

## Jackknife

Similar to the bootstrap is the jackknife, which uses resampling to estimate the bias of a sample statistic. Sometimes it is also used to estimate standard error of the sample statistic. The jackknife is implemented by the Statistics Toolbox function jackknife.

The jackknife resamples systematically, rather than at random as the bootstrap does. For a sample with n points, the jackknife computes sample statistics on $n$ separate samples of size $n-1$. Each sample is the original data with a single observation omitted.

In the previous bootstrap example you measured the uncertainty in estimating the correlation coefficient. You can use the jackknife to estimate the bias, which is the tendency of the sample correlation to over-estimate or under-estimate the true, unknown correlation. First compute the sample correlation on the data:

## load lawdata

```
rhohat = corr(lsat,gpa)
rhohat =
    0.7764
```

Next compute the correlations for jackknife samples, and compute their mean:

```
jackrho = jackknife(@corr,lsat,gpa);
meanrho = mean(jackrho)
meanrho =
    0.7759
```

Now compute an estimate of the bias:

```
n = length(lsat);
biasrho = (n-1) * (meanrho-rhohat)
biasrho =
    -0.0065
```

The sample correlation probably underestimates the true correlation by about this amount.

## Parallel Computing Support for Resampling Methods

For information on computing resampling statistics in parallel, see Parallel Computing Toolbox ${ }^{\mathrm{TM}}$.

## Data with Missing Values

Many data sets have one or more missing values. It is convenient to code missing values as NaN (Not a Number) to preserve the structure of data sets across multiple variables and observations.

For example:

```
X = magic(3);
X([1 5]) = [NaN NaN]
X =
    NaN 1 6
    3 NaN 7
    4 9 2
```

Normal MATLAB arithmetic operations yield NaN values when operands are NaN :

```
s1 = sum(X)
s1 =
    NaN NaN 15
```

Removing the NaN values would destroy the matrix structure. Removing the rows containing the NaN values would discard data. Statistics Toolbox functions in the following table remove NaN values only for the purposes of computation.

| Function | Description |
| :--- | :--- |
| nancov | Covariance matrix, ignoring NaN values |
| nanmax | Maximum, ignoring NaN values |
| nanmean | Mean, ignoring NaN values |
| nanmedian | Median, ignoring NaN values |
| nanmin | Minimum, ignoring NaN values |
| nanstd | Standard deviation, ignoring NaN values |
| nansum | Sum, ignoring NaN values |
| nanvar | Variance, ignoring NaN values |

```
For example:
s2 = nansum(X)
s2 =
    7 10
1 5
```

Other Statistics Toolbox functions also ignore NaN values. These include iqr, kurtosis, mad, prctile, range, skewness, and trimmean.

## Statistical Visualization

- "Introduction to Statistical Visualization" on page 4-2
- "Scatter Plots" on page 4-3
- "Box Plots" on page 4-6
- "Distribution Plots" on page 4-8

## Introduction to Statistical Visualization

Statistics Toolbox data visualization functions add to the extensive graphics capabilities already in MATLAB.

- Scatter plots are a basic visualization tool for multivariate data. They are used to identify relationships among variables. Grouped versions of these plots use different plotting symbols to indicate group membership. The gname function is used to label points on these plots with a text label or an observation number.
- Box plots display a five-number summary of a set of data: the median, the two ends of the interquartile range (the box), and two extreme values (the whiskers) above and below the box. Because they show less detail than histograms, box plots are most useful for side-by-side comparisons of two distributions.
- Distribution plots help you identify an appropriate distribution family for your data. They include normal and Weibull probability plots, quantile-quantile plots, and empirical cumulative distribution plots.

Advanced Statistics Toolbox visualization functions are available for specialized statistical analyses.

## Scatter Plots

A scatter plot is a simple plot of one variable against another. The MATLAB functions plot and scatter produce scatter plots. The MATLAB function plotmatrix can produce a matrix of such plots showing the relationship between several pairs of variables.

Statistics Toolbox functions gscatter and gplotmatrix produce grouped versions of these plots. These are useful for determining whether the values of two variables or the relationship between those variables is the same in each group.

Suppose you want to examine the weight and mileage of cars from three different model years.
load carsmall
gscatter(Weight, MPG, Model_Year, '', 'xos')

This shows that not only is there a strong relationship between the weight of a car and its mileage, but also that newer cars tend to be lighter and have better gas mileage than older cars.

The default arguments for gscatter produce a scatter plot with the different groups shown with the same symbol but different colors. The last two arguments above request that all groups be shown in default colors and with different symbols.

The carsmall data set contains other variables that describe different aspects of cars. You can examine several of them in a single display by creating a grouped plot matrix.

```
xvars = [Weight Displacement Horsepower];
yvars = [MPG Acceleration];
```

The upper right subplot displays MPG against Horsepower, and shows that over the years the horsepower of the cars has decreased but the gas mileage has improved.

The gplotmatrix function can also graph all pairs from a single list of variables, along with histograms for each variable. See "MANOVA" on page 8-39.

## Box Plots

The graph below, created with the boxplot command, compares petal lengths in samples from two species of iris.

```
load fisheriris
s1 = meas(51:100,3);
s2 = meas(101:150,3);
boxplot([s1 s2],'notch','on',...
    'labels',{'versicolor','virginica'})
```

This plot has the following features:

- The tops and bottoms of each "box" are the 25 th and 75 th percentiles of the samples, respectively. The distances between the tops and bottoms are the interquartile ranges.
- The line in the middle of each box is the sample median. If the median is not centered in the box, it shows sample skewness.
- The whiskers are lines extending above and below each box. Whiskers are drawn from the ends of the interquartile ranges to the furthest observations within the whisker length (the adjacent values).
- Observations beyond the whisker length are marked as outliers. By default, an outlier is a value that is more than 1.5 times the interquartile range away from the top or bottom of the box, but this value can be adjusted with additional input arguments. Outliers are displayed with a red + sign.
- Notches display the variability of the median between samples. The width of a notch is computed so that box plots whose notches do not overlap (as above) have different medians at the $5 \%$ significance level. The significance level is based on a normal distribution assumption, but comparisons of medians are reasonably robust for other distributions. Comparing box-plot medians is like a visual hypothesis test, analogous to the $t$ test used for means.

## Distribution Plots

In this section...<br>"Normal Probability Plots" on page 4-8<br>"Quantile-Quantile Plots" on page 4-10<br>"Cumulative Distribution Plots" on page 4-12<br>"Other Probability Plots" on page 4-14

## Normal Probability Plots

Normal probability plots are used to assess whether data comes from a normal distribution. Many statistical procedures make the assumption that an underlying distribution is normal, so normal probability plots can provide some assurance that the assumption is justified, or else provide a warning of problems with the assumption. An analysis of normality typically combines normal probability plots with hypothesis tests for normality.

The following example shows a normal probability plot created with the normplot function.
$\mathrm{x}=\operatorname{normrnd}(10,1,25,1)$;
normplot(x)

The plus signs plot the empirical probability versus the data value for each point in the data. A solid line connects the 25 th and 75 th percentiles in the data, and a dashed line extends it to the ends of the data. The $y$-axis values are probabilities from zero to one, but the scale is not linear. The distance between tick marks on the $y$-axis matches the distance between the quantiles of a normal distribution. The quantiles are close together near the median (probability $=0.5$ ) and stretch out symmetrically as you move away from the median.

In a normal probability plot, if all the data points fall near the line, an assumption of normality is reasonable. Otherwise, the points will curve away from the line, and an assumption of normality is not justified.

For example:
$x=\operatorname{exprnd}(10,100,1)$;
normplot(x)

The plot is strong evidence that the underlying distribution is not normal.

## Quantile-Quantile Plots

Quantile-quantile plots are used to determine whether two samples come from the same distribution family. They are scatter plots of quantiles computed from each sample, with a line drawn between the first and third quartiles. If the data falls near the line, it is reasonable to assume that the two samples come from the same distribution. The method is robust with respect to changes in the location and scale of either distribution.

To create a quantile-quantile plot, use the qqplot function.

The following example shows a quantile-quantile plot of two samples from Poisson distributions.

```
x = poissrnd(10,50,1);
y = poissrnd(5,100,1);
qqplot(x,y);
```

Even though the parameters and sample sizes are different, the approximate linear relationship suggests that the two samples may come from the same distribution family. As with normal probability plots, hypothesis tests can provide additional justification for such an assumption. For statistical procedures that depend on the two samples coming from the same distribution, however, a linear quantile-quantile plot is often sufficient.

The following example shows what happens when the underlying distributions are not the same.

```
x = normrnd(5,1,100,1);
y = wblrnd(2,0.5,100,1);
qqplot(x,y);
```

These samples clearly are not from the same distribution family.

## Cumulative Distribution Plots

An empirical cumulative distribution function (cdf) plot shows the proportion of data less than each $x$ value, as a function of $x$. The scale on the $y$-axis is linear; in particular, it is not scaled to any particular distribution. Empirical cdf plots are used to compare data cdfs to cdfs for particular distributions.

To create an empirical cdf plot, use the cdfplot function (or ecdf and stairs).
The following example compares the empirical cdf for a sample from an extreme value distribution with a plot of the cdf for the sampling distribution. In practice, the sampling distribution would be unknown, and would be chosen to match the empirical cdf.

```
y = evrnd(0,3,100,1);
cdfplot(y)
hold on
x = -20:0.1:10;
f = evcdf(x,0,3);
plot(x,f,'m')
legend('Empirical','Theoretical','Location','NW')
```

## Other Probability Plots

A probability plot, like the normal probability plot, is just an empirical cdf plot scaled to a particular distribution. The $y$-axis values are probabilities from zero to one, but the scale is not linear. The distance between tick marks is the distance between quantiles of the distribution. In the plot, a line is drawn between the first and third quartiles in the data. If the data falls near the line, it is reasonable to choose the distribution as a model for the data.

To create probability plots for different distributions, use the probplot function.

For example, the following plot assesses two samples, one from a Weibull distribution and one from a Rayleigh distribution, to see if they may have come from a Weibull population.

```
x1 = wblrnd(3,3,100,1);
x2 = raylrnd(3,100,1);
probplot('weibull',[x1 x2])
legend('Weibull Sample','Rayleigh Sample','Location','NW')
```

The plot gives justification for modeling the first sample with a Weibull distribution; much less so for the second sample.

A distribution analysis typically combines probability plots with hypothesis tests for a particular distribution.

## Probability Distributions

- "Probability Distributions Used for Multivariate Modeling" on page 5-100

## Using Probability Distributions

Probability distributions are theoretical distributions based on assumptions about a source population. They assign probability to the event that a random variable takes on a specific, discrete value, or falls within a specified range of continuous values. There are two main types of models:

- Parametric Models-Choose a model based on a parametric family of probability distributions and then adjust the parameters to fit the data. For information on supported parametric distributions, see "Parametric Distributions" on page 5-4.
- Nonparametric Models-When data or statistics do not follow any standard probability distribution, nonparametric models may be appropriate. For information on supported nonparametric distributions, see "Nonparametric Distributions" on page 5-9.

The Statistics Toolbox provides several ways of working with both parametric and nonparametric probability distributions:

- Graphic User Interfaces (GUIs)—Interact with the distributions to visualize distributions, fit a distribution to your data, or generate random data using a specific distribution. For more information, see "Working with Distributions Through GUIs" on page 5-10.
- Command Line Functions-Use command-line functions to further explore the distributions, fit relevant models to your data, or generate random data. For more information on using functions, see "Statistics Toolbox Distribution Functions" on page 5-53.
- Distribution Objects-Use objects to explore and fit your data to a distribution, save the results to a single entity, and generate random data from the resulting parameters. For more information, see "Using Probability Distribution Objects" on page 5-85.

## Supported Distributions

In this section...<br>"Parametric Distributions" on page 5-4<br>"Nonparametric Distributions" on page 5-9

Probability distributions supported by the Statistics Toolbox are cross-referenced with their supporting functions and GUIs in the following tables. The tables use the following abbreviations for distribution functions:

- pdf - Probability density functions
- cdf - Cumulative distribution functions
- inv - Inverse cumulative distribution functions
- stat - Distribution statistics functions
- fit - Distribution fitting functions
- like - Negative log-likelihood functions
- rnd - Random number generators

For more detailed explanations of each supported distribution, see Appendix B, "Distribution Reference".

## Parametric Distributions

# Working with Distributions Through GUIs 

In this section...<br>"Exploring Distributions" on page 5-10<br>"Modeling Data Using the Distribution Fitting Tool" on page 5-12<br>"Custom Distributions Using Distribution Fitting Tool" on page 5-49<br>"Visually Exploring Random Number Generation" on page 5-50

This section describes Statistics Toolbox GUIs that provide convenient, interactive access to the distribution functions described in "Statistics Toolbox Distribution Functions" on page 5-53.

## Exploring Distributions

To interactively see the influence of parameter changes on the shapes of the pdfs and cdfs of supported Statistics Toolbox distributions, use the Probability Distribution Function Tool.

Run the tool by typing disttool at the command line.

Start by selecting a distribution. Then choose the function type: probability density function (pdf) or cumulative distribution function (cdf).

After the plot appears, you can

- Calculate a new function value by
- Typing a new x value in the text box on the $x$-axis
- Dragging the vertical reference line.
- Clicking in the figure where you want the line to be.

The new function value appears in the text box to the left of the plot.

- For cdf plots, find critical values corresponding to a specific probability by typing the desired probability in the text box on the $y$-axis or by dragging the horizontal reference line.
- Use the controls at the bottom of the window to set parameter values for the distribution and to change their upper and lower bounds.

## Modeling Data Using the Distribution Fitting Tool

The Distribution Fitting Tool is a GUI for fitting univariate distributions to data. This section describes how to use the Distribution Fitting Tool this tool and covers the following topics:

- "Opening the Distribution Fitting Tool" on page 5-13
- "Creating and Managing Data Sets" on page 5-15
- "Creating a New Fit" on page 5-20
- "Displaying Results" on page 5-26
- "Managing Fits" on page 5-27
- "Evaluating Fits" on page 5-29
- "Excluding Data" on page 5-33
- "Saving and Loading Sessions" on page 5-39
- "Example: Fitting a Distribution" on page 5-40
- "Generating a File to Fit and Plot Distributions" on page 5-47
- "Additional Distributions Available in the Distribution Fitting Tool" on page 5-49

## Opening the Distribution Fitting Tool

To open the Distribution Fitting Tool, enter the command
dfittool

Adjusting the Plot. Buttons at the top of the tool allow you to adjust the plot displayed in this window:

- $\boxed{H}_{-}$— Toggle the legend on (default) or off.
- \#\# $^{\#}$ — Toggle grid lines on or off (default).
-     - Restore default axes limits.

Displaying the Data. The Display type field specifies the type of plot displayed in the main window. Each type corresponds to a probability function, for example, a probability density function. The following display types are available:

- Density (PDF) — Display a probability density function (PDF) plot for the fitted distribution.
- Cumulative probability (CDF) - Display a cumulative probability plot of the data.
- Quantile (inverse CDF) - Display a quantile (inverse CDF) plot.
- Probability plot - Display a probability plot.
- Survivor function - Display a survivor function plot of the data.
- Cumulative hazard - Display a cumulative hazard plot of the data.

Inputting and Fitting Data. The task buttons enable you to perform the tasks necessary to fit distributions to data. Each button opens a new dialog box in which you perform the task. The buttons include:

- Data - Import and manage data sets. See "Creating and Managing Data Sets" on page 5-15.
- New Fit - Create new fits. See "Creating a New Fit" on page 5-20.
- Manage Fits - Manage existing fits. See "Managing Fits" on page 5-27.
- Evaluate - Evaluate fits at any points you choose. See "Evaluating Fits" on page 5-29.
- Exclude - Create rules specifying which values to exclude when fitting a distribution. See "Excluding Data" on page 5-33.

The display pane displays plots of the data sets and fits you create. Whenever you make changes in one of the dialog boxes, the results in the display pane update.

Saving and Customizing Distributions. The Distribution Fitting Tool menus contain items that enable you to do the following:

- Save and load sessions. See "Saving and Loading Sessions" on page 5-39.
- Generate a file with which you can fit distributions to data and plot the results independently of the Distribution Fitting Tool. See "Generating a File to Fit and Plot Distributions" on page 5-47.
- Define and import custom distributions. See "Custom Distributions Using Distribution Fitting Tool" on page 5-49.

## Creating and Managing Data Sets

This section describes how to create and manage data sets.
To begin, click the Data button in the Distribution Fitting Tool to open the Data dialog box shown in the following figure.

Importing Data. The Import workspace vectors pane enables you to create a data set by importing a vector from the MATLAB workspace. The following sections describe the fields in this pane and give appropriate values for vectors imported from the MATLAB workspace:

- Data - The drop-down list in the Data field contains the names of all matrices and vectors, other than 1-by-1 matrices (scalars) in the MATLAB workspace. Select the array containing the data you want to fit. The actual data you import must be a vector. If you select a matrix in the Data field, the first column of the matrix is imported by default. To select a different column or row of the matrix, click Select Column or Row. This displays the matrix in the Variables editor, where you can select a row or column by highlighting it with the mouse.

Alternatively, you can enter any valid MATLAB expression in the Data field.

When you select a vector in the Data field, a histogram of the data appears in the Data preview pane.

- Censoring - If some of the points in the data set are censored, enter a Boolean vector, of the same size as the data vector, specifying the censored entries of the data. A 1 in the censoring vector specifies that the corresponding entry of the data vector is censored, while a 0 specifies that the entry is not censored. If you enter a matrix, you can select a column or row by clicking Select Column or Row. If you do not want to censor any data, leave the Censoring field blank.
- Frequency - Enter a vector of positive integers of the same size as the data vector to specify the frequency of the corresponding entries of the data vector. For example, a value of 7 in the 15 th entry of frequency vector specifies that there are 7 data points corresponding to the value in the 15 th entry of the data vector. If all entries of the data vector have frequency 1 , leave the Frequency field blank.
- Data set name - Enter a name for the data set you import from the workspace, such as My data.

After you have entered the information in the preceding fields, click Create Data Set to create the data set My data.

Managing Data Sets. The Manage data sets pane enables you to view and manage the data sets you create. When you create a data set, its name appears in the Data sets list. The following figure shows the Manage data sets pane after creating the data set My data.

| Plot | Conf bounds | Data set |  |
| :---: | :---: | :--- | :--- |
| $\nabla$ | $\square$ | My data |  |
|  |  |  |  |
|  |  |  |  |
|  |  |  |  |
|  |  | View | Set Bin Rules |
|  |  | Rename | Delete |

For each data set in the Data sets list, you can:

- Select the Plot check box to display a plot of the data in the main Distribution Fitting Tool window. When you create a new data set, Plot is selected by default. Clearing the Plot check box removes the data from the plot in the main window. You can specify the type of plot displayed in the Display type field in the main window.
- If Plot is selected, you can also select Bounds to display confidence interval bounds for the plot in the main window. These bounds are pointwise confidence bounds around the empirical estimates of these functions. The bounds are only displayed when you set Display Type in the main window to one of the following:
- Cumulative probability (CDF)
- Survivor function
- Cumulative hazard

The Distribution Fitting Tool cannot display confidence bounds on density (PDF), quantile (inverse CDF), or probability plots. Clearing the Bounds check box removes the confidence bounds from the plot in the main window.

When you select a data set from the list, the following buttons are enabled:

- View - Display the data in a table in a new window.
- Set Bin Rules - Defines the histogram bins used in a density (PDF) plot.
- Rename - Rename the data set.
- Delete - Delete the data set.

Setting Bin Rules. To set bin rules for the histogram of a data set, click Set Bin Rules. This opens the Set Bin Width Rules dialog box.

You can select from the following rules:

- Freedman-Diaconis rule - Algorithm that chooses bin widths and locations automatically, based on the sample size and the spread of the data. This rule, which is the default, is suitable for many kinds of data.
- Scott rule - Algorithm intended for data that are approximately normal. The algorithm chooses bin widths and locations automatically.
- Number of bins - Enter the number of bins. All bins have equal widths.
- Bins centered on integers - Specifies bins centered on integers.
- Bin width - Enter the width of each bin. If you select this option, you can also select:
- Automatic bin placement - Place the edges of the bins at integer multiples of the Bin width.
- Bin boundary at - Enter a scalar to specify the boundaries of the bins. The boundary of each bin is equal to this scalar plus an integer multiple of the Bin width.

The Set Bin Width Rules dialog box also provides the following options:

- Apply to all existing data sets - Apply the rule to all data sets. Otherwise, the rule is only applied to the data set currently selected in the Data dialog box.
- Save as default - Apply the current rule to any new data sets that you create. You can also set default bin width rules by selecting Set Default Bin Rules from the Tools menu in the main window.

## Creating a New Fit

This section describes how to create a new fit. To begin, click the New Fit button at the top of the main window to open the New Fit dialog box. If you created the data set My data, it appears in the Data field.

| Field Name | Description |
| :--- | :--- |
| Fit Name | Enter a name for the fit in the Fit Name field. |
| Data | The Data field contains a drop-down list of the data sets <br> you have created. Select the data set to which you want to <br> fit a distribution. |
| Distribution | Select the type of distribution to fit from the Distribution <br> drop-down list. See "Available Distributions" on page 5-23 <br> for a list of distributions supported by the Distribution <br> Fitting Tool. <br> Only the distributions that apply to the values of the <br> selected data set appear in the Distribution field. For <br> example, positive distributions are not displayed when the <br> data include values that are zero or negative. <br> You can specify either a parametric or a nonparametric <br> distribution. When you select a parametric distribution <br> from the drop-down list, a description of its parameters <br> appears in the Normal pane. The Distribution Fitting Tool <br> estimates these parameters to fit the distribution to the <br> data set. When you select Nonparametric fit, options for <br> the fit appear in the pane, as described in "Further Options <br> for Nonparametric Fits" on page 5-24. |
| Exclusion <br> rule | Specify a rule to exclude some data in the Exclusion rule <br> field. Create an exclusion rule by clicking Exclude in <br> the Distribution Fitting Tool. For more information, see <br> "Excluding Data" on page 5-33. |

Apply the New Fit. Click Apply to fit the distribution. For a parametric fit, the Results pane displays the values of the estimated parameters. For a nonparametric fit, the Results pane displays information about the fit.

When you click Apply, the Distribution Fitting Tool displays a plot of the distribution, along with the corresponding data.

Note When you click Apply, the title of the dialog box changes to Edit Fit. You can now make changes to the fit you just created and click Apply again to save them. After closing the Edit Fit dialog box, you can reopen it from the Fit Manager dialog box at any time to edit the fit.

After applying the fit, you can save the information to the workspace using probability distribution objects by clicking Save to workspace. See "Using Probability Distribution Objects" on page 5-85 for more information.

Available Distributions. This section lists the distributions available in the Distribution Fitting Tool.

Most, but not all, of the distributions available in the Distribution Fitting Tool are supported elsewhere in Statistics Toolbox software (see "Supported Distributions" on page 5-3), and have dedicated distribution fitting functions. These functions compute the majority of the fits in the Distribution Fitting Tool, and are referenced in the list below.

Other fits are computed using functions internal to the Distribution Fitting Tool. Distributions that do not have corresponding Statistics Toolbox fitting functions are described in "Additional Distributions Available in the Distribution Fitting Tool" on page 5-49.

Not all of the distributions listed below are available for all data sets. The Distribution Fitting Tool determines the extent of the data (nonnegative, unit interval, etc.) and displays appropriate distributions in the Distribution drop-down list. Distribution data ranges are given parenthetically in the list below.

- Beta (unit interval values) distribution, fit using the function betafit.
- Binomial (nonnegative values) distribution, fit using the function binopdf.
- Birnbaum-Saunders (positive values) distribution.
- Burr Type XII (positive values) distribution.
- Exponential (nonnegative values) distribution, fit using the function expfit.
- Extreme value (all values) distribution, fit using the function evfit.
- Gamma (positive values) distribution, fit using the function gamfit.
- Generalized extreme value (all values) distribution, fit using the function gevfit.
- Generalized Pareto (all values) distribution, fit using the function gpfit.
- Inverse Gaussian (positive values) distribution.
- Logistic (all values) distribution.
- Loglogistic (positive values) distribution.
- Lognormal (positive values) distribution, fit using the function lognfit.
- Nakagami (positive values) distribution.
- Negative binomial (nonnegative values) distribution, fit using the function nbinpdf.
- Nonparametric (all values) distribution, fit using the function ksdensity. See "Further Options for Nonparametric Fits" on page 5-24 for a description of available options.
- Normal (all values) distribution, fit using the function normfit.
- Poisson (nonnegative integer values) distribution, fit using the function poisspdf.
- Rayleigh (positive values) distribution using the function raylfit.
- Rician (positive values) distribution.
- $t$ location-scale (all values) distribution.
- Weibull (positive values) distribution using the function wblfit.

Further Options for Nonparametric Fits. When you select Non-parametric in the Distribution field, a set of options appears in the Non-parametric pane, as shown in the following figure.

The options for nonparametric distributions are:

- Kernel - Type of kernel function to use.
- Normal
- Box
- Triangle
- Epanechnikov
- Bandwidth - The bandwidth of the kernel smoothing window. Select Auto for a default value that is optimal for estimating normal densities. This value appears in the Fit results pane after you click Apply. Select Specify and enter a smaller value to reveal features such as multiple modes or a larger value to make the fit smoother.
- Domain - The allowed $x$-values for the density.
- Unbounded - The density extends over the whole real line.
- Positive - The density is restricted to positive values.
- Specify - Enter lower and upper bounds for the domain of the density.

When you select Positive or Specify, the nonparametric fit has zero probability outside the specified domain.

## Displaying Results

This section explains the different ways to display results in the Distribution Fitting Tool window. This window displays plots of:

- The data sets for which you select Plot in the Data dialog box
- The fits for which you select Plot in the Fit Manager dialog box
- Confidence bounds for:
- Data sets for which you select Bounds in the Data dialog box
- Fits for which you select Bounds in the Fit Manager dialog box

The following fields are available.
Display Type. The Display Type field in the main window specifies the type of plot displayed. Each type corresponds to a probability function, for example, a probability density function. The following display types are available:

- Density (PDF) - Display a probability density function (PDF) plot for the fitted distribution. The main window displays data sets using a probability histogram, in which the height of each rectangle is the fraction of data points that lie in the bin divided by the width of the bin. This makes the sum of the areas of the rectangles equal to 1 .
- Cumulative probability (CDF) - Display a cumulative probability plot of the data. The main window displays data sets using a cumulative probability step function. The height of each step is the cumulative sum of the heights of the rectangles in the probability histogram.
- Quantile (inverse CDF) - Display a quantile (inverse CDF) plot.
- Probability plot - Display a probability plot of the data. You can specify the type of distribution used to construct the probability plot in the Distribution field, which is only available when you select Probability plot. The choices for the distribution are:
- Exponential
- Extreme value
- Logistic
- Log-Logistic
- Lognormal
- Normal
- Rayleigh
- Weibull

In addition to these choices, you can create a probability plot against a parametric fit that you create in the New Fit pane. These fits are added at the bottom of the Distribution drop-down list when you create them.

- Survivor function - Display survivor function plot of the data.
- Cumulative hazard - Display cumulative hazard plot of the data.

Note Some distributions are unavailable if the plotted data includes 0 or negative values.

Confidence Bounds. You can display confidence bounds for data sets and fits when you set Display Type to Cumulative probability (CDF), Survivor function, Cumulative hazard, or, for fits only, Quantile (inverse CDF).

- To display bounds for a data set, select Bounds next to the data set in the Data sets pane of the Data dialog box.
- To display bounds for a fit, select Bounds next to the fit in the Fit Manager dialog box. Confidence bounds are not available for all fit types.

To set the confidence level for the bounds, select Confidence Level from the View menu in the main window and choose from the options.

## Managing Fits

This section describes how to manage fits that you have created. To begin, click the Manage Fits button in the Distribution Fitting Tool. This opens the Fit Manager dialog box as shown in the following figure.

The Table of fits displays a list of the fits you create, with the following options:

- Plot - Select Plot to display a plot of the fit in the main window of the Distribution Fitting Tool. When you create a new fit, Plot is selected by default. Clearing the Plot check box removes the fit from the plot in the main window.
- Bounds - If Plot is selected, you can also select Bounds to display confidence bounds in the plot. The bounds are displayed when you set Display Type in the main window to one of the following:
- Cumulative probability (CDF)
- Quantile (inverse CDF)
- Survivor function
- Cumulative hazard

The Distribution Fitting Tool cannot display confidence bounds on density (PDF) or probability plots. In addition, bounds are not supported for nonparametric fits and some parametric fits.

Clearing the Bounds check box removes the confidence intervals from the plot in the main window.

When you select a fit in the Table of fits, the following buttons are enabled below the table:

- New Fit - Open a New Fit window.
- Copy - Create a copy of the selected fit.
- Edit - Open an Edit Fit dialog box, where you can edit the fit.

Note You can only edit the currently selected fit in the Edit Fit dialog box. To edit a different fit, select it in the Table of fits and click Edit to open another Edit Fit dialog box.

- Save to workspace - Save the selected fit as a distribution object. See "Using Probability Distribution Objects" on page 5-85 for more information.
- Delete - Delete the selected fit.

## Evaluating Fits

The Evaluate dialog box enables you to evaluate any fit at whatever points you choose. To open the dialog box, click the Evaluate button in the Distribution Fitting Tool. The following figure shows the Evaluate dialog box.

The Evaluate dialog box contains the following items:

- Fit pane - Display the names of existing fits. Select one or more fits that you want to evaluate. Using your platform specific functionality, you can select multiple fits.
- Function - Select the type of probability function you want to evaluate for the fit. The available functions are
- Density (PDF) - Computes a probability density function.
- Cumulative probability (CDF) - Computes a cumulative probability function.
- Quantile (inverse CDF) - Computes a quantile (inverse CDF) function.
- Survivor function - Computes a survivor function.
- Cumulative hazard - Computes a cumulative hazard function.
- Hazard rate - Computes the hazard rate.
- At $\mathbf{x}=-$ Enter a vector of points or the name of a workspace variable containing a vector of points at which you want to evaluate the distribution function. If you change Function to Quantile (inverse CDF), the field name changes to At $\mathbf{p}=$ and you enter a vector of probability values.
- Compute confidence bounds - Select this box to compute confidence bounds for the selected fits. The check box is only enabled if you set Function to one of the following:
- Cumulative probability (CDF)
- Quantile (inverse CDF)
- Survivor function
- Cumulative hazard

The Distribution Fitting Tool cannot compute confidence bounds for nonparametric fits and for some parametric fits. In these cases, the tool returns NaN for the bounds.

- Level - Set the level for the confidence bounds.
- Plot function - Select this box to display a plot of the distribution function, evaluated at the points you enter in the At $\mathbf{x}=$ field, in a new window.

Note The settings for Compute confidence bounds, Level, and Plot function do not affect the plots that are displayed in the main window of the Distribution Fitting Tool. The settings only apply to plots you create by clicking Plot function in the Evaluate window.

Click Apply to apply these settings to the selected fit. The following figure shows the results of evaluating the cumulative density function for the fit My fit, created in "Example: Fitting a Distribution" on page 5-40, at the points in the vector $-4: 1: 6$.

The window displays the following values in the columns of the table to the right of the Fit pane:

- X - The entries of the vector you enter in At $\mathbf{x}=$ field
- $\mathrm{F}(\mathrm{X})$ - The corresponding values of the CDF at the entries of X
- LB - The lower bounds for the confidence interval, if you select Compute confidence bounds
- UB - The upper bounds for the confidence interval, if you select Compute confidence bounds

To save the data displayed in the Evaluate window, click Export to Workspace. This saves the values in the table to a matrix in the MATLAB workspace.

## Excluding Data

To exclude values from fit, click the Exclude button in the main window of the Distribution Fitting Tool. This opens the Exclude window, in which you can create rules for excluding specified values. You can use these rules to exclude data when you create a new fit in the New Fit window. The following figure shows the Exclude window.

To create an exclusion rule:
1 Exclusion Rule Name-Enter a name for the exclusion rule in the Exclusion rule name field.

2 Exclude Sections-In the Exclude sections pane, you can specify bounds for the excluded data:

- In the Lower limit: exclude $\mathbf{Y}$ drop-down list, select <= or < from the drop-down list and enter a scalar in the field to the right. This excludes values that are either less than or equal to or less than that scalar, respectively.
- In the Upper limit: exclude $\mathbf{Y}$ drop-down list, select >= or > from the drop-down list and enter a scalar in the field to the right to exclude values that are either greater than or equal to or greater than the scalar, respectively.

## OR

Exclude Graphically-The Exclude Graphically button enables you to define the exclusion rule by displaying a plot of the values in a data set and selecting the bounds for the excluded data with the mouse. For example, if you created the data set My data, described in "Creating and Managing Data Sets" on page $5-15$, select it from the drop-down list next to Exclude graphically and then click the Exclude graphically button. This displays the values in My data in a new window as shown in the following figure.

To set a lower limit for the boundary of the excluded region, click Add Lower Limit. This displays a vertical line on the left side of the plot window. Move the line with the mouse to the point you where you want the lower limit, as shown in the following figure.

Moving the vertical line changes the value displayed in the Lower limit: exclude data field in the Exclude window, as shown in the following figure.

The value displayed corresponds to the $x$-coordinate of the vertical line.
Similarly, you can set the upper limit for the boundary of the excluded region by clicking Add Upper Limit and moving the vertical line that
appears at the right side of the plot window. After setting the lower and upper limits, click Close and return to the Exclude window.

3 Create Exclusion Rule-Once you have set the lower and upper limits for the boundary of the excluded data, click Create Exclusion Rule to create the new rule. The name of the new rule now appears in the Existing exclusion rules pane.

When you select an exclusion rule in the Existing exclusion rules pane, the following buttons are enabled:

- Copy - Creates a copy of the rule, which you can then modify. To save the modified rule under a different name, click Create Exclusion Rule.
- View - Opens a new window in which you can see which data points are excluded by the rule. The following figure shows a typical example.

| 4 View Exclusion Rule | - 易 $\times$ |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |

|  | 12 | 4.60889 |  |  |  |
|  | 13 | 1.37557 |  |  |  |
|  | 14 | 0.27172 |  |  |  |
|  | 15 | 1.36064 |  |  |  |
| Excluded sections: | 16 | 0.07305 |  |  |  |
|  | 17 | 0.1862 |  |  |  |
| Exclude data <= -2.5 | 18 | 2.44558 |  |  |  |
| Exclude data > $=4$ | 19 | 2.33265 |  |  |  |
|  | 20 | 2.34407 |  |  | - |
|  |  |  |  | Close |  |

The shaded areas in the plot graphically display which data points are excluded. The table to the right lists all data points. The shaded rows indicate excluded points:

- Rename - Renames the rule
- Delete - Deletes the rule

Once you define an exclusion rule, you can use it when you fit a distribution to your data. The rule does not exclude points from the display of the data set.

## Saving and Loading Sessions

This section explains how to save your work in the current Distribution Fitting Tool session and then load it in a subsequent session, so that you can continue working where you left off.

Saving a Session. To save the current session, select Save Session from the File menu in the main window. This opens a dialog box that prompts you to enter a filename, such as my_session.dfit, for the session. Clicking Save saves the following items created in the current session:

- Data sets
- Fits
- Exclusion rules
- Plot settings
- Bin width rules

Loading a Session. To load a previously saved session, select Load Session from the File menu in the main window and enter the name of a previously saved session. Clicking Open restores the information from the saved session to the current session of the Distribution Fitting Tool.

## Example: Fitting a Distribution

This section presents an example that illustrates how to use the Distribution Fitting Tool. The example involves the following steps:

- "Step 1: Generate Random Data" on page 5-40
- "Step 2: Import Data" on page 5-40
- "Step 3: Create a New Fit" on page 5-43

Step 1: Generate Random Data. To try the example, first generate some random data to which you will fit a distribution. The following command generates a vector data, of length 100, whose entries are random numbers from a normal distribution with mean. 36 and standard deviation 1.4.

```
rng('default')
data = normrnd(.36, 1.4, 100, 1);
```

Step 2: Import Data. Open the distribution fitting tool:

```
dfittool
```

To import the vector data into the Distribution Fitting Tool, click the Data button in main window. This opens the window shown in the following figure.

The Data field displays all numeric arrays in the MATLAB workspace. Select data from the drop-down list, as shown in the following figure.

| Data: | \|none) |
| :--- | :--- |
| Censoring: | (none) |
| data |  |

This displays a histogram of the data in the Data preview pane.
In the Data set name field, type a name for the data set, such as My data, and click Create Data Set to create the data set. The main window of the Distribution Fitting Tool now displays a larger version of the histogram in the Data preview pane, as shown in the following figure.

Note Because the example uses random data, you might see a slightly different histogram if you try this example for yourself.

Step 3: Create a New Fit. To fit a distribution to the data, click New Fit in the main window of the Distribution Fitting Tool. This opens the window shown in the following figure.

To fit a normal distribution, the default entry of the Distribution field, to My data:

1 Enter a name for the fit, such as My fit, in the Fit name field.
2 Select My data from the drop-down list in the Data field.

## 3 Click Apply.

The Results pane displays the mean and standard deviation of the normal distribution that best fits My data, as shown in the following figure.

The main window of the Distribution Fitting Tool displays a plot of the normal distribution with this mean and standard deviation, as shown in the following figure.

## Generating a File to Fit and Plot Distributions

The Generate Code option in the File menu enables you to create a file that

- Fits the distributions used in the current session to any data vector in the MATLAB workspace.
- Plots the data and the fits.

After you end the current session, you can use the file to create plots in a standard MATLAB figure window, without having to reopen the Distribution Fitting Tool.

As an example, assuming you created the fit described in "Creating a New Fit" on page $5-20$, do the following steps:

1 Select Generate Code from the File menu.
2 Choose File > Save as in the MATLAB Editor window. Save the file as normal_fit.m in a folder on the MATLAB path.

You can then apply the function normal_fit to any vector of data in the MATLAB workspace. For example, the following commands

```
new_data = normrnd(4.1, 12.5, 100, 1);
newfit = normal_fit(new_data)
legend('New Data', 'My fit')
```

generate newfit, a fitted normal distribution of the data, and generates a plot of the data and the fit.

```
newfit =
normal distribution
    mu = 3.19148
    sigma = 12.5631
```

Note By default, the file labels the data in the legend using the same name as the data set in the Distribution Fitting Tool. You can change the label using the legend command, as illustrated by the preceding example.

## Additional Distributions Available in the Distribution Fitting Tool

The following distributions are available in the Distribution Fitting Tool, but do not have dedicated distribution functions as described in "Statistics Toolbox Distribution Functions" on page 5-53. The distributions can be used with the functions pdf, cdf, icdf, and mle in a limited capacity. See the reference pages for these functions for details on the limitations.

- "Birnbaum-Saunders Distribution" on page B-10
- "Burr Type XII Distribution" on page B-12
- "Inverse Gaussian Distribution" on page B-58
- "Loglogistic Distribution" on page B-63
- "Logistic Distribution" on page B-62
- "Nakagami Distribution" on page B-83
- "Rician Distribution" on page B-106
- "t Location-Scale Distribution" on page B-110

For a complete list of the distributions available for use with the Distribution Fitting Tool, see "Supported Distributions" on page 5-3. Distributions listing dfittool in the fit column of the tables in that section can be used with the Distribution Fitting Tool.

## Custom Distributions Using Distribution Fitting Tool

This section explains how to use custom distributions with the Distribution Fitting Tool.

## Defining Custom Distributions

To define a custom distribution, select Define Custom Distribution from the File menu. This opens a file template in the MATLAB editor. You then edit this file so that it computes the distribution you want.

The template includes example code that computes the Laplace distribution, beginning at the lines

```
%
% Remove the following return statement to define the
% Laplace distributon
%
return
```

To use this example, simply delete the command return and save the file. If you save the template in a folder on the MATLAB path, under its default name dfittooldists.m, the Distribution Fitting Tool reads it in automatically when you start the tool. You can also save the template under a different name, such as laplace.m, and then import the custom distribution as described in the following section.

## Importing Custom Distributions

To import a custom distribution, select Import Custom Distributions from the File menu. This opens a dialog box in which you can select the file that defines the distribution. For example, if you created the file laplace.m, as described in the preceding section, you can enter laplace.m and select Open in the dialog box. The Distribution field of the New Fit window now contains the option Laplace.

## Visually Exploring Random Number Generation

The Random Number Generation Tool is a graphical user interface that generates random samples from specified probability distributions and displays the samples as histograms. Use the tool to explore the effects of changing parameters and sample size on the distributions.

Run the tool by typing randtool at the command line.

Start by selecting a distribution, then enter the desired sample size.

You can also

- Use the controls at the bottom of the window to set parameter values for the distribution and to change their upper and lower bounds.
- Draw another sample from the same distribution, with the same size and parameters.
- Export the current sample to your workspace. A dialog box enables you to provide a name for the sample.

## Statistics Toolbox Distribution Functions

In this section...<br>"Probability Density Functions" on page 5-53<br>"Cumulative Distribution Functions" on page 5-63<br>"Inverse Cumulative Distribution Functions" on page 5-67<br>"Distribution Statistics Functions" on page 5-69<br>"Distribution Fitting Functions" on page 5-71<br>"Negative Log-Likelihood Functions" on page 5-78<br>"Random Number Generators" on page 5-81

For each distribution supported by Statistics Toolbox software, a selection of the distribution functions described in this section is available for statistical programming. This section gives a general overview of the use of each type of function, independent of the particular distribution. For specific functions available for specific distributions, see "Supported Distributions" on page 5-3.

## Probability Density Functions

- "Estimating PDFs with Parameters" on page 5-53
- "Estimating PDFs without Parameters" on page 5-56

## Estimating PDFs with Parameters

Probability density functions (pdfs) for supported Statistics Toolbox distributions all end with pdf, as in binopdf or exppdf. For more information on specific function names for specific distributions see "Supported Distributions" on page 5-3.

Each function represents a parametric family of distributions. Input arguments are arrays of outcomes followed by a list of parameter values specifying a particular member of the distribution family.

For discrete distributions, the pdf assigns a probability to each outcome. In this context, the pdf is often called a probability mass function (pmf).

For example, the discrete binomial pdf

$$
f(k)=\binom{n}{k} p^{k}(1-p)^{n-k}
$$

assigns probability to the event of $k$ successes in $n$ trials of a Bernoulli process (such as coin flipping) with probability $p$ of success at each trial. Each of the integers $k=0,1,2, \ldots, n$ is assigned a positive probability, with the sum of the probabilities equal to 1 . Compute the probabilities with the binopdf function:

```
p = 0.2; % Probability of success for each trial
n = 10; % Number of trials
k = 0:n; % Outcomes
m = binopdf(k,n,p); % Probability mass vector
bar(k,m) % Visualize the probability distribution
set(get(gca,'Children'),'FaceColor',[.8 .8 1])
grid on
```

For continuous distributions, the pdf assigns a probability density to each outcome. The probability of any single outcome is zero. The pdf must be integrated over a set of outcomes to compute the probability that an outcome falls within that set. The integral over the entire set of outcomes is 1 .

For example, the continuous exponential pdf

$$
f(t)=\lambda e^{-\lambda t}
$$

is used to model the probability that a process with constant failure rate $\lambda$ will have a failure within time $t$. Each time $t>0$ is assigned a positive probability density. Densities are computed with the exppdf function:

```
lambda = 2; % Failure rate
t = 0:0.01:3; % Outcomes
f = exppdf(t,1/lambda); % Probability density vector
plot(t,f) % Visualize the probability distribution
grid on
```

Probabilities for continuous pdfs can be computed with the integral function. In the example above, the probability of failure in the time interval $[0,1]$ is computed as follows:

```
f_lambda = @(t)exppdf(t,1/lambda); % Pdf with fixed lambda
P = integral(f_lambda,0,1) % Integrate from 0 to 1
P =
    0.8647
```

Alternatively, the cumulative distribution function (cdf) for the exponential function, expcdf, can be used:

```
P = expcdf(1,1/lambda) % Cumulative probability from 0 to 1
P =
    0.8647
```

## Estimating PDFs without Parameters

A distribution of data can be described graphically with a histogram:

```
cars = load('carsmall','MPG','Origin');
MPG = cars.MPG;
hist(MPG)
set(get(gca,'Children'),'FaceColor',[.8 . 8 1])
```

You can also describe a data distribution by estimating its density.
The ksdensity function does this using a kernel smoothing method. A nonparametric density estimate of the previous data, using the default kernel and bandwidth, is given by:

```
[f,x] = ksdensity(MPG);
plot(x,f);
title('Density estimate for MPG')
```

Density estimate for MPG

Controlling Probability Density Curve Smoothness. The choice of kernel bandwidth controls the smoothness of the probability density curve. The following graph shows the density estimate for the same mileage data using different bandwidths. The default bandwidth is in blue and looks like the preceding graph. Estimates for smaller and larger bandwidths are in red and green.

The first call to ksdensity returns the default bandwidth, $u$, of the kernel smoothing function. Subsequent calls modify this bandwidth.

```
[f,x,u] = ksdensity(MPG);
plot(x,f)
title('Density estimate for MPG')
hold on
```

```
[f,x] = ksdensity(MPG,'width',u/3);
plot(x,f,'r');
[f,x] = ksdensity(MPG,'width',u*3);
plot(x,f,'g');
legend('default width','1/3 default','3*default')
hold off
```

Density estimate for MPG

The default bandwidth seems to be doing a good job-reasonably smooth, but not so smooth as to obscure features of the data. This bandwidth is the one that is theoretically optimal for estimating densities for the normal distribution.

The green curve shows a density with the kernel bandwidth set too high. This curve smooths out the data so much that the end result looks just like the kernel function. The red curve has a smaller bandwidth and is rougher looking than the blue curve. It may be too rough, but it does provide an indication that there might be two major peaks rather than the single peak of the blue curve. A reasonable choice of width might lead to a curve that is intermediate between the red and blue curves.

Specifying Kernel Smoothing Functions. You can also specify a kernel function by supplying either the function name or a function handle. The four preselected functions, 'normal', 'epanechnikov', 'box', and 'triangle', are all scaled to have standard deviation equal to 1 , so they perform a comparable degree of smoothing.

Using default bandwidths, you can now plot the same mileage data, using each of the available kernel functions.

```
hname = {'normal' 'epanechnikov' 'box' 'triangle'};
colors = {'r' 'b' 'g' 'm'};
for j=1:4
    [f,x] = ksdensity(MPG,'kernel',hname{j});
    plot(x,f,colors{j});
    hold on;
end
legend(hname{:});
hold off
```

The density estimates are roughly comparable, but the box kernel produces a density that is rougher than the others.

Comparing Density Estimates. While it is difficult to overlay two histograms to compare them, you can easily overlay smooth density estimates. For example, the following graph shows the MPG distributions for cars from different countries of origin:

```
Origin = cellstr(cars.Origin);
I = strcmp('USA',Origin);
J = strcmp('Japan',Origin);
K = ~(I|J);
MPG_USA = MPG(I);
MPG_Japan = MPG(J);
MPG_Europe = MPG(K);
```

```
[fI,xI] = ksdensity(MPG_USA);
plot(xI,fI,'b')
hold on
[fJ,xJ] = ksdensity(MPG_Japan);
plot(xJ,fJ,'r')
[fK,xK] = ksdensity(MPG_Europe);
plot(xK,fK,'g')
legend('USA','Japan','Europe')
hold off
```

For piecewise probability density estimation, using kernel smoothing in the center of the distribution and Pareto distributions in the tails, see "Fitting Piecewise Distributions" on page 5-73.

## Cumulative Distribution Functions

- "Estimating Parametric CDFs" on page 5-63
- "Estimating Empirical CDFs" on page 5-64

## Estimating Parametric CDFs

Cumulative distribution functions (cdfs) for supported Statistics Toolbox distributions all end with cdf, as in binocdf or expcdf. Specific function names for specific distributions can be found in "Supported Distributions" on page 5-3.

Each function represents a parametric family of distributions. Input arguments are arrays of outcomes followed by a list of parameter values specifying a particular member of the distribution family.

For discrete distributions, the $\operatorname{cdf} F$ is related to the $\operatorname{pdf} f$ by

$$
F(x)=\sum_{y \leq x} f(y)
$$

For continuous distributions, the $\operatorname{cdf} F$ is related to the $\operatorname{pdf} f$ by

$$
F(x)=\int_{-\infty}^{x} f(y) d y
$$

Cdfs are used to compute probabilities of events. In particular, if $F$ is a cdf and $x$ and $y$ are outcomes, then

- $P(y \leq x)=F(x)$
- $P(y>x)=1-F(x)$
- $P\left(x_{1}<y \leq x_{2}\right)=F\left(x_{2}\right)-F\left(x_{1}\right)$

For example, the $t$-statistic

$$
t=\frac{\bar{x}-\mu}{s / \sqrt{n}}
$$

follows a Student's $t$ distribution with $n-1$ degrees of freedom when computed from repeated random samples from a normal population with mean $\mu$. Here $\bar{x}$ is the sample mean, $s$ is the sample standard deviation, and $n$ is the sample size. The probability of observing a $t$-statistic greater than or equal to the value computed from a sample can be found with the tcdf function:

```
mu = 1; % Population mean
sigma = 2; % Population standard deviation
n = 100; % Sample size
x = normrnd(mu,sigma,n,1); % Random sample from population
xbar = mean(x); % Sample mean
s = std(x); % Sample standard deviation
t = (xbar-mu)/(s/sqrt(n)) % t-statistic
t =
    0.2489
p = 1-tcdf(t,n-1) % Probability of larger t-statistic
p =
    0.4020
```

This probability is the same as the $p$ value returned by a $t$-test of the null hypothesis that the sample comes from a normal population with mean $\mu$ :

```
[h,ptest] = ttest(x,mu,0.05,'right')
h =
    0
ptest =
    0.4020
```

## Estimating Empirical CDFs

The ksdensity function produces an empirical version of a probability density function (pdf). That is, instead of selecting a density with a particular parametric form and estimating the parameters, it produces a nonparametric density estimate that adapts itself to the data.

Similarly, it is possible to produce an empirical version of the cumulative distribution function (cdf). The ecdf function computes this empirical cdf. It
returns the values of a function $F$ such that $F(x)$ represents the proportion of observations in a sample less than or equal to $x$.

The idea behind the empirical cdf is simple. It is a function that assigns probability $1 / n$ to each of $n$ observations in a sample. Its graph has a stair-step appearance. If a sample comes from a distribution in a parametric family (such as a normal distribution), its empirical cdf is likely to resemble the parametric distribution. If not, its empirical distribution still gives an estimate of the cdf for the distribution that generated the data.

The following example generates 20 observations from a normal distribution with mean 10 and standard deviation 2 . You can use ecdf to calculate the empirical cdf and stairs to plot it. Then you overlay the normal distribution curve on the empirical function.

```
x = normrnd(10,2,20,1);
[f,xf] = ecdf(x);
stairs(xf,f)
hold on
xx=linspace(5,15,100);
yy = normcdf(xx,10,2);
plot(xx,yy,'r:')
hold off
legend('Empirical cdf','Normal cdf',2)
```

The empirical cdf is especially useful in survival analysis applications. In such applications the data may be censored, that is, not observed exactly. Some individuals may fail during a study, and you can observe their failure time exactly. Other individuals may drop out of the study, or may not fail until after the study is complete. The ecdf function has arguments for dealing with censored data. In addition, you can use the coxphfit function with individuals that have predictors that are not the same.

For piecewise probability density estimation, using the empirical cdf in the center of the distribution and Pareto distributions in the tails, see "Fitting Piecewise Distributions" on page 5-73.

## Inverse Cumulative Distribution Functions

Inverse cumulative distribution functions for supported Statistics Toolbox distributions all end with inv, as in binoinv or expinv. Specific function names for specific distributions can be found in "Supported Distributions" on page 5-3.

Each function represents a parametric family of distributions. Input arguments are arrays of cumulative probabilities from 0 to 1 followed by a list of parameter values specifying a particular member of the distribution family.

For continuous distributions, the inverse cdf returns the unique outcome whose cdf value is the input cumulative probability.

For example, the expinv function can be used to compute inverses of exponential cumulative probabilities:

```
x = 0.5:0.2:1.5 % Outcomes
x =
    0.5000}00.7000 0.9000 1.1000 1.3000 1.5000
p = expcdf(x,1) % Cumulative probabilities
p =
    0.3935 0.5034 0.5934 0.6671 0.7275 0.7769
expinv(p,1) % Return original outcomes
ans =
    0.5000
```

For discrete distributions, there may be no outcome whose cdf value is the input cumulative probability. In these cases, the inverse cdf returns the first outcome whose cdf value equals or exceeds the input cumulative probability.

For example, the binoinv function can be used to compute inverses of binomial cumulative probabilities:

```
x = 0:5 % Some possible outcomes
p = binocdf(x,10,0.2) % Their cumulative probabilities
p =
    0.1074 0.3758 0.6778
q = [.1 .2 .3 .4] % New trial probabilities
```

```
q =
    0.1000 0.2000 0.3000 0.4000
binoinv(q,10,0.2) % Their corresponding outcomes
ans =
    0
```

The inverse cdf is useful in hypothesis testing, where critical outcomes of a test statistic are computed from cumulative significance probabilities. For example, norminv can be used to compute a $95 \%$ confidence interval under the assumption of normal variability:

```
p = [0.025 0.975]; % Interval containing 95% of [0,1]
x = norminv(p,0,1) % Assume standard normal variability
x =
    -1.9600 1.9600 % 95% confidence interval
n = 20; % Sample size
y = normrnd(8,1,n,1); % Random sample (assume mean is unknown)
ybar = mean(y);
ci = ybar + (1/sqrt(n))*x % Confidence interval for mean
ci =
    7.6779 8.5544
```

## Distribution Statistics Functions

Distribution statistics functions for supported Statistics Toolbox distributions all end with stat, as in binostat or expstat. Specific function names for specific distributions can be found in "Supported Distributions" on page 5-3.

Each function represents a parametric family of distributions. Input arguments are lists of parameter values specifying a particular member of the distribution family. Functions return the mean and variance of the distribution, as a function of the parameters.

For example, the wblstat function can be used to visualize the mean of the Weibull distribution as a function of its two distribution parameters:

```
a = 0.5:0.1:3;
b = 0.5:0.1:3;
[A,B] = meshgrid(a,b);
M = wblstat(A,B);
surfc(A,B,M)
```

## Distribution Fitting Functions

- "Fitting Regular Distributions" on page 5-71
- "Fitting Piecewise Distributions" on page 5-73

## Fitting Regular Distributions

Distribution fitting functions for supported Statistics Toolbox distributions all end with fit, as in binofit or expfit. Specific function names for specific distributions can be found in "Supported Distributions" on page 5-3.

Each function represents a parametric family of distributions. Input arguments are arrays of data, presumed to be samples from some member of the selected distribution family. Functions return maximum likelihood estimates (MLEs) of distribution parameters, that is, parameters for the distribution family member with the maximum likelihood of producing the data as a random sample.

The Statistics Toolbox function mle is a convenient front end to the individual distribution fitting functions, and more. The function computes MLEs for distributions beyond those for which Statistics Toolbox software provides specific pdf functions.

For some pdfs, MLEs can be given in closed form and computed directly. For other pdfs, a search for the maximum likelihood must be employed. The search can be controlled with an options input argument, created using the statset function. For efficient searches, it is important to choose a reasonable distribution model and set appropriate convergence tolerances.

MLEs can be heavily biased, especially for small samples. As sample size increases, however, MLEs become unbiased minimum variance estimators with approximate normal distributions. This is used to compute confidence bounds for the estimates.

For example, consider the following distribution of means from repeated random samples of an exponential distribution:

```
mu = 1; % Population parameter
n = 1e3; % Sample size
ns = 1e4; % Number of samples
```

```
samples = exprnd(mu,n,ns); % Population samples
means = mean(samples); % Sample means
```

The Central Limit Theorem says that the means will be approximately normally distributed, regardless of the distribution of the data in the samples. The normfit function can be used to find the normal distribution that best fits the means:

```
[muhat,sigmahat,muci,sigmaci] = normfit(means)
muhat =
    1.0003
sigmahat =
    0.0319
muci =
    0.9997
    1.0010
sigmaci =
    0.0314
    0.0323
```

The function returns MLEs for the mean and standard deviation and their $95 \%$ confidence intervals.

To visualize the distribution of sample means together with the fitted normal distribution, you must scale the fitted pdf, with area $=1$, to the area of the histogram being used to display the means:

```
numbins = 50;
hist(means,numbins)
set(get(gca,'Children'),'FaceColor',[.8 . 8 1])
hold on
[bincounts,binpositions] = hist(means,numbins);
binwidth = binpositions(2) - binpositions(1);
histarea = binwidth*sum(bincounts);
x = binpositions(1):0.001:binpositions(end);
y = normpdf(x,muhat,sigmahat);
plot(x,histarea*y,'r','LineWidth',2)
```

## Fitting Piecewise Distributions

The parametric methods discussed in "Fitting Regular Distributions" on page 5-71 fit data samples with smooth distributions that have a relatively low-dimensional set of parameters controlling their shape. These methods work well in many cases, but there is no guarantee that a given sample will be described accurately by any of the supported Statistics Toolbox distributions.

The empirical distributions computed by ecdf and discussed in "Estimating Empirical CDFs" on page 5-64 assign equal probability to each observation in a sample, providing an exact match of the sample distribution. However, the distributions are not smooth, especially in the tails where data may be sparse.

The paretotails function fits a distribution by piecing together the empirical distribution in the center of the sample with smooth generalized Pareto distributions (GPDs) in the tails. The output is an object of the paretotails class, with associated methods to evaluate the cdf, inverse cdf, and other functions of the fitted distribution.

As an example, consider the following data, with about $20 \%$ outliers:

```
left_tail = -exprnd(1,10,1);
right_tail = exprnd(5,10,1);
center = randn(80,1);
data = [left_tail;center;right_tail];
```

Neither a normal distribution nor a $t$ distribution fits the tails very well:

```
probplot(data);
p = fitdist(data,'tlocationscale');
h = probplot(gca,p);
set(h,'color','r','linestyle','-')
title('{\bf Probability Plot}')
legend('Normal','Data','t','Location','NW')
```

On the other hand, the empirical distribution provides a perfect fit, but the outliers make the tails very discrete:

```
ecdf(data)
```

Random samples generated from this distribution by inversion might include, for example, values around 4.33 and 9.25 , but nothing in-between.

The paretotails function provides a single, well-fit model for the entire sample. The following uses generalized Pareto distributions (GPDs) for the lower and upper $10 \%$ of the data:

```
pfit = paretotails(data,0.1,0.9)
pfit =
Piecewise distribution with 3 segments
    -Inf < x < -1.30726 (0 < p < 0.1)
        lower tail, GPD(-1.10167,1.12395)
    -1.30726 < x < 1.27213 (0.1< p < 0.9)
        interpolated empirical cdf
    1.27213 < x < Inf (0.9 < p < 1)
```

```
upper tail, GPD(1.03844,0.726038)
```

$x=-4: 0.01: 10 ;$
$\operatorname{plot}(x, \operatorname{cdf}($ pfit,$x))$

Access information about the fit using the methods of the paretotails class. Options allow for nonparametric estimation of the center of the cdf.

## Negative Log-Likelihood Functions

Negative log-likelihood functions for supported Statistics Toolbox distributions all end with like, as in explike. Specific function names for specific distributions can be found in "Supported Distributions" on page 5-3.

Each function represents a parametric family of distributions. Input arguments are lists of parameter values specifying a particular member of the distribution family followed by an array of data. Functions return the negative log-likelihood of the parameters, given the data.

Negative log-likelihood functions are used as objective functions in search algorithms such as the one implemented by the MATLAB function fminsearch. Additional search algorithms are implemented by Optimization Toolbox ${ }^{\text {TM }}$ functions and Global Optimization Toolbox functions.

When used to compute maximum likelihood estimates (MLEs), negative log-likelihood functions allow you to choose a search algorithm and exercise low-level control over algorithm execution. By contrast, the functions discussed in "Distribution Fitting Functions" on page 5-71 use preset algorithms with options limited to those set by the statset function.

Likelihoods are conditional probability densities. A parametric family of distributions is specified by its $\operatorname{pdf} f(x, a)$, where $x$ and $a$ represent the variables and parameters, respectively. When $a$ is fixed, the pdf is used to compute the density at $x, f(x \mid a)$. When $x$ is fixed, the pdf is used to compute the likelihood of the parameters $a, f(a \mid x)$. The joint likelihood of the parameters over an independent random sample $X$ is

$$
L(a)=\prod_{x \in X} f(a \mid x)
$$

Given $X$, MLEs maximize $L(a)$ over all possible $a$.
In numerical algorithms, the log-likelihood function, $\log (L(a))$, is (equivalently) optimized. The logarithm transforms the product of potentially small likelihoods into a sum of logs, which is easier to distinguish from 0 in computation. For convenience, Statistics Toolbox negative log-likelihood functions return the negative of this sum, since the optimization algorithms to which the values are passed typically search for minima rather than maxima.

For example, use gamrnd to generate a random sample from a specific gamma distribution:

```
a = [1,2];
X = gamrnd(a(1),a(2),1e3,1);
```

Given X, the gamlike function can be used to visualize the likelihood surface in the neighborhood of a:

```
mesh = 50;
delta = 0.5;
a1 = linspace(a(1)-delta,a(1)+delta,mesh);
a2 = linspace(a(2)-delta,a(2)+delta,mesh);
logL = zeros(mesh); % Preallocate memory
for i = 1:mesh
    for j = 1:mesh
        logL(i,j) = gamlike([a1(i),a2(j)],X);
    end
end
[A1,A2] = meshgrid(a1,a2);
surfc(A1,A2,logL)
```

The MATLAB function fminsearch is used to search for the minimum of the likelihood surface:

```
LL = @(u)gamlike([u(1),u(2)],X); % Likelihood given X
MLES = fminsearch(LL,[1,2])
MLES =
    1.0231 1.9729
```

These can be compared to the MLEs returned by the gamfit function, which uses a combination search and solve algorithm:

```
ahat = gamfit(X)
ahat =
    1.0231 1.9728
```

The MLEs can be added to the surface plot (rotated to show the minimum):
hold on
plot3(MLES(1), MLES(2), LL(MLES), ...
'ro','MarkerSize',5,...
'MarkerFaceColor', 'r')

## Random Number Generators

The Statistics Toolbox supports the generation of random numbers from various distributions. Each RNG represents a parametric family of distributions. RNGs return random numbers from the specified distribution in an array of the specified dimensions. Specific RNG names for specific distributions are in "Supported Distributions" on page 5-3.

Other random number generation functions which do not support specific distributions include:

- cvpartition
- datasample
- hmmgenerate
- lhsdesign
- lhsnorm
- mhsample
- random
- randsample
- slicesample

RNGs in Statistics Toolbox software depend on MATLAB's default random number stream via the rand and randn functions, each RNG uses one of the techniques discussed in "Common Generation Methods" on page 6-5 to generate random numbers from a given distribution.

By controlling the default random number stream and its state, you can control how the RNGs in Statistics Toolbox software generate random values. For example, to reproduce the same sequence of values from an RNG, you can save and restore the default stream's state, or reset the default stream. For details on managing the default random number stream, see "Managing the Global Stream".

MATLAB initializes the default random number stream to the same state each time it starts up. Thus, RNGs in Statistics Toolbox software will generate the same sequence of values for each MATLAB session unless you
modify that state at startup. One simple way to do that is to add commands to startup.m such as
rng('shuffle');
that initialize MATLAB's default random number stream to a different state for each session.

## Dependencies of the Random Number Generators

The following table lists the dependencies of Statistics Toolbox RNGs on the MATLAB base RNGs rand, randi, and/or randn.

| RNG | MATLAB Base RNG |
| :---: | :---: |
| betarnd | rand, randn |
| binornd | rand |
| chi2rnd | rand, randn |
| evrnd | rand |
| exprnd | rand |
| datasample | rand, randi, randperm |
| frnd | rand, randn |
| gamrnd | rand, randn |
| geornd | rand |
| gevrnd | rand |
| gprnd | rand |
| hygernd | rand |
| iwishrnd | rand, randn |
| johnsrnd | randn |
| lhsdesign | rand |
| lhsnorm | rand |
| lognrnd | randn |
| mhsample | rand or randn, depending on the RNG given for the proposal distribution |
| mvnrnd | randn |
| mvtrnd | rand, randn |

|  |  |
| :--- | :--- |
| RNG | MATLAB Base RNG |
| nbinrnd | rand, randn |
| ncfrnd | rand, randn |
| nctrnd | rand, randn |
| ncx2rnd | randn |
| normrnd | randn |
| pearsrnd | rand or randn, depending on the <br> distribution type |
| poissrnd | rand, randn |
| random | rand or randn, depending on the <br> specified distribution |
| randsample | rand |
| raylrnd | randn |
| slicesample | rand |
| trnd | rand, randn |
| unidrnd | rand |
| unifrnd | rand |
| wblrnd | rand, randn |
| wishrnd |  |

## Using Probability Distribution Objects

In this section...<br>"Using Distribution Objects" on page 5-85<br>"What are Objects?" on page 5-86<br>"Creating Distribution Objects" on page 5-89<br>"Object-Supported Distributions" on page 5-90<br>"Performing Calculations Using Distribution Objects" on page 5-91<br>"Capturing Results Using Distribution Objects" on page 5-98

## Using Distribution Objects

For many distributions supported by Statistics Toolbox software, objects are available for statistical analysis. This section gives a general overview of the uses of distribution objects, including sample work flows. For information on objects available for specific distributions, see "Object-Supported Distributions" on page 5-90.

Probability distribution objects allow you to easily fit, access, and store distribution information for a given data set. The following operations are easier to perform using distribution objects:

- Grouping a single dataset in a number of different ways using group names, and then fit a distribution to each group. For an example of how to fit distributions to grouped data, see "Example: Fitting Distributions to Grouped Data Within a Single Dataset" on page 5-92.
- Fitting different distributions to the same set of data. For an example of how objects make fitting multiple distribution types easier, see "Example: Fitting Multiple Distribution Types to a Single Dataset" on page 5-96.
- Sharing fitted distributions across workspaces. For an example of sharing information using probability distribution objects, see "Example: Saving and Sharing Distribution Fit Data" on page 5-98.

## Deciding to Use Distribution Objects

If you know the type of distribution you would like to use, objects provide a less complex interface than functions and a more efficient functionality than the dfittool GUI.

If you are a novice statistician who would like to explore how various distributions look without having to manipulate data, see "Working with Distributions Through GUIs" on page 5-10.

If you have no data to fit, but want to calculate a pdf, cdf, etc for various parameters, see "Statistics Toolbox Distribution Functions" on page 5-53.

## What are Objects?

Objects are, in short, a convenient way of storing data. They allow you to set rules for the types of data to store, while maintaining some flexibility for the actual values of the data. For example, in statistics groups of distributions have some general things in common:

- All distributions have a name (ex, Normal).
- Parametric distributions have parameters.
- Nonparametric distributions have kernel-smoothing functions.

Objects store all this information within properties. Classes of related objects (for example, all univariate parametric distributions) have the same properties with values and types relevant to a specified distribution. In addition to storing information within objects, you can perform certain actions (called methods) on objects.

Subclasses (for example, ProbDistParametric is a subclass of ProbDist) contain the same properties and methods as the original class, in addition to other properties relevant to that subclass. This concept is called inheritance. Inheritance means that subclasses of a class have all of its properties and methods. For example, parametric distributions, which are a subset (subclass) of probability distributions, have input data and a distribution name. The following diagram illustrates this point:

The left side of this diagram shows the inheritance line from all probability distributions down to univariate parametric probability distributions. The right side shows the lineage down to univariate kernel distributions. Here is how to interpret univariate parametric distribution lineage:

- ProbDist is a class of objects that includes all probability distributions. All probability distribution objects have at least these properties:
- DistName - the name of the distribution (for example Normal or Weibull)
- InputData - the data fit to the distribution

In addition, you can perform the following actions on these objects, using the following methods:

- cdf - Return the cumulative distribution function for a specified distribution.
- pdf - Return the probability density function for a specified distribution.
- random - Generate random numbers based on a specified distribution.
- ProbDistParametric is a class of objects that includes all parametric probability distributions. All parametric probability distribution objects have the properties and methods of a ProbDist object, in addition to at least the following properties:
- NLogL - Negative log likelihood for input data
- NumParams - Number of parameters for that distribution
- ParamCov - Covariance matrix of parameter estimates
- ParamDescription - Descriptions of parameters
- ParamNames - Names of parameters
- Params - Values of parameters

No additional unique methods apply to ProbDistParametric objects.

- ProbDistUnivParam is a class of objects that includes only univariate parametric probability distributions. In addition to the properties and methods of ProbDist and ProbDistParametric objects, these objects also have at least the following methods:
- icdf - Return the inverse cumulative distribution function for a specified distribution based on a given set of data.
- iqr - Return the interquartile range for a specified distribution based on a given set of data.
- mean - Return the mean for a specified distribution based on a given set of data.
- median - Return the median for a specified distribution based on a given set of data.
- paramci - Return the parameter confidence intervals for a specified distribution based on a given set of data.
- std - Return the standard deviation for a specified distribution based on a given set of data.
- var - Return the variance for a specified distribution based on a given set of data.
No additional unique properties apply to ProbDistUnivParam objects.

The univariate nonparametric lineage reads in a similar manner, with different properties and methods. For more information on nonparametric objects and their methods and properties, see ProbDistKernel and ProbDistUnivKernel.

## Creating Distribution Objects

There are two ways to create distribution objects:

- Use the fitdist function. See "Creating Distribution Objects Using fitdist" on page 5-89.
- Use the object constructor. See "Creating Distribution Objects Using Constructors" on page 5-89.

## Creating Distribution Objects Using fitdist

Using the fitdist function is the simplest way of creating distribution objects. Like the *fit functions, fitdist fits your data to a specified distribution and returns relevant distribution information. fitdist creates an object relevant to the type of distribution you specify: if you specify a parametric distribution, it returns a ProbDistUnivParam object. For examples of how to use fitdist to fit your data, see "Performing Calculations Using Distribution Objects" on page 5-91.

## Creating Distribution Objects Using Constructors

If you know the distribution you would like to use and would like to create a univariate parametric distribution with known parameters, you can use the ProbDistUnivParam constructor. For example, create a normal distribution with mean 100 and standard deviation 10 :

```
pd = ProbDistUnivParam('normal',[100 10])
```

For nonparametric distributions, you must have a dataset. Using fitdist is a simpler way to fit nonparametric data, but you can use the ProbDistUnivKernel constructor as well. For example, create a nonparametric distribution of the MPG data from carsmall.mat:
load carsmall
pd = ProbDistUnivKernel(MPG)

## Object-Supported Distributions

Object-oriented programming in the Statistics Toolbox supports the following distributions.

## Parametric Distributions

Use the following distribution to create ProbDistUnivParam objects using fitdist. For more information on the cumulative distribution function (cdf) and probability density function (pdf) methods, as well as other available methods, see the ProbDistUnivParam class reference page.

| Supported Distribution | Input to fitdist |
| :--- | :--- |
| "Beta Distribution" on page B-4 | 'beta' |
| "Binomial Distribution" on page B-7 | 'binomial' |
| "Birnbaum-Saunders Distribution" <br> on page B-10 | 'birnbaumsaunders ' |
| "Burr Type XII Distribution" on page <br> B-12 | 'burr' |
| "Exponential Distribution" on page <br> B-29 | 'exponential' |
| "Extreme Value Distribution" on <br> page B-32 | 'extreme value ' or 'ev' |
| "Gamma Distribution" on page B-40 | 'gamma' |
| "Generalized Extreme Value <br> Distribution" on page B-45 | 'generalized extreme value' or |
| 'gev' |  |
| "Generalized Pareto Distribution" on <br> page B-50 | 'generalized pareto' or 'gp' |
| "Inverse Gaussian Distribution" on <br> page B-58 | 'inversegaussian' |
| "Logistic Distribution" on page B-62 | 'logistic' |
| "Loglogistic Distribution" on page <br> B-63 | 'loglogistic' |

| Supported Distribution | Input to fitdist |
| :--- | :--- |
| "Lognormal Distribution" on page <br> B-64 | 'lognormal' |
| "Nakagami Distribution" on page <br> B-83 | 'nakagami' |
| "Negative Binomial Distribution" on <br> page B-85 | 'negative binomial' or 'nbin' |
| "Normal Distribution" on page B-96 | 'normal' |
| "Poisson Distribution" on page B-102 | 'poisson' |
| "Rayleigh Distribution" on page <br> B-104 | 'rayleigh' |
| "Rician Distribution" on page B-106 | 'rician' |
| "t Location-Scale Distribution" on <br> page B-110 | 'tlocationscale ' |
| "Weibull Distribution" on page B-116 | 'weibull' or 'wbl' |

## Nonparametric Distributions

Use the following distributions to create ProbDistUnivKernel objects. For more information on the cumulative distribution function (cdf) and probability density function (pdf) methods, as well as other available methods, see the ProbDistUnivKernel class reference page.

| Supported Distribution | Input to fitdist |
| :--- | :--- |
| "Nonparametric Distributions" on <br> page B-95 | 'kernel' |

## Performing Calculations Using Distribution Objects

Distribution objects make it easier for you to perform calculations on complex datasets. The following sample workflows show some of the functionality of these objects.

- "Example: Fitting a Single Distribution to a Single Dataset" on page 5-92
- "Example: Fitting Distributions to Grouped Data Within a Single Dataset" on page 5-92
- "Example: Fitting Multiple Distribution Types to a Single Dataset" on page 5-96

## Example: Fitting a Single Distribution to a Single Dataset

Fit a single Normal distribution to a dataset using fitdist:
load carsmall
NormDist = fitdist(MPG, 'normal')
NormDist =
normal distribution

```
    mu = 23.7181
    sigma = 8.03573
```

The output MATLAB returns is a ProbDistUnivParam object with a DistName property of 'normal distribution'. The ParamNames property contains the strings mu and sigma, while the Params property contains the parameter values.

## Example: Fitting Distributions to Grouped Data Within a Single Dataset

Often, datasets are collections of data you can group in different ways. Using fitdist and the data from carsmall.mat, group the MPG data by country of origin, then fit a Weibull distribution each group:

```
load carsmall
[WeiByOrig, Country] = fitdist(MPG,'weibull','by',Origin)
Warning: Error while fitting group 'Italy':
Not enough data in X to fit this distribution.
> In fitdist at 171
WeiByOrig =
```

```
Columns 1 through 4
    [1x1 ProbDistUnivParam] [1x1 ProbDistUnivParam] ...
    [1x1 ProbDistUnivParam] [1x1 ProbDistUnivParam]
Columns 5 through 6
    [1x1 ProbDistUnivParam] []
Country =
    'USA'
    'France'
    'Japan'
    'Germany'
    'Sweden'
    'Italy'
```

A warning appears informing you that, since the data only represents one Italian car, fitdist cannot fit a Weibull distribution to that group. Each one of the five other groups now has a distribution object associated with it, represented in the cell array wd. Each object contains properties that hold information about the data, the distribution, and the parameters. For more information on what properties exist and what information they contain, see ProbDistUnivParam or ProbDistUnivKernel.

Now access two of the objects and their properties:

```
% Get USA fit
distusa = WeiByOrig{1};
% Use the InputData property of ProbDistUnivParam objects to see
% the actual data used to fit the distribution:
dusa = distusa.InputData.data;
% Get Japan fit and data
distjapan = WeiByOrig{3};
djapan = distjapan.InputData.data;
```

Now you can easily compare PDFs using the pdf method of the ProbDistUnivParam class:

```
time = linspace(0,45);
pdfjapan = pdf(distjapan,time);
pdfusa = pdf(distusa,time);
hold on
plot(time,[pdfjapan;pdfusa])
l = legend('Japan','USA')
set(l,'Location','Best')
xlabel('MPG')
ylabel('Probability Density')
```

You could then further group the data and compare, for example, MPG by year for American cars:

```
load carsmall
[WeiByYearOrig, Names] = fitdist(MPG,'weibull','by',...
    {Origin Model_Year});
USA7O = WeiByYearOrig{1};
USA76 = WeiByYearOrig{2};
USA82 = WeiByYearOrig{3};
time = linspace(0,45);
pdf70 = pdf(USA70,time);
pdf76 = pdf(USA76,time);
pdf82 = pdf(USA82,time);
line(t,[pdf70;pdf76;pdf82])
l = legend('1970','1976','1982')
set(l,'Location','Best')
title('USA Car MPG by Year')
xlabel('MPG')
ylabel('Probability Density')
```

## Example: Fitting Multiple Distribution Types to a Single Dataset

Distribution objects make it easy to fit multiple distributions to the same dataset, while minimizing workspace clutter. For example, use fitdist to group the MPG data by country of origin, then fit Weibull, Normal, Logistic, and nonparametric distributions for each group:
load carsmall;
[WeiByOrig, Country] = fitdist(MPG,'weibull','by',Origin);
[NormByOrig, Country] = fitdist(MPG,'normal','by',Origin);
[LogByOrig, Country] = fitdist(MPG,'logistic','by',Origin);
[KerByOrig, Country] = fitdist(MPG,'kernel','by',Origin);

Extract the fits for American cars and compare the fits visually against a histogram of the original data:

```
WeiUSA = WeiByOrig{1};
NormUSA = NormByOrig{1};
LogUSA = LogByOrig{1};
KerUSA = KerByOrig{1};
% Since all three distributions use the same set of data,
% you can extract the data from any of them:
data = WeiUSA.InputData.data;
% Create a histogram of the data:
[n,y] = hist(data,10);
b = bar(y,n,'hist');
set(b,'FaceColor',[1,0.8,0])
% Scale the density by the histogram area, for easier display:
area = sum(n) * (y(2)-y(1));
time = linspace(0,45);
pdfWei = pdf(WeiUSA,time);
pdfNorm = pdf(NormUSA,time);
pdfLog = pdf(LogUSA,time);
pdfKer = pdf(KerUSA,time);
allpdf = [pdfWei;pdfNorm;pdfLog;pdfKer];
line(t,area * allpdf)
l = legend('Data','Weibull','Normal','Logistic','Kernel')
set(l,'Location','Best')
title('USA Car')
xlabel('MPG')
```

You can see that only the nonparametric kernel distribution, KerUSA, comes close to revealing the two modes in the data.

## Capturing Results Using Distribution Objects

Distribution objects allow you to share both your dataset and your analysis results simply by saving the information to a .mat file.

## Example: Saving and Sharing Distribution Fit Data

Using the premise from the previous set of examples, group the MPG data in carsmall.mat by country of origin and fit four different distributions to each of the six sets of data:

```
load carsmall;
[WeiByOrig, Country] = fitdist(MPG,'weibull','by',Origin);
[NormByOrig, Country] = fitdist(MPG,'normal','by',Origin);
[LogByOrig, Country] = fitdist(MPG,'logistic','by',Origin);
[KerByOrig, Country] = fitdist(MPG,'kernel','by',Origin);
```

Combine all four fits and the country labels into a single cell array, including "headers" to indicate which distributions correspond to which objects. Then, save the array to a .mat file:

```
AllFits = cell(['Country' Country'; 'Weibull' WeiByOrig;...
    'Normal' NormByOrig; 'Logistic' LogByOrig; 'Kernel',...
    KerByOrig]);
save('CarSmallFits.mat','AllFits');
```

To show that the data is both safely saved and easily restored, clear your workspace of relevant variables. This command clears only those variables associated with this example:

```
clear('Weight','Acceleration','AllFits','Country',...
'Cylinders','Displacement','Horsepower','KerByOrig',...
'LogByOrig','MPG','Model','Model_Year','NormByOrig',....
'Origin','WeiByOrig')
```

Now, load the data:
load CarSmallFits
AllFits

You can now access the distributions objects as in the previous examples.

# Probability Distributions Used for Multivariate Modeling 

In this section...<br>"Gaussian Mixture Models" on page 5-100<br>"Copulas: Generate Correlated Samples" on page 5-108

## Gaussian Mixture Models

- "Creating Gaussian Mixture Models" on page 5-100
- "Simulating Gaussian Mixtures" on page 5-106

Gaussian mixture models are formed by combining multivariate normal density components. For information on individual multivariate normal densities, see "Multivariate Normal Distribution" on page B-71 and related distribution functions listed under "Multivariate Distributions" on page 5-9.

In Statistics Toolbox software, use the gmdistribution class to fit data using an expectation maximization (EM) algorithm, which assigns posterior probabilities to each component density with respect to each observation. The fitting method uses an iterative algorithm that converges to a local optimum. Clustering using Gaussian mixture models is sometimes considered a soft clustering method. The posterior probabilities for each point indicate that each data point has some probability of belonging to each cluster.

For more information on clustering with Gaussian mixture models, see "Gaussian Mixture Models" on page 13-28. This section describes their creation.

## Creating Gaussian Mixture Models

- "Specifying a Model" on page 5-101
- "Fitting a Model to Data" on page 5-103

Specifying a Model. Use the gmdistribution constructor to create Gaussian mixture models with specified means, covariances, and mixture proportions. The following creates an object of the gmdistribution class defining a two-component mixture of bivariate Gaussian distributions:

```
MU = [1 2;-3 -5]; % Means
SIGMA = cat(3,[2 0;0 .5],[1 0;0 1]); % Covariances
p = ones(1,2)/2; % Mixing proportions
obj = gmdistribution(MU,SIGMA,p);
```

Display properties of the object with the MATLAB function fieldnames:

```
properties = fieldnames(obj)
properties =
    'NDimensions'
    'DistName'
    'NComponents'
    'PComponents'
    'mu'
    'Sigma'
    'NlogL'
    'AIC'
    'BIC'
    'Converged'
    'Iters'
    'SharedCov'
    'CovType'
    'RegV'
```

The gmdistribution reference page describes these properties. To access the value of a property, use dot indexing:

```
dimension = obj.NDimensions
dimension =
    2
name = obj.DistName
name =
gaussian mixture distribution
```

Use the methods pdf and cdf to compute values and visualize the object:
ezsurf(@(x,y)pdf(obj,[x y]),[-10 10],[-10 10])

```
ezsurf(@(x,y)cdf(obj,[x y]),[-10 10],[-10 10])
```

Fitting a Model to Data. You can also create Gaussian mixture models by fitting a parametric model with a specified number of components to data. The fit method of the gmdistribution class uses the syntax obj $=$ gmdistribution.fit ( $\mathrm{X}, \mathrm{k}$ ), where X is a data matrix and k is the specified number of components. Choosing a suitable number of components $k$ is essential for creating a useful model of the data-too few components fails to model the data accurately; too many components leads to an over-fit model with singular covariance matrices.

The following example illustrates this approach.
First, create some data from a mixture of two bivariate Gaussian distributions using the mvnrnd function:

```
MU1 = [1 2];
SIGMA1 = [2 0; 0 .5];
```

```
MU2 = [-3 -5];
SIGMA2 = [1 0; 0 1];
X = [mvnrnd(MU1,SIGMA1,1000);
mvnrnd(MU2,SIGMA2,1000)];
scatter(X(:,1),X(:,2),10,'.')
```

Next, fit a two-component Gaussian mixture model:

```
options = statset('Display','final');
obj = gmdistribution.fit(X,2,'Options',options);
hold on
h = ezcontour(@(x,y)pdf(obj,[x y]),[-8 6],[-8 6]);
hold off
```

Among the properties of the fit are the parameter estimates:

```
ComponentMeans = obj.mu
ComponentMeans =
    0.9391 2.0322
    -2.9823 -4.9737
ComponentCovariances = obj.Sigma
ComponentCovariances(:,:,1) =
    1.7786 -0.0528
    -0.0528 0.5312
ComponentCovariances(:,:,2) =
    1.0491 -0.0150
```

```
    -0.0150 0.9816
MixtureProportions = obj.PComponents
MixtureProportions =
    0.5000 0.5000
```

The two-component model minimizes the Akaike information:

```
AIC = zeros(1,4);
obj = cell(1,4);
for k = 1:4
    obj{k} = gmdistribution.fit(X,k);
    AIC(k)= obj{k}.AIC;
end
[minAIC,numComponents] = min(AIC);
numComponents
numComponents =
    2
model = obj{2}
model =
Gaussian mixture distribution
with 2 components in 2 dimensions
Component 1:
Mixing proportion: 0.500000
Mean: 0.9391 2.0322
Component 2:
Mixing proportion: 0.500000
Mean: -2.9823 -4.9737
```

Both the Akaike and Bayes information are negative log-likelihoods for the data with penalty terms for the number of estimated parameters. You can use them to determine an appropriate number of components for a model when the number of components is unspecified.

## Simulating Gaussian Mixtures

Use the method random of the gmdistribution class to generate random data from a Gaussian mixture model created with gmdistribution or fit.

For example, the following specifies a gmdistribution object consisting of a two-component mixture of bivariate Gaussian distributions:

```
MU = [1 2;-3 -5];
SIGMA = cat(3,[2 0;0 .5],[1 0;0 1]);
p = ones(1,2)/2;
obj = gmdistribution(MU,SIGMA,p);
ezcontour(@(x,y)pdf(obj,[x y]),[-10 10],[-10 10])
hold on
```

Use random (gmdistribution) to generate 1000 random values:

```
Y = random(obj,1000);
scatter(Y(:,1),Y(:,2),10,'.')
```

## Copulas: Generate Correlated Samples

- "Determining Dependence Between Simulation Inputs" on page 5-109
- "Constructing Dependent Bivariate Distributions" on page 5-113
- "Using Rank Correlation Coefficients" on page 5-117
- "Using Bivariate Copulas" on page 5-120
- "Higher Dimension Copulas" on page 5-127
- "Archimedean Copulas" on page 5-129
- "Simulating Dependent Multivariate Data Using Copulas" on page 5-131
- "Example: Fitting Copulas to Data" on page 5-136

Copulas are functions that describe dependencies among variables, and provide a way to create distributions that model correlated multivariate data. Using a copula, you can construct a multivariate distribution by specifying marginal univariate distributions, and then choose a copula to provide a correlation structure between variables. Bivariate distributions, as well as distributions in higher dimensions, are possible.

## Determining Dependence Between Simulation Inputs

One of the design decisions for a Monte Carlo simulation is a choice of probability distributions for the random inputs. Selecting a distribution for each individual variable is often straightforward, but deciding what dependencies should exist between the inputs may not be. Ideally, input data to a simulation should reflect what you know about dependence among the real quantities you are modeling. However, there may be little or no information on which to base any dependence in the simulation. In such cases, it is useful to experiment with different possibilities in order to determine the model's sensitivity.

It can be difficult to generate random inputs with dependence when they have distributions that are not from a standard multivariate distribution. Further, some of the standard multivariate distributions can model only limited types of dependence. It is always possible to make the inputs independent, and while that is a simple choice, it is not always sensible and can lead to the wrong conclusions.

For example, a Monte-Carlo simulation of financial risk could have two random inputs that represent different sources of insurance losses. You could model these inputs as lognormal random variables. A reasonable question to ask is how dependence between these two inputs affects the results of the simulation. Indeed, you might know from real data that the same random conditions affect both sources; ignoring that in the simulation could lead to the wrong conclusions.

## Example: Generate and Exponentiate Normal Random Variables.

The lognrnd function simulates independent lognormal random variables. In the following example, the mvnrnd function generates n pairs of independent normal random variables, and then exponentiates them. Notice that the covariance matrix used here is diagonal:

```
n = 1000;
sigma = .5;
SigmaInd = sigma.^2 .* [1 0; 0 1]
SigmaInd =
    0.25 0
    0 0.25
ZInd = mvnrnd([0 0],SigmaInd,n);
XInd = exp(ZInd);
plot(XInd(:, 1),XInd(:,2),'.')
axis([0
axis equal
xlabel('X1')
ylabel('X2')
```

Dependent bivariate lognormal random variables are also easy to generate using a covariance matrix with nonzero off-diagonal terms:

```
rho = .7;
```

SigmaDep = sigma.^2 .* [1 rho; rho 1]
SigmaDep =
0.25
0.175
0.175
0.25

```
ZDep = mvnrnd([0 0],SigmaDep,n);
```

XDep $=\exp (Z D e p) ;$

A second scatter plot demonstrates the difference between these two bivariate distributions:

```
plot(XDep(:,1),XDep(:,2),'.')
axis([0 5 0 5])
axis equal
xlabel('X1')
ylabel('X2')
```

It is clear that there is a tendency in the second data set for large values of X1 to be associated with large values of X2, and similarly for small values. The correlation parameter, $\rho$, of the underlying bivariate normal determines this dependence. The conclusions drawn from the simulation could well depend on whether you generate X1 and X2 with dependence. The bivariate lognormal distribution is a simple solution in this case; it easily generalizes to higher dimensions in cases where the marginal distributions are different lognormals.

Other multivariate distributions also exist. For example, the multivariate $t$ and the Dirichlet distributions simulate dependent $t$ and beta random variables, respectively. But the list of simple multivariate distributions is not long, and they only apply in cases where the marginals are all in the same family (or even the exact same distributions). This can be a serious limitation in many situations.

## Constructing Dependent Bivariate Distributions

Although the construction discussed in the previous section creates a bivariate lognormal that is simple, it serves to illustrate a method that is more generally applicable.

1 Generate pairs of values from a bivariate normal distribution. There is statistical dependence between these two variables, and each has a normal marginal distribution.

2 Apply a transformation (the exponential function) separately to each variable, changing the marginal distributions into lognormals. The transformed variables still have a statistical dependence.

If a suitable transformation can be found, this method can be generalized to create dependent bivariate random vectors with other marginal distributions. In fact, a general method of constructing such a transformation does exist, although it is not as simple as exponentiation alone.

By definition, applying the normal cumulative distribution function (cdf), denoted here by $\Phi$, to a standard normal random variable results in a random variable that is uniform on the interval $[0,1]$. To see this, if $Z$ has a standard normal distribution, then the cdf of $U=\Phi(Z)$ is

$$
\operatorname{Pr}\{U \leq u\}=\operatorname{Pr}\{\Phi(Z) \leq u\}=\operatorname{Pr}\left(Z \leq \Phi^{-1}(u)\right\}=u
$$

and that is the cdf of a $\operatorname{Unif}(0,1)$ random variable. Histograms of some simulated normal and transformed values demonstrate that fact:

```
n = 1000;
z = normrnd(0,1,n,1);
hist(z, -3.75:.5:3.75)
xlim([-4 4])
title('1000 Simulated N(0,1) Random Values')
xlabel('Z')
ylabel('Frequency')
set(get(gca,'Children'),'FaceColor',[.8 . 8 1])
```

Borrowing from the theory of univariate random number generation, applying the inverse cdf of any distribution, $F$, to a $\operatorname{Unif}(0,1)$ random variable results in a random variable whose distribution is exactly $F$ (see "Inversion Methods" on page 6-7). The proof is essentially the opposite of the preceding proof for the forward case. Another histogram illustrates the transformation to a gamma distribution:

```
x = gaminv(u,2,1);
hist(x,.25:.5:9.75)
title('1000 Simulated N(0,1) Values Transformed to Gamma(2,1)')
xlabel('X')
ylabel('Frequency')
set(get(gca,'Children'),'FaceColor',[.8 . 8 1])
```

You can apply this two-step transformation to each variable of a standard bivariate normal, creating dependent random variables with arbitrary marginal distributions. Because the transformation works on each component separately, the two resulting random variables need not even have the same marginal distributions. The transformation is defined as:

$$
\begin{aligned}
& Z=\left[Z_{1}, Z_{2}\right] \square N\left([0,0],\left[\begin{array}{ll}
1 & \rho \\
\rho & 1
\end{array}\right]\right) \\
& U=\left[\Phi\left(Z_{1}\right), \Phi\left(Z_{2}\right)\right] \\
& X=\left[G_{1}\left(U_{1}\right), G_{2}\left(U_{2}\right)\right]
\end{aligned}
$$

where $G_{1}$ and $G_{2}$ are inverse cdfs of two possibly different distributions. For example, the following generates random vectors from a bivariate distribution with $t_{5}$ and $\operatorname{Gamma}(2,1)$ marginals:
$\mathrm{n}=1000$; rho = .7;
Z = mvnrnd([0 0],[1 rho; rho 1],n);
U = normcdf(Z);
$X=[g a m i n v(U(:, 1), 2,1) \operatorname{tinv(U(:,2),5)];~}$
scatterhist(X(:,1),X(:,2),'Direction','out')

This plot has histograms alongside a scatter plot to show both the marginal distributions, and the dependence.

## Using Rank Correlation Coefficients

The correlation parameter, $\rho$, of the underlying bivariate normal determines the dependence between X1 and X2 in this construction. However, the linear correlation of X1 and X2 is not $\rho$. For example, in the original lognormal case, a closed form for that correlation is:

$$
\operatorname{cor}(X 1, X 2)=\frac{e^{\rho \sigma^{2}}-1}{e^{\sigma^{2}}-1}
$$

which is strictly less than $\rho$, unless $\rho$ is exactly 1 . In more general cases such as the Gamma/t construction, the linear correlation between X1 and X2 is difficult or impossible to express in terms of $\rho$, but simulations show that the same effect happens.

That is because the linear correlation coefficient expresses the linear dependence between random variables, and when nonlinear transformations are applied to those random variables, linear correlation is not preserved. Instead, a rank correlation coefficient, such as Kendall's $\tau$ or Spearman's $\rho$, is more appropriate.

Roughly speaking, these rank correlations measure the degree to which large or small values of one random variable associate with large or small values of another. However, unlike the linear correlation coefficient, they measure the association only in terms of ranks. As a consequence, the rank correlation is preserved under any monotonic transformation. In particular, the transformation method just described preserves the rank correlation. Therefore, knowing the rank correlation of the bivariate normal $Z$ exactly determines the rank correlation of the final transformed random variables, $X$. While the linear correlation coefficient, $\rho$, is still needed to parameterize the underlying bivariate normal, Kendall's $\tau$ or Spearman's $\rho$ are more useful in describing the dependence between random variables, because they are invariant to the choice of marginal distribution.

For the bivariate normal, there is a simple one-to-one mapping between Kendall's $\tau$ or Spearman's $\rho$, and the linear correlation coefficient $\rho$ :

$$
\begin{aligned}
& \tau=\frac{2}{\pi} \arcsin (\rho) \quad \text { or } \quad \rho=\sin \left(\tau \frac{\pi}{2}\right) \\
& \rho_{\mathrm{s}}=\frac{6}{\pi} \arcsin \left(\frac{\rho}{2}\right) \text { or } \quad \rho=2 \sin \left(\rho_{\mathrm{s}} \frac{\pi}{6}\right)
\end{aligned}
$$

The following plot shows the relationship:

```
rho = -1:.01:1;
```

```
tau = 2.*asin(rho)./pi;
rho_s = 6.*asin(rho./2)./pi;
plot(rho,tau,'b-','LineWidth',2)
hold on
plot(rho,rho_s,'g-','LineWidth', 2)
plot([-1 1],[-1 1],'k:','LineWidth',2)
axis([[-1 1 -1 1])
xlabel('rho')
ylabel('Rank correlation coefficient')
legend('Kendall''s {\it\tau}', ...
    'Spearman''s {\it\rho_s}', ...
    'location','NW')
```

Thus, it is easy to create the desired rank correlation between X1 and X2, regardless of their marginal distributions, by choosing the correct $\rho$ parameter value for the linear correlation between Z1 and Z2.

For the multivariate normal distribution, Spearman's rank correlation is almost identical to the linear correlation. However, this is not true once you transform to the final random variables.

## Using Bivariate Copulas

The first step of the construction described in the previous section defines what is known as a bivariate Gaussian copula. A copula is a multivariate probability distribution, where each random variable has a uniform marginal distribution on the unit interval $[0,1]$. These variables may be completely independent, deterministically related (e.g., U2 = U1), or anything in between. Because of the possibility for dependence among variables, you can use a copula to construct a new multivariate distribution for dependent variables. By transforming each of the variables in the copula separately using the inversion method, possibly using different cdfs, the resulting distribution can have arbitrary marginal distributions. Such multivariate distributions are often useful in simulations, when you know that the different random inputs are not independent of each other.

Statistics Toolbox functions compute:

- Probability density functions (copulapdf) and the cumulative distribution functions (copulacdf) for Gaussian copulas
- Rank correlations from linear correlations (copulastat) and vice versa (copulaparam)
- Random vectors (copularnd)
- Parameters for copulas fit to data (copulafit)

For example, use the copularnd function to create scatter plots of random values from a bivariate Gaussian copula for various levels of $\rho$, to illustrate the range of different dependence structures. The family of bivariate Gaussian copulas is parameterized by the linear correlation matrix:

$$
\mathrm{P}=\left(\begin{array}{ll}
1 & \rho \\
\rho & 1
\end{array}\right)
$$

U1 and U2 approach linear dependence as $\rho$ approaches $\pm 1$, and approach complete independence as $\rho$ approaches zero:

```
n = 500;
U = copularnd('Gaussian',[1 .8; . 8 1],n);
subplot(2,2,1)
plot(U(:,1),U(:,2),'.')
title('{\it\rho} = 0.8')
xlabel('U1')
ylabel('U2')
U = copularnd('Gaussian',[1 .1; .1 1],n);
subplot(2,2,2)
plot(U(:,1),U(:,2),'.')
title('{\it\rho} = 0.1')
xlabel('U1')
ylabel('U2')
U = copularnd('Gaussian',[1 -.1; -.1 1],n);
subplot(2,2,3)
plot(U(:,1),U(:,2),'.')
title('{\it\rho} = -0.1')
xlabel('U1')
ylabel('U2')
U = copularnd('Gaussian',[1 -.8; -.8 1],n);
subplot(2,2,4)
plot(U(:,1),U(:,2),'.')
title('{\it\rho} = -0.8')
xlabel('U1')
ylabel('U2')
```

The dependence between U 1 and U 2 is completely separate from the marginal distributions of $X 1=G(U 1)$ and $X 2=G(U 2) . X 1$ and $X 2$ can be given any marginal distributions, and still have the same rank correlation. This is one of the main appeals of copulas-they allow this separate specification of dependence and marginal distribution. You can also compute the pdf (copulapdf) and the cdf (copulacdf) for a copula. For example, these plots show the pdf and cdf for $\rho=.8$ :

```
u1 = linspace(1e-3,1-1e-3,50);
u2 = linspace(1e-3,1-1e-3,50);
[U1,U2] = meshgrid(u1,u2);
Rho = [1 .8; . 8 1];
f = copulapdf('t',[U1(:) U2(:)],Rho,5);
f = reshape(f,size(U1));
surf(u1,u2,log(f),'FaceColor','interp','EdgeColor','none')
```

```
view([-15,20])
xlabel('U1')
ylabel('U2')
zlabel('Probability Density')
```

```
u1 = linspace(1e-3,1-1e-3,50);
```

u1 = linspace(1e-3,1-1e-3,50);
u2 = linspace(1e-3,1-1e-3,50);
u2 = linspace(1e-3,1-1e-3,50);
[U1,U2] = meshgrid(u1,u2);
[U1,U2] = meshgrid(u1,u2);
F = copulacdf('t',[U1(:) U2(:)],Rho,5);
F = copulacdf('t',[U1(:) U2(:)],Rho,5);
F = reshape(F,size(U1));
F = reshape(F,size(U1));
surf(u1,u2,F,'FaceColor','interp','EdgeColor','none')
surf(u1,u2,F,'FaceColor','interp','EdgeColor','none')
view([-15,20])
view([-15,20])
xlabel('U1')
xlabel('U1')
ylabel('U2')
ylabel('U2')
zlabel('Cumulative Probability')

```
zlabel('Cumulative Probability')
```

A different family of copulas can be constructed by starting from a bivariate $t$ distribution and transforming using the corresponding $t$ cdf. The bivariate $t$ distribution is parameterized with $P$, the linear correlation matrix, and $v$, the degrees of freedom. Thus, for example, you can speak of a $t_{1}$ or a $t_{5}$ copula, based on the multivariate $t$ with one and five degrees of freedom, respectively.

Just as for Gaussian copulas, Statistics Toolbox functions for $t$ copulas compute:

- Probability density functions (copulapdf) and the cumulative distribution functions (copulacdf) for Gaussian copulas
- Rank correlations from linear correlations (copulastat) and vice versa (copulaparam)
- Random vectors (copularnd)
- Parameters for copulas fit to data (copulafit)

For example, use the copularnd function to create scatter plots of random values from a bivariate $t_{1}$ copula for various levels of $\rho$, to illustrate the range of different dependence structures:
n = 500;
nu = 1;
U = copularnd('t',[1 .8; . 8 1],nu,n);
subplot (2,2,1)
plot(U(:,1),U(:,2),'.')
title('\{\it\rho\} = 0.8')
xlabel('U1')
ylabel('U2')
U = copularnd('t',[1 .1; .1 1],nu,n); subplot (2,2,2)
plot(U(:,1),U(:,2),'.')
title('\{\it\rho\} = 0.1')
xlabel('U1')
ylabel('U2')
U = copularnd('t',[1-.1; -.1 1],nu,n);
subplot (2,2,3)
plot(U(:,1),U(:,2),'.')
title('\{\it\rho\} = -0.1')
xlabel('U1')
ylabel('U2')
U = copularnd('t',[1-.8; -. 8 1],nu, n);
subplot (2,2,4)
plot(U(:,1),U(:,2),'.')
title('\{\it\rho\} = -0.8')
xlabel('U1')
ylabel('U2')

A $t$ copula has uniform marginal distributions for U1 and U2, just as a Gaussian copula does. The rank correlation $\tau$ or $\rho_{s}$ between components in a $t$ copula is also the same function of $\rho$ as for a Gaussian. However, as these plots demonstrate, a $t_{1}$ copula differs quite a bit from a Gaussian copula, even when their components have the same rank correlation. The difference is in their dependence structure. Not surprisingly, as the degrees of freedom parameter $v$ is made larger, a $t_{v}$ copula approaches the corresponding Gaussian copula.

As with a Gaussian copula, any marginal distributions can be imposed over a $t$ copula. For example, using a $t$ copula with 1 degree of freedom, you can again generate random vectors from a bivariate distribution with $\operatorname{Gamma}(2,1)$ and $t_{5}$ marginals using copularnd:

```
n = 1000;
rho = .7;
nu = 1;
```

```
U = copularnd('t',[1 rho; rho 1],nu,n);
X = [gaminv(U(:,1),2,1) tinv(U(:,2),5)];
scatterhist(X(:,1),X(:,2),'Direction','out')
```

Compared to the bivariate Gamma/t distribution constructed earlier, which was based on a Gaussian copula, the distribution constructed here, based on a $t_{1}$ copula, has the same marginal distributions and the same rank correlation between variables but a very different dependence structure. This illustrates the fact that multivariate distributions are not uniquely defined by their marginal distributions, or by their correlations. The choice of a particular copula in an application may be based on actual observed data, or different copulas may be used as a way of determining the sensitivity of simulation results to the input distribution.

## Higher Dimension Copulas

The Gaussian and $t$ copulas are known as elliptical copulas. It is easy to generalize elliptical copulas to a higher number of dimensions. For example, simulate data from a trivariate distribution with $\operatorname{Gamma}(2,1)$, $\operatorname{Beta}(2,2)$, and $t_{5}$ marginals using a Gaussian copula and copularnd, as follows:

```
n = 1000;
Rho = [1 .4 .2; . 4 1 -. 8; .2 -. 8 1];
U = copularnd('Gaussian',Rho,n);
X = [gaminv(U(:,1),2,1) betainv(U(:,2),2,2) tinv(U(:, 3),5)];
subplot(1,1,1)
plot3(X(:, 1),X(:,2),X(:,3),'.')
grid on
view([-55, 15])
xlabel('X1')
ylabel('X2')
zlabel('X3')
```

Notice that the relationship between the linear correlation parameter $\rho$ and, for example, Kendall's $\tau$, holds for each entry in the correlation matrix $P$ used here. You can verify that the sample rank correlations of the data are approximately equal to the theoretical values:

```
tauTheoretical = 2.*asin(Rho)./pi
tauTheoretical =
```

```
\begin{tabular}{rrr}
1 & 0.26198 & 0.12819 \\
0.26198 & 1 & -0.59033 \\
0.12819 & -0.59033 & 1
\end{tabular}
tauSample = corr(X,'type','Kendall')
tauSample =
\begin{tabular}{rrr}
1 & 0.27254 & 0.12701 \\
0.27254 & 1 & -0.58182 \\
0.12701 & -0.58182 & 1
\end{tabular}
```

## Archimedean Copulas

Statistics Toolbox functions are available for three bivariate Archimedean copula families:

- Clayton copulas
- Frank copulas
- Gumbel copulas

These are one-parameter families that are defined directly in terms of their cdfs, rather than being defined constructively using a standard multivariate distribution.

To compare these three Archimedean copulas to the Gaussian and $t$ bivariate copulas, first use the copulastat function to find the rank correlation for a Gaussian or $t$ copula with linear correlation parameter of 0.8 , and then use the copulaparam function to find the Clayton copula parameter that corresponds to that rank correlation:

```
tau = copulastat('Gaussian',.8 ,'type','kendall')
tau =
    0.59033
alpha = copulaparam('Clayton',tau,'type','kendall')
alpha =
    2.882
```

Finally, plot a random sample from the Clayton copula with copularnd. Repeat the same procedure for the Frank and Gumbel copulas:

```
n = 500;
U = copularnd('Clayton',alpha,n);
subplot(3,1,1)
plot(U(:,1),U(:,2),'.');
title(['Clayton Copula, {\it\alpha} = ',sprintf('%0.2f',alpha)])
xlabel('U1')
ylabel('U2')
alpha = copulaparam('Frank',tau,'type','kendall');
U = copularnd('Frank',alpha,n);
subplot(3,1,2)
plot(U(:,1),U(:,2),'.')
title(['Frank Copula, {\it\alpha} = ',sprintf('%0.2f',alpha)])
xlabel('U1')
ylabel('U2')
alpha = copulaparam('Gumbel',tau,'type','kendall');
U = copularnd('Gumbel',alpha,n);
subplot(3,1,3)
plot(U(:,1),U(:,2),'.')
title(['Gumbel Copula, {\it\alpha} = ',sprintf('%0.2f',alpha)])
xlabel('U1')
ylabel('U2')
```

## Simulating Dependent Multivariate Data Using Copulas

To simulate dependent multivariate data using a copula, you must specify each of the following:

- The copula family (and any shape parameters)
- The rank correlations among variables
- Marginal distributions for each variable

Suppose you have return data for two stocks and want to run a Monte Carlo simulation with inputs that follow the same distributions as the data:

```
load stockreturns
nobs = size(stocks,1);
subplot(2,1,1)
hist(stocks(:,1),10)
xlim([-3.5 3.5])
xlabel('X1')
ylabel('Frequency')
set(get(gca,'Children'),'FaceColor',[.8 . 8 1])
subplot(2,1,2)
hist(stocks(:,2),10)
xlim([-3.5 3.5])
xlabel('X2')
ylabel('Frequency')
set(get(gca,'Children'),'FaceColor',[.8 . 8 1])
```

You could fit a parametric model separately to each dataset, and use those estimates as the marginal distributions. However, a parametric model may not be sufficiently flexible. Instead, you can use a nonparametric model to transform to the marginal distributions. All that is needed is a way to compute the inverse cdf for the nonparametric model.

The simplest nonparametric model is the empirical cdf, as computed by the ecdf function. For a discrete marginal distribution, this is appropriate. However, for a continuous distribution, use a model that is smoother than the step function computed by ecdf. One way to do that is to estimate the empirical cdf and interpolate between the midpoints of the steps with a piecewise linear function. Another way is to use kernel smoothing with ksdensity. For example, compare the empirical cdf to a kernel smoothed cdf estimate for the first variable:

```
[Fi,xi] = ecdf(stocks(:,1));
stairs(xi,Fi,'b','LineWidth',2)
hold on
Fi_sm = ksdensity(stocks(:,1),xi,'function','cdf','width',.15);
plot(xi,Fi_sm,'r-','LineWidth',1.5)
xlabel('X1')
ylabel('Cumulative Probability')
legend('Empirical','Smoothed','Location','NW')
grid on
```

For the simulation, experiment with different copulas and correlations. Here, you will use a bivariate $t$ copula with a fairly small degrees of freedom
parameter. For the correlation parameter, you can compute the rank correlation of the data, and then find the corresponding linear correlation parameter for the $t$ copula using copulaparam:

```
nu = 5;
tau = corr(stocks(:,1),stocks(:,2),'type','kendall')
tau =
    0.51798
rho = copulaparam('t', tau, nu, 'type','kendall')
rho =
    0.72679
```

Next, use copularnd to generate random values from the $t$ copula and transform using the nonparametric inverse cdfs. The ksdensity function allows you to make a kernel estimate of distribution and evaluate the inverse cdf at the copula points all in one step:

```
n = 1000;
U = copularnd('t',[1 rho; rho 1],nu,n);
X1 = ksdensity(stocks(:,1),U(:,1),...
    'function','icdf','width',.15);
X2 = ksdensity(stocks(:,2),U(:,2),\ldots.
    'function','icdf','width',.15);
```

Alternatively, when you have a large amount of data or need to simulate more than one set of values, it may be more efficient to compute the inverse cdf over a grid of values in the interval $(0,1)$ and use interpolation to evaluate it at the copula points:
$\mathrm{p}=$ linspace(0.00001,0.99999,1000);
G1 = ksdensity(stocks(:, 1), p,'function','icdf','width', 0.15);
$\mathrm{X} 1=$ interp1( $\mathrm{p}, \mathrm{G} 1, \mathrm{U}(:, 1)$, 'spline');
G2 = ksdensity(stocks(:,2), p,'function','icdf','width', 0.15);
X2 = interp1(p,G2,U(:,2),'spline');
scatterhist(X1,X2,'Direction','out')

The marginal histograms of the simulated data are a smoothed version of the histograms for the original data. The amount of smoothing is controlled by the bandwidth input to ksdensity.

## Example: Fitting Copulas to Data

The copulafit function is used to calibrate copulas with data. To generate data Xsim with a distribution "just like" (in terms of marginal distributions and correlations) the distribution of data in the matrix $X$ :

1 Fit marginal distributions to the columns of $X$.
2 Use appropriate cdf functions to transform $X$ to $U$, so that $U$ has values between 0 and 1 .

3 Use copulafit to fit a copula to $U$.
4 Generate new data Usim from the copula.

5 Use appropriate inverse cdf functions to transform Usim to Xsim.
The following example illustrates the procedure.
Load and plot simulated stock return data:
load stockreturns
x = stocks(:,1);
y = stocks(:,2);
scatterhist(x,y,'Direction','out')

Transform the data to the copula scale (unit square) using a kernel estimator of the cumulative distribution function:

```
u = ksdensity(x,x,'function','cdf');
v = ksdensity(y,y,'function','cdf');
```

```
scatterhist(u,v,'Direction','out')
xlabel('u')
ylabel('v')
```

Fit a $t$ copula:

```
[Rho,nu] = copulafit('t',[u v],'Method','ApproximateML')
Rho =
    1.0000 0.7220
    0.7220 1.0000
nu =
    3.2017e+006
```

Generate a random sample from the $t$ copula:

```
r = copularnd('t',Rho,nu,1000);
u1 = r(:,1);
v1 = r(:,2);
```

```
scatterhist(u1,v1,'Direction','out')
xlabel('u')
ylabel('v')
set(get(gca,'children'),'marker','.')
```

Transform the random sample back to the original scale of the data:

```
x1 = ksdensity(x,u1,'function','icdf');
y1 = ksdensity(y,v1,'function','icdf');
scatterhist(x1,y1,'Direction','out')
set(get(gca,'children'),'marker','.')
```

As the example illustrates, copulas integrate naturally with other distribution fitting functions.

## Generating Random Data

Pseudorandom numbers are generated by deterministic algorithms. They are "random" in the sense that, on average, they pass statistical tests regarding their distribution and correlation. They differ from true random numbers in that they are generated by an algorithm, rather than a truly random process.

Random number generators (RNGs) like those in MATLAB are algorithms for generating pseudorandom numbers with a specified distribution.

For more information on random number generators for supported distributions, see "Random Number Generators" on page 5-81.

For more information on the GUI for generating random numbers from supported distributions, see "Visually Exploring Random Number Generation" on page 5-50.

## Random Number Generation Functions

The following table lists the supported distributions and their respective random number generation functions. For more information on other functions for each distribution, see "Supported Distributions" on page 5-3. For more information on random number generators, see "Random Number Generators" on page 5-81.

| Distribution | Random Number Generation Function |

## Common Generation Methods

```
In this section...
"Direct Methods" on page 6-5
"Inversion Methods" on page 6-7
"Acceptance-Rejection Methods" on page 6-9
```

Methods for generating pseudorandom numbers usually start with uniform random numbers, like the MATLAB rand function produces. The methods described in this section detail how to produce random numbers from other distributions.

## Direct Methods

Direct methods directly use the definition of the distribution.
For example, consider binomial random numbers. A binomial random number is the number of heads in $N$ tosses of a coin with probability $p$ of a heads on any single toss. If you generate $N$ uniform random numbers on the interval $(0,1)$ and count the number less than $p$, then the count is a binomial random number with parameters $N$ and $p$.

This function is a simple implementation of a binomial RNG using the direct approach:

```
function X = directbinornd(N,p,m,n)
X = zeros(m,n); % Preallocate memory
for i = 1:m*n
    u = rand(N,1);
    X(i) = sum(u < p);
end
For example:
X = directbinornd(100,0.3,1e4,1);
hist(X,101)
set(get(gca,'Children'),'FaceColor',[.8 . 8 1])
```

The Statistics Toolbox function binornd uses a modified direct method, based on the definition of a binomial random variable as the sum of Bernoulli random variables.

You can easily convert the previous method to a random number generator for the Poisson distribution with parameter $\lambda$. The Poisson distribution is the limiting case of the binomial distribution as $N$ approaches infinity, $p$ approaches zero, and $N p$ is held fixed at $\lambda$. To generate Poisson random numbers, create a version of the previous generator that inputs $\lambda$ rather than $N$ and $p$, and internally sets $N$ to some large number and $p$ to $\lambda / N$.

The Statistics Toolbox function poissrnd actually uses two direct methods:

- A waiting time method for small values of $\lambda$
- A method due to Ahrens and Dieter for larger values of $\lambda$

## Inversion Methods

Inversion methods are based on the observation that continuous cumulative distribution functions (cdfs) range uniformly over the interval ( 0,1 ). If $u$ is a uniform random number on ( 0,1 ), then using $X=F^{-1}(U)$ generates a random number $X$ from a continuous distribution with specified cdf $F$.

For example, the following code generates random numbers from a specific exponential distribution using the inverse cdf and the MATLAB uniform random number generator rand:

```
mu = 1;
X = expinv(rand(1e4,1),mu);
```

Compare the distribution of the generated random numbers to the pdf of the specified exponential by scaling the pdf to the area of the histogram used to display the distribution:

```
numbins = 50;
hist(X, numbins)
set(get(gca,'Children'),'FaceColor',[.8 . 8 1])
hold on
[bincounts,binpositions] = hist(X,numbins);
binwidth = binpositions(2) - binpositions(1);
histarea = binwidth*sum(bincounts);
x = binpositions(1):0.001:binpositions(end);
y = exppdf(x,mu);
plot(x,histarea*y,'r','LineWidth',2)
```

Inversion methods also work for discrete distributions. To generate a random number $X$ from a discrete distribution with probability mass vector $P\left(X=x_{i}\right)=$ $p_{i}$ where $x_{0}<x_{1}<x_{2}<\ldots$, generate a uniform random number $u$ on $(0,1)$ and then set $X=x_{i}$ if $F\left(x_{i-1}\right)<u<F\left(x_{i}\right)$.

For example, the following function implements an inversion method for a discrete distribution with probability mass vector $p$ :

```
function X = discreteinvrnd(p,m,n)
X = zeros(m,n); % Preallocate memory
for i = 1:m*n
    u = rand;
    I = find(u < cumsum(p));
    X(i) = min(I);
end
```

Use the function to generate random numbers from any discrete distribution:

```
p = [0.1 0.2 0.3 0.2 0.1 0.1]; % Probability mass vector
X = discreteinvrnd(p,1e4,1);
[n,x] = hist(X,length(p));
bar(1:length(p),n)
set(get(gca,'Children'),'FaceColor',[.8 .8 1])
```

## Acceptance-Rejection Methods

The functional form of some distributions makes it difficult or time-consuming to generate random numbers using direct or inversion methods.
Acceptance-rejection methods provide an alternative in these cases.
Acceptance-rejection methods begin with uniform random numbers, but require an additional random number generator. If your goal is to generate a random number from a continuous distribution with $\operatorname{pdf} f$, acceptance-rejection methods first generate a random number from a continuous distribution with pdf $g$ satisfying $f(x) \leq \operatorname{cg}(x)$ for some $c$ and all $x$.

A continuous acceptance-rejection RNG proceeds as follows:
1 Chooses a density $g$.
2 Finds a constant $c$ such that $f(x) / g(x) \leq c$ for all $x$.
3 Generates a uniform random number $u$.
4 Generates a random number $v$ from $g$.
5 If $c u \leq f(v) / g(v)$, accepts and returns $v$.
6 Otherwise, rejects $v$ and goes to step 3 .
For efficiency, a "cheap" method is necessary for generating random numbers from $g$, and the scalar $c$ should be small. The expected number of iterations to produce a single random number is $c$.

The following function implements an acceptance-rejection method for generating random numbers from $\operatorname{pdf} f$, given $f$, $g$, the RNG grnd for $g$, and the constant $c$ :

```
function X = accrejrnd(f,g,grnd,c,m,n)
X = zeros(m,n); % Preallocate memory
for i = 1:m*n
    accept = false;
    while accept == false
        u = rand();
        v = grnd();
        if c*u <= f(v)/g(v)
            X(i) = v;
            accept = true;
        end
    end
end
```

For example, the function $f(x)=x \mathrm{e}^{-x_{2} / 2}$ satisfies the conditions for a pdf on $[0, \infty)$ (nonnegative and integrates to 1). The exponential pdf with mean $1, f(x)=\mathrm{e}^{-x}$, dominates $g$ for $c$ greater than about 2.2. Thus, you can use rand and exprnd to generate random numbers from $f$ :

```
f = @(x)x.*exp(-(x.^2)/2);
g = @(x)exp(-x);
grnd = @()exprnd(1);
X = accrejrnd(f,g,grnd,2.2,1e4,1);
```

The $\operatorname{pdf} f$ is actually a Rayleigh distribution with shape parameter 1 . This example compares the distribution of random numbers generated by the acceptance-rejection method with those generated by raylrnd:

```
Y = raylrnd(1,1e4,1);
hist([X Y])
h = get(gca,'Children');
set(h(1),'FaceColor',[.8 . 8 1])
legend('A-R RNG','Rayleigh RNG')
```

The Statistics Toolbox function raylrnd uses a transformation method, expressing a Rayleigh random variable in terms of a chi-square random variable, which you compute using randn.

Acceptance-rejection methods also work for discrete distributions. In this case, the goal is to generate random numbers from a distribution with probability mass $P_{p}(X=i)=p_{i}$, assuming that you have a method for generating random numbers from a distribution with probability mass $P_{q}(X=i)=q_{i}$. The RNG proceeds as follows:

1 Chooses a density $P_{q}$.
2 Finds a constant $c$ such that $p_{i} / q_{i} \leq c$ for all $i$.
3 Generates a uniform random number $u$.
4 Generates a random number $v$ from $P_{q}$.
5 If $c u \leq p_{v} / q_{v}$, accepts and returns $v$.
6 Otherwise, rejects $v$ and goes to step 3 .

## Representing Sampling Distributions Using Markov Chain Samplers

In this section...<br>"Using the Metropolis-Hastings Algorithm" on page 6-13<br>"Using Slice Sampling" on page 6-14

The methods in "Common Generation Methods" on page 6-5 might be inadequate when sampling distributions are difficult to represent in computations. Such distributions arise, for example, in Bayesian data analysis and in the large combinatorial problems of Markov chain Monte Carlo (MCMC) simulations. An alternative is to construct a Markov chain with a stationary distribution equal to the target sampling distribution, using the states of the chain to generate random numbers after an initial burn-in period in which the state distribution converges to the target.

## Using the Metropolis-Hastings Algorithm

The Metropolis-Hastings algorithm draws samples from a distribution that is only known up to a constant. Random numbers are generated from a distribution with a probability density function that is equal to or proportional to a proposal function.

To generate random numbers:
1 Assume an initial value $x(t)$.
2 Draw a sample, $y(t)$, from a proposal distribution $q(y \mid x(t))$.
3 Accept $y(t)$ as the next sample $x(t+1)$ with probability $r(x(t), y(t))$, and keep $x(t)$ as the next sample $x(t+1)$ with probability $1-r(x(t), y(t))$, where:

$$
r(x, y)=\min \left\{\frac{f(y)}{f(x)} \frac{q(x \mid y)}{q(y \mid x)}, 1\right\}
$$

4 Increment $t \rightarrow t+1$, and repeat steps 2 and 3 until you get the desired number of samples.

Generate random numbers using the Metropolis-Hastings method with the mhsample function. To produce quality samples efficiently with the Metropolis-Hastings algorithm, it is crucial to select a good proposal distribution. If it is difficult to find an efficient proposal distribution, use the slice sampling algorithm (slicesample) without explicitly specifying a proposal distribution.

## Using Slice Sampling

In instances where it is difficult to find an efficient Metropolis-Hastings proposal distribution, the slice sampling algorithm does not require an explicit specification. The slice sampling algorithm draws samples from the region under the density function using a sequence of vertical and horizontal steps. First, it selects a height at random from 0 to the density function $f(x)$. Then, it selects a new $x$ value at random by sampling from the horizontal "slice" of the density above the selected height. A similar slice sampling algorithm is used for a multivariate distribution.

If a function $f(x)$ proportional to the density function is given, then do the following to generate random numbers:

1 Assume an initial value $x(t)$ within the domain of $f(x)$.
2 Draw a real value $y$ uniformly from $(0, f(x(t))$ ), thereby defining a horizontal "slice" as $S=\{x: y<f(x)\}$.

3 Find an interval $I=(L, R)$ around $x(t)$ that contains all, or much of the "slice" $S$.

4 Draw the new point $x(t+1)$ within this interval.
5 Increment $t \rightarrow t+1$ and repeat steps 2 through 4 until you get the desired number of samples.

Slice sampling can generate random numbers from a distribution with an arbitrary form of the density function, provided that an efficient numerical procedure is available to find the interval $I=(L, R)$, which is the "slice" of the density.

Generate random numbers using the slice sampling method with the slicesample function.

## Generating Quasi-Random Numbers

In this section...<br>"Quasi-Random Sequences" on page 6-15<br>"Quasi-Random Point Sets" on page 6-16<br>"Quasi-Random Streams" on page 6-23

## Quasi-Random Sequences

Quasi-random number generators (QRNGs) produce highly uniform samples of the unit hypercube. QRNGs minimize the discrepancy between the distribution of generated points and a distribution with equal proportions of points in each sub-cube of a uniform partition of the hypercube. As a result, QRNGs systematically fill the "holes" in any initial segment of the generated quasi-random sequence.

Unlike the pseudorandom sequences described in "Common Generation Methods" on page 6-5, quasi-random sequences fail many statistical tests for randomness. Approximating true randomness, however, is not their goal. Quasi-random sequences seek to fill space uniformly, and to do so in such a way that initial segments approximate this behavior up to a specified density.

QRNG applications include:

- Quasi-Monte Carlo (QMC) integration. Monte Carlo techniques are often used to evaluate difficult, multi-dimensional integrals without a closed-form solution. QMC uses quasi-random sequences to improve the convergence properties of these techniques.
- Space-filling experimental designs. In many experimental settings, taking measurements at every factor setting is expensive or infeasible. Quasi-random sequences provide efficient, uniform sampling of the design space.
- Global optimization. Optimization algorithms typically find a local optimum in the neighborhood of an initial value. By using a quasi-random sequence of initial values, searches for global optima uniformly sample the basins of attraction of all local minima.

## Example: Using Scramble, Leap, and Skip

Imagine a simple 1-D sequence that produces the integers from 1 to 10 . This is the basic sequence and the first three points are [1,2,3]:

## 12345678910

Now look at how Scramble, Leap, and Skip work together:

- Scramble - Scrambling shuffles the points in one of several different ways. In this example, assume a scramble turns the sequence into $1,3,5,7,9,2,4,6,8,10$. The first three points are now [1,3,5]:

## 13579246810

- Skip - A Skip value specifies the number of initial points to ignore. In this example, set the Skip value to 2 . The sequence is now $5,7,9,2,4,6,8,10$ and the first three points are [5,7,9]:
$13 \lcm{579246810}$
- Leap - A Leap value specifies the number of points to ignore for each one you take. Continuing the example with the Skip set to 2 , if you set the Leap to 1 , the sequence uses every other point. In this example, the sequence is now $5,9,4,8$ and the first three points are [5,9,4]:

## Quasi-Random Point Sets

Statistics Toolbox functions support these quasi-random sequences:

- Halton sequences. Produced by the haltonset function. These sequences use different prime bases to form successively finer uniform partitions of the unit interval in each dimension.
- Sobol sequences. Produced by the sobolset function. These sequences use a base of 2 to form successively finer uniform partitions of the unit interval, and then reorder the coordinates in each dimension.
- Latin hypercube sequences. Produced by the lhsdesign function. Though not quasi-random in the sense of minimizing discrepancy, these sequences nevertheless produce sparse uniform samples useful in experimental designs.

Quasi-random sequences are functions from the positive integers to the unit hypercube. To be useful in application, an initial point set of a sequence must be generated. Point sets are matrices of size $n$-by- $d$, where $n$ is the number of points and $d$ is the dimension of the hypercube being sampled. The functions haltonset and sobolset construct point sets with properties of a specified quasi-random sequence. Initial segments of the point sets are generated by the net method of the qrandset class (parent class of the haltonset class and sobolset class), but points can be generated and accessed more generally using parenthesis indexing.

Because of the way in which quasi-random sequences are generated, they may contain undesirable correlations, especially in their initial segments, and especially in higher dimensions. To address this issue, quasi-random point sets often skip, leap over, or scramble values in a sequence. The haltonset and sobolset functions allow you to specify both a Skip and a Leap property of a quasi-random sequence, and the scramble method of the qrandset class allows you apply a variety of scrambling techniques. Scrambling reduces correlations while also improving uniformity.

## Example: Generate a Quasi-Random Point Set

This example uses haltonset to construct a 2-D Halton point set-an object, p, of the haltonset class-that skips the first 1000 values of the sequence and then retains every 101st point:

```
p = haltonset(2,'Skip',1e3,'Leap',1e2)
p =
    Halton point set in 2 dimensions (8.918019e+013 points)
    Properties:
                            Skip : 1000
            Leap : 100
    ScrambleMethod : none
```

The object p encapsulates properties of the specified quasi-random sequence. The point set is finite, with a length determined by the Skip and Leap properties and by limits on the size of point set indices (maximum value of $2^{53}$ ).

Use scramble to apply reverse-radix scrambling:

```
p = scramble(p,'RR2')
p =
    Halton point set in 2 dimensions (8.918019e+013 points)
    Properties:
            Skip : }100
            Leap : }10
    ScrambleMethod : RR2
```

Use net to generate the first 500 points:
$x 0=\operatorname{net}(p, 500) ;$
This is equivalent to:
$X 0=p(1: 500,:) ;$
Values of the point set X0 are not generated and stored in memory until you access $p$ using net or parenthesis indexing.

To appreciate the nature of quasi-random numbers, create a scatter of the two dimensions in XO :

```
scatter(XO(:,1),X0(:,2),5,'r')
axis square
title('{\bf Quasi-Random Scatter}')
```

## Quasi-Random Scatter

Compare this to a scatter of uniform pseudorandom numbers generated by the MATLAB rand function:

```
X = rand(500,2);
scatter(X(:,1),X(:,2),5,'b')
axis square
title('{\bf Uniform Random Scatter}')
```

The quasi-random scatter appears more uniform, avoiding the clumping in the pseudorandom scatter.

In a statistical sense, quasi-random numbers are too uniform to pass traditional tests of randomness. For example, a Kolmogorov-Smirnov test, performed by kstest, is used to assess whether or not a point set has a uniform random distribution. When performed repeatedly on uniform pseudorandom samples, such as those generated by rand, the test produces a uniform distribution of $p$-values:

```
nTests = 1e5;
sampSize = 50;
PVALS = zeros(nTests,1);
for test = 1:nTests
    x = rand(sampSize,1);
    [h,pval] = kstest(x,[x,x]);
```

```
    PVALS(test) = pval;
end
hist(PVALS,100)
set(get(gca,'Children'),'FaceColor',[.8 . 8 1])
xlabel('{\it p}-values')
ylabel('Number of Tests')
```

The results are quite different when the test is performed repeatedly on uniform quasi-random samples:

```
p = haltonset(1,'Skip',1e3,'Leap',1e2);
p = scramble(p,'RR2');
nTests = 1e5;
sampSize = 50;
PVALS = zeros(nTests,1);
for test = 1:nTests
```

```
    x = p(test:test+(sampSize-1),:);
    [h,pval] = kstest(x,[x,x]);
    PVALS(test) = pval;
end
hist(PVALS,100)
set(get(gca,'Children'),'FaceColor',[.8 . 8 1])
xlabel('{\it p}-values')
ylabel('Number of Tests')
```

Small $p$-values call into question the null hypothesis that the data are uniformly distributed. If the hypothesis is true, about $5 \%$ of the $p$-values are expected to fall below 0.05 . The results are remarkably consistent in their failure to challenge the hypothesis.

## Quasi-Random Streams

Quasi-random streams, produced by the qrandstream function, are used to generate sequential quasi-random outputs, rather than point sets of a specific size. Streams are used like pseudoRNGS, such as rand, when client applications require a source of quasi-random numbers of indefinite size that can be accessed intermittently. Properties of a quasi-random stream, such as its type (Halton or Sobol), dimension, skip, leap, and scramble, are set when the stream is constructed.

In implementation, quasi-random streams are essentially very large quasi-random point sets, though they are accessed differently. The state of a quasi-random stream is the scalar index of the next point to be taken from the stream. Use the qrand method of the qrandstream class to generate points from the stream, starting from the current state. Use the reset method to reset the state to 1 . Unlike point sets, streams do not support parenthesis indexing.

## Example: Generate a Quasi-Random Stream

For example, the following code, taken from the example at the end of "Quasi-Random Point Sets" on page 6-16, uses haltonset to create a quasi-random point set $p$, and then repeatedly increments the index into the point set, test, to generate different samples:

```
p = haltonset(1,'Skip',1e3,'Leap',1e2);
p = scramble(p,'RR2');
nTests = 1e5;
sampSize = 50;
PVALS = zeros(nTests,1);
for test = 1:nTests
    x = p(test:test+(sampSize-1),:);
    [h,pval] = kstest(x,[x,x]);
    PVALS(test) = pval;
end
```

The same results are obtained by using qrandstream to construct a quasi-random stream $q$ based on the point set $p$ and letting the stream take care of increments to the index:

```
p = haltonset(1,'Skip',1e3,'Leap',1e2);
p = scramble(p,'RR2');
q = qrandstream(p)
nTests = 1e5;
sampSize = 50;
PVALS = zeros(nTests,1);
for test = 1:nTests
    X = qrand(q,sampSize);
    [h,pval] = kstest(X,[X,X]);
    PVALS(test) = pval;
end
```

# Generating Data Using Flexible Families of Distributions 

In this section...<br>"Pearson and Johnson Systems" on page 6-25<br>"Generating Data Using the Pearson System" on page 6-26<br>"Generating Data Using the Johnson System" on page 6-28

## Pearson and Johnson Systems

As described in "Using Probability Distributions" on page 5-2, choosing an appropriate parametric family of distributions to model your data can be based on a priori or a posteriori knowledge of the data-producing process, but the choice is often difficult. The Pearson and Johnson systems can make such a choice unnecessary. Each system is a flexible parametric family of distributions that includes a wide range of distribution shapes, and it is often possible to find a distribution within one of these two systems that provides a good match to your data.

## Data Input

The following parameters define each member of the Pearson and Johnson systems

- Mean - Estimated by mean
- Standard deviation - Estimated by std
- Skewness - Estimated by skewness
- Kurtosis - Estimated by kurtosis

These statistics can also be computed with the moment function. The Johnson system, while based on these four parameters, is more naturally described using quantiles, estimated by the quantile function.

The Statistics Toolbox functions pearsrnd and johnsrnd take input arguments defining a distribution (parameters or quantiles, respectively) and return the type and the coefficients of the distribution in the corresponding system. Both functions also generate random numbers from the specified distribution.

As an example, load the data in carbig.mat, which includes a variable MPG containing measurements of the gas mileage for each car.

```
load carbig
MPG = MPG(~isnan(MPG));
[n,x] = hist(MPG,15);
bar(x,n)
set(get(gca,'Children'),'FaceColor',[.8 . 8 1])
```

The following two sections model the distribution with members of the Pearson and Johnson systems, respectively.

## Generating Data Using the Pearson System

The statistician Karl Pearson devised a system, or family, of distributions that includes a unique distribution corresponding to every valid combination of mean, standard deviation, skewness, and kurtosis. If you compute sample
values for each of these moments from data, it is easy to find the distribution in the Pearson system that matches these four moments and to generate a random sample.

The Pearson system embeds seven basic types of distribution together in a single parametric framework. It includes common distributions such as the normal and $t$ distributions, simple transformations of standard distributions such as a shifted and scaled beta distribution and the inverse gamma distribution, and one distribution-the Type IV-that is not a simple transformation of any standard distribution.

For a given set of moments, there are distributions that are not in the system that also have those same first four moments, and the distribution in the Pearson system may not be a good match to your data, particularly if the data are multimodal. But the system does cover a wide range of distribution shapes, including both symmetric and skewed distributions.

To generate a sample from the Pearson distribution that closely matches the MPG data, simply compute the four sample moments and treat those as distribution parameters.

```
moments = {mean(MPG),std(MPG),skewness(MPG),kurtosis(MPG)};
[r,type] = pearsrnd(moments{:},10000,1);
```

The optional second output from pearsrnd indicates which type of distribution within the Pearson system matches the combination of moments.

```
type
type =
1
```

In this case, pearsrnd has determined that the data are best described with a Type I Pearson distribution, which is a shifted, scaled beta distribution.

Verify that the sample resembles the original data by overlaying the empirical cumulative distribution functions.

```
ecdf(MPG);
[Fi,xi] = ecdf(r);
hold on, stairs(xi,Fi,'r'); hold off
```

## Generating Data Using the Johnson System

Statistician Norman Johnson devised a different system of distributions that also includes a unique distribution for every valid combination of mean, standard deviation, skewness, and kurtosis. However, since it is more natural to describe distributions in the Johnson system using quantiles, working with this system is different than working with the Pearson system.

The Johnson system is based on three possible transformations of a normal random variable, plus the identity transformation. The three nontrivial cases are known as SL, SU, and SB, corresponding to exponential, logistic, and hyperbolic sine transformations. All three can be written as

$$
\mathrm{X}=\gamma+\delta \cdot \Gamma\left(\frac{(\mathrm{Z}-\xi)}{\lambda}\right)
$$

where Z is a standard normal random variable, $\Gamma$ is the transformation, and $\gamma, \delta, \xi$, and $\lambda$ are scale and location parameters. The fourth case, SN , is the identity transformation.

To generate a sample from the Johnson distribution that matches the MPG data, first define the four quantiles to which the four evenly spaced standard normal quantiles of $-1.5,-0.5,0.5$, and 1.5 should be transformed. That is, you compute the sample quantiles of the data for the cumulative probabilities of $0.067,0.309,0.691$, and 0.933 .

```
probs = normcdf([-1.5 -0.5 0.5 1.5])
probs =
    0.066807 0.30854 0.69146 0.93319
```

quantiles = quantile(MPG, probs)
quantiles =
$13.0000 \quad 18.0000 \quad 27.2000 \quad 36.0000$

Then treat those quantiles as distribution parameters.

```
[r1,type] = johnsrnd(quantiles,10000,1);
```

The optional second output from johnsrnd indicates which type of distribution within the Johnson system matches the quantiles.

```
type
type =
SB
```

You can verify that the sample resembles the original data by overlaying the empirical cumulative distribution functions.

```
ecdf(MPG);
[Fi,xi] = ecdf(r1);
hold on, stairs(xi,Fi,'r'); hold off
```

In some applications, it may be important to match the quantiles better in some regions of the data than in others. To do that, specify four evenly spaced standard normal quantiles at which you want to match the data, instead of the default $-1.5,-0.5,0.5$, and 1.5 . For example, you might care more about matching the data in the right tail than in the left, and so you specify standard normal quantiles that emphasizes the right tail.

```
qnorm = [-.5 .25 1 1.75];
probs = normcdf(qnorm);
qemp = quantile(MPG,probs);
r2 = johnsrnd([qnorm; qemp],10000,1);
```

However, while the new sample matches the original data better in the right tail, it matches much worse in the left tail.

```
[Fj,xj] = ecdf(r2);
hold on, stairs(xj,Fj,'g'); hold off
```

## Hypothesis Tests

## Introduction to Hypothesis Tests

Hypothesis testing is a common method of drawing inferences about a population based on statistical evidence from a sample.

As an example, suppose someone says that at a certain time in the state of Massachusetts the average price of a gallon of regular unleaded gas was $\$ 1.15$. How could you determine the truth of the statement? You could try to find prices at every gas station in the state at the time. That approach would be definitive, but it could be time-consuming, costly, or even impossible.

A simpler approach would be to find prices at a small number of randomly selected gas stations around the state, and then compute the sample average.

Sample averages differ from one another due to chance variability in the selection process. Suppose your sample average comes out to be $\$ 1.18$. Is the $\$ 0.03$ difference an artifact of random sampling or significant evidence that the average price of a gallon of gas was in fact greater than $\$ 1.15$ ? Hypothesis testing is a statistical method for making such decisions.

## Hypothesis Test Terminology

All hypothesis tests share the same basic terminology and structure.

- A null hypothesis is an assertion about a population that you would like to test. It is "null" in the sense that it often represents a status quo belief, such as the absence of a characteristic or the lack of an effect. It may be formalized by asserting that a population parameter, or a combination of population parameters, has a certain value. In the example given in the "Introduction to Hypothesis Tests" on page 7-2, the null hypothesis would be that the average price of gas across the state was $\$ 1.15$. This is written $H_{0}: \mu=1.15$.
- An alternative hypothesis is a contrasting assertion about the population that can be tested against the null hypothesis. In the example given in the "Introduction to Hypothesis Tests" on page 7-2, possible alternative hypotheses are:
$H_{1}: \mu \neq 1.15$ - State average was different from $\$ 1.15$ (two-tailed test)
$H_{1}: \mu>1.15$ - State average was greater than $\$ 1.15$ (right-tail test)
$H_{1}: \mu<1.15$ - State average was less than $\$ 1.15$ (left-tail test)
- To conduct a hypothesis test, a random sample from the population is collected and a relevant test statistic is computed to summarize the sample. This statistic varies with the type of test, but its distribution under the null hypothesis must be known (or assumed).
- The $p$ value of a test is the probability, under the null hypothesis, of obtaining a value of the test statistic as extreme or more extreme than the value computed from the sample.
- The significance level of a test is a threshold of probability $a$ agreed to before the test is conducted. A typical value of $\alpha$ is 0.05 . If the $p$ value of a test is less than $a$, the test rejects the null hypothesis. If the $p$ value is greater than $a$, there is insufficient evidence to reject the null hypothesis. Note that lack of evidence for rejecting the null hypothesis is not evidence for accepting the null hypothesis. Also note that substantive "significance" of an alternative cannot be inferred from the statistical significance of a test.
- The significance level $\alpha$ can be interpreted as the probability of rejecting the null hypothesis when it is actually true-a type I error. The distribution of the test statistic under the null hypothesis determines the probability
$\alpha$ of a type I error. Even if the null hypothesis is not rejected, it may still be false-a type II error. The distribution of the test statistic under the alternative hypothesis determines the probability $\beta$ of a type II error. Type II errors are often due to small sample sizes. The power of a test, $1-\beta$, is the probability of correctly rejecting a false null hypothesis.
- Results of hypothesis tests are often communicated with a confidence interval. A confidence interval is an estimated range of values with a specified probability of containing the true population value of a parameter. Upper and lower bounds for confidence intervals are computed from the sample estimate of the parameter and the known (or assumed) sampling distribution of the estimator. A typical assumption is that estimates will be normally distributed with repeated sampling (as dictated by the Central Limit Theorem). Wider confidence intervals correspond to poor estimates (smaller samples); narrow intervals correspond to better estimates (larger samples). If the null hypothesis asserts the value of a population parameter, the test rejects the null hypothesis when the hypothesized value lies outside the computed confidence interval for the parameter.

## Hypothesis Test Assumptions

Different hypothesis tests make different assumptions about the distribution of the random variable being sampled in the data. These assumptions must be considered when choosing a test and when interpreting the results.

For example, the $z$-test (ztest) and the $t$-test (ttest) both assume that the data are independently sampled from a normal distribution. Statistics Toolbox functions are available for testing this assumption, such as chi2gof, jbtest, lillietest, and normplot.

Both the $z$-test and the $t$-test are relatively robust with respect to departures from this assumption, so long as the sample size $n$ is large enough. Both tests compute a sample mean $\bar{x}$, which, by the Central Limit Theorem, has an approximately normal sampling distribution with mean equal to the population mean $\mu$, regardless of the population distribution being sampled.

The difference between the $z$-test and the $t$-test is in the assumption of the standard deviation $\sigma$ of the underlying normal distribution. A $z$-test assumes that $\sigma$ is known; a $t$-test does not. As a result, a $t$-test must compute an estimate $s$ of the standard deviation from the sample.

Test statistics for the $z$-test and the $t$-test are, respectively,

$$
\begin{aligned}
& z=\frac{\bar{x}-\mu}{\sigma / \sqrt{n}} \\
& t=\frac{\bar{x}-\mu}{s / \sqrt{n}}
\end{aligned}
$$

Under the null hypothesis that the population is distributed with mean $\mu$, the $z$-statistic has a standard normal distribution, $N(0,1)$. Under the same null hypothesis, the $t$-statistic has Student's $t$ distribution with $n-1$ degrees of freedom. For small sample sizes, Student's $t$ distribution is flatter and wider than $N(0,1)$, compensating for the decreased confidence in the estimate $s$. As sample size increases, however, Student's $t$ distribution approaches the standard normal distribution, and the two tests become essentially equivalent.

Knowing the distribution of the test statistic under the null hypothesis allows for accurate calculation of $p$-values. Interpreting $p$-values in the context of the test assumptions allows for critical analysis of test results.

Assumptions underlying Statistics Toolbox hypothesis tests are given in the reference pages for implementing functions.

## Hypothesis Testing

This example uses the gas price data in the file gas.mat. The file contains two random samples of prices for a gallon of gas around the state of Massachusetts in 1993. The first sample, price1, contains 20 random observations around the state on a single day in January. The second sample, price2, contains 20 random observations around the state one month later.

```
load gas
prices = [price1 price2];
```

As a first step, you might want to test the assumption that the samples come from normal distributions.

A normal probability plot gives a quick idea.
normplot(prices)

Both scatters approximately follow straight lines through the first and third quartiles of the samples, indicating approximate normal distributions. The February sample (the right-hand line) shows a slight departure from normality in the lower tail. A shift in the mean from January to February is evident.

A hypothesis test is used to quantify the test of normality. Since each sample is relatively small, a Lilliefors test is recommended.

```
lillietest(price1)
ans =
    0
lillietest(price2)
ans =
    0
```

The default significance level of lillietest is $5 \%$. The logical 0 returned by each test indicates a failure to reject the null hypothesis that the samples are normally distributed. This failure may reflect normality in the population or it may reflect a lack of strong evidence against the null hypothesis due to the small sample size.

Now compute the sample means:

```
sample_means = mean(prices)
sample_means =
    115.1500 118.5000
```

You might want to test the null hypothesis that the mean price across the state on the day of the January sample was $\$ 1.15$. If you know that the standard deviation in prices across the state has historically, and consistently, been $\$ 0.04$, then a $z$-test is appropriate.

```
[h,pvalue,ci] = ztest(price1/100,1.15,0.04)
h =
    0
pvalue =
    0.8668
ci =
    1.1340
    1.1690
```

The logical output $\mathrm{h}=0$ indicates a failure to reject the null hypothesis at the default significance level of $5 \%$. This is a consequence of the high probability under the null hypothesis, indicated by the $p$ value, of observing a value as extreme or more extreme of the $z$-statistic computed from the sample. The $95 \%$ confidence interval on the mean [1.1340 1.1690] includes the hypothesized population mean of $\$ 1.15$.

Does the later sample offer stronger evidence for rejecting a null hypothesis of a state-wide average price of $\$ 1.15$ in February? The shift shown in the probability plot and the difference in the computed sample means suggest this. The shift might indicate a significant fluctuation in the market, raising questions about the validity of using the historical standard deviation. If a known standard deviation cannot be assumed, a $t$-test is more appropriate.

```
[h,pvalue,ci] = ttest(price2/100,1.15)
h =
    1
pvalue =
    4.9517e-004
ci =
    1.1675
    1.2025
```

The logical output $\mathrm{h}=1$ indicates a rejection of the null hypothesis at the default significance level of $5 \%$. In this case, the $95 \%$ confidence interval on the mean does not include the hypothesized population mean of $\$ 1.15$.

You might want to investigate the shift in prices a little more closely. The function ttest2 tests if two independent samples come from normal distributions with equal but unknown standard deviations and the same mean, against the alternative that the means are unequal.

```
[h,sig,ci] = ttest2(price1,price2)
\(\mathrm{h}=\)
    1
sig =
    0.0083
Ci \(=\)
    -5.7845
    -0.9155
```

The null hypothesis is rejected at the default $5 \%$ significance level, and the confidence interval on the difference of means does not include the hypothesized value of 0 .

A notched box plot is another way to visualize the shift.

```
boxplot(prices,1)
set(gca,'XTick',[1 2])
set(gca,'XtickLabel',{'January','February'})
xlabel('Month')
ylabel('Prices ($0.01)')
```

The plot displays the distribution of the samples around their medians. The heights of the notches in each box are computed so that the side-by-side boxes have nonoverlapping notches when their medians are different at a default $5 \%$ significance level. The computation is based on an assumption of normality in the data, but the comparison is reasonably robust for other distributions. The side-by-side plots provide a kind of visual hypothesis test, comparing medians rather than means. The plot above appears to barely reject the null hypothesis of equal medians.

The nonparametric Wilcoxon rank sum test, implemented by the function ranksum, can be used to quantify the test of equal medians. It tests if two independent samples come from identical continuous (not necessarily normal) distributions with equal medians, against the alternative that they do not have equal medians.

```
[p,h] = ranksum(price1,price2)
p =
    0.0095
h =
    1
```

The test rejects the null hypothesis of equal medians at the default $5 \%$ significance level.

## Available Hypothesis Tests

| Function | Description |
| :--- | :--- |
| ansaribradley | Ansari-Bradley test. Tests if two independent samples <br> come from the same distribution, against the alternative <br> that they come from distributions that have the same <br> median and shape but different variances. |
| barttest | Bartlett's test. Tests if the variances of the data values <br> along each principal component are equal, against the <br> alternative that the variances are not all equal. |
| chi2gof | Chi-square goodness-of-fit test. Tests if a sample comes <br> from a specified distribution, against the alternative <br> that it does not come from that distribution. |
| dwtest | Durbin-Watson test. Tests if the residuals from a linear <br> regression are uncorrelated, against the alternative <br> that there is autocorrelation among them. |
| friedman | Friedman's test. Tests if the column effects in a two-way <br> layout are all the same, against the alternative that the <br> column effects are not all the same. |
| jbtest | Jarque-Bera test. Tests if a sample comes from a <br> normal distribution with unknown mean and variance, <br> against the alternative that it does not come from a <br> normal distribution. |
| kruskalwallis | Kruskal-Wallis test. Tests if multiple samples are all <br> drawn from the same populations (or equivalently, <br> from different populations with the same distribution), <br> against the alternative that they are not all drawn from <br> the same population. |
| kstest | One-sample Kolmogorov-Smirnov test. Tests if a sample <br> comes from a continuous distribution with specified <br> parameters, against the alternative that it does not <br> come from that distribution. |

| Function | Description |
| :--- | :--- |
| kstest2 | Two-sample Kolmogorov-Smirnov test. Tests if two <br> samples come from the same continuous distribution, <br> against the alternative that they do not come from the <br> same distribution. |
| lillietest | Lilliefors test. Tests if a sample comes from a <br> distribution in the normal family, against the <br> alternative that it does not come from a normal <br> distribution. |
| linhyptest | Linear hypothesis test. Tests if $\mathrm{H} * \mathrm{~b}=\mathrm{c}$ f for parameter <br> estimates b with estimated covariance H and specified <br> c, against the alternative that $\mathrm{H} * \mathrm{~b}$ <br> c. |
| ranksum | Wilcoxon rank sum test. Tests if two independent <br> samples come from identical continuous distributions <br> with equal medians, against the alternative that they <br> do not have equal medians. |
| runstest | Runs test. Tests if a sequence of values comes in <br> random order, <br> is not randinst the alternative that the ordering |
| signrank | One-sample or paired-sample Wilcoxon signed rank test. <br> Tests if a sample comes from a continuous distribution |
| symmetric about a specified median, against the <br> alternative that it does not have that median. |  |
| signtest | One-sample or paired-sample sign test. Tests if a <br> sample comes from an arbitrary continuous distribution <br> with a specified median, against the alternative that it <br> does not have that median. |
| ttest | One-sample or paired-sample $t$-test. Tests if a sample <br> comes from a normal distribution with unknown <br> variance and a specified mean, against the alternative <br> that it does not have that mean. |

| Function | Description |
| :--- | :--- |
| ttest2 | Two-sample $t$-test. Tests if two independent samples <br> come from normal distributions with unknown but <br> equal (or, optionally, unequal) variances and the same <br> mean, against the alternative that the means are <br> unequal. |
| vartest | One-sample chi-square variance test. Tests if a sample <br> comes from a normal distribution with specified <br> variance, against the alternative that it comes from a <br> normal distribution with a different variance. |
| vartest2 | Two-sample $F$-test for equal variances. Tests if two <br> independent samples come from normal distributions <br> with the same variance, against the alternative that <br> they come from normal distributions with different <br> variances. |
| vartestn | Bartlett multiple-sample test for equal variances. Tests <br> if multiple samples come from normal distributions <br> with the same variance, against the alternative that <br> they come from normal distributions with different <br> variances. |
| ztest | One-sample $z$-test. Tests if a sample comes from a <br> normal distribution with known variance and specified <br> mean, against the alternative that it does not have that <br> mean. |

Note In addition to the previous functions, Statistics Toolbox functions are available for analysis of variance (ANOVA), which perform hypothesis tests in the context of linear modeling.

## Analysis of Variance

- "Introduction to Analysis of Variance" on page 8-2
- "ANOVA" on page 8-3
- "MANOVA" on page 8-39

## Introduction to Analysis of Variance

Analysis of variance (ANOVA) is a procedure for assigning sample variance to different sources and deciding whether the variation arises within or among different population groups. Samples are described in terms of variation around group means and variation of group means around an overall mean. If variations within groups are small relative to variations between groups, a difference in group means may be inferred. Hypothesis tests are used to quantify decisions.

- "Example: Multiple Comparisons" on page 8-7

## Introduction to One-Way ANOVA

The purpose of one-way ANOVA is to find out whether data from several groups have a common mean. That is, to determine whether the groups are actually different in the measured characteristic.

One-way ANOVA is a simple special case of the linear model. The one-way ANOVA form of the model is

$$
y_{i j}=\alpha_{. j}+\varepsilon_{i j}
$$

where:

- $y_{i j}$ is a matrix of observations in which each column represents a different group.
- $\alpha_{. j}$ is a matrix whose columns are the group means. (The "dot $j$ " notation means that $\alpha$ applies to all rows of column $j$. That is, the value $\alpha_{i j}$ is the same for all i.)
- $\varepsilon_{i j}$ is a matrix of random disturbances.

The model assumes that the columns of $y$ are a constant plus a random disturbance. You want to know if the constants are all the same.

## Example: One-Way ANOVA

The data below comes from a study by Hogg and Ledolter [48] of bacteria counts in shipments of milk. The columns of the matrix hogg represent different shipments. The rows are bacteria counts from cartons of milk chosen randomly from each shipment. Do some shipments have higher counts than others?

```
load hogg
hogg
hogg =
\begin{tabular}{rrrrr}
24 & 14 & 11 & 7 & 19 \\
15 & 7 & 9 & 7 & 24 \\
21 & 12 & 7 & 4 & 19 \\
27 & 17 & 13 & 7 & 15 \\
33 & 14 & 12 & 12 & 10 \\
23 & 16 & 18 & 18 & 20
\end{tabular}
[p,tbl,stats] = anova1(hogg);
p
p =
    1.1971e-04
```

The standard ANOVA table has columns for the sums of squares, degrees of freedom, mean squares (SS/df), $F$ statistic, and $p$ value.

You can use the $F$ statistic to do a hypothesis test to find out if the bacteria counts are the same. anova1 returns the $p$ value from this hypothesis test.

In this case the $p$ value is about 0.0001 , a very small value. This is a strong indication that the bacteria counts from the different shipments are not the same. An $F$ statistic as extreme as the observed $F$ would occur by chance only once in 10,000 times if the counts were truly equal.

The $p$ value returned by anova1 depends on assumptions about the random disturbances $\varepsilon_{i j}$ in the model equation. For the $p$ value to be correct, these disturbances need to be independent, normally distributed, and have constant variance.

You can get some graphical assurance that the means are different by looking at the box plots in the second figure window displayed by anova1. Note, however, that the notches are used for a comparison of medians, not a comparison of means. For more information on this display, see "Box Plots" on page 4-6.

## Multiple Comparisons

Sometimes you need to determine not just whether there are any differences among the means, but specifically which pairs of means are significantly different. It is tempting to perform a series of $t$ tests, one for each pair of means, but this procedure has a pitfall.

In a $t$ test, you compute a $t$ statistic and compare it to a critical value. The critical value is chosen so that when the means are really the same (any apparent difference is due to random chance), the probability that the $t$ statistic will exceed the critical value is small, say $5 \%$. When the means are different, the probability that the statistic will exceed the critical value is larger.

In this example there are five means, so there are 10 pairs of means to compare. It stands to reason that if all the means are the same, and if there is a $5 \%$ chance of incorrectly concluding that there is a difference in one pair,
then the probability of making at least one incorrect conclusion among all 10 pairs is much larger than $5 \%$.

Fortunately, there are procedures known as multiple comparison procedures that are designed to compensate for multiple tests.

## Example: Multiple Comparisons

You can perform a multiple comparison test using the multcompare function and supplying it with the stats output from anova1.

```
load hogg
[p,tbl,stats] = anova1(hogg);
[c,m] = multcompare(stats)
c =
\begin{tabular}{rrrrr}
1.0000 & 2.0000 & 2.4953 & 10.5000 & 18.5047 \\
1.0000 & 3.0000 & 4.1619 & 12.1667 & 20.1714 \\
1.0000 & 4.0000 & 6.6619 & 14.6667 & 22.6714 \\
1.0000 & 5.0000 & -2.0047 & 6.0000 & 14.0047 \\
2.0000 & 3.0000 & -6.3381 & 1.6667 & 9.6714 \\
2.0000 & 4.0000 & -3.8381 & 4.1667 & 12.1714 \\
2.0000 & 5.0000 & -12.5047 & -4.5000 & 3.5047 \\
3.0000 & 4.0000 & -5.5047 & 2.5000 & 10.5047 \\
3.0000 & 5.0000 & -14.1714 & -6.1667 & 1.8381 \\
4.0000 & 5.0000 & -16.6714 & -8.6667 & -0.6619
\end{tabular}
m =
    23.8333 1.9273
    13.3333 1.9273
    11.6667 1.9273
    9.1667 1.9273
    17.8333 1.9273
```

The first output from multcompare has one row for each pair of groups, with an estimate of the difference in group means and a confidence interval for that group. For example, the second row has the values

```
1.0000
    3.0000
    4.1619
12.1667
20.1714
```

indicating that the mean of group 1 minus the mean of group 3 is estimated to be 12.1667, and a $95 \%$ confidence interval for this difference is
[4.1619, 20.1714]. This interval does not contain 0 , so you can conclude that the means of groups 1 and 3 are different.

The second output contains the mean and its standard error for each group.
It is easier to visualize the difference between group means by looking at the graph that multcompare produces.

There are five groups. The graph instructs you to Click on the group you want to test. Three groups have slopes significantly different from group one.

Click on the group you want to test

The graph shows that group 1 is significantly different from groups 2,3 , and 4. By using the mouse to select group 4, you can determine that it is also significantly different from group 5. Other pairs are not significantly different.

## Two-Way ANOVA

- "Introduction to Two-Way ANOVA" on page 8-9
- "Example: Two-Way ANOVA" on page 8-10

## Introduction to Two-Way ANOVA

The purpose of two-way ANOVA is to find out whether data from several groups have a common mean. One-way ANOVA and two-way ANOVA differ in that the groups in two-way ANOVA have two categories of defining characteristics instead of one.

Suppose an automobile company has two factories, and each factory makes the same three models of car. It is reasonable to ask if the gas mileage in the cars varies from factory to factory as well as from model to model. There are two predictors, factory and model, to explain differences in mileage.

There could be an overall difference in mileage due to a difference in the production methods between factories. There is probably a difference in the mileage of the different models (irrespective of the factory) due to differences in design specifications. These effects are called additive.

Finally, a factory might make high mileage cars in one model (perhaps because of a superior production line), but not be different from the other factory for other models. This effect is called an interaction. It is impossible to detect an interaction unless there are duplicate observations for some combination of factory and car model.

Two-way ANOVA is a special case of the linear model. The two-way ANOVA form of the model is

$$
y_{i j k}=\mu+\alpha_{. j}+\beta_{i .}+\gamma_{i j}+\varepsilon_{i j k}
$$

where, with respect to the automobile example above:

- $y_{i j k}$ is a matrix of gas mileage observations (with row index $i$, column index $j$, and repetition index $k$ ).
- $\mu$ is a constant matrix of the overall mean gas mileage.
- $\alpha_{j}$ is a matrix whose columns are the deviations of each car's gas mileage (from the mean gas mileage $\mu$ ) that are attributable to the car's model. All values in a given column of $\alpha_{. j}$ are identical, and the values in each row of $a_{. j}$ sum to 0 .
- $\beta_{i .}$ is a matrix whose rows are the deviations of each car's gas mileage (from the mean gas mileage $\mu$ ) that are attributable to the car's factory. All values in a given row of $\beta_{i}$ are identical, and the values in each column of $\beta_{i}$. sum to 0 .
- $\gamma_{i j}$ is a matrix of interactions. The values in each row of $\gamma_{i j}$ sum to 0 , and the values in each column of $y_{i j}$ sum to 0 .
- $\varepsilon_{i j k}$ is a matrix of random disturbances.

## Example: Two-Way ANOVA

The purpose of the example is to determine the effect of car model and factory on the mileage rating of cars.

```
load mileage
mileage
mileage =
    33.3000 34.5000 37.4000
    33.4000 34.8000 36.8000
    32.9000 33.8000 37.6000
    32.6000 33.4000 36.6000
    32.5000 33.7000 37.0000
    33.0000 33.9000 36.7000
cars = 3;
[p,tbl,stats] = anova2(mileage,cars);
p
p =
    0.0000 0.0039 0.8411
```

There are three models of cars (columns) and two factories (rows). The reason there are six rows in mileage instead of two is that each factory provides
three cars of each model for the study. The data from the first factory is in the first three rows, and the data from the second factory is in the last three rows.

The standard ANOVA table has columns for the sums of squares, degrees-of-freedom, mean squares (SS/df), $F$ statistics, and $p$-values.

| - Figure No. 1: Two-way ANOVA |  |  |  | - $\square_{\text {a }}$ |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| File Edit Iools Window Help |  |  |  |  |  |
| ANOVA Table |  |  |  |  |  |
| Source | 55 | df | MS | F | Prob>F $\triangle$ |
| Columns | 53.3511 | 2 | 26.6756 | 234.22 | 0 |
| Rows | 1.445 | 1 | 1.445 | 12.69 | 0.0039 |
| Interaction | 0.04 | 2 | 0.02 | 0.18 | 0.8411 |
| Error | 1.3667 | 12 | 0.1139 |  |  |
| Total | 56.2028 | 17 |  |  | $\square$ |

You can use the $F$ statistics to do hypotheses tests to find out if the mileage is the same across models, factories, and model-factory pairs (after adjusting for the additive effects). anova2 returns the $p$ value from these tests.

The $p$ value for the model effect is zero to four decimal places. This is a strong indication that the mileage varies from one model to another. An $F$ statistic as extreme as the observed $F$ would occur by chance less than once in 10,000 times if the gas mileage were truly equal from model to model. If you used the multcompare function to perform a multiple comparison test, you would find that each pair of the three models is significantly different.

The $p$ value for the factory effect is 0.0039 , which is also highly significant. This indicates that one factory is out-performing the other in the gas mileage of the cars it produces. The observed $p$ value indicates that an $F$ statistic as extreme as the observed $F$ would occur by chance about four out of 1000 times if the gas mileage were truly equal from factory to factory.

There does not appear to be any interaction between factories and models. The $p$ value, 0.8411 , means that the observed result is quite likely ( 84 out 100 times) given that there is no interaction.

The $p$-values returned by anova2 depend on assumptions about the random disturbances $\varepsilon_{i j k}$ in the model equation. For the $p$-values to be correct these disturbances need to be independent, normally distributed, and have constant variance.

In addition, anova2 requires that data be balanced, which in this case means there must be the same number of cars for each combination of model and factory. The next section discusses a function that supports unbalanced data with any number of predictors.

## N-Way ANOVA

- "Introduction to N-Way ANOVA" on page 8-12
- "N-Way ANOVA with a Small Data Set" on page 8-13
- "N-Way ANOVA with a Large Data Set" on page 8-15
- "ANOVA with Random Effects" on page 8-19

## Introduction to N-Way ANOVA

You can use N -way ANOVA to determine if the means in a set of data differ when grouped by multiple factors. If they do differ, you can determine which factors or combinations of factors are associated with the difference.

N-way ANOVA is a generalization of two-way ANOVA. For three factors, the model can be written

$$
y_{i j k l}=\mu+\alpha_{. j .}+\beta_{i . .}+\gamma_{. . k}+(\alpha \beta)_{i j .}+(\alpha \gamma)_{i . k}+(\beta \gamma)_{. j k}+(\alpha \beta \gamma)_{i j k}+\varepsilon_{i j k l}
$$

In this notation parameters with two subscripts, such as $(\alpha \beta)_{i j}$, represent the interaction effect of two factors. The parameter $(\alpha \beta \gamma)_{i j k}$ represents the three-way interaction. An ANOVA model can have the full set of parameters or any subset, but conventionally it does not include complex interaction terms unless it also includes all simpler terms for those factors. For example, one would generally not include the three-way interaction without also including all two-way interactions.

The anovan function performs N-way ANOVA. Unlike the anova1 and anova2 functions, anovan does not expect data in a tabular form. Instead, it expects a vector of response measurements and a separate vector (or text array) containing the values corresponding to each factor. This input data format is more convenient than matrices when there are more than two factors or when the number of measurements per factor combination is not constant.

## N-Way ANOVA with a Small Data Set

Consider the following two-way example using anova2.

```
m = [23 15 20;27 17 63;43 3 55;41 9 90]
m =
    23 15 20
    27 17 63
    43 3 55
    41 9 90
anova2(m,2)
ans =
    0.0197 0.2234 0.2663
```

The factor information is implied by the shape of the matrix $m$ and the number of measurements at each factor combination (2). Although anova2 does not actually require arrays of factor values, for illustrative purposes you could create them as follows.

```
cfactor = repmat(1:3,4,1)
cfactor =
    1 2
    1 2
    1 2 3
    1 2 
rfactor = [ones(2,3); 2*ones(2,3)]
rfactor =
```

    \(1 \quad 1 \quad 1\)
    | 1 | 1 | 1 |
| :--- | :--- | :--- |
| 2 | 2 | 2 |
| 2 | 2 | 2 |

The cfactor matrix shows that each column of $m$ represents a different level of the column factor. The rfactor matrix shows that the top two rows of $m$ represent one level of the row factor, and bottom two rows of $m$ represent a second level of the row factor. In other words, each value $m(i, j)$ represents an observation at column factor level cfactor(i,j) and row factor level rfactor(i,j).

To solve the above problem with anovan, you need to reshape the matrices $m$, cfactor, and rfactor to be vectors.

```
m = m(:);
cfactor = cfactor(:);
rfactor = rfactor(:);
[m cfactor rfactor]
ans =
\begin{tabular}{rrr}
23 & 1 & 1 \\
27 & 1 & 1 \\
43 & 1 & 2 \\
41 & 1 & 2 \\
15 & 2 & 1 \\
17 & 2 & 1 \\
3 & 2 & 2 \\
9 & 2 & 2 \\
20 & 3 & 1 \\
63 & 3 & 1 \\
55 & 3 & 2 \\
90 & 3 & 2
\end{tabular}
anovan(m,{cfactor rfactor},2)
ans =
    0.0197
```

0.2234
0.2663

## N-Way ANOVA with a Large Data Set

The previous example used anova2 to study a small data set measuring car mileage. This example illustrates how to analyze a larger set of car data with mileage and other information on 406 cars made between 1970 and 1982. First, load the data set and look at the variable names.
load carbig
whos

| Name | Size | Bytes | Class |
| :--- | :--- | ---: | :--- |
|  |  |  |  |
| Acceleration | $406 \times 1$ | 3248 | double array |
| Cylinders | $406 \times 1$ | 3248 | double array |
| Displacement | $406 \times 1$ | 3248 | double array |
| Horsepower | $406 \times 1$ | 3248 | double array |
| MPG | $406 \times 1$ | 3248 | double array |
| Model | $406 \times 36$ | 29232 | char array |
| Model_Year | $406 \times 1$ | 3248 | double array |
| Origin | $406 \times 7$ | 5684 | char array |
| Weight | $406 \times 1$ | 3248 | double array |
| cyl4 | $406 \times 5$ | 4060 | char array |
| org | $406 \times 7$ | 5684 | char array |
| when | $406 \times 5$ | 4060 | char array |

The example focusses on four variables. MPG is the number of miles per gallon for each of 406 cars (though some have missing values coded as NaN). The other three variables are factors: cyl4 (four-cylinder car or not), org (car originated in Europe, Japan, or the USA), and when (car was built early in the period, in the middle of the period, or late in the period).

First, fit the full model, requesting up to three-way interactions and Type 3 sums-of-squares.

```
varnames = {'Origin';'4Cyl';'MfgDate'};
anovan(MPG,{org cyl4 when},3,3,varnames)
ans =
    0.0000
```

Note that many terms are marked by a \# symbol as not having full rank, and one of them has zero degrees of freedom and is missing a $p$ value. This can happen when there are missing factor combinations and the model has higher-order terms. In this case, the cross-tabulation below shows that there are no cars made in Europe during the early part of the period with other than four cylinders, as indicated by the 0 in table $(2,1,1)$.

```
[table, chi2, p, factorvals] = crosstab(org,when,cyl4)
table(:,:,1) =
\begin{tabular}{rrr}
82 & 75 & 25 \\
0 & 4 & 3 \\
3 & 3 & 4
\end{tabular}
```

```
table(:,:,2) =
    12 22 38
    23 26 17
    12 25 32
chi2 =
    207.7689
p =
    0
factorvals =
\begin{tabular}{llr} 
'USA' & 'Early' & 'Other' \\
'Europe' & 'Mid' & 'Four' \\
'Japan' & 'Late' & []
\end{tabular}
```

Consequently it is impossible to estimate the three-way interaction effects, and including the three-way interaction term in the model makes the fit singular.

Using even the limited information available in the ANOVA table, you can see that the three-way interaction has a $p$ value of 0.699 , so it is not significant. So this time you examine only two-way interactions.
[ $p$, tbl, stats,terms] = anovan(MPG,\{org cyl4 when\},2,3,varnames); terms
terms =

| 1 | 0 | 0 |
| :--- | :--- | :--- |
| 0 | 1 | 0 |
| 0 | 0 | 1 |
| 1 | 1 | 0 |
| 1 | 0 | 1 |
| 0 | 1 | 1 |

| - Figure No. 1: N-Way ANOVA |  |  |  | - |
| :---: | :---: | :---: | :---: | :---: |
| File Edit View Insert Iools Window Help Analysis of Variance |  |  |  |  |
|  |  |  |  |  |
| Source | Sum Sq. d.f | Mean Sq | F | Prob>F $\triangle$ |
| Origin | $532.6 \quad 2$ | 266.29 | 18.82 | 0 |
| 4 Cyl | 1769.81 | 1769.85 | 125.11 | 0 |
| MfgDate | 2887.12 | 1443.55 | 102.05 | 0 |
| Origin*4Cyl | 12.52 | 6.27 | 0.44 | 0.6422 |
| Origin*MfgDate | 350.44 | 87.59 | 6.19 | 0.0001 |
| $4 \mathrm{Cyl} * \mathrm{Mfg}$ Date | $31 \quad 2$ | 15.52 | 1.1 | 0.3348 |
| Error | 5432.1384 | 14.15 |  |  |
| Total | 24252.6397 |  |  |  |
| Constrained (Type III) sums of squares. |  |  |  |  |

Now all terms are estimable. The $p$-values for interaction term 4 (Origin*4Cyl) and interaction term 6 (4Cyl*MfgDate) are much larger than a typical cutoff value of 0.05 , indicating these terms are not significant. You could choose to omit these terms and pool their effects into the error term. The output terms variable returns a matrix of codes, each of which is a bit pattern representing a term. You can omit terms from the model by deleting their entries from terms and running anovan again, this time supplying the resulting vector as the model argument.

```
terms([4 6],:) = []
terms =
\begin{tabular}{lll}
1 & 0 & 0 \\
0 & 1 & 0 \\
0 & 0 & 1 \\
1 & 0 & 1
\end{tabular}
anovan(MPG,{org cyl4 when},terms,3,varnames)
ans =
    1.0e-003 *
```

Now you have a more parsimonious model indicating that the mileage of these cars seems to be related to all three factors, and that the effect of the manufacturing date depends on where the car was made.

## ANOVA with Random Effects

- "Introduction to ANOVA with Random Effects" on page 8-19
- "Setting Up the Model" on page 8-20
- "Fitting a Random Effects Model" on page 8-21
- "F Statistics for Models with Random Effects" on page 8-22
- "Variance Components" on page 8-24

Introduction to ANOVA with Random Effects. In an ordinary ANOVA model, each grouping variable represents a fixed factor. The levels of that factor are a fixed set of values. Your goal is to determine whether different factor levels lead to different response values. This section presents an example that shows how to use anovan to fit models where a factor's levels represent a random selection from a larger (infinite) set of possible levels.

Setting Up the Model. To set up the example, first load the data, which is stored in a 6-by-3 matrix, mileage.

```
load mileage
```

The anova2 function works only with balanced data, and it infers the values of the grouping variables from the row and column numbers of the input matrix. The anovan function, on the other hand, requires you to explicitly create vectors of grouping variable values. To create these vectors, do the following steps:

1 Create an array indicating the factory for each value in mileage. This array is 1 for the first column, 2 for the second, and 3 for the third.

```
factory = repmat(1:3,6,1);
```

2 Create an array indicating the car model for each mileage value. This array is 1 for the first three rows of mileage, and 2 for the remaining three rows.
carmod $=$ [ones $(3,3) ; 2 *$ ones $(3,3)]$;
3 Turn these matrices into vectors and display them.

```
mileage = mileage(:);
factory = factory(:);
carmod = carmod(:);
[mileage factory carmod]
ans =
```

| 33.3000 | 1.0000 | 1.0000 |
| :--- | :--- | :--- |
| 33.4000 | 1.0000 | 1.0000 |
| 32.9000 | 1.0000 | 1.0000 |
| 32.6000 | 1.0000 | 2.0000 |
| 32.5000 | 1.0000 | 2.0000 |
| 33.0000 | 1.0000 | 2.0000 |
| 34.5000 | 2.0000 | 1.0000 |
| 34.8000 | 2.0000 | 1.0000 |
| 33.8000 | 2.0000 | 1.0000 |
| 33.4000 | 2.0000 | 2.0000 |
| 33.7000 | 2.0000 | 2.0000 |

| 33.9000 | 2.0000 | 2.0000 |
| :--- | :--- | :--- |
| 37.4000 | 3.0000 | 1.0000 |
| 36.8000 | 3.0000 | 1.0000 |
| 37.6000 | 3.0000 | 1.0000 |
| 36.6000 | 3.0000 | 2.0000 |
| 37.0000 | 3.0000 | 2.0000 |
| 36.7000 | 3.0000 | 2.0000 |

Fitting a Random Effects Model. Continuing the example from the preceding section, suppose you are studying a few factories but you want information about what would happen if you build these same car models in a different factory-either one that you already have or another that you might construct. To get this information, fit the analysis of variance model, specifying a model that includes an interaction term and that the factory factor is random.

```
[pvals,tbl,stats] = anovan(mileage, {factory carmod}, ...
'model',2, 'random',1,'varnames',{'Factory' 'Car Model'});
```

Analysis of Variance

| Source | Sum Sq. | .f | Mean Sq. | F | Prob $>\mathrm{F}$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Factory | 53.3511 | 2 | 26.6756 | 1333.78 | 0.0007 |
| Car Model | 1. 445 | 1 | 1. 445 | 72.25 | 0.0136 |
| Factory*Car Model | 0.04 | 2 | 0.02 | 0.18 | 0.8411 |
| Error | 1.3667 | 12 | 0.1139 |  |  |
| Total | 56.2028 | 17 |  |  |  |

Constrained (Type III) sums of squares.

In the fixed effects version of this fit, which you get by omitting the inputs ' random ' , 1 in the preceding code, the effect of car model is significant, with a $p$ value of 0.0039 . But in this example, which takes into account the random variation of the effect of the variable 'Car Model' from one factory to another, the effect is still significant, but with a higher $p$ value of 0.0136 .

F Statistics for Models with Random Effects. The $F$ statistic in a model having random effects is defined differently than in a model having all fixed effects. In the fixed effects model, you compute the $F$ statistic for any term by taking the ratio of the mean square for that term with the mean square for error. In a random effects model, however, some $F$ statistics use a different mean square in the denominator.

In the example described in "Setting Up the Model" on page 8-20, the effect of the variable 'Factory' could vary across car models. In this case, the interaction mean square takes the place of the error mean square in the $F$ statistic. The $F$ statistic for factory is:

```
F = 26.6756 / 0.02
F =
```

1333.78

The degrees of freedom for the statistic are the degrees of freedom for the numerator (2) and denominator (2) mean squares. Therefore the $p$ value for the statistic is:

```
pval = 1 - fcdf(F,2,2)
pval =
    7.4919e-04
```

With random effects, the expected value of each mean square depends not only on the variance of the error term, but also on the variances contributed by the random effects. You can see these dependencies by writing the expected values as linear combinations of contributions from the various model terms. To find the coefficients of these linear combinations, enter stats.ems, which returns the ems field of the stats structure:
stats.ems
ans =

| 6.0000 | 0.0000 | 3.0000 | 1.0000 |
| :--- | :--- | :--- | :--- |
| 0.0000 | 9.0000 | 3.0000 | 1.0000 |

```
0.0000 0.0000 3.0000 1.0000
    0 0
```

To see text representations of the linear combinations, enter
stats.txtems
ans $=$

```
'6*V(Factory)+3*V(Factory*Car Model)+V(Error)'
'9*Q(Car Model)+3*V(Factory*Car Model)+V(Error)'
'3*V(Factory*Car Model)+V(Error)'
'V(Error)'
```

The expected value for the mean square due to car model (second term) includes contributions from a quadratic function of the car model effects, plus three times the variance of the interaction term's effect, plus the variance of the error term. Notice that if the car model effects were all zero, the expression would reduce to the expected mean square for the third term (the interaction term). That is why the $F$ statistic for the car model effect uses the interaction mean square in the denominator.

In some cases there is no single term whose expected value matches the one required for the denominator of the $F$ statistic. In that case, the denominator is a linear combination of mean squares. The stats structure contains fields giving the definitions of the denominators for each $F$ statistic. The txtdenom field, stats.txtdenom, gives a text representation, and the denom field gives a matrix that defines a linear combination of the variances of terms in the model. For balanced models like this one, the denom matrix, stats.denom, contains zeros and ones, because the denominator is just a single term's mean square:

```
stats.txtdenom
```

ans =

```
'MS(Factory*Car Model)'
'MS(Factory*Car Model)'
'MS(Error)'
```

stats.denom
ans $=$

| -0.0000 | 1.0000 | 0.0000 |
| ---: | ---: | ---: |
| 0.0000 | 1.0000 | -0.0000 |
| 0.0000 | 0 | 1.0000 |

Variance Components. For the model described in "Setting Up the Model" on page 8-20, consider the mileage for a particular car of a particular model made at a random factory. The variance of that car is the sum of components, or contributions, one from each of the random terms.

```
stats.rtnames
ans =
    'Factory'
    'Factory*Car Model'
    'Error'
```

You do not know those variances, but you can estimate them from the data. Recall that the ems field of the stats structure expresses the expected value of each term's mean square as a linear combination of unknown variances for random terms, and unknown quadratic forms for fixed terms. If you take the expected mean square expressions for the random terms, and equate those expected values to the computed mean squares, you get a system of equations that you can solve for the unknown variances. These solutions are the variance component estimates. The varest field contains a variance component estimate for each term. The rtnames field contains the names of the random terms.
stats.varest
ans =
4.4426
$-0.0313$
0.1139

Under some conditions, the variability attributed to a term is unusually low, and that term's variance component estimate is negative. In those cases it
is common to set the estimate to zero, which you might do, for example, to create a bar graph of the components.

```
bar(max(0,stats.varest))
set(gca,'xtick',1:3,'xticklabel',stats.rtnames)
```

You can also compute confidence bounds for the variance estimate. The anovan function does this by computing confidence bounds for the variance expected mean squares, and finding lower and upper limits on each variance component containing all of these bounds. This procedure leads to a set of bounds that is conservative for balanced data. (That is, $95 \%$ confidence bounds will have a probability of at least $95 \%$ of containing the true variances if the number of observations for each combination of grouping variables is the same.) For unbalanced data, these are approximations that are not guaranteed to be conservative.

```
[{'Term' 'Estimate' 'Lower' 'Upper'};
    stats.rtnames, num2cell([stats.varest stats.varci])]
ans =
    'Term' 'Estimate' 'Lower' 'Upper'
```

| 'Factory' | 4.4426] | [1.0736] | [175.6038] |
| :---: | :---: | :---: | :---: |
| 'Factory*Car Model' | [ -0.0313] | NaN ] | NaN ] |
| 'Error' | 0.1139] | [0.0586] | $0.3103]$ |

## Other ANOVA Models

The anovan function also has arguments that enable you to specify two other types of model terms. First, the 'nested' argument specifies a matrix that indicates which factors are nested within other factors. A nested factor is one that takes different values within each level its nested factor.

For example, the mileage data from the previous section assumed that the two car models produced in each factory were the same. Suppose instead, each factory produced two distinct car models for a total of six car models, and we numbered them 1 and 2 for each factory for convenience. Then, the car model is nested in factory. A more accurate and less ambiguous numbering of car model would be as follows:

However, it is common with nested models to number the nested factor the same way in each nested factor.

Second, the 'continuous ' argument specifies that some factors are to be treated as continuous variables. The remaining factors are categorical variables. Although the anovan function can fit models with multiple continuous and categorical predictors, the simplest model that combines one predictor of each type is known as an analysis of covariance model. The next section describes a specialized tool for fitting this model.

## Analysis of Covariance

- "Introduction to Analysis of Covariance" on page 8-27
- "Analysis of Covariance Tool" on page 8-27
- "Confidence Bounds" on page 8-31
- "Multiple Comparisons" on page 8-34

## Introduction to Analysis of Covariance

Analysis of covariance is a technique for analyzing grouped data having a response ( $y$, the variable to be predicted) and a predictor ( $x$, the variable used to do the prediction). Using analysis of covariance, you can model $y$ as a linear function of $x$, with the coefficients of the line possibly varying from group to group.

## Analysis of Covariance Tool

The aoctool function opens an interactive graphical environment for fitting and prediction with analysis of covariance (ANOCOVA) models. It fits the following models for the $i$ th group:

| Same mean | $y=a+\varepsilon$ |
| :--- | :--- |
| Separate means | $y=\left(a+a_{i}\right)+\varepsilon$ |
| Same line | $y=\alpha+\beta x+\varepsilon$ |
| Parallel lines | $y=\left(a+a_{i}\right)+\beta x+\varepsilon$ |
| Separate lines | $y=\left(\alpha+a_{i}\right)+\left(\beta+\beta_{i}\right) x+\varepsilon$ |

For example, in the parallel lines model the intercept varies from one group to the next, but the slope is the same for each group. In the same mean model, there is a common intercept and no slope. In order to make the group coefficients well determined, the tool imposes the constraints

$$
\sum \alpha_{j}=\sum \beta_{j}=0
$$

The following steps describe the use of aoctool.

1 Load the data. The Statistics Toolbox data set carsmall.mat contains information on cars from the years 1970, 1976, and 1982. This example studies the relationship between the weight of a car and its mileage, and whether this relationship has changed over the years. To start the demonstration, load the data set.
load carsmall
The Workspace Browser shows the variables in the data set.

| Workspace |  |  |  |
| :---: | :---: | :---: | :---: |
| Name - | Value | Min | Max |
| HAcceleration | <100x1 double> | 8 | 24.6000 |
| H Cylinders | <100x1 double> | 4 | 8 |
| $\boxplus$ Displacement | <100x1 double> | 85 | 455 |
| $\boxplus$ Horsepower | <100x1 double> | NaN | NaN |
| $\boxplus$ MPG | <100x1 double> | NaN | NaN |
| 2 acc Mfg | <100x13 char> |  |  |
| 20cc Model | <100x33 char> |  |  |
| Model_Year | <100x1 double> | 70 | 82 |
| 2bc Origin | <100x7 char> |  |  |
| W Weight | <100x1 double> | 1795 | 4732 |
| 1 | III |  | , |

You can also use aoctool with your own data.
2 Start the tool. The following command calls aoctool to fit a separate line to the column vectors Weight and MPG for each of the three model group defined in Model_Year. The initial fit models the $y$ variable, MPG, as a linear function of the $x$ variable, Weight.

```
[h,atab,ctab,stats] = aoctool(Weight,MPG,Model_Year);
```

See the aoctool function reference page for detailed information about calling aoctool.

3 Examine the output. The graphical output consists of a main window with a plot, a table of coefficient estimates, and an analysis of variance table. In the plot, each Model_Year group has a separate line. The data
points for each group are coded with the same color and symbol, and the fit for each group has the same color as the data points.

The coefficients of the three lines appear in the figure titled ANOCOVA Coefficients. You can see that the slopes are roughly -0.0078 , with a small deviation for each group:

- Model year 1970: $y=(45.9798-8.5805)+(-0.0078+0.002) x+\varepsilon$
- Model year 1976: $y=(45.9798-3.8902)+(-0.0078+0.0011) x+\varepsilon$
- Model year 1982: $y=(45.9798+12.4707)+(-0.0078-0.0031) x+\varepsilon$

| -) Figure No. 3: ANOCOVA Coefficients |  |  |  | - $\square$ 미 |  |
| :---: | :---: | :---: | :---: | :---: | :---: |

| 70 | -8.5805 | 1.96186 | -4.37 |  |  |
| 76 | -3.8902 | 1.86864 | -2.08 | 0.0403 |  |
| 82 | 12.4707 | 2.5568 | 4.88 | 0 |  |
| Slope | -0.0078 | 0.00056 | -14 | 0 |  |
| 70 | 0.002 | 0.00066 | 2.96 | 0.0039 |  |
| 76 | 0.0011 | 0.00065 | 1.74 | 0.0849 |  |
| 82 | -0.0031 | 0.001 | -3.1 | 0.0026 |  |

Because the three fitted lines have slopes that are roughly similar, you may wonder if they really are the same. The Model_Year*Weight interaction expresses the difference in slopes, and the ANOVA table shows a test for the significance of this term. With an $F$ statistic of 5.23 and a $p$ value of 0.0072 , the slopes are significantly different.

4 Constrain the slopes to be the same. To examine the fits when the slopes are constrained to be the same, return to the ANOCOVA Prediction Plot window and use the Model pop-up menu to select a Parallel Lines model. The window updates to show the following graph.

Though this fit looks reasonable, it is significantly worse than the Separate Lines model. Use the Model pop-up menu again to return to the original model.

## Confidence Bounds

The example in "Analysis of Covariance Tool" on page 8-27 provides estimates of the relationship between MPG and Weight for each Model_Year, but how accurate are these estimates? To find out, you can superimpose confidence bounds on the fits by examining them one group at a time.

1 In the Model_Year menu at the lower right of the figure, change the setting from All Groups to 82 . The data and fits for the other groups are dimmed, and confidence bounds appear around the 82 fit.

The dashed lines form an envelope around the fitted line for model year 82. Under the assumption that the true relationship is linear, these bounds provide a $95 \%$ confidence region for the true line. Note that the fits for the other model years are well outside these confidence bounds for Weight values between 2000 and 3000 .

2 Sometimes it is more valuable to be able to predict the response value for a new observation, not just estimate the average response value. Use the
aoctool function Bounds menu to change the definition of the confidence bounds from Line to Observation. The resulting wider intervals reflect the uncertainty in the parameter estimates as well as the randomness of a new observation.

Like the polytool function, the aoctool function has cross hairs that you can use to manipulate the Weight and watch the estimate and confidence bounds along the $y$-axis update. These values appear only when a single group is selected, not when All Groups is selected.

## Multiple Comparisons

You can perform a multiple comparison test by using the stats output structure from aoctool as input to the multcompare function. The multcompare function can test either slopes, intercepts, or population marginal means (the predicted MPG of the mean weight for each group). The example in "Analysis of Covariance Tool" on page $8-27$ shows that the slopes are not all the same, but could it be that two are the same and only the other one is different? You can test that hypothesis.

```
multcompare(stats,0.05,'on','','s')
ans =
\begin{tabular}{rrrrr}
1.0000 & 2.0000 & -0.0012 & 0.0008 & 0.0029 \\
1.0000 & 3.0000 & 0.0013 & 0.0051 & 0.0088 \\
2.0000 & 3.0000 & 0.0005 & 0.0042 & 0.0079
\end{tabular}
```

This matrix shows that the estimated difference between the intercepts of groups 1 and 2 (1970 and 1976) is 0.0008, and a confidence interval for the difference is $[-0.0012,0.0029]$. There is no significant difference between the two. There are significant differences, however, between the intercept for 1982 and each of the other two. The graph shows the same information.

Note that the stats structure was created in the initial call to the aoctool function, so it is based on the initial model fit (typically a separate-lines model). If you change the model interactively and want to base your multiple comparisons on the new model, you need to run aoctool again to get another stats structure, this time specifying your new model as the initial model.

## Nonparametric Methods

- "Introduction to Nonparametric Methods" on page 8-36
- "Kruskal-Wallis Test" on page 8-36
- "Friedman's Test" on page 8-37

## Introduction to Nonparametric Methods

Statistics Toolbox functions include nonparametric versions of one-way and two-way analysis of variance. Unlike classical tests, nonparametric tests make only mild assumptions about the data, and are appropriate when the distribution of the data is non-normal. On the other hand, they are less powerful than classical methods for normally distributed data.

Both of the nonparametric functions described here will return a stats structure that can be used as an input to the multcompare function for multiple comparisons.

## Kruskal-Wallis Test

The example "Example: One-Way ANOVA" on page 8-4 uses one-way analysis of variance to determine if the bacteria counts of milk varied from shipment to shipment. The one-way analysis rests on the assumption that the measurements are independent, and that each has a normal distribution with a common variance and with a mean that was constant in each column. You can conclude that the column means were not all the same. The following example repeats that analysis using a nonparametric procedure.

The Kruskal-Wallis test is a nonparametric version of one-way analysis of variance. The assumption behind this test is that the measurements come from a continuous distribution, but not necessarily a normal distribution. The test is based on an analysis of variance using the ranks of the data values, not the data values themselves. Output includes a table similar to an ANOVA table, and a box plot.

You can run this test as follows:
load hogg

```
p = kruskalwallis(hogg)
p =
0.0020
```

The low $p$ value means the Kruskal-Wallis test results agree with the one-way analysis of variance results.

## Friedman's Test

"Example: Two-Way ANOVA" on page 8-10 uses two-way analysis of variance to study the effect of car model and factory on car mileage. The example tests whether either of these factors has a significant effect on mileage, and whether there is an interaction between these factors. The conclusion of the example is there is no interaction, but that each individual factor has a significant effect. The next example examines whether a nonparametric analysis leads to the same conclusion.

Friedman's test is a nonparametric test for data having a two-way layout (data grouped by two categorical factors). Unlike two-way analysis of variance, Friedman's test does not treat the two factors symmetrically and it does not test for an interaction between them. Instead, it is a test for whether the columns are different after adjusting for possible row differences. The test is based on an analysis of variance using the ranks of the data across categories of the row factor. Output includes a table similar to an ANOVA table.

You can run Friedman's test as follows.

```
load mileage
p = friedman(mileage,3)
p =
    7.4659e-004
```

Recall the classical analysis of variance gave a $p$ value to test column effects, row effects, and interaction effects. This $p$ value is for column effects. Using either this $p$ value or the $p$ value from ANOVA ( $p<0.0001$ ), you conclude that there are significant column effects.

In order to test for row effects, you need to rearrange the data to swap the roles of the rows in columns. For a data matrix $x$ with no replications, you could simply transpose the data and type
p = friedman(x')
With replicated data it is slightly more complicated. A simple way is to transform the matrix into a three-dimensional array with the first dimension
representing the replicates, swapping the other two dimensions, and restoring the two-dimensional shape.

```
x = reshape(mileage, [3 2 3]);
x = permute(x,[\begin{array}{lll}{1 2 2]);}\end{array}]
x = reshape(x,[9 2])
x =
    33.3000 32.6000
    33.4000 32.5000
    32.9000 33.0000
    34.5000 33.4000
    34.8000 33.7000
    33.8000 33.9000
    37.4000 36.6000
    36.8000 37.0000
    37.6000 36.7000
friedman(x,3)
ans =
    0.0082
```

Again, the conclusion is similar to that of the classical analysis of variance. Both this $p$ value and the one from ANOVA ( $p=0.0039$ ) lead you to conclude that there are significant row effects.

You cannot use Friedman's test to test for interactions between the row and column factors.

## MANOVA

## In this section...

"Introduction to MANOVA" on page 8-39
"ANOVA with Multiple Responses" on page 8-39

## Introduction to MANOVA

The analysis of variance technique in "Example: One-Way ANOVA" on page 8-4 takes a set of grouped data and determine whether the mean of a variable differs significantly among groups. Often there are multiple response variables, and you are interested in determining whether the entire set of means is different from one group to the next. There is a multivariate version of analysis of variance that can address the problem.

## ANOVA with Multiple Responses

The carsmall data set has measurements on a variety of car models from the years 1970, 1976, and 1982. Suppose you are interested in whether the characteristics of the cars have changed over time.

First, load the data.

| load carsmall whos |  |  |  |
| :---: | :---: | :---: | :---: |
| Name | Size | Bytes | Class |
| Acceleration | 100x1 | 800 | double array |
| Cylinders | 100x1 | 800 | double array |
| Displacement | 100x1 | 800 | double array |
| Horsepower | 100x1 | 800 | double array |
| MPG | 100x1 | 800 | double array |
| Model | $100 \times 36$ | 7200 | char array |
| Model_Year | 100x1 | 800 | double array |
| Origin | 100x7 | 1400 | char array |
| Weight | 100x1 | 800 | double array |

Four of these variables (Acceleration, Displacement, Horsepower, and MPG) are continuous measurements on individual car models. The variable

Model_Year indicates the year in which the car was made. You can create a grouped plot matrix of these variables using the gplotmatrix function.

```
x = [MPG Horsepower Displacement Weight];
gplotmatrix(x,[],Model_Year,[],'+xo')
```

(When the second argument of gplotmatrix is empty, the function graphs the columns of the $x$ argument against each other, and places histograms along the diagonals. The empty fourth argument produces a graph with the default colors. The fifth argument controls the symbols used to distinguish between groups.)

It appears the cars do differ from year to year. The upper right plot, for example, is a graph of MPG versus Weight. The 1982 cars appear to have higher mileage than the older cars, and they appear to weigh less on average. But as a group, are the three years significantly different from one another? The manova1 function can answer that question.
[d,p,stats] = manova1(x,Model_Year)

```
d =
    2
p =
    1.0e-006 *
            0
        0.1141
stats =
                    W: [4x4 double]
                    B: [4x4 double]
                    T: [4x4 double]
                    dfW: 90
                    dfB: 2
                dfT: 92
        lambda: [2x1 double]
            chisq: [2x1 double]
        chisqdf: [2x1 double]
        eigenval: [4x1 double]
        eigenvec: [4x4 double]
            canon: [100x4 double]
            mdist: [100x1 double]
        gmdist: [3x3 double]
```

The manova1 function produces three outputs:

- The first output, d , is an estimate of the dimension of the group means. If the means were all the same, the dimension would be 0 , indicating that the means are at the same point. If the means differed but fell along a line, the dimension would be 1 . In the example the dimension is 2 , indicating that the group means fall in a plane but not along a line. This is the largest possible dimension for the means of three groups.
- The second output, p , is a vector of $p$-values for a sequence of tests. The first $p$ value tests whether the dimension is 0 , the next whether the dimension is 1 , and so on. In this case both $p$-values are small. That's why the estimated dimension is 2 .
- The third output, stats, is a structure containing several fields, described in the following section.

## The Fields of the stats Structure

The W, B, and T fields are matrix analogs to the within, between, and total sums of squares in ordinary one-way analysis of variance. The next three fields are the degrees of freedom for these matrices. Fields lambda, chisq, and chisqdf are the ingredients of the test for the dimensionality of the group means. (The $p$-values for these tests are the first output argument of manova1.)

The next three fields are used to do a canonical analysis. Recall that in principal components analysis ("Principal Component Analysis (PCA)" on page 12-78) you look for the combination of the original variables that has the largest possible variation. In multivariate analysis of variance, you instead look for the linear combination of the original variables that has the largest separation between groups. It is the single variable that would give the most significant result in a univariate one-way analysis of variance. Having found that combination, you next look for the combination with the second highest separation, and so on.

The eigenvec field is a matrix that defines the coefficients of the linear combinations of the original variables. The eigenval field is a vector measuring the ratio of the between-group variance to the within-group variance for the corresponding linear combination. The canon field is a matrix of the canonical variable values. Each column is a linear combination of the mean-centered original variables, using coefficients from the eigenvec matrix.

A grouped scatter plot of the first two canonical variables shows more separation between groups then a grouped scatter plot of any pair of original variables. In this example it shows three clouds of points, overlapping but with distinct centers. One point in the bottom right sits apart from the others. By using the gname function, you can see that this is the 20 th point.

```
c1 = stats.canon(:,1);
c2 = stats.canon(:,2);
gscatter(c2,c1,Model_Year,[],'oxs')
gname
```

Roughly speaking, the first canonical variable, c1, separates the 1982 cars (which have high values of c1) from the older cars. The second canonical variable, c2, reveals some separation between the 1970 and 1976 cars.

The final two fields of the stats structure are Mahalanobis distances. The mdist field measures the distance from each point to its group mean. Points with large values may be outliers. In this data set, the largest outlier is the one in the scatter plot, the Buick Estate station wagon. (Note that you could have supplied the model name to the gname function above if you wanted to label the point with its model name rather than its row number.)

```
max(stats.mdist)
ans =
    31.5273
find(stats.mdist == ans)
ans =
```

20

```
Model(20,:)
ans =
    buick_estate_wagon_(sw)
```

The gmdist field measures the distances between each pair of group means. The following commands examine the group means and their distances:

```
grpstats(x, Model_Year)
ans =
    1.0e+003 *
        0.0177 0.1489 0.2869 3.4413
        0.0216 0.1011 0.1978 3.0787
        0.0317 0.0815 0.1289 2.4535
stats.gmdist
ans =
\begin{tabular}{rrr}
0 & 3.8277 & 11.1106 \\
3.8277 & 0 & 6.1374 \\
11.1106 & 6.1374 & 0
\end{tabular}
```

As might be expected, the multivariate distance between the extreme years 1970 and 1982 (11.1) is larger than the difference between more closely spaced years (3.8 and 6.1). This is consistent with the scatter plots, where the points seem to follow a progression as the year changes from 1970 through 1976 to 1982. If you had more groups, you might find it instructive to use the manovacluster function to draw a diagram that presents clusters of the groups, formed using the distances between their means.

## Parametric Regression Analysis

In this section...<br>"What Is Parametric Regression?" on page 9-2<br>"Choose a Regression Function" on page 9-2<br>"Update Legacy Code with New Fitting Methods" on page 9-3

## What Is Parametric Regression?

Regression is the process of fitting models to data. The models must have numerical responses. For models with categorical responses, see "Parametric Classification" on page 14-2 or "Supervised Learning (Machine Learning) Workflow and Algorithms" on page 15-2. The regression process depends on the model. If a model is parametric, regression estimates the parameters from the data. If a model is linear in the parameters, estimation is based on methods from linear algebra that minimize the norm of a residual vector. If a model is nonlinear in the parameters, estimation is based on search methods from optimization that minimize the norm of a residual vector.

## Choose a Regression Function

## Update Legacy Code with New Fitting Methods

There are several Statistics Toolbox functions for performing regression. The following sections describe how to replace calls to older functions to new versions:

- "regress into LinearModel.fit" on page 9-4
- "regstats into LinearModel.fit" on page 9-4
- "robustfit into LinearModel.fit" on page 9-5
- "stepwisefit into LinearModel.stepwise" on page 9-5
- "glmfit into GeneralizedLinearModel.fit" on page 9-6
- "nlinfit into NonLinearModel.fit" on page 9-6

## regress into LinearModel.fit

## Previous Syntax.

[b,bint,r,rint,stats] = regress( $y, X$ )
where $X$ contains a column of ones.

## Current Syntax.

mdl = LinearModel.fit(X,y)
where you do not add a column of ones to $X$.
Equivalent values of the previous outputs:

- b — mdl. Coefficients.Estimate
- bint - coefCI (mdl)
- $r$ —mdl. Residuals.Raw
- rint - There is no exact equivalent. Try examining mdl.Residuals.Studentized to find outliers.
- stats - mdl contains various properties that replace components of stats.

## regstats into LinearModel.fit

## Previous Syntax.

stats $=$ regstats( $y, X$, model, whichstats)

## Current Syntax.

```
mdl = LinearModel.fit(X,y,model)
```

Obtain statistics from the properties and methods of mdl. For example, see the mdl.Diagnostics and mdl. Residuals properties.

## robustfit into LinearModel.fit

## Previous Syntax.

```
[b,stats] = robustfit(X,y,wfun,tune,const)
```

## Current Syntax.

```
mdl = LinearModel.fit(X,y,'robust','on') % bisquare
```

Or to use the wfun weight and the tune tuning parameter:

```
opt.RobustWgtFun = 'wfun';
opt.Tune = tune; % optional
mdl = LinearModel.fit(X,y,'robust',opt)
```

Obtain statistics from the properties and methods of mdl. For example, see the mdl.Diagnostics and mdl.Residuals properties.

## stepwisefit into LinearModel.stepwise

## Previous Syntax.

[b,se, pval,inmodel, stats, nextstep,history] = stepwisefit(X, y, Name, Value)

## Current Syntax.

```
mdl = LinearModel.stepwise(ds,modelspec,Name,Value)
```

or

```
mdl = LinearModel.stepwise(X,y,modelspec,Name,Value)
```

Obtain statistics from the properties and methods of mdl. For example, see the mdl.Diagnostics and mdl. Residuals properties.

## glmfit into GeneralizedLinearModel.fit

## Previous Syntax.

[b,dev,stats] = glmfit(X,y,distr, param1, val1, ...)

## Current Syntax.

mdl $=$ GeneralizedLinearModel.fit(X,y,distr,...)
Obtain statistics from the properties and methods of mdl. For example, the deviance is mdl. Deviance, and to compare mdl against a constant model, use devianceTest(mdl).

## nlinfit into NonLinearModel.fit

## Previous Syntax.

```
[beta,r,J,COVB,mse] = nlinfit(X,y,fun,beta0,options)
```

## Current Syntax.

```
mdl = NonLinearModel.fit(X,y,fun,beta0,'Options',options)
```

Equivalent values of the previous outputs:

- beta - mdl. Coefficients.Estimate
- r-mdl.Residuals.Raw
- covb - mdl.CoefficientCovariance
- mse - mdl.mse
mdl does not provide the Jacobian (J) output. The primary purpose of $J$ was to pass it into nlparci or nlpredci to obtain confidence intervals for the estimated coefficients (parameters) or predictions. Obtain those confidence intervals as:

```
parci = coefCI(mdl)
[pred,predci] = predict(mdl)
```

## What Are Linear Regression Models?

Regression models describe the relationship between a dependent variable, $y$, and independent variable or variables, $X$. The dependent variable is also called the response variable. Independent variables are also called explanatory or predictor variables. Continuous predictor variables might be called covariates, whereas categorical predictor variables might be also referred to as factors. The matrix, $X$, of observations on predictor variables is usually called the design matrix.

A multiple linear regression model is

$$
y_{i}=\beta_{0}+\beta_{1} X_{i 1}+\beta_{2} X_{i 2}+\cdots+\beta_{p} X_{i p}+\varepsilon_{i}, \quad i=1, \cdots, n,
$$

where

- $y_{i}$ is the $i$ th response.
- $\beta_{k}$ is the $k$ th coefficient, where $\beta_{0}$ is the constant term in the model.

Sometimes, design matrices might include information about the constant term. However, LinearModel.fit or LinearModel.stepwise by default includes a constant term in the model, so you must not enter a column of 1 s into your design matrix $X$.

- $X_{i j}$ is the $i$ th observation on the $j$ th predictor variable, $j=1, \ldots, p$.
- $\varepsilon_{i}$ is the $i$ th noise term, that is, random error.

In general, a linear regression model can be a model of the form

$$
y_{i}=\beta_{0}+\sum_{k=1}^{K} \beta_{k} f_{k}\left(X_{i 1}, X_{i 2}, \cdots, X_{i p}\right)+\varepsilon_{i}, \quad i=1, \cdots, n
$$

where $f($.$) is a scalar-valued function of the independent variables, X_{i j} \mathrm{~s}$. The functions, $f(X)$, might be in any form including nonlinear functions or polynomials. The linearity, in the linear regression models, refers to the linearity of the coefficients $\beta_{k}$. That is, the response variable, $y$, is a linear function of the coefficients, $\beta_{k}$.

Some examples of linear models are:

$$
\begin{aligned}
y_{i} & =\beta_{0}+\beta_{1} X_{1 i}+\beta_{2} X_{2 i}+\beta_{3} X_{3 i}+\varepsilon_{i} \\
y_{i} & =\beta_{0}+\beta_{1} X_{1 i}+\beta_{2} X_{2 i}+\beta_{3} X_{1 i}^{3}+\beta_{4} X_{2 i}^{2}+\varepsilon_{i} \\
y_{i} & =\beta_{0}+\beta_{1} X_{1 i}+\beta_{2} X_{2 i}+\beta_{3} X_{1 i} X_{2 i}+\beta_{4} \log X_{3 i}+\varepsilon_{i}
\end{aligned}
$$

The following, however, are not linear models since they are not linear in the unknown coefficients, $\beta_{k}$.

$$
\begin{aligned}
& \log y_{i}=\beta_{0}+\beta_{1} X_{1 i}+\beta_{2} X_{2 i}+\varepsilon_{i} \\
& y_{i}=\beta_{0}+\beta_{1} X_{1 i}+\frac{1}{\beta_{2} X_{2 i}}+e^{\beta_{3} X_{1 i} X_{2 i}}+\varepsilon_{i}
\end{aligned}
$$

The usual assumptions for linear regression models are:

- The noise terms, $\varepsilon_{i}$, are uncorrelated.
- The noise terms, $\varepsilon_{i}$, have independent and identical normal distributions with mean zero and constant variance, $\sigma^{2}$. Thus

$$
\begin{aligned}
E\left(y_{i}\right) & =E\left(\sum_{k=0}^{K} \beta_{k} f_{k}\left(X_{i 1}, X_{i 2}, \cdots, X_{i p}\right)+\varepsilon_{i}\right) \\
& =\sum_{k=0}^{K} \beta_{k} f_{k}\left(X_{i 1}, X_{i 2}, \cdots, X_{i p}\right)+E\left(\varepsilon_{i}\right) \\
& =\sum_{k=0}^{K} \beta_{k} f_{k}\left(X_{i 1}, X_{i 2}, \cdots, X_{i p}\right)
\end{aligned}
$$

and

$$
V\left(y_{i}\right)=V\left(\sum_{k=0}^{K} \beta_{k} f_{k}\left(X_{i 1}, X_{i 2}, \cdots, X_{i p}\right)+\varepsilon_{i}\right)=V\left(\varepsilon_{i}\right)=\sigma^{2}
$$

So the variance of $y_{i}$ is the same for all levels of $X_{i j}$.

- The responses $y_{i}$ are uncorrelated.

The fitted linear function is

$$
\hat{y}_{i}=b_{0}+\sum_{k=1}^{K} b_{k} f_{k}\left(X_{i 1}, X_{i 2}, \cdots, X_{i p}\right), \quad i=1, \cdots, n
$$

where $\hat{y}_{i}$ is the estimated response and $b_{k} \mathrm{~s}$ are the fitted coefficients. The coefficients are estimated so as to minimize the mean squared difference between the prediction vector $b f(X)$ and the true response vector $y$, that is $\hat{y}-y$. This method is called the method of least squares. Under the assumptions on the noise terms, these coefficients also maximize the likelihood of the prediction vector.

In a linear regression model of the form $y=\beta_{1} \mathrm{X}_{1}+\beta_{2} \mathrm{X}_{2}+\ldots+\beta_{p} \mathrm{X}_{p}$, the coefficient $\beta_{k}$ expresses the impact of a one-unit change in predictor variable, $X_{j}$, on the mean of the response, $\mathrm{E}(y)$ provided that all other variables are held constant. The sign of the coefficient gives the direction of the effect. For example, if the linear model is $\mathrm{E}(y)=1.8-2.35 X_{1}+X_{2}$, then -2.35 indicates a 2.35 unit decrease in the mean response with a one-unit increase in $X_{1}$, given $X_{2}$ is held constant. If the model is $\mathrm{E}(y)=1.1+1.5 X_{1}^{2}+X_{2}$, the coefficient of $X_{1}^{2}$ indicates a 1.5 unit increase in the mean of $Y$ with a one-unit increase in $X_{1}^{2}$ given all else held constant. However, in the case of $\mathrm{E}(y)=1.1+2.1 X_{1}$ $+1.5 X_{1}^{2}$, it is difficult to interpret the coefficients similarly, since it is not possible to hold $X_{1}$ constant when $X_{1}^{2}$ changes or vice versa.

## Prepare Data

To begin fitting a regression, put your data into a form that fitting functions expect. All regression techniques begin with input data in an array $X$ and response data in a separate vector $y$, or input data in a dataset array ds and response data as a column in ds. Each row of the input data represents one observation. Each column represents one predictor (variable).

For a dataset array ds, indicate the response variable with the 'ResponseVar' name-value pair:

```
mdl = LinearModel.fit(ds,'ResponseVar','BloodPressure');
% or
mdl = GeneralizedLinearModel.fit(ds,'ResponseVar','BloodPressure');
```

The response variable is the last column by default.
You can use numeric categorical predictors. A categorical predictor is one that takes values from a fixed set of possibilities.

- For a numeric array X, indicate the categorical predictors using the 'Categorical' name-value pair. For example, to indicate that predictors 2 and 3 out of six are categorical:

```
mdl = LinearModel.fit(X,y,'Categorical',[2,3]);
% or
mdl = GeneralizedLinearModel.fit(X,y,'Categorical',[2,3]);
% or equivalently
mdl = LinearModel.fit(X,y,'Categorical',logical([[0 1 1 1 0 0 0]));
```

- For a dataset array ds, fitting functions assume that these data types are categorical:
- Logical
- Categorical (nominal or ordinal)
- String or character array

If you want to indicate that a numeric predictor is categorical, use the 'Categorical' name-value pair.

Represent missing numeric data as NaN. To represent missing data for other data types, see "Missing Group Values" on page 2-53.

## Dataset Array for Input and Response Data

For example, to create a dataset array from an Excel spreadsheet:

```
ds = dataset('XLSFile','hospital.xls',...
    'ReadObsNames',true);
```

To create a dataset array from workspace variables:

```
load carsmall
ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);
```

## Numeric Matrix for Input Data, Numeric Vector for Response

For example, to create numeric arrays from workspace variables:

```
load carsmall
X = [Weight Horsepower Cylinders Model_Year];
y = MPG;
```

To create numeric arrays from an Excel spreadsheet:

```
[X Xnames] = xlsread('hospital.xls');
y = X(:,4); % response y is systolic pressure
X(:,4) = []; % remove y from the X matrix
```

Notice that the nonnumeric entries, such as sex, do not appear in $X$.

## Choose a Fitting Method

There are three ways to fit a model to data:

- "Least-Squares Fit" on page 9-13
- "Robust Fit" on page 9-13
- "Stepwise Fit" on page 9-13

## Least-Squares Fit

Use LinearModel.fit to construct a least-squares fit of a model to the data. This method is best when you are reasonably certain of the model's form, and mainly need to find its parameters. This method is also useful when you want to explore a few models. The method requires you to examine the data manually to discard outliers, though there are techniques to help (see "Residuals - Model Quality for Training Data" on page 9-24).

## Robust Fit

Use LinearModel.fit with the RobustOpts name-value pair to create a model that is little affected by outliers. Robust fitting saves you the trouble of manually discarding outliers. However, step does not work with robust fitting. This means that when you use robust fitting, you cannot search stepwise for a good model.

## Stepwise Fit

Use LinearModel.stepwise to find a model, and fit parameters to the model. LinearModel.stepwise starts from one model, such as a constant, and adds or subtracts terms one at a time, choosing an optimal term each time in a greedy fashion, until it cannot improve further. Use stepwise fitting to find a good model, which is one that has only relevant terms.

The result depends on the starting model. Usually, starting with a constant model leads to a small model. Starting with more terms can lead to a more complex model, but one that has lower mean squared error. See "Compare large and small stepwise models" on page 9-111.

You cannot use robust options along with stepwise fitting. So after a stepwise fit, examine your model for outliers (see "Residuals - Model Quality for Training Data" on page 9-24).

## Choose a Model or Range of Models

There are several ways of specifying a model for linear regression. Use whichever you find most convenient.

- "Brief String" on page 9-15
- "Terms Matrix" on page 9-15
- "Formula" on page 9-19

For LinearModel.fit, the model specification you give is the model that is fit. If you do not give a model specification, the default is 'linear'.

For LinearModel.stepwise, the model specification you give is the starting model, which the stepwise procedure tries to improve. If you do not give a model specification, the default starting model is 'constant', and the default upper bounding model is 'interactions'. Change the upper bounding model using the Upper name-value pair.

Note Thee are other ways of selecting models, such as using lasso, lassoglm, sequentialfs, or plsregress.

## Brief String

| String | Model Type |
| :--- | :--- |
| 'constant' | Model contains only a constant (intercept) term. |
| 'linear' | Model contains an intercept and linear terms for <br> each predictor. |
| 'interactions' | Model contains an intercept, linear terms, and <br> all products of pairs of distinct predictors (no <br> squared terms). |
| 'purequadratic' | Model contains an intercept, linear terms, and <br> squared terms. |
| 'quadratic' | Model contains an intercept, linear terms, <br> interactions, and squared terms. |
| 'polyijk' | Model is a polynomial with all terms up to degree <br> i in the first predictor, degree $j$ in the second <br> predictor, etc. Use numerals 0 through 9. For <br> example, 'poly2111' has a constant plus all <br> linear and product terms, and also contains <br> terms with predictor 1 squared. |

For example, to specify an interaction model using LinearModel.fit with matrix predictors:
mdl = LinearModel.fit(X,y,'interactions');

To specify a model using LinearModel.stepwise and a dataset array ds of predictors, suppose you want to start from a constant and have a linear model upper bound. Assume the response variable in ds is in the third column.

```
mdl2 = LinearModel.stepwise(ds,'constant',...
    'Upper','linear','ResponseVar',3);
```

## Terms Matrix

A terms matrix is a T-by-P+1 matrix specifying terms in a model, where T is the number of terms, P is the number of predictor variables, and plus one is for the response variable. The value of $T(i, j)$ is the exponent of variable $j$ in term i. For example, if there are three predictor variables A, B, and C:

```
[0 0 0 0] % constant term or intercept
[0 1 0 0] % B; equivalently, A^0 * B^1 * C^0
[\begin{array}{llll}{1}&{0}&{1}&{0}\end{array}]% %*C
[2 0 0 0] % A^2
[00 1 2 0] % B*(C^2)
```

The 0 at the end of each term represents the response variable. In general,

- If you have the variables in a dataset array, then a 0 must represent the response variable depending on the position of the response variable in the dataset array. For example:

Load sample data and define the dataset array.

```
load hospital
ds = dataset(hospital.Sex,hospital.BloodPressure(:,1),hospital.Age,...
hospital.Smoker,'VarNames',{'Sex','BloodPressure','Age','Smoker'});
Represent the linear model 'BloodPressure ~ 1 + Sex + Age + Smoker' in a terms matrix. The response variable is in the second column of the data set array, so there must be a column of zeros for the response variable in the second column of the term matrix.
```

```
T = [0 0 0 0;1 0 0 0;0 0 1 0;0 0 0 1]
T =
\begin{tabular}{llll}
0 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{tabular}
```

Redefine the dataset array.

```
ds = dataset(hospital.BloodPressure(:,1),hospital.Sex,hospital.Age,...
hospital.Smoker,'VarNames',{'BloodPressure','Sex','Age','Smoker'});
```

Now, the response variable is the first term in the data set array. Specify the same linear model, 'BloodPressure ~ 1 + Sex + Age + Smoker', using a term matrix.

```
T = [0 0 0 0;0 1 0 0;0 0 1 0;0 0 0 1]
```

$\mathrm{T}=$

| 0 | 0 | 0 | 0 |
| :--- | :--- | :--- | :--- |
| 0 | 1 | 0 | 0 |
| 0 | 0 | 1 | 0 |
| 0 | 0 | 0 | 1 |

- If you have the predictor and response variables in a matrix and column vector, then you must include a 0 for the response variable at the end of each term. For example:

Load sample data and define the matrix of predictors.
load carsmall
X = [Acceleration, Weight];

Specify the model 'MPG ~ Acceleration + Weight + Acceleration:Weight + Weight^2' using a term matrix and fit the model to data. This model includes the main effect and two way interaction terms for the variables, Acceleration and Weight, and a second order term for the variable, Weight.

```
T = [0 0 0;1 0 0;0 1 0;1 1 0;0 2 0]
```

$\mathrm{T}=$

| 0 | 0 | 0 |
| :--- | :--- | :--- |
| 1 | 0 | 0 |
| 0 | 1 | 0 |
| 1 | 1 | 0 |
| 0 | 2 | 0 |

Fit a linear model.
mdl = LinearModel.fit(X,MPG,T)
mdl =

Linear regression model:
$y-1+x 1^{*} x 2+x 2^{\wedge} 2$

Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | ---: |
| (Intercept) | 48.906 | 12.589 | 3.8847 | 0.00019665 |
| x1 | 0.54418 | 0.57125 | 0.95261 | 0.34337 |
| x2 | -0.012781 | 0.0060312 | -2.1192 | 0.036857 |
| x1: x2 | -0.00010892 | 0.00017925 | -0.6076 | 0.545 |
| x2^2 | $9.7518 \mathrm{e}-07$ | $7.5389 \mathrm{e}-07$ | 1.2935 | 0.19917 |

Number of observations: 94, Error degrees of freedom: 89
Root Mean Squared Error: 4.1
R-squared: 0.751, Adjusted R-Squared 0.739
F-statistic vs. constant model: 67, p-value $=4.99 \mathrm{e}-26$
Only the intercept and $x 2$ term, which corresponds to the Weight variable, are significant at the $5 \%$ significance level.

Now, perform a stepwise regression with a constant model as the starting model and a linear model with interactions as the upper model.

```
T = [0 0 0;1 0 0;0 1 0;1 1 0];
mdl = LinearModel.stepwise(X,MPG,[O O O],'upper',T)
1. Adding x2, FStat = 259.3087, pValue = 1.643351e-28
mdl =
Linear regression model:
    y ~ 1 + x2
Estimated Coefficients:
\begin{tabular}{lrrrl} 
& Estimate & \multicolumn{1}{l}{ SE } & \multicolumn{1}{l}{ tStat } & pValue \\
(Intercept) & 49.238 & 1.6411 & 30.002 & \(2.7015 \mathrm{e}-49\) \\
x2 & -0.0086119 & 0.0005348 & -16.103 & \(1.6434 \mathrm{e}-28\)
\end{tabular}
Number of observations: 94, Error degrees of freedom: 92
Root Mean Squared Error: 4.13
R-squared: 0.738, Adjusted R-Squared 0.735
F-statistic vs. constant model: 259, p-value = 1.64e-28
```

The results of the stepwise regression are consistent with the results of LinearModel.fit in the previous step.

## Formula

A formula for a model specification is a string of the form
'Y ~ terms',

- $Y$ is the response name.
- terms contains
- Variable names
-     + to include the next variable
-     - to exclude the next variable
- : to define an interaction, a product of terms
-     * to define an interaction and all lower-order terms
- ^ to raise the predictor to a power, exactly as in * repeated, so ^ includes lower order terms as well
- () to group terms

Tip Formulas include a constant (intercept) term by default. To exclude a constant term from the model, include - 1 in the formula.

Examples:
' $Y \sim A+B+C '$ is a three-variable linear model with intercept.
' $Y \sim A+B+C-1 '$ is a three-variable linear model without intercept.
' $Y$ ~ $A+B+C+B \wedge 2 '$ is a three-variable model with intercept and a $B^{\wedge} 2$ term.
' Y ~ $\mathrm{A}+\mathrm{B}^{\wedge} 2+C$ ' is the same as the previous example, since $\mathrm{B}^{\wedge} 2$
includes a $B$ term.
' $Y$ ~ A + B + C + A:B' includes an A*B term.
' $Y$ ~ $A * B+C$ ' is the same as the previous example, since $A * B=A+B+$
A:B.
' $Y \sim A^{*} B^{*} C-A: B: C '$ has all interactions among $A, B$, and $C$, except the three-way interaction.
' $Y$ ~ $A^{*}(B+C+D)^{\prime}$ has all linear terms, plus products of $A$ with each of the other variables.

For example, to specify an interaction model using LinearModel.fit with matrix predictors:

```
mdl = LinearModel.fit(X,y,'y ~ x1*x2*x3 - x1:x2:x3');
```

To specify a model using LinearModel.stepwise and a dataset array ds of predictors, suppose you want to start from a constant and have a linear model upper bound. Assume the response variable in ds is named 'y', and the predictor variables are named 'x1', 'x2', and 'x3'.

```
mdl2 = LinearModel.stepwise(ds,'y ~ 1','Upper','y ~ x1 + x2 + x3');
```

## Fit Model to Data

The most common optional arguments for fitting:

- For robust regression in LinearModel.fit, set the 'RobustOpts' name-value pair to 'on'.
- Specify an appropriate upper bound model in LinearModel.stepwise, such as set 'Upper' to 'linear'.
- Indicate which variables are categorical using the 'CategoricalVars' name-value pair. Provide a vector with column numbers, such as [1 6] to specify that predictors 1 and 6 are categorical. Alternatively, give a logical vector the same length as the data columns, with a 1 entry indicating that variable is categorical. If there are seven predictors, and predictors 1 and 6 are categorical, specify logical([1, $0,0,0,0,1,0])$.
- For a dataset array, specify the response variable using the 'ResponseVar' name-value pair. The default is the last column in the array.

For example,

```
mdl = LinearModel.fit(X,y,'linear',...
    'RobustOpts','on','CategoricalVars',3);
mdl2 = LinearModel.stepwise(ds,'constant',...
    'ResponseVar','MPG','Upper','quadratic');
```

## Examine Quality and Adjust the Fitted Model

After fitting a model, examine the result.

- "Model Display" on page 9-21
- "ANOVA" on page 9-22
- "Diagnostic Plots" on page 9-23
- "Residuals - Model Quality for Training Data" on page 9-24
- "Plots to Understand Predictor Effects" on page 9-29
- "Plots to Understand Terms Effects" on page 9-34
- "Change Models" on page 9-36

## Model Display

A linear regression model shows several diagnostics when you enter its name or enter disp (mdl). This display gives some of the basic information to check whether the fitted model represents the data adequately.

For example, fit a linear model to data constructed with two out of five predictors not present and with no intercept term:
$X=r a n d n(100,5) ;$
$y=X *[1 ; 0 ; 3 ; 0 ;-1]+r a n d n(100,1)$;
mdl $=$ LinearModel.fit(X,y)
mdl =

Linear regression model:

```
    y ~ 1 + x1 + x2 + x3 + x4 + x5
```

Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | ---: |
| (Intercept) | 0.038164 | 0.099458 | 0.38372 | 0.70205 |
| x1 | 0.92794 | 0.087307 | 10.628 | $8.5494 \mathrm{e}-18$ |
| x2 | -0.075593 | 0.10044 | -0.75264 | 0.45355 |
| x3 | 2.8965 | 0.099879 | 29 | $1.1117 \mathrm{e}-48$ |
| x4 | 0.045311 | 0.10832 | 0.41831 | 0.67667 |
| x5 | -0.99708 | 0.11799 | -8.4504 | $3.593 \mathrm{e}-13$ |

Number of observations: 100, Error degrees of freedom: 94
Root Mean Squared Error: 0.972
R-squared: 0.93, Adjusted R-Squared 0.926
F-statistic vs. constant model: 248, p-value $=1.5 e-52$

Notice that:

- The display contains the estimated values of each coefficient in the Estimate column. These values are reasonably near the true values [0;1;0;3;0;-1].
- There is a standard error column for the coefficient estimates.
- The reported pValue (which are derived from the $t$ statistics under the assumption of normal errors) for predictors 1,3 , and 5 are extremely small. These are the three predictors that were used to create the response data $y$.
- The pValue for (Intercept), $x 2$ and $\times 4$ are much larger than 0.01 . These three predictors were not used to create the response data y.
- The display contains $R^{2}$, adjusted $R^{2}$, and $F$ statistics.

## ANOVA

To examine the quality of the fitted model, consult an ANOVA table. For example, use anova on a linear model with five predictors:

```
X = randn(100,5);
y = X*[1;0;3;0;-1]+randn(100,1);
mdl = LinearModel.fit(X,y);
tbl = anova(mdl)
```

tbl =

|  | SumSq | DF | MeanSq | F | pValue |
| :--- | ---: | ---: | ---: | ---: | ---: |
| x1 | 106.62 | 1 | 106.62 | 112.96 | $8.5494 \mathrm{e}-18$ |
| x2 | 0.53464 | 1 | 0.53464 | 0.56646 | 0.45355 |
| x3 | 793.74 | 1 | 793.74 | 840.98 | $1.1117 \mathrm{e}-48$ |
| x4 | 0.16515 | 1 | 0.16515 | 0.17498 | 0.67667 |
| x5 | 67.398 | 1 | 67.398 | 71.41 | $3.593 e-13$ |
| Error | 88.719 | 94 | 0.94382 |  |  |

This table gives somewhat different results than the default display (see "Model Display" on page 9-21). The table clearly shows that the effects of x2 and $x 4$ are not significant. Depending on your goals, consider removing x2 and $x 4$ from the model.

## Diagnostic Plots

Diagnostic plots help you identify outliers, and see other problems in your model or fit. For example, load the carsmall data, and make a model of MPG as a function of Cylinders (nominal) and Weight:

```
load carsmall
ds = dataset(Weight,MPG,Cylinders);
ds.Cylinders = ordinal(ds.Cylinders);
mdl = LinearModel.fit(ds,'MPG ~ Cylinders*Weight + Weight^2');
```

Make a leverage plot of the data and model.
plotDiagnostics(mdl)

There are a few points with high leverage. But this plot does not reveal whether the high-leverage points are outliers.

Look for points with large Cook's distance.

```
plotDiagnostics(mdl,'cookd')
```

Case order plot of Cook's distance

There is one point with large Cook's distance. Identify it and remove it from the model. You can use the Data Cursor to click the outlier and identify it, or identify it programmatically:

```
[~,larg] = max(mdl.Diagnostics.CooksDistance);
mdl2 = LinearModel.fit(ds,'MPG ~ Cylinders*Weight + Weight^2',...
    'Exclude',larg);
```

## Residuals - Model Quality for Training Data

There are several residual plots to help you discover errors, outliers, or correlations in the model or data. The simplest residual plots are the default histogram plot, which shows the range of the residuals and their frequencies,
and the probability plot, which shows how the distribution of the residuals compares to a normal distribution with matched variance.

Load the carsmall data, and make a model of MPG as a function of Cylinders (nominal) and Weight:
load carsmall
ds = dataset(Weight,MPG,Cylinders);
ds.Cylinders = ordinal(ds.Cylinders);
mdl = LinearModel.fit(ds,'MPG ~ Cylinders*Weight + Weight^2');
Examine the residuals:
plotResiduals(mdl)

Histogram of residuals

The observations above 12 are potential outliers.

```
plotResiduals(mdl,'probability')
```

Normal probability plot of residuals

The two potential outliers appear on this plot as well. Otherwise, the probability plot seems reasonably straight, meaning a reasonable fit to normally distributed residuals.

You can identify the two outliers and remove them from the data:
outl $=$ find(mdl.Residuals.Raw > 12)
outl =

90
97
To remove the outliers, use the Exclude name-value pair:

```
mdl2 = LinearModel.fit(ds,'MPG ~ Cylinders*Weight + Weight^2',...
    'Exclude',outl);
```

Examine a residuals plot of mdl2:
plotResiduals(mdl2)

Histogram of residuals

The new residuals plot looks fairly symmetric, without obvious problems. However, there might be some serial correlation among the residuals. Create a new plot to see if such an effect exists.
plotResiduals(mdl2,'lagged')

Plot of residuals vs. lagged residuals

The scatter plot shows many more crosses in the upper-right and lower-left quadrants than in the other two quadrants, indicating positive serial correlation among the residuals.

Another potential issue is when residuals are large for large observations. See if the current model has this issue.
plotResiduals(mdl2,'fitted')

There is some tendency for larger fitted values to have larger residuals. Perhaps the model errors are proportional to the measured values.

## Plots to Understand Predictor Effects

This example shows how to understand the effect each predictor has on a regression model using a variety of available plots.

1 Create a model of mileage from some predictors in the carsmall data.

```
load carsmall
ds = dataset(Weight,MPG,Cylinders);
ds.Cylinders = ordinal(ds.Cylinders);
mdl = LinearModel.fit(ds,'MPG ~ Cylinders*Weight + Weight^2');
```

2 Examine a slice plot of the responses. This displays the effect of each predictor separately.
plotSlice(mdl)

You can drag the individual predictor values, which are represented by dashed blue vertical lines. You can also choose between simultaneous and non-simultaneous confidence bounds, which are represented by dashed red curves.

3 Use an effects plot to show another view of the effect of predictors on the response.
plotEffects(mdl)

This plot shows that changing Weight from about 2500 to 4732 lowers MPG by about 30 (the location of the upper blue circle). It also shows that changing the number of cylinders from 8 to 4 raises MPG by about 10 (the lower blue circle). The horizontal blue lines represent confidence intervals for these predictions. The predictions come from averaging over one predictor as the other is changed. In cases such as this, where the two predictors are correlated, be careful when interpreting the results.

4 Instead of viewing the effect of averaging over a predictor as the other is changed, examine the joint interaction in an interaction plot.

```
plotInteraction(mdl,'Weight','Cylinders')
```

Interaction of Weight and Cylinders

The interaction plot shows the effect of changing one predictor with the other held fixed. In this case, the plot is much more informative. It shows, for example, that lowering the number of cylinders in a relatively light car
(Weight = 1795) leads to an increase in mileage, but lowering the number of cylinders in a relatively heavy car $($ Weight $=4732)$ leads to a decrease in mileage.

5 For an even more detailed look at the interactions, look at an interaction plot with predictions. This plot holds one predictor fixed while varying the other, and plots the effect as a curve. Look at the interactions for various fixed numbers of cylinders.
plotInteraction(mdl,'Cylinders','Weight','predictions')

Now look at the interactions with various fixed levels of weight.
plotInteraction(mdl,'Weight','Cylinders','predictions')

## Plots to Understand Terms Effects

This example shows how to understand the effect of each term in a regression model using a variety of available plots.

1 Create a model of mileage from some predictors in the carsmall data.

```
load carsmall
ds = dataset(Weight,MPG,Cylinders);
ds.Cylinders = ordinal(ds.Cylinders);
mdl = LinearModel.fit(ds,'MPG ~ Cylinders*Weight + Weight^2');
```

2 Create an added variable plot with Weight^2 as the added variable.

```
plotAdded(mdl,'Weight^2')
```

This plot shows the results of fitting both Weight^2 and MPG to the terms other than Weight^2. The reason to use plotAdded is to understand what additional improvement in the model you get by adding Weight^2. The coefficient of a line fit to these points is the coefficient of Weight^2 in the full model. The Weight^2 predictor is just over the edge of significance ( $p$ Value $<0.05$ ) as you can see in the coefficients table display. You can see that in the plot as well. The confidence bounds look like they could not contain a horizontal line (constant y), so a zero-slope model is not consistent with the data.

3 Create an added variable plot for the model as a whole.
plotAdded(mdl)

The model as a whole is very significant, so the bounds don't come close to containing a horizontal line. The slope of the line is the slope of a fit to the predictors projected onto their best-fitting direction, or in other words, the norm of the coefficient vector.

## Change Models

There are two ways to change a model:

- step - Add or subtract terms one at a time, where step chooses the most important term to add or remove.
- addTerms and removeTerms - Add or remove specified terms. Give the terms in any of the forms described in "Choose a Model or Range of Models" on page 9-14.

If you created a model using LinearModel.stepwise, step can have an effect only if you give different upper or lower models. step does not work when you fit a model using RobustOpts.

For example, start with a linear model of mileage from the carbig data:
load carbig
ds = dataset(Acceleration, Displacement, Horsepower, Weight, MPG);
mdl = LinearModel.fit(ds,'linear','ResponseVar','MPG')
mdl =
Linear regression model:
MPG ~ 1 + Acceleration + Displacement + Horsepower + Weight
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :---: | :---: | :---: | :---: | :---: |
| (Intercept) | 45.251 | 2.456 | 18.424 | $7.0721 \mathrm{e}-55$ |
| Acceleration | -0.023148 | 0.1256 | -0.1843 | 0.85388 |
| Displacement | -0.0060009 | 0.0067093 | -0.89441 | 0.37166 |
| Horsepower | -0.043608 | 0.016573 | -2.6312 | 0.008849 |
| Weight | -0.0052805 | 0.00081085 | -6.5123 | 2.3025e-10 |

Number of observations: 392, Error degrees of freedom: 387
Root Mean Squared Error: 4.25
R-squared: 0.707, Adjusted R-Squared 0.704
F-statistic vs. constant model: 233, p-value = 9.63e-102
Try to improve the model using step for up to 10 steps:
mdl1 = step(mdl,'NSteps',10)

1. Adding Displacement:Horsepower, FStat $=87.4802, \mathrm{pValue}=7.05273 \mathrm{e}-19$
mdl1 $=$

Linear regression model:
MPG ~ 1 + Acceleration + Weight + Displacement*Horsepower

Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | ---: |
| (Intercept) | 61.285 | 2.8052 | 21.847 | $1.8593 \mathrm{e}-69$ |
| Acceleration | -0.34401 | 0.11862 | -2.9 | 0.0039445 |
| Displacement | -0.081198 | 0.010071 | -8.0623 | $9.5014 \mathrm{e}-15$ |
| Horsepower | -0.24313 | 0.026068 | -9.3265 | $8.6556 \mathrm{e}-19$ |
| Weight | -0.0014367 | 0.00084041 | -1.7095 | 0.088166 |
| Displacement:Horsepower | 0.00054236 | $5.7987 \mathrm{e}-05$ | 9.3531 | $7.0527 \mathrm{e}-19$ |

```
Number of observations: 392, Error degrees of freedom: 386
Root Mean Squared Error: 3.84
R-squared: 0.761, Adjusted R-Squared 0.758
F-statistic vs. constant model: 246, p-value = 1.32e-117
```

step stopped after just one change.
To try to simplify the model, remove the Acceleration and Weight terms from mdl1:
mdl2 = removeTerms(mdl1,'Acceleration + Weight')
mdl2 $=$

Linear regression model
MPG ~ 1 + Displacement*Horsepower

Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | :--- |
| (Intercept) | 53.051 | 1.526 | 34.765 | $3.0201 \mathrm{e}-121$ |
| Displacement | -0.098046 | 0.0066817 | -14.674 | $4.3203 \mathrm{e}-39$ |
| Horsepower | -0.23434 | 0.019593 | -11.96 | $2.8024 \mathrm{e}-28$ |
| Displacement:Horsepower | 0.00058278 | $5.193 \mathrm{e}-05$ | 11.222 | $1.6816 \mathrm{e}-25$ |

```
Number of observations: 392, Error degrees of freedom: 388
Root Mean Squared Error: 3.94
R-squared: 0.747, Adjusted R-Squared 0.745
```

```
F-statistic vs. constant model: 381, p-value \(=3 e-115\)
```

mdl2 uses just Displacement and Horsepower, and has nearly as good a fit to the data as mdl1 in the Adjusted R-Squared metric.

## Predict or Simulate Responses to New Data

There are three ways to use a linear model to predict or simulate the response to new data:

- "predict" on page 9-39
- "feval" on page 9-40
- "random" on page 9-41

## predict

This example shows how to predict and obtain confidence intervals on the predictions using the predict method.

1 Load the carbig data and make a default linear model of the response MPG to the Acceleration, Displacement, Horsepower, and Weight predictors.
load carbig
X = [Acceleration, Displacement, Horsepower, Weight];
mdl = LinearModel.fit(X,MPG);
2 Create a three-row array of predictors from the minimal, mean, and maximal values. There are some NaN values, so use functions that ignore NaN values.

Xnew $=[$ nanmin $(X) ;$ nanmean $(X) ; n a n m a x(X)] ;$ new data
3 Find the predicted model responses and confidence intervals on the predictions.
[NewMPG NewMPGCI] = predict(mdl,Xnew)
NewMPG =
34.1345
23.4078
4.7751

## NewMPGCI =

$$
\begin{array}{rr}
31.6115 & 36.6575 \\
22.9859 & 23.8298 \\
0.6134 & 8.9367
\end{array}
$$

The confidence bound on the mean response is narrower than those for the minimum or maximum responses, which is quite sensible.

## feval

When you construct a model from a dataset array, feval is often more convenient for predicting mean responses than predict. However, feval does not provide confidence bounds.

This example shows how to predict mean responses using the feval method.
1 Load the carbig data and make a default linear model of the response MPG to the Acceleration, Displacement, Horsepower, and Weight predictors.
load carbig
ds = dataset(Acceleration, Displacement,Horsepower, Weight, MPG);
mdl = LinearModel.fit(ds,'linear','ResponseVar','MPG');
2 Create a three-row array of predictors from the minimal, mean, and maximal values. There are some NaN values, so use functions that ignore NaN values.

X = [Acceleration,Displacement,Horsepower, Weight];
Xnew $=[$ nanmin $(X) ;$ nanmean $(X) ; n a n m a x(X)] ;$ new data
The Xnew array is not a dataset array. It has the right number of columns for prediction, so feval can use it for predictions.

3 Find the predicted model responses.

```
NewMPG = feval(mdl,Xnew)
```

```
NewMPG =
```

    34.1345
    23.4078
            4.7751
    
## random

The random method simulates new random response values, equal to the mean prediction plus a random disturbance with the same variance as the training data.

This example shows how to simulate responses using the random method.

1 Load the carbig data and make a default linear model of the response MPG to the Acceleration, Displacement, Horsepower, and Weight predictors.
load carbig
X = [Acceleration, Displacement, Horsepower, Weight];
mdl $=$ LinearModel.fit(X,MPG);
2 Create a three-row array of predictors from the minimal, mean, and maximal values. There are some NaN values, so use functions that ignore NaN values.

Xnew $=$ [nanmin $(X)$; nanmean $(X) ;$ nanmax $(X)]$; new data

3 Generate new predicted model responses including some randomness.

```
rng('default') % for reproducibility
NewMPG = random(mdl,Xnew)
NewMPG =
```

    36.4178
    31.1958
    -4.8176
    4 Because a negative value of MPG does not seem sensible, try predicting two more times.

NewMPG = random(mdl,Xnew)

NewMPG =
37.7959
24.7615
-0.7783

```
NewMPG = random(mdl,Xnew)
NewMPG =
```

    32.2931
    24.8628
    19.9715
    Clearly, the predictions for the third (maximal) row of Xnew are not reliable.

## Share Fitted Models

Suppose you have a linear regression model, such as mdl from the following commands:

```
load carbig
ds = dataset(Acceleration,Displacement,Horsepower,Weight,MPG);
mdl = LinearModel.fit(ds,'linear','ResponseVar','MPG');
```

To share the model with other people, you can:

- Provide the model display.
mdl
$\mathrm{mdl}=$

Linear regression model:
MPG ~ 1 + Acceleration + Displacement + Horsepower + Weight

Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | ---: |
| (Intercept) | 45.251 | 2.456 | 18.424 | $7.0721 \mathrm{e}-55$ |
| Acceleration | -0.023148 | 0.1256 | -0.1843 | 0.85388 |
| Displacement | -0.0060009 | 0.0067093 | -0.89441 | 0.37166 |
| Horsepower | -0.043608 | 0.016573 | -2.6312 | 0.008849 |
| Weight | -0.0052805 | 0.00081085 | -6.5123 | $2.3025 e-10$ |

Number of observations: 392, Error degrees of freedom: 387
Root Mean Squared Error: 4.25

```
R-squared: 0.707, Adjusted R-Squared 0.704
F-statistic vs. constant model: 233, p-value = 9.63e-102
```

- Provide just the model definition and coefficients.

```
mdl.CoefficientNames
ans =
    '(Intercept)' 'Acceleration' 'Displacement' 'Horsepower'
```

mdl. Coefficients.Estimate
ans =
45.2511
-0.0231
-0.0060
-0.0436
-0.0053
mdl.Formula
ans =
MPG ~ 1 + Acceleration + Displacement + Horsepower + Weight

## Linear Regression Workflow

This example shows a typical workflow: import data, fit a regression, test its quality, modify it to improve the quality, and share it.

## Step 1. Import the data into a dataset array.

hospital.xls is an Excel spreadsheet containing patient names, sex, age, weight, blood pressure, and dates of treatment in an experimental protocol. First read the data into a dataset array.

```
patients = dataset('XLSFile','hospital.xls',...
    'ReadObsNames',true);
```

Examine the first row of data.

```
patients(1,:)
ans =
    llllll
    lllllll
```

The sex and smoke fields seem to have two choices each. So change these fields to nominal.

```
patients.smoke = nominal(patients.smoke,{'No','Yes'});
patients.sex = nominal(patients.sex);
```

## Step 2. Create a fitted model.

Your goal is to model the systolic pressure as a function of a patient's age, weight, sex, and smoking status. Create a linear formula for 'sys' as a function of 'age', 'wgt', 'sex', and 'smoke'.

```
modelspec = 'sys ~ age + wgt + sex + smoke';
```

mdl = LinearModel.fit(patients,modelspec)
mdl =
Linear regression model:
sys ~ 1 + sex + age + wgt + smoke
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | :--- |
| (Intercept) | 118.28 | 7.6291 | 15.504 | $9.1557 \mathrm{e}-28$ |
| sex_m | 0.88162 | 2.9473 | 0.29913 | 0.76549 |
| age | 0.08602 | 0.06731 | 1.278 | 0.20438 |
| wgt | -0.016685 | 0.055714 | -0.29947 | 0.76524 |
| smoke_Yes | 9.884 | 1.0406 | 9.498 | $1.9546 \mathrm{e}-15$ |

[^1]```
R-squared: 0.508, Adjusted R-Squared 0.487
F-statistic vs. constant model: 24.5, p-value = 5.99e-14
```

The sex, age, and weight predictors have rather high $p$-values, indicating that some of these predictors might be unnecessary.

## Step 3. Locate and remove outliers.

See if there are outliers in the data that should be excluded from the fit. Plot the residuals.
plotResiduals(mdl)

Histogram of residuals

There is one possible outlier, with a value greater than 12 . This is probably not truly an outlier. For demonstration, here is how to find and remove it.

Find the outlier.

```
outlier = mdl.Residuals.Raw > 12;
find(outlier)
ans =
    84
```

Remove the outlier.

```
mdl = LinearModel.fit(patients,modelspec,...
    'Exclude', 84);
mdl.ObservationInfo(84,:)
ans =
\begin{tabular}{lllll} 
& Weights & Excluded & Missing & Subset \\
WXM-486 & 1 & true & false & false
\end{tabular}
```

Observation 84 is no longer in the model.

## Step 4. Simplify the model.

Try to obtain a simpler model, one with fewer predictors but the same predictive accuracy. step looks for a better model by adding or removing one term at a time. Allow step take up to 10 steps.

```
mdl1 = step(mdl,'NSteps',10)
1. Removing wgt, FStat = 4.6001e-05, pValue = 0.9946
2. Removing sex, FStat = 0.063241, pValue = 0.80199
mdl1 =
Linear regression model:
    sys ~ 1 + age + smoke
Estimated Coefficients:
\begin{tabular}{lrrrr} 
& Estimate & \multicolumn{1}{l}{ SE } & tStat & \multicolumn{1}{l}{ pValue } \\
(Intercept) & 115.11 & 2.5364 & 45.383 & \(1.1407 \mathrm{e}-66\) \\
age & 0.10782 & 0.064844 & 1.6628 & 0.09962 \\
smoke_Yes & 10.054 & 0.97696 & 10.291 & \(3.5276 \mathrm{e}-17\)
\end{tabular}
```

```
Number of observations: 99, Error degrees of freedom: 96
Root Mean Squared Error: 4.61
R-squared: 0.536, Adjusted R-Squared 0.526
F-statistic vs. constant model: 55.4, p-value = 1.02e-16
```

step took two steps. This means it could not improve the model further by adding or subtracting a single term.

Plot the effectiveness of the simpler model on the training data.
plotResiduals(mdl1)

Histogram of residuals

The residuals look about as small as those of the original model.

## Step 5. Predict responses to new data.

Suppose you have four new people, aged 25, 30, 40, and 65, and the first and third smoke. Predict their systolic pressure using mdl1.

```
ages = [25;30;40;65];
smoker = {'Yes';'No';'Yes';'No'};
systolicnew = feval(mdl1,ages,smoker)
systolicnew =
```

    127.8561
    118.3412
    129.4734
    122.1149
    To make predictions, you need only the variables that mdl1 uses.

## Step 6. Share the model.

You might want others to be able to use your model for prediction. Access the terms in the linear model.

```
coefnames = mdl1.CoefficientNames
coefnames =
    '(Intercept)' 'age' 'smoke_Yes'
```

View the model formula.
mdl1.Formula
ans $=$
sys ~ 1 + age + smoke
Access the coefficients of the terms.

```
coefvals = mdl1.Coefficients(:,1); % dataset array
coefvals = double(coefvals)
```

```
coefvals =
    115.1066
        0.1078
        10.0540
```

The model is sys $=115.1066+0.1078 *$ age $+10.0540 *$ smoke, where smoke is 1 for a smoker, and 0 otherwise.

## Regression Using Dataset Arrays

This example shows how to perform linear and stepwise regression analyses using dataset arrays.

## Load sample data.

load imports-85

## Store predictor and response variables in dataset array.

```
ds = dataset(X(:,7),X(:,8),X(:,9),X(:,15),'Varnames',...
```

\{'curb_weight','engine_size','bore', 'price'\});

## Fit linear regression model.

Fit a linear regression model that explains the price of a car in terms of its curb weight, engine size, and bore.

```
LinearModel.fit(ds,'price~curb_weight+engine_size+bore')
```

ans =

Linear regression model:

```
    price ~ 1 + curb_weight + engine_size + bore
```

Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | ---: |
| (Intercept) | 64.095 | 3.703 | 17.309 | $2.0481 \mathrm{e}-41$ |
| curb_weight | -0.0086681 | 0.0011025 | -7.8623 | $2.42 \mathrm{e}-13$ |
| engine_size | -0.015806 | 0.013255 | -1.1925 | 0.23452 |
| bore | -2.6998 | 1.3489 | -2.0015 | 0.046711 |

Number of observations: 201, Error degrees of freedom: 197
Root Mean Squared Error: 3.95
R-squared: 0.674, Adjusted R-Squared 0.669
F-statistic vs. constant model: 136, p-value $=1.14 \mathrm{e}-47$

The following command also returns the same result because LinearModel.fit, by default, assumes the predictor variable is in the last column of the dataset array ds.

```
LinearModel.fit(ds)
```

## Recreate dataset array and repeat analysis.

This time, put the response variable in the first column of the dataset array.

```
ds = dataset(X(:,15),X(:,7),X(:,8),X(:,9),'Varnames',...
{'price','curb_weight','engine_size','bore'});
```

When the response variable is in the first column of ds, define its location. For example, LinearModel.fit, by default, assumes that bore is the response variable. You can define the response variable in the model using either:

```
LinearModel.fit(ds,'ResponseVar','price');
```

or
LinearModel.fit(ds,'ResponseVar',logical([1 0000$])) ;$

## Perform stepwise regression.

```
LinearModel.stepwise(ds,'quadratic','lower','price~1',...
'ResponseVar','price')
1. Removing bore^2, FStat = 0.01282, pValue = 0.90997
2. Removing engine_size^2, FStat = 0.078043, pValue = 0.78027
3. Removing curb_weight:bore, FStat = 0.70558, pValue = 0.40195
ans =
```

Linear regression model:
price ~ 1 + curb_weight*engine_size + engine_size*bore + curb_weight^2
Estimated Coefficients:

|  | Estimate | SE |  | tStat |
| :--- | ---: | ---: | ---: | ---: |
| ( Intercept) | 131.13 |  | 14.273 | 9.1873 |
| curb_weight | -0.043315 | 0.0085114 | -5.0891 | 6.23 |

| engine_size | -0.17102 | 0.13844 | -1.2354 |
| :--- | ---: | ---: | ---: |
| bore | -12.244 | 4.999 | -2.4493 |
| curb_weight:engine_size | $-6.3411 e-05$ | $2.6577 e-05$ | -2.386 |
| engine_size:bore | 0.092554 | 0.037263 | 2.4838 |
| curb_weight^2 | $8.0836 e-06$ | $1.9983 e-06$ | 4.0451 |

```
Number of observations: 201, Error degrees of freedom: 194
Root Mean Squared Error: 3.59
R-squared: 0.735, Adjusted R-Squared 0.726
F-statistic vs. constant model: 89.5, p-value = 3.58e-53
```

The initial model is a quadratic formula, and the lowest model considered is the constant. Here, LinearModel.stepwise performs a backward elimination technique to determine the terms in the model. The final model is price ~ 1 + curb_weight*engine_size + engine_size*bore + curb_weight^2, which corresponds to

$$
\mathrm{P}=\beta_{0}+\beta_{C} C+\beta_{E} E+\beta_{B} B+\beta_{C E} C E+\beta_{E B} E B+\beta_{C^{2}} C^{2}+\varepsilon
$$

where $P$ is price, $C$ is curb weight, $E$ is engine size, $B$ is bore, $\beta_{i}$ is the coefficient for the corresponding term in the model, and $\varepsilon$ is the error term. The final model includes all three main effects, the interaction effects for curb weight and engine size and engine size and bore, and the second-order term for curb weight.

## Linear Regression with Interaction Effects

This example shows how to construct and analyze a linear regression model with interaction effects and interpret the results.

## Load sample data.

load hospital
To retain only the first column of blood pressure, store data in a new dataset array.
ds = dataset(hospital.Sex,hospital.Age,hospital.Weight,hospital.Smoker,... hospital.BloodPressure(:,1), 'Varnames',\{'Sex','Age','Weight','Smoker',... 'BloodPressure'\});

## Perform stepwise linear regression.

For the initial model, use the full model with all terms and their pairwise interactions.

```
mdl = LinearModel.stepwise(ds,'interactions')
```

1. Removing Sex:Smoker, FStat $=0.050738$, pValue $=0.8223$
2. Removing Weight:Smoker, FStat $=0.07758$, pValue $=0.78124$
3. Removing Age:Weight, FStat $=1.9717$, pValue $=0.16367$
4. Removing Sex:Age, FStat $=0.32389$, pValue $=0.57067$
5. Removing Age:Smoker, FStat $=2.4939$, pValue $=0.11768$
mdl =
Linear regression model:
BloodPressure ~ 1 + Age + Smoker + Sex*Weight
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | ---: |
| (Intercept) | 133.17 | 10.337 | 12.883 | $1.76 \mathrm{e}-22$ |
| Sex_Male | -35.269 | 17.524 | -2.0126 | 0.047015 |
| Age | 0.11584 | 0.067664 | 1.712 | 0.090198 |
| Weight | -0.1393 | 0.080211 | -1.7367 | 0.085722 |

| Smoker_1 | 9.8307 | 1.0229 | 9.6102 | $1.2391 \mathrm{e}-15$ |
| :--- | ---: | ---: | ---: | ---: |
| Sex_Male:Weight | 0.2341 | 0.11192 | 2.0917 | 0.039162 |

```
Number of observations: 100, Error degrees of freedom: 94
Root Mean Squared Error: 4.72
R-squared: 0.53, Adjusted R-Squared 0.505
F-statistic vs. constant model: 21.2, p-value = 4e-14
```

The final model in formula form is BloodPressure ~ $1+$ Age + Smoker + Sex*Weight. This model includes all four main effects (Age, Smoker, Sex, Weight) and the two-way interaction between Sex and Weight. This model corresponds to

$$
B P=\beta_{0}+\beta_{A} X_{A}+\beta_{S m} I_{S m}+\beta_{S} I_{S}+\beta_{W} X_{W}+\beta_{S W} X_{W} I_{S}+\varepsilon
$$

where

- $B P$ is the blood pressure
- $\beta_{i} \mathrm{~s}$ are the coefficients
- $I_{S m}$ is the indicator variable for smoking; $I_{S m}=1$ indicates a smoking patient whereas $I_{S m}=0$ indicates a nonsmoking patient
- $I_{S}$ is the indicator variable for sex; $I_{S}=1$ indicates a male patient whereas $I_{S}=0$ indicates a female patient
- $X_{A}$ is the Age variable
- $X_{W}$ is the Weight variable
- $\varepsilon$ is the error term

The following table shows the fitted linear model for each gender and smoking combination.

| $\mathbf{I}_{\mathbf{S m}}$ | $\mathbf{I}_{\mathbf{s}}$ | Linear Model |
| :--- | :--- | :--- |
| 1 (Male) | 1 (Smoker) | $B P=\left(\beta_{0}+\beta_{S m}+\beta_{S}\right)+\beta_{A} X_{A}+\left(\beta_{W}+\beta_{S W}\right) X_{W}$ <br> $B P=107.5617+0.11584 X_{A}+0.11826 X_{W}$ |
| 1 (Male) | 0 (Nonsmoker) | $B P=\left(\beta_{0}+\beta_{S m}\right)+\beta_{A} X_{A}+\beta_{W} X_{W}$ |
| 0 (Female) | 1 (Smoker) | $B P=\left(\beta_{0}+\beta_{S}\right)+\beta_{A} X_{A}+\left(\beta_{W}+\beta_{S W}\right) X W$ <br> $B P=97.901+0.11584 X_{A}+0.11826 X_{W}$ |
| 0 (Female) | 0 (Nonsmoker) | $B P=\beta_{0}+\beta_{A} X_{A}+\beta_{W} X_{W}$ <br> $B P=133.17+0.11584 X_{A}-0.1393 X_{W}$ |

As seen from these models, $\beta_{S m}$ and $\beta_{S}$ show how much the intercept of the response function changes when the indicator variable takes the value 1 compared to when it takes the value 0. $\beta_{S W}$, however, shows the effect of the Weight variable on the response variable when the indicator variable for sex takes the value 1 compared to when it takes the value 0 . You can explore the main and interaction effects in the final model using the methods of the LinearModel class as follows.

Plot prediction slice plots.
figure()
plotSlice(mdl)

This plot shows the main effects for all predictor variables. The green line in each panel shows the change in the response variable as a function of the predictor variable when all other predictor variables are held constant. For example, for a smoking male patient aged 37.5 , the expected blood pressure increases as the weight of the patient increases, given all else the same.

The dashed red curves in each panel show the $95 \%$ confidence bounds for the predicted response values.

The horizontal dashed blue line in each panel shows the predicted response for the specific value of the predictor variable corresponding to the vertical dashed blue line. You can drag these lines to get the predicted response values at other predictor values, as shown next.

For example, the predicted value of the response variable is 118.3497 when a patient is female, nonsmoking, age 40.3788 , and weighs 139.9545 pounds. The values in the square brackets, [114.621, 122.079], show the lower and upper limits of a $95 \%$ confidence interval for the estimated response. Note that, for a nonsmoking female patient, the expected blood pressure decreases as the weight increases, given all else is held constant.

## Plot main effects.

```
figure()
plotEffects(mdl)
```

This plot displays the main effects. The circles show the magnitude of the effect and the blue lines show the upper and lower confidence limits for the main effect. For example, being a smoker increases the expected blood pressure by 10 units, compared to being a nonsmoker, given all else is held constant. Expected blood pressure increases about two units for males compared to females, again, given other predictors held constant. An increase in age from 25 to 50 causes an expected increase of 4 units, whereas a change in weight from 111 to 202 causes about a 4 -unit decrease in the expected blood pressure, given all else held constant.

## Plot interaction effects.

```
figure()
plotInteraction(mdl,'Sex','Weight')
```

This plot displays the impact of a change in one factor given the other factor is fixed at a value.

> Note Be cautious while interpreting the interaction effects. When there is not enough data on all factor combinations or the data is highly correlated, it might be difficult to determine the interaction effect of changing one factor while keeping the other fixed. In such cases, the estimated interaction effect is an extrapolation from the data.

The blue circles show the main effect of a specific term, as in the main effects plot. The red circles show the impact of a change in one term for fixed values of the other term. For example, in the bottom half of this plot, the red circles show the impact of a weight change in female and male patients, separately. You can see that an increase in a female's weight from 111 to 202 pounds causes about a 14 -unit decrease in the expected blood pressure, while an increase of the same amount in the weight of a male patient causes about a 5 -unit increase in the expected blood pressure, again given other predictors are held constant.

## Plot prediction effects.

figure()
plotInteraction(mdl,'Sex','Weight','predictions')

This plot shows the effect of changing one variable as the other predictor variable is held constant. In this example, the last figure shows the response variable, blood pressure, as a function of weight, when the variable sex is fixed at males and females. The lines for males and females are crossing which indicates a strong interaction between weight and sex. You can see that the expected blood pressure increases as the weight of a male patient increases, but decreases as the weight of a female patient increases.

Examples

## Interpret Linear Regression Results

This example shows how to display and interpret linear regression output statistics.

## Load sample data and define predictor variables.

```
load carsmall
X = [Weight,Horsepower,Acceleration];
```

Fit linear regression model.

```
lm = LinearModel.fit(X,MPG,'linear')
lm =
```

Linear regression model:
$y \sim 1+x 1+x 2+x 3$
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | ---: |
| (Intercept) | 47.977 | 3.8785 | 12.37 | $4.8957 \mathrm{e}-21$ |
| x1 | -0.0065416 | 0.0011274 | -5.8023 | $9.8742 \mathrm{e}-08$ |
| x2 | -0.042943 | 0.024313 | -1.7663 | 0.08078 |
| x3 | -0.011583 | 0.19333 | -0.059913 | 0.95236 |

Number of observations: 93, Error degrees of freedom: 89 Root Mean Squared Error: 4.09
R-squared: 0.752, Adjusted R-Squared 0.744
F-statistic vs. constant model: 90, p-value = 7.38e-27
This linear regression outputs display shows the following.

| $\begin{aligned} & y \sim 1+x 1+x 2 \\ & +x 3 \end{aligned}$ | Linear regression model in the formula form using Wilkinson notation. Here it corresponds to: $y=\beta_{0}+\beta_{1} X_{1}+\beta_{2} X_{2}+\beta_{3} X_{3}+\varepsilon$ |
| :---: | :---: |
| First column (under Estimated Coefficients) | Terms included in the model. |
| Estimate | Coefficient estimates for each corresponding term in the model. For example, the estimate for the constant term (intercept) is 47.977 . |
| SE | Standard error of the coefficients. |
| tStat | $t$-statistic for each coefficient to test the null hypothesis that the corresponding coefficient is zero against the alternative that it is different from zero, given the other predictors in the model. Note that tStat $=$ Estimate/SE. For example, the $t$-statistic for the intercept is $47.977 / 3.8785=12.37$. |
| pValue | $p$-value for the F statistic of the hypotheses test that the corresponding coefficient is equal to zero or not. For example, the $p$-value of the F -statistic for x 2 is greater than 0.05 , so this term is not significant at the $5 \%$ significance level given the other terms in the model. |
| Number of observations | Number of rows without any NaN values. For example, Number of observations is 93 because the MPG data vector has 6 NaN values and one of the data vectors, Horsepower, has one NaN value for a different observation. |
| Error degrees of freedom | $n-p$, where $n$ is the number of observations, and $p$ is the number of coefficients in the model, including the intercept. For example, the model has four predictors, so the Error degrees of freedom is $93-4=89$. |
| Root mean squared error | Square root of the mean squared error, which estimates the standard deviation of the error distribution. |

| R-squared <br> and Adjusted <br> R-squared | Coefficient of determination and adjusted coefficient <br> of determination, respectively. For example, the <br> R-squared value suggests that the model explains <br> approximately $75 \%$ of the variability in the response <br> variable MPG. |
| :--- | :--- |
| F-statistic vs. <br> constant model | Test statistic for the F-test on the regression model. <br> It tests for a significant linear regression relationship <br> between the response variable and the predictor <br> variables. |
| p-value | $p$-value for the F-test on the model. For example, the <br> model is significant with a $p$-value of $7.3816 e-27$. |

You can request this display by using disp. For example, if you name your model lm, then you can display the outputs using disp(lm).

## Perform analysis of variance (ANOVA) for the model.

```
anova(lm,'summary')
```

ans =

|  | SumSq | DF | MeanSq | F | pValue |
| :--- | ---: | ---: | ---: | :--- | :--- |
| Total | 6004.8 | 92 | 65.269 |  |  |
| Model | 4516 | 3 | 1505.3 | 89.987 | $7.3816 \mathrm{e}-27$ |
| Residual | 1488.8 | 89 | 16.728 |  |  |

This ANOVA display shows the following.

| SumSq | Sum of squares for the regression model, Model, the error term, Residual, and the total, Total. |
| :---: | :---: |
| DF | Degrees of freedom for each term. Degrees of freedom is $n-1$ for the total, $p-1$ for the model, and $n-p$ for the error term, where $n$ is the number of observations, and $p$ is the number of coefficients in the model, including the intercept. For example, MPG data vector has six NaN values and one of the data vectors, Horsepower, has one NaN value for a different observation, so the total degrees of freedom is $93-1=92$. There are four coefficients in the model, so the model DF is $4-1=3$, and the DF for error term is $93-4=89$. |
| MeanSq | Mean squared error for each term. Note that MeanSq = SumSq/DF. For example, the mean squared error for the error term is $1488.8 / 89=16.728$. The square root of this value is the root mean squared error in the linear regression display, or 4.09. |
| F | F-statistic value, which is the same as F-statistic vs. constant model in the linear regression display. In this example, it is 89.987, and in the linear regression display this F-statistic value is rounded up to 90 . |
| pValue | $p$-value for the F-test on the model. In this example, it is 7.3816e-27. |

Note If there are higher-order terms in the regression model, anova partitions the model SumSq into the part explained by the higher-order terms and the rest. The corresponding F-statistics are for testing the significance of the linear terms and higher-order terms as separate groups.

If the data includes replicates, or multiple measurements at the same predictor values, then the anova partitions the error SumSq into the part for the replicates and the rest. The corresponding F-statistic is for testing the lack-of-fit by comparing the model residuals with the model-free variance estimate computed on the replicates.

See the anova method for details.

## Decompose ANOVA table for model terms.

```
anova(lm)
ans =
\begin{tabular}{lrrrrr} 
& \multicolumn{1}{l}{ SumSq } & DF & \multicolumn{1}{c}{ MeanSq } & \multicolumn{1}{l}{ F } & \multicolumn{1}{l}{ pValue } \\
x1 & 563.18 & 1 & 563.18 & 33.667 & \(9.8742 \mathrm{e}-08\) \\
x2 & 52.187 & 1 & 52.187 & 3.1197 & 0.08078 \\
x3 & 0.060046 & 1 & 0.060046 & 0.0035895 & 0.95236 \\
Error & 1488.8 & 89 & 16.728 & &
\end{tabular}
```

This anova display shows the following:

| First <br> column | Terms included in the model. |
| :--- | :--- |
| SumSq | Sum of squared error for each term except for the constant. |
| DF | Degrees of freedom. In this example, DF is 1 for each term in <br> the model and $n-p$ for the error term, where $n$ is the number <br> of observations, and $p$ is the number of coefficients in the <br> model, including the intercept. For example, the DF for the <br> error term in this model is $93-4=89$. <br> If any of the variables in the model is a categorical variable, <br> the DF for that variable is the number of indicator variables <br> created for its categories (number of categories - 1). |
| MeanSq | Mean squared error for each term. Note that MeanSq = <br> SumSq/DF. For example, the mean squared error for the error <br> term is 1488.8/89 =16.728. |

| F | F-values for each coefficient. The F-value is the ratio of the mean squared of each term and mean squared error, that is, F $=$ MeanSq $\left(\mathrm{x}_{\mathrm{i}}\right) / \mathrm{MeanSq}($ Error $)$. Each F-statistic has an F distribution, with the numerator degrees of freedom, DF value for the corresponding term, and the denominator degrees of freedom, $n-p . n$ is the number of observations, and $p$ is the number of coefficients in the model. In this example, each F -statistic has an $\mathrm{F}_{(1,89)}$ distribution. |
| :---: | :---: |
| pValue | $p$-value for each hypothesis test on the coefficient of the corresponding term in the linear model. For example, the $p$-value for the F-statistic coefficient of x 2 is 0.08078 , and is not significant at the $5 \%$ significance level given the other terms in the model. |

## Display coefficient confidence intervals.

coefCI (lm)
ans =
$40.2702 \quad 55.6833$
-0.0088 -0.0043
-0.0913 0.0054
-0.3957 0.3726
The values in each row are the lower and upper confidence limits, respectively, for the default $95 \%$ confidence intervals for the coefficients. For example, the first row shows the lower and upper limits, 40.2702 and 55.6833 , for the intercept, $\beta_{0}$. Likewise, the second row shows the limits for $\beta_{1}$ and so on. Confidence intervals provide a measure of precision for linear regression coefficient estimates. A $100(1-\alpha) \%$ confidence interval gives the range the corresponding regression coefficient will be in with $100(1-\alpha) \%$ confidence.

You can also change the confidence level. Find the $99 \%$ confidence intervals for the coefficients.
coefCI(lm, 0.01)
ans =

| -37.7677 | 58.1858 |
| :--- | ---: |
| -0.0095 | -0.0036 |
| -0.1069 | 0.0211 |
| -0.5205 | 0.4973 |

## Perform hypothesis test on coefficients.

Test the null hypothesis that all predictor variable coefficients are equal to zero versus the alternate hypothesis that at least one of them is different from zero.

```
[p,F,d] = coefTest(lm)
```

$p=$
7.3816e-27
$F=$
89.9874
d =

3
Here, coefTest performs an F-test for the hypothesis that all regression coefficients (except for the intercept) are zero versus at least one differs from zero, which essentially is the hypothesis on the model. It returns p , the $p$-value, F, the F-statistic, and d, the numerator degrees of freedom. The F-statistic and $p$-value are the same as the ones in the linear regression display and ANOVA for the model. The degrees of freedom is $4-1=3$ because there are four predictors (including the intercept) in the model.

Now, perform a hypothesis test on the coefficients of the first and second predictor variables.
$H=\left[\begin{array}{llllllll}0 & 1 & 0 & 0 ; & 0 & 0 & 1 & 0\end{array}\right] ;$
$[p, F, d]=\operatorname{coefTest}(l m, H)$

```
p =
    5.1702e-23
F =
    96.4873
d =
2
```

The numerator degrees of freedom is the number of coefficients tested, which is 2 in this example. The results indicate that at least one of $\beta_{2}$ and $\beta_{3}$ differs from zero.

## Cook's Distance

## Purpose

Cook's distance is useful for identifying outliers in the $X$ values (observations for predictor variables). It also shows the influence of each observation on the fitted response values. An observation with Cook's distance larger than three times the mean Cook's distance might be an outlier.

## Definition

Cook's distance is the scaled change in fitted values. Each element in CooksDistance is the normalized change in the vector of coefficients due to the deletion of an observation. The Cook's distance, $D_{i}$, of observation $i$ is

$$
D_{i}=\frac{\sum_{j=1}^{n}\left(\hat{y}_{j}-\hat{y}_{j(i)}\right)^{2}}{p M S E}
$$

where

- $\hat{y}_{j}$ is the $j$ th fitted response value.
- $\hat{y}_{j(i)}$ is the $j$ th fitted response value, where the fit does not include observation $i$.
- $M S E$ is the mean squared error.
- $p$ is the number of coefficients in the regression model.

Cook's distance is algebraically equivalent to the following expression:

$$
D_{i}=\frac{r_{i}^{2}}{p M S E}\left(\frac{h_{i i}}{\left(1-h_{i i}\right)^{2}}\right)
$$

where $r_{i}$ is the $i$ th residual, and $h_{i i}$ is the $i$ th leverage value.

CooksDistance is an $n$-by- 1 column vector in the Diagnostics dataset array of the LinearModel object.

## How To

After obtaining a fitted model, say, mdl, using LinearModel.fit or LinearModel.stepwise, you can:

- Display the Cook's distance values by indexing into the property using dot notation, mdl.Diagnostics.CooksDistance
- Plot the Cook's distance values using plotDiagnostics(mdl, 'cookd')

For details, see the plotDiagnostics method of the LinearModel class.

## Example

Load the sample data and define the independent and response variables.
load hospital
X = double(hospital(:,2:5));
y = hospital.BloodPressure(:,1);
Fit the linear regression model.
mdl = LinearModel.fit(X,y);

Plot the Cook's distance values.
plotDiagnostics(mdl, 'cookd')

The dashed line in the figure corresponds to the recommended threshold value, $3 *$ mean(mdl. Diagnostics.CooksDistance). The plot has some observations with Cook's distance values greater than the threshold value, which for this example is $3^{*}(0.0108)=0.0324$. In particular, there are two Cook's distance values that are relatively higher than the others, which exceed the threshold value. You might want to find and omit these from your data and rebuild your model.

Find the observations with Cook's distance values that exceed the threshold value.

```
find((mdl.Diagnostics.CooksDistance)>3*mean(mdl.Diagnostics.CooksDistance))
```

Find the observations with Cook's distance values that are relatively larger than the other observations with Cook's distances exceeding the threshold value.
find((mdl.Diagnostics.CooksDistance) $>5$ *mean(mdl.Diagnostics. CooksDistance))
ans =

2
84
Return to Summary of Measures.

## Coefficient Confidence Intervals

## Purpose

The coefficient confidence intervals provide a measure of precision for linear regression coefficient estimates. A 100(1-a)\% confidence interval gives the range that the corresponding regression coefficient will be in with $100(1-\alpha) \%$ confidence.

## Definition

The 100*(1- $\alpha$ )\% confidence intervals for linear regression coefficients are

$$
b_{i} \pm t_{(1-\alpha / 2, n-p)} S E\left(b_{i}\right),
$$

where $b_{i}$ is the coefficient estimate, $\operatorname{SE}\left(b_{i}\right)$ is the standard error of the coefficient estimate, and $t_{(1-\alpha / 2, n-p)}$ is the $100(1-\alpha / 2)$ percentile of $t$-distribution with $n-p$ degrees of freedom. $n$ is the number of observations and $p$ is the number of regression coefficients.

## How To

After obtaining a fitted model, say, mdl, using LinearModel.fit or LinearModel.stepwise, you can obtain the default $95 \%$ confidence intervals for coefficients using

```
coefCI(mdl)
```

You can also change the confidence level using

```
coefCI(mdl,alpha)
```

For details, see the coefCI and coefTest methods of LinearModel class.

## Example

Load the sample data and fit a linear regression model.

```
load hald
mdl = LinearModel.fit(ingredients,heat);
```

Display the $95 \%$ coefficient confidence intervals.

```
coefCI(mdl)
ans =
    -99.1786 223.9893
    -0.1663 3.2685
    -1.1589 2.1792
    -1.6385 1.8423
    -1.7791 1.4910
```

The values in each row are the lower and upper confidence limits, respectively, for the default $95 \%$ confidence intervals for the coefficients. For example, the first row shows the lower and upper limits, -99.1786 and 223.9893 , for the intercept, $\beta_{0}$. Likewise, the second row shows the limits for $\beta_{1}$ and so on.

Display the $90 \%$ confidence intervals for the coefficients ( $\alpha=0.1$ ).

```
coefCI(mdl,0.1)
ans =
    -67.8949 192.7057
        0.1662 2.9360
    -0.8358 1.8561
    -1.3015 1.5053
    -1.4626 1.1745
```

The confidence interval limits become narrower as the confidence level decreases.

Return to Summary of Measures.

## Coefficient Covariance

## Purpose

Estimated coefficient variances and covariances capture the precision of regression coefficient estimates. The coefficient variances and their square root, the standard errors, are useful in testing hypotheses for coefficients.

## Definition

The estimated covariance matrix is

$$
\Sigma=M S E\left(X^{\prime} X\right)^{-1}
$$

where $M S E$ is the mean squared error, and $X$ is the matrix of observations on the predictor variables. CoefficientCovariance, a property of the fitted model, is a $p$-by- $p$ covariance matrix of regression coefficient estimates. $p$ is the number of coefficients in the regression model. The diagonal elements are the variances of the individual coefficients.

## How To

After obtaining a fitted model, say, mdl, using LinearModel.fit or LinearModel.stepwise, you can display the coefficient covariances using

```
mdl.CoefficientCovariance
```

## Example

Load the sample data and define the predictor and response variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = LinearModel.fit(X,y);
```

Display the coefficient covariance matrix.

```
mdl.CoefficientCovariance
```

ans =

| 27.5113 | 11.0027 | -0.1542 | -0.2444 | 0.2702 |
| ---: | ---: | ---: | ---: | ---: |
| 11.0027 | 8.6864 | 0.0021 | -0.1547 | -0.0838 |
| -0.1542 | 0.0021 | 0.0045 | -0.0001 | -0.0029 |
| -0.2444 | -0.1547 | -0.0001 | 0.0031 | -0.0026 |
| 0.2702 | -0.0838 | -0.0029 | -0.0026 | 1.0829 |

Return to Summary of Measures.

## Coefficient of Determination (R-Squared)

## Purpose

Coefficient of determination (R-squared) indicates the proportionate amount of variation in the response variable $y$ explained by the independent variables $X$ in the linear regression model. The larger the R -squared is, the more variability is explained by the linear regression model.

## Definition

R -squared is the proportion of the total sum of squares explained by the model. Rsquared, a property of the fitted model, is a structure with two fields:

- Ordinary - Ordinary (unadjusted) R-squared

$$
R^{2}=\frac{S S R}{S S T}=1-\frac{S S E}{S S T} .
$$

- Adjusted - R-squared adjusted for the number of coefficients

$$
R_{a d j}^{2}=1-\left(\frac{n-1}{n-p}\right) \frac{S S E}{S S T} .
$$

$S S E$ is the sum of squared error, $S S R$ is the sum of squared regression, $S S T$ is the sum of squared total, $n$ is the number of observations, and $p$ is the number of regression coefficients (including the intercept). Because R -squared increases with added predictor variables in the regression model, the adjusted R -squared adjusts for the number of predictor variables in the model. This makes it more useful for comparing models with a different number of predictors.

## How To

After obtaining a fitted model, say, mdl, using LinearModel.fit or LinearModel.stepwise, you can obtain either $R$-squared value as a scalar by indexing into the property using dot notation, for example,
mdl.Rsquared.Ordinary
mdl.Rsquared.Adjusted

You can also obtain the SSE, SSR, and SST using the properties with the same name.
mdl.SSE
mdl.SSR
mdl.SST

## Example

Load the sample data and define the response and independent variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = LinearModel.fit(X,y)
mdl =
Linear regression model:
    y ~ 1 + x1 + x2 + x3 + x4
Estimated Coefficients:
\begin{tabular}{lrrrr} 
& Estimate & \multicolumn{1}{l}{ SE } & \multicolumn{1}{l}{ tStat } & \multicolumn{1}{l}{ pValue } \\
(Intercept) & 117.4 & 5.2451 & 22.383 & \(1.1667 \mathrm{e}-39\) \\
x1 & 0.88162 & 2.9473 & 0.29913 & 0.76549 \\

\end{tabular}
Number of observations: 100, Error degrees of freedom: 95
Root Mean Squared Error: 4.81
R-squared: 0.508, Adjusted R-Squared 0.487
F-statistic vs. constant model: 24.5, p-value = 5.99e-14
```

The R-squared and adjusted R -squared values are 0.508 and 0.487 , respectively. Model explains about $50 \%$ of the variability in the response variable.

Access the R-squared and adjusted R-squared values using the property of the fitted LinearModel object.
mdl. Rsquared.Ordinary
ans =
0.5078
mdl.Rsquared.Adjusted
ans =
0.4871

The adjusted R -squared value is smaller than the ordinary R -squared value.
Return to Summary of Measures.

## Delete-1 Change in Covariance (covratio)

## Purpose

Delete-1 change in covariance (covratio) identifies the observations that are influential in the regression fit. An influential observation is one where its exclusion from the model might significantly alter the regression function. Values of covratio larger than $1+3^{*} p / n$ or smaller than $1-3^{*} p / n$ indicate influential points, where $p$ is the number of regression coefficients, and $n$ is the number of observations.

## Definition

The covratio statistic is the ratio of the determinant of the coefficient covariance matrix with observation $i$ deleted to the determinant of the covariance matrix for the full model:

$$
\operatorname{cov} \text { ratio }=\frac{\operatorname{det}\left\{M S E(i)\left[X^{\prime}(i) X(i)\right]^{-1}\right\}}{\operatorname{det}\left[M S E\left(X^{\prime} X\right)^{-1}\right]}
$$

CovRatio is an $n$-by- 1 vector in the Diagnostics dataset array of the fitted LinearModel object. Each element is the ratio of the generalized variance of the estimated coefficients when the corresponding element is deleted to the generalized variance of the coefficients using all the data.

## How To

After obtaining a fitted model, say, mdl, using LinearModel.fit or LinearModel.stepwise, you can:

- Display the CovRatio by indexing into the property using dot notation
mdl.Diagnostics.CovRatio
- Plot the delete-1 change in covariance using

```
plotDiagnostics(mdl,'CovRatio')
```

For details, see the plotDiagnostics method of the LinearModel class.

## Example

Load the sample data and define the response and predictor variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.
mdl = LinearModel.fit(X,y);

Plot the CovRatio statistics.
plotDiagnostics(mdl,'CovRatio')

For this example, the threshold limits are $1+3 * 5 / 100=1.15$ and $1-3 * 5 / 100$ $=0.85$. There are a few points beyond the limits, which might be influential points.

Find the observations that are beyond the limits.
find((mdl.Diagnostics.CovRatio)>1.15|(mdl.Diagnostics.CovRatio)<0.85)
ans =

Return to Summary of Measures.

## Delete-1 Scaled Difference in Coefficient Estimates (Dfbetas)

## Purpose

The sign of a delete-1 scaled difference in coefficient estimate (Dfbetas) for coefficient $j$ and observation $i$ indicates whether that observation causes an increase or decrease in the estimate of the regression coefficient. The absolute value of a Dfbetas indicates the magnitude of the difference relative to the estimated standard deviation of the regression coefficient. A Dfbetas value larger than $3 / \operatorname{sqrt}(n)$ in absolute value indicates that the observation has a large influence on the corresponding coefficient.

## Definition

Dfbetas for coefficient $j$ and observation $i$ is the ratio of the difference in the estimate of coefficient $j$ using all observations and the one obtained by removing observation $i$, and the standard error of the coefficient estimate obtained by removing observation $i$. The Dfbetas for coefficient $j$ and observation $i$ is

$$
\text { Dfbetas }_{i j}=\frac{b_{j}-b_{j(i)}}{\sqrt{M S E_{(i)}}\left(1-h_{i i}\right)},
$$

where $b_{j}$ is the estimate for coefficient $j, b_{j(i)}$ is the estimate for coefficient $j$ by removing observation $i, M S E_{(i)}$ is the mean squared error of the regression fit by removing observation $i$, and $h_{i i}$ is the leverage value for observation $i$. Dfbetas is an $n$-by- $p$ matrix in the Diagnostics dataset array of the fitted LinearModel object. Each cell of Dfbetas corresponds to the Dfbetas value for the corresponding coefficient obtained by removing the corresponding observation.

## How To

After obtaining a fitted model, say, mdl, using LinearModel.fit or LinearModel.stepwise, you can obtain the Dfbetas values as an $n$-by- $p$ matrix by indexing into the property using dot notation,
mdl.Diagnostics.Dfbetas

## Example

Load the sample data and define the response and independent variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = LinearModel.fit(X,y);
```

Find the Dfbetas values that are high in absolute value.
[row,col] = find(abs(mdl.Diagnostics.Dfbetas)>3/sqrt(100)); disp([row col])

## Delete-1 Scaled Change in Fitted Values (Dffits)

## Purpose

The delete-1 scaled change in fitted values (Dffits) show the influence of each observation on the fitted response values. Dffits values with an absolute value larger than $2 * \operatorname{sqrt}(p / n)$ might be influential.

## Definition

Dffits for observation $i$ is

$$
\text { Dffits }_{i}=s r_{i} \sqrt{\frac{h_{i i}}{1-h_{i i}}}
$$

where $s r_{i}$ is the studentized residual, and $h_{i i}$ is the leverage value of the fitted LinearModel object. Dffits is an $n$-by- 1 column vector in the Diagnostics dataset array of the fitted LinearModel object. Each element in Dffits is the change in the fitted value caused by deleting the corresponding observation and scaling by the standard error.

## How To

After obtaining a fitted model, say, mdl, using LinearModel.fit or LinearModel.stepwise, you can:

- Display the Dffits values by indexing into the property using dot notation mdl.Diagnostics.Dffits
- Plot the delete-1 scaled change in fitted values using

```
plotDiagnostics(mdl,'Dffits')
```

For details, see the plotDiagnostics method of the LinearModel class for details.

## Example

Load the sample data and define the response and independent variables.
load hospital

```
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = LinearModel.fit(X,y);
```

Plot the Dffits values.
plotDiagnostics(mdl, 'Dffits')

Case order plot of scaled change in fit

The influential threshold limit for the absolute value of Dffits in this example is $2 * \operatorname{sqrt}(5 / 100)=0.45$. Again, there are some observations with Dffits values beyond the recommended limits.

Find the Dffits values that are large in absolute value.
find(abs(mdl.Diagnostics.Dffits)>2*sqrt(4/100))

## Delete-1 Variance (S2_i)

## Purpose

The delete-1 variance (S2_i) shows how the mean squared error changes when an observation is removed from the data set. You can compare the S2_i values with the value of the mean squared error.

## Definition

S2_i is a set of residual variance estimates obtained by deleting each observation in turn. The S2_i value for observation $i$ is

$$
S 2_{-} i=M S E_{(i)}=\frac{\sum_{j \neq i}^{n}\left[y_{j}-y_{j(i)}\right]^{2}}{n-p-1}
$$

where $y_{j}$ is the $j$ th observed response value. S2_i is an $n$-by- 1 vector in the Diagnostics dataset array of the fitted LinearModel object. Each element in S2 $i$ is the mean squared error of the regression obtained by deleting that observation.

## How To

After obtaining a fitted model, say, mdl, using LinearModel.fit or LinearModel.stepwise, you can:

- Display the S2_i vector by indexing into the property using dot notation mdl.Diagnostics.S2_i
- Plot the delete-1 variance values using
plotDiagnostics(mdl,'S2_i')
For details, see the plotDiagnostics method of the LinearModel class.

## Example

Load the sample data and define the response and independent variables.
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
Fit a linear regression model.
mdl = LinearModel.fit(X,y);
Display the MSE value for the model.
mdl.MSE
ans $=$
23.1140

Plot the S2_i values.
plotDiagnostics(mdl,'S2_i')

This plot makes it easy to compare the S2_i values to the MSE value of 23.114, indicated by the horizontal dashed lines. You can see how deleting one observation changes the error variance.

Return to Summary of Measures.

## Durbin-Watson Test

## Purpose

The Durbin-Watson test assesses whether there is autocorrelation among the residuals or not.

## Definition

The Durbin-Watson test statistic, DW, is

$$
D W=\frac{\sum_{i=1}^{n-1}\left(r_{i+1}-r_{i}\right)^{2}}{\sum_{i=1}^{n} r_{i}^{2}}
$$

Here, $r_{i}$ is the $i$ th raw residual, and $n$ is the number of observations.

## How To

After obtaining a fitted model, say, mdl, using LinearModel.fit or LinearModel.stepwise, you can perform the Durbin-Watson test using dwtest(mdl)

For details, see the dwtest method of the LinearModel class.

## Example

Load the sample data and fit a linear regression model.

```
load hald
mdl = LinearModel.fit(ingredients,heat);
```

Perform a two-sided Durbin-Watson test to determine if there is any autocorrelation among the residuals of the linear model, mdl.
[p,DW] = dwtest(mdl,'exact','both')
$\mathrm{p}=$
0.6285

DW =
2.0526

The value of the Durbin-Watson test statistic is 2.0526 . The $p$-value of 0.6285 suggest that the residuals are not autocorrelated.

## F-statistic

## Purpose

In linear regression, the F-statistic is the test statistic for the analysis of variance (ANOVA) approach to test the significance of the model or the components in the model.

## Definition

The F-statistic in the linear model output display is the test statistic for testing the statistical significance of the model. The F-statistic values in the anova display are for assessing the significance of the terms or components in the model.

## How To

After obtaining a fitted model, say, mdl, using LinearModel.fit or LinearModel.stepwise, you can:

- Find the F-statistic vs. constant model in the output display or by using

```
disp(mdl)
```

- Display the ANOVA for the model using anova(mdl,'summary')
- Obtain the F-statistic values for the components, except for the constant term using
anova(mdl)
For details, see the anova method of the LinearModel class.

## Example

Load the sample data.

```
load carbig
ds = dataset(Acceleration,Cylinders,Weight,MPG);
ds.Cylinders = ordinal(Cylinders);
```

Fit a linear regression model.

```
mdl = LinearModel.fit(ds,'MPG~Acceleration*Weight+Cylinders+Weight^2')
mdl =
```

Linear regression model:
MPG ~ 1 + Cylinders + Acceleration*Weight + Weight^2
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | ---: |
| (Intercept) | 50.816 | 7.5669 | 6.7156 | $6.661 \mathrm{e}-$ |
| Acceleration | 0.023343 | 0.33931 | 0.068796 | 0.945 |
| Cylinders_4 | 7.167 | 2.0596 | 3.4798 | 0.00055 |
| Cylinders_5 | 10.963 | 3.1299 | 3.5028 | 0.000513 |
| Cylinders_6 | 4.7415 | 2.1257 | 2.2306 | 0.0262 |
| Cylinders_8 | 5.057 | 2.2981 | 2.2005 | 0.0283 |
| Weight | -0.017497 | 0.0034674 | -5.0461 | $6.9371 \mathrm{e}-$ |
| Acceleration:Weight | $7.0745 \mathrm{e}-05$ | 0.00011171 | 0.6333 | 0.526 |
| Weight^2 | $1.5767 e-06$ | $3.6909 e-07$ | 4.2719 | $2.4396 e-$ |

Number of observations: 398, Error degrees of freedom: 389
Root Mean Squared Error: 4.02
R-squared: 0.741, Adjusted R-Squared 0.736
F-statistic vs. constant model: 139, p-value = 2.94e-109

The F-statistic of the linear fit versus the constant model is 139 , with a $p$-value of $2.94 \mathrm{e}-109$. The model is significant at the $5 \%$ significance level. The R-squared value of 0.741 means the model explains about $74 \%$ of the variability in the response.

Display the ANOVA table for the fitted model.

```
anova(mdl,'summary')
ans =
```

|  | SumSq | DF | MeanSq | F | pValue |
| :--- | ---: | ---: | ---: | :--- | :--- |
| Total | 24253 | 397 | 61.09 |  |  |
| Model | 17981 | 8 | 2247.6 | 139.41 | $2.9432 \mathrm{e}-109$ |
| . Linear | 17667 | 6 | 2944.4 | 182.63 | $7.5446 \mathrm{e}-110$ |
| . Nonlinear | 314.36 | 2 | 157.18 | 9.7492 | $7.3906 \mathrm{e}-05$ |
| Residual | 6271.6 | 389 | 16.122 |  |  |
| . Lack of fit | 6267.1 | 387 | 16.194 | 7.1973 | 0.12968 |
| . Pure error | 4.5 | 2 | 2.25 |  |  |

This display separates the variability in the model into linear and nonlinear terms. Since there are two non-linear terms (Weight^2 and the interaction between Weight and Acceleration), the nonlinear degrees of freedom in the DF column is 2. There are six linear terms in the model (four Cylinders indicator variables, Weight, and Acceleration). The corresponding $F$-statistics in the $F$ column are for testing the significance of the linear and nonlinear terms as separate groups.

The residual term is also separated into two parts; first is the error due to the lack of fit, and second is the pure error independent from the model, obtained from the replicated observations. The corresponding F-statistics in the F column are for testing the lack of fit, that is, whether the proposed model is an adequate fit or not.

Display the ANOVA table for the model terms.

```
anova(mdl)
```

ans =

|  | SumSq | DF | MeanSq | F | pValue |
| :--- | :--- | ---: | ---: | ---: | ---: |
| Acceleration | 104.99 | 1 | 104.99 | 6.5122 | 0.011095 |
| Cylinders | 408.94 | 4 | 102.23 | 6.3412 | $5.9573 \mathrm{e}-05$ |
| Weight | 2187.5 | 1 | 2187.5 | 135.68 | $4.1974 \mathrm{e}-27$ |
| Acceleration:Weight | 6.4662 | 1 | 6.4662 | 0.40107 | 0.52691 |
| Weight^2 | 294.22 | 1 | 294.22 | 18.249 | $2.4396 \mathrm{e}-05$ |

This display decomposes the ANOVA table into the model terms. The corresponding F -statistics in the F column are for assessing the statistical significance of each term. The F-test for Cylinders test whether at least one of the coefficients of indicator variables for cylinders categories is different from zero or not. That is, whether different numbers of cylinders have a significant effect on MPG or not. The degrees of freedom for each model term is the numerator degrees of freedom for the corresponding F-test. Most of the terms have 1 degree of freedom, but the degrees of freedom for Cylinders is 4. Because there are four indicator variables for this term.

Return to Summary of Measures.

## Hat Matrix

## Purpose

The hat matrix provides a measure of leverage. It is useful for investigating whether one or more observations are outlying with regard to their $X$ values, and therefore might be excessively influencing the regression results.

## Definition

The hat matrix is also known as the projection matrix because it projects the vector of observations, y, onto the vector of predictions, $\hat{y}$, thus putting the "hat" on $y$. The hat matrix $H$ is defined in terms of the data matrix $X$ :

$$
H=X\left(X^{T} X\right)^{-1} X^{T}
$$

and determines the fitted or predicted values since

$$
\hat{y}=H y=X b .
$$

The diagonal elements of $H, h_{i i}$, are called leverages and satisfy

$$
\begin{aligned}
& 0 \leq h_{i i} \leq 1 \\
& \sum_{i=1}^{n} h_{i i}=p
\end{aligned}
$$

where $p$ is the number of coefficients, and $n$ is the number of observations (rows of $X$ ) in the regression model. HatMatrix is an $n$-by- $n$ matrix in the Diagnostics dataset array.

## How To

After obtaining a fitted model, say, mdl, using LinearModel.fit or LinearModel.stepwise, you can:

- Display the HatMatrix by indexing into the property using dot notation mdl.Diagnostics.HatMatrix

When $n$ is large, HatMatrix might be computationally expensive. In those cases, you can obtain the diagonal values directly, using

```
mdl.Diagnostics.Leverage
```

Return to Summary of Measures.

## Leverage

## Purpose

Leverage is a measure of the effect of a particular observation on the regression predictions due to the position of that observation in the space of the inputs. In general, the farther a point is from the center of the input space, the more leverage it has. Because the sum of the leverage values is $p$, an observation $i$ can be considered as an outlier if its leverage substantially exceeds the mean leverage value, $p / n$, for example, a value larger than $2^{*} p / n$.

## Definition

The leverage of observation $i$ is the value of the $i$ th diagonal term, $h_{i i}$, of the hat matrix, $H$, where

$$
H=X\left(X^{T} X\right)^{-1} X^{T} .
$$

The diagonal terms satisfy

$$
\begin{aligned}
& 0 \leq h_{i i} \leq 1 \\
& \sum_{i=1}^{n} h_{i i}=p,
\end{aligned}
$$

where $p$ is the number of coefficients in the regression model, and $n$ is the number of observations. The minimum value of $h_{i i}$ is $1 / n$ for a model with a constant term. If the fitted model goes through the origin, then the minimum leverage value is 0 for an observation at $x=0$.

It is possible to express the fitted values, $\hat{y}$, by the observed values, $y$, since

$$
\hat{y}=H y=X b .
$$

Hence, $h_{i i}$ expresses how much the observation $y_{i}$ has impact on $\hat{y}_{i}$. A large value of $h_{i i}$ indicates that the $i$ th case is distant from the center of all X values for all $n$ cases and has more leverage. Leverage is an $n$-by- 1 column vector in the Diagnostics dataset array.

## How To

After obtaining a fitted model, say, mdl, using LinearModel.fit or LinearModel.stepwise, you can:

- Display the Leverage vector by indexing into the property using dot notation
mdl.Diagnostics.Leverage
- Plot the leverage for the values fitted by your model using
plotDiagnostics(mdl)
See the plotDiagnostics method of the LinearModel class for details.

## Example

Load the sample data and define the response and independent variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.
mdl = LinearModel.fit(X,y);

Plot the leverage values.
plotDiagnostics(mdl)

For this example, the recommended threshold value is $2 * 5 / 100=0.1$. There is no indication of high leverage observations.

Return to Summary of Measures.

## Residuals

## Purpose

Residuals are useful for detecting outlying $y$ values and checking the linear regression assumptions with respect to the error term in the regression model. High-leverage observations have smaller residuals because they often shift
the regression line or surface closer to them. You can also use residuals to detect some forms of heteroscedasticity and autocorrelation.

## Definition

The Residuals matrix is an $n$-by- 4 dataset array containing a table of four types of residuals, with one row for each observation.

Raw Residuals. Observed minus fitted values, that is,

$$
r_{i}=y_{i}-\hat{y}_{i} .
$$

Pearson Residuals. Raw residuals divided by the root mean squared error, that is,

$$
p r_{i}=\frac{r_{i}}{\sqrt{M S E}}
$$

where $r_{i}$ is the raw residual and $M S E$ is the mean squared error.
Standardized Residuals. Standardized residuals are raw residuals divided by their estimated standard deviation. The standardized residual for observation $i$ is

$$
s t_{i}=\frac{r_{i}}{\sqrt{M S E\left(1-h_{i i}\right)}}
$$

where $M S E$ is the mean squared error and $h_{i i}$ is the leverage value for observation $i$.

Studentized Residuals. Studentized residuals are the raw residuals divided by an independent estimate of the residual standard deviation. The residual for observation $i$ is divided by an estimate of the error standard deviation based on all observations except for observation $i$.

$$
s r_{i}=\frac{r_{i}}{\sqrt{M S E_{(i)}\left(1-h_{i i}\right)}},
$$

where $M S E_{(i)}$ is the mean squared error of the regression fit calculated by removing observation $i$, and $h_{i i}$ is the leverage value for observation $i$. The studentized residual $s r_{i}$ has a $t$-distribution with $n-p-1$ degrees of freedom.

## How To

After obtaining a fitted model, say, mdl, using LinearModel.fit or LinearModel.stepwise, you can:

- Find the Residuals dataset array under mdl object.
- Obtain any of these columns as a vector by indexing into the property using dot notation, for example,
mdl.Residuals.Raw
- Plot any of the residuals for the values fitted by your model using plotResiduals(mdl)

For details, see the plotResiduals method of the LinearModel class.

## Example

Load the sample data and store the independent and response variables in a dataset array.

```
load imports-85
ds = dataset(X(:,7),X(:,8),X(:,9),X(:,15),'Varnames',...
{'curb_weight','engine_size','bore','price'});
```

Fit a linear regression model.

```
mdl = LinearModel.fit(ds)
mdl =
Linear regression model:
    price ~ 1 + curb_weight + engine_size + bore
Estimated Coefficients:
\begin{tabular}{cccccl} 
& Estimate & SE & & tStat & pValue \\
(Intercept) & 64.095 & & 3.703 & 17.309 & \(2.0481 e-41\)
\end{tabular}
```

| curb_weight | -0.0086681 | 0.0011025 | -7.8623 | $2.42 \mathrm{e}-13$ |
| :--- | ---: | ---: | ---: | ---: |
| engine_size | -0.015806 | 0.013255 | -1.1925 | 0.23452 |
| bore | -2.6998 | 1.3489 | -2.0015 | 0.046711 |

Number of observations: 201, Error degrees of freedom: 197
Root Mean Squared Error: 3.95
R-squared: 0.674, Adjusted R-Squared 0.669
F-statistic vs. constant model: 136, p-value = 1.14e-47

Plot the histogram of raw residuals.
plotResiduals(mdl)

Histogram of residuals

The histogram shows that the residuals are slightly right skewed.
Plot the box plot of all four types of residuals.

```
Res = double(mdl.Residuals);
```

You can see the right-skewed structure of the residuals in the box plot as well.
Plot the normal probability plot of the raw residuals.
plotResiduals(mdl,'probability')
boxplot(Res)

This normal probability plot also shows the deviation from normality and the skewness on the right tail of the distribution of residuals.

Plot the residuals versus lagged residuals.
plotResiduals(mdl,'lagged')

This graph shows a trend, which indicates a possible correlation among the residuals. You can further check this using dwtest (mdl). Serial correlation among residuals usually means that the model can be improved.

Plot the symmetry plot of residuals.
plotResiduals(mdl, 'symmetry')

This plot also suggests that the residuals are not distributed equally around their median, as would be expected for normal distribution.

Plot the residuals versus the fitted values.
plotResiduals(mdl,'fitted')

The increase in the variance as the fitted values increase suggests possible heteroscedasticity.

Return to Summary of Measures.

## t-statistic

## Purpose

In linear regression, the $t$-statistic is useful for making inferences about the regression coefficients. The hypothesis test on coefficient $i$ tests the null hypothesis that it is equal to zero - meaning the corresponding term is not
significant - versus the alternate hypothesis that the coefficient is different from zero.

## Definition

For a hypotheses test on coefficient $i$, with
$\mathrm{H}_{0}: \beta_{i}=0$
$\mathrm{H}_{1}: \beta_{i} \neq 0$,
the $t$-statistic is:

$$
t=\frac{b_{i}}{S E\left(b_{i}\right)}
$$

where $S E\left(b_{i}\right)$ is the standard error of the estimated coefficient $b_{i}$.

## How To

After obtaining a fitted model, say, mdl, using LinearModel.fit or LinearModel.stepwise, you can:

- Find the coefficient estimates, the standard errors of the estimates (SE), and the $t$-statistic values of hypothesis tests for the corresponding coefficients (tStat) in the output display.
- Call for the display using
display(mdl)

## Example

Load the sample data and fit the linear regression model.

```
load hald
mdl = LinearModel.fit(ingredients,heat)
mdl =
Linear regression model:
    y ~ 1 + x1 + x2 + x3 + x4
```

```
Estimated Coefficients:
\begin{tabular}{lrrrr} 
& Estimate & \multicolumn{1}{l}{ SE } & tStat & \multicolumn{1}{l}{ pValue } \\
(Intercept) & 62.405 & 70.071 & 0.8906 & 0.39913 \\
x1 & 1.5511 & 0.74477 & 2.0827 & 0.070822 \\
x2 & 0.51017 & 0.72379 & 0.70486 & 0.5009 \\
x3 & 0.10191 & 0.75471 & 0.13503 & 0.89592 \\
x4 & -0.14406 & 0.70905 & -0.20317 & 0.84407
\end{tabular}
Number of observations: 13, Error degrees of freedom: 8 Root Mean Squared Error: 2.45
R-squared: 0.982, Adjusted R-Squared 0.974
F-statistic vs. constant model: 111, p-value = 4.76e-07
```

You can see that for each coefficient, tStat = Estimate/SE. The p-values for the hypotheses tests are in the pValue column. Each $t$-statistic tests for the significance of each term given other terms in the model. According to these results, none of the coefficients seem significant at the $5 \%$ significance level, although the R -squared value for the model is really high at 0.97 . This often indicates possible multicollinearity among the predictor variables.

Use stepwise regression to decide which variables to include in the model.

```
load hald
mdl = LinearModel.stepwise(ingredients,heat)
```

1. Adding $\mathrm{x} 4, \mathrm{FStat}=22.7985, \mathrm{pValue}=0.000576232$
2. Adding $\mathrm{x} 1, \mathrm{FStat}=108.2239, \mathrm{pValue}=1.105281 \mathrm{e}-06$
mdl =
Linear regression model:
$y \sim 1+x 1+x 4$
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | :--- |
| ( Intercept) | 103.1 | 2.124 | 48.54 | $3.3243 \mathrm{e}-13$ |
| x1 | 1.44 | 0.13842 | 10.403 | $1.1053 \mathrm{e}-06$ |

```
Number of observations: 13, Error degrees of freedom: 10
Root Mean Squared Error: 2.73
R-squared: 0.972, Adjusted R-Squared 0.967
F-statistic vs. constant model: 177, p-value = 1.58e-08
```

In this example, LinearModel.stepwise starts with the constant model (default) and uses forward selection to incrementally add $\times 4$ and $\times 1$. Each predictor variable in the final model is significant given the other one is in the model. The algorithm stops when adding none of the other predictor variables significantly improves in the model. For details on stepwise regression, see LinearModel.stepwise.

## Stepwise Regression to Select Appropriate Models

LinearModel.stepwise creates a linear model and automatically adds to or trims the model. To create a small model, start from a constant model. To create a large model, start with a model containing many terms. A large model usually has lower error as measured by the fit to the original data, but might not have any advantage in predicting new data.

LinearModel.stepwise can use all the name-value options from LinearModel.fit, with additional options relating to the starting and bounding models. In particular:

- For a small model, start with the default lower bounding model: 'constant' (a model that has no predictor terms).
- The default upper bounding model has linear terms and interaction terms (products of pairs of predictors). For an upper bounding model that also includes squared terms, set the Upper name-value pair to 'quadratic'.

## Compare large and small stepwise models

This example show how to compare the models that LinearModel.stepwise returns starting from a constant model and starting from a full interaction model.

Load the carbig data and create a dataset array from some of the data.

```
load carbig
ds = dataset(Acceleration,Displacement,Horsepower,Weight,MPG);
```

Create a mileage model stepwise starting from the constant model.

```
mdl1 = LinearModel.stepwise(ds,'constant','ResponseVar','MPG')
```

```
1. Adding Weight, FStat = 888.8507, pValue = 2.9728e-103
2. Adding Horsepower, FStat = 3.8217, pValue = 0.00049608
3. Adding Horsepower:Weight, FStat = 64.8709, pValue = 9.93362e-15
mdl1 =
Linear regression model:
    MPG ~ 1 + Horsepower*Weight
Estimated Coefficients:
\begin{tabular}{lrrrl} 
& \multicolumn{1}{l}{ Estimate } & \multicolumn{1}{l}{ SE } & \multicolumn{1}{l}{ tStat } & \multicolumn{1}{l}{ pValue } \\
(Intercept) & 63.558 & 2.3429 & 27.127 & \(1.2343 \mathrm{e}-91\) \\
Horsepower & -0.25084 & 0.027279 & -9.1952 & \(2.3226 \mathrm{e}-18\) \\
Weight & -0.010772 & 0.00077381 & -13.921 & \(5.1372 \mathrm{e}-36\) \\
Horsepower:Weight & \(5.3554 \mathrm{e}-05\) & \(6.6491 \mathrm{e}-06\) & 8.0542 & \(9.9336 \mathrm{e}-15\)
\end{tabular}
```

R-squared: 0.748, Adjusted R-Squared 0.746
F-statistic vs. constant model: 385, p-value = 7.26e-116

```
F-statistic vs. constant model: 385, p-value = 7.26e-116
```

Create a mileage model stepwise starting from the full interaction model.

```
mdl2 = LinearModel.stepwise(ds,'interactions','ResponseVar','MPG')
```

1. Removing Acceleration:Displacement, FStat $=0.024186, \mathrm{pValue}=0.8765$
2. Removing Displacement:Weight, FStat $=0.33103$, pValue $=0.56539$
3. Removing Acceleration:Horsepower, FStat $=1.7334$, pValue $=0.18876$
4. Removing Acceleration:Weight, FStat $=0.93269$, pValue $=0.33477$
5. Removing Horsepower:Weight, FStat $=0.64486, \mathrm{pValue}=0.42245$
mdl2 $=$
Linear regression model:
MPG ~ 1 + Acceleration + Weight + Displacement*Horsepower
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | ---: |
| (Intercept) | 61.285 | 2.8052 | 21.847 | $1.8593 \mathrm{e}-69$ |
| Acceleration | -0.34401 | 0.11862 | -2.9 | 0.0039445 |
| Displacement | -0.081198 | 0.010071 | -8.0623 | $9.5014 \mathrm{e}-15$ |
| Horsepower | -0.24313 | 0.026068 | -9.3265 | $8.6556 \mathrm{e}-19$ |
| Weight | -0.0014367 | 0.00084041 | -1.7095 | 0.088166 |
| Displacement:Horsepower | 0.00054236 | $5.7987 \mathrm{e}-05$ | 9.3531 | $7.0527 \mathrm{e}-19$ |

```
Number of observations: 392, Error degrees of freedom: 386
Root Mean Squared Error: 3.84
R-squared: 0.761, Adjusted R-Squared 0.758
F-statistic vs. constant model: 246, p-value = 1.32e-117
```

Notice that:

- mdl1 has four coefficients (the Estimate column), and mdl2 has six coefficients.
- The adjusted R-squared of mdl1 is 0.746 , which is slightly less (worse) than that of mdl2, 0.758.

Create a mileage model stepwise with a full quadratic model as the upper bound, starting from the full quadratic model:

```
mdl3 = LinearModel.stepwise(ds,'quadratic',...
    'ResponseVar','MPG','Upper','quadratic');
```

Compare the three model complexities by examining their formulas.

```
mdl1.Formula
ans =
MPG ~ 1 + Horsepower*Weight
mdl2.Formula
ans =
MPG ~ 1 + Acceleration + Weight + Displacement*Horsepower
```

mdl3.Formula

```
ans =
MPG ~ 1 + Weight + Acceleration*Displacement
    + Displacement*Horsepower + Acceleration^2
```

The adjusted $\mathrm{R}^{2}$ values improve slightly as the models become more complex:

```
RSquared = [mdl1.Rsquared.Adjusted, ...
    mdl2.Rsquared.Adjusted, mdl3.Rsquared.Adjusted]
RSquared =
    0.7465 0.7580 0.7599
```

Compare residual plots of the three models.

```
subplot(3,1,1)
plotResiduals(mdl1)
subplot(3,1,2)
plotResiduals(mdl2)
subplot(3,1,3)
plotResiduals(mdl3)
```

Histogram of residuals

The models have similar residuals. It is not clear which fits the data better. Interestingly, the more complex models have larger maximum deviations of the residuals:

```
Rrange1 = [min(mdl1.Residuals.Raw),max(mdl1.Residuals.Raw)];
Rrange2 = [min(mdl2.Residuals.Raw),max(mdl2.Residuals.Raw)];
Rrange3 = [min(mdl3.Residuals.Raw),max(mdl3.Residuals.Raw)];
Rranges = [range1;range2;range3]
Rranges =
\begin{tabular}{ll}
-10.7725 & 14.7314 \\
-11.4407 & 16.7562 \\
-12.2723 & 16.7927
\end{tabular}
```

# Robust Regression - Reduce Outlier Effects 

In this section...<br>"What Is Robust Regression?" on page 9-116<br>"Robust Regression versus Standard Least-Squares Fit" on page 9-116

## What Is Robust Regression?

The models described in "What Are Linear Regression Models?" on page 9-7 are based on certain assumptions, such as a normal distribution of errors in the observed responses. If the distribution of errors is asymmetric or prone to outliers, model assumptions are invalidated, and parameter estimates, confidence intervals, and other computed statistics become unreliable. Use LinearModel.fit with the RobustOpts name-value pair to create a model that is not much affected by outliers. The robust fitting method is less sensitive than ordinary least squares to large changes in small parts of the data.

Robust regression works by assigning a weight to each data point. Weighting is done automatically and iteratively using a process called iteratively reweighted least squares. In the first iteration, each point is assigned equal weight and model coefficients are estimated using ordinary least squares. At subsequent iterations, weights are recomputed so that points farther from model predictions in the previous iteration are given lower weight. Model coefficients are then recomputed using weighted least squares. The process continues until the values of the coefficient estimates converge within a specified tolerance.

## Robust Regression versus Standard Least-Squares Fit

This example shows how to use robust regression. It compares the results of a robust fit to a standard least-squares fit.

## Step 1. Prepare data.

Load the moore data. The data is in the first five columns, and the response in the sixth.
load moore

```
X = [moore(:,1:5)];
y = moore(:,6);
```

## Step 2. Fit robust and nonrobust models.

Fit two linear models to the data, one using robust fitting, one not.

```
mdl = LinearModel.fit(X,y); % not robust
mdlr = LinearModel.fit(X,y,'RobustOpts','on');
```

## Step 3. Examine model residuals.

Examine the residuals of the two models.

```
subplot(1,2,1);plotResiduals(mdl,'probability')
subplot(1,2,2);plotResiduals(mdlr,'probability')
```

The residuals from the robust fit (right half of the plot) are nearly all closer to the straight line, except for the one obvious outlier.

## 4. Remove the outlier from the standard model

Find the index of the outlier. Examine the weight of the outlier in the robust fit.
[~,outlier] = max(mdlr.Residuals.Raw); mdlr.Robust.Weights(outlier)
ans $=$
0.0246

This weight is much less than a typical weight of an observation:

```
median(mdlr.Robust.Weights)
ans =
    0.9718
```

## Ridge Regression

In this section...
"Introduction to Ridge Regression" on page 9-119
"Ridge Regression" on page 9-119

## Introduction to Ridge Regression

Coefficient estimates for the models described in "Linear Regression" on page $9-11$ rely on the independence of the model terms. When terms are correlated and the columns of the design matrix $X$ have an approximate linear dependence, the matrix $\left(X^{T} X\right)^{-1}$ becomes close to singular. As a result, the least-squares estimate

$$
\hat{\beta}=\left(X^{T} X\right)^{-1} X^{T} y
$$

becomes highly sensitive to random errors in the observed response $y$, producing a large variance. This situation of multicollinearity can arise, for example, when data are collected without an experimental design.

Ridge regression addresses the problem by estimating regression coefficients using

$$
\hat{\beta}=\left(X^{T} X+k I\right)^{-1} X^{T} y
$$

where $k$ is the ridge parameter and $I$ is the identity matrix. Small positive values of $k$ improve the conditioning of the problem and reduce the variance of the estimates. While biased, the reduced variance of ridge estimates often result in a smaller mean square error when compared to least-squares estimates.

The Statistics Toolbox function ridge carries out ridge regression.

## Ridge Regression

For example, load the data in acetylene.mat, with observations of the predictor variables $x 1, x 2, x 3$, and the response variable $y$ :
load acetylene
Plot the predictor variables against each other:

```
subplot(1,3,1)
plot(x1,x2,'.')
xlabel('x1'); ylabel('x2'); grid on; axis square
subplot(1,3,2)
plot(x1,x3,'.')
xlabel('x1'); ylabel('x3'); grid on; axis square
subplot(1,3,3)
plot(x2,x3,'.')
xlabel('x2'); ylabel('x3'); grid on; axis square
```

Note the correlation between $x 1$ and the other two predictor variables.
Use ridge and x2fx to compute coefficient estimates for a multilinear model with interaction terms, for a range of ridge parameters:

```
X = [x1 x2 x3];
D = x2fx(X,'interaction');
D(:,1) = []; % No constant term
k = 0:1e-5:5e-3;
betahat = ridge(y,D,k);
```

Plot the ridge trace:
figure

```
plot(k,betahat,'LineWidth',2)
ylim([-100 100])
grid on
xlabel('Ridge Parameter')
ylabel('Standardized Coefficient')
title('{\bf Ridge Trace}')
legend('x1','x2','x3','x1x2','x1x3','x2x3')
```

Ridge Trace

The estimates stabilize to the right of the plot. Note that the coefficient of the $\times 2 \times 3$ interaction term changes sign at a value of the ridge parameter $\approx$ $5 \times 10^{-4}$.

## Lasso and Elastic Net

# In this section... <br> "What Are Lasso and Elastic Net?" on page 9-123 <br> "Lasso Regularization" on page 9-123 <br> "Lasso and Elastic Net with Cross Validation" on page 9-126 <br> "Wide Data via Lasso and Parallel Computing" on page 9-129 <br> "Lasso and Elastic Net Details" on page 9-134 <br> "References" on page 9-136 

## What Are Lasso and Elastic Net?

Lasso is a regularization technique. Use lasso to:

- Reduce the number of predictors in a regression model.
- Identify important predictors.
- Select among redundant predictors.
- Produce shrinkage estimates with potentially lower predictive errors than ordinary least squares.

Elastic net is a related technique. Use elastic net when you have several highly correlated variables. lasso provides elastic net regularization when you set the Alpha name-value pair to a number strictly between 0 and 1.

See "Lasso and Elastic Net Details" on page 9-134.
For lasso regularization of regression ensembles, see regularize.

## Lasso Regularization

To see how lasso identifies and discards unnecessary predictors:
1 Generate 200 samples of five-dimensional artificial data $X$ from exponential distributions with various means:

```
rng(3,'twister') % for reproducibility
X = zeros(200,5);
for ii = 1:5
    X(:,ii) = exprnd(ii,200,1);
end
```

2 Generate response data $Y=X * r+e p s$ where $r$ has just two nonzero components, and the noise eps is normal with standard deviation 0.1:

```
r = [0;2;0;-3;0];
Y = X*r + randn(200,1)*.1;
```

3 Fit a cross-validated sequence of models with lasso, and plot the result:

```
[b fitinfo] = lasso(X,Y,'CV',10);
lassoPlot(b,fitinfo,'PlotType','Lambda','XScale','log');
```

Trace Plot of coefficients fit by Lasso

The plot shows the nonzero coefficients in the regression for various values of the Lambda regularization parameter. Larger values of Lambda appear on the left side of the graph, meaning more regularization, resulting in fewer nonzero regression coefficients.

The dashed vertical lines represent the Lambda value with minimal mean squared error (on the right), and the Lambda value with minimal mean squared error plus one standard deviation. This latter value is a recommended setting for Lambda. These lines appear only when you perform cross validation. Cross validate by setting the 'CV' name-value pair. This example uses 10 -fold cross validation.

The upper part of the plot shows the degrees of freedom (df), meaning the number of nonzero coefficients in the regression, as a function of Lambda. On the left, the large value of Lambda causes all but one coefficient to be 0 . On the right all five coefficients are nonzero, though the plot shows only two clearly. The other three coefficients are so small that you cannot visually distinguish them from 0 .

For small values of Lambda (toward the right in the plot), the coefficient values are close to the least-squares estimate. See step 5 on page 9-126.

4 Find the Lambda value of the minimal cross-validated mean squared error plus one standard deviation. Examine the MSE and coefficients of the fit at that Lambda:

```
lam = fitinfo.Index1SE;
fitinfo.MSE(lam)
ans =
    0.1398
b(:,lam)
ans =
0
    1.8855
0
```

    -2.9367
    0
lasso did a good job finding the coefficient vector $r$.
5 For comparison, find the least-squares estimate of $r$ :

```
rhat = X\Y
rhat =
    -0.0038
    1.9952
    0.0014
    -2.9993
    0.0031
```

The estimate $b(:, l a m)$ has slightly more mean squared error than the mean squared error of rhat:

```
res = X*rhat - Y; % calculate residuals
```

MSEmin $=$ res'*res/200 \% b(:,lam) value is 0.1398
MSEmin =
0.0088

But b(:, lam) has only two nonzero components, and therefore can provide better predictive estimates on new data.

## Lasso and Elastic Net with Cross Validation

Consider predicting the mileage (MPG) of a car based on its weight, displacement, horsepower, and acceleration. The carbig data contains these measurements. The data seem likely to be correlated, making elastic net an attractive choice.

1 Load the data:
load carbig

2 Extract the continuous (noncategorical) predictors (lasso does not handle categorical predictors):

X = [Acceleration Displacement Horsepower Weight];

3 Perform a lasso fit with 10 -fold cross validation:

```
[b fitinfo] = lasso(X,MPG,'CV',10);
```

4 Plot the result:

```
lassoPlot(b,fitinfo,'PlotType','Lambda','XScale','log');
```

Trace Plot of coefficients fit by Lasso
df

5 Calculate the correlation of the predictors:

```
% Eliminate NaNs so corr runs
nonan = ~any(isnan([X MPG]),2);
Xnonan = X(nonan,:);
MPGnonan = MPG(nonan,:);
corr(Xnonan)
ans =
```

| 1.0000 | -0.5438 | -0.6892 | -0.4168 |
| ---: | ---: | ---: | ---: |
| -0.5438 | 1.0000 | 0.8973 | 0.9330 |
| -0.6892 | 0.8973 | 1.0000 | 0.8645 |
| -0.4168 | 0.9330 | 0.8645 | 1.0000 |

6 Because some predictors are highly correlated, perform elastic net fitting. Use Alpha = 0.5:

```
[ba fitinfoa] = lasso(X,MPG,'CV',10,'Alpha',.5);
```

7 Plot the result. Name each predictor so you can tell which curve is which:
pnames = \{'Acceleration', 'Displacement',...
'Horsepower', 'Weight'\};
lassoPlot (ba,fitinfoa,'PlotType','Lambda', ...
'XScale','log','PredictorNames', pnames);
Trace Plot of coefficients fit by Elastic Net (Alpha $=0.5$ ) df

When you activate the data cursor

and click the plot, you see the name of the predictor, the coefficient, the value of Lambda, and the index of that point, meaning the column in $b$ associated with that fit.

Here, the elastic net and lasso results are not very similar. Also, the elastic net plot reflects a notable qualitative property of the elastic net technique. The elastic net retains three nonzero coefficients as Lambda increases (toward the left of the plot), and these three coefficients reach 0 at about the same Lambda value. In contrast, the lasso plot shows two of the three coefficients becoming 0 at the same value of Lambda, while another coefficient remains nonzero for higher values of Lambda.

This behavior exemplifies a general pattern. In general, elastic net tends to retain or drop groups of highly correlated predictors as Lambda increases. In contrast, lasso tends to drop smaller groups, or even individual predictors.

## Wide Data via Lasso and Parallel Computing

Lasso and elastic net are especially well suited to wide data, meaning data with more predictors than observations. Obviously, there are redundant predictors in this type of data. Use lasso along with cross validation to identify important predictors.

Cross validation can be slow. If you have a Parallel Computing Toolbox license, speed the computation using parallel computing.

1 Load the spectra data:

```
load spectra
```

Description

Description =
== Spectral and octane data of gasoline ==

```
NIR spectra and octane numbers of 60 gasoline samples
NIR: NIR spectra, measured in 2 nm intervals from 900 nm to 1700 nm
octane: octane numbers
spectra: a dataset array containing variables for NIR and octane
Reference:
Kalivas, John H., "Two Data Sets of Near Infrared Spectra," Chemometrics
and Intelligent Laboratory Systems, v. 37 (1997) pp. 255 259
```

2 Compute the default lasso fit:
[b fitinfo] = lasso(NIR,octane);

3 Plot the number of predictors in the fitted lasso regularization as a function of Lambda, using a logarithmic $x$-axis:

```
lassoPlot(b,fitinfo,'PlotType','Lambda','XScale','log');
```

Trace Plot of coefficients fit by Lasso
df

4 It is difficult to tell which value of Lambda is appropriate. To determine a good value, try fitting with cross validation:
tic
[b fitinfo] = lasso(NIR,octane,'CV',10);
\% A time-consuming operation
toc
Elapsed time is 226.876926 seconds.
5 Plot the result:
lassoPlot(b,fitinfo,'PlotType','Lambda','XScale','log');

Trace Plot of coefficients fit by Lasso
df

You can see the suggested value of Lambda is over $1 e-2$, and the Lambda with minimal MSE is under 1e-2. These values are in the fitinfo structure:
fitinfo.LambdaMinMSE
ans $=$
0.0057

```
fitinfo.Lambda1SE
ans =
    0.0190
```

6 Examine the quality of the fit for the suggested value of Lambda:

```
lambdaindex = fitinfo.Index1SE;
```

fitinfo.MSE(lambdaindex)
ans $=$
0.0532
fitinfo. DF(lambdaindex)
ans $=$
11

The fit uses just 11 of the 401 predictors, and achieves a cross-validated MSE of 0.0532 .

7 Examine the plot of cross-validated MSE:
lassoPlot(b,fitinfo,'PlotType','CV');
\% Use a log scale for MSE to see small MSE values better set(gca,'YScale','log');

As Lambda increases (toward the left), MSE increases rapidly. The coefficients are reduced too much and they do not adequately fit the responses.

As Lambda decreases, the models are larger (have more nonzero coefficients). The increasing MSE suggests that the models are overfitted.

The default set of Lambda values does not include values small enough to include all predictors. In this case, there does not appear to be a reason to look at smaller values. However, if you want smaller values than the default, use the LambdaRatio parameter, or supply a sequence of Lambda values using the Lambda parameter. For details, see the lasso reference page.

8 To compute the cross-validated lasso estimate faster, use parallel computing (available with a Parallel Computing Toolbox license):

```
matlabpool open
Starting matlabpool using the 'local' configuration ...
    connected to 4 labs.
opts = statset('UseParallel',true);
tic;
[b fitinfo] = lasso(NIR,octane,'CV',10,'Options',opts);
toc
Elapsed time is 107.539719 seconds.
```

Computing in parallel is more than twice as fast on this problem using a quad-core processor.

## Lasso and Elastic Net Details

## Overview of Lasso and Elastic Net

Lasso is a regularization technique for performing linear regression. Lasso includes a penalty term that constrains the size of the estimated coefficients. Therefore, it resembles ridge regression. Lasso is a shrinkage estimator: it generates coefficient estimates that are biased to be small. Nevertheless, a lasso estimator can have smaller mean squared error than an ordinary least-squares estimator when you apply it to new data.

Unlike ridge regression, as the penalty term increases, lasso sets more coefficients to zero. This means that the lasso estimator is a smaller model, with fewer predictors. As such, lasso is an alternative to stepwise regression and other model selection and dimensionality reduction techniques.

Elastic net is a related technique. Elastic net is a hybrid of ridge regression and lasso regularization. Like lasso, elastic net can generate reduced models by generating zero-valued coefficients. Empirical studies have suggested that the elastic net technique can outperform lasso on data with highly correlated predictors.

## Definition of Lasso

The lasso technique solves this regularization problem. For a given value of $\lambda$, a nonnegative parameter, lasso solves the problem

$$
\min _{\beta_{0}, \beta}\left(\frac{1}{2 N} \sum_{i=1}^{N}\left(y_{i}-\beta_{0}-x_{i}^{T} \beta\right)^{2}+\lambda \sum_{j=1}^{p}\left|\beta_{j}\right|\right)
$$

where

- $N$ is the number of observations.
- $y_{i}$ is the response at observation $i$.
- $x_{i}$ is data, a vector of $p$ values at observation $i$.
- $\lambda$ is a positive regularization parameter corresponding to one value of Lambda.
- The parameters $\beta_{0}$ and $\beta$ are scalar and $p$-vector respectively.

As $\lambda$ increases, the number of nonzero components of $\beta$ decreases.
The lasso problem involves the $L^{1}$ norm of $\beta$, as contrasted with the elastic net algorithm.

## Definition of Elastic Net

The elastic net technique solves this regularization problem. For an $\alpha$ strictly between 0 and 1 , and a nonnegative $\lambda$, elastic net solves the problem

$$
\min _{\beta_{0}, \beta}\left(\frac{1}{2 N} \sum_{i=1}^{N}\left(y_{i}-\beta_{0}-x_{i}^{T} \beta\right)^{2}+\lambda P_{\alpha}(\beta)\right),
$$

where

$$
P_{\alpha}(\beta)=\frac{(1-\alpha)}{2}\|\beta\|_{2}^{2}+\alpha\|\beta\|_{1}=\sum_{j=1}^{p}\left(\frac{(1-\alpha)}{2} \beta_{j}^{2}+\alpha\left|\beta_{j}\right|\right) .
$$

Elastic net is the same as lasso when $\alpha=1$. As $a$ shrinks toward 0 , elastic net approaches ridge regression. For other values of $a$, the penalty term $P_{a}(\beta)$ interpolates between the $L^{1}$ norm of $\beta$ and the squared $L^{2}$ norm of $\beta$.

## Partial Least Squares

In this section...<br>"Introduction to Partial Least Squares" on page 9-137<br>"Partial Least Squares" on page 9-138

## Introduction to Partial Least Squares

Partial least-squares (PLS) regression is a technique used with data that contain correlated predictor variables. This technique constructs new predictor variables, known as components, as linear combinations of the original predictor variables. PLS constructs these components while considering the observed response values, leading to a parsimonious model with reliable predictive power.

The technique is something of a cross between multiple linear regression and principal component analysis:

- Multiple linear regression finds a combination of the predictors that best fit a response.
- Principal component analysis finds combinations of the predictors with large variance, reducing correlations. The technique makes no use of response values.
- PLS finds combinations of the predictors that have a large covariance with the response values.

PLS therefore combines information about the variances of both the predictors and the responses, while also considering the correlations among them.

PLS shares characteristics with other regression and feature transformation techniques. It is similar to ridge regression in that it is used in situations with correlated predictors. It is similar to stepwise regression (or more general feature selection techniques) in that it can be used to select a smaller set of model terms. PLS differs from these methods, however, by transforming the original predictor space into the new component space.

The Statistics Toolbox function plsregress carries out PLS regression.

## Partial Least Squares

For example, consider the data on biochemical oxygen demand in moore.mat, padded with noisy versions of the predictors to introduce correlations:

```
load moore
y = moore(:,6); % Response
X0 = moore(:,1:5); % Original predictors
X1 = X0+10*randn(size(XO)); % Correlated predictors
X = [X0,X1];
```

Use plsregress to perform PLS regression with the same number of components as predictors, then plot the percentage variance explained in the response as a function of the number of components:

```
[XL,yl,XS,YS,beta,PCTVAR] = plsregress(X,y,10);
plot(1:10,cumsum(100*PCTVAR(2,:)),'-bo');
xlabel('Number of PLS components');
ylabel('Percent Variance Explained in y');
```

Choosing the number of components in a PLS model is a critical step. The plot gives a rough indication, showing nearly $80 \%$ of the variance in y explained by the first component, with as many as five additional components making significant contributions.

The following computes the six-component model:

```
[XL,yl,XS,YS,beta,PCTVAR,MSE,stats] = plsregress(X,y,6);
yfit = [ones(size(X,1),1) X]*beta;
plot(y,yfit,'o')
```

The scatter shows a reasonable correlation between fitted and observed responses, and this is confirmed by the $R^{2}$ statistic:

```
TSS = sum((y-mean(y)).^2);
RSS = sum((y-yfit).^2);
Rsquared = 1 - RSS/TSS
Rsquared =
    0.8421
```

A plot of the weights of the ten predictors in each of the six components shows that two of the components (the last two computed) explain the majority of the variance in X :

```
plot(1:10,stats.W,'o-');
legend({'c1','c2','c3','c4','c5','c6'},'Location','NW')
xlabel('Predictor');
ylabel('Weight');
```

A plot of the mean-squared errors suggests that as few as two components may provide an adequate model:

```
[axes,h1,h2] = plotyy(0:6,MSE(1,:),0:6,MSE(2,:));
set(h1,'Marker','o')
set(h2,'Marker','o')
legend('MSE Predictors','MSE Response')
xlabel('Number of Components')
```

The calculation of mean-squared errors by plsregress is controlled by optional parameter name/value pairs specifying cross-validation type and the number of Monte Carlo repetitions.

## Generalized Linear Models

In this section...<br>"What Are Generalized Linear Models?" on page 9-143<br>"Prepare Data" on page 9-144<br>"Choose Generalized Linear Model and Link Function" on page 9-146<br>"Choose Fitting Method and Model" on page 9-150<br>"Fit Model to Data" on page 9-155<br>"Examine Quality and Adjust the Fitted Model" on page 9-156<br>"Predict or Simulate Responses to New Data" on page 9-168<br>"Share Fitted Models" on page 9-171<br>"Generalized Linear Model Workflow" on page 9-173

## What Are Generalized Linear Models?

Linear regression models describe a linear relationship between a response and one or more predictive terms. Many times, however, a nonlinear relationship exists. "Nonlinear Regression" on page 9-198 describes general nonlinear models. A special class of nonlinear models, called generalized linear models, uses linear methods.

Recall that linear models have these characteristics:

- At each set of values for the predictors, the response has a normal distribution with mean $\mu$.
- A coefficient vector $b$ defines a linear combination $X b$ of the predictors $X$.
- The model is $\mu=X b$.

In generalized linear models, these characteristics are generalized as follows:

- At each set of values for the predictors, the response has a distribution that can be normal, binomial, Poisson, gamma, or inverse Gaussian, with parameters including a mean $\mu$.
- A coefficient vector $b$ defines a linear combination $X b$ of the predictors $X$.
- A link function $f$ defines the model as $f(\mu)=X b$.

## Prepare Data

To begin fitting a regression, put your data into a form that fitting functions expect. All regression techniques begin with input data in an array $X$ and response data in a separate vector $y$, or input data in a dataset array ds and response data as a column in ds. Each row of the input data represents one observation. Each column represents one predictor (variable).

For a dataset array ds, indicate the response variable with the 'ResponseVar ' name-value pair:

```
mdl = LinearModel.fit(ds,'ResponseVar','BloodPressure');
% or
mdl = GeneralizedLinearModel.fit(ds,'ResponseVar','BloodPressure');
```

The response variable is the last column by default.
You can use numeric categorical predictors. A categorical predictor is one that takes values from a fixed set of possibilities.

- For a numeric array $X$, indicate the categorical predictors using the 'Categorical' name-value pair. For example, to indicate that predictors 2 and 3 out of six are categorical:

```
mdl = LinearModel.fit(X,y,'Categorical',[2,3]);
% or
mdl = GeneralizedLinearModel.fit(X,y,'Categorical',[2,3]);
% or equivalently
mdl = LinearModel.fit(X,y,'Categorical',logical([00 1 1 0 0 0]));
```

- For a dataset array ds, fitting functions assume that these data types are categorical:
- Logical
- Categorical (nominal or ordinal)
- String or character array

If you want to indicate that a numeric predictor is categorical, use the 'Categorical' name-value pair.

Represent missing numeric data as NaN. To represent missing data for other data types, see "Missing Group Values" on page 2-53.

- For a 'binomial' model with data matrix $X$, the response $y$ can be:
- Binary column vector - Each entry represents success (1) or failure (0).
- Two-column matrix of integers - The first column is the number of successes in each observation, the second column is the number of trials in that observation.
- For a 'binomial' model with dataset ds:
- Use the ResponseVar name-value pair to specify the column of ds that gives the number of successes in each observation.
- Use the BinomialSize name-value pair to specify the column of ds that gives the number of trials in each observation.

## Dataset Array for Input and Response Data

For example, to create a dataset array from an Excel spreadsheet:

```
ds = dataset('XLSFile','hospital.xls',...
    'ReadObsNames',true);
```

To create a dataset array from workspace variables:

```
load carsmall
ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);
```

## Numeric Matrix for Input Data, Numeric Vector for Response

For example, to create numeric arrays from workspace variables:

```
load carsmall
X = [Weight Horsepower Cylinders Model_Year];
y = MPG;
```

To create numeric arrays from an Excel spreadsheet:

```
[X Xnames] = xlsread('hospital.xls');
y = X(:,4); % response y is systolic pressure
```

```
X(:,4) = []; % remove y from the X matrix
```

Notice that the nonnumeric entries, such as sex, do not appear in $X$.

## Choose Generalized Linear Model and Link Function

Often, your data suggests the distribution type of the generalized linear model.

| Response Data Type | Suggested Model Distribution <br> Type |
| :--- | :--- |
| Any real number | 'normal ' |
| Any positive number | 'gamma ' or 'inverse gaussian' |
| Any nonnegative integer | 'poisson ' |
| Integer from 0 to n, where $n$ is a fixed <br> positive value | 'binomial' |

Set the model distribution type with the Distribution name-value pair. After selecting your model type, choose a link function to map between the mean $\mu$ and the linear predictor $X b$.

| Value | Description |
| :--- | :--- |
| 'comploglog ' | $\log (-\log ((1-\mu)))=X b$ |
| 'identity ', default for the <br> distribution 'normal' | $\mu=X b$ |
| 'log', default for the <br> distribution ' poisson' | $\log (\mu)=X b$ |
| 'logit', default for the <br> distribution 'binomial' | $\log (\mu /(1-\mu))=X b$ |
| 'loglog' | $\log (-\log (\mu))=X b$ |
| 'probit' | $\Phi^{-1}(\mu)=X b$, where $\Phi$ is the normal <br> $(\operatorname{Gaussian}) \mathrm{CDF}$ function |
| 'reciprocal ', default for the <br> distribution 'gamma' | $\mu^{-1}=X b$ |

| Value | Description |
| :--- | :--- |
| p (a number), default for <br> the distribution 'inverse <br> gaussian' (with $p=-2$ ) | $\mu^{p}=X b$ |
| Cell array of the form <br> \{FL FD FI \}, containing <br> three function handles, created | Link Function" on page 9-147) |
| using @, that define the link |  |
| (FL), the derivative of the |  |
| link (FD), and the inverse link |  |
| (FI). Equivalently, can be a |  |
| structure of function handles |  |
| with field Link containing FL, |  |
| field Derivative containing |  |
| FD, and field Inverse |  |
| containing FI. |  |

The nondefault link functions are mainly useful for binomial models. These nondefault link functions are 'comploglog', 'loglog', and 'probit'.

## Custom Link Function

The link function defines the relationship $f(\mu)=X b$ between the mean response $\mu$ and the linear combination $X b=X^{*} b$ of the predictors. You can choose one of the built-in link functions or define your own by specifying the link function FL, its derivative FD, and its inverse FI:

- The link function FL calculates $f(\mu)$.
- The derivative of the link function FD calculates $d f(\mu) / d \mu$.
- The inverse function FI calculates $g(X b)=\mu$.

You can specify a custom link function in either of two equivalent ways. Each way contains function handles that accept a single array of values representing $\mu$ or $X b$, and returns an array the same size. The function handles are either in a cell array or a structure:

- Cell array of the form \{FL FD FI\}, containing three function handles, created using @, that define the link (FL), the derivative of the link (FD), and the inverse link (FI).
- Structure $s$ with three fields, each containing a function handle created using $@$ :
- s.Link - Link function
- s.Derivative - Derivative of the link function
- s.Inverse - Inverse of the link function

For example, to fit a model using the 'probit' link function:

```
x = [2100 2300 2500 2700 2900 ...
    3100 3300 3500 3700 3900 4100 4300]';
n = [48 42 31 34 31 21 23 23 21 16 17 21]';
y = [1 2 2 0 3 8 8 8 14 17 19 15 17 21]';
g = GeneralizedLinearModel.fit(x,[y n],...
    'linear','distr','binomial','link','probit')
g =
```

Generalized Linear regression model:
probit(y) ~ $1+x 1$
Distribution = Binomial
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | :--- |
| (Intercept) | -7.3628 | 0.66815 | -11.02 | $3.0701 \mathrm{e}-28$ |
| x1 | 0.0023039 | 0.00021352 | 10.79 | $3.8274 \mathrm{e}-27$ |

12 observations, 10 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 241, p-value $=2.25 e-54$

You can perform the same fit using a custom link function that performs identically to the 'probit' link function:

```
s = {@norminv,@(x)1./normpdf(norminv(x)),@normcdf};
g = GeneralizedLinearModel.fit(x,[y n],...
    'linear','distr','binomial','link',s)
```

```
g =
Generalized Linear regression model:
    link(y) ~ 1 + x1
    Distribution = Binomial
Estimated Coefficients:
\begin{tabular}{lcrrl} 
& Estimate & \multicolumn{1}{l}{ SE } & \multicolumn{1}{l}{ tStat } & pValue \\
(Intercept) & -7.3628 & 0.66815 & -11.02 & \(3.0701 \mathrm{e}-28\) \\
x1 & 0.0023039 & 0.00021352 & 10.79 & \(3.8274 \mathrm{e}-27\)
\end{tabular}
1 2 \text { observations, 10 error degrees of freedom}
Dispersion: 1
Chi^2-statistic vs. constant model: 241, p-value = 2.25e-54
```

The two models are the same.
Equivalently, you can write $s$ as a structure instead of a cell array of function handles:

```
s.Link = @norminv;
s.Derivative = @(x) 1./normpdf(norminv(x));
s.Inverse = @normcdf;
g = GeneralizedLinearModel.fit(x,[y n],...
    'linear','distr','binomial','link',s)
g =
Generalized Linear regression model:
    link(y) ~ 1 + x1
    Distribution = Binomial
```

Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | :--- |
| (Intercept) | -7.3628 | 0.66815 | -11.02 | $3.0701 \mathrm{e}-28$ |
| x1 | 0.0023039 | 0.00021352 | 10.79 | $3.8274 \mathrm{e}-27$ |

12 observations, 10 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 241, p-value $=2.25 e-54$

## Choose Fitting Method and Model

There are two ways to create a fitted model.

- Use GeneralizedLinearModel.fit when you have a good idea of your generalized linear model, or when you want to adjust your model later to include or exclude certain terms.
- Use GeneralizedLinearModel.stepwise when you want to fit your model using stepwise regression. GeneralizedLinearModel.stepwise starts from one model, such as a constant, and adds or subtracts terms one at a time, choosing an optimal term each time in a greedy fashion, until it cannot improve further. Use stepwise fitting to find a good model, one that has only relevant terms.

The result depends on the starting model. Usually, starting with a constant model leads to a small model. Starting with more terms can lead to a more complex model, but one that has lower mean squared error.

In either case, provide a model to the fitting function (which is the starting model for GeneralizedLinearModel.stepwise).

Specify a model using one of these methods.

- "Brief String" on page 9-150
- "Terms Matrix" on page 9-151
- "Formula" on page 9-154

## Brief String

| String | Model Type |
| :--- | :--- |
| 'constant' | Model contains only a constant (intercept) term. |
| 'linear' | Model contains an intercept and linear terms for <br> each predictor. |
| 'interactions' | Model contains an intercept, linear terms, and <br> all products of pairs of distinct predictors (no <br> squared terms). |

| String | Model Type |
| :--- | :--- |
| 'purequadratic' | Model contains an intercept, linear terms, and <br> squared terms. |
| 'quadratic' | Model contains an intercept, linear terms, <br> interactions, and squared terms. |
| 'polyijk' | Model is a polynomial with all terms up to degree <br> $i$ in the first predictor, degree $j$ in the second <br> predictor, etc. Use numerals 0 through 9. For <br> example, 'poly2111' has a constant plus all <br> linear and product terms, and also contains <br> terms with predictor 1 squared. |

## Terms Matrix

A terms matrix is a T-by- $P+1$ matrix specifying terms in a model, where $T$ is the number of terms, P is the number of predictor variables, and plus one is for the response variable. The value of $T(i, j)$ is the exponent of variable $j$ in term i. For example, if there are three predictor variables A, B, and C:
[0 0 0 0 ] \% constant term or intercept
[0 10000 \% B; equivalently, $\mathrm{A}^{\wedge} 0$ * $\mathrm{B}^{\wedge} 1$ * $\mathrm{C}^{\wedge} 0$
$\left[\begin{array}{llll}1 & 0 & 1 & 0\end{array}\right] \% A^{*} C$
[2000] \% A^2
[0 $\left.1 \begin{array}{lll}2 & 0\end{array}\right]$ \% $B^{*}\left(C^{\wedge} 2\right)$
The 0 at the end of each term represents the response variable. In general,

- If you have the variables in a dataset array, then a 0 must represent the response variable depending on the position of the response variable in the dataset array. For example:

Load sample data and define the dataset array.
load hospital
ds = dataset(hospital.Sex,hospital.BloodPressure(:,1),hospital.Age,... hospital.Smoker, 'VarNames', \{'Sex', 'BloodPressure', 'Age', 'Smoker'\});

Represent the linear model 'BloodPressure ~ 1 + Sex + Age + Smoker' in a terms matrix. The response variable is in the second column
of the data set array, so there must be a column of zeros for the response variable in the second column of the term matrix.

```
T =[[0 0 0 0;1 0 0 0;0 0 1 0;0}00001
T =
\begin{tabular}{llll}
0 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{tabular}
```

Redefine the dataset array.

```
ds = dataset(hospital.BloodPressure(:,1),hospital.Sex,hospital.Age,...
```

hospital.Smoker, 'VarNames', \{'BloodPressure','Sex','Age','Smoker'\});

Now, the response variable is the first term in the data set array. Specify the same linear model, 'BloodPressure ~ 1 + Sex + Age + Smoker', using a term matrix.

```
T = [0 0 0 0;0 1 0 0;0 0 1 0;0 0 0 1]
T =
```

| 0 | 0 | 0 | 0 |
| :--- | :--- | :--- | :--- |
| 0 | 1 | 0 | 0 |
| 0 | 0 | 1 | 0 |
| 0 | 0 | 0 | 1 |

- If you have the predictor and response variables in a matrix and column vector, then you must include a 0 for the response variable at the end of each term. For example:
Load sample data and define the matrix of predictors.
load carsmall
X = [Acceleration, Weight];
Specify the model 'MPG ~ Acceleration + Weight + Acceleration:Weight + Weight^2' using a term matrix and fit the model to data. This model includes the main effect and two way
interaction terms for the variables, Acceleration and Weight, and a second order term for the variable, Weight.

```
T = [0 0 0;1 0 0;0 1 0;1 1 0;0 2 0]
T =
\begin{tabular}{lll}
0 & 0 & 0 \\
1 & 0 & 0 \\
0 & 1 & 0 \\
1 & 1 & 0 \\
0 & 2 & 0
\end{tabular}
```

Fit a linear model.

```
mdl = LinearModel.fit(X,MPG,T)
```

mdl =
Linear regression model:
$y$ ~ 1 + x1*x2 + x2^2
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | ---: |
| (Intercept) | 48.906 | 12.589 | 3.8847 | 0.00019665 |
| x1 | 0.54418 | 0.57125 | 0.95261 | 0.34337 |
| x2 | -0.012781 | 0.0060312 | -2.1192 | 0.036857 |
| x1: x2 | -0.00010892 | 0.00017925 | -0.6076 | 0.545 |
| x2^2 | $9.7518 \mathrm{e}-07$ | $7.5389 \mathrm{e}-07$ | 1.2935 | 0.19917 |

Number of observations: 94, Error degrees of freedom: 89
Root Mean Squared Error: 4.1
R-squared: 0.751, Adjusted R-Squared 0.739
F-statistic vs. constant model: 67, p-value = 4.99e-26

Only the intercept and x2 term, which corresponds to the Weight variable, are significant at the $5 \%$ significance level.

Now, perform a stepwise regression with a constant model as the starting model and a linear model with interactions as the upper model.

```
T = [0 0 0;1 0 0;0 1 0;1 1 0];
mdl = LinearModel.stepwise(X,MPG,[0 O O],'upper',T)
1. Adding x2, FStat = 259.3087, pValue = 1.643351e-28
mdl =
Linear regression model:
    y ~ 1 + x2
Estimated Coefficients:
\begin{tabular}{lrrrl} 
& Estimate & \multicolumn{1}{l}{ SE } & tStat & PValue \\
(Intercept) & 49.238 & 1.6411 & 30.002 & \(2.7015 \mathrm{e}-49\) \\
x2 & -0.0086119 & 0.0005348 & -16.103 & \(1.6434 \mathrm{e}-28\)
\end{tabular}
Number of observations: 94, Error degrees of freedom: 92
Root Mean Squared Error: 4.13
R-squared: 0.738, Adjusted R-Squared 0.735
F-statistic vs. constant model: 259, p-value = 1.64e-28
```

The results of the stepwise regression are consistent with the results of LinearModel.fit in the previous step.

## Formula

A formula for a model specification is a string of the form

```
'Y ~ terms',
```

- $Y$ is the response name.
- terms contains
- Variable names
-     + to include the next variable
-     - to exclude the next variable
- : to define an interaction, a product of terms
-     * to define an interaction and all lower-order terms
- ^ to raise the predictor to a power, exactly as in * repeated, so ^ includes lower order terms as well
- () to group terms

Tip Formulas include a constant (intercept) term by default. To exclude a constant term from the model, include -1 in the formula.

Examples:
' $Y$ ~ A + B + C' is a three-variable linear model with intercept.
' $Y \sim A+B+C-1 '$ is a three-variable linear model without intercept.
' $Y$ ~ $A+B+C+B \wedge 2 '$ is a three-variable model with intercept and a $B^{\wedge} 2$ term.
' Y ~ $\mathrm{A}+\mathrm{B}^{\wedge} 2+C$ ' is the same as the previous example, since $\mathrm{B}^{\wedge} 2$
includes a $B$ term.
' $Y \sim A+B+C+A: B '$ includes an $A * B$ term.
' $Y$ ~ $A * B+C$ ' is the same as the previous example, since $A * B=A+B+$
A:B.
' $Y \sim A * B * C-A: B: C '$ has all interactions among $A, B$, and $C$, except the three-way interaction.
' Y ~ A* $(B+C+D)$ ' has all linear terms, plus products of $A$ with each of the other variables.

## Fit Model to Data

Create a fitted model using GeneralizedLinearModel.fit or GeneralizedLinearModel.stepwise. Choose between them as in "Choose Fitting Method and Model" on page 9-150. For generalized linear models other than those with a normal distribution, give a Distribution name-value pair as in "Choose Generalized Linear Model and Link Function" on page 9-146. For example,

```
mdl = GeneralizedLinearModel.fit(X,y,'linear','Distribution','poisson')
% or
mdl = GeneralizedLinearModel.fit(X,y,'quadratic',...
    'Distribution','binomial')
```

## Examine Quality and Adjust the Fitted Model

After fitting a model, examine the result.

- "Model Display" on page 9-156
- "Diagnostic Plots" on page 9-157
- "Residuals - Model Quality for Training Data" on page 9-160
- "Plots to Understand Predictor Effects and How to Modify a Model" on page 9-163

## Model Display

A linear regression model shows several diagnostics when you enter its name or enter disp (mdl). This display gives some of the basic information to check whether the fitted model represents the data adequately.

For example, fit a Poisson model to data constructed with two out of five predictors not affecting the response, and with no intercept term:

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[14 4 5])*[.4;.2;.3]);
y = poissrnd(mu);
mdl = GeneralizedLinearModel.fit(X,y,\ldots.
    'linear','Distribution','poisson')
mdl =
Generalized Linear regression model:
    log(y) ~ 1 + x1 + x2 + x3 + x4 + x5
    Distribution = Poisson
Estimated Coefficients:
\begin{tabular}{lrrrr} 
& \multicolumn{1}{l}{ Estimate } & \multicolumn{1}{l}{ SE } & \multicolumn{1}{l}{ tStat } & \multicolumn{1}{l}{ pValue } \\
(Intercept) & 0.039829 & 0.10793 & 0.36901 & 0.71212 \\
x1 & 0.38551 & 0.076116 & 5.0647 & \(4.0895 \mathrm{e}-07\) \\
x2 & -0.034905 & 0.086685 & -0.40266 & 0.6872 \\
x3 & -0.17826 & 0.093552 & -1.9054 & 0.056722 \\
X4 & 0.21929 & 0.09357 & 2.3436 & 0.019097
\end{tabular}
```

```
    x5
        0.28918
100 observations, 94 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 44.9, p-value = 1.55e-08
```

Notice that:

- The display contains the estimated values of each coefficient in the Estimate column. These values are reasonably near the true values [0;.4;0;0;.2;.3], except possibly the coefficient of $x 3$ is not terribly near 0 .
- There is a standard error column for the coefficient estimates.
- The reported pValue (which are derived from the $t$ statistics under the assumption of normal errors) for predictors 1,4 , and 5 are small. These are the three predictors that were used to create the response data $y$.
- The pValue for (Intercept), $x 2$ and $\times 3$ are larger than 0.01 . These three predictors were not used to create the response data $y$. The pValue for $x 3$ is just over . 05, so might be regarded as possibly significant.
- The display contains the Chi-square statistic.

## Diagnostic Plots

Diagnostic plots help you identify outliers, and see other problems in your model or fit. To illustrate these plots, consider binomial regression with a logistic link function.

The logistic model is useful for proportion data. It defines the relationship between the proportion $p$ and the weight $w$ by:

$$
\log [p /(1-p)]=b_{1}+b_{2} w
$$

This example fits a binomial model to data. The data are derived from carbig.mat, which contains measurements of large cars of various weights. Each weight in whas a corresponding number of cars in total and a corresponding number of poor-mileage cars in poor.

It is reasonable to assume that the values of poor follow binomial distributions, with the number of trials given by total and the percentage of successes depending on $w$. This distribution can be accounted for in the context of a logistic model by using a generalized linear model with link function $\log (\mu /(1-\mu))=X b$. This link function is called 'logit'.

```
w = [2100 2300 2500 2700 2900 3100 ...
    3300 3500 3700 3900 4100 4300]';
total = [48 42 31 34 31 21 23 23 21 16 17 21]';
poor = [1 2 0 3 8 8 14 17 19 15 17 21]';
mdl = GeneralizedLinearModel.fit(w,[poor total],...
    'linear','Distribution','binomial','link','logit')
mdl =
Generalized Linear regression model:
    logit(y) ~ 1 + x1
    Distribution = Binomial
Estimated Coefficients:
\begin{tabular}{lrrrl} 
& Estimate & SE & tStat & pValue \\
(Intercept) & -13.38 & & 1.394 & -9.5986 \\
x1 & 0.0041812 & 0.00044258 & 9.4474 & \(3.4739 \mathrm{e}-21\)
\end{tabular}
1 2 ~ o b s e r v a t i o n s , ~ 1 0 ~ e r r o r ~ d e g r e e s ~ o f ~ f r e e d o m
Dispersion: 1
Chi^2-statistic vs. constant model: 242, p-value = 1.3e-54
```

See how well the model fits the data.

```
plotSlice(mdl)
```

The fit looks reasonably good, with fairly wide confidence bounds.
To examine further details, create a leverage plot.
plotDiagnostics(mdl)

This is typical of a regression with points ordered by the predictor variable. The leverage of each point on the fit is higher for points with relatively extreme predictor values (in either direction) and low for points with average predictor values. In examples with multiple predictors and with points not ordered by predictor value, this plot can help you identify which observations have high leverage because they are outliers as measured by their predictor values.

## Residuals - Model Quality for Training Data

There are several residual plots to help you discover errors, outliers, or correlations in the model or data. The simplest residual plots are the default histogram plot, which shows the range of the residuals and their frequencies, and the probability plot, which shows how the distribution of the residuals compares to a normal distribution with matched variance.

This example shows residual plots for a fitted Poisson model. The data construction has two out of five predictors not affecting the response, and no intercept term:

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[14 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = GeneralizedLinearModel.fit(X,y,...
    'linear','Distribution','poisson');
```

Examine the residuals:
plotResiduals(mdl)

## Histogram of residuals

While most residuals cluster near 0 , there are several near $\pm 18$. So examine a different residuals plot.

```
plotResiduals(mdl,'fitted')
```

The large residuals don't seem to have much to do with the sizes of the fitted values.

Perhaps a probability plot is more informative.
plotResiduals(mdl,'probability')

Now it is clear. The residuals do not follow a normal distribution. Instead, they have fatter tails, much as an underlying Poisson distribution.

## Plots to Understand Predictor Effects and How to Modify a Model

This example shows how to understand the effect each predictor has on a regression model, and how to modify the model to remove unnecessary terms.

1 Create a model from some predictors in artificial data. The data do not use the second and third columns in X. So you expect the model not to show much dependence on those predictors.

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = GeneralizedLinearModel.fit(X,y,...
```

```
'linear','Distribution','poisson');
```

2 Examine a slice plot of the responses. This displays the effect of each predictor separately.
plotSlice(mdl)

Prediction Slice Plots
$\square \square$

The scale of the first predictor is overwhelming the plot. Disable it using the Predictors menu.

Prediction Slice Plots

## $\square$ 回 $x$

Now it is clear that predictors 2 and 3 have little to no effect.
You can drag the individual predictor values, which are represented by dashed blue vertical lines. You can also choose between simultaneous and non-simultaneous confidence bounds, which are represented by dashed red curves. Dragging the predictor lines confirms that predictors 2 and 3 have little to no effect.

3 Remove the unnecessary predictors using either removeTerms or step. Using step can be safer, in case there is an unexpected importance to a term that becomes apparent after removing another term. However, sometimes removeTerms can be effective when step does not proceed. In this case, the two give identical results.

```
mdl1 = removeTerms(mdl,'x2 + x3')
mdl1 =
Generalized Linear regression model:
    log(y) ~ 1 + x1 + x4 + x5
    Distribution = Poisson
Estimated Coefficients:
\begin{tabular}{lrllr} 
& Estimate & SE & tStat & pValue \\
(Intercept) & 0.17604 & 0.062215 & 2.8295 & 0.004662 \\
x1 & 1.9122 & 0.024638 & 77.614 & 0 \\
x4 & 0.98521 & 0.026393 & 37.328 & \(5.6696 \mathrm{e}-305\) \\
x5 & 0.61321 & 0.038435 & 15.955 & \(2.6473 \mathrm{e}-57\)
\end{tabular}
100 observations, 96 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 4.97e+04, p-value = 0
mdl1 = step(mdl,'NSteps',5,'Upper','linear')
1. Removing x3, Deviance = 93.856, Chi2Stat = 0.00075551, PValue = 0.97807
2. Removing x2, Deviance = 96.333, Chi2Stat = 2.4769, PValue = 0.11553
mdl1 =
Generalized Linear regression model:
    log(y) ~ 1 + x1 + x4 + x5
    Distribution = Poisson
Estimated Coefficients:
\begin{tabular}{lcllr} 
& Estimate & SE & tStat & \multicolumn{1}{l}{ pValue } \\
(Intercept) & 0.17604 & 0.062215 & 2.8295 & 0.004662 \\
x1 & 1.9122 & 0.024638 & 77.614 & 0 \\
x4 & 0.98521 & 0.026393 & 37.328 & \(5.6696 e-305\) \\
x5 & 0.61321 & 0.038435 & 15.955 & \(2.6473 e-57\)
\end{tabular}
```

100 observations, 96 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 4.97e+04, p-value $=0$

## Predict or Simulate Responses to New Data

There are three ways to use a linear model to predict the response to new data:

- "predict" on page 9-168
- "feval" on page 9-169
- "random" on page 9-170

## predict

The predict method gives a prediction of the mean responses and, if requested, confidence bounds.

This example shows how to predict and obtain confidence intervals on the predictions using the predict method.

1 Create a model from some predictors in artificial data. The data do not use the second and third columns in X. So you expect the model not to show much dependence on these predictors. Construct the model stepwise to include the relevant predictors automatically.

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = GeneralizedLinearModel.stepwise(X,y,...
    'constant','upper','linear','Distribution','poisson');
1. Adding x1, Deviance = 2515.02869, Chi2Stat = 47242.9622, PValue = 0
2. Adding x4, Deviance = 328.39679, Chi2Stat = 2186.6319, PValue = 0
3. Adding x5, Deviance = 96.3326, Chi2Stat = 232.0642, PValue = 2.114384e-52
```

2 Generate some new data, and evaluate the predictions from the data.

```
Xnew = randn(3,5) + repmat([1 2 3 4 5],[3,1]); % new data
```

[ynew,ynewci] = predict(mdl,Xnew)

```
ynew =
    1.0e+04 *
    0.1130
    1.7375
    3.7471
ynewci =
    1.0e+04 *
    0.0821 0.1555
    1.2167 2.4811
    2.8419 4.9407
```

## feval

When you construct a model from a dataset array, feval is often more convenient for predicting mean responses than predict. However, feval does not provide confidence bounds.

This example shows how to predict mean responses using the feval method.
1 Create a model from some predictors in artificial data. The data do not use the second and third columns in X. So you expect the model not to show much dependence on these predictors. Construct the model stepwise to include the relevant predictors automatically.

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[2;1;.5]);
y = poissrnd(mu);
ds = dataset({X,'x1','x2','x3','x4','x5'},{y,'y'});
mdl = GeneralizedLinearModel.stepwise(ds,...
    'constant','upper','linear','Distribution','poisson');
1. Adding x1, Deviance = 2515.02869, Chi2Stat = 47242.9622, PValue = 0
2. Adding x4, Deviance = 328.39679, Chi2Stat = 2186.6319, PValue =0
3. Adding x5, Deviance = 96.3326, Chi2Stat = 232.0642, PValue =2.114384e-52
```

2 Generate some new data, and evaluate the predictions from the data.

```
Xnew = randn(3,5) + repmat([1 2 3 4 5],[3,1]); % new data
ynew = feval(mdl,Xnew(:,1),Xnew(:,4),Xnew(:,5)) % only need predictors 1,
ynew =
    1.0e+04 *
    0.1130
    1.7375
    3.7471
Equivalently,
ynew = feval(mdl,Xnew(:,[\begin{array}{lll}{1 4 5])) % only need predictors 1,4,5}\end{array}]
ynew =
    1.0e+04 *
    0.1130
    1.7375
    3.7471
```

## random

The random method generates new random response values for specified predictor values. The distribution of the response values is the distribution used in the model. random calculates the mean of the distribution from the predictors, estimated coefficients, and link function. For distributions such as normal, the model also provides an estimate of the variance of the response. For the binomial and Poisson distributions, the variance of the response is determined by the mean; random does not use a separate "dispersion" estimate.

This example shows how to simulate responses using the random method.
1 Create a model from some predictors in artificial data. The data do not use the second and third columns in X. So you expect the model not to show
much dependence on these predictors. Construct the model stepwise to include the relevant predictors automatically.

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[11 4 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = GeneralizedLinearModel.stepwise(X,y,...
    'constant','upper','linear','Distribution','poisson');
1. Adding x1, Deviance = 2515.02869, Chi2Stat = 47242.9622, PValue = 0
2. Adding x4, Deviance = 328.39679, Chi2Stat = 2186.6319, PValue = 0
3. Adding x5, Deviance = 96.3326, Chi2Stat = 232.0642, PValue = 2.114384e-52
```

2 Generate some new data, and evaluate the predictions from the data.

```
Xnew = randn(3,5) + repmat([1 2 3 4 5],[3,1]); % new data
ysim = random(mdl,Xnew)
ysim =
```

1111
17121
37457
The predictions from random are Poisson samples, so are integers.
3 Evaluate the random method again, the result changes.

```
ysim = random(mdl,Xnew)
ysim =
```

1175
17320
37126

## Share Fitted Models

The model display contains enough information to enable someone else to recreate the model in a theoretical sense. For example,
rng('default') \% for reproducibility

```
X = randn(100,5);
mu = exp(X(:,[14 4 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = GeneralizedLinearModel.stepwise(X,y,...
    'constant','upper','linear','Distribution','poisson')
1. Adding x1, Deviance = 2515.02869, Chi2Stat = 47242.9622, PValue = 0
2. Adding x4, Deviance = 328.39679, Chi2Stat = 2186.6319, PValue = 0
3. Adding x5, Deviance = 96.3326, Chi2Stat = 232.0642, PValue = 2.114384e-52
mdl =
```

Generalized Linear regression model:
$\log (y) \sim 1+x 1+x 4+x 5$
Distribution = Poisson
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | :--- | :--- | ---: |
| (Intercept) | 0.17604 | 0.062215 | 2.8295 | 0.004662 |
| x1 | 1.9122 | 0.024638 | 77.614 | 0 |
| x4 | 0.98521 | 0.026393 | 37.328 | $5.6696 e-305$ |
| x5 | 0.61321 | 0.038435 | 15.955 | $2.6473 \mathrm{e}-57$ |

100 observations, 96 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 4.97e+04, $p$-value $=0$
You can access the model description programmatically, too. For example, mdl.Coefficients.Estimate
ans =
0.1760
1.9122
0.9852
0.6132
mdl.Formula
$\log (\mathrm{y}) \sim 1+\mathrm{x} 1+\mathrm{x} 4+\mathrm{x} 5$

## Generalized Linear Model Workflow

This example shows a typical workflow: import data, fit a generalized linear model, test its quality, modify it to improve the quality, and make predictions based on the model. It computes the probability that a flower is in one of two classes, based on the Fisher iris data.

## Step 1. Load the data.

Load the Fisher iris data. Extract the rows that have classification versicolor or virginica. These are rows 51 to 150 . Create logical response variables that are true for versicolor flowers.

```
load fisheriris
X = meas(51:end,:); % versicolor and virginica
y = strcmp('versicolor',species(51:end));
```

## Step 2. Fit a generalized linear model.

Fit a binomial generalized linear model to the data.

```
mdl = GeneralizedLinearModel.fit(X,y,'linear',...
    'distr','binomial')
mdl =
Generalized Linear regression model:
    logit(y) ~ 1 + x1 + x2 + x3 + x4
    Distribution = Binomial
Estimated Coefficients:
\begin{tabular}{lclrr} 
& Estimate & SE & \multicolumn{1}{l}{ tStat } & \multicolumn{1}{l}{ pValue } \\
( Intercept) & 42.638 & 25.708 & 1.6586 & 0.097204 \\
x1 & 2.4652 & 2.3943 & 1.0296 & 0.30319 \\
x2 & 6.6809 & 4.4796 & 1.4914 & 0.13585 \\
x3 & -9.4294 & 4.7372 & -1.9905 & 0.046537 \\
x4 & -18.286 & 9.7426 & -1.8769 & 0.060529
\end{tabular}
```

```
100 observations, 95 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 127, p-value = 1.95e-26
```

## Step 3. Examine the result, consider alternative models.

Some $p$-values in the pValue column are not very small. Perhaps the model can be simplified.

See if some $95 \%$ confidence intervals for the coefficients include 0 . If so, perhaps these model terms could be removed.

```
confint = coefCI(mdl)
confint =
    -8.3984 93.6740
    -2.2881 7.2185
    -2.2122 15.5739
    -18.8339 -0.0248
    -37.6277 1.0554
```

Only two of the predictors have coefficients whose confidence intervals do not include 0 .

The coefficients of ' $\mathrm{x} 1^{\prime}$ ' and ' x 2 ' have the largest $p$-values. Test whether both coefficients could be zero.

```
M = [0 1 0 0 0 % picks out coefficient for column 1
    0 0 1 0 0]; % picks out coefficient for column 2
p = coefTest(mdl,M)
p =
    0.1442
```

The $p$-value of about 0.14 is not very small. Drop those terms from the model.

```
mdl1 = removeTerms(mdl,'x1 + x2')
mdl1 =
Generalized Linear regression model:
```

```
    logit(y) ~ 1 + x3 + x4
    Distribution = Binomial
Estimated Coefficients:
\begin{tabular}{lrlrr} 
& Estimate & SE & \multicolumn{1}{c}{ tStat } & \multicolumn{1}{l}{ pValue } \\
(Intercept) & 45.272 & 13.612 & 3.326 & 0.00088103 \\
x3 & -5.7545 & 2.3059 & -2.4956 & 0.012576 \\
x4 & -10.447 & 3.7557 & -2.7816 & 0.0054092
\end{tabular}
100 observations, 97 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 118, p-value = 2.3e-26
Perhaps it would have been better to have GeneralizedLinearModel.stepwise identify the model initially.
```

```
mdl2 = GeneralizedLinearModel.stepwise(X,y,...
```

mdl2 = GeneralizedLinearModel.stepwise(X,y,...
'constant','Distribution','binomial','upper','linear')
'constant','Distribution','binomial','upper','linear')

1. Adding x4, Deviance = 33.4208, Chi2Stat = 105.2086, PValue = 1.099298e-24
2. Adding x3, Deviance = 20.5635, Chi2Stat = 12.8573, PValue = 0.000336166
3. Adding x2, Deviance = 13.2658, Chi2Stat = 7.29767, PValue = 0.00690441
mdl2 =
Generalized Linear regression model:
logit(y) ~ 1 + x2 + x3 + x4
Distribution = Binomial
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | :---: | :--- | :---: | :--- |
| (Intercept) | 50.527 | 23.995 | 2.1057 | 0.035227 |
| x2 | 8.3761 | 4.7612 | 1.7592 | 0.078536 |
| x3 | -7.8745 | 3.8407 | -2.0503 | 0.040334 |
| x4 | -21.43 | 10.707 | -2.0014 | 0.04535 |

100 observations, 96 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 125, p-value $=5.4 \mathrm{e}-27$

```

GeneralizedLinearModel.stepwise included 'x2' in the model, because it neither adds nor removes terms with \(p\)-values between 0.05 and 0.10 .

\section*{Step 4. Look for outliers and exclude them.}

Examine a leverage plot to look for influential outliers.
plotDiagnostics(mdl2,'leverage')

There is one observation with a leverage close to one. Using the Data Cursor, click the point, and find it has index 69.

See if the model coefficients change when you fit a model excluding this point.
```

oldCoeffs = mdl2.Coefficients.Estimate;
mdl3 = GeneralizedLinearModel.fit(X,y,'linear',...
'distr','binomial','pred',2:4,'exclude',69);
newCoeffs = mdl3.Coefficients.Estimate;
disp([oldCoeffs newCoeffs])

```
\begin{tabular}{rr}
50.5268 & 50.5268 \\
8.3761 & 8.3761 \\
-7.8745 & -7.8745 \\
-21.4296 & -21.4296
\end{tabular}

The model coefficients do not change, suggesting that the response at the high-leverage point is consistent with the predicted value from the reduced model.

\section*{Step 5. Predict the probability that a new flower is versicolor.}

Use mdl2 to predict the probability that a flower with average measurements is versicolor. Generate confidence intervals for your prediction.
[newf newc] \(=\) predict(mdl2,mean \((X)\) )
newf =
0.5086
newc =
\(0.1863 \quad 0.8239\)

The model gives almost a \(50 \%\) probability that the average flower is versicolor, with a wide confidence interval about this estimate.

\title{
Lasso Regularization of Generalized Linear Models
}

\author{
In this section... \\ "What is Generalized Linear Model Lasso Regularization?" on page 9-178 \\ "Regularize Poisson Regression" on page 9-178 \\ "Regularize Logistic Regression" on page 9-182 \\ "Regularize Wide Data in Parallel" on page 9-189 \\ "Generalized Linear Model Lasso and Elastic Net" on page 9-195 \\ "References" on page 9-197
}

\section*{What is Generalized Linear Model Lasso Regularization?}

Lasso is a regularization technique. Use lassoglm to:
- Reduce the number of predictors in a generalized linear model.
- Identify important predictors.
- Select among redundant predictors.
- Produce shrinkage estimates with potentially lower predictive errors than ordinary least squares.

Elastic net is a related technique. Use it when you have several highly correlated variables. lassoglm provides elastic net regularization when you set the Alpha name-value pair to a number strictly between 0 and 1.

For details about lasso and elastic net computations and algorithms, see "Generalized Linear Model Lasso and Elastic Net" on page 9-195. For a discussion of generalized linear models, see "What Are Generalized Linear Models?" on page 9-143.

\section*{Regularize Poisson Regression}

This example shows how to identify and remove redundant predictors from a generalized linear model.

Create data with 20 predictors, and Poisson responses using just three of the predictors, plus a constant.
```

rng('default') % for reproducibility
X = randn(100,20);
mu = exp(X(:,[5 10 15])*[.4;.2;.3] + 1);
y = poissrnd(mu);

```

Construct a cross-validated lasso regularization of a Poisson regression model of the data.
[B FitInfo] = lassoglm(X,y,'poisson','CV',10);
Examine the cross-validation plot to see the effect of the Lambda regularization parameter.
lassoPlot(B,FitInfo,'plottype','CV');

The green circle and dashed line locate the Lambda with minimal cross-validation error. The blue circle and dashed line locate the point with minimal cross-validation error plus one standard deviation.

Find the nonzero model coefficients corresponding to the two identified points.
```

minpts = find(B(:,FitInfo.IndexMinDeviance))
minpts =

```
    3
    5
    6
```

        10
        1 1
        15
        16
    min1pts = find(B(:,FitInfo.Index1SE))
min1pts =
5
10
15

```

The coefficients from the minimal plus one standard error point are exactly those coefficients used to create the data.

Find the values of the model coefficients at the minimal plus one standard error point.

B(min1pts,FitInfo.Index1SE)
ans =
0.2903
0.0789
0.2081

The values of the coefficients are, as expected, smaller than the original [0.4,0.2,0.3]. Lasso works by "shrinkage," which biases predictor coefficients toward zero. See "Lasso and Elastic Net Details" on page 9-134.

The constant term is in the FitInfo. Intercept vector.
FitInfo.Intercept(FitInfo.Index1SE)
ans =
1.0879

The constant term is near 1 , which is the value used to generate the data.

\section*{Regularize Logistic Regression}

This example shows a workflow for regularizing binomial regression. The default (canonical) link function for binomial regression is the logistic function.

\section*{Step 1. Prepare the data.}

Load the ionosphere data. The response \(Y\) is a cell array of ' \(g\) ' or ' \(b\) ' strings. Convert the cells to logical values, with true representing ' \(g\) '. Remove the first two columns of \(X\) because they have some awkward statistical properties, which are beyond the scope of this discussion.
load ionosphere
Ybool = strcmp(Y,'g');
X = X(: \(3:\) end);

\section*{Step 2. Create a cross-validated fit.}

Construct a regularized binomial regression using 25 Lambda values and 10 -fold cross validation. This process can take a few minutes.
```

rng('default') % for reproducibility
[B,FitInfo] = lassoglm(X,Ybool,'binomial',...
'NumLambda', 25,'CV',10);

```

\section*{Step 3. Examine plots to find appropriate regularization.}
lassoPlot can give both a standard trace plot and a cross-validated deviance plot. Examine both plots.
```

lassoPlot(B,FitInfo,'PlotType','CV');

```

The plot identifies the minimum-deviance point with a green circle and dashed line as a function of the regularization parameter Lambda. The blue circled point has minimum deviance plus no more than one standard deviation.
```

lassoPlot(B,FitInfo,'PlotType','Lambda','XScale','log');

```

Trace Plot of coefficients fit by Lasso
df

The trace plot shows nonzero model coefficients as a function of the regularization parameter Lambda. Because there are 32 predictors and a linear model, there are 32 curves. As Lambda increases to the left, lassoglm sets various coefficients to zero, removing them from the model.

The trace plot is somewhat compressed. Zoom in to see more detail.
```

xlim([.01 .1])
ylim([-3 3])

```

As Lambda increases toward the left side of the plot, fewer nonzero coefficients remain.

Find the number of nonzero model coefficients at the Lambda value with minimum deviance plus one standard deviation point. The regularized model coefficients are in column FitInfo. Index1SE of the B matrix.
```

indx = FitInfo.Index1SE;
BO = B(:,indx);
nonzeros = sum(BO ~= 0)
nonzeros =

```
14

When you set Lambda to FitInfo.Index1SE, lassoglm removes over half of the 32 original predictors.

\section*{Step 4. Create a regularized model.}

The constant term is in the FitInfo. IndexiSE entry of the FitInfo. Intercept vector. Call that value cnst.

The model is \(\operatorname{logit}(\mathrm{mu})=\log (\mathrm{mu} /(1-\mathrm{mu})) \mathrm{X} * B 0+\) cnst. Therefore, for predictions, \(m u=\exp (X * B O+c n s t) /(1+\exp (x * B O+c n s t))\).

The glmval function evaluates model predictions. It assumes that the first model coefficient relates to the constant term. Therefore, create a coefficient vector with the constant term first.
```

cnst = FitInfo.Intercept(indx);
B1 = [cnst;B0];

```

\section*{Step 5. Examine residuals.}

Plot the training data against the model predictions for the regularized lassoglm model.
```

preds = glmval(B1,X,'logit');

```
hist(Ybool - preds) \% plot residuals
title('Residuals from lassoglm model')

\section*{Step 6. Alternative: Use identified predictors in a least-squares generalized linear model.}

Instead of using the biased predictions from the model, you can make an unbiased model using just the identified predictors.
```

predictors = find(BO); % indices of nonzero predictors
mdl = GeneralizedLinearModel.fit(X,Ybool,'linear',...
'Distribution','binomial','PredictorVars',predictors)
mdl =

```
Generalized Linear regression model:
    y ~ [Linear formula with 15 terms in 14 predictors]
    Distribution = Binomial

Estimated Coefficients:
\begin{tabular}{lrlrr} 
& Estimate & \multicolumn{1}{l}{ SE } & \multicolumn{1}{l}{ tStat } & \multicolumn{1}{l}{ pValue } \\
(Intercept) & -2.9367 & 0.50926 & -5.7666 & \(8.0893 \mathrm{e}-09\) \\
x1 & 2.492 & 0.60795 & 4.099 & \(4.1502 \mathrm{e}-05\) \\
x3 & 2.5501 & 0.63304 & 4.0284 & \(5.616 \mathrm{e}-05\) \\
x4 & 0.48816 & 0.50336 & 0.9698 & 0.33215 \\
x5 & 0.6158 & 0.62192 & 0.99015 & 0.3221 \\
x6 & 2.294 & 0.5421 & 4.2317 & \(2.3198 \mathrm{e}-05\) \\
x7 & 0.77842 & 0.57765 & 1.3476 & 0.1778 \\
x12 & 1.7808 & 0.54316 & 3.2786 & 0.0010432 \\
x16 & -0.070993 & 0.50515 & -0.14054 & 0.88823 \\
x20 & -2.7767 & 0.55131 & -5.0365 & \(4.7402 e-07\) \\
x24 & 2.0212 & 0.57639 & 3.5067 & 0.00045372 \\
x25 & -2.3796 & 0.58274 & -4.0835 & \(4.4363 e-05\) \\
x27 & 0.79564 & 0.55904 & 1.4232 & 0.15467 \\
x29 & 1.2689 & 0.55468 & 2.2876 & 0.022162 \\
x32 & -1.5681 & 0.54336 & -2.8859 & 0.0039035
\end{tabular}

351 observations, 336 error degrees of freedom Dispersion: 1
Chi^2-statistic vs. constant model: 262, p -value \(=1 \mathrm{e}-47\)

Plot the residuals of the model.
plotResiduals(mdl)

Histogram of residuals

As expected, residuals from the least-squares model are slightly smaller than those of the regularized model. However, this does not mean that mdl is a better predictor for new data.

\section*{Regularize Wide Data in Parallel}

This example shows how to regularize a model with many more predictors than observations. Wide data is data with more predictors than observations. Typically, with wide data you want to identify important predictors. Use lassoglm as an exploratory or screening tool to select a smaller set of variables to prioritize your modeling and research. Use parallel computing to speed up cross validation.

Load the ovariancancer data. This data has 216 observations and 4000 predictors in the obs workspace variable. The responses are binary, either
```

'Cancer' or 'Normal', in the grp workspace variable. Convert the responses
to binary for use in lassoglm.
load ovariancancer
y = strcmp(grp,'Cancer');

```

Set options to use parallel computing. Prepare to compute in parallel using matlabpool.
```

opt = statset('UseParallel',true);
matlabpool open 4

```
```

Starting matlabpool using the 'local' profile ...
connected to 4 labs.

```

Fit a cross-validated set of regularized models. Use the Alpha parameter to favor retaining groups of highly correlated predictors, as opposed to eliminating all but one member of the group. Commonly, you use a relatively large value of Alpha.
```

rng('default') % for reproducibility
tic
[B,S] = lassoglm(obs,y,'binomial','NumLambda',100, ...
'Alpha',0.9,'LambdaRatio',1e-4,'CV',10,'Options',opt);
toc
Elapsed time is 480.451777 seconds.

```

Examine trace and cross-validation plots.
```

lassoPlot(B,S,'PlotType','CV');

```

Cross-validated Deviance of Elastic Net fit Alpha \(=0.9\)

```

lassoPlot(B,S,'PlotType','Lambda','XScale','log')

```

The right (green) vertical dashed line represents the Lambda providing the smallest cross-validated deviance. The left (blue) dashed line has the minimal deviance plus no more than one standard deviation. This blue line has many fewer predictors:
```

[S.DF(S.Index1SE) S.DF(S.IndexMinDeviance)]

```
ans =
\(50 \quad 86\)

You asked lassoglm to fit using 100 different Lambda values. How many did it use?
```

size(B)

```
lassoglm stopped after 84 values because the deviance was too small for small Lambda values. To avoid overfitting, lassoglm halts when the deviance of the fitted model is too small compared to the deviance in the binary responses, ignoring the predictor variables.

You can force lassoglm to include more terms by explicitly providing a set of Lambda values.
```

minLambda = min(S.Lambda);
explicitLambda = [minLambda*[.1 .01 .001] S.Lambda];
[B2,S2] = lassoglm(obs,y,'binomial','Lambda',explicitLambda,...
'LambdaRatio',1e-4, 'CV',10,'Options',opt);
length(S2.Lambda)

```
ans =

87
lassoglm used the three smaller values in fitting.

To save time, you can use:
- Fewer Lambda, meaning fewer fits
- Fewer cross-validation folds
- A larger value for LambdaRatio

Use serial computation and all three of these time-saving methods:
```

tic

```
[Bquick,Squick] = lassoglm(obs,y,'binomial','NumLambda',25,...
    'LambdaRatio',1e-2, 'CV',5);
toc
Elapsed time is 51.708074 seconds.

Graphically compare the new results to the first results.
lassoPlot(Bquick,Squick,'PlotType', 'CV');

```

lassoPlot(Bquick,Squick,'PlotType','Lambda','XScale','log')

```

The number of nonzero coefficients in the lowest plus one standard deviation model is around 50 , similar to the first computation.

\section*{Generalized Linear Model Lasso and Elastic Net}

\section*{Overview of Lasso and Elastic Net}

Lasso is a regularization technique for estimating generalized linear models. Lasso includes a penalty term that constrains the size of the estimated coefficients. Therefore, it resembles ridge regression. Lasso is a shrinkage estimator: it generates coefficient estimates that are biased to be small. Nevertheless, a lasso estimator can have smaller error than an ordinary maximum likelihood estimator when you apply it to new data.

Unlike ridge regression, as the penalty term increases, the lasso technique sets more coefficients to zero. This means that the lasso estimator is a smaller
model, with fewer predictors. As such, lasso is an alternative to stepwise regression and other model selection and dimensionality reduction techniques.

Elastic net is a related technique. Elastic net is akin to a hybrid of ridge regression and lasso regularization. Like lasso, elastic net can generate reduced models by generating zero-valued coefficients. Empirical studies suggest that the elastic net technique can outperform lasso on data with highly correlated predictors.

\section*{Definition of Lasso for Generalized Linear Models}

For a nonnegative value of \(\lambda\), lasso solves the problem
\[
\min _{\beta_{0}, \beta}\left(\frac{1}{N} \operatorname{Deviance}\left(\beta_{0}, \beta\right)+\lambda \sum_{j=1}^{p}\left|\beta_{j}\right|\right),
\]
where
- Deviance is the deviance of the model fit to the responses using intercept \(\beta_{0}\) and predictor coefficients \(\beta\). The formula for Deviance depends on the distr parameter you supply to lassoglm. Minimizing the \(\lambda\)-penalized deviance is equivalent to maximizing the \(\lambda\)-penalized log likelihood.
- \(N\) is the number of observations.
- \(\lambda\) is a nonnegative regularization parameter corresponding to one value of Lambda.
- Parameters \(\beta_{0}\) and \(\beta\) are scalar and \(p\)-vector respectively.

As \(\lambda\) increases, the number of nonzero components of \(\beta\) decreases.
The lasso problem involves the \(L^{1}\) norm of \(\beta\), as contrasted with the elastic net algorithm.

\section*{Definition of Elastic Net for Generalized Linear Models}

For an \(a\) strictly between 0 and 1 , and a nonnegative \(\lambda\), elastic net solves the problem
\[
\min _{\beta_{0}, \beta}\left(\frac{1}{N} \operatorname{Deviance}\left(\beta_{0}, \beta\right)+\lambda P_{\alpha}(\beta)\right)
\]
where
\[
P_{\alpha}(\beta)=\frac{(1-\alpha)}{2}\|\beta\|_{2}^{2}+\alpha\|\beta\|_{1}=\sum_{j=1}^{p}\left(\frac{(1-\alpha)}{2} \beta_{j}^{2}+\alpha\left|\beta_{j}\right|\right) .
\]

Elastic net is the same as lasso when \(\alpha=1\). For other values of \(\alpha\), the penalty term \(P_{a}(\beta)\) interpolates between the \(L^{1}\) norm of \(\beta\) and the squared \(L^{2}\) norm of \(\beta\). As \(\alpha\) shrinks toward 0 , elastic net approaches ridge regression.

"Nonlinear Regression Workflow" on page 9-212

\section*{What Are Parametric Nonlinear Regression Models?}

Parametric nonlinear models represent the relationship between a continuous response variable and one or more continuous predictor variables in the form
\[
y=f(X, \beta)+\varepsilon,
\]
where
- \(y\) is an \(n\)-by- 1 vector of observations of the response variable.
- \(f\) is any function of \(X\) and \(\beta\) that evaluates each row of \(X\) along with the vector \(\beta\) to compute the prediction for the corresponding row of \(y\).
- \(X\) is an \(n\)-by- \(p\) matrix of predictors, with one row for each observation, and one column for each predictor.
- \(\beta\) is a \(p\)-by- 1 vector of unknown parameters to be estimated.
- \(\varepsilon\) is an \(n\)-by- 1 vector of independent, identically distributed random disturbances.

In contrast, nonparametric models do not attempt to characterize the relationship between predictors and response with model parameters. Descriptions are often graphical, as in the case of "Classification Trees and Regression Trees" on page 15-30.

NonLinearModel.fit attempts to find values of the parameters \(\beta\) that minimize the mean squared differences between the observed responses \(y\) and the predictions of the model \(f(X, \beta)\). To do so, it needs a starting value betao before iteratively modifying the vector \(\beta\) to a vector with minimal mean squared error.

\section*{Prepare Data}

To begin fitting a regression, put your data into a form that fitting functions expect. All regression techniques begin with input data in an array \(X\) and response data in a separate vector \(y\), or input data in a dataset array ds and response data as a column in ds. Each row of the input data represents one observation. Each column represents one predictor (variable).

For a dataset array ds, indicate the response variable with the 'ResponseVar' name-value pair:
```

mdl = LinearModel.fit(ds,'ResponseVar','BloodPressure');

```

The response variable is the last column by default.
You cannot use numeric categorical predictors for nonlinear regression. A categorical predictor is one that takes values from a fixed set of possibilities.

Represent missing data as NaN for both input data and response data.

\section*{Dataset Array for Input and Response Data}

For example, to create a dataset array from an Excel spreadsheet:
```

ds = dataset('XLSFile','hospital.xls',...
'ReadObsNames',true);

```

To create a dataset array from workspace variables:
```

load carsmall
ds = dataset(Weight,Model_Year,MPG n);

```

\section*{Numeric Matrix for Input Data and Numeric Vector for Response}

For example, to create numeric arrays from workspace variables:
```

load carsmall
X = [Weight Horsepower Cylinders Model_Year];
y = MPG;

```

To create numeric arrays from an Excel spreadsheet:
```

[X Xnames] = xlsread('hospital.xls');
y = X(:,4); % response y is systolic pressure
X(:,4) = []; % remove y from the X matrix

```

Notice that the nonnumeric entries, such as sex, do not appear in \(X\).

\section*{Represent the Nonlinear Model}

There are several ways to represent a nonlinear model. Use whichever is most convenient.

The nonlinear model is a required input to NonLinearModel.fit, in the modelfun input.

NonLinearModel.fit assumes that the response function \(f(X, \beta)\) is smooth in the parameters \(\beta\). If your function is not smooth, NonLinearModel.fit can fail to provide optimal parameter estimates.
- "Function Handle to Anonymous Function or Function File" on page 9-200
- "String Representation of Formula" on page 9-202

\section*{Function Handle to Anonymous Function or Function File}

The function handle @modelfun ( \(\mathrm{b}, \mathrm{x}\) ) accepts a vector b and matrix or dataset array \(x\). The function handle should return a vector \(f\) with the same number of rows as \(x\). For example, the function file hougen.m computes
\[
\text { hougen }(b, x)=\frac{b(1) x(2)-x(3) / b(5)}{1+b(2) x(1)+b(3) x(2)+b(4) x(3)} .
\]

Examine the function by entering type hougen at the MATLAB command line.
```

function yhat = hougen(beta,x)
%HOUGEN Hougen-Watson model for reaction kinetics.
% YHAT = HOUGEN(BETA,X) gives the predicted values of the
% reaction rate, YHAT, as a function of the vector of
% parameters, BETA, and the matrix of data, X.
% BETA must have 5 elements and X must have three
% columns.
%
% The model form is:
% y = (b1*x2 - x3/b5)./(1+b2*x1+b3*x2+b4*x3)
%
% Reference:
% [1] Bates, Douglas, and Watts, Donald, "Nonlinear
% Regression Analysis and Its Applications", Wiley
% 1988 p. 271-272.
% Copyright 1993-2004 The MathWorks, Inc.
% \$Revision: 1.1.6.42.2.3 \$ \$Date: 2013/01/16 07:29:13 \$
% B.A. Jones 1-06-95.

```
b1 = beta(1);
b2 \(=\operatorname{beta}(2)\);
b3 \(=\operatorname{beta}(3)\);
b4 \(=\) beta(4);
b5 = beta(5);
\(\mathrm{x} 1=\mathrm{x}(:, 1)\);
x2 = \(x(:, 2)\);
x3 = \(x(:, 3)\);
yhat \(=(b 1 * x 2-x 3 / b 5) . /(1+b 2 * x 1+b 3 * x 2+b 4 * x 3)\);

You can write an anonymous function that performs the same calculation as hougen.m.
```

modelfun = @(b,x)(b(1)*x(:,2) - x(:,3)/b(5))./...
(1 + b(2)*x(:,1) + b(3)*x(:,2) + b(4)*x(:,3));

```

\section*{String Representation of Formula}

For data in a matrix \(X\) and response in a vector \(y\) :
- Represent the formula using ' x 1 ' as the first predictor (column) in X , ' x 2 ' as the second predictor, etc.
- Represent the vector of parameters to optimize as 'b1', 'b2', etc.
- Write the formula as 'y ~ (mathematical expressions)'.

For example, to represent the response to the reaction data:
```

modelfun = 'y ~ (b1*x2 - x3/b5)/(1 + b2*x1 + b3*x2 + b4*x3)';

```

For data in a dataset array, you can use formulas represented as strings with the variable names from the dataset array. Put the response variable name at the left of the formula, followed by a \(\sim\), followed by a string representing the response formula.

This example shows how to create a string to represent the response to the reaction data that is in a dataset array.

1 Load the reaction data.
```

load reaction

```

2 Put the data into a dataset array, where each variable has a name given in the xn or yn strings.
```

ds = dataset({reactants,xn(1,:),xn(2,:),xn(3,:)},···.
{rate,yn});

```

3 Examine the first row of the dataset array.
```

ds(1,:)
ans =

```
\begin{tabular}{llll} 
Hydrogen & n_Pentane & Isopentane & ReactionRate \\
470 & 300 & 10 & 8.55
\end{tabular}

4 Write the hougen formula using names in the dataset array.
```

modelfun = ['ReactionRate ~ (b1*n_Pentane - Isopentane/b5) /'...
' (1 + Hydrogen*b2 + n_Pentane*b3 + Isopentane*b4)']
modelfun =
ReactionRate ~ (b1*n_Pentane - Isopentane/b5) / ...
(1 + Hydrogen*b2 + n_Pentane*b3 + Isopentane*b4)

```

\section*{Choose Initial Vector beta0}

The initial vector for the fitting iterations, beta0, can greatly influence the quality of the resulting fitted model. beta0 gives the dimensionality of the problem, meaning it needs the correct length. A good choice of beta0 leads to a quick, reliable model, while a poor choice can lead to a long computation, or to an inadequate model.

It is difficult to give advice on choosing a good beta0. If you believe certain components of the vector should be positive or negative, set your beta0 to have those characteristics. If you know the approximate value of other components, include them in beta0. However, if you don't know good values, try a random vector, such as
```

betaO = randn(nVars,1);
% or
beta0 = 10*rand(nVars,1);

```

\section*{Fit Nonlinear Model to Data}

The syntax for fitting a nonlinear regression model using a dataset array ds is
```

mdl = NonLinearModel.fit(ds,modelfun,betaO)

```

The syntax for fitting a nonlinear regression model using a numeric array \(X\) and numeric response vector y is
mdl = NonLinearModel.fit(X,y,modelfun, beta0)
For information on representing the input parameters, see "Prepare Data" on page 9-199, "Represent the Nonlinear Model" on page 9-200, and "Choose Initial Vector beta0" on page 9-203.

NonLinearModel.fit assumes that the response variable in a dataset array ds is the last column. To change this, use the ResponseVar name-value pair to name the response column.

\section*{Examine Quality and Adjust the Fitted Model}

There are diagnostic plots to help you examine the quality of a model.
- plotDiagnostics(mdl) gives a variety of plots, including leverage and Cook's distance plots.
- plotResiduals(mdl) gives the difference between the fitted model and the data.

There are also properties of mdl that relate to the model quality.
- mdl. RMSE gives the root mean square error between the data and the fitted model.
- mdl.Residuals. Raw gives the raw residuals.
- mdl.Diagnostics contains several fields, such as Leverage and CooksDistance, that can help you identify particularly interesting observations.

This example shows how to examine a fitted nonlinear model using diagnostic, residual, and slice plots.

1 Load the reaction data.
```

load reaction

```

2 Create a nonlinear model of rate as a function of reactants using the hougen.m function, starting from beta0 \(=\) ones \((5,1)\);.
```

beta0 = ones(5,1);

```
mdl \(=\) NonLinearModel.fit(reactants, ...
    rate, @hougen, beta0);

3 Make a leverage plot of the data and model.
```

plotDiagnostics(mdl)

```

4 There is one point that has high leverage. Locate the point: [~,maxl] = max(mdl.Diagnostics.Leverage) \(\operatorname{maxl}=\)

6

5 Examine a residuals plot.
```

plotResiduals(mdl,'fitted')

```

Nothing stands out as an outlier.
6 Use a slice plot to show the effect of each predictor on the model. plotSlice(mdl)

You can drag the vertical dashed blue lines to see the effect of a change in one predictor on the response. For example, drag the X2 line to the right, and notice that the slope of the X3 line changes.

\section*{Predict or Simulate Responses to New Data}

There are three ways to use a linear model to predict or simulate the response to new data:
- "predict" on page 9-210
- "feval" on page 9-211
- "random" on page 9-211

The prediction method examples use the following synthetic data and model. The problem is to fit a nonlinear curve of known form, with unknown center and scale parameters.

1 Generate synthetic data from a Cauchy distribution.
```

rng('default')
X = rand(100,1);
X = tan(pi*x - pi/2);

```

2 Generate the response according to the model
\[
y=b_{1}^{*}\left(\Pi / 2+\operatorname{atan}\left(\left(x-b_{2}\right) / b_{3}\right)\right)
\]

Add noise to the response.
```

modelfun = @(b,x) b(1) * ...
(pi/2 + atan((x - b(2))/b(3)));
y = modelfun([12 5 10],X) + randn(100,1);

```

3 Fit a model starting from the arbitrary parameters \(b=[1,1,1]\).
```

beta0 = [11 1 1 1]; % an arbitrary guess
mdl = NonLinearModel.fit(X,y,modelfun,betaO)
mdl =
Nonlinear regression model:
y ~ b1*(pi/2 + atan((x - b2)/b3))
Estimated Coefficients:

|  | Estimate | SE | tStat | PValue |
| :--- | :---: | ---: | :--- | :--- |
| b1 | 12.082 | 0.80028 | 15.097 | $3.3151 \mathrm{e}-27$ |
| b2 | 5.0603 | 1.0825 | 4.6747 | $9.5063 \mathrm{e}-06$ |
| b3 | 9.64 | 0.46499 | 20.732 | $2.0382 \mathrm{e}-37$ |

```
Number of observations: 100, Error degrees of freedom: 97
Root Mean Squared Error: 1.02
R-Squared: 0.92, Adjusted R-Squared 0.918
F-statistic vs. constant model: 558, p -value \(=6.11 \mathrm{e}-54\)

The fitted values are within a few percent of the parameters \([12,5,10]\).
4 Examine the fit:
```

plotSlice(mdl)

```

\section*{predict}

The predict method predicts the mean responses and, if requested, gives confidence bounds. For example, to find the predicted response values and predicted confidence intervals about the response at \(X\) values \([-15 ; 5 ; 12]\) :

Xnew = [-15;5;12];
[ynew,ynewci] = predict(mdl,Xnew)
ynew =
5.4122
18.9022
26.5161
ynewci \(=\)
```

4.8233 6.0010
18.4555 19.3490
25.0170 28.0151

```

The confidence intervals are reflected in the slice plot.

\section*{feval}

The feval method predicts the mean responses. feval is often more convenient to use than predict when you construct a model from a dataset array. For example,

1 Create the nonlinear model from a dataset array.
```

ds = dataset({X,'X'},{y,'y'});
mdl2 = NonLinearModel.fit(ds,modelfun,betaO);

```

2 Find the predicted model responses (CDF) at X values [ \(-15 ; 5 ; 12]\).
```

Xnew = [-15;5;12];
ynew = feval(mdl2,Xnew)
ynew =

```
    5.4122
    18.9022
    26.5161

\section*{random}

The random method simulates new random response values, equal to the mean prediction plus a random disturbance with the same variance as the training data. For example,
```

Xnew = [-15;5;12];
ysim = random(mdl,Xnew)
ysim =

```
    6.0505
    19.0893
    25.4647

Rerun the random method. The results change.
```

ysim = random(mdl,Xnew)
ysim =

```
    6.3813
19.2157
26.6541

\section*{Nonlinear Regression Workflow}

This example shows a typical workflow: import data, fit a nonlinear regression, test its quality, modify it to improve the quality, and make predictions based on the model.

\section*{Step 1. Prepare the data.}

Load the reaction data
load reaction
Examine the data in the workspace. reactants is a matrix with 13 rows and 3 columns. Each row corresponds to one observation, and each column corresponds to one variable. The variable names are in xn :
xn
xn =

\section*{Hydrogen}
n-Pentane
Isopentane
Similarly, rate is a vector of 13 responses, with the variable name in yn:
```

yn

```
yn =
Reaction Rate

The hougen.m file contains a nonlinear model of reaction rate as a function of the three predictor variables. For a 5-D vector \(b\) and 3-D vector \(x\),
\[
\text { hougen }(b, x)=\frac{b(1) x(2)-x(3) / b(5)}{1+b(2) x(1)+b(3) x(2)+b(4) x(3)} .
\]

As a start point for the solution, take \(b\) as a vector of ones.
```

beta0 = ones(5,1);

```

\section*{Step 2. Fit a nonlinear model to the data.}
```

mdl = NonLinearModel.fit(reactants,...
rate,@hougen,beta0)

```
\(m d l=\)
Nonlinear regression model:
    \(y\) ~ hougen (b, X)
Estimated Coefficients:
\begin{tabular}{lrrll} 
& Estimate & SE & tStat & pValue \\
b1 & 1.2526 & 0.86702 & 1.4447 & 0.18654 \\
b2 & 0.062776 & 0.043562 & 1.4411 & 0.18753 \\
b3 & 0.040048 & 0.030885 & 1.2967 & 0.23089 \\
b4 & 0.11242 & 0.075158 & 1.4957 & 0.17309 \\
b5 & 1.1914 & 0.83671 & 1.4239 & 0.1923
\end{tabular}

Number of observations: 13, Error degrees of freedom: 8
Root Mean Squared Error: 0.193
R-Squared: 0.999, Adjusted R-Squared 0.998
F-statistic vs. constant model: 1.81e+03, p-value = 7.36e-12

\section*{Step 3. Examine the quality of the model.}

The root mean squared error is fairly low compared to the range of observed values.
mdl.RMSE
ans \(=\)
```

    0.1933
    [min(rate) max(rate)]
ans =
0.0200 14.3900

```

Examine a residuals plot.
plotResiduals(mdl)

Histogram of residuals

The model seems adequate for the data.
Examine a diagnostic plot to look for outliers.
```

plotDiagnostics(mdl,'cookd')

```

Observation 6 seems out of line.

\section*{Step 4. Remove the outlier.}

Remove the outlier from the fit using the Exclude name-value pair.
mdl1 = NonLinearModel.fit(reactants,...
rate, @hougen, ones (5,1),'Exclude',6)
mdl1 =

Nonlinear regression model:
y ~ hougen (b, X)

Estimated Coefficients:
\begin{tabular}{rrrll} 
& Estimate & \multicolumn{1}{l}{ SE } & tStat & pValue \\
b1 & 0.619 & 0.4552 & 1.3598 & 0.21605 \\
b2 & 0.030377 & 0.023061 & 1.3172 & 0.22924 \\
b3 & 0.018927 & 0.01574 & 1.2024 & 0.26828 \\
b4 & 0.053411 & 0.041084 & 1.3 & 0.23476 \\
b5 & 2.4125 & 1.7903 & 1.3475 & 0.2198
\end{tabular}
```

Number of observations: 12, Error degrees of freedom: 7
Root Mean Squared Error: 0.198
R-Squared: 0.999, Adjusted R-Squared 0.998
F-statistic vs. constant model: 1.24e+03, p-value = 4.73e-10

```

The model coefficients changed quite a bit from those in mdl.

\section*{Step 5. Examine slice plots of both models.}

To see the effect of each predictor on the response, make a slice plot using plotSlice(mdl).
plotSlice(mdl)

plotSlice(mdl1)

The plots look very similar, with slightly wider confidence bounds for mdl1. This difference is understandable, since there is one less data point in the fit, representing over 7\% fewer observations.

\section*{Step 6. Predict for new data.}

Create some new data and predict the response from both models.
```

Xnew = [200,200,200;100,200,100;500,50,5];

```
[ypred yci] = predict(mdl,Xnew)
ypred =
    1.8762
    6.2793
    1.6718
yci \(=\)
    \(1.6283 \quad 2.1242\)
    \(5.9789 \quad 6.5797\)
    \(1.5589 \quad 1.7846\)
[ypred1 yci1] = predict(mdl1,Xnew)
ypred1 \(=\)
```

    1.8984
    6.2555
    1.6594
    yci1 =
1.6260 2.1708
5.9323 6.5787
1.5345 1.7843

```

Even though the model coefficients are dissimilar, the predictions are nearly identical.

\section*{Introduction to Mixed-Effects Models}

In statistics, an effect is anything that influences the value of a response variable at a particular setting of the predictor variables. Effects are translated into model parameters. In linear models, effects become coefficients, representing the proportional contributions of model terms. In nonlinear models, effects often have specific physical interpretations, and appear in more general nonlinear combinations.

Fixed effects represent population parameters, assumed to be the same each time data is collected. Estimating fixed effects is the traditional domain of regression modeling. Random effects, by comparison, are sample-dependent random variables. In modeling, random effects act like additional error terms, and their distributions and covariances must be specified.

For example, consider a model of the elimination of a drug from the bloodstream. The model uses time \(t\) as a predictor and the concentration of the drug \(C\) as the response. The nonlinear model term \(C_{0} e^{-r t}\) combines parameters \(C_{0}\) and \(r\), representing, respectively, an initial concentration and an elimination rate. If data is collected across multiple individuals, it is reasonable to assume that the elimination rate is a random variable \(r_{i}\) depending on individual \(i\), varying around a population mean \(\bar{r}\). The term \(C_{0} e^{-r t}\) becomes
\[
C_{0} e^{-\left[\bar{r}+\left(r_{i}-\bar{r}\right) t t\right.}=C_{0} e^{-\left(\beta+b_{i}\right) t},
\]
where \(\beta=\bar{r}\) is a fixed effect and \(b_{i}=r_{i}-\bar{r}\) is a random effect.
Random effects are useful when data falls into natural groups. In the drug elimination model, the groups are simply the individuals under study. More sophisticated models might group data by an individual's age, weight, diet, etc. Although the groups are not the focus of the study, adding random effects to a model extends the reliability of inferences beyond the specific sample of individuals.

Mixed-effects models account for both fixed and random effects. As with all regression models, their purpose is to describe a response variable as a function of the predictor variables. Mixed-effects models, however, recognize correlations within sample subgroups. In this way, they provide a compromise between ignoring data groups entirely and fitting each group with a separate model.

\section*{Mixed-Effects Model Hierarchy}

Suppose data for a nonlinear regression model falls into one of \(m\) distinct groups \(i=1, \ldots, m\). To account for the groups in a model, write response \(j\) in group \(i\) as:
\[
y_{i j}=f\left(\varphi, x_{i j}\right)+\varepsilon_{i j}
\]
\(y_{i j}\) is the response, \(x_{i j}\) is a vector of predictors, \(\varphi\) is a vector of model parameters, and \(\varepsilon_{i j}\) is the measurement or process error. The index \(j\) ranges from 1 to \(n_{i}\), where \(n_{i}\) is the number of observations in group \(i\). The function \(f\) specifies the form of the model. Often, \(x_{i j}\) is simply an observation time \(t_{i j}\). The errors are usually assumed to be independent and identically, normally distributed, with constant variance.

Estimates of the parameters in \(\varphi\) describe the population, assuming those estimates are the same for all groups. If, however, the estimates vary by group, the model becomes
\[
y_{i j}=f\left(\varphi_{i}, x_{i j}\right)+\varepsilon_{i j}
\]

In a mixed-effects model, \(\varphi_{i}\) may be a combination of a fixed and a random effect:
\[
\varphi_{i}=\beta+b_{i}
\]

The random effects \(b_{i}\) are usually described as multivariate normally distributed, with mean zero and covariance \(\Psi\). Estimating the fixed effects \(\beta\) and the covariance of the random effects \(\Psi\) provides a description of the population that does not assume the parameters \(\varphi_{i}\) are the same across groups. Estimating the random effects \(b_{i}\) also gives a description of specific groups within the data.

Model parameters do not have to be identified with individual effects. In general, design matrices \(A\) and \(B\) are used to identify parameters with linear combinations of fixed and random effects:
\[
\varphi_{i}=A \beta+B b_{i}
\]

If the design matrices differ among groups, the model becomes
\[
\varphi_{i}=A_{i} \beta+B_{i} b_{i}
\]

If the design matrices also differ among observations, the model becomes
\[
\begin{aligned}
\varphi_{i j} & =A_{i j} \beta+B_{i j} b_{i} \\
y_{i j} & =f\left(\varphi_{i j}, x_{i j}\right)+\varepsilon_{i j}
\end{aligned}
\]

Some of the group-specific predictors in \(x_{i j}\) may not change with observation \(j\). Calling those \(v_{i}\), the model becomes
\[
y_{i j}=f\left(\varphi_{i j}, x_{i j}, v_{i}\right)+\varepsilon_{i j}
\]

\section*{Specifying Mixed-Effects Models}

Suppose data for a nonlinear regression model falls into one of \(m\) distinct groups \(i=1, \ldots, m\). (Specifically, suppose that the groups are not nested.) To specify a general nonlinear mixed-effects model for this data:

1 Define group-specific model parameters \(\varphi_{i}\) as linear combinations of fixed effects \(\beta\) and random effects \(b_{i}\).

2 Define response values \(y_{i}\) as a nonlinear function \(f\) of the parameters and group-specific predictor variables \(X_{i}\).

The model is:
\[
\begin{aligned}
& \varphi_{i}=A_{i} \beta+B_{i} b_{i} \\
& y_{i}=f\left(\varphi_{i}, X_{i}\right)+\varepsilon_{i} \\
& b_{i} \square N(0, \Psi) \\
& \varepsilon_{i} \square N\left(0, \sigma^{2}\right)
\end{aligned}
\]

This formulation of the nonlinear mixed-effects model uses the following notation:
\(\varphi_{i} \quad\) A vector of group-specific model parameters
\(\beta \quad\) A vector of fixed effects, modeling population parameters
\(b_{i} \quad\) A vector of multivariate normally distributed group-specific random effects
\(A_{i} \quad\) A group-specific design matrix for combining fixed effects
\(B_{i} \quad\) A group-specific design matrix for combining random effects
\(X_{i} \quad\) A data matrix of group-specific predictor values
\(y_{i} \quad\) A data vector of group-specific response values
\(f \quad\) A general, real-valued function of \(\varphi_{i}\) and \(X_{i}\)
\(\varepsilon_{i} \quad\) A vector of group-specific errors, assumed to be independent, identically, normally distributed, and independent of \(b_{i}\)
\(\Psi \quad\) A covariance matrix for the random effects
\(\sigma^{2} \quad\) The error variance, assumed to be constant across observations

For example, consider a model of the elimination of a drug from the bloodstream. The model incorporates two overlapping phases:
- An initial phase \(p\) during which drug concentrations reach equilibrium with surrounding tissues
- A second phase \(q\) during which the drug is eliminated from the bloodstream

For data on multiple individuals \(i\), the model is
\[
y_{i j}=C_{p i} e^{-r_{p i} t_{i j}}+C_{q i} e^{-r_{q i} t_{i j}}+\varepsilon_{i j},
\]
where \(y_{i j}\) is the observed concentration in individual \(i\) at time \(t_{i j}\). The model allows for different sampling times and different numbers of observations for different individuals.

The elimination rates \(r_{p i}\) and \(r_{q i}\) must be positive to be physically meaningful. Enforce this by introducing the log rates \(R_{p i}=\log \left(r_{p i}\right)\) and \(R_{q i}=\log \left(r_{q i}\right)\) and reparametrizing the model:
\[
y_{i j}=C_{p i} e^{-\exp \left(R_{p i} t_{i j}\right.}+C_{q i} e^{-\exp \left(R_{q i}\right) t_{i j}}+\varepsilon_{i j}
\]

Choosing which parameters to model with random effects is an important consideration when building a mixed-effects model. One technique is to add random effects to all parameters, and use estimates of their variances to determine their significance in the model. An alternative is to fit the model separately to each group, without random effects, and look at the variation of the parameter estimates. If an estimate varies widely across groups, or if confidence intervals for each group have minimal overlap, the parameter is a good candidate for a random effect.

To introduce fixed effects \(\beta\) and random effects \(b_{i}\) for all model parameters, reexpress the model as follows:
\[
\begin{aligned}
y_{i j}= & {\left[\bar{C}_{p}+\left(C_{p i}-\bar{C}_{p}\right)\right] e^{-\exp \left[\bar{R}_{p}+\left(R_{p i}-\bar{R}_{p}\right)\right] t_{i j}}+} \\
& {\left[\bar{C}_{q}+\left(C_{q i}-\bar{C}_{q}\right)\right] e^{-\exp \left[\bar{R}_{q}+\left(R_{q i}-\bar{R}_{q}\right)\right] t_{i j}}+\varepsilon_{i j} } \\
= & \left(\beta_{1}+b_{1 i}\right) e^{-\exp \left(\beta_{2}+b_{2 i}\right) t_{i j}}+ \\
& \left(\beta_{3}+b_{3 i}\right) e^{-\exp \left(\beta_{4}+b_{4 i}\right) t_{i j}}+\varepsilon_{i j}
\end{aligned}
\]

In the notation of the general model:
\[
\beta=\left(\begin{array}{c}
\beta_{1} \\
\vdots \\
\beta_{4}
\end{array}\right), b_{i}=\left(\begin{array}{c}
b_{i 1} \\
\vdots \\
b_{i 4}
\end{array}\right), y_{i}=\left(\begin{array}{c}
y_{i 1} \\
\vdots \\
y_{i n_{i}}
\end{array}\right), X_{i}=\left(\begin{array}{c}
t_{i 1} \\
\vdots \\
t_{i n_{i}}
\end{array}\right)
\]
where \(n_{i}\) is the number of observations of individual \(i\). In this case, the design matrices \(A_{i}\) and \(B_{i}\) are, at least initially, 4-by-4 identity matrices. Design matrices may be altered, as necessary, to introduce weighting of individual effects, or time dependency.

Fitting the model and estimating the covariance matrix \(\Psi\) often leads to further refinements. A relatively small estimate for the variance of a random effect suggests that it can be removed from the model. Likewise, relatively small estimates for covariances among certain random effects suggests that a full covariance matrix is unnecessary. Since random effects are unobserved, \(\Psi\) must be estimated indirectly. Specifying a diagonal or block-diagonal covariance pattern for \(\Psi\) can improve convergence and efficiency of the fitting algorithm.

Statistics Toolbox functions nlmefit and nlmefitsa fit the general nonlinear mixed-effects model to data, estimating the fixed and random effects. The functions also estimate the covariance matrix \(\Psi\) for the random effects. Additional diagnostic outputs allow you to assess tradeoffs between the number of model parameters and the goodness of fit.

\section*{Specifying Covariate Models}

If the model in "Specifying Mixed-Effects Models" on page 9-221 assumes a group-dependent covariate such as weight \((w)\) the model becomes:
\[
\left(\begin{array}{l}
\varphi_{1} \\
\varphi_{2} \\
\varphi_{3}
\end{array}\right)=\left(\begin{array}{llll}
1 & 0 & 0 & w_{i} \\
0 & 1 & 0 & 0 \\
0 & 0 & 1 & 0
\end{array}\right)\left(\begin{array}{l}
\beta_{1} \\
\beta_{2} \\
\beta_{3} \\
\beta_{4}
\end{array}\right)+\left(\begin{array}{lll}
1 & 0 & 0 \\
0 & 1 & 0 \\
0 & 0 & 1
\end{array}\right)\left(\begin{array}{l}
b_{1} \\
b_{2} \\
b_{3}
\end{array}\right)
\]

Thus, the parameter \(\varphi_{\mathrm{i}}\) for any individual in the ith group is:
\[
\left(\begin{array}{c}
\varphi_{1_{i}} \\
\varphi_{2_{i}} \\
\varphi_{3_{i}}
\end{array}\right)=\left(\begin{array}{c}
\beta_{1}+\beta_{4} * w_{i} \\
\beta_{2} \\
\beta_{3}
\end{array}\right)+\left(\begin{array}{l}
b_{1_{i}} \\
b_{2_{i}} \\
b_{3_{i}}
\end{array}\right)
\]

To specify a covariate model, use the 'FEGroupDesign' option.
'FEGroupDesign' is a \(p-b y-q-b y-m\) array specifying a different \(p-b y-q\) fixed-effects design matrix for each of the \(m\) groups. Using the previous example, the array resembles the following:

1 Create the array.
```

% Number of parameters in the model (Phi)
num_params = 3;
% Number of covariates
num_cov = 1;
% Assuming number of groups in the data set is 7
num_groups = 7;
% Array of covariate values
covariates = [75; 52; 66; 55; 70; 58; 62 ];
A = repmat(eye(num_params, num_params+num_cov),...
[1,1,num_groups]);
A(1,num_params+1,1:num_groups) = covariates(:,1)

```

2 Create a struct with the specified design matrix.
```

options.FEGroupDesign = A;

```

3 Specify the arguments for nlmefit (or nlmefitsa) as shown in "Mixed-Effects Models Using nlmefit and nlmefitsa" on page 9-234.

\section*{Choosing nlmefit or nlmefitsa}

Statistics Toolbox provides two functions, nlmefit and nlmefitsa for fitting nonlinear mixed-effects models. Each function provides different capabilities, which may help you decide which to use.
- "Approximation Methods" on page 9-226
- "Parameters Specific to nlmefitsa" on page 9-227
- "Model and Data Requirements" on page 9-228

\section*{Approximation Methods}
nlmefit provides the following four approximation methods for fitting nonlinear mixed-effects models:
- 'LME' - Use the likelihood for the linear mixed-effects model at the current conditional estimates of beta and B. This is the default.
- 'RELME ' - Use the restricted likelihood for the linear mixed-effects model at the current conditional estimates of beta and \(B\).
- 'FO' - First-order Laplacian approximation without random effects.
- ' \(F\) OCE ' - First-order Laplacian approximation at the conditional estimates of B.
nlmefitsa provides an additional approximation method, Stochastic Approximation Expectation-Maximization (SAEM) [24] with three steps :

1 Simulation: Generate simulated values of the random effects \(b\) from the posterior density \(p(b \mid \Sigma)\) given the current parameter estimates.

2 Stochastic approximation: Update the expected value of the log likelihood function by taking its value from the previous step, and moving part way toward the average value of the log likelihood calculated from the simulated random effects.

3 Maximization step: Choose new parameter estimates to maximize the log likelihood function given the simulated values of the random effects.

Both nlmefit and nlmefitsa attempt to find parameter estimates to maximize a likelihood function, which is difficult to compute. nlmefit deals with the problem by approximating the likelihood function in various ways, and maximizing the approximate function. It uses traditional optimization techniques that depend on things like convergence criteria and iteration limits.
nlmefitsa, on the other hand, simulates random values of the parameters in such a way that in the long run they converge to the values that maximize the exact likelihood function. The results are random, and traditional convergence tests don't apply. Therefore nlmefitsa provides options to plot the results as the simulation progresses, and to restart the simulation multiple times. You can use these features to judge whether the results have converged to the accuracy you desire.

\section*{Parameters Specific to nlmefitsa}

The following parameters are specific to nlmefitsa. Most control the stochastic algorithm.
- Cov0 - Initial value for the covariance matrix PSI. Must be an \(r\)-by- \(r\) positive definite matrix. If empty, the default value depends on the values of BETAO.
- ComputeStdErrors - true to compute standard errors for the coefficient estimates and store them in the output STATS structure, or false (default) to omit this computation.
- LogLikMethod - Specifies the method for approximating the log likelihood.
- NBurnIn - Number of initial burn-in iterations during which the parameter estimates are not recomputed. Default is 5 .
- NIterations - Controls how many iterations are performed for each of three phases of the algorithm.
- NMCMCIterations - Number of Markov Chain Monte Carlo (MCMC) iterations.

\section*{Model and Data Requirements}

There are some differences in the capabilities of nlmefit and nlmefitsa. Therefore some data and models are usable with either function, but some may require you to choose just one of them.
- Error models - nlmefitsa supports a variety of error models. For example, the standard deviation of the response can be constant, proportional to the function value, or a combination of the two. nlmefit fits models under the assumption that the standard deviation of the response is constant. One of the error models, 'exponential', specifies that the log of the response has a constant standard deviation. You can fit such models using nlmefit by providing the log response as input, and by rewriting the model function to produce the log of the nonlinear function value.
- Random effects - Both functions fit data to a nonlinear function with parameters, and the parameters may be simple scalar values or linear functions of covariates. nlmefit allows any coefficients of the linear functions to have both fixed and random effects. nlmefitsa supports random effects only for the constant (intercept) coefficient of the linear functions, but not for slope coefficients. So in the example in "Specifying Covariate Models" on page 9-224, nlmefitsa can treat only the first three beta values as random effects.
- Model form - nlmefit supports a very general model specification, with few restrictions on the design matrices that relate the fixed coefficients and the random effects to the model parameters. nlmefitsa is more restrictive:
- The fixed effect design must be constant in every group (for every individual), so an observation-dependent design is not supported.
- The random effect design must be constant for the entire data set, so neither an observation-dependent design nor a group-dependent design is supported.
- As mentioned under Random Effects, the random effect design must not specify random effects for slope coefficients. This implies that the design must consist of zeros and ones.
- The random effect design must not use the same random effect for multiple coefficients, and cannot use more than one random effect for any single coefficient.
- The fixed effect design must not use the same coefficient for multiple parameters. This implies that it can have at most one nonzero value in each column.
If you want to use nlmefitsa for data in which the covariate effects are random, include the covariates directly in the nonlinear model expression. Don't include the covariates in the fixed or random effect design matrices.
- Convergence - As described in the Model form, nlmefit and nlmefitsa have different approaches to measuring convergence. nlmefit uses traditional optimization measures, and nlmefitsa provides diagnostics to help you judge the convergence of a random simulation.

In practice, nlmefitsa tends to be more robust, and less likely to fail on difficult problems. However, nlmefit may converge faster on problems where it converges at all. Some problems may benefit from a combined strategy, for example by running nlmefitsa for a while to get reasonable parameter estimates, and using those as a starting point for additional iterations using nlmefit.

\section*{Using Output Functions with Mixed-Effects Models}

The Outputfon field of the options structure specifies one or more functions that the solver calls after each iteration. Typically, you might use an output function to plot points at each iteration or to display optimization quantities from the algorithm. To set up an output function:

1 Write the output function as a MATLAB file function or local function.
2 Use statset to set the value of Outputfon to be a function handle, that is, the name of the function preceded by the @ sign. For example, if the output function is outfun.m, the command
```

options = statset('OutputFcn', @outfun);

```
specifies OutputFen to be the handle to outfun. To specify multiple output functions, use the syntax:
```

options = statset('OutputFcn',{@outfun, @outfun2});

```

3 Call the optimization function with options as an input argument.

For an example of an output function, see "Sample Output Function" on page 9-234.

\section*{Structure of the Output Function}

The function definition line of the output function has the following form:
```

stop = outfun(beta,status,state)

```
where
- beta is the current fixed effects.
- status is a structure containing data from the current iteration. "Fields in status" on page 9-230 describes the structure in detail.
- state is the current state of the algorithm. "States of the Algorithm" on page 9-231 lists the possible values.
- stop is a flag that is true or false depending on whether the optimization routine should quit or continue. See "Stop Flag" on page 9-232 for more information.

The solver passes the values of the input arguments to outfun at each iteration.

\section*{Fields in status}

The following table lists the fields of the status structure:
\begin{tabular}{l|l}
\hline Field & Description \\
\hline procedure & \begin{tabular}{l} 
• 'ALT' - alternating algorithm for the optimization of \\
the linear mixed effects or restricted linear mixed effects \\
approximations
\end{tabular} \\
& \begin{tabular}{l} 
• 'LAP' - optimization of the Laplacian approximation for \\
first order or first order conditional estimation
\end{tabular} \\
\hline iteration & An integer starting from 0. \\
\hline
\end{tabular}
\begin{tabular}{|c|c|}
\hline Field & Description \\
\hline inner & \begin{tabular}{l}
A structure describing the status of the inner iterations within the ALT and LAP procedures, with the fields: \\
- procedure - When procedure is 'ALT': \\
- 'PNLS' (penalized nonlinear least squares) \\
- 'LME' (linear mixed-effects estimation) \\
- 'none' \\
When procedure is 'LAP', \\
- 'PNLS' (penalized nonlinear least squares) \\
- 'PLM' (profiled likelihood maximization) \\
- 'none' \\
- state - one of the following: \\
- 'init' \\
- 'iter' \\
- 'done' \\
- 'none' \\
- iteration - an integer starting from 0, or NaN. For nlmefitsa with burn-in iterations, the output function is called after each of those iterations with a negative value for STATUS.iteration.
\end{tabular} \\
\hline fval & The current log likelihood \\
\hline Psi & The current random-effects covariance matrix \\
\hline theta & The current parameterization of Psi \\
\hline mse & The current error variance \\
\hline
\end{tabular}

\section*{States of the Algorithm}

The following table lists the possible values for state:
\begin{tabular}{l|l}
\hline state & Description \\
\hline 'init' & \begin{tabular}{l} 
The algorithm is in the initial state before the first \\
iteration.
\end{tabular} \\
\hline 'iter' & The algorithm is at the end of an iteration. \\
\hline 'done' & The algorithm is in the final state after the last iteration. \\
\hline
\end{tabular}

The following code illustrates how the output function might use the value of state to decide which tasks to perform at the current iteration:
```

switch state
case 'iter'
% Make updates to plot or guis as needed
case 'init'
% Setup for plots or guis
case 'done'
% Cleanup of plots, guis, or final plot
otherwise
end

```

\section*{Stop Flag}

The output argument stop is a flag that is true or false. The flag tells the solver whether it should quit or continue. The following examples show typical ways to use the stop flag.

Stopping an Optimization Based on Intermediate Results. The output function can stop the estimation at any iteration based on the values of arguments passed into it. For example, the following code sets stop to true based on the value of the log likelihood stored in the 'fval'field of the status structure:
```

stop = outfun(beta,status,state)
stop = false;
% Check if loglikelihood is more than 132.
if status.fval > -132
stop = true;
end

```

Stopping an Iteration Based on GUI Input. If you design a GUI to perform nlmefit iterations, you can make the output function stop when a user clicks a Stop button on the GUI. For example, the following code implements a dialog to cancel calculations:
```

function retval = stop_outfcn(beta,str,status)
persistent h stop;
if isequal(str.inner.state,'none')
switch(status)
case 'init'
% Initialize dialog
stop = false;
h = msgbox('Press STOP to cancel calculations.',...
'NLMEFIT: Iteration O ');
button = findobj(h,'type','uicontrol');
set(button,'String','STOP','Callback',@stopper)
pos = get(h,'Position');
pos(3) = 1.1 * pos(3);
set(h,'Position',pos)
drawnow
case 'iter'
% Display iteration number in the dialog title
set(h,'Name',sprintf('NLMEFIT: Iteration %d',...
str.iteration))
drawnow;
case 'done'
% Delete dialog
delete(h);
end
end
if stop
% Stop if the dialog button has been pressed
delete(h)
end
retval = stop;
function stopper(varargin)
% Set flag to stop when button is pressed
stop = true;
disp('Calculation stopped.')

```
end
end

\section*{Sample Output Function}
nmlefitoutputfon is the sample Statistics Toolbox output function for nlmefit and nlmefitsa. It initializes or updates a plot with the fixed-effects (BETA) and variance of the random effects (diag(STATUS.Psi)). For nlmefit, the plot also includes the log-likelihood (STATUS.fval).
nlmefitoutputfen is the default output function for nlmefitsa. To use it with nlmefit, specify a function handle for it in the options structure:
```

opt = statset('OutputFcn', @nlmefitoutputfcn, )
beta = nlmefit( , 'Options', opt, )

```

To prevent nlmefitsa from using of this function, specify an empty value for the output function:
```

opt = statset('OutputFcn', [], )
beta = nlmefitsa( , 'Options', opt, )

```
nlmefitoutputfon stops nlmefit or nlmefitsa if you close the figure that it produces.

\section*{Mixed-Effects Models Using nlmefit and nlmefitsa}

The following example also works with nlmefitsa in place of nlmefit.
The data in indomethacin.mat records concentrations of the drug indomethacin in the bloodstream of six subjects over eight hours:
```

load indomethacin
gscatter(time,concentration,subject)
xlabel('Time (hours)')
ylabel('Concentration (mcg/ml)')
title('{\bf Indomethacin Elimination}')
hold on

```

Indomethacin Elimination

"Specifying Mixed-Effects Models" on page 9-221 discusses a useful model for this type of data. Construct the model via an anonymous function as follows:
```

model = @(phi,t)(phi(1)*exp(-exp(phi(2))*t) + ...
phi(3)*exp(-exp(phi(4))*t));

```

Use the nlinfit function to fit the model to all of the data, ignoring subject-specific effects:
```

phiO = [1 2 1 1];
[phi,res] = nlinfit(time,concentration,model,phi0);
numObs = length(time);
numParams = 4;
df = numObs-numParams;
mse = (res'*res)/df

```
```

mse =
0.0304
tplot = 0:0.01:8;
plot(tplot,model(phi,tplot),'k','LineWidth',2)
hold off

```

Indomethacin Elimination

A box plot of residuals by subject shows that the boxes are mostly above or below zero, indicating that the model has failed to account for subject-specific effects:
```

colors = 'rygcbm';
h = boxplot(res,subject,'colors',colors,'symbol','o');
set(h(~isnan(h)),'LineWidth',2)
hold on
boxplot(res,subject,'colors','k','symbol','ko')

```
```

grid on
xlabel('Subject')
ylabel('Residual')
hold off

```

To account for subject-specific effects, fit the model separately to the data for each subject:
```

phiO = [1 2 1 1];
PHI = zeros(4,6);
RES = zeros(11,6);
for I = 1:6
tI = time(subject == I);
cI = concentration(subject == I);
[PHI(:,I),RES(:,I)] = nlinfit(tI,cI,model,phiO);
end

```
```

PHI
PHI =

| 2.0293 | 2.8277 | 5.4683 | 2.1981 | 3.5661 | 3.0023 |
| ---: | ---: | ---: | ---: | ---: | ---: |
| 0.5794 | 0.8013 | 1.7498 | 0.2423 | 1.0408 | 1.0882 |
| 0.1915 | 0.4989 | 1.6757 | 0.2545 | 0.2915 | 0.9685 |
| -1.7878 | -1.6354 | -0.4122 | -1.6026 | -1.5069 | -0.8731 |

numParams = 24;
df = numObs-numParams;
mse = (RES(:)'*RES(:))/df
mse =
0.0057
gscatter(time,concentration, subject)
xlabel('Time (hours)')
ylabel('Concentration (mcg/ml)')
title('{\bf Indomethacin Elimination}')
hold on
for I = 1:6
plot(tplot,model(PHI(:, I),tplot),'Color',colors(I))
end
axis([0 8 0 3.5])
hold off

```

\section*{Indomethacin Elimination}

PHI gives estimates of the four model parameters for each of the six subjects. The estimates vary considerably, but taken as a 24 -parameter model of the data, the mean-squared error of 0.0057 is a significant reduction from 0.0304 in the original four-parameter model.

A box plot of residuals by subject shows that the larger model accounts for most of the subject-specific effects:
```

h = boxplot(RES,'colors',colors,'symbol','o');
set(h(~isnan(h)),'LineWidth',2)
hold on
boxplot(RES,'colors','k','symbol','ko')
grid on
xlabel('Subject')
ylabel('Residual')

```
hold off

The spread of the residuals (the vertical scale of the box plot) is much smaller than in the previous box plot, and the boxes are now mostly centered on zero.

While the 24-parameter model successfully accounts for variations due to the specific subjects in the study, it does not consider the subjects as representatives of a larger population. The sampling distribution from which the subjects are drawn is likely more interesting than the sample itself. The purpose of mixed-effects models is to account for subject-specific variations more broadly, as random effects varying around population means.

Use the nlmefit function to fit a mixed-effects model to the data.
The following anonymous function, nlme_model, adapts the four-parameter model used by nlinfit to the calling syntax of nlmefit by allowing separate
parameters for each individual. By default, nlmefit assigns random effects to all the model parameters. Also by default, nlmefit assumes a diagonal covariance matrix (no covariance among the random effects) to avoid overparametrization and related convergence issues.
```

nlme_model = @(PHI,t)(PHI(:,1).*exp(-exp(PHI(:,2)).*t) + ...
PHI(:,3).*exp(-exp(PHI (:,4)).*t));
phiO = [1 2 1 1];
[phi,PSI,stats] = nlmefit(time,concentration,subject, ...
[],nlme_model,phiO)
phi =
2.8277
0 . 7 7 2 9
0.4606
-1.3459
PSI =
0.3264 0 0 0
0
0 0
0 0 0
stats =
dfe: 57
logl: 54.5882
mse: 0.0066
rmse: 0.0787
errorparam: 0.0815
aic: -91.1765
bic: -93.0506
covb: [4x4 double]
sebeta: [0.2558 0.1066 0.1092 0.2244]
ires: [66x1 double]
pres: [66x1 double]
iwres: [66x1 double]
pwres: [66x1 double]
cwres: [66x1 double]

```

The mean-squared error of 0.0066 is comparable to the 0.0057 of the 24 -parameter model without random effects, and significantly better than the 0.0304 of the four-parameter model without random effects.

The estimated covariance matrix PSI shows that the variance of the fourth random effect is essentially zero, suggesting that you can remove it to simplify the model. To do this, use the REParamsSelect parameter to specify the indices of the parameters to be modeled with random effects in nlmefit:
```

[phi,PSI,stats] = nlmefit(time,concentration,subject, ...
[],nlme_model,phi0, ...
'REParamsSelect',[1 2 3])
phi =
2.8277
0.7728
0.4605
-1.3460
PSI =
0.3270 0 0
0 0.0250 0
0 0 0.0124
stats =
dfe: 58
logl: 54.5875
mse: 0.0066
rmse: 0.0780
errorparam: 0.0815
aic: -93.1750
bic: -94.8410
covb: [4x4 double]
sebeta: [0.2560 0.1066 0.1092 0.2244]
ires: [66x1 double]
pres: [66x1 double]
iwres: [66x1 double]
pwres: [66x1 double]
cwres: [66x1 double]

```

The log-likelihood logl is almost identical to what it was with random effects for all of the parameters, the Akaike information criterion aic is reduced from - 91.1765 to -93.1750 , and the Bayesian information criterion bic is reduced from -93.0506 to -94.8410 . These measures support the decision to drop the fourth random effect.

Refitting the simplified model with a full covariance matrix allows for identification of correlations among the random effects. To do this, use the CovPattern parameter to specify the pattern of nonzero elements in the covariance matrix:
```

[phi,PSI,stats] = nlmefit(time,concentration,subject, ...
[],nlme_model,phi0, ...
'REParamsSelect',[1 2 3], ...
'CovPattern',ones(3))
phi =
2.8148
0.8293
0.5613
-1.1407
PSI =
0.4767 0.1152 0.0499
0.1152 0.0321 0.0032
0.0499 0.0032 0.0236
stats =
dfe: 55
logl: 58.4731
mse: 0.0061
rmse: 0.0782
errorparam: 0.0781
aic: -94.9462
bic: -97.2369
covb: [4x4 double]
sebeta: [0.3028 0.1103 0.1179 0.1662]
ires: [66x1 double]
pres: [66x1 double]
iwres: [66x1 double]
pwres: [66x1 double]

```
```

cwres: [66x1 double]

```

The estimated covariance matrix PSI shows that the random effects on the first two parameters have a relatively strong correlation, and both have a relatively weak correlation with the last random effect. This structure in the covariance matrix is more apparent if you convert PSI to a correlation matrix using corrcov:
```

RHO = corrcov(PSI)
RHO =

| 1.0000 | 0.9316 | 0.4706 |
| :--- | :--- | :--- |
| 0.9316 | 1.0000 | 0.1178 |
| 0.4706 | 0.1178 | 1.0000 |

```
clf; imagesc (RHO)
set (gca,'XTick',[ 123 3],'YTick', \(\left.\left.\begin{array}{lll}1 & 2 & 3\end{array}\right]\right)\)
title('\{\bf Random Effect Correlation\}')
h = colorbar;
set(get(h,'YLabel'), 'String','Correlation');

\section*{Random Effect Correlation}

Incorporate this structure into the model by changing the specification of the covariance pattern to block-diagonal:
```

P = [1 1 0;1 1 0;0 0 1] % Covariance pattern
P =
1 1 0
1 1 0
0 0
[phi,PSI,stats,b] = nlmefit(time,concentration, subject, ...
[],nlme_model,phi0, ...
'REParamsSelect',[1 2 3], ...
'CovPattern',P)

```
```

phi =
2.7830
0.8981
0.6581
-1.0000
PSI =
0.5180 0.1069 0
0.1069 0.0221 0
0 0 0.0454
stats =
dfe: 57
logl: 58.0804
mse: 0.0061
rmse: 0.0768
errorparam: 0.0782
aic: -98.1608
bic: -100.0350
covb: [4x4 double]
sebeta: [l0.3171 0.1073 0.1384 0.1453]
ires: [66x1 double]
pres: [66x1 double]
iwres: [66x1 double]
pwres: [66x1 double]
cwres: [66x1 double]
b =

| -0.8507 | -0.1563 | 1.0427 | -0.7559 | 0.5652 | 0.1550 |
| ---: | ---: | ---: | ---: | ---: | ---: |
| -0.1756 | -0.0323 | 0.2152 | -0.1560 | 0.1167 | 0.0320 |
| -0.2756 | 0.0519 | 0.2620 | 0.1064 | -0.2835 | 0.1389 |

```

The block-diagonal covariance structure reduces aic from -94.9462 to -98.1608 and bic from -97.2368 to -100.0350 without significantly affecting the log-likelihood. These measures support the covariance structure used in the final model.

The output \(b\) gives predictions of the three random effects for each of the six subjects. These are combined with the estimates of the fixed effects in phi to produce the mixed-effects model.

Use the following commands to plot the mixed-effects model for each of the six subjects. For comparison, the model without random effects is also shown.
```

PHI = repmat(phi,1,6) + ... % Fixed effects
[b(1,:);b(2,:);b(3,:);zeros(1,6)]; % Random effects
RES = zeros(11,6); % Residuals
colors = 'rygcbm';
for I = 1:6
fitted_model = @(t)(PHI(1,I)*exp(-exp(PHI(2,I))*t) + ...
PHI(3,I)*exp(-exp(PHI (4,I))*t));
tI = time(subject == I);
cI = concentration(subject == I);
RES(:,I) = cI - fitted_model(tI);
subplot(2,3,I)
scatter(tI,cI,20,colors(I),'filled')
hold on
plot(tplot,fitted_model(tplot),'Color',colors(I))
plot(tplot,model(phi,tplot),'k')
axis([0 8 0 3.5])
xlabel('Time (hours)')
ylabel('Concentration (mcg/ml)')
legend(num2str(I),'Subject','Fixed')
end

```

If obvious outliers in the data (visible in previous box plots) are ignored, a normal probability plot of the residuals shows reasonable agreement with model assumptions on the errors:
```

clf; normplot(RES(:))

```

\section*{Examining Residuals for Model Verification}

You can examine the stats structure, which is returned by both nlmefit and nlmefitsa, to determine the quality of your model. The stats structure contains fields with conditional weighted residuals (cwres field) and individual weighted residuals (iwres field). Since the model assumes that residuals are normally distributed, you can examine the residuals to see how well this assumption holds.

This example generates synthetic data using normal distributions. It shows how the fit statistics look:
- Good when testing against the same type of model as generates the data
- Poor when tested against incorrect data models

1 Initialize a 2-D model with 100 individuals:
```

nGroups = 100; % 100 Individuals
nlmefun = @(PHI,t)(PHI(:,1)*5 + PHI(:,2)^2.*t); % Regression fcn
REParamSelect = [1 2]; % Both Parameters have random effect
errorParam = .03;
beta0 = [ 1.5 5]; % Parameter means
psi = [ 0.35 0; ... % Covariance Matrix
0 0.51 ];
time =[0.25;0.5;0.75;1;1.25;2;3;4;5;6];
nParameters = 2;
rng(0,'twister') % for reproducibility

```

2 Generate the data for fitting with a proportional error model:
```

b_i = mvnrnd(zeros(1, numel(REParamSelect)), psi, nGroups);
individualParameters = zeros(nGroups,nParameters);
individualParameters(:, REParamSelect) = ...
bsxfun(@plus,beta0(REParamSelect), b_i);
groups = repmat(1:nGroups,numel(time),1);
groups = vertcat(groups(:));
y = zeros(numel(time)*nGroups,1);
x = zeros(numel(time)*nGroups,1);
for i = 1:nGroups
idx = groups == i;
f = nlmefun(individualParameters(i,:), time);
% Make a proportional error model for y:
y(idx) = f + errorParam*f.*randn(numel(f),1);
x(idx) = time;
end
P = [ 1 0 ; 0 1 ];

```

3 Fit the data using the same regression function and error model as the model generator:
```

[~,~,stats] = nlmefit(x,y,groups, ...
[],nlmefun,[1 1],'REParamsSelect',REParamSelect,...
'ErrorModel','Proportional','CovPattern',P);

```

4 Create a plotting routine by copying the following function definition, and creating a file plotResiduals.m on your MATLAB path:
```

function plotResiduals(stats)
pwres = stats.pwres;
iwres = stats.iwres;
cwres = stats.cwres;
figure
subplot(2,3,1);
normplot(pwres); title('PWRES')
subplot(2,3,4);
createhistplot(pwres);
subplot(2,3,2);
normplot(cwres); title('CWRES')
subplot(2,3,5);
createhistplot(cwres);
subplot(2,3,3);
normplot(iwres); title('IWRES')
subplot(2,3,6);
createhistplot(iwres); title('IWRES')
function createhistplot(pwres)
[x, n] = hist(pwres);
d = n(2)- n(1);
x = x/sum(x*d);
bar(n,x);
ylim([0 max(x)*1.05]);
hold on;
x2 = -4:0.1:4;
f2 = normpdf(x2,0,1);
plot(x2,f2,'r');
end
end

```

5 Plot the residuals using the plotResiduals function:
plotResiduals(stats);

The upper probability plots look straight, meaning the residuals are normally distributed. The bottom histogram plots match the superimposed normal density plot. So you can conclude that the error model matches the data.

6 For comparison, fit the data using a constant error model, instead of the proportional model that created the data:
```

[~,~,stats] = nlmefit(x,y,groups, ...
[],nlmefun,[0 0],'REParamsSelect',REParamSelect,...
'ErrorModel','Constant','CovPattern',P);
plotResiduals(stats);

```

The upper probability plots are not straight, indicating the residuals are not normally distributed. The bottom histogram plots are fairly close to the superimposed normal density plots.

7 For another comparison, fit the data to a different structural model than created the data:
```

nlmefun2 = @(PHI,t)(PHI(:,1)*5 + PHI(:,2).*t.^4);
[~,~,stats] = nlmefit(x,y,groups, ...
[],nlmefun2,[0 0],'REParamsSelect',REParamSelect,...
'ErrorModel','constant', 'CovPattern',P);
plotResiduals(stats);

```

Not only are the upper probability plots not straight, but the histogram plot is quite skewed compared to the superimposed normal density. These residuals are not normally distributed, and do not match the model.

\section*{Pitfalls in Fitting Nonlinear Models by Transforming to Linearity}

This example shows pitfalls that can occur when fitting a nonlinear model by transforming to linearity. Imagine that we have collected measurements on two variables, x and y , and we want to model y as a function of x. Assume that x is measured exactly, while measurements of y are affected by additive, symmetric, zero-mean errors.
```

x = [5.72 4.22 5.72 3.59 5.04 2.66 5.02 3.11 0.13 2.26 ...
5.39 2.57 1.20 1.82 3.23 5.46 3.15 1.84 0.21 4.29 ...
4.61 0.36 3.76 1.59 1.87 3.14 2.45 5.36 3.44 3.41]';
y = [lllllllllllll
0.02 3.88 6.43 4.08 4.90 1.33 3.63 5.49 7.23 0.88 ...
3.08 8.12 1.22 4.24 6.21 5.48 4.89 2.30 4.13 2.17]';

```

Let's also assume that theory tells us that these data should follow a model of exponential decay, \(\mathrm{y}=\mathrm{p} 1^{*} \exp \left(\mathrm{p} 2^{*} \mathrm{x}\right)\), where p 1 is positive and p 2 is negative. To fit this model, we could use nonlinear least squares.
```

modelFun = @(p,x) p(1)*exp(p(2)*x);

```

But the nonlinear model can also be transformed to a linear one by taking the \(\log\) on both sides, to get \(\log (y)=\log (p 1)+p 2 * x\). That's tempting, because we can fit that linear model by ordinary linear least squares. The coefficients we'd get from a linear least squares would be \(\log (\mathrm{p} 1)\) and p 2 .
```

paramEstsLin = [ones(size(x)), x] \ log(y);
paramEstsLin(1) = exp(paramEstsLin(1))

```
paramEstsLin =
11.9312
\(-0.4462\)

How did we do? We can superimpose the fit on the data to find out.
```

xx = linspace(min(x), max(x));

```
```

yyLin = modelFun(paramEstsLin, xx);
plot(x,y,'o', xx,yyLin,'-');
xlabel('x'); ylabel('y');
legend({'Raw data','Linear fit on the log scale'},'location','NE');

```

Something seems to have gone wrong, because the fit doesn't really follow the trend that we can see in the raw data. What kind of fit would we get if we used nlinfit to do nonlinear least squares instead? We'll use the previous fit as a rough starting point, even though it's not a great fit.
```

paramEsts = nlinfit(x, y, modelFun, paramEstsLin)

```
paramEsts =
    8.8145
    \(-0.2885\)
```

yy = modelFun(paramEsts,xx);
plot(x,y,'o', xx,yyLin,'-', xx,yy,'-');
xlabel('x'); ylabel('y');
legend({'Raw data','Linear fit on the log scale', ...
'Nonlinear fit on the original scale'},'location','NE');

```

The fit using nlinfit more or less passes through the center of the data point scatter. A residual plot shows something approximately like an even scatter about zero.
```

r = y-modelFun(paramEsts,x);
plot(x,r,'+', [min(x) max(x)],[0 0],'k:');
xlabel('x'); ylabel('residuals');

```

So what went wrong with the linear fit? The problem is in log transform. If we plot the data and the two fits on the log scale, we can see that there's an extreme outlier.
```

plot(x,log(y),'o', xx,log(yyLin),'-', xx,log(yy),'-');
xlabel('x'); ylabel('log(y)');
ylim([-5,3]);
legend({'Raw data', 'Linear fit on the log scale', ...
'Nonlinear fit on the original scale'},'location','SW');

```

That observation is not an outlier in the original data, so what happened to make it one on the log scale? The log transform is exactly the right thing to straighten out the trend line. But the log is a very nonlinear transform, and so symmetric measurement errors on the original scale have become asymmetric on the log scale. Notice that the outlier had the smallest y value on the original scale -- close to zero. The log transform has "stretched out" that smallest y value more than its neighbors. We made the linear fit on the log scale, and so it is very much affected by that outlier.

Had the measurement at that one point been slightly different, the two fits might have been much more similar. For example,
```

y(11) = 1;
paramEsts = nlinfit(x, y, modelFun, [10;-.3])

```
```

paramEsts =
8.7618
-0.2833
paramEstsLin = [ones(size(x)), x] \ log(y);
paramEstsLin(1) = exp(paramEstsLin(1))
paramEstsLin =
9.6357
-0.3394
yy = modelFun(paramEsts,xx);
yyLin = modelFun(paramEstsLin, xx);
plot(x,y,'o', xx,yyLin,'-', xx,yy,'-');
xlabel('x'); ylabel('y');
legend({'Raw data', 'Linear fit on the log scale', ...
'Nonlinear fit on the original scale'},'location','NE');

```

Still, the two fits are different. Which one is "right"? To answer that, suppose that instead of additive measurement errors, measurements of y were affected by multiplicative errors. These errors would not be symmetric, and least squares on the original scale would not be appropriate. On the other hand, the log transform would make the errors symmetric on the log scale, and the linear least squares fit on that scale is appropriate.

So, which method is "right" depends on what assumptions you are willing to make about your data. In practice, when the noise term is small relative to the trend, the log transform is "locally linear" in the sense that y values near the same x value will not be stretched out too asymmetrically. In that case, the two methods lead to essentially the same fit. But when the noise term is not small, you should consider what assumptions are realistic, and choose an appropriate fitting method.

\section*{Generalized Linear Models}
- "Multinomial Models for Nominal Responses" on page 10-2
- "Multinomial Models for Ordinal Responses" on page 10-5
- "Hierarchical Multinomial Models" on page 10-9

\section*{Multinomial Models for Nominal Responses}

The outcome of a response variable might be one of a restricted set of possible values. If there are only two possible outcomes, such as a yes or no answer to a question, these responses are called binary responses. If there are multiple outcomes, then they are called polytomous responses. Some examples include the degree of a disease (mild, medium, severe), preferred districts to live in a city, and so on. When the response variable is nominal, there is no natural order among the response variable categories. Nominal response models explain and predict the probability that an observation is in each category of a categorical response variable.

A nominal response model is one of several natural extensions of the binary logit model and is also called a multinomial logit model. The multinomial logit model explains the relative risk of being in one category versus being in the reference category, \(k\), using a linear combination of predictor variables. Consequently, the probability of each outcome is expressed as a nonlinear function of \(p\) predictor variables. The 'interactions', 'on' name-value pair argument in mnrfit corresponds to this multinomial model with separate intercept and slopes among categories. mnrfit uses the default logit link function for multinomial models. You cannot specify a different link function for multinomial responses.

The multinomial logit model is
\[
\begin{aligned}
& \ln \left(\frac{\pi_{1}}{\pi_{k}}\right)=\alpha_{1}+\beta_{11} X_{1}+\beta_{12} X_{2}+\cdots+\beta_{1 p} X_{p} \\
& \ln \left(\frac{\pi_{2}}{\pi_{k}}\right)=\alpha_{2}+\beta_{21} X_{1}+\beta_{22} X_{2}+\cdots+\beta_{2 p} X_{p} \\
& \quad \vdots \\
& \ln \left(\frac{\pi_{k-1}}{\pi_{k}}\right)=\alpha_{(k-1)}+\beta_{(k-1) 1} X_{1}+\beta_{(k-1) 2} X_{2}+\cdots+\beta_{(k-1) p} X_{p}
\end{aligned}
\]
where \(\Pi_{j}=\mathrm{P}(y=j)\) is the probability of an outcome being in category \(j, k\) is the number of response categories, and \(p\) is the number of predictor variables. Theoretically, any category can be the reference category, but mnrfit chooses the last one, \(k\), as the reference category. Thus, mnrfit assumes the coefficients of the \(k\) th category are zero. The total of \(j-1\) equations are
solved simultaneously to estimate the coefficients. mnrfit uses the iteratively weighted least squares algorithm to find the maximum likelihood estimates.

The coefficients in the model express the effects of the predictor variables on the relative risk or the log odds of being in category \(j\) versus the reference category, here \(k\). For example, the coefficient \(\beta_{23}\) indicates that the probability of the response variable being in category 2 compared to the probability of being in category \(k\) increases \(\exp \left(\beta_{23}\right)\) times for each unit increase in \(X_{3}\), given all else is held constant. Or it indicates that the relative log odds of the response variable being category 2 versus in category \(k\) increases \(\beta_{23}\) times with a one-unit increase in \(X_{3}\), given all else equal.

Based on the nominal response model, and the assumption that the coefficients for the last category are zero, the probability of being in each category is
\[
\pi_{j}=P(y=j)=\frac{e^{\sum_{l=1}^{p} \beta_{j l} x_{l}}}{1+\sum_{j=1}^{k-1} e_{l=1}^{p} \beta_{j l} x_{l}}, \quad j=1, \cdots, k-1 .
\]

The probability of the \(k\) th category becomes
\[
\pi_{k}=P(y=k)=\frac{1}{1+\sum_{j=1}^{k-1} e^{l=1} \sum_{j i l}^{p} x_{l}},
\]
which is simply equal to \(1-\Pi_{1}-\Pi_{2}-\ldots-\Pi_{k-1}\).
After estimating the model coefficients using mnrfit, you can estimate the category probabilities or the number in each category using mnrval (the default name-value pair is 'type', 'category'). This function accepts the coefficient estimates and the model statistics mnrfit returns and estimates the categorical probabilities or the number in each category and their confidence bounds. You can also specify the cumulative or conditional probabilities or numbers to estimate using the 'type' name-value pair argument in mnrval.

Concepts - "Multinomial Models for Ordinal Responses" on page 10-5
- "Hierarchical Multinomial Models" on page 10-9

\section*{Multinomial Models for Ordinal Responses}

The outcome of a response variable might be one of a restricted set of possible values. If there are only two possible outcomes, such as male and female for gender, these responses are called binary responses. If there are multiple outcomes, then they are called polytomous responses. Some examples of polytomous responses include levels of a disease (mild, medium, severe), preferred districts to live in a city, the species for a certain flower type, and so on. Sometimes there might be a natural order among the response categories. These responses are called ordinal responses.

The ordering might be inherent in the category choices, such as an individual being not satisfied, satisfied, or very satisfied with an online customer service. The ordering might also be introduced by categorization of a latent (continuous) variable, such as in the case of an individual being in the low risk, medium risk, or high risk group for developing a certain disease, based on a quantitative medical measure such as blood pressure.

You can specify a multinomial regression model that uses the natural ordering among the response categories. This ordinal model describes the relationship between the cumulative probabilities of the categories and predictor variables.

Different link functions can describe this relationship with logit and probit being the most used.
- Logit: The default link function mnrfit uses for ordinal categories is the logit link function. This models the log cumulative odds. The 'link', 'logit' name-value pair specifies this in mnrfit. Log cumulative odds is the logarithm of the ratio of the probability that a response belongs to a category with a value less than or equal to category \(j, \mathrm{P}\left(y \leq c_{j}\right)\), and the probability that a response belongs to a category with a value greater than category \(j, \mathrm{P}\left(y>c_{j}\right)\).
Ordinal models are usually based on the assumption that the effects of predictor variables are the same for all categories on the logarithmic scale. That is, the model has different intercepts but common slopes (coefficients) among categories. This model is called parallel regression or the proportional odds model. It is the default for ordinal responses, and the 'interactions', 'off' name-value pair specifies this model in mnrfit.
The proportional odds model is
\[
\begin{aligned}
& \ln \left(\frac{P\left(y \leq c_{1}\right)}{P\left(y>c_{1}\right)}\right)=\ln \left(\frac{\pi_{1}}{\pi_{2}+\cdots+\pi_{k}}\right)=\alpha_{1}+\beta_{1} X_{1}+\beta_{2} X_{2}+\cdots+\beta_{p} X_{p}, \\
& \ln \left(\frac{P\left(y \leq c_{2}\right)}{P\left(y>c_{2}\right)}\right)=\ln \left(\frac{\pi_{1}+\pi_{2}}{\pi_{3}+\cdots+\pi_{k}}\right)=\alpha_{2}+\beta_{1} X_{1}+\beta_{2} X_{2}+\cdots+\beta_{p} X_{p}, \\
& \vdots \\
& \ln \left(\frac{P\left(y \leq c_{k-1}\right)}{P\left(y>c_{k-1}\right)}\right)=\ln \left(\frac{\pi_{1}+\pi_{2}+\cdots+\pi_{k-1}}{\pi_{k}}\right)=\alpha_{k-1}+\beta_{1} X_{1}+\beta_{2} X_{2}+\cdots+\beta_{p} X_{p},
\end{aligned}
\]
where \(\Pi_{j}, j=1,2, \ldots, k\), are the category probabilities.
For example, for a response variable with three categories, there are 3 \(1=2\) equations as follows:
\[
\begin{aligned}
& \ln \left(\frac{\pi_{1}}{\pi_{2}+\pi_{3}}\right)=\alpha_{1}+\beta_{1} X_{1}+\beta_{2} X_{2}+\cdots+\beta_{p} X_{p} \\
& \ln \left(\frac{\pi_{1}+\pi_{2}}{\pi_{3}}\right)=\alpha_{2}+\beta_{1} X_{1}+\beta_{2} X_{2}+\cdots+\beta_{p} X_{p}
\end{aligned}
\]

Under the proportional odds assumption, the partial effect of a predictor variable \(X\) is invariant to the choice of the response variable category, \(j\). For example, if there are three categories, then the coefficients express the impact of a predictor variable on the relative risk or log odds of the response value being in category 1 versus categories 2 or 3 , or in category 1 or 2 versus category 3 .

Thus, a unit change in variable \(X_{2}\) would mean a change in the cumulative odds of the response value being in category 1 versus categories 2 or 3 , or category 1 or 2 versus category 3 by a factor of \(\exp \left(\beta_{2}\right)\), given all else equal.
You can alternatively fit a model with different intercept and slopes among the categories by using the 'interactions', 'on' name-value pair argument. However, using this option for ordinal models when the equal slopes model is true causes a loss of efficiency (you lose the advantage of estimating fewer parameters).
- Probit: The 'link', 'probit' name-value pair argument uses the probit link function which is based on a normally distributed latent variable assumption. For ordinal response variables this is also called an ordered probit model. Consider the regression model that describes the relationship
of a latent variable \(y^{*}\) of an ordinal process and a vector of predictor variables, \(X\),
\[
y=\beta X+\varepsilon,
\]
where the error term \(\varepsilon\) has a standard normal distribution. Suppose there is the following relationship between the latent variable \(y^{*}\) and the observed variable \(y\) :
\[
\begin{array}{cccc}
y=c_{1} & \text { if } & \alpha_{0}<y^{*} \leq \alpha_{1}, \\
y=c_{2} & \text { if } & \alpha_{1}<y^{*} \leq \alpha_{2} \\
\vdots & & \vdots \\
y=c_{k} & \text { if } & \alpha_{k-1}<y^{*} \leq \alpha_{k},
\end{array}
\]
where \(\alpha_{0}=-\infty\) and \(\alpha_{k}=\infty\). Then, the cumulative probability of \(y\) being in category \(j\) or one of earlier categories, \(\mathrm{P}\left(y \leq c_{j}\right)\), is equal to
\[
P\left(y \leq c_{j}\right)=P\left(y^{*}<\alpha_{j}\right)=P\left(\beta X+\varepsilon<\alpha_{j}\right)=P\left(\varepsilon<\alpha_{j}-\beta X\right)=\Phi\left(\alpha_{j}-\beta X\right)
\]
where \(\Phi\) is standard normal cumulative distribution function. Thus,
\[
\Phi^{-1}\left(P\left(y \leq c_{j}\right)\right)=\alpha_{j}-\beta X,
\]
where \(\alpha_{j}\) corresponds to the cut points of the latent variable and the intercept in the regression model. This only holds under the assumptions of a normal latent variable and parallel regression. More generally, for a response variable with \(k\) categories and multiple predictors, the ordered probit model is
\[
\begin{gathered}
\Phi^{-1}\left(P\left(y \leq c_{1}\right)\right)=\alpha_{1}+\beta_{1} X_{1}+\cdots+\beta_{p} X_{p} \\
\Phi^{-1}\left(P\left(y \leq c_{2}\right)\right)=\alpha_{2}+\beta_{1} X_{1}+\cdots+\beta_{p} X_{p} \\
\vdots \\
\Phi^{-1}\left(P\left(y \leq c_{k-1}\right)\right)=\alpha_{k-1}+\beta_{1} X_{1}+\cdots+\beta_{p} X_{p}
\end{gathered}
\]
where \(\mathrm{P}\left(y \leq c_{j}\right)=\Pi_{1}+\Pi_{2}+\ldots+\Pi_{j}\).

The coefficients indicate the impact of a unit change in the predictor variable on the likelihood of a state. A positive coefficient, \(\beta_{1}\), for example, indicates an increase in the underlying latent variable with an increase in the corresponding predictor variable, \(X_{1}\). Hence, it causes a decrease in \(\mathrm{P}(y\) \(\left.\leq c_{1}\right)\) and an increase in \(\mathrm{P}\left(y \leq c_{k}\right)\).

After estimating the model coefficients using mnrfit, you can estimate the cumulative probabilities or the cumulative number in each category using mnrval with the 'type', 'cumulative' name-value pair option. mnrval accepts the coefficient estimates and the model statistics mnrfit returns, and estimates the categorical probabilities or the number in each category and their confidence intervals. You can specify which category or conditional probabilities or numbers to estimate by changing the value of the 'type' name-value pair argument.

Concepts - "Multinomial Models for Nominal Responses" on page 10-2
- "Hierarchical Multinomial Models" on page 10-9

\section*{Hierarchical Multinomial Models}

The outcome of a response variable might sometimes be one of a restricted set of possible values. If there are only two possible outcomes, such as male and female for gender, these responses are called binary responses. If there are multiple outcomes, then they are called polytomous responses. These responses are usually qualitative rather than quantitative, such as preferred districts to live in a city, the severity level of a disease, the species for a certain flower type, and so on. Polytomous responses might also have categories which are not independent of each other. Instead the response happens in a sequential manner, or one category is nested in the previous one. These types of responses are called hierarchical, or sequential, or nested multinomial responses.

For example, if the response is the number of cigarettes a person smokes in a given day, the first level is whether the person is a smoker or not. Given that he or she is a smoker, the number of cigarettes he or she smokes can be from one to five or more than five a day. Given that it is more than 5 , this person might be smoking from 6 to 10 or more than 10 cigarettes a day, and so on. The risk group at each level changes accordingly. At level one, the risk group is all of the individuals of interest (smoker or not), say \(m\). If out of \(m\) individuals, \(y_{1}\) of them are not smokers, then at level two, the risk group is the number of all smoking individuals, \(m-y_{1}\). If \(y_{2}\) of these \(m-y_{1}\) individuals smoke from one to five cigarettes a day, then at level three, the risk group is \(m-y_{1}-y_{2}\). So, at each level, the number of people in that category becomes a conditional binomial observation.

The hierarchical multinomial regression models are extensions of binary regression models based on conditional binary observations. The default is a model with different intercept and slopes (coefficients) among categories, in which case mnrfit fits a sequence of conditional binomial models. The 'interactions', 'on' name-value pair specifies this in mnrfit. The default link function is logit and the 'link', 'logit' name-value pair specifies this model in mnrfit.

Suppose the probability that an individual is in category \(j\) given that he or she is not in the previous categories is \(\Pi_{j}\), and the cumulative probability that a response belongs to a category \(j\) or a previous category is \(\mathrm{P}\left(y \leq c_{j}\right)\). Then the hierarchical model with a logit link function and different slopes assumption is
\[
\begin{aligned}
& \ln \left(\frac{\pi_{1}}{1-P\left(y \leq c_{1}\right)}\right)=\ln \left(\frac{\pi_{1}}{1-\pi_{1}}\right)=\alpha_{1}+\beta_{11} X_{1}+\beta_{12} X_{2}+\cdots+\beta_{1 p} X_{p} \\
& \ln \left(\frac{\pi_{2}}{1-P\left(y \leq c_{2}\right)}\right)=\ln \left(\frac{\pi_{2}}{1-\left(\pi_{1}+\pi_{2}\right)}\right)=\alpha_{2}+\beta_{21} X_{2}+\beta_{22} X_{2}+\cdots+\beta_{2 p} X_{p} \\
& \quad \vdots \\
& \ln \left(\frac{\pi_{k-1}}{1-P\left(y \leq c_{k-1}\right)}\right)=\ln \left(\frac{\pi_{k-1}}{1-\left(\pi_{1}+\cdots+\pi_{k-1}\right)}\right)=\alpha_{k-1}+\beta_{(k-1) 1} X_{1}+\beta_{(k-1) 2} X_{2}+\cdots+\beta_{(k-1) p}
\end{aligned}
\]

For example, for a response variable with four sequential categories, there are 4-1 = 3 equations as follows:
\[
\begin{aligned}
& \ln \left(\frac{\pi_{1}}{\pi_{2}+\pi_{3}+\pi_{4}}\right)=\alpha_{1}+\beta_{11} X_{1}+\beta_{12} X_{2}+\cdots+\beta_{1 p} X_{p}, \\
& \ln \left(\frac{\pi_{2}}{\pi_{3}+\pi_{4}}\right)=\alpha_{2}+\beta_{21} X_{1}+\beta_{22} X_{2}+\cdots+\beta_{2 p} X_{p}, \\
& \ln \left(\frac{\pi_{3}}{\pi_{4}}\right)=\alpha_{3}+\beta_{31} X_{1}+\beta_{32} X_{2}+\cdots+\beta_{3 p} X_{p} .
\end{aligned}
\]

The coefficients \(\beta_{i j}\) are interpreted within each level. For example, for the previous smoking example, \(\beta_{12}\) shows the impact of \(X_{2}\) on the log odds of a person being a smoker versus a nonsmoker, provided that everything else is held constant. Alternatively, \(\beta_{22}\) shows the impact of \(X_{2}\) on the log odds of a person smoking one to five cigarettes versus more than five cigarettes a day, given that he or she is a smoker, provided that everything else is held constant. Similarly, \(\beta_{23}\), shows the effect of \(X_{2}\) on the log odds of a person smoking 6 to 10 cigarettes versus more than 10 cigarettes a day, given that he or she smokes more than 5 cigarettes a day, provided that everything else is held constant.

You can specify other link functions for hierarchical models. The 'link', 'probit' name-value pair argument uses the probit link function. With the separate slopes assumption, the model becomes
\[
\begin{gathered}
\Phi^{-1}\left(\pi_{1}\right)=\alpha_{1}+\beta_{11} X_{1}+\cdots+\beta_{1 p} X_{p}, \\
\Phi^{-1}\left(\pi_{2}\right)=\alpha_{2}+\beta_{21} X_{1}+\cdots+\beta_{2 p} X_{p}, \\
\vdots \\
\vdots \\
\Phi^{-1}\left(\pi_{k}\right)=\alpha_{k}+\beta_{k 1} X_{1}+\cdots+\beta_{k p} X_{p},
\end{gathered}
\]
where \(\Pi_{j}\) is the conditional probability of being in category \(j\), given that it is not in categories previous to category \(j\). And \(\Phi^{-1}(\).\() is the inverse of the\) standard normal cumulative distribution function.

After estimating the model coefficients using mnrfit, you can estimate the cumulative probabilities or the cumulative number in each category using mnrval with the 'type', 'conditional' name-value pair argument. The function mnrval accepts the coefficient estimates and the model statistics mnrfit returns, and estimates the categorical probabilities or the number in each category and their confidence bounds. You can specify which category or cumulative probabilities or numbers to estimate by changing the value of the 'type' name-value pair argument in mnrval.

\section*{Introduction}

Survival analysis is time-to-event analysis, that is, when the outcome of interest is the time until an event occurs. Examples of time-to-events are the time until infection, reoccurrence of a disease, or recovery in health sciences, duration of unemployment in economics, time until the failure of a machine part or lifetime of light bulbs in engineering, and so on. Survival analysis is a part of reliability studies in engineering. In this case, it is usually used to study the lifetime of industrial components. In reliability analyses, survival times are usually called failure times as the variable of interest is how much time a component functions properly before it fails.

Survival analysis consists of parametric, semiparametric, and nonparametric methods. You can use these to estimate the most commonly used measures in survival studies, survivor and hazard functions, compare them for different groups, and assess the relationship of predictor variables to survival time. Some statistical probability distributions describe survival times well. Commonly used distributions are exponential, Weibull, lognormal, Burr, and Birnbaum-Saunders distributions. Statistics Toolbox functions ecdf and ksdensity compute the empirical and kernel density estimates of the cdf, cumulative hazard, and survivor functions. coxphfit fits the Cox proportional hazards model to the data.

\section*{Censoring}

One important concept in survival analysis is censoring. The survival times of some individuals might not be fully observed due to different reasons. In life sciences, this might happen when the survival study (e.g., the clinical trial)
stops before the full survival times of all individuals can be observed, or a person drops out of a study, or for long-term studies, when the patient is lost to follow up. In the industrial context, not all components might have failed before the end of the reliability study. In such cases, the individual survives beyond the time of the study, and the exact survival time is unknown. This is called right censoring.

During a survival study either the individual is observed to fail at time \(T\), or the observation on that individual ceases at time \(c\). Then the observation is \(\min (T, c)\) and an indicator variable \(I_{c}\) shows if the individual is censored or not. The calculations for hazard and survivor functions must be adjusted to account for censoring. Statistics Toolbox functions such as ecdf, ksdensity, coxphfit, mle account for censoring.

\section*{Data}

Survival data usually consists of the time until an event of interest occurs and the censoring information for each individual or component. The following table shows the fictitious unemployment time of individuals in a 6-month study. Two individuals are right censored (indicated by a censoring value of 1). One individual was still unemployed after the 24 th week, when the study ended. Contact with the other censored individual was lost at the end of the 21st week.
\begin{tabular}{c|c}
\hline Unemployment Time (Weeks) & Censoring \\
\hline 14 & 0 \\
\hline 23 & 0 \\
\hline 7 & 0 \\
\hline 21 & 1 \\
\hline 19 & 0 \\
\hline 16 & 0 \\
\hline 24 & 1 \\
\hline 8 & 0 \\
\hline
\end{tabular}

Survival data might also include the number of failures at a certain time (the number of times a particular survival or failure time was observed). The
following table shows the simulated time until a light-emitting diodes drops to \(70 \%\) of its full light output level, in hours, in an accelerated life test.
\begin{tabular}{c|c}
\hline Failure Time (hrs) & Frequency \\
\hline 8600 & 6 \\
\hline 15300 & 19 \\
\hline 22000 & 11 \\
\hline 28600 & 20 \\
\hline 35300 & 17 \\
\hline 42000 & 14 \\
\hline 48700 & 8 \\
\hline 55400 & 2 \\
\hline 62100 & 0 \\
\hline 68800 & 2 \\
\hline
\end{tabular}

Data might also have information on the predictor variables, to use in semi-parametric regression-like methods such as Cox proportional hazards regression.
\begin{tabular}{c|c|c|c|c}

\hline 17 & 1 & Male & 130 & 88 \\
\hline 8 & 0 & Female & 115 & 82 \\
\hline 14 & 0 & Male & 118 & 86 \\
\hline
\end{tabular}

\section*{Survivor Function}

The survivor function is the probability of survival as a function of time. It is also called the survival function. It gives the probability that the survival time of an individual exceeds a certain value. Since the cumulative distribution function, \(F(t)\), is the probability that the survival time is less than or equal to a given point in time, the survival function for a continuous distribution, \(S(t)\), is the complement of the cumulative distribution function:
\(S(t)=1-F(t)\).
For example, for data coming from a Burr distribution with parameters 50, 3, and 1 , you can calculate and plot the survivor function.
```

x = 0:0.1:200;
figure()
plot(x,1-cdf('Burr',x,50,3,1))
xlabel('Failure time');
ylabel('Survival probability');

```

The survivor function is also related to the hazard function. If the data has the hazard function, \(h(t)\), then the survivor function is
\[
S(t)=\exp \left(-\int_{0}^{t} h(u) d u\right)
\]
which corresponds to
\[
S(t)=\exp (-H(t))
\]
where \(H(t)\) is the cumulative hazard function.

\section*{Hazard Function}

The hazard function gives the instantaneous failure rate of an individual conditioned on the fact that the individual survived until a given time. That is,
\[
h(t)=\lim _{\Delta t \rightarrow 0} \frac{P(t \leq T<t+\Delta t \mid T \geq t)}{\Delta t},
\]
where \(\Delta t\) is a very small time interval. The hazard rate, therefore, is sometimes called the conditional failure rate. The hazard function always takes a positive value. However, these values do not correspond to probabilities and might be greater than 1.

The hazard function is related to the probability density function, \(f(t)\), cumulative distribution function, \(F(t)\), and survivor function, \(S(t)\), as follows:
\[
h(t)=\frac{f(t)}{S(t)}=\frac{f(t)}{1-F(t)},
\]
which is also equivalent to
\[
h(t)=-\frac{d}{d t} \ln S(t)
\]

So, if you know the shape of the survival function, you can also derive the corresponding hazard function.

For example, for data coming from a Burr distribution with parameters 50, 3, and 1 , you can calculate and plot the hazard function.
```

x = 0:1:200;
Burrhazard = pdf('Burr',x,50,3,1)./(1-cdf('Burr',x,50,3,1));
figure()
plot(x,Burrhazard)
xlabel('Failure time');
ylabel('Hazard rate');

```

There are different types of hazard functions. The previous figure shows a situation when the hazard rate increases for the early time periods and then gradually decreases. The hazard rate might also be monotonically decreasing, increasing, or constant over time. The following figure shows examples of different types of hazard functions for data coming from different Weibull distributions.
```

ax1 = subplot(3,1,1);
x1 = 0:0.5:30;
hazard1 = pdf('wbl',x1,3,0.6)./(1-cdf('wbl',x1,3,0.6));
plot(x1,hazard1)
ax2 = subplot(3,1,2);
x2 = 0:0.05:2;

```
```

hazard2 = pdf('wbl',x2,0.9,4)./(1-cdf('wbl',x2,0.9,4));
plot(x2,hazard2,'color','r')
ax3 = subplot(3,1,3);
x3 = 0:0.05:5;
hazard3 = pdf('wbl',x3,2.5,1)./(1-cdf('wbl',x3,2.5,1));
plot(x3,hazard3)
set(ax1,'Ylim',[0 0.4]);
legend(ax1,'a=3, b=0.6');
legend(ax2,'a=0.9, b=4','location','northwest');
legend(ax3,'a=2.5, b=1');

```

In the third case, the Weibull distribution has a shape parameter value of 1 , which corresponds to the exponential distribution. The exponential distribution always has a constant hazard rate over time.

\section*{Concepts}
- "Hazard and Survivor Functions for Different Groups" on page 11-19
- "Survivor Functions for Two Groups" on page 11-26
- "Cox Proportional Hazards Model for Censored Data" on page 11-34
- "Kaplan-Meier Method" on page 11-11
- "Cox Proportional Hazards Regression" on page 11-31

\section*{Kaplan-Meier Method}

Use the Kaplan-Meier nonparametric method to estimate the empirical hazard, survivor, and cumulative distribution functions. The Statistics Toolbox function ecdf produces the empirical cumulative hazard, survivor, and cumulative distribution functions. The Kaplan-Meier estimator for the survivor function is also called the product-limit estimator.

The Kaplan-Meier method uses survival data summarized in life tables. Life tables order data according to ascending failure times, but you don't have to enter the failure/survival times in an ordered manner to use ecdf.

A life table usually consists of:
- Failure times
- Number of items failed at a time/time period
- Number of items censored at a time/time period
- Number of items at risk at the beginning of a time/time period

The number at risk is the total number of survivors at the beginning of each period. The number at risk at the beginning of the first period is all individuals in the lifetime study. At the beginning of each remaining period, the number at risk is reduced by the number of failures plus individuals censored at the end of the previous period.

This life table shows fictitious survival data. At the beginning of the first failure time, there are seven items at risk. At time 4, three fail. So at the beginning of time 7, there are four items at risk. Only one fails at time 7, so the number at risk at the beginning of time 11 is three. Two fail at time 11, so at the beginning of time 12 , the number at risk is one. The remaining item fails at time 12 .
\begin{tabular}{c|c|c}
\hline Failure Time ( \(\mathbf{t}\) ) & Number Failed & Number at Risk \\
\hline 4 & 3 & 7 \\
\hline 7 & 1 & 4 \\
\hline
\end{tabular}
\begin{tabular}{c|c|c}
\hline Failure Time ( \(\mathbf{t})\) & Number Failed & Number at Risk \\
\hline 11 & 2 & 3 \\
\hline 12 & 1 & 1 \\
\hline
\end{tabular}

You can estimate the hazard, cumulative hazard, survival, and cumulative distribution functions using the life tables as described next.

\section*{Cumulative Hazard Rate (Failure Rate)}

The hazard rate at each period is the number of failures in the given period divided by the number of surviving individuals at the beginning of the period (number at risk).
\begin{tabular}{c|c|c}
\hline Failure Time (t) & Hazard Rate (h(t)) & \begin{tabular}{c} 
Cumulative Hazard \\
Rate
\end{tabular} \\
\hline 0 & 0 & 0 \\
\hline\(t_{1}\) & \(d_{1} / r_{1}\) & \(d_{1} / r_{1}\) \\
\hline\(t_{2}\) & \(d_{2} / r_{2}\) & \(h\left(t_{1}\right)+d_{2} / r_{2}\) \\
\hline\(\ldots\) & \(\ldots\) & \(\ldots\) \\
\hline\(t_{n}\) & \(d_{n} / r_{n}\) & \(h\left(t_{n-1}\right)+d_{n} / r_{n}\) \\
\hline
\end{tabular}

\section*{Survival Probability}

For each period, the survival probability is the product of the complement of hazard rates. The initial survival probability at the beginning of the first time period is 1 . If the hazard rate for the each period is \(h\left(t_{i}\right)\), then the survivor probability is as shown.
\begin{tabular}{c|c}
\hline Time ( \(\boldsymbol{t})\) & Survival Probability \((\mathbf{S}(\boldsymbol{t}))\) \\
\hline 0 & 1 \\
\hline\(t_{1}\) & \(1 *\left(1-h\left(t_{1}\right)\right)\) \\
\hline\(t_{2}\) & \(S\left(t_{1}\right) *\left(1-h\left(t_{2}\right)\right)\) \\
\hline
\end{tabular}
\begin{tabular}{c|c}
\hline Time ( \(\boldsymbol{t})\) & Survival Probability \((\mathbf{S}(\mathbf{t}))\) \\
\hline\(\ldots\) & \(\ldots\) \\
\hline\(t_{n}\) & \(S\left(t_{n-1}\right) *\left(1-h\left(t_{n}\right)\right)\) \\
\hline
\end{tabular}

\section*{Cumulative Distribution Function}

Because the cumulative distribution function (cdf) and the survivor function are complements of each other, you can find the cdf from the life tables using \(F(t)=1-S(t)\).

You can compute the cumulative hazard rate, survival rate, and cumulative distribution function for the simulated data in the first table on this page as follows.
\begin{tabular}{c|c|c|c|c|c}
\hline \(\boldsymbol{t}\) & \begin{tabular}{c} 
Number \\
Failed (d)
\end{tabular} & \begin{tabular}{c} 
Number \\
at Risk (r)
\end{tabular} & \begin{tabular}{c} 
Hazard \\
Rate
\end{tabular} & \begin{tabular}{c} 
Survival \\
Probability
\end{tabular} & \begin{tabular}{c} 
Cumulative \\
Distribution \\
Function
\end{tabular} \\
\hline 4 & 3 & 7 & \(3 / 7\) & \begin{tabular}{c}
\(1-3 / 7\) \\
\(=4 / 7=\) \\
0.5714
\end{tabular} & 0.4286 \\
\hline 7 & 1 & 4 & \(1 / 4\) & \begin{tabular}{c}
\(4 / 7^{*}(1-\) \\
\(1 / 4)=3 / 7\) \\
\(=.4286\)
\end{tabular} & 0.5714 \\
\hline 11 & 2 & 3 & \(2 / 3\) & \begin{tabular}{c}
\(3 / 7^{*}(1-\) \\
\(2 / 3)=1 / 7\) \\
\(=0.1429\)
\end{tabular} & 0.8571 \\
\hline 12 & 1 & 1 & \(1 / 1\) & \begin{tabular}{c}
\(1 / 7^{*}(1-\) \\
\(1)=0\)
\end{tabular} & 1 \\
\hline
\end{tabular}

This rates in this example are based on the discrete failure times, and hence the calculations do not necessarily follow the derivative-based definition in "What Is Survival Analysis?" on page 11-2

Here is how you can enter the data and calculate these measures using ecdf. The data does not necessarily have to be in ascending order. Suppose the failure times are stored in an array \(y\).
```

y = [4 7 11 12];
freq = [$$
\begin{array}{llll}{3 1 2 1];}\end{array}
$$;⿱⿻土㇒子小
[f,x] = ecdf(y,'frequency',freq)
f =
0
0.4286
0.5714
0.8571
1.0000
x =
4
4
7
11
1 2

```

When you have censored data，the life table might look like the following：
\begin{tabular}{c|c|c|c|c|c|c}
\hline Time（t） & \begin{tabular}{c} 
Number \\
failed \\
\((\boldsymbol{d})\)
\end{tabular} & CensoringNumber & \begin{tabular}{c} 
Hazard \\
at Risk \\
\((\boldsymbol{r})\)
\end{tabular} & \begin{tabular}{c} 
Survival \\
Rate
\end{tabular} & \begin{tabular}{c} 
Cumulative \\
Probabilitpistribution \\
Function
\end{tabular} \\
\hline 4 & 2 & 1 & 7 & \(2 / 7\) & \begin{tabular}{c}
\(1-2 / 7=\) \\
0.7143
\end{tabular} & 0.2857 \\
\hline 7 & 1 & 0 & 4 & \(1 / 4\) & \begin{tabular}{c}
\(0.7143^{*}(1\) \\
\(-1 / 4)=\) \\
0.5357
\end{tabular} & 0.4643 \\
\hline 11 & 1 & 1 & 3 & \(2 / 3\) & \begin{tabular}{c}
\(0.5357 *(1\) \\
\(-1 / 3)=\) \\
0.3571
\end{tabular} & 0.6429 \\
\hline 12 & 1 & 0 & 1 & \(1 / 1\) & \begin{tabular}{c}
\(0.3571^{*}(1\) \\
\(-1)=0\)
\end{tabular} & 1.0000 \\
\hline
\end{tabular}

At any given time, the censored items are also considered in the total of number at risk, and the hazard rate formula is based on the number failed and the total number at risk. While updating the number at risk at the beginning of each period, the total number failed and censored in the previous period is reduced from the number at risk at the beginning of that period.

While using ecdf, you must also enter the censoring information using an array of binary variables. Enter 1 for censored data, and enter 0 for exact failure time.
```

y = [4 4 4 4 7 7 11 11 12];
cens = [0 1 0 0 1 0 0];
[f,x] = ecdf(y,'censoring',cens)
f =
0
0.4643
0.6429
1.0000
x =
4
4
7
1 1
1 2

```
ecdf, by default, produces the cumulative distribution function values. You have to specify the survivor function or the hazard function using optional name-value pair arguments. You can also plot the results as follows.
```

figure()
ecdf(y,'censoring',cens,'function','survivor');

```

figure()
ecdf(y,'censoring', cens,'function','cumulative hazard');

\section*{Hazard and Survivor Functions for Different Groups}

This example shows how to estimate and plot the cumulative hazard and survivor functions for different groups.

\section*{Step 1. Load and organize sample data.}

Navigate to a folder containing sample data.
```

cd(matlabroot)
cd('help/toolbox/stats/examples')

```

Load the sample data.
load readmissiontimes
The data has readmission times of patients with information on their gender, age, weight, smoking status, and censorship. This is simulated data.

Create a matrix of readmission times and censoring for each gender.
```

female = [ReadmissionTime(Sex==1),Censored(Sex==1)];
male = [ReadmissionTime(Sex==0),Censored(Sex==0)];

```

\section*{Step 2. Estimate and plot cumulative distribution function for each gender.}

Plot the Kaplan-Meier estimate of the cumulative distribution function for female and male patients.
```

figure()
ecdf(gca,female(:,1),'Censoring',female(:,2));
hold on
[f,x] = ecdf(male(:,1),'Censoring',male(:,2));
stairs(x,f,'--r')
hold off
legend('female','male','Location','SouthEast')

```

\section*{Step 3. Plot survivor functions.}

Compare the survivor functions for female and male patients.
```

figure()
ax1 = gca;
ecdf(ax1,female(:,1),'Censoring',female(:,2),'function','survivor');
hold on
[f,x] = ecdf(male(:,1),'Censoring',male(:,2),'function','survivor');
stairs(x,f,'--r')
legend('female','male')

```

This figure shows that readmission times are shorter for male patients than female patients.

\section*{Step 4. Fit Weibull survivor functions.}

Fit Weibull distributions to readmission times of female and male patients.
```

pd = fitdist(female(:,1),'wbl','Censoring',female(:,2))
pd =

```
weibull distribution
```

        a = 12.5593
        b = 1.99834
    pd2 = fitdist(male(:,1),'wbl','Censoring',male(:,2))
pd2 =
weibull distribution
a = 4.63991
b = 1.94422

```

Plot the Weibull survivor functions for female and male patients on estimated survivor functions.
```

plot(0:1:25,1-cdf('wbl',0:1:25,12.5593,1.99834),'-.')
plot(0:1:25,1-cdf('wbl',0:1:25,4.63991,1.94422),':r')
hold off
legend('Festimated','Mestimated','FWeibull','MWeibull')

```

Weibull distribution provides a good fit for the data.

\section*{Step 5. Estimate cumulative hazard and fit Weibull cumulative hazard functions.}

Estimate the cumulative hazard function for the genders and fit Weibull cumulative hazard functions.
```

figure()
[f,x] = ecdf(female(:,1),'Censoring',female(:,2),...
'function','cumhazard');
plot(x,f)
hold on
plot(x,cumsum(pdf(pd,x)./(1-cdf(pd,x))),'-.')

```
```

[f,x] = ecdf(male(:,1),'Censoring',male(:,2),...
'function','cumhazard');
plot(x,f,'--r')
plot(x,cumsum(pdf(pd2,x)./(1-cdf(pd2,x))),':r')
legend('Festimated','FWeibull','Mestimated','MWeibull', ...
'Location','North')

```

\section*{Survivor Functions for Two Groups}

This example shows how to find the empirical survivor functions and the parametric survivor functions using the Burr type XII distribution fit to data for two groups.

\section*{Step 1. Load and prepare sample data.}

Navigate to a folder containing sample data.
```

cd(matlabroot)
cd('help/toolbox/stats/examples')

```

Load the sample data
```

load lightbulb

```

The first column of the data has the lifetime (in hours) of two types of light bulbs. The second column has information about the type of light bulb. 1 indicates fluorescent bulbs whereas 0 indicates the incandescent bulb. The third column has censoring information. 1 indicates censored data, and 0 indicates the exact failure time. This is simulated data.

Create a variable for each light bulb type and also include the censorship information.
```

fluo = [lightbulb(lightbulb(:,2)==0,1),...
lightbulb(lightbulb(:,2)==0,3)];
insc = [lightbulb(lightbulb(:,2)==1,1),...
lightbulb(lightbulb(:,2)==1,3)];

```

\section*{Step 2. Plot estimated survivor functions.}

Plot the estimated survivor functions for the two different types of light bulbs.
```

figure()
[f,x,flow,fup] = ecdf(fluo(:,1),'censoring',fluo(:,2),...
'function','survivor');
ax1 = stairs(x,f);
hold on
stairs(x,flow,':')

```
```

stairs(x,fup,':')
[f,x,flow,fup] = ecdf(insc(:,1),'censoring',insc(:,2),...
'function','survivor');
ax2 = stairs(x,f,'color','r');
stairs(x,flow,':r')
stairs(x,fup,':r')
legend([ax1,ax2],{'Fluorescent','Incandescent'})
xlabel('Lifetime (hours)')
ylabel('Survival probability')

```

You can see that the survival probability of incandescent light bulbs is much smaller than that of fluorescent light bulbs.

\section*{Step 3. Fit Burr Type XII distribution.}

Fit Burr distribution to the lifetime data of fluorescent and incandescent type bulbs.
```

pd = fitdist(fluo(:,1),'burr','Censoring',fluo(:,2))
pd =
burr distribution
alpha = 29143.5
c = 3.44582
k = 33.704
pd2 = fitdist(insc(:,1),'burr','Censoring',insc(:,2))
pd2 =
burr distribution
alpha = 2650.76
c = 3.41898
k = 4.5891

```

Superimpose Burr type XII survivor functions.
```

ax3 = plot(0:500:15000,1-cdf('burr',0:500:15000,29143.5,···
3.44582,33.704), 'm');
ax4 = plot(0:500:5000,1-cdf('burr',0:500:5000,2650.76,···
3.41898,4.5891), 'g');
legend([ax1;ax2;ax3;ax4],'Festimate','Iestimate','FBurr','IBurr')

```

Burr distribution provides a good fit for the lifetime of light bulbs in this example.

\section*{Step 4. Fit a Cox proportional hazards model.}

Fit a Cox proportional hazards regression where the type of the bulb is the explanatory variable.
[b,logl,H,stats] = coxphfit(lightbulb(:,2), lightbulb(:,1),...
'Censoring', lightbulb(:,3));
stats
stats =
```

covb: 1.0757
beta: 4.7262
se: 1.0372
z: 4.5568
p: 5.1936e-06

```

The \(p\)-value, p , indicates that the type of light bulb is statistically significant. The estimate of the hazard ratio is \(\exp (b)=112.8646\). This means that the hazard for the incandescent bulbs is 112.86 times the hazard for the fluorescent bulbs.

\section*{Related \\ Examples}
- "Hazard and Survivor Functions for Different Groups" on page 11-19
- "Cox Proportional Hazards Model for Censored Data" on page 11-34

\section*{Concepts}
- "What Is Survival Analysis?" on page 11-2
- "Kaplan-Meier Method" on page 11-11
- "Cox Proportional Hazards Regression" on page 11-31

\section*{Cox Proportional Hazards Regression}

Cox proportional hazards regression is a semiparametric method for adjusting survival rate estimates to quantify the effect of predictor variables. The method represents the effects of explanatory variables as a multiplier of a common baseline hazard function, \(h_{0}(t)\). The hazard function is the nonparametric part of the Cox proportional hazards regression function, whereas the impact of the predictor variables is a loglinear regression. For a baseline relative to 0 , this model corresponds to
\[
h_{X}(t)=h_{0}(t) e^{\sum_{i} X_{i} b_{i}},
\]
where \(h_{X}(t)\) is the hazard rate at \(X\) and \(h_{0}(t)\) is the baseline hazard rate function.

The Cox proportional hazards model relates the hazard rate for individuals or items at the value \(X\), to the hazard rate for individuals or items at the baseline value. It produces an estimate for the hazard ratio, \(H R=h_{X}(t) / h_{0}(t)\). The model is based on the assumption that the baseline hazard function depends on time, \(t\), but the predictor variables do not. This is also called the proportional hazards assumption, which states that the hazard rate does not change over time for any individual. The hazard ratio represents the relative risk of instant failure for individuals or items having the predictive variable value \(X\) compared to the ones having the baseline values. For example, if the predictive variable is smoking status, where nonsmoking is the baseline category, the hazard ratio shows the relative instant failure rate of smokers compared to the baseline category, that is, nonsmokers.

For a baseline relative to \(X^{*}\) and the predictor variable value \(X\), the hazard ratio is
\[
H R=\frac{h_{X}(t)}{h_{X^{*}}(t)}=\exp \left[\sum_{i}\left(X_{i}-X_{i}^{*}\right) b_{i}\right]
\]

For example, if the baseline is the mean values of the predictor variables (mean \((X)\) ), then the hazard rate model becomes
\[
h_{X}(t)=h_{\bar{X}}(t) \exp \left[\sum_{i}\left(X_{i}-\bar{X}\right) b_{i}\right] .
\]

Hazard rates are related to survival rates, such that the survival rate at time \(t\) for an individual with the explanatory variable value \(x\) is
\[
S_{X}(t)=S_{0}(t)^{H R_{X}(t)},
\]
where \(S_{0}(t)\) is the survivor function with the baseline hazard rate function \(h_{0}(t)\), and \(H R_{x}(t)\) is the hazard ratio of the predictor variable value \(x\) relative to the baseline value.

A point estimate of the effect of each explanatory variable, that is, the estimated hazard ratio for the effect of each explanatory variable is \(\exp (b)\), given all other variables are held constant, where \(b\) is the coefficient estimate for that variable. The coefficient estimates are found by maximizing the likelihood function of the model. The likelihood function for the proportional hazards regression model is based on the observed order of events. It is the product of likelihood of a failure estimated for each failure time. If there are \(n\) failures at \(n\) distinct failure times, then the likelihood is
\[
L=\left[\frac{h\left(t_{1}\right)}{\sum_{i=1}^{n} h\left(t_{i}\right)}\right] \times\left[\frac{h\left(t_{2}\right)}{\sum_{i=2}^{n} h\left(t_{i}\right)}\right] \times \cdots \times\left[\frac{h\left(t_{n}\right)}{h\left(t_{n}\right)}\right] .
\]

You can use a likelihood ratio test to assess the significance of adding a term or terms in a model. Consider the two models where the first model has \(p\) predictive variables and the second model has \(p+r\) predictive variables. Then, comparing the two models, \(-2^{*}\left(L_{1} / L_{2}\right)\) has a chi-square distribution with \(r\) degrees of freedom (the number of terms being tested).

- "What Is Survival Analysis?" on page 11-2
- "Kaplan-Meier Method" on page 11-11

\section*{Cox Proportional Hazards Model for Censored Data}

This example shows how to construct a Cox proportional hazards model, and assess the significance of the predictor variables.

\section*{Step 1. Load sample data.}

Navigate to a folder containing sample data.
```

cd(matlabroot)
cd('help/toolbox/stats/examples')

```

Load the sample data.
```

load readmissiontimes

```

The response variable is Readmission Time, which shows the readmission times for 100 patients. The predictor variables are Age, Sex, Weight, and the smoking status of each patient, Smoker. 1 indicates the patient is a smoker, and 0 indicates that the patient does not smoke. The column vector Censored has the censorship information for each patient, where 1 indicates censored data, and 0 indicates the exact readmission times are observed. This is simulated data.

\section*{Step 2. Fit Cox proportional hazards function.}

Fit a Cox proportional hazard function with the variable Sex as the predictor variable, taking the censoring into account.
```

X = Sex;
[b,logl,H,stats] = coxphfit(X,ReadmissionTime,...
'censoring',Censored);

```

Assess the statistical significance of the term Sex.
```

stats

```
stats =
    covb: 0.1016
    beta: -1.7642
```

se: 0.3188
z: -5.5335
p: 3.1392e-08

```

The \(p\)-value, p , indicates that the term Sex is statistically significant.
Save the loglikelihood value with a different name. You will use this to assess the significance of the extended models.
loglSex = logl
loglSex =
\(-262.1365\)

\section*{Step 3. Add Age and Weight to the model.}

Fit a Cox proportional hazards model with the variables Sex, Age, and Weight.
X = [Sex Age Weight];
[b,logl, H, stats] = coxphfit(X,ReadmissionTime,... 'censoring', Censored);

Assess the significance of the terms.
```

stats.beta

```
ans =
-0.5441
0.0143
0.0250
stats.p
ans =
0.4953
0.3842
0.0960

None of the terms, adjusted for others, is statistically significant.

Assess the significance of the terms using the log likelihood ratio. You can assess the significance of the new model using the likelihood ratio statistic. First find the difference between the log-likelihood statistic of the model without the terms Age and Weight and the log-likelihood of the model with Sex, Age, and Weight.
```

-2*[loglSex - logl]

```
ans =
3.6705

Now, compute the \(p\)-value for the likelihood ratio statistic. The likelihood ratio statistic has a Chi-square distribution with a degrees of freedom equal to the number of predictor variables being assessed. In this case, the degrees of freedom is 2 .
```

p = 1 - cdf('chi2',3.6705,2)

```
\(p=\)
0.1596

The \(p\)-value of 0.1596 indicates that the terms Age and Weight are not statistically significant, given the term Sex in the model.

\section*{Step 4. Add Smoker to the model.}

Fit a Cox proportional hazards model with the variables Sex and Smoker.
```

X = [Sex Smoker];
[b,logl,H,stats] = coxphfit(X,ReadmissionTime,...
'censoring',Censored);

```

Assess the significance of the terms in the model.
```

stats.p

```
ans =
0.0000
0.0148

Compare this model to the first model where Sex is the only term.
```

    -2*[loglSex - logl]
    ans =
5.5789

```

Compute the \(p\)-value for the likelihood ratio statistic. The likelihood ratio statistic has a Chi-square distribution with a degree of freedom of 1.
```

p = 1 - cdf('chi2',5.5789,1)
p =
0.0182

```

The \(p\)-value of 0.0182 indicates that Sex and Smoker are statistically significant given the other is in the model. The model with Sex and Smoker is a better fit compared to the model with only Sex.

Request the coefficient estimates.
```

stats.beta

```
ans =
-1.7165
0.6338

The default baseline is the mean of \(X\), so the final model for the hazard ratio is
\[
H R=\frac{h_{X}(t)}{h_{\bar{X}}(t)}=\exp \left[\beta_{s}\left(X_{s}-\bar{X}_{s}\right)+\beta_{a}\left(X_{a}-\bar{X}_{a}\right)\right] .
\]

Fit a Cox ph model with a baseline of 0 .
```

X = [Sex Smoker];
[b,logl,H,stats] = coxphfit(X,ReadmissionTime,...
'censoring',Censored,'baseline',0);

```

The model for the hazard ratio is
\[
H R=\frac{h_{X}(t)}{h_{0}(t)}=\exp \left[\beta_{s} X_{s}+\beta_{a} X_{a}\right] .
\]

Request the coefficient estimates.
```

stats.beta
ans =
-1.7165
0.6338

```

The coefficients are not affected, but the hazard rate differs from when the baseline is the mean of \(X\).

\section*{Introduction to Multivariate Methods}

Large, high-dimensional data sets are common in the modern era of computer-based instrumentation and electronic data storage. High-dimensional data present many challenges for statistical visualization, analysis, and modeling.

Data visualization, of course, is impossible beyond a few dimensions. As a result, pattern recognition, data preprocessing, and model selection must rely heavily on numerical methods.

A fundamental challenge in high-dimensional data analysis is the so-called curse of dimensionality. Observations in a high-dimensional space are necessarily sparser and less representative than those in a low-dimensional space. In higher dimensions, data over-represent the edges of a sampling distribution, because regions of higher-dimensional space contain the majority of their volume near the surface. (A d-dimensional spherical shell has a volume, relative to the total volume of the sphere, that approaches 1 as \(d\) approaches infinity.) In high dimensions, typical data points at the interior of a distribution are sampled less frequently.

Often, many of the dimensions in a data set-the measured features-are not useful in producing a model. Features may be irrelevant or redundant. Regression and classification algorithms may require large amounts of storage and computation time to process raw data, and even if the algorithms are successful the resulting models may contain an incomprehensible number of terms.

Because of these challenges, multivariate statistical methods often begin with some type of dimension reduction, in which data are approximated by points in a lower-dimensional space. Dimension reduction is the goal of the methods presented in this chapter. Dimension reduction often leads to simpler models and fewer measured variables, with consequent benefits when measurements are expensive and visualization is important.

\section*{Multivariate Linear Regression}

\section*{In this section...}
"Multivariate Linear Regression Model" on page 12-3
"Solving Multivariate Regression Problems" on page 12-4

\section*{Multivariate Linear Regression Model}

The multivariate linear regression model expresses a \(d\)-dimensional continuous response vector as a linear combination of predictor terms plus a vector of error terms with a multivariate normal distribution. Let \(\mathbf{y}_{i}=\left(y_{i 1}, \ldots, y_{i d}\right)^{\prime}\) denote the response vector for observation \(i, i=1, \ldots, n\). In the most general case, given the \(d\)-by- \(K\) design matrix \(\mathbf{X}_{i}\) and the \(K\)-by- 1 vector of coefficients \(\beta\), the multivariate linear regression model is
\[
\mathbf{y}_{i}=\mathbf{X}_{i} \beta+\varepsilon_{i}
\]
where the \(d\)-dimensional vector of error terms follows a multivariate normal distribution,
\[
\varepsilon_{i} \square M V N_{d}(\mathbf{0}, \Sigma) .
\]

The model assumes independence between observations, meaning the error variance-covariance matrix for the \(n\) stacked \(d\)-dimensional response vectors is
\[
\mathbf{I}_{n} \otimes \Sigma=\left(\begin{array}{lll}
\Sigma & & 0 \\
& \ddots & \\
0 & & \Sigma
\end{array}\right)
\]

If \(\mathbf{y}\) denotes the \(n d\)-by- 1 vector of stacked \(d\)-dimensional responses, and \(\mathbf{X}\) denotes the \(n d\)-by- \(K\) matrix of stacked design matrices, then the distribution of the response vector is
\[
\mathbf{y} \square M V N_{n d}\left(\mathbf{X} \beta, \mathbf{I}_{n} \otimes \Sigma\right) .
\]

\section*{Solving Multivariate Regression Problems}

To fit multivariate linear regression models of the form
\[
\mathbf{y}_{i}=\mathbf{X}_{i} \beta+\varepsilon_{i}, \varepsilon_{i} \square M V N_{d}(\mathbf{0}, \Sigma)
\]
in Statistics Toolbox, use mvregress. This function fits multivariate regression models with a diagonal (heteroscedastic) or unstructured (heteroscedastic and correlated) error variance-covariance matrix, \(\Sigma\), using least squares or maximum likelihood estimation.

Many variations of multivariate regression might not initially appear to be of the form supported by mvregress, such as:
- Multivariate general linear model
- Multivariate analysis of variance (MANOVA)
- Longitudinal analysis
- Panel data analysis
- Seemingly unrelated regression (SUR)
- Vector autoregressive (VAR) model

In many cases, you can frame these problems in the form used by mvregress (but mvregress does not support parameterized error variance-covariance matrices). For the special case of one-way MANOVA, you can alternatively use manova1. Econometrics Toolbox \({ }^{\text {TM }}\) has functions for VAR estimation.

Note The multivariate linear regression model is distinct from the multiple linear regression model, which models a univariate continuous response as a linear combination of exogenous terms plus an independent and identically distributed error term. To fit a multiple linear regression model, use LinearModel.fit.

\section*{Estimation of Multivariate Regression Models}

\author{
In this section... \\ "Least Squares Estimation" on page 12-6 \\ "Maximum Likelihood Estimation" on page 12-10 \\ "Missing Response Data" on page 12-12
}

\section*{Least Squares Estimation}
- "Ordinary Least Squares" on page 12-6
- "Covariance-Weighted Least Squares" on page 12-7
- "Error Covariance Estimation" on page 12-8
- "Feasible Generalized Least Squares" on page 12-9
- "Panel Corrected Standard Errors" on page 12-10

\section*{Ordinary Least Squares}

When you fit multivariate linear regression models using mvregress, you can use the optional name-value pair 'algorithm' , 'cwls' to choose least squares estimation. In this case, by default, mvregress returns ordinary
least squares (OLS) estimates using \(\Sigma=\mathbf{I}_{d}\). Alternatively, if you specify a covariance matrix for weighting, you can return covariance-weighted least squares (CWLS) estimates. If you combine OLS and CWLS, you can get feasible generalized least squares (FGLS) estimates.

The OLS estimate for the coefficient vector is the vector \(\mathbf{b}\) that minimizes
\[
\sum_{i=1}^{n}\left(\mathbf{y}_{i}-\mathbf{X}_{i} \mathbf{b}\right)^{\prime}\left(\mathbf{y}_{i}-\mathbf{X}_{i} \mathbf{b}\right)
\]

Let \(\mathbf{y}\) denote the \(n d\)-by- 1 vector of stacked \(d\)-dimensional responses, and \(\mathbf{X}\) denote the \(n d\)-by- \(K\) matrix of stacked design matrices. The \(K\)-by- 1 vector of OLS regression coefficient estimates is
\[
\mathbf{b}_{O L S}=\left(\mathbf{X}^{\prime} \mathbf{X}\right)^{-1} \mathbf{X}^{\prime} \mathbf{y}
\]

This is the first mvregress output.
Given \(\Sigma=\mathbf{I}_{d}\) (the mvregress OLS default), the variance-covariance matrix of the OLS estimates is
\[
V\left(\mathbf{b}_{O L S}\right)=\left(\mathbf{X}^{\prime} \mathbf{X}\right)^{-1}
\]

This is the fourth mvregress output. The standard errors of the OLS regression coefficients are the square root of the diagonal of this variance-covariance matrix.

If your data is not scaled such that \(\Sigma=\sigma^{2} \mathbf{I}_{d}\), then you can multiply the mvregress variance-covariance matrix by the mean squared error (MSE), an unbiased estimate of \(\sigma^{2}\). To compute the MSE, return the \(n\)-by- \(d\) matrix of residuals, \(\mathbf{E}\) (the third mvregress output). Then,
\[
\operatorname{MSE}=\frac{\sum_{i=1}^{n} \mathbf{e}_{i} \mathbf{e}_{i}^{\prime}}{n-K}
\]
where \(\mathbf{e}_{i}=\left(\mathbf{y}_{i}-\mathbf{X}_{i} \beta\right)^{\prime}\) is the \(i\) th row of \(\mathbf{E}\).

\section*{Covariance-Weighted Least Squares}

For most multivariate problems, an identity error covariance matrix is insufficient, and leads to inefficient or biased standard error estimates. You can specify a matrix for CWLS estimation using the optional name-value pair argument covaro, for example, an invertible \(d\)-by- \(d\) matrix named \(\mathbf{C}_{0}\). Usually, \(\mathbf{C}_{0}\) is a diagonal matrix such that the inverse matrix \(\mathbf{C}_{0}^{-1}\) contains weights for each dimension to model heteroscedasticity. However, \(\mathbf{C}_{0}\) can also be a nondiagonal matrix that models correlation.

Given \(\mathbf{C}_{0}\), the CWLS solution is the vector \(\mathbf{b}\) that minimizes
\[
\sum_{i=1}^{n}\left(\mathbf{y}_{i}-\mathbf{X}_{i} \mathbf{b}\right)^{\prime} \mathbf{C}_{0}\left(\mathbf{y}_{i}-\mathbf{X}_{i} \mathbf{b}\right)
\]

In this case, the \(K\)-by- 1 vector of CWLS regression coefficient estimates is
\[
\mathbf{b}_{C W L S}=\left(\mathbf{X}^{\prime}\left(\mathbf{I}_{n} \otimes \mathbf{C}_{0}\right)^{-1} \mathbf{X}\right)^{-1} \mathbf{X}^{\prime}\left(\mathbf{I}_{n} \otimes \mathbf{C}_{0}\right)^{-1} \mathbf{y}
\]

This is the first mvregress output.

If \(\Sigma=\mathbf{C}_{0}\), this is the generalized least squares (GLS) solution. The corresponding variance-covariance matrix of the CWLS estimates is
\[
V\left(\mathbf{b}_{C W L S}\right)=\left(\mathbf{X}^{\prime}\left(\mathbf{I}_{n} \otimes \mathbf{C}_{0}\right)^{-1} \mathbf{X}\right)^{-1}
\]

This is the fourth mvregress output. The standard errors of the CWLS regression coefficients are the square root of the diagonal of this variance-covariance matrix.

If you only know the error covariance matrix up to a proportion, that is, \(\Sigma=\sigma^{2} \mathbf{C}_{0}\), you can multiply the mvregress variance-covariance matrix by the MSE, as described in "Ordinary Least Squares" on page 12-6.

\section*{Error Covariance Estimation}

Regardless of which least squares method you use, the estimate for the error variance-covariance matrix is
\[
\hat{\Sigma}=\left(\begin{array}{cccc}
\hat{\sigma}_{1}^{2} & \hat{\sigma}_{12} & \cdots & \hat{\sigma}_{1 d} \\
\hat{\sigma}_{12} & \hat{\sigma}_{2}^{2} & \cdots & \hat{\sigma}_{2 d} \\
\vdots & \vdots & \ddots & \vdots \\
\hat{\sigma}_{1 d} & \hat{\sigma}_{2 d} & \cdots & \hat{\sigma}_{d}^{2}
\end{array}\right)=\frac{\mathbf{E}^{\prime} \mathbf{E}}{n}
\]
where \(\mathbf{E}\) is the \(n\)-by- \(d\) matrix of residuals. The \(i\) th row of \(\mathbf{E}\) is \(\mathbf{e}_{i}=\left(\mathbf{y}_{i}-\mathbf{X}_{i} \mathbf{b}\right)^{\prime}\).

The error covariance estimate, \(\hat{\Sigma}\), is the second mvregress output, and the matrix of residuals, \(\mathbf{E}\), is the third output. If you specify the optional name-value pair 'covtype', 'diagonal', then mvregress returns \(\hat{\Sigma}\) with zeros in the off-diagonal entries,
\[
\hat{\Sigma}=\left(\begin{array}{ccc}
\hat{\sigma}_{1}^{2} & & 0 \\
& \ddots & \\
0 & & \hat{\sigma}_{d}^{2}
\end{array}\right) .
\]

\section*{Feasible Generalized Least Squares}

The generalized least squares estimate is the CWLS estimate with a known covariance matrix. That is, given \(\Sigma\) is known, the GLS solution is
\[
\mathbf{b}_{G L S}=\left(\mathbf{X}^{\prime}\left(\mathbf{I}_{n} \otimes \Sigma\right)^{-1} \mathbf{X}\right)^{-1} \mathbf{X}^{\prime}\left(\mathbf{I}_{n} \otimes \Sigma\right)^{-1} \mathbf{y}
\]
with variance-covariance matrix
\[
V\left(\mathbf{b}_{G L S}\right)=\left(\mathbf{X}^{\prime}\left(\mathbf{I}_{n} \otimes \Sigma\right)^{-1} \mathbf{X}\right)^{-1}
\]

In most cases, the error covariance is unknown. The feasible generalized least squares (FGLS) estimate uses \(\hat{\Sigma}\) in place of \(\Sigma\). You can obtain two-step FGLS estimates as follows:

1 Perform OLS regression, and return an estimate \(\hat{\Sigma}\).

2 Perform CWLS regression, using \(\mathbf{C}_{0}=\hat{\Sigma}\).
You can also iterate between these two steps until convergence is reached.
For some data, the OLS estimate \(\hat{\Sigma}\) is positive semidefinite, and has no unique inverse. In this case, you cannot get the FGLS estimate using mvregress. As an alternative, you can use lscov, which uses a generalized inverse to return weighted least squares solutions for positive semidefinite covariance matrices.

\section*{Panel Corrected Standard Errors}

An alternative to FGLS is to use OLS coefficient estimates (which are consistent) and make a standard error correction to improve efficiency. One such standard error adjustment-which does not require inversion of the covariance matrix-is panel corrected standard errors (PCSE) [1]. The panel corrected variance-covariance matrix for OLS estimates is
\[
V_{\text {pcse }}\left(\mathbf{b}_{O L S}\right)=\left(\mathbf{X}^{\prime} \mathbf{X}\right)^{-1} \mathbf{X}^{\prime}\left(\mathbf{I}_{n} \otimes \Sigma\right) \mathbf{X}\left(\mathbf{X}^{\prime} \mathbf{X}\right)
\]

The PCSE are the square root of the diagonal of this variance-covariance matrix. "Fixed Effects Panel Model with Concurrent Correlation" on page 12-35 illustrates PCSE computation.

\section*{Maximum Likelihood Estimation}
- "Maximum Likelihood Estimates" on page 12-10
- "Standard Errors" on page 12-11

\section*{Maximum Likelihood Estimates}

The default estimation algorithm used by mvregress is maximum likelihood estimation (MLE). The loglikelihood function for the multivariate linear regression model is
\[
\begin{aligned}
\log L(\beta, \Sigma \mid \mathbf{y}, \mathbf{X}) & =\frac{1}{2} n d \log (2 \pi)+\frac{1}{2} n \log (\operatorname{det}(\Sigma)) \\
& +\frac{1}{2} \sum_{i=1}^{n}\left(\mathbf{y}_{i}-\mathbf{X}_{i} \beta\right)^{\prime} \Sigma^{-1}\left(\mathbf{y}_{i}-\mathbf{X}_{i} \beta\right)
\end{aligned}
\]

The MLEs for \(\beta\) and \(\Sigma\) are the values that maximize the loglikelihood objective function.
mvregress finds the MLEs using an iterative two-stage algorithm. At iteration \(m+1\), the estimates are
\[
\mathbf{b}_{M L E}^{(m+1)}=\left(\mathbf{X}^{\prime}\left(\mathbf{I}_{n} \otimes \Sigma^{(m)}\right)^{-1} \mathbf{X}\right)^{-1} \mathbf{X}^{\prime}\left(\mathbf{I}_{n} \otimes \Sigma^{(m)}\right)^{-1} \mathbf{y}
\]
and
\[
\hat{\Sigma}^{(m+1)}=\frac{1}{n} \sum_{i=1}^{n}\left(\mathbf{y}_{i}-\mathbf{X}_{i} \mathbf{b}_{M L E}^{(m+1)}\right)\left(\mathbf{y}_{i}-\mathbf{X}_{i} \mathbf{b}_{M L E}^{(m+1)}\right)^{\prime}
\]

The algorithm terminates when the changes in the coefficient estimates and loglikelihood objective function are less than a specified tolerance, or when the specified maximum number of iterations is reached. The optional name-value pair arguments for changing these convergence criteria are tolbeta, tolobj, and maxiter, respectively.

\section*{Standard Errors}

The variance-covariance matrix of the MLEs is an optional mvregress output. By default, mvregress returns the variance-covariance matrix for only the regression coefficients, but you can also get the variance-covariance matrix of \(\hat{\Sigma}\) using the optional name-value pair 'vartype', 'full'. In this case, mvregress returns the variance-covariance matrix for all \(K\) regression coefficients, and \(d\) or \(d(d+1) / 2\) covariance terms (depending on whether the error covariance is diagonal or full).

By default, the variance-covariance matrix is the inverse of the observed Fisher information matrix (the 'hessian' option). You can request the expected Fisher information matrix using the optional name-value pair 'vartype', 'fisher'. Provided there is no missing response data, the observed and expected Fisher information matrices are the same. If response data is missing, the observed Fisher information accounts for the added uncertainty due to the missing values, whereas the expected Fisher information matrix does not.

The variance-covariance matrix for the regression coefficient MLEs is
\[
V\left(\mathbf{b}_{M L E}\right)=\left(\mathbf{X}^{\prime}\left(\mathbf{I}_{n} \otimes \Sigma\right)^{-1} \mathbf{X}\right)^{-1}
\]
evaluated at the MLE of the error covariance matrix. This is the fourth mvregress output. The standard errors of the MLEs are the square root of the diagonal of this variance-covariance matrix.

For \(\hat{\Sigma}\), let \(\theta\) denote the vector of parameters in the estimated error variance-covariance matrix. For example, if \(d=2\), then:
- If the estimated covariance matrix is diagonal, then \(\theta=\left(\sigma_{1}^{2}, \sigma_{2}^{2}\right)\).
- If the estimated covariance matrix is full, then \(\theta=\left(\sigma_{1}^{2}, \sigma_{12}, \sigma_{2}^{2}\right)\).

The Fisher information matrix for \(\theta, I(\theta)\), has elements
\[
I(\theta)_{u, v}=\frac{1}{2} \operatorname{tr}\left(\Sigma^{-1} \frac{\partial \Sigma}{\partial \theta_{u}} \Sigma^{-1} \frac{\partial \Sigma}{\partial \theta_{v}}\right), u, v=1, \ldots, n_{\theta}
\]
where \(n_{\theta}\) is the length of \(\theta\) (either \(d\) or \(d(d+1) / 2\) ). The resulting variance-covariance matrix is
\[
V(\theta)=I(\theta)^{-1} .
\]

When you request the full variance-covariance matrix, mvregress returns (as the fourth output) the block diagonal matrix
\[
\left(\begin{array}{cc}
V\left(\mathbf{b}_{M L E}\right) & \mathbf{0} \\
\mathbf{0} & V(\theta)
\end{array}\right) .
\]

\section*{Missing Response Data}
- "Expectation/Conditional Maximization" on page 12-12
- "Observed Information Matrix" on page 12-14

\section*{Expectation/Conditional Maximization}

If any response values are missing, indicated by NaN, mvregress uses an expectation/conditional maximization (ECM) algorithm for estimation (if
enough data is available). In this case, the algorithm is iterative for both least squares and maximum likelihood estimation. During each iteration, mvregress imputes missing response values using their conditional expectation.

Consider organizing the data so that the joint distribution of the missing and observed responses, denoted \(\tilde{\mathbf{y}}\) and \(\mathbf{y}\) respectively, can be written as
\[
\binom{\tilde{\mathbf{y}}}{\mathbf{y}} \square M V N\left\{\binom{\tilde{\mathbf{x}} \beta}{\mathbf{x} \beta},\left(\begin{array}{cc}
\Sigma_{\tilde{y}} & \Sigma_{\tilde{y} y} \\
\Sigma_{y \tilde{y}} & \Sigma_{y}
\end{array}\right)\right\} .
\]

Using properties of the multivariate normal distribution, the conditional expectation of the missing responses given the observed responses is
\[
\mathrm{E}(\tilde{\mathbf{y}} \mid \mathbf{y})=\tilde{\mathbf{X}} \beta+\Sigma_{\tilde{y} y} \Sigma_{y}^{-1}(\mathbf{y}-\mathbf{X} \beta) .
\]

Also, the variance-covariance matrix of the conditional distribution is
\[
\operatorname{COV}(\tilde{\mathbf{y}} \mid \mathbf{y})=\Sigma_{\tilde{y}}-\Sigma_{\tilde{y} y} \Sigma_{y}^{-1} \Sigma_{y \tilde{y}} .
\]

At each iteration of the ECM algorithm, mvregress uses the parameter values from the previous iteration to:
- Update the regression coefficients using the combined vector of observed responses and conditional expectations of missing responses.
- Update the variance-covariance matrix, adjusting for missing responses using the variance-covariance matrix of the conditional distribution.

Finally, the residuals that mvregress returns for missing responses are the difference between the conditional expectation and the fitted value, both evaluated at the final parameter estimates.

If you prefer to ignore any observations that have missing response values, use the name-value pair 'algorithm', 'mvn'. Note that mvregress always ignores observations that have missing predictor values.

\section*{Observed Information Matrix}

By default, mvregress uses the observed Fisher information matrix (the 'hessian' option) to compute the variance-covariance matrix of the regression parameters. This accounts for the additional uncertainty due to missing response values.

The observed information matrix includes contributions from only the observed responses. That is, the observed Fisher information matrix for the parameters in the error variance-covariance matrix has elements
\[
I(\theta)_{u, v}=\frac{1}{2} \sum_{i=1}^{n} \operatorname{tr}\left(\Sigma_{i}^{-1} \frac{\partial \Sigma_{i}}{\partial \theta_{u}} \Sigma_{i}^{-1} \frac{\partial \Sigma_{i}}{\partial \theta_{v}}\right), u, v=1, \ldots, n_{\theta},
\]
where \(\hat{\Sigma}_{i}\) is the subset of \(\hat{\Sigma}\) corresponding to the observed responses in \(\mathbf{y}_{i}\).

For example, if \(d=3\), but \(y_{i 2}\) is missing, then
\[
\hat{\Sigma}_{i}=\left(\begin{array}{cc}
\hat{\sigma}_{1}^{2} & \hat{\sigma}_{13} \\
\hat{\sigma}_{13} & \hat{\sigma}_{3}^{2}
\end{array}\right) .
\]

The observed Fisher information for the regression coefficients has similar contributions from the design and covariance matrices.

\title{
Set Up Multivariate Regression Problems
}

\section*{In this section...}
"Response Matrix" on page 12-16
"Design Matrices" on page 12-21
"Common Multivariate Regression Problems" on page 12-22

\section*{Response Matrix}

To fit a multivariate linear regression model using mvregress, you must set up your response matrix and design matrices in a particular way. Given properly formatted inputs, mvregress can handle a variety of multivariate regression problems.
mvregress expects the \(n\) observations of potentially correlated \(d\)-dimensional responses to be in an \(n\)-by- \(d\) matrix, named \(Y\), for example. That is, set up your responses so that the dependency structure is between observations in the same row. If you specify Y as a vector of length \(n\) (either a row or column vector), then mvregress assumes that \(d=1\), and treats the elements as \(n\) independent observations. It does not model the vector as one realization of a correlated series (such as a time series).

To illustrate how to set up a response matrix, suppose that your multivariate responses are repeated measurements made on subjects at multiple time points, as in the following figure.

Suppose that observations within a subject are correlated.

In this case, set up the response matrix \(Y\) such that each row corresponds to a subject, and each column corresponds to a time point.

\section*{\(d=\) Number of Time Points}

Then again, suppose that observations made on subjects at the same time are correlated (concurrent correlation).

In this case, set up the response matrix \(Y\) such that each row corresponds to a time point, and each column corresponds to a subject.

\section*{\(n=\) Number of Time Points}
\(d=\) Number of Subjects
\begin{tabular}{|l|l|l|l|l|l|l|}
\hline & & & & & & \\
& & & & & & \\
& & & & & & \\
& & & & & & \\
& & & & & & \\
\end{tabular}

\section*{Design Matrices}

In the multivariate linear regression model, each \(d\)-dimensional response has a corresponding \(d\)-by- \(K\) design matrix, where \(K\) is the total number of regression coefficients in the model. Depending on the model, the design matrix might be comprised of exogenous predictor variables, dummy variables, lagged responses, or a combination of these and other covariate terms.

Specify the design matrices to mvregress using a length- \(n\) cell array of \(d\)-by- \(K\) arrays, named \(X\), for example. Note that the rows of the arrays in \(X\) correspond to the columns of the response matrix, Y .

- If all \(n\) observations have the same \(d\)-by- \(K\) design matrix, you can specify a cell array containing one \(d\)-by- \(K\) design matrix. In this case, mvregress applies the design matrix to all \(n\) observations. For example, this situation might arise if the predictors are functions of time, and all observations were measured at the same time points.
- In the special case that \(d=1\), you can specify one \(n\)-by- \(K\) design matrix (not in a cell array). However, you should consider using LinearModel.fit to fit regression models to univariate, continuous responses.

The following sections illustrate how to set up the some common multivariate regression problems for estimation using mvregress.

\section*{Common Multivariate Regression Problems}
- "Multivariate General Linear Model" on page 12-22
- "Longitudinal Analysis" on page 12-25
- "Panel Analysis" on page 12-26
- "Seemingly Unrelated Regression" on page 12-27
- "Vector Autoregressive Model" on page 12-28

\section*{Multivariate General Linear Model}

The multivariate general linear model is of the form
\[
\mathbf{Y}_{n \times d}=\mathbf{X}_{n \times(p+1)} \mathbf{B}_{(p+1) \times d}+\mathbf{E}_{n \times d}
\]

In expanded form,
\[
\left[\begin{array}{cccc}
y_{11} & y_{12} & \cdots & y_{1 d} \\
y_{21} & y_{22} & \cdots & y_{2 d} \\
\vdots & \vdots & \ddots & \vdots \\
y_{n 1} & y_{n 2} & \cdots & y_{n d}
\end{array}\right]=\left[\begin{array}{ccccc}
1 & x_{11} & x_{12} & \cdots & x_{1 p} \\
1 & x_{21} & x_{22} & \cdots & x_{2 p} \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
1 & x_{n 1} & x_{n 2} & \cdots & x_{n p}
\end{array}\right]\left[\begin{array}{cccc}
\beta_{01} & \beta_{02} & \cdots & \beta_{0 d} \\
\beta_{11} & \beta_{12} & \cdots & \beta_{1 d} \\
\vdots & \vdots & \ddots & \vdots \\
\beta_{p 1} & \beta_{p 2} & \cdots & \beta_{p d}
\end{array}\right]+\left[\begin{array}{cccc}
\varepsilon_{11} & \varepsilon_{12} & \cdots & \varepsilon_{1 d} \\
\varepsilon_{21} & \varepsilon_{22} & \cdots & \varepsilon_{2 d} \\
\vdots & \vdots & \ddots & \vdots \\
\varepsilon_{n 1} & \varepsilon_{n 2} & \cdots & \varepsilon_{n d}
\end{array}\right]
\]

That is, each \(d\)-dimensional response has an intercept and \(p\) predictor variables, and each dimension has its own set of regression coefficients. In this form, the least squares solution is \(B=X \backslash Y\). To estimate this model using mvregress, use the \(n\)-by- \(d\) matrix of responses, as above. Reformat the \(n\)-by- \((p+1)\) design matrix into a length- \(n\) cell array of \(d\)-by- \(K\) matrices, where here \(K=(p+1) d\) for an intercept and slopes for each dimension.

For example, suppose \(n=4, d=3\), and \(p=2\) (two predictor terms in addition to an intercept). This figure shows how to format the \(i\) th element in the cell array.
\(\left[\begin{array}{lll}y_{11} & y_{12} & y_{13} \\ y_{21} & y_{22} & y_{23} \\ y_{31} & y_{32} & y_{33} \\ y_{41} & y_{42} & y_{43}\end{array}\right]=\left[\begin{array}{lll}1 & x_{11} & x_{12} \\ 1 & x_{21} & x_{22} \\ 1 & x_{31} & x_{32} \\ 1 & x_{41} & x_{42}\end{array}\right]\left[\begin{array}{lll}\beta_{01} & \beta_{02} & \beta_{03} \\ \beta_{11} & \beta_{12} & \beta_{13} \\ \beta_{21} & \beta_{22} & \beta_{23}\end{array}\right]+\left[\begin{array}{lll}\varepsilon_{11} & \varepsilon_{12} & \varepsilon_{13} \\ \varepsilon_{21} & \varepsilon_{22} & \varepsilon_{23} \\ \varepsilon_{31} & \varepsilon_{32} & \varepsilon_{33} \\ \varepsilon_{41} & \varepsilon_{42} & \varepsilon_{43}\end{array}\right]\)

If you prefer, you can reshape the \(K\)-by- 1 vector of coefficients back into a \((p+1)\)-by- \(d\) matrix after estimation.

To put constraints on the model parameters, adjust the design matrix accordingly. For example, suppose that the three dimensions in the previous example have a common slope. That is, \(\beta_{11}=\beta_{12}=\beta_{13}=\beta_{1}\) and \(\beta_{21}=\beta_{22}=\beta_{23}=\beta_{2}\). In this case, each design matrix is 3-by-5, as shown in the following figure.

\section*{Longitudinal Analysis}

In a longitudinal analysis, you might measure responses on \(n\) subjects at \(d\) time points, with correlation between observations made on the same subject. For example, suppose that you measure responses \(y_{i j}\) at times \(t_{i j}, i=1, \ldots, n\) and \(j=1, \ldots, d\). In addition, suppose that each subject is in one of two groups (such as male or female), specified by the indicator variable \(G_{i}\). You could model \(y_{i j}\) as a function of \(G_{i}\) and \(t_{i j}\), with group-specific intercepts and slopes, as follows:
\[
y_{i j}=\beta_{0}+\beta_{1} G_{i}+\beta_{2} t_{i j}+\beta_{3} G_{i} \times t_{i j}+\varepsilon_{i j}, i=1, \ldots, n ; j=1, \ldots, d,
\]
where
\[
\varepsilon_{i}=\left(\varepsilon_{i 1}, \ldots, \varepsilon_{i d}\right)^{\prime} \square M V N(\mathbf{0}, \Sigma) .
\]

Most longitudinal models include time as an explicit predictor.
To fit this model using mvregress, arrange the responses in an \(n\)-by- \(d\) matrix, where \(n\) is the number of subjects and \(d\) is the number of time points. Specify the design matrices in an \(n\)-length cell array of \(d\)-by- \(K\) matrices, where here \(K\) \(=4\) for the four regression coefficients.

For example, suppose \(d=5\) (five observations per subject). The \(i\) th design matrix and corresponding parameter vector for the specified model are shown in the following figure.

\section*{Panel Analysis}

In a panel analysis, you might measure responses and covariates on \(d\) subjects (such as individuals or countries) at \(n\) time points. For example, suppose you measure responses \(y_{t j}\) and covariates \(x_{t j}\) on subjects \(j=1, \ldots, d\) at times \(t\) \(=1, \ldots, n\). A fixed effects panel model, with subject-specific fixed effects, and concurrent correlation might look like:
\[
y_{t j}=\alpha_{j}+\beta x_{t j}+\varepsilon_{t j}
\]
where
\[
\varepsilon_{t}=\left(\varepsilon_{t 1}, \ldots, \varepsilon_{t d}\right)^{\prime} \square M V N(\mathbf{0}, \Sigma)
\]

In contrast to longitudinal models, the panel analysis model typically includes covariates measured at each time point, instead of using time as an explicit predictor.

To fit this model using mvregress, arrange the responses in an \(n\)-by- \(d\) matrix, such that each column corresponds to a subject. Specify the design matrices in an \(n\)-length cell array of \(d\)-by- \(K\) matrices, where here \(K=d+1\) for the \(d\) intercepts and a slope term.

For example, suppose \(d=4\) (four subjects). The \(t\) th design matrix and corresponding parameter vector are shown in the following figure.

\section*{Seemingly Unrelated Regression}

In a seemingly unrelated regression (SUR), you model \(d\) separate regressions, each with its own intercept and slope, but a common error variance-covariance matrix. For example, suppose you measure responses \(y_{i j}\) and covariates \(x_{i j}\) for regression models \(j=1, \ldots, d\), with \(i=1, \ldots, n\) observations to fit each regression. The SUR model might look like:
\[
y_{i j}=\beta_{0 j}+\beta_{j} x_{i j}+\varepsilon_{i j},
\]
where
\[
\varepsilon_{i}=\left(\varepsilon_{i 1}, \ldots, \varepsilon_{i d}\right)^{\prime} \square M V N(\mathbf{0}, \Sigma) .
\]

This model is very similar to the multivariate general linear model, except that it has different covariates for each dimension.

To fit this model using mvregress, arrange the responses in an \(n\)-by- \(d\) matrix, such that each column has the data for the \(j\) th regression model. Specify the design matrices in an \(n\)-length cell array of \(d\)-by- \(K\) matrices, where here \(K\) \(=2 d\) for \(d\) intercepts and \(d\) slopes.

For example, suppose \(d=3\) (three regressions). The \(i\) th design matrix and corresponding parameter vector are shown in the following figure.
\[
\underbrace{\left[\begin{array}{llllll}
1 & 0 & 0 & x_{i 1} & 0 & 0 \\
0 & 1 & 0 & 0 & x_{i 2} & 0 \\
0 & 0 & 1 & 0 & 0 & x_{i 3}
\end{array}\right]}_{X\{i\}}\left[\begin{array}{l}
\beta_{01} \\
\beta_{02} \\
\beta_{03} \\
\beta_{1} \\
\beta_{2} \\
\beta_{3}
\end{array}\right]
\]

\section*{Vector Autoregressive Model}

The \(\operatorname{VAR}(p)\) vector autoregressive model expresses \(d\)-dimensional time series responses as a linear function of \(p\) lagged \(d\)-dimensional responses from previous times. For example, suppose you measure responses \(y_{t j}\) for time series \(j=1, \ldots, d\) at times \(t=1, \ldots, n\). The \(\operatorname{VAR}(p)\) model might look like:
\[
\left[\begin{array}{c}
y_{t 1} \\
y_{t 2} \\
\vdots \\
y_{t d}
\end{array}\right]=\left[\begin{array}{c}
c_{1} \\
c_{2} \\
\vdots \\
c_{d}
\end{array}\right]+\left[\begin{array}{cccc}
\varphi_{11}^{(1)} & \varphi_{12}^{(1)} & \cdots & \varphi_{1 d}^{(1)} \\
\vdots & \vdots & \ddots & \vdots \\
\varphi_{d 1}^{(1)} & \varphi_{d 2}^{(1)} & \cdots & \varphi_{d d}^{(1)}
\end{array}\right]\left[\begin{array}{c}
y_{t-1,1} \\
y_{t-1,2} \\
\vdots \\
y_{t-1, d}
\end{array}\right]+\cdots+\left[\begin{array}{ccc}
\varphi_{11}^{(p)} & \varphi_{12}^{(p)} & \cdots
\end{array} \varphi_{1 d}^{(p)} \begin{array}{c}
\vdots \\
\vdots \\
\varphi_{d 1}^{(p)}
\end{array} \varphi_{d 2}^{(p)} \cdots \varphi_{d d}^{(p)}\right]\left[\begin{array}{c}
y_{t-p, 1} \\
y_{t-p, 2} \\
\vdots \\
y_{t-p, d}
\end{array}\right]+\left[\begin{array}{c}
\varepsilon_{t 1} \\
\varepsilon_{t 2} \\
\vdots \\
\varepsilon_{t d}
\end{array}\right],
\]
where
\[
\varepsilon_{t}=\left(\varepsilon_{t 1}, \ldots, \varepsilon_{t d}\right)^{\prime} \square M V N(\mathbf{0}, \Sigma) .
\]

When estimating vector autoregressive models, you typically need to use the first \(p\) observations to initiate the model, or provide some other presample response values.

To fit this model using mvregress, arrange the responses in an \(n\)-by- \(d\) matrix, such that each column corresponds to a time series. Specify the design matrices in an \(n\)-length cell array of \(d\)-by- \(K\) matrices, where here \(K=d+p d^{2}\).

For example, suppose \(d=2\) (two time series) and \(p=1\) (one lag). The \(t\) th design matrix and corresponding parameter vector are shown in the following figure.

Alternatively, Econometrics Toolbox has functions for fitting and forecasting \(\operatorname{VAR}(p)\) models, including the option to specify exogenous predictor variables.

\section*{Multivariate General Linear Model}

This example shows how to set up a multivariate general linear model for estimation using mvregress.

\section*{Load sample data.}
load('imports-85')
This data contains measurements on a sample of 205 auto imports from 1985. Here, model the bivariate response of city and highway MPG (columns 14 and 15).

Y = X(:,14:15);
[n,d] = size(Y);
For predictors, use wheel base (column 3), curb weight (column 7), and fuel type (column 18). The first two predictors are continuous, and for this example are centered and scaled. Fuel type is a categorical variable with two categories (11 and 20), so a dummy indicator variable is needed for the regression.
\(\mathrm{X} 1=\operatorname{zscore}(\mathrm{X}(:, 3))\);
X2 = zscore(X(:,7));
X3 \(=X(:, 18)==20\);
The variable X3 is coded to have value 1 for the fuel type 20 , and value 0 otherwise.

For convenience, combine the three predictors (wheel base, curb weight, and fuel type indicator) into one design matrix, with an added intercept term.

Xmat \(=\) [ones(n,1) X1 X2 X3];

\section*{Set up design matrices.}

Given these predictors, the multivariate general linear model for the bivariate MPG response is
\[
\left[\begin{array}{cc}
y_{11} & y_{12} \\
y_{21} & y_{22} \\
\vdots & \vdots \\
y_{n 1} & y_{n 2}
\end{array}\right]=\left[\begin{array}{cccc}
1 & x_{11} & x_{12} & x_{13} \\
1 & x_{21} & x_{22} & x_{23} \\
\vdots & \vdots & \vdots & \vdots \\
1 & x_{n 1} & x_{n 2} & x_{n 3}
\end{array}\right]\left[\begin{array}{ll}
\beta_{01} & \beta_{02} \\
\beta_{11} & \beta_{12} \\
\beta_{21} & \beta_{22} \\
\beta_{31} & \beta_{32}
\end{array}\right]+\left[\begin{array}{cc}
\varepsilon_{11} & \varepsilon_{12} \\
\varepsilon_{21} & \varepsilon_{22} \\
\vdots & \vdots \\
\varepsilon_{n 1} & \varepsilon_{n 2}
\end{array}\right]
\]
where \(\varepsilon_{i}=\left(\varepsilon_{i 1}, \varepsilon_{i 2}\right)^{\prime} \square M V N(\mathbf{0}, \Sigma)\). There are \(K=8\) regression coefficients in total.

Create a length \(n=205\) cell array of 2-by-8 ( \(d\)-by- \(K\) ) matrices for use with mvregress. The \(i\) th matrix in the cell array is
```

    X{i}=[\begin{array}{ccccccccc}{1}&{0}&{\mp@subsup{x}{i1}{}}&{0}&{\mp@subsup{x}{i2}{}}&{0}&{\mp@subsup{x}{i3}{}}&{0}\\{0}&{1}&{0}&{\mp@subsup{x}{i1}{}}&{0}&{\mp@subsup{x}{i2}{}}&{0}&{\mp@subsup{x}{i3}{}}\end{array}].
    Xcell = cell(1,n);
for i = 1:n
Xcell{i} = [kron([Xmat(i,:)],eye(d))];
end

```

Given this specification of the design matrices, the corresponding parameter vector is
\[
\beta=\left[\begin{array}{l}
\beta_{01} \\
\beta_{02} \\
\beta_{11} \\
\beta_{12} \\
\beta_{21} \\
\beta_{22} \\
\beta_{31} \\
\beta_{32}
\end{array}\right] .
\]

\section*{Estimate regression coefficients.}

Fit the model using maximum likelihood estimation.
[beta,sigma, E, V] = mvregress(Xcell, Y);
beta
beta =
33.5476
38.5720
0.9723
0.3950
-6. 3064
- 6.3584
-9.2284
-8. 6663
These coefficient estimates show:
- The expected city and highway MPG for cars of average wheel base, curb weight, and fuel type 11 are 33.5 and 38.6 , respectively. For fuel type 20, the expected city and highway MPG are \(33.5476-9.2284=24.3192\) and \(38.5720-8.6663=29.9057\).
- An increase of one standard deviation in curb weight has almost the same effect on expected city and highway MPG. Given all else is equal, the expected MPG decreases by about 6.3 with each one standard deviation increase in curb weight, for both city and highway MPG.
- For each one standard deviation increase in wheel base, the expected city MPG increases 0.972 , while the expected highway MPG increases by only 0.395 , given all else is equal.

The standard errors for the regression coefficients are the square root of the diagonal of the variance-covariance matrix, V .
```

se = sqrt(diag(V))
se =
0.7365
0.7599
0.3589
0.3702
0.3497
0.3608

```
\[
\begin{aligned}
& 0.7790 \\
& 0.8037
\end{aligned}
\]

You can easily reshape the regression coefficients into the original 4 -by- 2 matrix.
```

B = reshape(beta,2,4)'
B =

| 33.5476 | 38.5720 |
| ---: | ---: |
| 0.9723 | 0.3950 |
| -6.3064 | -6.3584 |
| -9.2284 | -8.6663 |

```

\section*{Check model assumptions.}

Under the model assumptions, \(\mathbf{z}=\mathbf{E} \Sigma^{-1 / 2}\) should be independent, with a bivariate standard normal distribution. In this 2-D case, you can assess the validity of this assumption using a scatter plot.
```

z = E/chol(sigma);
figure()
plot(z(:,1),z(:,2),'.')
title('Standardized Residuals')
hold on
% Overlay standard normal contours
z1 = linspace(-5,5);
z2 = linspace(-5,5);
[zx,zy] = meshgrid(z1,z2);
zgrid = [reshape(zx,100^2,1),reshape(zy,100^2,1)];
zn = reshape(mvnpdf(zgrid),100,100);
[c,h] = contour(zx,zy,zn);
clabel(c,h)

```

Several residuals are larger than expected, but overall, there is little evidence against the multivariate normality assumption.

\section*{Fixed Effects Panel Model with Concurrent Correlation}

This example shows how to perform panel data analysis using mvregress. First, a fixed effects model with concurrent correlation is fit by ordinary least squares (OLS) to some panel data. Then, the estimated error covariance matrix is used to get panel corrected standard errors for the regression coefficients.

\section*{Load sample data.}

Navigate to the folder containing sample data.
```

cd(matlabroot)
cd('help/toolbox/stats/examples')

```

Load the sample panel data.
load('panelData')
The dataset array, panelData, contains yearly observations on eight cities for 6 years. This is simulated data.

The first variable, Growth, measures economic growth (the response variable). The second and third variables are city and year indicators, respectively. The last variable, Employ, measures employment (the predictor variable).
```

y = panelData.Growth;
city = panelData.City;
year = panelData.Year;
x = panelData.Employ;

```

\section*{Plot the data.}

To look for potential city-specific fixed effects, create a box plot of the response grouped by city.
```

figure()
boxplot(y,city)
xlabel('City')

```

There does not appear to be any systematic differences in the mean response among cities.

To look for potential year-specific fixed effects, create a box plot of the response grouped by year.
```

figure()
boxplot(y,year)
xlabel('Year')

```

Some evidence of systematic differences in the mean response between years seems to exist.

\section*{Format response and design matrices.}

Let \(y_{i j}\) denote the response for city \(j=1, \ldots, d\), in year \(i=1, \ldots, n\). Similarly, \(x_{i j}\) is the corresponding value of the predictor variable. In this example, \(n=\) 6 and \(d=8\).

Consider fitting a year-specific fixed effects model with a constant slope and concurrent correlation among cities in the same year,
\[
y_{i j}=\alpha_{i}+\beta_{1} x_{i j}+\varepsilon_{i j}, i=1, \ldots, n, j=1, \ldots, d,
\]
where \(\varepsilon_{i}=\left(\varepsilon_{i 1}, \ldots, \varepsilon_{i d}\right)^{\prime} \square M V N(\mathbf{0}, \Sigma)\). The concurrent correlation accounts for any unmeasured, time-static factors that might impact growth similarly for some cities. For example, cities with close spatial proximity might be more likely to have similar economic growth.

To fit this model using mvregress, first reshape the response data into an \(n\)-by- \(d\) matrix.
\(\mathrm{n}=6\); \(\mathrm{d}=8\);
\(Y=\operatorname{reshape}(y, n, d)\);

Next, create a length- \(n\) cell array of \(d\)-by- \(K\) design matrices. For this model, there are \(K=7\) parameters ( \(d=6\) intercept terms and a slope).

Suppose the vector of parameters is arranged as
\[
\beta=\left(\begin{array}{c}
\alpha_{1} \\
\alpha_{2} \\
\vdots \\
\alpha_{6} \\
\beta_{1}
\end{array}\right) .
\]

In this case, the first design matrix for year 1 looks like
\[
X\{1\}=\left(\begin{array}{ccccc}
1 & 0 & \cdots & 0 & x_{11} \\
1 & 0 & \cdots & 0 & x_{12} \\
\vdots & \vdots & \cdots & 0 & \vdots \\
1 & 0 & \cdots & 0 & x_{18}
\end{array}\right),
\]
and the second design matrix for year 2 looks like
\[
X\{2\}=\left(\begin{array}{cccccc}
0 & 1 & 0 & \cdots & 0 & x_{21} \\
0 & 1 & 0 & \cdots & 0 & x_{22} \\
\vdots & \vdots & 0 & \cdots & 0 & \vdots \\
0 & 1 & 0 & \cdots & 0 & x_{28}
\end{array}\right)
\]

The design matrices for the remaining 4 years are similar.
```

K = 7; N = n*d;
X = cell(n,1);
for i = 1:n
x0 = zeros(d,K-1);
x0(:,i) = 1;
X{i} = [x0,x(i:n:N)];

```
end

\section*{Fit the model.}

Fit the model using ordinary least squares (OLS).
```

[b,sig,E,V] = mvregress(X,Y,'algorithm','cwls');
b
b =

```
    41.6878
    26.1864
    \(-64.5107\)
    11.0924
    \(-59.1872\)
    71.3313
    4.9525

Plot the fitted model.
```

xx = linspace(min(x),max(x));
axx = repmat(b(1:K-1),1,length(xx));
bxx = repmat(b(K)*xx,n,1);
yhat = axx + bxx;
figure()
hPoints = gscatter(x,y,year);
hold on
hLines = plot(xx,yhat);
for i=1:n
set(hLines(i),'color',get(hPoints(i),'color'));
end
hold off

```

The model with year-specific intercepts and common slope appears to fit the data quite well.

\section*{Residual correlation.}

Plot the residuals, grouped by year.
```

figure()
gscatter(year,E(:),city)
ylabel('Residuals')

```

The residual plot suggests concurrent correlation is present. For examples, cities \(1,2,3\), and 4 are consistently above or below average as a group in any given year. The same is true for the collection of cities \(5,6,7\), and 8 . As seen in the exploratory plots, there are no systematic city-specific effects.

\section*{Panel corrected standard errors.}

Use the estimated error variance-covariance matrix to compute panel corrected standard errors for the regression coefficients.
```

XX = cell2mat(X);
S = kron(eye(n),sig);
Vpcse = inv(XX'*XX)*XX'*S*XX*inv(XX'*XX);
se = sqrt(diag(Vpcse))
se =

```
8.66989.34069.4286
9.5729
8.82070.1527

\section*{Longitudinal Analysis}

This example shows how to perform longitudinal analysis using mvregress.

\section*{Load sample data.}

Navigate to the folder containing sample data.
```

cd(matlabroot)
cd('help/toolbox/stats/examples')

```

Load the sample longitudinal data.
load('longitudinalData')
The matrix \(Y\) contains response data for 16 individuals. The response is the blood level of a drug measured at five time points ( \(t=0,2,4,6\), and 8 ). Each row of \(Y\) corresponds to an individual, and each column corresponds to a time point. The first eight subjects are female, and the second eight subjects are male. This is simulated data.

Plot the data for all 16 subjects.
```

figure()
t = [0,2,4,6,8];
plot(t,Y)
hold on
hf = plot(t,Y(1:8,:),'^');
hm = plot(t,Y(9:16,:),'o');
legend([hf(1),hm(1)],'Female','Male','Location','NorthEast')
title('Longitudinal Response')
ylabel('Blood Drug Level')
xlabel('Time')
hold off

```

\section*{Format design matrices.}

Let \(y_{i j}\) denote the response for individual \(i=1, \ldots, n\) measured at times \(t_{i j}\), \(j=1, \ldots, d\). In this example, \(n=16\) and \(d=5\). Let \(G_{i}\) denote the gender of individual \(i\), where \(G_{i}=1\) for males and 0 for females.

Consider fitting a quadratic longitudinal model, with a separate slope and intercept for each gender,
\[
y_{i j}=\beta_{0}+\beta_{1} G_{i}+\beta_{2} t_{i j}+\beta_{3} t_{i j}^{2}+\beta_{4} G_{i} \times t_{i j}+\beta_{5} G_{i} \times t_{i j}^{2}+\varepsilon_{i j}
\]
where \(\varepsilon_{i}=\left(\varepsilon_{i 1}, \ldots, \varepsilon_{i d}\right)^{\prime} \square M V N(\mathbf{0}, \Sigma)\). The error correlation accounts for clustering within an individual.

To fit this model using mvregress, the response data should be in an \(n\)-by- \(d\) matrix. Y is already in the proper format.

Next, create a length- \(n\) cell array of \(d\)-by- \(K\) design matrices. For this model, there are \(K=6\) parameters.

For individual \(i\), the 5 -by- 6 design matrix is
\[
X\{i\}=\left(\begin{array}{cccccc}
1 & G_{i} & t_{i 1} & t_{i 1}^{2} & G_{i} \times t_{i 1} & G_{i} \times t_{i 1}^{2} \\
1 & G_{i} & t_{i 2} & t_{i 2}^{2} & G_{i} \times t_{i 2} & G_{i} \times t_{i 2}^{2} \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
1 & G_{i} & t_{i 5} & t_{i 5}^{2} & G_{i} \times t_{i 5} & G_{i} \times t_{i 5}^{2}
\end{array}\right),
\]
corresponding to the parameter vector
\[
\beta=\left(\begin{array}{c}
\beta_{0} \\
\beta_{1} \\
\vdots \\
\beta_{5}
\end{array}\right)
\]

The matrix X 1 has the design matrix for a female, and X 2 has the design matrix for a male.

X1
\(\mathrm{X} 1=\)
\begin{tabular}{rrrrrr}
1 & 0 & 0 & 0 & 0 & 0 \\
1 & 0 & 2 & 4 & 0 & 0 \\
1 & 0 & 4 & 16 & 0 & 0 \\
1 & 0 & 6 & 36 & 0 & 0 \\
1 & 0 & 8 & 64 & 0 & 0
\end{tabular}

X2

X2 =
\begin{tabular}{rrrrrr}
1 & 1 & 0 & 0 & 0 & 0 \\
1 & 1 & 2 & 4 & 2 & 4 \\
1 & 1 & 4 & 16 & 4 & 16 \\
1 & 1 & 6 & 36 & 6 & 36 \\
1 & 1 & 8 & 64 & 8 & 64
\end{tabular}

Create a cell array of design matrices. The first eight individuals are females, and the second eight are males.
```

X = cell(8,1);
X(1:8) = {X1};
X(9:16) = {X2};

```

\section*{Fit the model.}

Fit the model using maximum likelihood estimation. Display the estimated coefficients and standard errors.
```

Yhatm = X2*b;
figure()
plot(t,Y)
hold on
plot(t,Y(1:8,:),'^',t,Y(9:16,:),'o')
hf = plot(t,Yhatf,'k--','LineWidth',3);
hm = plot(t,Yhatm,'k','LineWidth',3);
legend([hf,hm],'Females','Males','Location','NorthEast')
title('Longitudinal Response')
ylabel('Blood Drug Level')

```
```

xlabel('Time')
hold off

```

The coefficients on the interaction terms (in the last two rows of b) do not appear significant. You can use the value of the loglikelihood objective function for this fit, loglikF, to compare this model to one without the interaction terms using a likelihood ratio test.

\section*{Fit a reduced model.}

Fit the model without interaction terms,
\[
y_{i j}=\beta_{0}+\beta_{1} G_{i}+\beta_{2} t_{i j}+\beta_{3} t_{i j}^{2}+\varepsilon_{i j}
\]
where \(\varepsilon_{i}=\left(\varepsilon_{i 1}, \ldots, \varepsilon_{i d}\right)^{\prime} \square M V N(\mathbf{0}, \Sigma)\).
This model has four coefficients, which correspond to the first four columns of the design matrices X1 and X2 (for females and males, respectively).
```

X1R = X1(:,1:4);
X2R = X2(:,1:4);
XR = cell(8,1);
XR(1:8) = {X1R};
XR(9:16) = {X2R};

```

Fit this model using maximum likelihood estimation. Display the estimated coefficients and their standard errors.
```

[bR,sigR,ER,VR,loglikR] = mvregress(XR,Y);

```
[bR, sqrt(diag(VR))]
ans \(=\)
\begin{tabular}{rr}
19.3765 & 0.6898 \\
12.0936 & 0.8591 \\
2.2919 & 0.2139 \\
-0.3623 & 0.0283
\end{tabular}

\section*{Conduct a likelihood ratio test.}

Compare the two models using a likelihood ratio test. The null hypothesis is that the reduced model is sufficient. The alternative is that the reduced model is inadequate (compared to the full model with the interaction terms).

The likelihood ratio test statistic is compared to a chi-squared distribution with two degrees of freedom (for the two coefficients being dropped).
```

LR = 2*(loglikF-loglikR);
pval = 1 - chi2cdf(LR,2)
pval =
0.0803

```

The \(p\)-value 0.0803 indicates that the null hypothesis is not rejected at the \(5 \%\) significance level. Therefore, there is insufficient evidence that the extra terms improve the fit.

\section*{Introduction to Multidimensional Scaling}

One of the most important goals in visualizing data is to get a sense of how near or far points are from each other. Often, you can do this with a scatter plot. However, for some analyses, the data that you have might not be in the form of points at all, but rather in the form of pairwise similarities or dissimilarities between cases, observations, or subjects. There are no points to plot.

Even if your data are in the form of points rather than pairwise distances, a scatter plot of those data might not be useful. For some kinds of data, the relevant way to measure how near two points are might not be their Euclidean distance. While scatter plots of the raw data make it easy to compare Euclidean distances, they are not always useful when comparing other kinds of inter-point distances, city block distance for example, or even more general dissimilarities. Also, with a large number of variables, it is very difficult to visualize distances unless the data can be represented in a small number of dimensions. Some sort of dimension reduction is usually necessary.

Multidimensional scaling (MDS) is a set of methods that address all these problems. MDS allows you to visualize how near points are to each other for many kinds of distance or dissimilarity metrics and can produce a representation of your data in a small number of dimensions. MDS does not require raw data, but only a matrix of pairwise distances or dissimilarities.

\section*{Classical Multidimensional Scaling}
- "Introduction to Classical Multidimensional Scaling" on page 12-51
- "Example: Multidimensional Scaling" on page 12-53

\section*{Introduction to Classical Multidimensional Scaling}

The function cmdscale performs classical (metric) multidimensional scaling, also known as principal coordinates analysis. cmdscale takes as an input a matrix of inter-point distances and creates a configuration of points. Ideally, those points are in two or three dimensions, and the Euclidean distances between them reproduce the original distance matrix. Thus, a scatter plot of the points created by cmdscale provides a visual representation of the original distances.

As a very simple example, you can reconstruct a set of points from only their inter-point distances. First, create some four dimensional points with a small component in their fourth coordinate, and reduce them to distances.
```

X = [ normrnd(0,1,10,3), normrnd(0,.1,10,1) ];
D = pdist(X,'euclidean');

```

Next, use cmdscale to find a configuration with those inter-point distances. cmdscale accepts distances as either a square matrix, or, as in this example, in the vector upper-triangular form produced by pdist.
[Y,eigvals] = cmdscale(D);
cmdscale produces two outputs. The first output, Y , is a matrix containing the reconstructed points. The second output, eigvals, is a vector containing the sorted eigenvalues of what is often referred to as the "scalar product matrix," which, in the simplest case, is equal to \(Y^{*} Y^{\prime}\). The relative magnitudes of those eigenvalues indicate the relative contribution of the corresponding columns of \(Y\) in reproducing the original distance matrix \(D\) with the reconstructed points.
```

format short g
[eigvals eigvals/max(abs(eigvals))]
ans =
12.623 1
4.3699 0.34618
1.9307 0.15295
0.025884 0.0020505
1.7192e-015 1.3619e-016
6.8727e-016 5.4445e-017

```
```

4.4367e-017 3.5147e-018
-9.2731e-016 -7.3461e-017
-1.327e-015 -1.0513e-016
-1.9232e-015 -1.5236e-016

```

If eigvals contains only positive and zero (within round-off error) eigenvalues, the columns of \(Y\) corresponding to the positive eigenvalues provide an exact reconstruction of D, in the sense that their inter-point Euclidean distances, computed using pdist, for example, are identical (within round-off) to the values in \(D\).
```

maxerr4 = max(abs(D - pdist(Y))) % exact reconstruction
maxerr4 =
2.6645e-015

```

If two or three of the eigenvalues in eigvals are much larger than the rest, then the distance matrix based on the corresponding columns of \(Y\) nearly reproduces the original distance matrix D. In this sense, those columns form a lower-dimensional representation that adequately describes the data. However it is not always possible to find a good low-dimensional reconstruction.
```

% good reconstruction in 3D
maxerr3 = max(abs(D - pdist(Y(:,1:3))))
maxerr3 =
0.029728
% poor reconstruction in 2D
maxerr2 = max(abs(D - pdist(Y(:,1:2))))
maxerr2 =
0.91641

```

The reconstruction in three dimensions reproduces \(D\) very well, but the reconstruction in two dimensions has errors that are of the same order of magnitude as the largest values in \(D\).
```

max(max(D))
ans =
3.4686

```

Often, eigvals contains some negative eigenvalues, indicating that the distances in D cannot be reproduced exactly. That is, there might not be any configuration of points whose inter-point Euclidean distances are given by D. If the largest negative eigenvalue is small in magnitude relative to the largest positive eigenvalues, then the configuration returned by cmdscale might still reproduce \(D\) well.

\section*{Example: Multidimensional Scaling}

Given only the distances between 10 US cities, cmdscale can construct a map of those cities. First, create the distance matrix and pass it to cmdscale. In this example, D is a full distance matrix: it is square and symmetric, has positive entries off the diagonal, and has zeros on the diagonal.
```

cities = ...
{'Atl','Chi','Den','Hou','LA','Mia','NYC','SF', 'Sea', 'WDC'};
D = [ 0 0 587 1212 701 1936 604 748 2139 2182 543;
587 0 920 940 1745 1188 713 1858 1737 597;
1212 920 0 879 831 1726 1631 949 1021 1494;
701 940 879 0 1374 968 1420 1645 1891 1220;
1936 1745 831 1374 0 2339 2451 347 959 2300;
604 1188 1726 968 2339 0 1092 2594 2734 923;
748 713 1631 1420 2451 1092 0 2571 2408 205;
2139 1858 949 1645 347 2594 2571 0 678 2442;
2182 1737 1021 1891 959 2734 2408 678 0 2329;
543 597 1494 1220 2300 923 205 2442 2329 0];
[Y,eigvals] = cmdscale(D);

```

Next, look at the eigenvalues returned by cmdscale. Some of these are negative, indicating that the original distances are not Euclidean. This is because of the curvature of the earth.
```

format short g
[eigvals eigvals/max(abs(eigvals))]
ans =
9.5821e+006 1
1.6868e+006 0.17604
8157.3 0.0008513
1432.9 0.00014954
508.67 5.3085e-005
25.143 2.624e-006

```
```

5.3394e-010 5.5722e-017
-897.7 -9.3685e-005
-5467.6 -0.0005706
-35479 -0.0037026

```

However, in this case, the two largest positive eigenvalues are much larger in magnitude than the remaining eigenvalues. So, despite the negative eigenvalues, the first two coordinates of \(Y\) are sufficient for a reasonable reproduction of \(D\).
```

Dtriu = D(find(tril(ones(10),-1)))';
maxrelerr = max(abs(Dtriu-pdist(Y(:,1:2))))./max(Dtriu)
maxrelerr =
0.0075371

```

Here is a plot of the reconstructed city locations as a map. The orientation of the reconstruction is arbitrary. In this case, it happens to be close to, although not exactly, the correct orientation.
```

plot(Y(:,1),Y(:,2),'.')
text(Y(:,1)+25,Y(:,2),cities)
xlabel('Miles')
ylabel('Miles')

```

\section*{Nonclassical Multidimensional Scaling}

The function mdscale performs nonclassical multidimensional scaling. As with cmdcale, you use mdscale either to visualize dissimilarity data for which no "locations" exist, or to visualize high-dimensional data by reducing its dimensionality. Both functions take a matrix of dissimilarities as an input and produce a configuration of points. However, mdscale offers a choice of different criteria to construct the configuration, and allows missing data and weights.

For example, the cereal data include measurements on 10 variables describing breakfast cereals. You can use mdscale to visualize these data in two dimensions. First, load the data. For clarity, this example code selects a subset of 22 of the observations.
```

load cereal.mat
X = [Calories Protein Fat Sodium Fiber ...
Carbo Sugars Shelf Potass Vitamins];

```
```

% Take a subset from a single manufacturer
mfg1 = strcmp('G',cellstr(Mfg));
X = X(mfg1,:);
size(X)
ans =
22 10

```

Then use pdist to transform the 10 -dimensional data into dissimilarities. The output from pdist is a symmetric dissimilarity matrix, stored as a vector containing only the ( \(23 * 22 / 2\) ) elements in its upper triangle.
```

dissimilarities = pdist(zscore(X),'cityblock');
size(dissimilarities)
ans =
1 231

```

This example code first standardizes the cereal data, and then uses city block distance as a dissimilarity. The choice of transformation to dissimilarities is application-dependent, and the choice here is only for simplicity. In some applications, the original data are already in the form of dissimilarities.

Next, use mdscale to perform metric MDS. Unlike cmdscale, you must specify the desired number of dimensions, and the method to use to construct the output configuration. For this example, use two dimensions. The metric STRESS criterion is a common method for computing the output; for other choices, see the mdscale reference page in the online documentation. The second output from mdscale is the value of that criterion evaluated for the output configuration. It measures the how well the inter-point distances of the output configuration approximate the original input dissimilarities:
```

[Y,stress] =...
mdscale(dissimilarities,2,'criterion','metricstress');
stress
stress =
0.1856

```

A scatterplot of the output from mdscale represents the original 10 -dimensional data in two dimensions, and you can use the gname function to label selected points:
```

plot(Y(:,1),Y(:,2),'o','LineWidth',2);

```
gname (Name (mfg1))

\section*{Nonmetric Multidimensional Scaling}

Metric multidimensional scaling creates a configuration of points whose inter-point distances approximate the given dissimilarities. This is sometimes too strict a requirement, and non-metric scaling is designed to relax it a bit. Instead of trying to approximate the dissimilarities themselves, non-metric scaling approximates a nonlinear, but monotonic, transformation of them. Because of the monotonicity, larger or smaller distances on a plot of the output will correspond to larger or smaller dissimilarities, respectively. However, the nonlinearity implies that mdscale only attempts to preserve the
ordering of dissimilarities. Thus, there may be contractions or expansions of distances at different scales.

You use mdscale to perform nonmetric MDS in much the same way as for metric scaling. The nonmetric STRESS criterion is a common method for computing the output; for more choices, see the mdscale reference page in the online documentation. As with metric scaling, the second output from mdscale is the value of that criterion evaluated for the output configuration. For nonmetric scaling, however, it measures the how well the inter-point distances of the output configuration approximate the disparities. The disparities are returned in the third output. They are the transformed values of the original dissimilarities:
```

[Y,stress,disparities] = ...
mdscale(dissimilarities,2,'criterion','stress');
stress
stress =
0.1562

```

To check the fit of the output configuration to the dissimilarities, and to understand the disparities, it helps to make a Shepard plot:
```

distances = pdist(Y);
[dum,ord] = sortrows([disparities(:) dissimilarities(:)]);
plot(dissimilarities,distances,'bo', ...
dissimilarities(ord),disparities(ord),'r.-', ...
[0 25],[0 25],'k-')
xlabel('Dissimilarities')
ylabel('Distances/Disparities')
legend({'Distances' 'Disparities' '1:1 Line'},...
'Location','NorthWest');

```

This plot shows that mdscale has found a configuration of points in two dimensions whose inter-point distances approximates the disparities, which in turn are a nonlinear transformation of the original dissimilarities. The concave shape of the disparities as a function of the dissimilarities indicates that fit tends to contract small distances relative to the corresponding dissimilarities. This may be perfectly acceptable in practice.
mdscale uses an iterative algorithm to find the output configuration, and the results can often depend on the starting point. By default, mdscale uses cmdscale to construct an initial configuration, and this choice often leads to a globally best solution. However, it is possible for mdscale to stop at a configuration that is a local minimum of the criterion. Such
cases can be diagnosed and often overcome by running mdscale multiple times with different starting points. You can do this using the 'start' and 'replicates' parameters. The following code runs five replicates of MDS, each starting at a different randomly-chosen initial configuration. The criterion value is printed out for each replication; mdscale returns the configuration with the best fit.
```

opts = statset('Display','final');
[Y,stress] =...
mdscale(dissimilarities,2,'criterion','stress',...
'start','random','replicates',5,'Options',opts);
3 5 iterations, Final stress criterion = 0.156209
3 1 ~ i t e r a t i o n s , ~ F i n a l ~ s t r e s s ~ c r i t e r i o n ~ = ~ 0 . 1 5 6 2 0 9 ~
4 8 iterations, Final stress criterion = 0.171209
3 3 iterations, Final stress criterion = 0.175341
3 2 iterations, Final stress criterion = 0.185881

```

Notice that mdscale finds several different local solutions, some of which do not have as low a stress value as the solution found with the cmdscale starting point.

\section*{Procrustes Analysis}

\author{
In this section... \\ "Compare Landmark Data" on page 12-61 \\ "Data Input" on page 12-61 \\ "Preprocess Data for Accurate Results" on page 12-62 \\ "Compare Handwritten Shapes" on page 12-63
}

\section*{Compare Landmark Data}

The procrustes function analyzes the distribution of a set of shapes using Procrustes analysis. This analysis method matches landmark data (geometric locations representing significant features in a given shape) to calculate the best shape-preserving Euclidian transformations. These transformations minimize the differences in location between compared landmark data.

Procrustes analysis is also useful in conjunction with multidimensional scaling. In "Example: Multidimensional Scaling" on page 12-53 there is an observation that the orientation of the reconstructed points is arbitrary. Two different applications of multidimensional scaling could produce reconstructed points that are very similar in principle, but that look different because they have different orientations. The procrustes function transforms one set of points to make them more comparable to the other.

\section*{Data Input}

The procrustes function takes two matrices as input:
- The target shape matrix \(X\) has dimension \(n \times p\), where \(n\) is the number of landmarks in the shape and \(p\) is the number of measurements per landmark.
- The comparison shape matrix \(Y\) has dimension \(n \times q\) with \(q \leq p\). If there are fewer measurements per landmark for the comparison shape than the target shape ( \(q<p\) ), the function adds columns of zeros to \(Y\), yielding an \(n \times p\) matrix.

The equation to obtain the transformed shape, \(Z\), is
\[
\begin{equation*}
Z=b Y T+c \tag{12-1}
\end{equation*}
\]
where:
- \(b\) is a scaling factor that stretches \((b>1)\) or shrinks \((b<1)\) the points.
- \(T\) is the orthogonal rotation and reflection matrix.
- \(c\) is a matrix with constant values in each column, used to shift the points.

The procrustes function chooses \(b, T\), and \(c\) to minimize the distance between the target shape \(X\) and the transformed shape \(Z\) as measured by the least squares criterion:
\[
\sum_{i=1}^{n} \sum_{j=1}^{p}\left(X_{i j}-Z_{i j}\right)^{2}
\]

\section*{Preprocess Data for Accurate Results}

Procrustes analysis is appropriate when all \(p\) measurement dimensions have similar scales. The analysis would be inaccurate, for example, if the columns of \(Z\) had different scales:
- The first column is measured in milliliters ranging from 2,000 to 6,000 .
- The second column is measured in degrees Celsius ranging from 10 to 25 .
- The third column is measured in kilograms ranging from 50 to 230.

In such cases, standardize your variables by:
1 Subtracting the sample mean from each variable.
2 Dividing each resultant variable by its sample standard deviation.
Use the zscore function to perform this standardization.

\section*{Compare Handwritten Shapes}

In this example, use Procrustes analysis to compare two handwritten number threes. Visually and analytically explore the effects of forcing size and reflection changes as follows:
- "Step 1: Load and Display the Original Data" on page 12-63
- "Step 2: Calculate the Best Transformation" on page 12-64
- "Step 3: Examine the Similarity of the Two Shapes" on page 12-65
- "Step 4: Restrict the Form of the Transformations" on page 12-67

\section*{Step 1: Load and Display the Original Data}

Input landmark data for two handwritten number threes:
A = [11 39;17 42;25 42;25 40;23 36;19 35;30 34;35 29;...
30 20;18 19];
B = [15 31;20 37;30 40;29 35;25 29;29 31;31 31;35 20;...
29 10;25 18];
Create \(X\) and \(Y\) from \(A\) and \(B\), moving \(B\) to the side to make each shape more visible:
\(X=A ;\)
\(Y=B+\operatorname{repmat}([250], 10,1) ;\)
Plot the shapes, using letters to designate the landmark points. Lines in the figure join the points to indicate the drawing path of each shape.
```

plot(X(:,1), X(:,2),'r-', Y(:,1), Y(:,2),'b-');
text(X(:,1), X(:,2),('abcdefghij')')
text(Y(:,1), Y(:,2),('abcdefghij')')
legend('X = Target','Y = Comparison','location','SE')
set(gca,'YLim',[0 55],'XLim',[0 65]);

```

\section*{Step 2: Calculate the Best Transformation}

Use Procrustes analysis to find the transformation that minimizes distances between landmark data points.

Call procrustes as follows:
[d, Z, tr] = procrustes(X,Y);
The outputs of the function are:
- d - A standardized dissimilarity measure.)
- Z - A matrix of the transformed landmarks.
- tr - A structure array of the computed transformation with fields \(\mathrm{T}, \mathrm{b}\), and c which correspond to the transformation equation, Equation 12-1.

Visualize the transformed shape, Z , using a dashed blue line:
```

plot(X(:,1), X(:,2),'r-', Y(:,1), Y(:,2),'b-',...
Z(:,1),Z(:,2),'b:');
text(X(:,1), X(:,2),('abcdefghij')')
text(Y(:,1), Y(:,2),('abcdefghij')')
text(Z(:,1), Z(:,2),('abcdefghij')')
legend('X = Target','Y = Comparison',...
'Z = Transformed','location','SW')
set(gca,'YLim',[0 55],'XLim',[0 65]);

```

\section*{Step 3: Examine the Similarity of the Two Shapes}

Use two different numerical values to assess the similarity of the target shape and the transformed shape.

Dissimilarity Measure d. The dissimilarity measure d gives a number between 0 and 1 describing the difference between the target shape and the transformed shape. Values near 0 imply more similar shapes, while values near 1 imply dissimilarity. For this example:
d \(=\)
0.1502

The small value of \(d\) in this case shows that the two shapes are similar.
procrustes calculates \(d\) by comparing the sum of squared deviations between the set of points with the sum of squared deviations of the original points from their column means:
```

numerator = sum(sum((X-Z).^2))
numerator =
166.5321
denominator = sum(sum(bsxfun(@minus,X,mean(X)).^2))
denominator =
1.1085e+003
ratio = numerator/denominator
ratio =
0.1502

```

Note The resulting measure \(d\) is independent of the scale of the size of the shapes and takes into account only the similarity of landmark data. "Examine the Scaling Measure b" on page 12-66 shows how to examine the size similarity of the shapes.

Examine the Scaling Measure b. The target and comparison threes in the previous figure visually show that the two numbers are of a similar size. The closeness of calculated value of the scaling factor \(b\) to 1 supports this observation as well:
```

tr.b
ans =
0.9291

```

The sizes of the target and comparison shapes appear similar. This visual impression is reinforced by the value of \(b=0.93\), which implies that the best transformation results in shrinking the comparison shape by a factor . 93 (only 7\%).

\section*{Step 4: Restrict the Form of the Transformations}

Explore the effects of manually adjusting the scaling and reflection coefficients.

Fix the Scaling Factor \(\mathbf{b}=\mathbf{1}\). Force b to equal 1 (set 'Scaling' to false) to examine the amount of dissimilarity in size of the target and transformed figures:
```

ds = procrustes(X,Y,'Scaling',false)
ds =
0.1552

```

In this case, setting 'Scaling' to false increases the calculated value of d only 0.0049 , which further supports the similarity in the size of the two number threes. A larger increase in d would have indicated a greater size discrepancy.

Force a Reflection in the Transformation. This example requires only a rotation, not a reflection, to align the shapes. You can show this by observing that the determinant of the matrix T is 1 in this analysis:
```

det(tr.T)
ans =
1.0000

```

If you need a reflection in the transformation, the determinant of T is -1 . You can force a reflection into the transformation as follows:
```

[dr,Zr,trr] = procrustes(X,Y,'Reflection',true);
dr
dr =

```
\[
0.8130
\]

The d value increases dramatically, indicating that a forced reflection leads to a poor transformation of the landmark points. A plot of the transformed shape shows a similar result:
- The landmark data points are now further away from their target counterparts.
- The transformed three is now an undesirable mirror image of the target three.
```

plot(X(:,1), X(:,2),'r-', Y(:,1), Y(:,2),'b-',...
Zr(:,1),Zr(:,2),'b:');
text(X(:,1), X(:,2),('abcdefghij')')
text(Y(:,1), Y(:,2),('abcdefghij')')
text(Zr(:,1), Zr(:,2),('abcdefghij')')
legend('X = Target','Y = Comparison',...
'Z = Transformed','location','SW')
set(gca,'YLim',[0 55],'XLim',[0 65]);

```

It appears that the shapes might be better matched if you flipped the transformed shape upside down. Flipping the shapes would make the transformation even worse, however, because the landmark data points would be further away from their target counterparts. From this example, it is clear that manually adjusting the scaling and reflection parameters is generally not optimal.

\section*{Feature Selection}

\author{
In this section... \\ "Introduction to Feature Selection" on page 12-70 \\ "Sequential Feature Selection" on page 12-70
}

\section*{Introduction to Feature Selection}

Feature selection reduces the dimensionality of data by selecting only a subset of measured features (predictor variables) to create a model. Selection criteria usually involve the minimization of a specific measure of predictive error for models fit to different subsets. Algorithms search for a subset of predictors that optimally model measured responses, subject to constraints such as required or excluded features and the size of the subset.

Feature selection is preferable to feature transformation when the original units and meaning of features are important and the modeling goal is to identify an influential subset. When categorical features are present, and numerical transformations are inappropriate, feature selection becomes the primary means of dimension reduction.

\section*{Sequential Feature Selection}
- "Introduction to Sequential Feature Selection" on page 12-70
- "Example: Sequential Feature Selection" on page 12-71

\section*{Introduction to Sequential Feature Selection}

A common method of feature selection is sequential feature selection. This method has two components:
- An objective function, called the criterion, which the method seeks to minimize over all feasible feature subsets. Common criteria are mean squared error (for regression models) and misclassification rate (for classification models).
- A sequential search algorithm, which adds or removes features from a candidate subset while evaluating the criterion. Since an exhaustive
comparison of the criterion value at all \(2^{n}\) subsets of an \(n\)-feature data set is typically infeasible (depending on the size of \(n\) and the cost of objective calls), sequential searches move in only one direction, always growing or always shrinking the candidate set.

The method has two variants:
- Sequential forward selection (SFS), in which features are sequentially added to an empty candidate set until the addition of further features does not decrease the criterion.
- Sequential backward selection (SBS), in which features are sequentially removed from a full candidate set until the removal of further features increase the criterion.

Stepwise regression is a sequential feature selection technique designed specifically for least-squares fitting. The functions stepwise and stepwisefit make use of optimizations that are only possible with least-squares criteria. Unlike generalized sequential feature selection, stepwise regression may remove features that have been added or add features that have been removed.

The Statistics Toolbox function sequentialfs carries out sequential feature selection. Input arguments include predictor and response data and a function handle to a file implementing the criterion function. Optional inputs allow you to specify SFS or SBS, required or excluded features, and the size of the feature subset. The function calls cvpartition and crossval to evaluate the criterion at different candidate sets.

\section*{Example: Sequential Feature Selection}

For example, consider a data set with 100 observations of 10 predictors. The following generates random data from a logistic model, with a binomial distribution of responses at each set of values for the predictors. Some coefficients are set to zero so that not all of the predictors affect the response:
```

n = 100;
m = 10;
X = rand(n,m);
b = [11 0 0 2 .5 0 0 0.1 0 1];
Xb}= X*\mp@subsup{b}{}{\prime}
p = 1./(1+exp(-Xb));

```
```

N = 50;
y = binornd(N,p);

```

The glmfit function fits a logistic model to the data:
```

Y = [y N*ones(size(y))];
[bO,devO,stats0] = glmfit(X,Y,'binomial');
% Display coefficient estimates and their standard errors:
modelO = [bO statsO.se]
model0 =
0.3115 0.2596
0.9614 0.1656
-0.1100 0.1651
-0.2165 0.1683
1.9519 0.1809
0.5683 0.2018
-0.0062 0.1740
0.0651 0.1641
-0.1034 0.1685
0.0017 0.1815
0.7979 0.1806
% Display the deviance of the fit:
dev0
dev0 =
101.2594

```

This is the full model, using all of the features (and an initial constant term). Sequential feature selection searches for a subset of the features in the full model with comparative predictive power.

First, you must specify a criterion for selecting the features. The following function, which calls glmfit and returns the deviance of the fit (a generalization of the residual sum of squares) is a useful criterion in this case:
```

function dev = critfun(X,Y)
[b,dev] = glmfit(X,Y,'binomial');

```

You should create this function as a file on the MATLAB path.

The function sequentialfs performs feature selection, calling the criterion function via a function handle:
```

maxdev = chi2inv(.95,1);
opt = statset('display','iter',...
'TolFun',maxdev,...
'TolTypeFun', 'abs');
inmodel = sequentialfs(@critfun,X,Y,···
'cv','none',...
'nullmodel',true,...
'options',opt,...
'direction','forward');
Start forward sequential feature selection:
Initial columns included: none
Columns that can not be included: none
Step 1, used initial columns, criterion value 309.118
Step 2, added column 4, criterion value 180.732
Step 3, added column 1, criterion value 138.862
Step 4, added column 10, criterion value 114.238
Step 5, added column 5, criterion value 103.503
Final columns included: 14510

```

The iterative display shows a decrease in the criterion value as each new feature is added to the model. The final result is a reduced model with only four of the original ten features: columns \(1,4,5\), and 10 of X . These features are indicated in the logical vector inmodel returned by sequentialfs.

The deviance of the reduced model is higher than for the full model, but the addition of any other single feature would not decrease the criterion by more than the absolute tolerance, maxdev, set in the options structure. Adding a feature with no effect reduces the deviance by an amount that has a chi-square distribution with one degree of freedom. Adding a significant feature results in a larger change. By setting maxdev to chi2inv (.95, 1), you instruct sequentialfs to continue adding features so long as the change in deviance is more than would be expected by random chance.

The reduced model (also with an initial constant term) is:
```

[b,dev,stats] = glmfit(X(:,inmodel),Y,'binomial');

```
```

% Display coefficient estimates and their standard errors:
model = [b stats.se]
model =
0.0784 0.1642
1.0040 0.1592
1.9459 0.1789
0.6134 0.1872
0.8245 0.1730

```

\section*{Introduction to Feature Transformation}

Feature transformation is a group of methods that create new features (predictor variables). The methods are useful for dimension reduction when the transformed features have a descriptive power that is more easily ordered than the original features. In this case, less descriptive features can be dropped from consideration when building models.

Feature transformation methods are contrasted with the methods presented in "Feature Selection" on page 12-70, where dimension reduction is achieved by computing an optimal subset of predictive features measured in the original data.

The methods presented in this section share some common methodology. Their goals, however, are essentially different:
- Nonnegative matrix factorization is used when model terms must represent nonnegative quantities, such as physical quantities.
- Principal component analysis is used to summarize data in fewer dimensions, for example, to visualize it.
- Factor analysis is used to build explanatory models of data correlations.

\section*{Nonnegative Matrix Factorization}
- "Introduction to Nonnegative Matrix Factorization" on page 12-76
- "Example: Nonnegative Matrix Factorization" on page 12-76

\section*{Introduction to Nonnegative Matrix Factorization}

Nonnegative matrix factorization (NMF) is a dimension-reduction technique based on a low-rank approximation of the feature space. Besides providing a reduction in the number of features, NMF guarantees that the features are nonnegative, producing additive models that respect, for example, the nonnegativity of physical quantities.

Given a nonnegative \(m\)-by- \(n\) matrix \(X\) and a positive integer \(k<\min (m, n)\), NMF finds nonnegative \(m\)-by- \(k\) and \(k\)-by- \(n\) matrices \(W\) and \(H\), respectively, that minimize the norm of the difference \(X-W H . W\) and \(H\) are thus approximate nonnegative factors of \(X\).

The \(k\) columns of \(W\) represent transformations of the variables in \(X\); the \(k\) rows of \(H\) represent the coefficients of the linear combinations of the original \(n\) variables in \(X\) that produce the transformed variables in \(W\). Since \(k\) is generally smaller than the rank of \(X\), the product \(W H\) provides a compressed approximation of the data in \(X\). A range of possible values for \(k\) is often suggested by the modeling context.

The Statistics Toolbox function nnmf carries out nonnegative matrix factorization. nnmf uses one of two iterative algorithms that begin with random initial values for \(W\) and \(H\). Because the norm of the residual \(X\) - WH may have local minima, repeated calls to nnmf may yield different factorizations. Sometimes the algorithm converges to a solution of lower rank than \(k\), which may indicate that the result is not optimal.

\section*{Example: Nonnegative Matrix Factorization}

For example, consider the five predictors of biochemical oxygen demand in the data set moore.mat:
load moore
X = moore(: \(1: 5\) );
The following uses nnmf to compute a rank-two approximation of \(X\) with a multiplicative update algorithm that begins from five random initial values for W and H :
```

opt = statset('MaxIter',10,'Display','final');
[WO,HO] = nnmf(X,2,'replicates',5,...
'options',opt,...

```
```

    'algorithm','mult');
    rep iteration rms resid
2 10 78.3556 0.000351747
3 10 230.962 0.0172839
4 10 326.347 0.00739552
5 10 361.547 0.00705539
Final root mean square residual = 78.3556

```

The 'mult' algorithm is sensitive to initial values, which makes it a good choice when using 'replicates' to find W and H from multiple random starting values.

Now perform the factorization using an alternating least-squares algorithm, which converges faster and more consistently. Run 100 times more iterations, beginning from the initial WO and HO identified above:
```

opt = statset('Maxiter',1000,'Display','final');
[W,H] = nnmf(X,2,'wO',WO,'hO',HO,...
'options',opt,...
'algorithm','als');
rep iteration rms resid |delta x|
1 3 77.5315 3.52673e-005
Final root mean square residual = 77.5315

```

The two columns of \(W\) are the transformed predictors. The two rows of H give the relative contributions of each of the five predictors in \(X\) to the predictors in W:
```

H
H =

| 0.0835 | 0.0190 | 0.1782 | 0.0072 | 0.9802 |
| :--- | :--- | :--- | :--- | :--- |
| 0.0558 | 0.0250 | 0.9969 | 0.0085 | 0.0497 |

```

The fifth predictor in \(X\) (weight 0.9802 ) strongly influences the first predictor in W. The third predictor in \(X\) (weight 0.9969 ) strongly influences the second predictor in W .

Visualize the relative contributions of the predictors in \(X\) with a biplot, showing the data and original variables in the column space of w :
```

biplot(H','scores',W,'varlabels',{'','','v3','','v5'});
axis([0 1.1 0 1.1])
xlabel('Column 1')
ylabel('Column 2')

```

\section*{Principal Component Analysis (PCA)}

One of the difficulties inherent in multivariate statistics is the problem of visualizing data that has many variables. The MATLAB function plot displays a graph of the relationship between two variables. The plot3 and surf commands display different three-dimensional views. But when there are more than three variables, it is more difficult to visualize their relationships.

Fortunately, in data sets with many variables, groups of variables often move together. One reason for this is that more than one variable might be measuring the same driving principle governing the behavior of the system. In many systems there are only a few such driving forces. But an abundance
of instrumentation enables you to measure dozens of system variables. When this happens, you can take advantage of this redundancy of information. You can simplify the problem by replacing a group of variables with a single new variable.

Principal component analysis is a quantitatively rigorous method for achieving this simplification. The method generates a new set of variables, called principal components. Each principal component is a linear combination of the original variables. All the principal components are orthogonal to each other, so there is no redundant information. The principal components as a whole form an orthogonal basis for the space of the data.

There are an infinite number of ways to construct an orthogonal basis for several columns of data. What is so special about the principal component basis?

The first principal component is a single axis in space. When you project each observation on that axis, the resulting values form a new variable. And the variance of this variable is the maximum among all possible choices of the first axis.

The second principal component is another axis in space, perpendicular to the first. Projecting the observations on this axis generates another new variable. The variance of this variable is the maximum among all possible choices of this second axis.

The full set of principal components is as large as the original set of variables. But it is commonplace for the sum of the variances of the first few principal components to exceed \(80 \%\) of the total variance of the original data. By examining plots of these few new variables, researchers often develop a deeper understanding of the driving forces that generated the original data.

You can use the function pca to find the principal components. To use pca, you need to have the actual measured data you want to analyze. However, if you lack the actual data, but have the sample covariance or correlation matrix for the data, you can still use the function pcacov to perform a principal components analysis. See the reference page for pcacov for a description of its inputs and outputs.

\section*{Quality of Life in U.S. Cities}

This example shows how to perform a weighted principal components analysis and interpret the results.

\section*{Explore data.}

Load the sample data.
```

load cities

```

The data includes ratings for 9 different indicators of the quality of life in 329 U.S. cities. These are climate, housing, health, crime, transportation, education, arts, recreation, and economics. For each category, a higher rating is better. For example, a higher rating for crime means a lower crime rate.

The cities data set contains three variables:
- categories, a string matrix containing the names of the indices
- names, a string matrix containing the 329 city names
- ratings, the data matrix with 329 rows and 9 columns

Display the categories variable.
categories
categories =
climate
housing
health
crime
transportation
education
arts
recreation
economics
Display the first five rows of the names variable.
```

first5 = names(1:5,:)
first5 =
Abilene, TX
Akron, OH
Albany, GA
Albany-Troy, NY
Albuquerque, NM

```

Make a boxplot to look at the distribution of the ratings data.
```

figure()
boxplot(ratings,'orientation','horizontal','labels',categories)

```

There is more variability in the ratings of the arts and housing than in the ratings of crime and climate.

Now, check the pairwise correlation between the variables.
```

C = corr(ratings,ratings);

```

The correlation among some variables is as high as 0.85 . Principal components analysis constructs independent new variables which are linear combinations of the original variables.

\section*{Compute principal components.}

When all variables are in the same unit, it is appropriate to compute principal components for raw data. When the variables are in different units or the difference in the variance of different columns is substantial (as in this case), scaling of the data or use of weights is often preferable.

Perform the principal component analysis by using the inverse variances of the ratings as weights.
```

w = 1./var(ratings);
[wcoeff,score,latent,tsquared,explained] = pca(ratings,...
'VariableWeights',w);

```

Or equivalently:
```

[wcoeff,score,latent,tsquared,explained] = pca(ratings,...

```
'VariableWeights', 'variance');

The following sections explain the five outputs of pca.

\section*{Component coefficients.}

The first output, wcoeff, contains the coefficients of the principal components.
The first three principal component coefficient vectors are:
```

c3 = wcoeff(:,1:3)
c3 = wcoeff(:,1:3)
c3 =
1.0e+03 *

```
\begin{tabular}{rrr}
0.0249 & -0.0263 & -0.0834 \\
0.8504 & -0.5978 & -0.4965 \\
0.4616 & 0.3004 & -0.0073 \\
0.1005 & -0.1269 & 0.0661 \\
0.5096 & 0.2606 & 0.2124 \\
0.0883 & 0.1551 & 0.0737 \\
2.1496 & 0.9043 & -0.1229 \\
0.2649 & -0.3106 & -0.0411 \\
0.1469 & -0.5111 & 0.6586
\end{tabular}

These coefficients are weighted, hence the coefficient matrix is not orthonormal.

Compute the orthonormal coefficient matrix.
```

coefforth = inv(diag(std(ratings)))*wcoeff;

```

Or if you use a weights vector, w, while conducting the pca, then
```

coefforth = diag(sqrt(w))*wcoeff;

```

The first three transformed coefficients are:
```

c3 = coefforth(:,1:3)

```
c3 =
\begin{tabular}{rrr}
0.2064 & -0.2178 & -0.6900 \\
0.3565 & -0.2506 & -0.2082 \\
0.4602 & 0.2995 & -0.0073 \\
0.2813 & -0.3553 & 0.1851 \\
0.3512 & 0.1796 & 0.1464 \\
0.2753 & 0.4834 & 0.2297 \\
0.4631 & 0.1948 & -0.0265 \\
0.3279 & -0.3845 & -0.0509 \\
0.1354 & -0.4713 & 0.6073
\end{tabular}

The transformed coefficients are now orthonormal.
```

I = c3'*c3

```
```

I =

| 1.0000 | -0.0000 | -0.0000 |
| ---: | ---: | ---: |
| -0.0000 | 1.0000 | -0.0000 |
| -0.0000 | -0.0000 | 1.0000 |

```

\section*{Component scores.}

The second output, score, contains the coordinates of the original data in the new coordinate system defined by the principal components. The score matrix is the same size as the input data matrix. You can also obtain the component scores using the orthonormal coefficients and the standardized ratings as follows.
cscores = zscore(ratings)*coefforth;
cscores and score are identical matrices.
Create a plot of the first two columns of score.
```

figure()
plot(score(:,1),score(:,2),'+')
xlabel('1st Principal Component')
ylabel('2nd Principal Component')

```

This plot shows the centered and scaled ratings data projected onto the first two principal components. pca computes the scores to have mean zero.

Note the outlying points in the right half of the plot. You can graphically identify these points as follows.
gname

Move your cursor over the plot and click once near the rightmost seven points. This labels the points by their row numbers as in the following figure.

After labeling points, press Return.
Create an index variable containing the row numbers of all the cities you chose and get the names of the cities.
```

metro = [43 65 179 213 234 270 314];
names(metro,:)
ans =
Boston, MA
Chicago, IL
Los Angeles, Long Beach, CA
New York, NY

```
```

Philadelphia, PA-NJ
San Francisco, CA
Washington, DC-MD-VA

```

These labeled cities are some of the biggest population centers in the United States and they appear more extreme than the remainder of the data.

\section*{Component variances and percent explained.}

The third output, latent, is a vector containing the variance explained by the corresponding principal component. Each column of score has a sample variance equal to the corresponding row of latent.
latent
latent =
3.4083
1.2140
1.1415
0.9209
0.7533
0.6306
0.4930
0.3180
0.1204

The fifth output, explained, is a vector containing the percent variance explained by the corresponding principal component.
explained
explained =
37.8699
13.4886
12.6831
10.2324
8.3698
7.0062
5.4783
\[
\begin{aligned}
& 3.5338 \\
& 1.3378
\end{aligned}
\]

Make a scree plot of the percent variability explained by each principal component.
```

figure()
pareto(explained)
xlabel('Principal Component')
ylabel('Variance Explained (%)')

```

This scree plot only shows the first seven (instead of the total nine) components that explain \(95 \%\) of the total variance. The only clear break in
the amount of variance accounted for by each component is between the first and second components. However, the first component by itself explains less than \(40 \%\) of the variance, so more components might be needed. You can see that the first three principal components explain roughly two-thirds of the total variability in the standardized ratings, so that might be a reasonable way to reduce the dimensions.

\section*{Hotelling's T-squared statistic.}

The last output of pca is tsquared, which is Hotelling's \(\mathrm{T}^{2}\), a statistical measure of the multivariate distance of each observation from the center of the data set. This is an analytical way to find the most extreme points in the data.
```

[st2,index] = sort(tsquared,'descend'); % sort in descending order
extreme = index(1)
extreme =

```
    213
names(extreme,:)
ans =
New York, NY

The ratings for New York are the furthest from the average U.S. city.

\section*{Visualize the results.}

Visualize both the orthonormal principal component coefficients for each variable and the principal component scores for each observation in a single plot.
```

biplot(coefforth(:,1:2),'scores',score(:,1:2),'varlabels',categories);

```
axis([-. 26 0.6-.51 .51]);

All nine variables are represented in this bi-plot by a vector, and the direction and length of the vector indicate how each variable contributes to the two principal components in the plot. For example, the first principal component, on the horizontal axis, has positive coefficients for all nine variables. That is why the nine vectors are directed into the right half of the plot. The largest coefficients in the first principal component are the third and seventh elements, corresponding to the variables health and arts.

The second principal component, on the vertical axis, has positive coefficients for the variables education, health, arts, and transportation, and negative coefficients for the remaining five variables. This indicates that the
second component distinguishes among cities that have high values for the first set of variables and low for the second, and cities that have the opposite.

The variable labels in this figure are somewhat crowded. You can either exclude the VarLabels parameter when making the plot, or select and drag some of the labels to better positions using the Edit Plot tool from the figure window toolbar.

This 2-D bi-plot also includes a point for each of the 329 observations, with coordinates indicating the score of each observation for the two principal components in the plot. For example, points near the left edge of this plot have the lowest scores for the first principal component. The points are scaled with respect to the maximum score value and maximum coefficient length, so only their relative locations can be determined from the plot.

You can identify items in the plot by selecting Tools>Data Cursor from the figure window. By clicking a variable (vector), you can read that variable's coefficients for each principal component. By clicking an observation (point), you can read that observation's scores for each principal component.

You can also make a bi-plot in three dimensions.
```

figure()
biplot(coefforth(:,1:3),'scores',score(:,1:3),'obslabels',names);
axis([-. 26 0.8 -. 51 .51 -. 61 . 81]);
view([30 40]);

```

\section*{Component 1}

This graph is useful if the first two principal coordinates do not explain enough of the variance in your data. You can also rotate the figure to see it from different angles by selecting theTools> Rotate 3D.

\section*{Factor Analysis}
- "Introduction to Factor Analysis" on page 12-93
- "Example: Factor Analysis" on page 12-93

\section*{Introduction to Factor Analysis}

Multivariate data often includes a large number of measured variables, and sometimes those variables overlap, in the sense that groups of them might be dependent. For example, in a decathlon, each athlete competes in 10 events, but several of them can be thought of as speed events, while others can be thought of as strength events, etc. Thus, you can think of a competitor's 10 event scores as largely dependent on a smaller set of three or four types of athletic ability.

Factor analysis is a way to fit a model to multivariate data to estimate just this sort of interdependence. In a factor analysis model, the measured variables depend on a smaller number of unobserved (latent) factors. Because each factor might affect several variables in common, they are known as common factors. Each variable is assumed to be dependent on a linear combination of the common factors, and the coefficients are known as loadings. Each measured variable also includes a component due to independent random variability, known as specific variance because it is specific to one variable.

Specifically, factor analysis assumes that the covariance matrix of your data is of the form
\[
\sum_{x}=\Lambda \Lambda^{\mathrm{T}}+\Psi
\]
where \(\Lambda\) is the matrix of loadings, and the elements of the diagonal matrix \(\Psi\) are the specific variances. The function factoran fits the Factor Analysis model using maximum likelihood.

\section*{Example: Factor Analysis}
- "Factor Loadings" on page 12-94
- "Factor Rotation" on page 12-96
- "Factor Scores" on page 12-98
- "Visualize the Results" on page 12-99

Factor Loadings. Over the course of 100 weeks, the percent change in stock prices for ten companies has been recorded. Of the ten companies, the first four can be classified as primarily technology, the next three as financial, and the last three as retail. It seems reasonable that the stock prices for companies that are in the same sector might vary together as economic conditions change. Factor Analysis can provide quantitative evidence that companies within each sector do experience similar week-to-week changes in stock price.

In this example, you first load the data, and then call factoran, specifying a model fit with three common factors. By default, factoran computes rotated estimates of the loadings to try and make their interpretation simpler. But in this example, you specify an unrotated solution.

\section*{load stockreturns}
[Loadings,specificVar,T,stats] = ...
factoran(stocks,3,'rotate','none');

The first two factoran return arguments are the estimated loadings and the estimated specific variances. Each row of the loadings matrix represents one of the ten stocks, and each column corresponds to a common factor. With unrotated estimates, interpretation of the factors in this fit is difficult because most of the stocks contain fairly large coefficients for two or more factors.
```

Loadings
Loadings =

| 0.8885 | 0.2367 | -0.2354 |
| ---: | ---: | ---: |
| 0.7126 | 0.3862 | 0.0034 |
| 0.3351 | 0.2784 | -0.0211 |
| 0.3088 | 0.1113 | -0.1905 |
| 0.6277 | -0.6643 | 0.1478 |
| 0.4726 | -0.6383 | 0.0133 |
| 0.1133 | -0.5416 | 0.0322 |
| 0.6403 | 0.1669 | 0.4960 |
| 0.2363 | 0.5293 | 0.5770 |
| 0.1105 | 0.1680 | 0.5524 |

```

Note "Factor Rotation" on page 12-96 helps to simplify the structure in the Loadings matrix, to make it easier to assign meaningful interpretations to the factors.

From the estimated specific variances, you can see that the model indicates that a particular stock price varies quite a lot beyond the variation due to the common factors.
```

specificVar
specificVar =
0.0991
0.3431
0.8097
0.8559
0.1429
0.3691
0.6928
0.3162
0.3311
0.6544

```

A specific variance of 1 would indicate that there is no common factor component in that variable, while a specific variance of 0 would indicate that the variable is entirely determined by common factors. These data seem to fall somewhere in between.

The \(p\) value returned in the stats structure fails to reject the null hypothesis of three common factors, suggesting that this model provides a satisfactory explanation of the covariation in these data.
```

stats.p

```
ans =
    0.8144

To determine whether fewer than three factors can provide an acceptable fit, you can try a model with two common factors. The \(p\) value for this second fit is highly significant, and rejects the hypothesis of two factors, indicating that the simpler model is not sufficient to explain the pattern in these data.
```

[Loadings2,specificVar2,T2,stats2] = ...
factoran(stocks, 2,'rotate','none');
stats2.p
ans =
3.5610e-006

```

Factor Rotation. As the results illustrate, the estimated loadings from an unrotated factor analysis fit can have a complicated structure. The goal of factor rotation is to find a parameterization in which each variable has only a small number of large loadings. That is, each variable is affected by a small number of factors, preferably only one. This can often make it easier to interpret what the factors represent.

If you think of each row of the loadings matrix as coordinates of a point in \(M\)-dimensional space, then each factor corresponds to a coordinate axis. Factor rotation is equivalent to rotating those axes and computing new loadings in the rotated coordinate system. There are various ways to do this. Some methods leave the axes orthogonal, while others are oblique methods that change the angles between them. For this example, you can rotate the estimated loadings by using the promax criterion, a common oblique method.
[LoadingsPM,specVarPM] = factoran(stocks,3,'rotate','promax'); LoadingsPM
LoadingsPM =
\begin{tabular}{rrr}
0.9452 & 0.1214 & -0.0617 \\
0.7064 & -0.0178 & 0.2058 \\
0.3885 & -0.0994 & 0.0975 \\
0.4162 & -0.0148 & -0.1298 \\
0.1021 & 0.9019 & 0.0768 \\
0.0873 & 0.7709 & -0.0821 \\
-0.1616 & 0.5320 & -0.0888 \\
0.2169 & 0.2844 & 0.6635 \\
0.0016 & -0.1881 & 0.7849 \\
-0.2289 & 0.0636 & 0.6475
\end{tabular}

Promax rotation creates a simpler structure in the loadings, one in which most of the stocks have a large loading on only one factor. To see this structure more clearly, you can use the biplot function to plot each stock using its factor loadings as coordinates.
```

biplot(LoadingsPM, 'varlabels', num2str((1:10)'));
axis square
view(155,27);

```

This plot shows that promax has rotated the factor loadings to a simpler structure. Each stock depends primarily on only one factor, and it is possible to describe each factor in terms of the stocks that it affects. Based on which companies are near which axes, you could reasonably conclude that the first factor axis represents the financial sector, the second retail, and the third technology. The original conjecture, that stocks vary primarily within sector, is apparently supported by the data.

Factor Scores. Sometimes, it is useful to be able to classify an observation based on its factor scores. For example, if you accepted the three-factor model and the interpretation of the rotated factors, you might want to categorize each week in terms of how favorable it was for each of the three stock sectors, based on the data from the 10 observed stocks.

Because the data in this example are the raw stock price changes, and not just their correlation matrix, you can have factoran return estimates of the value of each of the three rotated common factors for each week. You can then plot the estimated scores to see how the different stock sectors were affected during each week.
```

[LoadingsPM,specVarPM,TPM,stats,F] = ...
factoran(stocks, 3,'rotate','promax');
plot3(F(:,1),F(:,2),F(:,3),'b.')
line([-4 4 NaN O O NaN O 0], [O O NaN -4 4 NaN O 0],...
[0 O NaN O O NaN -4 4], 'Color','black')
xlabel('Financial Sector')
ylabel('Retail Sector')
zlabel('Technology Sector')
grid on
axis square
view(-22.5, 8)

```

Oblique rotation often creates factors that are correlated. This plot shows some evidence of correlation between the first and third factors, and you can investigate further by computing the estimated factor correlation matrix.
```

inv(TPM'*TPM)
ans =

| 1.0000 | 0.1559 | 0.4082 |
| ---: | ---: | ---: |
| 0.1559 | 1.0000 | -0.0559 |
| 0.4082 | -0.0559 | 1.0000 |

```

Visualize the Results. You can use the biplot function to help visualize both the factor loadings for each variable and the factor scores for each observation in a single plot. For example, the following command plots the results from the factor analysis on the stock data and labels each of the 10 stocks.
```

biplot(LoadingsPM,'scores',F,'varlabels',num2str((1:10)'))
xlabel('Financial Sector')
ylabel('Retail Sector')
zlabel('Technology Sector')
axis square
view(155,27)

```

In this case, the factor analysis includes three factors, and so the biplot is three-dimensional. Each of the 10 stocks is represented in this plot by a vector, and the direction and length of the vector indicates how each stock depends on the underlying factors. For example, you have seen that after promax rotation, the first four stocks have positive loadings on the first factor, and unimportant loadings on the other two factors. That first factor, interpreted as a financial sector effect, is represented in this biplot as one of the horizontal axes. The dependence of those four stocks on that factor corresponds to the four vectors directed approximately along that axis. Similarly, the dependence
of stocks 5,6 , and 7 primarily on the second factor, interpreted as a retail sector effect, is represented by vectors directed approximately along that axis.

Each of the 100 observations is represented in this plot by a point, and their locations indicate the score of each observation for the three factors. For example, points near the top of this plot have the highest scores for the technology sector factor. The points are scaled to fit within the unit square, so only their relative locations can be determined from the plot.

You can use the Data Cursor tool from the Tools menu in the figure window to identify the items in this plot. By clicking a stock (vector), you can read off that stock's loadings for each factor. By clicking an observation (point), you can read off that observation's scores for each factor.

\section*{Partial Least Squares Regression and Principal Components Regression}

This example shows how to apply Partial Least Squares Regression (PLSR) and Principal Components Regression (PCR), and discusses the effectiveness of the two methods. PLSR and PCR are both methods to model a response variable when there are a large number of predictor variables, and those predictors are highly correlated or even collinear. Both methods construct new predictor variables, known as components, as linear combinations of the original predictor variables, but they construct those components in different ways. PCR creates components to explain the observed variability in the predictor variables, without considering the response variable at all. On the other hand, PLSR does take the response variable into account, and therefore often leads to models that are able to fit the response variable with fewer components. Whether or not that ultimately translates into a more parsimonious model, in terms of its practical use, depends on the context.

\section*{Loading the Data}

Load a data set comprising spectral intensities of 60 samples of gasoline at 401 wavelengths, and their octane ratings. These data are described in Kalivas, John H., "Two Data Sets of Near Infrared Spectra," Chemometrics and Intelligent Laboratory Systems, v. 37 (1997) pp.255-259.
```

load spectra
whos NIR octane

```
\begin{tabular}{llrlr} 
Name & Size & Bytes Class & Attributes \\
NIR & \(60 \times 401\) & 192480 & double \\
octane & \(60 \times 1\) & 480 & double
\end{tabular}
```

[dummy,h] = sort(octane);
oldorder = get(gcf,'DefaultAxesColorOrder');
set(gcf,'DefaultAxesColorOrder',jet(60));
plot3(repmat(1:401,60,1)',repmat(octane(h),1,401)',NIR(h,: )');
set(gcf,'DefaultAxesColorOrder',oldorder);
xlabel('Wavelength Index'); ylabel('Octane'); axis('tight');
grid on

```

\section*{Fitting the Data with Two Components}

Use the plsregress function to fit a PLSR model with ten PLS components and one response.
```

X = NIR;
y = octane;
[n,p] = size(X);
[Xloadings,Yloadings,Xscores,Yscores,betaPLS10,PLSPctVar] = plsregress(...
X,y,10);

```

Ten components may be more than will be needed to adequately fit the data, but diagnostics from this fit can be used to make a choice of a simpler model with fewer components. For example, one quick way to choose the number of components is to plot the percent of variance explained in the response variable as a function of the number of components.
```

plot(1:10,cumsum(100*PLSPctVar(2,:)),'-bo');
xlabel('Number of PLS components');
ylabel('Percent Variance Explained in Y');

```

In practice, more care would probably be advisable in choosing the number of components. Cross-validation, for instance, is a widely-used method that will be illustrated later in this example. For now, the above plot suggests that PLSR with two components explains most of the variance in the observed \(y\). Compute the fitted response values for the two-component model.
[Xloadings, Yloadings, Xscores,Yscores,betaPLS] = plsregress(X,y,2); yfitPLS = [ones(n,1) X]*betaPLS;

Next, fit a PCR model with two principal components. The first step is to perform Principal Components Analysis on X, using the pca function, and retaining two principal components. PCR is then just a linear regression of the response variable on those two components. It often makes sense to
normalize each variable first by its standard deviation when the variables have very different amounts of variability, however, that is not done here.
```

[PCALoadings,PCAScores,PCAVar] = pca(X,'Economy',false);
betaPCR = regress(y-mean(y), PCAScores(:,1:2));

```

To make the PCR results easier to interpret in terms of the original spectral data, transform to regression coefficients for the original, uncentered variables.
```

betaPCR = PCALoadings(:,1:2)*betaPCR;
betaPCR = [mean(y) - mean(X)*betaPCR; betaPCR];
yfitPCR = [ones(n,1) X]*betaPCR;

```

Plot fitted vs. observed response for the PLSR and PCR fits.
```

plot(y,yfitPLS,'bo',y,yfitPCR,'r^');
xlabel('Observed Response');
ylabel('Fitted Response');
legend({'PLSR with 2 Components' 'PCR with 2 Components'}, ...
'location','NW');

```

In a sense, the comparison in the plot above is not a fair one -- the number of components (two) was chosen by looking at how well a two-component PLSR model predicted the response, and there's no reason why the PCR model should be restricted to that same number of components. With the same number of components, however, PLSR does a much better job at fitting y. In fact, looking at the horizontal scatter of fitted values in the plot above, PCR with two components is hardly better than using a constant model. The \(r\)-squared values from the two regressions confirm that.
```

TSS = sum((y-mean(y)).^2);
RSS_PLS = sum((y-yfitPLS).^2);
rsquaredPLS = 1 - RSS_PLS/TSS

```
```

    0.9466
    RSS_PCR = sum((y-yfitPCR).^2);
rsquaredPCR = 1 - RSS_PCR/TSS
rsquaredPCR =
0.1962

```

Another way to compare the predictive power of the two models is to plot the response variable against the two predictors in both cases.
plot3(Xscores(:,1),Xscores(:,2),y-mean(y),'bo');
legend('PLSR');
grid on; view(-30,30);

It's a little hard to see without being able to interactively rotate the figure, but the PLSR plot above shows points closely scattered about a plane. On the other hand, the PCR plot below shows a cloud of points with little indication of a linear relationship.
plot3(PCAScores(:,1),PCAScores(:,2),y-mean(y),'r^');
legend('PCR');
grid on; view(-30,30);

Notice that while the two PLS components are much better predictors of the observed \(y\), the following figure shows that they explain somewhat less variance in the observed \(X\) than the first two principal components used in the PCR.
```

plot(1:10,100*cumsum(PLSPctVar(1,:)),'b-o',1:10, ...
100*cumsum(PCAVar(1:10))/sum(PCAVar(1:10)),'r-^');
xlabel('Number of Principal Components');
ylabel('Percent Variance Explained in X');
legend({'PLSR' 'PCR'},'location','SE');

```

The fact that the PCR curve is uniformly higher suggests why PCR with two components does such a poor job, relative to PLSR, in fitting y. PCR constructs components to best explain \(X\), and as a result, those first two components ignore the information in the data that is important in fitting the observed \(y\).

\section*{Fitting with More Components}

As more components are added in PCR, it will necessarily do a better job of fitting the original data \(y\), simply because at some point most of the important predictive information in X will be present in the principal components. For example, the following figure shows that the difference in residuals for the two methods is much less dramatic when using ten components than it was for two components.
```

yfitPLS10 = [ones(n,1) X]*betaPLS10;
betaPCR10 = regress(y-mean(y), PCAScores(:,1:10));
betaPCR10 = PCALoadings(:,1:10)*betaPCR10;

```
```

betaPCR10 = [mean(y) - mean(X)*betaPCR10; betaPCR10];
yfitPCR10 = [ones(n,1) X]*betaPCR10;
plot(y,yfitPLS10,'bo',y,yfitPCR10,'r^');
xlabel('Observed Response');
ylabel('Fitted Response');
legend({'PLSR with 10 components' 'PCR with 10 Components'}, ...
'location','NW');

```

Both models fit y fairly accurately, although PLSR still makes a slightly more accurate fit. However, ten components is still an arbitrarily-chosen number for either model.

\section*{Choosing the Number of Components with Cross-Validation}

It's often useful to choose the number of components to minimize the expected error when predicting the response from future observations on the predictor
variables. Simply using a large number of components will do a good job in fitting the current observed data, but is a strategy that leads to overfitting. Fitting the current data too well results in a model that does not generalize well to other data, and gives an overly-optimistic estimate of the expected error.

Cross-validation is a more statistically sound method for choosing the number of components in either PLSR or PCR. It avoids overfitting data by not reusing the same data to both fit a model and to estimate prediction error. Thus, the estimate of prediction error is not optimistically biased downwards.
plsregress has an option to estimate the mean squared prediction error (MSEP) by cross-validation, in this case using 10 -fold C-V.
[Xl, Yl, Xs,Ys,beta, pctVar,PLSmsep] = plsregress(X,y,10,'CV',10);
For PCR, crossval combined with a simple function to compute the sum of squared errors for PCR, can estimate the MSEP, again using 10 -fold cross-validation.

PCRmsep = sum(crossval(@pcrsse, X,y,'KFold',10),1) / n;
The MSEP curve for PLSR indicates that two or three components does about as good a job as possible. On the other hand, PCR needs four components to get the same prediction accuracy.
```

plot(0:10,PLSmsep(2,:),'b-o',0:10,PCRmsep,'r-^');
xlabel('Number of components');
ylabel('Estimated Mean Squared Prediction Error');
legend({'PLSR' 'PCR'},'location','NE');

```

In fact, the second component in PCR increases the prediction error of the model, suggesting that the combination of predictor variables contained in that component is not strongly correlated with y. Again, that's because PCR constructs components to explain variation in X , not y .

\section*{Model Parsimony}

So if PCR requires four components to get the same prediction accuracy as PLSR with three components, is the PLSR model more parsimonious? That depends on what aspect of the model you consider.

The PLS weights are the linear combinations of the original variables that define the PLS components, i.e., they describe how strongly each component in the PLSR depends on the original variables, and in what direction.
```

[Xl,Yl,Xs,Ys,beta,pctVar,mse,stats] = plsregress(X,y,3);
plot(1:401,stats.W,' -');

```
```

xlabel('Variable');
ylabel('PLS Weight');
legend({'1st Component' '2nd Component' '3rd Component'}, ...
'location','NW');

```

Similarly, the PCA loadings describe how strongly each component in the PCR depends on the original variables.
```

plot(1:401,PCALoadings(:,1:4),'-');
xlabel('Variable');
ylabel('PCA Loading');
legend({'1st Component' '2nd Component' '3rd Component' ...
'4th Component'},'location','NW');

```

For either PLSR or PCR, it may be that each component can be given a physically meaningful interpretation by inspecting which variables it weights most heavily. For instance, with these spectral data it may be possible to interpret intensity peaks in terms of compounds present in the gasoline, and then to observe that weights for a particular component pick out a small number of those compounds. From that perspective, fewer components are simpler to interpret, and because PLSR often requires fewer components to predict the response adequately, it leads to more parsimonious models.

On the other hand, both PLSR and PCR result in one regression coefficient for each of the original predictor variables, plus an intercept. In that sense, neither is more parsimonious, because regardless of how many components are used, both models depend on all predictors. More concretely, for these data, both models need 401 spectral intensity values in order to make a prediction.

However, the ultimate goal may to reduce the original set of variables to a smaller subset still able to predict the response accurately. For example, it may be possible to use the PLS weights or the PCA loadings to select only those variables that contribute most to each component. As shown earlier, some components from a PCR model fit may serve primarily to describe the variation in the predictor variables, and may include large weights for variables that are not strongly correlated with the response. Thus, PCR can lead to retaining variables that are unnecessary for prediction.

For the data used in this example, the difference in the number of components needed by PLSR and PCR for accurate prediction is not great, and the PLS weights and PCA loadings seem to pick out the same variables. That may not be true for other data.

\section*{Cluster Analysis}
- "Introduction to Cluster Analysis" on page 13-2
- "Hierarchical Clustering" on page 13-3
- "k-Means Clustering" on page 13-21
- "Gaussian Mixture Models" on page 13-28

\section*{Introduction to Cluster Analysis}

Cluster analysis, also called segmentation analysis or taxonomy analysis, creates groups, or clusters, of data. Clusters are formed in such a way that objects in the same cluster are very similar and objects in different clusters are very distinct. Measures of similarity depend on the application.
"Hierarchical Clustering" on page 13-3 groups data over a variety of scales by creating a cluster tree or dendrogram. The tree is not a single set of clusters, but rather a multilevel hierarchy, where clusters at one level are joined as clusters at the next level. This allows you to decide the level or scale of clustering that is most appropriate for your application. The Statistics Toolbox function clusterdata performs all of the necessary steps for you. It incorporates the pdist, linkage, and cluster functions, which may be used separately for more detailed analysis. The dendrogram function plots the cluster tree.
" k -Means Clustering" on page \(13-21\) is a partitioning method. The function kmeans partitions data into \(k\) mutually exclusive clusters, and returns the index of the cluster to which it has assigned each observation. Unlike hierarchical clustering, k -means clustering operates on actual observations (rather than the larger set of dissimilarity measures), and creates a single level of clusters. The distinctions mean that k -means clustering is often more suitable than hierarchical clustering for large amounts of data.
"Gaussian Mixture Models" on page 13-28 form clusters by representing the probability density function of observed variables as a mixture of multivariate normal densities. Mixture models of the gmdistribution class use an expectation maximization (EM) algorithm to fit data, which assigns posterior probabilities to each component density with respect to each observation. Clusters are assigned by selecting the component that maximizes the posterior probability. Clustering using Gaussian mixture models is sometimes considered a soft clustering method. The posterior probabilities for each point indicate that each data point has some probability of belonging to each cluster. Like k-means clustering, Gaussian mixture modeling uses an iterative algorithm that converges to a local optimum. Gaussian mixture modeling may be more appropriate than k -means clustering when clusters have different sizes and correlation within them.

\section*{Introduction to Hierarchical Clustering}

Hierarchical clustering groups data over a variety of scales by creating a cluster tree or dendrogram. The tree is not a single set of clusters, but rather a multilevel hierarchy, where clusters at one level are joined as clusters at the next level. This allows you to decide the level or scale of clustering that is most appropriate for your application. The Statistics Toolbox function clusterdata supports agglomerative clustering and performs all of the necessary steps for you. It incorporates the pdist, linkage, and cluster functions, which you can use separately for more detailed analysis. The dendrogram function plots the cluster tree.

\section*{Algorithm Description}

To perform agglomerative hierarchical cluster analysis on a data set using Statistics Toolbox functions, follow this procedure:

1 Find the similarity or dissimilarity between every pair of objects in the data set. In this step, you calculate the distance between objects using the pdist function. The pdist function supports many different ways to compute this measurement. See "Similarity Measures" on page 13-4 for more information.

2 Group the objects into a binary, hierarchical cluster tree. In this step, you link pairs of objects that are in close proximity using the linkage
function. The linkage function uses the distance information generated in step 1 to determine the proximity of objects to each other. As objects are paired into binary clusters, the newly formed clusters are grouped into larger clusters until a hierarchical tree is formed. See "Linkages" on page 13-6 for more information.

3 Determine where to cut the hierarchical tree into clusters. In this step, you use the cluster function to prune branches off the bottom of the hierarchical tree, and assign all the objects below each cut to a single cluster. This creates a partition of the data. The cluster function can create these clusters by detecting natural groupings in the hierarchical tree or by cutting off the hierarchical tree at an arbitrary point.

The following sections provide more information about each of these steps.

Note The Statistics Toolbox function clusterdata performs all of the necessary steps for you. You do not need to execute the pdist, linkage, or cluster functions separately.

\section*{Similarity Measures}

You use the pdist function to calculate the distance between every pair of objects in a data set. For a data set made up of \(m\) objects, there are \(m^{*}(m-\) \(1) / 2\) pairs in the data set. The result of this computation is commonly known as a distance or dissimilarity matrix.

There are many ways to calculate this distance information. By default, the pdist function calculates the Euclidean distance between objects; however, you can specify one of several other options. See pdist for more information.

Note You can optionally normalize the values in the data set before calculating the distance information. In a real world data set, variables can be measured against different scales. For example, one variable can measure Intelligence Quotient (IQ) test scores and another variable can measure head circumference. These discrepancies can distort the proximity calculations. Using the zscore function, you can convert all the values in the data set to use the same proportional scale. See zscore for more information.

For example, consider a data set, X , made up of five objects where each object is a set of \(x, y\) coordinates.
- Object 1: 1, 2
- Object 2: 2.5, 4.5
- Object 3: 2, 2
- Object 4: 4, 1.5
- Object 5: 4, 2.5

You can define this data set as a matrix
\(X=[12 ; 2.54 .5 ; 22 ; 41.5 ; 42.5]\)
and pass it to pdist. The pdist function calculates the distance between object 1 and object 2 , object 1 and object 3 , and so on until the distances between all the pairs have been calculated. The following figure plots these objects in a graph. The Euclidean distance between object 2 and object 3 is shown to illustrate one interpretation of distance.

\section*{Distance Information}

The pdist function returns this distance information in a vector, Y , where each element contains the distance between a pair of objects.
```

Y = pdist(X)
Y =
Columns 1 through 5
2.9155 1.0000 3.0414 3.0414 2.5495
Columns 6 through 10
3.3541 2.5000 2.0616 2.0616 1.0000

```

To make it easier to see the relationship between the distance information generated by pdist and the objects in the original data set, you can reformat the distance vector into a matrix using the squareform function. In this matrix, element \(i, j\) corresponds to the distance between object \(i\) and object \(j\) in the original data set. In the following example, element 1,1 represents the distance between object 1 and itself (which is zero). Element 1,2 represents the distance between object 1 and object 2 , and so on.
```

squareform(Y)
ans =

| 0 | 2.9155 | 1.0000 | 3.0414 | 3.0414 |
| ---: | ---: | ---: | ---: | ---: |
| 2.9155 | 0 | 2.5495 | 3.3541 | 2.5000 |
| 1.0000 | 2.5495 | 0 | 2.0616 | 2.0616 |
| 3.0414 | 3.3541 | 2.0616 | 0 | 1.0000 |
| 3.0414 | 2.5000 | 2.0616 | 1.0000 | 0 |

```

\section*{Linkages}

Once the proximity between objects in the data set has been computed, you can determine how objects in the data set should be grouped into clusters, using the linkage function. The linkage function takes the distance information generated by pdist and links pairs of objects that are close together into binary clusters (clusters made up of two objects). The linkage function then links these newly formed clusters to each other and to other objects to create bigger clusters until all the objects in the original data set are linked together in a hierarchical tree.

For example, given the distance vector \(Y\) generated by pdist from the sample data set of \(x\) - and \(y\)-coordinates, the linkage function generates a hierarchical cluster tree, returning the linkage information in a matrix, \(Z\).
```

Z = linkage(Y)
Z =
4.0000 5.0000 1.0000

```
\begin{tabular}{lll}
1.0000 & 3.0000 & 1.0000 \\
6.0000 & 7.0000 & 2.0616 \\
2.0000 & 8.0000 & 2.5000
\end{tabular}

In this output, each row identifies a link between objects or clusters. The first two columns identify the objects that have been linked. The third column contains the distance between these objects. For the sample data set of \(x\) and \(y\)-coordinates, the linkage function begins by grouping objects 4 and 5, which have the closest proximity (distance value \(=1.0000\) ). The linkage function continues by grouping objects 1 and 3 , which also have a distance value of 1.0000 .

The third row indicates that the linkage function grouped objects 6 and 7. If the original sample data set contained only five objects, what are objects 6 and 7 ? Object 6 is the newly formed binary cluster created by the grouping of objects 4 and 5 . When the linkage function groups two objects into a new cluster, it must assign the cluster a unique index value, starting with the value \(m+1\), where \(m\) is the number of objects in the original data set. (Values 1 through \(m\) are already used by the original data set.) Similarly, object 7 is the cluster formed by grouping objects 1 and 3 .
linkage uses distances to determine the order in which it clusters objects. The distance vector \(Y\) contains the distances between the original objects 1 through 5. But linkage must also be able to determine distances involving clusters that it creates, such as objects 6 and 7 . By default, linkage uses a method known as single linkage. However, there are a number of different methods available. See the linkage reference page for more information.

As the final cluster, the linkage function grouped object 8, the newly formed cluster made up of objects 6 and 7 , with object 2 from the original data set. The following figure graphically illustrates the way linkage groups the objects into a hierarchy of clusters.

\section*{Dendrograms}

The hierarchical, binary cluster tree created by the linkage function is most easily understood when viewed graphically. The Statistics Toolbox function dendrogram plots the tree, as follows:
dendrogram(Z)

In the figure, the numbers along the horizontal axis represent the indices of the objects in the original data set. The links between objects are represented as upside-down \(U\)-shaped lines. The height of the \(U\) indicates the distance between the objects. For example, the link representing the cluster containing objects 1 and 3 has a height of 1 . The link representing the cluster that groups object 2 together with objects 1, 3, 4, and 5, (which are already clustered as object 8 ) has a height of 2.5 . The height represents the distance linkage computes between objects 2 and 8 . For more information about creating a dendrogram diagram, see the dendrogram reference page.

\section*{Verify the Cluster Tree}

After linking the objects in a data set into a hierarchical cluster tree, you might want to verify that the distances (that is, heights) in the tree reflect the original distances accurately. In addition, you might want to investigate natural divisions that exist among links between objects. Statistics Toolbox functions are available for both of these tasks, as described in the following sections:
- "Verify Dissimilarity" on page 13-10
- "Verify Consistency" on page 13-11

\section*{Verify Dissimilarity}

In a hierarchical cluster tree, any two objects in the original data set are eventually linked together at some level. The height of the link represents the distance between the two clusters that contain those two objects. This height is known as the cophenetic distance between the two objects. One way to measure how well the cluster tree generated by the linkage function reflects your data is to compare the cophenetic distances with the original distance data generated by the pdist function. If the clustering is valid, the linking of objects in the cluster tree should have a strong correlation with the distances between objects in the distance vector. The cophenet function compares these two sets of values and computes their correlation, returning a value called the cophenetic correlation coefficient. The closer the value of the cophenetic correlation coefficient is to 1 , the more accurately the clustering solution reflects your data.

You can use the cophenetic correlation coefficient to compare the results of clustering the same data set using different distance calculation methods or clustering algorithms. For example, you can use the cophenet function to evaluate the clusters created for the sample data set
```

c = cophenet(Z,Y)
c =
0.8615

```
where \(Z\) is the matrix output by the linkage function and \(Y\) is the distance vector output by the pdist function.

Execute pdist again on the same data set, this time specifying the city block metric. After running the linkage function on this new pdist output using the average linkage method, call cophenet to evaluate the clustering solution.
```

Y = pdist(X,'cityblock');
Z = linkage(Y,'average');
c = cophenet(Z,Y)
c =
0.9047

```

The cophenetic correlation coefficient shows that using a different distance and linkage method creates a tree that represents the original distances slightly better.

\section*{Verify Consistency}

One way to determine the natural cluster divisions in a data set is to compare the height of each link in a cluster tree with the heights of neighboring links below it in the tree.

A link that is approximately the same height as the links below it indicates that there are no distinct divisions between the objects joined at this level of the hierarchy. These links are said to exhibit a high level of consistency, because the distance between the objects being joined is approximately the same as the distances between the objects they contain.

On the other hand, a link whose height differs noticeably from the height of the links below it indicates that the objects joined at this level in the cluster tree are much farther apart from each other than their components were when they were joined. This link is said to be inconsistent with the links below it.

In cluster analysis, inconsistent links can indicate the border of a natural division in a data set. The cluster function uses a quantitative measure of inconsistency to determine where to partition your data set into clusters.

The following dendrogram illustrates inconsistent links. Note how the objects in the dendrogram fall into two groups that are connected by links at a much higher level in the tree. These links are inconsistent when compared with the links below them in the hierarchy.

These links show inconsistency when compared to the links below them.

These links show consistency.

The relative consistency of each link in a hierarchical cluster tree can be quantified and expressed as the inconsistency coefficient. This value compares the height of a link in a cluster hierarchy with the average height of links below it. Links that join distinct clusters have a high inconsistency coefficient; links that join indistinct clusters have a low inconsistency coefficient.

To generate a listing of the inconsistency coefficient for each link in the cluster tree, use the inconsistent function. By default, the inconsistent
function compares each link in the cluster hierarchy with adjacent links that are less than two levels below it in the cluster hierarchy. This is called the depth of the comparison. You can also specify other depths. The objects at the bottom of the cluster tree, called leaf nodes, that have no further objects below them, have an inconsistency coefficient of zero. Clusters that join two leaves also have a zero inconsistency coefficient.

For example, you can use the inconsistent function to calculate the inconsistency values for the links created by the linkage function in "Linkages" on page 13-6.
```

I = inconsistent(Z)
I =

| 1.0000 | 0 | 1.0000 | 0 |
| ---: | ---: | ---: | ---: |
| 1.0000 | 0 | 1.0000 | 0 |
| 1.3539 | 0.6129 | 3.0000 | 1.1547 |
| 2.2808 | 0.3100 | 2.0000 | 0.7071 |

```

The inconsistent function returns data about the links in an ( \(m-1\) )-by- 4 matrix, whose columns are described in the following table.
\begin{tabular}{l|l}
\hline Column & Description \\
\hline 1 & Mean of the heights of all the links included in the calculation \\
\hline 2 & Standard deviation of all the links included in the calculation \\
\hline 3 & Number of links included in the calculation \\
\hline 4 & Inconsistency coefficient \\
\hline
\end{tabular}

In the sample output, the first row represents the link between objects 4 and 5 . This cluster is assigned the index 6 by the linkage function. Because both 4 and 5 are leaf nodes, the inconsistency coefficient for the cluster is zero. The second row represents the link between objects 1 and 3 , both of which are also leaf nodes. This cluster is assigned the index 7 by the linkage function.

The third row evaluates the link that connects these two clusters, objects 6 and 7. (This new cluster is assigned index 8 in the linkage output). Column 3 indicates that three links are considered in the calculation: the link itself and the two links directly below it in the hierarchy. Column 1 represents the mean of the heights of these links. The inconsistent function uses the height
information output by the linkage function to calculate the mean. Column 2 represents the standard deviation between the links. The last column contains the inconsistency value for these links, 1.1547. It is the difference between the current link height and the mean, normalized by the standard deviation:
```

(2.0616 - 1.3539) / .6129
ans =
1.1547

```

The following figure illustrates the links and heights included in this calculation.

Note In the preceding figure, the lower limit on the \(y\)-axis is set to 0 to show the heights of the links. To set the lower limit to 0 , select Axes Properties from the Edit menu, click the \(\mathbf{Y}\) Axis tab, and enter 0 in the field immediately to the right of \(\mathbf{Y}\) Limits.

Row 4 in the output matrix describes the link between object 8 and object 2 . Column 3 indicates that two links are included in this calculation: the link itself and the link directly below it in the hierarchy. The inconsistency coefficient for this link is 0.7071 .

The following figure illustrates the links and heights included in this calculation.

\section*{Create Clusters}

After you create the hierarchical tree of binary clusters, you can prune the tree to partition your data into clusters using the cluster function. The cluster function lets you create clusters in two ways, as discussed in the following sections:
- "Find Natural Divisions in Data" on page 13-17
- "Specify Arbitrary Clusters" on page 13-18

\section*{Find Natural Divisions in Data}

The hierarchical cluster tree may naturally divide the data into distinct, well-separated clusters. This can be particularly evident in a dendrogram diagram created from data where groups of objects are densely packed in certain areas and not in others. The inconsistency coefficient of the links in the cluster tree can identify these divisions where the similarities between objects change abruptly. (See "Verify the Cluster Tree" on page 13-10 for more information about the inconsistency coefficient.) You can use this value to determine where the cluster function creates cluster boundaries.

For example, if you use the cluster function to group the sample data set into clusters, specifying an inconsistency coefficient threshold of 1.2 as the value of the cutoff argument, the cluster function groups all the objects in the sample data set into one cluster. In this case, none of the links in the cluster hierarchy had an inconsistency coefficient greater than 1.2.
```

T = cluster(Z,'cutoff',1.2)
T =
1
1
1
1
1

```

The cluster function outputs a vector, T , that is the same size as the original data set. Each element in this vector contains the number of the cluster into which the corresponding object from the original data set was placed.

If you lower the inconsistency coefficient threshold to 0.8 , the cluster function divides the sample data set into three separate clusters.
```

T = cluster(Z,'cutoff',0.8)
T =
3
2
3
1
1

```

This output indicates that objects 1 and 3 were placed in cluster 1, objects 4 and 5 were placed in cluster 2 , and object 2 was placed in cluster 3 .

When clusters are formed in this way, the cutoff value is applied to the inconsistency coefficient. These clusters may, but do not necessarily, correspond to a horizontal slice across the dendrogram at a certain height. If you want clusters corresponding to a horizontal slice of the dendrogram, you can either use the criterion option to specify that the cutoff should be based on distance rather than inconsistency, or you can specify the number of clusters directly as described in the following section.

\section*{Specify Arbitrary Clusters}

Instead of letting the cluster function create clusters determined by the natural divisions in the data set, you can specify the number of clusters you want created.

For example, you can specify that you want the cluster function to partition the sample data set into two clusters. In this case, the cluster function creates one cluster containing objects \(1,3,4\), and 5 and another cluster containing object 2 .
```

T = cluster(Z,'maxclust',2)

```
T =

2
1
2
2
2
To help you visualize how the cluster function determines these clusters, the following figure shows the dendrogram of the hierarchical cluster tree. The horizontal dashed line intersects two lines of the dendrogram, corresponding to setting 'maxclust' to 2. These two lines partition the objects into two clusters: the objects below the left-hand line, namely \(1,3,4\), and 5 , belong to one cluster, while the object below the right-hand line, namely 2 , belongs to the other cluster.

On the other hand, if you set 'maxclust' to 3 , the cluster function groups objects 4 and 5 in one cluster, objects 1 and 3 in a second cluster, and object 2 in a third cluster. The following command illustrates this.
```

T = cluster(Z,'maxclust',3)
T =

```
    1
    3
    1
    2
    2

This time, the cluster function cuts off the hierarchy at a lower point, corresponding to the horizontal line that intersects three lines of the dendrogram in the following figure.

\section*{k-Means Clustering}

\author{
In this section... \\ "Introduction to k-Means Clustering" on page 13-21 \\ "Create Clusters and Determine Separation" on page 13-22 \\ "Determine the Correct Number of Clusters" on page 13-23 \\ "Avoid Local Minima" on page 13-26
}

\section*{Introduction to k-Means Clustering}
k -means clustering is a partitioning method. The function kmeans partitions data into \(k\) mutually exclusive clusters, and returns the index of the cluster to which it has assigned each observation. Unlike hierarchical clustering, k -means clustering operates on actual observations (rather than the larger set of dissimilarity measures), and creates a single level of clusters. The distinctions mean that k-means clustering is often more suitable than hierarchical clustering for large amounts of data.
kmeans treats each observation in your data as an object having a location in space. It finds a partition in which objects within each cluster are as close to each other as possible, and as far from objects in other clusters as possible. You can choose from five different distance measures, depending on the kind of data you are clustering.

Each cluster in the partition is defined by its member objects and by its centroid, or center. The centroid for each cluster is the point to which the sum of distances from all objects in that cluster is minimized. kmeans computes cluster centroids differently for each distance measure, to minimize the sum with respect to the measure that you specify.
kmeans uses an iterative algorithm that minimizes the sum of distances from each object to its cluster centroid, over all clusters. This algorithm moves objects between clusters until the sum cannot be decreased further. The result is a set of clusters that are as compact and well-separated as possible. You can control the details of the minimization using several optional input parameters to kmeans, including ones for the initial values of the cluster centroids, and for the maximum number of iterations.

\section*{Create Clusters and Determine Separation}

The following example explores possible clustering in four-dimensional data by analyzing the results of partitioning the points into three, four, and five clusters.

Note Because each part of this example generates random numbers sequentially, i.e., without setting a new state, you must perform all steps in sequence to duplicate the results shown. If you perform the steps out of sequence, the answers will be essentially the same, but the intermediate results, number of iterations, or ordering of the silhouette plots may differ.

First, load some data:
```

load kmeansdata;
size(X)
ans =
560 4

```

Even though these data are four-dimensional, and cannot be easily visualized, kmeans enables you to investigate whether a group structure exists in them. Call kmeans with k, the desired number of clusters, equal to 3. For this example, specify the city block distance measure, and use the default starting method of initializing centroids from randomly selected data points:
```

idx3 = kmeans(X,3,'distance','city');

```

To get an idea of how well-separated the resulting clusters are, you can make a silhouette plot using the cluster indices output from kmeans. The silhouette plot displays a measure of how close each point in one cluster is to points in the neighboring clusters. This measure ranges from +1 , indicating points that are very distant from neighboring clusters, through 0 , indicating points that are not distinctly in one cluster or another, to -1 , indicating points that are probably assigned to the wrong cluster. silhouette returns these values in its first output:
```

[silh3,h] = silhouette(X,idx3,'city');
set(get(gca,'Children'),'FaceColor',[.8 . 8 1])
xlabel('Silhouette Value')
ylabel('Cluster')

```

From the silhouette plot, you can see that most points in the third cluster have a large silhouette value, greater than 0.6 , indicating that the cluster is somewhat separated from neighboring clusters. However, the first cluster contains many points with low silhouette values, and the second contains a few points with negative values, indicating that those two clusters are not well separated.

\section*{Determine the Correct Number of Clusters}

Increase the number of clusters to see if kmeans can find a better grouping of the data. This time, use the optional 'display ' parameter to print information about each iteration:
```

idx4 = kmeans(X,4, 'dist','city', 'display','iter');
iter phase num sum
1 1 560 2897.56

```
\begin{tabular}{ccrc}
2 & 1 & 53 & 2736.67 \\
3 & 1 & 50 & 2476.78 \\
4 & 1 & 102 & 1779.68 \\
5 & 1 & 5 & 1771.1 \\
6 & 2 & 0 & 1771.1 \\
6 iterations, total sum of distances \(=1771.1\)
\end{tabular}

Notice that the total sum of distances decreases at each iteration as kmeans reassigns points between clusters and recomputes cluster centroids. In this case, the second phase of the algorithm did not make any reassignments, indicating that the first phase reached a minimum after five iterations. In some problems, the first phase might not reach a minimum, but the second phase always will.

A silhouette plot for this solution indicates that these four clusters are better separated than the three in the previous solution:
```

[silh4,h] = silhouette(X,idx4,'city');
set(get(gca,'Children'),'FaceColor',[.8 . 8 1])
xlabel('Silhouette Value')
ylabel('Cluster')

```

A more quantitative way to compare the two solutions is to look at the average silhouette values for the two cases:
```

mean(silh3)
ans =
0.52594
mean(silh4)
ans =
0.63997

```

Finally, try clustering the data using five clusters:
```

idx5 = kmeans(X,5,'dist','city','replicates',5);
[silh5,h] = silhouette(X,idx5,'city');
set(get(gca,'Children'),'FaceColor',[.8 .8 1])
xlabel('Silhouette Value')

```
```

ylabel('Cluster')
mean(silh5)
ans =
0.52657

```

This silhouette plot indicates that this is probably not the right number of clusters, since two of the clusters contain points with mostly low silhouette values. Without some knowledge of how many clusters are really in the data, it is a good idea to experiment with a range of values for \(k\).

\section*{Avoid Local Minima}

Like many other types of numerical minimizations, the solution that kmeans reaches often depends on the starting points. It is possible for kmeans to reach a local minimum, where reassigning any one point to a new cluster would increase the total sum of point-to-centroid distances, but where a
better solution does exist. However, you can use the optional 'replicates' parameter to overcome that problem.

For four clusters, specify five replicates, and use the 'display ' parameter to print out the final sum of distances for each of the solutions.
```

[idx4,cent4,sumdist] = kmeans(X,4,'dist','city',...
'display','final','replicates',5);
17 iterations, total sum of distances = 2303.36
5 iterations, total sum of distances = 1771.1
6 iterations, total sum of distances = 1771.1
5 iterations, total sum of distances = 1771.1
8 iterations, total sum of distances = 2303.36

```

The output shows that, even for this relatively simple problem, non-global minima do exist. Each of these five replicates began from a different randomly selected set of initial centroids, and kmeans found two different local minima. However, the final solution that kmeans returns is the one with the lowest total sum of distances, over all replicates.
```

sum(sumdist)
ans =
1771.1

```

\section*{Gaussian Mixture Models}

\author{
In this section... \\ "Introduction to Gaussian Mixture Models" on page 13-28 \\ "Cluster with Gaussian Mixtures" on page 13-28
}

\section*{Introduction to Gaussian Mixture Models}

Gaussian mixture models are formed by combining multivariate normal density components.

In Statistics Toolbox software, use the gmdistribution class to fit data using an expectation maximization (EM) algorithm, which assigns posterior probabilities to each component density with respect to each observation.

Gaussian mixture models are often used for data clustering. Clusters are assigned by selecting the component that maximizes the posterior probability. Like k-means clustering, Gaussian mixture modeling uses an iterative algorithm that converges to a local optimum. Gaussian mixture modeling may be more appropriate than k -means clustering when clusters have different sizes and correlation within them. Clustering using Gaussian mixture models is sometimes considered a soft clustering method. The posterior probabilities for each point indicate that each data point has some probability of belonging to each cluster.

\section*{Cluster with Gaussian Mixtures}

Gaussian mixture distributions can be used for clustering data, by realizing that the multivariate normal components of the fitted model can represent clusters.

1 To demonstrate the process, first generate some simulated data from a mixture of two bivariate Gaussian distributions using the mvnrnd function:
```

mu1 = [11 2];
sigma1 = [3 .2; .2 2];
mu2 = [-1 -2];
sigma2 = [2 0; 0 1];

```

2 Fit a two-component Gaussian mixture distribution. Here, you know the correct number of components to use. In practice, with real data, this decision would require comparing models with different numbers of components.
```

options = statset('Display','final');
gm = gmdistribution.fit(X,2,'Options',options);

```

This displays
```

4 9 iterations, log-likelihood = -1207.91

```

3 Plot the estimated probability density contours for the two-component mixture distribution. The two bivariate normal components overlap, but their peaks are distinct. This suggests that the data could reasonably be divided into two clusters:
```

hold on
ezcontour(@(x,y)pdf(gm,[x y]),[-8 6],[-8 6]);
hold off

```

4 Partition the data into clusters using the cluster method for the fitted mixture distribution. The cluster method assigns each point to one of the two components in the mixture distribution.
idx = cluster(gm,X);
```

cluster1 = (idx == 1);
cluster2 = (idx == 2);
scatter(X(cluster1,1),X(cluster1,2),10,'r+');
hold on
scatter(X(cluster2,1),X(cluster2,2),10,'bo');
hold off
legend('Cluster 1','Cluster 2','Location','NW')

```

Each cluster corresponds to one of the bivariate normal components in the mixture distribution. cluster assigns points to clusters based on the estimated posterior probability that a point came from a component; each point is assigned to the cluster corresponding to the highest posterior probability. The posterior method returns those posterior probabilities.

For example, plot the posterior probability of the first component for each point:
```

P = posterior(gm,X);
scatter(X(cluster1,1),X(cluster1,2),10,P(cluster1,1), '+')
hold on
scatter(X(cluster2,1),X(cluster2,2),10,P(cluster2,1),'o')
hold off
legend('Cluster 1','Cluster 2','Location','NW')
clrmap = jet(80); colormap(clrmap(9:72,:))
ylabel(colorbar,'Component 1 Posterior Probability')

```

\section*{Soft Clustering Using Gaussian Mixture Distributions}

An alternative to the previous example is to use the posterior probabilities for "soft clustering". Each point is assigned a membership score to each cluster. Membership scores are simply the posterior probabilities, and describe how similar each point is to each cluster's archetype, i.e., the mean of the
corresponding component. The points can be ranked by their membership score in a given cluster:
```

[~,order] = sort(P(:,1));
plot(1:size(X,1),P(order,1),'r-',1:size(X,1),P(order,2),'b-');
legend({'Cluster 1 Score' 'Cluster 2 Score'},'location','NW');
ylabel('Cluster Membership Score');
xlabel('Point Ranking');

```

Although a clear separation of the data is hard to see in a scatter plot of the data, plotting the membership scores indicates that the fitted distribution does a good job of separating the data into groups. Very few points have scores close to 0.5 .

Soft clustering using a Gaussian mixture distribution is similar to fuzzy k -means clustering, which also assigns each point to each cluster with a membership score. The fuzzy k-means algorithm assumes that clusters are roughly spherical in shape, and all of roughly equal size. This is comparable to a Gaussian mixture distribution with a single covariance matrix that is shared across all components, and is a multiple of the identity matrix. In contrast, gmdistribution allows you to specify different covariance options. The default is to estimate a separate, unconstrained covariance matrix for each component. A more restricted option, closer to k-means, would be to estimate a shared, diagonal covariance matrix:
```

gm2 = gmdistribution.fit(X,2,'CovType','Diagonal',...
'SharedCov',true);

```

This covariance option is similar to fuzzy k-means clustering, but provides more flexibility by allowing unequal variances for different variables.

You can compute the soft cluster membership scores without computing hard cluster assignments, using posterior, or as part of hard clustering, as the second output from cluster:
```

P2 = posterior(gm2,X); % equivalently [idx,P2] = cluster(gm2,X)
[~,order] = sort(P2(:,1));
plot(1:size(X,1),P2(order,1),'r-',1:size(X,1),P2(order,2),'b-');
legend({'Cluster 1 Score' 'Cluster 2 Score'},'location','NW');
ylabel('Cluster Membership Score');
xlabel('Point Ranking');

```

\section*{Assign New Data to Clusters}

In the previous example, fitting the mixture distribution to data using fit, and clustering those data using cluster, are separate steps. However, the same data are used in both steps. You can also use the cluster method to assign new data points to the clusters (mixture components) found in the original data.

1 Given a data set X , first fit a Gaussian mixture distribution. The previous code has already done that.
gm
gm =
Gaussian mixture distribution with 2 components in 2 dimensions
```

Component 1:
Mixing proportion: 0.312592
Mean: -0.9082 -2.1109
Component 2:
Mixing proportion: 0.687408
Mean: 0.9532 1.8940

```

2 You can then use cluster to assign each point in a new data set, \(Y\), to one of the clusters defined for the original data:
```

Y = [mvnrnd(mu1,sigma1,50);mvnrnd(mu2,sigma2,25)];
idx = cluster(gm,Y);
cluster1 = (idx == 1);
cluster2 = (idx == 2);
scatter(Y(cluster1,1),Y(cluster1,2),10,'r+');
hold on
scatter(Y(cluster2,1),Y(cluster2,2),10,'bo');
hold off
legend('Class 1','Class 2','Location','NW')

```

As with the previous example, the posterior probabilities for each point can be treated as membership scores rather than determining "hard" cluster assignments.

For cluster to provide meaningful results with new data, Y should come from the same population as \(X\), the original data used to create the mixture distribution. In particular, the estimated mixing probabilities for the Gaussian mixture distribution fitted to \(X\) are used when computing the posterior probabilities for Y .

\section*{Parametric Classification}
- "Parametric Classification" on page 14-2
- "Discriminant Analysis" on page 14-3
- "Naive Bayes Classification" on page 14-36
- "Performance Curves" on page 14-39

\section*{Parametric Classification}

Models of data with a categorical response are called classifiers. A classifier is built from training data, for which classifications are known. The classifier assigns new test data to one of the categorical levels of the response.

Parametric methods, like "Discriminant Analysis" on page 14-3, fit a parametric model to the training data and interpolate to classify test data.

Nonparametric methods, like classification and regression trees, use other means to determine classifications.

\section*{Discriminant Analysis}

\author{
In this section... \\ "What Is Discriminant Analysis?" on page 14-3 \\ "Create Discriminant Analysis Classifiers" on page 14-3 \\ "Creating a Classifier Using ClassificationDiscriminant.fit" on page 14-4 \\ "How the predict Method Classifies" on page 14-6 \\ "Create and Visualize a Discriminant Analysis Classifier" on page 14-9 \\ "Improve a Discriminant Analysis Classifier" on page 14-14 \\ "Regularize a Discriminant Analysis Classifier" on page 14-22 \\ "Examine the Gaussian Mixture Assumption" on page 14-29 \\ "Bibliography" on page 14-35
}

\section*{What Is Discriminant Analysis?}

Discriminant analysis is a classification method. It assumes that different classes generate data based on different Gaussian distributions.
- To train (create) a classifier, the fitting function estimates the parameters of a Gaussian distribution for each class (see "Creating a Classifier Using ClassificationDiscriminant.fit" on page 14-4).
- To predict the classes of new data, the trained classifier finds the class with the smallest misclassification cost (see "How the predict Method Classifies" on page 14-6).

Linear discriminant analysis is also known as the Fisher discriminant, named for its inventor, Sir R. A. Fisher [2].

\section*{Create Discriminant Analysis Classifiers}

To create the basic types of discriminant analysis classifiers for the Fisher iris data:

1 Load the data:
load fisheriris;
2 Create a default (linear) discriminant analysis classifier:
```

linclass = ClassificationDiscriminant.fit(meas,species);

```

To visualize the classification boundaries of a 2-D linear classification of the data, see Linear Discriminant Classification - Fisher Training Data on page 14-12.

3 Classify an iris with average measurements:
```

meanmeas = mean(meas);
meanclass = predict(linclass,meanmeas)
meanclass =
'versicolor'

```

4 Create a quadratic classifier:
```

quadclass = ClassificationDiscriminant.fit(meas,species,...
'discrimType','quadratic');

```

To visualize the classification boundaries of a \(2-\mathrm{D}\) quadratic classification of the data, see Quadratic Discriminant Classification - Fisher Training Data on page 14-14.

5 Classify an iris with average measurements using the quadratic classifier:
```

meanclass2 = predict(quadclass,meanmeas)
meanclass2 =
'versicolor'

```

\section*{Creating a Classifier Using ClassificationDiscriminant.fit}

The model for discriminant analysis is:
- Each class \((Y)\) generates data \((X)\) using a multivariate normal distribution. In other words, the model assumes \(X\) has a Gaussian mixture distribution (gmdistribution).
- For linear discriminant analysis, the model has the same covariance matrix for each class; only the means vary.
- For quadratic discriminant analysis, both means and covariances of each class vary.

Under this modeling assumption, ClassificationDiscriminant.fit infers the mean and covariance parameters of each class.
- For linear discriminant analysis, it computes the sample mean of each class. Then it computes the sample covariance by first subtracting the sample mean of each class from the observations of that class, and taking the empirical covariance matrix of the result.
- For quadratic discriminant analysis, it computes the sample mean of each class. Then it computes the sample covariances by first subtracting the sample mean of each class from the observations of that class, and taking the empirical covariance matrix of each class.

The fit method does not use prior probabilities or costs for fitting.

\section*{Weighted Observations}

The fit method constructs weighted classifiers using the following scheme. Suppose \(M\) is an \(N\)-by- \(K\) class membership matrix:
\(M_{n k}=1\) if observation \(n\) is from class \(k\)
\(M_{n k}=0\) otherwise.
The estimate of the class mean for unweighted data is
\[
\hat{\mu}_{k}=\frac{\sum_{n=1}^{N} M_{n k} x_{n}}{\sum_{n=1}^{N} M_{n k}} .
\]

For weighted data with positive weights \(w_{n}\), the natural generalization is
\[
\hat{\mu}_{k}=\frac{\sum_{n=1}^{N} M_{n k} w_{n} x_{n}}{\sum_{n=1}^{N} M_{n k} w_{n}} .
\]

The unbiased estimate of the pooled-in covariance matrix for unweighted data is
\[
\hat{\Sigma}=\frac{\sum_{n=1}^{N} \sum_{k=1}^{K} M_{n k}\left(x_{n}-\hat{\mu}_{k}\right)\left(x_{n}-\hat{\mu}_{k}\right)^{T}}{N-K} .
\]

For quadratic discriminant analysis, the fit method uses \(K=1\).
For weighted data, assuming the weights sum to 1 , the unbiased estimate of the pooled-in covariance matrix is
\[
\hat{\Sigma}=\frac{\sum_{n=1}^{N} \sum_{k=1}^{K} M_{n k} w_{n}\left(x_{n}-\hat{\mu}_{k}\right)\left(x_{n}-\hat{\mu}_{k}\right)^{T}}{1-\sum_{k=1}^{K} \frac{W_{k}^{(2)}}{W_{k}}}
\]
where
- \(W_{k}=\sum_{n=1}^{N} M_{n k} w_{n}\) is the sum of the weights for class \(k\).
- \(W_{k}^{(2)}=\sum_{n=1}^{N} M_{n k} w_{n}^{2}\) is the sum of squared weights per class.

\section*{How the predict Method Classifies}

There are three elements in the predict classification algorithm:
- "Posterior Probability" on page 14-7
- "Prior Probability" on page 14-8
- "Cost" on page 14-8
predict classifies so as to minimize the expected classification cost:
\[
\hat{y}=\underset{y=1, \ldots, K}{\arg \min } \sum_{k=1}^{K} \hat{P}(k \mid x) C(y \mid k),
\]
where
- \(\hat{y}\) is the predicted classification.
- \(K\) is the number of classes.
- \(\hat{P}(k \mid x)\) is the posterior probability of class \(k\) for observation \(x\).
- \(C(y \mid k)\) is the cost of classifying an observation as \(y\) when its true class is \(k\).

The space of \(X\) values divides into regions where a classification \(Y\) is a particular value. The regions are separated by straight lines for linear discriminant analysis, and by conic sections (ellipses, hyperbolas, or parabolas) for quadratic discriminant analysis. For a visualization of these regions, see "Create and Visualize a Discriminant Analysis Classifier" on page 14-9.

\section*{Posterior Probability}

The posterior probability that a point \(x\) belongs to class \(k\) is the product of the prior probability and the multivariate normal density. The density function of the multivariate normal with mean \(\mu_{k}\) and covariance \(\Sigma_{k}\) at a point \(x\) is
\[
P(x \mid k)=\frac{1}{\left(2 \pi\left|\Sigma_{k}\right|\right)^{1 / 2}} \exp \left(-\frac{1}{2}\left(x-\mu_{k}\right)^{T} \Sigma_{k}^{-1}\left(x-\mu_{k}\right)\right),
\]
where \(\left|\Sigma_{k}\right|\) is the determinant of \(\Sigma_{k}\), and \(\Sigma_{k}^{-1}\) is the inverse matrix.
Let \(P(k)\) represent the prior probability of class \(k\). Then the posterior probability that an observation \(x\) is of class \(k\) is
\[
\hat{P}(k \mid x)=\frac{P(x \mid k) P(k)}{P(x)}
\]
where \(P(x)\) is a normalization constant, namely, the sum over \(k\) of \(P(x \mid k) P(k)\).

\section*{Prior Probability}

The prior probability is one of three choices:
- 'uniform' - The prior probability of class k is 1 over the total number of classes.
- 'empirical' - The prior probability of class \(k\) is the number of training samples of class k divided by the total number of training samples.
- A numeric vector - The prior probability of class \(k\) is the \(j\) th element of the prior vector. See ClassificationDiscriminant.fit.

After creating a classifier obj, you can set the prior using dot addressing:
```

obj.Prior = v;

```
where \(v\) is a vector of positive elements representing the frequency with which each element occurs. You do not need to retrain the classifier when you set a new prior.

\section*{Cost}

There are two costs associated with discriminant analysis classification: the true misclassification cost per class, and the expected misclassification cost per observation.

True Misclassification Cost per Class. Cost (i,j) is the cost of classifying an observation into class \(j\) if its true class is \(i\). By default, \(\operatorname{Cost}(i, j)=1\) if \(i \sim=j\), and \(\operatorname{Cost}(i, j)=0\) if \(i=j\). In other words, the cost is 0 for correct classification, and 1 for incorrect classification.

You can set any cost matrix you like when creating a classifier. Pass the cost matrix in the Cost name-value pair in ClassificationDiscriminant.fit.

After you create a classifier obj, you can set a custom cost using dot addressing:
obj.Cost = B;
\(B\) is a square matrix of size K -by- K when there are K classes. You do not need to retrain the classifier when you set a new cost.

Expected Misclassification Cost per Observation. Suppose you have Nobs observations that you want to classify with a trained discriminant analysis classifier obj. Suppose you have K classes. You place the observations into a matrix Xnew with one observation per row. The command
```

[label,score,cost] = predict(obj,Xnew)

```
returns, among other outputs, a cost matrix of size Nobs-by-K. Each row of the cost matrix contains the expected (average) cost of classifying the observation into each of the \(K\) classes. cost ( \(n, k\) ) is
\[
\sum_{i=1}^{K} \hat{P}(i \mid X n e w(n)) C(k \mid i)
\]
where
- \(K\) is the number of classes.
- \(\hat{P}(i \mid X n e w(n))\) is the posterior probability of class \(i\) for observation Xnew( \(n\) ).
- \(C(k \mid i)\) is the cost of classifying an observation as \(k\) when its true class is \(i\).

\section*{Create and Visualize a Discriminant Analysis Classifier}

This example shows both linear and quadratic classification of the Fisher iris data. The example uses only two of the four predictors to enable simple plotting.

1 Load the data:
load fisheriris
2 Use the petal length (PL) and petal width (PW) measurements:
```

PL = meas(:,3);
PW = meas(:,4);

```

3 Plot the data, showing the classification:
```

h1 = gscatter(PL,PW,species,'krb','ov^',[],'off');
set(h1,'LineWidth',2)
legend('Setosa','Versicolor','Virginica',...
'Location','best')

```

4 Create a linear classifier:
```

X = [PL,PW];
cls = ClassificationDiscriminant.fit(X,species);

```

5 Plot the classification boundaries:
```

hold on
K = cls.Coeffs(2,3).Const;
L = cls.Coeffs(2,3).Linear;
% Plot the curve K + [x,y]*L = 0:
f = @(x1,x2) K + L(1)*x1 + L(2)*x2;
h2 = ezplot(f,[.9 7.1 0 2.5]);
set(h2,'Color','r','LineWidth',2)
K = cls.Coeffs(1,2).Const;
L = cls.Coeffs(1,2).Linear;
% Plot the curve K + [x1,x2]*L = 0:
f = @(x1,x2) K + L(1)*x1 + L(2)*x2;
h3 = ezplot(f,[.9 7.1 0 2.5]);
set(h3,'Color','k','LineWidth',2)
axis([.9 7.1 0 2.5])
xlabel('Petal Length')
ylabel('Petal Width')
title('{\bf Linear Classification with Fisher Training Data}')

```

\section*{Linear Discriminant Classification - Fisher Training Data}

6 Create a quadratic discriminant classifier:
```

cqs = ClassificationDiscriminant.fit(X,species,...
'DiscrimType', 'quadratic');

```

7 Plot the classification boundaries:
```

delete(h2); delete(h3) % remove the linear plots
K = cqs.Coeffs(2,3).Const;
L = cqs.Coeffs(2,3).Linear;
Q = cqs.Coeffs(2,3).Quadratic;
% Plot the curve K + [x1,x2]*L + [x1,x2]*Q*[x1, x2]'=0:

```
```

f = @(x1,x2) K + L(1)*x1 + L(2)*x2 + Q(1,1)*x1.^2 + ...
(Q(1,2)+Q(2,1))*x1.*x2 + Q(2,2)*x2.^2;
h2 = ezplot(f,[.9 7.1 0 2.5]);
set(h2,'Color','r','LineWidth',2)
K = cqs.Coeffs(1,2).Const;
L = cqs.Coeffs(1,2).Linear;
Q = cqs.Coeffs(1,2).Quadratic;
% Plot the curve K + [x1,x2]*L + [x1,x2]*Q*[x1,x2]'=0:
f = @(x1,x2) K + L(1)*x1 + L(2)*x2 + Q(1,1)*x1.^2 + ...
(Q(1,2)+Q(2,1))*x1.*x2 + Q(2,2)*x2.^2;
h3 = ezplot(f,[.9 7.1 0 1.02]); % plot the relevant
% portion of the curve
set(h3,'Color','k','LineWidth',2)
axis([.9 7.1 0 2.5])
xlabel('Petal Length')
ylabel('Petal Width')
title('{\bf Quadratic Classification with Fisher Training Data}')
hold off

```

\section*{Quadratic Discriminant Classification - Fisher Training Data}

\section*{Improve a Discriminant Analysis Classifier}
- "Deal with Singular Data" on page 14-15
- "Choose a Discriminant Type" on page 14-16
- "Examine the Resubstitution Error and Confusion Matrix" on page 14-17
- "Cross Validation" on page 14-18
- "Change Costs and Priors" on page 14-19

\section*{Deal with Singular Data}

Discriminant analysis needs data sufficient to fit Gaussian models with invertible covariance matrices. If your data is not sufficient to fit such a model uniquely, ClassificationDiscriminant.fit fails. This section shows methods for handling failures.

Tip To obtain a discriminant analysis classifier without failure, set the DiscrimType name-value pair to 'pseudoLinear' or 'pseudoQuadratic' in ClassificationDiscriminant.fit.
"Pseudo" discriminants never fail, because they use the pseudoinverse of the covariance matrix \(\Sigma_{k}\) (see pinv).

Example: Singular Covariance Matrix. When the covariance matrix of the fitted classifier is singular, ClassificationDiscriminant.fit can fail:
```

load popcorn
X = popcorn(:,[1 2]);
X(:,3) = 0; % a zero-variance column
Y = popcorn(:,3);
ppcrn = ClassificationDiscriminant.fit(X,Y);
Error using ClassificationDiscriminant (line 635)
Predictor x3 has zero variance. Either exclude this predictor or set 'discrimType' to
'pseudoLinear' or 'diagLinear'.
Error in classreg.learning.FitTemplate/fit (line 243)
obj = this.MakeFitObject(X,Y,W,this.ModelParams,fitArgs{:});
Error in ClassificationDiscriminant.fit (line 296)
this = fit(temp,X,Y);
To proceed with linear discriminant analysis, use a pseudoLinear or diagLinear discriminant type:
ppcrn = ClassificationDiscriminant.fit(X,Y,...
'discrimType','pseudoLinear');
meanpredict = predict(ppcrn,mean(X))

```
```

meanpredict =
3.5000

```

\section*{Choose a Discriminant Type}

There are six types of discriminant analysis classifiers: linear and quadratic, with diagonal and pseudo variants of each type.

Tip To see if your covariance matrix is singular, set discrimType to 'linear' or 'quadratic'. If the matrix is singular, the ClassificationDiscriminant.fit method fails for 'quadratic', and the Gamma property is nonzero for 'linear'.

To obtain a quadratic classifier even when your covariance matrix is singular, set discrimType to 'pseudoQuadratic' or 'diagQuadratic'.
obj = ClassificationDiscriminant.fit(X,Y,...
'discrimType','pseudoQuadratic') \% or 'diagQuadratic'

Choose a classifier type by setting the discrimType name-value pair to one of:
- 'linear' (default) - Estimate one covariance matrix for all classes.
- 'quadratic' - Estimate one covariance matrix for each class.
- 'diagLinear' - Use the diagonal of the 'linear' covariance matrix, and use its pseudoinverse if necessary.
- 'diagQuadratic' - Use the diagonals of the 'quadratic' covariance matrices, and use their pseudoinverses if necessary.
- 'pseudoLinear' - Use the pseudoinverse of the 'linear' covariance matrix if necessary.
- 'pseudoQuadratic' - Use the pseudoinverses of the 'quadratic' covariance matrices if necessary.

ClassificationDiscriminant.fit can fail for the 'linear' and 'quadratic' classifiers. When it fails, it returns an explanation, as shown in "Deal with Singular Data" on page 14-15.

ClassificationDiscriminant.fit always succeeds with the diagonal and pseudo variants. For information about pseudoinverses, see pinv.

You can set the discriminant type using dot addressing after constructing a classifier:
obj.DiscrimType = 'discrimType'
You can change between linear types or between quadratic types, but cannot change between a linear and a quadratic type.

\section*{Examine the Resubstitution Error and Confusion Matrix}

The resubstitution error is the difference between the response training data and the predictions the classifier makes of the response based on the input training data. If the resubstitution error is high, you cannot expect the predictions of the classifier to be good. However, having low resubstitution error does not guarantee good predictions for new data. Resubstitution error is often an overly optimistic estimate of the predictive error on new data.

The confusion matrix shows how many errors, and which types, arise in resubstitution. When there are K classes, the confusion matrix R is a K-by-K matrix with
\(R(i, j)=\) the number of observations of class \(i\) that the classifier predicts to be of class \(j\).

\section*{Example: Resubstitution Error of a Discriminant Analysis Classifier.}

Examine the resubstitution error of the default discriminant analysis classifier for the Fisher iris data:
```

load fisheriris
obj = ClassificationDiscriminant.fit(meas,species);
resuberror = resubLoss(obj)
resuberror =
0.0200

```

The resubstitution error is very low, meaning obj classifies nearly all the Fisher iris data correctly. The total number of misclassifications is:
```

resuberror * obj.NObservations
ans =
3.0000

```

To see the details of the three misclassifications, examine the confusion matrix:
```

R = confusionmat(obj.Y,resubPredict(obj))

```
R \(=\)
    \(50 \quad 0 \quad 0\)
    \(0 \quad 48 \quad 2\)
    \(0 \quad 1 \quad 49\)
obj.ClassNames
ans =
    'setosa'
    'versicolor'
    'virginica'
- \(R(1,:)=\left[\begin{array}{lll}50 & 0 & 0\end{array}\right]\) means obj classifies all 50 setosa irises correctly.
- \(R(2,:)=\left[\begin{array}{ll}0 & 48 \\ 2\end{array}\right]\) means obj classifies 48 versicolor irises correctly, and misclassifies two versicolor irises as virginica.
- \(R(3,:)=\left[\begin{array}{lll}0 & 1 & 49\end{array}\right]\) means obj classifies 49 virginica irises correctly, and misclassifies one virginica iris as versicolor.

\section*{Cross Validation}

Typically, discriminant analysis classifiers are robust and do not exhibit overtraining when the number of predictors is much less than the number of observations. Nevertheless, it is good practice to cross validate your classifier to ensure its stability.

Example: Cross Validating a Discriminant Analysis Classifier. Try five-fold cross validation of a quadratic discriminant analysis classifier:

1 Load the Fisher iris data:
load fisheriris
2 Create a quadratic discriminant analysis classifier for the data:
```

quadisc = ClassificationDiscriminant.fit(meas,species,...
'DiscrimType','quadratic');

```

3 Find the resubstitution error of the classifier:
```

qerror = resubLoss(quadisc)
qerror =
0.0200

```

The classifier does an excellent job. Nevertheless, resubstitution error can be an optimistic estimate of the error when classifying new data. So proceed to cross validation.

4 Create a cross-validation model:
```

cvmodel = crossval(quadisc,'kfold',5);

```

5 Find the cross-validation loss for the model, meaning the error of the out-of-fold observations:
```

cverror = kfoldLoss(cvmodel)

```
cverror =
    0.0333

The cross-validated loss is nearly as low as the original resubstitution loss. Therefore, you can have confidence that the classifier is reasonably accurate.

\section*{Change Costs and Priors}

Sometimes you want to avoid certain misclassification errors more than others. For example, it might be better to have oversensitive cancer detection instead of undersensitive cancer detection. Oversensitive detection gives more false positives (unnecessary testing or treatment). Undersensitive detection gives more false negatives (preventable illnesses or deaths). The
consequences of underdetection can be high. Therefore, you might want to set costs to reflect the consequences.

Similarly, the training data \(Y\) can have a distribution of classes that does not represent their true frequency. If you have a better estimate of the true frequency, you can include this knowledge in the classification prior property.

Example: Setting Custom Misclassification Costs. Consider the Fisher iris data. Suppose that the cost of classifying a versicolor iris as virginica is 10 times as large as making any other classification error. Create a classifier from the data, then incorporate this cost and then view the resulting classifier.

1 Load the Fisher iris data and create a default (linear) classifier as in "Example: Resubstitution Error of a Discriminant Analysis Classifier" on page 14-17:
load fisheriris
obj = ClassificationDiscriminant.fit(meas,species);
resuberror = resubLoss(obj)
resuberror =
0.0200

R = confusionmat(obj.Y,resubPredict(obj))
R =
\(50 \quad 0 \quad 0\)
\(0 \quad 48 \quad 2\)
\(0 \quad 1 \quad 49\)
obj.ClassNames
```

ans =
'setosa'
'versicolor'
'virginica'

```
\(R(2,:)=\left[\begin{array}{lll}0 & 48 & 2\end{array}\right]\) means obj classifies 48 versicolor irises correctly, and misclassifies two versicolor irises as virginica.

2 Change the cost matrix to make fewer mistakes in classifying versicolor irises as virginica:
```

obj.Cost(2,3) = 10;
R2 = confusionmat(obj.Y,resubPredict(obj))
R2 =
50 0 0
0 50 0
0 7 43

```
obj now classifies all versicolor irises correctly, at the expense of increasing the number of misclassifications of virginica irises from 1 to 7 .

Example: Setting Alternative Priors. Consider the Fisher iris data. There are 50 irises of each kind in the data. Suppose that, in a particular region, you have historical data that shows virginica are five times as prevalent as the other kinds. Create a classifier that incorporates this information.

1 Load the Fisher iris data and make a default (linear) classifier as in "Example: Resubstitution Error of a Discriminant Analysis Classifier" on page 14-17:
```

load fisheriris
obj = ClassificationDiscriminant.fit(meas,species);
resuberror = resubLoss(obj)
resuberror =
0.0200
R = confusionmat(obj.Y,resubPredict(obj))
R =
50 0 0
0 48 2
0 1 49
obj.ClassNames
ans =
'setosa'
'versicolor'

```
```

'virginica'

```
\(R(3,:)=\left[\begin{array}{lll}0 & 1 & 49\end{array}\right]\) means obj classifies 49 virginica irises correctly, and misclassifies one virginica iris as versicolor.

2 Change the prior to match your historical data, and examine the confusion matrix of the new classifier:
```

obj.Prior = [1 1 5];
R2 = confusionmat(obj.Y,resubPredict(obj))
R2 =
50 0 0
0 46 4
0 0 50

```

The new classifier classifies all virginica irises correctly, at the expense of increasing the number of misclassifications of versicolor irises from 2 to 4.

\section*{Regularize a Discriminant Analysis Classifier}

To make a more robust and simpler model, try to remove predictors from your model without hurting its predictive power. This is especially important when you have many predictors in your data. Linear discriminant analysis uses the two regularization parameters, Gamma and Delta, to identify and remove redundant predictors. The cvshrink method helps you identify appropriate settings for these parameters.

\section*{1. Load data and create a classifier.}

Create a linear discriminant analysis classifier for the ovariancancer data. Set the SaveMemory and FillCoeffs options to keep the resulting model reasonably small.
```

load ovariancancer
obj = ClassificationDiscriminant.fit(obs,grp,...
'SaveMemory','on','FillCoeffs', 'off');

```

\section*{2. Cross validate the classifier.}

Use 30 levels of Gamma and 30 levels of Delta to search for good parameters. This search is time consuming. Set Verbose to 1 to view the progress.
```

rng(8000,'twister') % for reproducibility
[err,gamma,delta,numpred] = cvshrink(obj,...
'NumGamma', 29,'NumDelta',29,'Verbose',1);
Done building cross-validated model.
Processing Gamma step 1 out of 30.
Processing Gamma step 2 out of 30.
Processing Gamma step 3 out of 30.
%%% (many lines removed) %%%
Processing Gamma step 28 out of 30.
Processing Gamma step 29 out of 30.
Processing Gamma step 30 out of 30.

```

\section*{3. Examine the quality of the regularized classifiers.}

Plot the number of predictors against the error.
```

figure;
plot(err,numpred,'k.')
xlabel('Error rate');
ylabel('Number of predictors');

```

Examine the lower-left part of the plot more closely. axis([0 . 1001000\(])\)

There is a clear tradeoff between lower number of predictors and lower error.
4. Choose an optimal tradeoff between model size and accuracy.

Find the values of Gamma and Delta that give minimal error.
minerr \(=\min (\min (e r r))\);
\([p, q]=\) find \((e r r==\) minerr \()\)
p =
24
25
q =
8
8

Two points have the same minimal error: [24,8] and [25,8], which correspond to
```

[gamma(p(1)),delta(p(1),q(1))]
ans =
0.8436 0.1463
[gamma(p(2)),delta(p(2),q(2))]
ans =
0.8697 0.1425

```

These points correspond to about a quarter of the total predictors having nonzero coefficients in the model.
```

numpred(p(1),q(1))

```
ans =
    957
numpred( \(p(2), q(2))\)
ans =
    960

To further lower the number of predictors, you must accept larger error rates. For example, to choose the Gamma and Delta that give the lowest error rate with 250 or fewer predictors:
```

low250 = min(min(err(numpred <= 250)))
low250 =
0.0278
lownum = min(min(numpred(err == low250)))
lownum =

```
    243

You need 243 predictors to achieve an error rate of 0.0278 , and this is the lowest error rate among those that have 250 predictors or fewer. The Gamma and Delta that achieve this error/number of predictors:
```

[r,s] = find((err == low250) \& (numpred == lownum));
gamma(r)
ans =
0.7133
delta(r,s)
ans =
0.2960

```

\section*{5. Set the regularization parameters.}

To set the classifier with these values of Gamma and Delta, use dot addressing.
```

obj.Gamma = gamma(r);
obj.Delta = delta(r,s);

```

\section*{6. Heat map plot.}

To compare the cvshrink calculation to that in Guo, Hastie, and Tibshirani [3], plot heat maps of error and number of predictors against Gamma and the index of the Delta parameter. (The Delta parameter range depends on the value of the Gamma parameter. So to get a rectangular plot, use the Delta index, not the parameter itself.)
```

% First create the Delta index matrix
indx = repmat(1:size(delta,2),size(delta,1),1);
figure
subplot(1,2,1)
imagesc(err);
colorbar;
title('Classification error');
xlabel('Delta index');
ylabel('Gamma index');

```
```

subplot(1,2,2)
imagesc(numpred);
colorbar;
title('Number of predictors in the model');
xlabel('Delta index');
ylabel('Gamma index');

```

You see the best classification error when Delta is small, but fewest predictors when Delta is large.

\section*{Examine the Gaussian Mixture Assumption}

Discriminant analysis assumes that the data comes from a Gaussian mixture model (see "Creating a Classifier Using ClassificationDiscriminant.fit" on page 14-4). If the data appears to come from a Gaussian mixture model, you can expect discriminant analysis to be a good classifier. Furthermore, the default linear discriminant analysis assumes that all class covariance matrices are equal. This section shows methods to check these assumptions:
- "Bartlett Test of Equal Covariance Matrices for Linear Discriminant Analysis" on page 14-29
- "Q-Q Plot" on page 14-31
- "Mardia Kurtosis Test of Multivariate Normality" on page 14-34

\section*{Bartlett Test of Equal Covariance Matrices for Linear Discriminant Analysis}

The Bartlett test (see Box [1]) checks equality of the covariance matrices of the various classes. If the covariance matrices are equal, the test indicates that linear discriminant analysis is appropriate. If not, consider using quadratic discriminant analysis, setting the DiscrimType name-value pair to 'quadratic' in ClassificationDiscriminant.fit.

The Bartlett test assumes normal (Gaussian) samples, where neither the means nor covariance matrices are known. To determine whether the covariances are equal, compute the following quantities:
- Sample covariance matrices per class \(\sigma_{i}, 1 \leq i \leq k\), where \(k\) is the number of classes.
- Pooled-in covariance matrix \(\sigma\).
- Test statistic \(V\) :
\[
V=(n-k) \log (|\Sigma|)-\sum_{i=1}^{k}\left(n_{i}-1\right) \log \left(\left|\Sigma_{i}\right|\right)
\]
where \(n\) is the total number of observations, and \(n_{i}\) is the number of observations in class \(i\), and \(|\Sigma|\) means the determinant of the matrix \(\Sigma\).
- Asymptotically, as the number of observations in each class \(n_{i}\) become large, \(V\) is distributed approximately \(x^{2}\) with \(k d(d+1) / 2\) degrees of freedom, where \(d\) is the number of predictors (number of dimensions in the data).

The Bartlett test is to check whether \(V\) exceeds a given percentile of the \(x^{2}\) distribution with \(k d(d+1) / 2\) degrees of freedom. If it does, then reject the hypothesis that the covariances are equal.

Example: Bartlett Test for Equal Covariance Matrices. Check whether the Fisher iris data is well modeled by a single Gaussian covariance, or whether it would be better to model it as a Gaussian mixture.
```

load fisheriris;
prednames = {'SepalLength','SepalWidth',...
'PetalLength', 'PetalWidth'};
L = ClassificationDiscriminant.fit(meas,species,...
'PredictorNames',prednames);
Q = ClassificationDiscriminant.fit(meas,species,...
'PredictorNames',prednames,'DiscrimType','quadratic');
D = 4; % Number of dimensions of X
Nclass = [50 50 50];
N = L.NObservations;
K = numel(L.ClassNames);
SigmaQ = Q.Sigma;
SigmaL = L.Sigma;
logV = (N-K)*log(det(SigmaL));
for k=1:K
logV = logV - (Nclass(k)-1)*log(det(SigmaQ(:,:,k)));
end
nu = (K-1)*D*(D+1)/2;
pval = 1-chi2cdf(logV,nu)
pval =
0

```

The Bartlett test emphatically rejects the hypothesis of equal covariance matrices. If pval had been greater than 0.05 , the test would not have rejected the hypothesis. The result indicates to use quadratic discriminant analysis, as opposed to linear discriminant analysis.

\section*{Q-Q Plot}

A Q-Q plot graphically shows whether an empirical distribution is close to a theoretical distribution. If the two are equal, the \(\mathrm{Q}-\mathrm{Q}\) plot lies on a \(45^{\circ}\) line. If not, the Q-Q plot strays from the \(45^{\circ}\) line.

Check Q-Q Plots for Linear and Quadratic Discriminants. For linear discriminant analysis, use a single covariance matrix for all classes.
```

load fisheriris;
prednames = {'SepalLength','SepalWidth',...
'PetalLength','PetalWidth'};
L = ClassificationDiscriminant.fit(meas,species,...
'PredictorNames',prednames);
N = L.NObservations;
K = numel(L.ClassNames);
mahL = mahal(L,L.X,'ClassLabels',L.Y);
D = 4;
expQ = chi2inv(((1:N)-0.5)/N,D); % expected quantiles
[mahL,sorted] = sort(mahL); % sorted obbserved quantiles
figure;
gscatter(expQ,mahL,L.Y(sorted),'bgr',[],[],'off');
legend('virginica','versicolor','setosa','Location','NW');
xlabel('Expected quantile');
ylabel('Observed quantile');
line([0 20],[0 20],'color','k');

```

Overall, the agreement between the expected and observed quantiles is good. Look at the right half of the plot. The deviation of the plot from the \(45^{\circ}\) line upward indicates that the data has tails heavier than a normal distribution. There are three possible outliers on the right: two observations from class 'setosa' and one observation from class 'virginica'.

As shown in "Bartlett Test of Equal Covariance Matrices for Linear Discriminant Analysis" on page 14-29, the data does not match a single covariance matrix. Redo the calculations for a quadratic discriminant.
```

load fisheriris;
prednames = {'SepalLength','SepalWidth',...
'PetalLength','PetalWidth'};
Q = ClassificationDiscriminant.fit(meas,species,...
'PredictorNames',prednames,'DiscrimType','quadratic');
Nclass = [50 50 50];

```
```

N = L.NObservations;
K = numel(L.ClassNames);
mahQ = mahal(Q,Q.X,'ClassLabels',Q.Y);
expQ = chi2inv(((1:N)-0.5)/N,D);
[mahQ,sorted] = sort(mahQ);
figure;
gscatter(expQ,mahQ,Q.Y(sorted),'bgr',[],[],'off');
legend('virginica','versicolor','setosa','Location','NW');
xlabel('Expected quantile');
ylabel('Observed quantile for QDA');
line([0 20],[0 20],'color','k');

```

The Q-Q plot shows a better agreement between the observed and expected quantiles. There is only one outlier candidate, from class 'setosa'.

\section*{Mardia Kurtosis Test of Multivariate Normality}

The Mardia kurtosis test (see Mardia [4]) is an alternative to examining a Q-Q plot. It gives a numeric approach to deciding if data matches a Gaussian mixture model.

In the Mardia kurtosis test you compute \(M\), the mean of the fourth power of the Mahalanobis distance of the data from the class means. If the data is normally distributed with constant covariance matrix (and is thus suitable for linear discriminant analysis), \(M\) is asymptotically distributed as normal with mean \(d(d+2)\) and variance \(8 d(d+2) / n\), where
- \(d\) is the number of predictors (number of dimensions in the data).
- \(n\) is the total number of observations.

The Mardia test is two sided: check whether \(M\) is close enough to \(d(d+2)\) with respect to a normal distribution of variance \(8 d(d+2) / n\).

\section*{Example: Mardia Kurtosis Test for Linear and Quadratic}

Discriminants. Check whether the Fisher iris data is approximately normally distributed for both linear and quadratic discriminant analysis. According to "Bartlett Test of Equal Covariance Matrices for Linear Discriminant Analysis" on page 14-29, the data is not normal for linear discriminant analysis (the covariance matrices are different). "Check Q-Q Plots for Linear and Quadratic Discriminants" on page 14-31 indicates that the data is well modeled by a Gaussian mixture model with different covariances per class. Check these conclusions with the Mardia kurtosis test:
```

load fisheriris;
prednames = {'SepalLength','SepalWidth',...
'PetalLength','PetalWidth'};
L = ClassificationDiscriminant.fit(meas,species,...
'PredictorNames',prednames);
mahL = mahal(L,L.X,'ClassLabels',L.Y);
D = 4;
N = L.NObservations;
obsKurt = mean(mahL.^2);
expKurt = D*(D+2);
varKurt = 8*D*(D+2)/N;
[~,pval] = ztest(obsKurt,expKurt,sqrt(varKurt))

```
```

pval =
0.0208

```

The Mardia test indicates to reject the hypothesis that the data is normally distributed.

Continuing the example with quadratic discriminant analysis:
```

Q = ClassificationDiscriminant.fit(meas,species,...
'PredictorNames',prednames,'DiscrimType','quadratic');
mahQ = mahal(Q,Q.X,'ClassLabels',Q.Y);
obsKurt = mean(mahQ.^2);
[~,pval] = ztest(obsKurt,expKurt,sqrt(varKurt))
pval =
0.7230

```

Because pval is high, you conclude the data are consistent with the multivariate normal distribution.

\section*{Naive Bayes Classification}

The Naive Bayes classifier is designed for use when features are independent of one another within each class, but it appears to work well in practice even when that independence assumption is not valid. It classifies data in two steps:

1 Training step: Using the training samples, the method estimates the parameters of a probability distribution, assuming features are conditionally independent given the class.

2 Prediction step: For any unseen test sample, the method computes the posterior probability of that sample belonging to each class. The method then classifies the test sample according the largest posterior probability.

The class-conditional independence assumption greatly simplifies the training step since you can estimate the one-dimensional class-conditional density for each feature individually. While the class-conditional independence between features is not true in general, research shows that this optimistic assumption works well in practice. This assumption of class independence allows the Naive Bayes classifier to better estimate the parameters required for accurate classification while using less training data than many other classifiers. This makes it particularly effective for datasets containing many predictors or features.

\section*{Supported Distributions}

Naive Bayes classification is based on estimating \(P(X \mid Y)\), the probability or probability density of features \(X\) given class \(Y\). The Naive Bayes classification object NaiveBayes provides support for normal (Gaussian), kernel, multinomial, and multivariate multinomial distributions. It is possible to use different distributions for different features.

\section*{Normal (Gaussian) Distribution}

The 'normal' distribution is appropriate for features that have normal distributions in each class. For each feature you model with a normal distribution, the Naive Bayes classifier estimates a separate normal
distribution for each class by computing the mean and standard deviation of the training data in that class.

\section*{Kernel Distribution}

The 'kernel' distribution is appropriate for features that have a continuous distribution. It does not require a strong assumption such as a normal distribution and you can use it in cases where the distribution of a feature may be skewed or have multiple peaks or modes. It requires more computing time and more memory than the normal distribution. For each feature you model with a kernel distribution, the Naive Bayes classifier computes a separate kernel density estimate for each class based on the training data for that class. By default the kernel is the normal kernel, and the classifier selects a width automatically for each class and feature. It is possible to specify different kernels for each feature, and different widths for each feature or class.

\section*{Multinomial Distribution}

The multinomial distribution (specify with the 'mn' keyword) is appropriate when all features represent counts of a set of words or tokens. This is sometimes called the "bag of words" model. For example, an email spam classifier might be based on features that count the number of occurrences of various tokens in an email. One feature might count the number of exclamation points, another might count the number of times the word "money" appears, and another might count the number of times the recipient's name appears. This is a Naive Bayes model under the further assumption that the total number of tokens (or the total document length) is independent of response class.

For the multinomial option, each feature represents the count of one token. The classifier counts the set of relative token probabilities separately for each class. The classifier defines the multinomial distribution for each row by the vector of probabilities for the corresponding class, and by N , the total token count for that row.

Classification is based on the relative frequencies of the tokens. For a row in which no token appears, N is 0 and no classification is possible. This classifier is not appropriate when the total number of tokens provides information about the response class.

\section*{Multivariate Multinomial Distribution}

The multivariate multinomial distribution (specify with the 'mvmn' keyword) is appropriate for categorical features. For example, you could fit a feature describing the weather in categories such as rain/sun/snow/clouds using the multivariate multinomial model. The feature categories are sometimes called the feature levels, and differ from the class levels for the response variable.

For each feature you model with a multivariate multinomial distribution, the Naive Bayes classifier computes a separate set of probabilities for the set of feature levels for each class.

\section*{Performance Curves}

\author{
In this section... \\ "Introduction to Performance Curves" on page 14-39 \\ "What are ROC Curves?" on page 14-39 \\ "Evaluate Classifier Performance Using perfcurve" on page 14-39
}

\section*{Introduction to Performance Curves}

After a classification algorithm such as NaiveBayes or TreeBagger has trained on data, you may want to examine the performance of the algorithm on a specific test dataset. One common way of doing this would be to compute a gross measure of performance such as quadratic loss or accuracy, averaged over the entire test dataset.

\section*{What are ROC Curves?}

You may want to inspect the classifier performance more closely, for example, by plotting a Receiver Operating Characteristic (ROC) curve. By definition, a ROC curve [1,2] shows true positive rate versus false positive rate (equivalently, sensitivity versus 1 -specificity) for different thresholds of the classifier output. You can use it, for example, to find the threshold that maximizes the classification accuracy or to assess, in more broad terms, how the classifier performs in the regions of high sensitivity and high specificity.

\section*{Evaluate Classifier Performance Using perfcurve}
perfcurve computes measures for a plot of classifier performance. You can use this utility to evaluate classifier performance on test data after you train the classifier. Various measures such as mean squared error, classification error, or exponential loss can summarize the predictive power of a classifier in a single number. However, a performance curve offers more information as it lets you explore the classifier performance across a range of thresholds on its output.

You can use perfcurve with any classifier or, more broadly, with any method that returns a numeric score for an instance of input data. By convention adopted here,
- A high score returned by a classifier for any given instance signifies that the instance is likely from the positive class.
- A low score signifies that the instance is likely from the negative classes.

For some classifiers, you can interpret the score as the posterior probability of observing an instance of the positive class at point \(X\). An example of such a score is the fraction of positive observations in a leaf of a decision tree. In this case, scores fall into the range from 0 to 1 and scores from positive and negative classes add up to unity. Other methods can return scores ranging between minus and plus infinity, without any obvious mapping from the score to the posterior class probability.
perfcurve does not impose any requirements on the input score range. Because of this lack of normalization, you can use perfcurve to process scores returned by any classification, regression, or fit method. perfcurve does not make any assumptions about the nature of input scores or relationships between the scores for different classes. As an example, consider a problem with three classes, A, B, and C, and assume that the scores returned by some classifier for two instances are as follows:
\begin{tabular}{llll} 
& A & B & C \\
instance 1 & 0.4 & 0.5 & 0.1 \\
instance 2 & 0.4 & 0.1 & 0.5
\end{tabular}

If you want to compute a performance curve for separation of classes A and B, with \(C\) ignored, you need to address the ambiguity in selecting A over B. You could opt to use the score ratio, \(s(A) / s(B)\), or score difference, \(s(A)-s(B)\); this choice could depend on the nature of these scores and their normalization. perfcurve always takes one score per instance. If you only supply scores for class A, perfcurve does not distinguish between observations 1 and 2. The performance curve in this case may not be optimal.
perfcurve is intended for use with classifiers that return scores, not those that return only predicted classes. As a counter-example, consider a decision tree that returns only hard classification labels, 0 or 1 , for data with two classes. In this case, the performance curve reduces to a single point because classified instances can be split into positive and negative categories in one way only.

For input, perfcurve takes true class labels for some data and scores assigned by a classifier to these data. By default, this utility computes a Receiver Operating Characteristic (ROC) curve and returns values of 1 -specificity, or false positive rate, for \(X\) and sensitivity, or true positive rate, for \(Y\). You can choose other criteria for \(X\) and \(Y\) by selecting one out of several provided criteria or specifying an arbitrary criterion through an anonymous function. You can display the computed performance curve using plot ( \(\mathrm{X}, \mathrm{Y}\) ).
perfcurve can compute values for various criteria to plot either on the \(x\) - or the \(y\)-axis. All such criteria are described by a 2 -by- 2 confusion matrix, a 2 -by- 2 cost matrix, and a 2 -by- 1 vector of scales applied to class counts.

The confusion matrix, \(C\), is defined as
\[
\left(\begin{array}{ll}
T P & F N \\
F P & T N
\end{array}\right)
\]
where
- \(P\) stands for "positive".
- \(N\) stands for "negative".
- \(T\) stands for "true".
- \(F\) stands for "false".

For example, the first row of the confusion matrix defines how the classifier identifies instances of the positive class: \(C(1,1)\) is the count of correctly identified positive instances and \(C(1,2)\) is the count of positive instances misidentified as negative.

The cost matrix defines the cost of misclassification for each category:
\[
\left(\begin{array}{ll}
\operatorname{Cost}(P \mid P) & \operatorname{Cost}(N \mid P) \\
\operatorname{Cost}(P \mid N) & \operatorname{Cost}(N \mid N)
\end{array}\right)
\]
where Cost (I \(\mid \mathrm{J})\) is the cost of assigning an instance of class \(J\) to class I. Usually Cost (I|J)=0 for I=J. For flexibility, perfcurve allows you to specify nonzero costs for correct classification as well.

The two scales include prior information about class probabilities. perfcurve computes these scales by taking scale ( P ) = prior \((P)\) *N and scale ( \(N\) ) =prior ( \(N\) ) *P and normalizing the sum scale ( P ) +scale ( \(N\) ) to 1. \(P=T P+F N\) and \(N=T N+F P\) are the total instance counts in the positive and negative class, respectively. The function then applies the scales as multiplicative factors to the counts from the corresponding class: perfcurve multiplies counts from the positive class by scale (P) and counts from the negative class by scale( \(N\) ). Consider, for example, computation of positive predictive value, PPV = TP/(TP+FP). TP counts come from the positive class and FP counts come from the negative class. Therefore, you need to scale TP by scale (P) and FP by scale(N), and the modified formula for PPV with prior probabilities taken into account is now:
\[
P P V=\frac{\operatorname{scale}(P) * T P}{\operatorname{scale}(P) * T P+\operatorname{scale}(N) * F P}
\]

If all scores in the data are above a certain threshold, perfcurve classifies all instances as 'positive'. This means that TP is the total number of instances in the positive class and FP is the total number of instances in the negative class. In this case, PPV is simply given by the prior:
\[
P P V=\frac{\operatorname{prior}(P)}{\operatorname{prior}(P)+\operatorname{prior}(N)}
\]

The perfcurve function returns two vectors, X and Y , of performance measures. Each measure is some function of confusion, cost, and scale values. You can request specific measures by name or provide a function handle to compute a custom measure. The function you provide should take confusion, cost, and scale as its three inputs and return a vector of output values.

The criterion for X must be a monotone function of the positive classification count, or equivalently, threshold for the supplied scores. If perfcurve cannot perform a one-to-one mapping between values of the X criterion and score thresholds, it exits with an error message.

By default, perfcurve computes values of the \(X\) and \(Y\) criteria for all possible score thresholds. Alternatively, it can compute a reduced number of specific \(X\) values supplied as an input argument. In either case, for \(M\) requested values, perfcurve computes \(M+1\) values for \(X\) and \(Y\). The first value out of these \(M+1\) values is special. perfcurve computes it by setting the TP instance count
to zero and setting TN to the total count in the negative class. This value corresponds to the 'reject all' threshold. On a standard ROC curve, this translates into an extra point placed at \((0,0)\).

If there are NaN values among input scores, perfcurve can process them in either of two ways:
- It can discard rows with NaN scores.
- It can add them to false classification counts in the respective class.

That is, for any threshold, instances with NaN scores from the positive class are counted as false negative (FN), and instances with NaN scores from the negative class are counted as false positive (FP). In this case, the first value of X or Y is computed by setting TP to zero and setting TN to the total count minus the NaN count in the negative class. For illustration, consider an example with two rows in the positive and two rows in the negative class, each pair having a NaN score:

Class
Negative
Negative
Positive
Positive

\section*{Score}
0.2 NaN
0.7 NaN

If you discard rows with NaN scores, then as the score cutoff varies, perfcurve computes performance measures as in the following table. For example, a cutoff of 0.5 corresponds to the middle row where rows 1 and 3 are classified correctly, and rows 2 and 4 are omitted.
\begin{tabular}{llll} 
TP & FN & FP & TN \\
0 & 1 & 0 & 1 \\
1 & 0 & 0 & 1 \\
1 & 0 & 1 & 0
\end{tabular}

If you add rows with NaN scores to the false category in their respective classes, perfcurve computes performance measures as in the following table. For example, a cutoff of 0.5 corresponds to the middle row where now rows

2 and 4 are counted as incorrectly classified. Notice that only the FN and FP columns differ between these two tables.
\begin{tabular}{llll} 
TP & FN & FP & TN \\
0 & 2 & 1 & 1 \\
1 & 1 & 1 & 1 \\
1 & 1 & 2 & 0
\end{tabular}

For data with three or more classes, perfcurve takes one positive class and a list of negative classes for input. The function computes the \(X\) and \(Y\) values using counts in the positive class to estimate TP and FN, and using counts in all negative classes to estimate TN and FP. perfcurve can optionally compute \(Y\) values for each negative class separately and, in addition to \(Y\), return a matrix of size M-by-C, where \(M\) is the number of elements in \(X\) or \(Y\) and \(C\) is the number of negative classes. You can use this functionality to monitor components of the negative class contribution. For example, you can plot TP counts on the X -axis and FP counts on the Y -axis. In this case, the returned matrix shows how the FP component is split across negative classes.

You can also use perfcurve to estimate confidence intervals. perfcurve computes confidence bounds using either cross-validation or bootstrap. If you supply cell arrays for labels and scores, perfcurve uses cross-validation and treats elements in the cell arrays as cross-validation folds. If you set input parameter NBoot to a positive integer, perfcurve generates nboot bootstrap replicas to compute pointwise confidence bounds.
perfcurve estimates the confidence bounds using one of two methods:
- Vertical averaging (VA) - estimate confidence bounds on \(Y\) and \(T\) at fixed values of \(X\). Use the XVals input parameter to use this method for computing confidence bounds.
- Threshold averaging (TA) - estimate confidence bounds for \(X\) and \(Y\) at fixed thresholds for the positive class score. Use the TVals input parameter to use this method for computing confidence bounds.

To use observation weights instead of observation counts, you can use the 'Weights' parameter in your call to perfcurve. When you use this parameter, to compute \(\mathrm{X}, \mathrm{Y}\) and T or to compute confidence bounds by cross-validation, perfcurve uses your supplied observation weights instead of
observation counts. To compute confidence bounds by bootstrap, perfcurve samples \(N\) out of \(N\) with replacement using your weights as multinomial sampling probabilities.

Supervised Learning (Machine Learning) Workflow and Algorithms
}

\author{
In this section... \\ "Steps in Supervised Learning (Machine Learning)" on page 15-2 \\ "Characteristics of Algorithms" on page 15-7
}

\section*{Steps in Supervised Learning (Machine Learning)}

Supervised learning (machine learning) takes a known set of input data and known responses to the data, and seeks to build a predictor model that generates reasonable predictions for the response to new data.

2

Suppose you want to predict if someone will have a heart attack within a year. You have a set of data on previous people, including age, weight, height, blood pressure, etc. You know if the previous people had heart attacks within a year of their data measurements. So the problem is combining all the existing data into a model that can predict whether a new person will have a heart attack within a year.

Supervised learning splits into two broad categories:
- Classification for responses that can have just a few known values, such as 'true' or 'false'. Classification algorithms apply to nominal, not ordinal response values.
- Regression for responses that are a real number, such as miles per gallon for a particular car.

You can have trouble deciding whether you have a classification problem or a regression problem. In that case, create a regression model first, because they are often more computationally efficient.

While there are many Statistics Toolbox algorithms for supervised learning, most use the same basic workflow for obtaining a predictor model. (Detailed instruction on the steps for ensemble learning is in "Framework for Ensemble Learning" on page 15-58.) The steps for supervised learning are:

1 "Prepare Data" on page 15-3
2 "Choose an Algorithm" on page 15-4
3 "Fit a Model" on page 15-4
4 "Choose a Validation Method" on page 15-5
5 "Examine Fit and Update Until Satisfied" on page 15-6
6 "Use Fitted Model for Predictions" on page 15-6

\section*{Prepare Data}

All supervised learning methods start with an input data matrix, usually called \(X\) here. Each row of \(X\) represents one observation. Each column of X represents one variable, or predictor. Represent missing entries with NaN values in X. Statistics Toolbox supervised learning algorithms can handle NaN values, either by ignoring them or by ignoring any row with a NaN value.

You can use various data types for response data \(Y\). Each element in \(Y\) represents the response to the corresponding row of \(X\). Observations with missing \(Y\) data are ignored.
- For regression, Y must be a numeric vector with the same number of elements as the number of rows of \(X\).
- For classification, Y can be any of these data types. This table also contains the method of including missing entries.
\begin{tabular}{l|l}
\hline Data Type & Missing Entry \\
\hline Numeric vector & NaN \\
\hline Categorical vector & <undefined> \\
\hline Character array & Row of spaces \\
\hline Cell array of strings & '' \\
\hline Logical vector & (Cannot represent) \\
\hline
\end{tabular}

\section*{Choose an Algorithm}

There are tradeoffs between several characteristics of algorithms, such as:
- Speed of training
- Memory usage
- Predictive accuracy on new data
- Transparency or interpretability, meaning how easily you can understand the reasons an algorithm makes its predictions

Details of the algorithms appear in "Characteristics of Algorithms" on page 15-7. More detail about ensemble algorithms is in "Choose an Applicable Ensemble Method" on page 15-61.

\section*{Fit a Model}

The fitting function you use depends on the algorithm you choose.
\begin{tabular}{l|l}
\hline Algorithm & Fitting Function \\
\hline Classification Trees & ClassificationTree.fit \\
\hline Regression Trees & RegressionTree.fit \\
\hline \begin{tabular}{l} 
Discriminant Analysis \\
(classification)
\end{tabular} & ClassificationDiscriminant.fit \\
\hline K-Nearest Neighbors (classification) & ClassificationKNN.fit \\
\hline Naive Bayes (classification) & NaiveBayes.fit \\
\hline
\end{tabular}
\begin{tabular}{l|l}
\hline Algorithm & Fitting Function \\
\hline \begin{tabular}{l} 
Classification or Regression \\
Ensembles
\end{tabular} & fitensemble \\
\hline \begin{tabular}{l} 
Classification or Regression \\
Ensembles in Parallel
\end{tabular} & TreeBagger \\
\hline
\end{tabular}

\section*{Choose a Validation Method}

The three main methods to examine the accuracy of the resulting fitted model are:
- Examine the resubstitution error. For examples, see:
- "Example: Resubstitution Error of a Classification Tree" on page 15-38
- "Example: Cross Validating a Regression Tree" on page 15-39
- "Example: Test Ensemble Quality" on page 15-71
- "Example: Resubstitution Error of a Discriminant Analysis Classifier" on page 14-17
- Examine the cross-validation error. For examples, see:
- "Example: Cross Validating a Regression Tree" on page 15-39
- "Example: Test Ensemble Quality" on page 15-71
- "Classification with Many Categorical Levels" on page 15-90
- "Example: Cross Validating a Discriminant Analysis Classifier" on page 14-18
- Examine the out-of-bag error for bagged decision trees. For examples, see:
- "Example: Test Ensemble Quality" on page 15-71
- "Workflow Example: Regression of Insurance Risk Rating for Car Imports with TreeBagger" on page 15-124
- "Workflow Example: Classifying Radar Returns for Ionosphere Data with TreeBagger" on page 15-133

\section*{Examine Fit and Update Until Satisfied}

After validating the model, you might want to change it for better accuracy, better speed, or to use less memory.
- Change fitting parameters to try to get a more accurate model. For examples, see:
- "Tuning RobustBoost" on page 15-114
- "Example: Unequal Classification Costs" on page 15-84
- "Improve a Discriminant Analysis Classifier" on page 14-14
- Change fitting parameters to try to get a smaller model. This sometimes gives a model with more accuracy. For examples, see:
- "Example: Selecting Appropriate Tree Depth" on page 15-40
- "Example: Pruning a Classification Tree" on page 15-43
- "Surrogate Splits" on page 15-94
- "Example: Regularizing a Regression Ensemble" on page 15-104
- "Workflow Example: Regression of Insurance Risk Rating for Car Imports with TreeBagger" on page 15-124
- "Workflow Example: Classifying Radar Returns for Ionosphere Data with TreeBagger" on page 15-133
- Try a different algorithm. For applicable choices, see:
- "Characteristics of Algorithms" on page 15-7
- "Choose an Applicable Ensemble Method" on page 15-61

When satisfied with a model of some types, you can trim it using the appropriate compact method (compact for classification trees, compact for classification ensembles, compact for regression trees, compact for regression ensembles, compact for discriminant analysis). compact removes training data and pruning information, so the model uses less memory.

\section*{Use Fitted Model for Predictions}

To predict classification or regression response for most fitted models, use the predict method:
```

Ypredicted = predict(obj,Xnew)

```
- obj is the fitted model object.
- Xnew is the new input data.
- Ypredicted is the predicted response, either classification or regression.

For classregtree, use the eval method instead of predict.

\section*{Characteristics of Algorithms}

This table shows typical characteristics of the various supervised learning algorithms. The characteristics in any particular case can vary from the listed ones. Use the table as a guide for your initial choice of algorithms, but be aware that the table can be inaccurate for some problems.

\section*{Characteristics of Supervised Learning Algorithms}
\begin{tabular}{l|l|l|l|l|l|l}
\hline Algorithm & \begin{tabular}{l} 
Predictive \\
Accuracy
\end{tabular} & \begin{tabular}{l} 
Fitting \\

\end{tabular} & \(* * *\) & Fast*** & Medium & High & No & Yes*** \\
\hline \begin{tabular}{l} 
Discriminant \\
Analysis
\end{tabular} & \(* * * *\) & Fast & Fast & Low & Yes & No \\
\hline Ensembles & \begin{tabular}{l} 
See "Suggestions for Choosing an Appropriate Ensemble Algorithm" on page \\
\(15-63 ~ a n d ~ " G e n e r a l ~ C h a r a c t e r i s t i c s ~ o f ~ E n s e m b l e ~ A l g o r i t h m s " ~ o n ~ p a g e ~ 15-64 ~\)
\end{tabular} \\
\hline
\end{tabular}
* - SVM prediction speed and memory usage are good if there are few support vectors, but can be poor if there are many support vectors. When you use a kernel function, it can be difficult to interpret how SVM classifies data, though the default linear scheme is easy to interpret.
** - Naive Bayes speed and memory usage are good for simple distributions, but can be poor for kernel distributions and large data sets.
*** - Nearest Neighbor usually has good predictions in low dimensions, but can have poor predictions in high dimensions. For linear search, Nearest Neighbor does not perform any fitting. For \(k\) d-trees, Nearest Neighbor does perform fitting. Nearest Neighbor can have either continuous or categorical predictors, but not both.
**** - Discriminant Analysis is accurate when the modeling assumptions are satisfied (multivariate normal by class). Otherwise, the predictive accuracy varies.

\section*{Classification Using Nearest Neighbors}

\author{
In this section... \\ "Pairwise Distance" on page 15-9 \\ " \(k\)-Nearest Neighbor Search and Radius Search" on page 15-12 \\ " \(K\)-Nearest Neighbor Classification for Supervised Learning" on page 15-25 \\ "Construct a KNN Classifier" on page 15-25 \\ "Examine the Quality of a KNN Classifier" on page 15-26 \\ "Predict Classification Based on a KNN Classifier" on page 15-27 \\ "Modify a KNN Classifier" on page 15-27
}

\section*{Pairwise Distance}

Categorizing query points based on their distance to points in a training dataset can be a simple yet effective way of classifying new points. You can use various metrics to determine the distance, described next. Use pdist2 to find the distance between a set of data and query points.

\section*{Distance Metrics}

Given an \(m x\)-by- \(n\) data matrix \(X\), which is treated as \(m x\) (1-by- \(n\) ) row vectors \(\mathrm{x}_{1}, \mathrm{x}_{2}, \ldots, \mathrm{x}_{m \mathrm{x}}\), and \(m y\)-by- \(n\) data matrix Y , which is treated as \(m y\) (1-by- \(n\) ) row vectors \(\mathrm{y}_{1}, \mathrm{y}_{2}, \ldots, \mathrm{y}_{m y}\), the various distances between the vector \(\mathrm{x}_{s}\) and \(\mathrm{y}_{t}\) are defined as follows:
- Euclidean distance
\[
d_{s t}^{2}=\left(x_{s}-y_{t}\right)\left(x_{s}-y_{t}\right)^{\prime}
\]

The Euclidean distance is a special case of the Minkowski metric, where p \(=2\).
- Standardized Euclidean distance
\[
d_{s t}^{2}=\left(x_{s}-y_{t}\right) V^{-1}\left(x_{s}-y_{t}\right)^{\prime}
\]
where V is the \(n\)-by- \(n\) diagonal matrix whose \(j\) th diagonal element is \(\mathrm{S}(j)^{2}\), where \(S\) is the vector containing the inverse weights.
- Mahalanobis distance
\[
d_{s t}^{2}=\left(x_{s}-y_{t}\right) C^{-1}\left(x_{s}-y_{t}\right)^{\prime}
\]
where C is the covariance matrix.
- City block metric
\[
d_{s t}=\sum_{j=1}^{n}\left|x_{s j}-y_{t j}\right|
\]

The city block distance is a special case of the Minkowski metric, where \(p\) \(=1\).
- Minkowski metric
\[
d_{s t}=\sqrt[p]{\sum_{j=1}^{n}\left|x_{s j}-y_{t j}\right|^{p}}
\]

For the special case of \(p=1\), the Minkowski metric gives the city block metric, for the special case of \(p=2\), the Minkowski metric gives the Euclidean distance, and for the special case of \(p=\infty\), the Minkowski metric gives the Chebychev distance.
- Chebychev distance
\[
d_{s t}=\max _{j}\left\{\left|x_{s j}-y_{t j}\right|\right\}
\]

The Chebychev distance is a special case of the Minkowski metric, where \(p\) \(=\infty\).
- Cosine distance
\[
d_{s t}=\left(1-\frac{x_{s} y_{t}^{\prime}}{\sqrt{\left(x_{s} x_{s}^{\prime}\right)\left(y_{t} y_{t}^{\prime}\right)}}\right)
\]
- Correlation distance
\[
d_{s t}=1-\frac{\left(x_{s}-\bar{x}_{s}\right)\left(y_{t}-\bar{y}_{t}\right)^{\prime}}{\sqrt{\left(x_{s}-\bar{x}_{s}\right)\left(x_{s}-\bar{x}_{s}\right)^{\prime}} \sqrt{\left(y_{t}-\bar{y}_{t}\right)\left(y_{t}-\bar{y}_{t}\right)^{\prime}}}
\]
where
\[
\begin{aligned}
& \bar{x}_{s}=\frac{1}{n} \sum_{j} x_{s j} \\
& \bar{y}_{t}=\frac{1}{n} \sum_{j} y_{t j}
\end{aligned}
\]
- Hamming distance
\[
d_{s t}=\left(\#\left(x_{s j} \neq y_{t j}\right) / n\right)
\]
- Jaccard distance
\[
d_{s t}=\frac{\#\left[\left(x_{s j} \neq y_{t j}\right) \cap\left(\left(x_{s j} \neq 0\right) \cup\left(y_{t j} \neq 0\right)\right)\right]}{\#\left[\left(x_{s j} \neq 0\right) \cup\left(y_{t j} \neq 0\right)\right]}
\]
- Spearman distance
\[
d_{s t}=1-\frac{\left(r_{s}-\bar{r}_{s}\right)\left(r_{t}-\bar{r}_{t}\right)^{\prime}}{\sqrt{\left(r_{s}-\bar{r}_{s}\right)\left(r_{s}-\bar{r}_{s}\right)^{\prime}} \sqrt{\left(r_{t}-\bar{r}_{t}\right)\left(r_{t}-\bar{r}_{t}\right)^{\prime}}}
\]
where
- \(r_{s j}\) is the rank of \(x_{s j}\) taken over \(x_{1 j}, x_{2 j}, \ldots x_{m x, j}\), as computed by tiedrank.
- \(r_{t j}\) is the rank of \(y_{t j}\) taken over \(y_{1 j}, y_{2 j}, \ldots y_{m y, j}\), as computed by tiedrank.
- \(r_{s}\) and \(r_{t}\) are the coordinate-wise rank vectors of \(x_{s}\) and \(y_{t}\), i.e., \(r_{s}=\left(r_{s l}\right.\), \(\left.r_{s 2}, \ldots r_{s n}\right)\) and \(r_{t}=\left(r_{t 1}, r_{t 2}, \ldots r_{t n}\right)\).
- \(\quad \bar{r}_{s}=\frac{1}{n} \sum_{j} r_{s j}=\frac{(n+1)}{2}\).
- \(\bar{r}_{t}=\frac{1}{n} \sum_{j} r_{t j}=\frac{(n+1)}{2}\).

\section*{\(\boldsymbol{k}\)-Nearest Neighbor Search and Radius Search}

Given a set \(X\) of \(n\) points and a distance function, \(k\)-nearest neighbor ( \(k \mathrm{NN}\) ) search lets you find the \(k\) closest points in \(X\) to a query point or set of points Y . The \(k \mathrm{NN}\) search technique and \(k \mathrm{NN}\)-based algorithms are widely used as benchmark learning rules. The relative simplicity of the \(k N N\) search technique makes it easy to compare the results from other classification techniques to \(k N N\) results. The technique has been used in various areas such as:
- bioinformatics
- image processing and data compression
- document retrieval
- computer vision
- multimedia database
- marketing data analysis

You can use \(k N N\) search for other machine learning algorithms, such as:
- \(k N N\) classification
- local weighted regression
- missing data imputation and interpolation
- density estimation

You can also use \(k \mathrm{NN}\) search with many distance-based learning functions, such as K-means clustering.

In contrast, for a positive real value \(r\), rangesearch finds all points in \(X\) that are within a distance \(r\) of each point in \(Y\). This fixed-radius search is closely
related to \(k\) NN search, as it supports the same distance metrics and search classes, and uses the same search algorithms.

\section*{k-Nearest Neighbor Search Using Exhaustive Search}

When your input data meets any of the following criteria, knnsearch uses the exhaustive search method by default to find the \(k\)-nearest neighbors:
- The number of columns of \(X\) is more than 10 .
- X is sparse.
- The distance measure is either:
- 'seuclidean'
- 'mahalanobis'
- 'cosine'
- 'correlation'
- 'spearman'
- 'hamming'
- 'jaccard'
- A custom distance function
knnsearch also uses the exhaustive search method if your search object is an ExhaustiveSearcher object. The exhaustive search method finds the distance from each query point to every point in \(X\), ranks them in ascending order, and returns the \(k\) points with the smallest distances. For example, this diagram shows the \(k=3\) nearest neighbors.

\section*{k-Nearest Neighbor Search Using a kd-Tree}

When your input data meets all of the following criteria, knnsearch creates a \(k\) d-tree by default to find the \(k\)-nearest neighbors:
- The number of columns of \(X\) is less than 10 .
- X is not sparse.
- The distance measure is either:
- 'euclidean' (default)
- 'cityblock'
- 'minkowski'
- 'chebychev'
knnsearch also uses a \(k\) d-tree if your search object is a KDTreeSearcher object.
\(k\) d-trees divide your data into nodes with at most BucketSize (default is 50) points per node, based on coordinates (as opposed to categories). The following diagrams illustrate this concept using patch objects to color code the different "buckets."

When you want to find the \(k\)-nearest neighbors to a given query point, knnsearch does the following:

1 Determines the node to which the query point belongs. In the following example, the query point \((32,90)\) belongs to Node 4.

2 Finds the closest \(k\) points within that node and its distance to the query point. In the following example, the points in red circles are equidistant from the query point, and are the closest points to the query point within Node 4.

3 Chooses all other nodes having any area that is within the same distance, in any direction, from the query point to the \(k\) th closest point. In this example, only Node 3 overlaps the solid black circle centered at the query point with radius equal to the distance to the closest points within Node 4.

4 Searches nodes within that range for any points closer to the query point. In the following example, the point in a red square is slightly closer to the query point than those within Node 4.

\begin{tabular}{|cc|}
\hline\(\times\) & Query \\
\(\square\) & Neighbors \\
& Cuts \\
\(\cdots \cdots \cdots\) & Neighborhood \\
\(\square\) & Node 1 \\
\(\square\) & Node 2 \\
\(\square\) & Node 3 \\
\(\square\) & Node 4 \\
\(\square\) & Node 5 \\
\(\square\) & Node 6 \\
\(\square\) & Node 7 \\
\(\square\) & Node 8 \\
\hline
\end{tabular}

Using a \(k\) d-tree for large datasets with fewer than 10 dimensions (columns) can be much more efficient than using the exhaustive search method, as knnsearch needs to calculate only a subset of the distances. To maximize the efficiency of \(k\) d-trees, use a KDTreeSearcher object.

\section*{What Are Search Objects?}

Basically, objects are a convenient way of storing information. Classes of related objects (for example, all search objects) have the same properties with values and types relevant to a specified search method. In addition to storing information within objects, you can perform certain actions (called methods) on objects.

All search objects have a knnsearch method specific to that class. This lets you efficiently perform a \(k\)-nearest neighbors search on your object for that specific object type. In addition, there is a generic knnsearch function that searches without creating or using an object.

To determine which type of object and search method is best for your data, consider the following:
- Does your data have many columns, say more than 10 ? The ExhaustiveSearcher object may perform better.
- Is your data sparse? Use the ExhaustiveSearcher object.
- Do you want to use one of these distance measures to find the nearest neighbors? Use the ExhaustiveSearcher object.
- 'seuclidean'
- 'mahalanobis'
- 'cosine'
- 'correlation'
- 'spearman'
- 'hamming'
- 'jaccard'
- A custom distance function
- Is your dataset huge (but with fewer than 10 columns)? Use the KDTreeSearcher object.
- Are you searching for the nearest neighbors for a large number of query points? Use the KDTreeSearcher object.

\section*{Example: Classifying Query Data Using knnsearch}

1 Classify a new point based on the last two columns of the Fisher iris data. Using only the last two columns makes it easier to plot:
```

load fisheriris
x = meas(:,3:4);
gscatter(x(:,1),x(:,2),species)
set(legend,'location','best')

```

2 Plot the new point:
```

newpoint = [5 1.45];
line(newpoint(1),newpoint(2),'marker','x','color','k',...
'markersize',10,'linewidth',2)

```

3 Find the 10 sample points closest to the new point:
```

[n,d] = knnsearch(x,newpoint,'k',10)
line(x(n,1),x(n,2),'color',[.5 .5 .5],'marker','o',...
'linestyle','none','markersize',10)

```

4 It appears that knnsearch has found only the nearest eight neighbors. In fact, this particular dataset contains duplicate values:
```

x(n,:)
ans =
5.0000 1.5000
4.9000 1.5000
4.9000 1.5000
5.1000 1.5000
5.1000 1.6000
4.8000 1.4000
5.0000 1.7000
4.7000 1.4000
4.7000 1.4000

```

\section*{\(4.7000 \quad 1.5000\)}

5 To make duplicate values visible on the plot, use the following code:
```

% jitter to make repeated points visible
xj = x + .05*(rand(150,2)-.5);
gscatter(xj(:,1),xj(:,2),species)

```

The jittered points do not affect any analysis of the data, only the visualization. This example does not jitter the points.

6 Make the axes equal so the calculated distances correspond to the apparent distances on the plot axis equal and zoom in to see the neighbors better:

7 Find the species of the 10 neighbors:
```

tabulate(species(n))

| Value | Count | Percent |
| ---: | ---: | ---: |
| virginica | 2 | $20.00 \%$ |
| versicolor | 8 | $80.00 \%$ |

```

Using a rule based on the majority vote of the 10 nearest neighbors, you can classify this new point as a versicolor.

8 Visually identify the neighbors by drawing a circle around the group of them:
```

% Define the center and diameter of a circle, based on the
% location of the new point:
ctr = newpoint - d(end);
diameter = 2*d(end);
% Draw a circle around the 10 nearest neighbors:
h = rectangle('position',[ctr,diameter,diameter],...
'curvature',[1 1]);
set(h,'linestyle',':')

```

9 Using the same dataset, find the 10 nearest neighbors to three new points:
```

figure
newpoint2 = [5 1.45;6 2;2.75 .75];
gscatter(x(:,1),x(:,2),species)
legend('location','best')
[n2,d2] = knnsearch(x,newpoint2,'k',10);
line(x(n2,1),x(n2,2),'color',[.5 .5 .5],'marker','o',...
'linestyle','none','markersize',10)
line(newpoint2(:,1),newpoint2(:,2),'marker','x','color','k',...
'markersize',10,'linewidth',2,'linestyle','none')

```

10 Find the species of the 10 nearest neighbors for each new point:
```

tabulate(species(n2(1,:)))
Value Count Percent
virginica 2 20.00%
versicolor 8 80.00%

```
tabulate(species(n2(2,:)))
            Value Count Percent
        virginica 10 100.00\%
tabulate(species(n2(3,:)))
            Value Count Percent
    versicolor \(7070.00 \%\)
            setosa 3 30.00\%

For more examples using knnsearch methods and function, see the individual reference pages.

\section*{K-Nearest Neighbor Classification for Supervised Learning}

The ClassificationKNN class lets you:
- "Construct a KNN Classifier" on page 15-25
- "Examine the Quality of a KNN Classifier" on page 15-26
- "Predict Classification Based on a KNN Classifier" on page 15-27
- "Modify a KNN Classifier" on page 15-27

Work with the classifier as you would with ClassificationTree or ClassificationDiscriminant. In particular, prepare your data for classification according to the procedure in "Steps in Supervised Learning (Machine Learning)" on page 15-2. Then construct the classifier using ClassificationKNN.fit.

\section*{Construct a KNN Classifier}

This example shows how to construct a \(k\)-nearest neighbor classifier for the Fisher iris data.

Load the Fisher iris data.
load fisheriris
X = meas; \% use all data for fitting \(Y=\) species; \% response data

Construct the classifier using ClassificationKNN.fit.
```

mdl = ClassificationKNN.fit(X,Y)

```
mdl =

\section*{ClassificationKNN}

PredictorNames: \{'x1' 'x2' 'x3' 'x4'\} ResponseName: 'Y'
```

    ClassNames: {'setosa' 'versicolor' 'virginica'}
    ScoreTransform: 'none'
NObservations: 150
Distance: 'euclidean'
NumNeighbors: 1

```
```

Properties, Methods

```

A default \(k\)-nearest neighbor classifier uses just the single nearest neighbor. Often, a classifier is more robust with more neighbors than that. Change the neighborhood size of mdl to 4, meaning mdl classifies using the four nearest neighbors:
```

mdl.NumNeighbors = 4;

```

\section*{Examine the Quality of a KNN Classifier}

This example shows how to examine the quality of a \(k\)-nearest neighbor classifier using resubstitution and cross validation.

Construct a KNN classifier for the Fisher iris data as in "Construct a KNN Classifier" on page 15-25.
load fisheriris
\(X=\) meas; \% use all data for fitting Y = species; \% response data mdl = ClassificationKNN.fit(X,Y,'NumNeighbors',4);

Examine the resubstitution loss, which, by default, is the fraction of misclassifications from the predictions of mdl. (For nondefault cost, weights, or priors, see ClassificationKNN.loss.)
rloss \(=\) resubLoss(mdl)
rloss =
0.0400

The classifier predicts incorrectly for \(4 \%\) of the training data.
Construct a cross-validated classifier from the model.
```

cvmdl = crossval(mdl);

```

Examine the cross-validation loss, which is the average loss of each cross-validation model when predicting on data that is not used for training.
```

kloss = kfoldLoss(cvmdl)
kloss =
0.0600

```

The cross-validated classification accuracy resembles the resubstitution accuracy. Therefore, you can expect mdl to misclassify approximately \(5 \%\) of new data, assuming that the new data has about the same distribution as the training data.

\section*{Predict Classification Based on a KNN Classifier}

This example shows how to predict classification for a \(k\)-nearest neighbor classifier.

Construct a default KNN classifier for the Fisher iris data as in "Construct a KNN Classifier" on page 15-25.
```

load fisheriris
X = meas; % use all data for fitting
Y = species; % response data
mdl = ClassificationKNN.fit(X,Y);

```

Predict the classification of an average flower.
```

flwr = mean(X); % an average flower
flwrClass = predict(mdl,flwr)
flwrClass =

```
'versicolor'

\section*{Modify a KNN Classifier}

This example shows how to modify a \(k\)-nearest neighbor classifier.

Construct a default KNN classifier for the Fisher iris data as in "Construct a KNN Classifier" on page 15-25.
```

load fisheriris
X = meas; % use all data for fitting
Y = species; % response data
mdl = ClassificationKNN.fit(X,Y);

```

Modify the model to use the three nearest neighbors, rather than the default one nearest neighbor.
```

mdl.NumNeighbors = 3;

```

Compare the resubstitution predictions and cross-validation loss with the new number of neighbors.
```

rloss = resubLoss(mdl)
rloss =
0.0400
rng('default')
cvmdl = crossval(mdl,'kfold',5);
kloss = kfoldLoss(cvmdl)
kloss =
0.0333

```

The model with three neighbors has lower cross-validated loss than a model with four neighbors (see "Examine the Quality of a KNN Classifier" on page 15-26).

Modify the model to use cosine distance instead of the default, and examine the loss. To use cosine distance, you must recreate the model using the exhaustive search method.
```

cmdl = ClassificationKNN.fit(X,Y,'NSMethod','exhaustive',...
'Distance','cosine');
cmdl.NumNeighbors = 3;
closs = resubLoss(cmdl)

```
```

closs =
0.0200

```

The classifier now has lower resubstitution error than before.
Check the quality of a cross-validated version of the new model.
cvemdl = crossval(cmdl);
kcloss \(=\) kfoldLoss(cvcmdl)
kcloss =
0.0333

The cross-validated loss is the same as before. The lesson is that improving the resubstitution error does not necessarily produce a model with better predictions.

\section*{Classification Trees and Regression Trees}

\author{
In this section... \\ "What Are Classification Trees and Regression Trees?" on page 15-30 \\ "Creating a Classification Tree" on page 15-31 \\ "Creating a Regression Tree" on page 15-31 \\ "Viewing a Tree" on page 15-32 \\ "How the Fit Methods Create Trees" on page 15-35 \\ "Predicting Responses With Classification and Regression Trees" on page 15-37 \\ "Improving Classification Trees and Regression Trees" on page 15-37 \\ "Alternative: classregtree" on page 15-47
}

\section*{What Are Classification Trees and Regression Trees?}

Classification trees and regression trees predict responses to data. To predict a response, follow the decisions in the tree from the root (beginning) node down to a leaf node. The leaf node contains the response. Classification trees give responses that are nominal, such as 'true' or 'false'. Regression trees give numeric responses.

Statistics Toolbox trees are binary. Each step in a prediction involves checking the value of one predictor (variable). For example, here is a simple classification tree:

This tree predicts classifications based on two predictors, x 1 and x 2 . To predict, start at the top node, represented by a triangle ( \(\Delta\) ). The first decision is whether \(x 1\) is smaller than 0.5 . If so, follow the left branch, and see that the tree classifies the data as type 0 .

If, however, \(x 1\) exceeds 0.5 , then follow the right branch to the lower-right triangle node. Here the tree asks if \(x 2\) is smaller than 0.5 . If so, then follow the left branch to see that the tree classifies the data as type 0 . If not, then follow the right branch to see that the that the tree classifies the data as type 1 .

To learn how to prepare your data for classification or regression using decision trees, see "Steps in Supervised Learning (Machine Learning)" on page 15-2.

\section*{Creating a Classification Tree}

To create a classification tree for the ionosphere data:
```

load ionosphere % contains X and Y variables
ctree = ClassificationTree.fit(X,Y)
ctree =
ClassificationTree
PredictorNames: {1x34 cell}
ResponseName: 'Y'
ClassNames: {'b' 'g'}
ScoreTransform: 'none'
CategoricalPredictors: [
NObservations: 351

```
    Properties, Methods

\section*{Creating a Regression Tree}

To create a regression tree for the carsmall data based on the Horsepower and Weight vectors for data, and MPG vector for response:
load carsmall \% contains Horsepower, Weight, MPG
```

X = [Horsepower Weight];
rtree = RegressionTree.fit(X,MPG)
rtree =
RegressionTree
PredictorNames: {'x1' 'x2'}
ResponseName: 'Y
ResponseTransform: 'none
CategoricalPredictors: []
NObservations: 94

```
    Properties, Methods

\section*{Viewing a Tree}

There are two ways to view a tree:
- view(tree) returns a text description of the tree.
- view(tree,'mode','graph') returns a graphic description of the tree.
"Creating a Classification Tree" on page 15-31 has the following two views:
```

load fisheriris
ctree = ClassificationTree.fit(meas,species);
view(ctree)
Decision tree for classification
1 if x3<2.45 then node 2 elseif x3>=2.45 then node 3 else setosa
2 class = setosa
3 if x4<1.75 then node 4 elseif x4>=1.75 then node 5 else versicolor
4 if x3<4.95 then node 6 elseif x3>=4.95 then node 7 else versicolor
5 class = virginica
6 if x4<1.65 then node 8 elseif x4>=1.65 then node 9 else versicolor
7 class = virginica
8 class = versicolor
9 class = virginica

```
```

view(ctree,'mode','graph')

```
\begin{tabular}{|c|c|c|c|c|c|c|c|c|}
\hline \multicolumn{6}{|l|}{- Classification tree viewer} & \(\square\) & [回 & - \\
\hline File Tools D & Desktop & Tree & Window & Help & & & & v \\
\hline \multicolumn{9}{|l|}{\(\Leftrightarrow \mid+\underbrace{+} \underbrace{+}\)} \\
\hline Click to display: & Identity & & \(\checkmark\) & Magnification: & 100\% & \(\checkmark\) & Pruni & ing lev \\
\hline
\end{tabular}

Similarly, "Creating a Regression Tree" on page 15-31 has the following two views:
```

load carsmall % contains Horsepower, Weight, MPG
X = [Horsepower Weight];
rtree = RegressionTree.fit(X,MPG,'MinParent',30);
view(rtree)
Decision tree for regression
1 if x2<3085.5 then node 2 elseif x2>=3085.5 then node 3 else 23.7181
2 if x1<89 then node 4 elseif x1>=89 then node 5 else 28.7931
3 if x1<115 then node 6 elseif x1>=115 then node 7 else 15.5417
4 if x2<2162 then node 8 elseif x2>=2162 then node 9 else 30.9375
5 fit = 24.0882
6 fit = 19.625
7 fit = 14.375
fit = 33.3056
9 fit = 29

```
```

view(rtree,'mode','graph')

```
```

view(rtree,'mode','graph')

```

\section*{How the Fit Methods Create Trees}

The ClassificationTree.fit and RegressionTree.fit methods perform the following steps to create decision trees:

1 Start with all input data, and examine all possible binary splits on every predictor.

2 Select a split with best optimization criterion.
- If the split leads to a child node having too few observations (less than the MinLeaf parameter), select a split with the best optimization criterion subject to the MinLeaf constraint.

3 Impose the split.

4 Repeat recursively for the two child nodes.
The explanation requires two more items: description of the optimization criterion, and stopping rule.

Stopping rule: Stop splitting when any of the following hold:
- The node is pure.
- For classification, a node is pure if it contains only observations of one class.
- For regression, a node is pure if the mean squared error (MSE) for the observed response in this node drops below the MSE for the observed response in the entire data multiplied by the tolerance on quadratic error per node (qetoler parameter).
- There are fewer than MinParent observations in this node.
- Any split imposed on this node would produce children with fewer than MinLeaf observations.

\section*{Optimization criterion:}
- Regression: mean-squared error (MSE). Choose a split to minimize the MSE of predictions compared to the training data.
- Classification: One of three measures, depending on the setting of the SplitCriterion name-value pair:
- 'gdi' (Gini's diversity index, the default)
- 'twoing'
- 'deviance'

For details, see ClassificationTree "Definitions" on page 20-287.
For a continuous predictor, a tree can split halfway between any two adjacent unique values found for this predictor. For a categorical predictor with \(L\) levels, a classification tree needs to consider \(2^{L-1}-1\) splits to find the optimal split. Alternatively, you can choose a heuristic algorithm to find a good split, as described in "Splitting Categorical Predictors" on page 15-55.

\section*{Predicting Responses With Classification and Regression Trees}

After creating a tree, you can easily predict responses for new data. Suppose Xnew is new data that has the same number of columns as the original data X . To predict the classification or regression based on the tree and the new data, enter

Ynew = predict(tree,Xnew);
For each row of data in Xnew, predict runs through the decisions in tree and gives the resulting prediction in the corresponding element of Ynew. For more information for classification, see the classification predict reference page; for regression, see the regression predict reference page.

For example, to find the predicted classification of a point at the mean of the ionosphere data:
```

load ionosphere % contains X and Y variables
ctree = ClassificationTree.fit(X,Y);
Ynew = predict(ctree,mean(X))
Ynew =

```
    ' g '

To find the predicted MPG of a point at the mean of the carsmall data:
```

load carsmall % contains Horsepower, Weight, MPG
X = [Horsepower Weight];
rtree = RegressionTree.fit(X,MPG);
Ynew = predict(rtree,mean(X))
Ynew =

```
    28.7931

\section*{Improving Classification Trees and Regression Trees}

You can tune trees by setting name-value pairs in ClassificationTree.fit and RegressionTree.fit. The remainder of this section describes how to
determine the quality of a tree, how to decide which name-value pairs to set, and how to control the size of a tree:
- "Examining Resubstitution Error" on page 15-38
- "Cross Validation" on page 15-38
- "Control Depth or "Leafiness'"" on page 15-39
- "Pruning" on page 15-43

\section*{Examining Resubstitution Error}

Resubstitution error is the difference between the response training data and the predictions the tree makes of the response based on the input training data. If the resubstitution error is high, you cannot expect the predictions of the tree to be good. However, having low resubstitution error does not guarantee good predictions for new data. Resubstitution error is often an overly optimistic estimate of the predictive error on new data.

Example: Resubstitution Error of a Classification Tree. Examine the resubstitution error of a default classification tree for the Fisher iris data:
```

load fisheriris
ctree = ClassificationTree.fit(meas,species);
resuberror = resubLoss(ctree)
resuberror =
0.0200

```

The tree classifies nearly all the Fisher iris data correctly.

\section*{Cross Validation}

To get a better sense of the predictive accuracy of your tree for new data, cross validate the tree. By default, cross validation splits the training data into 10 parts at random. It trains 10 new trees, each one on nine parts of the data. It then examines the predictive accuracy of each new tree on the data not included in training that tree. This method gives a good estimate of the predictive accuracy of the resulting tree, since it tests the new trees on new data.

Example: Cross Validating a Regression Tree. Examine the resubstitution and cross-validation accuracy of a regression tree for predicting mileage based on the carsmall data:
```

load carsmall
X = [Acceleration Displacement Horsepower Weight];
rtree = RegressionTree.fit(X,MPG);
resuberror = resubLoss(rtree)
resuberror =
4.7188

```

The resubstitution loss for a regression tree is the mean-squared error. The resulting value indicates that a typical predictive error for the tree is about the square root of 4.7 , or a bit over 2 .

Now calculate the error by cross validating the tree:
```

rng('default')
cvrtree = crossval(rtree);
cvloss = kfoldLoss(cvrtree)
cvloss =

```
    23.8065

The cross-validated loss is almost 25, meaning a typical predictive error for the tree on new data is about 5 . This demonstrates that cross-validated loss is usually higher than simple resubstitution loss.

\section*{Control Depth or "Leafiness"}

When you grow a decision tree, consider its simplicity and predictive power. A deep tree with many leaves is usually highly accurate on the training data. However, the tree is not guaranteed to show a comparable accuracy on an independent test set. A leafy tree tends to overtrain, and its test accuracy is often far less than its training (resubstitution) accuracy. In contrast, a shallow tree does not attain high training accuracy. But a shallow tree can be more robust - its training accuracy could be close to that of a representative test set. Also, a shallow tree is easy to interpret.

If you do not have enough data for training and test, estimate tree accuracy by cross validation.

For an alternative method of controlling the tree depth, see "Pruning" on page 15-43.

Example: Selecting Appropriate Tree Depth. This example shows how to control the depth of a decision tree, and how to choose an appropriate depth.

1 Load the ionosphere data:
load ionosphere
2 Generate minimum leaf occupancies for classification trees from 10 to 100, spaced exponentially apart:
leafs = logspace(1,2,10);

3 Create cross validated classification trees for the ionosphere data with minimum leaf occupancies from leafs:
```

rng('default')
N = numel(leafs);
err = zeros(N,1);
for n=1:N
t = ClassificationTree.fit(X,Y,'crossval','on',...
'minleaf',leafs(n));
err(n) = kfoldLoss(t);
end
plot(leafs,err);
xlabel('Min Leaf Size');
ylabel('cross-validated error');

```

The best leaf size is between about 20 and 50 observations per leaf.
4 Compare the near-optimal tree with at least 40 observations per leaf with the default tree, which uses 10 observations per parent node and 1 observation per leaf.

DefaultTree = ClassificationTree.fit(X,Y); view(DefaultTree,'mode','graph')

OptimalTree = ClassificationTree.fit(X,Y,'minleaf', 40); view(OptimalTree,'mode','graph')

```

resubOpt = resubLoss(OptimalTree);
lossOpt = kfoldLoss(crossval(OptimalTree));
resubDefault = resubLoss(DefaultTree);
lossDefault = kfoldLoss(crossval(DefaultTree));
resubOpt,resubDefault,lossOpt,lossDefault
resubOpt =

```
```

    0.0883
    resubDefault =
0.0114
lossOpt =
0.1054
lossDefault =
0.1111

```

The near-optimal tree is much smaller and gives a much higher resubstitution error. Yet it gives similar accuracy for cross-validated data.

\section*{Pruning}

Pruning optimizes tree depth (leafiness) is by merging leaves on the same tree branch. "Control Depth or "Leafiness"" on page 15-39 describes one method for selecting the optimal depth for a tree. Unlike in that section, you do not need to grow a new tree for every node size. Instead, grow a deep tree, and prune it to the level you choose.

Prune a tree at the command line using the prune method (classification) or prune method (regression). Alternatively, prune a tree interactively with the tree viewer:
```

view(tree,'mode','graph')

```

To prune a tree, the tree must contain a pruning sequence. By default, both ClassificationTree.fit and RegressionTree.fit calculate a pruning sequence for a tree during construction. If you construct a tree with the 'Prune ' name-value pair set to 'off', or if you prune a tree to a smaller level, the tree does not contain the full pruning sequence. Generate the full pruning sequence with the prune method (classification) or prune method (regression).

Example: Pruning a Classification Tree. This example creates a classification tree for the ionosphere data, and prunes it to a good level.

1 Load the ionosphere data:
load ionosphere
2 Construct a default classification tree for the data:
tree \(=\) ClassificationTree.fit( \(\mathrm{X}, \mathrm{Y}\) );
3 View the tree in the interactive viewer:
```

view(tree,'mode','graph')

```

Classification tree viewer

4 Find the optimal pruning level by minimizing cross-validated loss:
```

[~,~,~,bestlevel] = cvLoss(tree,...
'subtrees','all','treesize','min')

```
bestlevel =

5 Prune the tree to level 6 in the interactive viewer:

The pruned tree is the same as the near-optimal tree in "Example: Selecting Appropriate Tree Depth" on page 15-40.

6 Set 'treesize' to 'se' (default) to find the maximal pruning level for which the tree error does not exceed the error from the best level plus one standard deviation:
```

[~,~,~,bestlevel] = cvLoss(tree,'subtrees','all')
bestlevel =

```

6
In this case the level is the same for either setting of 'treesize'.
7 Prune the tree to use it for other purposes:
```

tree = prune(tree,'Level',6);

```
view(tree,'mode','graph')

\section*{Alternative: classregtree}

The ClassificationTree and RegressionTree classes are new in MATLAB R2011a. Previously, you represented both classification trees and regression trees with a classregtree object. The new classes provide all the functionality of the classregtree class, and are more convenient when used in conjunction with "Ensemble Methods" on page 15-58.

Before the classregtree class, there were treefit, treedisp, treeval, treeprune, and treetest functions. Statistics Toolbox software maintains these only for backward compatibility.

\section*{Example: Creating Classification Trees Using classregtree}

This example uses Fisher's iris data in fisheriris.mat to create a classification tree for predicting species using measurements of sepal length, sepal width, petal length, and petal width as predictors. Here, the predictors are continuous and the response is categorical.

1 Load the data and use the classregtree constructor of the classregtree class to create the classification tree:
```

load fisheriris
t = classregtree(meas,species,...
'names',{'SL' 'SW' 'PL' 'PW'})
t =
Decision tree for classification
1 if PL<2.45 then node 2 elseif PL>=2.45 then node 3 else setosa
2 class = setosa
3 if PW<1.75 then node 4 elseif PW>=1.75 then node 5 else versicolor
4 if PL<4.95 then node 6 elseif PL>=4.95 then node 7 else versicolor
5 class = virginica
6 if PW<1.65 then node 8 elseif PW>=1.65 then node 9 else versicolor
7 class = virginica
8 class = versicolor
9 class = virginica

```
\(t\) is a classregtree object and can be operated on with any class method.
2 Use the type method of the classregtree class to show the type of the tree:
```

treetype = type(t)
treetype =
classification

```
classregtree creates a classification tree because species is a cell array of strings, and the response is assumed to be categorical.

3 To view the tree, use the view method of the classregtree class:
```

view(t)

```
Click to display: \begin{tabular}{|l|l|l|l|l|}
\hline Identity & \(\square\) & Magnification: & \(100 \%\) & \(\square\) \\
\hline
\end{tabular}

The tree predicts the response values at the circular leaf nodes based on a series of questions about the iris at the triangular branching nodes. A true answer to any question follows the branch to the left. A false follows the branch to the right.

4 The tree does not use sepal measurements for predicting species. These can go unmeasured in new data, and you can enter them as NaN values for predictions. For example, to use the tree to predict the species of an iris with petal length 4.8 and petal width 1.6 , type:
```

predicted = t([NaN NaN 4.8 1.6])
predicted =
'versicolor'

```

The object allows for functional evaluation, of the form \(t(X)\). This is a shorthand way of calling the eval method of the classregtree class. The predicted species is the left leaf node at the bottom of the tree in the previous view.

5 You can use a variety of methods of the classregtree class, such as cutvar and cuttype to get more information about the split at node 6 that makes the final distinction between versicolor and virginica:
```

var6 = cutvar(t,6) % What variable determines the split?
var6 =
'PW'
type6 = cuttype(t,6) % What type of split is it?
type6 =
'continuous'

```

6 Classification trees fit the original (training) data well, but can do a poor job of classifying new values. Lower branches, especially, can be strongly affected by outliers. A simpler tree often avoids overfitting. You can use the prune method of the classregtree class to find the next largest tree from an optimal pruning sequence:
```

pruned = prune(t,'level',1)
pruned =
Decision tree for classification
if PL<2.45 then node 2 elseif PL>=2.45 then node 3 else setosa
class = setosa
if PW<1.75 then node 4 elseif PW>=1.75 then node 5 else versicolor
if PL<4.95 then node 6 elseif PL>=4.95 then node 7 else versicolor
class = virginica
class = versicolor
7 class = virginica
view(pruned)

```

To find the best classification tree, employing the techniques of resubstitution and cross validation, use the test method of the classregtree class.

\section*{Example: Creating Regression Trees Using classregtree}

This example uses the data on cars in carsmall.mat to create a regression tree for predicting mileage using measurements of weight and the number of cylinders as predictors. Here, one predictor (weight) is continuous and the other (cylinders) is categorical. The response (mileage) is continuous.

1 Load the data and use the classregtree constructor of the classregtree class to create the regression tree:
```

load carsmall
t = classregtree([Weight, Cylinders],MPG,...
'cat',2,'splitmin',20,...
'names',{'W','C'})
t =
Decision tree for regression
if W<3085.5 then node 2 elseif W>=3085.5 then node 3 else 23.7181
if W<2371 then node 4 elseif W>=2371 then node 5 else 28.7931
if C=8 then node 6 elseif C in {4 6} then node 7 else 15.5417
if W<2162 then node 8 elseif W>=2162 then node 9 else 32.0741
if C=6 then node 10 elseif C=4 then node 11 else 25.9355
if W<4381 then node 12 elseif W>=4381 then node 13 else 14.2963
fit = 19.2778
fit = 33.3056
fit = 29.6111
fit = 23.25
if W<2827.5 then node 14 elseif W>=2827.5 then node 15 else 27.2143
if W<3533.5 then node 16 elseif W>=3533.5 then node 17 else 14.8696
fit = 11
fit = 27.6389
fit = 24.6667
fit = 16.6
7 fit = 14.3889

```
t is a classregtree object and can be operated on with any of the methods of the class.

2 Use the type method of the classregtree class to show the type of the tree:
```

treetype = type(t)
treetype =
regression

```
classregtree creates a regression tree because MPG is a numerical vector, and the response is assumed to be continuous.

3 To view the tree, use the view method of the classregtree class:
```

view(t)

```

The tree predicts the response values at the circular leaf nodes based on a series of questions about the car at the triangular branching nodes. A true answer to any question follows the branch to the left; a false follows the branch to the right.

4 Use the tree to predict the mileage for a 2000 -pound car with either 4,6 , or 8 cylinders:
```

mileage2K = t([2000 4; 2000 6; 2000 8])
mileage2K =
33.3056
33.3056
33.3056

```

The object allows for functional evaluation, of the form \(t(X)\). This is a shorthand way of calling the eval method of the classregtree class.

5 The predicted responses computed above are all the same. This is because they follow a series of splits in the tree that depend only on weight, terminating at the leftmost leaf node in the view above. A 4000-pound car, following the right branch from the top of the tree, leads to different predicted responses:
```

mileage4K = t([4000 4; 4000 6; 4000 8])

```
```

mileage4K =
19.2778
19.2778
14.3889

```

6 You can use a variety of other methods of the classregtree class, such as cutvar, cuttype, and cutcategories, to get more information about the split at node 3 that distinguishes the 8 -cylinder car:
```

var3 = cutvar(t,3) % What variable determines the split?
var3 =
'C'
type3 = cuttype(t,3) % What type of split is it?
type3 =
'categorical'
c = cutcategories(t,3) % Which classes are sent to the left
% child node, and which to the right?
c =
[8] [1x2 double]
c {1}
ans =
8
c {2}
ans =
4 6

```

Regression trees fit the original (training) data well, but may do a poor job of predicting new values. Lower branches, especially, may be strongly affected by outliers. A simpler tree often avoids overfitting. To find the best regression tree, employing the techniques of resubstitution and cross validation, use the test method of the classregtree class.

\section*{Splitting Categorical Predictors}

\author{
In this section... \\ "Challenges in Splitting Multilevel Predictors" on page 15-55 \\ "Pull Left By Purity" on page 15-56 \\ "Principle Component-Based Partitioning" on page 15-56 \\ "One Versus All By Class" on page 15-57
}

\section*{Challenges in Splitting Multilevel Predictors}

When growing a classification tree, finding an optimal binary split for a categorical predictor with many levels is significantly more computationally challenging than finding a split for a continuous predictor. For a continuous predictor, a tree can split halfway between any two adjacent unique values of this predictor.

In contrast, to find an exact optimal binary split for a categorical predictor with \(L\) levels, a classification tree needs to consider \(2^{L-1}-1\) splits. To obtain this formula, observe that you can assign \(L\) distinct values to the left and right nodes in \(2^{L}\) ways. Two out of these \(2^{L}\) configurations leave either the left or right node empty, and therefore should be discarded. Now, divide by 2 because left and right can be swapped.

For regression and binary classification problems, with \(K=2\) response classes, there is a computational shortcut [1]. The tree can order the categories by mean response (for regression) or class probability for one of the classes (for classification). Then, the optimal split is one of the \(L-1\) splits for the ordered list. When \(K=2\), ClassificationTree.fit always uses an exact search.

Therefore, computational challenges really only arise when growing classification trees for data with \(K \geq 3\) classes. To reduce computation, there are several heuristic algorithms for finding a good split. When using ClassificationTree.fit to grow a classification tree, you can choose an algorithm for splitting categorical predictors using the AlgorithmForCategorical name-value pair argument. You can also set this algorithm when creating a classification template.

If you do not specify an algorithm, ClassificationTree.fit splits categorical predictors using the exact search algorithm, provided the predictor has at most MaxCat levels (the default is 10 levels, and, depending on your platform, you cannot perform an exact search on categorical predictors with more than 32 or 64 levels). Otherwise, ClassificationTree.fit chooses a good inexact search algorithm based on the number of classes and levels.

The available heuristic algorithms are: pull left by purity, a principle component-based partitioning, and one versus all by class.

\section*{Pull Left By Purity}

This algorithm starts with all \(L\) categorical levels on the right branch. Inspect the \(K\) categories that have the largest class probabilities for each class. Move the category with the maximum value of the split criterion to the left branch. Continue moving categories from right to left, recording the split criterion at each move, until the right child has only one category remaining. Out of this sequence, the chosen split is the one that maximizes the split criterion.

Select this pull left by purity algorithm by using the 'AlgorithmForCategorial', 'PullLeft' name-value pair in ClassificationTree.fit.

\section*{Principle Component-Based Partitioning}

This algorithm was developed by Coppersmith, Hong, and Hosking [2]. It finds a close-to-optimal binary partition of the \(L\) predictor levels by searching for a separating hyperplane that is perpendicular to the first principal component of the weighted covariance matrix of the centered class probability matrix.

The algorithm assigns a score to each of the \(L\) categories, computed as the inner product between the found principal component and the vector of class probabilities for that category. Then, the chosen split is the one of the \(L-1\) splits of the scores that maximizes the split criterion.

Select this principle component-based partitioning by using the 'AlgorithmForCategorical','PCA' name-value pair in ClassificationTree.fit.

\section*{One Versus All By Class}

This algorithm starts with all \(L\) categorical levels on the right branch. For each of the \(K\) classes, order the categories based on their probability for that class.

For the first class, move each category to the left branch in order, recording the split criterion at each move. Repeat for the remaining classes. Out of this sequence, the chosen split is the one that maximizes the split criterion.

Select this one versus all by class algorithm by using the 'AlgorithmForCategorial','OVAbyClass' name-value pair in ClassificationTree.fit.

\section*{Framework for Ensemble Learning}

You have several methods for melding results from many weak learners into one high-quality ensemble predictor. These methods closely follow the same syntax, so you can try different methods with minor changes in your commands.

Create an ensemble with the fitensemble function. Its syntax is
ens = fitensemble( \(\mathrm{X}, \mathrm{Y}\), model, numberens, learners)
- \(X\) is the matrix of data. Each row contains one observation, and each column contains one predictor variable.
- Y is the vector of responses, with the same number of observations as the rows in \(X\).
- model is a string naming the type of ensemble.
- numberens is the number of weak learners in ens from each element of learners. So the number of elements in ens is numberens times the number of elements in learners.
- learners is either a string naming a weak learner, a weak learner template, or a cell array of such templates.

Pictorially, here is the information you need to create an ensemble:

For all classification or nonlinear regression problems, follow these steps to create an ensemble:

1 "Put Predictor Data in a Matrix" on page 15-60
2 "Prepare the Response Data" on page 15-60
3 "Choose an Applicable Ensemble Method" on page 15-61
4 "Set the Number of Ensemble Members" on page 15-64
5 "Prepare the Weak Learners" on page 15-65
6 "Call fitensemble" on page 15-67

\section*{Put Predictor Data in a Matrix}

All supervised learning methods start with a data matrix, usually called X in this documentation. Each row of \(X\) represents one observation. Each column of \(X\) represents one variable, or predictor.

\section*{Prepare the Response Data}

You can use a wide variety of data types for response data.
- For regression ensembles, \(Y\) must be a numeric vector with the same number of elements as the number of rows of \(X\).
- For classification ensembles, Y can be any of the following data types. This table also contains the method of including missing entries.
\begin{tabular}{l|l}
\hline Data Type & Missing Entry \\
\hline Numeric vector & NaN \\
\hline Categorical vector & <undefined> \\
\hline Character array & Row of spaces \\
\hline Cell array of strings & '' \\
\hline Logical vector & (not possible to represent) \\
\hline
\end{tabular}
fitensemble ignores missing values in \(Y\) when creating an ensemble.
For example, suppose your response data consists of three observations in the following order: true, false, true. You could express Y as:
- [1;0;1] (numeric vector)
- nominal(\{'true', 'false','true'\}) (categorical vector)
- [true;false;true] (logical vector)
- ['true ';'false';'true '] (character array, padded with spaces so each row has the same length)
- \{'true','false', 'true'\} (cell array of strings)

Use whichever data type is most convenient. Because you cannot represent missing values with logical entries, do not use logical entries when you have missing values in Y .

\section*{Choose an Applicable Ensemble Method}
fitensemble uses one of these algorithms to create an ensemble.
- For classification with two classes:
- 'AdaBoostM1'
- 'LogitBoost'
- 'GentleBoost'
- 'RobustBoost' (requires an Optimization Toolbox license)
- 'LPBoost' (requires an Optimization Toolbox license)
- 'TotalBoost' (requires an Optimization Toolbox license)
- 'RUSBoost'
- 'Subspace'
- 'Bag'
- For classification with three or more classes:
- 'AdaBoostM2'
- 'LPBoost' (requires an Optimization Toolbox license)
- 'TotalBoost' (requires an Optimization Toolbox license)
- 'RUSBoost'
- 'Subspace'
- 'Bag'
- For regression:
- 'LSBoost'
- 'Bag'
'Bag' applies to all methods. When using 'Bag', indicate whether you want a classifier or regressor with the type name-value pair set to 'classification' or 'regression'.

For descriptions of the various algorithms, see "Ensemble Algorithms" on page 15-145.

See "Suggestions for Choosing an Appropriate Ensemble Algorithm" on page 15-63.

This table lists characteristics of the various algorithms. In the table titles:
- Regress. - Regression
- Classif. - Classification
- Preds. - Predictors
- Imbalance - Good for imbalanced data (one class has many more observations than the other)
- Stop - Algorithm self-terminates
- Sparse - Requires fewer weak learners than other ensemble algorithms
\begin{tabular}{l|l|l|l|l|l|l|l}
\hline Algorithm & Regress. & \begin{tabular}{l} 
Binary \\
Classif.
\end{tabular} & \begin{tabular}{l} 
Binary \\
Classif. \\
Multi- \\
Level \\
Preds.
\end{tabular} & \begin{tabular}{l} 
Classif. \\
3+ \\
Classes
\end{tabular} & \begin{tabular}{l} 
Class \\
Imbalance
\end{tabular} & Stop & Sparse \\
\hline Bag & \(\times\) & \(\times\) & & \(\times\) & & & \\
\hline AdaBoostM1 & & \(\times\) & & & & & \\
\hline AdaBoostM2 & & & & \(\times\) & & & \\
\hline LogitBoost & & \(\times\) & \(\times\) & & & & \\
\hline GentleBoost & & \(\times\) & \(\times\) & & & & \\
\hline RobustBoost & & \(\times\) & & & & \(\times\) & \(\times\) \\
\hline LPBoost & & \(\times\) & & \(\times\) & & \(\times\) & \\
\hline TotalBoost & & \(\times\) & & \(\times\) & & & \\
\hline
\end{tabular}
\begin{tabular}{l|l|l|l|l|l|l|l}
\hline Algorithm & Regress. & \begin{tabular}{l} 
Binary \\
Classif.
\end{tabular} & \begin{tabular}{l} 
Binary \\
Classif. \\
Multi- \\
Level \\
Preds.
\end{tabular} & \begin{tabular}{l} 
Classif. \\
3+ \\
Classes
\end{tabular} & \begin{tabular}{l} 
Class \\
Imbalance
\end{tabular} & Stop & Sparse \\
\hline RUSBoost & & \(\times\) & & \(\times\) & \(\times\) & & \\
\hline LSBoost & \(\times\) & & & & & & \\
\hline Subspace & & \(\times\) & & \(\times\) & & & \\
\hline
\end{tabular}

RobustBoost, LPBoost, and TotalBoost require an Optimization Toolbox license. Try TotalBoost before LPBoost, as TotalBoost can be more robust.

\section*{Suggestions for Choosing an Appropriate Ensemble Algorithm.}
- Regression - Your choices are LSBoost or Bag. See "General Characteristics of Ensemble Algorithms" on page 15-64 for the main differences between boosting and bagging.
- Binary Classification - Try AdaBoostM1 first, with these modifications:
\begin{tabular}{l|l}
\hline Data Characteristic & Recommended Algorithm \\
\hline Many predictors & Subspace \\
\hline \begin{tabular}{l} 
Skewed data (many more \\
observations of one class)
\end{tabular} & RUSBoost \\
\hline \begin{tabular}{l} 
Categorical predictors with over 31 \\
levels
\end{tabular} & LogitBoost or GentleBoost \\
\hline \begin{tabular}{l} 
Label noise (some training data has \\
the wrong class)
\end{tabular} & RobustBoost \\
\hline Many observations & \begin{tabular}{l} 
Avoid LPBoost, TotalBoost, and \\
Bag
\end{tabular} \\
\hline
\end{tabular}
- Multiclass Classification - Try AdaBoostM2 first, with these modifications:
\begin{tabular}{l|l}
\hline Data Characteristic & Recommended Algorithm \\
\hline Many predictors & Subspace \\
\hline \begin{tabular}{l} 
Skewed data (many more \\
observations of one class)
\end{tabular} & RUSBoost \\
\hline Many observations & \begin{tabular}{l} 
Avoid LPBoost, TotalBoost, and \\
Bag
\end{tabular} \\
\hline
\end{tabular}

For details of the algorithms, see "Ensemble Algorithms" on page 15-145.

\section*{General Characteristics of Ensemble Algorithms.}
- Bag generally constructs deep trees. This construction is both time consuming and memory-intensive. This also leads to relatively slow predictions.
- Boost algorithms generally use very shallow trees. This construction uses relatively little time or memory. However, for effective predictions, boosted trees might need more ensemble members than bagged trees. Therefore it is not always clear which class of algorithms is superior.
- Bag can estimate the generalization error without additional cross validation. See oobLoss.
- Except for Subspace, all boosting and bagging algorithms are based on tree learners. Subspace can use either discriminant analysis or \(k\)-nearest neighbor learners.

For details of the characteristics of individual ensemble members, see "Characteristics of Algorithms" on page 15-7.

\section*{Set the Number of Ensemble Members}

Choosing the size of an ensemble involves balancing speed and accuracy.
- Larger ensembles take longer to train and to generate predictions.
- Some ensemble algorithms can become overtrained (inaccurate) when too large.

To set an appropriate size, consider starting with several dozen to several hundred members in an ensemble, training the ensemble, and then checking the ensemble quality, as in "Example: Test Ensemble Quality" on page 15-71. If it appears that you need more members, add them using the resume method (classification) or the resume method (regression). Repeat until adding more members does not improve ensemble quality.

Tip For classification, the LPBoost and TotalBoost algorithms are self-terminating, meaning you do not have to investigate the appropriate ensemble size. Try setting numberens to 500 . The algorithms usually terminate with fewer members.

\section*{Prepare the Weak Learners}

Currently the weak learner types are:
- 'Discriminant' (for Subspace ensemble)
- 'KNN' (for Subspace ensemble)
- 'Tree' (for any ensemble except Subspace)

There are two ways to set the weak learner type in the ensemble:
- To create an ensemble with default weak learner options, pass in the string as the weak learner. For example,
```

ens = fitensemble(X,Y,'AdaBoostM2',50,'Tree');
% or
ens = fitensemble(X,Y,'Subspace',50,'KNN');

```
- To create an ensemble with nondefault weak learner options, create a nondefault weak learner using the appropriate template method. For example, if you have missing data, and want to use trees with surrogate splits for better accuracy:
```

templ = ClassificationTree.template('Surrogate','all');
ens = fitensemble(X,Y,'AdaBoostM2',50,templ);

```

To grow trees with roughly 10 leaf nodes per tree:
```

templ = ClassificationTree.template('MinLeaf',size(X,1)/10);
ens = fitensemble(X,Y,'AdaBoostM2',50,templ);

```

While you can give fitensemble a cell array of learner templates, the most common usage is to give just one weak learner template.

For examples using a template, see "Example: Unequal Classification Costs" on page 15-84 and "Surrogate Splits" on page 15-94.

Decision trees can handle NaN values in X. Such values are called "missing." If you have some missing values in a row of \(X\), a decision tree finds optimal splits using nonmissing values only. If an entire row consists of NaN, fitensemble ignores that row. If you have data with a large fraction of missing values in \(X\), use surrogate decision splits. For examples of surrogate splits, see "Example: Unequal Classification Costs" on page 15-84 and "Surrogate Splits" on page 15-94.

\section*{Common Settings for Tree Weak Learners.}
- The depth of a weak learner tree makes a difference for training time, memory usage, and predictive accuracy. You control the depth with two parameters:
- MinLeaf - Each leaf has at least MinLeaf observations. Set small values of MinLeaf to get a deep tree.
- MinParent - Each branch node in the tree has at least MinParent observations. Set small values of MinParent to get a deep tree.

If you supply both MinParent and MinLeaf, the learner uses the setting that gives larger leaves:
```

MinParent = max(MinParent,2*MinLeaf)

```
- Surrogate - Grow decision trees with surrogate splits when Surrogate is ' on '. Use surrogate splits when your data has missing values.

Note Surrogate splits cause training to be slower and use more memory.

\section*{Call fitensemble}

The syntax of fitensemble is
ens = fitensemble(X, Y, model, numberens, learners)
- \(X\) is the matrix of data. Each row contains one observation, and each column contains one predictor variable.
- Y is the responses, with the same number of observations as rows in X .
- model is a string naming the type of ensemble.
- numberens is the number of weak learners in ens from each element of learners. So the number of elements in ens is numberens times the number of elements in learners.
- learners is a string naming a weak learner, a weak learner template, or a cell array of such strings and templates.

The result of fitensemble is an ensemble object, suitable for making predictions on new data. For a basic example of creating a classification ensemble, see "Create a Classification Ensemble" on page 15-68. For a basic example of creating a regression ensemble, see "Creating a Regression Ensemble" on page 15-69.

Where to Set Name-Value Pairs. There are several name-value pairs you can pass to fitensemble, and several that apply to the weak learners (ClassificationDiscriminant.template, ClassificationKNN.template, ClassificationTree.template and RegressionTree.template). To determine which option (name-value pair) is appropriate, the ensemble or the weak learner:
- Use template name-value pairs to control the characteristics of the weak learners.
- Use fitensemble name-value pairs to control the ensemble as a whole, either for algorithms or for structure.

For example, to have an ensemble of boosted classification trees with each tree deeper than the default, set the ClassificationTree.template name-value pairs (MinLeaf and MinParent) to smaller values than the defaults. This causes the trees to be leafier (deeper).

To name the predictors in the ensemble (part of the structure of the ensemble), use the PredictorNames name-value pair in fitensemble.

\section*{Basic Ensemble Examples}

\section*{Create a Classification Ensemble}

Create a classification tree ensemble for the Fisher iris data, and use it to predict the classification of a flower with average measurements.

1 Load the data:
load fisheriris
2 The predictor data \(X\) is the meas matrix.
3 The response data \(Y\) is the species cell array.
4 For classification trees with three or more classes, "Suggestions for Choosing an Appropriate Ensemble Algorithm" on page 15-63 suggests using an 'AdaBoostM2' ensemble.

5 For this example, arbitrarily take an ensemble of 100 trees.
6 Use a default tree template.
7 Create the ensemble:
```

ens = fitensemble(meas,species,'AdaBoostM2',100,'Tree')
ens =
classreg.learning.classif.ClassificationEnsemble
PredictorNames: {'x1' 'x2' 'x3' 'x4'}
ResponseName: 'Y'
ClassNames: {'setosa' 'versicolor' 'virginica'}
ScoreTransform: 'none'
NObservations: 150
NTrained: 100
Method: 'AdaBoostM2'
LearnerNames: {'Tree'}

```
```

ReasonForTermination: [1x77 char]
FitInfo: [100x1 double]
FitInfoDescription: {2x1 cell}

```
Properties, Methods

8 Predict the classification of a flower with average measurements:
```

flower = predict(ens,mean(meas))

```
flower =
    'versicolor'

\section*{Creating a Regression Ensemble}

Create a regression ensemble to predict mileage of cars based on their horsepower and weight, trained on the carsmall data. Use the resulting ensemble to predict the mileage of a car with 150 horsepower weighing 2750 lbs.

1 Load the data:
load carsmall
2 Prepare the input data.
X = [Horsepower Weight];
3 The response data \(Y\) is MPG.
4 The only boosted regression ensemble type is 'LSBoost'.
5 For this example, arbitrarily take an ensemble of 100 trees.
6 Use a default tree template.
7 Create the ensemble:
ens = fitensemble(X,MPG,'LSBoost',100,'Tree')
ens \(=\)
```

classreg.learning.regr.RegressionEnsemble
PredictorNames: {'x1' 'x2'}
ResponseName: 'Y'
ResponseTransform: 'none'
NObservations: 94
NTrained: 100
Method: 'LSBoost'
LearnerNames: {'Tree'}
ReasonForTermination: [1x77 char]
FitInfo: [100x1 double]
FitInfoDescription: {2x1 cell}
Regularization: []
Properties, Methods

```

8 Predict the mileage of a car with 150 horsepower weighing 2750 lbs:
```

mileage = ens.predict([150 2750])

```
mileage =
22.4180

\section*{Test Ensemble Quality}

Usually you cannot evaluate the predictive quality of an ensemble based on its performance on training data. Ensembles tend to "overtrain," meaning they produce overly optimistic estimates of their predictive power. This means the result of resubLoss for classification (resubLoss for regression) usually indicates lower error than you get on new data.

To obtain a better idea of the quality of an ensemble, use one of these methods:
- Evaluate the ensemble on an independent test set (useful when you have a lot of training data).
- Evaluate the ensemble by cross validation (useful when you don't have a lot of training data).
- Evaluate the ensemble on out-of-bag data (useful when you create a bagged ensemble with fitensemble).

\section*{Example: Test Ensemble Quality}

This example uses a bagged ensemble so it can use all three methods of evaluating ensemble quality.

1 Generate an artificial dataset with 20 predictors. Each entry is a random number from 0 to 1 . The initial classification:
\[
\begin{aligned}
& Y=1 \text { when } X(1)+X(2)+X(3)+X(4)+X(5)>2.5 \\
& Y=0 \text { otherwise. }
\end{aligned}
\]
```

rng(1,'twister') % for reproducibility
X = rand(2000,20);
Y = sum(X(:,1:5),2) > 2.5;

```

In addition, to add noise to the results, randomly switch \(10 \%\) of the classifications:
```

idx = randsample(2000,200);
Y(idx) = ~Y(idx);

```

\section*{2 Independent Test Set}

Create independent training and test sets of data. Use \(70 \%\) of the data for a training set by calling cupartition using the holdout option:
```

cvpart = cvpartition(Y,'holdout',0.3);
Xtrain = X(training(cvpart),:);
Ytrain = Y(training(cvpart),:);
Xtest = X(test(cvpart),:);
Ytest = Y(test(cvpart),:);

```

3 Create a bagged classification ensemble of 200 trees from the training data:
```

bag = fitensemble(Xtrain,Ytrain,'Bag',200,'Tree',...
'type','classification')
bag =

```
```

classreg.learning.classif.ClassificationBaggedEnsemble
PredictorNames: {1x20 cell}
ResponseName: 'Y'
ClassNames: [0 1]
ScoreTransform: 'none'
NObservations: 1400
NTrained: 200
Method: 'Bag'
LearnerNames: {'Tree'}
ReasonForTermination: [1x77 char]
FitInfo: []
FitInfoDescription: 'None'
FResample: 1
Replace: 1
UseObsForLearner: [1400x200 logical]
Properties, Methods

```

4 Plot the loss (misclassification) of the test data as a function of the number of trained trees in the ensemble:
figure;
plot(loss(bag,Xtest,Ytest,'mode','cumulative'));
xlabel('Number of trees');
ylabel('Test classification error');

\section*{5 Cross Validation}

Generate a five-fold cross-validated bagged ensemble:
```

cv = fitensemble(X,Y,'Bag',200,'Tree',...
'type','classification','kfold',5)
cv =
classreg.learning.partition.ClassificationPartitionedEnsemble
CrossValidatedModel: 'Bag'
PredictorNames: {1x20 cell}
CategoricalPredictors: []

```
```

    ResponseName: 'Y'
    NObservations: 2000
                            KFold: 5
            Partition: [1x1 cvpartition]
    NTrainedPerFold: [200 200 200 200 200]
ClassNames: [0 1]
ScoreTransform: 'none'

```

\section*{Properties, Methods}

6 Examine the cross-validation loss as a function of the number of trees in the ensemble:
```

figure;
plot(loss(bag,Xtest,Ytest,'mode','cumulative'));
hold on;
plot(kfoldLoss(cv,'mode','cumulative'),'r.');
hold off;
xlabel('Number of trees');
ylabel('Classification error');
legend('Test','Cross-validation','Location','NE');

```

Cross validating gives comparable estimates to those of the independent set.

\section*{7 Out-of-Bag Estimates}

Generate the loss curve for out-of-bag estimates, and plot it along with the other curves:
figure;
plot(loss(bag,Xtest,Ytest,'mode','cumulative'));
hold on;
plot(kfoldLoss(cv,'mode','cumulative'),'r.');
plot(oobLoss(bag,'mode','cumulative'),'k--');
```

hold off;
xlabel('Number of trees');
ylabel('Classification error');
legend('Test','Cross-validation','Out of bag','Location','NE');

```

The out-of-bag estimates are again comparable to those of the other methods.

\section*{Classification with Imbalanced Data}

This example shows how to classify when one class has many more observations than another. Try the RUSBoost algorithm first, because it is designed to handle this case.

This example uses the "Cover type" data from the UCI machine learning archive, described in http://archive.ics.uci.edu/ml/datasets/Covertype. The data classifies types of forest (ground cover), based on predictors such as elevation, soil type, and distance to water. The data has over 500,000 observations and over 50 predictors, so training and using a classifier is time consuming.

Blackard and Dean [1] describe a neural net classification of this data. They quote a \(70.6 \%\) classification accuracy. RUSBoost obtains over \(76 \%\) classification accuracy; see steps 6 and 7 .

\section*{Step 1. Obtain the data.}
urlwrite('http://archive.ics.uci.edu/ml/machine-learning-databases/covtype/
Then, extract the data from the forestcover.gz file. The data is in the covtype.data file.

\section*{Step 2. Import the data and prepare it for classification.}

Import the data into your workspace. Extract the last data column into a variable named Y .
load covtype.data
Y = covtype(:,end);
covtype(:,end) = [];

\section*{Step 3. Examine the response data.}
tabulate( Y )
\begin{tabular}{rcc} 
Value & Count & Percent \\
1 & 211840 & \(36.46 \%\) \\
2 & 283301 & \(48.76 \%\) \\
3 & 35754 & \(6.15 \%\) \\
4 & 2747 & \(0.47 \%\) \\
5 & 9493 & \(1.63 \%\) \\
6 & 17367 & \(2.99 \%\) \\
7 & 20510 & \(3.53 \%\)
\end{tabular}

There are hundreds of thousands of data points. Those of class 4 are less than \(0.5 \%\) of the total. This imbalance indicates that RUSBoost is an appropriate algorithm.

\section*{Step 4. Partition the data for quality assessment.}

Use half the data to fit a classifier, and half to examine the quality of the resulting classifier.
```

part = cvpartition(Y,'holdout',0.5);
istrain = training(part); % data for fitting
istest = test(part); % data for quality assessment
tabulate(Y(istrain))

```
\begin{tabular}{rll} 
Value & Count & Percent \\
1 & 105920 & \(36.46 \%\) \\
2 & 141651 & \(48.76 \%\) \\
3 & 17877 & \(6.15 \%\) \\
4 & 1374 & \(0.47 \%\) \\
5 & 4746 & \(1.63 \%\) \\
6 & 8683 & \(2.99 \%\) \\
7 & 10255 & \(3.53 \%\)
\end{tabular}

\section*{Step 5. Create the ensemble.}

Use deep trees for higher ensemble accuracy. To do so, set the trees to have minimal leaf size of 5 . Set LearnRate to 0.1 in order to achieve higher accuracy as well. The data is large, and, with deep trees, creating the ensemble is time consuming.
```

t = ClassificationTree.template('minleaf',5);
tic
rusTree = fitensemble(covtype(istrain,:),Y(istrain),'RUSBoost',1000,t,...
'LearnRate',0.1,'nprint',100);
toc

```
Training RUSBoost...
Grown weak learners: 100
Grown weak learners: 200
Grown weak learners: 300
Grown weak learners: 400
```

Grown weak learners: 500
Grown weak learners: 600
Grown weak learners: 700
Grown weak learners: 800
Grown weak learners: 900
Grown weak learners: 1000
Elapsed time is 918.258401 seconds.

```

\section*{Step 6. Inspect the classification error.}

Plot the classification error against the number of members in the ensemble.
```

figure;
tic
plot(loss(rusTree,covtype(istest,:),Y(istest),'mode','cumulative'));
toc
grid on;
xlabel('Number of trees');
ylabel('Test classification error');
Elapsed time is 775.646935 seconds.

```

The ensemble achieves a classification error of under \(24 \%\) using 150 or more trees. It achieves the lowest error for 400 or more trees.

Examine the confusion matrix for each class as a percentage of the true class.
tic
Yfit = predict(rusTree, covtype(istest,:));
toc
tab = tabulate(Y(istest));
bsxfun(@rdivide, confusionmat(Y(istest), Yfit), tab(: 2) )*100
Elapsed time is 427.293168 seconds.

Columns 1 through 6
\begin{tabular}{rrrrrr}
83.3771 & 7.4056 & 0.0736 & 0 & 1.7051 & 0.2681 \\
18.3156 & 66.4652 & 2.1193 & 0.0162 & 9.3435 & 2.8239 \\
0 & 0.0839 & 90.8038 & 2.3885 & 0.6545 & 6.0693 \\
0 & 0 & 2.4763 & 95.8485 & 0 & 1.6752 \\
0 & 0.2739 & 0.6530 & 0 & 98.6518 & 0.4213 \\
0 & 0.1036 & 3.8346 & 1.1400 & 0.4030 & 94.5187 \\
0.2340 & 0 & 0 & 0 & 0.0195 & 0
\end{tabular}

Column 7
7.1705
0.9163

0

0
0
0
99.7465

All classes except class 2 have over \(80 \%\) classification accuracy, and classes 3 through 7 have over \(90 \%\) accuracy. But class 2 makes up close to half the data, so the overall accuracy is not that high.

\section*{Step 7. Compact the ensemble.}

The ensemble is large. Remove the data using the compact method.
```

cmpctRus = compact(rusTree);
sz(1) = whos('rusTree');
sz(2) = whos('cmpctRus');
[sz(1).bytes sz(2).bytes]
ans =
1.0e+09 *
1.6947 0.9790

```

The compacted ensemble is about half the size of the original.
Remove half the trees from cmpctRus. This action is likely to have minimal effect on the predictive performance, based on the observation that 400 out of 1000 trees give nearly optimal accuracy.
```

cmpctRus = removeLearners(cmpctRus,[500:1000]);
sz(3) = whos('cmpctRus');
sz(3).bytes
ans =

```

475495669

The reduced compact ensemble takes about a quarter the memory of the full ensemble. Its overall loss rate is under \(24 \%\) :
```

L = loss(cmpctRus,covtype(istest,:),Y(istest))

```

L =
0.2326

The predictive accuracy on new data might differ, because the ensemble accuracy might be biased. The bias arises because the same data used for assessing the ensemble was used for reducing the ensemble size. To obtain an unbiased estimate of requisite ensemble size, you should use cross validation. However, that procedure is time consuming.

\section*{Classification: Imbalanced Data or Unequal Misclassification Costs}

In many real-world applications, you might prefer to treat classes in your data asymmetrically. For example, you might have data with many more observations of one class than of any other. Or you might work on a problem in which misclassifying observations of one class has more severe consequences than misclassifying observations of another class. In such situations, you can use two optional parameters for fitensemble: prior and cost.

By using prior, you set prior class probabilities (that is, class probabilities used for training). Use this option if some classes are under- or overrepresented in your training set. For example, you might obtain your training data by simulation. Because simulating class \(A\) is more expensive than class B, you opt to generate fewer observations of class A and more observations of class B. You expect, however, that class A and class B are mixed in a different proportion in the real world. In this case, set prior probabilities for class \(A\) and \(B\) approximately to the values you expect to observe in the real world. fitensemble normalizes prior probabilities to make them add up to 1 ; multiplying all prior probabilities by the same positive factor does not affect the result of classification.

If classes are adequately represented in the training data but you want to treat them asymmetrically, use the cost parameter. Suppose you want to classify benign and malignant tumors in cancer patients. Failure to identify a malignant tumor (false negative) has far more severe consequences than misidentifying benign as malignant (false positive). You should assign high cost to misidentifying malignant as benign and low cost to misidentifying benign as malignant.

You must pass misclassification costs as a square matrix with nonnegative elements. Element \(C(i, j)\) of this matrix is the cost of classifying an observation into class \(j\) if the true class is \(i\). The diagonal elements C(i,i) of the cost matrix must be 0 . For the previous example, you can choose malignant tumor to be class 1 and benign tumor to be class 2 . Then you can set the cost matrix to
\[
\left[\begin{array}{ll}
0 & c \\
1 & 0
\end{array}\right]
\]
where \(c>1\) is the cost of misidentifying a malignant tumor as benign. Costs are relative-multiplying all costs by the same positive factor does not affect the result of classification.

If you have only two classes, fitensemble adjusts their prior probabilities using \(\tilde{P}_{i}=C_{i j} P_{i}\) for class \(i=1,2\) and \(j \neq i\). \(P_{i}\) are prior probabilities either passed into fitensemble or computed from class frequencies in the training
data, and \(\tilde{P}_{i}\) are adjusted prior probabilities. Then fitensemble uses the default cost matrix
\(\left[\begin{array}{ll}0 & 1 \\ 1 & 0\end{array}\right]\)
and these adjusted probabilities for training its weak learners. Manipulating the cost matrix is thus equivalent to manipulating the prior probabilities.

If you have three or more classes, fitensemble also converts input costs into adjusted prior probabilities. This conversion is more complex. First, fitensemble attempts to solve a matrix equation described in Zhou and Liu [20]. If it fails to find a solution, fitensemble applies the "average cost" adjustment described in Breiman et al. [6]. For more information, see Zadrozny, Langford, and Abe [19].

\section*{Example: Unequal Classification Costs}

This example uses data on patients with hepatitis to see if they live or die as a result of the disease. The data is described at http://archive.ics.uci.edu/ml/datasets/Hepatitis.

1 Load the data into a file named hepatitis.txt:
```

s = urlread(['http://archive.ics.uci.edu/ml/' ...
'machine-learning-databases/hepatitis/hepatitis.data']);
fid = fopen('hepatitis.txt','w');
fwrite(fid,s);
fclose(fid);

```

2 Load the data hepatitis.txt into a dataset, with variable names describing the fields in the data:
```

VarNames = {'die_or_live' 'age' 'sex' 'steroid' 'antivirals' 'fatigue' ...
'malaise' 'anorexia' 'liver_big' 'liver_firm' 'spleen_palpable' ...
'spiders' 'ascites' 'varices' 'bilirubin' 'alk_phosphate' 'sgot' ...
'albumin' 'protime' 'histology'};
ds = dataset('file','hepatitis.txt','VarNames',VarNames,...
'Delimiter',',','ReadVarNames',false,'TreatAsEmpty','?',...
'Format',''%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f');
ds is a dataset with }155\mathrm{ observations and 20 variables:
size(ds)
ans =
155 20

```

3 Convert the data in the dataset to the format for ensembles: a numeric matrix of predictors, and a cell array with outcome names: 'Die' or 'Live'. The first field in the dataset has the outcomes.

X = double(ds(:,2:end));
ClassNames = \{'Die' 'Live'\};
Y = ClassNames(ds.die_or_live);

4 Inspect the data for missing values:

\section*{figure;}
bar(sum(isnan(X),1)/size(X,1));
xlabel('Predictor');
ylabel('Fraction of missing values');

Most predictors have missing values, and one has nearly \(45 \%\) of missing values. Therefore, use decision trees with surrogate splits for better accuracy. Because the dataset is small, training time with surrogate splits should be tolerable.

5 Create a classification tree template that uses surrogate splits:
```

rng(0,'twister') % for reproducibility
t = ClassificationTree.template('surrogate','all');

```

6 Examine the data or the description of the data to see which predictors are categorical:

X(1:5,:)
ans \(=\)

\section*{Columns 1 through 6}
\begin{tabular}{rrrrrr}
30.0000 & 2.0000 & 1.0000 & 2.0000 & 2.0000 & 2.0000 \\

\end{tabular}

Column 19
1.0000
1.0000
1.0000
1.0000
1.0000

It appears that predictors 2 through 13 are categorical, as well as predictor 19. You can confirm this inference with the dataset description at http://archive.ics.uci.edu/ml/datasets/Hepatitis.

7 List the categorical variables:
```

ncat = [2:13,19];

```

8 Create a cross-validated ensemble using 150 learners and the GentleBoost algorithm:
```

a = fitensemble(X,Y,'GentleBoost',150,t,...
'PredictorNames',VarNames(2:end),'LearnRate',0.1,···
'CategoricalPredictors',ncat,'kfold',5);
figure;
plot(kfoldLoss(a,'mode','cumulative','lossfun','exponential'));
xlabel('Number of trees');
ylabel('Cross-validated exponential loss');

```

9 Inspect the confusion matrix to see which people the ensemble predicts correctly:
[Yfit,Sfit] = kfoldPredict(a); \% confusionmat(Y,Yfit, 'order', ClassNames)
```

11
112

```

Of the 123 people who live, the ensemble predicts correctly that 112 will live. But for the 32 people who die of hepatitis, the ensemble only predicts correctly that about half will die of hepatitis.

10 There are two types of error in the predictions of the ensemble:
- Predicting that the patient lives, but the patient dies
- Predicting that the patient dies, but the patient lives

Suppose you believe that the first error is five times worse than the second. Make a new classification cost matrix that reflects this belief:
```

cost.ClassNames = ClassNames;
cost.ClassificationCosts = [0 5; 1 0];

```

11 Create a new cross-validated ensemble using cost as misclassification cost, and inspect the resulting confusion matrix:
```

aC = fitensemble(X,Y,'GentleBoost',150,t,...
'PredictorNames',VarNames(2:end),'LearnRate',0.1,...
'CategoricalPredictors',ncat,'kfold',5,...
'cost',cost);
[YfitC,SfitC] = kfoldPredict(aC);
confusionmat(Y,YfitC,'order',ClassNames)
ans =
19 13
8 115

```

As expected, the new ensemble does a better job classifying the people who die. Somewhat surprisingly, the new ensemble also does a better job classifying the people who live, though the result is not statistically significantly better. The results of the cross validation are random, so this result is simply a statistical fluctuation. The result seems to indicate that the classification of people who live is not very sensitive to the cost.

\section*{Classification with Many Categorical Levels}

Generally, you cannot use classification with more than 31 levels in any categorical predictor. However, two boosting algorithms can classify data with many categorical predictor levels and binary responses: LogitBoost and GentleBoost. For details, see "LogitBoost" on page 15-152 and "GentleBoost" on page 15-152.

This example uses demographic data from the U.S. Census, available at http://archive.ics.uci.edu/ml/machine-learning-databases/adult/. The objective of the researchers who posted the data is predicting whether an individual makes more than \(\$ 50,000 /\) year, based on a set of characteristics. You can see details of the data, including predictor names, in the adult. names file at the site.

1 Load the 'adult.data' file from the UCI Machine Learning Repository:
```

s = urlread(['http://archive.ics.uci.edu/ml/' ...
'machine-learning-databases/adult/adult.data']);

```

2 'adult.data' represents missing data as '?'. Replace instances of missing data with the blank string ' ':
```

s = strrep(s,'?','');

```

3 Put the data into a MATLAB dataset array:
```

fid = fopen('adult.txt','w');
fwrite(fid,s);
fclose(fid);
clear s;
VarNames = {'age' 'workclass' 'fnlwgt' 'education' 'education_num' ...
'marital_status' 'occupation' 'relationship' 'race' ...
'sex' 'capital_gain' 'capital_loss' ...
'hours_per_week' 'native_country' 'income'};
ds = dataset('file','adult.txt','VarNames',VarNames,...
'Delimiter',',','ReadVarNames',false,'Format',...
'%u%s%u%s%u%S%s%s%s%s%u%u%u%s%s');
cat = ~datasetfun(@isnumeric,ds(:,1:end-1)); % Logical indices
% of categorical variables

```
```

catcol = find(cat); % indices of categorical variables

```

4 Many predictors in the data are categorical. Convert those fields in the dataset array to nominal:
```

ds.workclass = nominal(ds.workclass);
ds.education = nominal(ds.education);
ds.marital_status = nominal(ds.marital_status);
ds.occupation = nominal(ds.occupation);
ds.relationship = nominal(ds.relationship);
ds.race = nominal(ds.race);
ds.sex = nominal(ds.sex);
ds.native_country = nominal(ds.native_country);
ds.income = nominal(ds.income);

```

5 Convert the dataset array into numerical variables for fitensemble:
```

X = double(ds(:,1:end-1));
Y = ds.income;

```

6 Some variables have many levels. Plot the number of levels of each predictor:
```

ncat = zeros(1,numel(catcol));
for c=1:numel(catcol)
[~,gn] = grp2idx(X(:,catcol(c)));
ncat(c) = numel(gn);
end
figure;
bar(catcol,ncat);
xlabel('Predictor');
ylabel('Number of categories');

```

Predictor 14 ('native_country') has more than 40 categorical levels. For binary classification, ClassificationTree.fit uses a computational shortcut to find an optimal split for categorical predictors with many categories. For classification with more than two classes, you can choose a heuristic algorithm for finding a good split. See "Splitting Categorical Predictors" on page 15-55.

7 Create classification ensembles using both LogitBoost and GentleBoost:
```

lb = fitensemble(X,Y,'LogitBoost',300,'Tree','CategoricalPredictors',cat,...
'PredictorNames',VarNames(1:end-1),'ResponseName','income');
gb = fitensemble(X,Y,'GentleBoost',300,'Tree','CategoricalPredictors',cat,...
'PredictorNames',VarNames(1:end-1),'ResponseName','income');

```

8 Examine the resubstitution error for the two ensembles:
```

figure;
plot(resubLoss(lb,'mode','cumulative'));
hold on
plot(resubLoss(gb,'mode','cumulative'),'r--');
hold off
xlabel('Number of trees');
ylabel('Resubstitution error');

```
```

legend('LogitBoost','GentleBoost','Location','NE');

```

The GentleBoost algorithm has slightly smaller resubstitution error.
9 Estimate the generalization error for the two algorithms by cross validation.
```

lbcv = crossval(lb,'kfold',5);
gbcv = crossval(gb,'kfold',5);
figure;
plot(kfoldLoss(lbcv,'mode','cumulative'));
hold on
plot(kfoldLoss(gbcv,'mode','cumulative'),'r--');
hold off

```
```

xlabel('Number of trees');
ylabel('Cross-validated error');
legend('LogitBoost', 'GentleBoost','Location', 'NE');

```

The cross-validated loss is nearly the same as the resubstitution error.

\section*{Surrogate Splits}

When you have missing data, trees and ensembles of trees give better predictions when they include surrogate splits. Furthermore, estimates of predictor importance are often different with surrogate splits. Eliminating unimportant predictors can save time and memory for predictions, and can make predictions easier to understand.

This example shows the effects of surrogate splits for predictions for data containing missing entries in the test set.

1 Load sample data. Partition it into a training and test set.
load ionosphere;
rng(10) \% for reproducibility
cv = cvpartition(Y,'holdout', 0.3);
Xtrain = X(training(cv),:);
Ytrain = Y(training(cv));
Xtest = X(test(cv),:);
Ytest = Y(test(cv));
2 Bag decision trees with and without surrogate splits.
```

b = fitensemble(Xtrain,Ytrain,'Bag',50,'Tree',...
'type','class');
templS = ClassificationTree.template('surrogate','on');
bs = fitensemble(Xtrain,Ytrain,'Bag',50,templS,...
'type','class');

```

3 Suppose half of the values in the test set are missing.
```

Xtest(rand(size(Xtest))>0.5) = NaN;

```

4 Test accuracy with and without surrogate splits.
```

figure;
plot(loss(b,Xtest,Ytest,'mode','cumulative'));
hold on;
plot(loss(bs,Xtest,Ytest,'mode','cumulative'),'r--');
legend('Regular trees','Trees with surrogate splits');
xlabel('Number of trees');
ylabel('Test classification error');

```

5 Check the statistical significance of the difference in results with the McNemar test. Convert the labels to a nominal data type to make it easier to check for equality.
```

Yfit = nominal(predict(b,Xtest));
YfitS = nominal(predict(bs,Xtest));
N10 = sum(Yfit==nominal(Ytest) \& YfitS~=nominal(Ytest));
N01 = sum(Yfit~=nominal(Ytest) \& YfitS==nominal(Ytest));
mcnemar = (abs(N1O-N01) - 1)^2/(N10+NO1);
pval = 1 - chi2cdf(mcnemar,1)
pval =

```

\section*{\(1.7683 e-04\)}

The extremely low \(p\)-value indicates that the ensemble with surrogate splits is better in a statistically significant manner.

\section*{LPBoost and TotalBoost for Small Ensembles}

This example shows how to obtain the benefits of the LPBoost and TotalBoost algorithms. These algorithms share two beneficial characteristics:

They are self-terminating, so you don't have to guess how many members to include.

They produce ensembles with some very small weights, so you can safely remove ensemble members.

Caution The algorithms require an Optimization Toolbox license.

\section*{Step 1. Load the data.}

Load the ionosphere data.
load ionosphere

\section*{Step 2. Create the classification ensembles.}

Create ensembles for classifying the ionosphere data using the LPBoost, TotalBoost, and, for comparison, AdaBoostM1 algorithms. It is hard to know how many members to include in an ensemble. For LPBoost and TotalBoost, try using 500. For comparison, also use 500 for AdaBoostM1.
```

rng default % for reproducibility
T = 500;
adaStump = fitensemble(X,Y,'AdaBoostM1',T,'Tree');
totalStump = fitensemble(X,Y,'TotalBoost',T,'Tree');
lpStump = fitensemble(X,Y,'LPBoost',T,'Tree');
figure;
plot(resubLoss(adaStump,'mode','cumulative'));
hold on

```
```

plot(resubLoss(totalStump,'mode','cumulative'),'r');
plot(resubLoss(lpStump,'mode','cumulative'),'g');
hold off
xlabel('Number of stumps');
ylabel('Training error');
legend('AdaBoost','TotalBoost','LPBoost','Location','NE');

```

All three algorithms achieve perfect prediction on the training data after a while. Examine the number of members in all three ensembles.
[adaStump.NTrained totalStump.NTrained lpStump.NTrained]
ans \(=\)

\section*{500 52 67}

AdaBoostM1 trained all 500 members. The other two algorithms stopped training early.

\section*{Step 3. Cross validate the ensembles.}

Cross validate the ensembles to better determine ensemble accuracy.
```

cvlp = crossval(lpStump,'kfold',5);
cvtotal = crossval(totalStump,'kfold',5);
cvada = crossval(adaStump,'kfold',5);
figure;
plot(kfoldLoss(cvada,'mode','cumulative'));
hold on
plot(kfoldLoss(cvtotal,'mode','cumulative'),'r');
plot(kfoldLoss(cvlp,'mode','cumulative'),'g');
hold off
xlabel('Ensemble size');
ylabel('Cross-validated error');
legend('AdaBoost','TotalBoost','LPBoost','Location', 'NE');

```

It appears that each boosting algorithms achieves \(10 \%\) or lower loss with 50 ensemble members, and AdaBoostM1 achieves near \(6 \%\) error with 150 or more ensemble members.

\section*{Step 4. Compact and remove ensemble members.}

To reduce the ensemble sizes, compact them, and then use the removeLearners method. The question is, how many learners should you remove? The cross-validated loss curves give you one measure. For another, examine the learner weights for LPBoost and TotalBoost after compacting.
```

cada = compact(adaStump);
clp = compact(lpStump);

```
```

ctotal = compact(totalStump);
figure
subplot(2,1,1)
plot(clp.TrainedWeights)
title('LPBoost weights')
subplot(2,1,2)
plot(ctotal.TrainedWeights)
title('TotalBoost weights')

```

Both LPBoost and TotalBoost show clear points where the ensemble member weights become negligible.

Remove the unimportant ensemble members.
```

cada = removeLearners(cada,150:cada.NTrained);
clp = removeLearners(clp,60:clp.NTrained);
ctotal = removeLearners(ctotal,40:ctotal.NTrained);

```

Check that removing these learners does not affect ensemble accuracy on the training data.
```

[loss(cada,X,Y) loss(clp,X,Y) loss(ctotal,X,Y)]
ans =
0 0 0

```

Check the resulting compact ensemble sizes.
```

s(1) = whos('cada');
s(2) = whos('clp');
s(3) = whos('ctotal');
s.bytes
ans =
6 0 5 6 0 5
ans =
241375
ans =
1 6 0 4 3 5

```

The sizes of the compact ensembles are approximately proportional to the number of members in each.

\section*{Ensemble Regularization}

Regularization is a process of choosing fewer weak learners for an ensemble in a way that does not diminish predictive performance. Currently you can regularize regression ensembles. (You can also regularize a discriminant analysis classifier in a non-ensemble context; see "Regularize a Discriminant Analysis Classifier" on page 14-22.)

The regularize method finds an optimal set of learner weights \(a_{t}\) that minimize
\[
\sum_{n=1}^{N} w_{n} g\left(\left(\sum_{t=1}^{T} \alpha_{t} h_{t}\left(x_{n}\right)\right), y_{n}\right)+\lambda \sum_{t=1}^{T}\left|\alpha_{t}\right|
\]

\section*{Here}
- \(\lambda \geq 0\) is a parameter you provide, called the lasso parameter.
- \(h_{t}\) is a weak learner in the ensemble trained on \(N\) observations with predictors \(x_{n}\), responses \(y_{n}\), and weights \(w_{n}\).
- \(g(f, y)=(f-y)^{2}\) is the squared error.

The ensemble is regularized on the same \(\left(x_{n}, y_{n}, w_{n}\right)\) data used for training, so
\[
\sum_{n=1}^{N} w_{n} g\left(\left(\sum_{t=1}^{T} \alpha_{t} h_{t}\left(x_{n}\right)\right), y_{n}\right)
\]
is the ensemble resubstitution error. The error is measured by mean squared error (MSE).

If you use \(\lambda=0\), regularize finds the weak learner weights by minimizing the resubstitution MSE. Ensembles tend to overtrain. In other words, the resubstitution error is typically smaller than the true generalization error. By making the resubstitution error even smaller, you are likely to make the ensemble accuracy worse instead of improving it. On the other hand, positive values of \(\lambda\) push the magnitude of the \(\alpha_{t}\) coefficients to 0 . This often improves the generalization error. Of course, if you choose \(\lambda\) too large, all the optimal coefficients are 0 , and the ensemble does not have any accuracy. Usually you can find an optimal range for \(\lambda\) in which the accuracy of the regularized ensemble is better or comparable to that of the full ensemble without regularization.

A nice feature of lasso regularization is its ability to drive the optimized coefficients precisely to 0 . If a learner's weight \(\alpha_{t}\) is 0 , this learner can be
excluded from the regularized ensemble. In the end, you get an ensemble with improved accuracy and fewer learners.

\section*{Example: Regularizing a Regression Ensemble}

This example uses data for predicting the insurance risk of a car based on its many attributes.

1 Load the imports-85 data into the MATLAB workspace:
load imports-85;
2 Look at a description of the data to find the categorical variables and predictor names:

Description
```

Description =
1 9 8 5 Auto Imports Database from the UCI repository
http://archive.ics.uci.edu/ml/machine-learning-databases/autos/imports-85.names
Variables have been reordered to place variables with numeric values (referred
to as "continuous" on the UCI site) to the left and categorical values to the
right. Specifically, variables 1:16 are: symboling, normalized-losses,
wheel-base, length, width, height, curb-weight, engine-size, bore, stroke,
compression-ratio, horsepower, peak-rpm, city-mpg, highway-mpg, and price.
Variables 17:26 are: make, fuel-type, aspiration, num-of-doors, body-style,
drive-wheels, engine-location, engine-type, num-of-cylinders, and fuel-system.

```

The objective of this process is to predict the "symboling," the first variable in the data, from the other predictors. "symboling" is an integer from -3 (good insurance risk) to 3 (poor insurance risk). You could use a classification ensemble to predict this risk instead of a regression ensemble. As stated in "Steps in Supervised Learning (Machine Learning)" on page 15-2, when you have a choice between regression and classification, you should try regression first. Furthermore, this example is to show regularization, which currently works only for regression.

3 Prepare the data for ensemble fitting:
```

Y = X(:,1);
X(:,1) = [];
VarNames = {'normalized-losses' 'wheel-base' 'length' 'width' 'height' ...
'curb-weight' 'engine-size' 'bore' 'stroke' 'compression-ratio' ...
'horsepower' 'peak-rpm' 'city-mpg' 'highway-mpg' 'price' 'make' ...
'fuel-type' 'aspiration' 'num-of-doors' 'body-style' 'drive-wheels' ...
'engine-location' 'engine-type' 'num-of-cylinders' 'fuel-system'};
catidx = 16:25; % indices of categorical predictors

```

4 Create a regression ensemble from the data using 300 default trees:
```

ls = fitensemble(X,Y,'LSBoost',300,'Tree','LearnRate',0.1,...
'PredictorNames',VarNames,'ResponseName','symboling',...
'CategoricalPredictors',catidx)
ls =
classreg.learning.regr.RegressionEnsemble
PredictorNames: {1x25 cell}
ResponseName: 'symboling'
ResponseTransform: 'none'
NObservations: 205
NTrained: 300
Method: 'LSBoost'
LearnerNames: {'Tree'}
ReasonForTermination: [1x77 char]
FitInfo: [300x1 double]
FitInfoDescription: {2x1 cell}
Regularization: []

```

Properties, Methods
The final line, Regularization, is empty ([ ]). To regularize the ensemble, you have to use the regularize method.

5 Cross validate the ensemble, and inspect its loss curve.
```

cv = crossval(ls,'kfold',5);
figure;

```
```

plot(kfoldLoss(cv,'mode','cumulative'));
xlabel('Number of trees');
ylabel('Cross-validated MSE');
ylim([0.2,2])

```

It appears you might obtain satisfactory performance from a smaller ensemble, perhaps one containing from 50 to 100 trees.

6 Call the regularize method to try to find trees that you can remove from the ensemble. By default, regularize examines 10 values of the lasso (Lambda) parameter spaced exponentially.
```

ls = regularize(ls)
ls =
classreg.learning.regr.RegressionEnsemble
PredictorNames: {1x25 cell}

```
```

    ResponseName: 'symboling
    ResponseTransform: 'none'
    NObservations: 205
    NTrained: 300
                    Method: 'LSBoost
    LearnerNames: {'Tree'}
    ReasonForTermination: [1x77 char]
FitInfo: [300x1 double]
FitInfoDescription: {2x1 cell}
Regularization: [1x1 struct]

```

\section*{Properties, Methods}

The Regularization property is no longer empty.
7 Plot the resubstitution mean-squared error (MSE) and number of learners with nonzero weights against the lasso parameter. Separately plot the value at Lambda=0. Use a logarithmic scale because the values of Lambda are exponentially spaced.
```

figure;
semilogx(ls.Regularization.Lambda,ls.Regularization.ResubstitutionMSE);
line([1e-3 1e-3],[ls.Regularization.ResubstitutionMSE(1) ...
ls.Regularization.ResubstitutionMSE(1)],...
'marker','x','markersize',12,'color','b');
r0 = resubLoss(ls);
line([ls.Regularization.Lambda(2) ls.Regularization.Lambda(end)],...
[rO rO],'color','r','LineStyle','--');
xlabel('Lambda');
ylabel('Resubstitution MSE');
annotation('textbox',[0.5 0.22 0.5 0.05],'String','unregularized ensemble',...
'color','r','FontSize',14,'LineStyle','none');
figure;
loglog(ls.Regularization.Lambda,sum(ls.Regularization.TrainedWeights>0,1));
line([1e-3 1e-3],...
[sum(ls.Regularization.TrainedWeights(:,1)>0) ...
sum(ls.Regularization.TrainedWeights(:,1)>0)],...

```
```

    'marker','x','markersize',12,'color','b');
    line([ls.Regularization.Lambda(2) ls.Regularization.Lambda(end)],...
[ls.NTrained ls.NTrained],...
'color','r','LineStyle','--');
xlabel('Lambda');
ylabel('Number of learners');
annotation('textbox',[0.3 0.8 0.5 0.05],'String','unregularized ensemble',...
'color','r','FontSize',14,'LineStyle','none');

```

8 The resubstitution MSE values are likely to be overly optimistic. To obtain more reliable estimates of the error associated with various values of Lambda, cross validate the ensemble using cvshrink. Plot the resulting cross-validation loss (MSE) and number of learners against Lambda.
```

rng(0,'Twister') % for reproducibility
[mse,nlearn] = cvshrink(ls,'lambda',ls.Regularization.Lambda,'kfold',5);
figure;
semilogx(ls.Regularization.Lambda,ls.Regularization.ResubstitutionMSE);
hold;
semilogx(ls.Regularization.Lambda,mse,'r--');
hold off;
xlabel('Lambda');
ylabel('Mean squared error');
legend('resubstitution','cross-validation','Location','NW');

```
```

line([1e-3 1e-3],[ls.Regularization.ResubstitutionMSE(1) ...
ls.Regularization.ResubstitutionMSE(1)],...
'marker','x','markersize',12,'color','b');
line([1e-3 1e-3],[mse(1) mse(1)],'marker','o',...
'markersize',12,'color','r','LineStyle','--');
figure;
loglog(ls.Regularization.Lambda,sum(ls.Regularization.TrainedWeights>0,1));
hold;
loglog(ls.Regularization.Lambda,nlearn,'r--');
hold off;
xlabel('Lambda');
ylabel('Number of learners');
legend('resubstitution','cross-validation','Location','NE');
line([1e-3 1e-3],...
[sum(ls.Regularization.TrainedWeights(:,1)>0) ...
sum(ls.Regularization.TrainedWeights(:,1)>0)],...
'marker','x','markersize',12,'color','b');
line([1e-3 1e-3],[nlearn(1) nlearn(1)],'marker','o',...

```
'markersize', 12, 'color','r','LineStyle','--');

Examining the cross-validated error shows that the cross-validation MSE is almost flat for Lambda up to a bit over 1e-2.

9 Examine ls. Regularization. Lambda to find the highest value that gives MSE in the flat region (up to a bit over 1e-2):
jj = 1:length(ls.Regularization.Lambda);
[jj;ls.Regularization.Lambda]
ans \(=\)
Columns 1 through 6
1.0000
2.0000
3.0000
4.0000
5.0000
6.0000
\(\begin{array}{llllll}0 & 0.0014 & 0.0033 & 0.0077 & 0.0183 & 0.0435\end{array}\)

Columns 7 through 10
\begin{tabular}{rrrr}
7.0000 & 8.0000 & 9.0000 & 10.0000 \\
0.1031 & 0.2446 & 0.5800 & 1.3754
\end{tabular}

Element 5 of ls.Regularization.Lambda has value 0.0183, the largest in the flat range.

10 Reduce the ensemble size using the shrink method. shrink returns a compact ensemble with no training data. The generalization error for the new compact ensemble was already estimated by cross validation in mse (5).
cmp = shrink(ls,'weightcolumn',5)
cmp \(=\)
classreg.learning.regr.CompactRegressionEnsemble
PredictorNames: \{1x25 cell\}
ResponseName: 'symboling
ResponseTransform: 'none'
NTrained: 15

Properties, Methods
There are only 15 trees in the new ensemble, notably reduced from the 300 in ls.

11 Compare the sizes of the ensembles:
```

sz(1) = whos('cmp'); sz(2) = whos('ls');
[sz(1).bytes sz(2).bytes]
ans =

The reduced ensemble is about $5 \%$ the size of the original.
12 Compare the MSE of the reduced ensemble to that of the original ensemble:
figure;
plot(kfoldLoss(cv,'mode','cumulative'));
hold on

```
plot(cmp.NTrained,mse(5),'ro','MarkerSize',12);
xlabel('Number of trees');
ylabel('Cross-validated MSE');
legend('unregularized ensemble','regularized ensemble',...
    'Location','NE');
hold off
```

The reduced ensemble gives low loss while using many fewer trees.

## Tuning RobustBoost

The RobustBoost algorithm can make good classification predictions even when the training data has noise. However, the default RobustBoost parameters can produce an ensemble that does not predict well. This example shows one way of tuning the parameters for better predictive accuracy.

Note RobustBoost requires an Optimization Toolbox license.

1 Generate data with label noise. This example has twenty uniform random numbers per observation, and classifies the observation as 1 if the sum of the first five numbers exceeds 2.5 (so is larger than average), and 0 otherwise:

```
rng(0,'twister') % for reproducibility
Xtrain = rand(2000,20);
Ytrain = sum(Xtrain(:,1:5),2) > 2.5;
```

2 To add noise, randomly switch $10 \%$ of the classifications:

```
idx = randsample(2000,200);
Ytrain(idx) = ~Ytrain(idx);
```

3 Create an ensemble with AdaBoostM1 for comparison purposes:

```
ada = fitensemble(Xtrain,Ytrain,'AdaBoostM1',...
```

    300,'Tree','LearnRate', 0.1);
    4 Create an ensemble with RobustBoost. Because the data has $10 \%$ incorrect classification, perhaps an error goal of $15 \%$ is reasonable.

```
rb1 = fitensemble(Xtrain,Ytrain,'RobustBoost',300,...
    'Tree','RobustErrorGoal',0.15,'RobustMaxMargin',1);
```

5 Try setting a high value of the error goal, 0.6. You get an error:

```
rb2 = fitensemble(Xtrain,Ytrain,'RobustBoost',300,'Tree','RobustErrorGoal',0.6)
```

Error using RobustBoost>RobustBoost.RobustBoost
For the chosen values of 'RobustMaxMargin' and 'RobustMarginSigma', you must set 'RobustErrorGoal' to a value between 0 and 0.5.

6 Create an ensemble with very optimistic error goal, 0.01:

```
rb2 = fitensemble(Xtrain,Ytrain,'RobustBoost',300,...
    'Tree','RobustErrorGoal',0.01);
```

```
7 Compare the resubstitution error of the four ensembles:
```

```
figure
```

figure
plot(resubLoss(rb1,'mode','cumulative'));
plot(resubLoss(rb1,'mode','cumulative'));
hold on
hold on
plot(resubLoss(rb2,'mode','cumulative'),'r--');
plot(resubLoss(rb2,'mode','cumulative'),'r--');
plot(resubLoss(ada,'mode','cumulative'),'g.');
plot(resubLoss(ada,'mode','cumulative'),'g.');
hold off;
hold off;
xlabel('Number of trees');
xlabel('Number of trees');
ylabel('Resubstitution error');
ylabel('Resubstitution error');
legend('ErrorGoal=0.15','ErrorGoal=0.01',...
legend('ErrorGoal=0.15','ErrorGoal=0.01',...
'AdaBoostM1','Location','NE');

```
    'AdaBoostM1','Location','NE');
```

All the RobustBoost curves show lower resubstitution error than the AdaBoostM1 curve. The error goal of 0.15 curve shows the lowest resubstitution error over most of the range.

8 Generate test data to see the predictive power of the ensembles. Test the four ensembles:

```
Xtest = rand(2000,20);
Ytest = sum(Xtest(:,1:5),2) > 2.5;
idx = randsample(2000,200);
Ytest(idx) = ~Ytest(idx);
figure;
plot(loss(rb1,Xtest,Ytest,'mode','cumulative'));
hold on
plot(loss(rb2,Xtest,Ytest,'mode','cumulative'),'r--');
plot(loss(ada,Xtest,Ytest,'mode','cumulative'),'g.');
hold off;
xlabel('Number of trees');
ylabel('Test error');
legend('ErrorGoal=0.15','ErrorGoal=0.01',...
    'AdaBoostM1','Location','NE');
```

The error curve for error goal 0.15 is lowest (best) in the plotted range. AdaBoostM1 has higher error than the curve for error goal 0.15 . The curve for the too-optimistic error goal 0.01 remains substantially higher (worse) than the other algorithms for most of the plotted range.

## Random Subspace Classification

This example shows how to use a random subspace ensemble to increase the accuracy of classification. It also shows how to use cross validation to determine good parameters for both the weak learner template and the ensemble.

## 1. Load the data.

Load the ionosphere data. This data has 351 binary responses to 34 predictors.

```
load ionosphere;
[N,D] = size(X)
N =
    351
D =
    34
resp = unique(Y)
resp =
    'b'
    'g'
```

## 2. Choose the number of nearest neighbors.

Find a good choice for $k$, the number of nearest neighbors in the classifier, by cross validation. Choose the number of neighbors approximately evenly spaced on a logarithmic scale.

```
rng(8000,'twister') % for reproducibility
K = round(logspace(0,log10(N),10)); % number of neighbors
cvloss = zeros(numel(K),1);
for k=1:numel(K)
    knn = ClassificationKNN.fit(X,Y,...
        'NumNeighbors',K(k),'crossval','on');
    cvloss(k) = kfoldLoss(knn);
end
figure; % plot the accuracy versus k
semilogx(K,cvloss);
xlabel('Number of nearest neighbors');
ylabel('10 fold classification error');
title('k-NN classification');
```

The lowest cross-validation error occurs for $\mathrm{k}=2$.

## 3. Create the ensembles.

Create ensembles for 2-nearest neighbor classification with various numbers of dimensions, and examine the cross-validated loss of the resulting ensembles.

This step takes a long time. To keep track of the progress, print a message as each dimension finishes.

```
NPredToSample = round(linspace(1,D,10)); % linear spacing of dimensions
cvloss = zeros(numel(NPredToSample),1);
learner = ClassificationKNN.template('NumNeighbors',2);
```

```
for npred=1:numel(NPredToSample)
end
plot(NPredToSample,cvloss);
ylabel('10 fold classification error');
Random Subspace 1 done.
Random Subspace 2 done.
Random Subspace 3 done.
Random Subspace 4 done.
Random Subspace 5 done.
Random Subspace 6 done.
Random Subspace 7 done.
Random Subspace 8 done.
Random Subspace 9 done.
Random Subspace 10 done.
```

    subspace \(=\) fitensemble(X,Y,'subspace',200,learner,...
            'npredtosample',NPredToSample(npred), 'crossval', 'on');
    cvloss(npred) = kfoldLoss(subspace);
    fprintf('Random Subspace \%i done. \({ }^{\prime}\) ', npred);
    figure; \% plot the accuracy versus dimension
xlabel('Number of predictors selected at random');
title('k-NN classification with Random Subspace');

The ensemble with five predictors per learner has the lowest cross-validated error. The error rate, about 0.06 , is about half the amount for the individual learners, which was over 0.10.

## 4. Find a good ensemble size.

Find the smallest number of learners in the ensemble that still give good classification.

```
ens = fitensemble(X,Y,'subspace',200,learner,...
    'npredtosample',5,'crossval','on');
figure; % plot the accuracy versus number in ensemble
plot(kfoldLoss(ens,'mode','cumulative'))
xlabel('Number of learners in ensemble');
```

```
ylabel('10 fold classification error');
title('k-NN classification with Random Subspace');
```

k-NN classification with Random Subspace

There seems to be no advantage in an ensemble with more than 150 or so learners. It is not clear whether there is any advantage with more than 50 learners. It is possible that 25 learners gives good predictions.

## 5. Create a final ensemble.

Construct a final ensemble with 50 learners. Compact the ensemble and see if the compacted version saves an appreciable amount of memory.

```
ens = fitensemble(X,Y,'subspace',50,learner,...
    'npredtosample',5);
```

```
cens = compact(ens);
s1 = whos('ens');s2 = whos('cens');
[s1.bytes s2.bytes] % si.bytes = size in bytes
ans =
    2317803
        2087370
```

The compact ensemble is about $10 \%$ smaller than the full ensemble. Both give the same predictions.

## TreeBagger Examples

TreeBagger ensembles have more functionality than those constructed with fitensemble; see TreeBagger Features Not in fitensemble on page 15-150. Also, some property and method names differ from their fitensemble counterparts. This section contains examples of workflow for regression and classification that use this extra TreeBagger functionality.

## Workflow Example: Regression of Insurance Risk Rating for Car Imports with TreeBagger

In this example, use a database of 1985 car imports with 205 observations, 25 input variables, and one response variable, insurance risk rating, or "symboling." The first 15 variables are numeric and the last 10 are categorical. The symboling index takes integer values from -3 to 3 .

1 Load the dataset and split it into predictor and response arrays:

```
load imports-85;
```

$Y=X(:, 1)$;
$X=X(:, 2: e n d) ;$

2 Because bagging uses randomized data drawings, its exact outcome depends on the initial random seed. To reproduce the exact results in this example, use the random stream settings:

```
rng(1945,'twister')
```

Finding the Optimal Leaf Size. For regression, the general rule is to set leaf size to 5 and select one third of input features for decision splits at random. In the following step, verify the optimal leaf size by comparing mean-squared errors obtained by regression for various leaf sizes. oobError computes MSE versus the number of grown trees. You must set oobpred to 'on' to obtain out-of-bag predictions later.

```
leaf = [1 5 10 20 50 100];
col = 'rgbcmy';
figure(1);
for i=1:length(leaf)
    b = TreeBagger(50,X,Y,'method','r','oobpred','on',...
    'cat',16:25,'minleaf',leaf(i));
    plot(oobError(b),col(i));
    hold on;
end
xlabel('Number of Grown Trees');
ylabel('Mean Squared Error');
legend({'1' '5' '10' '20' '50' '100'},'Location','NorthEast');
hold off;
```

The red (leaf size 1) curve gives the lowest MSE values.

## Estimating Feature Importance.

1 In practical applications, you typically grow ensembles with hundreds of trees. Only 50 trees were used in "Finding the Optimal Leaf Size" on page 15-125 for faster processing. Now that you have estimated the optimal leaf size, grow a larger ensemble with 100 trees and use it for estimation of feature importance:
b = TreeBagger(100,X,Y,'method','r','oobvarimp','on',...
'cat',16:25,'minleaf',1);

2 Inspect the error curve again to make sure nothing went wrong during training:
figure(2);
plot(oobError(b));
xlabel('Number of Grown Trees');
ylabel('Out-of-Bag Mean Squared Error');

Prediction ability should depend more on important features and less on unimportant features. You can use this idea to measure feature importance.

For each feature, you can permute the values of this feature across all of the observations in the data set and measure how much worse the mean-squared
error (MSE) becomes after the permutation. You can repeat this for each feature.

1 Using the following code, plot the increase in MSE due to permuting out-of-bag observations across each input variable. The OOBPermutedVarDeltaError array stores the increase in MSE averaged over all trees in the ensemble and divided by the standard deviation taken over the trees, for each variable. The larger this value, the more important the variable. Imposing an arbitrary cutoff at 0.65 , you can select the five most important features.

```
figure(3);
bar(b.00BPermutedVarDeltaError);
xlabel('Feature Number');
ylabel('Out-Of-Bag Feature Importance');
idxvar = find(b.O0BPermutedVarDeltaError>0.65)
idxvar =
```

    \(\begin{array}{lllll}1 & 2 & 4 & 16 & 19\end{array}\)
    

2 The 00BIndices property of TreeBagger tracks which observations are out of bag for what trees. Using this property, you can monitor the fraction of observations in the training data that are in bag for all trees. The curve starts at approximately $2 / 3$, the fraction of unique observations selected by one bootstrap replica, and goes down to 0 at approximately 10 trees.

```
finbag = zeros(1,b.NTrees);
for t=1:b.NTrees
    finbag(t) = sum(all(~b.OOBIndices(:,1:t),2));
end
finbag = finbag / size(X,1);
figure(4);
plot(finbag);
```

```
xlabel('Number of Grown Trees');
ylabel('Fraction of in-Bag Observations');
```

Growing Trees on a Reduced Set of Features. Using just the five most powerful features selected in "Estimating Feature Importance" on page $15-126$, determine if it is possible to obtain a similar predictive power. To begin, grow 100 trees on these features only. The first three of the five selected features are numeric and the last two are categorical.
b5v = TreeBagger(100,X(:,idxvar),Y,'method','r',...
'oobvarimp','on','cat',4:5,'minleaf',1);
figure(5);
plot(oobError(b5v));

```
xlabel('Number of Grown Trees');
ylabel('Out-of-Bag Mean Squared Error');
figure(6);
bar(b5v.00BPermutedVarDeltaError);
xlabel('Feature Index');
ylabel('Out-of-Bag Feature Importance');
```

These five most powerful features give the same MSE as the full set, and the ensemble trained on the reduced set ranks these features similarly to each other. Features 1 and 2 from the reduced set perhaps could be removed without a significant loss in the predictive power.

Finding Outliers. To find outliers in the training data, compute the proximity matrix using fillProximities:
b5v = fillProximities(b5v);
The method normalizes this measure by subtracting the mean outlier measure for the entire sample, taking the magnitude of this difference and dividing the result by the median absolute deviation for the entire sample:
figure(7);
hist(b5v.OutlierMeasure);
xlabel('Outlier Measure');
ylabel('Number of Observations');

Discovering Clusters in the Data. By applying multidimensional scaling to the computed matrix of proximities, you can inspect the structure of the input data and look for possible clusters of observations. The mdsProx method returns scaled coordinates and eigenvalues for the computed proximity matrix. If run with the colors option, this method makes a scatter plot of two scaled coordinates, first and second by default.
figure(8);
[~,e] = mdsProx(b5v,'colors','k');
xlabel('1st Scaled Coordinate');
ylabel('2nd Scaled Coordinate');

Assess the relative importance of the scaled axes by plotting the first 20 eigenvalues:

```
figure(9);
bar(e(1:20));
xlabel('Scaled Coordinate Index');
ylabel('Eigenvalue');
```

Saving the Ensemble Configuration for Future Use. To use the trained ensemble for predicting the response on unseen data, store the ensemble to disk and retrieve it later. If you do not want to compute predictions for out-of-bag data or reuse training data in any other way, there is no need to store the ensemble object itself. Saving the compact version of the ensemble would be enough in this case. Extract the compact object from the ensemble:

```
c = compact(b5v)
c =
Ensemble with 100 decision trees:
Method: regression
Nvars:
5
```

This object can be now saved in a *.mat file as usual.

## Workflow Example: Classifying Radar Returns for Ionosphere Data with TreeBagger

You can also use ensembles of decision trees for classification. For this example, use ionosphere data with 351 observations and 34 real-valued predictors. The response variable is categorical with two levels:

- 'g' for good radar returns
- 'b' for bad radar returns

The goal is to predict good or bad returns using a set of 34 measurements. The workflow resembles that for "Workflow Example: Regression of Insurance Risk Rating for Car Imports with TreeBagger" on page 15-124.

1 Fix the initial random seed, grow 50 trees, inspect how the ensemble error changes with accumulation of trees, and estimate feature importance. For classification, it is best to set the minimal leaf size to 1 and select the square root of the total number of features for each decision split at random. These are the default settings for a TreeBagger used for classification.

```
load ionosphere;
rng(1945,'twister')
b = TreeBagger(50,X,Y,'oobvarimp','on');
figure(10);
plot(oobError(b));
xlabel('Number of Grown Trees');
ylabel('Out-of-Bag Classification Error');
```

2 The method trains ensembles with few trees on observations that are in bag for all trees. For such observations, it is impossible to compute the true
out-of-bag prediction, and TreeBagger returns the most probable class for classification and the sample mean for regression. You can change the default value returned for in-bag observations using the DefaultYfit property. If you set the default value to an empty string for classification, the method excludes in-bag observations from computation of the out-of-bag error. In this case, the curve is more variable when the number of trees is small, either because some observations are never out of bag (and are therefore excluded) or because their predictions are based on few trees.

```
b.DefaultYfit = '';
figure(11);
plot(oobError(b));
xlabel('Number of Grown Trees');
ylabel('Out-of-Bag Error Excluding in-Bag Observations');
```

3 The OOBIndices property of TreeBagger tracks which observations are out of bag for what trees. Using this property, you can monitor the fraction of observations in the training data that are in bag for all trees. The curve starts at approximately $2 / 3$, the fraction of unique observations selected by one bootstrap replica, and goes down to 0 at approximately 10 trees.

```
finbag = zeros(1,b.NTrees);
for t=1:b.NTrees
    finbag(t) = sum(all(~b.OOBIndices(:,1:t),2));
```

```
end
finbag = finbag / size(X,1);
figure(12);
plot(finbag);
xlabel('Number of Grown Trees');
ylabel('Fraction of in-Bag Observations');
```

4 Estimate feature importance:

```
figure(13);
bar(b.OOBPermutedVarDeltaError);
xlabel('Feature Index');
ylabel('Out-of-Bag Feature Importance');
idxvar = find(b.OOBPermutedVarDeltaError>0.8)
idxvar =
    3 
```

5 Having selected the five most important features, grow a larger ensemble on the reduced feature set. Save time by not permuting out-of-bag observations to obtain new estimates of feature importance for the reduced feature set (set oobvarimp to 'off'). You would still be interested in obtaining out-of-bag estimates of classification error (set oobpred to 'on ').

```
b5v = TreeBagger(100,X(:,idxvar),Y,'oobpred','on');
figure(14);
plot(oobError(b5v));
xlabel('Number of Grown Trees');
ylabel('Out-of-Bag Classification Error');
```

6 For classification ensembles, in addition to classification error (fraction of misclassified observations), you can also monitor the average classification margin. For each observation, the margin is defined as the difference between the score for the true class and the maximal score for other classes predicted by this tree. The cumulative classification margin uses the scores averaged over all trees and the mean cumulative classification margin is the cumulative margin averaged over all observations. The oobMeanMargin method with the 'mode' argument set to 'cumulative' (default) shows how the mean cumulative margin changes as the ensemble grows: every new element in the returned array represents the cumulative margin obtained by including a new tree in the ensemble. If training is successful, you would expect to see a gradual increase in the mean classification margin.

For decision trees, a classification score is the probability of observing an instance of this class in this tree leaf. For example, if the leaf of a grown decision tree has five 'good' and three 'bad' training observations in it, the scores returned by this decision tree for any observation fallen on this leaf are $5 / 8$ for the 'good' class and $3 / 8$ for the 'bad' class. These probabilities are called 'scores' for consistency with other classifiers that might not have an obvious interpretation for numeric values of returned predictions.

```
figure(15);
plot(oobMeanMargin(b5v));
```

```
xlabel('Number of Grown Trees');
ylabel('Out-of-Bag Mean Classification Margin');
```

7 Compute the matrix of proximities and look at the distribution of outlier measures. Unlike regression, outlier measures for classification ensembles are computed within each class separately.

```
b5v = fillProximities(b5v);
figure(16);
hist(b5v.OutlierMeasure);
xlabel('Outlier Measure');
ylabel('Number of Observations');
```

8 All extreme outliers for this dataset come from the 'good ' class:

```
b5v.Y(b5v.OutlierMeasure>40)
ans =
'g'
'g'
'g'
'g'
'g''
```

9 As for regression, you can plot scaled coordinates, displaying the two classes in different colors using the colors argument of mdsProx. This argument takes a string in which every character represents a color. To find the order of classes used by the ensemble, look at the ClassNames property:
b5v.ClassNames
ans $=$
' g
b
'

The 'good' class is first and the 'bad' class is second. Display scaled coordinates using red for 'good ' and blue for 'bad' observations:

```
figure(17);
[s,e] = mdsProx(b5v,'colors','rb');
xlabel('1st Scaled Coordinate');
ylabel('2nd Scaled Coordinate');
```

10 Plot the first 20 eigenvalues obtained by scaling. The first eigenvalue in this case clearly dominates and the first scaled coordinate is most important.

```
figure(18);
bar(e(1:20));
xlabel('Scaled Coordinate Index');
ylabel('Eigenvalue');
```

Plotting a Classification Performance Curve. Another way of exploring the performance of a classification ensemble is to plot its Receiver Operating Characteristic (ROC) curve or another performance curve suitable for the current problem. First, obtain predictions for out-of-bag observations. For a classification ensemble, the oobPredict method returns a cell array of classification labels (' $g$ ' or ' $b$ ' for ionosphere data) as the first output argument and a numeric array of scores as the second output argument. The returned array of scores has two columns, one for each class. In this case, the first column is for the 'good ' class and the second column is for the 'bad ' class. One column in the score matrix is redundant because the scores represent class probabilities in tree leaves and by definition add up to 1 .
[Yfit,Sfit] = oobPredict(b5v);
Use the perfcurve utility (see "Performance Curves" on page 14-39) to compute a performance curve. By default, perfcurve returns the standard ROC curve, which is the true positive rate versus the false positive rate. perfcurve requires true class labels, scores, and the positive class label for input. In this case, choose the 'good' class as positive. The scores for this class are in the first column of Sfit.

```
[fpr,tpr] = perfcurve(b5v.Y,Sfit(:,1),'g');
figure(19);
plot(fpr,tpr);
```

```
xlabel('False Positive Rate');
ylabel('True Positive Rate');
```

Instead of the standard ROC curve, you might want to plot, for example, ensemble accuracy versus threshold on the score for the 'good' class. The ycrit input argument of perfcurve lets you specify the criterion for the $y$-axis, and the third output argument of perfcurve returns an array of thresholds for the positive class score. Accuracy is the fraction of correctly classified observations, or equivalently, 1 minus the classification error.

```
[fpr,accu,thre] = perfcurve(b5v.Y,Sfit(:,1),'g','ycrit','accu');
figure(20);
plot(thre,accu);
xlabel('Threshold for ''good'' Returns');
ylabel('Classification Accuracy');
```

The curve shows a flat region indicating that any threshold from 0.2 to 0.6 is a reasonable choice. By default, the function assigns classification labels using 0.5 as the boundary between the two classes. You can find exactly what accuracy this corresponds to:

```
i50 = find(accu>=0.50,1,'first')
accu(abs(thre-0.5)<eps)
returns
i50 =
    2
ans =
    0.9430
```

The maximal accuracy is a little higher than the default one:

```
[maxaccu,iaccu] = max(accu)
```

returns
maxaccu =
0.9459

```
iaccu =
    91
```

The optimal threshold is therefore:
thre(iaccu)
ans =
0.5056

## AdaBoostM1

AdaBoostM1 is a very popular boosting algorithm for binary classification. The algorithm trains learners sequentially. For every learner with index $t$, AdaBoostM1 computes the weighted classification error

$$
\varepsilon_{t}=\sum_{n=1}^{N} d_{n}^{(t)} I\left(y_{n} \neq h_{t}\left(x_{n}\right)\right)
$$

where

- $x_{n}$ is a vector of predictor values for observation $n$.
- $y_{n}$ is the true class label.
- $h_{t}$ is the prediction of learner (hypothesis) with index $t$.
- I is the indicator function.
- $d_{n}^{(t)}$ is the weight of observation $n$ at step $t$.

AdaBoostM1 then increases weights for observations misclassified by learner $t$ and reduces weights for observations correctly classified by learner $t$. The next learner $t+1$ is then trained on the data with updated weights $d_{n}^{(t+1)}$.

After training finishes, AdaBoostM1 computes prediction for new data using

$$
f(x)=\sum_{t=1}^{T} \alpha_{t} h_{t}(x)
$$

where

$$
\alpha_{t}=\frac{1}{2} \log \frac{1-\varepsilon_{t}}{\varepsilon_{t}}
$$

are weights of the weak hypotheses in the ensemble.
Training by AdaBoostM1 can be viewed as stagewise minimization of the exponential loss

$$
\sum_{n=1}^{N} w_{n} \exp \left(-y_{n} f\left(x_{n}\right)\right)
$$

where

- $y_{n} \in\{-1,+1\}$ is the true class label.
- $w_{n}$ are observation weights normalized to add up to 1 .
- $f\left(x_{n}\right) \in(-\infty,+\infty)$ is the predicted classification score.

The observation weights $w_{n}$ are the original observation weights you passed to fitensemble.

The second output from the predict method of an AdaBoostM1 classification ensemble is an N -by- 2 matrix of classification scores for the two classes and $N$ observations. The second column in this matrix is always equal to minus the first column. predict returns two scores to be consistent with multiclass models, though this is redundant because the second column is always the negative of the first.

Most often AdaBoostM1 is used with decision stumps (default) or shallow trees. If boosted stumps give poor performance, try setting the minimal parent node size to one quarter of the training data.

By default, the learning rate for boosting algorithms is 1. If you set the learning rate to a lower number, the ensemble learns at a slower rate, but can converge to a better solution. 0.1 is a popular choice for the learning rate. Learning at a rate less than 1 is often called "shrinkage".

For examples using AdaBoostM1, see "Tuning RobustBoost" on page 15-114.
For references related to AdaBoostM1, see Freund and Schapire [9], Schapire et al. [15], Friedman, Hastie, and Tibshirani [11], and Friedman [10].

## AdaBoostM2

AdaBoostM2 is an extension of AdaBoostM1 for multiple classes. Instead of weighted classification error, AdaBoostM2 uses weighted pseudo-loss for $N$ observations and $K$ classes

$$
\varepsilon_{t}=\frac{1}{2} \sum_{n=1}^{N} \sum_{k \neq y_{n}} d_{n, k}^{(t)}\left(1-h_{t}\left(x_{n}, y_{n}\right)+h_{t}\left(x_{n}, k\right)\right),
$$

where

- $h_{t}\left(x_{n}, k\right)$ is the confidence of prediction by learner at step $t$ into class $k$ ranging from 0 (not at all confident) to 1 (highly confident).
- $d_{n, k}^{(t)}$ are observation weights at step $t$ for class $k$.
- $y_{n}$ is the true class label taking one of the $K$ values.
- The second sum is over all classes other than the true class $y_{n}$.

Interpreting the pseudo-loss is harder than classification error, but the idea is the same. Pseudo-loss can be used as a measure of the classification accuracy from any learner in an ensemble. Pseudo-loss typically exhibits the same behavior as a weighted classification error for AdaBoostM1: the first few learners in a boosted ensemble give low pseudo-loss values. After the first few training steps, the ensemble begins to learn at a slower pace, and the pseudo-loss value approaches 0.5 from below.

For examples using AdaBoostM2, see "Create a Classification Ensemble" on page 15-68.

For references related to AdaBoostM2, see Freund and Schapire [9].

## Bag

Bagging, which stands for "bootstrap aggregation," is a type of ensemble learning. To bag a weak learner such as a decision tree on a dataset, generate many bootstrap replicas of this dataset and grow decision trees on these replicas. Obtain each bootstrap replica by randomly selecting $N$ observations out of $N$ with replacement, where $N$ is the dataset size. To find the predicted response of a trained ensemble, take an average over predictions from individual trees.

Bagged decision trees were introduced in MATLAB R2009a as TreeBagger. The fitensemble function lets you bag in a manner consistent with boosting. An ensemble of bagged trees, either ClassificationBaggedEnsemble or RegressionBaggedEnsemble, returned by fitensemble offers almost the same functionally as TreeBagger. Discrepancies between TreeBagger and the new framework are described in detail in TreeBagger Features Not in fitensemble on page 15-150.

Bagging works by training learners on resampled versions of the data. This resampling is usually done by bootstrapping observations, that is, selecting $N$ out of $N$ observations with replacement for every new learner. In addition, every tree in the ensemble can randomly select predictors for decision splits-a technique known to improve the accuracy of bagged trees.

By default, the minimal leaf sizes for bagged trees are set to 1 for classification and 5 for regression. Trees grown with the default leaf size are usually very deep. These settings are close to optimal for the predictive power of an ensemble. Often you can grow trees with larger leaves without losing predictive power. Doing so reduces training and prediction time, as well as memory usage for the trained ensemble.

Another important parameter is the number of predictors selected at random for every decision split. This random selection is made for every split, and every deep tree involves many splits. By default, this parameter is set to a square root of the number of predictors for classification, and one third of predictors for regression.

Several features of bagged decision trees make them a unique algorithm. Drawing N out of N observations with replacement omits on average $37 \%$ of observations for each decision tree. These are "out-of-bag" observations. You can use them to estimate the predictive power and feature importance. For each observation, you can estimate the out-of-bag prediction by averaging over predictions from all trees in the ensemble for which this observation is out of bag. You can then compare the computed prediction against the observed response for this observation. By comparing the out-of-bag predicted responses against the observed responses for all observations used for training, you can estimate the average out-of-bag error. This out-of-bag average is an unbiased estimator of the true ensemble error. You can also obtain out-of-bag estimates of feature importance by randomly permuting out-of-bag data across one variable or column at a time and estimating the increase in the out-of-bag error due to this permutation. The larger the increase, the more important the feature. Thus, you need not supply test data for bagged ensembles because you obtain reliable estimates of the predictive power and feature importance in the process of training, which is an attractive feature of bagging.

Another attractive feature of bagged decision trees is the proximity matrix. Every time two observations land on the same leaf of a tree, their proximity
increases by 1. For normalization, sum these proximities over all trees in the ensemble and divide by the number of trees. The resulting matrix is symmetric with diagonal elements equal to 1 and off-diagonal elements ranging from 0 to 1 . You can use this matrix for finding outlier observations and discovering clusters in the data through multidimensional scaling.

For examples using bagging, see:

- "Example: Test Ensemble Quality" on page 15-71
- "Surrogate Splits" on page 15-94
- "Workflow Example: Regression of Insurance Risk Rating for Car Imports with TreeBagger" on page 15-124
- "Workflow Example: Classifying Radar Returns for Ionosphere Data with TreeBagger" on page 15-133

For references related to bagging, see Breiman [3], [4], and [5].
Comparison of TreeBagger and Bagged Ensembles. fitensemble produces bagged ensembles that have most, but not all, of the functionality of TreeBagger objects. Additionally, some functionality has different names in the new bagged ensembles.

## TreeBagger Features Not in fitensemble

| Feature | TreeBagger Property | TreeBagger Merhod |
| :--- | :--- | :--- |
| Computation of proximity <br> matrix | Proximity | fillProximities, mdsProx |
| Computation of outliers | OutlierMeasure | N/A |

In addition, two important changes were made to training and prediction for bagged classification ensembles:

- If you pass a misclassification cost matrix to TreeBagger, it passes this matrix along to the trees. If you pass a misclassification cost matrix to fitensemble, it uses this matrix to adjust the class prior probabilities. fitensemble then passes the adjusted prior probabilities and the default cost matrix to the trees. The default cost matrix is ones (K) -eye (K) for K classes.
- Unlike the loss and edge methods in the new framework, the TreeBagger error and meanMargin methods do not normalize input observation weights of the prior probabilities in the respective class.

## GentleBoost

GentleBoost (also known as Gentle AdaBoost) combines features of AdaBoostM1 and LogitBoost. Like AdaBoostM1, GentleBoost minimizes the exponential loss. But its numeric optimization is set up differently. Like LogitBoost, every weak learner fits a regression model to response values $y_{n} \in\{-1,+1\}$. This makes GentleBoost another good candidate for binary classification of data with multilevel categorical predictors.
fitensemble computes and stores the mean-squared error in the FitInfo property of the ensemble object. The mean-squared error is

$$
\sum_{n=1}^{N} d_{n}^{(t)}\left(\tilde{y}_{n}-h_{t}\left(x_{n}\right)\right)^{2}
$$

where

- $d_{n}^{(t)}$ are observation weights at step $t$ (the weights add up to 1 ).
- $h_{t}\left(x_{n}\right)$ are predictions of the regression model $h_{t}$ fitted to response values $y_{n}$.

As the strength of individual learners weakens, the weighted mean-squared error approaches 1 .

For examples using GentleBoost, see "Example: Unequal Classification Costs" on page 15-84 and "Classification with Many Categorical Levels" on page 15-90.

For references related to GentleBoost, see Friedman, Hastie, and Tibshirani [11].

## LogitBoost

LogitBoost is another popular algorithm for binary classification. LogitBoost works similarly to AdaBoostM1, except it minimizes binomial deviance

$$
\sum_{n=1}^{N} w_{n} \log \left(1+\exp \left(-2 y_{n} f\left(x_{n}\right)\right)\right)
$$

where

- $y_{n} \epsilon\{-1,+1\}$ is the true class label.
- $w_{n}$ are observation weights normalized to add up to 1 .
- $f\left(x_{n}\right) \in(-\infty,+\infty)$ is the predicted classification score.

Binomial deviance assigns less weight to badly misclassified observations (observations with large negative values of $y_{n} f\left(x_{n}\right)$ ). LogitBoost can give better average accuracy than AdaBoostM1 for data with poorly separable classes.

Learner $t$ in a LogitBoost ensemble fits a regression model to response values

$$
\tilde{y}_{n}=\frac{y_{n}^{*}-p_{t}\left(x_{n}\right)}{p_{t}\left(x_{n}\right)\left(1-p_{t}\left(x_{n}\right)\right)},
$$

where

- $y^{*}{ }_{n} \epsilon\{0,+1\}$ are relabeled classes ( 0 instead of -1 ).
- $p_{t}\left(x_{n}\right)$ is the current ensemble estimate of the probability for observation $x_{n}$ to be of class 1 .

Fitting a regression model at each boosting step turns into a great computational advantage for data with multilevel categorical predictors. Take a categorical predictor with $L$ levels. To find the optimal decision split on such a predictor, classification tree needs to consider $2^{L-1}-1$ splits. A regression tree needs to consider only $L-1$ splits, so the processing time can be much shorter. LogitBoost is recommended for categorical predictors with many levels.
fitensemble computes and stores the mean-squared error in the FitInfo property of the ensemble object. The mean-squared error is

$$
\sum_{n=1}^{N} d_{n}^{(t)}\left(\tilde{y}_{n}-h_{t}\left(x_{n}\right)\right)^{2}
$$

where

- $d_{n}^{(t)}$ are observation weights at step $t$ (the weights add up to 1 ).
- $h_{t}\left(x_{n}\right)$ are predictions of the regression model $h_{t}$ fitted to response values $\tilde{y}_{n}$.

Values $y_{n}$ can range from $-\infty$ to $+\infty$, so the mean-squared error does not have well-defined bounds.

For examples using LogitBoost, see "Classification with Many Categorical Levels" on page 15-90.

For references related to LogitBoost, see Friedman, Hastie, and Tibshirani [11].

## LPBoost

LPBoost (linear programming boost), like TotalBoost, performs multiclass classification by attempting to maximize the minimal margin in the training set. This attempt uses optimization algorithms, namely linear programming for LPBoost. So you need an Optimization Toolbox license to use LPBoost or TotalBoost.

The margin of a classification is the difference between the predicted soft classification score for the true class, and the largest score for the false classes. For trees, the score of a classification of a leaf node is the posterior probability of the classification at that node. The posterior probability of the classification at a node is the number of training sequences that lead to that node with the classification, divided by the number of training sequences that lead to that node. For more information, see "Definitions" on page 20-1485 in margin.

Why maximize the minimal margin? For one thing, the generalization error (the error on new data) is the probability of obtaining a negative margin. Schapire and Singer [16] establish this inequality on the probability of obtaining a negative margin:

$$
P_{\text {test }}(m \leq 0) \leq P_{\text {train }}(m \leq \theta)+O\left(\frac{1}{\sqrt{N}} \sqrt{\frac{V \log ^{2}(N / V)}{\theta^{2}}+\log (1 / \delta)}\right)
$$

Here $m$ is the margin, $\theta$ is any positive number, $V$ is the Vapnik-Chervonenkis dimension of the classifier space, $N$ is the size of the training set, and $\delta$ is a small positive number. The inequality holds with probability $1-\delta$ over many i.i.d. training and test sets. This inequality says: To obtain a low generalization error, minimize the number of observations below margin $\theta$ in the training set.

LPBoost iteratively maximizes the minimal margin through a sequence of linear programming problems. Equivalently, by duality, LPBoost minimizes the maximal edge, where edge is the weighted mean margin (see "Definitions" on page 20-651). At each iteration, there are more constraints in the problem. So, for large problems, the optimization problem becomes increasingly constrained, and slow to solve.

LPBoost typically creates ensembles with many learners having weights that are orders of magnitude smaller than those of other learners. Therefore, to better enable you to remove the unimportant ensemble members, the compact method reorders the members of an LPBoost ensemble from largest weight to smallest. Therefore, you can easily remove the least important members of the ensemble using the removeLearners method.

For examples using LPBoost, see "LPBoost and TotalBoost for Small Ensembles" on page 15-97.

For references related to LPBoost, see Warmuth, Liao, and Ratsch [18].

## LSBoost

LSBoost (least squares boosting) fits regression ensembles. At every step, the ensemble fits a new learner to the difference between the observed response and the aggregated prediction of all learners grown previously. The ensemble fits to minimize mean-squared error.

You can use LSBoost with shrinkage by passing in the LearnRate parameter. By default this parameter is set to 1 , and the ensemble learns at the maximal speed. If you set LearnRate to a value from 0 to 1 , the ensemble fits every new learner to $y_{n}-\eta f\left(x_{n}\right)$, where

- $y_{n}$ is the observed response.
- $f\left(x_{n}\right)$ is the aggregated prediction from all weak learners grown so far for observation $x_{n}$.
- $\eta$ is the learning rate.

For examples using LSBoost, see "Creating a Regression Ensemble" on page 15-69 and "Example: Regularizing a Regression Ensemble" on page 15-104.

For references related to LSBoost, see Hastie, Tibshirani, and Friedman [12], Chapters 7 (Model Assessment and Selection) and 15 (Random Forests).

## RobustBoost

Boosting algorithms such as AdaBoostM1 and LogitBoost increase weights for misclassified observations at every boosting step. These weights can become very large. If this happens, the boosting algorithm sometimes concentrates on a few misclassified observations and neglects the majority of training data. Consequently the average classification accuracy suffers.

In this situation, you can try using RobustBoost. This algorithm does not assign almost the entire data weight to badly misclassified observations. It can produce better average classification accuracy.

Unlike AdaBoostM1 and LogitBoost, RobustBoost does not minimize a specific loss function. Instead, it maximizes the number of observations with the classification margin above a certain threshold.

RobustBoost trains based on time evolution. The algorithm starts at $t=0$. At every step, RobustBoost solves an optimization problem to find a positive step in time $\Delta t$ and a corresponding positive change in the average margin for training data $\Delta m$. RobustBoost stops training and exits if at least one of these three conditions is true:

- Time $t$ reaches 1.
- RobustBoost cannot find a solution to the optimization problem with positive updates $\Delta t$ and $\Delta m$.
- RobustBoost grows as many learners as you requested.

Results from RobustBoost can be usable for any termination condition. Estimate the classification accuracy by cross validation or by using an independent test set.

To get better classification accuracy from RobustBoost, you can adjust three parameters in fitensemble: RobustErrorGoal, RobustMaxMargin, and RobustMarginSigma. Start by varying values for RobustErrorGoal from 0 to 1. The maximal allowed value for RobustErrorGoal depends on the two other parameters. If you pass a value that is too high, fitensemble produces an error message showing the allowed range for RobustErrorGoal.

For examples using RobustBoost, see "Tuning RobustBoost" on page 15-114.
For references related to RobustBoost, see Freund [8].

## RUSBoost

RUSBoost is especially effective at classifying imbalanced data, meaning some class in the training data has many fewer members than another. RUS stands for Random Under Sampling. The algorithm takes $N$, the number of members in the class with the fewest members in the training data, as the basic unit for sampling. Classes with more members are under sampled by taking only $N$ observations of every class. In other words, if there are $K$ classes, then, for each weak learner in the ensemble, RUSBoost takes a subset of the data with $N$ observations from each of the $K$ classes. The boosting procedure follows the procedure in "AdaBoostM2" on page 15-147 for reweighting and constructing the ensemble.

When you construct a RUSBoost ensemble, there is an optional name-value pair called RatioToSmallest. Give a vector of $K$ values, each value representing the multiple of $N$ to sample for the associated class. For example, if the smallest class has $N=100$ members, then RatioToSmallest $=$ [ $2,3,4$ ] means each weak learner has 200 members in class 1,300 in class 2 , and 400 in class 3 . If RatioToSmallest leads to a value that is larger than the number of members in a particular class, then RUSBoost samples the members with replacement. Otherwise, RUSBoost samples the members without replacement.

For examples using RUSBoost, see "Classification with Imbalanced Data" on page 15-76.

For references related to RUSBoost, see Seiffert et al. [17].

## Subspace

Use random subspace ensembles (Subspace) to improve the accuracy of discriminant analysis (ClassificationDiscriminant) or $k$-nearest neighbor (ClassificationKNN) classifiers. Subspace ensembles also have the advantage of using less memory than ensembles with all predictors, and can handle missing values ( NaNs ).

The basic random subspace algorithm uses these parameters.

- $m$ is the number of dimensions (variables) to sample in each learner. Set $m$ using the NPredToSample name-value pair.
- $d$ is the number of dimensions in the data, which is the number of columns (predictors) in the data matrix X .
- $n$ is the number of learners in the ensemble. Set $n$ using the NLearn input.

The basic random subspace algorithm performs the following steps:
1 Choose without replacement a random set of $m$ predictors from the $d$ possible values.

2 Train a weak learner using just the $m$ chosen predictors.
3 Repeat steps 1 and 2 until there are $n$ weak learners.
4 Predict by taking an average of the score prediction of the weak learners, and classify the category with the highest average score.

You can choose to create a weak learner for every possible set of $m$ predictors from the $d$ dimensions. To do so, set $n$, the number of learners, to 'AllPredictorCombinations'. In this case, there are nchoosek(size ( $\mathrm{X}, 2$ ) , NPredToSample) weak learners in the ensemble.
fitensemble downweights predictors after choosing them for a learner, so subsequent learners have a lower chance of using a predictor that was previously used. This weighting tends to make predictors more evenly distributed among learners than in uniform weighting.

For examples using Subspace, see "Random Subspace Classification" on page 15-118.

For references related to random subspace ensembles, see Ho [13].

## TotalBoost

TotalBoost, like linear programming boost (LPBoost), performs multiclass classification by attempting to maximize the minimal margin in the training set. This attempt uses optimization algorithms, namely quadratic programming for TotalBoost. So you need an Optimization Toolbox license to use LPBoost or TotalBoost.

The margin of a classification is the difference between the predicted soft classification score for the true class, and the largest score for the false classes. For trees, the score of a classification of a leaf node is the posterior probability of the classification at that node. The posterior probability of the classification at a node is the number of training sequences that lead to that node with the classification, divided by the number of training sequences that lead to that node. For more information, see "Definitions" on page 20-1485 in margin.

Why maximize the minimal margin? For one thing, the generalization error (the error on new data) is the probability of obtaining a negative margin. Schapire and Singer [16] establish this inequality on the probability of obtaining a negative margin:

$$
P_{\text {test }}(m \leq 0) \leq P_{\text {train }}(m \leq \theta)+O\left(\frac{1}{\sqrt{N}} \sqrt{\frac{V \log ^{2}(N / V)}{\theta^{2}}+\log (1 / \delta)}\right)
$$

Here $m$ is the margin, $\theta$ is any positive number, $V$ is the Vapnik-Chervonenkis dimension of the classifier space, $N$ is the size of the training set, and $\delta$ is a small positive number. The inequality holds with probability $1-\delta$ over many i.i.d. training and test sets. This inequality says: To obtain a low generalization error, minimize the number of observations below margin $\theta$ in the training set.

TotalBoost minimizes a proxy of the Kullback-Leibler divergence between the current weight distribution and the initial weight distribution, subject to
the constraint that the edge (the weighted margin) is below a certain value. The proxy is a quadratic expansion of the divergence:

$$
D\left(W, W_{0}\right)=\sum_{n=1}^{N} \log \frac{W(n)}{W_{0}(n)} \approx \sum_{n=1}^{N}\left(1+\frac{W(n)}{W_{0}(n)}\right) \Delta+\frac{1}{2 W(n)} \Delta^{2},
$$

where $\Delta$ is the difference between $W(n)$, the weights at the current and next iteration, and $W_{0}$, the initial weight distribution, which is uniform. This optimization formulation keeps weights from becoming zero. At each iteration, there are more constraints in the problem. So, for large problems, the optimization problem becomes increasingly constrained, and slow to solve.

TotalBoost typically creates ensembles with many learners having weights that are orders of magnitude smaller than those of other learners. Therefore, to better enable you to remove the unimportant ensemble members, the compact method reorders the members of a TotalBoost ensemble from largest weight to smallest. Therefore you can easily remove the least important members of the ensemble using the removeLearners method.

For examples using TotalBoost, see "LPBoost and TotalBoost for Small Ensembles" on page 15-97.

For references related to TotalBoost, see Warmuth, Liao, and Ratsch [18].

## Support Vector Machines (SVM)

In this section...<br>"Understanding Support Vector Machines" on page 15-161<br>"Using Support Vector Machines" on page 15-167<br>"Nonlinear Classifier with Gaussian Kernel" on page 15-169<br>"SVM Classification with Cross Validation" on page 15-173

## Understanding Support Vector Machines

- "Separable Data" on page 15-161
- "Nonseparable Data" on page 15-164
- "Nonlinear Transformation with Kernels" on page 15-166

## Separable Data

You can use a support vector machine (SVM) when your data has exactly two classes. An SVM classifies data by finding the best hyperplane that separates all data points of one class from those of the other class. The best hyperplane for an SVM means the one with the largest margin between the two classes. Margin means the maximal width of the slab parallel to the hyperplane that has no interior data points.

The support vectors are the data points that are closest to the separating hyperplane; these points are on the boundary of the slab. The following figure illustrates these definitions, with + indicating data points of type 1 , and indicating data points of type -1 .

Mathematical Formulation: Primal. This discussion follows Hastie, Tibshirani, and Friedman [12] and Christianini and Shawe-Taylor [7].

The data for training is a set of points (vectors) $x_{i}$ along with their categories $y_{i}$. For some dimension $d$, the $x_{i} \in R^{d}$, and the $y_{i}= \pm 1$. The equation of a hyperplane is

$$
<w, x>+b=0,
$$

where $w \in R^{d},\langle w, x\rangle$ is the inner (dot) product of $w$ and $x$, and $b$ is real.
The following problem defines the best separating hyperplane. Find $w$ and $b$ that minimize $||w||$ such that for all data points $\left(x_{i}, y_{i}\right)$,

$$
y_{i}\left(<w, x_{i}>+b\right) \geq 1 .
$$

The support vectors are the $x_{i}$ on the boundary, those for which $y_{i}\left(<w, x_{i}>+b\right)=1$.

For mathematical convenience, the problem is usually given as the equivalent problem of minimizing $\langle w, w\rangle / 2$. This is a quadratic programming problem. The optimal solution $w, b$ enables classification of a vector $z$ as follows:

$$
\operatorname{class}(z)=\operatorname{sign}(<w, z>+b) .
$$

Mathematical Formulation: Dual. It is computationally simpler to solve the dual quadratic programming problem. To obtain the dual, take positive Lagrange multipliers $a_{i}$ multiplied by each constraint, and subtract from the objective function:

$$
L_{P}=\frac{1}{2}\langle w, w\rangle-\sum_{i} \alpha_{i}\left(y_{i}\left(\left\langle w, x_{i}\right\rangle+b\right)-1\right),
$$

where you look for a stationary point of $L_{P}$ over $w$ and $b$. Setting the gradient of $L_{P}$ to 0, you get

$$
\begin{align*}
w & =\sum_{i} \alpha_{i} y_{i} x_{i} \\
0 & =\sum_{i} \alpha_{i} y_{i} . \tag{15-1}
\end{align*}
$$

Substituting into $L_{P}$, you get the dual $L_{D}$ :

$$
L_{D}=\sum_{i} \alpha_{i}-\frac{1}{2} \sum_{i} \sum_{j} \alpha_{i} \alpha_{j} y_{i} y_{j}\left\langle x_{i}, x_{j}\right\rangle,
$$

which you maximize over $a_{i} \geq 0$. In general, many $a_{i}$ are 0 at the maximum. The nonzero $a_{i}$ in the solution to the dual problem define the hyperplane, as seen in Equation 15-1, which gives $w$ as the sum of $a_{i} y_{i} x_{i}$. The data points $x_{i}$ corresponding to nonzero $a_{i}$ are the support vectors.

The derivative of $L_{D}$ with respect to a nonzero $\alpha_{i}$ is 0 at an optimum. This gives

$$
\left.y_{i}\left(<w, x_{i}\right\rangle+b\right)-1=0 .
$$

In particular, this gives the value of $b$ at the solution, by taking any $i$ with nonzero $a_{i}$.

The dual is a standard quadratic programming problem. For example, the Optimization Toolbox quadprog solver solves this type of problem.

## Nonseparable Data

Your data might not allow for a separating hyperplane. In that case, SVM can use a soft margin, meaning a hyperplane that separates many, but not all data points.

There are two standard formulations of soft margins. Both involve adding slack variables $s_{i}$ and a penalty parameter $C$.

- The $L^{1}$-norm problem is:

$$
\min _{w, b, s}\left(\frac{1}{2}\langle w, w\rangle+C \sum_{i} s_{i}\right)
$$

such that

$$
\begin{aligned}
y_{i}\left(\left\langle w, x_{i}\right\rangle+b\right) & \geq 1-s_{i} \\
s_{i} & \geq 0 .
\end{aligned}
$$

The $L^{1}$-norm refers to using $s_{i}$ as slack variables instead of their squares. The SMO svmtrain method minimizes the $L^{1}$-norm problem.

- The $L^{2}$-norm problem is:

$$
\min _{w, b, s}\left(\frac{1}{2}\langle w, w\rangle+C \sum_{i} s_{i}^{2}\right)
$$

subject to the same constraints. The QP svmtrain method minimizes the $L^{2}$-norm problem.

In these formulations, you can see that increasing $C$ places more weight on the slack variables $s_{i}$, meaning the optimization attempts to make a stricter separation between classes. Equivalently, reducing $C$ towards 0 makes misclassification less important.

Mathematical Formulation: Dual. For easier calculations, consider the $L^{1}$ dual problem to this soft-margin formulation. Using Lagrange multipliers $\mu_{i}$, the function to minimize for the $L^{1}$-norm problem is:

$$
L_{P}=\frac{1}{2}\langle w, w\rangle+C \sum_{i} s_{i}-\sum_{i} \alpha_{i}\left(y_{i}\left(\left\langle w, x_{i}\right\rangle+b\right)-\left(1-s_{i}\right)\right)-\sum_{i} \mu_{i} s_{i}
$$

where you look for a stationary point of $L_{P}$ over $w, b$, and positive $s_{i}$. Setting the gradient of $L_{P}$ to 0 , you get

$$
\begin{aligned}
b & =\sum_{i} \alpha_{i} y_{i} x_{i} \\
\sum_{i} \alpha_{i} y_{i} & =0 \\
\alpha_{i} & =C-\mu_{i} \\
\alpha_{i}, \mu_{i}, s_{i} & \geq 0 .
\end{aligned}
$$

These equations lead directly to the dual formulation:

$$
\max _{\alpha} \sum_{i} \alpha_{i}-\frac{1}{2} \sum_{i} \sum_{j} \alpha_{i} \alpha_{j} y_{i} y_{j}\left\langle x_{i}, x_{j}\right\rangle
$$

subject to the constraints

$$
\begin{aligned}
& \sum_{i} y_{i} \alpha_{i}=0 \\
& 0 \leq \alpha_{i} \leq C .
\end{aligned}
$$

The final set of inequalities, $0 \leq a_{i} \leq C$, shows why $C$ is sometimes called a box constraint. $C$ keeps the allowable values of the Lagrange multipliers $\alpha_{i}$ in a "box", a bounded region.

The gradient equation for $b$ gives the solution $b$ in terms of the set of nonzero $a_{i}$, which correspond to the support vectors.

You can write and solve the dual of the $L^{2}$-norm problem in an analogous manner. For details, see Christianini and Shawe-Taylor [7], Chapter 6.
svmtrain Implementation. Both dual soft-margin problems are quadratic programming problems. Internally, svmtrain has several different algorithms for solving the problems. The default Sequential Minimal Optimization (SMO) algorithm minimizes the one-norm problem. SMO is a relatively fast algorithm. If you have an Optimization Toolbox license, you can choose to use quadprog as the algorithm. quadprog minimizes the $L^{2}$-norm problem. quadprog uses a good deal of memory, but solves quadratic programs to a high degree of precision (see Bottou and Lin [2]). For details, see the svmtrain function reference page.

## Nonlinear Transformation with Kernels

Some binary classification problems do not have a simple hyperplane as a useful separating criterion. For those problems, there is a variant of the mathematical approach that retains nearly all the simplicity of an SVM separating hyperplane.

This approach uses these results from the theory of reproducing kernels:

- There is a class of functions $K(x, y)$ with the following property. There is a linear space $S$ and a function $\varphi$ mapping $x$ to $S$ such that

$$
K(x, y)=\langle\varphi(x), \varphi(y)\rangle .
$$

The dot product takes place in the space $S$.

- This class of functions includes:
- Polynomials: For some positive integer $d$,

$$
K(x, y)=(1+<x, y>)^{d} .
$$

- Radial basis function: For some positive number $\sigma$,

$$
K(x, y)=\exp \left(-<(x-y),(x-y)>/\left(2 \sigma^{2}\right)\right) .
$$

- Multilayer perceptron (neural network): For a positive number $p_{1}$ and a negative number $p_{2}$,

$$
K(x, y)=\tanh \left(p_{1}<x, y>+p_{2}\right) .
$$

Note Not every set of $p_{1}$ and $p_{2}$ gives a valid reproducing kernel.

The mathematical approach using kernels relies on the computational method of hyperplanes. All the calculations for hyperplane classification use nothing more than dot products. Therefore, nonlinear kernels can use identical calculations and solution algorithms, and obtain classifiers that are nonlinear. The resulting classifiers are hypersurfaces in some space $S$, but the space $S$ does not have to be identified or examined.

## Using Support Vector Machines

As with any supervised learning model, you first train a support vector machine, then use the trained machine to classify (predict) new data. In addition, to obtain satisfactory predictive accuracy, you can use various SVM kernel functions, and you must tune the parameters of the kernel functions.

- "Training an SVM Classifier" on page 15-167
- "Classifying New Data with an SVM Classifier" on page 15-168
- "Tuning an SVM Classifier" on page 15-168

## Training an SVM Classifier

Train an SVM classifier with the svmtrain function. The most common syntax is:

```
SVMstruct = svmtrain(data,groups,'Kernel_Function','rbf');
```

The inputs are:

- data - Matrix of data points, where each row is one observation, and each column is one feature.
- groups - Column vector with each row corresponding to the value of the corresponding row in data. groups should have only two types of entries. So groups can have logical entries, or can be a double vector or cell array with two values.
- Kernel_Function - The default value of 'linear' separates the data by a hyperplane. The value 'rbf' uses a Gaussian radial basis function. Hsu, Chang, and Lin [14] suggest using 'rbf' as your first try.

The resulting structure, SVMstruct, contains the optimized parameters from the SVM algorithm, enabling you to classify new data.

For more name-value pairs you can use to control the training, see the svmtrain reference page.

## Classifying New Data with an SVM Classifier

Classify new data with the svmclassify function. The syntax for classifying new data with a SVMstruct structure is:

```
newClasses = svmclassify(SVMstruct,newData)
```

The resulting vector, newClasses, represents the classification of each row in newData.

## Tuning an SVM Classifier

Hsu, Chang, and Lin [14] recommend tuning parameters of your classifier according to this scheme:

- Start with Kernel_Function set to 'rbf' and default parameters.
- Try different parameters for training, and check via cross validation to obtain the best parameters.

The most important parameters to try changing are:

- boxconstraint - One strategy is to try a geometric sequence of the box constraint parameter. For example, take 11 values, from $1 e-5$ to $1 e 5$ by a factor of 10 .
- rbf_sigma - One strategy is to try a geometric sequence of the RBF sigma parameter. For example, take 11 values, from $1 e-5$ to 1 e 5 by a factor of 10 .

For the various parameter settings, try cross validating the resulting classifier. Use crossval with 5 -way or the default 10 -way cross validation.

After obtaining a reasonable initial parameter, you might want to refine your parameters to obtain better accuracy. Start with your initial parameters and perform another cross validation step, this time using a factor of 1.2. Alternatively, optimize your parameters with fminsearch, as shown in "SVM Classification with Cross Validation" on page 15-173.

## Nonlinear Classifier with Gaussian Kernel

This example generates one class of points inside the unit disk in two dimensions, and another class of points in the annulus from radius 1 to radius 2. It then generates a classifier based on the data with the Gaussian radial basis function kernel. The default linear classifier is obviously unsuitable for this problem, since the model is circularly symmetric. Set the box constraint parameter to Inf to make a strict classification, meaning no misclassified training points.

Note Other kernel functions might not work with this strict box constraint, since they might be unable to provide a strict classification. Even though the rbf classifier can separate the classes, the result can be overtrained.

1 Generate 100 points uniformly distributed in the unit disk. To do so, generate a radius $r$ as the square root of a uniform random variable, generate an angle $t$ uniformly in $(0,2 \pi)$, and put the point at $(r \cos (t), r \sin (t)$.

```
r = sqrt(rand(100,1)); % radius
t = 2*pi*rand(100,1); % angle
data1 = [r.*cos(t), r.*sin(t)]; % points
```

2 Generate 100 points uniformly distributed in the annulus. The radius is again proportional to a square root, this time a square root of the uniform distribution from 1 through 4.

```
r2 = sqrt(3*rand(100,1)+1); % radius
t2 = 2*pi*rand(100,1); % angle
data2 = [r2.*cos(t2), r2.*sin(t2)]; % points
```

3 Plot the points, and plot circles of radii 1 and 2 for comparison:

```
plot(data1(:,1),data1(:,2),'r.')
```

```
hold on
plot(data2(:,1),data2(:,2),'b.')
ezpolar(@(x)1);ezpolar(@(x)2);
axis equal
hold off
```

4 Put the data in one matrix, and make a vector of classifications:

```
data3 = [data1;data2];
theclass = ones(200,1);
theclass(1:100) = -1;
```

5 Train an SVM classifier with:

- Kernel_Function set to 'rbf'
- boxconstraint set to Inf

```
cl = svmtrain(data3,theclass,'Kernel_Function','rbf',...
    'boxconstraint',Inf,'showplot',true);
hold on
axis equal
ezpolar(@(x)1)
hold off
```

svmtrain generates a classifier that is close to a circle of radius 1 . The difference is due to the random training data.

6 Training with the default parameters makes a more nearly circular classification boundary, but one that misclassifies some training data.

```
cl = svmtrain(data3,theclass,'Kernel_Function','rbf',...
    'showplot',true);
hold on
axis equal
ezpolar(@(x)1)
hold off
```

## SVM Classification with Cross Validation

This example classifies points from a Gaussian mixture model. The model is described in Hastie, Tibshirani, and Friedman [12], page 17. It begins with generating 10 base points for a "green" class, distributed as 2-D independent normals with mean ( 1,0 ) and unit variance. It also generates 10 base points for a "red" class, distributed as 2-D independent normals with mean $(0,1)$ and unit variance. For each class (green and red), generate 100 random points as follows:

1 Choose a base point $m$ of the appropriate color uniformly at random.
2 Generate an independent random point with 2-D normal distribution with mean $m$ and variance $\mathrm{I} / 5$, where I is the 2 -by- 2 identity matrix.

After generating 100 green and 100 red points, classify them using svmtrain, and tune the classification using cross validation.

To generate the points and classifier:
1 Generate the 10 base points for each class:

```
grnpop = mvnrnd([1,0],eye(2),10);
redpop = mvnrnd([0,1],eye(2),10);
```

2 View the base points:

```
plot(grnpop(:,1),grnpop(:,2),'go')
hold on
plot(redpop(:,1),redpop(:,2),'ro')
hold off
```

Since many red base points are close to green base points, it is difficult to classify the data points.

3 Generate the 100 data points of each class:

```
redpts = zeros(100,2);grnpts = redpts;
for i = 1:100
    grnpts(i,:) = mvnrnd(grnpop(randi(10),:),eye(2)*0.2);
    redpts(i,:) = mvnrnd(redpop(randi(10),:),eye(2)*0.2);
end
```

4 View the data points:
figure
plot(grnpts(:,1),grnpts(:,2),'go')
hold on

```
plot(redpts(:,1),redpts(:,2),'ro')
hold off
```

5 Put the data into one matrix, and make a vector grp that labels the class of each point:

```
cdata = [grnpts;redpts];
grp = ones(200,1);
% green label 1, red label -1
grp(101:200) = -1;
```

6 Check the basic classification of all the data using the default parameters:

```
svmStruct = svmtrain(cdata,grp,'Kernel_Function','rbf',...
```

```
'showplot',true);
```

7 Write a function called crossfun to calculate the predicted classification yfit from a test vector xtest, when the SVM is trained on a sample xtrain that has classification ytrain. Since you want to find the best parameters rbf_sigma and boxconstraint, include those in the function.

```
function yfit = ...
crossfun(xtrain,ytrain,xtest,rbf_sigma,boxconstraint)
```

\% Train the model on xtrain, ytrain, \% and get predictions of class of xtest svmStruct $=$ svmtrain(xtrain,ytrain, 'Kernel_Function','rbf',...

```
    'rbf_sigma',rbf_sigma,'boxconstraint',boxconstraint);
yfit = svmclassify(svmStruct,xtest);
```

8 Set up a partition for cross validation. This step causes the cross validation to be fixed. Without this step, the cross validation is random, so a minimization procedure can find a spurious local minimum.
c = cvpartition(200,'kfold', 10);
9 Set up a function that takes an input z=[rbf_sigma, boxconstraint], and returns the cross-validation value of $\exp (z)$. The reason to take $\exp (z)$ is twofold:

- rbf_sigma and boxconstraint must be positive.
- You should look at points spaced approximately exponentially apart.

This function handle computes the cross validation at parameters exp([rbf_sigma,boxconstraint]):

```
minfn = @(z)crossval('mcr',cdata,grp,'Predfun', ...
    @(xtrain,ytrain,xtest)crossfun(xtrain,ytrain,...
    xtest, exp(z(1)), exp(z(2))),'partition',c);
```

10 Search for the best parameters [rbf_sigma, boxconstraint] with fminsearch, setting looser tolerances than the defaults.

Tip If you have a Global Optimization Toolbox license, use patternsearch for faster, more reliable minimization. Give bounds on the components of $z$ to keep the optimization in a sensible region, such as [-5,5], and give a relatively loose TolMesh tolerance.

```
opts = optimset('TolX',5e-4,'TolFun',5e-4);
[searchmin fval] = fminsearch(minfn,randn(2,1),opts)
searchmin =
    0.9758
    -0.1569
```

```
fval =
    0.3350
```

The best parameters [rbf_sigma; boxconstraint] in this run are:

```
z = exp(searchmin)
z =
    2.6534
    0.8548
```

11 Since the result of fminsearch can be a local minimum, not a global minimum, try again with a different starting point to check that your result is meaningful:

```
[searchmin fval] = fminsearch(minfn,randn(2,1),opts)
```

searchmin =
0.2778
0.6395
fval =
0.3100

The best parameters [rbf_sigma; boxconstraint] in this run are:

```
z = exp(searchmin)
z =
    1.3202
    1.8956
```

12 Try another search:

```
[searchmin fval] = fminsearch(minfn,randn(2,1),opts)
```

searchmin =
-0.0749
0.6085
fval =
0.2850

The third search obtains the lowest function value. The final parameters are:

```
z = exp(searchmin)
Z =
    0.9278
    1.8376
```

The default parameters [1,1] are close to optimal for this data and partition.
13 Use the z parameters to train a new SVM classifier:
svmStruct = svmtrain(cdata,grp,'Kernel_Function','rbf',...
'rbf_sigma', z(1), 'boxconstraint', z(2), 'showplot', true);

14 Generate and classify some new data points:

```
grnobj = gmdistribution(grnpop,.2*eye(2));
redobj = gmdistribution(redpop,.2*eye(2));
newData = random(grnobj,10);
newData = [newData;random(redobj,10)];
grpData = ones(20,1);
grpData(11:20) = -1; % red = -1
v = svmclassify(svmStruct,newData,'showplot',true);
```

15 See which new data points are correctly classified. Circle the correctly classified points in red, and the incorrectly classified points in black.

```
mydiff = (v == grpData); % classified correctly
hold on
for ii = mydiff % plot red circles around correct pts
    plot(newData(ii, 1), newData(ii, 2),'ro','MarkerSize', 12)
end
for ii = not(mydiff) % plot black circles around incorrect pts
    plot(newData(ii,1),newData(ii,2),'ko','MarkerSize', 12)
end
hold off
```

- "Hidden Markov Models (HMM)" on page 16-5

## Introduction to Markov Models

Markov processes are examples of stochastic processes-processes that generate random sequences of outcomes or states according to certain probabilities. Markov processes are distinguished by being memoryless-their next state depends only on their current state, not on the history that led them there. Models of Markov processes are used in a wide variety of applications, from daily stock prices to the positions of genes in a chromosome.

## Markov Chains

A Markov model is given visual representation with a state diagram, such as the one below.

## State Diagram for a Markov Model

The rectangles in the diagram represent the possible states of the process you are trying to model, and the arrows represent transitions between states. The label on each arrow represents the probability of that transition. At each step of the process, the model may generate an output, or emission, depending on which state it is in, and then make a transition to another state. An important characteristic of Markov models is that the next state depends only on the current state, and not on the history of transitions that lead to the current state.

For example, for a sequence of coin tosses the two states are heads and tails. The most recent coin toss determines the current state of the model and each subsequent toss determines the transition to the next state. If the coin is fair, the transition probabilities are all $1 / 2$. The emission might simply be the current state. In more complicated models, random processes at each state will generate emissions. You could, for example, roll a die to determine the emission at any step.

Markov chains are mathematical descriptions of Markov models with a discrete set of states. Markov chains are characterized by:

- A set of states $\{1,2, \ldots, M\}$
- An $M$-by- $M$ transition matrix $T$ whose $i, j$ entry is the probability of a transition from state $i$ to state $j$. The sum of the entries in each row of $T$ must be 1 , because this is the sum of the probabilities of making a transition from a given state to each of the other states.
- A set of possible outputs, or emissions, $\left\{s_{1}, s_{2}, \ldots, s_{N}\right\}$. By default, the set of emissions is $\{1,2, \ldots, N\}$, where $N$ is the number of possible emissions, but you can choose a different set of numbers or symbols.
- An $M$-by- $N$ emission matrix $E$ whose $i, k$ entry gives the probability of emitting symbol $s_{\mathrm{k}}$ given that the model is in state $i$.

Markov chains begin in an initial state $i_{0}$ at step 0 . The chain then transitions to state $i_{1}$ with probability $T_{1 i_{1}}$, and emits an output $s_{k_{1}}$ with probability
$E_{i_{1} k_{1}}$. Consequently, the probability of observing the sequence of states $i_{1} i_{2} \ldots i_{r}$ and the sequence of emissions $s_{k_{1}} s_{k_{2}} \ldots s_{k_{r}}$ in the first $r$ steps, is

$$
T_{1 i_{1}} E_{i_{1} k_{1}} T_{i_{1} i_{2}} E_{i_{2} k_{2}} \ldots T_{i_{r-1} i_{r}} E_{i_{r} k}
$$

## Hidden Markov Models (HMM)

In this section...<br>"Introduction to Hidden Markov Models (HMM)" on page 16-5<br>"Analyzing Hidden Markov Models" on page 16-7

## Introduction to Hidden Markov Models (HMM)

A hidden Markov model (HMM) is one in which you observe a sequence of emissions, but do not know the sequence of states the model went through to generate the emissions. Analyses of hidden Markov models seek to recover the sequence of states from the observed data.

As an example, consider a Markov model with two states and six possible emissions. The model uses:

- A red die, having six sides, labeled 1 through 6.
- A green die, having twelve sides, five of which are labeled 2 through 6 , while the remaining seven sides are labeled 1.
- A weighted red coin, for which the probability of heads is .9 and the probability of tails is .1.
- A weighted green coin, for which the probability of heads is .95 and the probability of tails is .05 .

The model creates a sequence of numbers from the set $\{1,2,3,4,5,6\}$ with the following rules:

- Begin by rolling the red die and writing down the number that comes up, which is the emission.
- Toss the red coin and do one of the following:
- If the result is heads, roll the red die and write down the result.
- If the result is tails, roll the green die and write down the result.
- At each subsequent step, you flip the coin that has the same color as the die you rolled in the previous step. If the coin comes up heads, roll the same die as in the previous step. If the coin comes up tails, switch to the other die.

The state diagram for this model has two states, red and green, as shown in the following figure.

You determine the emission from a state by rolling the die with the same color as the state. You determine the transition to the next state by flipping the coin with the same color as the state.

The transition matrix is:

$$
T=\left[\begin{array}{ll}
0.9 & 0.1 \\
0.05 & 0.95
\end{array}\right]
$$

The emissions matrix is:

$$
E=\left[\begin{array}{cccccc}
\frac{1}{6} & \frac{1}{6} & \frac{1}{6} & \frac{1}{6} & \frac{1}{6} & \frac{1}{6} \\
\frac{7}{12} & \frac{1}{12} & \frac{1}{12} & \frac{1}{12} & \frac{1}{12} & \frac{1}{12}
\end{array}\right]
$$

The model is not hidden because you know the sequence of states from the colors of the coins and dice. Suppose, however, that someone else is generating
the emissions without showing you the dice or the coins. All you see is the sequence of emissions. If you start seeing more 1 s than other numbers, you might suspect that the model is in the green state, but you cannot be sure because you cannot see the color of the die being rolled.

Hidden Markov models raise the following questions:

- Given a sequence of emissions, what is the most likely state path?
- Given a sequence of emissions, how can you estimate transition and emission probabilities of the model?
- What is the forward probability that the model generates a given sequence?
- What is the posterior probability that the model is in a particular state at any point in the sequence?

## Analyzing Hidden Markov Models

- "Generating a Test Sequence" on page 16-8
- "Estimating the State Sequence" on page 16-8
- "Estimating Transition and Emission Matrices" on page 16-9
- "Estimating Posterior State Probabilities" on page 16-11
- "Changing the Initial State Distribution" on page 16-12

Statistics Toolbox functions related to hidden Markov models are:

- hmmgenerate - Generates a sequence of states and emissions from a Markov model
- hmmestimate - Calculates maximum likelihood estimates of transition and emission probabilities from a sequence of emissions and a known sequence of states
- hmmtrain - Calculates maximum likelihood estimates of transition and emission probabilities from a sequence of emissions
- hmmviterbi - Calculates the most probable state path for a hidden Markov model
- hmmdecode - Calculates the posterior state probabilities of a sequence of emissions

This section shows how to use these functions to analyze hidden Markov models.

## Generating a Test Sequence

The following commands create the transition and emission matrices for the model described in the "Introduction to Hidden Markov Models (HMM)" on page 16-5:

```
TRANS = [.9 .1; .05 .95;];
EMIS = [1/6, 1/6, 1/6, 1/6, 1/6, 1/6;...
7/12, 1/12, 1/12, 1/12, 1/12, 1/12];
```

To generate a random sequence of states and emissions from the model, use hmmgenerate:

```
[seq,states] = hmmgenerate(1000,TRANS,EMIS);
```

The output seq is the sequence of emissions and the output states is the sequence of states.
hmmgenerate begins in state 1 at step 0 , makes the transition to state $i_{1}$ at step 1 , and returns $i_{1}$ as the first entry in states. To change the initial state, see "Changing the Initial State Distribution" on page 16-12.

## Estimating the State Sequence

Given the transition and emission matrices TRANS and EMIS, the function hmmviterbi uses the Viterbi algorithm to compute the most likely sequence of states the model would go through to generate a given sequence seq of emissions:
likelystates = hmmviterbi(seq, TRANS, EMIS);
likelystates is a sequence the same length as seq.
To test the accuracy of hmmviterbi, compute the percentage of the actual sequence states that agrees with the sequence likelystates.

```
sum(states==likelystates)/1000
ans =
    0.8200
```

In this case, the most likely sequence of states agrees with the random sequence $82 \%$ of the time.

## Estimating Transition and Emission Matrices

- "Using hmmestimate" on page 16-9
- "Using hmmtrain" on page 16-10

The functions hmmestimate and hmmtrain estimate the transition and emission matrices TRANS and EMIS given a sequence seq of emissions.

Using hmmestimate. The function hmmestimate requires that you know the sequence of states states that the model went through to generate seq.

The following takes the emission and state sequences and returns estimates of the transition and emission matrices:
[TRANS_EST, EMIS_EST] = hmmestimate(seq, states)
TRANS EST =
$0.8989 \quad 0.1011$
$0.0585 \quad 0.9415$

EMIS_EST =

| 0.1721 | 0.1721 | 0.1749 | 0.1612 | 0.1803 | 0.1393 |
| :--- | :--- | :--- | :--- | :--- | :--- |
| 0.5836 | 0.0741 | 0.0804 | 0.0789 | 0.0726 | 0.1104 |

You can compare the outputs with the original transition and emission matrices, TRANS and EMIS:

TRANS
TRANS =
$0.9000 \quad 0.1000$
$0.0500 \quad 0.9500$

EMIS

| EMIS $=$ |  |  |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- |
| 0.1667 | 0.1667 | 0.1667 | 0.1667 | 0.1667 | 0.1667 |
| 0.5833 | 0.0833 | 0.0833 | 0.0833 | 0.0833 | 0.0833 |

Using hmmtrain. If you do not know the sequence of states states, but you have initial guesses for TRANS and EMIS, you can still estimate TRANS and EMIS using hmmtrain.

Suppose you have the following initial guesses for TRANS and EMIS.

```
TRANS_GUESS = [.85 .15; .1 .9];
EMIS_GUESS = [.17 .16 .17 .16 .17 .17;.6 . 08 . 08 . 08 . 08 08];
```

You estimate TRANS and EMIS as follows:
[TRANS_EST2, EMIS_EST2] = hmmtrain(seq, TRANS_GUESS, EMIS_GUESS)
TRANS_EST2 =
$0.2286 \quad 0.7714$
$0.0032 \quad 0.9968$

EMIS_EST2 =

| 0.1436 | 0.2348 | 0.1837 | 0.1963 | 0.2350 | 0.0066 |
| :--- | :--- | :--- | :--- | :--- | :--- |
| 0.4355 | 0.1089 | 0.1144 | 0.1082 | 0.1109 | 0.1220 |

hmmtrain uses an iterative algorithm that alters the matrices TRANS_GUESS and EMIS_GUESS so that at each step the adjusted matrices are more likely to generate the observed sequence, seq. The algorithm halts when the matrices in two successive iterations are within a small tolerance of each other.

If the algorithm fails to reach this tolerance within a maximum number of iterations, whose default value is 100 , the algorithm halts. In this case, hmmtrain returns the last values of TRANS_EST and EMIS_EST and issues a warning that the tolerance was not reached.

If the algorithm fails to reach the desired tolerance, increase the default value of the maximum number of iterations with the command:

```
hmmtrain(seq,TRANS_GUESS,EMIS_GUESS,'maxiterations',maxiter)
```

where maxiter is the maximum number of steps the algorithm executes.

Change the default value of the tolerance with the command:
hmmtrain(seq, TRANS_GUESS, EMIS_GUESS, 'tolerance', tol)
where tol is the desired value of the tolerance. Increasing the value of tol makes the algorithm halt sooner, but the results are less accurate.

Two factors reduce the reliability of the output matrices of hmmtrain:

- The algorithm converges to a local maximum that does not represent the true transition and emission matrices. If you suspect this, use different initial guesses for the matrices TRANS_EST and EMIS_EST.
- The sequence seq may be too short to properly train the matrices. If you suspect this, use a longer sequence for seq.

## Estimating Posterior State Probabilities

The posterior state probabilities of an emission sequence seq are the conditional probabilities that the model is in a particular state when it generates a symbol in seq, given that seq is emitted. You compute the posterior state probabilities with hmmdecode:

PSTATES = hmmdecode(seq,TRANS,EMIS)
The output PSTATES is an $M$-by- $L$ matrix, where $M$ is the number of states and $L$ is the length of seq. $\operatorname{PSTATES}(i, j)$ is the conditional probability that the model is in state $i$ when it generates the $j$ th symbol of seq, given that seq is emitted.
hmmdecode begins with the model in state 1 at step 0 , prior to the first emission. $\operatorname{PSTATES}(i, 1)$ is the probability that the model is in state $i$ at the following step 1. To change the initial state, see "Changing the Initial State Distribution" on page 16-12.

To return the logarithm of the probability of the sequence seq, use the second output argument of hmmdecode:
[PSTATES,logpseq] = hmmdecode(seq,TRANS,EMIS)
The probability of a sequence tends to 0 as the length of the sequence increases, and the probability of a sufficiently long sequence becomes less
than the smallest positive number your computer can represent. hmmdecode returns the logarithm of the probability to avoid this problem.

## Changing the Initial State Distribution

By default, Statistics Toolbox hidden Markov model functions begin in state 1. In other words, the distribution of initial states has all of its probability mass concentrated at state 1 . To assign a different distribution of probabilities, $p=$ [ $p_{1}, p_{2}, \ldots, p_{M}$ ], to the $M$ initial states, do the following:

1 Create an $M+1$-by- $M+1$ augmented transition matrix, $\hat{T}$ of the following form:

$$
\hat{T}=\left[\begin{array}{ll}
0 & p \\
0 & T
\end{array}\right]
$$

where $T$ is the true transition matrix. The first column of $\hat{T}$ contains $M+1$ zeros. $p$ must sum to 1 .

2 Create an $M+1$-by- $N$ augmented emission matrix, $\hat{E}$, that has the following form:

$$
\hat{E}=\left[\begin{array}{l}
0 \\
E
\end{array}\right]
$$

If the transition and emission matrices are TRANS and EMIS, respectively, you create the augmented matrices with the following commands:

```
TRANS_HAT = [0 p; zeros(size(TRANS,1),1) TRANS];
EMIS_HAT = [zeros(1,size(EMIS,2)); EMIS];
```

## Design of Experiments

- "Design of Experiments" on page 17-2
- "Full Factorial Designs" on page 17-3
- "Fractional Factorial Designs" on page 17-5
- "Response Surface Designs" on page 17-9
- "D-Optimal Designs" on page 17-15

## Design of Experiments

Passive data collection leads to a number of problems in statistical modeling. Observed changes in a response variable may be correlated with, but not caused by, observed changes in individual factors (process variables). Simultaneous changes in multiple factors may produce interactions that are difficult to separate into individual effects. Observations may be dependent, while a model of the data considers them to be independent.

Designed experiments address these problems. In a designed experiment, the data-producing process is actively manipulated to improve the quality of information and to eliminate redundant data. A common goal of all experimental designs is to collect data as parsimoniously as possible while providing sufficient information to accurately estimate model parameters.

For example, a simple model of a response $y$ in an experiment with two controlled factors $x_{1}$ and $x_{2}$ might look like this:

$$
y=\beta_{0}+\beta_{1} x_{1}+\beta_{2} x_{2}+\beta_{3} x_{1} x_{2}+\varepsilon
$$

Here $\varepsilon$ includes both experimental error and the effects of any uncontrolled factors in the experiment. The terms $\beta_{1} x_{1}$ and $\beta_{2} x_{2}$ are main effects and the term $\beta_{3} x_{1} x_{2}$ is a two-way interaction effect. A designed experiment would systematically manipulate $x_{1}$ and $x_{2}$ while measuring $y$, with the objective of accurately estimating $\beta_{0}, \beta_{1}, \beta_{2}$, and $\beta_{3}$.

## Full Factorial Designs

In this section...<br>"Multilevel Designs" on page 17-3<br>"Two-Level Designs" on page 17-4

## Multilevel Designs

To systematically vary experimental factors, assign each factor a discrete set of levels. Full factorial designs measure response variables using every treatment (combination of the factor levels). A full factorial design for $n$ factors with $N_{1}, \ldots, N_{n}$ levels requires $N_{1} \times \ldots \times N_{n}$ experimental runs-one for each treatment. While advantageous for separating individual effects, full factorial designs can make large demands on data collection.

As an example, suppose a machine shop has three machines and four operators. If the same operator always uses the same machine, it is impossible to determine if a machine or an operator is the cause of variation in production. By allowing every operator to use every machine, effects are separated. A full factorial list of treatments is generated by the Statistics Toolbox function fullfact:

```
dFF = fullfact([3,4])
dFF =
    1
    2 1
    3 1
    2
    2
    3
    3
    2 3
    3 3
    4
    2 4
    3 4
```

Each of the $3 \times 4=12$ rows of dFF represent one machine/operator combination.

## Two-Level Designs

Many experiments can be conducted with two-level factors, using two-level designs. For example, suppose the machine shop in the previous example always keeps the same operator on the same machine, but wants to measure production effects that depend on the composition of the day and night shifts. The Statistics Toolbox function ff2n generates a full factorial list of treatments:

| dFF 2 | $=f f 2 n(4)$ |  |  |
| ---: | :--- | :--- | :--- |
| dFF 2 | $=$ |  |  |
| 0 | 0 | 0 | 0 |
| 0 | 0 | 0 | 1 |
| 0 | 0 | 1 | 0 |
| 0 | 0 | 1 | 1 |
| 0 | 1 | 0 | 0 |
| 0 | 1 | 0 | 1 |
| 0 | 1 | 1 | 0 |
| 0 | 1 | 1 | 1 |
| 1 | 0 | 0 | 0 |
| 1 | 0 | 0 | 1 |
| 1 | 0 | 1 | 0 |
| 1 | 0 | 1 | 1 |
| 1 | 1 | 0 | 0 |
| 1 | 1 | 0 | 1 |
| 1 | 1 | 1 | 0 |
| 1 | 1 | 1 | 1 |

Each of the $2^{4}=16$ rows of dFF2 represent one schedule of operators for the day (0) and night (1) shifts.

## Fractional Factorial Designs

In this section...<br>"Introduction to Fractional Factorial Designs" on page 17-5<br>"Plackett-Burman Designs" on page 17-5<br>"General Fractional Designs" on page 17-6

## Introduction to Fractional Factorial Designs

Two-level designs are sufficient for evaluating many production processes. Factor levels of $\pm 1$ can indicate categorical factors, normalized factor extremes, or simply "up" and "down" from current factor settings. Experimenters evaluating process changes are interested primarily in the factor directions that lead to process improvement.

For experiments with many factors, two-level full factorial designs can lead to large amounts of data. For example, a two-level full factorial design with 10 factors requires $2^{10}=1024$ runs. Often, however, individual factors or their interactions have no distinguishable effects on a response. This is especially true of higher order interactions. As a result, a well-designed experiment can use fewer runs for estimating model parameters.

Fractional factorial designs use a fraction of the runs required by full factorial designs. A subset of experimental treatments is selected based on an evaluation (or assumption) of which factors and interactions have the most significant effects. Once this selection is made, the experimental design must separate these effects. In particular, significant effects should not be confounded, that is, the measurement of one should not depend on the measurement of another.

## Plackett-Burman Designs

Plackett-Burman designs are used when only main effects are considered significant. Two-level Plackett-Burman designs require a number of experimental runs that are a multiple of 4 rather than a power of 2 . The MATLAB function hadamard generates these designs:

```
dPB = hadamard(8)
```

```
dPB =
\begin{tabular}{rrrrrrrr}
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\
1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \\
1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 \\
1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 \\
1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \\
1 & -1 & 1 & -1 & -1 & 1 & -1 & 1 \\
1 & 1 & -1 & -1 & -1 & -1 & 1 & 1 \\
1 & -1 & -1 & 1 & -1 & 1 & 1 & -1
\end{tabular}
```

Binary factor levels are indicated by $\pm 1$. The design is for eight runs (the rows of dPB ) manipulating seven two-level factors (the last seven columns of dPB). The number of runs is a fraction $8 / 2^{7}=0.0625$ of the runs required by a full factorial design. Economy is achieved at the expense of confounding main effects with any two-way interactions.

## General Fractional Designs

At the cost of a larger fractional design, you can specify which interactions you wish to consider significant. A design of resolution $R$ is one in which no $n$-factor interaction is confounded with any other effect containing less than $R-n$ factors. Thus, a resolution III design does not confound main effects with one another but may confound them with two-way interactions (as in "Plackett-Burman Designs" on page 17-5), while a resolution IV design does not confound either main effects or two-way interactions but may confound two-way interactions with each other.

Specify general fractional factorial designs using a full factorial design for a selected subset of basic factors and generators for the remaining factors. Generators are products of the basic factors, giving the levels for the remaining factors. Use the Statistics Toolbox function fracfact to generate these designs:

```
dfF = fracfact('a b c d bcd acd')
dfF =
\begin{tabular}{rrrrrr}
-1 & -1 & -1 & -1 & -1 & -1 \\
-1 & -1 & -1 & 1 & 1 & 1 \\
-1 & -1 & 1 & -1 & 1 & 1 \\
-1 & -1 & 1 & 1 & -1 & -1 \\
-1 & 1 & -1 & -1 & 1 & -1
\end{tabular}
```

| -1 | 1 | -1 | 1 | -1 | 1 |
| ---: | ---: | ---: | ---: | ---: | ---: |
| -1 | 1 | 1 | -1 | -1 | 1 |
| -1 | 1 | 1 | 1 | 1 | -1 |
| 1 | -1 | -1 | -1 | -1 | 1 |
| 1 | -1 | -1 | 1 | 1 | -1 |
| 1 | -1 | 1 | -1 | 1 | -1 |
| 1 | -1 | 1 | 1 | -1 | 1 |
| 1 | 1 | -1 | -1 | 1 | 1 |
| 1 | 1 | -1 | 1 | -1 | -1 |
| 1 | 1 | 1 | -1 | -1 | -1 |
| 1 | 1 | 1 | 1 | 1 | 1 |

This is a six-factor design in which four two-level basic factors (a, b, c, and $d$ in the first four columns of dfF) are measured in every combination of levels, while the two remaining factors (in the last three columns of dfF) are measured only at levels defined by the generators bcd and acd, respectively. Levels in the generated columns are products of corresponding levels in the columns that make up the generator.

The challenge of creating a fractional factorial design is to choose basic factors and generators so that the design achieves a specified resolution in a specified number of runs. Use the Statistics Toolbox function fracfactgen to find appropriate generators:

```
generators = fracfactgen('a b c d e f',4,4)
generators =
    'a'
    'b'
    'c'
    'd'
    'bcd'
    'acd'
```

These are generators for a six-factor design with factors a through f, using $2^{4}$ $=16$ runs to achieve resolution IV. The fracfactgen function uses an efficient search algorithm to find generators that meet the requirements.

An optional output from fracfact displays the confounding pattern of the design:
[dfF, confounding] = fracfact(generators);

```
confounding
confounding =
        'Term' 'Generator' 'Confounding'
        'X1' 'a' 'X1'
        'X2' 'b' 'X2'
        'X3' 'c' 'X3'
        'X4' 'd' 'X4'
        'X5' 'bcd' 'X5'
        'X6' 'acd' 'X6'
        'X1*X2' 'ab' 'X1*X2 + X5*X6'
        'X1*X3' 'ac' 'X1*X3 + X4*X6'
        'X1*X4' 'ad' 'X1*X4 + X3*X6'
        'X1*X5' 'abcd' 'X1*X5 + X2*X6'
        'X1*X6' 'cd' 'X1*X6 + X2*X5 + X3*X4'
        'X2*X3' 'bc' 'X2*X3 + X4*X5'
        'X2*X4' 'bd' 'X2*X4 + X3*X5'
        'X2*X5' 'cd' 'X1*X6 + X2*X5 + X3*X4'
        'X2*X6' 'abcd' 'X1*X5 + X2*X6'
        'X3*X4' 'cd' 'X1*X6 + X2*X5 + X3*X4'
        'X3*X5' 'bd' 'X2*X4 + X3*X5'
        'X3*X6' 'ad' 'X1*X4 + X3*X6'
        'X4*X5' 'bc' 'X2*X3 + X4*X5'
        'X4*X6' 'ac' 'X1*X3 + X4*X6'
        'X5*X6' 'ab' 'X1*X2 + X5*X6'
```

The confounding pattern shows that main effects are effectively separated by the design, but two-way interactions are confounded with various other two-way interactions.

## Response Surface Designs

```
In this section...
"Introduction to Response Surface Designs" on page 17-9
"Central Composite Designs" on page 17-9
"Box-Behnken Designs" on page 17-13
```

## Introduction to Response Surface Designs

Quadratic response surfaces are simple models that provide a maximum or minimum without making additional assumptions about the form of the response. Quadratic models can be calibrated using full factorial designs with three or more levels for each factor, but these designs generally require more runs than necessary to accurately estimate model parameters. This section discusses designs for calibrating quadratic models that are much more efficient, using three or five levels for each factor, but not using all combinations of levels.

## Central Composite Designs

Central composite designs (CCDs), also known as Box-Wilson designs, are appropriate for calibrating full quadratic models. There are three types of CCDs-circumscribed, inscribed, and faced-pictured below:

Each design consists of a factorial design (the corners of a cube) together with center and star points that allow for estimation of second-order effects. For a full quadratic model with $n$ factors, CCDs have enough design points to estimate the $(n+2)(n+1) / 2$ coefficients in a full quadratic model with $n$ factors.

The type of CCD used (the position of the factorial and star points) is determined by the number of factors and by the desired properties of the design. The following table summarizes some important properties. A design is rotatable if the prediction variance depends only on the distance of the design point from the center of the design.

| Design | Rotatable | Factor <br> Levels | Uses Points <br> Outside $\mathbf{1}$ | Accuracy of <br> Estimates |
| :--- | :--- | :--- | :--- | :--- |
| Circumscribed <br> (CCC) | Yes | 5 | Yes | Good over entire <br> design space |
| Inscribed <br> (CCI) | Yes | 5 | No | Good over central <br> subset of design space |
| Faced (CCF) | No | 3 | No | Fair over entire <br> design space; poor <br> for pure quadratic <br> coefficients |

Generate CCDs with the Statistics Toolbox function ccdesign:

```
dCC = ccdesign(3,'type','circumscribed')
dCC =
    -1.0000 -1.0000 1.0000
    -1.0000 1.0000 -1.0000
    -1.0000 1.0000 1.0000
    1.0000 -1.0000 -1.0000
    1.0000 -1.0000 1.0000
    1.0000 1.0000 -1.0000
    1.0000 1.0000 1.0000
    -1.6818 0 0
    1.6818 0 0
        0 -1.6818 0
        0 1.6818 0
        0 0 -1.6818
        0 0 1.6818
        0 0 0
        0 0 0
        0 0
        0 0 0
        0 0 0
        0 0 0
        0 0 0
        0 0 0
        0 0
```

The repeated center point runs allow for a more uniform estimate of the prediction variance over the entire design space.

## Box-Behnken Designs

Like the designs described in "Central Composite Designs" on page 17-9, Box-Behnken designs are used to calibrate full quadratic models. Box-Behnken designs are rotatable and, for a small number of factors (four or less), require fewer runs than CCDs. By avoiding the corners of the design space, they allow experimenters to work around extreme factor combinations. Like an inscribed CCD, however, extremes are then poorly estimated.

The geometry of a Box-Behnken design is pictured in the following figure.

Design points are at the midpoints of edges of the design space and at the center, and do not contain an embedded factorial design.

Generate Box-Behnken designs with the Statistics Toolbox function bbdesign:

| $\mathrm{dBB}=$ |  |  |
| ---: | :--- | ---: |
| dBB | $=$ |  |
|  | bbdesign (3) |  |
| -1 | -1 | 0 |
| -1 | 1 | 0 |
| 1 | -1 | 0 |
| 1 | 1 | 0 |
| -1 | 0 | -1 |
| -1 | 0 | 1 |
| 1 | 0 | -1 |
| 1 | 0 | 1 |
| 0 | -1 | -1 |
| 0 | -1 | 1 |
| 0 | 1 | -1 |
| 0 | 1 | 1 |
| 0 | 0 | 0 |
| 0 | 0 | 0 |
| 0 | 0 | 0 |

Again, the repeated center point runs allow for a more uniform estimate of the prediction variance over the entire design space.

## D-Optimal Designs

In this section...<br>"Introduction to D-Optimal Designs" on page 17-15<br>"Generate D-Optimal Designs" on page 17-16<br>"Augment D-Optimal Designs" on page 17-19<br>"Specify Fixed Covariate Factors" on page 17-20<br>"Specify Categorical Factors" on page 17-21<br>"Specify Candidate Sets" on page 17-21

## Introduction to D-Optimal Designs

Traditional experimental designs ("Full Factorial Designs" on page 17-3, "Fractional Factorial Designs" on page 17-5, and "Response Surface Designs" on page 17-9) are appropriate for calibrating linear models in experimental settings where factors are relatively unconstrained in the region of interest. In some cases, however, models are necessarily nonlinear. In other cases, certain treatments (combinations of factor levels) may be expensive or infeasible to measure. D-optimal designs are model-specific designs that address these limitations of traditional designs.

A D-optimal design is generated by an iterative search algorithm and seeks to minimize the covariance of the parameter estimates for a specified model. This is equivalent to maximizing the determinant $D=\left|X^{T} X\right|$, where $X$ is the design matrix of model terms (the columns) evaluated at specific treatments in the design space (the rows). Unlike traditional designs, D-optimal designs do not require orthogonal design matrices, and as a result, parameter estimates may be correlated. Parameter estimates may also be locally, but not globally, D-optimal.

There are several Statistics Toolbox functions for generating D-optimal designs:

| Function | Description |
| :--- | :--- |
| candexch | Uses a row-exchange algorithm to generate a D-optimal design <br> with a specified number of runs for a specified model and a <br> specified candidate set. This is the second component of the <br> algorithm used by rowexch. |
| candgen | Generates a candidate set for a specified model. This is the <br> first component of the algorithm used by rowexch. |
| cordexch | Uses a coordinate-exchange algorithm to generate a D-optimal <br> design with a specified number of runs for a specified model. |
| daugment | Uses a coordinate-exchange algorithm to augment an existing <br> D-optimal design with additional runs to estimate additional <br> model terms. |
| dcovary | Uses a coordinate-exchange algorithm to generate a D-optimal <br> design with fixed covariate factors. |
| rowexch | Uses a row-exchange algorithm to generate a D-optimal design <br> with a specified number of runs for a specified model. The <br> algorithm calls candgen and then candexch. (Call candexch <br> separately to specify a candidate set.) |

The following sections explain how to use these functions to generate D-optimal designs.

Note The Statistics Toolbox function rsmdemo generates simulated data for experimental settings specified by either the user or by a D-optimal design generated by cordexch. It uses the rstool interface to visualize response surface models fit to the data, and it uses the nlintool interface to visualize a nonlinear model fit to the data.

## Generate D-Optimal Designs

Two Statistics Toolbox algorithms generate D-optimal designs:

- The cordexch function uses a coordinate-exchange algorithm
- The rowexch function uses a row-exchange algorithm

Both cordexch and rowexch use iterative search algorithms. They operate by incrementally changing an initial design matrix $X$ to increase $D=\left|X^{T} X\right|$ at each step. In both algorithms, there is randomness built into the selection of the initial design and into the choice of the incremental changes. As a result, both algorithms may return locally, but not globally, D-optimal designs. Run each algorithm multiple times and select the best result for your final design. Both functions have a 'tries' parameter that automates this repetition and comparison.

At each step, the row-exchange algorithm exchanges an entire row of $X$ with a row from a design matrix $C$ evaluated at a candidate set of feasible treatments. The rowexch function automatically generates a $C$ appropriate for a specified model, operating in two steps by calling the candgen and candexch functions in sequence. Provide your own $C$ by calling candexch directly. In either case, if $C$ is large, its static presence in memory can affect computation.

The coordinate-exchange algorithm, by contrast, does not use a candidate set. (Or rather, the candidate set is the entire design space.) At each step, the coordinate-exchange algorithm exchanges a single element of $X$ with a new element evaluated at a neighboring point in design space. The absence of a candidate set reduces demands on memory, but the smaller scale of the search means that the coordinate-exchange algorithm is more likely to become trapped in a local minimum than the row-exchange algorithm.

For example, suppose you want a design to estimate the parameters in the following three-factor, seven-term interaction model:

$$
y=\beta_{0}+\beta_{1} x_{1}+\beta_{2} x_{2}+\beta_{3} x_{3}+\beta_{12} x_{1} x_{2}+\beta_{13} x_{1} x_{3}+\beta_{23} x_{2} x_{3}+\varepsilon
$$

Use cordexch to generate a D-optimal design with seven runs:

```
nfactors = 3;
nruns = 7;
[dCE,X] = cordexch(nfactors,nruns,'interaction','tries',10)
dCE =
    -1 1 1
    -1
    1 1 1
    -1 1
    1 -1 1
```

$\mathrm{X}=$| 1 | -1 | -1 |  |  |  |  |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| -1 | -1 | 1 |  |  |  |  |
|  |  |  |  |  |  |  |
| 1 | -1 | 1 | 1 | -1 | -1 | 1 |
| 1 | -1 | -1 | -1 | 1 | 1 | 1 |
| 1 | 1 | 1 | 1 | 1 | 1 | 1 |
| 1 | -1 | 1 | -1 | -1 | 1 | -1 |
| 1 | 1 | -1 | 1 | -1 | 1 | -1 |
| 1 | 1 | -1 | -1 | -1 | -1 | 1 |
| 1 | -1 | -1 | 1 | 1 | -1 | -1 |

Columns of the design matrix $X$ are the model terms evaluated at each row of the design dCE. The terms appear in order from left to right:

1 Constant term
2 Linear terms (1, 2, 3)
3 Interaction terms (12, 13, 23)
Use $X$ in a linear regression model fit to response data measured at the design points in dCE.

Use rowexch in a similar fashion to generate an equivalent design:

```
[dRE,X] = rowexch(nfactors,nruns,'interaction','tries',10)
```

dRE =

| -1 | -1 | 1 |  |  |  |
| ---: | ---: | ---: | ---: | ---: | ---: |
| 1 | -1 | 1 |  |  |  |
| 1 | -1 | -1 |  |  |  |
| 1 | 1 | 1 |  |  |  |
| -1 | -1 | -1 |  |  |  |
| -1 | 1 | -1 |  |  |  |
| -1 | 1 | 1 |  |  |  |
|  |  |  |  |  |  |
| 1 | -1 | -1 | 1 | 1 | -1 |
| 1 | 1 | -1 | 1 | -1 | 1 |
| 1 | 1 | -1 | -1 | -1 | -1 |
| 1 | 1 | 1 | 1 | 1 | 1 |
| 1 | -1 | -1 | -1 | 1 | 1 |
| 1 | -1 | 1 | -1 | -1 | 1 |

| 1 | -1 | 1 | 1 | -1 | -1 | 1 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |

## Augment D-Optimal Designs

In practice, you may want to add runs to a completed experiment to learn more about a process and estimate additional model coefficients. The daugment function uses a coordinate-exchange algorithm to augment an existing D-optimal design.

For example, the following eight-run design is adequate for estimating main effects in a four-factor model:

To estimate the six interaction terms in the model, augment the design with eight additional runs:

```
dCEinteraction = daugment(dCEmain,8,'interaction')
dCEinteraction =
\begin{tabular}{rrrr}
1 & -1 & -1 & 1 \\
-1 & -1 & 1 & 1 \\
-1 & 1 & -1 & 1 \\
1 & 1 & 1 & -1 \\
1 & 1 & 1 & 1 \\
-1 & 1 & -1 & -1 \\
1 & -1 & -1 & -1 \\
-1 & -1 & 1 & -1 \\
-1 & 1 & 1 & 1 \\
-1 & -1 & -1 & -1 \\
1 & -1 & 1 & -1 \\
1 & 1 & -1 & 1 \\
-1 & 1 & 1 & -1
\end{tabular}
```

| 1 | 1 | -1 | -1 |
| ---: | ---: | ---: | ---: |
| 1 | -1 | 1 | 1 |
| 1 | 1 | 1 | -1 |

The augmented design is full factorial, with the original eight runs in the first eight rows.

The 'start' parameter of the candexch function provides the same functionality as daugment, but uses a row exchange algorithm rather than a coordinate-exchange algorithm.

## Specify Fixed Covariate Factors

In many experimental settings, certain factors and their covariates are constrained to a fixed set of levels or combinations of levels. These cannot be varied when searching for an optimal design. The dcovary function allows you to specify fixed covariate factors in the coordinate exchange algorithm.

For example, suppose you want a design to estimate the parameters in a three-factor linear additive model, with eight runs that necessarily occur at different times. If the process experiences temporal linear drift, you may want to include the run time as a variable in the model. Produce the design as follows:

```
time = linspace(-1,1,8)';
[dCV,X] = dcovary(3,time,'linear')
dCV =
\begin{tabular}{rrrrr}
-1.0000 & 1.0000 & 1.0000 & -1.0000 & \\
1.0000 & -1.0000 & -1.0000 & -0.7143 & \\
-1.0000 & -1.0000 & -1.0000 & -0.4286 & \\
1.0000 & -1.0000 & 1.0000 & -0.1429 & \\
1.0000 & 1.0000 & -1.0000 & 0.1429 & \\
-1.0000 & 1.0000 & -1.0000 & 0.4286 & \\
1.0000 & 1.0000 & 1.0000 & 0.7143 & \\
-1.0000 & -1.0000 & 1.0000 & 1.0000 & \\
& & & & \\
1.0000 & -1.0000 & 1.0000 & 1.0000 & -1.0000 \\
1.0000 & 1.0000 & -1.0000 & -1.0000 & -0.7143 \\
1.0000 & -1.0000 & -1.0000 & -1.0000 & -0.4286 \\
1.0000 & 1.0000 & -1.0000 & 1.0000 & -0.1429
\end{tabular}
```

| 1.0000 | 1.0000 | 1.0000 | -1.0000 | 0.1429 |
| ---: | ---: | ---: | ---: | ---: |
| 1.0000 | -1.0000 | 1.0000 | -1.0000 | 0.4286 |
| 1.0000 | 1.0000 | 1.0000 | 1.0000 | 0.7143 |
| 1.0000 | -1.0000 | -1.0000 | 1.0000 | 1.0000 |

The column vector time is a fixed factor, normalized to values between $\pm 1$. The number of rows in the fixed factor specifies the number of runs in the design. The resulting design dCV gives factor settings for the three controlled model factors at each time.

## Specify Categorical Factors

Categorical factors take values in a discrete set of levels. Both cordexch and rowexch have a 'categorical' parameter that allows you to specify the indices of categorical factors and a 'levels' parameter that allows you to specify a number of levels for each factor.

For example, the following eight-run design is for a linear additive model with five factors in which the final factor is categorical with three levels:

```
dCEcat = cordexch(5,8,'linear','categorical',5,'levels',3)
dCEcat =
\begin{tabular}{rrrrr}
-1 & -1 & 1 & 1 & 2 \\
-1 & -1 & -1 & -1 & 3 \\
1 & 1 & 1 & 1 & 3 \\
1 & 1 & -1 & -1 & 2 \\
1 & -1 & -1 & 1 & 3 \\
-1 & 1 & -1 & 1 & 1 \\
-1 & 1 & 1 & -1 & 3 \\
1 & -1 & 1 & -1 & 1
\end{tabular}
```

## Specify Candidate Sets

The row-exchange algorithm exchanges rows of an initial design matrix $X$ with rows from a design matrix $C$ evaluated at a candidate set of feasible treatments. The rowexch function automatically generates a $C$ appropriate for a specified model, operating in two steps by calling the candgen and candexch functions in sequence. Provide your own $C$ by calling candexch directly.

For example, the following uses rowexch to generate a five-run design for a two-factor pure quadratic model using a candidate set that is produced internally:

```
dRE1 = rowexch(2,5,'purequadratic','tries',10)
dRE1 =
    -1 1
    0
    -1
    1 0
    1
```

The same thing can be done using candgen and candexch in sequence:

```
[dC,C] = candgen(2,'purequadratic') % Candidate set, C
dC =
    -1 -1
        0 -1
        1 -1
        -1 0
        0
        1 0
        -1 1
        0
C =
    1
    1 0
    1
    1
    1 0}00
    1
    1
    1
treatments = candexch(C,5,'tries',10) % D-opt subset
treatments =
    2
    1
    7
    3
```

```
    4
dRE2 = dC(treatments,:) % Display design
dRE2 =
    0 -1
    -1 -1
    -1 1
    1 -1
    -1 0
```

You can replace C in this example with a design matrix evaluated at your own candidate set. For example, suppose your experiment is constrained so that the two factors cannot have extreme settings simultaneously. The following produces a restricted candidate set:

```
constraint = sum(abs(dC),2) < 2; % Feasible treatments
my_dC = dC(constraint,:)
my_dC =
    0 -1
    -1 0
    0
    0
    0 1
```

Use the x2fx function to convert the candidate set to a design matrix:

```
my_C = x2fx(my_dC,'purequadratic')
my_C =
\begin{tabular}{lllll}
1 & 0 & -1 & 0 & 1
\end{tabular}
    1
    1 0}00
    1 1 1 0
    1 0
```

Find the required design in the same manner:

```
my_treatments = candexch(my_C,5,'tries',10) % D-opt subset
my_treatments =
    2
    4
    5
    1
```

```
    3
my_dRE = my_dC(my_treatments,:) % Display design
my_dRE =
    -1 0
    0
    0 1
    0 -1
    0
```

## Statistical Process Control

- "Introduction to Statistical Process Control" on page 18-2
- "Control Charts" on page 18-3
- "Capability Studies" on page 18-6

## Introduction to Statistical Process Control

Statistical process control (SPC) refers to a number of different methods for monitoring and assessing the quality of manufactured goods. Combined with methods from the design of experiments, SPC is used in programs that define, measure, analyze, improve, and control development and production processes. These programs are often implemented using "Design for Six Sigma" methodologies.

## Control Charts

A control chart displays measurements of process samples over time. The measurements are plotted together with user-defined specification limits and process-defined control limits. The process can then be compared with its specifications-to see if it is in control or out of control.

The chart is just a monitoring tool. Control activity might occur if the chart indicates an undesirable, systematic change in the process. The control chart is used to discover the variation, so that the process can be adjusted to reduce it.

Control charts are created with the controlchart function. Any of the following chart types may be specified:

- Xbar or mean
- Standard deviation
- Range
- Exponentially weighted moving average
- Individual observation
- Moving range of individual observations
- Moving average of individual observations
- Proportion defective
- Number of defectives
- Defects per unit
- Count of defects

Control rules are specified with the controlrules function.
For example, the following commands create an xbar chart, using the "Western Electric 2" rule (2 of 3 points at least 2 standard errors above the center line) to mark out of control measurements:
load parts;
st = controlchart(runout,'rules','we2');

```
x = st.mean;
cl = st.mu;
se = st.sigma./sqrt(st.n);
hold on
plot(cl+2*se,'m')
```

XBAR control chart

Measurements that violate the control rule can then be identified:
R = controlrules('we2', x, cl, se);
I = find(R)

I =
21
23
24
25

## Capability Studies

Before going into production, many manufacturers run a capability study to determine if their process will run within specifications enough of the time. Capability indices produced by such a study are used to estimate expected percentages of defective parts.

Capability studies are conducted with the capability function. The following capability indices are produced:

- mu - Sample mean
- sigma - Sample standard deviation
- P - Estimated probability of being within the lower (L) and upper (U) specification limits
- Pl - Estimated probability of being below L
- Pu - Estimated probability of being above U
- $\mathrm{Cp}-(\mathrm{U}-\mathrm{L}) /(6 *$ sigma)
- Cpl-(mu-L)./(3.*sigma)
- Cpu - (U-mu). /(3.*sigma)
- Cpk - min(Cpl,Cpu)

As an example, simulate a sample from a process with a mean of 3 and a standard deviation of 0.005 :

```
data = normrnd(3,0.005,100,1);
```

Compute capability indices if the process has an upper specification limit of 3.01 and a lower specification limit of 2.99:

```
S = capability(data,[2.99 3.01])
S =
    mu: 3.0006
    sigma: 0.0047
            P: 0.9669
            Pl: 0.0116
            Pu: 0.0215
```

$$
\begin{array}{rr}
\text { Cp: } & 0.7156 \\
\text { Cpl: } & 0.7567 \\
\text { Cpu: } & 0.6744 \\
\text { Cpk: } & 0.6744
\end{array}
$$

Visualize the specification and process widths:

```
capaplot(data,[2.99 3.01]);
```

grid on

Probability Between Limits $=0.96688$

## Parallel Statistics

- "Quick Start Parallel Computing for Statistics Toolbox" on page 19-2
- "Concepts of Parallel Computing in Statistics Toolbox" on page 19-7
- "When to Run Statistical Functions in Parallel" on page 19-8
- "Working with parfor" on page 19-10
- "Reproducibility in Parallel Statistical Computations" on page 19-13
- "Examples of Parallel Statistical Functions" on page 19-19

## Quick Start Parallel Computing for Statistics Toolbox

Note To use parallel computing as described in this chapter, you must have a Parallel Computing Toolbox license.

```
In this section...
"What Is Parallel Statistics Functionality?" on page 19-2
"How To Compute in Parallel" on page 19-3
"Parallel Treebagger" on page 19-5
```

## What Is Parallel Statistics Functionality?

You can use any of the Statistics Toolbox functions with Parallel Computing Toolbox constructs such as parfor and spmd. However, some functions, such as those with interactive displays, can lose functionality in parallel. In particular, displays and interactive usage are not effective on workers (see "Vocabulary for Parallel Computation" on page 19-7).

Additionally, the following functions are enhanced to use parallel computing internally. These functions use parfor internally to parallelize calculations.

- bootci
- bootstrp
- candexch
- cordexch
- crossval
- daugment
- dcovary
- jackknife
- lasso
- lassoglm
- nnmf
- plsregress
- rowexch
- sequentialfs
- TreeBagger
- TreeBagger.growTrees

This chapter gives the simplest way to use these enhanced functions in parallel. For more advanced topics, including the issues of reproducibility and nested parfor loops, see the other sections in this chapter.

For information on parallel statistical computing at the command line, enter help parallelstats

## How To Compute in Parallel

To have a function compute in parallel:
l "Open matlabpool" on page 19-3
2 "Set the UseParallel Option to true" on page 19-5
3 "Call the Function Using the Options Structure" on page 19-5

## Open matlabpool

To run a statistical computation in parallel, first set up a parallel environment.

Note Setting up a parallel environment can take several seconds.

Multicore. For a multicore machine, enter the following at the MATLAB command line:
matlabpool open $n$
$n$ is the number of workers you want to use.

Network. If you have multiple processors on a network, use Parallel Computing Toolbox functions and MATLAB Distributed Computing Server ${ }^{\text {TM }}$ software to establish parallel computation. Make sure that your system is configured properly for parallel computing.

Many parallel statistical functions call a function that can be one you define in a file. For example, jackknife calls a function (jackfun) that can be a built-in MATLAB function such as corr, but can also be a function you define. Built-in functions are available to all workers. However, you must take extra steps to enable workers to access a function file that you define.

To place a function file on the path of all workers, and check that it is accessible:

1 At the command line, enter

```
matlabpool open conf
or
matlabpool open conf n
```

where conf is your configuration, and $n$ is the number of processors you want to use.

2 If network_file_path is the network path to your function file, enter pctRunOnAll('addpath network_file_path')
so the worker processors can access your function file.
3 Check whether the file is on the path of every worker by entering:

```
pctRunOnAll('which filename')
```

If any worker does not have a path to the file, it reports:

```
filename not found.
```

## Set the UseParallel Option to true

Create an options structure with the statset function. To run in parallel, set the UseParallel option to true:

```
paroptions = statset('UseParallel',true);
```

## Call the Function Using the Options Structure

Call your function with syntax that uses the options structure. For example:

```
% Run crossval in parallel
cvMse = crossval('mse',x,y,'predfun',regf,'Options',paroptions);
% Run bootstrp in parallel
sts = bootstrp(100,@(x)[mean(x) std(x)],y,'Options',paroptions);
% Run TreeBagger in parallel
b = TreeBagger(50,meas,spec,'OOBPred','on','Options',paroptions);
For more complete examples of parallel statistical functions, see "Parallel Treebagger" on page 19-5 and "Examples of Parallel Statistical Functions" on page 19-19.
```

After you have finished computing in parallel, close the parallel environment:
matlabpool close

Tip To save time, keep the pool open if you expect to compute in parallel again soon.

## Parallel Treebagger

To run the example "Workflow Example: Regression of Insurance Risk Rating for Car Imports with TreeBagger" on page 15-124 in parallel:

1 Set up the parallel environment to use two cores:

```
matlabpool open 2
```

Starting matlabpool using the 'local' configuration ...
connected to 2 labs.

2 Set the options to use parallel processing:

```
paroptions = statset('UseParallel',true);
```

3 Load the problem data and separate it into input and response:

```
load imports-85;
Y = X(:,1);
X = X(:,2:end);
```

4 Estimate feature importance using leaf size 1 and 1000 trees in parallel. Time the function for comparison purposes:

```
tic
b = TreeBagger(1000,X,Y,'Method','r','OOBVarImp','on',...
    'cat',16:25,'MinLeaf',1,'Options',paroptions);
toc
Elapsed time is 37.357930 seconds.
```

5 Perform the same computation in serial for timing comparison:

```
tic
b = TreeBagger(1000,X,Y,'Method','r','OOBVarImp','on',...
    'cat',16:25,'MinLeaf',1); % No options gives serial
toc
Elapsed time is 63.921864 seconds.
```

Computing in parallel took less than $60 \%$ of the time of computing serially.

# Concepts of Parallel Computing in Statistics Toolbox 

In this section...<br>"Subtleties in Parallel Computing" on page 19-7<br>"Vocabulary for Parallel Computation" on page 19-7

## Subtleties in Parallel Computing

There are two main subtleties in parallel computations:

- Nested parallel evaluations (see "No Nested parfor Loops" on page 19-11). Only the outermost parfor loop runs in parallel, the others run serially.
- Reproducible results when using random numbers (see "Reproducibility in Parallel Statistical Computations" on page 19-13). How can you get exactly the same results when repeatedly running a parallel computation that uses random numbers?

## Vocabulary for Parallel Computation

- worker - An independent MATLAB session that runs code distributed by the client.
- client - The MATLAB session with which you interact, and that distributes jobs to workers.
- parfor - A Parallel Computing Toolbox function that distributes independent code segments to workers (see "Working with parfor" on page 19-10).
- random stream - A pseudorandom number generator, and the sequence of values it generates. MATLAB implements random streams with the RandStream class.
- reproducible computation - A computation that can be exactly replicated, even in the presence of random numbers (see "Reproducibility in Parallel Statistical Computations" on page 19-13).

# When to Run Statistical Functions in Parallel 

In this section...<br>"Why Run in Parallel?" on page 19-8<br>"Factors Affecting Speed" on page 19-8<br>"Factors Affecting Results" on page 19-9

## Why Run in Parallel?

The main reason to run statistical computations in parallel is to gain speed, meaning to reduce the execution time of your program or functions. "Factors Affecting Speed" on page 19-8 discusses the main items affecting the speed of programs or functions. "Factors Affecting Results" on page 19-9 discusses details that can cause a parallel run to give different results than a serial run.

## Factors Affecting Speed

Some factors that can affect the speed of execution of parallel processing are:

- Parallel environment setup. It takes time to run matlabpool to begin computing in parallel. If your computation is fast, the setup time can exceed any time saved by computing in parallel.
- Parallel overhead. There is overhead in communication and coordination when running in parallel. If function evaluations are fast, this overhead could be an appreciable part of the total computation time. Thus, solving a problem in parallel can be slower than solving the problem serially. For an example, see Improving Optimization Performance with Parallel Computing in MATLAB Digest, March 2009.
- No nested parfor loops. This is described in "Working with parfor" on page 19-10. parfor does not work in parallel when called from within another parfor loop. If you have programmed your custom functions to take advantage of parallel processing, the limitation of no nested parfor loops can cause a parallel function to run slower than expected.
- When executing serially, parfor loops run slightly slower than for loops.
- Passing parameters. Parameters are automatically passed to worker sessions during the execution of parallel computations. If there are many
parameters, or they take a large amount of memory, passing parameters can slow the execution of your computation.
- Contention for resources: network and computing. If the pool of workers has low bandwidth or high latency, parallel computation can be slow.

## Factors Affecting Results

Some factors can affect results when using parallel processing. There are several caveats related to parfor listed in "Limitations" in the Parallel Computing Toolbox documentation. Some important factors are:

- Persistent or global variables. If any functions use persistent or global variables, these variables can take different values on different worker processors. Furthermore, they might not be cleared properly on the worker processors.
- Accessing external files. External files can be accessed unpredictably during a parallel computation. The order of computations is not guaranteed during parallel processing, so external files can be accessed in unpredictable order, leading to unpredictable results. Furthermore, if multiple processors try to read an external file simultaneously, the file can become locked, leading to a read error, and halting function execution.
- Noncomputational functions, such as input, plot, and keyboard, can behave badly when used in your custom functions. When called in a parfor loop, these functions are executed on worker machines. This can cause a worker to become nonresponsive, since it is waiting for input.
- parfor does not allow break or return statements.
- The random numbers you use can affect the results of your computations. See "Reproducibility in Parallel Statistical Computations" on page 19-13.

## Working with parfor

In this section...<br>"How Statistical Functions Use parfor" on page 19-10<br>"Characteristics of parfor" on page 19-11

## How Statistical Functions Use parfor

parfor is a Parallel Computing Toolbox function similar to a for loop. Parallel statistical functions call parfor internally. parfor distributes computations to worker processors.

## Characteristics of parfor

More caveats related to parfor appear in "Limitations" in the Parallel Computing Toolbox documentation.

## No Nested parfor Loops

parfor does not work in parallel when called from within another parfor loop, or from an spmd block. Parallelization occurs only at the outermost level.

Suppose, for example, you want to apply jackknife to your function userfcn, which calls parfor, and you want to call jackknife in a loop. The following figure shows three cases:

1 The outermost loop is parfor. Only that loop runs in parallel.
2 The outermost parfor loop is in jackknife. Only jackknife runs in parallel.

3 The outermost parfor loop is in userfon. userfon uses parfor in parallel.

Bold indicates the function that runs in parallel

end
(3) for $i=1: 10$ If UseParallel = 'never' userfen can use parfor in parallel
(3)
$x(\mathrm{i})=\mathrm{jackknife}$ (@userfcn,...)
end

## When parfor Runs in Parallel

## Reproducibility in Parallel Statistical Computations

In this section...<br>"Issues and Considerations in Reproducing Parallel Computations" on page 19-13<br>"Running Reproducible Parallel Computations" on page 19-14<br>"Parallel Statistical Computation Using Random Numbers" on page 19-15

## Issues and Considerations in Reproducing Parallel Computations

A reproducible computation is one that gives the same results every time it runs. Reproducibility is important for:

- Debugging - To correct an anomalous result, you need to reproduce the result.
- Confidence - When you can reproduce results, you can investigate and understand them.
- Modifying existing code - When you change existing code, you want to ensure that you do not break anything.

Generally, you do not need to ensure reproducibility for your computation. Often, when you want reproducibility, the simplest technique is to run in serial instead of in parallel. In serial computation you can simply call the rng function as follows:

```
s = rng % Obtain the current state of the random stream
% run the statistical function
rng(s) % Reset the stream to the previous state
% run the statistical function again, obtain identical results
```

This section addresses the case when your function uses random numbers, and you want reproducible results in parallel. This section also addresses the case when you want the same results in parallel as in serial.

## Running Reproducible Parallel Computations

To run a Statistics Toolbox function reproducibly:
1 Set the UseSubstreams option to true.
2 Set the Streams option to a type that supports substreams: 'mlfg6331_64' or 'mrg32k3a'. For information on these streams, see "Choosing a Random Number Generator" in the MATLAB Mathematics documentation.

3 To compute in parallel, set the UseParallel option to true.
4 Call the function with the options structure.
5 To reproduce the computation, reset the stream, then call the function again.

To understand why this technique gives reproducibility, see "How Substreams Enable Reproducible Parallel Computations" on page 19-15.

For example, to use the 'mlfg6331_64' stream for reproducible computation:
1 Create an appropriate options structure:

```
s = RandStream('mlfg6331_64');
options = statset('UseParallel',true, ...
    'Streams',s,'UseSubstreams',true);
```

2 Run your parallel computation. For instructions, see "Quick Start Parallel Computing for Statistics Toolbox" on page 19-2.

3 Reset the random stream:

```
reset(s);
```

4 Rerun your parallel computation. You obtain identical results.
For an example of a parallel computation run this reproducible way, see "Reproducible Parallel Bootstrap" on page 19-23.

## Parallel Statistical Computation Using Random Numbers

## What Are Substreams?

A substream is a portion of a random stream that RandStream can access quickly. There is a number $M$ such that for any positive integer $k$, RandStream can go the kMth pseudorandom number in the stream. From that point, RandStream can generate the subsequent entries in the stream. Currently, RandStream has $M=2^{72}$, about 5e21, or more.

The entries in different substreams have good statistical properties, similar to the properties of entries in a single stream: independence, and lack of $k$-way correlation at various lags. The substreams are so long that you can view the substreams as being independent streams, as in the following picture.

| Substream 1 |
| :--- |
| Random Number 1 |
| Random Number 2 |
| Random Number 3 |
| $\ldots$ |

Two RandStream stream types support substreams: 'mlfg6331_64' and 'mrg32k3a'.

## How Substreams Enable Reproducible Parallel Computations

When MATLAB performs computations in parallel with parfor, each worker receives loop iterations in an unpredictable order. Therefore, you cannot
predict which worker gets which iteration, so cannot determine the random numbers associated with each iteration.

Substreams allow MATLAB to tie each iteration to a particular sequence of random numbers. parfor gives each iteration an index. The iteration uses the index as the substream number. Since the random numbers are associated with the iterations, not with the workers, the entire computation is reproducible.

To obtain reproducible results, simply reset the stream, and all the substreams generate identical random numbers when called again. This method succeeds when all the workers use the same stream, and the stream supports substreams. This concludes the discussion of how the procedure in "Running Reproducible Parallel Computations" on page 19-14 gives reproducible parallel results.

## Random Numbers on the Client or Workers

A few functions generate random numbers on the client before distributing them to parallel workers. The workers do not use random numbers, so operate purely deterministically. For these functions, you can run a parallel computation reproducibly using any random stream type.

The functions that operate this way include:

- crossval
- plsregress
- sequentialfs

To obtain identical results, reset the random stream on the client, or the random stream you pass to the client. For example:

```
s = rng % Obtain the current state of the random stream
% run the statistical function
rng(s) % Reset the stream to the previous state
% run the statistical function again, obtain identical results
```

While this method enables you to run reproducibly in parallel, the results can differ from a serial computation. The reason for the difference is parfor loops run in reverse order from for loops. Therefore, a serial computation can
generate random numbers in a different order than a parallel computation. For unequivocal reproducibility, use the technique in "Running Reproducible Parallel Computations" on page 19-14.

## Distributing Streams Explicitly

For testing or comparison using particular random number algorithms, you must set the random number generators. How do you set these generators in parallel, or initialize streams on each worker in a particular way? Or you might want to run a computation using a different sequence of random numbers than any other you have run. How can you ensure the sequence you use is statistically independent?

Parallel Statistics Toolbox functions allow you to set random streams on each worker explicitly. For information on creating multiple streams, enter help RandStream/create at the command line. To create four independent streams using the 'mrg32k3a' generator:

```
s = RandStream.create('mrg32k3a','NumStreams',4,...
    'CellOutput',true);
```

Pass these streams to a statistical function using the Streams option. For example:

```
matlabpool open 4 % if you have at least 4 cores
s = RandStream.create('mrg32k3a','NumStreams',4,...
    'CellOutput',true); % create 4 independent streams
paroptions = statset('UseParallel',true,...
    'Streams',s); % set the 4 different streams
x = [randn(700,1); 4 + 2*randn(300,1)];
latt = -4:0.01:12;
myfun = @(X) ksdensity(X,latt);
pdfestimate = myfun(x);
B = bootstrp(200,myfun,x,'Options',paroptions);
```

See "Parallel Bootstrap" on page 19-21 for a plot of the results of this computation.

This method of distributing streams gives each worker a different stream for the computation. However, it does not allow for a reproducible computation, because the workers perform the 200 bootstraps in an unpredictable order. If
you want to perform a reproducible computation, use substreams as described in "Running Reproducible Parallel Computations" on page 19-14.

If you set the UseSubstreams option to true, then set the Streams option to a single random stream of the type that supports substreams ('mlfg6331_64' or 'mrg32k3a'). This setting gives reproducible computations.

## Examples of Parallel Statistical Functions

## In this section...

"Parallel Jackknife" on page 19-19
"Parallel Cross Validation" on page 19-20
"Parallel Bootstrap" on page 19-21

## Parallel Jackknife

This example is from the jackknife function reference page, but runs in parallel.

```
matlabpool open
opts = statset('UseParallel',true);
sigma = 5;
y = normrnd(0,sigma,100,1);
m = jackknife(@var, y,1,'Options',opts);
n = length(y);
bias = -sigma^2 / n % known bias formula
jbias = (n - 1)*(mean(m)-var(y,1)) % jackknife bias estimate
bias =
    -0.2500
jbias =
    -0.2698
```

This simple example is not a good candidate for parallel computation:

```
% How long to compute in serial?
tic;m = jackknife(@var,y,1);toc
Elapsed time is 0.023852 seconds.
```

\% How long to compute in parallel?
tic;m = jackknife(@var,y,1,'Options',opts);toc
Elapsed time is 1.911936 seconds.
jackknife does not use random numbers, so gives the same results every time, whether run in parallel or serial.

## Parallel Cross Validation

- "Simple Parallel Cross Validation" on page 19-20
- "Reproducible Parallel Cross Validation" on page 19-20

## Simple Parallel Cross Validation

This example is the same as the first in the crossval function reference page, but runs in parallel.

```
matlabpool open
opts = statset('UseParallel',true);
load('fisheriris');
y = meas(:,1);
X = [ones(size(y,1),1),meas(:,2:4)];
regf=@(XTRAIN,ytrain,XTEST)(XTEST*regress(ytrain,XTRAIN));
cvMse = crossval('mse',X,y,'Predfun',regf,'Options',opts)
cvMse =
    0.0999
```

This simple example is not a good candidate for parallel computation:

```
% How long to compute in serial?
tic;cvMse = crossval('mse',X,y,'Predfun',regf);toc
Elapsed time is 0.046005 seconds.
% How long to compute in parallel?
tic;cvMse = crossval('mse',X,y,'Predfun',regf,...
    'Options',opts);toc
Elapsed time is 1.333021 seconds.
```

## Reproducible Parallel Cross Validation

To run crossval in parallel in a reproducible fashion, set the options and reset the random stream appropriately (see "Running Reproducible Parallel Computations" on page 19-14).
matlabpool open

```
s = RandStream('mlfg6331_64');
options = statset('UseParallel',true,...
    'Streams',s,'UseSubstreams',true);
load('fisheriris');
y = meas(:,1);
X = [ones(size(y,1),1),meas(:,2:4)];
regf=@(XTRAIN,ytrain,XTEST)(XTEST*regress(ytrain,XTRAIN));
cvMse = crossval('mse',X,y,'Predfun',regf,'Options',opts)
cvMse =
    0.1020
```

Reset the stream and the result is identical:

```
reset(s)
cvMse = crossval('mse',X,y,'Predfun',regf,'Options',opts)
cvMse =
    0.1020
```

## Parallel Bootstrap

- "Bootstrap in Serial and Parallel" on page 19-21
- "Reproducible Parallel Bootstrap" on page 19-23

## Bootstrap in Serial and Parallel

Here is an example timing a bootstrap in parallel versus in serial. The example generates data from a mixture of two Gaussians, constructs a nonparametric estimate of the resulting data, and uses a bootstrap to get a sense of the sampling variability.

1 Generate the data:

```
% Generate a random sample of size 1000,
% from a mixture of two Gaussian distributions
x = [randn(700,1); 4 + 2*randn(300,1)];
```

2 Construct a nonparametric estimate of the density from the data:

```
latt = -4:0.01:12;
myfun = @(X) ksdensity(X,latt);
pdfestimate = myfun(x);
```

3 Bootstrap the estimate to get a sense of its sampling variability. Run the bootstrap in serial for timing comparison.

```
tic;B = bootstrp(200,myfun,x);toc
Elapsed time is 17.455586 seconds.
```

4 Run the bootstrap in parallel for timing comparison:

```
matlabpool open
Starting matlabpool using the 'local' configuration ...
connected to 2 labs.
opt = statset('UseParallel',true);
tic;B = bootstrp(200,myfun,x,'Options',opt);toc
Elapsed time is 9.984345 seconds.
```

Computing in parallel is nearly twice as fast as computing in serial for this example.

Overlay the ksdensity density estimate with the 200 bootstrapped estimates obtained in the parallel bootstrap. You can get a sense of how to assess the accuracy of the density estimate from this plot.

```
hold on
```

for $i=1:$ size $(B, 1)$,
plot(latt, B(i,:),'c:')
end
plot(latt,pdfestimate);
xlabel('x');ylabel('Density estimate')

## Reproducible Parallel Bootstrap

To run the example in parallel in a reproducible fashion, set the options appropriately (see "Running Reproducible Parallel Computations" on page 19-14). First set up the problem and parallel environment as in "Bootstrap in Serial and Parallel" on page 19-21. Then set the options to use substreams along with a stream that supports substreams.

```
s = RandStream('mlfg6331_64'); % has substreams
opts = statset('UseParallel',true,...
    'Streams',s,'UseSubstreams',true);
B2 = bootstrp(200,myfun,x,'Options',opts);
```

To rerun the bootstrap and get the same result:

```
reset(s) % set the stream to initial state
B3 = bootstrp(200,myfun,x,'Options',opts);
isequal(B2,B3) % check if same results
ans =
    1
```

Purpose Added variable plot

Syntax $\quad$| addedvarplot $(X, y, n u m, i n m o d e l)$ |
| :--- |
| addedvarplot $(X, y, n u m, i n m o d e l, ~ s t a t s) ~$ |

Description
addedvarplot ( $\mathrm{X}, \mathrm{y}$, num, inmodel) displays an added variable plot using the predictive terms in X , the response values in y , the added term in column num of $X$, and the model with current terms specified by inmodel. X is an $n$-by- $p$ matrix of $n$ observations of $p$ predictive terms. y is vector of $n$ response values. num is a scalar index specifying the column of X with the term to be added. inmodel is a logical vector of $p$ elements specifying the columns of $X$ in the current model. By default, all elements of inmodel are false.

Note addedvarplot automatically includes a constant term in all models. Do not enter a column of 1 s directly into $X$.
addedvarplot ( $\mathrm{X}, \mathrm{y}$, num, inmodel, stats) uses the stats output from the stepwisefit function to improve the efficiency of repeated calls to addedvarplot. Otherwise, this syntax is equivalent to the previous syntax.
Added variable plots are used to determine the unique effect of adding a new term to a multilinear model. The plot shows the relationship between the part of the response unexplained by terms already in the model and the part of the new term unexplained by terms already in the model. The "unexplained" parts are measured by the residuals of the respective regressions. A scatter of the residuals from the two regressions forms the added variable plot.

In addition to the scatter of residuals, the plot produced by addedvarplot shows $95 \%$ confidence intervals on predictions from the fitted line. The fitted line has intercept zero because, under typical linear model assumptions, both of the plotted variables have mean zero. The slope of the fitted line is the coefficient that the new term would have if it were added to the model with terms inmodel.

Added variable plots are sometimes known as partial regression leverage plots.

Examples Load the data in hald.mat, which contains observations of the heat of reaction of various cement mixtures:

| load hald <br> whos <br> Name | Size | Bytes | Class |
| :--- | :--- | ---: | :--- | Attributes

Create an added variable plot to investigate the addition of the third column of ingredients to a model consisting of the first two columns:

```
inmodel = [true true false false];
addedvarplot(ingredients, heat,3,inmodel)
```

Added variable plot for X 3 Adjusted for $\mathrm{X} 1, \mathrm{X} 2$

The wide scatter and the low slope of the fitted line are evidence against the statistical significance of adding the third column to the model.

## Purpose Add levels to categorical array <br> Syntax $\quad B=\operatorname{addlevels}(A$, newlevels $)$

Description $\quad B=$ addlevels ( $A$, newlevels) adds new levels to the categorical array A. newlevels is a cell array of strings or a 2-D character matrix that specifies the levels to add. addlevels adds the new levels at the end of the list of possible categorical levels in A, but does not modify the value of any element. B does not contain elements at the new levels.

## Examples Example 1

Add levels for additional species in Fisher's iris data:

```
load fisheriris
species = nominal(species,...
    {'Species1','Species2','Species3'},...
    {'setosa','versicolor','virginica'});
species = addlevels(species,{'Species4','Species5'});
getlabels(species)
ans =
    'Species1' 'Species2' 'Species3' 'Species4' 'Species5'
```

## Example 2

1 Load patient data from the CSV file hospital. dat and store the information in a dataset array with observation names given by the first column in the data (patient identification):

```
patients = dataset('file','hospital.dat',...
    'delimiter',',',...
    'ReadObsNames',true);
```

2 Make the $\{0,1\}$-valued variable smoke nominal, and change the labels to 'No' and 'Yes':

```
patients.smoke = nominal(patients.smoke,{'No','Yes'});
```

3 Add new levels to smoke as placeholders for more detailed histories of smokers:

```
patients.smoke = addlevels(patients.smoke,...
    {'0-5 Years','5-10 Years','LongTerm'});
```

4 Assuming the nonsmokers have never smoked, relabel the 'No' level:

```
patients.smoke = setlabels(patients.smoke,'Never','No');
```

5 Drop the undifferentiated 'Yes' level from smoke:

```
patients.smoke = droplevels(patients.smoke,'Yes');
Warning: OLDLEVELS contains categorical levels that
were present in A, caused some array elements to have
undefined levels.
```

Note that smokers now have an undefined level.
6 Set each smoker to one of the new levels, by observation name:

```
patients.smoke('YPL-320') = '5-10 Years';
```

See Also
droplevels | getlabels | islevel | mergelevels | reorderlevels

## Purpose Add listener for event

```
Syntax
el = addlistener(hsource,'eventname',callback)
el = addlistener(hsource,property,'eventname',callback)
```

Description
el = addlistener(hsource,'eventname',callback) creates a listener for the event named eventname, the source of which is handle object hsource. If hsource is an array of source handles, the listener responds to the named event on any handle in the array. callback is a function handle that is invoked when the event is triggered.
el = addlistener(hsource,property,'eventname',callback) adds a listener for a property event. eventname must be one of the strings 'PreGet', 'PostGet', 'PreSet', and 'PostSet'. property must be either a property name or cell array of property names, or a meta.property or array of meta.property. The properties must belong to the class of hsource. If hsource is scalar, property can include dynamic properties.

For all forms, addlistener returns an event.listener. To remove a listener, delete the object returned by addlistener. For example, delete(el) calls the handle class delete method to remove the listener and delete it from the workspace.

[^2]
## GeneralizedLinearModel.addTerms

## Purpose Add terms to generalized linear model

Syntax mdl1 = addTerms(mdl,terms)

Description

Input
Arguments
mdl1 = addTerms(mdl,terms) returns a generalized linear model the same as mdl but with additional terms.
mdl
Generalized linear model, as constructed by GeneralizedLinearModel.fit or GeneralizedLinearModel.stepwise.

## terms

Terms to add to the mdl regression model. Specify as either a:

- Text string representing one or more terms to add. For details, see "Wilkinson Notation" on page 20-9.
- Row or rows in the terms matrix (see modelspec in LinearModel.fit). For example, if there are three variables $\mathrm{A}, \mathrm{B}$, and C :
[0 0 0] represents a constant term or intercept
[0 100$]$ represents $B$; equivalently, $A^{\wedge} 0$ * $B^{\wedge 1}$ * $C^{\wedge} 0$
$\left[\begin{array}{lll}1 & 0 & 1\end{array}\right]$ represents $A^{*} C$
[2 0 0 0 ] represents $A^{\wedge} 2$
[0 102$]$ represents $B^{*}\left(C^{\wedge} 2\right)$

## Output <br> mdll

Arguments
Generalized linear model, the same as mdl but with additional terms given in terms. You can set mdl1 equal to mdl to overwrite mdl.

## GeneralizedLinearModel.addTerms

## Definitions

## Examples

## Wilkinson Notation

Wilkinson notation describes the factors present in models. The notation relates to factors present in models, not to the multipliers (coefficients) of those factors.

| Wilkinson Notation | Factors in Standard Notation |
| :--- | :--- |
| 1 | Constant (intercept) term |
| $A^{\wedge} k$, where $k$ is a positive integer | $A, A^{2}, \ldots, A^{k}$ |
| $A+B$ | $A, B$ |
| $A * B$ | $A, B, A * B$ |
| $A: B$ | $A * B$ only |
| $-B$ | Do not include $B$ |
| $A * B+C$ | $A, B, C, A * B$ |
| $A+B+C+A: B$ | $A, B, C, A * B$ |
| $A * B * C-A: B: C$ | $A, B, C, A * B, A * C, B * C$ |
| $A *(B+C)$ | $A, B, C, A * B, A * C$ |

Statistics Toolbox notation always includes a constant term unless you explicitly remove the term using - 1 .
For details, see Wilkinson and Rogers [1].

## Add a term to a generalized linear regression model

Create a model using just one predictor, then add a second.
Generate artificial data for the model, Poisson random numbers with two underlying predictors $\mathrm{X}(1)$ and $\mathrm{X}(2)$.

```
rng('default') % for reproducibility
rndvars = randn(100,2);
X = [2+rndvars(:,1),rndvars(:,2)];
mu = exp(1 + X*[1;2]);
```

## GeneralizedLinearModel.addTerms

```
y = poissrnd(mu);
Create a generalized linear regression model of Poisson data. Use just the first predictor in the model.
mdl = GeneralizedLinearModel.fit(X,y,...
    'y ~ x1','distr','poisson')
mdl =
Generalized Linear regression model:
    log(y) ~ 1 + x1
    Distribution = Poisson
Estimated Coefficients:
\begin{tabular}{llrrl} 
& Estimate & \multicolumn{1}{l}{ SE } & tStat & pValue \\
(Intercept) & 2.7784 & 0.014043 & 197.85 & 0 \\
x1 & 1.1732 & 0.0033653 & 348.6 & 0
\end{tabular}
100 observations, 98 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 1.25e+05, p-value = 0
```

Add the second predictor to the model.

```
mdl1 = addTerms(mdl,'x2')
mdl1 =
Generalized Linear regression model:
    log(y) ~ 1 + x1 + x2
    Distribution = Poisson
Estimated Coefficients:
\begin{tabular}{lccll} 
& Estimate & SE & tStat & pValue \\
(Intercept) & 1.0405 & 0.022122 & 47.034 & 0 \\
x1 & 0.9968 & 0.003362 & 296.49 & 0 \\
x2 & 1.987 & 0.0063433 & 313.24 & 0
\end{tabular}
```

## GeneralizedLinearModel.addTerms

```
100 observations, }97\mathrm{ error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 2.95e+05, p-value = 0
```

| $A *(B+C)$ | $A, B, C, A * B, A * C$ |

Statistics Toolbox notation always includes a constant term unless you explicitly remove the term using - 1 .

For details, see Wilkinson and Rogers [1].

## Examples Add a Term to a Model

Create a model of the carsmall data without any interactions, then add an interaction term.

Load the carsmall data and make a model of the MPG as a function of weight and model year.

```
load carsmall
ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);
mdl = LinearModel.fit(ds,'MPG ~ Year + Weight^2');
```

Add an interaction term to mdl.

```
terms = 'Year*Weight';
mdl1 = addTerms(mdl,terms)
```

## LinearModel.addTerms

## Purpose Anderson-Darling test

Syntax

```
h = adtest(x)
h = adtest(x,Name,Value)
[h,p] = adtest(___)
[h,p,adstat,cv] = adtest(___ )
```

Description

## Input Arguments

$\mathrm{h}=$ adtest $(\mathrm{x})$ returns a test decision for the null hypothesis that the data in vector x is from a population with a normal distribution, using the Anderson-Darling test. The alternative hypothesis is that x is not from a population with a normal distribution. The result h is 1 if the test rejects the null hypothesis at the $5 \%$ significance level, or 0 otherwise.
$\mathrm{h}=$ adtest(x,Name, Value) returns a test decision for the Anderson-Darling test with additional options specified by one or more name-value pair arguments. For example, you can specify a null distribution other than normal, or select an alternative method for calculating the $p$-value.
[ $\mathrm{h}, \mathrm{p}$ ] = adtest (__ ) also returns the $p$-value, p , of the Anderson-Darling test, using any of the input arguments from the previous syntaxes.
[h, p, adstat, cv] = adtest (__ ) also returns the test statistic, adstat, and the critical value, cv, for the Anderson-Darling test.

## x-Sample data

vector
Sample data, specified as a vector. Missing observations in x , indicated by NaN , are ignored.

Data Types
single | double

## adtest

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ..., NameN, ValueN.

Example: 'Alpha',0.01,'MCTol', 0.01 conducts the hypothesis test at the $1 \%$ significance level, and determines the p-value, $p$, using a Monte Carlo simulation with a maximum Monte Carlo standard error for $p$ of 0.01 .

## 'Distribution' - Hypothesized distribution <br> 'norm' (default) | 'exp' | 'ev' | 'logn' | 'weibull' | probability distribution object

Hypothesized distribution of data vector $x$, specified as the comma-separated pair consisting of 'Distribution' and one of the following.

```
'norm' Normal distribution
'exp' Exponential distribution
'ev' Extreme value distribution
'logn' Lognormal distribution
'weibull' Weibull distribution
```

In this case, you do not need to specify population parameters. Instead, adtest estimates the distribution parameters from the sample data and tests x against a composite hypothesis that it comes from the selected distribution family with parameters unspecified.
Alternatively, you can specify any continuous probability distribution object for the null distribution. In this case, you must specify all the distribution parameters, and adtest tests $x$ against a simple hypothesis that it comes from the given distribution with its specified parameters.

## Example: 'Distribution','exp'

## 'Alpha' - Significance level

```
0.05 (default) | scalar value in the range (0,1)
```

Significance level of the hypothesis test, specified as the comma-separated pair consisting of 'Alpha' and a scalar value in the range $(0,1)$.

Example: 'Alpha', 0.01
Data Types
single | double
'MCTol' - Maximum Monte Carlo standard error
positive scalar value
Maximum Monte Carlo standard error for the $p$-value, p , specified as the comma-separated pair consisting of 'MCTol' and a positive scalar value. If you use MCTol, adtest determines p using a Monte Carlo simulation, and the name-value pair argument Asymptotic must have the value false.

Example: 'MCTol',0.01

## Data Types

single | double

## 'Asymptotic' - Method for calculating p-value <br> false (default) | true

Method for calculating the $p$-value of the Anderson-Darling test, specified as the comma-separated pair consisting of 'Asymptotic' and either true or false. If you specify 'true', adtest estimates the $p$-value using the limiting distribution of the Anderson-Darling test statistic. If you specify false, adtest calculates the $p$-value based on an analytical formula. For sample sizes greater than 120, the limiting distribution estimate is likely to be more accurate than the small sample size approximation method.

## adtest

- If you specify a distribution family with unknown parameters for the Distribution name-value pair, Asymptotic must be false.
- If you use MCTol to calculate the $p$-value using a Monte Carlo simulation, Asymptotic must be false.
Example: 'Asymptotic', true

## Data Types

logical

## Output <br> Arguments

h - Hypothesis test result

## 1 | 0

Hypothesis test result, returned as a logical value.

- If $\mathrm{h}=1$, this indicates the rejection of the null hypothesis at the Alpha significance level.
- If $\mathrm{h}=0$, this indicates a failure to reject the null hypothesis at the Alpha significance level.

## p-p-value

## scalar value in the range $[0,1]$

$p$-value of the Anderson-Darling test, returned as a scalar value in the range $[0,1] . p$ is the probability of observing a test statistic as extreme as, or more extreme than, the observed value under the null hypothesis. p is calculated using one of these methods:

- If the hypothesized distribution is a fully specified probability distribution object, adtest calculates $p$ analytically. If 'Asymptotic' is true, adtest uses the asymptotic distribution of the test statistic. If you specify a value for 'MCTol', adtest uses a Monte Carlo simulation.
- If the hypothesized distribution is specified as a distribution family with unknown parameters, adtest retrieves the critical value from a table and uses inverse interpolation to determine the $p$-value. If you specify a value for 'MCTol', adtest uses a Monte Carlo simulation.

## adstat - Test statistic

scalar value
Test statistic for the Anderson-Darling test, returned as a scalar value.

- If the hypothesized distribution is a fully specified probability distribution object, adtest computes adstat using specified parameters.
- If the hypothesized distribution is specified as a distribution family with unknown parameters, adtest computes adstat using parameters estimated from the sample data.

## cv-Critical value

## scalar value

Critical value for the Anderson-Darling test at the significance level Alpha, returned as a scalar value. adtest determines cv by interpolating into a table based on the specified Alpha significance level.

## Examples Test for a Normal Distribution

Load the data set. Create a vector containing the first column of the students' exam grades data.

```
load examgrades;
x = grades(:,1);
```

Test the null hypothesis that the exam grades come from a normal distribution. You do not need to specify values for the population parameters.

```
[h,p,adstat,cv] = adtest(x);
h =
    0
p =
    0.1854
```

## adtest

```
adstat =
    0.5194
CV =
    0.7470
```

The returned value of $\mathrm{h}=0$ indicates that adtest fails to reject the null hypothesis at the default $5 \%$ significance level.

## Test for an Extreme Value Distribution

Load the data set. Create a vector containing the first column of the students' exam grades data.
load examgrades;
$x=\operatorname{grades}(:, 1)$;
Test the null hypothesis that the exam grades come from an extreme value distribution. You do not need to specify values for the population parameters.

```
[h,p] = adtest(x,'Distribution','ev')
h =
    0
p =
    0.0714
```

The returned value of $\mathrm{h}=0$ indicates that adtest fails to reject the null hypothesis at the default $5 \%$ significance level.

## Specify the Hypothesized Distribution Using a Probability Distribution Object

Load the data set. Create a vector containing the first column of the students' exam grades data.
load examgrades;

```
x = grades(:,1);
Create a normal probability distribution object with mean mu = 75 and
standard deviation sigma = 10.
dist = makedist('normal','mu',75,'sigma', 10)
dist =
    prob.NormalDistribution
    Package: prob
    Normal distribution
            mu = 75
        sigma = 10
    Properties, Methods
```

Test the null hypothesis that x comes from the hypothesized normal distribution.

```
[h,p] = adtest(x,'Distribution',dist)
```

$\mathrm{h}=$
0
p =
0.4687

The returned value of $h=0$ indicates that adtest fails to reject the null hypothesis at the default $5 \%$ significance level.

## Definitions Anderson-Darling Test

The Anderson-Darling test is commonly used to test whether a data sample comes from a normal distribution. However, it can be used to test for another hypothesized distribution, even if you do not fully specify the distribution parameters. Instead, the test estimates any unknown parameters from the data sample.

## adtest

The test statistic belongs to the family of quadratic empirical distribution function statistics, which measure the distance between the hypothesized distribution, $F(x)$ and the empirical cdf, $F_{n}(x)$ as

$$
n \int_{-\infty}^{\infty}\left(F_{n}(x)-F(x)\right)^{2} w(x) d F(x)
$$

over the ordered sample values $x_{1}<x_{2}<\ldots<x_{n}$, where $w(x)$ is a weight function and $n$ is the number of data points in the sample.

The weight function for the Anderson-Darling test is

$$
w(x)=[F(x)(1-F(x))]^{-1},
$$

which places greater weight on the observations in the tails of the distribution, thus making the test more sensitive to outliers and better at detecting departure from normality in the tails of the distribution.

The Anderson-Darling test statistic is

$$
A_{n}^{2}=-n-\sum_{i=1}^{n} \frac{2 i-1}{n}\left[\ln \left(F\left(X_{i}\right)\right)+\ln \left(1-F\left(X_{n+1-i}\right)\right)\right],
$$

where $\left\{X_{1}<\ldots<X_{n}\right\}$ are the ordered sample data points and $n$ is the number of data points in the sample.

In adtest, the decision to reject or not reject the null hypothesis is based on comparing the $p$-value for the hypothesis test with the specified significance level, not on comparing the test statistic with the critical value.

## Monte Carlo Standard Error

The Monte Carlo standard error is calculated as

$$
S E=\sqrt{\frac{(\hat{\mathrm{p}})(1-\hat{\mathrm{p}})}{\mathrm{mcreps}}},
$$

where $\hat{\mathrm{p}}$ is the estimated $p$-value of the hypothesis test, and moreps is the number of Monte Carlo replications performed.
adtest chooses the number of Monte Carlo replications, mcreps, large enough to make the Monte Carlo standard error for $\hat{p}$ less than the value specified for MCTol.

See Also kstest | jbtest

## gmdistribution.AIC property

Purpose Akaike Information Criterion
Description The Akaike Information Criterion: $2 * \mathrm{NlogL}+2 * \mathrm{~m}$, where m is the number of estimated parameters.

Note This property applies only to gmdistribution objects constructed with fit.

## Purpose <br> Syntax <br> Description

Andrews plot
andrewsplot(X)
andrewsplot(X,...,'Standardize',standopt)
andrewsplot(X,...,'Quantile', alpha)
andrewsplot( $\mathrm{X}, \ldots$, , $\mathrm{Group}^{\prime}$, group)
andrewsplot(X,...,'PropName', PropVal,...)
$\mathrm{h}=$ andrewsplot $(\mathrm{X}, \ldots$ )
andrewsplot ( X ) creates an Andrews plot of the multivariate data in the matrix $X$. The rows of $X$ correspond to observations, the columns to variables. Andrews plots represent each observation by a function $f(t)$ of a continuous dummy variable $t$ over the interval $[0,1] . f(t)$ is defined for the $i$ th observation in X as

$$
f(t)=X(i, 1) / \sqrt{2}+X(i, 2) \sin (2 \pi t)+X(i, 3) \cos (2 \pi t)+\ldots
$$

andrewsplot treats NaN values in X as missing values and ignores the corresponding rows.
andrewsplot (X,...,'Standardize',standopt) creates an Andrews plot where standopt is one of the following:

- ' on' - scales each column of $X$ to have mean 0 and standard deviation 1 before making the plot.
- 'PCA' - creates an Andrews plot from the principal component scores of $X$, in order of decreasing eigenvalue. (See pca.)
- 'PCAStd ' - creates an Andrews plot using the standardized principal component scores. (See pca.)
andrewsplot (X,...,'Quantile', alpha) plots only the median and the alpha and ( $1-$ alpha) quantiles of $f(t)$ at each value of $t$. This is useful if $X$ contains many observations.
andrewsplot ( $\mathrm{X}, \ldots$, ' 'Group ', group) plots the data in different groups with different colors. Groups are defined by group, a numeric array containing a group index for each observation. group can also be a

## andrewsplot

categorical array, character matrix, or cell array of strings containing a group name for each observation.
andrewsplot(X,...,'PropName',PropVal,...) sets optional lineseries object properties to the specified values for all lineseries objects created by andrewsplot. (See lineseriesproperties.)
$\mathrm{h}=$ andrewsplot $(\mathrm{X}, \ldots$ ) returns a column vector of handles to the lineseries objects created by andrewsplot, one handle per row of X. If you use the 'Quantile' input parameter, h contains one handle for each of the three lineseries objects created. If you use both the 'Quantile' and the 'Group' input parameters, $h$ contains three handles for each group.

## Examples Make a grouped plot of the Fisher iris data:

load fisheriris
andrewsplot(meas,'group',species)

Plot only the median and quartiles of each group:

```
andrewsplot(meas,'group',species,'quantile',.25)
```

## Purpose Analysis of variance for linear model

Syntax<br>\section*{Description}

tbl = anova(mdl)
tbl = anova(mdl,anovatype)
tbl = anova(mdl,anovatype,sstype)

## Input Arguments

 statistics. type. using the chosen type of sum of squares.
## mdl

tbl = anova(mdl) returns a dataset array with summary ANOVA
tbl = anova(mdl, anovatype) returns ANOVA statistics of the chosen
tbl = anova(mdl, anovatype,sstype) computes ANOVA statistics

Linear model, as constructed by LinearModel.fit or LinearModel.stepwise.

## anovatype

ANOVA type:

- 'component ' - tbl displays a 'components' ANOVA table, with sums of squares and $F$ tests attributable to each term in the model except the constant term.
- ' summary ' — tbl displays a summary ANOVA table with an $F$ test for the model as a whole.
- If there are both linear and higher-order terms, there is also an $F$ test for the higher-order terms as a group.
- If there are replications (multiple observations sharing the same predictor values), there is also an $F$ test for lack-of-fit computed by decomposing the residual sum of squares into a sum of squares for the replicated observations and the remaining sum of squares.

## LinearModel.anova

Default: 'component'

## sstype

When anovatype is 'component ', choose the sum of squares type:

- 1
- 2
- 3
- 'h'

For details, see "Sum of Squares" on page 20-46.
Default: ' h '

## Output Arguments

## tbl

Dataset array containing summary ANOVA statistics. tbl depends on anovatype:

- 'component':
- Sum of squares
- Degrees of freedom
- Mean squares
- $F$ statistic
- $p$-value
- Formula used for model
- 'summary':
- Total Sum of Squares
- Model Sum of Squares

## LinearModel.anova

- Linear Sum of Squares (present if model has powers or interactions)
- Nonlinear Sum of Squares (present if model has powers or interactions)
- Residual Sum of Squares
- Lack-of-fit Sum of Squares (present if model has replicates)
- Pure error Sum of Squares (present if model has replicates)

## Examples Component ANOVA Table

Create a component ANOVA table from a model of the carsmall data.
Load the carsmall data and make a model of the MPG as a function of weight and model year.

```
load carsmall
ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);
mdl = LinearModel.fit(ds,'MPG ~ Year + Weight^2');
```

Create an ANOVA table.

```
tbl = anova(mdl)
```

tbl =

|  | SumSq | DF | MeanSq | F | pValue |
| :--- | :--- | ---: | ---: | :--- | :--- |
| Weight | 2050.2 | 1 | 2050.2 | 265.11 | $1.9885 \mathrm{e}-28$ |
| Year | 849.55 | 2 | 424.77 | 54.927 | $2.9042 \mathrm{e}-16$ |
| Weight^2 | 76.688 | 1 | 76.688 | 9.9164 | 0.0022303 |
| Error | 688.27 | 89 | 7.7334 |  |  |

## Summary ANOVA Table

Create a summary ANOVA table from a model of the carsmall data.

## LinearModel.anova

Load the carsmall data and make a model of the MPG as a function of weight and model year.
load carsmall
ds = dataset(MPG, Weight);
ds.Year = ordinal(Model_Year);
mdl = LinearModel.fit(ds,'MPG ~ Year + Weight^2');

Create a summary ANOVA table.

```
tbl = anova(mdl,'summary')
```

tbl =

|  | SumSq | DF | MeanSq | F | pValue |
| :--- | ---: | ---: | ---: | :--- | ---: |
| Total | 6005.3 | 93 | 64.573 |  |  |
| Model | 5317 | 4 | 1329.3 | 171.88 | $5.5208 \mathrm{e}-41$ |
| . Linear | 5240.3 | 3 | 1746.8 | 225.87 | $1.7302 \mathrm{e}-41$ |
| . Nonlinear | 76.688 | 1 | 76.688 | 9.9164 | 0.0022303 |
| Residual | 688.27 | 89 | 7.7334 |  |  |
| . Lack of fit | 663.77 | 86 | 7.7183 | 0.9451 | 0.62874 |
| . Pure error | 24.5 | 3 | 8.1667 |  |  |

The summary ANOVA table shows tests for groups of terms. The nonlinear group consists of just the Weight^2 term, so it has the same $p$-value as that term in "Component ANOVA Table" on page 20-31. The $F$ statistic comparing the residual sum of squares to a "pure error" estimate from replicated observations shows no evidence of lack of fit.and anovan functions.

Alternatives More complete ANOVA statistics are available in the anova1, anova2,

One-way analysis of variance

```
\(p\) = anova1 (X)
p = anova1 (X,group)
p = anova1(X,group,displayopt)
[p,table] = anova1(...)
[p,table,stats] = anova1(...)
```

$\mathrm{p}=$ anova1(X) performs balanced one-way ANOVA for comparing the means of two or more columns of data in the matrix $X$, where each column represents an independent sample containing mutually independent observations. The function returns the $p$-value under the null hypothesis that all samples in $X$ are drawn from populations with the same mean.

If $p$ is near zero, it casts doubt on the null hypothesis and suggests that at least one sample mean is significantly different than the other sample means. Common significance levels are 0.05 or 0.01 .

The anova1 function displays two figures, the standard ANOVA table and a box plot of the columns of $X$.

The standard ANOVA table divides the variability of the data into two parts:

- Variability due to the differences among the column means (variability between groups)
- Variability due to the differences between the data in each column and the column mean (variability within groups)

The standard ANOVA table has six columns:
1 The source of the variability.
2 The sum of squares (SS) due to each source.
3 The degrees of freedom (df) associated with each source.
4 The mean squares (MS) for each source, which is the ratio SS/df.

5 The $F$-statistic, which is the ratio of the mean squares.
6 The $p$-value, which is derived from the cdf of $F$.
The box plot of the columns of X suggests the size of the $F$-statistic and the $p$-value. Large differences in the center lines of the boxes correspond to large values of $F$ and correspondingly small values of $p$.
anova1 treats NaN values as missing, and disregards them.
p = anova1(X,group) performs ANOVA by group. For more information on grouping variables, see "Grouping Variables" on page 2-51.

If $X$ is a matrix, anova1 treats each column as a separate group, and evaluates whether the population means of the columns are equal. This form of anova1 is appropriate when each group has the same number of elements (balanced ANOVA). group can be a character array or a cell array of strings, with one row per column of X , containing group names. Enter an empty array ([ ]) or omit this argument if you do not want to specify group names.

If $X$ is a vector, group must be a categorical variable, vector, string array, or cell array of strings with one name for each element of X. X values corresponding to the same value of group are placed in the same group. This form of anova1 is appropriate when groups have different numbers of elements (unbalanced ANOVA).

If group contains empty or NaN -valued cells or strings, the corresponding observations in X are disregarded.
p = anova1(X,group,displayopt) enables the ANOVA table and box plot displays when displayopt is 'on' (default) and suppresses the displays when displayopt is 'off'. Notches in the boxplot provide a test of group medians (see boxplot) different from the $F$ test for means in the ANOVA table.
[p,table] = anova1(...) returns the ANOVA table (including column and row labels) in the cell array table. Copy a text version of the ANOVA table to the clipboard using the Copy Text item on the Edit menu.
[p,table,stats] = anova1(...) returns a structure stats used to perform a follow-up multiple comparison test. anova1 evaluates the hypothesis that the samples all have the same mean against the alternative that the means are not all the same. Sometimes it is preferable to perform a test to determine which pairs of means are significantly different, and which are not. Use the multcompare function to perform such tests by supplying the stats structure as input.

## Assumptions

The ANOVA test makes the following assumptions about the data in X :

- All sample populations are normally distributed.
- All sample populations have equal variance.
- All observations are mutually independent.

The ANOVA test is known to be robust with respect to modest violations of the first two assumptions.

## Examples Example 1

Create X with columns that are constants plus random normal disturbances with mean zero and standard deviation one:

Perform one-way ANOVA:
$p=\operatorname{anova1}(X)$
$p=$
$7.9370 e-006$

The very small $p$ value indicates that differences between column means are highly significant. The probability of this outcome under the null hypothesis (that samples drawn from the same population would have means differing by the amounts seen in X ) is equal to the $p$-value.

## Example 2

The following example is from a study of the strength of structural beams in Hogg. The vector strength measures deflections of beams in thousandths of an inch under 3,000 pounds of force. The vector alloy identifies each beam as steel ('st'), alloy 1 ('al1'), or alloy 2 ('al2'). (Although alloy is sorted in this example, grouping variables do not need to be sorted.) The null hypothesis is that steel beams are equal in strength to beams made of the two more expensive alloys.

```
strength = [82 86 79 83 84 85 86 87 74 82 ...
    78 75 76 77 79 79 77 78 82 79];
alloy = {'st','st','st','st','st','st','st','st',\ldots.
    'al1','al1','al1','al1','al1','al1',...
    'al2','al2','al2','al2','al2','al2'};
p = anova1(strength,alloy)
p =
    1.5264e-004
```

## ANOVA Table

| Source | SS | df | MS | F | Prob>F | $\Delta$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| $-------------------------------------------~$ |  |  |  |  |  |  |
| Columns | 184.8 | 2 | 92.4 | 15.4 | 0.0002 |  |
| Error | 102 | 17 | 6 |  |  |  |
| Total | 286.8 | 19 |  |  |  |  |

The $p$-value suggests rejection of the null hypothesis. The box plot shows that steel beams deflect more than beams made of the more expensive alloys.

How To

- "Grouping Variables" on page 2-51

## Purpose Two-way analysis of variance

## Syntax

```
p = anova2(X,reps)
p = anova2(X,reps,displayopt)
[p,table] = anova2(...)
[p,table,stats] = anova2(...)
```

p = anova2(X,reps) performs a balanced two-way ANOVA for comparing the means of two or more columns and two or more rows of the observations in X. The data in different columns represent changes in factor $A$. The data in different rows represent changes in factor $B$. If there is more than one observation for each combination of factors, input reps indicates the number of replicates in each position, which must be constant. (For unbalanced designs, use anovan.)

The matrix below shows the format for a set-up where column factor A has two levels, row factor B has three levels, and there are two replications (reps $=2$ ). The subscripts indicate row, column, and replicate, respectively.

$$
\begin{aligned}
& A=1 \quad A=2 \\
& \left.\left.\begin{array}{l}
{\left[\begin{array}{ll}
x_{111} & x_{121} \\
x_{112} & x_{122} \\
x_{211} & x_{221} \\
x_{212} & x_{222} \\
x_{311} & x_{321} \\
x_{312} & x_{322}
\end{array}\right]}
\end{array}\right\} B=1 \begin{array}{l}
B=1
\end{array}\right\} B=3
\end{aligned}
$$

When reps is 1 (default), anova2 returns two $p$-values in vector $p$ :
1 The $p$ value for the null hypothesis, $\mathrm{H}_{0 \mathrm{~A}}$, that all samples from factor A (i.e., all column-samples in X ) are drawn from the same population

2 The $p$ value for the null hypothesis, $\mathrm{H}_{0 \mathrm{~B}}$, that all samples from factor $B$ (i.e., all row-samples in $X$ ) are drawn from the same population

When reps is greater than 1 , anova2 returns a third $p$ value in vector p:

3 The $p$ value for the null hypothesis, $\mathrm{H}_{0 \mathrm{AB}}$, that the effects due to factors A and B are additive (i.e., that there is no interaction between factors A and B)

If any $p$ value is near zero, this casts doubt on the associated null hypothesis. A sufficiently small $p$ value for $\mathrm{H}_{0 \mathrm{~A}}$ suggests that at least one column-sample mean is significantly different that the other column-sample means; i.e., there is a main effect due to factor A. A sufficiently small $p$ value for $\mathrm{H}_{0 \mathrm{~B}}$ suggests that at least one row-sample mean is significantly different than the other row-sample means; i.e., there is a main effect due to factor B. A sufficiently small $p$ value for $\mathrm{H}_{0 A B}$ suggests that there is an interaction between factors A and B . The choice of a limit for the $p$ value to determine whether a result is "statistically significant" is left to the researcher. It is common to declare a result significant if the $p$ value is less than 0.05 or 0.01 .
anova2 also displays a figure showing the standard ANOVA table, which divides the variability of the data in X into three or four parts depending on the value of reps:

- The variability due to the differences among the column means
- The variability due to the differences among the row means
- The variability due to the interaction between rows and columns (if reps is greater than its default value of one)
- The remaining variability not explained by any systematic source

The ANOVA table has five columns:

- The first shows the source of the variability.
- The second shows the Sum of Squares (SS) due to each source.
- The third shows the degrees of freedom (df) associated with each source.
- The fourth shows the Mean Squares (MS), which is the ratio SS/df.
- The fifth shows the $F$ statistics, which is the ratio of the mean squares.
$\mathrm{p}=$ anova2(X,reps, displayopt) enables the ANOVA table display when displayopt is 'on' (default) and suppresses the display when displayopt is 'off'.
[ $p$, table] = anova2(...) returns the ANOVA table (including column and row labels) in cell array table. (Copy a text version of the ANOVA table to the clipboard by using the Copy Text item on the Edit menu.)
[ $p$,table,stats] $=$ anova2(...) returns a stats structure that you can use to perform a follow-up multiple comparison test.
The anova2 test evaluates the hypothesis that the row, column, and interaction effects are all the same, against the alternative that they are not all the same. Sometimes it is preferable to perform a test to determine which pairs of effects are significantly different, and which are not. Use the multcompare function to perform such tests by supplying the stats structure as input.

## Examples

The data below come from a study of popcorn brands and popper type (Hogg 1987). The columns of the matrix popcorn are brands (Gourmet, National, and Generic). The rows are popper type (Oil and Air.) The study popped a batch of each brand three times with each popper. The values are the yield in cups of popped popcorn.
$\left.\begin{array}{l}\text { load popcorn } \\ \begin{array}{l}\text { popcorn } \\ \text { popcorn }= \\ 5.5000\end{array} \\ 5.5000\end{array}\right] 3.5000$

```
p = anova2(popcorn,3)
p =
    0.0000 0.0001 0.7462
```

| ANOVA Table |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Source | 55 | df | MS | F | Prob>F | ) |
| Columns | 15.75 | 2 | 7.875 | 56.7 | 0 |  |
| Rows | 4.5 | 1 | 4.5 | 32.4 | 0.0001 |  |
| Interaction | 0.0833 | 2 | 0.04167 | 0.3 | 0.7462 |  |
| Error | 1.6667 | 12 | 0.13889 |  |  |  |
| Total | 22 | 17 |  |  |  |  |

The vector p shows the $p$-values for the three brands of popcorn, 0.0000 , the two popper types, 0.0001 , and the interaction between brand and popper type, 0.7462 . These values indicate that both popcorn brand and popper type affect the yield of popcorn, but there is no evidence of a synergistic (interaction) effect of the two.

The conclusion is that you can get the greatest yield using the Gourmet brand and an Air popper (the three values popcorn(4:6,1)).

anova1 | anovan

| Purpose | $N$-way analysis of variance |
| :--- | :--- |
| Syntax | $p=\operatorname{anovan}(y$, group $)$ |
|  | $p=\operatorname{anovan}(y$, group, param, val $)$ |
|  | $[p$, table $=$ anovan $(y$, group, param, val $)$ |
|  | $[p$, table, stats $]=$ anovan $(y$, group, param, val $)$ |
|  | $[p$, table, stats, terms $]=\operatorname{anovan}(y$, group, param, val $)$ |

Description
$\mathrm{p}=$ anovan(y,group) performs multiway (n-way) analysis of variance (ANOVA) for testing the effects of multiple factors on the mean of the vector $y$. This test compares the variance explained by factors to the left over variance that cannot be explained. The factors and factor levels of the observations in y are assigned by the cell array group. Each of the cells in the cell array group contains a list of factor levels identifying the observations in $y$ with respect to one of the factors. The list within each cell can be a categorical array, numeric vector, character matrix, or single-column cell array of strings, and must have the same number of elements as $y$. The fitted ANOVA model includes the main effects of each grouping variable. All grouping variables are treated as fixed effects by default. The result $p$ is a vector of $p$-values, one per term. For an example, see "Example of Three-Way ANOVA" on page 20-47.
$p=\operatorname{anovan}(y$, group, param, val) specifies one or more of the parameter name/value pairs described in the following table.

| Parameter | Value |
| :--- | :--- |
| 'alpha' | A number between 0 and 1 requesting 100(1- <br> alpha)\% confidence bounds (default 0.05 for 95\% <br> confidence) |
| 'continuous ' | A vector of indices indicating which grouping <br> variables should be treated as continuous predictors <br> rather than as categorical predictors. |
| 'display' | 'on' displays an ANOVA table (the default) <br> 'off ' omits the display |

| Parameter | Value |
| :--- | :--- |
| 'model' | The type of model used. See "Model Type" on page <br> $20-45$ for a description of this parameter. |
| 'nested' | A matrix M of 0's and 1's specifying the nesting <br> relationships among the grouping variables. M(i,j) is <br> 1 if variable i is nested in variable j. |
| 'random' | A vector of indices indicating which grouping <br> variables are random effects (all are fixed by default). <br> See "ANOVA with Random Effects" on page 8-19 for <br> an example of how to use 'random '. |
| 'sstype' | $1,2,3$ (default), or h specifies the type of sum of <br> squares. See "Sum of Squares" on page 20-46 for a <br> description of this parameter. |
| 'varnames' ' | A character matrix or a cell array of strings specifying <br> names of grouping variables, one per grouping <br> variable. When you do not specify 'varnames', the <br> default labels 'X1', 'X2', 'X3', ..., 'XN' are used. <br> See "ANOVA with Random Effects" on page 8-19 for <br> an example of how to use 'varnames'. |

[p,table] = anovan(y,group, param, val) returns the ANOVA table (including factor labels) in cell array table. (Copy a text version of the ANOVA table to the clipboard by using the Copy Text item on the Edit menu.)
[p,table,stats] = anovan(y,group,param,val) returns a stats structure that you can use to perform a follow-up multiple comparison test with the multcompare function. See "The Stats Structure" on page 20-50The Stats Structure for more information.
[p,table, stats,terms] = anovan(y, group, param, val) returns the main and interaction terms used in the ANOVA computations. The terms are encoded in the output matrix terms using the same format described above for input 'model'. When you specify 'model' itself in this matrix format, the matrix returned in terms is identical.

## Model Type

This section explains how to use the argument 'model' with the syntax:

```
[...] = anovan(y,group,'model',modeltype)
```

The argument model type, which specifies the type of model the function uses, can be any one of the following:

- 'linear' - The default 'linear' model computes only the $p$-values for the null hypotheses on the $N$ main effects.
- 'interaction' - The 'interaction' model computes the $p$-values
for null hypotheses on the $N$ main effects and the $\binom{N}{2}$ two-factor
interactions.
- 'full' - The 'full' model computes the $p$-values for null hypotheses on the $N$ main effects and interactions at all levels.
- An integer - For an integer value of modeltype, $k(k \leq N)$, anovan computes all interaction levels through the kth level. For example, the value 3 means main effects plus two- and three-factor interactions. The values $\mathrm{k}=1$ and $\mathrm{k}=2$ are equivalent to the 'linear' and 'interaction' specifications, respectively, while the value $k=N$ is equivalent to the 'full' specification.
- A matrix of term definitions having the same form as the input to the x2fx function. All entries must be 0 or 1 (no higher powers).

For more precise control over the main and interaction terms that anovan computes, modeltype can specify a matrix containing one row for each main or interaction term to include in the ANOVA model. Each row defines one term using a vector of $N$ zeros and ones. The table below illustrates the coding for a 3 -factor ANOVA.

| Matrix Row | ANOVA Term |
| :--- | :--- | :--- |
| $\left[\begin{array}{lll}1 & 0 & 0\end{array}\right]$ | Main term A |
| $\left[\begin{array}{lll}0 & 1 & 0\end{array}\right]$ | Main term B |

| Matrix Row | ANOVA Term |
| :--- | :--- |
| $\left[\begin{array}{lll}0 & 0 & 1\end{array}\right]$ | Main term C |
| $\left[\begin{array}{lll}1 & 1 & 0\end{array}\right]$ | Interaction term AB |
| $\left[\begin{array}{lll}1 & 0 & 1\end{array}\right]$ | Interaction term AC |
| $\left[\begin{array}{lll}0 & 1 & 1\end{array}\right]$ | Interaction term BC |
| $\left[\begin{array}{lll}1 & 1 & 1\end{array}\right]$ | Interaction term ABC |

For example, if modeltype is the matrix $\left[\begin{array}{lllllll}0 & 1 & 0 ; 0 & 0 & 1 ; 0 & 1 & 1\end{array}\right]$, the output vector $p$ contains the $p$-values for the null hypotheses on the main effects $B$ and $C$ and the interaction effect $B C$, in that order. $A$ simple way to generate the modeltype matrix is to modify the terms output, which codes the terms in the current model using the format described above. If anovan returns [ $010 ; 001 ; 0111]$ for terms, for example, and there is no significant result for interaction BC , you can recompute the ANOVA on just the main effects B and C by specifying [0 1 0;0 0 1] for modeltype.

## Sum of Squares

This section explains how to use the argument 'sstype' with the syntax:

$$
[\ldots]=\operatorname{anovan}(y, \text { group,'sstype',type) }
$$

This syntax computes the ANOVA using the type of sum of squares specified by type, which can be $1,2,3$, or h . While the numbers $1-3$ designate Type 1, Type 2, or Type 3 sum of squares, respectively, h represents a hierarchical model similar to type 2 , but with continuous as well as categorical factors used to determine the hierarchy of terms. The default value is 3 . For a model containing main effects but no interactions, the value of type only influences computations on unbalanced data.

The sum of squares for any term is determined by comparing two models. The Type 1 sum of squares for a term is the reduction in residual sum of squares obtained by adding that term to a fit that already includes the terms listed before it. The Type 2 sum of squares is
the reduction in residual sum of squares obtained by adding that term to a model consisting of all other terms that do not contain the term in question. The Type 3 sum of squares is the reduction in residual sum of squares obtained by adding that term to a model containing all other terms, but with their effects constrained to obey the usual "sigma restrictions" that make models estimable.

Suppose you are fitting a model with two factors and their interaction, and that the terms appear in the order $A, B, A B$. Let $R(\cdot)$ represent the residual sum of squares for a model, so for example $R(A, B, A B)$ is the residual sum of squares fitting the whole model, $R(A)$ is the residual sum of squares fitting just the main effect of $A$, and $R(1)$ is the residual sum of squares fitting just the mean. The three types of sums of squares are as follows:

| Term | Type 1 Sum of Squares | Type 2 Sum of <br> Squares | Type 3 Sum of <br> Squares |
| :--- | :--- | :--- | :--- |
| $A$ | $R(1)-R(A)$ | $R(B)-R(A, B)$ | $R(B, A B)-R(A, B, A B)$ |
| $B$ | $R(A)-R(A, B)$ | $R(A)-R(A, B)$ | $R(A, A B)-R(A, B, A B)$ |
| $A B$ | $R(A, B)-R(A, B, A B)$ | $R(A, B)-R(A, B, A B)$ | $R(A, B)-R(A, B, A B)$ |

The models for Type 3 sum of squares have sigma restrictions imposed. This means, for example, that in fitting $R(B, A B)$, the array of $A B$ effects is constrained to sum to 0 over $A$ for each value of $B$, and over $B$ for each value of $A$.

## Example of Three-Way ANOVA

As an example of three-way ANOVA, consider the vector y and group inputs below.

```
y = [52.7 57.5 45.9 44.5 53.0 57.0 45.9 44.0]';
g1 = [1 2 1 2 1 2 1 2];
g2 = {'hi';'hi';'lo';'lo';'hi';'hi';'lo';'lo'};
g3 = {'may';'may';'may';'may';'june';'june';'june';'june'};
```

This defines a three-way ANOVA with two levels of each factor. Every observation in $y$ is identified by a combination of factor levels. If the factors are $A, B$, and $C$, then observation $y(1)$ is associated with

- Level 1 of factor A
- Level 'hi' of factor B
- Level 'may' of factor C

Similarly, observation y (6) is associated with

- Level 2 of factor A
- Level 'hi' of factor B
- Level 'june' of factor C

To compute the ANOVA, enter
$p=\operatorname{anovan}(y,\{g 1$ g2 g3 $\}$ )
$p=$
0.4174
0.0028
0.9140

Output vector p contains $p$-values for the null hypotheses on the N main effects. Element $p(1)$ contains the $p$ value for the null hypotheses, $\mathrm{H}_{0 \mathrm{~A}}$, that samples at all levels of factor A are drawn from the same population; element $\mathrm{p}(2)$ contains the $p$ value for the null hypotheses, $\mathrm{H}_{0 \mathrm{~B}}$, that samples at all levels of factor B are drawn from the same population; and so on.

If any $p$ value is near zero, this casts doubt on the associated null hypothesis. For example, a sufficiently small $p$ value for $\mathrm{H}_{0 \mathrm{~A}}$ suggests that at least one A-sample mean is significantly different from the other A-sample means; that is, there is a main effect due to factor A. You need to choose a bound for the $p$ value to determine whether a result is statistically significant. It is common to declare a result significant if the $p$ value is less than 0.05 or 0.01 .
anovan also displays a figure showing the standard ANOVA table, which by default divides the variability of the data in $x$ into

- The variability due to differences between the levels of each factor accounted for in the model (one row for each factor)
- The remaining variability not explained by any systematic source

The ANOVA table has six columns:

- The first shows the source of the variability.
- The second shows the sum of squares (SS) due to each source.
- The third shows the degrees of freedom (df) associated with each source.
- The fourth shows the mean squares (MS), which is the ratio SS/df.
- The fifth shows the $F$ statistics, which are the ratios of the mean squares.
- The sixth shows the $p$-values for the $F$ statistics.

The table is shown in the following figure:

| Analysis of Variance |  |  |  |  |  |  |
| :---: | ---: | :---: | :---: | :---: | :---: | :---: |
| Source | Sum Sq. | d.f. | Mean Sq. | F | Prob $>$ F |  |
| X1 | 3.781 | 1 | 3.781 | 0.82 | 0.4174 |  |
| X2 | 199.001 | 1 | 199.001 | 42.95 | 0.0028 |  |
| X3 | 0.061 | 1 | 0.061 | 0.01 | 0.914 |  |
| Error | 18.535 | 4 | 4.634 |  |  |  |
| Total | 221.379 | 7 |  |  |  |  |
|  |  |  |  |  |  |  |

Constrained (Type III) sums of squares.

## Two-Factor Interactions

By default, anovan computes $p$-values just for the three main effects. To also compute $p$-values for the two-factor interactions, $\mathrm{X} 1 * \mathrm{X} 2, \mathrm{X} 1 * \mathrm{X} 3$, and $\mathrm{X} 2 * \times 3$, add the name/value pair 'model', 'interaction' as input arguments.

```
p = anovan(y,{g1 g2 g3},'model','interaction')
p =
    0.0347
    0.0048
    0.2578
    0.0158
    0.1444
    0.5000
```

The first three entries of p are the $p$-values for the main effects. The last three entries are the $p$-values for the two-factor interactions. You can determine the order in which the two-factor interactions occur from the ANOVAN table shown in the following figure.

| Analysis of Variance |  |  |  |  |  |  |
| :---: | ---: | ---: | :---: | ---: | ---: | ---: |
| Source | Sum Sq. | d.f. | Mean Sq. | F | Prob $>\mathrm{F}$ |  |
| X1 | 3.781 | 1 | 3.781 | 336.11 | 0.0347 |  |
| X2 | 199.001 | 1 | 199.001 | 17689 | 0.0048 |  |
| X3 | 0.061 | 1 | 0.061 | 5.44 | 0.2578 |  |
| X1*X2 | 18.301 | 1 | 18.301 | 1626.78 | 0.0158 |  |
| X1*X3 | 0.211 | 1 | 0.211 | 18.78 | 0.1444 |  |
| X2*X3 | 0.011 | 1 | 0.011 | 1 | 0.5 |  |
| Error | 0.011 | 1 | 0.011 |  |  |  |
| Total | 221.379 | 7 |  |  |  |  |

Constrained (Type III) sums of squares.

## The Stats Structure

The anovan test evaluates the hypothesis that the different levels of a factor (or more generally, a term) have the same effect, against the alternative that they do not all have the same effect. Sometimes it is preferable to perform a test to determine which pairs of levels are significantly different, and which are not. Use the multcompare function to perform such tests by supplying the stats structure as input.

The stats structure contains the fields listed below, in addition to a number of other fields required for doing multiple comparisons using the multcompare function:

| Field | Description |
| :--- | :--- |
| coeffs | Estimated coefficients |
| coeffnames | Name of term for each coefficient |
| vars | Matrix of grouping variable values for each term |
| resid | Residuals from the fitted model |

The stats structure also contains the following fields if there are random effects:

| Field | Description |
| :--- | :--- |
| ems | Expected mean squares |
| denom | Denominator definition |
| rtnames | Names of random terms |
| varest | Variance component estimates (one per random term) |
| varci | Confidence intervals for variance components |

## Examples

"Example: Two-Way ANOVA" on page 8-10 shows how to use anova2 to analyze the effects of two factors on a response in a balanced design. For a design that is not balanced, use anovan instead.
The data in carbig.mat gives measurements on 406 cars. Use anonvan to study how the mileage depends on where and when the cars were made:

```
load carbig
```

p = anovan(MPG,\{org when\},'model',2,'sstype',3,...
'varnames',\{'Origin';'Mfg date'\})
$p=$

```
    0
    0
0.3059
```

| Analysis of Variance |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Source | Sum Sq. |  | Mean Sq | F | Prob>F |
| Origin | 5727.2 | 2 | 2863.58 | 115.09 | 0 |
| Mfg date | 4710.3 | 2 | 2355.15 | 94.65 | 0 |
| Origin*Mfg date | 120.5 | 4 | 30.12 | 1.21 | 0.3059 |
| Error | 9679.1 |  | 24.88 |  |  |
| Total | 24252.6 | 397 |  |  |  |

Constrained (Type III) sums of squares.
The $p$ value for the interaction term is not small, indicating little evidence that the effect of the year or manufacture (when) depends on where the car was made (org). The linear effects of those two factors, however, are significant.

| Purpose | Ansari-Bradley test |
| :--- | :--- |
| Syntax | $h=$ ansaribradley $(x, y)$ |
|  | $h=$ ansaribradley $(x, y$, Name, Value $)$ |
|  | $[h, p]=$ ansaribradley $(\square)$ |
|  | $[h, p$, stats $]=$ ansaribradley $(\ldots \ldots)$ |

Description

## Input Arguments

$\mathrm{h}=$ ansaribradley $(\mathrm{x}, \mathrm{y})$ returns a test decision for the null hypothesis that the data in vectors $x$ and $y$ comes from the same distribution, using the Ansari-Bradley test. The alternative hypothesis is that the data in $x$ and $y$ comes from distributions with the same median and shape but different dispersions (e.g., variances). The result h is 1 if the test rejects the null hypothesis at the $5 \%$ significance level, or 0 otherwise.
$\mathrm{h}=$ ansaribradley ( $\mathrm{x}, \mathrm{y}$, Name, Value) returns a test decision for the Ansari-Bradley test with additional options specified by one or more name-value pair arguments. For example, you can change the significance level, conduct a one-sided test, or use a normal approximation to calculate the value of the test statistic.
[h, p] = ansaribradley (__ ) also returns the $p$-value, p , of the test, using any of the input arguments in the previous syntaxes.
[h,p,stats] = ansaribradley( __ ) also returns the structure stats containing information about the test statistic.

## x-Sample data

vector | matrix | multidimensional array
Sample data, specified as a vector, matrix, or multidimensional array.

- If $x$ and $y$ are specified as vectors, they do not need to be the same length.
- If $x$ and $y$ are specified as matrices, they must have the same number of columns. ansaribradley performs separate tests along each column and returns a vector of results.
- If $x$ and $y$ are specified as multidimensional arrays, ansaribradley works along the first nonsingleton dimension. $x$ and $y$ must have the same size along all remaining dimensions.

## Data Types

single | double

## $y$-Sample data

vector | matrix | multidimensional array
Sample data, specified as a vector, matrix, or multidimensional array.

- If $x$ and $y$ are specified as vectors, they do not need to be the same length.
- If $x$ and $y$ are specified as matrices, they must have the same number of columns. ansaribradley performs separate tests along each column and returns a vector of results.
- If $x$ and $y$ are specified as multidimensional arrays, ansaribradley works along the first nonsingleton dimension. $x$ and $y$ must have the same size along all remaining dimensions.

## Data Types <br> single | double

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN.
Example: 'Tail', 'right', 'Alpha', 0.01 specifies a right-tailed hypothesis test at the $1 \%$ significance level.

## 'Alpha' - Significance level

### 0.05 (default) | scalar value in the range $(0,1)$

Significance level of the hypothesis test, specified as the comma-separated pair consisting of 'Alpha' and a scalar value in the range $(0,1)$.

Example: 'Alpha',0.01

## Data Types

single | double

## 'Dim' - Dimension

first nonsingleton dimension (default) | positive integer value
Dimension of the input matrix along which to test the means, specified as the comma-separated pair consisting of 'Dim' and a positive integer value. For example, specifying 'Dim', 1 tests the column means, while 'Dim' , 2 tests the row means.

## Example: 'Dim',2

```
Data Types
single | double
```

## 'Tail' - Type of alternative hypothesis

'both' (default) | 'left' | 'right'
Type of alternative hypothesis to evaluate, specified as the comma-separated pair consisting of 'Tail' and one of the following.

| 'both' | Test the alternative hypothesis that the dispersion <br> parameters of $x$ and $y$ are not equal. |
| :--- | :--- |
| 'right' | Test the alternative hypothesis that the dispersion <br> parameter of $x$ is greater than that of $y$. |
| 'left' | Test the alternative hypothesis that the dispersion <br> parameter of $x$ is less than that of $y$. |

Example: 'Tail','right'
'Method' - Computation method

## ansaribradley

'exact' | 'approximate'
Computation method for the test statistic, specified as the comma-separated pair consisting of 'Method' and one of the following.
> 'exact' Compute p using an exact calculation of the distribution of the test statistic W. This is the default if $n$, the total number of rows in X and y , is 25 or less. Note that $n$ is computed before any NaN values (representing missing data) are removed.
> 'approximate 'Compute p using a normal approximation for the statistic $\mathrm{W}^{*}$. This is the default if $n$, the total number of rows in $x$ and $y$, is greater than 25 .

Example: 'Method','exact'

## Output Arguments <br> h - Hypothesis test result <br> 1 | 0

Hypothesis test result, returned as a logical value.

- If $\mathrm{h}=1$, this indicates the rejection of the null hypothesis at the Alpha significance level.
- If $\mathrm{h}=0$, this indicates a failure to reject the null hypothesis at the Alpha significance level.

## p-p-value

scalar value in the range $(0,1)$
$p$-value of the test, returned as a scalar value in the range $(0,1) . \mathrm{p}$ is the probability of observing a test statistic as extreme as, or more extreme than, the observed value under the null hypothesis. Small values of $p$ cast doubt on the validity of the null hypothesis.

## stats - Test statistics

structure

Test statistics for the Ansari-Bradley test, returned as a structure containing:

- W-Value of the test statistic, which is the sum of the Ansari-Bradley ranks for the x sample.
- Wstar - Approximate normal statistic W*.

## Examples Test for Equal Variances

Load the sample data. Create data vectors of miles per gallon (MPG) measurements for the model years 1982 and 1976.

```
load carsmall;
x = MPG(Model_Year==82);
y = MPG(Model_Year==76);
```

Test the null hypothesis that the miles per gallon measured in cars from 1982 and 1976 have equal variances.

```
[h,p,stats] = ansaribradley(x,y)
h =
    0
p =
    0.8426
stats =
    W: 526.9000
    Wstar: 0.1986
```

The returned value of $h=0$ indicates that ansaribradley does not reject the null hypothesis at the default $5 \%$ significance level.

## One-Sided Hypothesis Test

Load the sample data. Create data vectors of miles per gallon (MPG) measurements for the model years 1982 and 1976.

## ansaribradley

```
load carsmall;
x = MPG(Model_Year==82);
y = MPG(Model_Year==76);
```

Test the null hypothesis that the miles per gallon measured in cars from 1982 and 1976 have equal variances, against the alternative hypothesis that the variance of cars from 1982 is greater than that of cars from 1976.

```
[h,p,stats] = ansaribradley(x,y,'Tail','right')
h =
    0
p =
    0.5787
stats =
    W: 526.9000
    Wstar: 0.1986
```

The returned value of $\mathrm{h}=0$ indicates that ansaribradley does not reject the null hypothesis that the variance in miles per gallon is the same for the two model years, when the alternative is that the variance of cars from 1982 is greater than that of cars from 1976.

## Definitions <br> Ansari-Bradley Test

The Ansari-Bradley test is a nonparametric alternative to the two-sample $F$-test of equal variances. It does not require the assumption that x and y come from normal distributions. The dispersion of a distribution is generally measured by its variance or standard deviation, but the Ansari-Bradley test can be used with samples from distributions that do not have finite variances.

This test requires that the samples have equal medians. Under that assumption, and if the distributions of the samples are continuous and identical, the test is independent of the distributions. If the samples
do not have the same medians, the results can be misleading. In that case, Ansari and Bradley recommend subtracting the median, but then the distribution of the resulting test under the null hypothesis is no longer independent of the common distribution of $x$ and $y$. If you want to perform the tests with medians subtracted, you should subtract the medians from $x$ and $y$ before calling ansaribradley.

## Multidimensional Array

A multidimensional array has more than two dimensions. For example, if $x$ is a 1-by- 3 -by- 4 array, then $x$ is a three-dimensional array.

## First Nonsingleton Dimension

The first nonsingleton dimension is the first dimension of an array whose size is not equal to 1 . For example, if x is a 1 -by- 2 -by- 3 -by- 4 array, then the second dimension is the first nonsingleton dimension of $x$.

Purpose Interactive analysis of covariance
Syntax

```
aoctool(x,y,group)
aoctool(x,y,group,alpha)
aoctool(x,y,group,alpha, xname, yname,gname)
aoctool(x,y,group, alpha, xname, yname, gname,displayopt)
aoctool(x,y,group, alpha, xname, yname, gname, displayopt,model)
h = aoctool(...)
[h,atab,ctab] = aoctool(...)
[h,atab,ctab,stats] = aoctool(...)
```

## Description

aoctool( $x, y$, group) fits a separate line to the column vectors, $x$ and $y$, for each group defined by the values in the array group. group may be a categorical variable, vector, character array, or cell array of strings. These types of models are known as one-way analysis of covariance (ANOCOVA) models. The output consists of three figures:

- An interactive graph of the data and prediction curves
- An ANOVA table
- A table of parameter estimates

You can use the figures to change models and to test different parts of the model. More information about interactive use of the aoctool function appears in "Analysis of Covariance Tool" on page 8-27.
aoctool( $x, y$, group, alpha) determines the confidence levels of the prediction intervals. The confidence level is 100(1-alpha)\%. The default value of alpha is 0.05 .
aoctool( $x, y$, group, alpha, xname, yname, gname) specifies the name to use for the $x, y$, and $g$ variables in the graph and tables. If you enter simple variable names for the $\mathrm{x}, \mathrm{y}$, and g arguments, the aoctool function uses those names. If you enter an expression for one of these arguments, you can specify a name to use in place of that expression by supplying these arguments. For example, if you enter $m(:, 2)$ as the $x$ argument, you might choose to enter 'Col 2 ' as the xname argument.
aoctool(x,y,group, alpha, xname, yname, gname, displayopt) enables the graph and table displays when displayopt is 'on' (default) and suppresses those displays when displayopt is 'off'.
aoctool(x,y,group, alpha, xname, yname, gname, displayopt, model) specifies the initial model to fit. The value of model can be any of the following:

- 'same mean' - Fit a single mean, ignoring grouping
- 'separate means' - Fit a separate mean to each group
- 'same line' - Fit a single line, ignoring grouping
- 'parallel lines' - Fit a separate line to each group, but constrain the lines to be parallel
- 'separate lines' - Fit a separate line to each group, with no constraints
$\mathrm{h}=\operatorname{aoctool}(\ldots)$ returns a vector of handles to the line objects in the plot.
[h,atab, ctab] = aoctool(...) returns cell arrays containing the entries in ANOVA table (atab) and the table of coefficient estimates (ctab). (You can copy a text version of either table to the clipboard by using the Copy Text item on the Edit menu.)
[h,atab,ctab,stats] = aoctool(...) returns a stats structure that you can use to perform a follow-up multiple comparison test. The ANOVA table output includes tests of the hypotheses that the slopes or intercepts are all the same, against a general alternative that they are not all the same. Sometimes it is preferable to perform a test to determine which pairs of values are significantly different, and which are not. You can use the multcompare function to perform such tests by supplying the stats structure as input. You can test either the slopes, the intercepts, or population marginal means (the heights of the curves at the mean $x$ value).

Examples This example illustrates how to fit different models non-interactively. After loading the smaller car data set and fitting a separate-slopes model, you can examine the coefficient estimates.
load carsmall

```
[h,a,c,s] = aoctool(Weight,MPG,Model_Year,0.05,...
                                    '','','','off','separate lines');
c(:,1:2)
ans =
    'Term' 'Estimate'
    'Intercept' [45.97983716833132]
    ' 70' [-8.58050531454973]
    ' 76' [-3.89017396094922]
    ' 82' [12.47067927549897]
    'Slope' [-0.00780212907455]
    ' 70' [ 0.00195840368824]
    ' 76' [ 0.00113831038418]
    ' 82' [-0.00309671407243]
```

Roughly speaking, the lines relating MPG to Weight have an intercept close to 45.98 and a slope close to -0.0078 . Each group's coefficients are offset from these values somewhat. For instance, the intercept for the cars made in 1970 is $45.98-8.58=37.40$.

Next, try a fit using parallel lines. (The ANOVA table shows that the parallel-lines fit is significantly worse than the separate-lines fit.)

```
[h,a,c,s] = aoctool(Weight,MPG,Model_Year,0.05,...
                                    '','','','off','parallel lines');
c(:,1:2)
ans =
    'Term' 'Estimate'
    'Intercept' [43.38984085130596]
    ' 70' [-3.27948192983761]
    ' 76' [-1.35036234809006]
```

```
82' [ 4.62984427792768]
'Slope ' [-0.00664751826198]
```

Again, there are different intercepts for each group, but this time the slopes are constrained to be the same.

## TreeBagger.append

Purpose Append new trees to ensemble
Syntax $\quad B=\operatorname{append}(B$, other $)$
Description $B=$ append $(B, o t h e r)$ appends the trees from the other ensemble to those in B. This method checks for consistency of the $X$ and $Y$ properties of the two ensembles, as well as consistency of their compact objects and out-of-bag indices, before appending the trees. The output ensemble B takes training parameters such as FBoot, Prior, Cost, and other from the B input. There is no attempt to check if these training parameters are consistent between the two objects.

See Also<br>CompactTreeBagger.combine

## ProbDistKernel.BandWidth property

| Purpose | Read-only value specifying bandwidth of kernel smoothing function <br> for ProbDistKernel object |
| :--- | :--- |
| Description | BandWidth is a read-only property of the ProbDistKernel class. <br> BandWidth is a value specifying the width of the kernel smoothing <br> function used to compute a nonparametric estimate of the probability <br> distribution when creating a ProbDistKernel object. |
| Values | For a distribution specified to cover only the positive numbers or only <br> a finite interval, the data are transformed before the kernel density is <br> applied, and the bandwidth is on the scale of the transformed data. |
| See Also | Use this information to view and compare the width of the kernel <br> smoothing function used to create distributions. |
| ksdensity |  |

## barttest

## Purpose Bartlett's test

```
Syntax
ndim = barttest(X,alpha)
[ndim,prob,chisquare] = barttest(X,alpha)
```

ndim = barttest(X, alpha) returns the number of dimensions necessary to explain the nonrandom variation in the data matrix $X$, using the significance probability alpha. The dimension is determined by a series of hypothesis tests. The test for ndim=1 tests the hypothesis that the variances of the data values along each principal component are equal, the test for ndim=2 tests the hypothesis that the variances along the second through last components are equal, and so on.
[ndim, prob, chisquare] = barttest(X, alpha) returns the number of dimensions, the significance values for the hypothesis tests, and the $\chi^{2}$ values associated with the tests.

```
Examples }\quad\textrm{X}=\textrm{mvnrnd([0 0],[1 0.99; 0.99 1],20);
X(:,3:4) = mvnrnd([0 0],[1 0.99; 0.99 1],20);
X(:,5:6) = mvnrnd([0 0],[1 0.99; 0.99 1],20);
[ndim, prob] = barttest(X,0.05)
ndim =
    3
prob =
    0
        0
        0
    0.5081
    0.6618
```

## bbdesign

## Purpose

Box-Behnken design
Syntax
$\mathrm{dBB}=$ bbdesign( n )
[dBB,blocks] = bbdesign(n)
[...] = bbdesign(n,param,val)

## Description

$d B B=b b d e s i g n(n)$ generates a Box-Behnken design for $n$ factors. $n$ must be an integer 3 or larger. The output matrix $d B B$ is $m$-by- $n$, where $m$ is the number of runs in the design. Each row represents one run, with settings for all factors represented in the columns. Factor values are normalized so that the cube points take values between -1 and 1 .
[dBB,blocks] = bbdesign(n) requests a blocked design. The output blocks is an $m$-by- 1 vector of block numbers for each run. Blocks indicate runs that are to be measured under similar conditions to minimize the effect of inter-block differences on the parameter estimates.
[...] = bbdesign(n, param,val) specifies one or more optional parameter/value pairs for the design. The following table lists valid parameter/value pairs.

| Parameter | Description | Values |
| :--- | :--- | :--- |
| 'center' | Number of <br> center points. | Integer. The default depends on <br> n. |
| 'blocksize' | Maximum <br> number of <br> points per block. | Integer. The default is Inf. |

Examples The following creates a 3 -factor Box-Behnken design:

```
dBB = bbdesign(3)
dBB =
\begin{tabular}{rrr}
-1 & -1 & 0 \\
-1 & 1 & 0 \\
1 & -1 & 0
\end{tabular}
```

## bbdesign

| 1 | 1 | 0 |
| ---: | ---: | ---: |
| -1 | 0 | -1 |
| -1 | 0 | 1 |
| 1 | 0 | -1 |
| 1 | 0 | 1 |
| 0 | -1 | -1 |
| 0 | -1 | 1 |
| 0 | 1 | -1 |
| 0 | 1 | 1 |
| 0 | 0 | 0 |
| 0 | 0 | 0 |
| 0 | 0 | 0 |

The center point is run 3 times to allow for a more uniform estimate of the prediction variance over the entire design space.

Visualize the design as follows:

```
plot3(dBB(:,1),dBB(:,2),dBB(:,3),'ro',...
    'MarkerFaceColor','b')
X = [1 -1 -1 -1 1 1 -1 -1 -1 1 1 -1 -1; ...
    1 1 1 1 -1 1 1 1 1 1 - 1 1 1 1 -1 -1];
Y = [-1 -1 1 1 -1 - -1 -1 1 1 -1 1 1-1 1 - 1; ...
    1 -1 1 1 1 1 1 - - 1 1 1 1 1 - - 1 1 - 1];
Z = [11 1 1 1 1 - - 1 -1 -1 -1 - 1 - 1 -1 -1; ...
    1 1 1 1 1 -1 -1 -1 -1 1 1 1 1 1];
line(X,Y,Z,'Color','b')
axis square equal
```

## prob.BetaDistribution

Superclasses ToolboxFittableParametricDistribution

## Purpose Beta probability distribution object

Description prob.BetaDistribution is an object consisting of parameters, a model description, and sample data for a beta probability distribution.

Create a probability distribution object with specified parameter values using makedist. Alternatively, fit a distribution to data using fitdist or dfittool.

## Construction

pd = makedist('Beta') creates a beta probability distribution object using the default parameter values.
pd = makedist('Beta','a', a, 'b', b) creates a beta probability distribution object using the specified parameter values.

## Input Arguments

## a - First shape parameter

## 1 (default) | positive scalar value

First shape parameter of the beta distribution, specified as a positive scalar value.

```
Data Types
single | double
b - Second shape parameter
1 (default) | positive scalar value
```

Second shape parameter of the beta distribution, specified as a positive scalar value.

## Data Types

single | double

## Properties

## a

First shape parameter of the beta distribution, stored as a positive scalar value.

```
Data Types
single | double
b
```

Second shape parameter of the beta distribution, stored as a positive scalar value.

## Data Types

single | double

## DistributionName

Name of the probability distribution, stored as a valid probability distribution name string. This property is read-only.

## Data Types

char

## InputData

Data used for distribution fitting, stored as a structure containing the following:

- data: Data vector used for distribution fitting.
- cens: Censoring vector, or empty if none.
- freq: Frequency vector, or empty if none.

This property is read-only.

## Data Types

single | double

## IsTruncated

Logical flag for truncated distribution, stored as a logical value. If IsTruncated equals 0 , the distribution is not truncated. If IsTruncated equals 1 , the distribution is truncated. This property is read-only.

## Data Types

logical

## prob.BetaDistribution

## NumParameters

Number of parameters for the probability distribution, stored as a positive integer value. This property is read-only.

Data Types<br>single | double

## ParameterCovariance

Covariance matrix of the parameter estimates, stored as a $p$-by- $p$ matrix, where $p$ is the number of parameters in the distribution. The ( $i, j$ ) element is the covariance between the estimates of the $i$ ith parameter and the $j$ th parameter. The ( $i, i$ ) element is the estimated variance of the ith parameter. If parameter $i$ is fixed rather than estimated by fitting the distribution to data, then the (i,i) elements of the covariance matrix are 0 . This property is read-only.

## Data Types

single | double

## ParameterDescription

Descriptions of distribution parameters, stored as a cell array of strings. Each cell contains a short description of one distribution parameter. This property is read-only.

## Data Types <br> char

## ParameterlsFixed

Logical flag for fixed parameters, stored as an array of logical values. If 0 , the corresponding parameter in the ParameterNames array is not fixed. If 1 , the corresponding parameter in the ParameterNames array is fixed. This property is read-only.

Data Types

logical

## ParameterNames

Names of distribution parameters, stored as a cell array of strings. This property is read-only.

## Data Types

char

## ParameterValues

Values of distribution parameters, stored as a vector. This property is read-only.

## Data Types

single | double

## Truncation

Truncation interval for the probability distribution, stored as a vector containing the lower and upper truncation boundaries. This property is read-only.

```
Data Types
single | double
```

## Definitions

## Beta Distribution

The beta distribution describes a family of curves that are unique in that they are nonzero only on the interval $(0,1)$. A more general version of the distribution assigns parameters to the endpoints of the interval.

The beta distribution uses the following parameters.

| Parameter | Description | Support |
| :--- | :--- | :--- |
| a | First shape parameter | $a>0$ |
| b | Second shape parameter | $b>0$ |

The probability density function (pdf) is

$$
f(x \mid a, b)=\frac{1}{B(a, b)} x^{a-1}(1-x)^{b-1} \quad ; \quad 0<x<1,
$$

where $B(\cdot)$ is the beta function.

## Examples Create a Beta Distribution Object Using Default Parameters

Create a beta distribution object using the default parameter values.

```
pd = makedist('Beta')
pd =
```

    BetaDistribution

## Purpose

Beta cumulative distribution function

## Syntax <br> $p=\operatorname{betacdf}(X, A, B)$

$p=\operatorname{betacdf}(X, A, B)$ returns the beta cdf at each of the values in $X$ using the corresponding parameters in $A$ and $B . X, A$, and $B$ can be vectors, matrices, or multidimensional arrays that all have the same size. A scalar input is expanded to a constant array with the same dimensions as the other inputs. The parameters in A and B must all be positive, and the values in $X$ must lie on the interval [0,1].

The beta cdf for a given value $x$ and given pair of parameters $a$ and $b$ is

$$
p=F(x \mid a, b)=\frac{1}{B(a, b)} \int_{0}^{x} t^{a-1}(1-t)^{b-1} d t
$$

where $B(\cdot)$ is the Beta function.

## Examples

```
x = 0.1:0.2:0.9;
a = 2;
b = 2;
p = betacdf( \(x, a, b)\)
\(\mathrm{p}=\)
    \(\begin{array}{lllll}0.0280 & 0.2160 & 0.5000 & 0.7840 & 0.9720\end{array}\)
```

$a=\left[\begin{array}{lll}1 & 2 & 3\end{array}\right] ;$
$p=\operatorname{betacdf}(0.5, a, a)$
p $=$
$0.5000 \quad 0.5000 \quad 0.5000$

See Also cdf | betapdf | betainv | betastat | betalike | betarnd | betafit
How To . "Beta Distribution" on page B-4

## Purpose Beta parameter estimates

Syntax phat = betafit(data)
[phat,pci] = betafit(data,alpha)

Description

Examples
phat $=$ betafit(data) computes the maximum likelihood estimates of the beta distribution parameters $a$ and $b$ from the data in the vector data and returns a column vector containing the $a$ and $b$ estimates, where the beta cdf is given by

$$
F(x \mid a, b)=\frac{1}{B(a, b)} \int_{0}^{x} t^{a-1}(1-t)^{b-1} d t
$$

and $B(\cdot)$ is the Beta function. The elements of data must lie in the open interval $(0,1)$, where the beta distribution is defined. However, it is sometimes also necessary to fit a beta distribution to data that include exact zeros or ones. For such data, the beta likelihood function is unbounded, and standard maximum likelihood estimation is not possible. In that case, betafit maximizes a modified likelihood that incorporates the zeros or ones by treating them as if they were values that have been left-censored at sqrt (realmin) or right-censored at 1 -eps/2, respectively.
[phat,pci] = betafit(data,alpha) returns confidence intervals on the $a$ and $b$ parameters in the 2 -by- 2 matrix pci. The first column of the matrix contains the lower and upper confidence bounds for parameter $a$, and the second column contains the confidence bounds for parameter $b$. The optional input argument alpha is a value in the range $[0,1]$ specifying the width of the confidence intervals. By default, alpha is 0.05 , which corresponds to $95 \%$ confidence intervals. The confidence intervals are based on a normal approximation for the distribution of the logs of the parameter estimates.

This example generates 100 beta distributed observations. The true $a$ and $b$ parameters are 4 and 3 , respectively. Compare these to the
values returned in $p$ by the beta fit. Note that the columns of ci both bracket the true parameters.

```
data = betarnd(4,3,100,1);
[p,ci] = betafit(data,0.01)
p =
    5.5328 3.8097
ci =
    3.6538 2.6197
    8.3781 5.5402
```

How To . "Beta Distribution" on page B-4

Purpose Beta inverse cumulative distribution function

## Syntax $\quad X=\operatorname{betainv}(P, A, B)$

Description

## Algorithms

## Examples

$X=$ betainv ( $\mathrm{P}, \mathrm{A}, \mathrm{B}$ ) computes the inverse of the beta cdf with parameters specified by $A$ and $B$ for the corresponding probabilities in $P$. $P, A$, and $B$ can be vectors, matrices, or multidimensional arrays that are all the same size. A scalar input is expanded to a constant array with the same dimensions as the other inputs. The parameters in $A$ and $B$ must all be positive, and the values in P must lie on the interval $[0,1]$.

The inverse beta cdf for a given probability $p$ and a given pair of parameters $a$ and $b$ is

$$
x=F^{-1}(p \mid a, b)=\{x: F(x \mid a, b)=p\}
$$

where

$$
p=F(x \mid a, b)=\frac{1}{B(a, b)} \int_{0}^{x} t^{a-1}(1-t)^{b-1} d t
$$

and $B(\cdot)$ is the Beta function. Each element of output X is the value whose cumulative probability under the beta cdf defined by the corresponding parameters in $A$ and $B$ is specified by the corresponding value in $P$.

The betainv function uses Newton's method with modifications to constrain steps to the allowable range for $x$, i.e., [ $\left.\begin{array}{ll}1 & 1\end{array}\right]$.

```
p = [0.01 0.5 0.99];
x = betainv(p,10,5)
x =
    0.3726 0.6742 0.8981
```

According to this result, for a beta cdf with $a=10$ and $b=5$, a value less than or equal to 0.3726 occurs with probability 0.01 . Similarly,
values less than or equal to 0.6742 and 0.8981 occur with respective probabilities 0.5 and 0.99 .

Purpose Beta negative log-likelihood

| Syntax | nlogL $=$ betalike $($ params, data $)$ |
| :--- | :--- |
| $[n \log L, A V A R]$ |  |$=$ betalike $($ params, data $)$.

Description nlogL = betalike(params, data) returns the negative of the beta log-likelihood function for the beta parameters $a$ and $b$ specified in vector params and the observations specified in the column vector data.
The elements of data must lie in the open interval $(0,1)$, where the beta distribution is defined. However, it is sometimes also necessary to fit a beta distribution to data that include exact zeros or ones. For such data, the beta likelihood function is unbounded, and standard maximum likelihood estimation is not possible. In that case, betalike computes a modified likelihood that incorporates the zeros or ones by treating them as if they were values that have been left-censored at sqrt (realmin) or right-censored at $1-\mathrm{eps} / 2$, respectively.
[nlogL,AVAR] = betalike(params,data) also returns AVAR, which is the asymptotic variance-covariance matrix of the parameter estimates if the values in params are the maximum likelihood estimates. AVAR is the inverse of Fisher's information matrix. The diagonal elements of AVAR are the asymptotic variances of their respective parameters.
betalike is a utility function for maximum likelihood estimation of the beta distribution. The likelihood assumes that all the elements in the data sample are mutually independent. Since betalike returns the negative beta log-likelihood function, minimizing betalike using fminsearch is the same as maximizing the likelihood.

Examples This example continues the betafit example, which calculates estimates of the beta parameters for some randomly generated beta distributed data.
$r=\operatorname{betarnd}(4,3,100,1)$;
[nlogl,AVAR] = betalike(betafit(r), r)
nlogl =

How To - "Beta Distribution" on page B-4

Purpose Beta probability density function
Syntax $\quad Y=\operatorname{betapdf}(X, A, B)$
Description
$Y=$ betapdf( $X, A, B$ ) computes the beta pdf at each of the values in $X$ using the corresponding parameters in $A$ and $B . X, A$, and $B$ can be vectors, matrices, or multidimensional arrays that all have the same size. A scalar input is expanded to a constant array with the same dimensions of the other inputs. The parameters in A and B must all be positive, and the values in X must lie on the interval [ 0,1 ].

The beta probability density function for a given value $x$ and given pair of parameters $a$ and $b$ is

$$
y=f(x \mid a, b)=\frac{1}{B(a, b)} x^{a-1}(1-x)^{b-1} I_{(0,1)}(x)
$$

where $B(\cdot)$ is the Beta function. The indicator function $I_{(0,1)}(x)$ ensures that only values of $x$ in the range ( 01 ) have nonzero probability. The uniform distribution on (01) is a degenerate case of the beta pdf where $a=1$ and $b=1$.

A likelihood function is the pdf viewed as a function of the parameters. Maximum likelihood estimators (MLEs) are the values of the parameters that maximize the likelihood function for a fixed value of $x$.

## Examples

```
a = [0.5 1; 2 4]
a =
    0.5000 1.0000
    2.0000 4.0000
y = betapdf(0.5,a,a)
y =
    0.6366 1.0000
    1.5000 2.1875
```

- "Beta Distribution" on page B-4

## betarnd

## Purpose Beta random numbers

Syntax $\quad$| $R$ | $=\operatorname{betarnd}(A, B)$ |
| ---: | :--- |
| $R$ | $=\operatorname{betarnd}(A, B, m, n, \ldots)$ |
| $R$ | $=\operatorname{betarnd}(A, B,[m, n, \ldots])$ |

$R=$ betarnd $(A, B)$ generates random numbers from the beta distribution with parameters specified by A and B. A and B can be vectors, matrices, or multidimensional arrays that have the same size, which is also the size of R. A scalar input for A or B is expanded to a constant array with the same dimensions as the other input.
$R=\operatorname{betarnd}(A, B, m, n, \ldots)$ or $R=$ betarnd(A,B,[m,n,...]) generates an $m$-by-n-by-... array containing random numbers from the beta distribution with parameters A and B. A and B can each be scalars or arrays of the same size as R.

## Examples

```
a = [1 1;2 2];
b = [1 2;1 2];
r = betarnd(a,b)
r =
    0.6987 0.6139
    0.9102 0.8067
r = betarnd(10,10,[1 5])
r =
    0.5974 0.4777 0.5538
r = betarnd(4,2,2,3)
r =
    0.3943 0.6101 0.5768

## betastat

Purpose Beta mean and variance

## Syntax $\quad[M, V]=\operatorname{betastat}(A, B)$

Description $[M, V]=$ betastat $(A, B)$, with $A>0$ and $B>0$, returns the mean of and variance for the beta distribution with parameters specified by $A$ and B. A and B can be vectors, matrices, or multidimensional arrays that have the same size, which is also the size of M and V . A scalar input for $A$ or $B$ is expanded to a constant array with the same dimensions as the other input.

The mean of the beta distribution with parameters $a$ and $b$ is $a /(a+b)$ and the variance is

$$
\frac{a b}{(a+b+1)(a+b)^{2}}
$$

## Examples

If parameters $a$ and $b$ are equal, the mean is $1 / 2$.

```
a = 1:6;
[m,v] = betastat(a,a)
m =
    0.5000}00.5000 0.5000 0.5000 0.5000 0.5000
v =
    0.0833 0.0500
```

## prob.BinomialDistribution

Superclasses ToolboxFittableParametricDistribution
Purpose Binomial probability distribution object
Description prob.BinomialDistribution is an object consisting of parameters, a model description, and sample data for a binomial probability distribution.

Create a probability distribution object with specified parameter values using makedist. Alternatively, fit a distribution to data using fitdist or dfittool.

## Construction

pd = makedist('Binomial') creates a binomial probability distribution object using the default parameter values.
pd = makedist('Binomial', 'N', $n$, ' p ', p ) creates a binomial probability distribution object using the specified parameter values.

## Input Arguments

## n - Number of trials

1 (default) | positive integer value
Number of trials for the binomial distribution, specified as a positive integer value.

```
Data Types
single | double
```

## p - Probability of success

0.5 (default) | positive scalar value in the range [0,1]

Probability of success of any individual trial for the binomial distribution, specified as a positive scalar value in the range $[0,1]$.

Data Types<br>single | double

## Properties

 NNumber of trials for the binomial distribution, stored as a positive integer value.

## Data Types

single | double

## p

Probability of success of any individual trial for the binomial distribution, stored as a positive scalar value in the range $[0,1]$.

## Data Types

single | double

## DistributionName

Name of the probability distribution, stored as a valid probability distribution name string. This property is read-only.

## Data Types

char

## InputData

Data used for distribution fitting, stored as a structure containing the following:

- data: Data vector used for distribution fitting.
- cens: Censoring vector, or empty if none.
- freq: Frequency vector, or empty if none.

This property is read-only.
Data Types
single | double
IsTruncated
Logical flag for truncated distribution, stored as a logical value. If IsTruncated equals 0 , the distribution is not truncated.

## prob.BinomialDistribution

If IsTruncated equals 1 , the distribution is truncated. This property is read-only.

## Data Types

logical

## NumParameters

Number of parameters for the probability distribution, stored as a positive integer value. This property is read-only.

## Data Types <br> single | double

## ParameterCovariance

Covariance matrix of the parameter estimates, stored as a $p$-by- $p$ matrix, where $p$ is the number of parameters in the distribution. The ( $\mathrm{i}, \mathrm{j}$ ) element is the covariance between the estimates of the $i$ th parameter and the $j$ th parameter. The ( $i, i$ ) element is the estimated variance of the ith parameter. If parameter $i$ is fixed rather than estimated by fitting the distribution to data, then the (i,i) elements of the covariance matrix are 0 . This property is read-only.

## Data Types

single | double

## ParameterDescription

Descriptions of distribution parameters, stored as a cell array of strings. Each cell contains a short description of one distribution parameter. This property is read-only.

## Data Types <br> char

## Parameterlsfixed

Logical flag for fixed parameters, stored as an array of logical values. If 0 , the corresponding parameter in the ParameterNames array is not fixed. If 1 , the corresponding parameter in the ParameterNames array is fixed. This property is read-only.

## Data Types

logical

## ParameterNames

Names of distribution parameters, stored as a cell array of strings. This property is read-only.

## Data Types

char

## ParameterValues

Values of distribution parameters, stored as a vector. This property is read-only.

## Definitions Binomial Distribution

The binomial distribution models the total number of successes in repeated trials from an infinite population under the following conditions:

- Only two outcomes are possible for each of $n$ trials.
- The probability of success for each trial is constant.
- All trials are independent of each other.

The binomial distribution uses the following parameters.

| Parameter | Description | Support |
| :--- | :--- | :--- |
| N | Number of trials | positive integer |
| p | Probability of success | $0 \leq p \leq 1$ |

The probability density function (pdf) is

$$
f(x \mid n, p)=\binom{n}{x} p^{x}(1-p)^{n-x} \quad ; \quad x=0,1,2, \ldots, n
$$

where $x$ is the number of successes in $n$ trials of a Bernoulli process with probability of success $p$.

## Examples

## Create a Binomial Distribution Object Using Default Parameters

Create a binomial distribution object using the default parameter values.

## Concepts <br> - "Binomial Distribution" on page B-7

- "Bernoulli Distribution" on page B-3
- Class Attributes
- Property Attributes

## Purpose

## Syntax

Description

## Examples

Binomial cumulative distribution function
$Y=\operatorname{binocdf}(X, N, P)$
$Y=\operatorname{binocdf}(X, N, P)$ computes a binomial cdf at each of the values in $X$ using the corresponding number of trials in $N$ and probability of success for each trial in P. X, N, and P can be vectors, matrices, or multidimensional arrays that are all the same size. A scalar input is expanded to a constant array with the same dimensions of the other inputs. The values in $N$ must all be positive integers, the values in $X$ must lie on the interval $[0, N]$, and the values in $P$ must lie on the interval $[0,1]$.

The binomial cdf for a given value $x$ and a given pair of parameters $n$ and $p$ is

$$
y=F(x \mid n, p)=\sum_{i=0}^{x}\binom{n}{i} p^{i}(1-p)^{(n-i)} I_{(0,1, \ldots, n)}(i)
$$

The result, $y$, is the probability of observing up to $x$ successes in $n$ independent trials, where the probability of success in any given trial is $p$. The indicator function $I_{(0,1, \ldots, n)}(i)$ ensures that $x$ only adopts values of $0,1, \ldots, n$.

If a baseball team plays 162 games in a season and has a 50-50 chance of winning any game, then the probability of that team winning more than 100 games in a season is:

1 - binocdf(100,162,0.5)
The result is 0.001 (i.e., $1-0.999$ ). If a team wins 100 or more games in a season, this result suggests that it is likely that the team's true probability of winning any game is greater than 0.5 .

[^3]
## binocdf

How To . "Binomial Distribution" on page B-7

Purpose
Syntax

Description

Binomial parameter estimates
phat = binofit(x, n)
[phat,pci] = binofit(x,n)
[phat,pci] = binofit(x, n,alpha)
phat $=$ binofit $(x, n)$ returns a maximum likelihood estimate of the probability of success in a given binomial trial based on the number of successes, $x$, observed in $n$ independent trials. If $x=(x(1), x(2)$, $\ldots x(k))$ is a vector, binofit returns a vector of the same size as x whose ith entry is the parameter estimate for $\mathrm{x}(\mathrm{i})$. All k estimates are independent of each other. If $n=(n(1), n(2), \ldots, n(k))$ is a vector of the same size as $x$, the binomial fit, binofit, returns a vector whose ith entry is the parameter estimate based on the number of successes $x$ (i) in $n(i)$ independent trials. A scalar value for $x$ or $n$ is expanded to the same size as the other input.
[phat, pci] = binofit(x,n) returns the probability estimate, phat, and the $95 \%$ confidence intervals, pci. binofit uses the Clopper-Pearson method to calculate confidence intervals.
[phat,pci] = binofit(x,n,alpha) returns the 100(1-alpha)\% confidence intervals. For example, alpha $=0.01$ yields $99 \%$ confidence intervals.

Note binofit behaves differently than other Statistics Toolbox functions that compute parameter estimates, in that it returns independent estimates for each entry of $x$. By comparison, expfit returns a single parameter estimate based on all the entries of $x$.

Unlike most other distribution fitting functions, the binofit function treats its input $x$ vector as a collection of measurements from separate samples. If you want to treat $x$ as a single sample and compute a single parameter estimate for it, you can use binofit (sum (x), sum(n)) when n is a vector, and binofit (sum ( X$), \mathrm{N} *$ length $(\mathrm{X})$ ) when n is a scalar.

## binofit

```
Examples This example generates a binomial sample of 100 elements, where the probability of success in a given trial is 0.6 , and then estimates this probability from the outcomes in the sample.
\(r=\) binornd(100,0.6);
[phat,pci] = binofit(r,100)
phat \(=\)
0.5800
pci \(=\)
\(0.4771 \quad 0.6780\)
```

The $95 \%$ confidence interval, pci, contains the true value, 0.6 .

```

How To . "Binomial Distribution" on page B-7

## binopdf

## Purpose Binomial probability density function

## Syntax $\quad Y=\operatorname{binopdf}(X, N, P)$

Description

Examples
$Y=$ binopdf( $X, N, P$ ) computes the binomial pdf at each of the values in $X$ using the corresponding number of trials in $N$ and probability of success for each trial in P. Y, N, and P can be vectors, matrices, or multidimensional arrays that all have the same size. A scalar input is expanded to a constant array with the same dimensions of the other inputs.

The parameters in $N$ must be positive integers, and the values in $P$ must lie on the interval $[0,1]$.

The binomial probability density function for a given value $x$ and given pair of parameters $n$ and $p$ is

$$
y=f(x \mid n, p)=\binom{n}{x} p^{x} q^{(n-x)} I_{(0,1, \ldots, n)}(x)
$$

where $q=1-p$. The result, $y$, is the probability of observing $x$ successes in $n$ independent trials, where the probability of success in any given trial is $p$. The indicator function $I_{(0,1, \ldots, n)}(x)$ ensures that $x$ only adopts values of $0,1, \ldots, n$.

A Quality Assurance inspector tests 200 circuit boards a day. If $2 \%$ of the boards have defects, what is the probability that the inspector will find no defective boards on any given day?
binopdf(0,200, 0.02)
ans =
0.0176

What is the most likely number of defective boards the inspector will find?
defects=0:200;
y = binopdf(defects,200,.02);

## binopdf

```
[x,i]=max(y);
defects(i)
ans =
    4
```

## binostat

Purpose Binomial mean and variance

$$
\text { Syntax } \quad[M, V]=\text { binostat }(N, P)
$$

Description
$[M, V]=$ binostat $(N, P)$ returns the mean of and variance for the binomial distribution with parameters specified by the number of trials, N , and probability of success for each trial, P. N and P can be vectors, matrices, or multidimensional arrays that have the same size, which is also the size of M and V . A scalar input for N or P is expanded to a constant array with the same dimensions as the other input.

The mean of the binomial distribution with parameters $n$ and $p$ is $n p$. The variance is $n p q$, where $q=1-p$.

## Purpose Biplot

$\begin{array}{ll}\text { Syntax } & \text { biplot(coefs) } \\ & h=\operatorname{biplot}(\operatorname{coefs}, \text { 'Name' }, \text { Value })\end{array}$
Description

Input
Arguments
biplot (coefs) creates a biplot of the coefficients in the matrix coefs. The biplot is 2-D if coefs has two columns or 3-D if it has three columns. coefs usually contains principal component coefficients created with pca, pcacov, or factor loadings estimated with factoran. The axes in the biplot represent the principal components or latent factors (columns of coefs), and the observed variables (rows of coefs) are represented as vectors.

A biplot allows you to visualize the magnitude and sign of each variable's contribution to the first two or three principal components, and how each observation is represented in terms of those components.
biplot imposes a sign convention, forcing the element with largest magnitude in each column of coefs to be positive. This flips some of the vectors in coefs to the opposite direction, but often makes the plot easier to read. Interpretation of the plot is unaffected, because changing the sign of a coefficient vector does not change its meaning.
biplot scales the scores so that they fit on the plot: It divides each score by the maximum absolute value of all scores, and multiplies by the maximum coefficient length of coefs. Then biplot changes the sign of score coordinates according to the sign convention for the coefs.
h = biplot(coefs,'Name', Value) specifies one or more name/value input pairs and returns a column vector of handles to the graphics objects created by biplot. The h contains, in order, handles corresponding to variables (line handles, followed by marker handles, followed by text handles), to observations (if present, marker handles followed by text handles), and to the axis lines.

## Name-Value Pair Arguments

## 'Scores'

## biplot

Plots both coefs and the scores in the matrix scores in the biplot. scores usually contains principal component scores created with pca or factor scores estimated with factoran. Each observation (row of scores) is represented as a point in the biplot.

## 'VarLabels'

Labels each vector (variable) with the text in the character array or cell array varlabels.

## 'ObsLabels'

Uses the text in the character array or cell array obslabels as observation names when displaying data cursors.

## 'Positive'

- 'true ' - restricts the biplot to the positive quadrant (in 2-D) or octant (in 3-D).
- 'false' - makes the biplot over the range +/- max (coefs(:)) for all coordinates.

## Default: false

## 'PropertyName'

Specifies optional property name/value pairs for all line graphics objects created by biplot.

## Examples

Perform a principal component analysis of the data in carsmall.mat:

```
load carsmall
x = [Acceleration Displacement Horsepower MPG Weight];
x = x(all(~isnan(x),2),:);
[coefs,score] = pca(zscore(x));
```

View the data and the original variables in the space of the first three principal components:

```
vbls = {'Accel','Disp','HP','MPG','Wgt'};
biplot(coefs(:,1:3),'scores',score(:,1:3),\ldots
```

## prob.BirnbaumSaundersDistribution

Superclasses ToolboxFittableParametricDistribution
Purpose Birnbaum-Saunders probability distribution object
Description prob.BirnbaumSaundersDistribution is an object consisting of parameters, a model description, and sample data for a Birnbaum-Saunders probability distribution.
Create a probability distribution object with specified parameter values using makedist. Alternatively, fit a distribution to data using fitdist or dfittool.

## Construction

pd = makedist('BirnbaumSaunders') creates a Birnbaum-Saunders probability distribution object using the default parameter values.
pd = makedist('BirnbaumSaunders','beta', beta, 'gamma', gamma) creates a Birnbaum-Saunders distribution object using the specified parameter values.

## Input Arguments

## beta-Scale parameter

1 (default) | positive scalar value
Scale parameter of the Birnbaum-Saunders distribution, specified as a positive scalar value.
Data Types
single | double
gamma-Shape parameter
1 (default) | nonnegative scalar value
Shape parameter of the Birnbaum-Saunders distribution, specified as a nonnegative scalar value.

Data Types<br>single | double

## Properties

## beta

Scale parameter of the Birnbaum-Saunders distribution, stored as a positive scalar value.

## Data Types

single | double

## gamma

Shape parameter of the Birnbaum-Saunders distribution, stored as a nonnegative scalar value.

## Data Types

single | double

## DistributionName

Name of the probability distribution, stored as a valid probability distribution name string. This property is read-only.

## Data Types

char

## InputData

Data used for distribution fitting, stored as a structure containing the following:

- data: Data vector used for distribution fitting.
- cens: Censoring vector, or empty if none.
- freq: Frequency vector, or empty if none.

This property is read-only.

## Data Types

single | double

## IsTruncated

Logical flag for truncated distribution, stored as a logical value. If IsTruncated equals 0 , the distribution is not truncated.

## prob.BirnbaumSaundersDistribution

If IsTruncated equals 1 , the distribution is truncated. This property is read-only.

## Data Types

logical

## NumParameters

Number of parameters for the probability distribution, stored as a positive integer value. This property is read-only.

## Data Types <br> single | double

## ParameterCovariance

Covariance matrix of the parameter estimates, stored as a $p$-by- $p$ matrix, where $p$ is the number of parameters in the distribution. The ( $\mathrm{i}, \mathrm{j}$ ) element is the covariance between the estimates of the $i$ th parameter and the $j$ th parameter. The ( $i, i$ ) element is the estimated variance of the ith parameter. If parameter $i$ is fixed rather than estimated by fitting the distribution to data, then the (i,i) elements of the covariance matrix are 0 . This property is read-only.

## Data Types

single | double

## ParameterDescription

Descriptions of distribution parameters, stored as a cell array of strings. Each cell contains a short description of one distribution parameter. This property is read-only.

## Data Types <br> char

## Parameterlsfixed

Logical flag for fixed parameters, stored as an array of logical values. If 0 , the corresponding parameter in the ParameterNames array is not fixed. If 1 , the corresponding parameter in the ParameterNames array is fixed. This property is read-only.

# prob.BirnbaumSaundersDistribution 

## Data Types

logical

## ParameterNames

Names of distribution parameters, stored as a cell array of strings. This property is read-only.

## Data Types

char

## ParameterValues

Values of distribution parameters, stored as a vector. This property is read-only.

## Data Types

single | double

## Truncation

Truncation interval for the probability distribution, stored as a vector containing the lower and upper truncation boundaries. This property is read-only.

## Data Types

single | double

## Methods Inherited Methods

## Definitions Birnbaum-Saunders Distribution

The Birnbaum-Saunders distribution was originally proposed as a lifetime model for materials subject to cyclic patterns of stress and strain, where the ultimate failure of the material comes from the growth of a prominent flaw. It is also called the fatigue life distribution.

The Birnbaum-Saunders distribution uses the following parameters.

# prob.BirnbaumSaundersDistribution 

| Parameter | Description | Support |
| :--- | :--- | :--- |
| beta | Scale parameter | $\beta>0$ |
| gamma | Shape parameter | $\gamma \geq 0$ |

The probability density function (pdf) is

$$
f(x \mid \beta, \gamma)=\frac{1}{\sqrt{2 \pi}} \exp \left\{-\frac{\left(\sqrt{\frac{x}{\beta}}-\sqrt{\frac{\beta}{x}}\right)^{2}}{2 \gamma^{2}}\right\}\left(\left(\frac{\left(\sqrt{\frac{x}{\beta}}-\sqrt{\frac{\beta}{x}}\right)}{2 \gamma x}\right) ; x>0 .\right.
$$

## Examples Create a Birnbaum-Saunders Distribution Object Using Default Parameters

Create a Birnbaum-Saunders distribution object using the default parameter values.

```
pd = makedist('BirnbaumSaunders')
```

pd $=$
BirnbaumSaundersDistribution
Birnbaum-Saunders distribution
beta = 1 gamma $=1$

## Create a Birnbaum-Saunders Distribution Object Using Specified Parameter Values

Create a Birnbaum-Saunders distribution object by specifying the parameter values.

```
pd = makedist('BirnbaumSaunders','beta',2,'gamma',5)
```

## prob.BirnbaumSaundersDistribution

$\mathrm{pd}=$

BirnbaumSaundersDistribution

```
Birnbaum-Saunders distribution
        beta = 2
        gamma = 5
```

Compute the mean of the distribution.
$m=\operatorname{mean}(p d)$
$m=$

| Purpose | Bootstrap confidence interval |
| :---: | :---: |
| Syntax | ```ci = bootci(nboot,bootfun,...) ci = bootci(nboot,{bootfun,...},'alpha',alpha) ci = bootci(nboot,{bootfun,...},...,'type',type) ci = bootci(nboot,{bootfun,...},...,'type','student', 'nbootstd',nbootstd) ci = bootci(nboot,{bootfun,...},...,'type','student','stderr', stderr) ci = bootci(nboot,{bootfun,...},...,'Weights',weights) ci = bootci(nboot,{bootfun,...},...,'Options',options) [ci,bootstat] = bootci(...)``` |
| Description | ci $=$ bootci(nboot, bootfun,...) computes the $95 \%$ bootstrap confidence interval of the statistic computed by the function bootfun. nooot is a positive integer indicating the number of bootstrap samples used in the computation. bootfun is a function handle specified with @. The third and later input arguments to bootci are data (scalars, column vectors, or matrices) that are used to create inputs to bootfun. bootci creates each bootstrap sample by sampling with replacement from the rows of the non-scalar data arguments (these must have the same number of rows). Scalar data are passed to bootfun unchanged. |
|  | If bootfun returns a scalar, ci is a vector containing the lower and upper bounds of the confidence interval. If bootfun returns a vector of length $m$, ci is an array of size 2 -by- $m$, where $\mathrm{ci}(1,:)$ are lower bounds and $\mathrm{ci}(2,:)$ are upper bounds. If bootfun returns an array of size $m$-by- $n$-by- $p$-by-..., ci is an array of size 2 -by- $m$-by- $n$-by- $p$-by-..., where $\mathrm{ci}(1,:,:,:, \ldots)$ is an array of lower bounds and ci(2,:,:,:,,..) is an array of upper bounds. |
|  | ci $=$ bootci(nboot, \{bootfun, $\ldots$, ,'alpha', alpha) computes the 100* ( 1 -alpha) bootstrap confidence interval of the statistic defined by the function bootfun. bootfun and the data that bootci passes to it are contained in a single cell array. alpha is a scalar between 0 and 1 . The default value of alpha is 0.05 . |

ci = bootci(nboot,\{bootfun,...\},...,'type',type) computes the bootstrap confidence interval of the statistic defined by the function bootfun. type is the confidence interval type, chosen from among the following strings:

- 'norm' or 'normal' - Normal approximated interval with bootstrapped bias and standard error.
- 'per' or 'percentile' - Basic percentile method.
- 'cper' or 'corrected percentile' - Bias corrected percentile method.
- 'bca' - Bias corrected and accelerated percentile method. This is the default.
- 'stud' or 'student' - Studentized confidence interval.
ci $=$
bootci(nboot,\{bootfun,...\},..., 'type','student', 'nbootstd', nbootstd)
computes the studentized bootstrap confidence interval of the statistic
defined by the function bootfun. The standard error of the
bootstrap statistics is estimated using bootstrap, with nbootstd bootstrap data samples. nbootstd is a positive integer value. The default value of nbootstd is 100 .
ci $=$
bootci(nboot, \{bootfun,...\},...,'type','student', 'stderr',stderr)
computes the studentized bootstrap confidence interval of statistics
defined by the function bootfun. The standard error of the bootstrap statistics is evaluated by the function stderr. stderr is a function handle. stderr takes the same arguments as bootfun and returns the standard error of the statistic computed by bootfun.
ci = bootci(nboot,\{bootfun, ...\},...,'Weights', weights) specifies observation weights. weights must be a vector of non-negative numbers with at least one positive element. The number of elements in weights must be equal to the number of rows in non-scalar input arguments to bootfun. To obtain one bootstrap replicate, bootstrp samples $N$ out of $N$ with replacement using these weights as multinomial sampling probabilities.
ci = bootci(nboot,\{bootfun,...\},...,'Options',options) specifies options that govern the computation of bootstrap iterations. One option requests that bootci perform bootstrap iterations using multiple processors, if the Parallel Computing Toolbox is available. Two options specify the random number streams to be used in bootstrap resampling. This argument is a struct that you can create with a call to statset. You can retrieve values of the individual fields with a call to statget. Applicable statset parameters are:
- 'UseParallel' - If true and if a matlabpool of the Parallel Computing Toolbox is open, compute bootstrap iterations in parallel. If the Parallel Computing Toolbox is not installed, or a matlabpool is not open, computation occurs in serial mode. Default is false, or serial computation.
- UseSubstreams - Set to true to compute in parallel in a reproducible fashion. Default is false. To compute reproducibly, set Streams to a type allowing substreams: 'mlfg6331_64' or 'mrg32k3a'.
- Streams - A RandStream object or cell array of such objects. If you do not specify Streams, bootci uses the default stream or streams. If you choose to specify Streams, use a single object except in the case
- You have an open MATLAB pool
- UseParallel is true
- UseSubstreams is false

In that case, use a cell array the same size as the MATLAB pool.
[ci,bootstat] = bootci(...) also returns the bootstrapped statistic computed for each of the nboot bootstrap replicate samples. Each row of bootstat contains the results of applying bootfun to one bootstrap sample. If bootfun returns a matrix or array, then this output is converted to a row vector for storage in bootstat.

## Examples

Compute the confidence interval for the capability index in statistical process control:

[^4]
## bootci

```
LSL = -3; USL = 3; % Process specifications
capable = @(x)(USL-LSL)./(6* std(x)); % Process capability
ci = bootci(2000,capable,y) % BCa confidence interval
Ci =
    0.8122
    1.2657
sci = bootci(2000,{capable,y},'type','student') % Studentized ci
sci =
    0.7739
    1.2707
```

See Also
bootstrp | jackknife | statget | statset | randsample | parfor

Bootstrap sampling

```
bootstat = bootstrp(nboot,bootfun,d1,...)
[bootstat,bootsam] = bootstrp(...)
bootstat = bootstrp(...,'Name',Value)
```

bootstat $=$ bootstrp(nboot, bootfun, d1, ...) draws nboot bootstrap data samples, computes statistics on each sample using bootfun, and returns the results in the matrix bootstat. nboot must be a positive integer. bootfun is a function handle specified with @. Each row of bootstat contains the results of applying bootfun to one bootstrap sample. If bootfun returns a matrix or array, then this output is converted to a row vector for storage in bootstat.

The third and later input arguments ( $\mathrm{d} 1, \ldots$ ) are data (scalars, column vectors, or matrices) used to create inputs to bootfun. bootstrp creates each bootstrap sample by sampling with replacement from the rows of the non-scalar data arguments (these must have the same number of rows). bootfun accepts scalar data unchanged.
[bootstat, bootsam] = bootstrp(...) returns an n-by-nboot matrix of bootstrap indices, bootsam. Each column in bootsam contains indices of the values that were drawn from the original data sets to constitute the corresponding bootstrap sample. For example, if $\mathrm{d} 1, \ldots$ each contain 16 values, and nboot $=4$, then bootsam is a 16 -by- 4 matrix. The first column contains the indices of the 16 values drawn from $\mathrm{d} 1, \ldots$, for the first of the four bootstrap samples, the second column contains the indices for the second of the four bootstrap samples, and so on. (The bootstrap indices are the same for all input data sets.) To get the output samples bootsam without applying a function, set bootfun to empty ([]).
bootstat $=$ bootstrp(...,'Name', Value) uses additional arguments specified by one or more Name, Value pair arguments. The name-value pairs must appear after the data arguments. The available name-value pairs:

- 'Weights' - Observation weights. The weights value must be a vector of nonnegative numbers with at least one positive element.

The number of elements in weights must be equal to the number of rows in non-scalar input arguments to bootstrp. To obtain one bootstrap replicate, bootstrp samples $N$ out of $N$ with replacement using these weights as multinomial sampling probabilities.

- 'Options' - The value is a structure that contains options specifying whether to compute bootstrap iterations in parallel, and specifying how to use random numbers during the bootstrap sampling. Create the options structure with statset. Applicable statset parameters are:
- 'UseParallel' - If true and if a matlabpool of the Parallel Computing Toolbox is open, compute bootstrap iterations in parallel. If the Parallel Computing Toolbox is not installed, or a matlabpool is not open, computation occurs in serial mode. Default is false, meaning serial computation.
- UseSubstreams - Set to true to compute in parallel in a reproducible fashion. Default is false. To compute reproducibly, set Streams to a type allowing substreams: 'mlfg6331_64' or 'mrg32k3a'.
- Streams - A RandStream object or cell array of such objects. If you do not specify Streams, bootstrp uses the default stream or streams. If you choose to specify Streams, use a single object except in the case
- You have an open MATLAB pool
- UseParallel is true
- UseSubstreams is false

In that case, use a cell array the same size as the MATLAB pool.

## Examples

## Bootstrapping a Correlation Coefficient Standard Error

Load a data set containing the LSAT scores and law-school GPA for 15 students. These 15 data points are resampled to create 1000 different data sets, and the correlation between the two variables is computed for each data set.

```
load lawdata
[bootstat,bootsam] = bootstrp(1000,@corr,lsat,gpa);
```

Display the first 5 bootstrapped correlation coefficients.

```
bootstat(1:5,:)
ans =
    0.6600
    0.7969
    0.5807
    0.8766
    0.9197
```

Display the indices of the data selected for the first 5 bootstrap samples.

| 9 | 8 | 15 | 11 | 15 |
| :---: | :---: | :---: | :---: | :---: |
| 14 | 7 | 6 | 7 | 14 |
| 4 | 6 | 10 | 3 | 11 |
| 3 | 10 | 11 | 9 | 2 |
| 15 | 4 | 13 | 4 | 14 |
| 9 | 4 | 5 | 2 | 10 |
| 8 | 5 | 4 | 3 | 13 |
| 1 | 9 | 1 | 15 | 11 |
| 10 | 8 | 6 | 12 | 3 |
| 1 | 4 | 5 | 2 | 8 |
| 1 | 1 | 10 | 6 | 2 |
| 3 | 10 | 15 | 10 | 8 |
| 14 | 6 | 10 | 3 | 8 |
| 13 | 12 | 1 | 2 | 4 |
| 12 | 6 | 4 | 9 | 8 |
| hist(bo | stat |  |  |  |

## bootstrp

The histogram shows the variation of the correlation coefficient across all the bootstrap samples. The sample minimum is positive, indicating that the relationship between LSAT score and GPA is not accidental.

Finally, compute a bootstrap standard of error for the estimated correlation coefficient.

```
se = std(bootstat)
se =
    0.1327
```

## Estimating the Density of Bootstrapped Statistic

Compute a sample of 100 bootstrapped means of random samples taken from the vector Y , and plot an estimate of the density of these bootstrapped means:

```
y = exprnd(5,100,1);
m = bootstrp(100,@mean,y);
[fi,xi] = ksdensity(m);
plot(xi,fi);
```

## bootstrp

## Bootstrapping More Than One Statistic

Compute a sample of 100 bootstrapped means and standard deviations of random samples taken from the vector Y , and plot the bootstrap estimate pairs:

```
y = exprnd(5,100,1);
stats = bootstrp(100,@(x)[mean(x) std(x)],y);
plot(stats(:,1),stats(:,2),'o')
```

## Bootstrapping a Regression Model

Estimate the standard errors for a coefficient vector in a linear regression by bootstrapping residuals:

```
load hald
x = [ones(size(heat)),ingredients];
y = heat;
b = regress(y,x);
yfit = x*b;
resid = y - yfit;
se = std(bootstrp(...
    1000,@(bootr)regress(yfit+bootr,x),resid));
```

See Also hist | bootci | ksdensity | parfor | random | randsample | RandStream | statget | statset

## boxplot

| Purpose | Box plot |
| :--- | :--- |
| Syntax | boxplot $(X)$ <br>  <br> boxplot $(X, G)$ <br>  <br>  <br>  <br>  <br>  <br>  <br>  |

boxplot $(X)$ produces a box plot of the data in $X$. If $X$ is a matrix, there is one box per column; if $X$ is a vector, there is just one box. On each box, the central mark is the median, the edges of the box are the 25th and 75 th percentiles, the whiskers extend to the most extreme data points not considered outliers, and outliers are plotted individually. For controlling how much the whiskers extend, see the 'whiskers' name-value pair argument.
boxplot $(X, G)$ specifies one or more grouping variables $G$, producing a separate box for each set of $X$ values sharing the same $G$ value or values. Grouping variables must have one row per element of $X$, or one row per column of $X$. Specify a single grouping variable in $G$ using a vector, a character array, a cell array of strings, or a vector categorical array; specify multiple grouping variables in $G$ using a cell array of these variable types, such as \{G1 G2 G3\}, or by using a matrix. If multiple grouping variables are used, they must all be the same length. Groups that contain a NaN value or an empty string in a grouping variable are omitted, and are not counted in the number of groups considered by other parameters.

By default, character and string grouping variables are sorted in the order they initially appear in the data, categorical grouping variables are sorted by the order of their levels, and numeric grouping variables are sorted in numeric order. To control the order of groups, do one of the following:

- Use categorical variables in $G$ and specify the order of their levels.
- Use the 'grouporder' parameter described below.
- Pre-sort your data.
boxplot (axes, $\mathrm{X}, \ldots$ ) creates the plot in the axes with handle axes.

## boxplot

boxplot(..., 'Name', value) specifies one or more optional parameter name/value pairs, as described in the following table. Specify Name in single quotes.

| Name | Value |
| :---: | :---: |
| plotstyle' | - 'traditional' - Traditional box style. This is the default. <br> - 'compact' - Box style designed for plots with many groups. This style changes the defaults for some other parameters, as described in the following table. |
| 'boxstyle' | - 'outline' - Draws an unfilled box with dashed whiskers. This is the default. <br> - 'filled ' - Draws a narrow filled box with lines for whiskers. |
| 'colorgroup ' | One or more grouping variables, of the same type as permitted for $G$, specifying that the box color should change when the specified variables change. The default is [ ] for no box color change. |
| 'colors' | Colors for boxes, specified as a single color (such as ' $r$ ' or [ $\left.\begin{array}{lll}1 & 0 & 0\end{array}\right]$ ) or multiple colors (such as 'rgbm' or a three-column matrix of RGB values). The sequence is replicated or truncated as required, so for example 'rb' gives boxes that alternate in color. The default when no 'colorgroup' is specified is to use the same color scheme for all boxes. The default when 'colorgroup' is specified is a modified hsv colormap. |

## boxplot

| Name | Value |
| :--- | :--- |
| 'datalim' | A two-element vector containing lower and <br> upper limits, used by 'extrememode' to <br> determine which points are extreme. The <br> default is [ - Inf Inf]. |
| 'extrememode' | - 'clip' - Moves data outside the datalim <br> limits to the limit. This is the default. <br> - ' compress' - Evenly distributes data <br> outside the datalim limits in a region just <br> outside the limit, retaining the relative <br> order of the points. |
| A dotted line marks the limit if any points |  |
| are outside it, and two gray lines mark |  |
| the compression region if any points are |  |
| compressed. Values at +/-Inf can be clipped |  |
| or compressed, but NaN values still do not |  |
| appear on the plot. Box notches are drawn to |  |
| scale and may extend beyond the bounds if the |  |
| median is inside the limit; they are not drawn |  |
| if the median is outside the limits. |  |

## boxplot

| Name | Value <br> 'fullfactors' <br> - 'off' — One group for each unique row of <br> - 'on' — Create a group for each possible <br> combination of group variable values, <br> including combinations that do not appear <br> in the data. |
| :--- | :--- |
| 'factorseparator' | Specifies which factors should have their <br> values separated by a grid line. The value <br> may be 'auto' or a vector of grouping variable <br> numbers. For example, [1 2] adds a separator <br> line when the first or second grouping variable <br> changes value. 'auto' is [ ] for one grouping <br> variable and [1] for two or more grouping <br> variables. The default is [ ]. |
| 'factorgap' | Specifies an extra gap to leave between boxes <br> when the corresponding grouping factor <br> changes value, expressed as a percentage of <br> the width of the plot. For example, with [3 1], <br> the gap is 3\% of the width of the plot between <br> groups with different values of the first <br> grouping variable, and 1\% between groups <br> with the same value of the first grouping <br> variable but different values for the second. <br> 'auto' specifies that boxplot should choose a <br> gap automatically. The default is [ ]. |
| 'grouporder' | Order of groups for plotting, specified as a <br> cell array of strings. With multiple grouping <br> variables, separate values within each string <br> with a comma. Using categorical arrays as <br> grouping variables is an easier way to control <br> the order of the boxes. The default is [ ], which <br> does not reorder the boxes. |

## boxplot

| Name | Value |
| :---: | :---: |
| 'jitter' | Maximum distance $d$ to displace outliers along the factor axis by a uniform random amount, in order to make duplicate points visible. A $d$ of 1 makes the jitter regions just touch between the closest adjacent groups. The default is 0 . |
| 'labels' | A character array, cell array of strings, or numeric vector of box labels. There may be one label per group or one label per X value. Multiple label variables may be specified via a numeric matrix or a cell array containing any of these types. |
|  | Tip To remove labels from a plot, use the following command: <br> set(gca,'XTickLabel', \{' '\}) |
| 'labelorientation' | - 'inline ' - Rotates the labels to be vertical. This is the default when plotstyle is 'compact'. <br> - 'horizontal' - Leaves the labels horizontal. This is the default when plotstyle has the default value of 'traditional'. <br> When the labels are on the $y$ axis, both settings leave the labels horizontal. |

| Name | Value |
| :---: | :---: |
| 'labelverbosity' | - 'all' - Displays every label. This is the default. <br> - 'minor' - Displays a label for a factor only when that factor has a different value from the previous group. <br> - 'majorminor' - Displays a label for a factor when that factor or any factor major to it has a different value from the previous group. |
| 'medianstyle' | - 'line ' - Draws a line for the median. This is the default. <br> - 'target' - Draws a black dot inside a white circle for the median. |
| 'notch ' | - 'on' - Draws comparison intervals using notches when plotstyle is 'traditional', or triangular markers when plotstyle is 'compact'. <br> - 'marker' - Draws comparison intervals using triangular markers. <br> - 'off' - Omits notches. This is the default. <br> Two medians are significantly different at the $5 \%$ significance level if their intervals do not overlap. Interval endpoints are the extremes of the notches or the centers of the triangular markers. The extremes correspond to $q_{2}-1.57\left(q_{3}-q_{1}\right) / \operatorname{sqrt}(n)$ and $q_{2}+1.57\left(q_{3}\right.$ $\left.-q_{1}\right) / \operatorname{sqrt}(n)$, where $q_{2}$ is the median (50th percentile), $q_{1}$ and $q_{3}$ are the 25 th and 75 th percentiles, respectively, and $n$ is the number of observations without any NaN values. When |

## boxplot

| Name | Value |
| :---: | :---: |
|  | the sample size is small, notches may extend beyond the end of the box. |
| 'orientation' | - 'vertical' - Plots X on the $y$ axis. This is the default. <br> - 'horizontal' - Plots X on the $x$ axis. |
| 'outliersize' | Size of the marker used for outliers, in points. The default is 6 ( $6 / 72$ inch). |
| 'positions' | Box positions specified as a numeric vector with one entry per group or X value. The default is 1 : numGroups, where numGroups is the number of groups. |
| 'symbol' | Symbol and color to use for outliers, using the same values as the LineSpec parameter in plot. The default is ' $r+$ '. If the symbol is omitted then the outliers are invisible; if the color is omitted then the outliers have the same color as their corresponding box. |
| 'whisker' | Maximum whisker length $w$. The default is a $w$ of 1.5. Points are drawn as outliers if they are larger than $q_{3}+w\left(q_{3}-q_{1}\right)$ or smaller than $q_{1}-w\left(q_{3}-q_{1}\right)$, where $q_{1}$ and $q_{3}$ are the 25th and 75 th percentiles, respectively. The default of 1.5 corresponds to approximately $+/-2.7 \sigma$ and 99.3 coverage if the data are normally distributed. The plotted whisker extends to the adjacent value, which is the most extreme data value that is not an outlier. Set whisker to 0 to give no whiskers and to make every point outside of $q_{1}$ and $q_{3}$ an outlier. |
| 'widths' | A scalar or vector of box widths for when boxstyle is 'outline'. The default is half of the minimum separation between boxes, |

## boxplot

| Name | Value |
| :--- | :--- |
|  | which is 0.5 when the positions argument <br> takes its default value. The list of values is <br> replicated or truncated as necessary. |

When the plotstyle parameter takes the value 'compact', the following default values for other parameters apply.

| Parameter | Default when plotstyle is 'compact' |
| :--- | :--- |
| 'boxstyle' | 'filled' |
| 'factorseparator' | 'auto' |
| 'factorgap' | 'auto' |
| 'jitter' | 0.5 |
| 'labelorientation' | 'inline' |
| 'labelverbosity' | 'majorminor' |
| 'medianstyle' | 'target' |
| 'outliersize' | 4 |
| 'symbol' | 'o' |

You can see data values and group names using the data cursor in the figure window. The cursor shows the original values of any points affected by the datalim parameter. You can label the group to which an outlier belongs using the gname function.

To modify graphics properties of a box plot component, use findobj with the Tag property to find the component's handle. Tag values for box plot components depend on parameter settings, and are listed in the table below.

## boxplot

| Parameter Settings | Tag Values |
| :---: | :---: |
| All settings | - 'Box' <br> - 'Outliers' |
| When 'plotstyle' is 'traditional' | - 'Median' <br> - 'Upper Whisker' <br> - 'Lower Whisker' <br> - 'Upper Adjacent Value' <br> - 'Lower Adjacent Value' |
| When 'plotstyle' is 'compact' | - 'Whisker' <br> - 'MedianOuter' <br> - 'MedianInner' |
| When 'notch' is 'marker' | - 'NotchLo' <br> - 'NotchHi' |

## Examples Example 1

Create a box plot of car mileage, grouped by country:
load carsmall
boxplot(MPG,Origin)

## Example 2

Create notched box plots for two groups of sample data:
$\mathrm{x} 1=\operatorname{normrnd}(5,1,100,1)$;
x2 = normrnd(6,1,100,1);
boxplot([x1, x2],'notch','on')

## boxplot

The difference between the medians of the two groups is approximately 1. Since the notches in the box plot do not overlap, you can conclude, with $95 \%$ confidence, that the true medians do differ.

The following figure shows the box plot for the same data with the length of the whiskers specified as 1.0 times the interquartile range. Points beyond the whiskers are displayed using +.

```
boxplot([x1,x2],'notch','on','whisker',1)
```

## Example 3

A plotstyle of 'compact' is useful for large numbers of groups:
X = randn(100,25);
subplot (2, 1, 1)
boxplot(X)
subplot (2, 1, 2)
boxplot(X,'plotstyle','compact')

## boxplot

## piecewisedistribution.boundary

```
Purpose Piecewise distribution boundaries
Syntax \(\quad \begin{aligned} & {[p, q]=\text { boundary }(o b j)} \\ & {[p, q]=\operatorname{boundary}(o b j, i)}\end{aligned}\)
Description \([p, q]=\) boundary \((o b j)\) returns the boundary points between
segments of the piecewise distribution object, obj. p is a vector of
cumulative probabilities at each boundary. \(q\) is a vector of quantiles at
each boundary.
\([p, q]=\) boundary (obj,i) returns \(p\) and \(q\) for the \(i\) th boundary.
Examples \(\quad\) Fit Pareto tails to a \(t\) distribution at cumulative probabilities 0.1 and
0.9:
\(\mathrm{t}=\operatorname{trnd}(3,100,1)\);
obj = paretotails(t,0.1,0.9);
[p,q] = boundary(obj)
\(p=\)

## Superclasses ToolboxFittableParametricDistribution

## Purpose

Burr probability distribution object
Description prob.BurrDistribution is an object consisting of parameters, a model description, and sample data for a Burr probability distribution.

Create a probability distribution object with specified parameter values using makedist. Alternatively, fit a distribution to data using fitdist or dfittool.

## Construction

pd = makedist('Burr') creates a Burr probability distribution object
using the default parameter values.
pd = makedist('Burr','alpha',alpha,'c', c,'k',k) creates a Burr probability distribution object using the specified parameter values.

## Input Arguments

## alpha-Scale parameter

1 (default) | positive scalar value
Scale parameter of the Burr distribution, specified as a positive scalar value.

## Data Types

single | double

## c- First shape parameter

1 (default) | positive scalar value
First shape parameter of the Burr distribution, specified as a positive scalar value.

## Data Types

single | double
k - Second shape parameter
1 (default) | positive scalar value

## prob.BurrDistribution

Second shape parameter of the Burr distribution, specified as a positive scalar value.

Data Types<br>single | double

## Properties

## alpha

Scale parameter of the Burr distribution, stored as a positive scalar value.

```
Data Types
single | double
```

c
First shape parameter of the Burr distribution, stored as a positive scalar value.

## Data Types <br> single | double

k
Second shape parameter of the Burr distribution, stored as a positive scalar value.

## Data Types <br> single | double

## DistributionName

Name of the probability distribution, stored as a valid probability distribution name string. This property is read-only.

## Data Types <br> char

## InputData

Data used for distribution fitting, stored as a structure containing the following:

- data: Data vector used for distribution fitting.
- cens: Censoring vector, or empty if none.
- freq: Frequency vector, or empty if none.

This property is read-only.

## Data Types

single | double

## IsTruncated

Logical flag for truncated distribution, stored as a logical value.
If IsTruncated equals 0 , the distribution is not truncated.
If IsTruncated equals 1 , the distribution is truncated. This property is read-only.

## Data Types

logical

## NumParameters

Number of parameters for the probability distribution, stored as a positive integer value. This property is read-only.

## Data Types

single | double

## ParameterCovariance

Covariance matrix of the parameter estimates, stored as a $p$-by- $p$ matrix, where $p$ is the number of parameters in the distribution. The ( $\mathrm{i}, \mathrm{j}$ ) element is the covariance between the estimates of the ith parameter and the $j$ th parameter. The ( $i, i$ ) element is the estimated variance of the ith parameter. If parameter $i$ is fixed rather than estimated by fitting the distribution to data, then the (i,i) elements of the covariance matrix are 0 . This property is read-only.

## Data Types

single | double

## ParameterDescription

Descriptions of distribution parameters, stored as a cell array of strings. Each cell contains a short description of one distribution parameter. This property is read-only.

## Data Types <br> char

## ParameterlsFixed

Logical flag for fixed parameters, stored as an array of logical values. If 0 , the corresponding parameter in the ParameterNames array is not fixed. If 1 , the corresponding parameter in the ParameterNames array is fixed. This property is read-only.

## Data Types

logical

## ParameterNames

Names of distribution parameters, stored as a cell array of strings. This property is read-only.

## Data Types <br> char <br> ParameterValues

Values of distribution parameters, stored as a vector. This property is read-only.

## Data Types

single | double

## Truncation

Truncation interval for the probability distribution, stored as a vector containing the lower and upper truncation boundaries. This property is read-only.

Data Types<br>single | double

| Methods | Inherited Methods |  |
| :---: | :---: | :---: |
|  | cdf | Cumulative distribution function of probability distribution object |
|  | icdf | Inverse cumulative distribution function of probability distribution object |
|  | iqr | Interquartile range of probability distribution object |
|  | median | Median of probability distribution object |
|  | pdf | Probability density function of probability distribution object |
|  | random | Generate random numbers from probability distribution object |
|  | truncate | Truncate probability distribution object |
|  | mean | Mean of probability distribution object |
|  | negloglik | Negative loglikelihood of probability distribution object |
|  | paramci | Confidence intervals for probability distribution parameters |
|  | proflik | Profile likelihood function for probability distribution object |
|  | std | Standard deviation of probability distribution object |
|  | var | Variance of probability distribution object |

## prob.BurrDistribution

## Definitions

## Burr Distribution

The Burr distribution is a three-parameter family of distributions on the positive real line. It can fit a wide range of empirical data, and is used in various fields such as finance, hydrology, and reliability to model a variety of data types.

The Burr distribution uses the following parameters.

| Parameter | Description | Support |
| :--- | :--- | :--- |
| alpha | Scale parameter | $\alpha>0$ |
| c | First shape <br> parameter | $c>0$ |
| k | Second shape <br> parameter | $k>0$ |

The probability density function (pdf) is

$$
f(x \mid \alpha, c, k)=\frac{\frac{k c}{\alpha}\left(\frac{x}{\alpha}\right)^{c-1}}{\left(1+\left(\frac{x}{\alpha}\right)^{c}\right)^{k+1}} ; x>0 .
$$

## Examples Create a Burr Distribution Object Using Default Parameters

Create a Burr distribution object using the default parameter values.
pd = makedist('Burr')
pd $=$

BurrDistribution

```
Burr distribution
    alpha = 1
        c = 1
        k = 1
```

## Create a Burr Distribution Object Using Specified Parameters

Create a Burr distribution object by specifying parameter values.

```
pd = makedist('Burr','alpha',1,'c',2,'k',5)
pd =
```

    BurrDistribution
    Burr distribution
        alpha = 1
            \(c=2\)
            \(k=5\)
    Compute the mean of the distribution.
$\mathrm{m}=\mathrm{mean}(\mathrm{pd})$
$\mathrm{m}=$
0.4295

Purpose $\quad D$-optimal design from candidate set using row exchanges

```
Syntax
rlist = candexch(C,nrows)
rlist = candexch(C, nrows, Name, Value)
```

Description rlist $=$ candexch(C, nrows) uses a row-exchange algorithm to select a $D$-optimal design from the candidate set C .
rlist $=$ candexch (C, nrows, Name, Value) generates a $D$-optimal design with additional options specified by one or more Name, Value pair arguments.

## Input <br> Arguments

## C

N -by- P matrix containing the values of P model terms at each of N points.

## nrows

The desired number of rows in the design.

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ..., NameN, ValueN.

## 'display'

When 'on ', displays iteration number. Disable the display by setting to 'off'.

Default: ' on ', except when the UseParallel option is true

## 'init'

nrows-by-P matrix giving an initial design.
Default: A random subset of the rows of C

## 'maxiter'

Maximum number of iterations, a positive integer.
Default: 10

## 'options'

A structure that specifies whether to run in parallel, and specifies the random stream or streams. Create the options structure with statset. Option fields:

- UseParallel - Set to true to compute in parallel. Default is false.
- UseSubstreams - Set to true to compute in parallel in a reproducible fashion. Default is false. To compute reproducibly, set Streams to a type allowing substreams: 'mlfg6331_64' or 'mrg32k3a'.
- Streams - A RandStream object or cell array of such objects. If you do not specify Streams, candexch uses the default stream or streams. If you choose to specify Streams, use a single object except in the case
- You have an open MATLAB pool
- UseParallel is true
- UseSubstreams is false

In that case, use a cell array the same size as the MATLAB pool.

## Default: []

## 'start'

An nobs-by- $p$ matrix of factor settings, specifying a set of nobs fixed design points to include in the design. candexch finds nrows additional rows to add to the start design. The parameter provides the same functionality as the daugment function, using a row-exchange algorithm rather than a coordinate-exchange algorithm.

Default: []

## 'tries'

Number of times to try to generate a design from a new starting point. The algorithm uses random points for each try, except possibly the first.

## Default: 1

## Output Arguments

## Examples

## rlist

Vector of length nrows listing the selected rows.

This example shows how to generate a $D$-optimal design when there is a restriction on the candidate set, so the rowexch function isn't appropriate.

```
F = (fullfact([5 5 5])-1)/4; % factor settings in unit cube
T = sum(F,2)<=1.51; % find rows matching a restriction
F = F(T,:); % take only those rows
C = [ones(size(F,1),1) F F.^2];
                                % compute model terms including
                                % a constant and all squared terms
R = candexch(C,12); % find a D-optimal 12-point subset
X = F(R,:); % get factor settings
```

candexch selects a starting design $X$ at random, and uses a row-exchange algorithm to iteratively replace rows of $X$ by rows of $C$ in an attempt to improve the determinant of $\mathrm{X}^{\prime *} \mathrm{X}$.

## Algorithms

Alternatives

See AlsoAlternatives

The rowexch function also generates $D$-optimal designs using a row-exchange algorithm, but it automatically generates a candidate set that is appropriate for a specified model. The daugment function augments a set of fixed design points using a coordinate-exchange algorithm; the 'start' parameter provides the same functionality using the row exchange algorithm.

```
candgen | rowexch | cordexch | daugment | x2fx
```

Tutorials . "Specify Candidate Sets" on page 17-21<br>How To - "D-Optimal Designs" on page 17-15

Purpose Candidate set generation

```
Syntax dC = candgen(nfactors,'model')
[dC,C] = candgen(nfactors,'model')
[...] = candgen(nfactors,'model','Name',value)
```

## Description

dC = candgen(nfactors,'model') generates a candidate set dC of treatments appropriate for estimating the parameters in the model with nfactors factors. dC has nfactors columns and one row for each candidate treatment. model is one of the following strings, specified inside single quotes:

- linear - Constant and linear terms. This is the default.
- interaction - Constant, linear, and interaction terms
- quadratic - Constant, linear, interaction, and squared terms
- purequadratic - Constant, linear, and squared terms

Alternatively, model can be a matrix specifying polynomial terms of arbitrary order. In this case, model should have one column for each factor and one row for each term in the model. The entries in any row of model are powers for the factors in the columns. For example, if a model has factors $\mathrm{X} 1, \mathrm{X} 2$, and X 3 , then a row [ $0 \begin{array}{ll}0 & 1\end{array} 2$ ] in model specifies the term (X1.^0) .* (X2.^1) .* (X3.^2). A row of all zeros in model specifies a constant term, which can be omitted.
[dC, C] = candgen(nfactors,'model') also returns the design matrix $C$ evaluated at the treatments in $d C$. The order of the columns of $C$ for a full quadratic model with $n$ terms is:

1 The constant term
2 The linear terms in order $1,2, \ldots, n$
3 The interaction terms in order (1, 2), (1, 3), $\ldots,(1, n),(2,3), \ldots,(n-1, n)$
4 The squared terms in order $1,2, \ldots, n$

Other models use a subset of these terms, in the same order.
Pass C to candexch to generate a $D$-optimal design using a coordinate-exchange algorithm.
[...] = candgen(nfactors,'model','Name',value) specifies one or more optional name/value pairs for the design. Valid parameters and their values are listed in the following table. Specify Name inside single quotes.

| Name | Value |
| :--- | :--- |
| bounds | Lower and upper bounds for each factor, specified as <br> a 2-by-nfactors matrix. Alternatively, this value <br> can be a cell array containing nfactors elements, <br> each element specifying the vector of allowable <br> values for the corresponding factor. |
| categorical | Indices of categorical predictors. |
| levels | Vector of number of levels for each factor. |

Note The rowexch function automatically generates a candidate set using candgen, and then creates a $D$-optimal design from that candidate set using candexch. Call candexch separately to specify your own candidate set to the row-exchange algorithm.

## Examples

The following example uses rowexch to generate a five-run design for a two-factor pure quadratic model using a candidate set that is produced internally:

```
dRE1 = rowexch(2,5,'purequadratic','tries',10)
dRE1 =
    -1 1
    0
    1 -1
    0
```

$1 \quad 1$

The same thing can be done using candgen and candexch in sequence:

```
[dC,C] = candgen(2,'purequadratic') % Candidate set, C
dC =
    -1 -1
        0 -1
        1 -1
        -1 0
        0
        0
        -1 1
        0 1
        1 1
C =
\begin{tabular}{rrrrr}
1 & -1 & -1 & 1 & 1 \\
1 & 0 & -1 & 0 & 1 \\
1 & 1 & -1 & 1 & 1 \\
1 & -1 & 0 & 1 & 0 \\
1 & 0 & 0 & 0 & 0 \\
1 & 1 & 0 & 1 & 0 \\
1 & -1 & 1 & 1 & 1 \\
1 & 0 & 1 & 0 & 1 \\
1 & 1 & 1 & 1 & 1
\end{tabular}
treatments = candexch(C,5,'tries',10) % Find D-opt subset
treatments =
    2
        1
        7
        3
            4
dRE2 = dC(treatments,:) % Display design
dRE2 =
    0 -1
    -1 -1
    -1 1
```

| 1 | -1 |
| ---: | ---: |
| -1 | 0 |

| Purpose | Canonical correlation |
| :--- | :--- |
| Syntax | $[A, B]=$ canoncorr $(X, Y)$ |
|  | $[A, B, r]=$ canoncorr $(X, Y)$ |
|  | $[A, B, r, U, V]=$ canoncorr $(X, Y)$ |
|  | $[A, B, r, U, V$, stats $]=$ canoncorr $(X, Y)$ |

## Description

$[A, B]=$ canoncorr $(X, Y)$ computes the sample canonical coefficients for the $n$-by-d1 and $n$-by-d2 data matrices $X$ and $Y$. $X$ and $Y$ must have the same number of observations (rows) but can have different numbers of variables (columns). A and B are d1-by-d and d2-by-d matrices, where $d=\min (\operatorname{rank}(X), \operatorname{rank}(Y))$. The $j$ th columns of $A$ and $B$ contain the canonical coefficients, i.e., the linear combination of variables making up the $j$ th canonical variable for $X$ and $Y$, respectively. Columns of $A$ and $B$ are scaled to make the covariance matrices of the canonical variables the identity matrix (see $U$ and $V$ below). If $X$ or $Y$ is less than full rank, canoncorr gives a warning and returns zeros in the rows of A or $B$ corresponding to dependent columns of $X$ or $Y$.
$[A, B, r]=$ canoncorr $(X, Y)$ also returns a 1-by-d vector containing the sample canonical correlations. The $j$ th element of $r$ is the correlation between the $j$ th columns of $U$ and $V$ (see below).
$[A, B, r, U, V]=$ canoncorr $(X, Y)$ also returns the canonical variables, scores. $U$ and $V$ are $n$-by- $d$ matrices computed as
$U=(X-r e p m a t(m e a n(X), N, 1)) * A$
$V=(Y$-repmat $(\operatorname{mean}(Y), N, 1)) * B$
$[\mathrm{A}, \mathrm{B}, \mathrm{r}, \mathrm{U}, \mathrm{V}, \mathrm{stats}]=$ canoncorr$(\mathrm{X}, \mathrm{Y})$ also returns a structure stats containing information relating to the sequence of $d$ null
hypotheses $H_{0}^{(k)}$, that the ( $\mathrm{k}+1$ ) st through dth correlations are all zero, for $k=0:(d-1)$. stats contains seven fields, each a 1-by-d vector with elements corresponding to the values of $k$, as described in the following table:

| Field | Description |
| :--- | :--- |
| Wilks | Wilks' lambda (likelihood ratio) statistic |
| chisq | Bartlett's approximate chi-squared statistic for $H_{0}^{(k)}$ <br> with Lawley's modification |
| pChisq | Right-tail significance level for chisq |
| F | Rao's approximate $F$ statistic for $H_{0}^{(k)}$ |
| pF | Right-tail significance level for $F$ |
| df1 | Degrees of freedom for the chi-squared statistic, and <br> the numerator degrees of freedom for the $F$ statistic |
| df2 | Denominator degrees of freedom for the $F$ statistic |

```
Examples load carbig;
X = [Displacement Horsepower Weight Acceleration MPG];
nans = sum(isnan(X),2) > 0;
[A B r U V] = canoncorr(X(~nans,1:3),X(~nans,4:5));
plot(U(:,1),V(:,1),'.')
xlabel('0.0025*Disp+0.020*HP-0.000025*Wgt')
ylabel('-0.17*Accel-0.092*MPG')
```

## Purpose

Process capability indices
Syntax $\quad S=$ capability (data, specs)
Description
$S=$ capability(data, specs) estimates capability indices for measurements in data given the specifications in specs. data can be either a vector or a matrix of measurements. If data is a matrix, indices are computed for the columns. specs can be either a two-element vector of the form [ $\mathrm{L}, \mathrm{U}$ ] containing lower and upper specification limits, or (if data is a matrix) a two-row matrix with the same number of columns as data. If there is no lower bound, use - Inf as the first element of specs. If there is no upper bound, use Inf as the second element of specs.

The output S is a structure with the following fields:

- mu - Sample mean
- sigma - Sample standard deviation
- P — Estimated probability of being within limits
- Pl - Estimated probability of being below L
- Pu - Estimated probability of being above U
- Cp - (U-L)/(6*sigma)
- Cpl-(mu-L)./(3.*sigma)
- Cpu - (U-mu)./(3.*sigma)
- Cpk - min (Cpl, Cpu)

Indices are computed under the assumption that data values are independent samples from a normal population with constant mean and variance.

Indices divide a "specification width" (between specification limits) by a "process width" (between control limits). Higher ratios indicate a process with fewer measurements outside of specification.

Examples Simulate a sample from a process with a mean of 3 and a standard deviation of 0.005 :
data $=$ normrnd (3, 0.005, 100, 1);
Compute capability indices if the process has an upper specification limit of 3.01 and a lower specification limit of 2.99:

```
S = capability(data,[2.99 3.01])
S =
    mu: 3.0006
    sigma: 0.0047
            P: 0.9669
            Pl: 0.0116
            Pu: 0.0215
            Cp: 0.7156
            Cpl: 0.7567
            Cpu: 0.6744
            Cpk: 0.6744
```

Visualize the specification and process widths:

```
capaplot(data,[2.99 3.01]);
grid on
```

capaplot | histfit

Purpose Process capability plot

| Syntax | $p=$ capaplot(data, specs) |
| :--- | :--- |
| $[p, h]=\operatorname{capaplot}($ data, $s p e c s)$ |  |

Description
$p=$ capaplot(data, specs) estimates the mean of and variance for the observations in input vector data, and plots the pdf of the resulting T distribution. The observations in data are assumed to be normally distributed. The output, $p$, is the probability that a new observation from the estimated distribution will fall within the range specified by the two-element vector specs. The portion of the distribution between the lower and upper bounds specified in specs is shaded in the plot.
[ $p, h$ ] = capaplot(data, specs) additionally returns handles to the plot elements in $h$.
capaplot treats NaN values in data as missing, and ignores them.

## Examples

Simulate a sample from a process with a mean of 3 and a standard deviation of 0.005 :

```
data = normrnd(3,0.005,100,1);
```

Compute capability indices if the process has an upper specification limit of 3.01 and a lower specification limit of 2.99:

```
S = capability(data,[2.99 3.01])
S =
    mu: 3.0006
    sigma: 0.0047
            P: 0.9669
            Pl: 0.0116
            Pu: 0.0215
            Cp: 0.7156
            Cpl: 0.7567
            Cpu: 0.6744
            Cpk: 0.6744
```

Visualize the specification and process widths:

```
capaplot(data,[2.99 3.01]);
grid on
```

Probability Between Limits $=0.96688$

Purpose Read case names from file

```
Syntax names = caseread('filename')
names = caseread
```

names $=$ caseread('filename') reads the contents of filename and returns a string matrix of names. filename is the name of a file in the current folder, or the complete path name of any file elsewhere. caseread treats each line as a separate case.
names $=$ caseread displays the Select File to Open dialog box for interactive selection of the input file.

## Examples <br> Read the file months. dat created using the casewrite function.

type months.dat

January
February
March
April
May
names $=$ caseread('months.dat')
names =

Purpose Concatenate categorical arrays

$$
\text { Syntax } \quad c=\operatorname{cat}(\operatorname{dim}, A, B, \ldots)
$$

Description $\quad c=\operatorname{cat}(\operatorname{dim}, A, B, \ldots)$ concatenates the categorical arrays $A, B, \ldots$ along dimension dim. All inputs must have the same size except along dimension dim. The set of categorical levels for C is the sorted union of the sets of levels of the inputs, as determined by their labels.

Purpose Create categorical array
Description $\begin{aligned} & \text { categorical is an abstract class, and you cannot create instances of it } \\ & \text { directly. You must create nominal or ordinal arrays. }\end{aligned}$
See Also nominal | ordinal

Purpose Concatenate dataset arrays

$$
\text { Syntax } \quad d s=\text { cat (dim, ds1, ds2, ...) }
$$

Description ds = cat(dim, ds1, ds2, ...) concatenates the dataset arrays ds1, ds2, ... along dimension dim by calling the dataset/horzcat or dataset/vertcat method. dim must be 1 or 2 .

See Also horzcat | vertcat

## classregtree.catsplit

Purpose Categorical splits used for branches in decision tree

```
Syntax
v=catsplit(t)
v=catsplit(t,j)
```

Description
v=catsplit(t) returns an n-by-2 cell array v. Each row in v gives left and right values for a categorical split. For each branch node $j$ based on a categorical predictor variable $z$, the left child is chosen if $z$ is in $v(j, 1)$ and the right child is chosen if $z$ is in $v(j, 2)$. The splits are in the same order as nodes of the tree. Nodes for these splits can be found by running cuttype and selecting 'categorical' cuts from top to bottom. $\mathrm{v}=\mathrm{catsplit}(\mathrm{t}, \mathrm{j})$ takes an array j of rows and returns the splits for the specified rows.

See Also<br>classregtree

## Purpose

Cumulative distribution function for Gaussian mixture distribution

## Syntax <br> $y=\operatorname{cdf}(o b j, X)$

$y=\operatorname{cdf}(o b j, X)$ returns a vector $y$ of length $n$ containing the values of the cumulative distribution function (cdf) for the gmdistribution object obj, evaluated at the $n$-by- $d$ data matrix X , where $n$ is the number of observations and $d$ is the dimension of the data. obj is an object created by gmdistribution or fit. $\mathrm{y}(\mathrm{I})$ is the cdf of observation I.

Examples Create a gmdistribution object defining a two-component mixture of bivariate Gaussian distributions:

```
MU = [1 2;-3 -5];
SIGMA = cat(3,[2 0;0 .5],[1 0;0 1]);
p = ones(1,2)/2;
obj = gmdistribution(MU,SIGMA,p);
ezsurf(@(x,y)cdf(obj,[x y]),[-10 10],[-10 10])
```

## gmdistribution.cdf

Purpose
Central composite design
Syntax

```
dCC = ccdesign(n)
[dCC,blocks] = ccdesign(n)
[...] = ccdesign(n,'Name',value)
```

## Description

dCC $=\operatorname{ccdesign}(\mathrm{n})$ generates a central composite design for n factors. n must be an integer 2 or larger. The output matrix dCC is $m$-by-n, where $m$ is the number of runs in the design. Each row represents one run, with settings for all factors represented in the columns. Factor values are normalized so that the cube points take values between -1 and 1 .
[dCC,blocks] = ccdesign(n) requests a blocked design. The output blocks is an $m$-by- 1 vector of block numbers for each run. Blocks indicate runs that are to be measured under similar conditions to minimize the effect of inter-block differences on the parameter estimates.
[...] = ccdesign(n, 'Name', value) specifies one or more optional name/value pairs for the design. Valid parameters and their values are listed in the following table. Specify Name in single quotes.

| Parameter | Description | Values | Value <br> Description |
| :--- | :--- | :--- | :--- |
| center | Number of <br> center points. | Integer | Number of center <br> points to include. |
|  |  | 'uniform' | Select number <br> of center points <br> to give uniform <br> precision. |
|  |  | 'orthogonal' | Select number of <br> center points to <br> give an orthogonal <br> design. This is the <br> default. |

| Parameter | Description | Values | Value Description |
| :---: | :---: | :---: | :---: |
| fraction | Fraction of full-factorial cube, expressed as an exponent of $1 / 2$. | 0 | Whole design. Default when $\mathrm{n} \leq$ 4. |
|  |  | 1 | 1/2 fraction. Default when $4<n \leq 7$ or $n>11$. |
|  |  | 2 | 1/4 fraction. Default when $7<\mathrm{n} \leq 9$ |
|  |  | 3 | 1/8 fraction. Default when $\mathrm{n}=10$. |
|  |  | 4 | 1/16 fraction. Default when n $=11$. |
| type | Type of CCD. | 'circumscrib | dCircumscribed (CCC). This is the default. |
|  |  | 'inscribed' | Inscribed (CCI). |
|  |  | 'faced' | Faced (CCF). |
| blocksize | Maximum number of points per block. | Integer | The default is Inf. |

Examples The following creates a 2 -factor CCC:

```
dCC = ccdesign(2,'type','circumscribed')
dCC =
    -1.0000 -1.0000
```

| -1.0000 | 1.0000 |
| ---: | ---: |
| 1.0000 | -1.0000 |
| 1.0000 | 1.0000 |
| -1.4142 | 0 |
| 1.4142 | 0 |
| 0 | -1.4142 |
| 0 | 1.4142 |
| 0 | 0 |
| 0 | 0 |
| 0 | 0 |
| 0 | 0 |
| 0 | 0 |
| 0 | 0 |
| 0 | 0 |
| 0 | 0 |

The center point is run 8 times to reduce the correlations among the coefficient estimates.

Visualize the design as follows:

```
plot(dCC(:,1),dCC(:,2),'ro','MarkerFaceColor','b')
X = [1 -1 -1 -1; 1 1 1 -1];
Y = [-1 -1 1 -1; 1 -1 1 1];
line(X,Y,'Color','b')
axis square equal
```

## Purpose Cumulative distribution functions

Syntax $\quad Y=\operatorname{cdf}\left(\right.$ ' $^{\prime}$ name $\left.{ }^{\prime}, X, A\right)$
$Y=c d f(' n a m e ', X, A, B)$
$Y=\operatorname{cdf}('$ name', $X, A, B, C)$

## Description

$Y=\operatorname{cdf}($ ' name', $X, A)$ computes the cumulative distribution function for the one-parameter family of distributions specified by name. A contains parameter values for the distribution. The cumulative distribution function is evaluated at the values in $X$ and its values are returned in Y .

If $X$ and $A$ are arrays, they must be the same size. If $X$ is a scalar, it is expanded to a constant matrix the same size as $A$. If A is a scalar, it is expanded to a constant matrix the same size as $X$.
$Y$ is the common size of $X$ and $A$ after any necessary scalar expansion.
$Y=\operatorname{cdf}($ ' name' $, X, A, B)$ computes the cumulative distribution function for two-parameter families of distributions, where parameter values are given in $A$ and $B$.

If $X, A$, and $B$ are arrays, they must be the same size. If $X$ is a scalar, it is expanded to a constant matrix the same size as $A$ and $B$. If either $A$ or $B$ are scalars, they are expanded to constant matrices the same size as $X$.
$Y$ is the common size of $X, A$, and $B$ after any necessary scalar expansion.
$Y=\operatorname{cdf}($ ' $n a m e ', X, A, B, C)$ computes the cumulative distribution function for three-parameter families of distributions, where parameter values are given in $A, B$, and $C$.

If $X, A, B$, and $C$ are arrays, they must be the same size. If $X$ is a scalar, it is expanded to a constant matrix the same size as $A, B$, and $C$. If any of $A, B$ or $C$ are scalars, they are expanded to constant matrices the same size as $X$.
$Y$ is the common size of $X, A, B$, and $C$ after any necessary scalar expansion.
Acceptable strings for name (specified in single quotes) are:

## Examples

Compute the cdf of the normal distribution with mean 0 and standard deviation 1 at inputs $-2,-1,0,1,2$ :

```
p1 = cdf('Normal',-2:2,0,1)
p1 =
    0.0228
```

The order of the parameters is the same as for normcdf.
Compute the cdfs of Poisson distributions with rate parameters $0,1, \ldots$, 4 at inputs $1,2, \ldots, 5$, respectively:

```
p2 = cdf('Poisson',0:4,1:5)
p2 =
    0.3679
```

The order of the parameters is the same as for poisscdf.

## piecewisedistribution.cdf

Purpose Cumulative distribution function for piecewise distribution

$$
\text { Syntax } \quad P=\operatorname{cdf}(o b j, x)
$$

Description $\quad P=c d f(o b j, X)$ returns an array $P$ of values of the cumulative distribution function for the piecewise distribution object obj, evaluated at the values in the array $X$.

Examples $\quad$ Fit Pareto tails to a $t$ distribution at cumulative probabilities 0.1 and 0.9:

```
t = trnd(3,100,1);
obj = paretotails(t,0.1,0.9);
[p,q] = boundary(obj)
p =
    0.1000
    0.9000
q =
    -1.7766
    1.8432
cdf(obj,q)
ans =
    0.1000
    0.9000
```

See Also paretotails \| pdf | icdf

## Purpose

Return cumulative distribution function (CDF) for ProbDist object
Syntax $\quad Y=\operatorname{cdf}(P D, X)$
Description
$Y=\operatorname{cdf}(P D, X)$ returns $Y$, an array containing the cumulative distribution function (CDF) for the ProbDist object PD, evaluated at values in $X$.

## Input <br> Arguments

## Output <br> Arguments

## See Also

cdf

An object of the class ProbDistUnivParam or ProbDistUnivKernel.

A numeric array of values where you want to evaluate the CDF.

An array containing the cumulative distribution function (CDF) for the ProbDist object $P D$.

## prob.TruncatableDistribution.cdf

Purpose Cumulative distribution function of probability distribution object
Syntax $\quad y=\operatorname{cdf}(p d, x)$
Description $\quad y=\operatorname{cdf}(p d, x)$ returns the cumulative distribution function (cdf) of the probability distribution $p d$ at the values in $x$.

Input
Arguments

## Output Arguments

## Examples

pd - Probability distribution

probability distribution object
Probability distribution, specified as a probability distribution object. Create a probability distribution object with specified parameter values using makedist. Alternatively, for fittable distributions, create a probability distribution object by fitting it to data using fitdist or dfittool.

## $\mathbf{x}$ - Values at which to calculate cdf

array
Values at which to calculate the cdf, specified as an array.

```

## y-Cumulative distribution function

array
Cumulative distribution function of the specified probability distribution, evaluated at the values in $x$, returned as a array. $y$ has the same dimensions as x .

Plot the cdf of a Standard Normal Distribution
Create a standard normal distribution object.

```
pd = makedist('Normal')
pd =
```

NormalDistribution

```
Normal distribution
    mu = 0
    sigma = 1
```

Specify the x values and compute the cdf.
$x=-3: .1: 3 ;$
cdf_normal = cdf(pd,x);
Plot the cdf of the standard normal distribution.
plot(x,cdf_normal,'LineWidth', 2)

## Plot the cdf of a Gamma Distribution

Create three gamma distribution objects. The first uses the default parameter values. The second specifies $a=1$ and $b=2$. The third specifies $\mathrm{a}=2$ and $\mathrm{b}=1$.
pd_gamma = makedist('Gamma')
pd_gamma =

```
    GammaDistribution
    Gamma distribution
    a = 1
    b = 1
pd_12 = makedist('Gamma','a',1,'b',2)
pd_12 =
    GammaDistribution
    Gamma distribution
        a = 1
        b = 2
pd_21 = makedist('Gamma','a',2,'b',1)
pd_21 =
```

## GammaDistribution

```
Gamma distribution
\(a=2\)
b \(=1\)
```

Specify the $x$ values and compute the cdf for each distribution.

```
x = 0:.1:5;
cdf_gamma = cdf(pd_gamma,x);
cdf_12 = cdf(pd_12,x);
cdf_21 = cdf(pd_21,x);
```

Create a plot to visualize how the cdf of the gamma distribution changes when you specify different values for the shape parameters a and b .
figure; J = plot(x,cdf_gamma)

```
hold on;
K = plot(x,cdf_gamma_12,'r--')
L = plot(x,cdf_gamma_21,'k-.')
set(J,'LineWidth',2);
set(K,'LineWidth',2);
legend([J K L],'a = 1, b = 1','a = 1, b = 2','a = 2, b = 1','Location','s
hold off;
```

Purpose Empirical cumulative distribution function plot
Syntax
cdfplot(X)
h = cdfplot (X)
[h,stats] = cdfplot(X)

## Description

## Examples

cdfplot( $X$ ) displays a plot of the empirical cumulative distribution function (cdf) for the data in the vector $X$. The empirical $\operatorname{cdf} F(x)$ is defined as the proportion of X values less than or equal to $x$.
This plot, like those produced by hist and normplot, is useful for examining the distribution of a sample of data. You can overlay a theoretical cdf on the same plot to compare the empirical distribution of the sample to the theoretical distribution.

The kstest, kstest2, and lillietest functions compute test statistics that are derived from the empirical cdf. You may find the empirical cdf plot produced by cdfplot useful in helping you to understand the output from those functions.
$\mathrm{h}=\operatorname{cdfplot}(\mathrm{X})$ returns a handle to the cdf curve.
[h,stats] = cdfplot(X) also returns a stats structure with the following fields.

| Field | Description |
| :--- | :--- |
| stats.min | Minimum value |
| stats.max | Maximum value |
| stats.mean | Sample mean |
| stats.median | Sample median (50th percentile) |
| stats.std | Sample standard deviation |

The following example compares the empirical cdf for a sample from an extreme value distribution with a plot of the cdf for the sampling distribution. In practice, the sampling distribution would be unknown, and would be chosen to match the empirical cdf.

```
y = evrnd(0,3,100,1);
cdfplot(y)
hold on
x = -20:0.1:10;
f = evcdf(x,0,3);
plot(x,f,'m')
legend('Empirical','Theoretical','Location','NW')
```

## Purpose Convert cell array to dataset array

Syntax $\quad$| ds | $=$ cell2dataset $(C)$ |
| ---: | :--- |
| ds | $=$ cell2dataset $(C$, Name, Value $)$ |

Description $\quad d s=$ cell2dataset ( $C$ ) converts a cell array to a dataset array.
ds = cell2dataset(C,Name, Value) performs the conversion using additional options specified by one or more Name, Value pair arguments.

## Input Arguments

## C - Input cell array

cell array
Input cell array to convert to a dataset array, specified as an $M$-by- $N$ cell array. Each column of C becomes a variable in the output dataset array, ds. By default, cell2dataset assumes that the first row of $C$ contains variable names.

## Data Types

cell

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ..., NameN, ValueN.

Example: 'ReadVarNames',false,'ReadObsNames', true specifies that the first row of the cell array does not contain variable names, but the first column contains observation names.

## 'ReadVarNames' - Indicator for whether or not to read variable names <br> true (default) | false

Indicator for whether or not to read variable names from the first row of the input cell array, specified as the comma-separated pair consisting of 'ReadVarNames' and either true or false. The default value is true, unless variable names are specified using the name-value pair argument VarNames. When ReadVarNames is false, cell2dataset creates default variable names if you do not provide any.

Example: 'ReadVarNames',false

## 'VarNames' - Variable names for output dataset array

cell array of strings
Variable names for the output dataset array, specified as the comma-separated pair consisting of 'VarNames' and a cell array of strings. You must provide a variable name for each variable in ds. The names must be valid MATLAB identifiers, and must be unique.

Example: 'VarNames', \{'myVar1','myVar2','myVar3'\}

## 'ReadObsNames' - Indicator for whether or not to read observation names <br> false (default) | true

Indicator for whether or not to read observation names from the input cell array, specified as the comma-separated pair consisting of 'ReadObsNames' and either true or false. When ReadObsNames has the value true, cell2dataset creates observation names in ds using the first column of C , and sets ds. Properties. DimNames equal to \{C\{1,1\},'Variables'\}.

Example: 'ReadObsNames', true

## 'ObsNames' - Observation names for output dataset array cell array of strings

Observation names for the output dataset array, specified as the comma-separated pair consisting of 'ObsNames' and a cell array of strings. The names do not need to be valid MATLAB identifiers, but they must be unique.

## 'NumCols' - Number of columns for each variable <br> vector of nonnegative integers

Number of columns for each variable in ds, specified as the comma-separated pair consisting of 'NumCols' and a vector of nonnegative integers. When the number of columns for a variable is greater than one, cell2dataset combines multiple columns in C into a single variable in ds. The vector you assign to NumCols must sum to size (C,2), or size (C,1) of ReadObsNames is equal to true.

For example, to convert a cell array with eight columns into a dataset array with five variables, specify a vector with five elements that sum to eight, such as 'NumCols', [1, 1, 3, 1, 2].

## Output Arguments

## ds - Output dataset array

dataset array
Output dataset array, returned by default with a variable for each column of C, an observation for each row of C (except for the first row), and variable names corresponding to the first row of C .

- If you set ReadVarNames equal to false (or specify VarNames), then there is an observation in ds for each row of C , and cell2dataset creates default variable names (or uses the names in VarNames).
- If you set ReadObsNames equal to true, then cell2dataset uses the first column of C as observation names.
- If you specify NumCols, then the number of variables in ds is equal to the length of the specified vector of column numbers.

## Examples Convert Cell Array to Dataset Array

Convert a cell array to a dataset array using the default options.
Create a cell array to convert.

```
C = {'Name','Gender','SystolicBP','DiastolicBP';
    'CLARK','M',124,93;
    'BROWN','F',122,80;
    'MARTIN','M',130,92}
```

## cell2dataset

$C=$

| ' Name ' | 'Gender ${ }^{\text {' }}$ | 'SystolicBP' | DiastolicBP' |
| :---: | :---: | :---: | :---: |
| ' CLARK' | 'M' | [ 124] | 93] |
| 'BROWN' | 'F' | [ 122] | 80] |
| 'MARTIN ' | 'M' | $130]$ | 92] |

Convert the cell array to a dataset array.

```
ds = cell2dataset(C)
ds =
\begin{tabular}{llll} 
Name & Gender & SystolicBP & DiastolicBP \\
'CLARK' & 'M' & 124 & 93 \\
'BROWN' & 'F' & 122 & 80 \\
'MARTIN' & 'M' & 130 & 92
\end{tabular}
```

The first row of C become the variable names in the output dataset array, ds.

## Create a Dataset Array with Multicolumn Variables

Convert a cell array to a dataset array containing multicolumn variables.

Create a cell array to convert.

```
C = {'Name','Gender','SystolicBP','DiastolicBP';
    'CLARK','M',124,93;
        'BROWN','F',122,80;
        'MARTIN','M',130,92}
C =
\begin{tabular}{|c|c|c|c|}
\hline 'Name' & 'Gender' & 'SystolicBP' & DiastolicBP' \\
\hline ' CLARK ' & 'M' & [ 124] & \(93]\) \\
\hline 'BROWN' & 'F' & [ 122] & 80] \\
\hline 'MARTIN' & 'M' & \(130]\) & 92] \\
\hline
\end{tabular}
```

Convert the cell array to a dataset array, combining the systolic and diastolic blood pressure measurements into one variable named BloodPressure.
ds = cell2dataset(C, 'NumCols', [1, 1, 2]); ds.Properties.VarNames $\{3\}=$ 'BloodPressure'; ds
ds =

| Name | Gender | BloodPressure |  |
| :--- | :--- | :--- | :--- |
| 'CLARK' | 'M' | 124 | 93 |
| 'BROWN' | 'F' | 122 | 80 |
| 'MARTIN' | 'M' | 130 | 92 |

The output dataset array has three observations and three variables.
size(ds)
ans =
$3 \quad 3$

Purpose Convert categorical array to cell array of strings

## Syntax <br> $B=$ cellstr(A)

Description $B=$ cellstr $(A)$ converts the categorical array $A$ to a cell array of strings. Each element of B contains the categorical level label for the corresponding element of A.

See Also char | getlabels

## Purpose Create cell array of strings from dataset array

Syntax
$\mathrm{B}=\mathrm{cellstr}(\mathrm{A})$
$\mathrm{B}=\mathrm{cellstr}(\mathrm{A}, \mathrm{VARS})$

Description
$\mathrm{B}=$ cellstr(A) returns the contents of the dataset A , converted to a cell array of strings. The variables in the dataset must support the conversion and must have compatible sizes.
$B=$ cellstr(A,VARS) returns the contents of the dataset variables specified by VARS. VARS is a positive integer, a vector of positive integers, a variable name, a cell array containing one or more variable names, or a logical vector.

See Also<br>dataset.double | dataset.replacedata

Purpose $\quad$ Convert categorical array to character array

## Syntax <br> $B=\operatorname{char}(A)$

Description $\quad B=\operatorname{char}(A)$ converts the categorical array $A$ to a 2-D character matrix. char does not preserve the shape of $A$. $B$ contains numel ( $A$ ) rows, and each row of $B$ contains the categorical level label for the corresponding element of $A(:)$.

See Also cellstr | getlabels

## Purpose <br> Chi-square cumulative distribution function

## Syntax <br> $P=\operatorname{chi2cdf}(X, V)$

Description
$P=\operatorname{chi2cdf}(X, V)$ computes the chi-square cdf at each of the values in $X$ using the corresponding degrees of freedom in $V$. $X$ and $V$ can be vectors, matrices, or multidimensional arrays that have the same size. A scalar input is expanded to a constant array with the same dimensions as the other input.

The degrees of freedom parameters in $V$ must be positive integers, and the values in X must lie on the interval [ 0 Inf].

The $x^{2} \operatorname{cdf}$ for a given value $x$ and degrees-of-freedom $v$ is

$$
p=F(x \mid v)=\int_{0}^{x} \frac{t^{(v-2) / 2} e^{-t / 2}}{2^{v / 2} \Gamma(v / 2)} d t
$$

where $\Gamma(\cdot)$ is the Gamma function.
The chi-square density function with $v$ degrees-of-freedom is the same as the gamma density function with parameters $v / 2$ and 2 .

How To

- "Chi-Square Distribution" on page B-25

## Purpose Chi-square goodness-of-fit test

Syntax

```
h = chi2gof(x)
[h,p] = chi2gof(...)
[h,p,stats] = chi2gof(...)
[...] = chi2gof(X,'Name',value)
```

## Description

$h=c h i 2 g o f(x)$ performs a chi-square goodness-of-fit test of the default null hypothesis that the data in vector x are a random sample from a normal distribution with mean and variance estimated from $x$, against the alternative that the data are not normally distributed with the estimated mean and variance. The result $h$ is 1 if the null hypothesis can be rejected at the $5 \%$ significance level. The result h is 0 if the null hypothesis cannot be rejected at the $5 \%$ significance level.

The null distribution can be changed from a normal distribution to an arbitrary discrete or continuous distribution. See the syntax for specifying optional argument name/value pairs below.

The test is performed by grouping the data into bins, calculating the observed and expected counts for those bins, and computing the chi-square test statistic

$$
\chi^{2}=\sum_{i=1}^{N}\left(O_{i}-E_{i}\right)^{2} / E_{i}
$$

where $O_{i}$ are the observed counts and $E_{i}$ are the expected counts. The statistic has an approximate chi-square distribution when the counts are sufficiently large. Bins in either tail with an expected count less than 5 are pooled with neighboring bins until the count in each extreme bin is at least 5 . If bins remain in the interior with counts less than 5 , chi2gof displays a warning. In this case, you should use fewer bins, or provide bin centers or edges, to increase the expected counts in all bins. (See the syntax for specifying optional argument name/value pairs below.) chi2gof sets the number of bins, nbins, to 10 by default, and compares the test statistic to a chi-square distribution with nbins - 3 degrees of freedom to take into account the two estimated parameters.
$[\mathrm{h}, \mathrm{p}]=$ chi2gof(...) also returns the $p$ value of the test, p . The $p$ value is the probability, under assumption of the null hypothesis, of observing the given statistic or one more extreme.
[h,p,stats] = chi2gof(...) also returns a structure stats with the following fields:

- chi2stat - The chi-square statistic
- df - Degrees of freedom
- edges - Vector of bin edges after pooling
- 0-Observed count in each bin
- E - Expected count in each bin
[...] = chi2gof(X, 'Name', value) specifies one or more optional argument name/value pairs chosen from the following lists. Argument names are case insensitive and partial matches are allowed. Specify Name in single quotes.

The following name/value pairs control the initial binning of the data before pooling. You should not specify more than one of these options.

- nbins - The number of bins to use. Default is 10.
- ctrs - A vector of bin centers
- edges - A vector of bin edges

The following name/value pairs determine the null distribution for the test. Do not specify both cdf and expected.

- cdf - A fully specified cumulative distribution function. This can be a function name, a function handle, or a ProbDist object of the ProbDistUnivParam class or ProbDistUnivKernel class. When 'cdf' is a function name or handle, the distribution function must take $x$ as its only argument. Alternately, you can provide a cell array whose first element is a function name or handle, and whose later elements are parameter values, one per cell. The function must take $x$ as its first argument, and other parameters as later arguments.

## chi2gof

- expected - A vector with one element per bin specifying the expected counts for each bin.
- nparams - The number of estimated parameters; used to adjust the degrees of freedom to be nbins - 1 - nparams, where nbins is the number of bins.

If your cdf or expected input depends on estimated parameters, you should use nparams to ensure that the degrees of freedom for the test is correct. If cdf is a cell array, the default value of nparams is the number of parameters in the array; otherwise the default is 0 .

The following name/value pairs control other aspects of the test.

- emin - The minimum allowed expected value for a bin; any bin in either tail having an expected value less than this amount is pooled with a neighboring bin. Use the value 0 to prevent pooling. The default is 5 .
- frequency - A vector the same length as $x$ containing the frequency of the corresponding xvalues
- alpha - Significance level for the test. The default is 0.05 .

## Examples

## Example 1

Equivalent ways to test against an unspecified normal distribution with estimated parameters:

```
x = normrnd(50,5,100,1);
[h,p] = chi2gof(x)
h =
    0
p =
    0.7532
[h,p] = chi2gof(x,'cdf',@(z)normcdf(z,mean(x),std(x)),'nparams',2)
h =
    0
p =
```

0.7532

```
[h,p] = chi2gof(x,'cdf',{@normcdf,mean(x),std(x)})
h =
    0
p =
    0.7532
```

## Example 2

Test against the standard normal:
$x=\operatorname{randn}(100,1) ;$
[h,p] = chi2gof(x,'cdf', @normcdf)
$\mathrm{h}=$
0
$p=$
0.9443

## Example 3

Test against the standard uniform:
$x=\operatorname{rand}(100,1) ;$
$\mathrm{n}=$ length( x$)$;
edges $=$ linspace $(0,1,11)$; expectedCounts $=n$ * diff(edges); [h,p,st] = chi2gof(x,'edges',edges,... 'expected', expectedCounts)
$\mathrm{h}=$
0
$p=$
0.3191
st $=$

edges: [1x6 double]
0: [ $\left.\begin{array}{lllll}6 & 16 & 10 & 12 & 6\end{array}\right]$
E: $\left[\begin{array}{lllll}7.0429 & 13.8041 & 13.5280 & 8.8383 & 6.0284\end{array}\right]$
See Also crosstab | lillietest | kstest | chi2cdf | chi2pdf | chi2inv |
How To . "Chi-Square Distribution" on page B-25

## Purpose

Chi-square inverse cumulative distribution function

## Syntax

$X=\operatorname{chi2inv}(P, V)$
$X=$ chi2inv $(P, V)$ computes the inverse of the chi-square cdf with degrees of freedom specified by $V$ for the corresponding probabilities in P. P and V can be vectors, matrices, or multidimensional arrays that have the same size. A scalar input is expanded to a constant array with the same dimensions as the other inputs.
The degrees of freedom parameters in $V$ must be positive integers, and the values in P must lie in the interval [01].
The inverse chi-square cdf for a given probability $p$ and v degrees of freedom is

$$
x=F^{-1}(p \mid v)=\{x: F(x \mid v)=p\}
$$

where

$$
p=F(x \mid v)=\int_{0}^{x} \frac{t^{(v-2) / 2} e^{-t / 2}}{2^{v / 2} \Gamma(v / 2)} d t
$$

and $\Gamma(\cdot)$ is the Gamma function. Each element of output X is the value whose cumulative probability under the chi-square cdf defined by the corresponding degrees of freedom parameter in $V$ is specified by the corresponding value in P .

## Examples

Find a value that exceeds $95 \%$ of the samples from a chi-square distribution with 10 degrees of freedom.

```
x = chi2inv(0.95,10)
x =
    18.3070
```

You would observe values greater than 18.3 only $5 \%$ of the time by chance.

See Also icdf | chi2cdf | chi2pdf | chi2stat | chi2rnd<br>How To . "Chi-Square Distribution" on page B-25

## Purpose

Chi-square probability density function

## Syntax

$Y=\operatorname{chi2pdf}(X, V)$
$Y=$ chi2pdf $(X, V)$ computes the chi-square pdf at each of the values in $X$ using the corresponding degrees of freedom in $V . X$ and $V$ can be vectors, matrices, or multidimensional arrays that have the same size, which is also the size of the output Y . A scalar input is expanded to a constant array with the same dimensions as the other input.

The degrees of freedom parameters in $V$ must be positive integers, and the values in X must lie on the interval [ 0 Inf].

The chi-square pdf for a given value $x$ and $v$ degrees of freedom is

$$
y=f(x \mid v)=\frac{x^{(v-2) / 2} e^{-x / 2}}{2^{v / 2} \Gamma(v / 2)}
$$

where $\Gamma(\cdot)$ is the Gamma function.
If $x$ is standard normal, then $x^{2}$ is distributed chi-square with one degree of freedom. If $x_{1}, x_{2}, \ldots, x_{\mathrm{n}}$ are $n$ independent standard normal observations, then the sum of the squares of the $x$ 's is distributed chi-square with $n$ degrees of freedom (and is equivalent to the gamma density function with parameters $v / 2$ and 2 ).

## Examples

See Also

```
nu = 1:6;
x = nu;
y = chi2pdf(x,nu)
y =
```

The mean of the chi-square distribution is the value of the degrees of freedom parameter, nu. The above example shows that the probability density of the mean falls as nu increases.

How To<br>- "Chi-Square Distribution" on page B-25

## Purpose <br> Syntax <br> Description

Chi-square random numbers
$\mathrm{R}=\mathrm{chi2} \mathrm{rnd}(\mathrm{V})$
R = chi2rnd(V,m,n,...)
$R=\operatorname{chi2rnd}(V,[m, n, \ldots])$

## Examples

## Purpose Shift categorical array circularly

Syntax
B = circshift(A,shiftsize)

Description
$B=\operatorname{circshift}(A, s h i f t s i z e)$ circularly shifts the values in the categorical array A by shiftsize elements. shiftsize is a vector of integer scalars where the $n$-th element specifies the shift amount for the $n$-th dimension of array $A$. If an element in shiftsize is positive, the values of A are shifted down (or to the right). If it is negative, the values of A are shifted up (or to the left).

See Also permute | shiftdim

## NaiveBayes.ClsNonEmpty property

Purpose Flag for non-empty classes
Description The CIsNonEmpty property is a logical vector of length NClasses specifying which classes are not empty. When the grouping variable is categorical, it may contain categorical levels that don't appear in the elements of the grouping variable. Those levels are empty and NaiveBayes ignores them for the purposes of training the classifier.

## Purpose Class counts

```
Syntax
P = classcount(t)
P = classcount(t,nodes)
```

Description
$P=c l a s s c o u n t(t)$ returns an $n$-by- $m$ array $P$ of class counts for the nodes in the classification tree t , where $n$ is the number of nodes and $m$ is the number of classes. For any node number i, the class counts $P(i,:)$ are counts of observations (from the data used in fitting the tree) from each class satisfying the conditions for node i.

P = classcount( t , nodes) takes a vector nodes of node numbers and returns the class counts for the specified nodes.

## Examples

Create a classification tree for Fisher's iris data:

```
load fisheriris;
t = classregtree(meas,species,...
    'names',{'SL' 'SW' 'PL' 'PW'})
t =
Decision tree for classification
1 if PL<2.45 then node 2 elseif PL>=2.45 then node 3 else setosa
2 class = setosa
3 if PW<1.75 then node 4 elseif PW>=1.75 then node 5 else versicolor
4 if PL<4.95 then node 6 elseif PL>=4.95 then node 7 else versicolor
5 class = virginica
6 if PW<1.65 then node 8 elseif PW>=1.65 then node 9 else versicolor
7 class = virginica
8 class = versicolor
9 class = virginica
view(t)
```

| $P=$ classcount $(t)$ |  |  |
| :--- | ---: | ---: |
| $P=$ |  |  |

## ClassificationBaggedEnsemble

Purpose Classification ensemble grown by resampling
Description
Construction
ens =fitensemble(X,Y,'bag', nlearn, learners,'type','classification')creates a bagged classification ensemble. For syntax details,see the fitensemble reference page.
Properties CategoricalPredictors
List of categorical predictors. CategoricalPredictors is a numeric vector with indices from 1 to $p$, where $p$ is the number of columns of X .

## CombineWeights

String describing how ens combines weak learner weights, either 'WeightedSum' or 'WeightedAverage'.

## FitInfo

Numeric array of fit information. The FitInfoDescription property describes the content of this array.

## FitInfoDescription

String describing the meaning of the FitInfo array.

## FResample

Numeric scalar between 0 and 1. FResample is the fraction of training data fitensemble resampled at random for every weak learner when constructing the ensemble.

## Method

String describing the method that creates ens.

## ModelParams

## ClassificationBaggedEnsemble

Parameters used in training ens.

## NTrained

Number of trained weak learners in ens, a scalar.

## PredictorNames

Cell array of names for the predictor variables, in the order in which they appear in $X$.

## ReasonForTermination

String describing the reason fitensemble stopped adding weak learners to the ensemble.

## Replace

Logical value indicating if the ensemble was trained with replacement (true) or without replacement (false).

## ResponseName

String with the name of the response variable $Y$.

## ScoreTransform

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means @(x)x. For a list of built-in transformation functions and the syntax of custom transformation functions, see ClassificationTree.fit.

Add or change a ScoreTransform function by dot addressing:

```
ens.ScoreTransform = 'function'
```

or
ens.ScoreTransform = @function

## Trained

Trained learners, a cell array of compact classification models.

## ClassificationBaggedEnsemble

## TrainedWeights

Numeric vector of trained weights for the weak learners in ens. TrainedWeights has $T$ elements, where $T$ is the number of weak learners in learners.

## UseObsForLearner

Logical matrix of size N -by-NTrained, where N is the number of observations in the training data and NTrained is the number of trained weak learners. UseObsForLearner ( $I, J$ ) is true if observation I was used for training learner $J$, and is false otherwise.

## w

Scaled weights, a vector with length $n$, the number of rows in X . The sum of the elements of $W$ is 1 .

## X

Matrix of predictor values that trained the ensemble. Each column of $X$ represents one variable, and each row represents one observation.

Y
Numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. Each row of $Y$ represents the classification of the corresponding row of X .

## Methods

oobEdge
oobLoss
oobMargin
oobPredict

Out-of-bag classification edge
Out-of-bag classification error
Out-of-bag classification margins
Predict out-of-bag response of ensemble

## ClassificationBaggedEnsemble

Copy Value. To learn how value classes affect copy operations, see Copying Semantics Objects in the MATLAB documentation.

Examples Construct a bagged ensemble for the ionosphere data, and examine its resubstitution loss:

```
load ionosphere
rng(0,'twister') % for reproducibility
ens = fitensemble(X,Y,'bag',100,'Tree',...
```

## ClassificationBaggedEnsemble

```
    'type','classification');
L = resubLoss(ens)
L =
    0
```

The ensemble does a perfect job classifying its training data.

## ClassificationDiscriminant

## Superclasses CompactClassificationDiscriminant <br> Purpose Discriminant analysis classification <br> Description A ClassificationDiscriminant object encapsulates a discriminant analysis classifier, which is a Gaussian mixture model for data generation. A ClassificationDiscriminant object can predict responses for new data using the predict method. The object contains the data used for training, so can compute resubstitution predictions. <br> Construction <br> obj $=$ ClassificationDiscriminant.fit $(X, Y)$ creates a discriminant classification object based on the input variables (also known as predictors, features, or attributes) $X$ and output (response) Y. For syntax details, see ClassificationDiscriminant.fit. <br> obj = ClassificationDiscriminant.fit(X,Y,Name, Value) creates a classifier with additional options specified by one or more Name, Value pair arguments. If you use one of the following five options, obj is of class ClassificationPartitionedModel: 'crossval', 'kfold', 'holdout', 'leaveout', or 'cvpartition'. Otherwise, obj is of class ClassificationDiscriminant. <br> Input Arguments

## x

Matrix of numeric predictor values. Each column of $X$ represents one variable, and each row represents one observation.

NaN values in $X$ are considered missing values. Observations with missing values for $X$ are not used in the fit.

## Y

Numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. Each row of $Y$ represents the classification of the corresponding row of $X$. NaN values in $Y$ are considered missing values. Observations with missing values for $Y$ are not used in the fit.

## ClassificationDiscriminant

## Properties

## BetweenSigma

p -by-p matrix, the between-class covariance, where p is the number of predictors.

## CategoricalPredictors

List of categorical predictors, always empty ([ ]) for discriminant analysis.

## ClassNames

List of the elements in the training data $Y$ with duplicates removed. ClassNames can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. ClassNames has the same data type as the data in the argument $Y$.

## Coeffs

$k$-by-k structure of coefficient matrices, where $k$ is the number of classes. Coeffs ( $i, j$ ) contains coefficients of the linear or quadratic boundaries between classes i and j. Fields in Coeffs(i,j):

- DiscrimType
- Class1 - ClassNames(i)
- Class2 - ClassNames(j)
- Const - A scalar
- Linear - A vector with $p$ components, where $p$ is the number of columns in $X$
- Quadratic - p-by-p matrix, exists for quadratic DiscrimType

The equation of the boundary between class $i$ and class $j$ is
Const + Linear * x + x' * Quadratic * x = 0,
where $x$ is a column vector of length $p$.

## ClassificationDiscriminant

If ClassificationDiscriminant.fit had the FillCoeffs name-value pair set to 'off' when constructing the classifier, Coeffs is empty ([]).

## Cost

Square matrix, where $\operatorname{Cost}(i, j)$ is the cost of classifying a point into class $j$ if its true class is $i$. Cost is $K$-by- $K$, where $K$ is the number of classes.

Change a Cost matrix using dot addressing:
obj.Cost = costMatrix

## Delta

Value of the Delta threshold for a linear discriminant model, a nonnegative scalar. If a coefficient of obj has magnitude smaller than Delta, obj sets this coefficient to 0 , and so you can eliminate the corresponding predictor from the model. Set Delta to a higher value to eliminate more predictors.

Delta must be 0 for quadratic discriminant models.
Change Delta by dot addressing:
obj.Delta $=$ newDelta

## DeltaPredictor

Row vector of length equal to the number of predictors in obj. If DeltaPredictor(i) < Delta then coefficient $i$ of the model is 0 .

If obj is a quadratic discriminant model, all elements of DeltaPredictor are 0.

## DiscrimType

String specifying the discriminant type. One of:

- 'linear'
- 'quadratic'

## ClassificationDiscriminant

- 'diagLinear'
- 'diagQuadratic'
- 'pseudoLinear'
- 'pseudoQuadratic'

Change DiscrimType using dot addressing:
obj.DiscrimType = newDiscrimType
You can change between linear types, or between quadratic types, but cannot change between linear and quadratic types.

## Gamma

Value of the Gamma regularization parameter, a scalar from 0 to 1. Change Gamma using dot addressing:
obj.Gamma $=$ newGamma

- If you set 1 for linear discriminant, the discriminant sets its type to 'diagLinear'.
- If you set a value between MinGamma and 1 for linear discriminant, the discriminant sets its type to 'linear'.
- You cannot set values below the value of the MinGamma property.
- For quadratic discriminant, you can set either 0 (for DiscrimType 'quadratic') or 1 (for DiscrimType 'diagQuadratic').

## LogDetSigma

Logarithm of the determinant of the within-class covariance matrix. The type of LogDetSigma depends on the discriminant type:

- Scalar for linear discriminant analysis

## ClassificationDiscriminant

- Vector of length $K$ for quadratic discriminant analysis, where $K$ is the number of classes

## MinGamma

Nonnegative scalar, the minimal value of the Gamma parameter so that the correlation matrix is invertible. If the correlation matrix is not singular, MinGamma is 0 .

## ModelParams

Parameters used in training obj.

## Mu

Matrix of class means of size K-by-p, where K is the number of classes, and $p$ is the number of predictors. Each row of Mu represents the mean of the multivariate normal distribution of the corresponding class. The class indices are in the ClassNames attribute.

## NObservations

Number of observations in the training data, a numeric scalar. NObservations can be less than the number of rows of input data $X$ when there are missing values in $X$ or response $Y$.

## PredictorNames

Cell array of names for the predictor variables, in the order in which they appear in the training data $X$.

## Prior

Prior probabilities for each class. Prior is a numeric vector whose entries relate to the corresponding ClassNames property.

Add or change a Prior vector using dot addressing:
obj. Prior = priorVector

## ResponseName

String describing the response variable Y.

## ClassificationDiscriminant

## ScoreTransform

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means @(x)x. For a list of built-in transformation functions and the syntax of custom transformation functions, see ClassificationDiscriminant.fit.

Add or change a ScoreTransform function by dot addressing:
cobj.ScoreTransform = 'function'
or
cobj.ScoreTransform = @function

## Sigma

Within-class covariance matrix or matrices. The dimensions depend on DiscrimType:

- 'linear' (default) - Matrix of size $p$-by-p, where $p$ is the number of predictors
- 'quadratic' - Array of size $p$-by-p-by-K, where $K$ is the number of classes
- 'diagLinear' - Row vector of length $p$
- 'diagQuadratic' - Array of size 1-by-p-by-K
- 'pseudoLinear' - Matrix of size p-by-p
- 'pseudoQuadratic' - Array of size p-by-p-by-K

## W

Scaled weights, a vector with length $n$, the number of rows in $X$.

## X

Matrix of predictor values. Each column of X represents one predictor (variable), and each row represents one observation.

## ClassificationDiscriminant

## Xcentered

$X$ data with class means subtracted. If $Y(i)$ is of class $j$,

$$
\text { Xcentered(i,: })=X(i,:)-M u(j,:),
$$

where Mu is the class mean property.

```
Y
```

Numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. Each row of $Y$ represents the classification of the corresponding row of $X$.

## Methods

## Definitions Discriminant Classification

The model for discriminant analysis is:

- Each class (Y) generates data (X) using a multivariate normal distribution. That is, the model assumes X has a Gaussian mixture distribution (gmdistribution).
- For linear discriminant analysis, the model has the same covariance matrix for each class, only the means vary.
- For quadratic discriminant analysis, both means and covariances of each class vary.
predict classifies so as to minimize the expected classification cost:

## ClassificationDiscriminant

$$
\hat{y}=\underset{y=1, \ldots, K}{\arg \min } \sum_{k=1}^{K} \hat{P}(k \mid x) C(y \mid k),
$$

where

- $\hat{y}$ is the predicted classification.
- $K$ is the number of classes.
- $\hat{P}(k \mid x)$ is the posterior probability of class $k$ for observation $x$.
- $C(y \mid k)$ is the cost of classifying an observation as $y$ when its true class is $k$.

For details, see "How the predict Method Classifies" on page 14-6.

## Regularization

Regularization is the process of finding a small set of predictors that yield an effective predictive model. For linear discriminant analysis, there are two parameters, $\gamma$ and $\delta$, that control regularization as follows. cvshrink helps you select appropriate values of the parameters.

Let $\Sigma$ represent the covariance matrix of the data $X$, and let $\hat{X}$ be the centered data (the data $X$ minus the mean by class). Define

$$
D=\operatorname{diag}\left(\hat{X}^{T} * \hat{X}\right)
$$

The regularized covariance matrix $\tilde{\Sigma}$ is

$$
\tilde{\Sigma}=(1-\gamma) \Sigma+\gamma D .
$$

Whenever $\gamma \geq$ MinGamma, $\tilde{\Sigma}$ is nonsingular.
Let $\mu_{k}$ be the mean vector for those elements of $X$ in class $k$, and let $\mu_{0}$ be the global mean vector (the mean of the rows of $X$ ). Let $C$ be

## ClassificationDiscriminant

the correlation matrix of the data $X$, and let $\tilde{C}$ be the regularized correlation matrix:

$$
\tilde{C}=(1-\gamma) C+\gamma I,
$$

where $I$ is the identity matrix.
The linear term in the regularized discriminant analysis classifier for a data point $x$ is

$$
\left(x-\mu_{0}\right)^{T} \tilde{\Sigma}^{-1}\left(\mu_{k}-\mu_{0}\right)=\left[\left(x-\mu_{0}\right)^{T} D^{-1 / 2}\right]\left[\tilde{C}^{-1} D^{-1 / 2}\left(\mu_{k}-\mu_{0}\right)\right] .
$$

The parameter $\delta$ enters into this equation as a threshold on the final term in square brackets. Each component of the vector
$\left[\tilde{C}^{-1} D^{-1 / 2}\left(\mu_{k}-\mu_{0}\right)\right]$ is set to zero if it is smaller in magnitude than the threshold $\delta$. Therefore, for class $k$, if component $j$ is thresholded to zero, component $j$ of $x$ does not enter into the evaluation of the posterior probability.
The DeltaPredictor property is a vector related to this threshold. When $\delta \geq$ DeltaPredictor(i), all classes $k$ have

$$
\left|\tilde{C}^{-1} D^{-1 / 2}\left(\mu_{k}-\mu_{0}\right)\right| \leq \delta .
$$

Therefore, when $\delta \geq$ DeltaPredictor(i), the regularized classifier does not use predictor i.

$$

## Properties

## CategoricalPredictors

List of categorical predictors. CategoricalPredictors is a numeric vector with indices from 1 to $p$, where $p$ is the number of columns of X .

## ClassNames

List of the elements in $Y$ with duplicates removed. ClassNames can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. ClassNames has the same data type as the data in the argument Y .

## CombineWeights

String describing how ens combines weak learner weights, either 'WeightedSum' or 'WeightedAverage'.

## Cost

## ClassificationEnsemble

Square matrix where $\operatorname{Cost}(i, j)$ is the cost of classifying a point into class $j$ if its true class is $i$.

## FitInfo

Numeric array of fit information. The FitInfoDescription property describes the content of this array.

## FitInfoDescription

String describing the meaning of the FitInfo array.

## LearnerNames

Cell array of strings with names of weak learners in the ensemble. The name of each learner appears just once. For example, if you have an ensemble of 100 trees, LearnerNames is \{'Tree'\}.

## Method

String describing the method that creates ens.

## ModelParams

Parameters used in training ens.

## NObservations

Numeric scalar containing the number of observations in the training data.

## NTrained

Number of trained weak learners in ens, a scalar.

## PredictorNames

Cell array of names for the predictor variables, in the order in which they appear in $X$.

## Prior

Prior probabilities for each class. Prior is a numeric vector whose entries relate to the corresponding ClassNames property.

## ReasonForTermination

## ClassificationEnsemble

String describing the reason fitensemble stopped adding weak learners to the ensemble.

## ResponseName

String with the name of the response variable Y.

## ScoreTransform

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means @(x)x. For a list of built-in transformation functions and the syntax of custom transformation functions, see ClassificationTree.fit.

Add or change a ScoreTransform function by dot addressing:
ens.ScoreTransform = 'function'
or
ens.ScoreTransform = @function

## Trained

Trained learners, a cell array of compact classification models.

## TrainedWeights

Numeric vector of trained weights for the weak learners in ens. TrainedWeights has T elements, where $T$ is the number of weak learners in learners.

## UsePredForLearner

Logical matrix of size $P$-by-NTrained, where $P$ is the number of predictors (columns) in the training data $X$. UsePredForLearner ( $\mathrm{i}, \mathrm{j}$ ) is true when learner j uses predictor $i$, and is false otherwise. For each learner, the predictors have the same order as the columns in the training data $X$.
If the ensemble is not of type Subspace, all entries in UsePredForLearner are true.

## ClassificationEnsemble

## W

Scaled weights, a vector with length n , the number of rows in X . The sum of the elements of $W$ is 1 .

## X

Matrix of predictor values that trained the ensemble. Each column of $X$ represents one variable, and each row represents one observation.

## Y

Numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. Each row of $Y$ represents the classification of the corresponding row of $X$.

## Methods

| compact | Compact classification ensemble |

## ClassificationKNN

## Purpose $\quad k$-nearest neighbor classification

Description

Construction

A nearest-neighbor classification object, where both distance metric ("nearest") and number of neighbors can be altered. The object classifies new observations using the predict method. The object contains the data used for training, so can compute resubstitution predictions.
mdl $=$ ClassificationKNN.fit $(X, Y)$ creates a $k$-nearest neighbor classification model. For details, see ClassificationKNN.fit.
mdl = ClassificationKNN.fit(X,Y,Name,Value) creates a classifier with additional options specified by one or more Name, Value pair arguments. For details, see ClassificationKNN.fit.

## Input Arguments

## X

Matrix of predictor values. Each column of $X$ represents one variable, and each row represents one observation.

## Y

Grouping variables of response values with the same number of elements (rows) as X. Each entry in $Y$ is the response to the data in the corresponding row of $X$.

## Properties

## BreakTies

String specifying the method predict uses to break ties if multiple classes have the same smallest cost. By default, ties occur when multiple classes have the same number of nearest points among the K nearest neighbors.

- 'nearest' - Use the class with the nearest neighbor among tied groups.
- 'random' - Use a random tiebreaker among tied groups.
- 'smallest' - Use the smallest index among tied groups.

## ClassificationKNN

'BreakTies' applies when 'IncludeTies' is false.
Change BreakTies using dot addressing:
mdl.BreakTies = newBreakTies

## CategoricalPredictors

Specification of which predictors are categorical.

- 'all' - All predictors are categorical.
- [ ] - No predictors are categorical.

## ClassNames

List of elements in the training data $Y$ with duplicates removed. ClassNames can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. ClassNames has the same data type as the data in the argument $Y$.

Change ClassNames using dot addressing:
mdl.ClassNames = newClassNames

## Cost

Square matrix, where Cost (i,j) is the cost of classifying a point into class $j$ if its true class is $i$. Cost is $K-b y-K$, where $K$ is the number of classes.

Change a Cost matrix using dot addressing:
mdl.Cost $=$ costMatrix

## Distance

String or function handle specifying the distance metric. The allowable strings depend on the NSMethod parameter, which you set in ClassificationKNN.fit, and which exists as a field in ModelParams.

## ClassificationKNN

| NSMethod | Distance Metric Names |
| :--- | :--- |
| exhaustive | Any distance metric of ExhaustiveSearcher |
| kdtree | 'cityblock', 'chebychev ', 'euclidean ', or <br> 'minkowski' |

For definitions, see "Distance Metrics" on page 15-9.
The distance metrics of ExhaustiveSearcher:

| Value | Description |
| :--- | :--- |
| 'cityblock' | City block distance. |
| 'chebychev' | Chebychev distance (maximum coordinate <br> difference). |
| 'correlation' | One minus the sample linear correlation <br> between observations (treated as <br> sequences of values). |
| 'cosine' | One minus the cosine of the included angle <br> between observations (treated as vectors). |
| 'euclidean' | Euclidean distance. |
| 'hamming' | Hamming distance, percentage of <br> coordinates that differ. |
| ' jaccard' | One minus the Jaccard coefficient, the <br> percentage of nonzero coordinates that <br> differ. |
| 'mahalanobis' | Mahalanobis distance, computed using a <br> positive definite covariance matrix C. The <br> default value of C is the sample covariance <br> matrix of X, as computed by nancov(X). <br> To specify a different value for C, use the <br> 'Cov' name-value pair. |

## ClassificationKNN

| Value | Description |
| :--- | :--- |
| 'minkowski' | Minkowski distance. The default exponent <br> is 2. To specify a different exponent, use <br> the 'P' name-value pair. |
| 'seuclidean' | Standardized Euclidean distance. Each <br> coordinate difference between X and a <br> query point is scaled, meaning divided by <br> a scale value S. The default value of S is <br> the standard deviation computed from X, <br> S = nanstd (X). To specify another value <br> for S, use the Scale name-value pair. |
| 'spearman' | One minus the sample Spearman's rank <br> correlation between observations (treated <br> as sequences of values). |
| @distfun | Distance function handle. distfun has <br> the form <br> function D2 = DISTFUN (ZI , ZJ) <br> \% calculation of distance <br> I |
| where |  |
| - ZI is a 1-by-N vector containing one row |  |
| of X or Y. |  |

Change Distance using dot addressing:

```
mdl.Distance = newDistance
```

## ClassificationKNN

If NSMethod is kdtree, you can use dot addressing to change Distance only among the types 'cityblock', 'chebychev', 'euclidean', or 'minkowski'.

## DistanceWeight

String or function handle specifying the distance weighting function.

| DistanceWeight | Meaning |
| :--- | :--- |
| 'equal' | No weighting |
| 'inverse' | Weight is 1/distance |
| 'inversesquared ' | Weight is 1/distance ${ }^{2}$ |
| @fcn | fcn is a function that accepts a matrix <br> of nonnegative distances, and returns <br> a matrix the same size containing <br> nonnegative distance weights. For <br> example, 'inversesquared ' is equivalent <br> to @(d)d.^(-2). |

Change DistanceWeight using dot addressing:
mdl.DistanceWeight = newDistanceWeight

## DistParameter

Additional parameter for the distance metric.

| Distance Metric | Parameter |
| :--- | :--- |
| 'mahalanobis' | Positive definite covariance matrix C. |
| 'minkowski' | Minkowski distance exponent, a positive <br> scalar. |
| 'seuclidean' | Vector of positive scale values with length <br> equal to the number of columns of X. |

## ClassificationKNN

For values of the distance metric other than those in the table, DistParameter must be []. Change DistParameter using dot addressing:
mdl.DistParameter = newDistParameter

## IncludeTies

Logical value indicating whether predict includes all the neighbors whose distance values are equal to the Kth smallest distance. If IncludeTies is true, predict includes all these neighbors. Otherwise, predict uses exactly K neighbors (see 'BreakTies').

Change IncludeTies using dot addressing:
mdl.IncludeTies $=$ newIncludeTies

## ModelParams

Parameters used in training mdl.

## NObservations

Number of observations used in training mdl. This can be less than the number of rows in the training data, because data rows containing NaN values are not part of the fit.

## NumNeighbors

Positive integer specifying the number of nearest neighbors in $X$ to find for classifying each point when predicting. Change NumNeighbors using dot addressing:
mdl.NumNeighbors = newNumNeighbors

## PredictorNames

Cell array of names for the predictor variables, in the order in which they appear in the training data X . Change PredictorNames using dot addressing:

## ClassificationKNN

mdl.PredictorNames $=$ newPredictorNames

## Prior

Prior probabilities for each class. Prior is a numeric vector whose entries relate to the corresponding ClassNames property.

Add or change a Prior vector using dot addressing:
obj.Prior = priorVector

## ResponseName

String describing the response variable Y. Change ResponseName using dot addressing:
mdl.ResponseName = newResponseName

## W

Numeric vector of nonnegative weights with the same number of rows as $Y$. Each entry in $W$ specifies the relative importance of the corresponding observation in Y . Change W using dot addressing:
mdl.w = newW

X
Numeric matrix of predictor values. Each column of $X$ represents one predictor (variable), and each row represents one observation.

## $\mathbf{Y}$

Numeric vector of response values with the same number of rows as $X$. Each entry in $Y$ is the response to the data in the corresponding row of X .

## ClassificationKNN

## Methods

| crossval | Cross-validated $k$-nearest <br> neighbor classifier |
| :--- | :--- |
| edge | Edge of $k$-nearest neighbor <br> classifier |
| fit | Fit $k$-nearest neighbor classifier <br> Loss of $k$-nearest neighbor <br> classifier |
| margin | Margin of $k$-nearest neighbor <br> classifier |
| predict | Predict $k$-nearest neighbor <br> classification |
| resubEdge | Edge of $k$-nearest neighbor <br> classifier by resubstitution |
| resubLoss | Loss of $k$-nearest neighbor <br> classifier by resubstitution |
| resubMargin | Margin of $k$-nearest neighbor <br> classifier by resubstitution |
| resubPredict | Predict resubstitution response of <br> $k$-nearest neighbor classifier |
| template | $k$-nearest neighbor classifier <br> template for ensemble |

## Definitions Prediction

ClassificationKNN predicts the classification of a point Xnew using a procedure equivalent to this:

1 Find the NumNeighbors points in the training set $X$ that are nearest to Xnew.

2 Find the NumNeighbors response values $Y$ to those nearest points.

## ClassificationKNN

3 Assign the classification label Ynew that has smallest expected misclassification cost among the values in Y .

For details, see "Posterior Probability" on page 20-2181 and "Expected Cost" on page 20-2182 in the predict documentation.

## Copy <br> Semantics

Value. To learn how value classes affect copy operations, see Copying Objects in the MATLAB documentation.

## Examples

## Construct a KNN Classifier

Construct a $k$-nearest neighbor classifier for the Fisher iris data, where $k=5$.

Load the data.
load fisheriris
X = meas;
Y = species;
Construct a classifier for 5-nearest neighbors.
mdl = ClassificationKNN.fit(X,Y,'NumNeighbors',5)
mdl =
ClassificationKNN:
PredictorNames: \{'x1' 'x2' 'x3' 'x4'\}
ResponseName: ' $Y$ '
ClassNames: \{'setosa' 'versicolor' 'virginica'\}
ScoreTransform: 'none'
NObservations: 150
Distance: 'euclidean'
NumNeighbors: 5

## Alternatives

knnsearch finds the $k$-nearest neighbors of points. rangesearch finds all the points within a fixed distance. You can use these functions for classification, as shown in "Example: Classifying Query

## ClassificationKNN

Data Using knnsearch" on page $15-18$. If you want to perform classification, ClassificationKNN can be more convenient, in that you can construct a classifier in one step and classify in other steps. Also, ClassificationKNN has cross-validation options.

## ClassificationPartitionedEnsemble

## Construction

## Properties

## Purpose Cross-validated classification ensemble <br> ClassificationPartitionedEnsemble is a set of classification ensembles trained on cross-validated folds. Estimate the quality of classification by cross validation using one or more "kfold" methods: kfoldPredict, kfoldLoss, kfoldMargin, kfoldEdge, and kfoldfun.

Every "kfold" method uses models trained on in-fold observations to predict response for out-of-fold observations. For example, suppose you cross validate using five folds. In this case, every training fold contains roughly $4 / 5$ of the data and every test fold contains roughly $1 / 5$ of the data. The first model stored in Trained\{1\} was trained on $X$ and $Y$ with the first $1 / 5$ excluded, the second model stored in Trained\{2\} was trained on $X$ and $Y$ with the second $1 / 5$ excluded, and so on. When you call kfoldPredict, it computes predictions for the first $1 / 5$ of the data using the first model, for the second $1 / 5$ of data using the second model, and so on. In short, response for every observation is computed by kfoldPredict using the model trained without this observation.
cvens = crossval(ens) creates a cross-validated ensemble from ens, a classification ensemble. For syntax details, see the crossval method reference page.
cvens = fitensemble(X,Y,method, nlearn, learners, name, value) creates a cross-validated ensemble when name is one of 'crossval', 'kfold', 'holdout', 'leaveout', or 'cvpartition'. For syntax details, see the fitensemble function reference page.

## CategoricalPredictors

List of categorical predictors. CategoricalPredictors is a numeric vector with indices from 1 to $p$, where $p$ is the number of columns of X .

## ClassNames

List of the elements in Y with duplicates removed. ClassNames can be a numeric vector, vector of categorical variables (nominal

## ClassificationPartitionedEnsemble

or ordinal), logical vector, character array, or cell array of strings. ClassNames has the same data type as the data in the argument Y .

## Combiner

Cell array of combiners across all folds.

## Cost

Square matrix, where $\operatorname{Cost}(i, j)$ is the cost of classifying a point into class $j$ if its true class is $i$.

## CrossValidatedModel

Name of the cross-validated model, a string.

## Kfold

Number of folds used in a cross-validated ensemble, a positive integer.

## ModelParams

Object holding parameters of cvens.

## NObservations

Number of data points used in training the ensemble, a positive integer.

## NTrainedPerFold

Number of data points used in training each fold of the ensemble, a positive integer.

## Partition

Partition of class cvpartition used in creating the cross-validated ensemble.

## PredictorNames

Cell array of names for the predictor variables, in the order in which they appear in $X$.

## Prior

## ClassificationPartitionedEnsemble

Prior probabilities for each class. Prior is a numeric vector whose entries relate to the corresponding ClassNames property.

## ResponseName

Name of the response variable Y , a string.

## ScoreTransform

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means @(x)x. For a list of built-in transformation functions and the syntax of custom transformation functions, see ClassificationTree.fit.

Add or change a ScoreTransform function by dot addressing:
ens.ScoreTransform = 'function'
or
ens.ScoreTransform = @function

## Trainable

Cell array of ensembles trained on cross-validation folds. Every ensemble is full, meaning it contains its training data and weights.

## Trained

Cell array of compact ensembles trained on cross-validation folds.

## W

Scaled weights, a vector with length $n$, the number of rows in $X$.
X
A matrix of predictor values. Each column of $X$ represents one variable, and each row represents one observation.

Y
A numeric column vector with the same number of rows as $X$. Each entry in $Y$ is the response to the data in the corresponding row of $X$.

## ClassificationPartitionedEnsemble

## Methods

kfoldEdge
kfoldLoss
resume
Inherited Methods

| kfoldEdge | Classification edge for <br> observations not used for <br> training |
| :--- | :--- |
| kfoldfun | Cross validate function |
| kfoldLoss | Classification loss for <br> observations not used for <br> training |
| kfoldMargin | Classification margins for <br> observations not used for training |
| kfoldPredict | Predict response for observations <br> not used for training |

## Copy Semantics

Examples

Value. To learn how value classes affect copy operations, see Copying Objects in the MATLAB documentation.

Evaluate the k-fold cross-validation error for a classification ensemble that models the Fisher iris data:

```
load fisheriris
ens = fitensemble(meas,species,'AdaBoostM2',100,'Tree');
cvens = crossval(ens);
L = kfoldLoss(cvens)
```

## ClassificationPartitionedModel

## Purpose Cross-validated classification model <br> Description <br> Construction <br> ClassificationPartitionedModel is a set of classification models trained on cross-validated folds. Estimate the quality of classification by cross validation using one or more "kfold" methods: kfoldPredict, kfoldLoss, kfoldMargin, kfoldEdge, and kfoldfun. <br> Every "kfold" method uses models trained on in-fold observations to predict response for out-of-fold observations. For example, suppose you cross validate using five folds. In this case, every training fold contains roughly $4 / 5$ of the data and every test fold contains roughly $1 / 5$ of the data. The first model stored in Trained\{1\} was trained on $X$ and $Y$ with the first $1 / 5$ excluded, the second model stored in Trained $\{2\}$ was trained on $X$ and $Y$ with the second $1 / 5$ excluded, and so on. When you call kfoldPredict, it computes predictions for the first $1 / 5$ of the data using the first model, for the second $1 / 5$ of data using the second model, and so on. In short, response for every observation is computed by kfoldPredict using the model trained without this observation. <br> cvmodel $=$ crossval(obj) creates a cross-validated classification model from a classification model. <br> cvmodel = ClassificationTree.fit(X,Y, name, value) or cvmodel $=$ ClassificationDiscriminant.fit(X,Y, name, value) creates a cross-validated model when name is one of 'crossval', 'kfold', 'holdout', 'leaveout', or 'cvpartition'. For syntax details, see the ClassificationTree.fit or ClassificationDiscriminant.fit function reference pages. <br> Input Arguments <br> obi <br> A classification model. obj can be a classification tree constructed using ClassificationTree.fit, or a discriminant analysis classifier constructed using ClassificationDiscriminant.fit.

## ClassificationPartitionedModel

## Properties

## CategoricalPredictors

List of categorical predictors. CategoricalPredictors is a numeric vector with indices from 1 to $p$, where $p$ is the number of columns of X .

## ClassNames

List of the elements in $Y$ with duplicates removed. ClassNames can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. ClassNames has the same data type as the data in the argument Y .

## Cost

Square matrix, where $\operatorname{Cost}(i, j)$ is the cost of classifying a point into class $j$ if its true class is $i$.

If cvmodel is a cross-validated ClassificationDiscriminant model, you can change a cost matrix by dot addressing:
cvmodel. Cost $=$ costMatrix

## CrossValidatedModel

Name of the cross-validated model, a string.

## Kfold

Number of folds used in cross-validated model, a positive integer.

## ModelParams

Object holding parameters of cvmodel.

## Partition

The partition of class cvpartition used in creating the cross-validated model.

## PredictorNames

A cell array of names for the predictor variables, in the order in which they appear in X .

## ClassificationPartitionedModel

## Prior

Prior probabilities for each class. Prior is a numeric vector whose entries relate to the corresponding ClassNames property.
If cvmodel is a cross-validated ClassificationDiscriminant model, you can change a Prior vector by dot addressing:
cvmodel.Prior = priorVector

## ResponseName

Name of the response variable Y , a string.

## ScoreTransform

Function handle for transforming scores, or string representing a built-in transformation function.

| String | Formula |
| :--- | :--- |
| 'symmetric' | $2 x-1$ |
| 'invlogit' | $\log (x /(1-x))$ |
| 'ismax' | Set score for the class with the <br> largest score to 1, and scores for all <br> other classes to 0. |
| 'symmetricismax' | Set score for the class with the <br> largest score to 1, and scores for <br> all other classes to -1. |
| 'none' | $x$ |
| 'logit' | $1 /\left(1+e^{-x}\right)$ |
| 'doublelogit' | $1 /\left(1+e^{-2 x}\right)$ |
| 'symmetriclogit' | $2 /\left(1+e^{-x}\right)-1$ |
| 'sign' | -1 for $x<0$ <br> 0 <br> for $x=0$ <br> 1 for $x>0$ |

## ClassificationPartitionedModel

You can include your own function handle for transforming scores. Your function should accept a matrix (the original scores) and return a matrix of the same size (the transformed scores).

Add or change a ScoreTransform function by dot addressing:
cvmodel.ScoreTransform = 'function'
or
cvmodel.ScoreTransform = @function

## Trained

The trained learners, a cell array of compact classification models.

## W

The scaled weights, a vector with length n , the number of rows in $X$.

## X

A matrix of predictor values. Each column of X represents one variable, and each row represents one observation.

Y
A numeric column vector with the same number of rows as $X$. Each entry in $Y$ is the response to the data in the corresponding row of $X$.

## Methods

| kfoldEdge | Classification edge for <br> observations not used for <br> training |
| :--- | :--- |
| kfoldfun | Cross validate function |
| kfoldLoss | Classification loss for <br> observations not used for <br> training |

## ClassificationPartitionedModel

$\left.\begin{array}{ll} & \begin{array}{l}\text { kfoldMargin } \\ \text { kfoldPredict }\end{array} \\ \text { Copy } \\ \text { Semantics } & \begin{array}{l}\text { Value. To learn how value classes affect copy operations, see Copying } \\ \text { Objects in the MATLAB documentation. }\end{array} \\ \text { Examples } & \begin{array}{l}\text { Evaluate the k-fold cross-validation error for a classification tree margins for } \\ \text { of the Fisher iris data: }\end{array} \\ \text { observations not used for training } \\ \text { Predict response for observations }\end{array}\right\}$

## ClassificationTree

| Superclasses | CompactClassificationTree |
| :---: | :---: |
| Purpose | Binary decision tree for classification |
| Description | A decision tree with binary splits for classification. An object of class ClassificationTree can predict responses for new data with the predict method. The object contains the data used for training, so can compute resubstitution predictions. |
| Construction | tree = ClassificationTree.fit( $\mathrm{X}, \mathrm{Y}$ ) returns a classification tree based on the input variables (also known as predictors, features, or attributes) X and output (response) Y . tree is a binary tree, where each branching node is split based on the values of a column of $X$. <br> tree $=$ ClassificationTree.fit(X,Y,Name, Value) fits a tree with additional options specified by one or more Name, Value pair arguments. If you use one of the following five options, tree is of class ClassificationPartitionedModel: 'crossval', 'kfold', 'holdout', 'leaveout', or 'cvpartition'. Otherwise, tree is of class ClassificationTree. |
|  | Input Arguments |
|  | x |
|  | A matrix of numeric predictor values. Each column of X represents one variable, and each row represents one observation. |
|  | NaN values in X are taken to be missing values. Observations with all missing values for X are not used in the fit. Observations with some missing values for X are used to find splits on variables for which these observations have valid values. |

## $\mathbf{Y}$

A numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. Each row of $Y$ represents the classification of the corresponding

## ClassificationTree

> row of X. For numeric Y, consider using RegressionTree.fit instead of ClassificationTree.fit.
> NaN values in Y are taken to be missing values. Observations with missing values for Y are not used in the fit.

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN.

## AlgorithmForCategorical

Algorithm to find the best split on a categorical predictor with $L$ levels for data with $K \geq 3$ classes. The available algorithms are:

| 'Exact' | Consider all $2^{L-1}-1$ <br> combinations |
| :--- | :--- |
| 'PullLeft' | Pull left by purity <br> 'PCA' |
| Principle component-based |  |
| partition[1] |  |

Descriptions of the algorithms are in "Splitting Categorical Predictors" on page 15-55.

Default: ClassificationTree.fit selects the optimal subset of algorithms for each split using the known number of classes and levels of a categorical predictor. For $K=2$ classes, ClassificationTree.fit always performs the exact search.

## CategoricalPredictors

List of categorical predictors. Pass CategoricalPredictors as one of:

## ClassificationTree

- A numeric vector with indices from 1 to $p$, where $p$ is the number of columns of $X$.
- A logical vector of length $p$, where a true entry means that the corresponding column of X is a categorical variable.
- 'all', meaning all predictors are categorical.
- A cell array of strings, where each element in the array is the name of a predictor variable. The names must match entries in PredictorNames values.
- A character matrix, where each row of the matrix is a name of a predictor variable. The names must match entries in PredictorNames values. Pad the names with extra blanks so each row of the character matrix has the same length.

Default: []

## ClassNames

Array of class names. Use the data type that exists in $Y$.
Use ClassNames to order the classes or to select a subset of classes for training.

Default: The class names that exist in $Y$

## Cost

Square matrix, where $\operatorname{Cost}(i, j)$ is the cost of classifying a point into class $j$ if its true class is $i$. Alternatively, Cost can be a structure $S$ having two fields: S . ClassNames containing the group names as a variable of the same type as Y , and S.ClassificationCosts containing the cost matrix.

Default: $\operatorname{Cost}(i, j)=1$ if $i \sim=j$, and $\operatorname{Cost}(i, j)=0$ if $i=j$

## crossval

## ClassificationTree

Flag to grow a cross-validated decision tree. Possible value are 'on' or 'off'.

If 'on', ClassificationTree.fit grows a cross-validated decision tree with 10 folds. You can override this cross-validation setting using one of the 'kfold', 'holdout', 'leaveout', or 'cvpartition' name-value pair arguments. Note that you can only use one of these four options ('kfold', 'holdout', 'leaveout', or 'cvpartition') at a time when creating a cross-validated tree.

Alternatively, cross validate tree later using the crossval method.

Default: 'off'

## cvpartition

Partition created with cvpartition to use in a cross-validated tree.

Note that if you use 'cvpartition', you cannot use any of the 'kfold', 'holdout', or 'leaveout ' name-value pair arguments.

## holdout

Holdout validation tests the specified fraction of the data, and uses the rest of the data for training. Specify a numeric scalar from 0 to 1 .

Note that if you use 'holdout', you cannot use any of the 'cvpartition', 'kfold', or 'leaveout' name-value pair arguments.

## kfold

Number of folds to use in a cross-validated tree, a positive integer.
Note that if you use 'kfold', you cannot use any of the 'cvpartition', 'holdout', or 'leaveout' name-value pair arguments.

## ClassificationTree

Default: 10

## leaveout

Use leave-one-out cross validation by setting to 'on'.
Note that if you use 'leaveout', you cannot use any of the 'cvpartition', 'holdout', or 'kfold' name-value pair arguments.

## MaxCat

ClassificationTree.fit splits a categorical predictor using the exact search algorithm if the predictor has at most MaxCat levels in the split node. Otherwise, ClassificationTree.fit finds the best categorical split using one of the inexact algorithms.
Specify MaxCat as a numeric nonnegative scalar value. Passing a small value can lead to loss of accuracy and passing a large value can lead to long computation time and memory overload.

Default: 10

## MergeLeaves

When 'on', ClassificationTree.fit merges leaves that originate from the same parent node, and that give a sum of risk values greater or equal to the risk associated with the parent node. When 'off', ClassificationTree.fit does not merge leaves.

Default: 'on'

## MinLeaf

Each leaf has at least MinLeaf observations per tree leaf. If you supply both MinParent and MinLeaf, ClassificationTree.fit uses the setting that gives larger leaves: MinParent=max(MinParent,2*MinLeaf).

Default: 1

## ClassificationTree

## MinParent

Each branch node in the tree has at least MinParent observations. If you supply both MinParent and MinLeaf, ClassificationTree.fit uses the setting that gives larger leaves: MinParent=max (MinParent,2*MinLeaf).

Default: 10

## NVarToSample

Number of predictors to select at random for each split. Can be a positive integer or 'all', which means use all available predictors.

Default: 'all'

## PredictorNames

A cell array of names for the predictor variables, in the order in which they appear in $X$.

Default: \{'x1', 'x2', ...\}

## prior

Prior probabilities for each class. Specify as one of:

- A string:
- 'empirical' determines class probabilities from class frequencies in Y . If you pass observation weights, they are used to compute the class probabilities.
- 'uniform' sets all class probabilities equal.
- A vector (one scalar value for each class)
- A structure S with two fields:

## ClassificationTree

- S.ClassNames containing the class names as a variable of the same type as $Y$
- S.ClassProbs containing a vector of corresponding probabilities

If you set values for both weights and prior, the weights are renormalized to add up to the value of the prior probability in the respective class.

Default: 'empirical'

## Prune

When 'on', ClassificationTree.fit grows the classification tree, and computes the optimal sequence of pruned subtrees. When 'off' ClassificationTree.fit grows the classification tree without pruning.

Default: 'on'

## PruneCriterion

String with the pruning criterion, either 'error' or 'impurity'.
Default: 'error'

## ResponseName

Name of the response variable Y , a string.
Default: 'Response'

## ScoreTransform

Function handle for transforming scores, or string representing a built-in transformation function.

## ClassificationTree

| String | Formula |
| :--- | :--- |
| 'symmetric' | $2 x-1$ |
| 'invlogit' | $\log (x /(1-x))$ |
| 'ismax' | Set score for the class with the <br> largest score to 1, and scores for all <br> other classes to 0. |
| 'symmetricismax' | Set score for the class with the <br> largest score to 1, and scores for <br> all other classes to -1. |
| 'none' | $x$ |
| 'logit' | $1 /\left(1+e^{-x}\right)$ |
| 'doublelogit' | $1 /\left(1+e^{-2 x}\right)$ |
| 'symmetriclogit' | $2 /\left(1+e^{-x}\right)-1$ |
| 'sign' | -1 for $x<0$ <br> 0 for $x=0$ <br> 1 for $x>0$ |

You can include your own function handle for transforming scores. Your function should accept a matrix (the original scores) and return a matrix of the same size (the transformed scores).

Default: 'none'

## SplitCriterion

Criterion for choosing a split. One of 'gdi' (Gini's diversity index), 'twoing' for the twoing rule, or 'deviance' for maximum deviance reduction (also known as cross entropy).

Default: 'gdi'

## Surrogate

## ClassificationTree

String describing whether to find surrogate decision splits at each branch node. Specify as 'on', 'off', 'all', or a positive scalar value.

- When 'on', ClassificationTree.fit finds at most 10 surrogate splits at each branch node.
- When set to a positive integer value, ClassificationTree.fit finds at most the specified number of surrogate splits at each branch node.
- When set to 'all', ClassificationTree.fit finds all surrogate splits at each branch node. The 'all' setting can use much time and memory.

Use surrogate splits to improve the accuracy of predictions for data with missing values. The setting also enables you to compute measures of predictive association between predictors.

Default: 'off'

## weights

Vector of observation weights. The length of weights is the number of rows in X. ClassificationTree.fit normalizes the weights in each class to add up to the value of the prior probability of the class.

Default: ones(size(X,1),1)

## Properties

## CategoricalPredictors

List of categorical predictors, a numeric vector with indices from 1 to $p$, where $p$ is the number of columns of $X$.

## CatSplit

An $n$-by- 2 cell array, where $n$ is the number of categorical splits in tree. Each row in CatSplit gives left and right values for a categorical split. For each branch node with categorical split j

## ClassificationTree

based on a categorical predictor variable $z$, the left child is chosen if $z$ is in CatSplit ( $j, 1$ ) and the right child is chosen if $z$ is in CatSplit ( $\mathrm{j}, 2$ ). The splits are in the same order as nodes of the tree. Find the nodes for these splits by selecting 'categorical' cuts from top to bottom in the CutType property.

## Children

An $n$-by- 2 array containing the numbers of the child nodes for each node in tree, where $n$ is the number of nodes. Leaf nodes have child node 0 .

## ClassCount

An $n$-by- $k$ array of class counts for the nodes in tree, where $n$ is the number of nodes and $k$ is the number of classes. For any node number i, the class counts ClassCount(i,:) are counts of observations (from the data used in fitting the tree) from each class satisfying the conditions for node i.

## ClassNames

List of the elements in $Y$ with duplicates removed. ClassNames can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. ClassNames has the same data type as the data in the argument Y .

## ClassProb

An $n$-by- $k$ array of class probabilities for the nodes in tree, where $n$ is the number of nodes and $k$ is the number of classes. For any node number $i$, the class probabilities ClassProb(i,:) are the estimated probabilities for each class for a point satisfying the conditions for node i.

## Cost

Square matrix, where $\operatorname{Cost}(i, j)$ is the cost of classifying a point into class $j$ if its true class is $i$.

## CutCategories

## ClassificationTree

An $n$-by- 2 cell array of the categories used at branches in tree, where $n$ is the number of nodes. For each branch node i based on a categorical predictor variable $x$, the left child is chosen if $x$ is among the categories listed in CutCategories $\{i, 1\}$, and the right child is chosen if $x$ is among those listed in CutCategories $\{i, 2\}$. Both columns of CutCategories are empty for branch nodes based on continuous predictors and for leaf nodes.

CutPoint contains the cut points for 'continuous ' cuts, and CutCategories contains the set of categories.

## CutPoint

An $n$-element vector of the values used as cut points in tree, where $n$ is the number of nodes. For each branch node i based on a continuous predictor variable $x$, the left child is chosen if $x<C u t P o i n t(i)$ and the right child is chosen if $x>=C u t P o i n t(i)$. CutPoint is NaN for branch nodes based on categorical predictors and for leaf nodes.

CutPoint contains the cut points for 'continuous' cuts, and CutCategories contains the set of categories.

## CutType

An $n$-element cell array indicating the type of cut at each node in tree, where $n$ is the number of nodes. For each node i, CutType\{i\} is:

- 'continuous' - If the cut is defined in the form $x<v$ for a variable x and cut point v .
- 'categorical' - If the cut is defined by whether a variable $x$ takes a value in a set of categories.
- ' ' - If i is a leaf node.

CutPoint contains the cut points for 'continuous ' cuts, and CutCategories contains the set of categories.

## CutVar

## ClassificationTree

An $n$-element cell array of the names of the variables used for branching in each node in tree, where $n$ is the number of nodes. These variables are sometimes known as cut variables. For leaf nodes, CutVar contains an empty string.

CutPoint contains the cut points for 'continuous' cuts, and CutCategories contains the set of categories.

## IsBranch

An $n$-element logical vector that is true for each branch node and false for each leaf node of tree.

## ModelParams

Parameters used in training tree.

## NObservations

Number of observations in the training data, a numeric scalar. NObservations can be less than the number of rows of input data $X$ when there are missing values in $X$ or response $Y$.

## NodeClass

An $n$-element cell array with the names of the most probable classes in each node of tree, where $n$ is the number of nodes in the tree. Every element of this array is a string equal to one of the class names in ClassNames.

## NodeErr

An $n$-element vector of the errors of the nodes in tree, where $n$ is the number of nodes. NodeErr(i) is the misclassification probability for node i.

## NodeProb

An $n$-element vector of the probabilities of the nodes in tree, where $n$ is the number of nodes. The probability of a node is computed as the proportion of observations from the original data that satisfy the conditions for the node. This proportion is adjusted for any prior probabilities assigned to each class.

## ClassificationTree

## NodeRisk

An $n$-element vector of the risk of the nodes in the tree, where $n$ is the number of nodes. The risk for each node is the measure of impurity (Gini index or deviance) for this node weighted by the node probability. If the tree is grown by twoing, the risk for each node is zero.

## NodeSize

An $n$-element vector of the sizes of the nodes in tree, where $n$ is the number of nodes. The size of a node is defined as the number of observations from the data used to create the tree that satisfy the conditions for the node.

## NumNodes

The number of nodes in tree.

## Parent

An $n$-element vector containing the number of the parent node for each node in tree, where $n$ is the number of nodes. The parent of the root node is 0 .

## PredictorNames

A cell array of names for the predictor variables, in the order in which they appear in X .

## Prior

Prior probabilities for each class. Prior is a numeric vector whose entries relate to the corresponding ClassNames property.

## PruneAlpha

Numeric vector with one element per pruning level. If the pruning level ranges from 0 to $M$, then PruneAlpha has $M+1$ elements sorted in ascending order. PruneAlpha(1) is for pruning level 0 (no pruning), PruneAlpha(2) is for pruning level 1, and so on.

## PruneList

## ClassificationTree

An $n$-element numeric vector with the pruning levels in each node of tree, where $n$ is the number of nodes. The pruning levels range from 0 (no pruning) to $M$, where $M$ is the distance between the deepest leaf and the root node.

## ResponseName

String describing the response variable Y .

## ScoreTransform

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means @(x)x.
Add or change a ScoreTransform function by dot addressing:
tree.ScoreTransform = 'function'
or
tree.ScoreTransform = @function

## SurrCutCategories

An $n$-element cell array of the categories used for surrogate splits in tree, where $n$ is the number of nodes in tree. For each node k, SurrCutCategories $\{\mathrm{k}\}$ is a cell array. The length of SurrCutCategories $\{\mathrm{k}\}$ is equal to the number of surrogate predictors found at this node. Every element of SurrCutCategories $\{\mathrm{k}\}$ is either an empty string for a continuous surrogate predictor, or is a two-element cell array with categories for a categorical surrogate predictor. The first element of this two-element cell array lists categories assigned to the left child by this surrogate split, and the second element of this two-element cell array lists categories assigned to the right child by this surrogate split. The order of the surrogate split variables at each node is matched to the order of variables in SurrCutVar. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrCutCategories contains an empty cell.

## SurrCutFlip

## ClassificationTree

An $n$-element cell array of the numeric cut assignments used for surrogate splits in tree, where $n$ is the number of nodes in tree. For each node k, SurrCutFlip $\{k\}$ is a numeric vector. The length of SurrCutFlip $\{\mathrm{k}\}$ is equal to the number of surrogate predictors found at this node. Every element of SurrCutFlip\{k\} is either zero for a categorical surrogate predictor, or a numeric cut assignment for a continuous surrogate predictor. The numeric cut assignment can be either -1 or +1 . For every surrogate split with a numeric cut $C$ based on a continuous predictor variable $Z$, the left child is chosen if $Z<C$ and the cut assignment for this surrogate split is +1 , or if $Z \geq C$ and the cut assignment for this surrogate split is -1 . Similarly, the right child is chosen if $Z \geq C$ and the cut assignment for this surrogate split is +1 , or if $Z<C$ and the cut assignment for this surrogate split is -1 . The order of the surrogate split variables at each node is matched to the order of variables in SurrCutVar. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrCutFlip contains an empty array.

## SurrCutPoint

An $n$-element cell array of the numeric values used for surrogate splits in tree, where $n$ is the number of nodes in tree. For each node $k$, SurrCutPoint $\{k\}$ is a numeric vector. The length of SurrCutPoint $\{k\}$ is equal to the number of surrogate predictors found at this node. Every element of SurrCutPoint $\{k\}$ is either NaN for a categorical surrogate predictor, or a numeric cut for a continuous surrogate predictor. For every surrogate split with a numeric cut $C$ based on a continuous predictor variable $Z$, the left child is chosen if $Z<C$ and SurrCutFlip for this surrogate split is -1 . Similarly, the right child is chosen if $Z \geq C$ and SurrCutFlip for this surrogate split is +1 , or if $Z<C$ and SurrCutFlip for this surrogate split is -1 . The order of the surrogate split variables at each node is matched to the order of variables returned by SurrCutVar. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrCutPoint contains an empty cell.

## ClassificationTree

## SurrCutType

An $n$-element cell array indicating types of surrogate splits at each node in tree, where $n$ is the number of nodes in tree. For each node k, SurrCutType $\{k\}$ is a cell array with the types of the surrogate split variables at this node. The variables are sorted by the predictive measure of association with the optimal predictor in the descending order, and only variables with the positive predictive measure are included. The order of the surrogate split variables at each node is matched to the order of variables in SurrCutVar. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrCutType contains an empty cell. A surrogate split type can be either 'continuous' if the cut is defined in the form $Z<V$ for a variable $Z$ and cut point V or 'categorical' if the cut is defined by whether $Z$ takes a value in a set of categories.

## SurrCutVar

An $n$-element cell array of the names of the variables used for surrogate splits in each node in tree, where $n$ is the number of nodes in tree. Every element of SurrCutVar is a cell array with the names of the surrogate split variables at this node. The variables are sorted by the predictive measure of association with the optimal predictor in the descending order, and only variables with the positive predictive measure are included. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrCutVar contains an empty cell.

## SurrVarAssoc

An $n$-element cell array of the predictive measures of association for surrogate splits in tree, where $n$ is the number of nodes in tree. For each node k, SurrVarAssoc $\{k\}$ is a numeric vector. The length of SurrVarAssoc $\{k\}$ is equal to the number of surrogate predictors found at this node. Every element of SurrVarAssoc \{k\} gives the predictive measure of association between the optimal split and this surrogate split. The order of the surrogate split variables at each node is the order of variables in SurrCutVar.

## ClassificationTree

The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrVarAssoc contains an empty cell.

## w

The scaled weights, a vector with length $n$, the number of rows in $X$.

## X

A matrix of predictor values. Each column of X represents one variable, and each row represents one observation.

## Y

A numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. Each row of $Y$ represents the classification of the corresponding row of $X$.

## Definitions Impurity and Node Error

ClassificationTree splits nodes based on either impurity or node error. Impurity means one of several things, depending on your choice of the SplitCriterion name-value pair:

- Gini’s Diversity Index (gdi) - The Gini index of a node is

$$
1-\sum_{i} p^{2}(i),
$$

where the sum is over the classes $i$ at the node, and $p(i)$ is the observed fraction of classes with class $i$ that reach the node. A node with just one class (a pure node) has Gini index 0 ; otherwise the Gini index is positive. So the Gini index is a measure of node impurity.

- Deviance ('deviance') - With $p(i)$ defined as for the Gini index, the deviance of a node is

## ClassificationTree

$$
-\sum_{i} p(i) \log p(i) .
$$

A pure node has deviance 0 ; otherwise, the deviance is positive.

- Twoing rule ('twoing') — Twoing is not a purity measure of a node, but is a different measure for deciding how to split a node. Let $L(i)$ denote the fraction of members of class $i$ in the left child node after a split, and $R(i)$ denote the fraction of members of class $i$ in the right child node after a split. Choose the split criterion to maximize

$$
P(L) P(R)\left(\sum_{i}|L(i)-R(i)|\right)^{2},
$$

where $P(L)$ and $P(R)$ are the fractions of observations that split to the left and right respectively. If the expression is large, the split made each child node purer. Similarly, if the expression is small, the split made each child node similar to each other, and hence similar to the parent node, and so the split did not increase node purity.

- Node error - The node error is the fraction of misclassified classes at a node. If $j$ is the class with largest number of training samples at a node, the node error is

$$
1-p(j)
$$

How To . "Classification Trees and Regression Trees" on page 15-30

Purpose
Discriminant analysis
Syntax

```
class = classify(sample,training,group)
class = classify(sample,training,group,'type')
class = classify(sample,training,group,'type',prior)
[class,err] = classify(...)
[class,err,POSTERIOR] = classify(...)
[class,err,POSTERIOR,logp] = classify(...)
[class,err,POSTERIOR,logp,coeff] = classify(...)
```

## Description

class = classify(sample,training, group) classifies each row of the data in sample into one of the groups in training. sample and training must be matrices with the same number of columns. group is a grouping variable for training. Its unique values define groups; each element defines the group to which the corresponding row of training belongs. group can be a categorical variable, a numeric vector, a string array, or a cell array of strings. training and group must have the same number of rows. classify treats NaNs or empty strings in group as missing values, and ignores the corresponding rows of training. The output class indicates the group to which each row of sample has been assigned, and is of the same type as group.
class = classify(sample,training, group, 'type') allows you to specify the type of discriminant function. Specify type inside single quotes. type is one of:

- linear - Fits a multivariate normal density to each group, with a pooled estimate of covariance. This is the default.
- diaglinear - Similar to linear, but with a diagonal covariance matrix estimate (naive Bayes classifiers).
- quadratic - Fits multivariate normal densities with covariance estimates stratified by group.
- diagquadratic - Similar to quadratic, but with a diagonal covariance matrix estimate (naive Bayes classifiers).
- mahalanobis - Uses Mahalanobis distances with stratified covariance estimates.
class = classify(sample,training,group,'type',prior) allows you to specify prior probabilities for the groups. prior is one of:
- A numeric vector the same length as the number of unique values in group (or the number of levels defined for group, if group is categorical). If group is numeric or categorical, the order of prior must correspond to the ordered values in group, or, if group contains strings, to the order of first occurrence of the values in group.
- A 1-by-1 structure with fields:
- prob - A numeric vector.
- group - Of the same type as group, containing unique values indicating the groups to which the elements of prob correspond.

As a structure, prior can contain groups that do not appear in group. This can be useful if training is a subset a larger training set. classify ignores any groups that appear in the structure but not in the group array.

- The string 'empirical', indicating that group prior probabilities should be estimated from the group relative frequencies in training.
prior defaults to a numeric vector of equal probabilities, i.e., a uniform distribution. prior is not used for discrimination by Mahalanobis distance, except for error rate calculation.
[class,err] = classify(...) also returns an estimate err of the misclassification error rate based on the training data. classify returns the apparent error rate, i.e., the percentage of observations in training that are misclassified, weighted by the prior probabilities for the groups.
[class,err,POSTERIOR] = classify(...) also returns a matrix POSTERIOR of estimates of the posterior probabilities that the $j$ th training group was the source of the $i$ th sample observation, i.e., $\operatorname{Pr}($ group $j \mid o b s i)$. POSTERIOR is not computed for Mahalanobis discrimination.
[class,err,POSTERIOR,logp] = classify(...) also returns a vector logp containing estimates of the logarithms of the unconditional
predictive probability density of the sample observations, $p($ obs $i)=$ $\sum p(o b s i \mid$ group $j) \operatorname{Pr}($ group $j)$ over all groups. logp is not computed for Mahalanobis discrimination.
[class,err, POSTERIOR, logp,coeff] = classify(...) also returns a structure array coeff containing coefficients of the boundary curves between pairs of groups. Each element coeff (I, J) contains information for comparing group I to group $J$ in the following fields:
- type - Type of discriminant function, from the type input.
- name1 - Name of the first group.
- name2 - Name of the second group.
- const - Constant term of the boundary equation (K)
- linear - Linear coefficients of the boundary equation (L)
- quadratic - Quadratic coefficient matrix of the boundary equation (Q)

For the linear and diaglinear types, the quadratic field is absent, and a row $x$ from the sample array is classified into group I rather than group $J$ if $0<K+x * L$. For the other types, $x$ is classified into group I if $0<K+x^{*} L+X^{*} Q^{*} x^{\prime}$.

## Examples For training data, use Fisher's sepal measurements for iris versicolor and virginica:

```
load fisheriris
SL = meas(51:end,1);
SW = meas(51:end,2);
group = species(51:end);
h1 = gscatter(SL,SW,group,'rb','v^',[],'off');
set(h1,'LineWidth',2)
legend('Fisher versicolor','Fisher virginica',...
    'Location','NW')
```

Classify a grid of measurements on the same scale:

```
[X,Y] = meshgrid(linspace(4.5,8),linspace(2,4));
X = X(:); Y = Y(:);
[C,err,P,logp,coeff] = classify([X Y],[SL SW],...
                                    group,'quadratic');
```

Visualize the classification:
hold on;
gscatter(X,Y,C,'rb','.',1,'off');
$K=\operatorname{coeff}(1,2)$. const;
L = coeff(1,2).linear;

```
Q = coeff(1,2).quadratic;
% Function to compute K + L*v + v'*Q*v for multiple vectors
% v=[x;y]. Accepts x and y as scalars or column vectors.
f = @(x,y) K + [x y]*L + sum(([x y]*Q) .* [x y], 2);
h2 = ezplot(f,[4.5 8 2 4]);
set(h2,'Color','m','LineWidth',2)
axis([4.5 8 2 4])
xlabel('Sepal Length')
ylabel('Sepal Width')
title('{\bf Classification with Fisher Training Data}')
```

## classregtree.classname

Purpose Class names for classification decision tree
Syntax
CNAMES = classname(T)
CNAMES = classname(T,J)

Description
CNAMES = classname $(\mathrm{T})$ returns a cell array of strings with class names for this classification decision tree.

CNAMES = classname ( $\mathrm{T}, \mathrm{J}$ ) takes an array J of class numbers and returns the class names for the specified numbers.

See Also<br>classregtree

## TreeBagger.ClassNames property

Purpose Names of classes
Description The ClassNames property is a cell array containing the class names for the response variable Y . This property is empty for regression trees.

## classregtree.classprob

Purpose Class probabilities
Syntax $\quad \begin{aligned} P & =\text { classprob }(t) \\ P & =\text { classprob }(t, \text { nodes })\end{aligned}$
Description
$\mathrm{P}=$ classprob( t ) returns an $n$-by- $m$ array P of class probabilities for the nodes in the classification tree t , where $n$ is the number of nodes and $m$ is the number of classes. For any node number $i$, the class probabilities $\mathrm{P}(\mathrm{i},:$ ) are the estimated probabilities for each class for a point satisfying the conditions for node i.

P = classprob(t, nodes) takes a vector nodes of node numbers and returns the class probabilities for the specified nodes.

## Examples

Create a classification tree for Fisher's iris data:

```
load fisheriris;
t = classregtree(meas,species,...
    'names',{'SL' 'SW' 'PL' 'PW'})
t =
Decision tree for classification
1 if PL<2.45 then node 2 elseif PL>=2.45 then node 3 else setosa
2 class = setosa
3 if PW<1.75 then node 4 elseif PW>=1.75 then node 5 else versicolor
4 if PL<4.95 then node 6 elseif PL>=4.95 then node 7 else versicolor
5 class = virginica
6 if PW<1.65 then node 8 elseif PW>=1.65 then node 9 else versicolor
7 class = virginica
8 class = versicolor
9 class = virginica
view(t)
```

```
P = classprob(t)
P =

How To

Objects of the classregtree class have no properties accessible by dot indexing, get methods, or set methods. To obtain information about a classregtree object, use the appropriate method.

Value. To learn how this affects your use of the class, see Comparing Handle and Value Classes in the MATLAB Object-Oriented Programming documentation.

- "Ensemble Methods" on page 15-58
- "Classification Trees and Regression Trees" on page 15-30
- "Grouping Variables" on page 2-51

Purpose Construct classification and regression trees

```
Syntax
\(\mathrm{t}=\mathrm{classregtree}(\mathrm{X}, \mathrm{y})\)
t = classregtree(X,y,'Name',value)
```

$t=$ classregtree $(X, y)$ creates a decision tree $t$ for predicting the response $y$ as a function of the predictors in the columns of $X . X$ is an $n$-by- $m$ matrix of predictor values. If y is a vector of $n$ response values, classregtree performs regression. If $y$ is a categorical variable, character array, or cell array of strings, classregtree performs classification. Either way, t is a binary tree where each branching node is split based on the values of a column of X . NaN values in X or y are taken to be missing values. Observations with all missing values for $X$ or missing values for $y$ are not used in the fit. Observations with some missing values for X are used to find splits on variables for which these observations have valid values.
$\mathrm{t}=$ classregtree (X, y, 'Name', value) specifies one or more optional parameter name/value pairs. Specify Name in single quotes. The following options are available:

## For all trees:

- categorical - Vector of indices of the columns of $X$ that are to be treated as unordered categorical variables
- method - Either 'classification' (default if y is text or a categorical variable) or 'regression' (default if $y$ is numeric).
- names - A cell array of names for the predictor variables, in the order in which they appear in the $X$ from which the tree was created.
- prune - 'on' (default) to compute the full tree and the optimal sequence of pruned subtrees, or 'off' for the full tree without pruning.
- minparent - A number $k$ such that impure nodes must have $k$ or more observations to be split (default is 10).
- minleaf - A minimal number of observations per tree leaf (default is 1). If you supply both 'minparent' and 'minleaf', classregtree uses the setting which results in larger leaves: minparent $=$ max(minparent, 2*minleaf)
- mergeleaves - ' on ' (default) to merge leaves that originate from the same parent node and give the sum of risk values greater or equal to the risk associated with the parent node. If 'off', classregtree does not merge leaves.
- nvartosample - Number of predictor variables randomly selected for each split. By default all variables are considered for each decision split.
- stream - Random number stream. Default is the MATLAB default random number stream.
- surrogate - ' on' to find surrogate splits at each branch node. Default is 'off'. If you set this parameter to 'on',classregtree can run significantly slower and consume significantly more memory.
- weights - Vector of observation weights. By default the weight of every observation is 1 . The length of this vector must be equal to the number of rows in $X$.

For regression trees only:

- qetoler - Defines tolerance on quadratic error per node for regression trees. Splitting nodes stops when quadratic error per node drops below qetoler*qed, where qed is the quadratic error for the entire data computed before the decision tree is grown: qed $=$ norm( $y-y b a r$ ) with ybar estimated as the average of the input array Y. Default value is 1e-6.

For classification trees only:

- cost - Square matrix C, where $C(i, j)$ is the cost of classifying a point into class $j$ if its true class is $i$ (default has $C(i, j)=1$ if $i \sim=j$, and $C(i, j)=0$ if $i=j)$. Alternatively, this value can be a structure $S$ having two fields: S.group containing the group names as a categorical variable, character array, or cell array of strings; and S.cost containing the cost matrix C.
- splitcriterion - Criterion for choosing a split. One of 'gdi' (default) or Gini's diversity index, 'twoing' for the twoing rule, or 'deviance' for maximum deviance reduction.
- priorprob - Prior probabilities for each class, specified as a string ('empirical' or 'equal') or as a vector (one value for each distinct group name) or as a structure $S$ with two fields:
- S.group containing the group names as a categorical variable, character array, or cell array of strings
- S.prob containing a vector of corresponding probabilities.

If the input value is 'empirical' (default), class probabilities are determined from class frequencies in Y . If the input value is 'equal ', all class probabilities are set equal. If both observation weights and class prior probabilities are supplied, the weights are renormalized to add up to the value of the prior probability in the respective class.

## Examples Create a classification tree for Fisher's iris data:

```
load fisheriris;
```

```
t = classregtree(meas,species,...
    'names',{'SL' 'SW' 'PL' 'PW'})
t =
Decision tree for classification
1 if PL<2.45 then node 2 elseif PL>=2.45 then node 3 else setosa
2 class = setosa
3 if PW<1.75 then node 4 elseif PW>=1.75 then node 5 else versicolor
4 if PL<4.95 then node 6 elseif PL>=4.95 then node 7 else versicolor
5 class = virginica
6 if PW<1.65 then node 8 elseif PW>=1.65 then node 9 else versicolor
7 class = virginica
8 class = versicolor
9 class = virginica
view(t)
```

## classregtree

How To . "Grouping Variables" on page 2-51

- "Ensemble Methods" on page 15-58

Purpose Class levels
Description The CLevels property is a vector of the same type as the grouping variable, containing the unique levels of the grouping variable.

## Purpose <br> Syntax <br> Description

Construct agglomerative clusters from linkages

T = cluster(Z,'cutoff', c)
T = cluster(Z,'cutoff', c,'depth',d)
T = cluster(Z,'cutoff',c,'criterion',criterion)
T = cluster(Z,'maxclust', $n$ )

## Examples

T = cluster ( $Z$, 'cutoff', c ) constructs clusters from the agglomerative hierarchical cluster tree, $Z$, as generated by the linkage function. $Z$ is a matrix of size ( $m-1$ )-by- 3 , where $m$ is the number of observations in the original data. c is a threshold for cutting Z into clusters. Clusters are formed when a node and all of its subnodes have inconsistent value less than c. All leaves at or below the node are grouped into a cluster. t is a vector of size m containing the cluster assignments of each observation.

If $c$ is a vector, $T$ is a matrix of cluster assignments with one column per cutoff value.

T = cluster (Z,'cutoff', c, 'depth', d) evaluates inconsistent values by looking to a depth $d$ below each node. The default depth is 2 .

T = cluster(Z,'cutoff', c,'criterion',criterion) uses the specified criterion for forming clusters, where criterion is one of the strings 'inconsistent' (default) or 'distance'. The 'distance' criterion uses the distance between the two subnodes merged at a node to measure node height. All leaves at or below a node with height less than c are grouped into a cluster.

T = cluster( Z, 'maxclust', n ) constructs a maximum of n clusters using the 'distance' criterion. cluster finds the smallest height at which a horizontal cut through the tree leaves n or fewer clusters.

If n is a vector, T is a matrix of cluster assignments with one column per maximum value.

Compare clusters from Fisher iris data with species:
load fisheriris

```
d = pdist(meas);
Z = linkage(d);
c = cluster(Z,'maxclust',3:5);
crosstab(c(:,1),species)
ans =
        0 0 2
        0 50 48
        50 0 0
crosstab(c(:,2),species)
ans =
        0 0 1
        0 50 47
        0 0 2
        50 0 0
crosstab(c(:,3),species)
ans =
        0 4 0
        0 46 47
        0 0 1
        0}
        50 0 0
```

| Purpose | Construct clusters from Gaussian mixture distribution |
| :---: | :---: |
| Syntax | idx = cluster(obj, X) |
|  | [idx, nlogl] = cluster(obj, X) |
|  | [idx, nlogl, P] = cluster(obj, X ) |
|  | [idx, nlogl, P, logpdf] = cluster(obj, X) |
|  | [idx, nlogl, P, logpdf, M] = cluster(obj, X) |
| Description | idx $=$ cluster (obj, X) partitions data in the $n$-by- $d$ matrix X , where $n$ is the number of observations and $d$ is the dimension of the data, into |
|  | $k$ clusters determined by the $k$ components of the Gaussian mixture |
|  | distribution defined by obj. obj is an object created by gmdistribution or fit. idx is an $n$-by- 1 vector, where idx (I) is the cluster index of |
|  | observation I. The cluster index gives the component with the largest |
|  | posterior probability for the observation, weighted by the component |
|  |  |

Note The data in X is typically the same as the data used to create the Gaussian mixture distribution defined by obj. Clustering with cluster is treated as a separate step, apart from density estimation. For cluster to provide meaningful clustering with new data, $X$ should come from the same population as the data used to create obj.
cluster treats NaN values as missing data. Rows of X with NaN values are excluded from the partition.
[idx, nlogl] = cluster(obj, X) also returns nlogl, the negative log-likelihood of the data.
[idx, nlogl, P] = cluster(obj,X) also returns the posterior probabilities of each component for each observation in the $n$-by- $k$ matrix $P . P(I, J)$ is the probability of component $J$ given observation $I$.
[idx, nlogl, P, logpdf] = cluster(obj, X) also returns the $n$-by- 1 vector logpdf containing the logarithm of the estimated probability density function for each observation. The density estimate for
observation I is a sum over all components of the component density at I times the component probability.
[idx, nlogl, P, logpdf, M] = cluster(obj, X) also returns an $n$-by- $k$ matrix $M$ containing Mahalanobis distances in squared units. $M(I, J)$ is the Mahalanobis distance of observation I from the mean of component $J$ J.

## Examples

Generate data from a mixture of two bivariate Gaussian distributions using the mvnrnd function:

```
MU1 = [1 2];
SIGMA1 = [2 0; 0 .5];
MU2 = [-3 -5];
SIGMA2 = [1 0; 0 1];
X = [mvnrnd(MU1,SIGMA1,1000);mvnrnd(MU2,SIGMA2,1000)];
scatter(X(:,1),X(:,2),10,'.')
hold on
```

Fit a two-component Gaussian mixture model:

```
obj = gmdistribution.fit(X,2);
h = ezcontour(@(x,y)pdf(obj,[x y]),[-8 6],[-8 6]);
```

Use the fit to cluster the data:

```
idx = cluster(obj,X);
cluster1 = X(idx == 1,:);
cluster2 = X(idx == 2,:);
delete(h)
h1 = scatter(cluster1(:,1),cluster1(:,2),10,'r.');
h2 = scatter(cluster2(:,1),cluster2(:,2),10,'g.');
legend([h1 h2],'Cluster 1','Cluster 2','Location','NW')
```

See Also<br>fit | gmdistribution | mahal | posterior

## Purpose Agglomerative clusters from data

```
Syntax
T = clusterdata(X,cutoff)
T = clusterdata(X,Name,Value)
```

$\mathrm{T}=$ clusterdata(X, cutoff)

T = clusterdata(X,Name, Value) clusters with additional options specified by one or more Name, Value pair arguments.

Tips

- The centroid and median methods can produce a cluster tree that is not monotonic. This occurs when the distance from the union of two clusters, $r$ and $s$, to a third cluster is less than the distance between $r$ and $s$. In this case, in a dendrogram drawn with the default orientation, the path from a leaf to the root node takes some downward steps. To avoid this, use another method. The following image shows a nonmonotonic cluster tree.

In this case, cluster 1 and cluster 3 are joined into a new cluster, while the distance between this new cluster and cluster 2 is less than the distance between cluster 1 and cluster 3 . This leads to a nonmonotonic tree.

## clusterdata

- You can provide the output T to other functions including dendrogram to display the tree, cluster to assign points to clusters, inconsistent to compute inconsistent measures, and cophenet to compute the cophenetic correlation coefficient.

## Input Arguments

## X

Matrix with two or more rows. The rows represent observations, the columns represent categories or dimensions.

## cutoff

When 0 < cutoff < 2, clusterdata forms clusters when inconsistent values are greater than cutoff (see inconsistent). When cutoff is an integer $\geq 2$, clusterdata interprets cutoff as the maximum number of clusters to keep in the hierarchical tree generated by linkage.

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN.

## 'criterion'

Either 'inconsistent' or 'distance'.

## 'cutoff'

Cutoff for inconsistent or distance measure, a positive scalar. When $0<$ cutoff < 2, clusterdata forms clusters when inconsistent values are greater than cutoff (see inconsistent). When cutoff is an integer $\geq$ 2, clusterdata interprets cutoff as the maximum number of clusters to keep in the hierarchical tree generated by linkage.

## 'depth'

Depth for computing inconsistent values, a positive integer.

## 'distance'

Any of the distance metric names allowed by pdist (follow the 'minkowski' option by the value of the exponent $p$ ):

| Metric | Description |
| :--- | :--- |
| 'euclidean' | Euclidean distance (default). |
| 'seuclidean' | Standardized Euclidean distance. Each <br> coordinate difference between rows in X is <br> scaled by dividing by the corresponding <br> element of the standard deviation <br> S=nanstd (X). To specify another value for <br> S, use D=pdist (X, ' seuclidean' , S). |
| 'cityblock' | City block metric. |
| 'minkowski' | Minkowski distance. The default exponent is <br> 2. To specify a different exponent, use D $=$ <br> pdist(X, 'minkowski' , P), where P is a scalar |
| 'chebychev' | Chebychev distance (maximum coordinate <br> difference). |
| 'mahalanobis' | Mahalanobis distance, using the sample <br> covariance of X as computed by nancov. To <br> compute the distance with a different covariance, <br> use D = pdist (X, 'mahalanobis' , C), where <br> the matrix C is symmetric and positive definite. |
| 'cosine' | One minus the cosine of the included angle <br> between points (treated as vectors). |
| 'correlation' | One minus the sample correlation between <br> points (treated as sequences of values). |
| 'spearman' | One minus the sample Spearman's rank <br> correlation between observations (treated as <br> sequences of values). |

## clusterdata

| Metric | Description |
| :---: | :---: |
| ' namming ' | Hamming distance, which is the percentage of coordinates that differ. |
| 'jaccard' | One minus the Jaccard coefficient, which is the percentage of nonzero coordinates that differ. |
| custom distance function | A distance function specified using @: <br> D = pdist(X, @distfun) <br> A distance function must be of form d2 = distfun(XI, XJ) <br> taking as arguments a 1-by-n vector XI, corresponding to a single row of X , and an $m 2$-by- $n$ matrix XJ , corresponding to multiple rows of $X$. distfun must accept a matrix $X J$ with an arbitrary number of rows. distfun must return an $m 2$-by- 1 vector of distances d2, whose $k$ th element is the distance between XI and $\mathrm{XJ}(\mathrm{k},:$ ). |

## 'linkage'

Any of the linkage methods allowed by the linkage function:

- 'average'
- 'centroid'
- 'complete'
- 'median'
- 'single'
- 'ward'
- 'weighted'

For details, see the definitions in the linkage function reference page.

## clusterdata

## 'maxclust'

Maximum number of clusters to form, a positive integer.

## 'savememory'

A string, either 'on' or 'off'. When applicable, the 'on' setting causes clusterdata to construct clusters without computing the distance matrix. savememory is applicable when:

- linkage is 'centroid', 'median', or 'ward'
- distance is 'euclidean' (default)

When savememory is 'on', linkage run time is proportional to the number of dimensions (number of columns of $X$ ). When savememory is 'off', linkage memory requirement is proportional to $N^{2}$, where $N$ is the number of observations. So choosing the best (least-time) setting for savememory depends on the problem dimensions, number of observations, and available memory. The default savememory setting is a rough approximation of an optimal setting.

Default: 'on' when $X$ has 20 columns or fewer, or the computer does not have enough memory to store the distance matrix; otherwise 'off'

## Output $\quad$ T

Arguments $\quad \mathrm{T}$ is a vector of size m containing a cluster number for each observation.

- When $0<$ cutoff $<2, T=c l u s t e r d a t a(X$, cutoff $)$ is equivalent to:

```
Y = pdist(X,'euclid');
Z = linkage(Y,'single');
T = cluster(Z,'cutoff',cutoff);
```

- When cutoff is an integer $\geq 2$, $T=$ clusterdata $(X$, cutoff $)$ is equivalent to:

```
Y = pdist(X,'euclid');
Z = linkage(Y,'single');
```

## clusterdata

T = cluster(Z,'maxclust',cutoff);

Examples The example first creates a sample data set of random numbers. It then uses clusterdata to compute the distances between items in the data set and create a hierarchical cluster tree from the data set. Finally, the clusterdata function groups the items in the data set into three clusters. The example uses the find function to list all the items in cluster 2 , and the scatter3 function to plot the data with each cluster shown in a different color.

```
X = [gallery('uniformdata',[10 3],12);...
gallery('uniformdata',[10 3],13)+1.2;...
gallery('uniformdata',[10 3],14)+2.5];
T = clusterdata(X,'maxclust',3);
find(T==2)
ans =
    11
    12
    1 3
    14
    15
    16
    1 7
    18
    1 9
    20
scatter3(X(:,1),X(:,2),X(:,3),100,T,'filled')
```

Create a hierarchical cluster tree for a data with 20000 observations using Ward's linkage. If you set savememory to 'off', you can get an out-of-memory error if your machine doesn't have enough memory to hold the distance matrix.

```
X = rand(20000,3);
c = clusterdata(X,'linkage','ward','savememory','on',...
    'maxclust',4);
scatter3(X(:,1),X(:,2),X(:,3),10,c)
```

## clusterdata

| Purpose | Classical multidimensional scaling |
| :---: | :---: |
| Syntax | $\begin{aligned} & Y=\text { cmdscale(D) } \\ & {[Y, e]=\text { cmdscale(D) }} \end{aligned}$ |
| Description | $Y=$ cmdscale( $D$ ) takes an $n$-by-n distance matrix $D$, and returns an $n$-by- $p$ configuration matrix $Y$. Rows of $Y$ are the coordinates of $n$ points in $p$-dimensional space for some $p<n$. When $D$ is a Euclidean distance matrix, the distances between those points are given by D. $p$ is the dimension of the smallest space in which the n points whose inter-point distances are given by D can be embedded. <br> $[Y, e]=$ cmdscale ( $D$ ) also returns the eigenvalues of $Y * Y$. When $D$ is Euclidean, the first $p$ elements of $e$ are positive, the rest zero. If the first $k$ elements of $e$ are much larger than the remaining ( $n-k$ ), then you can use the first $k$ columns of $Y$ as $k$-dimensional points whose inter-point distances approximate $D$. This can provide a useful dimension reduction for visualization, e.g., for $\mathrm{k}=2$. |
|  | D need not be a Euclidean distance matrix. If it is non-Euclidean or a more general dissimilarity matrix, then some elements of e are negative, and cmdscale chooses $p$ as the number of positive eigenvalues. In this case, the reduction to $p$ or fewer dimensions provides a reasonable approximation to $D$ only if the negative elements of e are small in magnitude. |
|  | You can specify D as either a full dissimilarity matrix, or in upper triangle vector form such as is output by pdist. A full dissimilarity matrix must be real and symmetric, and have zeros along the diagonal and positive elements everywhere else. A dissimilarity matrix in upper triangle form must have real, positive entries. You can also specify D as a full similarity matrix, with ones along the diagonal and all other elements less than one. cmdscale transforms a similarity matrix to a dissimilarity matrix in such a way that distances between the points returned in Y equal or approximate sqrt(1-D). To use a different transformation, you must transform the similarities prior to calling cmdscale. |

```
Examples Generate some points in 4-D space, but close to 3-D space, then reduce them to distances only.
```

```
X = [normrnd(0,1,10,3) normrnd(0,.1,10,1)];
```

X = [normrnd(0,1,10,3) normrnd(0,.1,10,1)];
D = pdist(X,'euclidean');
D = pdist(X,'euclidean');
Find a configuration with those inter-point distances.

```
```

[Y,e] = cmdscale(D);

```
[Y,e] = cmdscale(D);
% Four, but fourth one small
% Four, but fourth one small

```

\section*{LinearModel.coefCI}
\(\begin{array}{lr}-18.582 & -1.5036 \\ -17.311 & -0.96419\end{array}\)

\section*{Custom Confidence Intervals}

Create a linear model for auto mileage based on the carbig data. Then obtain confidence intervals for the resulting model coefficients at the 99\% level.

Load the data and create a model.
```

load carbig
Origin = nominal(Origin);
ds = dataset(Horsepower,Weight,MPG,Origin);
modelspec = 'MPG ~ 1 + Horsepower + Weight + Origin';
mdl = LinearModel.fit(ds,modelspec);

```

Find \(99 \%\) confidence intervals for the coefficients.
```

ci = coefCI(mdl,.01)
ci =
40.737 62.564
-0.081629 -0.024647
-0.006208 -0.0033711
-20.056 2.3459
-18.361 3.3546
-19.943 2.7955
-17.104 4.4676
-21.286 1.2002
-19.899 1.6238

```

The confidence intervals are wider than the default \(5 \%\) confidence intervals of "Default Confidence Intervals" on page 20-332.

Alternatives You can create the intervals from the model coefficients in \(m d l\). Coefficients.Estimate and an appropriate multiplier of the standard errors sqrt(diag(mdl.CoefficientCovariance)). The multiplier is tinv(1-alpha/2,dof), where level is the confidence

\section*{LinearModel.coefCI}
level, and dof is the degrees of freedom (number of data points minus the number of coefficients).

ci = coefCI(mdl,alpha)

```
\(\mathrm{ci}=\operatorname{coefCI}(\mathrm{mdl})\) returns confidence intervals for the coefficients in mdl.
ci = coefCI(mdl,alpha) returns confidence intervals with confidence level 1 - alpha.

\section*{mdl}

Nonlinear regression model, constructed by NonLinearModel.fit.

\section*{alpha}

Scalar from 0 to 1, the probability that the confidence interval does not contain the true value.

Default: 0.05

\section*{ci}
k-by-2 matrix of confidence intervals. The \(j\) th row of ci is the confidence interval of coefficient j of mdl . The name of coefficient \(j\) of mdl is in mdl. CoefNames.

\section*{Confidence Interval}

Assume that model assumptions hold (the data comes from a model represented by the formula \(m d l\). Formula, with independent normally distributed errors). Then row \(j\) of the confidence interval matrix ci gives a confidence interval \([\mathrm{ci}(\mathrm{j}, 1), \mathrm{ci}(\mathrm{j}, 2)]\) that contains coefficient j with probability 1 - alpha.

\section*{NonLinearModel.coefCI}

\section*{Examples Default Confidence Intervals}

Create a nonlinear model for auto mileage based on the carbig data. Then obtain confidence intervals for the resulting model coefficients.

Load the data and create a nonlinear model.
```

load carbig
ds = dataset(Horsepower,Weight,MPG);
modelfun = @(b,x)b(1) + b(2)*x(:,1) + ...
b(3)*x(:,2) + b(4)*x(:,1).*x(:,2);
betaO = [1 1 1 1];
mdl = NonLinearModel.fit(ds,modelfun,betaO)
mdl =

```
Nonlinear regression model:
    MPG ~ b1 + b2*Horsepower + b3*Weight + b4*Horsepower*Weight
Estimated Coefficients:
    Estimate SE tStat pValue
\begin{tabular}{lrrrr} 
b1 & 63.558 & 2.3429 & 27.127 & \(1.2343 \mathrm{e}-91\) \\
b2 & -0.25084 & 0.027279 & -9.1952 & \(2.3226 \mathrm{e}-18\) \\
b3 & -0.010772 & 0.00077381 & -13.921 & \(5.1372 \mathrm{e}-36\) \\
b4 & \(5.3554 \mathrm{e}-05\) & \(6.6491 \mathrm{e}-06\) & 8.0542 & \(9.9336 \mathrm{e}-15\)
\end{tabular}
Number of observations: 392, Error degrees of freedom: 388
Root Mean Squared Error: 3.93
R-Squared: 0.748, Adjusted R-Squared 0.746
F-statistic vs. constant model: 385, p-value \(=7.26 e-116\)

All the coefficients have extremely small \(p\)-values. This means a confidence interval around the coefficients will not contain the point 0 , unless the confidence level is very high.

Find \(95 \%\) confidence intervals for the coefficients of the model.
```

ci = coefCI(mdl)

```
ci =
\begin{tabular}{rr}
58.9515 & 68.1644 \\
-0.3045 & -0.1972 \\
-0.0123 & -0.0093 \\
0.0000 & 0.0001
\end{tabular}

The confidence interval for b4 seems to contain 0 . Examine it in more detail.
```

ci(4,:)
ans =
1.0e-04
0.4048 0.6663

```

As expected, the confidence interval does not contain the point 0.
Alternatives \(\quad\)\begin{tabular}{l} 
You can create the intervals from the model coefficients in \\
mdl. Coefficients.Estimate and an appropriate multiplier of the \\
standard errors sqrt(diag(mdl. CoefficientCovariance)). The \\
multiplier is tinv(1-alpha/2, dof), where level is the confidence \\
level, and dof is the degrees of freedom (number of data points minus \\
the number of coefficients).
\end{tabular}

\section*{GeneralizedLinearModel.coefTest}

\section*{Purpose}

Syntax

\section*{Description}

\section*{Input}

Arguments
\(\mathrm{p}=\) coefTest(mdl)
p = coefTest(mdl, H)
p = coefTest(mdl, H, C)
\([\mathrm{p}, \mathrm{F}]=\) coefTest(mdl,...)
\([p, F, r]=\) coefTest(mdl,...)
Linear hypothesis test on generalized linear regression model coefficients
\[
[p, F, r]=\operatorname{coefTest}(m d l, \ldots)
\]
\(\mathrm{p}=\) coefTest (mdl) computes the \(p\)-value for an \(F\) test that all coefficient estimates in mdl are zero, except for the intercept term.
\(\mathrm{p}=\) coefTest(mdl,H) performs an \(F\) test that H*B \(=0\), where B represents the coefficient vector.
\(\mathrm{p}=\) coefTest(mdl, \(\mathrm{H}, \mathrm{C})\) performs an \(F\) test that \(\mathrm{H} * \mathrm{~B}=\mathrm{C}\).
\([\mathrm{p}, \mathrm{F}]=\) coefTest \((\mathrm{mdl}, \ldots)\) returns the \(F\) test statistic.
\([p, F, r]=\) coefTest \((\mathrm{mdl}, \ldots)\) returns the numerator degrees of freedom for the test.

\section*{mdl}

Generalized linear model, as constructed by GeneralizedLinearModel.fit or GeneralizedLinearModel.stepwise.

H
Numeric matrix having one column for each coefficient in the model. When H is an input, the output p is the \(p\)-value for an \(F\) test that \(\mathrm{H} * \mathrm{~B}=0\), where B represents the coefficient vector.

\section*{C}

Numeric vector with the same number of rows as \(H\). When C is an input, the output p is the \(p\)-value for an \(F\) test that \(\mathrm{H}^{*} \mathrm{~B}=\mathrm{C}\), where \(B\) represents the coefficient vector.

\section*{GeneralizedLinearModel.coefTest}

\section*{Output Arguments}

\section*{p}
\(p\)-value of the \(F\) test (see "Definitions" on page 20-339).

\section*{F}

Value of the test statistic for the \(F\) test (see "Definitions" on page 20-339).
r
Numerator degrees of freedom for the \(F\) test (see "Definitions" on page 20-339). The \(F\) statistic has r degrees of freedom in the numerator and mdl. DFE degrees of freedom in the denominator.

\section*{Definitions}

\section*{Test Statistics}

The \(p\)-value, \(F\) statistic, and numerator degrees of freedom are valid under these assumptions:
- The data comes from a model represented by the formula mdl. Formula.
- The observations are independent conditional on the predictor values.

Suppose these assumptions hold. Let \(\beta\) represent the (unknown) coefficient vector of the linear regression. Suppose \(H\) is a full-rank matrix of size \(r\)-by- \(s\), where \(s\) is the number of terms in \(\beta\). Let \(v\) be a vector the same size as \(\beta\). The following is a test statistic for the hypothesis that \(H \beta=v\) :
\[
F=(H \hat{\beta}-v)^{\prime}\left(H C H^{\prime}\right)^{-1}(H \hat{\beta}-v) .
\]

Here \(\hat{\beta}\) is the estimate of the coefficient vector \(\beta\) in mdl. Coefs, and \(C\) is the estimated covariance of the coefficient estimates in mdl. CoefCov. When the hypothesis is true, the test statistic \(F\) has an "F Distribution" on page B-38 with \(r\) and \(u\) degrees of freedom.

\section*{GeneralizedLinearModel.coefTest}

\section*{Examples Test Generalized Linear Model Coefficients}

Test a generalized linear model to see if its coefficients differ from zero.
Create a generalized linear regression model of Poisson data.
```

X = 2 + randn(100,1);
mu = exp(1 + X/2);
y = poissrnd(mu);
mdl = GeneralizedLinearModel.fit(X,y,...
'y ~ x1','distr','poisson');

```

Test whether the fitted model has coefficients that differ significantly from zero.
\(\mathrm{p}=\) coefTest(mdl)
\(p=\)

\section*{Examples Test Linear Regression Model}

Make a linear model of mileage as a function of the weight, weight squared, and model year from the carsmall data set. Test the coefficients to see if all should be zero.

Load the data and make a dataset array, where the model year is an ordinal variable.
```

load carsmall
ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);
mdl = LinearModel.fit(ds,'MPG ~ Year + Weight + Weight^2');

```

Test the model for significant differences from a constant model.
```

p = coefTest(mdl)
p =
5.5208e-41

```

There is no doubt that the model contains more than the intercept term.

\section*{Test a Particular Coefficient}

Test the Weight^2 coefficient in a linear model of mileage as a function of the weight, weight squared, and model year.

Load the data and make a dataset array, where the model year is an ordinal variable.
```

load carsmall
ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);
mdl = LinearModel.fit(ds,'MPG ~ Year + Weight + Weight^2');

```

Test the significance of the Weight \({ }^{\wedge} 2\) coefficient. To do so, find the coefficient corresponding to Weight^2.
mdl.CoefficientNames
ans =
'(Intercept)' 'Weight' 'Year_76' 'Year_82' 'Weight^2'

\section*{LinearModel.coefTest}

Weight^2 is the fifth (final) coefficient.
Test the significance of the Weight^2 coefficient.
```

p = coefTest(mdl,[0 0 0 0 1])
p =
0.0022

```

\section*{CompactTreeBagger.combine}

Purpose Combine two ensembles
Syntax \(\quad B 1=\operatorname{combine}(B 1, B 2)\)
Description \(\quad B 1=\operatorname{combine}(B 1, B 2)\) appends decision trees from ensemble \(B 2\) to those stored in B1 and returns ensemble B1. This method requires that the class and variable names be identical in both ensembles.

See Also TreeBagger.append
Purpose Enumeration of combinations
Syntax C = combnk(v,k)
Description \(\mathrm{C}=\) combnk \((\mathrm{v}, \mathrm{k})\) returns all combinations of the \(n\) elements in v takenk at a time.\(\mathrm{C}=\) combnk( \(\mathrm{v}, \mathrm{k})\) produces a matrix C with k columns and \(n!/ k!(n-k)\) !rows, where each row contains k of the elements in the vector v .It is not practical to use this function if v has more than about 15elements.
Examples Combinations of characters from a string.
```

C = combnk('tendril',4);
last5 = C(31:35,:)
last5 =
tedr
tenl
teni
tenr
tend

```
Combinations of elements from a numeric vector.
c = combnk (1:4,2)

\section*{ClassificationDiscriminant.compact}

\section*{Purpose Compact discriminant analysis classifier}

Syntax \(\quad\) cobj \(=\) compact \((o b j)\)
Description
cobj \(=\) compact \((\mathrm{obj})\) creates a compact version of obj.
Input
Arguments
obi
Discriminant analysis classifier created using ClassificationDiscriminant.fit.

Output cobi
Arguments
Compact classifier. cobj has class CompactClassificationDiscriminant. You can predict classifications using cobj exactly as you can using obj. However, since cobj does not contain training data, you cannot perform some actions, such as cross validation.

\section*{Examples Compare the size of the discriminant analysis classifier for Fisher's iris data to the compact version of the classifier:}
```

load fisheriris
fullobj = ClassificationDiscriminant.fit(meas,species);
cobj = compact(fullobj);
b = whos('fullobj'); % b.bytes = size of fullobj
c = whos('cobj'); % c.bytes = size of cobj
[b.bytes c.bytes] % shows cobj uses 60% of the memory
ans =
18578 11498

```

TreeBagger class because it does not contain information for growing \\
more trees for the ensemble. In particular, it does not contain X and \\
Y used for training.
\end{tabular} \\
See Also & CompactTreeBagger
\end{tabular}

\section*{CompactClassificationDiscriminant}

\section*{Purpose Compact discriminant analysis class}

Description

\section*{Construction}

A CompactClassificationDiscriminant object is a compact version of a discriminant analysis classifier. The compact version does not include the data for training the classifier. Therefore, you cannot perform some tasks with a compact classifier, such as cross validation. Use a compact classifier for making predictions (classifications) of new data.
cobj \(=\) compact (obj) constructs a compact classifier from a full classifier.
cobj = ClassificationDiscriminant.make(Mu,Sigma) constructs a compact discriminant analysis classifier from the class means Mu and covariance matrix Sigma. For syntax details, see ClassificationDiscriminant.make.

\section*{Input Arguments}

\section*{obi}

Discriminant analysis classifier, created with ClassificationDiscriminant.fit.

\section*{Properties}

\section*{BetweenSigma}
p -by-p matrix, the between-class covariance, where p is the number of predictors.

\section*{CategoricalPredictors}

List of categorical predictors, always empty ([ ]) for discriminant analysis.

\section*{ClassNames}

List of the elements in the training data \(Y\) with duplicates removed. ClassNames can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. ClassNames has the same data type as the data in the argument \(Y\).

\section*{CompactClassificationDiscriminant}

\section*{Coeffs}
\(k\)-by-k structure of coefficient matrices, where \(k\) is the number of classes. Coeffs ( \(\mathrm{i}, \mathrm{j}\) ) contains coefficients of the linear or quadratic boundaries between classes i and j. Fields in Coeffs(i,j):
- DiscrimType
- Class1 - ClassNames(i)
- Class2 - ClassNames(j)
- Const - A scalar
- Linear - A vector with \(p\) components, where \(p\) is the number of columns in \(X\)
- Quadratic - p-by-p matrix, exists for quadratic DiscrimType

The equation of the boundary between class \(i\) and class \(j\) is
\[
\text { Const }+ \text { Linear * } x+x \text { ' * Quadratic * } x=0
\]
where \(x\) is a column vector of length \(p\).
If ClassificationDiscriminant.fit had the FillCoeffs name-value pair set to 'off' when constructing the classifier, Coeffs is empty ([]).

\section*{Cost}

Square matrix, where \(\operatorname{Cost}(i, j)\) is the cost of classifying a point into class \(j\) if its true class is i. Cost is \(K\)-by- \(K\), where \(K\) is the number of classes.

Change a Cost matrix using dot addressing:
obj. Cost = costMatrix

\section*{Delta}

\section*{CompactClassificationDiscriminant}

Value of the Delta threshold for a linear discriminant model, a nonnegative scalar. If a coefficient of obj has magnitude smaller than Delta, obj sets this coefficient to 0 , and so you can eliminate the corresponding predictor from the model. Set Delta to a higher value to eliminate more predictors.
Delta must be 0 for quadratic discriminant models.
Change Delta by dot addressing:
obj.Delta \(=\) newDelta

\section*{DeltaPredictor}

Row vector of length equal to the number of predictors in obj. If DeltaPredictor(i) < Delta then coefficient \(i\) of the model is 0 .

If obj is a quadratic discriminant model, all elements of DeltaPredictor are 0.

\section*{DiscrimType}

String specifying the discriminant type. One of:
- 'linear'
- 'quadratic'
- 'diagLinear'
- 'diagQuadratic'
- 'pseudoLinear'
- 'pseudoQuadratic'

Change DiscrimType using dot addressing:
obj.DiscrimType \(=\) newDiscrimType
You can change between linear types, or between quadratic types, but cannot change between linear and quadratic types.

\section*{Gamma}

\section*{CompactClassificationDiscriminant}

Value of the Gamma regularization parameter, a scalar from 0 to 1. Change Gamma using dot addressing:
obj.Gamma \(=\) newGamma
- If you set 1 for linear discriminant, the discriminant sets its type to 'diagLinear'.
- If you set a value between MinGamma and 1 for linear discriminant, the discriminant sets its type to 'linear'.
- You cannot set values below the value of the MinGamma property.
- For quadratic discriminant, you can set either 0 (for DiscrimType 'quadratic') or 1 (for DiscrimType 'diagQuadratic').

\section*{LogDetSigma}

Logarithm of the determinant of the within-class covariance matrix. The type of LogDetSigma depends on the discriminant type:
- Scalar for linear discriminant analysis
- Vector of length K for quadratic discriminant analysis, where K is the number of classes

\section*{MinGamma}

Nonnegative scalar, the minimal value of the Gamma parameter so that the correlation matrix is invertible. If the correlation matrix is not singular, Mingamma is 0 .

\section*{Mu}

Matrix of class means of size K-by-p, where \(K\) is the number of classes, and p is the number of predictors. Each row of Mu represents the mean of the multivariate normal distribution of the corresponding class. The class indices are in the ClassNames attribute.

\section*{CompactClassificationDiscriminant}

\section*{PredictorNames}

Cell array of names for the predictor variables, in the order in which they appear in the training data \(X\).

\section*{Prior}

Prior probabilities for each class. Prior is a numeric vector whose entries relate to the corresponding ClassNames property.

Add or change a Prior vector using dot addressing:
obj.Prior = priorVector

\section*{ResponseName}

String describing the response variable Y.

\section*{ScoreTransform}

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means @(x)x. For a list of built-in transformation functions and the syntax of custom transformation functions, see ClassificationDiscriminant.fit.

Add or change a ScoreTransform function by dot addressing:
cobj.ScoreTransform = 'function'
or
cobj.ScoreTransform = @function

\section*{Sigma}

Within-class covariance matrix or matrices. The dimensions depend on DiscrimType:
- 'linear' (default) - Matrix of size p -by-p, where p is the number of predictors

\section*{CompactClassificationDiscriminant}
- 'quadratic ' - Array of size p-by-p-by-K, where \(K\) is the number of classes
- 'diagLinear' - Row vector of length \(p\)
- 'diagQuadratic' - Array of size 1-by-p-by-K
- 'pseudoLinear' - Matrix of size p-by-p
- 'pseudoQuadratic' - Array of size p-by-p-by-K

\section*{Methods}

\end{tabular}

\section*{Definitions Discriminant Classification}

The model for discriminant analysis is:
- Each class (Y) generates data (X) using a multivariate normal distribution. That is, the model assumes X has a Gaussian mixture distribution (gmdistribution).
- For linear discriminant analysis, the model has the same covariance matrix for each class, only the means vary.
- For quadratic discriminant analysis, both means and covariances of each class vary.

\section*{CompactClassificationDiscriminant}
predict classifies so as to minimize the expected classification cost:
\[
\hat{y}=\underset{y=1, \ldots, K}{\arg \min } \sum_{k=1}^{K} \hat{P}(k \mid x) C(y \mid k),
\]
where
- \(\hat{y}\) is the predicted classification.
- \(K\) is the number of classes.
- \(\hat{P}(k \mid x)\) is the posterior probability of class \(k\) for observation \(x\).
- \(C(y \mid k)\) is the cost of classifying an observation as \(y\) when its true class is \(k\).

For details, see "How the predict Method Classifies" on page 14-6.

\section*{Regularization}

Regularization is the process of finding a small set of predictors that yield an effective predictive model. For linear discriminant analysis, there are two parameters, \(\gamma\) and \(\delta\), that control regularization as follows. cvshrink helps you select appropriate values of the parameters.

Let \(\Sigma\) represent the covariance matrix of the data \(X\), and let \(\hat{X}\) be the centered data (the data \(X\) minus the mean by class). Define
\[
D=\operatorname{diag}\left(\hat{X}^{T} * \hat{X}\right)
\]

The regularized covariance matrix \(\tilde{\Sigma}\) is
\[
\tilde{\Sigma}=(1-\gamma) \Sigma+\gamma D .
\]

Whenever \(y \geq\) MinGamma, \(\tilde{\Sigma}\) is nonsingular.
Let \(\mu_{k}\) be the mean vector for those elements of \(X\) in class \(k\), and let \(\mu_{0}\) be the global mean vector (the mean of the rows of \(X\) ). Let \(C\) be

\section*{CompactClassificationDiscriminant}
the correlation matrix of the data \(X\), and let \(\tilde{C}\) be the regularized correlation matrix:
\[
\tilde{C}=(1-\gamma) C+\gamma I,
\]
where \(I\) is the identity matrix.
The linear term in the regularized discriminant analysis classifier for a data point \(x\) is
\[
\left(x-\mu_{0}\right)^{T} \tilde{\Sigma}^{-1}\left(\mu_{k}-\mu_{0}\right)=\left[\left(x-\mu_{0}\right)^{T} D^{-1 / 2}\right]\left[\tilde{C}^{-1} D^{-1 / 2}\left(\mu_{k}-\mu_{0}\right)\right] .
\]

The parameter \(\delta\) enters into this equation as a threshold on the final term in square brackets. Each component of the vector
\(\left[\tilde{C}^{-1} D^{-1 / 2}\left(\mu_{k}-\mu_{0}\right)\right]\) is set to zero if it is smaller in magnitude than the threshold \(\delta\). Therefore, for class \(k\), if component \(j\) is thresholded to zero, component \(j\) of \(x\) does not enter into the evaluation of the posterior probability.

The DeltaPredictor property is a vector related to this threshold. When \(\delta \geq\) DeltaPredictor(i), all classes \(k\) have
\[
\left|\tilde{C}^{-1} D^{-1 / 2}\left(\mu_{k}-\mu_{0}\right)\right| \leq \delta .
\]

Therefore, when \(\delta \geq\) DeltaPredictor(i), the regularized classifier does not use predictor i.

Examples

Value. To learn how value classes affect copy operations, see Copying Objects in the MATLAB documentation.

Construct a compact discriminant analysis classifier for the Fisher iris data, and compare its size to that of the full classifier:
load fisheriris
fullobj = ClassificationDiscriminant.fit(meas,species);

\section*{CompactClassificationDiscriminant}
```

cobj = compact(fullobj);
b = whos('fullobj'); % b.bytes = size of fullobj
c = whos('cobj'); % c.bytes = size of cobj
[b.bytes c.bytes] % shows cobj uses 60% of the memory
ans =
18578 11498

```

Construct a compact discriminant analysis classifier from the means and covariances of the Fisher iris data:
```

load fisheriris
mu(1,:) = mean(meas(1:50,:));
mu(2,:) = mean(meas(51:100,:));
mu(3,:) = mean(meas(101:150,:));
mm1 = repmat(mu(1,:),50,1);
mm2 = repmat(mu(2,:),50,1);
mm3 = repmat(mu(3,:),50,1);
cc = meas;
cc(1:50,:) = cc(1:50,:) - mm1;
cc(51:100,:) = cc(51:100,:) - mm2;
cc(101:150,:) = cc(101:150,:) - mm3;
sigstar = cc' * cc / 147;
cpct = ClassificationDiscriminant.make(mu,sigstar,...
'ClassNames',{'setosa','versicolor','virginica'});

```

\end{tabular}

A classification ensemble created by fitensemble.

\section*{Properties}

\section*{CategoricalPredictors}

List of categorical predictors. CategoricalPredictors is a numeric vector with indices from 1 to \(p\), where \(p\) is the number of columns of \(X\).

\section*{ClassNames}

List of the elements in Y with duplicates removed. ClassNames can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. ClassNames has the same data type as the data in the argument Y .

\section*{CombineWeights}

String describing how ens combines weak learner weights, either 'WeightedSum' or 'WeightedAverage'.

\section*{Cost}

Square matrix where \(\operatorname{Cost}(i, j)\) is the cost of classifying a point into class \(j\) if its true class is \(i\).

\section*{NTrained}

\section*{CompactClassificationEnsemble}

Number of trained weak learners in cens, a scalar.

\section*{PredictorNames}

A cell array of names for the predictor variables, in the order in which they appear in X .

\section*{Prior}

Prior probabilities for each class. Prior is a numeric vector whose entries relate to the corresponding ClassNames property.

\section*{ResponseName}

String with the name of the response variable \(Y\).

\section*{ScoreTransform}

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means @(x)x. For a list of built-in transformation functions and the syntax of custom transformation functions, see ClassificationTree.fit.

Add or change a ScoreTransform function by dot addressing:
cens.ScoreTransform = 'function'
or
cens.ScoreTransform = @function

\section*{Trained}

Trained learners, a cell array of compact classification models.

\section*{TrainedWeights}

Numeric vector of trained weights for the weak learners in ens. TrainedWeights has T elements, where \(T\) is the number of weak learners in learners.

\section*{UsePredForLearner}

Logical matrix of size \(P\)-by-NTrained, where \(P\) is the number of predictors (columns) in the training data \(X\). UsePredForLearner ( \(\mathrm{i}, \mathrm{j}\) ) is true when learner j uses predictor \(i\), and is false otherwise. For each learner, the predictors have the same order as the columns in the training data \(X\).

If the ensemble is not of type Subspace, all entries in UsePredForLearner are true.

\section*{See Also \\ fitensemble | ClassificationEnsemble | predict | compact}

\section*{CompactClassificationTree}

\section*{Purpose Compact classification tree}

Description

Construction

Compact version of a classification tree (of class ClassificationTree). The compact version does not include the data for training the classification tree. Therefore, you cannot perform some tasks with a compact classification tree, such as cross validation. Use a compact classification tree for making predictions (classifications) of new data.
ctree \(=\) compact(tree) constructs a compact decision tree from a full decision tree.

\section*{Input Arguments}

\section*{tree}

A decision tree constructed by ClassificationTree.fit.

\section*{CategoricalPredictors}

List of categorical predictors. CategoricalPredictors is a numeric vector with indices from 1 to \(p\), where \(p\) is the number of columns of \(X\).

\section*{CatSplit}

An \(n\)-by- 2 cell array, where \(n\) is the number of categorical splits in tree. Each row in CatSplit gives left and right values for a categorical split. For each branch node with categorical split \(j\) based on a categorical predictor variable \(z\), the left child is chosen if \(z\) is in CatSplit ( \(j, 1\) ) and the right child is chosen if \(z\) is in CatSplit (j,2). The splits are in the same order as nodes of the tree. Find the nodes for these splits by selecting 'categorical' cuts from top to bottom in the CutType property.

\section*{Children}

An \(n\)-by- 2 array containing the numbers of the child nodes for each node in tree, where \(n\) is the number of nodes. Leaf nodes have child node 0 .

\section*{ClassCount}

\section*{CompactClassificationTree}

An \(n\)-by- \(k\) array of class counts for the nodes in tree, where \(n\) is the number of nodes and \(k\) is the number of classes. For any node number \(i\), the class counts ClassCount (i,:) are counts of observations (from the data used in fitting the tree) from each class satisfying the conditions for node i.

\section*{ClassNames}

List of the elements in Y with duplicates removed. ClassNames can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. ClassNames has the same data type as the data in the argument Y .

\section*{ClassProb}

An \(n\)-by- \(k\) array of class probabilities for the nodes in tree, where \(n\) is the number of nodes and \(k\) is the number of classes. For any node number \(i\), the class probabilities ClassProb(i,:) are the estimated probabilities for each class for a point satisfying the conditions for node i.

\section*{Cost}

Square matrix, where \(\operatorname{Cost}(i, j)\) is the cost of classifying a point into class \(j\) if its true class is \(i\).

\section*{CutCategories}

An \(n\)-by- 2 cell array of the categories used at branches in tree, where \(n\) is the number of nodes. For each branch node i based on a categorical predictor variable x , the left child is chosen if x is among the categories listed in CutCategories \(\{\mathrm{i}, 1\}\), and the right child is chosen if \(x\) is among those listed in CutCategories \(\{i, 2\}\). Both columns of CutCategories are empty for branch nodes based on continuous predictors and for leaf nodes.

CutPoint contains the cut points for 'continuous ' cuts, and CutCategories contains the set of categories.

\section*{CutPoint}

\section*{CompactClassificationTree}

An \(n\)-element vector of the values used as cut points in tree, where \(n\) is the number of nodes. For each branch node i based on a continuous predictor variable \(x\), the left child is chosen if \(x<\) CutPoint ( \(i\) ) and the right child is chosen if \(x>=\) CutPoint ( \(i\) ). CutPoint is NaN for branch nodes based on categorical predictors and for leaf nodes.

CutPoint contains the cut points for 'continuous' cuts, and CutCategories contains the set of categories.

\section*{CutType}

An \(n\)-element cell array indicating the type of cut at each node in tree, where \(n\) is the number of nodes. For each node \(i\), CutType\{i\} is:
- 'continuous' - If the cut is defined in the form \(x<v\) for a variable x and cut point v .
- 'categorical' - If the cut is defined by whether a variable \(x\) takes a value in a set of categories.
- ' ' - If i is a leaf node.

CutPoint contains the cut points for 'continuous ' cuts, and CutCategories contains the set of categories.

\section*{CutVar}

An \(n\)-element cell array of the names of the variables used for branching in each node in tree, where \(n\) is the number of nodes. These variables are sometimes known as cut variables. For leaf nodes, CutVar contains an empty string.

CutPoint contains the cut points for 'continuous ' cuts, and CutCategories contains the set of categories.

\section*{IsBranch}

An \(n\)-element logical vector that is true for each branch node and false for each leaf node of tree.

\section*{CompactClassificationTree}

\section*{NodeClass}

An \(n\)-element cell array with the names of the most probable classes in each node of tree, where \(n\) is the number of nodes in the tree. Every element of this array is a string equal to one of the class names in ClassNames.

\section*{NodeErr}

An \(n\)-element vector of the errors of the nodes in tree, where \(n\) is the number of nodes. NodeErr(i) is the misclassification probability for node i.

\section*{NodeProb}

An \(n\)-element vector of the probabilities of the nodes in tree, where \(n\) is the number of nodes. The probability of a node is computed as the proportion of observations from the original data that satisfy the conditions for the node. This proportion is adjusted for any prior probabilities assigned to each class.

\section*{NodeRisk}

An \(n\)-element vector of the risk of the nodes in the tree, where \(n\) is the number of nodes. The risk for each node is the measure of impurity (Gini index or deviance) for this node weighted by the node probability. If the tree is grown by twoing, the risk for each node is zero.

\section*{NodeSize}

An \(n\)-element vector of the sizes of the nodes in tree, where \(n\) is the number of nodes. The size of a node is defined as the number of observations from the data used to create the tree that satisfy the conditions for the node.

\section*{NumNodes}

The number of nodes in tree.

\section*{Parent}

\section*{CompactClassificationTree}

An \(n\)-element vector containing the number of the parent node for each node in tree, where \(n\) is the number of nodes. The parent of the root node is 0 .

\section*{PredictorNames}

A cell array of names for the predictor variables, in the order in which they appear in X .

\section*{Prior}

Prior probabilities for each class. Prior is a numeric vector whose entries relate to the corresponding ClassNames property.

\section*{PruneAlpha}

Numeric vector with one element per pruning level. If the pruning level ranges from 0 to \(M\), then PruneAlpha has \(M+1\) elements sorted in ascending order. PruneAlpha(1) is for pruning level 0 (no pruning), PruneAlpha(2) is for pruning level 1, and so on.

\section*{PruneList}

An \(n\)-element numeric vector with the pruning levels in each node of tree, where \(n\) is the number of nodes. The pruning levels range from 0 (no pruning) to \(M\), where \(M\) is the distance between the deepest leaf and the root node.

\section*{ResponseName}

String describing the response variable Y.

\section*{ScoreTransform}

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means @(x)x. For a list of built-in transformation functions and the syntax of custom transformation functions, see ClassificationTree.fit.

Add or change a ScoreTransform function by dot addressing:
ctree.ScoreTransform = 'function'
or

\section*{CompactClassificationTree}
ctree.ScoreTransform = @function

\section*{SurrCutCategories}

An \(n\)-element cell array of the categories used for surrogate splits in tree, where \(n\) is the number of nodes in tree. For each node \(k\), SurrCutCategories \(\{k\}\) is a cell array. The length of SurrCutCategories \(\{\mathrm{k}\}\) is equal to the number of surrogate predictors found at this node. Every element of SurrCutCategories \(\{k\}\) is either an empty string for a continuous surrogate predictor, or is a two-element cell array with categories for a categorical surrogate predictor. The first element of this two-element cell array lists categories assigned to the left child by this surrogate split and the second element of this two-element cell array lists categories assigned to the right child by this surrogate split. The order of the surrogate split variables at each node is matched to the order of variables in SurrCutVar. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrCutCategories contains an empty cell.

\section*{SurrCutFlip}

An \(n\)-element cell array of the numeric cut assignments used for surrogate splits in tree, where \(n\) is the number of nodes in tree. For each node k, SurrCutFlip \(\{\mathrm{k}\}\) is a numeric vector. The length of SurrCutFlip \(\{k\}\) is equal to the number of surrogate predictors found at this node. Every element of SurrCutFlip\{k\} is either zero for a categorical surrogate predictor, or a numeric cut assignment for a continuous surrogate predictor. The numeric cut assignment can be either -1 or +1 . For every surrogate split with a numeric cut \(C\) based on a continuous predictor variable \(Z\), the left child is chosen if \(Z<C\) and the cut assignment for this surrogate split is +1 , or if \(Z \geq C\) and the cut assignment for this surrogate split is -1 . Similarly, the right child is chosen if \(Z \geq C\) and the cut assignment for this surrogate split is +1 , or if \(Z<C\) and the cut assignment for this surrogate split is -1 . The order of the surrogate split variables at each node is matched to the order of variables in SurrCutVar. The optimal-split variable at this

\section*{CompactClassificationTree}
node does not appear. For nonbranch (leaf) nodes, SurrCutFlip contains an empty array.

\section*{SurrCutPoint}

An \(n\)-element cell array of the numeric values used for surrogate splits in tree, where \(n\) is the number of nodes in tree. For each node \(k\), SurrCutPoint \(\{\mathrm{k}\}\) is a numeric vector. The length of SurrCutPoint \(\{\mathrm{k}\}\) is equal to the number of surrogate predictors found at this node. Every element of SurrCutPoint \{k\} is either NaN for a categorical surrogate predictor, or a numeric cut for a continuous surrogate predictor. For every surrogate split with a numeric cut \(C\) based on a continuous predictor variable \(Z\), the left child is chosen if \(Z<C\) and SurrCutFlip for this surrogate split is -1 . Similarly, the right child is chosen if \(Z \geq C\) and SurrCutFlip for this surrogate split is +1 , or if \(Z<C\) and SurrCutFlip for this surrogate split is -1 . The order of the surrogate split variables at each node is matched to the order of variables returned by SurrCutVar. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrCutPoint contains an empty cell.

\section*{SurrCutType}

An \(n\)-element cell array indicating types of surrogate splits at each node in tree, where \(n\) is the number of nodes in tree. For each node \(k\), SurrCutType \(\{k\}\) is a cell array with the types of the surrogate split variables at this node. The variables are sorted by the predictive measure of association with the optimal predictor in the descending order, and only variables with the positive predictive measure are included. The order of the surrogate split variables at each node is matched to the order of variables in SurrCutVar. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrCutType contains an empty cell. A surrogate split type can be either 'continuous' if the cut is defined in the form \(Z<V\) for a variable \(Z\) and cut point V or 'categorical' if the cut is defined by whether \(Z\) takes a value in a set of categories.

\section*{CompactClassificationTree}

\section*{SurrCutVar}

An \(n\)-element cell array of the names of the variables used for surrogate splits in each node in tree, where \(n\) is the number of nodes in tree. Every element of SurrCutVar is a cell array with the names of the surrogate split variables at this node. The variables are sorted by the predictive measure of association with the optimal predictor in the descending order, and only variables with the positive predictive measure are included. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrCutVar contains an empty cell.

\section*{SurrVarAssoc}

An \(n\)-element cell array of the predictive measures of association for surrogate splits in tree, where \(n\) is the number of nodes in tree. For each node k, SurrVarAssoc \(\{k\}\) is a numeric vector. The length of SurrVarAssoc \(\{k\}\) is equal to the number of surrogate predictors found at this node. Every element of SurrVarAssoc\{k\} gives the predictive measure of association between the optimal split and this surrogate split. The order of the surrogate split variables at each node is the order of variables in SurrCutVar. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrVarAssoc contains an empty cell.

\section*{Methods}

\end{tabular}

\section*{CompactClassificationTree}

\section*{Definitions Impurity and Node Error}

ClassificationTree splits nodes based on either impurity or node error. Impurity means one of several things, depending on your choice of the SplitCriterion name-value pair:
- Gini's Diversity Index (gdi) - The Gini index of a node is
\[
1-\sum_{i} p^{2}(i),
\]
where the sum is over the classes \(i\) at the node, and \(p(i)\) is the observed fraction of classes with class \(i\) that reach the node. A node with just one class (a pure node) has Gini index 0; otherwise the Gini index is positive. So the Gini index is a measure of node impurity.
- Deviance ('deviance') - With \(p(i)\) defined as for the Gini index, the deviance of a node is
\[
-\sum_{i} p(i) \log p(i) .
\]

A pure node has deviance 0 ; otherwise, the deviance is positive.
- Twoing rule ('twoing') - Twoing is not a purity measure of a node, but is a different measure for deciding how to split a node. Let \(L(i)\) denote the fraction of members of class \(i\) in the left child node after a split, and \(R(i)\) denote the fraction of members of class \(i\) in the right child node after a split. Choose the split criterion to maximize
\[
P(L) P(R)\left(\sum_{i}|L(i)-R(i)|\right)^{2},
\]
where \(P(L)\) and \(P(R)\) are the fractions of observations that split to the left and right respectively. If the expression is large, the split made each child node purer. Similarly, if the expression is small, the split made each child node similar to each other, and hence similar to the parent node, and so the split did not increase node purity.

\section*{CompactClassificationTree}
- Node error - The node error is the fraction of misclassified classes at a node. If \(j\) is the class with largest number of training samples at a node, the node error is
\[
1-p(j) .
\]

\section*{CompactRegressionTree}

\section*{Purpose Compact regression tree}

Description

\section*{Construction}

Compact version of a regression tree (of class RegressionTree). The compact version does not include the data for training the regression tree. Therefore, you cannot perform some tasks with a compact regression tree, such as cross validation. Use a compact regression tree for making predictions (regressions) of new data.
ctree \(=\) compact(tree) constructs a compact decision tree from a full decision tree.

\section*{Input Arguments}

\section*{tree}

A decision tree constructed by RegressionTree.fit.

\section*{Properties}

\section*{CategoricalPredictors}

List of categorical predictors. CategoricalPredictors is a numeric vector with indices from 1 to \(p\), where \(p\) is the number of columns of \(X\).

\section*{CatSplit}

An \(n\)-by- 2 cell array, where \(n\) is the number of categorical splits in tree. Each row in CatSplit gives left and right values for a categorical split. For each branch node with categorical split j based on a categorical predictor variable \(z\), the left child is chosen if \(z\) is in CatSplit ( \(j, 1\) ) and the right child is chosen if \(z\) is in CatSplit ( \(\mathrm{j}, 2\) ). The splits are in the same order as nodes of the tree. Nodes for these splits can be found by running cuttype and selecting 'categorical' cuts from top to bottom.

\section*{Children}

An \(n\)-by- 2 array containing the numbers of the child nodes for each node in tree, where \(n\) is the number of nodes. Leaf nodes have child node 0 .

\section*{CutCategories}

\section*{CompactRegressionTree}

An \(n\)-by- 2 cell array of the categories used at branches in tree, where \(n\) is the number of nodes. For each branch node i based on a categorical predictor variable x , the left child is chosen if x is among the categories listed in CutCategories \(\{i, 1\}\), and the right child is chosen if \(x\) is among those listed in CutCategories \(\{i, 2\}\). Both columns of CutCategories are empty for branch nodes based on continuous predictors and for leaf nodes.

CutVar contains the cut points for 'continuous' cuts, and CutCategories contains the set of categories.

\section*{CutPoint}

An \(n\)-element vector of the values used as cut points in tree, where \(n\) is the number of nodes. For each branch node i based on a continuous predictor variable \(x\), the left child is chosen if CutPoint \(<v\) (i) and the right child is chosen if \(x>=\) CutPoint(i). CutPoint is NaN for branch nodes based on categorical predictors and for leaf nodes.

\section*{CutType}

An \(n\)-element cell array indicating the type of cut at each node in tree, where \(n\) is the number of nodes. For each node i, CutType\{i\} is:
- 'continuous' - If the cut is defined in the form \(\mathrm{x}<\mathrm{v}\) for a variable x and cut point v .
- 'categorical' - If the cut is defined by whether a variable \(x\) takes a value in a set of categories.
- ' ' - If i is a leaf node.

CutVar contains the cut points for 'continuous' cuts, and CutCategories contains the set of categories.

\section*{CutVar}

An \(n\)-element cell array of the names of the variables used for branching in each node in tree, where \(n\) is the number of nodes.

\section*{CompactRegressionTree}

These variables are sometimes known as cut variables. For leaf nodes, CutVar contains an empty string.

CutVar contains the cut points for 'continuous' cuts, and CutCategories contains the set of categories.

\section*{IsBranch}

An \(n\)-element logical vector ib that is true for each branch node and false for each leaf node of tree.

\section*{NodeErr}

An \(n\)-element vector e of the errors of the nodes in tree, where \(n\) is the number of nodes. \(e(i)\) is the misclassification probability for node i.

\section*{NodeMean}

An \(n\)-element numeric array with mean values in each node of tree, where \(n\) is the number of nodes in the tree. Every element in NodeMean is the average of the true \(Y\) values over all observations in the node.

\section*{NodeProb}

An \(n\)-element vector p of the probabilities of the nodes in tree, where \(n\) is the number of nodes. The probability of a node is computed as the proportion of observations from the original data that satisfy the conditions for the node. This proportion is adjusted for any prior probabilities assigned to each class.

\section*{NodeRisk}

An \(n\)-element vector of the risk of the nodes in the tree, where \(n\) is the number of nodes. The risk for each node is the node error weighted by the node probability.

\section*{NodeSize}

An \(n\)-element vector sizes of the sizes of the nodes in tree, where \(n\) is the number of nodes. The size of a node is defined as

\section*{CompactRegressionTree}
the number of observations from the data used to create the tree that satisfy the conditions for the node.

\section*{NumNodes}

The number of nodes n in tree.

\section*{Parent}

An \(n\)-element vector \(p\) containing the number of the parent node for each node in tree, where \(n\) is the number of nodes. The parent of the root node is 0 .

\section*{PredictorNames}

A cell array of names for the predictor variables, in the order in which they appear in X .

\section*{PruneAlpha}

Numeric vector with one element per pruning level. If the pruning level ranges from 0 to \(M\), then PruneAlpha has \(M+1\) elements sorted in ascending order. PruneAlpha(1) is for pruning level 0 (no pruning), PruneAlpha(2) is for pruning level 1, and so on.

\section*{PruneList}

An \(n\)-element numeric vector with the pruning levels in each node of tree, where \(n\) is the number of nodes. The pruning levels range from 0 (no pruning) to \(M\), where \(M\) is the distance between the deepest leaf and the root node.

\section*{ResponseName}

Name of the response variable Y , a string.

\section*{ResponseTransform}

Function handle for transforming the raw response values (mean squared error). The function handle should accept a matrix of response values and return a matrix of the same size. The default string 'none' means @(x)x, or no transformation.

Add or change a ResponseTransform function by dot addressing:

\section*{CompactRegressionTree}
ctree.ResponseTransform = @function

\section*{SurrCutCategories}

An \(n\)-element cell array of the categories used for surrogate splits in tree, where \(n\) is the number of nodes in tree. For each node \(k\), SurrCutCategories \(\{k\}\) is a cell array. The length of SurrCutCategories \(\{k\}\) is equal to the number of surrogate predictors found at this node. Every element of SurrCutCategories \(\{k\}\) is either an empty string for a continuous surrogate predictor, or is a two-element cell array with categories for a categorical surrogate predictor. The first element of this two-element cell array lists categories assigned to the left child by this surrogate split, and the second element of this two-element cell array lists categories assigned to the right child by this surrogate split. The order of the surrogate split variables at each node is matched to the order of variables in SurrCutVar. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrCutCategories contains an empty cell.

\section*{SurrCutFlip}

An \(n\)-element cell array of the numeric cut assignments used for surrogate splits in tree, where \(n\) is the number of nodes in tree. For each node k, SurrCutFlip \(\{\mathrm{k}\}\) is a numeric vector. The length of SurrCutFlip \(\{\mathrm{k}\}\) is equal to the number of surrogate predictors found at this node. Every element of SurrCutFlip\{k\} is either zero for a categorical surrogate predictor, or a numeric cut assignment for a continuous surrogate predictor. The numeric cut assignment can be either -1 or +1 . For every surrogate split with a numeric cut \(C\) based on a continuous predictor variable \(Z\), the left child is chosen if \(Z<C\) and the cut assignment for this surrogate split is +1 , or if \(Z \geq C\) and the cut assignment for this surrogate split is -1 . Similarly, the right child is chosen if \(Z \geq C\) and the cut assignment for this surrogate split is +1 , or if \(Z<C\) and the cut assignment for this surrogate split is -1 . The order of the surrogate split variables at each node is matched to the order of variables in SurrCutVar. The optimal-split variable at this

\section*{CompactRegressionTree}
node does not appear. For nonbranch (leaf) nodes, SurrCutFlip contains an empty array.

\section*{SurrCutPoint}

An \(n\)-element cell array of the numeric values used for surrogate splits in tree, where \(n\) is the number of nodes in tree. For each node \(k\), SurrCutPoint \(\{\mathrm{k}\}\) is a numeric vector. The length of SurrCutPoint \(\{\mathrm{k}\}\) is equal to the number of surrogate predictors found at this node. Every element of SurrCutPoint \{k\} is either NaN for a categorical surrogate predictor, or a numeric cut for a continuous surrogate predictor. For every surrogate split with a numeric cut \(C\) based on a continuous predictor variable \(Z\), the left child is chosen if \(Z<C\) and SurrCutFlip for this surrogate split is -1 . Similarly, the right child is chosen if \(Z \geq C\) and SurrCutFlip for this surrogate split is +1 , or if \(Z<C\) and SurrCutFlip for this surrogate split is -1 . The order of the surrogate split variables at each node is matched to the order of variables returned by SurrCutVar. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrCutPoint contains an empty cell.

\section*{SurrCutType}

An \(n\)-element cell array indicating types of surrogate splits at each node in tree, where \(n\) is the number of nodes in tree. For each node \(k\), SurrCutType \(\{k\}\) is a cell array with the types of the surrogate split variables at this node. The variables are sorted by the predictive measure of association with the optimal predictor in the descending order, and only variables with the positive predictive measure are included. The order of the surrogate split variables at each node is matched to the order of variables in SurrCutVar. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrCutType contains an empty cell. A surrogate split type can be either 'continuous' if the cut is defined in the form \(Z<V\) for a variable \(Z\) and cut point V or 'categorical' if the cut is defined by whether \(Z\) takes a value in a set of categories.

\section*{CompactRegressionTree}

\section*{SurrCutVar}

An \(n\)-element cell array of the names of the variables used for surrogate splits in each node in tree, where \(n\) is the number of nodes in tree. Every element of SurrCutVar is a cell array with the names of the surrogate split variables at this node. The variables are sorted by the predictive measure of association with the optimal predictor in the descending order, and only variables with the positive predictive measure are included. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrCutVar contains an empty cell.

\section*{SurrVarAssoc}

An \(n\)-element cell array of the predictive measures of association for surrogate splits in tree, where \(n\) is the number of nodes in tree. For each node k, SurrVarAssoc \(\{k\}\) is a numeric vector. The length of SurrVarAssoc \(\{k\}\) is equal to the number of surrogate predictors found at this node. Every element of SurrVarAssoc\{k\} gives the predictive measure of association between the optimal split and this surrogate split. The order of the surrogate split variables at each node is the order of variables in SurrCutVar. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, SurrVarAssoc contains an empty cell.

\section*{CompactRegressionTree}

Copy
Semantics
Examples

Value. To learn how value classes affect copy operations, see Copying Objects in the MATLAB documentation.

Construct a regression tree for the carsmall data. Make a compact version of the tree, and compare its size to that of the full tree:
```

load carsmall
tree = RegressionTree.fit([Weight, Cylinders],MPG,...
'MinParent',20,...
'PredictorNames',{'W','C'});
ctree = compact(tree);
t = whos('tree'); % t.bytes = size of tree in bytes
c = whos('ctree'); % c.bytes = size of ctree in bytes
[c.bytes t.bytes]
ans =
4972 8173

```

See Also RegressionTree.fit | RegressionTree | compact

\section*{CompactTreeBagger}
\begin{tabular}{|c|c|}
\hline Purpose & Compact ensemble of decision trees grown by bootstrap aggregation \\
\hline Description & \begin{tabular}{l}
CompactTreeBagger class is a lightweight class that contains the tr grown using TreeBagger. CompactTreeBagger does not preserve any information about how TreeBagger grew the decision trees. It does not contain the input data used for growing trees, nor does it contain training parameters such as minimal leaf size or number of variables sampled for each decision split at random. You can only u CompactTreeBagger for predicting the response of the trained ensen given new data \(X\), and other related functions. \\
CompactTreeBagger lets you save the trained ensemble to disk, or use it in any other way, while discarding training data and various parameters of the training configuration irrelevant for predicting response of the fully grown ensemble. This reduces storage and men requirements, especially for ensembles trained on large data sets.
\end{tabular} \\
\hline Construction & \begin{tabular}{ll}

\section*{CompactTreeBagger}
\begin{tabular}{ll} 
proximity & Proximity matrix for data \\
setDefaultYfit & Set default value for predict
\end{tabular}

\section*{Properties}

\section*{ClassNames}

The ClassNames property is a cell array containing the class names for the response variable \(Y\) supplied to TreeBagger. This property is empty for regression trees.

\section*{DeltaCritDecisionSplit}

The DeltaCritDecisionSplit property is a numeric array of size 1-by-Nvars of changes in the split criterion summed over splits on each variable, averaged across the entire ensemble of grown trees.

See also TreeBagger.DeltaCritDecisionSplit, classregtree.varimportance

\section*{DefaulłYfit}

The DefaultYfit property controls what predicted value CompactTreeBagger returns when no prediction is possible, for example when the predict method needs to predict for an observation which has only false values in the matrix supplied through 'useifort' argument.

For classification, you can set this property to either ' ' or 'MostPopular'. If you choose 'MostPopular' (default), the property value becomes the name of the most probable class in the training data.

For regression, you can set this property to any numeric scalar. The default is the mean of the response for the training data.

See also predict, setDefaultYfit, TreeBagger.DefaultYfit.

\section*{Method}

The Method property is 'classification' for classification ensembles and 'regression' for regression ensembles.

\section*{CompactTreeBagger}

\section*{NTrees}

The NTrees property is a scalar equal to the number of decision trees in the ensemble.

\section*{NVarSplit}

The NVarSplit property is a numeric array of size 1-by-Nvars, where every element gives a number of splits on this predictor summed over all trees.

\section*{Trees}

The Trees property is a cell array of size NTrees-by- 1 containing the trees in the ensemble.

\section*{VarAssoc}

The VarAssoc property is a matrix of size Nuars-by-Nvars with predictive measures of variable association, averaged across the entire ensemble of grown trees. If you grew the ensemble setting 'surrogate' to 'on', this matrix for each tree is filled with predictive measures of association averaged over the surrogate splits. If you grew the ensemble setting 'surrogate' to 'off' (default), VarAssoc is diagonal.

See also classregtree.MeanSurrVarAssoc

\section*{VarNames}

The VarNames property is a cell array containing the names of the predictor variables (features). These names are taken from the optional 'names' parameter that supplied to TreeBagger. The default names are 'x1', 'x2', etc.

\section*{Copy Semantics}

Value. To learn how this affects your use of the class, see Comparing Handle and Value Classes in the MATLAB Object-Oriented Programming documentation.

0 & 1 & 1 & 0 \\
0 & 0 & 0 & 1 \\
0 & 0 & 0 & 0 \\
order \(=\) & & & \\
1 & & & \\
2 & & & \\
3 & & & \\
4 & & &
\end{tabular}

\section*{Example 2}

Randomize the measurements and groups in Fisher's iris data:
```

load fisheriris
numObs = length(species);
p = randperm(numObs);
meas = meas(p,:);
species = species(p);

```

Use classify to classify measurements in the second half of the data, using the first half of the data for training:
```

half = floor(numObs/2);
training = meas(1:half,:);
trainingSpecies = species(1:half);
sample = meas(half+1:end,:);
grouphat = classify(sample,training,trainingSpecies);

```

Display the confusion matrix for the resulting classification:
```

group = species(half+1:end);
C =
22 0 0
2 02 0
0 0 29
order =
'virginica'

```
[C,order] = confusionmat(group,grouphat)
```

'versicolor'
'setosa'

```

\section*{Purpose \\ Shewhart control charts}

\author{
Syntax \\ \section*{Description}
}
controlchart(X)
controlchart(x,group)
controlchart(X,group)
[stats,plotdata] = controlchart(x,[group])
controlchart(x,group, 'name', value)
controlchart ( X ) produces an xbar chart of the measurements in matrix \(X\). Each row of \(X\) is considered to be a subgroup of measurements containing replicate observations taken at the same time. The rows should be in time order. If \(X\) is a time series object, the time samples should contain replicate observations.

The chart plots the means of the subgroups in time order, a center line (CL) at the average of the means, and upper and lower control limits (UCL, LCL) at three standard errors from the center line. The standard error is the estimated process standard deviation divided by the square root of the subgroup size. Process standard deviation is estimated from the average of the subgroup standard deviations. Out of control measurements are marked as violations and drawn with a red circle. Data cursor mode is enabled, so clicking any data point displays information about that point.
controlchart ( \(\mathrm{x}, \mathrm{group}\) ) accepts a grouping variable group for a vector of measurements \(x\). group is a categorical variable, vector, string array, or cell array of strings the same length as \(x\). Consecutive measurements \(x(n)\) sharing the same value of group ( \(n\) ) for \(1 \leq n \leq\) length ( \(x\) ) are defined to be a subgroup. Subgroups can have different numbers of observations.
controlchart (X, group) accepts a grouping variable group for a matrix of measurements in \(X\). In this case, group is only used to label the time axis; it does not change the default grouping by rows.
[stats, plotdata] = controlchart(x,[group]) returns a structure stats of subgroup statistics and parameter estimates, and a structure plotdata of plotted values. plotdata contains one record for each chart.

The fields in stats and plotdata depend on the chart type.
The fields in stats are selected from the following:
- mean - Subgroup means
- std - Subgroup standard deviations
- range - Subgroup ranges
- n - Subgroup size, or total inspection size or area
- i - Individual data values
- ma - Moving averages
- mr - Moving ranges
- count - Count of defects or defective items
- mu - Estimated process mean
- sigma - Estimated process standard deviation
- p - Estimated proportion defective
- m - Estimated mean defects per unit

The fields in plotdata are the following:
- pts - Plotted point values
- cl - Center line
- lcl - Lower control limit
- ucl - Upper control limit
- se - Standard error of plotted point
- n - Subgroup size
- ooc - Logical that is true for points that are out of control controlchart(x,group, 'name', value) specifies one or more of the following optional parameter name/value pairs, with name in single quotes:
- charttype - The name of a chart type chosen from among the following:
- 'xbar' - Xbar or mean
- 's' - Standard deviation
- 'r' - Range
- 'ewma' - Exponentially weighted moving average
- 'i' - Individual observation
- 'mr' - Moving range of individual observations
- 'ma' - Moving average of individual observations
- ' \(p\) ' - Proportion defective
- 'np' - Number of defectives
- 'u' - Defects per unit
- 'c' - Count of defects

Alternatively, a parameter can be a cell array listing multiple compatible chart types. There are four sets of compatible types:
- 'xbar', 's', 'r', and 'ewma'
- 'i', 'mr', and 'ma'
- 'p' and 'np'
- 'u' and 'c'
- display - Either 'on' (default) to display the control chart, or 'off' to omit the display
- label - A string array or cell array of strings, one per subgroup. This label is displayed as part of the data cursor for a point on the plot.
- lambda - A parameter between 0 and 1 controlling how much the current prediction is influenced by past observations in an EWMA
plot. Higher values of 'lambda ' give less weight to past observations and more weight to the current observation. The default is 0.4.
- limits' - A three-element vector specifying the values of the lower control limit, center line, and upper control limits. Default is to estimate the center line and to compute control limits based on the estimated value of sigma. Not permitted if there are multiple chart types.
- mean - Value for the process mean, or an empty value (default) to estimate the mean from \(X\). This is the \(p\) parameter for \(p\) and \(n p\) charts, the mean defects per unit for \(u\) and \(c\) charts, and the normal mu parameter for other charts.
- nsigma - The number of sigma multiples from the center line to a control limit. Default is 3 .
- parent - The handle of the axes to receive the control chart plot. Default is to create axes in a new figure. Not permitted if there are multiple chart types.
- rules - The name of a control rule, or a cell array containing multiple control rule names. These rules, together with the control limits, determine if a point is marked as out of control. The default is to apply no control rules, and to use only the control limits to decide if a point is out of control. See controlrules for more information. Control rules are applied to charts that measure the process level (xbar, i, c, u, p, and np) rather than the variability ( \(r, s\) ), and they are not applied to charts based on moving statistics (ma, mr, ewma).
- sigma - Either a value for sigma, or a method of estimating sigma chosen from among 'std' (the default) to use the average within-subgroup standard deviation, 'range' to use the average subgroup range, and 'variance' to use the square root of the pooled variance. When creating i, mr, or ma charts for data not in subgroups, the estimate is always based on a moving range.
- specs - A vector specifying specification limits. Typically this is a two-element vector of lower and upper specification limits. Since specification limits typically apply to individual measurements, this
parameter is primarily suitable for i charts. These limits are not plotted on \(r\), \(s\), or mr charts.
- unit - The total number of inspected items for \(p\) and \(n p\) charts, and the size of the inspected unit for \(u\) and \(c\) charts. In both cases \(X\) must be the count of the number of defects or defectives found. Default is 1 for \(u\) and \(c\) charts. This argument is required (no default) for \(p\) and \(n p\) charts.
- width - The width of the window used for computing the moving ranges and averages in mr and ma charts, and for computing the sigma estimate in i, mr, and ma charts. Default is 5 .

\section*{Examples Create xbar and \(r\) control charts for the data in parts.mat:}
```

load parts
st = controlchart(runout,'chart',{'xbar' 'r'});

```

Control charts

Display the process mean and standard deviation:
fprintf('Parameter estimates: mu \(=\%\), sigma \(=\% g \backslash n '\) st.mu,st.sigma);
Parameter estimates: mu \(=-0.0863889\), sigma \(=0.130215\)
\begin{tabular}{ll} 
See Also & controlrules \\
How To & . "Grouping Variables" on page 2-51
\end{tabular}

\section*{Purpose Western Electric and Nelson control rules}
```

Syntax
R = controlrules('rules',x,cl,se)
[R,RULES] = controlrules('rules',x,cl,se)

```

\section*{Description}
\(\mathrm{R}=\) controlrules('rules', \(\mathrm{x}, \mathrm{cl}, \mathrm{se})\) determines which points in the vector x violate the control rules in rules. cl is a vector of center-line values. se is a vector of standard errors. (Typically, control limits on a control chart are at the values \(\mathrm{cl}-3^{*}\) se and \(\mathrm{cl}+3 * \mathrm{se}\).) rules is the name of a control rule, or a cell array containing multiple control rule names, from the list below. If \(x\) has \(n\) values and rules contains \(m\) rules, then \(R\) is an \(n\)-by- \(m\) logical array, with \(R(i, j)\) assigned the value 1 if point i violates rule \(j, 0\) if it does not.

The following are accepted values for rules (specified inside single quotes):
- we1 - 1 point above cl + 3*se
- we \(2-2\) of 3 above cl + 2*se
- we3 - 4 of 5 above cl + se
- we4 - 8 of 8 above cl
- we5 - 1 below cl \(3 *\) se
- we6 - 2 of 3 below cl 2*se
- we \(7-4\) of 5 below cl se
- we8 - 8 of 8 below cl
- we9 - 15 of 15 between cl se and cl + se
- we10-8 of 8 below cl se or above cl + se
- n1-1 point below cl \(3^{*}\) se or above cl +3 *se
- n2 - 9 of 9 on the same side of cl
- n3 - 6 of 6 increasing or decreasing
- n4-14 alternating up/down
- n5-2 of 3 below cl 2*se or above cl + 2*se, same side
- n6-4 of 5 below cl se or above cl + se, same side
- n7-15 of 15 between cl se and cl + se
- n8 - 8 of 8 below cl se or above cl + se, either side
- we - All Western Electric rules
- n - All Nelson rules

For multi-point rules, a rule violation at point i indicates that the set of points ending at point \(i\) triggered the rule. Point \(i\) is considered to have violated the rule only if it is one of the points violating the rule's condition.

Any points with NaN as their \(\mathrm{x}, \mathrm{cl}\), or se values are not considered to have violated rules, and are not counted in the rules for other points.

Control rules can be specified in the controlchart function as values for the 'rules' parameter.
[R,RULES] = controlrules('rules', \(x, c l, s e)\) returns a cell array of text strings RULES listing the rules applied.

\section*{Examples}

Create an xbar chart using the we2 rule to mark out of control measurements:
```

load parts;
st = controlchart(runout,'rules','we2');
x = st.mean;
cl = st.mu;
se = st.sigma./sqrt(st.n);
hold on
plot(cl+2*se,'m')

```

Use controlrules to identify the measurements that violate the control rule:
```

R = controlrules('we2',x,cl,se);
I = find(R)
I =
21
23

```

\section*{gmdistribution.Converged property}

Purpose Determine if algorithm converged
Description Logical true if the algorithm has converged; logical false if the algorithm has not converged.

Note This property applies only to gmdistribution objects constructed with fit.

Purpose
Cophenetic correlation coefficient

\section*{Syntax}
\(\mathrm{c}=\operatorname{cophenet}(\mathrm{Z}, \mathrm{Y})\)
\([\mathrm{c}, \mathrm{d}]=\operatorname{cophenet}(\mathrm{Z}, \mathrm{Y})\)
\(c=\) cophenet \((Z, Y)\) computes the cophenetic correlation coefficient for the hierarchical cluster tree represented by \(Z . Z\) is the output of the linkage function. Y contains the distances or dissimilarities used to construct \(Z\), as output by the pdist function. \(Z\) is a matrix of size ( \(m-1\) )-by- 3 , with distance information in the third column. Y is a vector of size \(m^{*}(m-1) / 2\).
\([c, d]=\) cophenet \((Z, Y)\) returns the cophenetic distances \(d\) in the same lower triangular distance vector format as Y .

The cophenetic correlation for a cluster tree is defined as the linear correlation coefficient between the cophenetic distances obtained from the tree, and the original distances (or dissimilarities) used to construct the tree. Thus, it is a measure of how faithfully the tree represents the dissimilarities among observations.

The cophenetic distance between two observations is represented in a dendrogram by the height of the link at which those two observations are first joined. That height is the distance between the two subclusters that are merged by that link.

The output value, \(c\), is the cophenetic correlation coefficient. The magnitude of this value should be very close to 1 for a high-quality solution. This measure can be used to compare alternative cluster solutions obtained using different algorithms.

The cophenetic correlation between \(Z(:, 3)\) and \(Y\) is defined as
\[
c=\frac{\sum_{i<j}\left(Y_{i j}-y\right)\left(Z_{i j}-z\right)}{\sqrt{\Sigma_{i<j}\left(Y_{i j}-y\right)^{2} \Sigma_{i<j}\left(Z_{i j}-z\right)^{2}}}
\]
where:
- \(Y_{i j}\) is the distance between objects \(i\) and \(j\) in \(Y\).
- \(Z_{i j}\) is the cophenetic distance between objects \(i\) and \(j\), from \(\mathrm{Z}(:, 3)\).
- \(y\) and \(z\) are the average of \(Y\) and \(Z(:, 3)\), respectively.
```

Examples
$X=[r a n d(10,3) ; r a n d(10,3)+1 ; r a n d(10,3)+2] ;$
Y = pdist(X);
Z = linkage(Y,'average');
\% Compute Spearman's rank correlation between the
\% dissimilarities and the cophenetic distances
[c,D] = cophenet(Z,Y);
$r=\operatorname{corr}\left(\mathrm{Y}^{\prime}, \mathrm{D}^{\prime}, ' t y p \mathrm{C}^{\prime}\right.$, 'spearman')
$r=$
0.8279

```

\section*{Purpose Fit copula to data}

\author{
Syntax \\ \section*{Description}
}
```

RHOHAT = copulafit('Gaussian',U)
[RHOHAT,nuhat] = copulafit('t',U)
[RHOHAT,nuhat,nuci] = copulafit('t',U)
paramhat = copulafit('family',U)
[paramhat,paramci] = copulafit('family',U)
[...] = copulafit(...,'alpha',alpha)
[...] = copulafit('t',U,'Method','ApproximateML')
[...] = copulafit(...,'Options',options)

```

RHOHAT = copulafit('Gaussian', U) returns an estimate RHOHAT of the matrix of linear correlation parameters for a Gaussian copula, given data in \(\mathrm{U} . \mathrm{U}\) is an \(n\)-by- \(p\) matrix of values in the open interval \((0,1)\) representing \(n\) points in the \(p\)-dimensional unit hypercube.
[RHOHAT, nuhat] = copulafit('t', U) returns an estimate RHOHAT of the matrix of linear correlation parameters for a \(t\) copula and an estimate nuhat of the degrees of freedom parameter, given data in U . U is an \(n\)-by- \(p\) matrix of values in the open interval \((0,1)\) representing \(n\) points in the \(p\)-dimensional unit hypercube.
[RHOHAT, nuhat, nuci] = copulafit('t', U) also returns an approximate \(95 \%\) confidence interval nuci for the degrees of freedom parameter estimated in nuhat.
paramhat \(=\) copulafit('family', U) returns an estimate paramhat of the copula parameter for an Archimedean copula specified by family, given data in \(U\). U is an \(n\)-by- 2 matrix of values in the open interval \((0,1)\) representing \(n\) points in the unit square. family is one of Clayton, Frank, or Gumbel.
[paramhat,paramci] = copulafit('family',U) also returns an approximate \(95 \%\) confidence interval paramci for the copula parameter estimated in paramhat.
[...] = copulafit(...,'alpha', alpha) returns approximate 100*(1-alpha) \% confidence intervals in nuci or paramci.

Note By default, copulafit uses maximum likelihood to fit a copula to \(U\). When \(U\) contains data transformed to the unit hypercube by parametric estimates of their marginal cumulative distribution functions, this is known as the Inference Functions for Margins (IFM) method. When U contains data transformed by the empirical cdf (see ecdf), this is known as Canonical Maximum Likelihood (CML).
[...] = copulafit('t',U,'Method','ApproximateML') fits a \(t\) copula for large samples \(U\) by maximizing an objective function that approximates the profile log-likelihood for the degrees of freedom parameter (see [1]). This method can be significantly faster than maximum likelihood, but the estimates and confidence limits may not be accurate for small to moderate sample sizes.
[...] = copulafit(...,'Options',options) specifies control parameters for the iterative parameter estimation algorithm using an options structure options as created by statset. Type statset('copulafit') at the command prompt for fields and default values used by copulafit. This argument is not applicable to the 'Gaussian' family.

\section*{References}

Examples Load and plot simulated stock return data:
load stockreturns
x = stocks(:,1);
y = stocks(:,2);
scatterhist( \(x, y\) )

Transform the data to the copula scale (unit square) using a kernel estimator of the cumulative distribution function:
```

u = ksdensity(x,x,'function','cdf');
v = ksdensity(y,y,'function','cdf');
scatterhist(u,v)
xlabel('u')
ylabel('v')

```

Fit a \(t\) copula:
```

[Rho,nu] = copulafit('t',[u v],'Method','ApproximateML')
Rho =
1.0000 0.7220
0.7220 1.0000
nu =
2.8934e+006

```

Generate a random sample from the \(t\) copula:
```

r = copularnd('t',Rho,nu,1000);

```
```

u1 = r(:,1);
v1 = r(:,2);
scatterhist(u1,v1)
xlabel('u')
ylabel('v')
set(get(gca,'children'),'marker','.')

```

Transform the random sample back to the original scale of the data:
x1 = ksdensity(x,u1,'function','icdf');
```

y1 = ksdensity(y,v1,'function','icdf');
scatterhist(x1,y1)
set(get(gca,'children'),'marker','.')

```

\section*{See Also \\ copulacdf | copulaparam | copulapdf | copulastat}

\section*{Purpose Coordinate exchange}

Syntax
```

dCE = cordexch(nfactors,nruns)
[dCE,X] = cordexch(nfactors,nruns)
[dCE,X] = cordexch(nfactors,nruns,'model')
[dCE,X] = cordexch(...,'name',value)

```

Description
dCE = cordexch(nfactors, nruns) uses a coordinate-exchange algorithm to generate a \(D\)-optimal design dCE with nruns runs (the rows of dCE) for a linear additive model with nfactors factors (the columns of dCE). The model includes a constant term.
[dCE,X] = cordexch(nfactors,nruns) also returns the associated design matrix \(X\), whose columns are the model terms evaluated at each treatment (row) of dCE.
[dCE, X] = cordexch(nfactors,nruns,'model') uses the linear regression model specified in model. model is one of the following strings, specified inside single quotes:
- linear - Constant and linear terms. This is the default.
- interaction - Constant, linear, and interaction terms
- quadratic - Constant, linear, interaction, and squared terms
- purequadratic - Constant, linear, and squared terms

The order of the columns of X for a full quadratic model with \(n\) terms is:

\section*{1 The constant term}

2 The linear terms in order \(1,2, \ldots, n\)
3 The interaction terms in order \((1,2),(1,3), \ldots,(1, n),(2,3), \ldots,(n-1, n)\)
4 The squared terms in order \(1,2, \ldots, n\)
Other models use a subset of these terms, in the same order.

Alternatively, model can be a matrix specifying polynomial terms of arbitrary order. In this case, model should have one column for each factor and one row for each term in the model. The entries in any row of model are powers for the factors in the columns. For example, if a model has factors \(\mathrm{X} 1, \mathrm{X} 2\), and X 3 , then a row [ 0 1 12 2] in model specifies the term (X1.^0).*(X2.^1).*(X3.^2). A row of all zeros in model specifies a constant term, which can be omitted.
[dCE,X] = cordexch(...,'name', value) specifies one or more optional name/value pairs for the design. Valid parameters and their values are listed in the following table. Specify name inside single quotes.
\begin{tabular}{|c|c|}
\hline name & Value \\
\hline bounds & Lower and upper bounds for each factor, specified as a 2-by-nfactors matrix. Alternatively, this value can be a cell array containing nfactors elements, each element specifying the vector of allowable values for the corresponding factor. \\
\hline categorical & Indices of categorical predictors. \\
\hline display & Either 'on' or 'off' to control display of the iteration counter. The default is 'on'. \\
\hline excludefun & Handle to a function that excludes undesirable runs. If the function is \(f\), it must support the syntax \(b=f(S)\), where \(S\) is a matrix of treatments with nfactors columns and \(b\) is a vector of Boolean values with the same number of rows as \(S . b(i)\) is true if the method should exclude \(i\) th row \(S\). \\
\hline init & Initial design as a nruns-by-nfactors matrix. The default is a randomly selected set of points. \\
\hline levels & Vector of number of levels for each factor. Not used when hounds is snecified as a cell arrav \\
\hline maxiter & Maximum number of iterations. The default is 10. \\
\hline
\end{tabular}
\begin{tabular}{|c|c|}
\hline name & Value \\
\hline tries & Number of times to try to generate a design from a new starting point. The algorithm uses random points for each try, except possibly the first. The default is 1 . \\
\hline options & \begin{tabular}{l}
A structure that specifies whether to run in parallel, and specifies the random stream or streams. Create the options structure with statset. Option fields: \\
- UseParallel - Set to true to compute in parallel. Default is false. \\
- UseSubstreams - Set to true to compute in parallel in a reproducible fashion. Default is false. To compute reproducibly, set Streams to a type allowing substreams: 'mlfg6331_64' or 'mrg32k3a'. \\
- Streams - A RandStream object or cell array of such objects. If you do not specify Streams, cordexch uses the default stream or streams. If you choose to specify Streams, use a single object except in the case \\
- You have an open MATLAB pool \\
- UseParallel is true \\
- UseSubstreams is false \\
In that case, use a cell array the same size as the MATLAB pool.
\end{tabular} \\
\hline
\end{tabular}

\section*{Algorithms}

Both cordexch and rowexch use iterative search algorithms. They operate by incrementally changing an initial design matrix \(X\) to increase \(D=\left|X^{T} X\right|\) at each step. In both algorithms, there is randomness built into the selection of the initial design and into the choice of the incremental changes. As a result, both algorithms may return locally, but not globally, \(D\)-optimal designs. Run each algorithm multiple times
and select the best result for your final design. Both functions have a 'tries ' parameter that automates this repetition and comparison.

Unlike the row-exchange algorithm used by rowexch, cordexch does not use a candidate set. (Or rather, the candidate set is the entire design space.) At each step, the coordinate-exchange algorithm exchanges a single element of \(X\) with a new element evaluated at a neighboring point in design space. The absence of a candidate set reduces demands on memory, but the smaller scale of the search means that the coordinate-exchange algorithm is more likely to become trapped in a local minimum.

\section*{Examples}

Suppose you want a design to estimate the parameters in the following three-factor, seven-term interaction model:
\[
y=\beta_{0}+\beta_{1} x_{1}+\beta_{2} x_{2}+\beta_{3} x_{3}+\beta_{12} x_{1} x_{2}+\beta_{13} x_{1} x_{3}+\beta_{23} x_{2} x_{3}+\varepsilon
\]

Use cordexch to generate a \(D\)-optimal design with seven runs:
```

nfactors = 3;
nruns = 7;
[dCE,X] = cordexch(nfactors,nruns,'interaction','tries',10)
dCE =

| -1 | 1 | 1 |  |  |  |  |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| -1 | -1 | -1 |  |  |  |  |
| 1 | 1 | 1 |  |  |  |  |
| -1 | 1 | -1 |  |  |  |  |
| 1 | -1 | 1 |  |  |  |  |
| 1 | -1 | -1 |  |  |  |  |
| -1 | -1 | 1 |  |  | 1 | 1 |
|  |  |  |  | 1 | 1 | 1 |
| 1 | -1 | 1 | 1 | 1 | 1 | 1 |
| 1 | -1 | -1 | -1 | 1 | 1 | -1 |
| 1 | 1 | 1 | 1 | -1 | 1 | -1 |
| 1 | -1 | 1 | -1 | -1 | 1 | -1 |
| 1 | 1 | -1 | 1 | -1 | 1 |  |
| 1 | 1 | -1 | -1 | -1 | -1 | 1 |
| 1 | -1 | -1 | 1 | 1 | -1 | -1 |

```

Columns of the design matrix X are the model terms evaluated at each row of the design dCE. The terms appear in order from left to right: constant term, linear terms ( \(1,2,3\) ), interaction terms ( \(12,13,23\) ). Use \(X\) to fit the model, as described in "Linear Regression" on page 9-11, to response data measured at the design points in dCE.

See Also rowexch | daugment | dcovary

\section*{Purpose Linear or rank correlation}
```

Syntax
RHO $=\operatorname{corr}(X)$
RHO $=\operatorname{corr}(X, Y)$
[RHO,PVAL] $=\operatorname{corr}(X, Y)$
[RHO,PVAL] = corr(X,Y,'name',value)

```

\section*{Description}

RHO \(=\operatorname{corr}(\mathrm{X})\) returns a \(p\)-by- \(p\) matrix containing the pairwise linear correlation coefficient between each pair of columns in the \(n\)-by- \(p\) matrix X.

RHO \(=\operatorname{corr}(\mathrm{X}, \mathrm{Y})\) returns a \(p 1\)-by- \(p 2\) matrix containing the pairwise correlation coefficient between each pair of columns in the \(n\)-by- \(p 1\) and \(n\)-by- \(p 2\) matrices X and Y .

The difference between \(\operatorname{corr}(X, Y)\) and the MATLAB function corrcoef \((X, Y)\) is that corrcoef \((X, Y)\) returns a matrix of correlation coefficients for the two column vectors \(X\) and \(Y\). If \(X\) and \(Y\) are not column vectors, corrcoef \((X, Y)\) converts them to column vectors.
[RHO, PVAL] \(=\operatorname{corr}(\mathrm{X}, \mathrm{Y})\) also returns PVAL, a matrix of \(p\)-values for testing the hypothesis of no correlation against the alternative that there is a nonzero correlation. Each element of PVAL is the \(p\) value for the corresponding element of RHO. If PVAL \((i, j)\) is small, say less than 0.05 , then the correlation \(\operatorname{RHO}(i, j)\) is significantly different from zero.
[RHO, PVAL] \(=\operatorname{corr}(X, Y\), 'name ', value) specifies one or more optional name/value pairs. Specify name inside single quotes. The following table lists valid parameters and their values.
\begin{tabular}{l|l}
\hline Parameter & Values \\
\hline type & \begin{tabular}{l} 
- 'Pearson' (the default) computes Pearson's \\
linear correlation coefficient
\end{tabular} \\
& • 'Kendall' computes Kendall's tau \\
- 'Spearman' computes Spearman's rho
\end{tabular}

Using the 'pairwise' option for the rows parameter may return a matrix that is not positive definite. The 'complete' option always returns a positive definite matrix, but in general the estimates are based on fewer observations.
corr computes \(p\)-values for Pearson's correlation using a Student's \(t\) distribution for a transformation of the correlation. This correlation is exact when \(X\) and \(Y\) are normal. corr computes \(p\)-values for Kendall's tau and Spearman's rho using either the exact permutation distributions (for small sample sizes), or large-sample approximations.
corr computes \(p\)-values for the two-tailed test by doubling the more significant of the two one-tailed \(p\)-values.

Example
Find the correlation between two matrices and compare to the correlation between two column vectors.

Generate sample data.
rng('default')
\(x=r a n d n(30,4)\);
\(y=r a n d n(30,4)\);
\(y(:, 4)=\operatorname{sum}(x, 2) ;\) introduce correlation
Calculate the correlation between columns of \(X\) and \(Y\).
\([\mathrm{r}, \mathrm{p}]=\operatorname{corr}(\mathrm{x}, \mathrm{y})\)
\(r=\)
\begin{tabular}{rrrr}
-0.1686 & -0.0363 & 0.2278 & 0.6901 \\
0.3022 & 0.0332 & -0.0866 & 0.2617 \\
-0.3632 & -0.0987 & -0.0200 & 0.3504 \\
-0.1365 & -0.1804 & 0.0853 & 0.4908
\end{tabular}
\(p=\)
\begin{tabular}{llll}
0.3731 & 0.8489 & 0.2260 & 0.0000 \\
0.1045 & 0.8619 & 0.6491 & 0.1624 \\
0.0485 & 0.6039 & 0.9166 & 0.0577 \\
0.4721 & 0.3400 & 0.6539 & 0.0059
\end{tabular}

Calculate the correlation between \(X\) and \(Y\) using corrcoef.
\([r, p]=\operatorname{corrcoef}(x, y)\)
\(r=\)
\[
\begin{array}{ll}
1.0000 & 0.1252 \\
0.1252 & 1.0000
\end{array}
\]
\(p=\)
```

1.0000 0.1729
0.1729 1.0000

```

MATLAB function corrcoef converts \(X\) and \(Y\) into column vectors before computing the correlation between them.

\end{tabular}

Compare R with the correlation matrix computed from C by corrcov:
corrcov(C)
ans =
\begin{tabular}{lll}
1.0000 & 0.1558 & 0.2227 \\
0.1558 & 1.0000 & 0.5118 \\
0.2227 & 0.5118 & 1.0000
\end{tabular}

\section*{See Also}

\section*{TreeBagger.Cost property}
Purpose Misclassification costs
Description The cost property is a matrix with misclassification costs. This property is empty for ensembles of regression trees.
See Also classregtree

\section*{gmdistribution.CovType property}

\section*{Purpose Type of covariance matrices}

Description The string 'diagonal' if the covariance matrices are restricted to be diagonal; the string 'full' otherwise.

\section*{Purpose Cox proportional hazards regression}

Syntax
b \(=\operatorname{coxphfit}(\mathrm{X}, \mathrm{T})\)
b = coxphfit(X, T,Name, Value)
[b,logl,H,stats] = coxphfit(__)

\section*{Description}

\section*{Input Arguments}
\(\mathrm{b}=\) coxphfit \((\mathrm{X}, \mathrm{T})\) returns a \(p\)-by- 1 vector, b , of coefficient estimates for a Cox proportional hazards regression of the observed responses in an \(n\)-by- 1 vector, T , on the predictors in an \(n\)-by- \(p\) matrix X .

The model does not include a constant term, and \(X\) cannot contain a column of 1 s .
b = coxphfit (X, T, Name, Value) returns a vector of coefficient estimates, with additional options specified by one or more Name, Value pair arguments.
[b, logl, H, stats] = coxphfit( __ ) also returns the loglikelihood, logl, a structure, stats, that contains additional statistics, and a two-column matrix, H , that contains the T values in the first column and the estimated baseline cumulative hazard, in the second column. You can use any of the input arguments in the previous syntaxes.

\section*{X - Observations on predictor variables}
matrix
Observations on predictor variables, specified as an \(n\)-by- \(p\) matrix of \(p\) predictors for each of \(n\) observations.

The model does not include a constant term, thus X cannot contain a column of 1 s .

\section*{Data Types \\ single | double}

\section*{T - Time-to-event data}

\author{
vector
}

Time-to-event data, specified as an \(n\)-by- 1 vector.

\author{
Data Types \\ single | double
}

\section*{Name-Value Pair Arguments}

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN.

Example:
'baseline', 0,'censoring', censoreddata, 'frequency',freq specifies that coxphfit calculates the baseline hazard rate relative to 0 , considering the censoring information in the vector censoreddata, and the frequency of observations on \(T\) and \(X\) given in the vector freq.

\section*{'baseline' - X values at which to compute the baseline hazard mean(X) (default) | scalar value}
\(X\) values at which to compute the baseline hazard, specified as the comma-separated pair consisting of 'baseline' and a scalar value.

The default is mean \((X)\), so the hazard rate at \(X\) is \(h(t) * \exp ((X-\operatorname{mean}(X)) * b)\). Enter 0 to compute the baseline relative to 0 , so the hazard rate at \(X\) is \(h(t) * \exp (X * b)\). Changing the baseline does not affect the coefficient estimates, but the hazard ratio changes.

\section*{Example: 'baseline',0}

Data Types
single | double

\section*{'censoring' - Indicator for censoring}
array of 0 s (default) | array of 0 s and 1 s
Indicator for censoring, specified as the comma-separated pair consisting of 'censoring' and a Boolean array of the same size as T .

Use 1 for observations that are right censored and 0 for observations that are fully observed. The default is all observations are fully observed.

Example: 'censoring', cens

\section*{Data Types}
logical

\section*{'frequency' - Frequency of observations}

\section*{array of 1s (default) | vector of nonnegative integer counts}

Frequency of observations, specified as the comma-separated pair consisting of 'frequency' and an array that is the same size as \(T\) containing nonnegative integer counts.
The \(j^{\text {th }}\) element of this vector gives the number of times the method observes the \(j^{\text {th }}\) element of T and the \(j^{\text {th }}\) row of X . The default is one observation per row of \(X\) and \(T\).

Example: 'frequency',freq
Data Types
single | double

\section*{'init' - Initial values for estimated coefficients}
vector
Initial values for estimated coefficients, specified as the comma-separated pair consisting of 'init' and a vector containing the coefficient initial values.

Example: 'init', initcoef
Data Types
single | double

\section*{'options' - Algorithm control parameters}
structure
Algorithm control parameters for the iterative algorithm used to estimate \(b\), specified as the comma-separated pair consisting of
'options ' and a structure. A call to statset creates this argument. For parameter names and default values, type statset('coxphfit'). You can set the options under a new name and use that in the name-value pair argument.

\section*{Example: 'options',statset('coxphfit')}

\section*{Data Types}
char

\section*{Output Arguments}

\section*{b - Coefficient estimates}
vector
Coefficient estimates for a Cox proportional hazards regression, returned as a \(p\)-by- 1 vector.

\section*{logl - Loglikelihood}
scalar
Loglikelihood of the fitted model, returned as a scalar.
You can use log likelihood values to compare different models and assess the significance of effects of terms in the model.

\section*{H - Estimated baseline cumulative hazard \\ two-column matrix}

Estimated baseline cumulative hazard rate evaluated at \(T\) values, returned as a two-column matrix. The first column of the matrix contains \(T\) values, and the second column contains cumulative hazard rate estimates.

\section*{stats - Coefficient statistics}

\section*{structure}

Coefficient statistics, returned as a structure that contains the following fields.
\begin{tabular}{l|l}
\hline beta & Coefficient estimates (same as b ) \\
\hline se & Standard errors of coefficient estimates, b \\
\hline z & \(z\)-statistics for b (that is, b divided by standard error) \\
\hline p & \(p\)-values for b \\
\hline covb & Estimated covariance matrix for b \\
\hline
\end{tabular}

\section*{Examples Lifetime of Light Bulbs}

Navigate to a folder containing sample data.
```

cd(matlabroot)
cd('help/toolbox/stats/examples')

```

Load the sample data.
load lightbulb
The first column of the light bulb data has the lifetime (in hours) of two different types of bulbs. The second column has the binary variable indicating whether the bulb is fluorescent or incandescent. 0 indicates that the bulb is incandescent, and 1 indicates that it is fluorescent. The third column contains the censorship information, where 0 indicates the bulb was observed until failure, and 1 indicates the bulb was censored.

Fit a Cox proportional hazards model for the lifetime of the light bulbs, also accounting for censoring. The predictor variable is the type of bulb.
```

b = coxphfit(lightbulb(:,2),lightbulb(:,1),...
'censoring',lightbulb(:,3))

```
b \(=\)

The estimate of the hazard ratio is \(\exp (b)=112.8646\). This means that the hazard for the incandescent bulbs is 112.86 times the hazard for the fluorescent bulbs.

\section*{Change the Algorithm Parameters}

Navigate to a folder containing sample data.
```

cd(matlabroot)
cd('help/toolbox/stats/examples')

```

Load the sample data.
load lightbulb
The first column of the data has the lifetime (in hours) of two types of bulbs. The second column has the binary variable indicating whether the bulb is fluorescent or incandescent. 0 indicates that the bulb is incandescent, and 1 indicates that it is fluorescent. The third column contains the censorship information, where 0 indicates the bulb is observed until failure, and 1 indicates the item (bulb) is censored.

Fit a Cox proportional hazards model, also accounting for censoring. The predictor variable is the type of bulb.
```

b = coxphfit(lightbulb(:,2),lightbulb(:,1),...
'censoring',lightbulb(:,3))
b =

```
\[
4.7262
\]

Display the default control parameters for the algorithm coxphfit uses to estimate the coefficients.
```

statset('coxphfit')

```
ans =
```

    Display: 'off'
    ```
```

    MaxFunEvals: 200
        MaxIter: 100
            TolBnd: 1.0000e-06
            TolFun: 1.0000e-08

            TolX: 1.0000e-08
            TolTypeX: []
            GradObj: []
            Jacobian: []
            DerivStep: []
            FunValCheck: []
            Robust: []
    RobustWgtFun: []
        WgtFun: []
            Tune: []
    UseParallel: []
    UseSubstreams: []
Streams: {}
OutputFen: []

```

Save the options under a different name and change how the results will be displayed and the maximum number of iterations, Display and MaxIter.
```

coxphopt = statset('coxphfit');
coxphopt.Display = 'final';
coxphopt.MaxIter = 50;

```

Run coxphfit with the new algorithm parameters.
b = coxphfit(lightbulb(:,2), lightbulb(:,1),... 'censoring', lightbulb(:,3),'options', coxphopt)

Successful convergence: Norm of gradient less than OPTIONS.TolFun
b =
4.7262
coxphfit displays a report on the final iteration. Changing the maximum number of iterations did not affect the coefficient estimate.

\section*{Fit and Compare Cox and Weibull Survivor Functions}

Generate Weibull data depending on predictor X .
```

rng('default') % for reproducibility
X = 4*rand(100,1);
A = 50*exp(-0.5*X);
B = 2;
y = wblrnd(A,B);

```

The response values are generated from a Weibull distribution with a shape parameter depending on the predictor variable \(X\) and a scale parameter of 2 .

Fit a Cox proportional hazards model.
```

[b,logL,H,stats] = coxphfit(X,y);
[b logL]
ans =
0.9409 -331.1479

```

The coefficient estimate is 0.9409 and the log likelihood value is -331.1479 . Request the model statistics.
```

stats

```
stats \(=\)
    covb: 0.0158
    beta: 0.9409
    se: 0.1256
    z: 7.4889
    p: 6.9462e-14

The covariance matrix of the coefficient estimates, covb, contains only one value, which is equal to the variance of the coefficient estimate in this example. The coefficient estimate, beta, is the same as \(b\) and is equal to 0.9409. The standard error of the coefficient estimate, se, is 0.1256 , which is the square root of the variance 0.0158 . The \(z\)-statistic, \(z\), is beta/se \(=0.9409 / 0.1256=7.4880\). The \(p\)-value, \(p\), indicates that the effect of \(X\) is significant.

Plot the Cox estimate of the baseline survivor function together with the known Weibull function.
```

stairs(H(:,1), exp(-H(:,2)),'LineWidth', 2)
xx = linspace(0,100);
line(xx,1-wblcdf(xx,50*exp(-0.5*mean(X)),B),'color','r','LineWidth',2)
xlim([0,50])
legend('Estimated Survivor Function','Weibull Survivor Function')

```

The fitted model gives a close estimate to the survivor function of the actual distribution.

\section*{Definitions Cox Proportional Hazards Regression}

Cox proportional hazards regression is a semiparametric method for adjusting survival rate estimates to remove the effect of confounding variables and to quantify the effect of predictor variables. The method represents the effects of explanatory and confounding variables as a multiplier of a common baseline hazard function, \(h_{0}(t)\). For a baseline relative to 0 , this model corresponds to
\[
h_{X}(t)=h_{0}(t) e^{\sum_{i} X_{i} b_{i}},
\]
where \(h_{\mathrm{X}}(t)\) is the hazard rate at X and \(h_{0}(t)\) is the baseline hazard rate function. The baseline hazard function is the nonparametric part of the Cox proportional hazards regression function, whereas the impact of the predictor variables is a loglinear regression. The assumption is that the baseline hazard function depends on time, \(t\), but the predictor variables do not depend on time.

\section*{NaiveBayes.CPrior property}

\section*{Purpose Class priors}

Description The CPrior property is a vector of length NClasses containing the class priors. The priors for empty classes are zero.
Purpose Create object to use in \(k\)-nearest neighbors search

\section*{Syntax}

\section*{Input} Arguments

Description

NS = createns (X)
NS = createns(X,'Name', Value)
\(N S=\) createns \((X)\) uses the data observations in an \(m x\)-by- \(n\) matrix \(X\) to create an object NS. Rows of \(X\) correspond to observations and columns correspond to variables. NS is either an ExhaustiveSearcher or a KDTreeSearcher object which you can use to find nearest neighbors in \(X\) for desired query points. When NS is an ExhaustiveSearcher object, knnsearch uses the exhaustive search algorithm to find nearest neighbors. When NS is a KDTreeSearcher, createns creates and saves a \(k\) d-tree based on \(X\) in NS. knnsearch uses the \(k d\)-tree to find nearest neighbors. For information on these search methods, see " \(k\)-Nearest Neighbor Search and Radius Search" on page 15-12.
NS \(=\) createns (X,'Name', Value) accepts one or more optional name/value pairs. Specify Name inside single quotes. Specify NSMethod to determine which type of object to create. The object's properties save the information when you specify other arguments. For more information on the objects' properties, see ExhaustiveSearcher and KDTreeSearcher.

\section*{Name-Value Pair Arguments}

\section*{'NSMethod'}
Nearest neighbors search method, used to define the type of object created. Value is either:
- 'kdtree ' - Create a KDTreeSearcher object. If you do not specify NSMethod, this is the default value when the number of columns of \(X\) is less than \(10, \mathrm{X}\) is not sparse, and the distance measure is one of the following measures:
- 'euclidean' (default)
- 'cityblock'
- 'minkowski'
- 'chebychev'
- 'exhaustive' - Create an ExhaustiveSearcher object. If you do not specify NSMethod, this is the default value when the default criteria for 'kdtree' do not apply.

\section*{'Distance'}

A string or a function handle specifying the default distance metric used when you call the knnsearch method to find nearest neighbors for future query points. If you specify a distance metric but not an NSMethod, this input determines the type of object createns creates, according to the default values described in NSMethod.

For both KDTreeSearcher and ExhaustiveSearcher objects, the following options apply:
- 'euclidean' (default) - Euclidean distance.
- 'cityblock' - City block distance.
- 'chebychev' - Chebychev distance (maximum coordinate difference).
- 'minkowski' - Minkowski distance.

The following options apply only to ExhaustiveSearcher objects:
- 'seuclidean' - Standardized Euclidean distance. Each coordinate difference between rows in \(X\) and the query matrix is scaled by dividing by the corresponding element of the standard deviation computed from \(X, S=\) nanstd (X). To specify another value for \(S\), use the Scale argument.
- 'mahalanobis' - Mahalanobis distance, which is computed using a positive definite covariance matrix \(C\). The default value of \(C\) is the sample covariance matrix of \(X\), as computed by nancov ( \(X\) ). To change the value of C , use the Cov parameter.
- 'cosine' - One minus the cosine of the included angle between observations (treated as vectors).
- 'correlation' - One minus the sample linear correlation between observations (treated as sequences of values).
- 'spearman' - One minus the sample Spearman's rank correlation between observations (treated as sequences of values).
- 'hamming' - Hamming distance, which is percentage of coordinates that differ.
- 'jaccard' - One minus the Jaccard coefficient, which is the percentage of nonzero coordinates that differ.
- custom distance function - A distance function specified using @ (for example, @distfun). A distance function must be of the form function D2 = distfun(ZI, ZJ), taking as arguments a 1-by-n vector ZI containing a single row from \(X\) or from the query points \(Y\), and an \(m 2\)-by- \(n\) matrix ZJ containing multiple rows of X or Y , and returning an \(m 2\)-by- 1 vector of distances \(d 2\), whose \(j\) th element is the distance between the observations ZI and ZJ ( \(j,:\) ).

\section*{'P'}

A positive scalar, \(p\), indicating the exponent of the Minkowski distance. This parameter is only valid when Distance is 'minkowski'. Default is 2 .

\section*{'Cov'}

A positive definite matrix indicating the covariance matrix when computing the Mahalanobis distance. This parameter is only valid when Distance is 'mahalanobis'. Default is nancov (X).

\section*{'Scale'}

A vector \(S\) with the length equal to the number of columns in \(X\). Each coordinate of \(X\) and each query point is scaled by the corresponding element of S when computing the standardized Euclidean distance. This parameter is only valid when Distance is 'seuclidean'. Default is nanstd ( X ).

\section*{'BucketSize'}

A positive integer, indicating the maximum number of data points in each leaf node of the \(k d\)-tree. This argument is only meaningful when using the \(k\) d-tree search method. Default is 50 .

\section*{Examples Create a kd-tree with a Minkowski distance metric and a P value of 5:}
```

load fisheriris
x = meas(:,3:4);
% Since x has only two columns and the Distance is Minkowski,
% createns creates a KDTreeSearcher object by default:
knnobj = createns(x,'Distance','minkowski','P',5)
knnobj =
KDTreeSearcher
Properties:
BucketSize: 50
X: [150x2 double]
Distance: 'minkowski'
DistParameter: 5

```
See Also ExhaustiveSearcher.knnsearch | KDTreeSearcher.knnsearch |
How To . " \(k\)-Nearest Neighbor Search and Radius Search" on page 15-12

\section*{Purpose Cross-tabulation}
```

Syntax table $=$ crosstab $(x 1, x 2)$
table $=$ crosstab(x1, x2,..., xn)
[table,chi2,p] = crosstab(x1,..., xn)
[table,chi2, p,labels] = crosstab(x1,....,xn)

```

\section*{Description}

\section*{Examples}

\section*{Example 1}

Cross-tabulate two vectors with three and four distinct values, respectively:
```

x = [1 1 2 3 1]; y = [1 2 5 3 1];

```
```

table = crosstab(x,y)
table =

| 2 | 1 | 0 | 0 |
| :--- | :--- | :--- | :--- |
| 0 | 0 | 0 | 1 |
| 0 | 0 | 1 | 0 |

```

\section*{Example 2}

Generate two independent vectors, each containing 50 discrete uniform random numbers in the range \(1: 3\) :
```

x1 = unidrnd(3,50,1);
x2 = unidrnd(3,50,1);
[table,chi2,p] = crosstab(x1,x2)
table =
1
5 5 2
11 7 6
chi2 =
7.5449
p =
0.1097

```

At the \(95 \%\) confidence level, the \(p\) value fails to reject the null hypothesis that table is independent in each dimension.

\section*{Example 3}

The file carbig.mat contains measurements of large model cars during the years 1970-1982:
```

load carbig
[table,chi2,p,labels] = crosstab(cyl4,when,org)
table(:,:,1) =
82 75 25
12 22 38
table(:,:,2) =
0 4 3
23 26 17
table(:,:,3) =

```
```

    3 3 4
    12 25 32
    chi2 =
207.7689
p =
0
label =
'Other' 'Early' 'USA'
'Four' 'Mid' 'Europe'
[] 'Late' 'Japan'

```
table and label together show that the number of four-cylinder cars made in the USA during the late period of the data was table \((2,3,1)\) or 38 cars.

\section*{See Also \\ grp2idx | tabulate}

How To
- "Grouping Variables" on page 2-51

\section*{Purpose Loss estimate using cross validation}

\author{
Syntax \\ \section*{Description}
}
vals \(=\) crossval(fun, \(X)\)
vals \(=\) crossval(fun, \(X, Y, \ldots\) )
mse \(=\) crossval('mse', \(X, y\), 'Predfun', predfun)
\(m c r=c r o s s v a l(' m c r ', X, y, ' P r e d f u n ', p r e d f u n)\)
val \(=\) crossval(criterion, X1, X2, ..., y, 'Predfun', predfun)
vals \(=\) crossval(...,'name', value)
vals \(=\) crossval(fun, X ) performs 10 -fold cross validation for the function fun, applied to the data in \(X\).
fun is a function handle to a function with two inputs, the training subset of \(X\), XTRAIN, and the test subset of \(X\), XTEST, as follows:
testval = fun(XTRAIN,XTEST)
Each time it is called, fun should use XTRAIN to fit a model, then return some criterion testval computed on XTEST using that fitted model.
\(X\) can be a column vector or a matrix. Rows of \(X\) correspond to observations; columns correspond to variables or features. Each row of vals contains the result of applying fun to one test set. If testval is a non-scalar value, crossval converts it to a row vector using linear indexing and stored in one row of vals.
vals \(=\) crossval(fun, \(X, Y, \ldots\) ) is used when data are stored in separate variables X, Y, ... . All variables (column vectors, matrices, or arrays) must have the same number of rows. fun is called with the training subsets of \(\mathrm{X}, \mathrm{Y}, \ldots\), followed by the test subsets of \(\mathrm{X}, \mathrm{Y}, \ldots\), as follows:
testvals = fun(XTRAIN, YTRAIN,...,XTEST,YTEST, ...)
mse \(=\) crossval('mse', X,y,'Predfun', predfun) returns mse, a scalar containing a 10 -fold cross validation estimate of mean-squared error for the function predfun. X can be a column vector, matrix, or array of predictors. y is a column vector of response values. X and y must have the same number of rows.
predfun is a function handle called with the training subset of \(X\), the training subset of \(y\), and the test subset of \(X\) as follows:
```

yfit = predfun(XTRAIN,ytrain,XTEST)

```

Each time it is called, predfun should use XTRAIN and ytrain to fit a regression model and then return fitted values in a column vector yfit. Each row of yfit contains the predicted values for the corresponding row of XTEST. crossval computes the squared errors between yfit and the corresponding response test set, and returns the overall mean across all test sets.
mcr = crossval('mcr', X, y,'Predfun', predfun) returns mcr, a scalar containing a 10 -fold cross validation estimate of misclassification rate (the proportion of misclassified samples) for the function predfun. The matrix \(X\) contains predictor values and the vector y contains class labels. predfun should use XTRAIN and YTRAIN to fit a classification model and return yfit as the predicted class labels for XTEST. crossval computes the number of misclassifications between yfit and the corresponding response test set, and returns the overall misclassification rate across all test sets.
val = crossval(criterion, X1, X2, ...,y,'Predfun', predfun), where criterion is 'mse' or 'mcr', returns a cross validation estimate of mean-squared error (for a regression model) or misclassification rate (for a classification model) with predictor values in \(\mathrm{X} 1, \mathrm{X} 2, \ldots\) and, respectively, response values or class labels in y . \(\mathrm{X} 1, \mathrm{X} 2, \ldots\) and y must have the same number of rows. predfun is a function handle called with the training subsets of \(\mathrm{X} 1, \mathrm{X} 2, \ldots\), the training subset of y , and the test subsets of \(\mathrm{X} 1, \mathrm{X} 2, \ldots\), as follows:
yfit=predfun(X1TRAIN, X2TRAIN, ...,ytrain,X1TEST,X2TEST,....)
yfit should be a column vector containing the fitted values.
vals = crossval(..., 'name', value) specifies one or more optional parameter name/value pairs from the following table. Specify name inside single quotes.
\begin{tabular}{l|l}
\hline Name & Value \\
\hline holdout & \begin{tabular}{l} 
A scalar specifying the ratio or the number \\
of observations p for holdout cross validation. \\
When \(0<p<1\), approximately p*n observations \\
for the test set are randomly selected. When \(p\) \\
is an integer, p observations for the test set are \\
randomly selected.
\end{tabular} \\
\hline kfold & \begin{tabular}{l} 
A scalar specifying the number of folds k for \\
k-fold cross validation.
\end{tabular} \\
\hline leaveout & \begin{tabular}{l} 
Specifies leave-one-out cross validation. The \\
value must be 1.
\end{tabular} \\
\hline mcreps & \begin{tabular}{l} 
A positive integer specifying the number of \\
Monte-Carlo repetitions for validation. Ifthe \\
first input of crossval is 'mse ' or 'mcr ' \\
crossval returns the mean of mean-squared \\
error or misclassification rate across all of the \\
Monte-Carlo repetitions. Otherwise, crossval \\
concatenates the values vals from all of \\
the Monte-Carlo repetitions along the first \\
dimension.
\end{tabular} \\
\hline partition & \begin{tabular}{l} 
An object c of the cvpartition class, specifying \\
the cross validation type and partition.
\end{tabular} \\
\hline stratify & \begin{tabular}{l} 
A column vector group specifying groups for \\
stratification. Both training and test sets have \\
roughly the same class proportions as in group. \\
NaNs or empty strings in group are treated as \\
missing values, and the corresponding rows of \\
the data are ignored.
\end{tabular} \\
\hline options & \begin{tabular}{l} 
A structure that specifies whether to run in \\
parallel, and specifies the random stream or \\
streams. Create the options structure with \\
statset. Option fields:
\end{tabular} \\
\hline
\end{tabular}
\begin{tabular}{l|l}
\hline Name & Value \\
& \begin{tabular}{l} 
- UseParallel — Set to true to compute in \\
parallel. Default is false. \\
- UseSubstreams — Set to true to compute in \\
parallel in a reproducible fashion. Default is \\
false. To compute reproducibly, set Streams \\
to a type allowing substreams: 'mlfg6331_64' \\
or 'mrg32k3a'. \\
- Streams - A RandStream object or cell array \\
consisting of one such object. If you do not \\
specify Streams, crossval uses the default \\
stream.
\end{tabular} \\
\hline
\end{tabular}

Only one of kfold, holdout, leaveout, or partition can be specified, and partition cannot be specified with stratify. If both partition and mcreps are specified, the first Monte-Carlo repetition uses the partition information in the cvpartition object, and the repartition method is called to generate new partitions for each of the remaining repetitions. If no cross validation type is specified, the default is 10 -fold cross validation.

Note When using cross validation with classification algorithms, stratification is preferred. Otherwise, some test sets may not include observations from all classes.

\section*{Examples Example 1}

Compute mean-squared error for regression using 10 -fold cross validation:
```

load('fisheriris');
y = meas(:,1);
X = [ones(size(y,1),1),meas(:,2:4)];

```
```

regf=@(XTRAIN, ytrain,XTEST)(XTEST*regress(ytrain,XTRAIN));
cvMse = crossval('mse',X,y,'predfun',regf)
cvMse =
0.1015

```

\section*{Example 2}

Compute misclassification rate using stratified 10 -fold cross validation:
```

load('fisheriris');
y = species;
X = meas;
cp = cvpartition(y,'k',10); % Stratified cross-validation
classf = @(XTRAIN, ytrain,XTEST)(classify(XTEST,XTRAIN,...
ytrain));
cvMCR = crossval('mcr',X,y,'predfun',classf,'partition',cp)
cvMCR =
0.0200

```

\section*{Example 3}

Compute the confusion matrix using stratified 10 -fold cross validation:
```

load('fisheriris');
y = species;
X = meas;
order = unique(y); % Order of the group labels
cp = cvpartition(y,'k',10); % Stratified cross-validation
f = @(xtr,ytr,xte,yte)confusionmat(yte,...
classify(xte,xtr,ytr),'order',order);
cfMat = crossval(f,X,y,'partition',cp);
cfMat = reshape(sum(cfMat),3,3)
cfMat =

```
\begin{tabular}{rrr}
50 & 0 & 0 \\
0 & 48 & 2 \\
0 & 1 & 49
\end{tabular}
cfMat is the summation of 10 confusion matrices from 10 test sets.

\section*{ClassificationDiscriminant.crossval}

\section*{Purpose Cross-validated discriminant analysis classifier}

\author{
Syntax \\ Description
}

Tips

Input
Arguments
cvmodel = crossval(obj)
cvmodel = crossval(obj,Name,Value)
cvmodel = crossval(obj) creates a partitioned model from obj, a fitted discriminant analysis classifier. By default, crossval uses 10 -fold cross validation on the training data to create cvmodel.
cvmodel \(=\) crossval(obj,Name, Value) creates a partitioned model with additional options specified by one or more Name, Value pair arguments.
- Assess the predictive performance of obj on cross-validated data using the "kfold" methods and properties of cvmodel, such as kfoldLoss.
obi
Discriminant analysis classifier, produced using ClassificationDiscriminant.fit.

\section*{Name-Value Pair Arguments}

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN.

\section*{'cvpartition'}

Object of class cvpartition, created by the cvpartition function. crossval splits the data into subsets with cvpartition.
Use only one of these options at a time: 'cvpartition', 'holdout', 'kfold', or 'leaveout'.

Default: []

\section*{ClassificationDiscriminant.crossval}

\section*{'holdout'}

Holdout validation tests the specified fraction of the data, and uses the rest of the data for training. Specify a numeric scalar from 0 to 1 . Use only one of these options at a time: 'cvpartition', 'holdout', 'kfold', or 'leaveout'.

\section*{'kfold'}

Number of folds to use in a cross-validated classifier, a positive integer.

Use only one of these options at a time: 'cvpartition', 'holdout', 'kfold', or 'leaveout'.

Default: 10

\section*{'leaveout'}

Set to 'on' for leave-one-out cross validation.
Use only one of these options at a time: 'cvpartition', 'holdout', 'kfold', or 'leaveout'.

\section*{Examples}

\section*{Alternatives}

Create a classification model for the Fisher iris data, and then create a cross-validation model. Evaluate the quality the model using kfoldLoss.
```

load fisheriris
obj = ClassificationDiscriminant.fit(meas,species);
cvmodel = crossval(obj);
L = kfoldLoss(cvmodel)
L =
0.0200

```

You can create a cross-validation classifier directly from the data, instead of creating a discriminant analysis classifier followed by a cross-validation classifier. To do so, include one of these options in

\section*{ClassificationEnsemble.crossval}

\section*{Purpose \\ Cross validate ensemble}

Syntax \(\quad \begin{aligned} \text { cvens } & =\operatorname{crossval(ens)} \\ \text { cvens } & =\operatorname{crossval}(\text { ens, Name, Value })\end{aligned}\)
Description
cvens = crossval(ens) creates a cross-validated ensemble from ens, a classification ensemble. Default is 10 -fold cross validation.
cvens \(=\) crossval(ens,Name,Value) creates a cross-validated ensemble with additional options specified by one or more Name, Value pair arguments. You can specify several name-value pair arguments in any order as Name1, Value1, , NameN, ValueN.

\section*{Input \\ Arguments}
ens
A classification ensemble created with fitensemble.

\section*{Name-Value Pair Arguments}

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN.

\section*{'cvpartition'}

A partition of class cvpartition. Sets the partition for cross validation.

Use no more than one of the name-value pairs cvpartition, holdout, kfold, or leaveout.

\section*{'holdout'}

Holdout validation tests the specified fraction of the data, and uses the rest of the data for training. Specify a numeric scalar from 0 to 1 . You can only use one of these four options at a time for creating a cross-validated tree: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

\section*{ClassificationEnsemble.crossval}

\section*{'kfold'}

Number of folds for cross validation, a numeric positive scalar.
Use no more than one of the name-value pairs 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

\section*{'leaveout'}

If 'on ', use leave-one-out cross validation.
Use no more than one of the name-value pairs 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

\section*{'nprint'}

Printout frequency, a positive integer scalar. Use this parameter to observe the training of cross-validation folds.

Default: 'off', meaning no printout

\section*{Output Arguments}

Alternatives

Examples
cvens
A cross-validated classification ensemble of class ClassificationPartitionedEnsemble.

You can create a cross-validation ensemble directly from the data, instead of creating an ensemble followed by a cross-validation ensemble. To do so, include one of these five options in fitensemble: 'crossval', 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

Create a cross-validated classification model for the Fisher iris data, and assess its quality using the kfoldLoss method.
```

load fisheriris
ens = fitensemble(meas,species,'AdaBoostM2',100,'Tree');
cvens = crossval(ens);
L = kfoldLoss(cvens)
L =
0.0467

```

Syntax \(\quad\)\begin{tabular}{rl} 
cvmodel & \(=\operatorname{crossval}(m d l)\) \\
cvmodel & \(=\operatorname{crossval}(m d l\), Name, Value \()\)
\end{tabular}

Description cvmodel = crossval(mdl) creates a partitioned model from mdl, a fitted KNN classification model. By default, crossval uses 10 -fold cross validation on the training data to create cvmodel.
cvmodel \(=\) crossval(mdl,Name,Value) creates a partitioned model with additional options specified by one or more Name, Value pair arguments.
- Assess the predictive performance of mdl on cross-validated data using the "kfold" methods and properties of cvmodel, such as kfoldLoss.

\section*{Input \\ Arguments}

\section*{mdl}
\(k\)-nearest neighbor classifier, created by ClassificationKNN.fit.

\section*{Name-Value Pair Arguments}

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ..., NameN, ValueN.

\section*{'cvpartition'}

Object of class cvpartition, created by the cvpartition function. crossval splits the data into subsets with cvpartition.

Use only one of these four options at a time: 'kfold', 'holdout ', 'leaveout', or 'cvpartition'.

\section*{'holdout'}

\section*{ClassificationKNN.crossval}

Holdout validation tests the specified fraction of the data, and uses the remaining data for training. Specify a numeric scalar from 0 to 1 . Use only one of these four options at a time: ' \(k f o l d '\), 'holdout', 'leaveout', or 'cvpartition'.

\section*{'kfold'}

Number of folds to use in a cross-validated tree, a positive integer.
Use only one of these four options at a time: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

Default: 10

\section*{'leaveout'}

Set to 'on' for leave-one-out cross validation.
Use only one of these four options at a time: 'kfold ', 'holdout', 'leaveout', or 'cvpartition'.

\section*{Output Arguments}

\section*{Examples}
cvmodel
Partitioned model of class ClassificationPartitionedModel.

\section*{Cross-Validared K-Nearest Neighbor Model}

Construct a cross-validated \(k\)-nearest neighbor model, and assess classification performance using the model.

Load the data.
load fisheriris
X = meas;
Y = species;
Construct a classifier for nearest neighbors.
mdl \(=\) ClassificationKNN.fit( \(\mathrm{X}, \mathrm{Y}\) );
Construct a cross-validated classifier.

\section*{ClassificationKNN.crossval}
```

cvmdl = crossval(mdl)
cvmdl =
classreg.learning.partition.ClassificationPartitionedModel:
CrossValidatedModel: 'KNN'
PredictorNames: {'x1' 'x2' 'x3' 'x4'}
CategoricalPredictors: []
ResponseName: 'Y'
NObservations: 150
KFold: 10
Partition: [1x1 cvpartition]
ClassNames: {'setosa' 'versicolor' 'virginica'}
ScoreTransform: 'none'

```

Find the cross-validated loss of the classifier.
```

cvmdlloss = kfoldLoss(cvmdl)

```
cvmdlloss =
    0.0400

The cross-validated loss is less than \(5 \%\). You can expect mdl to have a similar error rate.

Purpose Transpose categorical matrix
Syntax

\(B=\) ctranspose(A)
\(\begin{array}{ll}\text { Description } & B=\text { ctranspose (A) returns the transpose of the 2-D categorical matrix } \\ \text { A. Note that ctranspose is identical to transpose for categorical arrays. }\end{array}\)
See Also transpose | permute

\section*{classregtree.cutcategories}

\section*{Purpose Cut categories}
```

Syntax C = cutcategories(t)
C = cutcategories(t,nodes)

```

\section*{Description}
\(\mathrm{C}=\) cutcategories( t ) returns an \(n\)-by- 2 cell array C of the categories used at branches in the decision tree \(t\), where \(n\) is the number of nodes. For each branch node i based on a categorical predictor variable x, the left child is chosen if \(x\) is among the categories listed in C \(\{i, 1\}\), and the right child is chosen if \(x\) is among those listed in \(C\{i, 2\}\). Both columns of C are empty for branch nodes based on continuous predictors and for leaf nodes.
\(C=\) cutcategories(t, nodes) takes a vector nodes of node numbers and returns the categories for the specified nodes.

\section*{Examples Create a classification tree for car data:}
```

load carsmall
t = classregtree([MPG Cylinders],Origin,...
'names',{'MPG' 'Cyl'},'cat',2)
t =
Decision tree for classification

See Also classregtree | cutpoint | cuttype | cutvar

\section*{Purpose}

Decision tree cut point values

\section*{Syntax}
v = cutpoint(t)
v = cutpoint(t,nodes)

Description
\(\mathrm{v}=\) cutpoint( t ) returns an \(n\)-element vector v of the values used as cut points in the decision tree t , where \(n\) is the number of nodes. For each branch node i based on a continuous predictor variable \(x\), the left child is chosen if \(x<v(i)\) and the right child is chosen if \(x>=\) \(v\) (i). \(v\) is NaN for branch nodes based on categorical predictors and for leaf nodes.
\(v=\) cutpoint( \(t\), nodes) takes a vector nodes of node numbers and returns the cut points for the specified nodes.

\section*{Examples Create a classification tree for car data:}
```

load carsmall
t = classregtree([MPG Cylinders],Origin,...
'names',{'MPG' 'Cyl'},'cat',2)
t =
Decision tree for classification

}

\section*{classregtree.cuttype}

\section*{Purpose \\ Cut types}
Syntax
c = cuttype(t)
c = cuttype(t,nodes)

\section*{Description}
\(c=\) cuttype( t ) returns an \(n\)-element cell array c indicating the type of cut at each node in the tree \(t\), where \(n\) is the number of nodes. For each node i, c\{i\} is:
- 'continuous ' - If the cut is defined in the form \(\mathrm{x}<\mathrm{v}\) for a variable \(x\) and cut point \(v\).
- 'categorical' - If the cut is defined by whether a variable \(x\) takes a value in a set of categories.
- ' ' - If \(i\) is a leaf node.
cutvar returns the cut points for 'continuous' cuts, and cutcategories returns the set of categories.
c = cuttype(t, nodes) takes a vector nodes of node numbers and returns the cut types for the specified nodes.

\section*{Examples \\ Create a classification tree for car data:}
```

load carsmall
t = classregtree([MPG Cylinders],Origin,...
'names',{'MPG' 'Cyl'},'cat',2)

\(\mathrm{v}=\) cutvar( t\()\)
v = cutvar(t,nodes)
[v, num] = cutvar(...)
Cut variable names
\(\mathrm{v}=\) cutvar \((\mathrm{t})\) returns an \(n\)-element cell array v of the names of the variables used for branching in each node of the tree \(t\), where \(n\) is the number of nodes. These variables are sometimes known as cut variables. For leaf nodes, v contains an empty string.
\(\mathrm{v}=\) cutvar(t, nodes) takes a vector nodes of node numbers and returns the cut variables for the specified nodes.
[ v , num] \(=\) cutvar(...) also returns a vector num containing the number of each variable.

Create a classification tree for car data:
```

load carsmall
t = classregtree([MPG Cylinders],Origin,...
'names',{'MPG' 'Cyl'},'cat',2)
t =
Decision tree for classification
if Cyl=4 then node 2 elseif Cyl in {6 8} then node 3 else USA
if MPG<31.5 then node 4 elseif MPG>=31.5 then node 5 else USA
if Cyl=6 then node 6 elseif Cyl=8 then node 7 else USA
if MPG<21.5 then node 8 elseif MPG>=21.5 then node 9 else USA
if MPG<41 then node 10 elseif MPG>=41 then node 11 else Japan
if MPG<17 then node 12 elseif MPG>=17 then node 13 else USA
class = USA
class = France
class = USA
class = Japan
class = Germany
class = Germany
class = USA

```

\section*{classregtree.cutvar}

\section*{ClassificationTree.cvLoss}

Purpose Classification error by cross validation
Syntax \(\quad E=\) cvLoss(tree)
[E,SE] = cvLoss(tree)
[E,SE,Nleaf] = cvLoss(tree)
[E,SE,Nleaf,BestLevel] = cvLoss(tree)
[ \(\mathrm{E}, \ldots\)...] = cvLoss(tree, Name, Value)

Description

Input
Arguments
\(\mathrm{E}=\mathrm{cvLoss}(\) tree \()\) returns the cross-validated classification error (loss) for tree, a classification tree.
[ \(E, S E]=\) cvLoss(tree) returns the standard error of \(E\).
[ \(\mathrm{E}, \mathrm{SE}, \mathrm{Nleaf}]=\) cvLoss(tree) returns the number of leaves of tree.
[E,SE,Nleaf,BestLevel] = cvLoss(tree) returns the optimal pruning level for tree.
\([E, \ldots]=\) cvLoss(tree, Name, Value) cross validates with additional options specified by one or more Name, Value pair arguments. You can specify several name-value pair arguments in any order as Name1, Value1, , NameN, ValueN.

\section*{tree}

A classification tree produced by ClassificationTree.fit.

\section*{Name-Value Pair Arguments}

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ..., NameN, ValueN.

\section*{'subtrees'}

Vector of pruning levels, with 0 representing the full, unpruned tree. tree must include a pruning sequence as created either by ClassificationTree.fit with 'prune' set to 'on', or by the

\section*{ClassificationTree.cvLoss}
prune method. The returned E, SE, and Nleaf are vectors of the same length as subtrees; BestLevel is a scalar. If you set subtrees to 'all', cvLoss uses the entire pruning sequence.

Default: 0

\section*{'treesize'}

One of the following strings:
- 'se' - cvLoss uses the smallest tree whose cost is within one standard error of the minimum cost.
- 'min' - cvLoss uses the minimal cost tree.

Default: 'se'

\section*{'kfold'}

Number of cross-validation samples, a positive integer.
Default: 10

Output E
Arguments

The cross-validation classification error (loss). A vector or scalar depending on the setting of the subtrees name-value pair.

SE
The standard error of \(E\). A vector or scalar depending on the setting of the subtrees name-value pair.

\section*{Nleaf}

Number of leaf nodes in tree. Leaf nodes are terminal nodes, which give classifications, not splits. A vector or scalar depending on the setting of the subtrees name-value pair.

\section*{BestLevel}

\section*{ClassificationTree.cvLoss}

By default, a scalar representing the largest pruning level that achieves a value of \(E\) within \(S E\) of the minimum error. If you set treesize to 'min', BestLevel is the smallest value in subtrees.

Examples Compute the cross-validation error for the default classification tree for the ionosphere data:
```

load ionosphere
tree = ClassificationTree.fit(X,Y);
[E,SE,Nleaf,BestLevel] = cvLoss(tree)
E =
0.1282
SE =
0.0178
Nleaf =
1 9
BestLevel =
0

```

Find the best level by using the subtrees name-value pair:
[~,~,~,BestLevel] = cvLoss(tree,'subtrees','all')
BestLevel =
6

\footnotetext{
Alternatives You can construct a cross-validated tree model with crossval, and call kfoldLoss instead of cvLoss. The alternative can save time if you are going to examine the cross-validated tree more than once.

However, unlike cvLoss, kfoldLoss does not return SE,Nleaf, or BestLevel. kfoldLoss also does not allow you to examine any error other than classification error.
}

\section*{RegressionTree.cvLoss}

\section*{Purpose Regression error by cross validation}
```

Syntax $\quad E=$ cuLoss(tree)
[E,SE] = cvLoss(tree)
[E,SE,Nleaf] = cvLoss(tree)
[E,SE,Nleaf,BestLevel] = cvLoss(tree)
[E,...] = cvLoss(tree,Name,Value)

```

\section*{Description}

Input Arguments

E = cvLoss(tree) returns the cross-validated regression error (loss) for tree, a regression tree.
[ \(\mathrm{E}, \mathrm{SE}]=\) cvLoss(tree) returns the standard error of E .
[ \(\mathrm{E}, \mathrm{SE}, \mathrm{Nleaf}]=\) cvLoss(tree) returns the number of leaves (terminal nodes) in tree.
[E,SE,Nleaf,BestLevel] = cvLoss(tree) returns the optimal pruning level for tree.
[ \(\mathrm{E}, \ldots\)...] = cvLoss(tree, Name, Value) cross validates with additional options specified by one or more Name, Value pair arguments. You can specify several name-value pair arguments in any order as Name1, Value1, ,NameN, ValueN.

\section*{tree}

A regression tree produced by RegressionTree.fit.

\section*{Name-Value Pair Arguments}

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN.

\section*{'subtrees'}

Vector of pruning levels, with 0 representing the full, unpruned tree. tree must include a pruning sequence as created either by

\section*{RegressionTree.cvLoss}

ClassificationTree.fit with 'prune' set to 'on', or by the prune method. The returned E, SE, and Nleaf are vectors of the same length as subtrees; BestLevel is a scalar. If you set subtrees to 'all', cvLoss uses the entire pruning sequence.

Default: 0

\section*{'treesize'}

One of the following strings:
- 'se' - cvLoss uses the smallest tree whose cost is within one standard error of the minimum cost.
- 'min' - cvLoss uses the minimal cost tree.

Default: 'se'

\section*{'kfold'}

Number of cross-validation samples, a positive integer.
Default: 10

\section*{Output E}

Arguments
The cross-validation mean squared error (loss). A vector or scalar depending on the setting of the subtrees name-value pair.

SE
The standard error of E . A vector or scalar depending on the setting of the subtrees name-value pair.

\section*{Nleaf}

Number of leaf nodes in tree. Leaf nodes are terminal nodes, which give responses, not splits. A vector or scalar depending on the setting of the subtrees name-value pair.

\section*{BestLevel}

\section*{RegressionTree.cvLoss}

By default, a scalar representing the largest pruning level that achieves a value of \(E\) within \(S E\) of the minimum error. If you set treesize to 'min', BestLevel is the smallest value in subtrees.

Examples Compute the cross-validation error for the default classification tree for the carsmall data:
```

load carsmall
X = [Displacement Horsepower Weight];
tree = RegressionTree.fit(X,MPG);
[E,SE,Nleaf,BestLevel] = cvLoss(tree)
E =
30.7558
SE =
6.0651
Nleaf =
1 9
BestLevel =
O

```

Find the best level by using the subtrees name-value pair:
[~,~,~,BestLevel] = cvLoss(tree,'subtrees','all')
BestLevel =
15

Alternatives You can construct a cross-validated tree model with crossval, and call kfoldLoss instead of cvLoss. The alternative can save time if you are going to examine the cross-validated tree more than once.

However, unlike cvLoss, kfoldLoss does not return SE,Nleaf, or BestLevel.

\section*{RegressionTree.cvLoss}

See Also crossval | kfoldLoss | RegressionTree.fit | loss

\section*{Purpose Data partitions for cross validation}

Description
An object of the cupartition class defines a random partition on a set of data of a specified size. Use this partition to define test and training sets for validating a statistical model using cross validation.

\section*{Construction}

Create cross validation partition
for data

Display cvpartition object
Display cvpartition object
Repartition data for cross-validation

Test indices for cross-validation
Training indices for cross-validation

Number of observations (including observations with missing group values)
Number of test sets
Size of each test set
Size of each training set
Type of partition

Value. To learn how this affects your use of the class, see Comparing Handle and Value Classes in the MATLAB Object-Oriented Programming documentation.
```

Examples Use a 10-fold stratified cross validation to compute the misclassification error for classify on iris data.
load('fisheriris');
CVO = cvpartition(species,'k',10);
err = zeros(CVO.NumTestSets,1);
for i = 1:CVO.NumTestSets
trIdx = CVO.training(i);
teIdx = CVO.test(i);
ytest = classify(meas(teIdx,:),meas(trIdx,:),...
species(trIdx,:));
err(i) = sum(~strcmp(ytest,species(teIdx)));
end
cvErr = sum(err)/sum(CVO.TestSize);
See Also crossval
How To

- "Grouping Variables" on page 2-51

```

Purpose Create cross validation partition for data
\begin{tabular}{|c|c|}
\hline Syntax & \begin{tabular}{l}
\(c=\) cvpartition( n, 'kfold', k ) \\
c = cvpartition(group, 'kfold',k) \\
\(\mathrm{c}=\) cvpartition( n, 'holdout', p ) \\
\(c=\) cvpartition(group, 'holdout ', \(p\) ) \\
c = cvpartition( n, 'leaveout') \\
c = cvpartition(n,'resubstitution')
\end{tabular} \\
\hline
\end{tabular}

\section*{Description}
\(c=\) cvpartition( \(\mathrm{n},{ }^{\prime} \mathrm{kfold}{ }^{\prime}, \mathrm{k}\) ) constructs an object c of the cvpartition class defining a random partition for \(k\)-fold cross validation on \(n\) observations. The partition divides the observations into k disjoint subsamples (or folds), chosen randomly but with roughly equal size. The default value of \(k\) is 10 .
c = cvpartition(group, 'kfold', k) creates a random partition for a stratified \(k\)-fold cross validation. group is a numeric vector, categorical array, string array, or cell array of strings indicating the class of each observation. Each subsample has roughly equal size and roughly the same class proportions as in group. cupartition treats NaNs or empty strings in group as missing values.
\(c=\) cvpartition( \(n\), 'holdout', \(p\) ) creates a random partition for holdout validation on \(n\) observations. This partition divides the observations into a training set and a test (or holdout) set. The parameter \(p\) must be a scalar. When \(0<p<1\), cvpartition randomly selects approximately \(p * n\) observations for the test set. When \(p\) is an integer, cvpartition randomly selects p observations for the test set. The default value of \(p\) is \(1 / 10\).
c = cvpartition(group, 'holdout', p ) randomly partitions observations into a training set and a test set with stratification, using the class information in group; that is, both training and test sets have roughly the same class proportions as in group.
c = cvpartition( \(n\), 'leaveout') creates a random partition for leave-one-out cross validation on \(n\) observations. Leave-one-out is a special case of ' \(k f o l d\) ', in which the number of folds equals the number of observations.
\(c=\) cvpartition(n, 'resubstitution') creates an object \(c\) that does not partition the data. Both the training set and the test set contain all of the original \(n\) observations.

\section*{Examples}

Use stratified 10 -fold cross validation to compute misclassification rate:
load fisheriris;
y = species;
c = cvpartition(y, 'k', 10);
fun \(=@(x T, y T, x t, y t)(\operatorname{sum}(\sim \operatorname{strcmp}(y t, c l a s s i f y(x t, x T, y T)))) ;\)
rate \(=\) sum(crossval(fun,meas,y,'partition', c))...
/sum(c.TestSize)
rate = 0.0200

\section*{ClassificationDiscriminant.cvshrink}

\section*{ClassificationDiscriminant.cvshrink}

\section*{Name-Value Pair Arguments}

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ..., NameN, ValueN.

\section*{'delta'}
- Scalar delta - cvshrink uses this value of delta with every value of gamma for regularization.
- Row vector delta - For each i and j, cvshrink uses delta(j) with gamma(i) for regularization.
- Matrix delta - The number of rows of delta must equal the number of elements in gamma. For each i and j, cvshrink uses delta(i,j) with gamma(i) for regularization.

Default: 0

\section*{'gamma'}

Vector of Gamma values for cross-validation.
Default: 0:0.1:1

\section*{'NumDelta'}

Number of Delta intervals for cross-validation. For every value of Gamma, cvshrink cross-validates the discriminant using NumDelta +1 values of Delta, uniformly spaced from zero to the maximal Delta at which all predictors are eliminated for this value of Gamma. If you set delta, cvshrink ignores NumDelta.

Default: 0
'NumGamma'

\section*{ClassificationDiscriminant.cvshrink}

Number of Gamma intervals for cross-validation. cvshrink cross-validates the discriminant using NumGamma +1 values of Gamma, uniformly spaced from MinGamma to 1. If you set gamma, cvshrink ignores NumGamma.

Default: 10

\section*{'verbose'}

Verbosity level, an integer from 0 to 2. Higher values give more progress messages.

Default: 0

\section*{Output} Arguments

Numeric vector or matrix of errors. err is the misclassification error rate, meaning the average fraction of misclassified data over all folds.
- If delta is a scalar (default), err(i) is the misclassification error rate for obj regularized with gamma(i).
- If delta is a vector, \(\operatorname{err}(i, j)\) is the misclassification error rate for obj regularized with gamma(i) and delta(j).
- If delta is a matrix, err( \(i, j\) ) is the misclassification error rate for obj regularized with gamma(i) and delta(i,j).

\section*{gamma}

Vector of Gamma values used for regularization. See "Gamma and Delta" on page 20-513.

\section*{delta}

Vector or matrix of Delta values used for regularization. See "Gamma and Delta" on page 20-513.

\section*{ClassificationDiscriminant.cvshrink}
- If you give a scalar for the delta name-value pair, the output delta is a row vector the same size as gamma, with entries equal to the input scalar.
- If you give a row vector for the delta name-value pair, the output delta is a matrix with the same number of columns as the row vector, and with the number of rows equal to the number of elements of gamma. The output delta(i,j) is equal to the input delta(j).
- If you give a matrix for the delta name-value pair, the output delta is the same as the input matrix. The number of rows of delta must equal the number of elements in gamma.

\section*{numpred}

Numeric vector or matrix containing the number of predictors in the model at various regularizations. numpred has the same size as err.
- If delta is a scalar (default), numpred(i) is the number of predictors for obj regularized with gamma(i) and delta.
- If delta is a vector, numpred \((i, j)\) is the number of predictors for obj regularized with gamma(i) and delta(j).
- If delta is a matrix, numpred \((i, j)\) is the number of predictors for obj regularized with gamma(i) and delta(i,j).

\section*{Definitions Gamma and Delta}

Regularization is the process of finding a small set of predictors that yield an effective predictive model. For linear discriminant analysis, there are two parameters, \(\gamma\) and \(\delta\), that control regularization as follows. cvshrink helps you select appropriate values of the parameters.

Let \(\Sigma\) represent the covariance matrix of the data \(X\), and let \(\hat{X}\) be the centered data (the data \(X\) minus the mean by class). Define

\section*{ClassificationDiscriminant.cvshrink}
\[
D=\operatorname{diag}\left(\hat{X}^{T} * \hat{X}\right) .
\]

The regularized covariance matrix \(\tilde{\Sigma}\) is
\[
\tilde{\Sigma}=(1-\gamma) \Sigma+\gamma D .
\]

Whenever \(y \geq\) MinGamma, \(\tilde{\Sigma}\) is nonsingular.
Let \(\mu_{k}\) be the mean vector for those elements of \(X\) in class \(k\), and let \(\mu_{0}\) be the global mean vector (the mean of the rows of \(X\) ). Let \(C\) be the correlation matrix of the data \(X\), and let \(\tilde{C}\) be the regularized correlation matrix:
\[
\tilde{C}=(1-\gamma) C+\gamma I,
\]
where \(I\) is the identity matrix.
The linear term in the regularized discriminant analysis classifier for a data point \(x\) is
\[
\left(x-\mu_{0}\right)^{T} \tilde{\Sigma}^{-1}\left(\mu_{k}-\mu_{0}\right)=\left[\left(x-\mu_{0}\right)^{T} D^{-1 / 2}\right]\left[\tilde{C}^{-1} D^{-1 / 2}\left(\mu_{k}-\mu_{0}\right)\right] .
\]

The parameter \(\delta\) enters into this equation as a threshold on the final term in square brackets. Each component of the vector \(\left[\tilde{C}^{-1} D^{-1 / 2}\left(\mu_{k}-\mu_{0}\right)\right]\) is set to zero if it is smaller in magnitude than the threshold \(\delta\). Therefore, for class \(k\), if component \(j\) is thresholded to zero, component \(j\) of \(x\) does not enter into the evaluation of the posterior probability.
The DeltaPredictor property is a vector related to this threshold. When \(\delta \geq\) DeltaPredictor(i), all classes \(k\) have
\[
\left|\tilde{C}^{-1} D^{-1 / 2}\left(\mu_{k}-\mu_{0}\right)\right| \leq \delta .
\]

Therefore, when \(\delta \geq\) DeltaPredictor(i), the regularized classifier does not use predictor \(i\).

\section*{ClassificationDiscriminant.cvshrink}

\section*{Examples Regularize Data with Many Predictors}

This example shows how to regularize a discriminant analysis classifier, and how to view the tradeoff between the number of predictors in the model and the classification accuracy.

Create a linear discriminant analysis classifier for the ovariancancer data. Set the SaveMemory and FillCoeffs options to keep the resulting model reasonably small.
```

load ovariancancer
obj = ClassificationDiscriminant.fit(obs,grp,...
'SaveMemory','on','FillCoeffs','off');

```

Use 10 levels of Gamma and 10 levels of Delta to search for good parameters. This search is time-consuming. Set Verbose to 1 to view the progress.
```

rng('default') % for reproducibility
[err,gamma,delta,numpred] = cvshrink(obj,...
'NumGamma',9,'NumDelta',9,'Verbose',1);

```
Done building cross-validated model.
Processing Gamma step 1 out of 10.
Processing Gamma step 2 out of 10 .
Processing Gamma step 3 out of 10 .
Processing Gamma step 4 out of 10.
Processing Gamma step 5 out of 10 .
Processing Gamma step 6 out of 10 .
Processing Gamma step 7 out of 10 .
Processing Gamma step 8 out of 10.
Processing Gamma step 9 out of 10.
Processing Gamma step 10 out of 10.

Plot the classification error rate against the number of predictors.
```

plot(err,numpred,'k.')
xlabel('Error rate');
ylabel('Number of predictors');

```

\section*{RegressionEnsemble.cvshrink}

\section*{Purpose}

Syntax

\section*{Description}

\section*{Input Arguments}

Cross validate shrinking (pruning) ensemble
vals = cvshrink(ens)
[vals,nlearn] = cvshrink(ens)
[vals,nlearn] = cvshrink(ens,Name,Value)
vals = cvshrink(ens) returns an L-by-T matrix with cross-validated values of the mean squared error. \(L\) is the number of lambda values in the ens.Regularization structure. \(T\) is the number of threshold values on weak learner weights. If ens does not have a Regularization property filled in by the regularize method, pass a lambda name-value pair.
[vals, nlearn] = cvshrink(ens) returns an L-by-T matrix of the mean number of learners in the cross-validated ensemble.
[vals, nlearn] = cvshrink(ens,Name, Value) cross validates with additional options specified by one or more Name, Value pair arguments. You can specify several name-value pair arguments in any order as Name1, Value1, ,NameN, ValueN.

\section*{ens}

A regression ensemble, created with fitensemble.

\section*{Name-Value Pair Arguments}

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ..., NameN, ValueN.

\section*{'cvpartition'}

A partition created with cvpartition to use in a cross-validated tree. You can only use one of these four options at a time: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

\section*{'holdout'}

\section*{RegressionEnsemble.cvshrink}

Holdout validation tests the specified fraction of the data, and uses the rest of the data for training. Specify a numeric scalar from 0 to 1. You can only use one of these four options at a time for creating a cross-validated tree: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

\section*{'kfold'}

Number of folds to use in a cross-validated tree, a positive integer. If you do not supply a cross-validation method, cvshrink uses 10 -fold cross validation. You can only use one of these four options at a time: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

Default: 10

\section*{'lambda'}

Vector of nonnegative regularization parameter values for lasso. If empty, cvshrink does not perform cross validation.

Default: []

\section*{'leaveout'}

Use leave-one-out cross validation by setting to 'on'. You can only use one of these four options at a time: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

\section*{'threshold'}

Numeric vector with lower cutoffs on weights for weak learners. cvshrink discards learners with weights below threshold in its cross-validation calculation.

Default: 0

\section*{Output vals \\ Arguments \\ L-by-T matrix with cross-validated values of the mean squared error. \(L\) is the number of values of the regularization parameter}

\section*{RegressionEnsemble.cvshrink}
'lambda', and T is the number of 'threshold' values on weak learner weights.

\section*{nlearn}

L-by-T matrix with cross-validated values of the mean number of learners in the cross-validated ensemble. L is the number of values of the regularization parameter ' lambda', and \(T\) is the number of 'threshold' values on weak learner weights.

\section*{Examples}

Create a regression ensemble for predicting mileage from the carsmall data. Cross validate the ensemble for three values each of lambda and threshold.
```

load carsmall
X = [Displacement Horsepower Weight];
ens = fitensemble(X,MPG,'bag',100,'Tree',...
'type','regression');
[vals nlearn] = cvshrink(ens,'lambda',[.01 .1 1],...
'threshold',[0 .01 .1])
vals =
20.0949 19.9007 131.6316
20.0924 19.8431 128.0989
19.9759 19.7987 119.5574
nlearn =
13.3000 11.6000 3.5000
13.2000 11.5000 3.6000
13.4000 11.4000 3.9000

```

Clearly, setting a threshold of 0.1 leads to unacceptable errors, while a threshold of 0.01 gives similar errors to a threshold of 0 . The mean number of learners with a threshold of 0.1 is about 11.5 , whereas the mean number is about 13.2 when the threshold is 0 .

regularize | shrink
```}

Purpose
Syntax

\section*{Description}

Tips

Input
Arguments
```

```
y = datasample(data,k)
```

```
y = datasample(data,k)
\(y=\) datasample(data,k,dim)
\(y=\) datasample(data,k,dim)
[y,idx] = datasample(data,k,...)
[y,idx] = datasample(data,k,...)
[y,...] = datasample(s,data,k,...)
[y,...] = datasample(s,data,k,...)
[y,...] = datasample(data,k,Name, Value)
[y,...] = datasample(data,k,Name, Value)
[y,...] = datasample(data, \(k\), dim,Name, Value)
```

```
[y,...] = datasample(data, \(k\), dim,Name, Value)
```

```

Randomly sample from data, with or without replacement
\(\mathrm{y}=\) datasample(data, k\()\) returns k observations sampled uniformly at random, with replacement, from the data in data.
\(\mathrm{y}=\) datasample(data, \(\mathrm{k}, \mathrm{dim})\) returns a sample taken along dimension dim of data.
[y,idx] = datasample(data, \(k, \ldots\) ) returns an index vector indicating which values datasample sampled from data.
\([y, \ldots]=\) datasample(s,data,k,...) uses the random number stream \(s\) to generate random numbers.
[y,...] = datasample(data,k,Name,Value) or [y,...] = datasample(data, k, dim, Name, Value) samples with additional options specified by one or more Name, Value pair arguments.
- To sample random integers with replacement from a range, use randi.
- To sample random integers without replacement, use randperm or datasample.
- To randomly sample from data, with or without replacement, use datasample.

\section*{data}

Vector, matrix, \(N\)-dimensional array, or dataset array representing the data from which to sample. By default, datasample regards the rows of a data matrix, or the first nonsingleton dimension of a data array, as data elements. Change this behavior with the dim argument.

\section*{k}

Positive integer, the number of samples.

\section*{\(\operatorname{dim}\)}

Integer specifying the dimension on which to take samples. For example, if data is a matrix and dim is 2 , \(y\) contains a selection of columns in data. If data is a dataset array and dim is 2 , \(y\) contains a selection of variables in data. Use dim to ensure sampling along a specific dimension regardless of whether data is a vector, matrix or \(N\)-dimensional array.

Default: 1

\section*{s}

Random number stream. Create s using rng or RandStream.
Default: The global random number stream

\section*{Name-Value Pair Arguments}

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ..., NameN, ValueN.

\section*{'Replace'}

Select the sample with replacement if Replace is true, or without replacement if Replace is false. If Replace is false, \(k\) must not be larger than the number of data elements in data.

Default: true

\section*{'Weights'}

Vector with the same number of elements as data elements in data, and with nonnegative elements. Sample with probability proportional to the elements of Weights.

Default: ones(datasize, 1), where datasize is the number of data elements in data

\section*{Output Arguments}

\section*{\(y\)}
- If data is a vector, y is a vector containing k elements selected from data.
- If data is a matrix, y is a matrix containing k rows selected from data. Or, if dim \(=2\), \(y\) is a matrix containing \(k\) columns selected from data
- If data is an \(N\)-dimensional array, datasample samples along its first non-singleton dimension. Or, if you give a dim name-value pair, datasample samples along the dimension dim.

When the sample is taken with replacement (default), y can contain repeated observations from data. Set the Replace name-value pair to false to sample without replacement.

\section*{idx}

Vector of indices indicating which elements datasample chose from data to create y. For example:
- If data is a vector, \(y=d a t a(i d x)\).
- If data is a matrix, \(\mathrm{y}=\operatorname{data}(\mathrm{idx},:)\).

Examples Draw five unique values from the integers 1:10.
```

y = datasample(1:10,5,'Replace',false)
y =
6

```

Generate a random sequence of the characters ACGT, with replacement, according to specified probabilities.
```

seq = datasample('ACGT',48,'Weights',[0.15 0.35 0.35 0.15])
seq =
CTTCGACTGTGAGTGGGCGCGACAAGGCTACCGGCCCGGGCGGCACTC

```

Select a random subset of columns from a data matrix.
```

X = randn(10,1000);
Y = datasample(X,5,2,'Replace',false)
Y =

| 0.7007 | 0.3382 | 2.1298 | -0.1891 | 0.5026 |
| ---: | ---: | ---: | ---: | ---: |
| 0.6520 | -0.6693 | -0.1961 | -0.9915 | 1.9107 |
| 0.1785 | 0.6640 | 2.3247 | -1.1735 | -1.0020 |
| 1.6760 | 2.6102 | -0.8902 | -0.7735 | 1.8676 |
| -0.3251 | -0.6415 | -0.2572 | -0.1629 | -1.0523 |
| 0.1011 | 0.9323 | -1.3088 | -0.4477 | 0.8036 |
| -0.5767 | -0.5778 | -0.8556 | 0.8672 | -0.0727 |
| -0.0615 | -0.9084 | 0.9020 | -0.4185 | -1.9520 |
| 0.7256 | -1.1228 | 0.7558 | 1.2691 | 2.4997 |
| -1.2273 | 0.5754 | -0.8755 | -0.8224 | -1.2066 |

```

Resample observations from a dataset array to create a bootstrap replicate dataset.
load hospital
y = datasample(hospital,size(hospital,1));

Use the second output to sample "in parallel" from two data vectors. \(x 1=\operatorname{randn}(100,1) ;\)

\section*{datasample}
```

x2 = randn(100,1);
[y1,idx] = datasample(x1,10);
y2 = x2(idx);

```

\section*{Purpose Arrays for statistical data}

\section*{Construction}

Use the dataset constructor to create a dataset array from variables in the MATLAB workspace. You can also create a dataset array by reading data from a text or spreadsheet file. You can access each variable in a dataset array much like fields in a structure, using dot subscripting. See the following section for a list of operations available for dataset arrays.
\[
\text { dataset } \quad \text { Construct dataset array }

How To - "Dataset Arrays" on page 2-135

Purpose Construct dataset array
Syntax \(\quad \begin{aligned} \text { A } & =\operatorname{dataset}(\text { varspec, 'ParamName', Value) } \\ \text { A } & =\operatorname{dataset}(' F i l e ', f i l e n a m e, ' P a r a m N a m e ', ~ V a l u e) ~ \\ A & =\operatorname{dataset}(' X L S F i l e ', f i l e n a m e, ' P a r a m N a m e ', ~ V a l u e) ~ \\ A & =\operatorname{dataset}(' X P T F i l e ', x p t f i l e n a m e, ' P a r a m N a m e ', ~ V a l u e) ~\end{aligned}\)

\section*{Description}

A = dataset(varspec,'ParamName', Value) creates dataset array A using the workspace variable input method varspec and one or more optional name/value pairs (see Parameter Name/Value Pairs).

The input method varspec can be one or more of the following:
- VAR - a workspace variable. dataset uses the workspace name for the variable name in \(A\). To include multiple variables, specify VAR_1,VAR_2,...,VAR_N. Variables can be arrays of any size, but all variables must have the same number of rows. VAR can also be an expression. In this case, dataset creates a default name automatically.
- \{VAR,name\} - a workspace variable, VAR and a variable name, name . dataset uses name as the variable name. To include multiple variables and names, specify \(\left\{V A R \_1\right.\), name_1\}, \{VAR_2,name_2\},..., \{VAR_N,name_N\}.
- \{VAR,name_1,...,name_m - an \(m\)-columned workspace variable, VAR. dataset uses the names name_1, ..., name_m as variable names. You must include a name for every column in VAR. Each column becomes a separate variable in A.

You can combine these input methods to include as many variables and names as needed. Names must be valid, unique MATLAB identifier strings. For example input combinations, see Examples. For optional name/value pairs see Inputs.
To convert numeric arrays, cell arrays, or structure arrays to dataset arrays, you can also use (respectively):
- mat2dataset
- cell2dataset
- struct2dataset

Note Dataset arrays may contain built-in types or array objects as variables. Array objects must implement each of the following:
- Standard MATLAB parenthesis indexing of the form var(i,....), where \(i\) is a numeric or logical vector corresponding to rows of the variable
- A size method with a dim argument
- A vertcat method

A = dataset('File',filename,'ParamName', Value) creates dataset array A from column-oriented data in the text file specified by the string filename. Variables in A are of type double if data in the corresponding column of the file, following the column header, are entirely numeric; otherwise the variables in A are cell arrays of strings. dataset converts empty fields to either NaN (for a numeric variable) or the empty string (for a string-valued variable). dataset ignores insignificant white space in the file. You cannot specify both a file and workspace variables as input. See Name/Value Pairs for more information.

A = dataset('XLSFile',filename,'ParamName', Value) creates dataset array A from column-oriented data in the Excel spreadsheet specified by the string filename. Variables in A are of type double if data in the corresponding column of the spreadsheet, following the column header, are entirely numeric; otherwise the variables in A are cell arrays of strings. See Name/Value Pairs for more information.

A = dataset('XPTFile',xptfilename,'ParamName', Value) creates a dataset array from a SAS \({ }^{\circledR}\) XPORT format file. Variable names from the XPORT format file are preserved. Numeric data types in the XPORT format file are preserved but all other data types are converted to cell
arrays of strings. The XPORT format allows for 28 missing data types. dataset represents these in the file by an upper case letter, '. ' or '_ '. dataset converts all missing data to NaN values in A. However, if you need the specific missing types you can use the xptread function to recover the information. See Name/Value Pairs for more information.

\section*{Parameter Specify one or more of the following name/value pairs when constructing Name/Value Pairs \\ a dataset:}

\section*{VarNames}

A cell array \{name_1, ... , name_m \} naming the \(m\) variables in \(A\) with the specified variable names. Names must be valid, unique MATLAB identifier strings. The number of names must equal the number of variables in A. You cannot use the VarNames parameter if you provide names for individual variables using \{VAR, name\} pairs. To specify VarNames when using a file as input, set ReadVarNames to false.

\section*{ObsNames}

A cell array \(\{\) name_1,.. , name_n\} naming the \(n\) observations in A with the specified observation names. The names need not be valid MATLAB identifier strings, but must be unique. The number of names must equal the number of observations (rows) in A. To specify ObsNames when using a file as input, set ReadObsNames to false.

\section*{Name/value pairs available when using text files as inputs:}

\section*{Delimiter}

A string indicating the character separating columns in the file.
Values are
- ' \(\backslash t\) ' (tab, the default when no format is specified)
- ' ' (space, the default when a format is specified)
- ', ' (comma)
- ';' (semicolon)
- ' \(\mid\) ' (bar)

\section*{Format}

A format string, as accepted by textscan. dataset reads the file using textscan, and creates variables in A according to the conversion specifiers in the format string. You may also provide any name/value pairs accepted by textscan. Using the Format parameter is much faster for large files. If ReadObsNames is true, the format string should include a format specifier for the first column of the file.

\section*{HeaderLines}

Numeric value indicating the number of lines to skip at the beginning of a file.

Default: 0

\section*{TreatAsEmpty}

Specifies strings to treat as the empty string in a numeric column. Values may be a character string or a cell array of strings. The parameter applies only to numeric columns in the file; dataset does not accept numeric literals such as '-99'.

\section*{Name/value pairs available when using text files or Excel spreadsheets as inputs:}

\section*{ReadVarNames}

A logical value indicating whether (true) or not (false) to read variable names from the first row of the file. The default is true. If ReadVarNames is true, variable names in the column headers of the file or range (if using an Excel spreadsheet) cannot be empty.

\section*{ReadObsNames}

A logical value indicating whether (true) or not (false) to read observation names from the first column of the file or range (if using an Excel spreadsheet). The default is false. If ReadObsNames and ReadVarNames are both true, dataset saves the header of the first column in the file or range as the name of the first dimension in A. Properties.DimNames.

When reading from an XPT format file, the ReadObsNames parameter name/value pair determines whether or not to try to use the first variable in the file as observation names. Specify as a logical value (default false). If the contents of the first variable are not valid observation names then dataset reads the variable into a variable of the dataset array and does not set the observation names.

\section*{Name/value pairs available when using Excel spreadsheets as input:}

\section*{Sheet}

A positive scalar value of type double indicating the sheet number, or a quoted string indicating the sheet name.

\section*{Range}

A string of the form 'C1: C 2 ' where C1 and C2 are the names of cells at opposing corners of a rectangular region to be read, as for xlsread. By default, the rectangular region extends to the right-most column containing data. If the spreadsheet contains empty columns between columns of data, or if the spreadsheet contains figures or other non-tabular information, specify a range that contains only data.
```

Examples Create a dataset array from workspace variables, including observation names:

```
```

load cereal

```
load cereal
cereal = dataset(Calories,Protein,Fat,Sodium,Fiber,Carbo,...
cereal = dataset(Calories,Protein,Fat,Sodium,Fiber,Carbo,...
    Sugars,'ObsNames',Name)
```

    Sugars,'ObsNames',Name)
    ```
```

cereal.Properties.VarDescription = Variables(4:10,2);

```

Create a dataset array from a single, multi-columned workspace variable, designating variable names for each column:
```

load cities
categories = cellstr(categories);
cities = dataset({ratings,categories{:}},...
'ObsNames',cellstr(names))

```

Load data from a text or spreadsheet file
```

patients = dataset('File','hospital.dat',...
'Delimiter',',','ReadObsNames',true)
patients2 = dataset('XLSFile','hospital.xls',...
'ReadObsNames',true)

```

1 Load patient data from the CSV file hospital.dat and store the information in a dataset array with observation names given by the first column in the data (patient identification):
```

patients = dataset('file','hospital.dat', ...
'format','%S%S%S%f%f%f%f%f%f%f%f%f', ...
'Delimiter',',','ReadObsNames',true);

```

You can also load the data without specifying a format string. dataset will automatically create dataset variables that are either double arrays or cell arrays of strings, depending on the contents of the file:
```

patients = dataset('file','hospital.dat',...
'delimiter',',',...
'ReadObsNames',true);

```

2 Make the \(\{0,1\}\)-valued variable smoke nominal, and change the labels to 'No' and 'Yes':
```

patients.smoke = nominal(patients.smoke,{'No','Yes'});

```

3 Add new levels to smoke as placeholders for more detailed histories of smokers:
```

patients.smoke = addlevels(patients.smoke,...
{'0-5 Years','5-10 Years','LongTerm'});

```

4 Assuming the nonsmokers have never smoked, relabel the 'No ' level:
```

patients.smoke = setlabels(patients.smoke,'Never','No');

```

5 Drop the undifferentiated 'Yes' level from smoke:
```

patients.smoke = droplevels(patients.smoke,'Yes');

```

Warning: OLDLEVELS contains categorical levels that were present in A, caused some array elements to have undefined levels.

Note that smokers now have an undefined level.
6 Set each smoker to one of the new levels, by observation name:
```

patients.smoke('YPL-320') = '5-10 Years';

```

Purpose Convert dataset array to cell array
Syntax \(\quad C=\) dataset2cell (D)
Description \(\quad C=\) dataset2cell( \(D\) ) converts the dataset array \(D\) to a cell array \(C\). Each variable of \(D\) becomes a column in C. If \(D\) is an \(M\)-by- \(N\) array, then \(C\) is \((M+1)\)-by- \(N\), with the variable names of \(D\) in the first row. If \(D\) contains observation names, then \(C\) is \((M+1)\)-by- \((N+1)\), with the observation names in the first column.

Input
Arguments

\section*{Output}

Arguments

\section*{Examples}

\section*{Convert Dataset Array to Structure Array}

Load sample dataset array.
load('hospital')
Create a dataset array, D, that has only a subset of the observations and variables.
```

D = hospital(1:8,{'LastName','Sex','Age'});

```
size(D)
ans =

83
The dataset array D has 8 observations and 3 variables.
Convert D to a structure array.
```

S = dataset2struct(D)
S =
8x1 struct array with fields:
ObsNames
LastName
Sex
Age

```

The structure is \(8 \times 1\), corresponding to the 8 observations in the dataset array. \(S\) also has the field ObsNames, since \(D\) had observation names.

Display the field data for the first element of \(S\).
S(1)
ans =
ObsNames: 'YPL-320'
LastName: 'SMITH'
Sex: [1x1 nominal]
Age: 38
This information corresponds to the first observation (row) of the dataset array.

\section*{Convert Dataset Array to Scalar Structure}

Load sample dataset array.

\section*{dataset.dataset2struct}
```

load('hospital')

```

Create a dataset array, D, that has only a subset of the observations and variables.

D = hospital(1:8,\{'LastName','Sex','Age'\});
size(D)
ans =

83

The dataset array D has 8 observations and 3 variables.
Convert D to a scalar structure array.
S = dataset2struct(D, 'AsScalar',true)
S =

ObsNames: \{8x1 cell\}
LastName: \{8x1 cell\}
Sex: [8x1 nominal]
Age: [ \(8 \times 1\) double]
The data in the fields of the scalar structure is \(8 \times 1\), corresponding to the 8 observations in the dataset array. S also has the field ObsNames, since \(D\) had observation names.

Display the data for the field LastName.
S.LastName
ans =
'SMITH '
'JOHNSON'
'WILLIAMS'
'JONES'
```

'BROWN'
'DAVIS'
'MILLER'
'WILSON'

```

The structure field LastName contains all of the data that was in the original dataset array variable, LastName.

\section*{dataset.datasetfun}

Purpose Apply function to dataset array variables
Syntax
b = datasetfun(fun, A)
[b,c,...] = datasetfun(fun,A)
[b,...] = datasetfun(fun,A,...,'UniformOutput',false)
\([b, \ldots]=\) datasetfun(fun, \(A, \ldots\), '...DatasetOutput',true)
[b,...] = datasetfun(fun,A,...,'DataVars', vars)
[b,...] = datasetfun(fun,A,...,'ObsNames',obsnames)
[b,...] = datasetfun(fun,A,...,'ErrorHandler',efun)

\section*{Description}
b = datasetfun(fun, A) applies the function specified by fun to each variable of the dataset array \(A\), and returns the results in the vector \(b\). The \(i\) th element of b is equal to fun applied to the \(i\) th dataset variable of A. fun is a function handle to a function that takes one input argument and returns a scalar value. fun must return values of the same class each time it is called, and datasetfun concatenates them into the vector b. The outputs from fun must be one of the following types: numeric, logical, character, structure, or cell.

To apply functions that return results that are nonscalar or of different sizes and types, use the 'UniformOutput' or 'DatasetOutput' parameters described below.

Do not rely on the order in which datasetfun computes the elements of \(b\), which is unspecified.

If fun is bound to more than one built-in function or file, (that is, if it represents a set of overloaded functions), datasetfun follows MATLAB dispatching rules in calling the function. (See "Function Precedence Order".)
[b,c,...] = datasetfun(fun, A), where fun is a function handle to a function that returns multiple outputs, returns vectors \(\mathrm{b}, \mathrm{c}, \ldots\), each corresponding to one of the output arguments of fun. datasetfun calls fun each time with as many outputs as there are in the call to datasetfun. fun may return output arguments having different classes, but the class of each output must be the same each time fun is called.
[b,...] = datasetfun(fun,A,...,'UniformOutput',false) allows you to specify a function fun that returns values of different sizes or types. datasetfun returns a cell array (or multiple cell arrays), where the \(i\) th cell contains the value of fun applied to the \(i\) th dataset variable of A. Setting 'Uniform0utput' to true is equivalent to the default behavior.
[b, ...] = datasetfun(fun, A, ...,'DatasetOutput', true) specifies that the output(s) of fun are returned as variables in a dataset array (or multiple dataset arrays). fun must return values with the same number of rows each time it is called, but it may return values of any type. The variables in the output dataset array(s) have the same names as the variables in the input. Setting 'DatasetOutput' to false (the default) specifies that the type of the output(s) from datasetfun is determined by 'Uniform0utput'.
[b, ...] = datasetfun(fun, A, ...,'DataVars', vars) allows you to apply fun only to the dataset variables in A specified by vars. vars is a positive integer, a vector of positive integers, a variable name, a cell array containing one or more variable names, or a logical vector.
[b,...] = datasetfun(fun,A,..., 'ObsNames', obsnames) specifies observation names for the dataset output when 'DatasetOutput' is true.
[b,...] = datasetfun(fun,A,...,'ErrorHandler', efun), where efun is a function handle, specifies the MATLAB function to call if the call to fun fails. The error-handling function is called with the following input arguments:
- A structure with the fields identifier, message, and index, respectively containing the identifier of the error that occurred, the text of the error message, and the linear index into the input array(s) at which the error occurred
- The set of input arguments at which the call to the function failed

The error-handling function should either re-throw an error, or return the same number of outputs as fun. These outputs are then returned as

\section*{dataset.datasetfun}
the outputs of datasetfun. If 'UniformOutput' is true, the outputs of the error handler must also be scalars of the same type as the outputs of fun. For example, the following code could be saved in a file as the error-handling function:
function \([A, B]=\) errorFunc(S,varargin)
warning(S.identifier,S.message);
A = NaN;
B = NaN;
If an error-handling function is not specified, the error from the call to fun is rethrown.

Examples Compute statistics on selected variables in the hospital dataset array:
load hospital
stats = ...
datasetfun(@mean, hospital,...
'DataVars', \{'Weight', 'BloodPressure'\},...
'UniformOutput',false)
```

stats =

```
[154] [1x2 double]
stats\{2\}
ans =
122.780082 .9600

Display the blood pressure variable:
```

datasetfun(@hist,hospital,...
'DataVars','BloodPressure',...
'UniformOutput',false);
title('{\bf Blood Pressure}')
legend('Systolic','Diastolic','Location','N')

```

Blood Pressure

See Also
grpstats

Purpose \(\quad D\)-optimal augmentation
```

Syntax
dCE2 = daugment(dCE,mruns)
[dCE2,X] = daugment(dCE,mruns)
[dCE2,X] = daugment(dCE,mruns,model)
[dCE2,X] = daugment(...,param1,val1,param2,val2,...)

```

\section*{Description}
dCE2 = daugment(dCE, mruns) uses a coordinate-exchange algorithm to \(D\)-optimally add mruns runs to an existing experimental design dCE for a linear additive model.
[dCE2, X] = daugment (dCE, mruns) also returns the design matrix \(X\) associated with the augmented design.
[dCE2, X] = daugment(dCE,mruns,model) uses the linear regression model specified in model. model is one of the following strings:
- 'linear' - Constant and linear terms. This is the default.
- 'interaction' - Constant, linear, and interaction terms
- 'quadratic' - Constant, linear, interaction, and squared terms
- 'purequadratic' - Constant, linear, and squared terms

The order of the columns of \(X\) for a full quadratic model with \(n\) terms is:
1 The constant term
2 The linear terms in order \(1,2, \ldots, n\)
3 The interaction terms in order (1, 2), (1, 3), \(\ldots,(1, n),(2,3), \ldots,(n-1, n)\)
4 The squared terms in order \(1,2, \ldots, n\)
Other models use a subset of these terms, in the same order.
Alternatively, model can be a matrix specifying polynomial terms of arbitrary order. In this case, model should have one column for each factor and one row for each term in the model. The entries in any row of model are powers for the factors in the columns. For example, if a
model has factors \(\mathrm{X} 1, \mathrm{X} 2\), and X 3 , then a row [ \(\left.\begin{array}{lll}0 & 1 & 2\end{array}\right]\) in model specifies the term (X1.^0).*(X2.^1).*(X3.^2). A row of all zeros in model specifies a constant term, which can be omitted.
[dCE2,X] = daugment(..., param1,val1,param2,val2,...) specifies additional parameter/value pairs for the design. Valid parameters and their values are listed in the following table.
\begin{tabular}{l|l}
\hline Parameter & Value \\
\hline 'bounds ' & \begin{tabular}{l} 
Lower and upper bounds for each factor, specified \\
as a 2-by-nfactors matrix, where nfactors is the \\
number of factors. Alternatively, this value can be \\
a cell array containing nfactors elements, each \\
element specifying the vector of allowable values for \\
the corresponding factor.
\end{tabular} \\
\hline 'categorical' & Indices of categorical predictors. \\
\hline 'display' & \begin{tabular}{l} 
Either ' on ' or ' off' to control display of the \\
iteration counter. The default is ' on '.
\end{tabular} \\
\hline 'excludefun' & \begin{tabular}{l} 
Handle to a function that excludes undesirable \\
runs. If the function is \(f\), it must support the syntax \\
\(b=f(S)\), where \(S\) is a matrix of treatments with \\
nfactors columns, where nfactors is the number \\
of factors, and \(b\) is a vector of Boolean values with \\
the same number of rows as \(S . b(i)\) is true if the \(i\) th \\
row \(S\) should be excluded.
\end{tabular} \\
\hline 'init' & \begin{tabular}{l} 
Initial design as an mruns-by-nfactors matrix, \\
where nfactors is the number of factors. The \\
default is a randomly selected set of points.
\end{tabular} \\
\hline 'levels ' & \begin{tabular}{l} 
Vector of number of levels for each factor.
\end{tabular} \\
\hline 'maxiter' & \begin{tabular}{l} 
Maximum number of iterations. The default is 10. \\
\hline
\end{tabular} \\
\hline
\end{tabular}
\begin{tabular}{|c|c|}
\hline Parameter & Value \\
\hline 'options' & \begin{tabular}{l}
The value is a structure that contains options specifying whether to compute multiple tries in parallel, and specifying how to use random numbers when generating the starting points for the tries. Create the options structure with statset. Applicable statset parameters are: \\
- 'UseParallel' - If true and if a matlabpool of the Parallel Computing Toolbox is open, compute in parallel. If the Parallel Computing Toolbox is not installed, or a matlabpool is not open, computation occurs in serial mode. Default is false, meaning serial computation. \\
- UseSubstreams - Set to true to compute in parallel in a reproducible fashion. Default is false. To compute reproducibly, set Streams to a type allowing substreams: 'mlfg6331_64' or 'mrg32k3a'. \\
- Streams - A RandStream object or cell array of such objects. If you do not specify Streams, daugment uses the default stream or streams. If you choose to specify Streams, use a single object except in the case \\
- You have an open MATLAB pool \\
- UseParallel is true \\
- UseSubstreams is false \\
In that case, use a cell array the same size as the MATLAB pool.
\end{tabular} \\
\hline 'tries' & Number of times to try to generate a design from a new starting point. The algorithm uses random points for each try, except possibly the first. The default is 1 . \\
\hline
\end{tabular}

> Note The daugment function augments an existing design using a coordinate-exchange algorithm; the 'start ' parameter of the candexch function provides the same functionality using a row-exchange algorithm.

\section*{Examples}

The following eight-run design is adequate for estimating main effects in a four-factor model:
\begin{tabular}{|c|c|c|c|}
\hline \multicolumn{4}{|l|}{```
dCEmain = cordexch(4,8)
dCEmain =
```} \\
\hline 1 & -1 & -1 & 1 \\
\hline -1 & -1 & 1 & 1 \\
\hline -1 & 1 & -1 & 1 \\
\hline 1 & 1 & 1 & -1 \\
\hline 1 & 1 & 1 & 1 \\
\hline -1 & 1 & -1 & -1 \\
\hline 1 & -1 & -1 & -1 \\
\hline -1 & -1 & 1 & -1 \\
\hline
\end{tabular}

To estimate the six interaction terms in the model, augment the design with eight additional runs:
```

dCEinteraction = daugment(dCEmain,8,'interaction')
dCEinteraction =

| 1 | -1 | -1 | 1 |
| ---: | ---: | ---: | ---: |
| -1 | -1 | 1 | 1 |
| -1 | 1 | -1 | 1 |
| 1 | 1 | 1 | -1 |
| 1 | 1 | 1 | 1 |
| -1 | 1 | -1 | -1 |
| 1 | -1 | -1 | -1 |
| -1 | -1 | 1 | -1 |
| -1 | 1 | 1 | 1 |
| -1 | -1 | -1 | -1 |
| 1 | -1 | 1 | -1 |

```
\begin{tabular}{rrrr}
1 & 1 & -1 & 1 \\
-1 & 1 & 1 & -1 \\
1 & 1 & -1 & -1 \\
1 & -1 & 1 & 1 \\
1 & 1 & 1 & -1
\end{tabular}

The augmented design is full factorial, with the original eight runs in the first eight rows.

\section*{Purpose}
\(D\)-optimal design with fixed covariates
Syntax
dCV = dcovary(nfactors,fixed)
[dCV,X] = dcovary(nfactors,fixed)
[dCV,X] = dcovary(nfactors,fixed,model)
[dCV, X] = daugment(...,param1,val1,param2,val2,...)
Description
dCV = dcovary(nfactors,fixed) uses a coordinate-exchange
algorithm to generate a \(D\)-optimal design for a linear additive model with nfactors factors, subject to the constraint that the model include the fixed covariate factors in fixed. The number of runs in the design is the number of rows in fixed. The design dCV augments fixed with initial columns for treatments of the model terms.
\([d C V, X]=\) dcovary (nfactors, fixed) also returns the design matrix X associated with the design.
[dCV, X] = dcovary(nfactors,fixed,model) uses the linear regression model specified in model. model is one of the following strings:
- 'linear' - Constant and linear terms. This is the default.
- 'interaction' - Constant, linear, and interaction terms
- 'quadratic ' - Constant, linear, interaction, and squared terms
- 'purequadratic' - Constant, linear, and squared terms

The order of the columns of \(X\) for a full quadratic model with \(n\) terms is:
1 The constant term
2 The linear terms in order \(1,2, \ldots, n\)
3 The interaction terms in order \((1,2),(1,3), \ldots,(1, n),(2,3), \ldots,(n-1, n)\)
4 The squared terms in order \(1,2, \ldots, n\)
Other models use a subset of these terms, in the same order.

Alternatively, model can be a matrix specifying polynomial terms of arbitrary order. In this case, model should have one column for each factor and one row for each term in the model. The entries in any row of model are powers for the factors in the columns. For example, if a model has factors \(\mathrm{X} 1, \mathrm{X} 2\), and X 3 , then a row [ 012 1 2 ] in model specifies the term (X1.^0).*(X2.^1).*(X3.^2). A row of all zeros in model specifies a constant term, which can be omitted.
[dCV,X] = daugment(...,param1,val1,param2,val2,...) specifies additional parameter/value pairs for the design. Valid parameters and their values are listed in the following table.
\begin{tabular}{l|l}
\hline Parameter & Value \\
\hline 'bounds ' & \begin{tabular}{l} 
Lower and upper bounds for each factor, specified as \\
a 2-by-nfactors matrix. Alternatively, this value \\
can be a cell array containing nfactors elements, \\
each element specifying the vector of allowable \\
values for the corresponding factor.
\end{tabular} \\
\hline 'categorical' & Indices of categorical predictors. \\
\hline 'display ' & \begin{tabular}{l} 
Either ' on ' or ' off' to control display of the \\
iteration counter. The default is ' on '.
\end{tabular} \\
\hline 'excludefun' & \begin{tabular}{l} 
Handle to a function that excludes undesirable \\
runs. If the function is \(f\), it must support the syntax \\
\(b=f(S)\), where \(S\) is a matrix of treatments with \\
nfactors columns and \(b\) is a vector of Boolean \\
values with the same number of rows as \(S . b(i)\) is \\
true if the \(i\) th row \(S\) should be excluded.
\end{tabular} \\
\hline 'init' & \begin{tabular}{l} 
Initial design as an mruns-by-nfactors matrix. The \\
default is a randomly selected set of points.
\end{tabular} \\
\hline 'levels' & \begin{tabular}{l} 
Vector of number of levels for each factor. \\
\hline 'maxiter'
\end{tabular} \begin{tabular}{l} 
Maximum number of iterations. The default is 10. \\
\hline
\end{tabular} \\
\hline
\end{tabular}
\begin{tabular}{|c|c|}
\hline Parameter & Value \\
\hline 'options' & \begin{tabular}{l}
The value is a structure that contains options specifying whether to compute multiple tries in parallel, and specifying how to use random numbers when generating the starting points for the tries. Create the options structure with statset. Applicable statset parameters are: \\
- 'UseParallel' - If true and if a matlabpool of the Parallel Computing Toolbox is open, compute in parallel. If the Parallel Computing Toolbox is not installed, or a matlabpool is not open, computation occurs in serial mode. Default is false, meaning serial computation. \\
- UseSubstreams - Set to true to compute in parallel in a reproducible fashion. Default is false. To compute reproducibly, set Streams to a type allowing substreams: 'mlfg6331_64' or 'mrg32k3a'. \\
- Streams - A RandStream object or cell array of such objects. If you do not specify Streams, dcovary uses the default stream or streams. If you choose to specify Streams, use a single object except in the case \\
- You have an open MATLAB pool \\
- UseParallel is true \\
- UseSubstreams is false \\
In that case, use a cell array the same size as the MATLAB pool.
\end{tabular} \\
\hline 'tries' & Number of times to try to generate a design from a new starting point. The algorithm uses random points for each try, except possibly the first. The default is 1 . \\
\hline
\end{tabular}

\section*{Examples \\ Example 1}

Suppose you want a design to estimate the parameters in a three-factor linear additive model, with eight runs that necessarily occur at different times. If the process experiences temporal linear drift, you may want to include the run time as a variable in the model. Produce the design as follows:
```

time = linspace(-1,1,8)';
[dCV1,X] = dcovary(3,time,'linear')
dCV1 =

| -1.0000 | 1.0000 | 1.0000 | -1.0000 |  |
| ---: | ---: | ---: | ---: | ---: |
| 1.0000 | -1.0000 | -1.0000 | -0.7143 |  |
| -1.0000 | -1.0000 | -1.0000 | -0.4286 |  |
| 1.0000 | -1.0000 | 1.0000 | -0.1429 |  |
| 1.0000 | 1.0000 | -1.0000 | 0.1429 |  |
| -1.0000 | 1.0000 | -1.0000 | 0.4286 |  |
| 1.0000 | 1.0000 | 1.0000 | 0.7143 |  |
| -1.0000 | -1.0000 | 1.0000 | 1.0000 |  |
|  |  |  |  |  |
| 1.0000 | -1.0000 | 1.0000 | 1.0000 | -1.0000 |
| 1.0000 | 1.0000 | -1.0000 | -1.0000 | -0.7143 |
| 1.0000 | -1.0000 | -1.0000 | -1.0000 | -0.4286 |
| 1.0000 | 1.0000 | -1.0000 | 1.0000 | -0.1429 |
| 1.0000 | 1.0000 | 1.0000 | -1.0000 | 0.1429 |
| 1.0000 | -1.0000 | 1.0000 | -1.0000 | 0.4286 |
| 1.0000 | 1.0000 | 1.0000 | 1.0000 | 0.7143 |
| 1.0000 | -1.0000 | -1.0000 | 1.0000 | 1.0000 |

```

The column vector time is a fixed factor, normalized to values between \(\pm 1\). The number of rows in the fixed factor specifies the number of runs in the design. The resulting design dCV gives factor settings for the three controlled model factors at each time.

\section*{Example 2}

The following example uses the dummyvar function to block an eight-run experiment into 4 blocks of size 2 for estimating a linear additive model with two factors:
```

fixed = dummyvar([[11 1 2 2 3 3 4 4 4]);
dCV2 = dcovary(2,fixed(:,1:3),'linear')
dCV2 =

| 1 | 1 | 1 | 0 | 0 |
| ---: | ---: | :--- | :--- | :--- |
| -1 | -1 | 1 | 0 | 0 |
| -1 | 1 | 0 | 1 | 0 |
| 1 | -1 | 0 | 1 | 0 |
| 1 | 1 | 0 | 0 | 1 |
| -1 | -1 | 0 | 0 | 1 |
| -1 | 1 | 0 | 0 | 0 |
| 1 | -1 | 0 | 0 | 0 |

```

The first two columns of dCV2 contain the settings for the two factors; the last three columns are dummy variable codings for the four blocks.

\section*{Purpose Dendrogram plot}

Syntax dendrogram(tree)
dendrogram(tree, Name, Value)
dendrogram(tree, P)
dendrogram(tree, \(P\), Name, Value)
H = dendrogram( \(\qquad\) )
[ \(\mathrm{H}, \mathrm{T}\), outperm] = dendrogram( __ )

\section*{Description}
dendrogram(tree) generates a dendrogram plot of the hierarchical binary cluster tree. A dendrogram consists of many \(U\)-shaped lines that connect data points in a hierarchical tree. The height of each \(U\) represents the distance between the two data points being connected.
- If there are 30 or fewer data points in the original data set, then each leaf in the dendrogram corresponds to one data point.
- If there are more than 30 data points, then dendrogram collapses lower branches so that there are 30 leaf nodes. As a result, some leaves in the plot correspond to more than one data point.
dendrogram(tree, Name, Value) uses additional options specified by one or more name-value pair arguments.
dendrogram(tree, \(P\) ) generates a dendrogram plot with no more than \(P\) leaf nodes. If there are more than \(P\) data points in the original data set, then dendrogram collapses the lower branches of the tree. As a result, some leaves in the plot correspond to more than one data point.
dendrogram(tree, P, Name, Value) uses additional options specified by one or more name-value pair arguments.

H = dendrogram( _ _ ) generates a dendrogram plot and returns a vector of line handles. You can use any of the input arguments from the previous syntaxes.
[H, T, outperm] = dendrogram(__ ) also returns a vector containing the leaf node number for each object in the original data set, T , and a vector giving the order of the node labels of the leaves as shown in the dendrogram, outperm.
- It is useful to return \(T\) when the number of leaf nodes, \(P\), is less than the total number of data points, so that some leaf nodes in the display correspond to multiple data points.
- The order of the node labels given in outperm is from left to right for a horizontal dendrogram, and from bottom to top for a vertical dendrogram.

\section*{Input Arguments}

\section*{tree - Hierarchical binary cluster tree}
matrix returned by linkage
Hierarchical binary cluster tree, specified as an \((M-1)\)-by- 3 matrix that you generate using linkage, where \(M\) is the number of data points in the original data set.

\section*{P-Maximum number of leaf nodes}

30 (default) | positive integer value
Maximum number of leaf nodes to include in the dendrogram plot, specified as a positive integer value.
- If there are \(P\) or fewer data points in the original data set, then each leaf in the dendrogram corresponds to one data point.
- If there are more than P data points, then dendrogram collapses lower branches so that there are \(P\) leaf nodes. As a result, some leaves in the plot correspond to more than one data point.

If you do not specify \(P\), then dendrogram uses 30 as the maximum number of leaf nodes. To display the complete tree, set P equal to 0 .

\section*{Data Types \\ single | double}

\section*{Name-Value Pair Arguments}

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ..., NameN, ValueN.

Example: 'Orientation','left', 'Reorder', myOrder, specifies a vertical dendrogram with leaves in the order specified by myOrder.

\section*{'Reorder' - Order of leaf nodes}
vector
Order of leaf nodes in the dendrogram plot, specified as the comma-separated pair consisting of 'Reorder' and a vector giving the order of nodes in the complete tree. The order vector must be a permutation of the vector \(1: \mathrm{M}\), where \(M\) is the number of data points in the original data set. Specify the order from left to right for horizontal dendrograms, and from bottom to top for vertical dendrograms.

If \(M\) is greater than the number of leaf nodes in the dendrogram plot, \(P\) (by default, \(P\) is 30 ), then you can only specify a permutation vector that does not separate the groups of leaves that correspond to collapsed nodes.

\section*{Example:}

\section*{Data Types}
single | double

\section*{'CheckCrossing' - Indicator for whether to check for crossing branches \\ true (default) | false}

Indicator for whether to check for crossing branches in the dendrogram plot, specified as the comma-separated pair consisting of
'CheckCrossing ' and either true or false. This option is only useful when you specify a value for Reorder.

When CheckCrossing has the value true, dendrogram issues a warning if the order of the leaf nodes causes crossing branches in the plot. If the dendrogram plot does not show a complete tree (because the number of data points in the original data set is greater than \(P\) ), dendrogram only issues a warning when the order of the leaf nodes causes branch to cross in the dendrogram as shown in the plot. That is, there is no warning if the order causes crossing branches in the complete tree but not in the dendrogram as shown in the plot.

\section*{Data Types}
logical

\section*{'ColorThreshold' - Threshold for unique colors \\ 'default' | scalar value in the range ( \(0, \max (\operatorname{tree}(:, 3)\) )}

Threshold for unique colors in the dendrogram plot, specified as the comma-separated pair consisting of 'ColorThreshold' and either the string 'default' or a scalar value in the range ( \(0, \max (\operatorname{tree}(:, 3)\) ). If ColorThreshold has the value \(T\), then dendrogram assigns a unique color to each group of nodes in the dendrogram whose linkage is less than \(T\).
- If ColorThreshold has the value 'default', then the threshold, \(T\), is \(70 \%\) of the maximum linkage, \(0.7 * \max (\operatorname{tree}(:, 3)\) ).
- If you do not specify a value for ColorThreshold, or if you specify a threshold outside the range ( \(0, \max (\operatorname{tree}(:, 3)\) ), then dendrogram uses only one color for the dendrogram plot.

\section*{'Orientation' - Orientation of dendrogram}
'top' (default) | 'bottom' | 'left' | 'right'
Orientation of the dendrogram in the figure window, specified as the comma-separated pair consisting of 'Orientation' and one of these strings:
\begin{tabular}{ll} 
'top' & Top to bottom \\
'bottom' & Bottom to top \\
'left' & Left to right \\
'right' & Right to left
\end{tabular}

\section*{Data Types}
char

\section*{'Labels' - Label for each data point}
character array | cell array of strings
Label for each data point in the original data set, specified as the comma-separated pair consisting of 'Labels' and a character array or cell array of strings. dendrogram labels any leaves in the dendrogram plot containing a single data point with that data point's label.

\section*{Data Types}
char | cell

\section*{Output Arguments}

\section*{H - Handles to lines}
vector
Handles to lines in the dendrogram plot, returned as a vector.

\section*{T-Leaf node numbers}

\section*{column vector}

Leaf node numbers for each data point in the original data set, returned as a column vector of length \(M\), where \(M\) is the number of data points in the original data set.

When there are fewer than P data points in the original data ( P is 30 , by default), all data points are displayed in the dendrogram, with each node containing a single data point. In this case, \(T\) is the identity map, T = (1:M)'.
\(T\) is useful when \(P\) is less than the total number of data points. That is, when some leaf nodes in the dendrogram display correspond to multiple
data points. For example, to find out which data points are contained in leaf node \(k\) of the dendrogram plot, use find ( \(T==k\) ).

\section*{outperm - Permutation of node labels}
vector
Permutation of the node labels of the leaves of the dendrogram as shown in the plot, returned as a row vector. outperm gives the order from left to right for a horizontal dendrogram, and from bottom to top for a vertical dendrogram. If there are \(P\) leaves in the dendrogram plot, outperm is a permutation of the vector \(1: P\).

\section*{Examples}

\section*{Plot Dendrogram}

Generate sample data.
```

rng('default') % For reproducibility

```
\(X=\operatorname{rand}(10,3)\);

Create a hierarchical binary cluster tree using linkage. Then, plot the dendrogram using the default options.
```

tree = linkage(X,'average');
figure()
dendrogram(tree)

```

\section*{Specify Dendrogram Leaf Node Order}

Generate sample data.
```

rng('default') % For reproducibility
X = rand(10,3);

```

Create a hierarchical binary cluster tree using linkage. Then, plot the dendrogram using an optimal leaf order.
tree = linkage( X, 'average');
D = pdist(X);
leafOrder = optimalleaforder(tree,D)
leafOrder =

The order of the leaf nodes in the dendrogram plot corresponds-from left to right-to the permutation in leafOrder.

\section*{Specify Number of Nodes in Dendrogram Plot}

Generate sample data.
```

rng('default') % For reproducibility
X = rand(100,2);

```

There are 100 data points in the original data set, X .

Create a hierarchical binary cluster tree using linkage. Then, plot the dendrogram for the complete tree ( 100 leaf nodes) by setting the input argument \(P\) equal to 0 .
tree = linkage( X, 'average');
figure()
dendrogram(tree, 0)

Now, plot the dendrogram with only 25 leaf nodes. Return the mapping of the original data points to the leaf nodes shown in the plot.
figure()
[~,T] = dendrogram(tree, 25);

List the original data points that are in leaf node 7 of the dendrogram plot.
```

find(T==7)

```
ans =

7

\section*{Change Dendrogram Orientation and Line Width}

Generate sample data.
```

rng('default') % For reproducibility
X = rand(10,3);

```

Create a hierarchical binary cluster tree using linkage. Then, plot the dendrogram with a vertical orientation, using the default color threshold. Return handles to the lines so you can change the dendrogram line widths.
```

tree = linkage(X,'average');

```
figure()
H = dendrogram(tree,'Orientation','left','ColorThreshold','default');
set(H,'LineWidth',2)

See Also
cluster | clusterdata | cophenet | inconsistent | linkage pdist | silhouette

Purpose String describing data set
Description Description is a string describing the data set. The default is an empty string.

\section*{GeneralizedLinearModel.devianceTest}

\section*{Purpose Analysis of deviance}

Syntax tbl = devianceTest (mdl)

Description

Input
Arguments

\section*{Output}

Arguments

\section*{Definitions}
tbl = devianceTest(mdl) returns an analysis of deviance table for the mdl generalized linear model. tbl gives the result of a test of whether the fitted model fits significantly better than a constant model.
mdl
Generalized linear model, as constructed by GeneralizedLinearModel.fit or GeneralizedLinearModel.stepwise.
tbl
Dataset array containing two rows and four columns.
- The first row relates to a constant model.
- The second row relates to the full model in mdl.
- The columns are (see "Definitions" on page 20-572):
- Deviance
- DFE (Error Degrees of Freedom)
- F statistic or Chi-squared statistic, depending on whether the dispersion is estimated ( F statistic) or not (Chi-squared statistic)
- \(p\)-value associated with the test

\section*{Deviance Test Statistics for a Generalized Linear Model}
- Deviance is twice the difference between the log likelihoods of the models (full or constant).

\section*{GeneralizedLinearModel.devianceTest}
- \(D F E\) is the number of observations minus the number of parameters in the model.
- Chi-squared statistic is the difference between the deviance of the constant model and the deviance of the full model.
- F statistic is the difference between the deviance of the constant model and the deviance of the full model, divided by the estimated dispersion.
- p-value is the Chi-squared statistic with (number of coefficients in the model minus one) degrees of freedom, or \(F\) statistic with (number of coefficients in the model minus one) numerator degrees of freedom, and DFE denominator degrees of freedom.

\section*{Examples Deviance Test}

Perform a deviance test on a generalized linear model.
Construct a generalized linear model.
```

rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[14 4 5])*[.4;.2;.3]);
y = poissrnd(mu);
mdl = GeneralizedLinearModel.fit(X,y,...
'linear','Distribution','poisson');

```

Test whether the model differs from a constant in a statistically significant way.
```

tbl = devianceTest(mdl)

```
tbl =
\begin{tabular}{lllll} 
& Deviance & DFE & chi2Stat & pValue \\
\(\log (y) \sim 1\) & 128.58 & 99 & & \\
\(\log (y) \sim 1+x 1+x 2+x 3+x 4+x 5\) & 83.726 & 94 & 44.858 & \(1.5502 e-08\)
\end{tabular}

\section*{GeneralizedLinearModel.devianceTest}

The \(p\)-value is very small, indicating that the model significantly differs from a constant.

\begin{tabular}{|c|c|}
\hline Purpose & Interactive distribution fitting \\
\hline \multirow[t]{5}{*}{Syntax} & dfittool \\
\hline & dfittool(y) \\
\hline & dfittool(y, cens) \\
\hline & dfittool (y, cens, freq) \\
\hline & dfittool (y, cens,freq, dsname) \\
\hline
\end{tabular}

Description
dfittool opens a graphical user interface for displaying fit distributions to data. To fit distributions to your data and display them over plots of the empirical distributions, you can import data from the workspace.
dfittool(y) displays the Distribution Fitting Tool and creates a data set with data specified by the vector \(y\).
dfittool (y, cens) uses the vector cens to specify whether the observation \(\mathrm{y}(\mathrm{j})\) is censored, ( cens \((\mathrm{j})==1\) ) and/or observed, exactly (cens \((\mathrm{j})==0\) ). If cens is omitted or empty, no y values are censored.
dfittool (y, cens, freq) uses the vector freq to specify the frequency of each element of \(y\). If freq is omitted or empty, all \(y\) values have a frequency of 1 .
dfittool(y, cens,freq, dsname) creates a data set with the name dsname using the data vector \(y\), censoring indicator cens, and frequency vector freq.
For more information, see "Modeling Data Using the Distribution Fitting Tool" on page 5-12.

See Also mle | randtool | disttool

\section*{qrandset.Dimensions property}

Purpose Number of dimensions
Description Number of dimensions in the point set. The Dimensions property of a point set contains a positive integer that indicates the number of dimensions for which the points have values. For example, a point set with Dimensions=5 produces points that each have five values.

Set this property by specifying the number of dimensions when constructing a new point set. After construction, you cannot change the value. The default number of dimensions is 2 .

\section*{dataset.DimNames property}

Purpose Two-element cell array of strings giving names of dimensions of data set
Description A two-element cell array of strings giving the names of the two dimensions of the data set. The default is \{'Observations' 'Variables'\}.

Purpose Display categorical array

\section*{Syntax \(\quad \operatorname{disp}(A)\)}

Description disp(A) prints the categorical array A without printing the array name. In all other ways it's the same as leaving the semicolon off an expression, except that empty arrays don't display.

\author{
See Also categorical | display
}
Purpose Display classregtree object
Syntax display(t)
Description display(t) prints the classregtree object \(t\).
See Also ..... classregtree | view

\section*{cvpartition.disp}

\section*{Purpose Display cvpartition object}

\section*{Syntax disp(c)}

Description disp(c) prints the cvpartition object c.
See Also cvpartition
Purpose Display dataset array
Syntax ..... disp(ds)
Description

disp(ds) prints the dataset array ds, including variable names and observation names (if present), without printing the dataset name. In all other ways it's the same as leaving the semicolon off an expression.
For numeric or categorical variables that are 2-D and have three or fewer columns, disp prints the actual data using either short g, long g , or bank format, depending on the current command line setting. Otherwise, disp prints the size and type of each dataset element.
For character variables that are 2 -D and 10 or fewer characters wide, disp prints quoted strings. Otherwise, disp prints the size and type of each dataset element.
For cell variables that are 2-D and have three or fewer columns, disp prints the contents of each cell (or its size and type if too large). Otherwise, disp prints the size of each dataset element.
For time series variables, disp prints columns for both the time and the data. If the variable is 2-D and has three or fewer columns, disp prints the actual data Otherwise, disp prints the size and type of each dataset element.
For other types of variables, disp prints the size and type of each dataset element.

\section*{ProbDist.DistName property}
```

Purpose Read-only string containing probability distribution name of ProbDist object

```

\section*{Description \\ DistName is a read-only property of the ProbDist class. DistName is a}
``` string containing the type of distribution used to create the object.
```

## Values <br> Possible values are:

```
- 'kernel'
- 'beta'
- 'binomial'
- 'birnbaumsaunders'
- 'exponential'
- 'extreme value'
- 'gamma'
- 'generalized extreme value'
- 'generalized pareto'
- 'inversegaussian'
- 'logistic'
- 'loglogistic'
- 'lognormal'
- 'nakagami'
- 'negative binomial'
- 'normal'
- 'poisson'
- 'rayleigh'
- 'rician'
```

## ProbDist.DistName property

- 'tlocationscale'
- 'weibull'

Use this information to view and compare the type of distribution used to create distribution objects.

## NaiveBayes.Dist property

Purpose Distribution names
Description The Dist property is a string or a 1-by-NDims cell array of strings indicating the types of distributions for all the features. If all the features use the same type of distribution, Dist is a single string. Otherwise Dist(j) indicates the distribution type used for the j th feature.

The valid strings for this property are the following:

| 'normal' | Normal distribution. |
| :--- | :--- |
| 'kernel' | Kernel smoothing density <br> estimate. |
| 'mvmn' | Multivariate multinomial <br> distribution. |
| 'mn' | Multinomial bag-of-tokens model. |

## gmdistribution.DistName property

Purpose Type of distribution<br>Description The string 'gaussian mixture distribution'.

## disttool

Purpose Interactive density and distribution plots

## Syntax disttool

Description disttool is a graphical interface for exploring the effects of changing parameters on the plot of a cdf or pdf.

See Also randtool | dfittool

Purpose Convert categorical array to double array
Syntax $\quad B=\operatorname{double}(A)$
Description $\quad B=$ double $(A)$ converts the categorical array $A$ to a double array. Each element of B contains the internal categorical level code for the corresponding element of $A$.

See Also single

Purpose Convert dataset variables to double array
Syntax
b = double(A)
b = double(a, vars)

Description
$b=\operatorname{double}(A)$ returns the contents of the dataset $A$, converted to one double array. The classes of the variables in the dataset must support the conversion.
b = double(a,vars) returns the contents of the dataset variables specified by vars. vars is a positive integer, a vector of positive integers, a variable name, a cell array containing one or more variable names, or a logical vector.

## See Also

dataset | single | replacedata

## Purpose Drop levels

Syntax $\quad B=\operatorname{droplevels}(A)$
B = droplevels(A,oldlevels)
Description $\quad B=\operatorname{droplevels}(A)$ removes unused levels from the categorical array
A. B is a categorical array with the same size and values as A, but with a list of potential levels that includes only those present in some element of A .

B = droplevels(A, oldlevels) removes specified levels from the categorical array A. oldlevels is a cell array of strings or a 2-D character matrix specifying the levels to be removed.
droplevels removes levels, but does not remove elements. Elements of $B$ that correspond to elements of A having levels in oldlevels all have an undefined level.

## Examples

## Example 1

Drop unused age levels from the data in hospital.mat:

```
load hospital
edges = 0:10:100;
labels = strcat(num2str((0:10:90)','%d'),{'s'});
AgeGroup = ordinal(hospital.Age,labels,[],edges);
AgeGroup = droplevels(AgeGroup);
getlabels(AgeGroup)
ans =
    '20s' '30s' '40s' '50s'
```

## Example 2

1 Load patient data from the CSV file hospital. dat and store the information in a dataset array with observation names given by the first column in the data (patient identification):

```
patients = dataset('file','hospital.dat',...
    'delimiter',',',...
```

## 'ReadObsNames', true);

2 Make the $\{0,1\}$-valued variable smoke nominal, and change the labels to 'No' and 'Yes':
patients.smoke $=$ nominal(patients.smoke, \{'No', 'Yes'\});
3 Add new levels to smoke as placeholders for more detailed histories of smokers:

```
patients.smoke = addlevels(patients.smoke,...
    {'0-5 Years','5-10 Years','LongTerm'});
```

4 Assuming the nonsmokers have never smoked, relabel the 'No ' level:
patients.smoke = setlabels(patients.smoke,'Never','No');
5 Drop the undifferentiated 'Yes' level from smoke:
patients.smoke = droplevels(patients.smoke,'Yes');
Warning: OLDLEVELS contains categorical levels that were present in A, caused some array elements to have undefined levels.

Note that smokers now have an undefined level.
6 Set each smoker to one of the new levels, by observation name:

```
patients.smoke('YPL-320') = '5-10 Years';
```

See Also
addlevels | getlabels | islevel | mergelevels | reorderlevels

Purpose
Create dummy variables
Syntax
Description
D = dummyvar (group)
$D=$ dummyvar(group) returns a matrix $D$ containing zeros and ones, whose columns are dummy variables for the grouping variable group. Columns of group represent categorical predictor variables, with values indicating categorical levels. Rows of group represent observations across variables.
group can be a numeric vector or categorical column vector representing levels within a single variable, a cell array containing one or more grouping variables, or a numeric matrix or cell array of categorical column vectors representing levels within multiple variables. If group is a numeric vector or matrix, values in any column must be positive integers in the range from 1 to the number of levels for the corresponding variable. In this case, dummyvars treats each column as a separate numeric grouping variable. With multiple grouping variables, the sets of dummy variable columns are in the same order as the grouping variables in group.

The order of the dummy variable columns in D matches the order of the groups defined by group. When group is a categorical vector, the groups and their order match the output of the getlabels (group) method. When group is a numeric vector, dummyvar assumes that the groups and their order are 1: max (group). In this respect, dummyvars treats a numeric grouping variable differently than grp2idx.
If group is $n$-by- $p, \mathrm{D}$ is $n$-by- $S$, where $S$ is the sum of the number of levels in each of the columns of group. The number of levels $s$ in any column of group is the maximum positive integer in the column or the number of categorical levels. Levels are considered distinct if they appear in different columns of group, even if they have the same value. Columns of $D$ are, from left to right, dummy variables created from the first column of group, followed by dummy variables created from the second column of group, etc.
dummyvar treats NaN values or undefined categorical levels in group as missing data and returns NaN values in D.

Dummy variables are used in regression analysis and ANOVA to indicate values of categorical predictors.

Note If a column of 1 s is introduced in the matrix D , the resulting matrix $X=$ [ones(size ( $\mathrm{D}, 1$ ), 1) D] will be rank deficient. The matrix $D$ itself will be rank deficient if group has multiple columns. This is because dummy variables produced from any column of group always sum to a column of 1s. Regression and ANOVA calculations often address this issue by eliminating one dummy variable (implicitly setting the coefficients for dropped columns to zero) from each group of dummy variables produced by a column of group.

## Examples

Suppose you are studying the effects of two machines and three operators on a process. Use group to organize predictor data on machine-operator combinations:

```
machine = [11 1 1 1 1 2 2 2 2]';
operator = [1 2 % 3 1 2 3 1 1 2]';
group = [machine operator]
group =
    1
    2
    1 3
    1
    2 2
    2
    2 1
    2
```

Use dummyvar to create dummy variables for a regression or ANOVA calculation:

```
D = dummyvar(group)
```

D =

| 1 | 0 | 1 | 0 | 0 |
| :--- | :--- | :--- | :--- | :--- |

| 1 | 0 | 0 | 1 | 0 |
| :--- | :--- | :--- | :--- | :--- |
| 1 | 0 | 0 | 0 | 1 |
| 1 | 0 | 1 | 0 | 0 |
| 0 | 1 | 0 | 1 | 0 |
| 0 | 1 | 0 | 0 | 1 |
| 0 | 1 | 1 | 0 | 0 |
| 0 | 1 | 0 | 1 | 0 |

The first two columns of $D$ represent observations of machine 1 and machine 2 , respectively; the remaining columns represent observations of the three operators.

How To . "Grouping Variables" on page 2-51

- "Dummy Indicator Variables" on page 2-55
- "Regression with Categorical Covariates" on page 2-59

Purpose Durbin-Watson test
$\left.\begin{array}{cl}\text { Syntax } & p=\operatorname{dwtest}(r, x) \\ & p=\operatorname{dwtest}(r, x, \text { Name }, \text { Value }) \\ {[p, d w]=\operatorname{dwtest}(\ldots}\end{array}\right)$

Description

## Input <br> Arguments

$p=\operatorname{dwtest}(r, x)$ returns the $p$-value for the Durbin-Watson test of the null hypothesis that the residuals from a linear regression are uncorrelated. The alternative hypothesis is that there is autocorrelation among the residuals.
$\mathrm{p}=$ dwtest( $\mathrm{r}, \mathrm{x}$, Name, Value) returns the $p$-value for the Durbin-Watson test with additional options specified by one or more name-value pair arguments. For example, you can conduct a one-sided test or calculate the $p$-value using a normal approximation.
[ $\mathrm{p}, \mathrm{dw}$ ] = dwtest (__ ) also returns the Durbin-Watson test statistic, dw , using any of the input arguments from the previous syntaxes.

## x - Design matrix

matrix
Design matrix for a linear regression, specified as a matrix. Include a column of 1 values in the design matrix so the model contains a constant term.

Data Types
single | double

## $\mathbf{r}$ - Regression residuals

## vector

Regression residuals, specified as a vector. Obtain $r$ by performing a linear regression using a function such as regress, or by using the backslash operator.

## Data Types <br> single | double

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ..., NameN, ValueN.

Example: 'Tail','right','Method', 'approximate' specifies a right-tailed hypothesis test and calculates the p-value using a normal approximation.

## 'Method' - Computation method for p-value

'exact' | 'approximate'
Computation method for the $p$-value, specified as the comma-separated pair consisting of 'Method' and one of the following.
'exact $\quad$ Calculate an exact $p$-value using the Pan algorithm. This is the default if the sample size is less than 400.
' approximate Calculate the $p$-value using a normal approximation.
This is the default if the sample size is 400 or larger.

## Example: 'Method','exact'

## 'Tail' - Type of alternative hypothesis <br> 'both' (default) | 'right' | 'left'

Type of alternative hypothesis to evaluate, specified as the comma-separated pair consisting of 'Tail' and one of the following.

| 'both' | Test the alternate hypothesis that autocorrelation <br> among the residuals is not zero. |
| :--- | :--- |
| 'right' | Test the alternative hypothesis that autocorrelation <br> among the residuals is greater than zero. |
| 'left' | Test the alternative hypothesis that autocorrelation <br> among the residuals is less than zero. |

Example: 'Tail','right'

## Output p-p-value

Arguments
scalar value in the range $(0,1)$
$p$-value of the test, returned as a scalar value in the range $(0,1) . \mathrm{p}$ is the probability of observing a test statistic as extreme as, or more extreme than, the observed value under the null hypothesis. Small values of $p$ cast doubt on the validity of the null hypothesis.

## dw - Test statistic

nonnegative scalar value
Test statistic of the hypothesis test, returned as a nonnegative scalar value.

## Examples Test Residuals for Correlation

Load the sample census data.
load census;
Create a design matrix using the census date (cdate) as the predictor. Add a column of 1 values to include a constant term.

```
n = length(cdate);
x = [ones(n,1),cdate];
```

Fit a linear regression to the data.

```
[b,bint,r] = regress(pop,x);
```

Test the null hypothesis that there is no autocorrelation among the residuals, $r$.

```
[p,dw] = dwtest(r,x)
```

p =
0
dw =
0.1308

The returned value $\mathrm{p}=0$ indicates rejection of the null hypothesis at the $5 \%$ significance level.

## One-Sided Hypothesis Test

Load the sample census data.

```
load census;
```

Create a design matrix using the census date (cdate) as the predictor. Add a column of 1 values to include a constant term.

```
n = length(cdate);
x = [ones(n,1),cdate];
```

Fit a linear regression to the data.
[b,bint,r] = regress(pop,x);
Test the null hypothesis that there is no autocorrelation among regression residuals, against the alternative hypothesis that the autocorrelation is greater than zero.

```
[p,dw] = dwtest(r,x,'Tail','right')
p =
    0
```

$\mathrm{d} w=$
0.1308

The returned value $\mathrm{p}=0$ indicates rejection of the null hypothesis at the $5 \%$ significance level, in favor of the alternative hypothesis that the autocorrelation among residuals is greater than zero.

## Definitions

## Durbin-Watson Test

The Durbin-Watson test is used to test if linear regression residuals are uncorrelated, against the alternative that autocorrelation exists.

The test statistic is

$$
d=\frac{\sum_{t=2}^{T}\left(e_{t}-e_{t-1}\right)^{2}}{\sum_{t=1}^{T} e_{t}^{2}}
$$

where $T$ is the number of observations, and $e_{t}$ is the residual at time $t$.
The $p$-value can be calculated exactly using the Pan algorithm. Alternatively, the $p$-value can be estimated using a normal approximation. Significantly small $p$-values indicate correlation among residuals.

## See Also <br> regress

## LinearModel.dwtest

Purpose Durbin-Watson test of linear model
Syntax

P = dwtest(mdl)
[P,DW] = dwtest(mdl)
[P,DW] = dwtest(mdl,method)
[P,DW] = dwtest(mdl,method,tail)

## Input

Arguments
$\mathrm{P}=\mathrm{dwtest}(\mathrm{mdl})$ returns the $p$-value of the Durbin-Watson test on the mdl linear model.
[P,DW] = dwtest(mdl) returns the Durbin-Watson statistic.
[P,DW] = dwtest(mdl,method) specifies the method dwtest uses to compute the $p$-value.
[P,DW] = dwtest(mdl,method,tail) specifies the alternative hypothesis.
mdl
Linear model, as constructed by LinearModel.fit or LinearModel.stepwise.

## method

Algorithm for computing the $p$-value:

- 'exact ' - Calculates an exact $p$-value using Pan's algorithm.
- 'approximate' - Calculates the $p$-value using a normal approximation.

Default: 'exact' when the sample size is less than 400 , 'approximate' otherwise

## tail

dwtest tests whether mdl has no serial correlation against one of these alternative hypotheses:

## LinearModel.dwtest

| Tail | Alternative Hypothesis |
| :--- | :--- |
| 'both' | Serial correlation is not 0. |
| 'right' | Serial correlation is greater than 0 (right-tailed <br> test). |
| 'left' | Serial correlation is less than 0 (left-tailed test). |

Default: 'both'

## Output P

Arguments

## Definitions

## Durbin-Watson Statistic

Let $r$ be the vector of residuals (in mdl.residuals.response). The Durbin-Watson statistic is

$$
D W=\frac{\sum_{i=1}^{n-1}\left(r_{i+1}-r_{i}\right)^{2}}{\sum_{i=1}^{n} r_{i}^{2}} .
$$

## Examples <br> Test Residuals for Autocorrelation

Examine whether the residuals from a fitted model of census data over time have autocorrelated residuals.

Load the census data and create a linear model.

## LinearModel.dwtest

load census
mdl = LinearModel.fit(cdate,pop);
Find the $p$-value of the Durbin-Watson autocorrelation test.
P = dwtest(mdl)
$P=$
0
There is significant autocorrelation in the residuals.

## Algorithms

How To . "Linear Regression" on page 9-11

Purpose Empirical cumulative distribution function
Syntax

```
[f,x] = ecdf(y)
[f,x] = ecdf(y,Name,Value)
[f,x,flo,fup] = ecdf(___)
ecdf(
```

$\qquad$

```
ecdf(ax, ___)
```

## Description

$[f, x]=\operatorname{ecdf}(y)$ returns the empirical cumulative distribution function (cdf), $f$, evaluated at the points in $x$, using the data in the vector y .

In survival and reliability analysis, this empirical cdf is called the Kaplan-Meier estimate. And the data might correspond to survival or failure times.
$[f, x]=\operatorname{ecdf}(y, N a m e$, Value $)$ returns the empirical function values, $f$, evaluated at the points in $x$, with additional options specified by one or more Name, Value pair arguments.

For example, you can specify the type of function to evaluate or which data is censored.
[f,x,flo,fup] $=\operatorname{ecdf}(\ldots$ ) also returns the $95 \%$ lower and upper confidence bounds for the evaluated function values. You can use any of the input arguments in the previous syntaxes.
ecdf computes the confidence bounds using Greenwood's formula. They are not simultaneous confidence bounds.
$\operatorname{ecdf}(\ldots$,$) plots the evaluated function.$
ecdf(ax, __ ) plots the evaluated function using axes with the handle, ax, instead of the current axes returned by gca.

## Input Arguments

## y-Input data <br> column vector

Input data, specified as a column vector. For example, in survival or reliability analysis, data might be survival or failure times for each item or individual.

## Data Types

single | double

## ax-Axes handle

handle
Axes handle for the figure ecdf plots to, specified as a handle.
For instance, if $h$ is a handle for a figure, then ecdf can plot to that figure as follows.

## Example: $\operatorname{ecdf(h,x)~}$

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN.

Example: 'censoring', c,'function', 'cumulative hazard', 'alpha', 0.025,'bounds', 'on' specifies that ecdf returns the cumulative hazard function and plots the $97.5 \%$ confidence bounds, accounting for the censored data specified by vector c .

## 'censoring' - Indicator of censored data

array of 0 s (default) | vector of 0 s and 1 s
Indicator of censored data, specified as the comma-separated pair including 'censoring' and a Boolean array of the same size as x. Enter 1 for observations that are right-censored and 0 for observations that are fully observed. Default is all observations are fully observed.

For instance, if vector cdatastores the censored data information, you can enter the censoring information as follows.

Example: 'censoring', cdata

## Data Types

logical

## 'frequency' - Frequency of observations

array of 1 s (default) | vector of nonnegative scalars
Frequency of observations, specified as the comma-separated pair consisting of 'frequency' and a vector containing nonnegative integer counts. This vector is the same size as the vector $x$. The $j$ th element of this vector gives the number of times the $j$ th element of $x$ was observed. Default is one observation per element of $x$.

For instance, if failurefreq is a vector of frequencies, then you can enter it as follows.

```
Example: 'frequency',failurefreq
```

```
Data Types
single | double
```

## 'alpha' - Confidence level

0.05 (default) | scalar value in the range ( 0,1 )

Confidence level for the confidence interval of the evaluated function, specified as the comma-separated pair consisting of 'alpha' and a scalar value between in the range ( 0,1 ). Default is 0.05 for $95 \%$ confidence. For a given value alpha, the confidence level is $100(1$-alpha) $\%$.

For instance, for a $99 \%$ confidence interval, you can specify the alpha value as follows.

Example: 'alpha', 0.01

## Data Types <br> single | double

## 'function' - Type of function returned

```
'cdf'(default) | 'survivor' | 'cumulative hazard'
```

Type of function that ecdf evaluates and returns, specified as the comma-separated pair consisting of 'function' and one of the following.

| 'cdf' | Default. Cumulative distribution function. |
| :--- | :--- |
| 'survivor' | Survivor function. |
| 'cumulative <br> hazard ' | Cumulative hazard function. |

Example: 'function','cumulative hazard'

## Data Types

char

## 'bounds' - Indicator for including bounds

'off' (default) | 'on'
Indicator for including bounds, specified as the comma-separated pair consisting of 'bounds ' and one of the following.

| 'off' | Default. Specify to omit bounds. |
| :--- | :--- |
| 'on' | Specify to include bounds. |

Note This name-value argument is used only for plotting.

Example: 'bounds', 'on'

## Data Types

char

## Output Arguments

## f-Function values

column vector
Function values evaluated at the points in x , returned as a column vector.

## x - Distinct observed points

column vector
Distinct observed points in data vector y , returned as a column vector.

## flo - Lower confidence bound

column vector
Lower confidence bound for the evaluated function, returned as a column vector. ecdf computes the confidence bounds using Greenwood's formula. They are not simultaneous confidence bounds.

## fup - Upper confidence bound <br> column vector

Upper confidence bound for the evaluated function, returned as a column vector. ecdf computes the confidence bounds using Greenwood's formula. They are not simultaneous confidence bounds.

## Examples Compute Empirical Cumulative Distribution Function

Compute the Kaplan-Meier estimate of the cumulative distribution function (cdf) for simulated survival data.

Generate survival data from a Weibull distribution with parameters 3 and 1.

```
rng('default') % for reproducibility
failuretime = random('wbl',3,1,15,1);
```

Compute the Kaplan-Meier estimate of the cdf for survival data.
[f,x] = ecdf(failuretime);
[f,x]
ans =

| 0 | 0.0895 |
| ---: | ---: |
| 0.0667 | 0.0895 |
| 0.1333 | 0.1072 |
| 0.2000 | 0.1303 |
| 0.2667 | 0.1313 |
| 0.3333 | 0.2718 |
| 0.4000 | 0.2968 |
| 0.4667 | 0.6147 |
| 0.5333 | 0.6684 |
| 0.6000 | 1.3749 |
| 0.6667 | 1.8106 |
| 0.7333 | 2.1685 |
| 0.8000 | 3.8350 |
| 0.8667 | 5.5428 |
| 0.9333 | 6.1910 |
| 1.0000 | 6.9825 |

Plot the estimated cdf.
figure()
plot(x,f)

## Empirical Hazard Function of Right-Censored Data

Compute and plot the hazard function of simulated right-censored survival data.

Generate failure times from a Birnbaum-Saunders distribution.

```
rng('default') % for reproducibility
failuretime = random('birnbaumsaunders',0.3,1,100,1);
```

Assuming that the end of the study is at time 0.9 , generate a logical array that indicates simulated failure times that are larger than 0.9 as censored data, and store this information in a vector.

T = 0.9;
cens = (failuretime>T);
Plot the empirical hazard function for the data.

```
ecdf(failuretime,'function','cumulative hazard',...
'censoring',cens,'bounds','on');
```

## Compare Empirical Cumulative Distribution Function (CDF) with Known CDF

Generate right-censored survival data and compare the empirical cumulative distribution function (cdf) with the known cdf.

Generate failure times from an exponential distribution with mean failure time of 15 .

```
rng('default')
y = exprnd(15,75,1);
```

Generate drop-out times from an exponential distribution with mean failure time of 30 .

```
d = exprnd(30,75,1);
```

Generate the observed failure times. They are the minimum of the generated failure times and the drop-out times.
$\mathrm{t}=\min (\mathrm{y}, \mathrm{d})$;
Create a logical array that indicates generated failure times that are larger than the drop-out times. The data for which this is true are censored.

```
censored = (y>d);
```

Compute the empirical cdf and confidence bounds.

```
[f,x,flo,fup] = ecdf(t,'censoring',censored);
```

Plot the cdf and confidence bounds.

```
figure()
ecdf(t,'censoring',censored,'bounds','on');
hold on
```

Superimpose a plot of the known population cdf.

```
xx = 0:.1:max(t);
yy = 1-exp(-xx/15);
plot(xx,yy,'g-','LineWidth',2)
axis([0 50 0 1])
legend('Empirical','LCB','UCB','Population',...
    'Location','SE')
hold off
```

## Empirical Survivor Function with 99\% Confidence Bounds

Generate survival data and plot the empirical survivor function with $99 \%$ confidence bounds.

Generate lifetime data from a Weibull distribution with parameters 100 and 2.
rng('default') \% for reproducibility
R = wblrnd(100,2,100,1);

Plot the survivor function for the data with $99 \%$ confidence bounds.

```
ecdf(R,'function','survivor','alpha',0.01,'bounds','on')
hold on
```

Fit the Weibull survivor function.
$x=1: 1: 250 ;$
wblsurv = 1-cdf('weibull',x,100,2); plot(x,wblsurv,'g-','LineWidth', 2) legend('Empirical','LCB','UCB', 'Population',... 'Location', 'NE')

The survivor function based on the actual distribution is within the confidence bounds.

## Definitions <br> Greenwood's Formula

Approximation for the variance of Kaplan-Meier estimator. The variance estimate is given by

$$
V(S(t))=S^{2}(t) \sum_{t_{i}<T} \frac{d_{i}}{r_{i}\left(r_{i}-d_{i}\right)},
$$

where $r_{i}$ is the number at risk at time $t_{i}$, and $d_{i}$ is the number of failures at time $t_{i}$.

Purpose
Syntax

Description

Input
Arguments

Histogram based on empirical cumulative distribution function

```
[n,c] = ecdfhist(f,x)
[n,c] = ecdfhist(f,x,m)
n = ecdfhist(f,x,centers)
ecdfhist(
```

$\qquad$
[ $n, c$ ] = ecdfhist (f, $x$ ) returns the heights, $n$, of histogram bars for 10 equally spaced bins and the position of the bin centers, c.
ecdfhist computes the bar heights from the increases in the empirical cumulative distribution function, $f$, at evaluation points, $x$. It normalizes the bar heights so that the area of the histogram is equal to 1. In contrast, hist produces bars with heights representing bin counts.
[ $n, c$ ] = ecdfhist(f,x,m) returns the histogram bars using $m$ bins.
$\mathrm{n}=$ ecdfhist(f,x,centers) returns the heights of the histogram bars with bin centers specified by centers.
ecdfhist ( _ _ ) plots the histogram bars.

## f-Empirical cdf values

vector
Empirical cdf values at given evaluation points, $x$, specified as a vector.
For instance, you can use ecdf to obtain the empirical cdf values and enter them in ecdfhist as follows.

Example: [f,x] = ecdf(failure); ecdfhist(f,x);
Data Types
single | double

## x-Evaluation points

## vector

Evaluation points at which empirical cdf values, f, are calculated, specified as a vector.
For instance, you can use ecdf to obtain the empirical cdf values and enter them in ecdfhist as follows.

Example: [f,x] = ecdf(failure); ecdfhist(f,x);
Data Types
single | double

## m - Number of bins

## scalar

Number of bins, specified as a scalar.
For instance, you can draw a histogram with 8 bins as follows.
Example: ecdfhist(f,x,8)
Data Types
single | double
centers - Center points of bins
vector
Center points of bins, specified as a vector.
Example: centers = 2:2:10; ecdfhist(f,x,centers);
Data Types
single | double

## Output <br> Arguments

## n - Heights of histogram bars

row vector
Heights of histogram bars ecdfhist calculates based on the empirical cdf values, returned as a row vector.

## c-Position of bin centers

row vector
Position of bin centers, returned as a row vector.

## Examples Return Histogram Bar Heights and Bin Centers

Compute the histogram bar heights based on the empirical cumulative distribution function.

Generate failure times from a Birnbaum-Saunders distribution.

```
rng('default') % for reproducibility
failuretime = random('birnbaumsaunders',0.3,1,100,1);
```

Assuming that the end of the study is at time 0.9 , mark the generated failure times that are larger than 0.9 as censored data and store that information in a vector.

```
T = 0.9;
cens = (failuretime>T);
```

Compute the empirical cumulative distribution function for the data.
[f,x] = ecdf(failuretime,'censoring',cens);
Now, find the bar heights of the histogram using the cumulative distribution function estimate.

```
n = ecdfhist(f,x);
[n' c']
ans =
    2.3529 0.0715
    1.7647 0.1565
    1.4117 0.2415
    1.5294 0.3265
    1.0588 0.4115
    0.4706 0.4965
```

| 0.4706 | 0.5815 |
| :--- | :--- |
| 0.9412 | 0.6665 |
| 0.2353 | 0.7515 |
| 0.2353 | 0.8365 |

## Return Bar Heights and Bin Centers for a Given Number of Bins

Compute the bar heights for six bins using the empirical cumulative distribution function and also return the bin centers.

Generate failure times from a Birnbaum-Saunders distribution.

```
rng('default') % for reproducibility
failuretime = random('birnbaumsaunders',0.3,1,100,1);
```

Assuming that the end of the study is at time 0.9, mark the generated failure times that are larger than 0.9 as censored data and store that information in a vector.

```
T = 0.9;
cens = (failuretime>T);
```

First, compute the empirical cumulative distribution function for the data.
[f,x] = ecdf(failuretime,'censoring',cens);
Now, estimate the histogram with six bins using the cumulative distribution function estimate.

```
[n,c] = ecdfhist(f,x,6);
[n' c']
ans =
    1.9764 0.0998
    1.7647 0.2415
    1.1294 0.3831
```

| 0.4235 | 0.5248 |
| :--- | :--- |
| 0.7764 | 0.6665 |
| 0.2118 | 0.8081 |

## Draw Histogram for Given Bin Centers

Draw the histogram of the empirical cumulative distribution histogram for specified bin centers.

Generate failure times from a Birnbaum-Saunders distribution.
rng('default') \% for reproducibility
failuretime $=$ random('birnbaumsaunders', 0.3,1,100,1);

Assuming that the end of the study is at time 0.9 , mark the generated failure times that are larger than 0.9 as censored data and store that information in a vector.

```
T = 0.9;
cens = (failuretime>T);
```

Define bin centers.
centers = 0.1:0.1:1;

Compute the empirical cumulative distribution function for the data and draw the histogram for specified bin centers.

```
[f,x] = ecdf(failuretime,'censoring',cens);
ecdfhist(f,x,centers)
axis([0 1 0 2.5])
```

## Compare Histogram with Known Probability Distribution Function

Generate right-censored survival data and compare the histogram from cumulative distribution function with the known probability distribution function.

Generate failure times from an exponential distribution with mean failure time of 15 .

```
rng('default')
y = exprnd(15,75,1);
```

Generate drop-out times from an exponential distribution with mean failure time of 30 .
$d=\operatorname{exprnd}(30,75,1) ;$
Record the minimum of these times as the observed failure times.
$\mathrm{t}=\mathrm{min}(\mathrm{y}, \mathrm{d})$;
Generate censoring by finding the generated failure times that are greater than the drop-out times.
censored $=(y>d)$;
Calculate the empirical cdf and plot a histogram using the empirical cumulative distribution function.

```
[f,x] = ecdf(t,'censoring',censored);
ecdfhist(f,x)
set(get(gca,'Children'),'FaceColor',[.8 .8 1])
hold on
```

Superimpose a plot of the known population pdf.

```
xx = 0:.1:max(t);
yy = exp(-xx/15)/15;
plot(xx,yy,'r-','LineWidth',2)
hold off
```

## ClassificationKNN.edge

Purpose Edge of $k$-nearest neighbor classifier
Syntax $\quad \begin{aligned} E & =\operatorname{edge}(m d l, X, Y) \\ E & =\operatorname{edge}(m d l, X, Y, \text { Name, Value })\end{aligned}$
Description $E=$ edge ( $m d l, X, Y$ ) returns the classification edge for $m d l$ with data $X$ and classification $Y$.
$\mathrm{E}=$ edge(mdl, $\mathrm{X}, \mathrm{Y}$, Name, Value) computes the edge with additional options specified by one or more Name, Value pair arguments.

## Input <br> Arguments

## mdl

$k$-nearest neighbor classifier, created by ClassificationKNN.fit.

## X

Matrix of predictor values. Each column of X represents one variable, and each row represents one observation.

## Y

Grouping variables of response values with the same number of elements (rows) as $X$. Each entry in $Y$ is the response to the data in the corresponding row of $X$.

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ..., NameN, ValueN.

## 'weights'

Observation weights, a numeric vector of length size ( $X, 1$ ). If you supply weights, edge computes weighted classification edge.

Default: ones(size(X,1))

## ClassificationKNN.edge

## Output Arguments <br> \section*{E}

## Definitions

Classification edge, a scalar that is the mean classification margin (see "Margin" on page 20-643).

## Edge

The edge is the mean value of the classification margin.

## Margin

The classification margin is the difference between the classification score for the true class and maximal classification score for the false classes.

Margin is a column vector with the same number of rows as $X$.

## Score

The score of a classification is the posterior probability of the classification. The posterior probability is the number of neighbors that have that classification, divided by the number of neighbors. For a more detailed definition that includes weights and prior probabilities, see "Posterior Probability" on page 20-2181.

## Examples Edge Calculation

Construct a $k$-nearest neighbor classifier for the Fisher iris data, where $k=5$.

Load the data.

```
load fisheriris
```

$X=$ meas;
$Y=$ species;

Construct a classifier for five-nearest neighbors.

```
mdl = ClassificationKNN.fit(X,Y,'NumNeighbors',5);
```

## ClassificationKNN.edge

Examine the edge of the classifier for minimum, mean, and maximum observations classified 'setosa', 'versicolor', and 'virginica' respectively.

NewX = [min(X); mean(X);max $(X)]$;
$Y=$ \{'setosa';'versicolor';'virginica'\};
E = edge(mdl,NewX,Y)

E =

1

The classifier has no doubt that the $Y$ entries are correct classifications (all five nearest neighbors of each NewX point classify as the corresponding $Y$ entry).

## CompactClassificationDiscriminant.edge

| Purpose | Classification edge |
| :---: | :---: |
| Syntax | $E=$ edge (obj, $\mathrm{X}, \mathrm{Y}$ ) |
|  | $\mathrm{E}=$ edge(obj, $\mathrm{X}, \mathrm{Y}$, Name, Value) |
| Description | $\mathrm{E}=\mathrm{edge}(\mathrm{obj}, \mathrm{X}, \mathrm{Y})$ returns the classification edge for obj with data X and classification $Y$. |
|  | E = edge(obj, X, Y, Name, Value) computes the edge with additional options specified by one or more Name, Value pair arguments. |
| Input <br> Arguments | obi |
|  | Discriminant analysis classifier of class ClassificationDiscriminant or CompactClassificationDiscriminant, typically constructed with ClassificationDiscriminant.fit. |
|  | X |
|  | Matrix where each row represents an observation, and each column represents a predictor. The number of columns in X must equal the number of predictors in obj. |
|  | Y |
|  | Class labels, with the same data type as exists in obj. The number of elements of $Y$ must equal the number of rows of $X$. |
|  | Name-Value Pair Arguments |
|  | Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN. |
|  | 'weights' |

Observation weights, a numeric vector of length size ( $\mathrm{X}, 1$ ). If you supply weights, edge computes the weighted classification edge.

## CompactClassificationDiscriminant.edge

Default: ones(size (X,1))

## Output

Arguments

## Definitions

## Edge

The edge is the weighted mean value of the classification margin. The weights are the class probabilities in obj. Prior. If you supply weights in the weights name-value pair, those weights are normalized to sum to the prior probabilities in the respective classes, and are then used to compute the weighted average.

## Margin

The classification margin is the difference between the classification score for the true class and maximal classification score for the false classes. Margin is a column vector with the same number of rows as in the matrix X . A high value of margin indicates a more reliable prediction than a low value.

## Score (discriminant analysis)

For discriminant analysis, the score of a classification is the posterior probability of the classification. For the definition of posterior probability in discriminant analysis, see "Posterior Probability" on page 14-7.

Examples Compute the classification edge and margin for the Fisher iris data, trained on its first two columns of data, and view the last 10 entries:

```
load fisheriris
X = meas(:,1:2);
obj = ClassificationDiscriminant.fit(X,species);
E = edge(obj,X,species)
E =
    0.4980
```

## CompactClassificationDiscriminant.edge

```
M = margin(obj,X,species);
M(end-10: end)
ans =
    0.6551
    0.4838
    0.6551
    -0.5127
    0.5659
    0.4611
    0.4949
    0.1024
    0.2787
    -0.1439
    -0.4444
```

The classifier trained on all the data is better:
obj = ClassificationDiscriminant.fit(meas,species);
E = edge(obj,meas,species)
E =
0.9454

M = margin(obj,meas,species);
$M$ (end-10: end)

## CompactClassificationEnsemble.edge

| Purpose | Classification edge |
| :--- | :--- |
| Syntax | $E=$ edge $(e n s, X, Y)$ |
|  | $E=$ edge $(e n s, X, Y$, Name, Value $)$ |

Description

## Input Arguments

$E=$ edge (ens, $X, Y$ ) returns the classification edge for ens with data $X$ and classification $Y$.
$\mathrm{E}=$ edge(ens, $\mathrm{X}, \mathrm{Y}$, Name, Value) computes the edge with additional options specified by one or more Name, Value pair arguments.

## ens

A classification ensemble constructed with fitensemble, or a compact classification ensemble constructed with compact.

## X

A matrix where each row represents an observation, and each column represents a predictor. The number of columns in X must equal the number of predictors in ens.

## Y

Class labels, with the same data type as exists in ens. The number of elements of $Y$ must equal the number of rows of $X$.

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ..., NameN, ValueN.
'learners'
Indices of weak learners in the ensemble ranging from 1 to ens.NTrained. edge uses only these learners for calculating loss.

Default: 1:NTrained

## CompactClassificationEnsemble.edge

## 'mode'

String representing the meaning of the output E :

- 'ensemble' - E is a scalar value, the edge for the entire ensemble.
- 'individual' - E is a vector with one element per trained learner.
- 'cumulative' - E is a vector in which element J is obtained by using learners $1: \mathrm{J}$ from the input list of learners.

Default: 'ensemble'

## 'UseObsForLearner'

A logical matrix of size N -by-T, where:

- N is the number of rows of X .
- T is the number of weak learners in ens.

When UseObsForLearner ( $\mathrm{i}, \mathrm{j}$ ) is true, learner j is used in predicting the class of row i of $X$.

Default: $\operatorname{true}(\mathrm{N}, \mathrm{T})$

## 'weights'

Observation weights, a numeric vector of length size ( $\mathrm{X}, 1$ ). If you supply weights, edge computes weighted classification edge.

Default: ones(size(X,1))

## Output E Arguments

The classification edge, a vector or scalar depending on the setting of the mode name-value pair. Classification edge is weighted average classification margin.

# CompactClassificationEnsemble.edge 

## Definitions Margin

The classification margin is the difference between the classification score for the true class and maximal classification score for the false classes. Margin is a column vector with the same number of rows as in the matrix X .

## Score (ensemble)

For ensembles, a classification score represents the confidence of a classification into a class. The higher the score, the higher the confidence.

Different ensemble algorithms have different definitions for their scores. Furthermore, the range of scores depends on ensemble type. For example:

- AdaBoostM1 scores range from $-\infty$ to $\infty$.
- Bag scores range from 0 to 1 .

## Edge

The edge is the weighted mean value of the classification margin. The weights are the class probabilities in ens.Prior. If you supply weights in the weights name-value pair, those weights are used instead of class probabilities.

## Examples

Make a boosted ensemble classifier for the ionosphere data, and find the classification edge for the last few rows:

```
load ionosphere
ens = fitensemble(X,Y,'AdaboostM1',100,'Tree');
E = edge(ens,X(end-10:end,:),Y(end-10:end))
E =
    8.3310
```

See Also margin | edge

## CompactClassificationTree.edge

\section*{Purpose Classification edge <br> Syntax $\quad$| $E=\operatorname{edge}($ tree $, X, Y)$ |  |
| ---: | :--- |
| $E$ | $=$ edge(tree $, X, Y$, Name, Value $)$ | <br> Description $E=$ edge(tree $, X, Y)$ returns the classification edge for tree with data $X$ and classification $Y$. <br> $\mathrm{E}=$ edge(tree, $\mathrm{X}, \mathrm{Y}$, Name, Value) computes the edge with additional options specified by one or more Name, Value pair arguments. <br> Input <br> Arguments <br> A classification tree created by ClassificationTree.fit, or a compact classification tree created by compact. <br> x <br> A matrix where each row represents an observation, and each column represents a predictor. The number of columns in X must equal the number of predictors in tree.}

## Y

Class labels, with the same data type as exists in tree. The number of elements of $Y$ must equal the number of rows of $X$.

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ..., NameN, ValueN.

## 'weights'

Observation weights, a numeric vector of length size ( $X, 1$ ). If you supply weights, edge computes weighted classification edge.

Default: ones(size(X,1))

## CompactClassificationTree.edge

## Output Arguments <br> \section*{E}

## Definitions

The edge, a scalar representing the weighted average value of the margin.

## Margin

The classification margin is the difference between the classification score for the true class and maximal classification score for the false classes. Margin is a column vector with the same number of rows as the matrix $X$.

## Score (tree)

For trees, the score of a classification of a leaf node is the posterior probability of the classification at that node. The posterior probability of the classification at a node is the number of training sequences that lead to that node with the classification, divided by the number of training sequences that lead to that node.

For example, consider classifying a predictor X as true when $\mathrm{X}<0.15$ or $X>0.95$, and $X$ is false otherwise.

1
Generate 100 random points and classify them:

```
rng(0,'twister') % for reproducibility
X = rand(100,1);
Y = (abs(X - . 55) > .4);
tree = ClassificationTree.fit(X,Y);
view(tree,'mode','graph')
```

## CompactClassificationTree.edge

2
Prune the tree:

```
tree1 = prune(tree,'level',1);
view(tree1,'mode','graph')
```

## CompactClassificationTree.edge

The pruned tree correctly classifies observations that are less than 0.15 as true. It also correctly classifies observations from .15 to .94 as false. However, it incorrectly classifies observations that are greater than . 94 as false. Therefore, the score for observations that are greater than . 15 should be about $.05 / .85=.06$ for true, and about $.8 / .85=.94$ for false.

## 3

Compute the prediction scores for the first 10 rows of X :

```
[~,score] = predict(tree1,X(1:10));
[score X(1:10,:)]
ans =
\begin{tabular}{rrr}
0.9059 & 0.0941 & 0.8147 \\
0.9059 & 0.0941 & 0.9058 \\
0 & 1.0000 & 0.1270 \\
0.9059 & 0.0941 & 0.9134 \\
0.9059 & 0.0941 & 0.6324 \\
0 & 1.0000 & 0.0975
\end{tabular}
\(0.9059 \quad 0.0941 \quad 0.2785\)
```

## CompactClassificationTree.edge

| 0.9059 | 0.0941 | 0.5469 |
| :--- | :--- | :--- |
| 0.9059 | 0.0941 | 0.9575 |
| 0.9059 | 0.0941 | 0.9649 |

Indeed, every value of $X$ (the rightmost column) that is less than 0.15 has associated scores (the left and center columns) of 0 and 1, while the other values of $X$ have associated scores of 0.91 and 0.09 . The difference (score 0.09 instead of the expected .06) is due to a statistical fluctuation: there are 8 observations in $X$ in the range (. 95,1 ) instead of the expected 5 observations.

## Edge

The edge is the weighted mean value of the classification margin. The weights are the class probabilities in tree. Prior. If you supply weights in the weights name-value pair, those weights are normalized to sum to the prior probabilities in the respective classes, and are then used to compute the weighted average.

Examples Compute the classification margin and edge for the Fisher iris data, trained on its first two columns of data, and view the last 10 entries:

```
load fisheriris
X = meas(:,1:2);
tree = ClassificationTree.fit(X,species);
E = edge(tree,X,species)
E =
    0.6299
M = margin(tree,X,species);
M(end-10:end)
ans =
    0.1111
    0 . 1 1 1 1
    0.1111
    -0.2857
```

## CompactClassificationTree.edge

$$
\begin{aligned}
& 0.6364 \\
& 0.6364 \\
& 0.1111 \\
& 0.7500 \\
& 1.0000 \\
& 0.6364 \\
& 0.2000
\end{aligned}
$$

The classification tree trained on all the data is better:

```
tree = ClassificationTree.fit(meas,species);
E = edge(tree,meas,species)
E =
    0.9384
M = margin(tree,meas,species);
M(end-10: end)
ans =
    0.9565
    0.9565
    0.9565
    0.9565
    0.9565
    0.9565
    0.9565
    0.9565
    0.9565
    0.9565
    0.9565
```

See Also margin | loss | predict

Purpose Last index in indexing expression for categorical array

## Syntax end $(A, k, n)$

Description end ( $A, k, n$ ) indexes expressions involving the categorical array $A$ when end is part of the $k$-th index out of $n$ indices. For example, the expression $A(e n d-1,:)$ calls A's end method with end (A, 1,2).

See Also single

Purpose
Last index in indexing expression for dataset array

## Syntax <br> end ( $A, k, n$ )

Description end $(A, k, n)$ is called for indexing expressions involving the dataset $A$ when end is part of the $k$-th index out of $n$ indices. For example, the expression A(end-1,:) calls A's end method with end (A, 1,2).

## qrandset.end

Purpose Last index in indexing expression for point set

## Syntax <br> end ( $\mathrm{p}, \mathrm{k}, \mathrm{n}$ )

## Description end $(p, k, n)$ is called for indexing expressions involving the point set $p$ when end is part of the $k$-th index out of $n$ indices. For example, the expression $p$ (end-1,:) calls p's end method with end $(p, 1,2)$.

See Also qrandset

## Purpose <br> Extreme value cumulative distribution function

## Syntax

P = evcdf(X,mu,sigma)
[P,PLO,PUP] = evcdf(X,mu,sigma,pcov,alpha)
Description
$P=\operatorname{evcdf}(X, m u$, sigma) computes the cumulative distribution function
(cdf) for the type 1 extreme value distribution, with location parameter mu and scale parameter sigma, at each of the values in $\mathrm{X} . \mathrm{X}, \mathrm{mu}$, and sigma can be vectors, matrices, or multidimensional arrays that all have the same size. A scalar input is expanded to a constant array of the same size as the other inputs. The default values for mu and sigma are 0 and 1, respectively.
[P,PLO,PUP] = evcdf(X,mu,sigma,pcov,alpha) produces confidence bounds for $P$ when the input parameters mu and sigma are estimates. pcov is a 2 -by- 2 covariance matrix of the estimated parameters. alpha has a default value of 0.05 , and specifies $100(1$ - alpha) $\%$ confidence bounds. PLO and PUP are arrays of the same size as P, containing the lower and upper confidence bounds.

The function evcdf computes confidence bounds for P using a normal approximation to the distribution of the estimate

$$
\frac{X-\hat{\mu}}{\hat{\sigma}}
$$

and then transforming those bounds to the scale of the output P. The computed bounds give approximately the desired confidence level when you estimate mu, sigma, and pcov from large samples, but in smaller samples other methods of computing the confidence bounds might be more accurate.

The type 1 extreme value distribution is also known as the Gumbel distribution. The version used here is suitable for modeling minima; the mirror image of this distribution can be used to model maxima by negating X. See "Extreme Value Distribution" on page B-32 for more details. If $x$ has a Weibull distribution, then $X=\log (x)$ has the type 1 extreme value distribution.

See Also cdf | evpdf | evinv \| evstat | evfit | evlike | evrnd<br>How To . "Extreme Value Distribution" on page B-32

Purpose
Syntax
Description
Extreme value parameter estimates

```
parmhat = evfit(data)
[parmhat,parmci] = evfit(data)
[parmhat,parmci] = evfit(data,alpha)
[...] = evfit(data,alpha,censoring)
[...] = evfit(data,alpha,censoring,freq)
[...] = evfit(data,alpha,censoring,freq,options)
```

parmhat = evfit(data) returns maximum likelihood estimates of the parameters of the type 1 extreme value distribution given the data in the vector data. parmhat (1) is the location parameter, , and parmhat(2) is the scale parameter, $\sigma$.
[parmhat, parmci] = evfit(data) returns $95 \%$ confidence intervals for the parameter estimates on the and $\sigma$ parameters in the 2 -by- 2 matrix parmci. The first column of the matrix of the extreme value fit contains the lower and upper confidence bounds for the parameter , and the second column contains the confidence bounds for the parameter $\sigma$.
[parmhat,parmci] = evfit(data,alpha) returns 100(1-alpha)\% confidence intervals for the parameter estimates, where alpha is a value in the range [ $\left.\begin{array}{ll}0 & 1\end{array}\right]$ specifying the width of the confidence intervals. By default, alpha is 0.05 , which corresponds to $95 \%$ confidence intervals.
[...] = evfit(data,alpha, censoring) accepts a Boolean vector, censoring, of the same size as data, which is 1 for observations that are right-censored and 0 for observations that are observed exactly.
[...] = evfit(data,alpha,censoring,freq) accepts a frequency vector, freq of the same size as data. Typically, freq contains integer frequencies for the corresponding elements in data, but can contain any nonnegative values. Pass in [] for alpha, censoring, or freq to use their default values.
[...] = evfit(data,alpha, censoring,freq,options) accepts a structure, options, that specifies control parameters for the iterative algorithm the function uses to compute maximum likelihood
estimates. You can create options using the function statset. Enter statset('evfit') to see the names and default values of the parameters that evfit accepts in the options structure. See the reference page for statset for more information about these options.
The type 1 extreme value distribution is also known as the Gumbel distribution. The version used here is suitable for modeling minima; the mirror image of this distribution can be used to model maxima by negating X. See "Extreme Value Distribution" on page B-32 for more details. If $x$ has a Weibull distribution, then $X=\log (x)$ has the type 1 extreme value distribution.

## How To <br> - "Extreme Value Distribution" on page B-32

## Purpose <br> Extreme value inverse cumulative distribution function

Syntax

Description
$X=\operatorname{evinv(P,mu,sigma)~}$
[X,XLO,XUP] = evinv(P,mu,sigma,pcov,alpha)
$X=\operatorname{evinv}(P, m u$, sigma) returns the inverse cumulative distribution function (cdf) for a type 1 extreme value distribution with location parameter mu and scale parameter sigma, evaluated at the values in $P$. $P$, mu, and sigma can be vectors, matrices, or multidimensional arrays that all have the same size. A scalar input is expanded to a constant array of the same size as the other inputs. The default values for mu and sigma are 0 and 1, respectively.
[X,XLO,XUP] = evinv(P,mu,sigma,pcov,alpha) produces confidence bounds for $X$ when the input parameters mu and sigma are estimates. pcov is the covariance matrix of the estimated parameters. alpha is a scalar that specifies $100(1-a l p h a) \%$ confidence bounds for the estimated parameters, and has a default value of 0.05 . XLO and XUP are arrays of the same size as $X$ containing the lower and upper confidence bounds.

The function evinv computes confidence bounds for P using a normal approximation to the distribution of the estimate

$$
\hat{\mu}+\hat{\sigma} q
$$

where $q$ is the Pth quantile from an extreme value distribution with parameters $\mu=0$ and $\sigma=1$. The computed bounds give approximately the desired confidence level when you estimate mu, sigma, and pcov from large samples, but in smaller samples other methods of computing the confidence bounds might be more accurate.

The type 1 extreme value distribution is also known as the Gumbel distribution. The version used here is suitable for modeling minima; the mirror image of this distribution can be used to model maxima by negating X. See "Extreme Value Distribution" on page B-32 for more details. If $x$ has a Weibull distribution, then $X=\log (x)$ has the type 1 extreme value distribution.

## Purpose Test handle equality

Syntax
h1 == h2
tf = eq(h1, h2)

Description $\quad \mathrm{h} 1==\mathrm{h} 2$ performs element-wise comparisons between handle arrays h 1 and h2. h 1 and h2 must be of the same dimensions unless one is a scalar. The result is a logical array of the same dimensions, where each element is an element-wise equality result. If one of h1 or h2 is scalar, scalar expansion is performed and the result will match the dimensions of the array that is not scalar.
$\mathrm{tf}=\mathrm{eq}(\mathrm{h} 1, \mathrm{~h} 2)$ stores the result in a logical array of the same dimensions.

## CompactTreeBagger.error

| Purpose | Error (misclassification probability or MSE) |
| :---: | :---: |
| Syntax | $\operatorname{err}=\operatorname{error}(\mathrm{B}, \mathrm{X}, \mathrm{Y})$ |
|  | err = error(B,X,Y,'param1', val1,'param2', val2,...) |

err $=\operatorname{error}(B, X, Y)$ computes the misclassification probability (for classification trees) or mean squared error (MSE, for regression trees) for each tree, for predictors $X$ given true response $Y$. For classification, $Y$ can be either a numeric vector, character matrix, cell array of strings, categorical vector or logical vector. For regression, Y must be a numeric vector. err is a vector with one error measure for each of the NTrees trees in the ensemble B.
err = error(B,X,Y,'param1',val1,'param2', val2,...) specifies optional parameter name/value pairs:
'mode ' String indicating how the method computes errors. If set to 'cumulative' (default), error computes cumulative errors and err is a vector of length NTrees, where the first element gives error from trees(1), second element gives error fromtrees(1:2) etc, up to trees(1:NTrees). If set to 'individual', err is a vector of length NTrees, where each element is an error from each tree in the ensemble. If set to 'ensemble', err is a scalar showing the cumulative error for the entire ensemble.
'trees ' Vector of indices indicating what trees to include in this calculation. By default, this argument is set to 'all' and the method uses all trees. If 'trees' is a numeric vector, the method returns a vector of length NTrees for 'cumulative' and 'individual' modes, where NTrees is the number of elements in the input vector, and a scalar for 'ensemble' mode. For example, in the 'cumulative ' mode, the first element gives error from trees (1), the second element gives error from trees(1:2) etc.

## CompactTreeBagger.error

> 'treeweights ' Vector of tree weights. This vector must have the same length as the 'trees ' vector. The method uses these weights to combine output from the specified trees by taking a weighted average instead of the simple non-weighted majority vote. You cannot use this argument in the 'individual' mode.

See Also TreeBagger.error

## TreeBagger.error

| Purpose | Error (misclassification probability or MSE) |
| :---: | :---: |
| Syntax | ```err = error(B,X,Y) err = error(B,X,Y,'param1',val1,'param2',val2,...)``` |
| Description | err $=\operatorname{error}(B, X, Y)$ computes the misclassification probability for classification trees or mean squared error (MSE) for regression trees for each tree, for predictors $X$ given true response $Y$. For classification, $Y$ can be either a numeric vector, character matrix, cell array of strings, categorical vector or logical vector. For regression, Y must be a numeric vector. err is a vector with one error measure for each of the NTrees trees in the ensemble B. |
|  | err $=\operatorname{error}(B, X, Y, ' p a r a m 1 '$, val1, 'param2', val2,.. ) specifies optional parameter name/value pairs: |
|  | 'mode ' String indicating how the method computes errors. If set to 'cumulative' (default), error computes cumulative errors and err is a vector of length NTrees, where the first element gives error from trees(1), second element gives error fromtrees (1:2) etc, up to trees(1:NTrees). If set to 'individual', err is a vector of length NTrees, where each element is an error from each tree in the ensemble. If set to 'ensemble', err is a scalar showing the cumulative error for the entire ensemble. |
|  | 'trees ' Vector of indices indicating what trees to include in this calculation. By default, this argument is set to 'all' and the method uses all trees. If 'trees' is a numeric vector, the method returns a vector of length NTrees for 'cumulative' and 'individual' modes, where NTrees is the number of elements in the input vector, and a scalar for 'ensemble' mode. For example, in the 'cumulative ' mode, the first element gives error from trees(1), the second element gives error from trees(1:2) etc. |

> 'treeweights ' Vector of tree weights. This vector must have the same length as the 'trees' vector. The method uses these weights to combine output from the specified trees by taking a weighted average instead of the simple non-weighted majority vote. You cannot use this argument in the 'individual' mode.

See Also CompactTreeBagger.error

Purpose Predicted responses
Syntax $\quad$ yfit $=\operatorname{eval}(t, x)$
yfit = eval(t, X,s)
[yfit, nodes] = eval(...)
[yfit,nodes,cnums] = eval(...)
[...] = t(X)
$[\ldots]=t(X, s)$

## Description

yfit $=$ eval( $\mathrm{t}, \mathrm{X}$ ) takes a classification or regression tree t and a matrix $X$ of predictors, and produces a vector yfit of predicted response values. For a regression tree, yfit(i) is the fitted response value for a point having the predictor values $\mathrm{X}(\mathrm{i},:$ ). For a classification tree, yfit(i) is the class into which the tree assigns the point with data X(i,:).
yfit $=$ eval( $\mathrm{t}, \mathrm{x}, \mathrm{s})$ takes an additional vector s of pruning levels, with 0 representing the full, unpruned tree. $t$ must include a pruning sequence as created by classregtree or by prune. If s has $k$ elements and X has $n$ rows, the output yfit is an $n$-by- $k$ matrix, with the j th column containing the fitted values produced by the $s(j)$ subtree. $s$ must be sorted in ascending order.

To compute fitted values for a tree that is not part of the optimal pruning sequence, first use prune to prune the tree.
[yfit, nodes] = eval(...) also returns a vector nodes the same size as yfit containing the node number assigned to each row of $X$. Use view to display the node numbers for any node you select.
[yfit,nodes,cnums] = eval(...) is valid only for classification trees. It returns a vector cnum containing the predicted class numbers.

NaN values in X are treated as missing. If eval encounters a missing value when it attempts to evaluate the split rule at a branch node, it cannot determine whether to proceed to the left or right child node. Instead, it sets the corresponding fitted value equal to the fitted value assigned to the branch node.

$$
[\ldots]=t(X) \text { or }[\ldots]=t(X, s) \text { also invoke eval. }
$$

Examples Create a classification tree for Fisher's iris data:

```
load fisheriris;
t = classregtree(meas,species,...
    'names',{'SL' 'SW' 'PL' 'PW'})
t =
Decision tree for classification
1 if PL<2.45 then node 2 elseif PL>=2.45 then node 3 else setosa
2 class = setosa
3 if PW<1.75 then node 4 elseif PW>=1.75 then node 5 else versicolor
4 if PL<4.95 then node 6 elseif PL>=4.95 then node 7 else versicolor
5 class = virginica
6 if PW<1.65 then node 8 elseif PW>=1.65 then node 9 else versicolor
7 class = virginica
8 class = versicolor
9 class = virginica
view(t)
```

Find assigned class names:
sfit = eval(t,meas);
Compute that proportion is correctly classified:

```
pct = mean(strcmp(sfit,species))
pct =
    0.9800
```

| Purpose | Extreme value negative log-likelihood |
| :---: | :---: |
| Syntax | nlogL = evlike(params,data) |
|  | [nlogL,AVAR] = evlike(params,data) |
|  | [...] = evlike(params,data, censoring) |
|  | [...] = evlike(params,data, censoring,freq) |

How To . "Extreme Value Distribution" on page B-32

## Description

nlogL = evlike(params, data) returns the negative of the log-likelihood for the type 1 extreme value distribution. params(1) is the tail location parameter, mu, and params (2) is the scale parameter, sigma. nlogL is a scalar.
[nlogL,AVAR] = evlike(params, data) returns the inverse of Fisher's information matrix, AVAR. If the input parameter values in params are the maximum likelihood estimates, the diagonal elements of AVAR are their asymptotic variances. AVAR is based on the observed Fisher's information, not the expected information.
[...] = evlike(params,data, censoring) accepts a Boolean vector of the same size as data, which is 1 for observations that are right-censored and 0 for observations that are observed exactly.
[...] = evlike(params,data, censoring,freq) accepts a frequency vector of the same size as data. freq typically contains integer frequencies for the corresponding elements in data, but can contain any nonnegative values. Pass in [] for censoring to use its default value.
The type 1 extreme value distribution is also known as the Gumbel distribution. The version used here is suitable for modeling minima; the mirror image of this distribution can be used to model maxima by negating data. See "Extreme Value Distribution" on page B-32 for more details. If $x$ has a Weibull distribution, then $X=\log (x)$ has the type 1 extreme value distribution.

## prob.ExponentialDistribution

Superclasses ToolboxFittableParametricDistribution
Purpose Exponential probability distribution object
Description prob.ExponentialDistribution is an object consisting of parameters, a model description, and sample data for an exponential probability distribution.

Create a probability distribution object with specified parameter values using makedist. Alternatively, fit a distribution to data using fitdist or dfittool.

## Construction

pd $=$ makedist('Exponential') creates an exponential probability distribution object using the default parameter values.
pd = makedist('Exponential','mu',mu) creates an exponential probability distribution object using the specified parameter value.

## Input Arguments

## mu - Mean

1 (default) | positive scalar value
Mean of the exponential distribution, specified as a positive scalar value.

```
Data Types
single | double
```

## Properties

mu
Mean of the exponential distribution, stored as a positive scalar value.

## Data Types <br> single | double <br> DistributionName

Name of the probability distribution, stored as a valid probability distribution name string. This property is read-only.

## Data Types <br> char <br> InputData

Data used for distribution fitting, stored as a structure containing the following:

- data: Data vector used for distribution fitting.
- cens: Censoring vector, or empty if none.
- freq: Frequency vector, or empty if none.

This property is read-only.

## Data Types

single | double
IsTruncated
Logical flag for truncated distribution, stored as a logical value. If IsTruncated equals 0 , the distribution is not truncated.
If IsTruncated equals 1 , the distribution is truncated. This property is read-only.

## Data Types

logical

## NumParameters

Number of parameters for the probability distribution, stored as a positive integer value. This property is read-only.

## Data Types

single | double

## ParameterCovariance

Covariance matrix of the parameter estimates, stored as a $p$-by- $p$ matrix, where $p$ is the number of parameters in the distribution. The ( $i, j$ ) element is the covariance between the estimates of the ith parameter and the $j$ th parameter. The ( $\mathrm{i}, \mathrm{i}$ ) element is the

## prob.ExponentialDistribution

estimated variance of the ith parameter. If parameter $i$ is fixed rather than estimated by fitting the distribution to data, then the ( $i, i$ ) elements of the covariance matrix are 0 . This property is read-only.

## Data Types

single | double

## ParameterDescription

Descriptions of distribution parameters, stored as a cell array of strings. Each cell contains a short description of one distribution parameter. This property is read-only.

## Data Types <br> char

## ParameterlsFixed

Logical flag for fixed parameters, stored as an array of logical values. If 0 , the corresponding parameter in the ParameterNames array is not fixed. If 1, the corresponding parameter in the ParameterNames array is fixed. This property is read-only.

## Definitions Exponential Distribution

The exponential distribution is used to model events that occur randomly over time, and its main application area is studies of lifetimes. It is a special case of the gamma distribution with the shape parameter $a=1$.

The exponential distribution uses the following parameters.

| Parameter | Description | Support |
| :--- | :--- | :--- |
| mu | Mean | $\mu>0$ |

The probability density function (pdf) is

$$
f(x \mid \mu)=\frac{1}{\mu} e^{\frac{-x}{\mu}} \quad ; \quad x \geq 0
$$

## Examples Create an Exponential Distribution Object Using Default Parameters

Create an exponential distribution object using the default parameter values.

```
pd = makedist('Exponential')
pd =
```

```
Exponential distribution
    mu = 1
```

## Create an Exponential Distribution Object Using Specified Parameters

Create an exponential distribution object by specifying the parameter values.

```
pd = makedist('Exponential','mu',2)
pd =
```

    ExponentialDistribution
    Exponential distribution
        mu = 2
    Compute the variance of the distribution.

Purpose Exponential cumulative distribution function
Syntax $\quad \begin{aligned} & P=\operatorname{expcdf}(X, m u) \\ & {[P, \operatorname{PLO}, P U P]=\operatorname{expcdf}(X, m u, p c o v, \text { alpha })}\end{aligned}$
Description

Examples
The following code shows that the median of the exponential distribution is $* \log (2)$.

```
mu = 10:10:60;
p = expcdf(log(2)*mu,mu)
p =
    0.5000}00.5000 0.5000 0.5000 0.5000 0.5000
```

What is the probability that an exponential random variable is less than or equal to the mean, $\mu$ ?

```
mu = 1:6;
x = mu;
p = expcdf(x,mu)
p =
    0.6321 0.6321 0.6321 0.6321 0.6321 0.6321
```

Purpose Exponential parameter estimates

```
Syntax muhat = expfit(data)
[muhat,muci] = expfit(data)
[muhat,muci] = expfit(data,alpha)
[...] = expfit(data,alpha,censoring)
[...] = expfit(data,alpha,censoring,freq)
```

## Description

## Examples

muhat $=$ expfit(data) estimates the mean of an exponentially distributed sample data. Each entry of muhat corresponds to the data in a column of data.
[muhat,muci] = expfit(data) returns $95 \%$ confidence intervals for the mean parameter estimates in matrix muci. The first row of muci contains the lower bounds of the confidence intervals, and the second row contains the upper bounds.
[muhat,muci] = expfit(data,alpha) returns 100(1-alpha)\% confidence intervals for the parameter estimates, where alpha is a value in the range [ 0 1] specifying the width of the confidence intervals. By default, alpha is 0.05 , which corresponds to $95 \%$ confidence intervals.
[...] = expfit(data, alpha, censoring) accepts a Boolean vector, censoring, of the same size as data, which is 1 for observations that are right-censored and 0 for observations that are observed exactly. data must be a vector in order to pass in the argument censoring.
[...] = expfit(data,alpha, censoring,freq) accepts a frequency vector, freq of the same size as data. Typically, freq contains integer frequencies for the corresponding elements in data, but can contain any nonnegative values. Pass in [] for alpha, censoring, or freq to use their default values.

The following estimates the mean mu of exponentially distributed data, and returns a $95 \%$ confidence interval for the estimate:

```
mu = 3;
data = exprnd(mu,100,1); % Simulated data
```

```
[muhat,muci] = expfit(data)
muhat =
    2.7511
muci =
    2.2826
    3.3813
```

## ExhaustiveSearcher

Superclasses NeighborSearcher
Purpose Nearest neighbors search using exhaustive search
Description

An ExhaustiveSearcher object performs $k \mathrm{NN}$ ( $k$-nearest neighbor) search using exhaustive search. Search objects store information about the data used, and the distance metric and parameters. The search performance for this object, compared with the KDTreeSearcher object, tends to be better for larger dimensions ( 10 or more) and worse for smaller dimensions. For more information on search objects, see "What Are Search Objects?" on page 15-17.

## Construction NS = ExhaustiveSearcher(X, 'Name', Value) constructs an

 ExhaustiveSearcher object based on $X$, where rows of $X$ correspond to observations and columns correspond to variables, using one or more optional name/value pairs. You can then use this object to find neighbors in $X$ nearest to the query points.NS = createns(X,'NSMethod','exhaustive','Name',Value) creates an ExhaustiveSearcher object based on $X$ using createns, where rows of $X$ correspond to observations and columns correspond to variables, using one or more optional name/value pairs. You can use this object to find neighbors in X nearest to the query points.

## Name-Value Pair Arguments

Both the ExhaustiveSearcher and the createns functions accept one or more of the following optional name/value pairs as input:

## 'Distance'

A string or function handle specifying the default distance metric used when you call the knnsearch method.

- 'euclidean' - Euclidean distance (default).
- 'seuclidean' - Standardized Euclidean distance. Each coordinate difference between rows in $X$ and the query matrix is scaled by dividing by the corresponding element of the standard
deviation computed from X, S=nanstd (X). To specify another value for $S$, use the Scale argument.
- 'cityblock' - City block distance.
- 'chebychev' - Chebychev distance (maximum coordinate difference).
- 'minkowski' - Minkowski distance.
- 'mahalanobis' - Mahalanobis distance, computed using a positive definite covariance matrix $C$. The default value of $C$ is nancov ( X ). To change the value of C , use the Cov parameter.
- 'cosine' - One minus the cosine of the included angle between observations (treated as vectors).
- 'correlation' - One minus the sample linear correlation between observations (treated as sequences of values).
- 'spearman' - One minus the sample Spearman's rank correlation between observations (treated as sequences of values).
- 'hamming' - Hamming distance, percentage of coordinates that differ.
- 'jaccard' - One minus the Jaccard coefficient, the percentage of nonzero coordinates that differ.
- custom distance function - A distance function specified using @ (for example, @distfun). A distance function must be of the form function D2 = distfun(ZI, ZJ), taking as arguments a 1-by- $n$ vector ZI containing a single row from X or from the query points Y , an $m 2$-by- $n$ matrix ZJ containing multiple rows of $X$ or $Y$, and returning an $m 2$-by- 1 vector of distances D2, whose $j$ th element is the distance between the observations ZI and $\mathrm{ZJ}(j,:)$.

For more information on these distance metrics, see "Distance Metrics" on page 15-9.

## ExhaustiveSearcher

## 'P'

A positive scalar indicating the exponent of Minkowski distance. This parameter is only valid when Distance is 'minkowski'. Default is 2 .

## 'Cov'

A positive definite matrix indicating the covariance matrix when computing the Mahalanobis distance. This parameter is only valid when Distance is 'mahalanobis'. Default is nancov ( X ).

## 'Scale'

A vector $S$ with the length equal to the number of columns in X. Each coordinate of $X$ and each query point is scaled by the corresponding element of $S$ when computing the standardized Euclidean distance. This parameter is only valid when Distance is 'seuclidean'. Default is nanstd ( X ).

## Properties <br> X

A matrix used to create the object

## Distance

A string specifying a built-in distance metric or a function handle that you provide when you create the object. This property is the default distance metric used when you call the knnsearch method to find nearest neighbors for future query points.

## DistParameter

Specifies the additional parameter for the chosen distance metric. The value is:

- If 'Distance' is 'minkowski': A positive scalar indicating the exponent of the Minkowski distance.
- If 'Distance' is 'mahalanobis': A positive definite matrix representing the covariance matrix used for computing the Mahalanobis distance.
- If 'Distance' is 'seuclidean': A vector representing the scale value of the data when computing the 'seuclidean' distance.
- Otherwise: Empty.

Create an ExhaustiveSearcher object using createns:

```
load fisheriris
x = meas(:,3:4);
NS = createns(x,'NsMethod','exhaustive',...
    'distance','minkowski')
```

## ExhaustiveSearcher

NS =
ExhaustiveSearcher
Properties:
X: [150x2 double]
Distance: 'minkowski'
DistParameter: 2
For more in-depth examples using the knnsearch method, see the method reference page or see "Example: Classifying Query Data Using knnsearch" on page 15-18.

## Purpose

Exponential inverse cumulative distribution function
Syntax
$\mathrm{X}=\operatorname{expinv}(\mathrm{P}, \mathrm{mu})$
[X,XLO,XUP] = expinv(X,mu,pcov,alpha)
$X=\operatorname{expinv}(P, m u)$ computes the inverse of the exponential cdf with parameters specified by mean parameter mu for the corresponding probabilities in P. P and mu can be vectors, matrices, or multidimensional arrays that all have the same size. A scalar input is expanded to a constant array with the same dimensions as the other input. The parameters in mu must be positive and the values in $P$ must lie on the interval [01].
$[\mathrm{X}, \mathrm{XLO}, \mathrm{XUP}]=\operatorname{expinv}(\mathrm{X}, \mathrm{mu}, \mathrm{pcov}, \mathrm{alpha})$ produces confidence bounds for $X$ when the input mean parameter $m u$ is an estimate. $p c o v$ is the variance of the estimated mu. alpha specifies $100(1-$ alpha $) \%$ confidence bounds. The default value of alpha is 0.05 . XLO and XUP are arrays of the same size as $X$ containing the lower and upper confidence bounds. The bounds are based on a normal approximation for the distribution of the log of the estimate of mu. If you estimate mu from a set of data, you can get a more accurate set of bounds by applying expfit to the data to get a confidence interval for mu, and then evaluating expinv at the lower and upper end points of that interval.
The inverse of the exponential cdf is

$$
x=F^{-1}(p \mid \mu)=-\mu \ln (1-p)
$$

The result, $x$, is the value such that an observation from an exponential distribution with parameter $\mu$ will fall in the range $[0 x]$ with probability $p$.

## Examples

Let the lifetime of light bulbs be exponentially distributed with $\mu=700$ hours. What is the median lifetime of a bulb?

```
expinv(0.50,700)
ans =
```

Suppose you buy a box of " 700 hour" light bulbs. If 700 hours is the mean life of the bulbs, half of them will burn out in less than 500 hours.

Purpose Write dataset array to file

```
Syntax export(DS,'file',filename)
export(DS)
export(DS,'file',filename,'Delimiter',delim)
export(DS,'XLSfile',filename)
export(DS,'XPTFile',filename)
export(DS,...,'WriteVarNames',false)
export(DS,...,'WriteObsNames',false)
```

## Description

export(DS,'file',filename) writes the dataset array DS to a tab-delimited text file, including variable names and observation names, if present. If the observation names exist, the name in the first column of the first line of the file is the first dimension name for the dataset (by default, 'Observations'). export overwrites any existing file named filename.
export(DS) writes to a text file whose default name is the name of the dataset array DS appended by '.txt'. If export cannot construct the file name from the dataset array input, it writes to the file 'dataset.txt'. export overwrites any existing file.
export(DS,'file',filename,'Delimiter', delim) writes the dataset array DS to a text file using the delimiter delim. delim must be one of the following:

- ' ' or 'space'
- ' $\backslash t$ ' or 'tab'
- ', ' or 'comma'
- ';' or 'semi'
- '|' or 'bar'
export(DS,'XLSfile', filename) writes the dataset array DS to a Microsoft ${ }^{\circledR}$ Excel spreadsheet file, including variable names and observation names (if present). You can specify the 'Sheet' and
'Range' parameter name/value pairs, with parameter values as accepted by the xlsread function.
export(DS, 'XPTFile', filename) writes the dataset array DS to a SAS XPORT format file. When writing to an XPORT format file, variables must be scalar valued. export saves observation names to a variable called obsnames, unless the WriteObsNames parameter described below is false. The XPORT format restricts the length of variable names to eight characters; longer variable names are truncated.
export(DS,..., 'WriteVarNames', false) does not write the variable names to the text file. export(DS,..., 'WriteVarNames', true) is the default, writing the names as column headings in the first line of the file.
export(DS,...,'WriteObsNames',false) does not write the observation names to the text file. export(DS,...,'WriteObsNames', true) is the default, writing the names as the first column of the file.

In some cases, export creates a text file that does not represent A exactly, as described below. If you use dataset to read the file back into MATLAB, the new dataset array may not have exactly the same contents as the original dataset array. Save A as a MAT-file if you need to import it again as a dataset array.
export writes out numeric variables using long g format, and categorical or character variables as unquoted strings.

For non-character variables with more than one column, export writes out multiple delimiter-separated fields on each line, and constructs suitable column headings for the first line of the file.
export writes out variables that have more than two dimensions as a single empty field in each line of the file.
For cell-valued variables, export writes out the contents of each cell only when the cell contains a single row, and writes out a single empty field otherwise.

## dataset.export

In some cases, export creates a file that cannot be read back into MATLAB using dataset. Writing a dataset array that contains a cell-valued variable whose cell contents are not scalars results in a mismatch in the file between the number of fields on each line and the number of column headings on the first line. Writing a dataset array that contains a cell-valued variable whose cell contents are not all the same length results in a different number of fields on each line in the file. Therefore, if you might need to import a dataset array again, save it as a .mat file.

## Examples Move data between external text files and dataset arrays in the

 MATLAB workspace:```
A = dataset('file','sat2.dat','delimiter',',')
A =
    Test Gender Score
    'Verbal' 'Male' 470
    'Verbal' 'Female' 530
    'Quantitative' 'Male' 520
    'Quantitative' 'Female' 480
export(A(A.Score > 500,:),'file','HighScores.txt')
B = dataset('file','HighScores.txt','delimiter','\t')
B =
    Test
    'Verbal' 'Female' 530
    'Quantitative' 'Male' 520
```

How To
The exponential pdf is

$$
y=f(x \mid \mu)=\frac{1}{\mu} e^{\frac{-x}{\mu}}
$$

The exponential distribution is appropriate for modeling waiting

```
y = exppdf(5,1:5)
y =
    0.0067
y = exppdf(1:5,1:5)
y =
    0.3679
```

pdf | expcdf | expinv | expstat | expfit | explike | exprnd

- "Exponential Distribution" on page B-29
$Y=\operatorname{exppdf}(X, m u)$ returns the pdf of the exponential distribution with mean parameter mu, evaluated at the values in $X . X$ and mu can be vectors, matrices, or multidimensional arrays that have the same size. A scalar input is expanded to a constant array with the same dimensions as the other input. The parameters in mu must be positive.

The exponential pdf is the gamma pdf with its first parameter equal to 1 . times when the probability of waiting an additional period of time is independent of how long you have already waited. For example, the probability that a light bulb will burn out in its next minute of use is relatively independent of how many minutes it has already burned.
Purpose Exponential random numbers

```
Syntax \(\quad R=\operatorname{exprnd}(m u)\)
\(R=\operatorname{exprnd}(m u, m, n, \ldots)\)
\(R=\operatorname{exprnd}(m u,[m, n, \ldots])\)
```

## prob.ExtremeValueDistribution

Superclasses ToolboxFittableParametricDistribution
Purpose Extreme value probability distribution object
Description prob.ExtremeValueDistribution is an object consisting of parameters, a model description, and sample data for an extreme value probability distribution.

Create a probability distribution object with specified parameter values using makedist. Alternatively, fit a distribution to data using fitdist or dfittool.

## Construction

pd = makedist('ExtremeValue') creates an extreme value probability distribution object using the default parameter values.
pd = makedist('ExtremeValue','mu',mu,'sigma',sigma) creates an extreme value probability distribution object using the specified parameter values.

## Input Arguments

## mu - Location parameter

0 (default) | scalar value
Location parameter of the extreme value distribution, specified as a scalar value.

Data Types
single | double

## sigma-Scale parameter

1 (default) | nonnegative scalar value
Scale parameter of the extreme value distribution, specified as a nonnegative scalar value.

Data Types<br>single | double

## Properties

mu
Location parameter of the extreme value distribution, stored as a scalar value.

## Data Types <br> single | double <br> sigma

Scale parameter of the extreme value distribution, stored as a nonnegative scalar value.

Data Types
single | double

## DistributionName

Name of the probability distribution, stored as a valid probability distribution name string. This property is read-only.

## Data Types

char

## InputData

Data used for distribution fitting, stored as a structure containing the following:

- data: Data vector used for distribution fitting.
- cens: Censoring vector, or empty if none.
- freq: Frequency vector, or empty if none.

This property is read-only.
Data Types
single | double

## IsTruncated

Logical flag for truncated distribution, stored as a logical value. If IsTruncated equals 0 , the distribution is not truncated.

## prob.ExtremeValueDistribution

If IsTruncated equals 1 , the distribution is truncated. This property is read-only.

## Data Types

logical

## NumParameters

Number of parameters for the probability distribution, stored as a positive integer value. This property is read-only.

## Data Types <br> single | double

## ParameterCovariance

Covariance matrix of the parameter estimates, stored as a $p$-by- $p$ matrix, where $p$ is the number of parameters in the distribution. The ( $\mathrm{i}, \mathrm{j}$ ) element is the covariance between the estimates of the $i$ th parameter and the $j$ th parameter. The ( $i, i$ ) element is the estimated variance of the ith parameter. If parameter $i$ is fixed rather than estimated by fitting the distribution to data, then the (i,i) elements of the covariance matrix are 0 . This property is read-only.

## Data Types

single | double

## ParameterDescription

Descriptions of distribution parameters, stored as a cell array of strings. Each cell contains a short description of one distribution parameter. This property is read-only.

## Data Types <br> char

## Parameterlsfixed

Logical flag for fixed parameters, stored as an array of logical values. If 0 , the corresponding parameter in the ParameterNames array is not fixed. If 1 , the corresponding parameter in the ParameterNames array is fixed. This property is read-only.

## Data Types

logical

## ParameterNames

Names of distribution parameters, stored as a cell array of strings. This property is read-only.

## Data Types

char

## ParameterValues

Values of distribution parameters, stored as a vector. This property is read-only.

## Data Types

single | double

## Truncation

Truncation interval for the probability distribution, stored as a vector containing the lower and upper truncation boundaries. This property is read-only.

## Data Types

## Definitions Extreme Value Distribution

The extreme value distribution is appropriate for modeling the smallest value from a distribution whose tails decay exponentially fast, for example, the normal distribution. It can also model the largest value from a distribution, such as the normal or exponential distributions, by using the negative of the original values.

The extreme value distribution uses the following parameters.

| Parameter | Description | Support |
| :--- | :--- | :--- |
| mu | Location parameter | $-\infty<\mu<\infty$ |
| sigma | Scale parameter | $\sigma \geq 0$ |

The probability density function (pdf) is

$$
f(x \mid \mu, \sigma)=\sigma^{-1} \exp \left(\frac{x-\mu}{\sigma}\right) \exp \left(-\exp \left(\frac{x-\mu}{\sigma}\right)\right) ;-\infty<x<\infty .
$$

This form of the probability density function is suitable for modeling the minimum value. To model the maximum value, use the negative of the original values.

## Examples Create an Extreme Value Distribution Object Using Default Parameters

Create an extreme value distribution object using the default parameter values.

```
pd = makedist('ExtremeValue')
pd =
```

## ExtremeValueDistribution

```
Extreme Value distribution
        mu = 0
        sigma = 1
```

## Create an Extreme Value Distribution Object Using Specified Parameters

Create an extreme value distribution object by specifying the parameter values.

```
pd = makedist('ExtremeValue', 'mu',-1,'sigma',2)
```

## prob.ExtremeValueDistribution

```
pd =
    ExtremeValueDistribution
    Extreme Value distribution
            mu = -1
    sigma = 2
```

Compute the standard deviation for the distribution.
$s=s t d(p d)$
s =

## Purpose Factor analysis

## Syntax

```
lambda = factoran(X,m)
[lambda,psi] = factoran(X,m)
[lambda,psi,T] = factoran(X,m)
[lambda,psi,T,stats] = factoran(X,m)
[lambda,psi,T,stats,F] = factoran(X,m)
[...] = factoran(...,param1,val1,param2,val2,...)
```

## Definitions

## Description

factoran computes the maximum likelihood estimate (MLE) of the factor loadings matrix $\Lambda$ in the factor analysis model

$$
x=\mu+\Lambda f+e
$$

where $x$ is a vector of observed variables, $\mu$ is a constant vector of means, $\Lambda$ is a constant d-by-m matrix of factor loadings, $f$ is a vector of independent, standardized common factors, and $e$ is a vector of independent specific factors. $x, \mu$, and $e$ are of length d . $f$ is of length m.
Alternatively, the factor analysis model can be specified as

$$
\operatorname{cov}(x)=\Lambda \Lambda^{T}+\Psi
$$

where $\Psi=\operatorname{cov}(e)$ is a d-by-d diagonal matrix of specific variances.
lambda $=$ factoran $(X, m)$ returns the maximum likelihood estimate, lambda, of the factor loadings matrix, in a common factor analysis model with $m$ common factors. $X$ is an $n$-by-d matrix where each row is an observation of $d$ variables. The ( $i, j$ ) th element of the $d-b y-m$ matrix lambda is the coefficient, or loading, of the $j$ th factor for the ith variable. By default, factoran calls the function rotatefactors to rotate the estimated factor loadings using the 'varimax' option.
[lambda,psi] = factoran(X,m) also returns maximum likelihood estimates of the specific variances as a column vector psi of length $d$.
[lambda, psi,T] = factoran(X,m) also returns the m-by-m factor loadings rotation matrix $T$.
[lambda, psi, T,stats] = factoran(X,m) also returns a structure stats containing information relating to the null hypothesis, $\mathrm{H}_{0}$, that the number of common factors is m . stats includes the following fields:

| Field | Description |
| :--- | :--- |
| loglike | Maximized log-likelihood value |
| $d f e$ | Error degrees of freedom $=\left((d-m)^{\wedge} 2-(d+m)\right) / 2$ |
| chisq | Approximate chi-squared statistic for the null hypothesis |
| $p$ | Right-tail significance level for the null hypothesis |

factoran does not compute the chisq and $p$ fields unless dfe is positive and all the specific variance estimates in psi are positive (see "Heywood Case" on page 20-718 below). If $X$ is a covariance matrix, then you must also specify the 'nobs ' parameter if you want factoran to compute the chisq and $p$ fields.
[lambda, psi, T, stats, F] = factoran(X,m) also returns, in F, predictions of the common factors, known as factor scores. $F$ is an $n$-by-m matrix where each row is a prediction of $m$ common factors. If $X$ is a covariance matrix, factoran cannot compute $F$. factoran rotates $F$ using the same criterion as for lambda.
[...] = factoran(..., param1, val1,param2, val2,...) enables you to specify optional parameter name/value pairs to control the model fit and the outputs. The following are the valid parameter/value pairs.

| Parameter | Value |  |
| :--- | :--- | :--- |
| 'xtype' | Type of input in the matrix X . 'xtype ' can be one <br> of: |  |
|  | 'data' | Raw data (default) |
|  | 'covariance | Positive definite covariance or <br> correlation matrix |

| Parameter | Value |  |
| :---: | :---: | :---: |
| 'scores' | Method for predicting factor scores. 'scores ' is ignored if X is not raw data. |  |
|  | $\begin{aligned} & \text { 'wls' } \\ & \hline \text { 'Bartlett' } \end{aligned}$ | Synonyms for a weighted least-squares estimate that treats F as fixed (default) |
|  | 'regression <br> 'Thomson' | Synonyms for a minimum mean squared error prediction that is equivalent to a ridge regression |
| 'start' | Starting point for the specific variances psi in the maximum likelihood optimization. Can be specified as: |  |
|  | 'random' | Chooses d uniformly distributed values on the interval $[0,1]$. |
|  | 'Rsquared' | Chooses the starting vector as a scale factor times diag (inv(corrcoef(X))) (default). For examples, see Jöreskog [2]. |
|  | Positive integer | Performs the given number of maximum likelihood fits, each initialized as with 'random'. factoran returns the fit with the highest likelihood. |
|  | Matrix | Performs one maximum likelihood fit for each column of the specified matrix. The ith optimization is initialized with the values from the ith column. The matrix must have d rows. |

$\left.\begin{array}{l|l|l}\hline \text { Parameter } & \text { Value } \\ \hline \text { 'rotate' } & \begin{array}{l}\text { Method used to rotate factor loadings and scores. } \\ \text { 'rotate' can have the same values as the } \\ \text { 'Method ' parameter of rotatefactors. See } \\ \text { the reference page for rotatefactors for a full } \\ \text { description of the available methods. }\end{array} \\ \hline & \text { 'none' } & \text { Performs no rotation. } \\ \hline & \text { 'equamax' } & \begin{array}{l}\text { Special case of the orthomax } \\ \text { rotation. Use the 'normalize', } \\ \text { 'reltol', and 'maxit 'parameters } \\ \text { to control the details of the rotation. }\end{array} \\ \hline & \text { 'orthomax' } & \begin{array}{l}\text { Orthogonal rotation that maximizes } \\ \text { a criterion based on the variance of } \\ \text { the loadings. } \\ \text { Use the ' coeff', 'normalize', }\end{array} \\ \text { 'reltol', and 'maxit 'parameters } \\ \text { to control the details of the rotation. }\end{array}\right\}$

| Parameter | Value |  |
| :---: | :---: | :---: |
|  | 'procrustes ${ }^{\text {' }}$ | Performs either an oblique (the default) or an orthogonal rotation to best match a specified target matrix in the least squares sense. <br> Use the 'type ' parameter to choose the type of rotation. Use 'target to specify the target matrix. |
|  | 'promax ' | Performs an oblique procrustes rotation to a target matrix determined by factoran as a function of an orthomax solution. <br> Use the 'power' parameter to specify the exponent for creating the target matrix. Because 'promax' uses 'orthomax' internally, you can also specify the parameters that apply to 'orthomax'. |
|  | 'quartimax' | Special case of the orthomax rotation (default). Use the 'normalize', 'reltol', and 'maxit' parameters to control the details of the rotation. |
|  | 'varimax' | Special case of the orthomax rotation (default). Use the 'normalize', <br> 'reltol', and 'maxit' parameters to control the details of the rotation. |

| Parameter | Value |
| :---: | :---: |
|  | Function <br> Function handle to rotation function of the form <br> $[B, T]=$ <br> myrotation(A,...) <br> where $A$ is a d-by-m matrix of unrotated factor loadings, $B$ is a d-by-m matrix of rotated loadings, and T is the corresponding m -by-m rotation matrix. <br> Use the factoran parameter 'userargs' to pass additional arguments to this rotation function. See "Example 4" on page 20-723. |
| 'coeff' | Coefficient, often denoted as $\gamma$, defining the specific 'orthomax' criterion. Must be from 0 to 1. The value 0 corresponds to quartimax, and 1 corresponds to varimax. Default is 1 . |
| 'normalize' | Flag indicating whether the loading matrix should be row-normalized (1) or left unnormalized (0) for 'orthomax' or 'varimax' rotation. Default is 1 . |
| 'reltol' | Relative convergence tolerance for 'orthomax' or 'varimax' rotation. Default is sqrt(eps). |
| 'maxit' | Iteration limit for 'orthomax' or 'varimax' rotation. Default is 250. |
| 'target' | Target factor loading matrix for 'procrustes' rotation. Required for 'procrustes ' rotation. No default value. |
| 'type' | Type of 'procrustes' rotation. Can be 'oblique' (default) or 'orthogonal'. |

| Parameter | Value |
| :--- | :--- |
| 'power' | Exponent for creating the target matrix in the <br> 'promax' rotation. Must be $\geq$ 1. Default is 4. |
| 'userargs' | Denotes the beginning of additional input values <br> for a user-defined rotation function. factoran <br> appends all subsequent values, in order and <br> without processing, to the rotation function <br> argument list, following the unrotated factor <br> loadings matrix A. See "Example 4" on page 20-723. |
| 'nobs' | If x is a covariance or correlation matrix, indicates <br> the number of observations that were used in its <br> estimation. This allows calculation of significance <br> for the null hypothesis even when the original data <br> are not available. There is no default. 'nobs ' is <br> ignored if X is raw data. |
| 'delta' | Lower bound for the specific variances psi during <br> the maximum likelihood optimization. Default is |
| 0.005. |  | | Structure that specifies control parameters for |
| :--- |
| the iterative algorithm the function uses to |
| compute maximum likelihood estimates. Create |
| this structure with the function statset. Enter |
| statset ( 'factoran' ) to see the names and |
| default values of the parameters that factoran |
| accepts in the options structure. See the reference |
| page for statset for more information about these |
| options. |

Tips

## Observed Data Variables

The variables in the observed data matrix $X$ must be linearly independent, i.e., $\operatorname{cov}(X)$ must have full rank, for maximum likelihood estimation to succeed. factoran reduces both raw data and a covariance matrix to a correlation matrix before performing the fit.
factoran standardizes the observed data $X$ to zero mean and unit variance before estimating the loadings lambda. This does not affect the model fit, because MLEs in this model are invariant to scale. However, lambda and psi are returned in terms of the standardized variables, i.e., lambda*lambda'+diag(psi) is an estimate of the correlation matrix of the original data $X$ (although not after an oblique rotation). See "Example 1" on page 20-718 and "Example 3" on page 20-720.

## Heywood Case

If elements of psi are equal to the value of the 'delta' parameter (i.e., they are essentially zero), the fit is known as a Heywood case, and interpretation of the resulting estimates is problematic. In particular, there can be multiple local maxima of the likelihood, each with different estimates of the loadings and the specific variances. Heywood cases can indicate overfitting (i.e., $m$ is too large), but can also be the result of underfitting.

## Rotation of Factor Loadings and Scores

Unless you explicitly specify no rotation using the 'rotate' parameter, factoran rotates the estimated factor loadings, lambda, and the factor scores, F. The output matrix T is used to rotate the loadings, i.e., lambda $=$ lambda0*T, where lambda0 is the initial (unrotated) MLE of the loadings. T is an orthogonal matrix for orthogonal rotations, and the identity matrix for no rotation. The inverse of T is known as the primary axis rotation matrix, while $T$ itself is related to the reference axis rotation matrix. For orthogonal rotations, the two are identical.
factoran computes factor scores that have been rotated by inv( $T^{\prime}$ ), i.e., $F=F 0$ * $\operatorname{inv}\left(T^{\prime}\right)$, where $F 0$ contains the unrotated predictions. The estimated covariance of $F$ is $\operatorname{inv}\left(T^{\prime} * T\right)$, which, for orthogonal or no rotation, is the identity matrix. Rotation of factor loadings and scores is an attempt to create a more easily interpretable structure in the loadings matrix after maximum likelihood estimation.

## Examples Example 1

Load the carbig data, and fit the default model with two factors.

```
load carbig
X = [Acceleration Displacement Horsepower MPG Weight];
X = X(all(~isnan(X),2),:);
[Lambda,Psi,T,stats,F] = factoran(X,2,...
    'scores','regression');
inv(T'*T) % Estimated correlation matrix of F, == eye(2)
Lambda*Lambda'+diag(Psi) % Estimated correlation matrix
Lambda*inv(T) % Unrotate the loadings
F*T' % Unrotate the factor scores
biplot(Lambda,... % Create biplot of two factors
    'LineWidth',2,...
    'MarkerSize',20)
```

## factoran

## Example 2

Although the estimates are the same, the use of a covariance matrix rather than raw data doesn't let you request scores or significance level:
[Lambda,Psi,T] = factoran(cov(X),2,'xtype','cov')
[Lambda,Psi,T] = factoran(corrcoef(X),2,'xtype','cov')

## Example 3

Use promax rotation:
[Lambda,Psi,T,stats,F] = factoran(X,2,'rotate','promax',... 'powerpm',4);

```
inv(T'*T) % Est'd corr of F,
    % no longer eye(2)
Lambda*inv(T'*T)*Lambda'+diag(Psi) % Est'd corr of X
```

Plot the unrotated variables with oblique axes superimposed.

```
invT = inv(T)
LambdaO = Lambda*invT
line([-invT(1,1) invT(1,1) NaN -invT(2,1) invT(2,1)], ...
    [-invT(1,2) invT(1,2) NaN -invT(2,2) invT(2,2)], ...
    'Color','r','linewidth',2)
hold on
biplot(Lambda0,...
    'LineWidth',2,...
    'MarkerSize',20)
xlabel('Loadings for unrotated Factor 1')
ylabel('Loadings for unrotated Factor 2')
```

## factoran

Plot the rotated variables against the oblique axes:
biplot(Lambda,'LineWidth', 2, 'MarkerSize', 20)

## Example 4

Syntax for passing additional arguments to a user-defined rotation function:
[Lambda,Psi,T] = ...
factoran(X,2,'rotate',@myrotation,'userargs',1,'two');

See Also<br>biplot | pca | procrustes | pcacov | rotatefactors | statset

Purpose Fraction of in-bag observations
Description The FBoot property is the fraction of observations to be randomly selected with replacement for each bootstrap replica. The size of each replica is given by $n *$ FBoot, where $n$ is the number of observations in the training set. The default value is 1 .

Purpose $\quad F$ cumulative distribution function

## Syntax $\quad P=\operatorname{fcdf}(X, V 1, V 2)$

Description $\quad P=\operatorname{fcdf}(X, V 1, V 2)$ computes the $F$ cdf at each of the values in $X$ using the corresponding numerator degrees of freedom V1 and denominator degrees of freedom V2. X, V1, and V2 can be vectors, matrices, or multidimensional arrays that are all the same size. A scalar input is expanded to a constant matrix with the same dimensions as the other inputs. V1 and V2 parameters must contain real positive values.

The $F$ cdf is

$$
p=F\left(x \mid v_{1}, v_{2}\right)=\int_{0}^{x} \frac{\Gamma\left[\frac{\left(v_{1}+v_{2}\right)}{2}\right]}{\Gamma\left(\frac{v_{1}}{2}\right) \Gamma\left(\frac{v_{2}}{2}\right)}\left(\frac{v_{1}}{v_{2}}\right)^{\frac{v_{1}}{2}} \frac{t^{\frac{v_{1}-2}{2}}}{\left[1+\left(\frac{v_{1}}{v_{2}}\right) t\right]^{\frac{v_{1}+v_{2}}{2}}} d t
$$

The result, $p$, is the probability that a single observation from an $F$ distribution with parameters $v_{1}$ and $v_{2}$ will fall in the interval [ $\left.0 x\right]$.

Examples
The following illustrates a useful mathematical identity for the $F$ distribution:

```
nu1 = 1:5;
nu2 = 6:10;
x = 2:6;
F1 = fcdf(x,nu1,nu2)
F1 =
    0.7930
F2 = 1 - fcdf(1./x,nu2,nu1)
F2 =
    0.7930
```

## GeneralizedLinearModel.feval

## Purpose Evaluate generalized linear regression model prediction

```
Syntax \(\quad\) ypred \(=\) feval \((m d l, \operatorname{Xnew}(1), \operatorname{Xnew}(2), \ldots\), Xnew \((n)\)
```

Description

Tips

Input
Arguments

## Output Arguments

ypred
Predicted mean values at Xnew. ypred is the same size as each component of Xnew.

## GeneralizedLinearModel.feval

For binomial models, feval uses 1 as the BinomialSize parameter, so ypred is predicted probabilities.

For models with an offset, feval uses 0 as the offset value.

## Examples Predict Responses Using feval

Generate a generalized linear model, and plot its responses to a range of input data.

Generate artificial data for the model, Poisson random numbers with two underlying predictors $\mathrm{X}(1)$ and $\mathrm{X}(2)$.

```
rng('default') % for reproducibility
rndvars = randn(100,2);
X = [2+rndvars(:,1),rndvars(:,2)];
mu = exp(1 + X*[1;2]);
y = poissrnd(mu);
```

Create a generalized linear regression model of Poisson data.

```
mdl = GeneralizedLinearModel.fit(X,y,...
    'y ~ x1 + x2','distr','poisson');
```

Generate a range of values for $X(1)$ and $X(2)$, and plot the model predictions at those values.

```
[Xtest1 Xtest2] = meshgrid(-1:.5:3,-2:.5:2);
Z = feval(mdl,Xtest1,Xtest2);
surf(Xtest1,Xtest2,Z)
```

## GeneralizedLinearModel.feval

Alternatives

Related Examples

## See Also

predict gives the same predictions, but uses a single input array with one observation in each row, rather than one component in each input argument.
random predicts with added noise.

## LinearModel.feval

## Purpose Evaluate linear regression model prediction

```
Syntax
ypred = feval(mdl,Xnew(1),Xnew(2),\ldots.,Xnew(n)
```

Description

## Input Arguments

## Output <br> Arguments

## Examples

ypred
Predicted mean values at Xnew. ypred is the same size as each component of Xnew.

For models with an offset, feval uses 0 as the offset value.

## Plot Different Categorical Levels

Fit a mileage model to the smallcar data, including the Year categorical predictor. Superimpose fitted curves on a scatter plot of the data.

Load the data and fit a model.

```
load carsmall
ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);
mdl = LinearModel.fit(ds,'MPG ~ Year + Weight^2');
```

Create a scatter plot of the mileage versus weight.
gscatter(ds.Weight,ds.MPG,ds.Year);

Use feval to plot curves of the model predictions for the various years and weights.

```
w = linspace(min(ds.Weight),max(ds.Weight))';
line(w, feval(mdl,w, '70'), 'Color', 'r')
line(w,feval(mdl,w,'76'),'Color', 'g')
line(w,feval(mdl,w,'82'),'Color','b')
```

## Alternatives

predict gives the same predictions, but uses a single input array with one observation in each row, rather than one component in each input argument. predict also gives confidence intervals on its predictions. random predicts with added noise.

[^5]Tutorials<br>- "feval" on page 9-40<br>- "Linear Regression Workflow" on page 9-43

How To . "Linear Regression" on page 9-11

## Purpose Evaluate nonlinear regression model prediction

```
Syntax
ypred = feval(mdl,Xnew(1),Xnew(2),\ldots.,Xnew(n)
```

Description

## Input

Arguments

## Output Arguments

## Examples

## ypred

Predicted mean values at Xnew. ypred is the same size as each component of Xnew.

## Predict a Nonlinear Model from a Dataset Array

Create a nonlinear model for auto mileage based on the carbig data. Predict the mileage of an average automobile.

Load the data and create a nonlinear model.

## NonLinearModel.feval

```
load carbig
ds = dataset(Horsepower,Weight,MPG);
modelfun = @(b,x)b(1) + b(2)*x(:,1).^b(3) + ...
    b(4)*x(:,2).^b(5);
beta0 = [-50 500 -1 500 -1];
mdl = NonLinearModel.fit(ds,modelfun,beta0);
```

Find the predicted mileage of an average auto. The data contain some observations with NaN , so compute the mean using nanmean.

Xnew = nanmean([Horsepower Weight]); MPGnew = feval(mdl,Xnew)

MPGnew =
21.8073
Alternatives predict gives the same predictions, but uses a single input array withone observation in each row, rather than one component in each inputargument. predict also gives confidence intervals on its predictions.random predicts with added noise.

Purpose Two-level full factorial design
Syntax dFF2 = ff2n(n)
Description dFF2 $=f f 2 n(n)$ gives factor settings dFF2 for a two-level full factorialdesign with n factors. dFF2 is $m$-by-n, where $m$ is the number oftreatments in the full-factorial design. Each row of dFF2 correspondsto a single treatment. Each column contains the settings for a singlefactor, with values of 0 and 1 for the two levels.
Examples

dFF2 $=\mathrm{ff} 2 \mathrm{n}(3)$

dFF2 =

    \(0 \quad 0 \quad 0\)
    
    \(0 \quad 0 \quad 1\)
    
    \(0 \quad 1 \quad 0\)
    
    011
    
    100
    
    \(1 \quad 0 \quad 1\)
    
    \(1 \quad 10\)
    
    \(1 \quad 1 \quad 1\)

## TreeBagger.fillProximities

Purpose Proximity matrix for training data

```
Syntax
\(B=\) fillProximities(B)
B = fillProximities(B,'param1',val1,'param2',val2,...)
```

Description $\quad B=$ fillProximities $(B)$ computes a proximity matrix for the training data and stores it in the Properties field of B.

B = fillProximities(B,'param1',val1,'param2', val2,...) specifies optional parameter name/value pairs:

| 'trees' | Either 'all' or a vector of indices of the trees in <br> the ensemble to be used in computing the proximity <br> matrix. Default is 'all'. |
| :--- | :--- |
| 'nprint' | Number of training cycles (grown trees) after which <br> TreeBagger displays a diagnostic message showing <br> training progress. Default is no diagnostic messages. |
|  |  |

See Also CompactTreeBagger.outlierMeasure | CompactTreeBagger.proximity

## Purpose Find objects matching specified conditions

Syntax $\quad h m=$ findobj(h, 'conditions')

Description The findobj method of the handle class follows the same syntax as the MATLAB findobj command, except that the first argument must be an array of handles to objects.
hm = findobj(h, 'conditions') searches the handle object array $h$ and returns an array of handle objects matching the specified conditions. Only the public members of the objects of $h$ are considered when evaluating the conditions.

See Also<br>findobj | qrandstream

## qrandstream.findprop

Purpose Find property of MATLAB handle object

## Syntax $\quad p=$ findprop(h,'propname')

Description $\quad p=$ findprop( $h$, 'propname') finds and returns the meta.property object associated with property name propname of scalar handle object h. propname must be a string. It can be the name of a property defined by the class of $h$ or a dynamic property added to scalar object $h$.

If no property named propname exists for object $h$, an empty meta.property array is returned.

See Also dynamicprops | findobj | meta.property | qrandstream

## Purpose $\quad F$ inverse cumulative distribution function

$$
\text { Syntax } \quad x=\operatorname{finv}(P, V 1, V 2)
$$

Description $\quad \mathrm{X}=\mathrm{finv}(\mathrm{P}, \mathrm{V} 1, \mathrm{~V} 2)$ computes the inverse of the $F$ cdf with numerator degrees of freedom V1 and denominator degrees of freedom V2 for the corresponding probabilities in P. P, V1, and V2 can be vectors, matrices, or multidimensional arrays that all have the same size. A scalar input is expanded to a constant array with the same dimensions as the other inputs.

V1 and V2 parameters must contain real positive values, and the values in $P$ must lie on the interval [01].

The $F$ inverse function is defined in terms of the $F$ cdf as

$$
x=F^{-1}\left(p \mid v_{1}, v_{2}\right)=\left\{x: F\left(x \mid v_{1}, v_{2}\right)=p\right\}
$$

where

$$
p=F\left(x \mid v_{1}, v_{2}\right)=\int_{0}^{x} \frac{\Gamma\left[\frac{\left(v_{1}+v_{2}\right)}{2}\right]}{\Gamma\left(\frac{v_{1}}{2}\right) \Gamma\left(\frac{v_{2}}{2}\right)}\left(\frac{v_{1}}{v_{2}}\right)^{\frac{v_{1}}{2}} \frac{t^{\frac{v_{1}-2}{2}}}{\left[1+\left(\frac{v_{1}}{v_{2}}\right) t^{\frac{v_{1}+v_{2}}{2}}\right.} d t
$$

Examples Find a value that should exceed $95 \%$ of the samples from an $F$ distribution with 5 degrees of freedom in the numerator and 10 degrees of freedom in the denominator.

$$
\begin{aligned}
& x=\operatorname{finv}(0.95,5,10) \\
& x= \\
& 3.3258
\end{aligned}
$$

You would observe values greater than 3.3258 only $5 \%$ of the time by chance.

How To . "F Distribution" on page B-38

## ClassificationDiscriminant.fit

## Purpose

Fit discriminant analysis classifier
obj = ClassificationDiscriminant.fit(X,Y)
obj = ClassificationDiscriminant.fit(X,Y,Name, Value)

## Input

Arguments
obj $=$ ClassificationDiscriminant.fit( $\mathrm{X}, \mathrm{Y}$ ) returns a discriminant analysis classifier based on the input variables (also known as predictors, features, or attributes) $X$ and output (response) $Y$.
obj = ClassificationDiscriminant.fit(X,Y,Name, Value) fits a classifier with additional options specified by one or more Name, Value pair arguments. If you use one of the following five options, obj is of class ClassificationPartitionedModel: 'crossval', 'kfold', 'holdout', 'leaveout', or 'cvpartition'. Otherwise, obj is of class ClassificationDiscriminant.

## X

Matrix of numeric predictor values. Each column of X represents one variable, and each row represents one observation.

ClassificationDiscriminant.fit considers NaN values in X as missing values. ClassificationDiscriminant.fit does not use observations with missing values for X in the fit.

## Y

Numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. Each row of $Y$ represents the classification of the corresponding row of $X$.

ClassificationDiscriminant.fit considers NaN values in $Y$ to be missing values. ClassificationDiscriminant.fit does not use observations with missing values for $Y$ in the fit.

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding

## ClassificationDiscriminant.fit

value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ..., NameN, ValueN.

## 'ClassNames'

Array of class names. Use the data type that exists in Y.
Use ClassNames to order the classes or to select a subset of classes for training.

Default: Class names that exist in $Y$

## 'Cost'

Square matrix, where $\operatorname{Cost}(i, j)$ is the cost of classifying a point into class $j$ if its true class is i. Alternatively, Cost can be a structure S having two fields: $\mathrm{S} . \mathrm{Cl}$ assNames containing the group names as a variable of the same type as Y , and S.ClassificationCosts containing the cost matrix.

Default: $\operatorname{Cost}(i, j)=1$ if $i \sim=j$, and $\operatorname{Cost}(i, j)=0$ if $i=j$

## 'crossval'

If 'on ', creates a cross-validated classifier with 10 folds. You can use 'kfold', 'holdout', 'leaveout', or 'cvpartition' parameters to override this cross-validation setting. You can only use one of these options at a time for creating a cross-validated classifier: 'cvpartition', 'holdout', 'kfold', or 'leaveout'.

Alternatively, cross validate obj later using the crossval method.
Default: 'off'

## 'cvpartition'

Partition created with cvpartition to use in a cross-validated classifier. You can only use one of these options at a time for

## ClassificationDiscriminant.fit

creating a cross-validated classifier: 'cvpartition', 'holdout', 'kfold', or 'leaveout'.

## 'delta'

Threshold on linear coefficients, a nonnegative scalar. If a coefficient of obj has magnitude smaller than delta, obj sets this coefficient to 0 , and so you can eliminate the corresponding predictor from the model. Set delta to a higher value to eliminate more predictors.
delta must be 0 for quadratic discriminant models.
Default: 0

## 'discrimType'

String specifying the discriminant type. Case-insensitive. One of:

- 'linear'
- 'quadratic'
- 'diagLinear'
- 'diagQuadratic'
- 'pseudoLinear'
- 'pseudoQuadratic'

Default: 'linear'

## 'fillCoeffs'

String, either 'on' or 'off', specifying whether to populate the Coeffs property in the classifier object. Setting to 'on' can be computationally intensive, especially when cross validating.

Default: 'on', except 'off' when cross validating

## 'gamma'

## ClassificationDiscriminant.fit

Parameter for regularizing the correlation matrix of predictors.

- Linear discriminant - Scalar from 0 to 1.
- If you pass a value strictly between 0 and 1 , ClassificationDiscriminant.fit sets the discriminant type to 'Linear'.
- If you pass 0 for gamma and 'Linear' for DiscrimType, and if the correlation matrix is singular, ClassificationDiscriminant.fit sets gamma to the minimal value required for inverting the covariance matrix.
- If you set gamma to 1, ClassificationDiscriminant.fit sets the discriminant type to 'diagLinear'.
- Quadratic discriminant - Either 0 or 1.
- If you pass 0 for gamma and 'Quadratic' for DiscrimType, and if one of the classes has a singular covariance matrix, ClassificationDiscriminant.fit errors.
- If you set gamma to 1, ClassificationDiscriminant.fit sets the discriminant type to 'diagQuadratic'.

## 'holdout'

Holdout validation tests the specified fraction of the data, and uses the rest of the data for training. Specify a numeric scalar from 0 to 1 . You can only use one of these options at a time for creating a cross-validated classifier: 'cvpartition', 'holdout', 'kfold', or 'leaveout'.

## 'kfold'

Number of folds to use in a cross-validated classifier, a positive integer. You can only use one of these options at a time for creating a cross-validated classifier: 'cvpartition', 'holdout', 'kfold', or 'leaveout'.

## ClassificationDiscriminant.fit

Default: 10

## 'leaveout'

Use leave-one-out cross validation by setting to 'on '. You can only use one of these options at a time for creating a cross-validated classifier: 'cvpartition', 'holdout', 'kfold', or 'leaveout'.

## 'PredictorNames'

Cell array of names for the predictor variables, in the order in which they appear in X .

Default: \{'x1', 'x2', ...\}

## 'prior'

Prior probabilities for each class. Specify as one of:

- A string:
- 'empirical' determines class probabilities from class frequencies in Y. If you pass observation weights, they are used to compute the class probabilities.
- 'uniform' sets all class probabilities equal.
- A vector (one scalar value for each class)
- A structure S with two fields:
- S.ClassNames containing the class names as a variable of the same type as Y
- S.ClassProbs containing a vector of corresponding probabilities

Default: 'empirical'

## 'ResponseName'

Name of the response variable Y , a string.

## ClassificationDiscriminant.fit

Default: ' $Y$ '

## 'SaveMemory'

When 'on', ClassificationDiscriminant.fit does not store the full covariance matrix, but instead stores enough information to compute the matrix. The predict method computes the full covariance matrix for prediction, and does not store the matrix. When 'off', ClassificationDiscriminant.fit computes and stores the full covariance matrix in obj.

Set SaveMemory to 'on' when X has thousands of predictors.
Default: 'off'

## 'ScoreTransform'

Function handle for transforming scores, or string representing a built-in transformation function.

| String | Formula |
| :--- | :--- |
| ' symmetric' | $2 x-1$ |
| 'invlogit' | $\log (x /(1-x))$ |
| 'ismax' | Set score for the class with the <br> largest score to 1, and scores for all <br> other classes to 0. |
| 'symmetricismax' | Set score for the class with the <br> largest score to 1, and scores for <br> all other classes to -1. |
| 'none' | $x$ |
| 'logit' | $1 /\left(1+e^{-x}\right)$ |
| 'doublelogit ' | $1 /\left(1+e^{-2 x}\right)$ |

## ClassificationDiscriminant.fit

| String | Formula |
| :--- | :--- |
| 'symmetriclogit' | $2 /\left(1+e^{-x}\right)-1$ |
| 'sign' | -1 for $x<0$ |
|  | 0 for $x=0$ |
|  | 1 for $x>0$ |

You can include your own function handle for transforming scores. Your function should accept a matrix (the original scores) and return a matrix of the same size (the transformed scores).

Default: 'none'

## 'weights'

Vector of observation weights. The length of weights is the number of rows in X. ClassificationDiscriminant.fit normalizes the weights to sum to 1 .

Default: ones(size (X, 1), 1)

## Output obj

Arguments

## Definitions

Discriminant analysis classifier. You can use obj to predict the response of new data using the predict method.

## Discriminant Classification

The model for discriminant analysis is:

- Each class (Y) generates data (X) using a multivariate normal distribution. That is, the model assumes X has a Gaussian mixture distribution (gmdistribution).
- For linear discriminant analysis, the model has the same covariance matrix for each class, only the means vary.
- For quadratic discriminant analysis, both means and covariances of each class vary.

## ClassificationDiscriminant.fit

predict classifies so as to minimize the expected classification cost:

$$
\hat{y}=\underset{y=1, \ldots, K}{\arg \min } \sum_{k=1}^{K} \hat{P}(k \mid x) C(y \mid k),
$$

where

- $\hat{y}$ is the predicted classification.
- $K$ is the number of classes.
- $\hat{P}(k \mid x)$ is the posterior probability of class $k$ for observation $x$.
- $C(y \mid k)$ is the cost of classifying an observation as $y$ when its true class is $k$.

For details, see "How the predict Method Classifies" on page 14-6.

## Examples <br> Construct a discriminant analysis classifier for the Fisher iris data:

```
load fisheriris
obj = ClassificationDiscriminant.fit(meas,species)
obj =
ClassificationDiscriminant:
    PredictorNames: {'x1' 'x2' 'x3' 'x4'}
        ResponseName: 'Y'
            ClassNames: {'setosa' 'versicolor' 'virginica'}
    ScoreTransform: 'none'
    NObservations: 150
        DiscrimType: 'linear'
                            Mu: [3x4 double]
            Coeffs: [3x3 struct]
```

Alternatives
The classify function also performs discriminant analysis. classify is usually more awkward to use:

## ClassificationDiscriminant.fit

- classify requires you to fit the classifier every time you make a new prediction.
- classify does not perform cross validation.
- classify requires you to fit the classifier when changing prior probabilities.

How To . "Discriminant Analysis" on page 14-3

## ClassificationKNN.fit

Purpose Fit $k$-nearest neighbor classifier

Syntax $\quad$| $m d l$ | $=$ ClassificationKNN.fit $(X, Y)$ |
| :--- | :--- |
| $m d l$ | $=$ ClassificationKNN.fit $(X, Y$, Name, Value $)$ |

Description mdl = ClassificationKNN.fit( $\mathrm{X}, \mathrm{Y}$ ) returns a classification model based on the input variables (also known as predictors, features, or attributes) X and output (response) Y .
mdl = ClassificationKNN.fit(X,Y,Name, Value) fits a model with additional options specified by one or more Name, Value pair arguments.

If you use one of these options, mdl is of class ClassificationPartitionedModel: 'crossval', 'kfold', 'holdout', 'leaveout', or 'cvpartition'. Otherwise, mdl is of class ClassificationKNN.

## Input $x$ <br> Arguments

Matrix of predictor values. Each column of X represents one variable, and each row represents one observation.

## $\mathbf{Y}$

Grouping variables of response values with the same number of elements (rows) as $X$. Each entry in $Y$ is the response to the data in the corresponding row of $X$.

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN.

## 'BreakTies'

## ClassificationKNN.fit

String specifying the method predict uses to break ties if multiple classes have the same smallest cost. By default, ties occur when multiple classes have the same number of nearest points among the $K$ nearest neighbors.

- 'nearest' - Use the class with the nearest neighbor among tied groups.
- 'random' - Use a random tiebreaker among tied groups.
- 'smallest' - Use the smallest index among tied groups.

Default: 'smallest'

## 'BucketSize'

Maximum number of data points in the leaf node of the $k$ d-tree. This argument is meaningful only when NSMethod is 'kdtree'.

Default: 50

## 'CategoricalPredictors'

Specification of which predictors are categorical:

- 'all' - All predictors are categorical.
- [ ] - No predictors are categorical.

When you set CategoricalPredictors to 'all', the default Distance is 'hamming'.

Default: []

## 'ClassNames'

Array of class names. Use the data type that exists in Y .
Use ClassNames to order the classes or to select a subset of classes for training.

## ClassificationKNN.fit

Default: Class names in $Y$

## 'Cost'

Square matrix, where $\operatorname{Cost}(i, j)$ is the cost of classifying a point into class $j$ if its true class is i. Alternatively, Cost can be a structure S having two fields: S . ClassNames containing the group names as a variable of the same type as Y , and S.ClassificationCosts containing the cost matrix.

Default: $\operatorname{Cost}(i, j)=1$ if $i \sim=j$, and $\operatorname{Cost}(i, j)=0$ if $i=j$

## 'Cov'

Positive definite matrix, the covariance matrix when computing the Mahalanobis distance. This argument is only valid when 'Distance' is 'mahalanobis'.

Default: nancov (X)

## 'crossval'

If 'on', create a cross-validated model with 10 folds. Use the 'kfold', 'holdout', 'leaveout', or 'cvpartition' parameters to override this cross-validation setting. You can only use one parameter at a time to create a cross-validated model.

Alternatively, cross validate model later using the crossval method.

Default: 'off'

## 'cvpartition'

Partition created with cvpartition to use in a cross-validated model. You can only use one of these four options at a time for creating a cross-validated model: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

## 'Distance'

## ClassificationKNN.fit

String or function handle specifying the distance metric. The allowable strings depend on the NSMethod parameter, which you set in ClassificationKNN.fit, and which exists as a field in ModelParams.

| NSMethod | Distance Metric Names |
| :--- | :--- |
| exhaustive | Any distance metric of ExhaustiveSearcher |
| kdtree | 'cityblock', 'chebychev', 'euclidean ', or <br> 'minkowski' |

For definitions, see "Distance Metrics" on page 15-9.
The distance metrics of ExhaustiveSearcher:

| Value | Description |
| :--- | :--- |
| 'cityblock' | City block distance. |
| 'chebychev' | Chebychev distance (maximum coordinate <br> difference). |
| 'correlation' | One minus the sample linear correlation <br> between observations (treated as <br> sequences of values). |
| 'cosine' | One minus the cosine of the included angle <br> between observations (treated as vectors). |
| 'euclidean' | Euclidean distance. |
| 'hamming' | Hamming distance, percentage of <br> coordinates that differ. |
| 'jaccard' | One minus the Jaccard coefficient, the <br> percentage of nonzero coordinates that <br> differ. |

## ClassificationKNN.fit

\(\left.$$
\begin{array}{l|l}\hline \text { Value } & \text { Description } \\
\hline \text { 'mahalanobis' } & \begin{array}{l}\text { Mahalanobis distance, computed using a } \\
\text { positive definite covariance matrix C. The } \\
\text { default value of C is the sample covariance } \\
\text { matrix of X, as computed by nancov (X). } \\
\text { To specify a different value for C, use the } \\
\text { 'Cov' name-value pair. }\end{array} \\
\hline \text { 'minkowski' } & \begin{array}{l}\text { Minkowski distance. The default exponent } \\
\text { is 2. To specify a different exponent, use } \\
\text { the 'P' name-value pair. }\end{array} \\
\hline \text { 'seuclidean' } & \begin{array}{l}\text { Standardized Euclidean distance. Each } \\
\text { coordinate difference between X and a } \\
\text { query point is scaled, meaning divided by } \\
\text { a scale value S. The default value of S is } \\
\text { the standard deviation computed from X, } \\
\text { S = nanstd (X). To specify another value } \\
\text { for S, use the Scale name-value pair. }\end{array} \\
\hline \text { 'spearman' } & \begin{array}{l}\text { One minus the sample Spearman's rank } \\
\text { correlation between observations (treated } \\
\text { as sequences of values). }\end{array} \\
\hline \text { @distfun } & \begin{array}{l}\text { Distance function handle. distfun has } \\
\text { the form }\end{array}
$$ <br>
function D2 = DISTFUN(ZI , ZJ) <br>
\% calculation of distance <br>
I. <br>
where <br>
- ZI is a 1-by-N vector containing one row <br>

of X or Y.\end{array}\right\}\)| - ZJ is an M2-by-N matrix containing |
| :--- |
| multiple rows of X or Y. |

## ClassificationKNN.fit

| Value | Description |
| :--- | :--- |
|  | - D2 is an M2-by-1 vector of distances, <br> and D2 $(k)$ is the distance between <br> observations ZI and $\mathrm{ZJ}(J,:)$. |

Default: 'euclidean', except the default is 'hamming' when CategoricalPredictors is 'all'

## 'DistanceWeight'

String or function handle specifying the distance weighting function.

| DistanceWeight | Meaning |
| :--- | :--- |
| 'equal' | No weighting |
| 'inverse' | Weight is $1 /$ distance |
| 'squaredinverse' | Weight is $1 /$ distance $^{2}$ |
| @fcn | fcn is a function that accepts a matrix <br> of nonnegative distances, and returns <br> a matrix the same size containing |
| nonnegative distance weights. For |  |
| example, 'squaredinverse' is equivalent |  |
| to @(d)d.^(-2). |  |

Default: 'equal'

## 'Exponent'

Positive scalar specifying the exponent of Minkowski distance. This argument is only valid when 'Distance' is 'minkowski'.

Default: 2
'holdout'

## ClassificationKNN.fit

Holdout validation tests the specified fraction of the data, and uses the remaining data for training. Specify a numeric scalar from 0 to 1 . You can only use one of these four options at a time for creating a cross-validated model: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

## 'IncludeTies'

Logical value indicating whether predict includes all the neighbors whose distance values are equal to the Kth smallest distance. If IncludeTies is true, predict includes all these neighbors. Otherwise, predict uses exactly K neighbors.

Default: false

## 'kfold'

Number of folds to use in a cross-validated model, a positive integer. You can only use one of these four options at a time for creating a cross-validated model: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

Default: 10

## 'leaveout'

Use leave-one-out cross validation by setting to 'on'. You can only use one of these four options at a time for creating a cross-validated model: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

## 'NSMethod'

String specifying the nearest neighbor search method:

- 'kdtree' - Create and use a $k$ d-tree to find nearest neighbors. 'kdtree' is valid when the distance metric is one of the following:
- 'euclidean'

## ClassificationKNN.fit

- 'cityblock'
- 'minkowski'
- 'chebyshev'
- 'exhaustive' - Use the exhaustive search algorithm. The distance values from all points in X to each point in Y are computed to find nearest neighbors.

Default: 'kdtree' when $X$ has 10 or fewer columns, $X$ is not sparse, and the distance metric is a 'kdtree' type; otherwise, 'exhaustive'

## 'NumNeighbors'

Positive integer specifying the number of nearest neighbors in $X$ to find for classifying each point when predicting.

Default: 1

## 'PredictorNames'

Cell array of names for the predictor variables, in the order in which they appear in $X$.

Default: \{'x1', 'x2', ...\}

## 'prior'

Prior probabilities for each class. Specify as one of:

- A string:
- 'empirical' determines class probabilities from class frequencies in Y. If you pass observation weights, they are used to compute the class probabilities.
- 'uniform' sets all class probabilities equal.
- A vector (one scalar value for each class)

## ClassificationKNN.fit

- A structure S with two fields:
- S.ClassNames containing the class names as a variable of the same type as Y
- S.ClassProbs containing a vector of corresponding probabilities

If you set values for both weights and prior, the weights are renormalized to add up to the value of the prior probability in the respective class.

Default: 'empirical'

## 'ResponseName'

Name of the response variable Y , a string.
Default: 'Response'

## 'Scale'

Vector containing nonnegative values, with length equal to the number of columns in $X$. Each coordinate difference between $X$ and a query point is scaled by the corresponding element of Scale. This argument is only valid when 'Distance' is 'seuclidean'.

Default: nanstd (X)

## 'weights'

Vector of observation weights. The length of weights is the number of rows in X. ClassificationKNN. fit normalizes the weights in each class to add up to the value of the prior probability of the class.

Default: ones(size (X, 1), 1)

## ClassificationKNN.fit

Output mdl

mdl
$k$-nearest neighbor classifier model.

## Prediction

ClassificationKNN predicts the classification of a point Xnew using a procedure equivalent to this:

1 Find the NumNeighbors points in the training set $X$ that are nearest to Xnew.

2 Find the NumNeighbors response values $Y$ to those nearest points.
3 Assign the classification label Ynew that has largest posterior probability among the values in Y .

For details, see "Posterior Probability" on page 20-2181 in the predict documentation.

## Examples Construct a KNN Classifier

Construct a $k$-nearest neighbor classifier for the Fisher iris data, where $k=5$.

Load the data.
load fisheriris
$X=$ meas;
Y = species;
Construct a classifier for 5-nearest neighbors.
mdl = ClassificationKNN.fit(X,Y,'NumNeighbors',5)
mdl =
ClassificationKNN:
PredictorNames: \{'x1' 'x2' 'x3' 'x4'\}

## ClassificationKNN．fit

```
    ResponseName: 'Y'
    ClassNames: {'setosa' 'versicolor' 'virginica'}
ScoreTransform: 'none'
NObservations: 150
            Distance: 'euclidean'
    NumNeighbors: 5
```

## Use a Different Metric

To use the Minkowski metric，you must use an exhaustive searcher．
Load the data．
load fisheriris
$X=$ meas；
$Y=$ species；
Construct a classifier for 3－nearest neighbors with the Minkowski metric．

```
mdl = ClassificationKNN.fit(X,Y,'NumNeighbors',3,...
    'NSMethod','exhaustive','Distance','minkowski');
```

To examine mdl properties，double－click mdl in the Workspace window to open the Variable Editor．

| Workspace $\quad \rightarrow 1 \square$ |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
| 甸 $\square^{-1}$ 匋畦岛 | Stack：$\triangle$ Select | data to |  | $\checkmark$ |
| Name－ | Value | Min | Max |  |
| \＃x | ＜150x4 dou．．． | 0.1000 | 7.9000 |  |
| （3）Y | ＜150x1 cell＞ |  |  |  |
| （4）md | ＜1x1 Classi．．． |  |  |  |
| $\square$ meas | ＜150x4 dou．．． | 0.1000 | 7.9000 |  |
| （\}) species | ＜150x1 cell＞ |  |  |  |

## ClassificationTree.fit

## Purpose <br> Syntax <br> Description

## Input Arguments <br> X

Fit classification tree
tree = ClassificationTree.fit(X,Y)
tree = ClassificationTree.fit(X,Y,Name, Value)
tree $=$ ClassificationTree.fit $(X, Y)$ returns a classification tree based on the input variables (also known as predictors, features, or attributes) X and output (response) Y . tree is a binary tree, where each branching node is split based on the values of a column of $X$.
tree = ClassificationTree.fit(X,Y,Name, Value) fits a tree with additional options specified by one or more Name, Value pair arguments. You can specify several name-value pair arguments in any order as Name1, Value1, ,NameN, ValueN.

Note that using the 'crossval', 'kfold', 'holdout', 'leaveout', or 'cvpartition' options results in a tree of class ClassificationPartitionedModel. You cannot use a partitioned tree for prediction, so this kind of tree does not have a predict method.
Otherwise, tree is of class ClassificationTree, and you can use the predict method to make predictions.

A matrix of floating-point predictor values. Each column of X represents one variable, and each row represents one observation.

ClassificationTree.fit considers NaN values in $X$ as missing values. ClassificationTree.fit does not use observations with all missing values for X in the fit. ClassificationTree.fit uses observations with some missing values for $X$ to find splits on variables for which these observations have valid values.

## $\mathbf{Y}$

A numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. Each row of Y represents the classification of the corresponding

## ClassificationTree.fit

row of X . For numeric Y , consider using RegressionTree.fit instead of ClassificationTree.fit.

ClassificationTree.fit considers NaN values in $Y$ to be missing values. ClassificationTree.fit does not use observations with missing values for Y in the fit.

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN.

## 'AlgorithmForCategorical'

Algorithm to find the best split on a categorical predictor with $L$ levels for data with $K \geq 3$ classes. The available algorithms are:

| 'Exact' | Consider all $2^{L-1}-1$ <br> combinations |
| :--- | :--- |
| 'PullLeft' | Pull left by purity |
| 'PCA' | Principle component-based <br> partition[1] |
| 'OVAbyClass ' | One versus all by class |

Descriptions of the algorithms are in "Splitting Categorical Predictors" on page 15-55.

Default: ClassificationTree.fit selects the optimal subset of algorithms for each split using the known number of classes and levels of a categorical predictor. For $K=2$ classes, ClassificationTree.fit always performs the exact search.

## 'CategoricalPredictors'

## ClassificationTree.fit

List of categorical predictors. Pass CategoricalPredictors as one of:

- A numeric vector with indices from 1 to $p$, where $p$ is the number of columns of $X$.
- A logical vector of length $p$, where a true entry means that the corresponding column of X is a categorical variable.
- 'all', meaning all predictors are categorical.
- A cell array of strings, where each element in the array is the name of a predictor variable. The names must match entries in PredictorNames values.
- A character matrix, where each row of the matrix is a name of a predictor variable. The names must match entries in PredictorNames values. Pad the names with extra blanks so each row of the character matrix has the same length.

## Default: []

## 'ClassNames'

Array of class names. Use the data type that exists in $Y$.
Use ClassNames to order the classes or to select a subset of classes for training.

Default: The class names that exist in $Y$

## 'Cost'

Square matrix, where $\operatorname{Cost}(i, j)$ is the cost of classifying a point into class $j$ if its true class is $i$. Alternatively, Cost can be a structure S having two fields: S.ClassNames containing the group names as a variable of the same type as Y , and S.ClassificationCosts containing the cost matrix.

Default: $\operatorname{Cost}(i, j)=1$ if $i \sim=j$, and $\operatorname{Cost}(i, j)=0$ if $i=j$

## ClassificationTree.fit

## 'crossval'

Flag to grow a cross-validated decision tree. Possible value are 'on' or 'off'.

If 'on', ClassificationTree.fit grows a cross-validated decision tree with 10 folds. You can override this cross-validation setting using one of the 'kfold', 'holdout', 'leaveout', or 'cvpartition' name-value pair arguments. Note that you can only use one of these four options ('kfold', 'holdout', 'leaveout', or 'cvpartition') at a time when creating a cross-validated tree.

Alternatively, cross validate tree later using the crossval method.

Default: 'off'

## 'cvpartition'

Partition created with cvpartition to use in a cross-validated tree.

Note that if you use 'cvpartition', you cannot use any of the 'kfold', 'holdout', or 'leaveout ' name-value pair arguments.

## 'holdout'

Holdout validation tests the specified fraction of the data, and uses the rest of the data for training. Specify a numeric scalar from 0 to 1 .

Note that if you use 'holdout', you cannot use any of the 'cvpartition', 'kfold', or 'leaveout' name-value pair arguments.

## 'kfold'

Number of folds to use in a cross-validated tree, a positive integer.

## ClassificationTree.fit

Note that if you use 'kfold', you cannot use any of the 'cvpartition', 'holdout', or 'leaveout' name-value pair arguments.

Default: 10

## 'leaveout'

Use leave-one-out cross validation by setting to 'on'.
Note that if you use 'leaveout', you cannot use any of the 'cvpartition', 'holdout', or 'kfold' name-value pair arguments.

## 'MaxCat'

ClassificationTree.fit splits a categorical predictor using the exact search algorithm if the predictor has at most MaxCat levels in the split node. Otherwise, ClassificationTree.fit finds the best categorical split using one of the inexact algorithms.

Specify MaxCat as a numeric nonnegative scalar value. Passing a small value can lead to loss of accuracy and passing a large value can lead to long computation time and memory overload.

Default: 10

## 'MergeLeaves'

When 'on', ClassificationTree.fit merges leaves that originate from the same parent node, and that give a sum of risk values greater or equal to the risk associated with the parent node. When 'off', ClassificationTree.fit does not merge leaves.

Default: 'on'

## 'MinLeaf'

Each leaf has at least MinLeaf observations per tree leaf. If you supply both MinParent and MinLeaf,

## ClassificationTree.fit

ClassificationTree.fit uses the setting that gives larger leaves: MinParent=max (MinParent, 2*MinLeaf).

Default: 1

## 'MinParent'

Each branch node in the tree has at least MinParent observations. If you supply both MinParent and MinLeaf, ClassificationTree.fit uses the setting that gives larger leaves: MinParent=max(MinParent, 2*MinLeaf).

Default: 10

## 'NVarToSample'

Number of predictors to select at random for each split. Can be a positive integer or 'all', which means use all available predictors.

Default: 'all'

## 'PredictorNames'

A cell array of names for the predictor variables, in the order in which they appear in $X$.

Default: \{'x1','x2',...\}

## 'prior'

Prior probabilities for each class. Specify as one of:

- A string:
- 'empirical' determines class probabilities from class frequencies in Y. If you pass observation weights, they are used to compute the class probabilities.
- 'uniform' sets all class probabilities equal.

## ClassificationTree.fit

- A vector (one scalar value for each class)
- A structure S with two fields:
- S.ClassNames containing the class names as a variable of the same type as Y
- S.ClassProbs containing a vector of corresponding probabilities

If you set values for both weights and prior, the weights are renormalized to add up to the value of the prior probability in the respective class.

Default: 'empirical'

## 'Prune'

When 'on', ClassificationTree.fit grows the classification tree, and computes the optimal sequence of pruned subtrees. When 'off' ClassificationTree.fit grows the classification tree without pruning.

Default: 'on'

## 'PruneCriterion'

String with the pruning criterion, either 'error' or 'impurity'.
Default: 'error'

## 'ResponseName'

Name of the response variable Y , a string.
Default: 'Response'

## 'ScoreTransform'

## ClassificationTree.fit

Function handle for transforming scores, or string representing a built-in transformation function.

| String | Formula |
| :--- | :--- |
| 'symmetric' | $2 x-1$ |
| 'invlogit' | $\log (x /(1-x))$ |
| 'ismax' | Set score for the class with the <br> largest score to 1, and scores for all <br> other classes to 0. |
| 'symmetricismax' | Set score for the class with the <br> largest score to 1, and scores for <br> all other classes to -1. |
| 'none' | $x$ |
| 'logit' | $1 /\left(1+e^{-x}\right)$ |
| 'doublelogit' | $1 /\left(1+e^{-2 x}\right)$ |
| 'symmetriclogit' | $2 /\left(1+e^{-x}\right)-1$ |
| 'sign' | -1 for $x<0$ <br> 0 for $x=0$ <br> 1 for $x>0$ |

You can include your own function handle for transforming scores. Your function should accept a matrix (the original scores) and return a matrix of the same size (the transformed scores).

Default: 'none'

## 'SplitCriterion'

Criterion for choosing a split. One of 'gdi' (Gini's diversity index), 'twoing' for the twoing rule, or 'deviance' for maximum deviance reduction (also known as cross entropy).

Default: 'gdi'

## ClassificationTree.fit

## 'Surrogate'

String describing whether to find surrogate decision splits at each branch node. Specify as 'on', 'off', 'all', or a positive scalar value.

- When 'on', ClassificationTree.fit finds at most 10 surrogate splits at each branch node.
- When set to a positive integer value, ClassificationTree.fit finds at most the specified number of surrogate splits at each branch node.
- When set to 'all', ClassificationTree.fit finds all surrogate splits at each branch node. The 'all' setting can use much time and memory.

Use surrogate splits to improve the accuracy of predictions for data with missing values. The setting also enables you to compute measures of predictive association between predictors.

Default: 'off'

## 'weights'

Vector of observation weights. The length of weights is the number of rows in X. ClassificationTree.fit normalizes the weights in each class to add up to the value of the prior probability of the class.

Default: ones(size(X,1),1)

## Output tree

Arguments
A classification tree object.
Note that using the 'crossval', 'kfold', 'holdout', 'leaveout', or 'cvpartition' options results in a tree of class ClassificationPartitionedModel. You cannot use a partitioned

## ClassificationTree.fit

tree for prediction, so this kind of tree does not have a predict method.

Otherwise, tree is of class ClassificationTree, and you can use the predict method to make predictions.

## Definitions Impurity and Node Error

ClassificationTree splits nodes based on either impurity or node error. Impurity means one of several things, depending on your choice of the SplitCriterion name-value pair:

- Gini's Diversity Index (gdi) - The Gini index of a node is

$$
1-\sum_{i} p^{2}(i),
$$

where the sum is over the classes $i$ at the node, and $p(i)$ is the observed fraction of classes with class $i$ that reach the node. A node with just one class (a pure node) has Gini index 0; otherwise the Gini index is positive. So the Gini index is a measure of node impurity.

- Deviance ('deviance') - With $p(i)$ defined as for the Gini index, the deviance of a node is

$$
-\sum_{i} p(i) \log p(i)
$$

A pure node has deviance 0 ; otherwise, the deviance is positive.

- Twoing rule ('twoing') - Twoing is not a purity measure of a node, but is a different measure for deciding how to split a node. Let $L(i)$ denote the fraction of members of class $i$ in the left child node after a split, and $R(i)$ denote the fraction of members of class $i$ in the right child node after a split. Choose the split criterion to maximize

## ClassificationTree.fit

$$
P(L) P(R)\left(\sum_{i}|L(i)-R(i)|\right)^{2},
$$

where $P(L)$ and $P(R)$ are the fractions of observations that split to the left and right respectively. If the expression is large, the split made each child node purer. Similarly, if the expression is small, the split made each child node similar to each other, and hence similar to the parent node, and so the split did not increase node purity.

- Node error - The node error is the fraction of misclassified classes at a node. If $j$ is the class with largest number of training samples at a node, the node error is

$$
1-p(j)
$$

## Examples Construct a classification tree for the data in ionosphere.mat:

```
load ionosphere
tc = ClassificationTree.fit(X,Y)
tc =
    ClassificationTree
            PredictorNames: {1x34 cell}
                ResponseName: 'Y'
                    ClassNames: {'b' 'g'}
            ScoreTransform: 'none'
        CategoricalPredictors: []
            NObservations: 351
    Properties, Methods
```

## ClassificationTree.fit

## GeneralizedLinearModel.fit

Purpose<br>Syntax<br>Description

Create generalized linear regression model

Tips

## Input <br> Arguments

 model of a dataset array ds.mdl = GeneralizedLinearModel.fit(X,y) creates a generalized linear model of the responses $y$ to a data matrix $X$.
mdl = GeneralizedLinearModel.fit(...,modelspec) creates a generalized linear model as specified by modelspec.
mdl = GeneralizedLinearModel.fit(...,Name, Value) or mdl = more Name, Value pair arguments. you specify otherwise with the Distribution name-value pair.

## ds

```
mdl = GeneralizedLinearModel.fit(ds)
mdl = GeneralizedLinearModel.fit(X,y)
mdl = GeneralizedLinearModel.fit(...,modelspec)
mdl = GeneralizedLinearModel.fit(...,Name,Value)
mdl = GeneralizedLinearModel.fit(...,modelspec,Name,Value)
```

mdl = GeneralizedLinearModel.fit(ds) creates a generalized linear GeneralizedLinearModel.fit(..., modelspec, Name,Value) creates a generalized linear model with additional options specified by one or

- The generalized linear model mdl is a standard linear model unless
- For other methods such as stepwise or devianceTest, or properties of the GeneralizedLinearModel object, see GeneralizedLinearModel.

Dataset array, where by default the last column is the response variable, and all other columns are the predictors. Predictors can be numeric, or can be any grouping variable type, such as logical or categorical (see "Grouping Variables" on page 2-51). The response must be numeric or logical.

To set a different column as the response variable, use the ResponseVar name-value pair. To use a subset of the columns as predictors, use the PredictorVars name-value pair.

## GeneralizedLinearModel.fit

## X

Matrix of predictor values. Each column of X represents one variable, and each row represents one observation.

## $y$

Vector of response values with the same number of rows as X . Each entry in $y$ is the response to the data in the corresponding row of $X$.

## modelspec

Model specification. This is the starting model for the stepwise method. Possibilities:

- String specifying the type of model.

| String | Model Type |
| :--- | :--- |
| 'constant' | Model contains only a constant <br> (intercept) term. |
| 'linear' | Model contains an intercept and linear <br> terms for each predictor. |
| 'interactions' | Model contains an intercept, linear <br> terms, and all products of pairs of <br> distinct predictors (no squared terms). |
| 'purequadratic' | Model contains an intercept, linear <br> terms, and squared terms. |

## GeneralizedLinearModel.fit

| String | Model Type |
| :--- | :--- |
| 'quadratic' | Model contains an intercept, linear <br> terms, interactions, and squared terms. |
| 'polyijk' | Model is a polynomial with all terms <br> up to degree $i$ in the first predictor, <br> degree $j$ in the second predictor, <br> etc. Use numerals 0 through 9. For <br> example, 'poly2111' has a constant <br> plus all linear and product terms, and <br> also contains terms with predictor 1 <br> squared. |

- T-by-P+1 matrix, namely "Terms Matrix" on page 20-784, specifying terms to include in model, where $T$ is the number of terms and $P$ is the number of predictor variables, and plus one is for the response variable.
- String representing a "Formula" on page 20-787 in the form
'Y ~ terms',
where the terms are in "Wilkinson Notation" on page 20-788.

## Name-Value Pair Arguments

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN.

## 'BinomialSize'

Vector or name of a variable of the same length as the response, specifying the size of the sample (number of trials) used in fitting the binomial distribution. This is the $n$ parameter for the fitted binomial distribution. BinomialSize applies only when the Distribution parameter is 'binomial'.

## GeneralizedLinearModel.fit

BinomialSize can be a scalar, meaning all observations have the same number of trials.

As an alternative to BinomialSize, you can specify the response as a two-column vector with counts in column 1 and BinomialSize in column 2.

Default: 1

## 'CategoricalVars'

Identify the categorical variables. Choices:

- Cell array of strings of the variable names in the ds dataset array.
- Logical or numerical index vector indicating which data columns are categorical. For example, if predictors 2 and 3 out of 6 are categorical, pass either
$[2,3]$
or
logical([0 $\left.1 \begin{array}{lllll}1 & 1 & 0 & 0 & 0\end{array}\right]$

Default: For data matrix X, default is [] (none). For dataset array ds, default is to treat ds variables as categorical if they are categorical, logical, character arrays, or cell arrays of strings.

## 'DispersionFlag'

Logical value that applies only to 'binomial' and 'poisson' distributions. true causes the fitting function to estimate a dispersion parameter when computing standard errors. false causes the fitting function to use the theoretical value. The fitting function always estimates the dispersion for other distributions.

Default: false for 'binomial' and 'poisson' distributions

## GeneralizedLinearModel.fit

## 'Distribution'

Name of the distribution of the response, one of:

| 'normal' | Normal distribution |
| :--- | :--- |
| 'binomial' | Binomial distribution |
| 'poisson' | Poisson distribution |
| 'gamma' | Gamma distribution |
| 'inverse | Inverse Gaussian distribution |

Default: 'normal'

## 'Exclude'

Logical or numerical index vector indicating which observations to exclude from the fit. For example, to exclude observations 2 and 3 out of 6 , pass either
$[2,3]$
or
logical([0 $\left.1 \times 1 \begin{array}{lll}0 & 0\end{array}\right)$
Default: []

## 'Intercept'

Logical value indicating whether to include a constant term (intercept) in the model. Use Intercept only when you specify the model by a string, not a formula or matrix.

Default: true

## 'Link'

## GeneralizedLinearModel.fit

The link function to use in place of the canonical link. The link function defines the relationship $f(\mu)=X^{*} b$ between the mean response $\mu$ and the linear combination of predictors $X^{*} b$. Specify the link as follows.

| Link Function Name | Link Function | Mean (Inverse) Function |
| :---: | :---: | :---: |
| 'identity' | $f(\mu)=\mu$ | $\mu=X b$ |
| 'log' | $f(\mu)=\log (\mu)$ | $\mu=\exp (X b)$ |
| 'logit' | $f(\mu)=\log (\mu /(1-\mu))$ | $\mu=\exp (X b) /(1+\exp (X b))$ |
| 'probit' | $f(\mu)=\Phi^{-1}(\mu)$ | $\mu=\Phi(X b)$ |
| 'comploglog' | $f(\mu)=\log (-\log (1-\mu))$ | $\mu=1-\exp (-\exp (X b))$ |
| 'reciprocal' | $f(\mu)=\log (-\log (\mu))$ | $\mu=\exp (-\exp (X b))$ |
| p (a number) | $f(\mu)=\mu^{p}$ | $\mu=X b^{1 / p}$ |
| $S$ (a structure) <br> $S$ has three fields, each a function handle that accepts a vector of inputs and returns a vector the same size: <br> - S.Link - The link function <br> - S.Inverse - The inverse link function <br> - S.Derivative - The derivative of the link function | $f(\mu)=$ S. $\operatorname{Link}(\mu)$ | $\mu=$ S.Inverse( $X b$ ) |

Default: The canonical link function (see "Definitions" on page 20-784)

## 'Offset'

## GeneralizedLinearModel.fit

Vector or name of a variable with the same length as the response. GeneralizedLinearModel.fit and GeneralizedLinearModel.stepwise use Offset as an additional predictor, with a coefficient value fixed at 1.0. In other words, the formula for fitting is

```
\mu ~ Offset + (terms involving real predictors)
```

with the Offset predictor having coefficient 1.
For example, consider a Poisson regression model. Suppose the number of counts is known for theoretical reasons to be proportional to a predictor A. By using the log link function and by specifying $\log (A)$ as an offset, you can force the model to satisfy this theoretical constraint.

Default: []

## 'PredictorVars'

Identify the predictors to use for fitting. Choices:

- Cell array of strings of the variable names. The strings should be names in the ds dataset array, or the VarNames name-value pair.
- Logical or numerical index vector indicating which predictors to use. For example, to use predictors 2 and 3 out of 6, pass either
or
logical([0 1 1 0 O 0 ))
Default: All variables in X, or all variables in ds except for ResponseVar

## 'ResponseVar'

## GeneralizedLinearModel.fit

Variable that the fitting function uses for response data. Give either the variable name or its column number. Typically, you use ResponseVar when fitting a dataset array ds. Choices are:

- String of the variable name.
- Logical or numerical index vector indicating which predictors to use. For example, to use the fourth variable as the response out of six variables, pass either
'ResponseVar',[4]
or
'ResponseVar',logical([0 0001000$])$
Default: Last column of ds

## 'VarNames'

Cell array of strings, first naming the columns of $X$, and with the response variable y last. Not applicable to variables in a dataset array, because those variables already have names.

Default: \{'x1','x2', ...,'xn', 'y'\}, where $n$ is the number of columns of $X$

## 'Weights'

Vector of nonnegative observation weights.
Default: ones(size(y))

| Output mdl |  |
| :--- | :--- |
| Arguments | Generalized linear model representing a least-squares fit of the <br> link of the response to the data. |

## GeneralizedLinearModel.fit

## Definitions

## Terms Matrix

A terms matrix is a T-by- $\mathrm{P}+1$ matrix specifying terms in a model, where T is the number of terms, P is the number of predictor variables, and plus one is for the response variable. The value of $T(i, j)$ is the exponent of variable $j$ in term i. For example, if there are three predictor variables A, B, and C:

```
[0 0 0 0] % constant term or intercept
[0 1 0 0] % B; equivalently, A^0 * B^1 * C^0
[1 0 1 0] % A*C
[2 0 0 0] % A^2
[0 1 2 0] % B*(C^2)
```

The 0 at the end of each term represents the response variable. In general,

- If you have the variables in a dataset array, then a 0 must represent the response variable depending on the position of the response variable in the dataset array. For example:

Load sample data and define the dataset array.

```
load hospital
```

ds = dataset(hospital.Sex,hospital.BloodPressure(:,1), hospital.Age,...
hospital.Smoker,'VarNames',\{'Sex','BloodPressure', 'Age', 'Smoker'\});

Represent the linear model 'BloodPressure ~ 1 + Sex + Age + Smoker' in a terms matrix. The response variable is in the second column of the data set array, so there must be a column of zeros for the response variable in the second column of the term matrix.

```
T = [0 0 0 0;1 0 0 0;0 0 1 0;0 0 0 1]
\(\mathrm{T}=\)
```

| 0 | 0 | 0 | 0 |
| :--- | :--- | :--- | :--- |
| 1 | 0 | 0 | 0 |
| 0 | 0 | 1 | 0 |

## GeneralizedLinearModel.fit

$\begin{array}{llll}0 & 0 & 0 & 1\end{array}$
Redefine the dataset array.

```
ds = dataset(hospital.BloodPressure(:,1),hospital.Sex,hospital.Age,
```

hospital.Smoker, 'VarNames', \{'BloodPressure', 'Sex', 'Age', 'Smoker'\});

Now, the response variable is the first term in the data set array. Specify the same linear model, 'BloodPressure ~ 1 + Sex + Age + Smoker', using a term matrix.

```
T = [0 0 0 0;0 1 0 0;0 0 1 0;0 0 0 1]
```

$\mathrm{T}=$

| 0 | 0 | 0 | 0 |
| :--- | :--- | :--- | :--- |
| 0 | 1 | 0 | 0 |
| 0 | 0 | 1 | 0 |
| 0 | 0 | 0 | 1 |

- If you have the predictor and response variables in a matrix and column vector, then you must include a 0 for the response variable at the end of each term. For example:

Load sample data and define the matrix of predictors.

```
load carsmall
X = [Acceleration,Weight];
```

Specify the model 'MPG ~ Acceleration + Weight + Acceleration:Weight + Weight^2' using a term matrix and fit the model to data. This model includes the main effect and two way interaction terms for the variables, Acceleration and Weight, and a second order term for the variable, Weight.

```
T = [0 0 0;1 0 0;0 1 0;1 1 0;0 2 0]
T =
```

## GeneralizedLinearModel.fit

| 0 | 0 | 0 |
| :--- | :--- | :--- |
| 1 | 0 | 0 |
| 0 | 1 | 0 |
| 1 | 1 | 0 |
| 0 | 2 | 0 |

Fit a linear model.

```
mdl = LinearModel.fit(X,MPG,T)
mdl =
Linear regression model:
    y ~ 1 + x1*x2 + x2^2
```

Estimated Coefficients:

|  | Estimate | SE | tStat | PValue |
| :--- | ---: | ---: | ---: | ---: |
| ( Intercept) | 48.906 | 12.589 | 3.8847 | 0.00019665 |
| x1 | 0.54418 | 0.57125 | 0.95261 | 0.34337 |
| x2 | -0.012781 | 0.0060312 | -2.1192 | 0.036857 |
| x1: x2 | -0.00010892 | 0.00017925 | -0.6076 | 0.545 |
| x2^2 | $9.7518 e-07$ | $7.5389 e-07$ | 1.2935 | 0.19917 |

Number of observations: 94, Error degrees of freedom: 89
Root Mean Squared Error: 4.1
R-squared: 0.751, Adjusted R-Squared 0.739
F-statistic vs. constant model: 67, p-value $=4.99 \mathrm{e}-26$

Only the intercept and x2 term, which corresponds to the Weight variable, are significant at the $5 \%$ significance level.

Now, perform a stepwise regression with a constant model as the starting model and a linear model with interactions as the upper model.

```
T = [0 0 0;1 0 0;0 1 0;1 1 0];
mdl = LinearModel.stepwise(X,MPG,[0 O 0],'upper',T)
```

## GeneralizedLinearModel.fit

```
1. Adding x2, FStat = 259.3087, pValue = 1.643351e-28
mdl =
Linear regression model:
    y ~ 1 + x2
Estimated Coefficients:
\begin{tabular}{lcrrl} 
& Estimate & \multicolumn{1}{l}{ SE } & \multicolumn{1}{l}{ tStat } & pValue \\
( Intercept) & 49.238 & 1.6411 & 30.002 & \(2.7015 \mathrm{e}-49\) \\
x2 & -0.0086119 & 0.0005348 & -16.103 & \(1.6434 \mathrm{e}-28\)
\end{tabular}
Number of observations: 94, Error degrees of freedom: 92
Root Mean Squared Error: 4.13
R-squared: 0.738, Adjusted R-Squared 0.735
F-statistic vs. constant model: 259, p-value = 1.64e-28
```

The results of the stepwise regression are consistent with the results of LinearModel.fit in the previous step.

## Formula

A formula for model specification is a string of the form

```
'Y ~ terms',
```

where

- $Y$ is the response name.
- terms contains
- Variable names
-     + means include the next variable
-     - means do not include the next variable
- : defines an interaction, a product of terms
-     * defines an interaction and all lower-order terms

## GeneralizedLinearModel.fit

- ^ raises the predictor to a power, exactly as in * repeated, so ^ includes lower order terms as well
- () groups terms

Note Formulas include a constant (intercept) term by default. To exclude a constant term from the model, include -1 in the formula.

For example,

```
'Y ~ A + B + C' means a three-variable linear model with
intercept.
'Y ~ A + B + C - 1' is a three-variable linear model without
intercept.
' Y ~ A + B + C + B^2' is a three-variable model with intercept
and a \(B^{\wedge} 2\) term.
' \(Y\) ~ \(A+B^{\wedge} 2+C '\) is the same as the previous example because
\(B^{\wedge} 2\) includes a \(B\) term.
' \(Y \sim A+B+C+A: B '\) includes an \(A * B\) term.
\(' Y \sim A * B+C\) ' is the same as the previous example because \(A * B=\)
A + B + A:B.
'Y ~ A*B*C - A:B:C' has all interactions among A, B, and C, except
the three-way interaction.
'Y ~ A* (B + C + D)' has all linear terms, plus products of A with
each of the other variables.
```

## Wilkinson Notation

Wilkinson notation describes the factors present in models. The notation relates to factors present in models, not to the multipliers (coefficients) of those factors.

| Wilkinson Notation | Factors in Standard Notation |
| :--- | :--- |
| 1 | Constant (intercept) term |
| $A^{\wedge} k$, where $k$ is a positive integer | $A, A^{2}, \ldots, A^{k}$ |

## GeneralizedLinearModel.fit

| Wilkinson Notation | Factors in Standard Notation |
| :--- | :--- |
| $A+B$ | $A, B$ |
| $A * B$ | $A, B, A * B$ |
| $A: B$ | $A * B$ only |
| $-B$ | Do not include $B$ |
| $A * B+C$ | $A, B, C, A * B$ |
| $A+B+C+A: B$ | $A, B, C, A * B$ |
| $A * B * C-A: B: C$ | $A, B, C, A * B, A * C, B * C$ |
| $A *(B+C)$ | $A, B, C, A * B, A * C$ |

Statistics Toolbox notation always includes a constant term unless you explicitly remove the term using -1 .

## Canonical Link Function

The default link function for a generalized linear model is the canonical link function.

## Canonical Link Functions for Generalized Linear Models

| Distribution | Link Function <br> Name | Link Function | Mean (Inverse) <br> Function |
| :--- | :--- | :--- | :--- |
| 'normal' | 'identity' | $f(\mu)=\mu$ | $\mu=X b$ |
| 'binomial' | 'logit' | $f(\mu)=\log (\mu /(1-\mu))$ | $\mu=\exp (X b) /(1+\exp (X b))$ |
| 'poisson' | 'log' | $f(\mu)=\log (\mu)$ | $\mu=\exp (X b)$ |
| 'gamma' | -1 | $f(\mu)=1 / \mu$ | $\mu=1 /(X b)$ |
| 'inverse <br> gaussian' | -2 | $f(\mu)=1 / \mu^{2}$ | $\mu=(X b)^{-1 / 2}$ |

## GeneralizedLinearModel.fit

## Examples Fit a Generalized Linear Model

Make a logistic binomial model of the probability of smoking as a function of age, weight, and sex, using a two-way interactions model.

Load the hospital dataset array.

```
load hospital
ds = hospital; % just to use the ds name
```

Specify the model using a formula that allows up to two-way interactions.
modelspec = 'Smoker ~ Age*Weight*Sex - Age:Weight:Sex';
Create the generalized linear model.

```
mdl = GeneralizedLinearModel.fit(ds,...
    modelspec,'Distribution','binomial')
```

mdl $=$

Generalized Linear regression model:
logit(Smoker) ~ 1 + Sex*Age + Sex*Weight + Age*Weight
Distribution = Binomial

Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | :--- |
| (Intercept) | -6.0492 | 19.749 | -0.3063 | 0.75938 |
| Sex_Male | -2.2859 | 12.424 | -0.18399 | 0.85402 |
| Age | 0.11691 | 0.50977 | 0.22934 | 0.81861 |
| Weight | 0.031109 | 0.15208 | 0.20455 | 0.83792 |
| Sex_Male:Age | 0.020734 | 0.20681 | 0.10025 | 0.92014 |
| Sex_Male:Weight | 0.01216 | 0.053168 | 0.22871 | 0.8191 |
| Age:Weight | -0.00071959 | 0.0038964 | -0.18468 | 0.85348 |

[^6]
## GeneralizedLinearModel.fit

Dispersion: 1
Chi^2-statistic vs. constant model: 5.07, p-value $=0.535$

The large $p$-value indicates the model might not differ statistically from a constant.

## Alternatives <br> References

Use GeneralizedLinearModel.stepwise to select a model specification automatically. Use step, addTerms, or removeTerms to adjust a fitted model.

## Syntax

Description
obj = gmdistribution.fit( $\mathrm{X}, \mathrm{k}$ )
obj = gmdistribution.fit(...,param1,val1,param2,val2,...)
obj $=$ gmdistribution.fit ( $\mathrm{X}, \mathrm{k}$ ) uses an Expectation Maximization (EM) algorithm to construct an object obj of the gmdistribution class containing maximum likelihood estimates of the parameters in a Gaussian mixture model with k components for data in the $n$-by- $d$ matrix X , where $n$ is the number of observations and $d$ is the dimension of the data.
gmdistribution treats NaN values as missing data. Rows of X with NaN values are excluded from the fit.
obj = gmdistribution.fit(...,param1,val1,param2,val2,...) provides control over the iterative EM algorithm. Parameters and values are listed below.

| Parameter | Value |
| :--- | :--- |
| 'Start' | Method used to choose initial component parameters. <br> One of the following: |
|  | - 'randSample ' - To select k observations from X at <br> random as initial component means. The mixing <br> proportions are uniform. The initial covariance <br> matrices for all components are diagonal, where <br> the element j on the diagonal is the variance of <br> $\mathrm{X}(:, \mathrm{j})$. This is the default. |
|  | - $\mathrm{s}-\mathrm{A}$ structure array with fields mu, Sigma, <br> and PComponents. See gmdistribution for <br> descriptions of values. <br> - s-A vector of length $n$ containing an initial guess <br> of the component index for each point. |
| 'Replicates' | A positive integer giving the number of times to <br> repeat the EM algorithm, each time with a new set of |

| Parameter | Value |
| :--- | :--- |
|  | parameters. The solution with the largest likelihood <br> is returned. A value larger than 1 requires the <br> 'randSample' start method. The default is 1. |
| 'CovType' | 'diagonal' if the covariance matrices are restricted <br> to be diagonal; ' full' otherwise. The default is <br> 'full'. |
| 'SharedCov' | Logical true if all the covariance matrices are <br> restricted to be the same (pooled estimate); logical <br> false otherwise. |
| 'Regularize' | A nonnegative regularization number added to <br> the diagonal of covariance matrices to make them <br> positive-definite. The default is 0. |
| 'Options' | Options structure for the iterative EM algorithm, as <br> created by statset. gmdistribution.fit uses the <br> parameters 'Display' with a default value of 'off ', <br> 'MaxIter' with a default value of 100, and 'TolFun' <br> with a default value of 1e-6. |

In some cases, gmdistribution may converge to a solution where one or more of the components has an ill-conditioned or singular covariance matrix.

The following issues may result in an ill-conditioned covariance matrix:

- The number of dimension of your data is relatively high and there are not enough observations.
- Some of the features (variables) of your data are highly correlated.
- Some or all the features are discrete.
- You tried to fit the data to too many components.

In general, you can avoid getting ill-conditioned covariance matrices by using one of the following precautions:

- Pre-process your data to remove correlated features.
- Set 'SharedCov' to true to use an equal covariance matrix for every component.
- Set 'CovType' to 'diagonal'.
- Use 'Regularize' to add a very small positive number to the diagonal of every covariance matrix.
- Try another set of initial values.

In other cases gmdistribution may pass through an intermediate step where one or more of the components has an ill-conditioned covariance matrix. Trying another set of initial values may avoid this issue without altering your data or model.

Examples $\begin{aligned} & \text { Generate data from a mixture of two bivariate Gaussian distributions } \\ & \text { using the mvnrnd function: }\end{aligned}$

```
MU1 = [1 2];
SIGMA1 = [2 0; 0 .5];
MU2 = [-3 -5];
SIGMA2 = [1 0; 0 1];
X = [mvnrnd(MU1,SIGMA1,1000);mvnrnd(MU2,SIGMA2,1000)];
scatter(X(:,1),X(:,2),10,'.')
hold on
```

Next, fit a two-component Gaussian mixture model:

```
options = statset('Display','final');
obj = gmdistribution.fit(X,2,'Options',options);
10 iterations, log-likelihood = -7046.78
h = ezcontour(@(x,y)pdf(obj,[x y]),[-8 6],[-8 6]);
```

Among the properties of the fit are the parameter estimates:

```
ComponentMeans = obj.mu
ComponentMeans =
\[
\begin{array}{rr}
0.9391 & 2.0322 \\
-2.9823 & -4.9737
\end{array}
\]
```

```
ComponentCovariances = obj.Sigma
```

ComponentCovariances = obj.Sigma
ComponentCovariances(:,:,1) =

$$
\begin{array}{rr}
1.7786 & -0.0528 \\
-0.0528 & 0.5312
\end{array}
$$

```
```

ComponentCovariances(:,:,2) =
1.0491 -0.0150
-0.0150 0.9816
MixtureProportions = obj.PComponents
MixtureProportions =
0.5000 0.5000

```

The Akaike information is minimized by the two-component model:
```

AIC = zeros(1,4);
obj = cell(1,4);
for k = 1:4
obj{k} = gmdistribution.fit(X,k);
AIC(k)= obj{k}.AIC;
end
[minAIC,numComponents] = min(AIC);
numComponents
numComponents =
2
model = obj{2}
model =
Gaussian mixture distribution
with 2 components in 2 dimensions
Component 1:
Mixing proportion: 0.500000
Mean: 0.9391 2.0322
Component 2:
Mixing proportion: 0.500000
Mean: -2.9823 -4.9737

```

Both the Akaike and Bayes information are negative log-likelihoods for the data with penalty terms for the number of estimated parameters. They are often used to determine an appropriate number of components for a model when the number of components is unspecified.

\section*{gmdistribution.fit}

\author{
References [1] McLachlan, G., and D. Peel. Finite Mixture Models. Hoboken, NJ: John Wiley \& Sons, Inc., 2000. \\ See Also gmdistribution | cluster
}
\begin{tabular}{|c|c|}
\hline Purpose & Create linear regression model \\
\hline Syntax & ```
mdl = LinearModel.fit(ds)
mdl = LinearModel.fit(X,y)
mdl = LinearModel.fit(...,modelspec)
mdl = LinearModel.fit(...,Name,Value)
mdl = LinearModel.fit(...,modelspec,Name,Value)
``` \\
\hline Description & ```
mdl = LinearModel.fit(ds) creates a linear model of a dataset array
ds.
mdl = LinearModel.fit(X,y) creates a linear model of the responses
y to a data matrix X.
mdl = LinearModel.fit(...,modelspec) creates a linear model of the
specified type.
mdl = LinearModel.fit(...,Name,Value) or mdl =
LinearModel.fit(...,modelspec,Name,Value) creates a linear model
with additional options specified by one or more Name, Value pair
arguments.
``` \\
\hline Tips & \begin{tabular}{l}
- Use robust fitting (RobustOpts name-value pair) to reduce the effect of outliers automatically. \\
- Do not use robust fitting when you want to subsequently adjust a model using step. \\
- For other methods such as stepwise or anova, or properties of the LinearModel object, see LinearModel.
\end{tabular} \\
\hline Input Arguments & \begin{tabular}{l}
ds \\
Dataset array, where by default the last column is the response variable, and all other columns are the predictors. Predictors can be numeric, or can be any grouping variable type, such as logical or categorical (see "Grouping Variables" on page 2-51). The response must be numeric or logical.
\end{tabular} \\
\hline
\end{tabular}

\section*{LinearModel.fit}

To set a different column as the response variable, use the ResponseVar name-value pair. To use a subset of the columns as predictors, use the PredictorVars name-value pair.

\section*{X}

Matrix of predictor values. Each column of X represents one variable, and each row represents one observation.
\(y\)
Vector of response values with the same number of rows as X . Each entry in \(y\) is the response to the data in the corresponding row of \(X\).

\section*{modelspec}

Model specification. This is the starting model for the stepwise method. Possibilities:
\begin{tabular}{l|l}
\hline String & Model Type \\
\hline 'constant' & \begin{tabular}{l} 
Model contains only a constant (intercept) \\
term.
\end{tabular} \\
\hline 'linear' & \begin{tabular}{l} 
Model contains an intercept and linear \\
terms for each predictor.
\end{tabular} \\
\hline 'interactions' & \begin{tabular}{l} 
Model contains an intercept, linear \\
terms, and all products of pairs of distinct \\
predictors (no squared terms).
\end{tabular} \\
\hline 'purequadratic' & \begin{tabular}{l} 
Model contains an intercept, linear \\
terms, and squared terms.
\end{tabular} \\
\hline
\end{tabular}
\begin{tabular}{l|l}
\hline String & Model Type \\
\hline 'quadratic' & \begin{tabular}{l} 
Model contains an intercept, linear \\
terms, interactions, and squared terms.
\end{tabular} \\
\hline 'polyijk' & \begin{tabular}{l} 
Model is a polynomial with all terms \\
up to degree \(i\) in the first predictor, \\
degree \(j\) in the second predictor, etc. \\
Use numerals 0 through 9. For example, \\
'poly2111' has a constant plus all linear \\
and product terms, and also contains \\
terms with predictor 1 squared.
\end{tabular} \\
\hline
\end{tabular}
- T-by-P+1 matrix, namely "Terms Matrix" on page 20-805, specifying terms to include in model, where \(T\) is the number of terms and \(P\) is the number of predictor variables, and plus one is for the response variable.
- String representing a "Formula" on page 20-809 in the form
'Y ~ terms',
where the terms are in "Wilkinson Notation" on page 20-810.

\section*{Name-Value Pair Arguments}

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN.

\section*{'CategoricalVars'}

Identify the categorical variables. Choices:
- Cell array of strings of the variable names in the ds dataset array.

\section*{LinearModel.fit}
- Logical or numerical index vector indicating which data columns are categorical. For example, if predictors 2 and 3 out of 6 are categorical, pass either
\([2,3]\)
or
logical([0 \(\left.11 \begin{array}{llll}1 & 0 & 0 & 0\end{array}\right)\)
Default: For data matrix X, default is [] (none). For dataset array ds, default is to treat ds variables as categorical if they are categorical, logical, character arrays, or cell arrays of strings.

\section*{'Exclude'}

Logical or numerical index vector indicating which observations to exclude from the fit. For example, to exclude observations 2 and 3 out of 6 , pass either
\([2,3]\)
or
logical([0 \(\left.1 \times 1 \begin{array}{llll}0 & 0 & 0\end{array}\right)\)

Default: []

\section*{'Intercept'}

Logical value indicating whether to include a constant term (intercept) in the model. Use Intercept only when you specify the model by a string, not a formula or matrix.

Default: true

\section*{'PredictorVars'}

Identify the predictors to use for fitting. Choices:
- Cell array of strings of the variable names. The strings should be names in the ds dataset array, or the VarNames name-value pair.
- Logical or numerical index vector indicating which predictors to use. For example, to use predictors 2 and 3 out of 6 , pass either \([2,3]\)
or
```

logical([0 1 1 0 0 0])

```

Default: All variables in X, or all variables in ds except for ResponseVar

\section*{'ResponseVar'}

Variable that the fitting function uses for response data. Give either the variable name or its column number. Typically, you use ResponseVar when fitting a dataset array ds. Choices are:
- String of the variable name.
- Logical or numerical index vector indicating which predictors to use. For example, to use the fourth variable as the response out of six variables, pass either
'ResponseVar',[4]
or
'ResponseVar',logical([0 0 0 1 0 0])
Default: Last column of ds

\section*{'RobustOpts'}

Indicator of which type of robust fitting to use:

\section*{LinearModel.fit}
- 'off' — No robust fitting, LinearModel.fit uses ordinary least squares.
- 'on' — Robust fitting using the 'bisquare ' weight function.
- String - Name of the robust fitting weight function from the following table. LinearModel.fit uses the listed default tuning constant.
- Structure with the string RobustWgtFun and optional scalar Tune fields - LinearModel.fit uses the RobustWgtFun weight function and Tune tuning constant from the structure. If you do not supply a Tune field, the fitting function uses the default tuning constant.
\begin{tabular}{|c|c|c|}
\hline Weight Function & Equation & Default Tuning Constant \\
\hline 'andrews ' & \[
\begin{aligned}
& w=(\operatorname{abs}(r)<p i) \cdot * \sin (r) \\
& . / r
\end{aligned}
\] & 1.339 \\
\hline \begin{tabular}{l}
'bisquare' \\
(default)
\end{tabular} & \[
\begin{aligned}
& w=(\operatorname{abs}(r)<1) \cdot *(1- \\
& \left.r . \wedge^{2}\right) \cdot{ }^{\wedge} 2
\end{aligned}
\] & 4.685 \\
\hline 'cauchy' & \(w=1 . /(1+r . \wedge 2)\) & 2.385 \\
\hline 'fair' & \(w=1 . /(1+\operatorname{abs}(r))\) & 1.400 \\
\hline 'huber' & \(w=1 . / \max (1, \operatorname{abs}(r))\) & 1.345 \\
\hline 'logistic' & \(w=\tanh (r) . / r\) & 1.205 \\
\hline 'ols' & Ordinary least squares (no weighting function) & None \\
\hline 'talwar' & \(w=1\) * (abs (r)<1) & 2.795 \\
\hline 'welsch' & \(w=\exp (-(r . \wedge 2))\) & 2.985 \\
\hline
\end{tabular}
- Structure with the function handle RobustWgtFun and optional scalar Tune fields - LinearModel.fit uses the RobustWgtFun weight function and Tune tuning constant from the structure. Specify RobustWgtFun as a function handle that accepts a

\section*{LinearModel.fit}
or of residuals, and returns a vector of weights the same size. The fitting function scales the residuals, dividing by the tuning constant (default 1 ) and by an estimate of the error standard deviation before it calls the weight function.

Default: 'off'

\section*{'VarNames'}

Cell array of strings, first naming the columns of \(X\), and with the response variable \(y\) last. Not applicable to variables in a dataset array, because those variables already have names.

Default: \{'x1','x2',...,'xn', 'y'\}, where \(n\) is the number of columns of \(X\)

\section*{'Weights'}

Vector of nonnegative observation weights.
Default: ones(size(y))

Output
Arguments

\section*{Definitions}
mdl
Linear model representing a least-squares fit of the response to the data. If the Robust name-value pair was not [] or 'ols', the model is not a least-squares fit, but uses the robust fitting function.

\section*{Terms Matrix}

A terms matrix is a T-by- \(\mathrm{P}+1\) matrix specifying terms in a model, where T is the number of terms, P is the number of predictor variables, and plus one is for the response variable. The value of \(T(i, j)\) is the exponent of variable \(j\) in term \(i\). For example, if there are three predictor variables \(\mathrm{A}, \mathrm{B}\), and C :
```

[0 0 0 0] % constant term or intercept
[0 1 0 0] % B; equivalently, A^0 * B^1 * C^0

```

\section*{LinearModel.fit}
\(\left[\begin{array}{llll}1 & 0 & 1 & 0\end{array}\right] \% A^{*} C\)
\(\left[\begin{array}{llll}2 & 0 & 0 & 0\end{array}\right] \% A^{\wedge} 2\)
\(\left[\begin{array}{llll}0 & 1 & 2 & 0\end{array}\right] \% B^{*}\left(C^{\wedge} 2\right)\)
The 0 at the end of each term represents the response variable. In general,
- If you have the variables in a dataset array, then a 0 must represent the response variable depending on the position of the response variable in the dataset array. For example:

Load sample data and define the dataset array.
```

load hospital

```
ds = dataset(hospital.Sex, hospital.BloodPressure(:,1), hospital.Age,...
hospital.Smoker,'VarNames', \{'Sex', 'BloodPressure', 'Age','Smoker'\});

Represent the linear model 'BloodPressure ~ 1 + Sex + Age + Smoker' in a terms matrix. The response variable is in the second column of the data set array, so there must be a column of zeros for the response variable in the second column of the term matrix.
```

T = [0 0 0 0;1 0 0 0;0 0 1 0;0 0 0 1]

```
T =
\begin{tabular}{llll}
0 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{tabular}

Redefine the dataset array.
```

ds = dataset(hospital.BloodPressure(:,1),hospital.Sex,hospital.Age,...
hospital.Smoker,'VarNames',{'BloodPressure','Sex','Age','Smoker'});
Now, the response variable is the first term in the data set array. Specify the same linear model, 'BloodPressure ~ 1 + Sex + Age + Smoker', using a term matrix.

```
```

T = [0 0 0 0;0 1 0 0;0 0 1 0;0 0 0 1]
T =

| 0 | 0 | 0 | 0 |
| :--- | :--- | :--- | :--- |
| 0 | 1 | 0 | 0 |
| 0 | 0 | 1 | 0 |
| 0 | 0 | 0 | 1 |

```
- If you have the predictor and response variables in a matrix and column vector, then you must include a 0 for the response variable at the end of each term. For example:

Load sample data and define the matrix of predictors.
```

load carsmall

```
X = [Acceleration, Weight];

Specify the model 'MPG ~ Acceleration + Weight + Acceleration:Weight + Weight^2' using a term matrix and fit the model to data. This model includes the main effect and two way interaction terms for the variables, Acceleration and Weight, and a second order term for the variable, Weight.
```

T = [0 0 0;1 0 0;0 1 0;1 1 0;0 2 0]

```

T =
\begin{tabular}{lll}
0 & 0 & 0 \\
1 & 0 & 0 \\
0 & 1 & 0 \\
1 & 1 & 0 \\
0 & 2 & 0
\end{tabular}

Fit a linear model.
```

mdl = LinearModel.fit(X,MPG,T)

```
```

mdl =
Linear regression model:
y ~ 1 + x1*x2 + x2^2
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | ---: |
| (Intercept) | 48.906 | 12.589 | 3.8847 | 0.00019665 |
| x1 | 0.54418 | 0.57125 | 0.95261 | 0.34337 |
| x2 | -0.012781 | 0.0060312 | -2.1192 | 0.036857 |
| x1:x2 | -0.00010892 | 0.00017925 | -0.6076 | 0.545 |
| x2^2 | $9.7518 e-07$ | $7.5389 e-07$ | 1.2935 | 0.19917 |

```

Number of observations: 94, Error degrees of freedom: 89 Root Mean Squared Error: 4.1
R-squared: 0.751, Adjusted R-Squared 0.739
F-statistic vs. constant model: 67, p-value \(=4.99 \mathrm{e}-26\)
Only the intercept and \(x 2\) term, which corresponds to the Weight variable, are significant at the \(5 \%\) significance level.

Now, perform a stepwise regression with a constant model as the starting model and a linear model with interactions as the upper model.
```

T = [0 0 0;1 0 0;0 1 0;1 1 0];
mdl = LinearModel.stepwise(X,MPG,[0 O O],'upper',T)

```
1. Adding \(x 2\), FStat \(=259.3087, p V a l u e=1.643351 \mathrm{e}-28\)
mdl =
Linear regression model:
    \(y \sim 1+x 2\)
Estimated Coefficients:
\begin{tabular}{ccccl} 
& Estimate & SE & tStat & pValue \\
(Intercept) & 49.238 & & 1.6411 & 30.002
\end{tabular}
```

x2 -0.0086119 0.0005348 -16.103 1.6434e-28
Number of observations: 94, Error degrees of freedom: 92
Root Mean Squared Error: 4.13
R-squared: 0.738, Adjusted R-Squared 0.735
F-statistic vs. constant model: 259, p-value = 1.64e-28

```

The results of the stepwise regression are consistent with the results of LinearModel.fit in the previous step.

\section*{Formula}

A formula for model specification is a string of the form
' \(Y\) ~ terms',
where
- \(Y\) is the response name.
- terms contains
- Variable names
- + means include the next variable
- - means do not include the next variable
- : defines an interaction, a product of terms
- * defines an interaction and all lower-order terms
- ^ raises the predictor to a power, exactly as in * repeated, so ^ includes lower order terms as well
- () groups terms

\footnotetext{
Note Formulas include a constant (intercept) term by default. To exclude a constant term from the model, include -1 in the formula.
}

\section*{LinearModel.fit}

For example,
' \(Y\) ~ A + B + C' means a three-variable linear model with intercept.
' \(Y \sim A+B+C-1 '\) is a three-variable linear model without intercept.
'Y ~ A + B + C + B^2' is a three-variable model with intercept and a \(B^{\wedge} 2\) term.
'Y ~ \(A+B^{\wedge} 2+C\) ' is the same as the previous example because \(\mathrm{B}^{\wedge} 2\) includes a \(B\) term.
\(' Y \sim A+B+C+A: B '\) includes an \(A * B\) term.
' \(Y \sim A * B+C\) ' is the same as the previous example because \(A * B=\) \(A+B+A: B\).
' \(Y\) ~ A*B*C - A:B:C' has all interactions among \(A, B\), and \(C\), except the three-way interaction.
'Y ~ A* (B + C + D) ' has all linear terms, plus products of A with each of the other variables.

\section*{Wilkinson Notation}

Wilkinson notation describes the factors present in models. The notation relates to factors present in models, not to the multipliers (coefficients) of those factors.
\begin{tabular}{l|l}
\hline Wilkinson Notation & Factors in Standard Notation \\
\hline 1 & Constant (intercept) term \\
\hline\(A^{\wedge} k\), where \(k\) is a positive integer & \(A, A^{2}, \ldots, A^{k}\) \\
\hline\(A+B\) & \(A, B\) \\
\hline\(A * B\) & \(A, B, A * B\) \\
\hline\(A: B\) & \(A * B\) only \\
\hline\(-B\) & Do not include B \\
\hline\(A * B+C\) & \(A, B, C, A * B\) \\
\hline\(A+B+C+A: B\) & \(A, B, C, A * B\) \\
\hline
\end{tabular}

\section*{LinearModel.fit}
\begin{tabular}{l|l}
\hline Wilkinson Notation & Factors in Standard Notation \\
\hline\(A * B * C-A: B: C\) & \(A, B, C, A * B, A * C, B * C\) \\
\hline\(A *(B+C)\) & \(A, B, C, A * B, A * C\) \\
\hline
\end{tabular}

Statistics Toolbox notation always includes a constant term unless you explicitly remove the term using - 1 .

\section*{Examples Linear Regression Model of Matrix Data}

Fit a linear model of the Hald data.
Load the data.
load hald
X = ingredients; \% predictor variables
y = heat; \% response
Fit a default linear model to the data.
mdl = LinearModel.fit(X,y)
mdl =
Linear regression model:
\(y \sim 1+x 1+x 2+x 3+x 4\)
Estimated Coefficients:
\begin{tabular}{lrrrr} 
& Estimate & \multicolumn{1}{l}{ SE } & tStat & \multicolumn{1}{c}{ pValue } \\
(Intercept) & 62.405 & 70.071 & 0.8906 & 0.39913 \\
x1 & 1.5511 & 0.74477 & 2.0827 & 0.070822 \\
x2 & 0.51017 & 0.72379 & 0.70486 & 0.5009 \\
x3 & 0.10191 & 0.75471 & 0.13503 & 0.89592 \\
x4 & -0.14406 & 0.70905 & -0.20317 & 0.84407
\end{tabular}

Number of observations: 13, Error degrees of freedom: 8
Root Mean Squared Error: 2.45
R-squared: 0.982, Adjusted R-Squared 0.974

F-statistic vs. constant model: 111, p-value \(=4.76 \mathrm{e}-07\)

\section*{Linear Regression with Categorical Predictor and Nonlinear Model}

Fit a model of a dataset array that contains a categorical predictor. Use a nonlinear response formula.

Load the carsmall data.
load carsmall
Construct a dataset containing continuous predictor variable Weight, nominal predictor variable Year, and response variable MPG.
```

ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);

```

Create a fitted model of MPG as a function of Year, Weight, and Weight \({ }^{2}\). (You don't have to include Weight explicitly in your formula because it is a lower-order term of Weight \({ }^{2}\). For details, see "Definitions" on page 20-805.)
```

mdl = LinearModel.fit(ds,'MPG ~ Year + Weight^2')

```
mdl =
Linear regression model:
    MPG ~ 1 + Weight + Year + Weight^2
Estimated Coefficients:
\begin{tabular}{lrrrr} 
& Estimate & \multicolumn{1}{l}{ SE } & \multicolumn{1}{l}{ tStat } & \multicolumn{1}{l}{ pValue } \\
(Intercept) & 54.206 & 4.7117 & 11.505 & \(2.6648 \mathrm{e}-19\) \\
Weight & -0.016404 & 0.0031249 & -5.2493 & \(1.0283 \mathrm{e}-06\) \\
Year_76 & 2.0887 & 0.71491 & 2.9215 & 0.0044137 \\
Year_82 & 8.1864 & 0.81531 & 10.041 & \(2.6364 \mathrm{e}-16\) \\
Weight^2 & \(1.5573 \mathrm{e}-06\) & \(4.9454 \mathrm{e}-07\) & 3.149 & 0.0022303
\end{tabular}

Number of observations: 94, Error degrees of freedom: 89

\section*{LinearModel.fit}
```

Root Mean Squared Error: 2.78
R-squared: 0.885, Adjusted R-Squared 0.88
F-statistic vs. constant model: 172, p-value = 5.52e-41

```

\section*{Simultaneously Specify the Variables and Use Formula}

Simultaneously identify response and predictor variables and specify the model using formula in linear regression.

Load sample data.
load hospital

Fit a linear model with interaction terms to the data.
```

mdl = LinearModel.fit(hospital,'Weight~1+Age*Sex*Smoker-Age:Sex:Smoker
mdl =
Linear regression model:
Weight ~ 1 + Sex*Age + Sex*Smoker + Age*Smoker
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | ---: | ---: |
| (Intercept) | 118.7 | 7.0718 | 16.785 | $6.821 \mathrm{e}-3$ |
| Sex_Male | 68.336 | 9.7153 | 7.0339 | $3.3386 \mathrm{e}-1$ |
| Age | 0.31068 | 0.18531 | 1.6765 | 0.09699 |
| Smoker_1 | 3.0425 | 10.446 | 0.29127 | 0.7714 |
| Sex_Male:Age | -0.49094 | 0.24764 | -1.9825 | 0.05037 |
| Sex_Male:Smoker_1 | 0.9509 | 3.8031 | 0.25003 | 0.8031 |
| Age:Smoker_1 | -0.07288 | 0.26275 | -0.27737 | 0.7821 |

```
```

Number of observations: 100, Error degrees of freedom: 93
Root Mean Squared Error: 8.75
R-squared: 0.898, Adjusted R-Squared 0.892
F-statistic vs. constant model: 137, p-value = 6.91e-44

```

\section*{LinearModel.fit}

The weight of the patients do not seem to differ significantly according to age, or the status of smoking, or interaction of these factors with gender at the \(5 \%\) significance level.

\section*{Robust Linear Regression Model}

Fit a linear regression model of the Hald data using robust fitting.
Load the data.
```

load hald
X = ingredients; % predictor variables
y = heat; % response

```

Fit a robust linear model to the data.
```

mdl = LinearModel.fit(X,y,'linear','RobustOpts','on')
mdl =
Linear regression model (robust fit):
y ~ 1 + x1 + x2 + x3 + x4

```

Estimated Coefficients:
\begin{tabular}{lrrrr} 
& Estimate & \multicolumn{1}{l}{ SE } & tStat & \multicolumn{1}{l}{ pValue } \\
(Intercept) & 60.09 & 75.818 & 0.79256 & 0.4509 \\
x1 & 1.5753 & 0.80585 & 1.9548 & 0.086346 \\
x2 & 0.5322 & 0.78315 & 0.67957 & 0.51596 \\

R-squared: 0.979, Adjusted R-Squared 0.969
F-statistic vs. constant model: 94.6, p-value = 9.03e-07

\section*{Algorithms}

The main fitting algorithm is QR decomposition. For robust fitting, the algorithm is robustfit.

\section*{LinearModel.fit}
Alternatives You can construct a model in a range of possible models usingLinearModel.stepwise. However, you cannot use robust regressionand stepwise regression together.
See Also LinearModel | predict | LinearModel.stepwise

How To - "Linear Regression" on page 9-11

\section*{NaiveBayes.fit}
\begin{tabular}{|c|c|}
\hline Purpose & Create Naive Bayes classifier object by fitting training data \\
\hline Syntax & \[
\begin{aligned}
& \mathrm{nb}=\text { NaiveBayes.fit(training, class) } \\
& \mathrm{nb}=\text { NaiveBayes.fit(..., 'param1',val1, 'param2', val2, ...) }
\end{aligned}
\] \\
\hline \multirow[t]{3}{*}{Description} & \begin{tabular}{l}
\(\mathrm{nb}=\) NaiveBayes.fit(training, class) builds a NaiveBayes classifier object nb. training is an \(N\)-by-D numeric matrix of training data. Rows of training correspond to observations; columns correspond to features. class is a classing variable for training taking \(K\) distinct levels. Each element of class defines which class the corresponding row of training belongs to. training and class must have the same number of rows. \\
nb = NaiveBayes.fit(..., 'param1',val1, 'param2',val2, ...) specifies one or more of the following name/value pairs: \\
- 'Distribution' - a string or a 1-by-D cell vector of strings, specifying which distributions fit uses to model the data. If the value is a string, fit models all the features using one type of distribution. fit can also model different features using different types of distributions. If the value is a cell vector, its \(j\) th element specifies the distribution fit uses for the \(j\) th feature. The available types of distributions are:
\end{tabular} \\
\hline & 'normal' \({ }^{\text {(default) }}\) Normal (Gaussian) distribution. \\
\hline & 'kernel' Kernel smoothing density estimate. \\
\hline
\end{tabular}
'mvmn'
'mn' Multinomial distribution for classifying the count-based data such as the bag-of-tokens model. In the bag-of-tokens model, the value of the \(j\) th feature is the number of occurrences of the \(j\) th token in this observation, so it must be a non-negative integer. When 'mn' is used, fit considers each observation as multiple trials of a multinomial distribution, and considers each occurrence of a token as one trial. The number of categories (bins) in this multinomial model is the number of distinct tokens, i.e., the number of columns of training.
- 'Prior' - The prior probabilities for the classes, specified as one of the following:
\begin{tabular}{ll} 
'empirical' & \begin{tabular}{l} 
fit estimates the prior probabilities from the \\
(default)
\end{tabular} \\
relative frequencies of the classes in training.
\end{tabular}

\section*{NaiveBayes.fit}
\begin{tabular}{ll} 
vector & \begin{tabular}{l} 
A numeric vector of length K specifying the \\
prior probabilities in the class order of class.
\end{tabular} \\
structure & \begin{tabular}{l} 
A structure S containing class levels and their \\
prior probabilities. \(S\) must have two fields:
\end{tabular}
\end{tabular}
- S.prob: A numeric vector of prior probabilities.
- S.class: A vector of the same type as class, containing unique class levels indicating the class for the corresponding element of prob. S.class must contain all the K levels in class. It can also contain classes that do not appear in class. This can be useful if training is a subset of a larger training set. fit ignores any classes that appear in S.class but not in class.

If the prior probabilities don't sum to one, fit will normalize them.
- 'KSWidth' - The bandwidth of the kernel smoothing window. The default is to select a default bandwidth automatically for each combination of feature and class, using a value that is optimal for a Gaussian distribution. You can specify the value as one of the following:
\[
\begin{array}{ll}
\text { scalar } & \text { Width for all features in all classes. } \\
\text { row } & \begin{array}{l}
\text { 1-by-D vector where the jth element is the bandwidth for } \\
\text { vector } \\
\text { the } j \text { th feature in all classes. }
\end{array} \\
\text { column } & \begin{array}{l}
\text { K-by-1 vector where the ith element specifies the }
\end{array} \\
\text { vector } & \begin{array}{l}
\text { bandwidth for all features in the ith class. K represents } \\
\text { the number of class levels. }
\end{array}
\end{array}
\]

\section*{NaiveBayes.fit}
matrix K-by-D matrix \(M\) where \(M(i, j)\) specifies the bandwidth for the \(j\) th feature in the ith class.
structure A structure \(S\) containing class levels and their bandwidths. S must have two fields:
- S.width - A numeric array of bandwidths specified as a row vector, or a matrix with \(D\) columns.
- S.class - A vector of the same type as class, containing unique class levels indicating the class for the corresponding row of width.
- 'KSSupport' - The regions where the density can be applied. It can be a string, a two-element vector as shown below, or a 1-by-D cell array of these values:
\begin{tabular}{ll}
\begin{tabular}{l} 
'unbounded' \\
(default)
\end{tabular} & \begin{tabular}{l} 
The density can extend over the whole real \\
line.
\end{tabular} \\
'positive' & The density is restricted to positive values. \\
{\([\mathrm{L}, \mathrm{U}]\)} & \begin{tabular}{l} 
A two-element vector specifying the finite \\
lower bound L and upper bound \(U\) for the \\
support of the density.
\end{tabular}
\end{tabular}
- 'KSType ' - The type of kernel smoother to use. It can be a string or a 1-by-D cell array of strings. Each string can be 'normal' (default), 'box', 'triangle', or 'epanechnikov'.

How To
- "Naive Bayes Classification" on page 14-36
- "Grouping Variables" on page 2-51

\section*{NonLinearModel.fit}

Purpose Fit nonlinear regression model
```

Syntax
mdl = NonLinearModel.fit(ds,modelfun,betaO)
mdl = NonLinearModel.fit(X,y,modelfun,betaO)
mdl = NonLinearModel.fit(...,modelfun,beta0,Name,Value)

```

\section*{Description}

\section*{Input Arguments}
mdl = NonLinearModel.fit(ds,modelfun,beta0) fits the model specified by modelfun to variables in the dataset array ds, and returns the nonlinear model mdl. NonLinearModel.fit estimates model coefficients using an iterative procedure starting from the initial values in betao.
mdl = NonLinearModel.fit(X,y,modelfun,betaO) fits a nonlinear regression model using the column vector y as a response variable and the columns of the matrix \(X\) as predictor variables.
mdl = NonLinearModel.fit(..., modelfun, beta0, Name, Value) fits a nonlinear regression model with additional options specified by one or more Name, Value pair arguments.

\section*{ds}

Dataset array, where by default the last column is the response variable, and all other columns are the predictors. Predictors and response must be numeric.

To set a different column as the response variable, use the ResponseVar name-value pair. To use a subset of the columns as predictors, use the PredictorVars name-value pair.

\section*{X}

Matrix of predictor values. Each column of \(X\) represents one variable, and each row represents one observation.

\section*{\(y\)}

Vector of response values with the same number of rows as \(X\). Each entry in \(y\) is the response to the data in the corresponding row of \(X\).

\section*{NonLinearModel.fit}

\section*{modelfun}

Functional form of the model. Either a:
- Function handle @modelfun or \(@(b, x)\) modelfun, where
- b is a coefficient vector with the same number of elements as beta0.
- x is a matrix with the same number of columns as X or the data columns of ds.
modelfun ( \(\mathrm{b}, \mathrm{x}\) ) returns a column vector that contains the same number of rows as \(x\). Each row of the vector is the result of evaluating modelfun on the corresponding row of \(x\). In other words, modelfun is a vectorized function, one that operates on all data rows and returns all evaluations in one function call.
- String of the form
\[
' y \sim f(b 1, b 2, \ldots, b k, x 1, x 2, \ldots, x k) '
\]
\(f\) represents a scalar function of the scalar coefficient variables \(\mathrm{b} 1, \ldots, \mathrm{bk}\) and the scalar data variables \(\mathrm{x} 1, \ldots, \mathrm{xk}\).

\section*{beta0}

Numeric vector of coefficients for the modelfun nonlinear model. NonLinearModel.fit starts its search for optimal coefficients from beta0.

\section*{Name-Value Pair Arguments}

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, ... , NameN, ValueN.

\section*{'CoefficientNames'}

\section*{NonLinearModel.fit}

Cell array of strings specifying the names of the model coefficients. modelfun gives the model.

Default: \{'b1','b2',...,'bk'\}

\section*{'ErrorModel'}

String specifying the form of the error variance model. Each model defines the error using a standard mean-zero and unit-variance variable \(e\) in combination with independent components: the function value \(f\), and one or two parameters \(a\) and \(b\).
```

'constant' (default)
$y=f+a e$
'proportional'
$y=f+b f e$
'combined'
$y=f+(a+b|f|) e$

```

The only allowed error model when using Weights is 'constant'.

Note options.RobustWgtFun must have value [] when using an error model other than 'constant'.

Default: 'constant'

\section*{'ErrorParameters'}

Numeric array containing the initial estimates of the error model parameters for the chosen ErrorModel.

\section*{NonLinearModel.fit}
\begin{tabular}{l|l|l}
\hline Error Model & Parameters & Default Values \\
\hline 'constant' & \(a\) & 1 \\
\hline 'proportional' & \(b\) & 1 \\
\hline 'combined' & \(a, b\) & {\([1,1]\)} \\
\hline
\end{tabular}

For example, if 'ErrorModel' has the value 'combined', you can specify the starting value 1 for \(a\) and the starting value 2 for \(b\) as follows.

\section*{Example: 'ErrorParameters',[1,2]}

You can only use the 'constant ' error model when using Weights.

Note options.RobustWgtFun must have value [] when using an error model other than 'constant'.

Default: 1 or [1,1]

\section*{'Exclude'}

Logical or numerical index vector indicating which observations to exclude from the fit. For example, to exclude observations 2 and 3 out of 6 , pass either
[2,3]
or
logical([0 \(\left.1 \begin{array}{lllll}1 & 1 & 0 & 0\end{array}\right]\)
Default: [ ]

\section*{'Options'}

\section*{NonLinearModel.fit}

Structure as created by statset for controlling the iterative fitting procedure. The relevant fields are the nonempty fields in the structure returned by the call statset('nlinfit').
\begin{tabular}{l|l|l}
\hline Option & Meaning & Default \\
\hline DerivStep & \begin{tabular}{l} 
Relative difference used in finite difference \\
derivative calculations. A positive scalar, or \\
a vector of positive scalars the same size as \\
the vector of parameters estimated by the \\
Statistics Toolbox function using the options \\
structure.
\end{tabular} & \(\mathrm{eps}^{\wedge}(1 / 3)\) \\
\hline Display & \begin{tabular}{l} 
Amount of information displayed by the fitting \\
algorithm. \\
- 'off' — Displays no information. \\
- 'final' — Displays the final output. \\
- 'iter' — Displays iterative output to the \\
Command Window.
\end{tabular} & \\
\hline FunValCheck & \begin{tabular}{l} 
String indicating to check for invalid values, \\
such as NaN or Inf, from the model function.
\end{tabular} & 'on' \\
\hline MaxIter & \begin{tabular}{l} 
Maximum number of iterations allowed. \\
Positive integer.
\end{tabular} & 200 \\
\hline RobustWgtFun & \begin{tabular}{l} 
Weight function for robust fitting. Can also be \\
a function handle that accepts a normalized \\
residual as input and returns the robust \\
weights as output. If you use a function \\
handle, give a Tune constant. See "Robust \\
Options" on page 20-827.
\end{tabular} & [] \\
\hline
\end{tabular}

\section*{NonLinearModel.fit}
\begin{tabular}{l|l|l}
\hline Option & Meaning & Default \\
\hline Tune & \begin{tabular}{l} 
Tuning constant used in robust fitting to \\
normalize the residuals before applying the \\
weight function. A positive scalar. Required if \\
the weight function is specified as a function \\
handle.
\end{tabular} & \begin{tabular}{l} 
See "Robust \\
Options" on page \\
\(20-827\) for the \\
default, which \\
depends on \\
RobustWgtFun.
\end{tabular} \\
\hline TolFun & \begin{tabular}{l} 
Termination tolerance for the objective \\
function value. Positive scalar.
\end{tabular} & \(1 \mathrm{e}-8\) \\
\hline TolX & \begin{tabular}{l} 
Termination tolerance for the parameters. \\
Positive scalar.
\end{tabular} & \(1 \mathrm{e}-8\) \\
\hline
\end{tabular}

\section*{Default: []}

\section*{'PredictorVars'}

Description of the variables that NonLinearModel.fit uses for fitting. Either a:
- Cell array of strings of variable names in the ds dataset array, or in the VarNames name-value pair
- Vector of integer or logical indices into the variables in ds or the columns of X

Default: All variables in matrix X, or all variables except for the last in dataset array ds

\section*{'ResponseVar'}

Variable that NonLinearModel.fit uses for response data. Either a:
- Variable name in ds
- Index of variable in ds

\section*{NonLinearModel.fit}

Default: Last column of dataset array ds

\section*{'VarNames'}

Cell array of strings giving the variable names of the data, followed by the response variable name.

Default: \{'x1','x2',...,'xk','y'\}

\section*{'Weights'}

Vector of nonnegative weights or a function handle.
- If you specify a vector, then it must have \(N\) elements, where \(N\) is the number of rows in ds or \(y\).
- If you specify a function handle, then the function must accept a vector of predicted response values as input, and return a vector of real positive weights as output.

Given weights, W, NonLinearModel.fit estimates the error variance at observation \(i\) by \(\operatorname{MSE}^{*}(1 / \mathrm{W}(\mathrm{i}))\), where MSE is the mean squared error.

Default: Vector of 1s

\section*{Output Arguments}

Nonlinear model representing a least-squares fit of the response to the data. If the Options structure contains a nonempty RobustWgtFun field, the model is not a least-squares fit, but uses the RobustWgtFun robust fitting function.

\section*{NonLinearModel.fit}

\section*{Definitions Robust Options}
\begin{tabular}{|c|c|c|}
\hline Weight Function & Equation & Default Tuning Constant \\
\hline ' andrews ' & \[
\begin{aligned}
& w=(a b s(r)<p i) . * \sin (r) . / \\
& r
\end{aligned}
\] & 1.339 \\
\hline 'bisquare (default) & \[
\begin{aligned}
& w=(\operatorname{abs}(r)<1) \cdot *(1- \\
& r \cdot \wedge 2) .^{\wedge} 2
\end{aligned}
\] & 4.685 \\
\hline 'cauchy' & \(w=1 . /(1+r . \wedge 2)\) & 2.385 \\
\hline 'fair' & \(w=1 . /(1+\operatorname{abs}(r))\) & 1.400 \\
\hline 'huber' & \(w=1 . / \max (1, \operatorname{abs}(r))\) & 1.345 \\
\hline 'logistic' & \(w=\tanh (r) . / r\) & 1.205 \\
\hline 'talwar' & \(w=1 *(\operatorname{abs}(r)<1)\) & 2.795 \\
\hline 'welsch' & \(w=\exp (-(r . \wedge 2))\) & 2.985 \\
\hline [] & No robust fitting & - \\
\hline
\end{tabular}

\section*{Examples Nonlinear Model from a Dataset Array}

Create a nonlinear model for auto mileage based on the carbig data.
Load the data and create a nonlinear model.
```

load carbig
ds = dataset(Horsepower,Weight,MPG);
modelfun = a(b,x)b(1) + b(2)*x(:,1).^b(3) + ...
b(4)*x(:, 2).^b(5);
beta0 = [-50 500 -1 500 -1];
mdl = NonLinearModel.fit(ds,modelfun,beta0)
mdl =

```

\section*{NonLinearModel.fit}
\begin{tabular}{|c|c|c|c|c|}
\hline \multirow[t]{2}{*}{Estimated} & \multicolumn{4}{|l|}{Coefficients:} \\
\hline & Estimate & SE & tStat & pValue \\
\hline b1 & -49.383 & 119.97 & -0.41164 & 0.68083 \\
\hline b2 & 376.43 & 567.05 & 0.66384 & 0.50719 \\

\hline b4 & 422.37 & 776.02 & 0.54428 & 0.58656 \\
\hline b5 & -0.24127 & 0.48325 & -0.49926 & 0.61788 \\
\hline
\end{tabular}
```

Number of observations: 392, Error degrees of freedom: 387
Root Mean Squared Error: 3.96
R-Squared: 0.745, Adjusted R-Squared 0.743
F-statistic vs. constant model: 283, p-value = 1.79e-113

```

\section*{Nonlinear Model from Matrix Data}

Create a nonlinear model for auto mileage based on the carbig data.
Load the data and create a nonlinear model.
```

load carbig
X = [Horsepower,Weight];
y = MPG;
modelfun = @(b,x)b(1) + b(2)*x(:,1).^b(3) + ...
b(4)*x(:,2).^b(5);
beta0 = [-50 500 -1 500 -1];
mdl = NonLinearModel.fit(X,y,modelfun,betaO)
mdl =

```
Nonlinear regression model:
    \(y\) ~ b1 + b2*x1^b3 + b4*x2^b5
Estimated Coefficients:
    Estimate SE tStat pValue

\section*{NonLinearModel.fit}
\begin{tabular}{lrrrr} 
b1 & -49.383 & 119.97 & -0.41164 & 0.68083 \\
b2 & 376.43 & 567.05 & 0.66384 & 0.50719 \\
b3 & -0.78193 & 0.47168 & -1.6578 & 0.098177 \\
b4 & 422.37 & 776.02 & 0.54428 & 0.58656 \\
b5 & -0.24127 & 0.48325 & -0.49926 & 0.61788
\end{tabular}
```

Number of observations: 392, Error degrees of freedom: 387
Root Mean Squared Error: 3.96
R-Squared: 0.745, Adjusted R-Squared 0.743
F-statistic vs. constant model: 283, p-value = 1.79e-113

```

\section*{Adjust Fitting Options in the Nonlinear Model}

Create a nonlinear model for auto mileage based on the carbig data. Strive for more accuracy by lowering the TolFun option, and observe the iterations by setting the Display option.

Load the data and create a nonlinear model.
```

load carbig
X = [Horsepower,Weight];
y = MPG;
modelfun = @(b,x)b(1) + b(2)*x(:,1).^b(3) + ...
b(4)*x(:,2).^b(5);
beta0 = [-50 500 -1 500 -1];

```

Create options to lower TolFun and to report iterative display, and create a model using the options.
```

opts = statset('Display','iter','TolFun',1e-10);
mdl = NonLinearModel.fit(X,y,modelfun,betaO,'Options',opts);

```
\begin{tabular}{|c|c|c|c|}
\hline Iteration & SSE & Norm of Gradient & Norm of Step \\
\hline 0 & \(1.82248 \mathrm{e}+06\) & & \\
\hline 1 & 678600 & 788810 & 1691.07 \\
\hline 2 & 616716 & \(6.12739 \mathrm{e}+06\) & 45.4738 \\
\hline
\end{tabular}

\section*{NonLinearModel.fit}
\%\%\% Many iterations deleted \%\%\%
\begin{tabular}{rrrr}
122 & 6068.48 & 1.56393 & 0.629325 \\
123 & 6068.48 & 1.13809 & 0.432543 \\
124 & 6068.48 & 0.295962 & 0.297511
\end{tabular}

Iterations terminated: relative change in SSE less than OPTIONS. TolFun

\section*{Specify Nonlinear Regression Using Model String Syntax}

Specify a nonlinear regression model for estimation using a function handle or model string syntax.

Load sample data.
S = load('reaction');
X = S.reactants;
y = S.rate;
beta0 = S.beta;
Use a function handle to specify the Hougen-Watson model for the rate data.
```

mdl = NonLinearModel.fit(X,y,@hougen,betaO)
mdl =

```
Nonlinear regression model:
    \(y \quad \sim \operatorname{hougen}(b, X)\)
\begin{tabular}{|c|c|c|c|c|}
\hline \multirow[t]{2}{*}{Estimated} & \multicolumn{4}{|l|}{Coefficients:} \\
\hline & Estimate & SE & tStat & pValue \\
\hline b1 & 1.2526 & 0.86701 & 1.4447 & 0.18654 \\
\hline b2 & 0.062776 & 0.043561 & 1.4411 & 0.18753 \\
\hline b3 & 0.040048 & 0.030885 & 1.2967 & 0.23089 \\
\hline b4 & 0.11242 & 0.075157 & 1.4957 & 0.17309 \\
\hline b5 & 1.1914 & 0.83671 & 1.4239 & 0.192 \\
\hline
\end{tabular}
```

Number of observations: 13, Error degrees of freedom: 8
Root Mean Squared Error: 0.193
R-Squared: 0.999, Adjusted R-Squared 0.998
F-statistic vs. zero model: 3.91e+03, p-value = 2.54e-13

```

Alternatively, you can use a string expression to specify the Hougen-Watson model for the rate data.
```

myfun = 'y~(b1*x2-x3/b5)/(1+b2*x1+b3*x2+b4*x3)';
mdl2 = NonLinearModel.fit(X,y,myfun,beta0)
mdl2 =
Nonlinear regression model:
y ~ (b1*x2 - x3/b5)/(1 + b2*x1 + b3*x2 + b4*x3)
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | ---: | ---: | :--- | :--- |
| b1 | 1.2526 | 0.86701 | 1.4447 | 0.18654 |
| b2 | 0.062776 | 0.043561 | 1.4411 | 0.18753 |
| b3 | 0.040048 | 0.030885 | 1.2967 | 0.23089 |
| b4 | 0.11242 | 0.075157 | 1.4957 | 0.17309 |
| b5 | 1.1914 | 0.83671 | 1.4239 | 0.1923 |

```
```

Number of observations: 13, Error degrees of freedom: 8
Root Mean Squared Error: 0.193
R-Squared: 0.999, Adjusted R-Squared 0.998
F-statistic vs. zero model: 3.91e+03, p-value = 2.54e-13

```

\section*{Estimate Nonlinear Regression Using Robust Fitting Options}

Generate sample data from the nonlinear regression model
\[
y=b_{1}+b_{2} \exp \left\{-b_{3} x\right\}+\varepsilon,
\]

\section*{NonLinearModel.fit}
where \(b_{1}, b_{2}\), and \(b_{3}\) are coefficients, and the error term is normally distributed with mean 0 and standard deviation 0.5 .
```

modelfun = @(b,x)(b(1)+b(2)*exp(-b(3)*x));
rng('default') % for reproducibility
b = [1;3;2];
x = exprnd(2,100,1);
y = modelfun(b,x) + normrnd(0,0.5,100,1);

```

Set robust fitting options.
```

opts = statset('nlinfit');
opts.RobustWgtFun = 'bisquare';

```

Fit the nonlinear model using the robust fitting options. Here, use a string expression to specify the model.
```

bO = [2;2;2];
modelstr = 'y ~ b1 + b2*exp(-b3*x)';
mdl = NonLinearModel.fit(x,y,modelstr,bO,'Options',opts)
mdl =
Nonlinear regression model (robust fit):
y ~ b1 + b2*exp( - b3*x)
Estimated Coefficients:

|  | Estimate | SE | tStat | pValue |
| :--- | :--- | :--- | :--- | :--- |
| b1 | 1.0218 | 0.07202 | 14.188 | $2.1344 \mathrm{e}-25$ |
| b2 | 3.6619 | 0.25429 | 14.401 | $7.974 \mathrm{e}-26$ |
| b3 | 2.9732 | 0.38496 | 7.7232 | $1.0346 \mathrm{e}-11$ |

```

Number of observations: 100, Error degrees of freedom: 97
Root Mean Squared Error: 0.501
```

R-Squared: 0.807, Adjusted R-Squared 0.803
F-statistic vs. constant model: 203, p-value = 2.34e-35

```

\section*{Fit Nonlinear Regression Model Using Weights Function Handle}

Load sample data.
```

S = load('reaction');
X = S.reactants;
y = S.rate;
betaO = S.beta;

```

Specify a function handle for observation weights. The function accepts the model fitted values as input, and returns a vector of weights.
```

a = 1; b = 1;
weights = @(yhat) 1./((a + b*abs(yhat)).^2);

```

Fit the Hougen-Watson model to the rate data using the specified observation weights function.
```

mdl = NonLinearModel.fit(X,y,@hougen,beta0,'Weights',weights)
mdl =

```
Nonlinear regression model:
    \(y \sim \operatorname{hougen}(b, x)\)
\begin{tabular}{rrrrl}

\section*{RegressionTree.fit}

\section*{Purpose \\ Syntax \\ Description}

Binary decision tree for regression

\section*{Input Arguments \\ X}
tree = RegressionTree.fit(X,Y)
tree = RegressionTree.fit(X,Y,Name,Value) node is split based on the values of a column of \(X\). order as Name1, Value1, ,NameN, ValueN.

Note that using the 'crossval', 'kfold', 'holdout', predict method to make predictions.
tree \(=\) RegressionTree.fit \((X, Y)\) returns a regression tree based on the input variables (also known as predictors, features, or attributes) \(X\) and output (response) Y . tree is a binary tree where each branching
tree = RegressionTree.fit(X,Y,Name,Value) fits a tree with additional options specified by one or more Name, Value pair arguments. You can specify several name-value pair arguments in any 'leaveout', or 'cvpartition' options results in a tree of class RegressionPartitionedModel. You cannot use a partitioned tree for prediction, so this kind of tree does not have a predict method.
Otherwise, tree is of class RegressionTree, and you can use the

A matrix of predictor values. Each column of X represents one variable, and each row represents one observation.

RegressionTree.fit considers NaN values in X as missing values. RegressionTree.fit does not use observations with all missing values for X the fit. RegressionTree.fit uses observations with some missing values for \(X\) to find splits on variables for which these observations have valid values.

\section*{\(\mathbf{Y}\)}

A numeric column vector with the same number of rows as \(X\). Each entry in Y is the response to the data in the corresponding row of X .

RegressionTree.fit considers NaN values in \(Y\) to be missing values. RegressionTree.fit does not use observations with missing values for \(Y\) in the fit.

\section*{Name-Value Pair Arguments}

Specify optional comma-separated pairs of Name, Value arguments. Name is the argument name and Value is the corresponding value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN.

\section*{'CategoricalPredictors'}

List of categorical predictors. Pass CategoricalPredictors as one of:
- A numeric vector with indices from 1 to \(p\), where \(p\) is the number of columns of \(X\).
- A logical vector of length \(p\), where a true entry means that the corresponding column of X is a categorical variable.
- 'all', meaning all predictors are categorical.
- A cell array of strings, where each element in the array is the name of a predictor variable. The names must match entries in the PredictorNames property.
- A character matrix, where each row of the matrix is a name of a predictor variable. Pad the names with extra blanks so each row of the character matrix has the same length.

Default: []

\section*{'crossval'}

Flag to grow a cross-validated decision tree. Possible value are 'on' or 'off'.

\section*{RegressionTree.fit}

If 'on', RegressionTree.fit grows a cross-validated decision tree with 10 folds. You can override this cross-validation setting using one of the 'kfold', 'holdout', 'leaveout', or 'cvpartition' name-value pair arguments. Note that you can only use one of these four options ('kfold', 'holdout', 'leaveout', or 'cvpartition') at a time when creating a cross-validated tree.

Alternatively, cross-validate tree later using the crossval method.

Default: 'off'

\section*{'cvpartition'}

Partition created with cvpartition to use in cross-validated tree.
Note that if you use 'cvpartition', you cannot use any of the 'kfold', 'holdout', or 'leaveout' name-value pair arguments.

\section*{'holdout'}

Holdout validation tests the specified fraction of the data, and uses the rest of the data for training. Specify a numeric scalar from 0 to 1 .

Note that if you use 'holdout ', you cannot use any of the 'cvpartition', 'kfold', or 'leaveout' name-value pair arguments.

\section*{'kfold'}

Number of folds to use in a cross-validated tree, a positive integer.
Note that if you use 'kfold', you cannot use any of the 'cvpartition', 'holdout', or 'leaveout' name-value pair arguments.

Default: 10

\section*{'leaveout'}

Use leave-one-out cross validation by setting to 'on'.
Note that if you use 'leaveout', you cannot use any of the 'cvpartition', 'holdout', or 'kfold' name-value pair arguments.

\section*{'MergeLeaves'}

When 'on', RegressionTree merges leaves that originate from the same parent node, and that give a sum of risk values greater or equal to the risk associated with the parent node. When 'off', RegressionTree does not merge leaves.

Default: 'on'

\section*{'MinLeaf'}

Each leaf has at least MinLeaf observations per tree leaf. If you supply both MinParent and MinLeaf, RegressionTree uses the setting that gives larger leaves: MinParent=max(MinParent, 2*MinLeaf).

Default: 1

\section*{'MinParent'}

Each branch node in the tree has at least MinParent observations. If you supply both MinParent and MinLeaf, RegressionTree uses the setting that gives larger leaves: MinParent=max (MinParent, 2*MinLeaf).

Default: 10

\section*{'NVarToSample'}

Number of predictors to select at random for each split. Can be a positive integer or 'all', which means use all available predictors.

Default: 'all'

\section*{RegressionTree.fit}

\section*{'PredictorNames'}

A cell array of names for the predictor variables, in the order in which they appear in \(X\).

Default: \{'x1','x2',...\}

\section*{'Prune'}

When 'on', RegressionTree computes the full tree and the optimal sequence of pruned subtrees. When 'off' RegressionTree computes the full tree without pruning.

Default: 'on'

\section*{'PruneCriterion'}

String with the pruning criterion, always 'error'.
Default: 'error'

\section*{'QEToler'}

Defines tolerance on quadratic error per node for regression trees. Splitting nodes stops when quadratic error per node drops below QEToler*QED, where QED is the quadratic error for the entire data computed before the decision tree is grown.

Default: 1e-6

\section*{'ResponseName'}

Name of the response variable Y , a string.
Default: ' \(\gamma\) '

\section*{'ResponseTransform'}

Function handle for transforming the raw response values. The function handle should accept a matrix of response values and
return a matrix of the same size. The default string ' none ' means \(@(x) x\), or no transformation.
Add or change a ResponseTransform function by dot addressing:
tree. ResponseTransform = @function
Default: 'none'

\section*{'SplitCriterion'}

Criterion for choosing a split, always the string 'MSE', meaning mean squared error.

Default: 'MSE'

\section*{'Surrogate'}

String describing whether to find surrogate decision splits at each branch node. Specify as 'on', 'off', 'all', or a positive scalar value.
- When 'on', RegressionTree.fit finds at most 10 surrogate splits at each branch node.
- When set to a positive integer value, RegressionTree.fit finds at most the specified number of surrogate splits at each branch node.
- When set to 'all', RegressionTree.fit finds all surrogate splits at each branch node. The 'all' setting can use much time and memory.

Use surrogate splits to improve the accuracy of predictions for data with missing values. The setting also enables you to compute measures of predictive association between predictors.

Default: 'off'

\section*{'Weights'}

\section*{RegressionTree.fit}

Vector of observation weights. The length of weights is the number of rows in \(X\).

Default: ones(size (X,1), 1)

\section*{Output tree}

A regression tree object.
Note that using the 'crossval', 'kfold', 'holdout', 'leaveout', or 'cvpartition' options results in a tree of class RegressionPartitionedModel. You cannot use a partitioned tree for prediction, so this kind of tree does not have a predict method.

Otherwise, tree is of class RegressionTree, and you can use the predict method to make predictions.

\section*{Examples}

Load the data in carsmall.mat, and make a regression tree to predict the mileage of cars based on their weights and numbers of cylinders:
```

load carsmall
tree = RegressionTree.fit([Weight, Cylinders],MPG,...
'MinParent',20,...
'PredictorNames',{'W','C'})
tree =
RegressionTree
PredictorNames: {'W' 'C'}
ResponseName: 'Y'
ResponseTransform: 'none'
CategoricalPredictors: []
NObservations: 94
Properties, Methods

```

Predict the mileage of a car that weighs 2200 lbs and has four cylinders:
predict(tree,[2200,4])
ans =
29.6111

See Also predict

\section*{fitdist}

Purpose Fit probability distribution object to data

Syntax
Description

Input Arguments
```

pd = fitdist(x,distname)
pd = fitdist(x,distname,Name,Value)
[pdca,gn,gl] = fitdist(x,distname,'By',groupvar)
[pdca,gn,gl] = fitdist(x,distname,'By',groupvar,Name,Value)

```
pd = fitdist(x,distname) creates a probability distribution object by fitting the distribution specified by distname to the data in column vector x .
pd = fitdist(x, distname, Name, Value) creates the probability distribution object with additional options specified by one or more name-value pair arguments. For example, you can indicate censored data or specify control parameters for the iterative fitting algorithm.
[pdca,gn,gl] = fitdist(x,distname,'By',groupvar) creates probability distribution objects by fitting the distribution specified by distname to the data in \(x\) based on the grouping variable groupvar. It returns a cell array of fitted probability distribution objects, pdca, a cell array of group labels, gn, and a cell array of grouping variable levels, gl .
[pdca,gn,gl] = fitdist(x,distname,'By',groupvar, Name, Value) returns the above output arguments using additional options specified by one or more name-value pair arguments. For example, you can indicate censored data or specify control parameters for the iterative fitting algorithm.

\section*{x - Input data}
column vector
Input data, specified as a column vector. fitdist ignores NaN values in \(x\). Additionally, any NaN values in the censoring vector or frequency vector causes fitdist to ignore the corresponding values in x .

\section*{Data Types}
single | double

\section*{distname - Distribution name}
string
Distribution name, specified as one of the following strings. The distribution specified by distname determines the class type of the returned probability distribution object.
\begin{tabular}{|c|c|c|}
\hline Distribution Name & Description & Distribution Class \\
\hline 'Beta' & Beta distribution & prob.BetaDistribution \\
\hline 'Binomial' & Binomial distribution & prob.BinomialDistribution \\
\hline 'BirnbaumSaunders' & Birnbaum-Saunders distribution & prob.BirnbaumSaundersDistribl \\
\hline 'Burr ' & Burr distribution & prob.BurrDistribution \\
\hline 'Exponential' & Exponential distribution & prob.ExponentialDistribution \\
\hline 'ExtremeValue' & Extreme Value distribution & prob.ExtremeValueDistributior \\
\hline 'Gamma ' & Gamma distribution & prob.GammaDistribution \\
\hline 'GeneralizedExtreme & V Value distribution & prob.GeneralizedExtremeValue \\
\hline 'GeneralizedPareto' & Generalized Pareto distribution & prob.GeneralizedParetoDistrit \\
\hline 'InverseGaussian ' & Inverse Gaussian distribution & prob.InverseGaussianDistribut \\
\hline 'Kernel' & Kernel distribution & prob.KernelDistribution \\
\hline 'Logistic' & Logistic distribution & prob.LogisticDistribution \\
\hline 'Loglogistic' & Loglogistic distribution & prob.LoglogisticDistribution \\
\hline
\end{tabular}

\section*{fitdist}
\begin{tabular}{l|l|l}
\hline Distribution Name & Description & Distribution Class \\
\hline 'Lognormal' & \begin{tabular}{l} 
Lognormal \\
distribution
\end{tabular} & prob.LognormalDistribution \\
\hline 'Multinomial' & \begin{tabular}{l} 
Multinomial \\
distribution
\end{tabular} & prob.MultinomialDistribution \\
\hline 'Nakagami' & \begin{tabular}{l} 
Nakagami \\
distribution
\end{tabular} & prob.NakagamiDistribution \\
\hline 'NegativeBinomial' & \begin{tabular}{l} 
Negative Binomial \\
distribution
\end{tabular} & prob.NegativeBinomialDistributio \\
\hline 'Normal' & Normal distribution & prob.NormalDistribution
\end{tabular}

\section*{groupvar - Grouping variable}
categorical array | logical or numeric vector | cell array of strings
Grouping variable, specified as a categorical array, logical or numeric vector, or cell array of strings. Each unique value in a grouping variable defines a group.

For example, if Gender is a cell array of strings with values 'Male' and 'Female', you can use Gender as a grouping variable to fit a distribution to your data by gender.
