The software described in this document is furnished under a license agreement. The software may be used or copied only under the terms of the license agreement. No part of this manual may be photocopied or reproduced in any form without prior written consent from The MathWorks, Inc.

FEDERAL ACQUISITION: This provision applies to all acquisitions of the Program and Documentation by, for, or through the federal government of the United States. By accepting delivery of the Program or Documentation, the government hereby agrees that this software or documentation qualifies as commercial computer software or commercial computer software documentation as such terms are used or defined in FAR 12.212, DFARS Part 227.72, and DFARS 252.227-7014. Accordingly, the terms and conditions of this Agreement and only those rights specified in this Agreement, shall pertain to and govern the use, modification, reproduction, release, performance, display, and disclosure of the Program and Documentation by the federal government (or other entity acquiring for or through the federal government) and shall supersede any conflicting contractual terms or conditions. If this License fails to meet the government's needs or is inconsistent in any respect with federal procurement law, the government agrees to return the Program and Documentation, unused, to The MathWorks, Inc.

### Trademarks

MATLAB and Simulink are registered trademarks of The MathWorks, Inc. See [www.mathworks.com/trademarks](http://www.mathworks.com/trademarks) for a list of additional trademarks. Other product or brand names may be trademarks or registered trademarks of their respective holders.

### Patents

MathWorks products are protected by one or more U.S. patents. Please see [www.mathworks.com/patents](http://www.mathworks.com/patents) for more information.

## Revision History

September 1993	First printing	Version 1.0
March 1996	Second printing	Version 2.0
January 1997	Third printing	Version 2.11
November 2000	Fourth printing	Revised for Version 3.0 (Release 12)
May 2001	Fifth printing	Minor revisions
July 2002	Sixth printing	Revised for Version 4.0 (Release 13)
February 2003	Online only	Revised for Version 4.1 (Release 13.0.1)
June 2004	Seventh printing	Revised for Version 5.0 (Release 14)
October 2004	Online only	Revised for Version 5.0.1 (Release 14SP1)
March 2005	Online only	Revised for Version 5.0.2 (Release 14SP2)
September 2005	Online only	Revised for Version 5.1 (Release 14SP3)
March 2006	Online only	Revised for Version 5.2 (Release 2006a)
September 2006	Online only	Revised for Version 5.3 (Release 2006b)
March 2007	Eighth printing	Revised for Version 6.0 (Release 2007a)
September 2007	Ninth printing	Revised for Version 6.1 (Release 2007b)
March 2008	Online only	Revised for Version 6.2 (Release 2008a)
October 2008	Online only	Revised for Version 7.0 (Release 2008b)
March 2009	Online only	Revised for Version 7.1 (Release 2009a)
September 2009	Online only	Revised for Version 7.2 (Release 2009b)
March 2010	Online only	Revised for Version 7.3 (Release 2010a)
September 2010	Online only	Revised for Version 7.4 (Release 2010b)
April 2011	Online only	Revised for Version 7.5 (Release 2011a)
September 2011	Online only	Revised for Version 7.6 (Release 2011b)
March 2012	Online only	Revised for Version 8.0 (Release 2012a)
September 2012	Online only	Revised for Version 8.1 (Release 2012b)
March 2013	Online only	Revised for Version 8.2 (Release 2013a)
September 2013	Online only	Revised for Version 8.3 (Release 2013b)

## Getting Started

### 1

<b>Statistics Toolbox Product Description</b> .....	1-2
Key Features .....	1-2

## Organizing Data

### 2

<b>Create Nominal and Ordinal Arrays</b> .....	2-3
Create Nominal Arrays .....	2-3
Create Ordinal Arrays .....	2-5
<b>Change Category Labels</b> .....	2-8
<b>Reorder Category Levels</b> .....	2-10
Reorder Category Levels in Ordinal Arrays .....	2-10
Reorder Category Levels in Nominal Arrays .....	2-11
<b>Categorize Numeric Data</b> .....	2-15
<b>Merge Category Levels</b> .....	2-18
<b>Add and Drop Category Levels</b> .....	2-20
<b>Plot Data Grouped by Category</b> .....	2-24
<b>Test Differences Between Category Means</b> .....	2-28
<b>Summary Statistics Grouped by Category</b> .....	2-37

<b>Sort Ordinal Arrays</b> .....	<b>2-39</b>
<b>Categorical Arrays</b> .....	<b>2-41</b>
What Are Categorical Arrays? .....	2-41
Categorical Array Conversion .....	2-41
<b>Advantages of Using Categorical Arrays</b> .....	<b>2-43</b>
Manipulate Category Levels .....	2-43
Analysis Using Categorical Arrays .....	2-43
Reduce Memory Requirements .....	2-44
<b>Index and Search Using Categorical Arrays</b> .....	<b>2-46</b>
Index By Category .....	2-46
Common Indexing and Searching .....	2-46
<b>Grouping Variables</b> .....	<b>2-51</b>
What Are Grouping Variables? .....	2-51
Group Definition .....	2-52
Analysis Using Grouping Variables .....	2-52
Missing Group Values .....	2-53
<b>Dummy Indicator Variables</b> .....	<b>2-55</b>
What Are Dummy Variables? .....	2-55
Creating Dummy Variables .....	2-56
<b>Regression with Categorical Covariates</b> .....	<b>2-59</b>
<b>Create a Dataset Array from Workspace Variables</b> ....	<b>2-65</b>
Create a Dataset Array from a Numeric Array .....	2-65
Create Dataset Array from Heterogeneous Workspace Variables .....	2-68
<b>Create a Dataset Array from a File</b> .....	<b>2-71</b>
Create a Dataset Array from a Tab-Delimited Text File ..	2-71
Create a Dataset Array from a Comma-Separated Text File .....	2-74
Create a Dataset Array from an Excel File .....	2-77
<b>Add and Delete Observations</b> .....	<b>2-79</b>

<b>Add and Delete Variables</b> .....	<b>2-83</b>
<b>Access Data in Dataset Array Variables</b> .....	<b>2-87</b>
<b>Select Subsets of Observations</b> .....	<b>2-93</b>
<b>Sort Observations in Dataset Arrays</b> .....	<b>2-97</b>
<b>Merge Dataset Arrays</b> .....	<b>2-101</b>
<b>Stack or Unstack Dataset Arrays</b> .....	<b>2-106</b>
<b>Calculations on Dataset Arrays</b> .....	<b>2-111</b>
<b>Export Dataset Arrays</b> .....	<b>2-115</b>
<b>Clean Messy and Missing Data</b> .....	<b>2-117</b>
<b>Dataset Arrays in the Variables Editor</b> .....	<b>2-122</b>
Open Dataset Arrays in the Variables Editor .....	<b>2-122</b>
Modify Variable and Observation Names .....	<b>2-123</b>
Reorder or Delete Variables .....	<b>2-125</b>
Add New Data .....	<b>2-127</b>
Sort Observations .....	<b>2-129</b>
Select a Subset of Data .....	<b>2-130</b>
Create Plots .....	<b>2-133</b>
<b>Dataset Arrays</b> .....	<b>2-135</b>
What Are Dataset Arrays? .....	<b>2-135</b>
Dataset Array Conversion .....	<b>2-135</b>
Dataset Array Properties .....	<b>2-136</b>
<b>Index and Search Dataset Arrays</b> .....	<b>2-138</b>
Ways To Index and Search .....	<b>2-138</b>
Common Indexing and Searching .....	<b>2-138</b>

## Descriptive Statistics

### 3

<b>Introduction to Descriptive Statistics</b> .....	3-2
<b>Measures of Central Tendency</b> .....	3-3
<b>Measures of Dispersion</b> .....	3-5
<b>Quantiles and Percentiles</b> .....	3-7
<b>Exploratory Analysis of Data</b> .....	3-11
<b>Resampling Statistics</b> .....	3-16
Bootstrap .....	3-16
Jackknife .....	3-19
Parallel Computing Support for Resampling Methods .....	3-20
<b>Data with Missing Values</b> .....	3-21

## Statistical Visualization

### 4

<b>Introduction to Statistical Visualization</b> .....	4-2
<b>Create Scatter Plots Using Grouped Data</b> .....	4-3
<b>Box Plots</b> .....	4-7
<b>Distribution Plots</b> .....	4-9
Normal Probability Plots .....	4-9
Quantile-Quantile Plots .....	4-12
Cumulative Distribution Plots .....	4-15
Other Probability Plots .....	4-16

<b>Working with Probability Distributions</b> .....	5-3
Types of Probability Distributions .....	5-3
How to Work with Probability Distributions .....	5-4
<b>Maximum Likelihood Estimation</b> .....	5-5
<b>Negative Loglikelihood Functions</b> .....	5-8
<b>Random Number Generation</b> .....	5-11
<b>Nonparametric and Empirical Probability Distributions</b> .....	5-14
Overview .....	5-14
Kernel Distribution .....	5-14
Piecewise Linear Distribution .....	5-14
Empirical Cumulative Distribution Function .....	5-15
Pareto Tails .....	5-15
Triangular Distribution .....	5-15
<b>Fit Kernel Distribution Object to Data</b> .....	5-16
<b>Fit Kernel Distribution Using ksdensity</b> .....	5-21
<b>Fit Kernel Distributions to Grouped Data Using ksdensity</b> .....	5-23
<b>Create and Plot Empirical Cumulative Distribution Functions</b> .....	5-26
<b>Fit a Nonparametric Distribution with Pareto Tails</b> ..	5-27
<b>Generate Random Numbers Using the Triangular Distribution</b> .....	5-32
<b>Explore the Probability Distribution Function UI</b> ....	5-37

<b>Model Data Using the Distribution Fitting App</b> .....	<b>5-40</b>
Opening the Distribution Fitting App .....	<b>5-40</b>
Creating and Managing Data Sets .....	<b>5-43</b>
Creating a New Fit .....	<b>5-48</b>
Displaying Results .....	<b>5-53</b>
Managing Fits .....	<b>5-55</b>
Evaluating Fits .....	<b>5-57</b>
Excluding Data .....	<b>5-61</b>
Saving and Loading Sessions .....	<b>5-67</b>
Example: Fitting a Distribution .....	<b>5-68</b>
Generating a File to Fit and Plot Distributions .....	<b>5-75</b>
<b>Custom Distributions Using the Distribution Fitting App</b> .....	<b>5-77</b>
Opening the Distribution Fitting App .....	<b>5-77</b>
Defining Custom Distributions .....	<b>5-78</b>
Importing Custom Distributions .....	<b>5-79</b>
<b>Explore the Random Number Generation UI</b> .....	<b>5-80</b>
<b>Compare Multiple Distribution Fits</b> .....	<b>5-83</b>
<b>Fit Probability Distribution Objects to Grouped Data</b> .....	<b>5-89</b>
<b>Multinomial Probability Distribution Objects</b> .....	<b>5-94</b>
<b>Multinomial Probability Distribution Functions</b> .....	<b>5-98</b>
<b>Generate Random Numbers Using Uniform Distribution Inversion</b> .....	<b>5-101</b>
<b>Use <math>t</math> Location-Scale to Represent Cauchy Distribution</b> .....	<b>5-104</b>
<b>Use Student's <math>t</math> to Generate Standard Cauchy Random Numbers</b> .....	<b>5-108</b>

<b>Probability Distributions Used for Multivariate</b>	
<b>Modeling</b> .....	<b>5-110</b>
Gaussian Mixture Models .....	<b>5-110</b>
Copulas: Generate Correlated Samples .....	<b>5-120</b>

## Random Number Generation

# 6

<b>Generating Random Data</b> .....	<b>6-2</b>
<b>Random Number Generation Functions</b> .....	<b>6-3</b>
<b>Common Generation Methods</b> .....	<b>6-5</b>
Direct Methods .....	<b>6-5</b>
Inversion Methods .....	<b>6-7</b>
Acceptance-Rejection Methods .....	<b>6-9</b>
<b>Representing Sampling Distributions Using Markov</b>	
<b>Chain Samplers</b> .....	<b>6-13</b>
Using the Metropolis-Hastings Algorithm .....	<b>6-13</b>
Using Slice Sampling .....	<b>6-14</b>
<b>Generating Quasi-Random Numbers</b> .....	<b>6-15</b>
Quasi-Random Sequences .....	<b>6-15</b>
Quasi-Random Point Sets .....	<b>6-16</b>
Quasi-Random Streams .....	<b>6-24</b>
<b>Generating Data Using Flexible Families of</b>	
<b>Distributions</b> .....	<b>6-26</b>
Pearson and Johnson Systems .....	<b>6-26</b>
Generating Data Using the Pearson System .....	<b>6-28</b>
Generating Data Using the Johnson System .....	<b>6-30</b>

## Hypothesis Tests

---

### 7

<b>Introduction to Hypothesis Tests</b> .....	<b>7-2</b>
<b>Hypothesis Test Terminology</b> .....	<b>7-3</b>
<b>Hypothesis Test Assumptions</b> .....	<b>7-5</b>
<b>Hypothesis Testing</b> .....	<b>7-7</b>
<b>Available Hypothesis Tests</b> .....	<b>7-14</b>

## Analysis of Variance

---

### 8

<b>Introduction to Analysis of Variance</b> .....	<b>8-2</b>
<b>ANOVA</b> .....	<b>8-3</b>
One-Way ANOVA .....	<b>8-3</b>
Two-Way ANOVA .....	<b>8-9</b>
N-Way ANOVA .....	<b>8-12</b>
Other ANOVA Models .....	<b>8-26</b>
Analysis of Covariance .....	<b>8-27</b>
Nonparametric Methods .....	<b>8-35</b>
<b>MANOVA</b> .....	<b>8-39</b>
Introduction to MANOVA .....	<b>8-39</b>
ANOVA with Multiple Responses .....	<b>8-39</b>

<b>Parametric Regression Analysis</b> .....	<b>9-3</b>
What Is Parametric Regression? .....	9-3
Choose a Regression Function .....	9-3
Update Legacy Code with New Fitting Methods .....	9-4
<b>What Are Linear Regression Models?</b> .....	<b>9-8</b>
<b>Linear Regression</b> .....	<b>9-12</b>
Prepare Data .....	9-12
Choose a Fitting Method .....	9-14
Choose a Model or Range of Models .....	9-15
Fit Model to Data .....	9-21
Examine Quality and Adjust the Fitted Model .....	9-21
Predict or Simulate Responses to New Data .....	9-40
Share Fitted Models .....	9-43
Linear Regression Workflow .....	9-44
<b>Regression Using Dataset Arrays</b> .....	<b>9-51</b>
<b>Linear Regression with Interaction Effects</b> .....	<b>9-54</b>
<b>Interpret Linear Regression Results</b> .....	<b>9-64</b>
<b>Cook's Distance</b> .....	<b>9-72</b>
Purpose .....	9-72
Definition .....	9-72
How To .....	9-73
Example .....	9-73
<b>Coefficient Standard Errors and Confidence Intervals</b> .....	<b>9-76</b>
Coefficient Covariance and Standard Errors .....	9-76
Compute Coefficient Covariance and Standard Errors ...	9-76
Coefficient Confidence Intervals .....	9-77
Compute Coefficient Confidence Intervals .....	9-78

<b>Coefficient of Determination (R-Squared)</b> .....	<b>9-80</b>
Purpose .....	9-80
Definition .....	9-80
How To .....	9-80
Example .....	9-81
<b>Delete-1 Statistics</b> .....	<b>9-83</b>
Delete-1 Change in Covariance (covratio) .....	9-83
CovRatio Example .....	9-84
Delete-1 Scaled Difference in Coefficient Estimates (Dfbetas) .....	9-86
Dfbetas Example .....	9-87
Delete-1 Scaled Change in Fitted Values (Dffits) .....	9-87
Dffits Example .....	9-88
Delete-1 Variance (S2_i) .....	9-90
Delete-1 Variance Example .....	9-91
<b>Durbin-Watson Test</b> .....	<b>9-93</b>
Purpose .....	9-93
Definition .....	9-93
How To .....	9-93
Example .....	9-93
<b>F-statistic and t-statistic</b> .....	<b>9-95</b>
F-statistic .....	9-95
F-statistic Example .....	9-96
t-statistic .....	9-98
t-statistic Example .....	9-99
<b>Hat Matrix and Leverage</b> .....	<b>9-102</b>
Hat Matrix .....	9-102
Leverage .....	9-103
Determine High Leverage Observations .....	9-104
<b>Residuals</b> .....	<b>9-107</b>
Purpose .....	9-107
Definition .....	9-107
How To .....	9-108
Example .....	9-108
<b>Summary of Output and Diagnostic Statistics</b> .....	<b>9-117</b>

<b>Stepwise Regression</b> .....	<b>9-119</b>
Stepwise Regression to Select Appropriate Models .....	<b>9-119</b>
Compare large and small stepwise models .....	<b>9-119</b>
<b>Robust Regression — Reduce Outlier Effects</b> .....	<b>9-125</b>
What Is Robust Regression? .....	<b>9-125</b>
Robust Regression versus Standard Least-Squares Fit ...	<b>9-125</b>
<b>Ridge Regression</b> .....	<b>9-128</b>
Introduction to Ridge Regression .....	<b>9-128</b>
Ridge Regression .....	<b>9-128</b>
<b>Lasso and Elastic Net</b> .....	<b>9-132</b>
What Are Lasso and Elastic Net? .....	<b>9-132</b>
Lasso Regularization .....	<b>9-132</b>
Lasso and Elastic Net with Cross Validation .....	<b>9-135</b>
Wide Data via Lasso and Parallel Computing .....	<b>9-138</b>
Lasso and Elastic Net Details .....	<b>9-144</b>
References .....	<b>9-145</b>
<b>Partial Least Squares</b> .....	<b>9-147</b>
Introduction to Partial Least Squares .....	<b>9-147</b>
Partial Least Squares .....	<b>9-148</b>
<b>Linear Mixed-Effects Models</b> .....	<b>9-153</b>
<b>Prepare Data for Linear Mixed-Effects Models</b> .....	<b>9-158</b>
Dataset Arrays .....	<b>9-158</b>
Design Matrices .....	<b>9-160</b>
Relation of Matrix Form to Dataset Arrays .....	<b>9-162</b>
<b>Relationship Between Formula and Design Matrices</b> ..	<b>9-164</b>
Formula .....	<b>9-164</b>
Design Matrices for Fixed and Random Effects .....	<b>9-166</b>
Grouping Variables .....	<b>9-169</b>
<b>Estimating Parameters in Linear Mixed-Effects</b>	
<b>Models</b> .....	<b>9-172</b>
Maximum Likelihood (ML) .....	<b>9-173</b>
Restricted Maximum Likelihood (REML) .....	<b>9-174</b>

<b>Multinomial Models for Nominal Responses</b> .....	10-2
<b>Multinomial Models for Ordinal Responses</b> .....	10-5
<b>Hierarchical Multinomial Models</b> .....	10-9
<b>Generalized Linear Models</b> .....	10-12
What Are Generalized Linear Models? .....	10-12
Prepare Data .....	10-13
Choose Generalized Linear Model and Link Function ....	10-15
Choose Fitting Method and Model .....	10-19
Fit Model to Data .....	10-24
Examine Quality and Adjust the Fitted Model .....	10-24
Predict or Simulate Responses to New Data .....	10-37
Share Fitted Models .....	10-40
Generalized Linear Model Workflow .....	10-42
<b>Lasso Regularization of Generalized Linear Models</b> ..	10-48
What is Generalized Linear Model Lasso Regularization? .....	10-48
Regularize Poisson Regression .....	10-48
Regularize Logistic Regression .....	10-52
Regularize Wide Data in Parallel .....	10-59
Generalized Linear Model Lasso and Elastic Net .....	10-65
References .....	10-67

## Nonlinear Regression

<b>Nonlinear Regression</b> .....	11-2
What Are Parametric Nonlinear Regression Models? ....	11-2
Prepare Data .....	11-3
Represent the Nonlinear Model .....	11-4
Choose Initial Vector $\beta_0$ .....	11-7
Fit Nonlinear Model to Data .....	11-7

Examine Quality and Adjust the Fitted Model .....	11-8
Predict or Simulate Responses to New Data .....	11-12
Nonlinear Regression Workflow .....	11-16
<b>Mixed-Effects Models .....</b>	<b>11-23</b>
Introduction to Mixed-Effects Models .....	11-23
Mixed-Effects Model Hierarchy .....	11-24
Specifying Mixed-Effects Models .....	11-25
Specifying Covariate Models .....	11-28
Choosing nlmeFit or nlmeFitsa .....	11-30
Using Output Functions with Mixed-Effects Models .....	11-33
Mixed-Effects Models Using nlmeFit and nlmeFitsa .....	11-38
Examining Residuals for Model Verification .....	11-55
<b>Pitfalls in Fitting Nonlinear Models by Transforming to Linearity .....</b>	<b>11-61</b>

## Survival Analysis

# 12

<b>What Is Survival Analysis? .....</b>	<b>12-2</b>
Introduction .....	12-2
Censoring .....	12-2
Data .....	12-3
Survivor Function .....	12-5
Hazard Function .....	12-7
<b>Kaplan-Meier Method .....</b>	<b>12-11</b>
<b>Hazard and Survivor Functions for Different Groups .....</b>	<b>12-19</b>
<b>Survivor Functions for Two Groups .....</b>	<b>12-26</b>
<b>Cox Proportional Hazards Regression .....</b>	<b>12-31</b>
<b>Cox Proportional Hazards Model for Censored Data ..</b>	<b>12-34</b>

<b>Introduction to Multivariate Methods</b> .....	13-2
<b>Multivariate Linear Regression</b> .....	13-3
Multivariate Linear Regression Model .....	13-3
Solving Multivariate Regression Problems .....	13-4
<b>Estimation of Multivariate Regression Models</b> .....	13-6
Least Squares Estimation .....	13-6
Maximum Likelihood Estimation .....	13-10
Missing Response Data .....	13-12
<b>Set Up Multivariate Regression Problems</b> .....	13-16
Response Matrix .....	13-16
Design Matrices .....	13-21
Common Multivariate Regression Problems .....	13-22
<b>Multivariate General Linear Model</b> .....	13-30
<b>Fixed Effects Panel Model with Concurrent Correlation</b> .....	13-35
<b>Longitudinal Analysis</b> .....	13-43
<b>Multidimensional Scaling</b> .....	13-50
Introduction to Multidimensional Scaling .....	13-50
Classical Multidimensional Scaling .....	13-50
Nonclassical Multidimensional Scaling .....	13-56
Nonmetric Multidimensional Scaling .....	13-58
<b>Procrustes Analysis</b> .....	13-62
Compare Landmark Data .....	13-62
Data Input .....	13-62
Preprocess Data for Accurate Results .....	13-63
Compare Handwritten Shapes .....	13-64
<b>Feature Selection</b> .....	13-71

Introduction to Feature Selection .....	13-71
Sequential Feature Selection .....	13-71
<b>Feature Transformation .....</b>	<b>13-76</b>
Introduction to Feature Transformation .....	13-76
Nonnegative Matrix Factorization .....	13-76
Principal Component Analysis (PCA) .....	13-80
Quality of Life in U.S. Cities .....	13-81
Factor Analysis .....	13-94
<b>Partial Least Squares Regression and Principal Components Regression .....</b>	<b>13-106</b>

## Cluster Analysis

# 14

<b>Introduction to Cluster Analysis .....</b>	<b>14-2</b>
<b>Hierarchical Clustering .....</b>	<b>14-3</b>
Introduction to Hierarchical Clustering .....	14-3
Algorithm Description .....	14-3
Similarity Measures .....	14-4
Linkages .....	14-6
Dendrograms .....	14-8
Verify the Cluster Tree .....	14-10
Create Clusters .....	14-16
<b>k-Means Clustering .....</b>	<b>14-22</b>
Introduction to k-Means Clustering .....	14-22
Create Clusters and Determine Separation .....	14-23
Determine the Correct Number of Clusters .....	14-25
Avoid Local Minima .....	14-28
<b>Gaussian Mixture Models .....</b>	<b>14-30</b>
Introduction to Gaussian Mixture Models .....	14-30
Cluster with Gaussian Mixtures .....	14-30

<b>Parametric Classification</b> .....	<b>15-2</b>
<b>Discriminant Analysis</b> .....	<b>15-3</b>
What Is Discriminant Analysis? .....	15-3
Create Discriminant Analysis Classifiers .....	15-3
Creating a Classifier Using	
ClassificationDiscriminant.fit .....	15-4
How the predict Method Classifies .....	15-6
Create and Visualize Discriminant Analysis Classifier ...	15-9
Improve a Discriminant Analysis Classifier .....	15-15
Regularize a Discriminant Analysis Classifier .....	15-23
Examine the Gaussian Mixture Assumption .....	15-29
Bibliography .....	15-37
 <b>Naive Bayes Classification</b> .....	 <b>15-38</b>
Supported Distributions .....	15-38
 <b>Performance Curves</b> .....	 <b>15-41</b>
Introduction to Performance Curves .....	15-41
What are ROC Curves? .....	15-41
Evaluate Classifier Performance Using perfcurve .....	15-41

**Nonparametric Supervised Learning**

<b>Supervised Learning (Machine Learning) Workflow</b>	
<b>and Algorithms</b> .....	<b>16-2</b>
Steps in Supervised Learning (Machine Learning) .....	16-2
Characteristics of Algorithms .....	16-7
 <b>Classification Using Nearest Neighbors</b> .....	 <b>16-9</b>
Pairwise Distance .....	16-9
k-Nearest Neighbor Search and Radius Search .....	16-12
K-Nearest Neighbor Classification for Supervised	
Learning .....	16-26

Construct a KNN Classifier .....	16-27
Examine the Quality of a KNN Classifier .....	16-27
Predict Classification Based on a KNN Classifier .....	16-28
Modify a KNN Classifier .....	16-29
<b>Classification Trees and Regression Trees .....</b>	<b>16-31</b>
What Are Classification Trees and Regression Trees? ....	16-31
Creating a Classification Tree .....	16-32
Creating a Regression Tree .....	16-32
Viewing a Classification or Regression Tree .....	16-33
How the Fit Methods Create Trees .....	16-36
Predicting Responses With Classification and Regression Trees .....	16-38
Improving Classification Trees and Regression Trees ....	16-39
Alternative: classregtree .....	16-48
<b>Splitting Categorical Predictors .....</b>	<b>16-56</b>
Challenges in Splitting Multilevel Predictors .....	16-56
Pull Left By Purity .....	16-57
Principle Component-Based Partitioning .....	16-57
One Versus All By Class .....	16-58
<b>Ensemble Methods .....</b>	<b>16-59</b>
Framework for Ensemble Learning .....	16-59
Basic Ensemble Examples .....	16-69
Test Ensemble Quality .....	16-71
Classification with Imbalanced Data .....	16-77
Classification: Imbalanced Data or Unequal Misclassification Costs .....	16-83
Classification with Many Categorical Levels .....	16-91
Surrogate Splits .....	16-95
LPBoost and TotalBoost for Small Ensembles .....	16-98
Ensemble Regularization .....	16-103
Tuning RobustBoost .....	16-115
Random Subspace Classification .....	16-119
TreeBagger Examples .....	16-125
Ensemble Algorithms .....	16-146
<b>Support Vector Machines (SVM) .....</b>	<b>16-162</b>
Understanding Support Vector Machines .....	16-162
Using Support Vector Machines .....	16-168
Nonlinear Classifier with Gaussian Kernel .....	16-170

SVM Classification with Cross Validation .....	16-174
<b>Bibliography</b> .....	16-184

## Markov Models

# 17

<b>Introduction to Markov Models</b> .....	17-2
<b>Markov Chains</b> .....	17-3
<b>Hidden Markov Models (HMM)</b> .....	17-5
Introduction to Hidden Markov Models (HMM) .....	17-5
Analyzing Hidden Markov Models .....	17-7

## Design of Experiments

# 18

<b>Design of Experiments</b> .....	18-2
<b>Full Factorial Designs</b> .....	18-3
Multilevel Designs .....	18-3
Two-Level Designs .....	18-4
<b>Fractional Factorial Designs</b> .....	18-5
Introduction to Fractional Factorial Designs .....	18-5
Plackett-Burman Designs .....	18-5
General Fractional Designs .....	18-6
<b>Response Surface Designs</b> .....	18-9
Introduction to Response Surface Designs .....	18-9
Central Composite Designs .....	18-9

## Statistics Toolbox Product Description

### Perform statistical modeling and analysis

Statistics Toolbox™ provides algorithms and tools for organizing, analyzing, and modeling data. You can use regression or classification for predictive modeling, generate random numbers for Monte Carlo simulations, use statistical plots for exploratory data analysis, and perform hypothesis tests.

For analyzing multidimensional data, Statistics Toolbox includes algorithms that let you identify key variables that impact your model with sequential feature selection, transform your data with principal component analysis, apply regularization and shrinkage, or use partial least-squares regression.

Statistics Toolbox includes specialized data types for organizing and accessing heterogeneous data. Dataset arrays store numeric data, text, and metadata in a single data container. Built-in methods enable you to merge datasets using a common key (join), calculate summary statistics on grouped data, and convert between tall and wide data representations. Categorical arrays provide a memory-efficient data container for storing information drawn from a finite, discrete set of categories.

### Key Features

- Statistical arrays for storing heterogeneous and categorical data
- Regression techniques, including linear, nonlinear, robust, and ridge, and nonlinear mixed-effects models
- Classification algorithms, including boosted and bagged decision trees, k-Nearest Neighbor, and linear discriminant analysis
- Analysis of variance (ANOVA)
- Probability distributions, including copulas and Gaussian mixtures
- Random number generation
- Hypothesis testing
- Design of experiments and statistical process control

## Create Nominal and Ordinal Arrays

### In this section...

“Create Nominal Arrays” on page 2-3

“Create Ordinal Arrays” on page 2-5

### Create Nominal Arrays

This example shows how to create nominal arrays using `nominal`.

#### Load sample data.

The variable `species` is a 150-by-1 cell array of strings containing the species name for each observation. The unique species types are `setosa`, `versicolor`, and `virginica`.

```
load('fisheriris')
unique(species)
```

```
ans =

    'setosa'
    'versicolor'
    'virginica'
```

#### Create a nominal array.

Convert `species` to a nominal array using the categories occurring in the data.

```
speciesNom = nominal(species);
class(speciesNom)
```

```
ans =

nominal
```

#### Explore category levels.

The nominal array, `speciesNom`, has three levels corresponding to the three unique species. The levels of a nominal array are the set of possible values that its elements can take.

```
getlevels(speciesNom)

ans =

    setosa    versicolor    virginica
```

A nominal array can have more levels than actually appear in the data. For example, a nominal array named `AllSizes` might have levels `small`, `medium`, and `large`, but you might only have observations that are `medium` and `large` in your data. To see which levels of a nominal array are actually present in the data, use `unique`, for instance, `unique(AllSizes)`.

### Explore category labels.

Each level has a label, which is a string used to name the level. By default, nominal labels the category levels with the values occurring in the data. For `speciesNom`, these labels are the species types.

```
getlabels(speciesNom)

ans =

    'setosa'    'versicolor'    'virginica'
```

### Specify your own category labels.

You can specify your own labels for each category level. You can specify labels when you create the nominal array.

```
speciesNom2 = nominal(species,{'seto','vers','virg'});
getlabels(speciesNom2)

ans =

    'seto'    'vers'    'virg'
```

You can also change category labels on an existing nominal array using `setlabels`

**Verify new category labels.**

Verify that the new labels correspond to the original labels in `speciesNom`.

```
isequal(speciesNom=='setosa',speciesNom2=='seto')
```

```
ans =
```

```
1
```

The logical value 1 indicates that the two labels, 'setosa' and 'seto', correspond to the same observations.

**Create Ordinal Arrays**

This example shows how to create ordinal arrays using `ordinal`.

**Load sample data.**

```
AllSizes = {'medium','large','small','small','medium',...
            'large','medium','small'};
```

The created variable, `AllSizes`, is a cell array of strings containing size measurements on eight objects.

**Create an ordinal array.**

Create an ordinal array with category levels and labels corresponding to the values in the cell array (the default levels and labels).

```
sizeOrd = ordinal(AllSizes);
getlevels(sizeOrd)
```

```
ans =
```

```
large    medium    small
```

**Explore category labels.**

By default, `ordinal` uses the original strings as category labels. The default order of the categories is ascending alphabetical order.

```
getlabels(sizeOrd)

ans =

    'large'    'medium'    'small'
```

### **Add additional categories.**

Suppose that you want to include additional levels for the ordinal array, `xsmall` and `xlarge`, even though they do not occur in the original data. To specify additional levels, use the third input argument to `ordinal`.

```
sizeOrd2 = ordinal(AllSizes, {}, ...
                  {'xsmall', 'small', 'medium', 'large', 'xlarge'});
getlevels(sizeOrd2)

ans =

    xsmall    small    medium    large    xlarge
```

### **Explore category labels.**

To see which levels are actually present in the data, use `unique`.

```
unique(sizeOrd2)

ans =

    small    medium    large
```

### **Specify the category order.**

Convert `AllSizes` to an ordinal array with categories `small < medium < large`. Generally, an ordinal array is distinct from a nominal array because there is a natural ordering for levels of an ordinal array. You can use the third input argument to `ordinal` to specify the ascending order of the levels. Here, the order of the levels is smallest to largest.

```
sizeOrd = ordinal(AllSizes, {}, {'small', 'medium', 'large'});
getlevels(sizeOrd)

ans =
```

```
small    medium    large
```

The second input argument for `ordinal` is a list of labels for the category levels. When you use braces `{}` for the level labels, `ordinal` uses the labels specified in the third input argument (the labels come from the levels present in the data if only one input argument is used).

### **Compare elements.**

Verify that the first object (with size `medium`) is smaller than the second object (with size `large`).

```
sizeOrd(1) < sizeOrd(2)
```

```
ans =
```

```
1
```

The logical value `1` indicates that the inequality holds.

- “Index and Search Using Categorical Arrays” on page 2-46

## **Concepts**

- “Categorical Arrays” on page 2-41
- “Advantages of Using Categorical Arrays” on page 2-43

## Change Category Labels

This example shows how to change the labels for category levels in categorical arrays using `setlabels`. You also have the option to specify labels when creating a categorical array.

### Load sample data.

The variable `Cylinders` contains the number of cylinders in 100 sample cars.

```
load('carsmall')
unique(Cylinders)
```

```
ans =
```

```
4
6
8
```

The sample has 4-, 6-, and 8-cylinder cars.

### Create an ordinal array.

Convert `Cylinders` to a nominal array with the default category labels (taken from the values in the data).

```
cyl = ordinal(Cylinders);
getlabels(cyl)
```

```
ans =
```

```
'4'    '6'    '8'
```

`ordinal` created labels using the integer values in `Cylinders`, but you should provide labels for numeric data.

### Change category labels.

Relabel the categories in `cyl` to Four, Six, and Eight.

```
cyl = setlabels(cyl ,{'Four', 'Six', 'Eight'});
getlabels(cyl)
```

```
ans =  
  
      'Four'      'Six'      'Eight'
```

Alternatively, you can specify category labels when you create a nominal or ordinal array using the second input argument, for example by specifying `ordinal(Cylinders,{'Four','Six','Eight'})`.

## Concepts

- “Categorical Arrays” on page 2-41
- “Advantages of Using Categorical Arrays” on page 2-43

## Reorder Category Levels

<b>In this section...</b>
“Reorder Category Levels in Ordinal Arrays” on page 2-10
“Reorder Category Levels in Nominal Arrays” on page 2-11

### Reorder Category Levels in Ordinal Arrays

This example shows how to reorder the category levels in an ordinal array using `reorderlevels`.

#### Load sample data.

```
AllSizes = {'medium', 'large', 'small', 'small', 'medium', ...  
           'large', 'medium', 'small'};
```

The created variable, `AllSizes`, is a cell array of strings containing size measurements on eight objects.

#### Create an ordinal array.

Convert `AllSizes` to an ordinal array without specifying the order of the category levels.

```
size = ordinal(size);  
getlevels(size)
```

```
ans =
```

```
       large       medium       small
```

By default, the categories are ordered by their labels in ascending alphabetical order, `large < medium < small`.

#### Compare elements.

Check whether or not the first object (which has size `medium`) is smaller than the second object (which has size `large`).

```
size(1) < size(2)
```

```
ans =  
  
      0
```

The logical value 0 indicates that the medium object is not smaller than the large object.

### **Reorder category levels.**

Reorder the category levels so that `small < medium < large`.

```
size = reorderlevels(size,{'small','medium','large'});  
getlevels(size)
```

```
ans =  
  
      small      medium      large
```

### **Compare elements.**

Verify that the first object is now smaller than the second object.

```
size(1) < size(2)
```

```
ans =  
  
      1
```

The logical value 1 indicates that the expected inequality now holds.

## **Reorder Category Levels in Nominal Arrays**

This example shows how to reorder the category levels in nominal arrays using `reorderlevels`. By definition, nominal array categories have no natural ordering. However, you might want to change the order of levels for display or analysis purposes. For example, when fitting a regression model with categorical covariates, `fitlm` uses the first level of a nominal independent variable as the reference category.

### **Load sample data.**

The dataset array, `hospital`, contains variables measured on 100 sample patients. The variable `Weight` contains the weight of each patient. The variable `Sex` is a nominal variable containing the gender, `Male` or `Female`, for each patient.

```
load('hospital')
getlevels(hospital.Sex)
```

```
ans =
```

```
      Female      Male
```

By default, the order of the nominal categories is in ascending alphabetical order of the labels.

### **Plot data grouped by category level.**

Draw box plots of weight, grouped by gender.

```
figure()
boxplot(hospital.Weight,hospital.Sex)
title('Weight by Gender')
```

The box plots appear in the same alphabetical order returned by `getlevels`.

**Change the category order.**

Change the order of the category levels.

```
hospital.Sex = reorderlevels(hospital.Sex, {'Male', 'Female'});
getlevels(hospital.Sex)
```

```
ans =
```

```
    Male    Female
```

The levels are in the newly specified order.

**Plot data in new order.**

Draw box plots of weight by gender.

```
figure()
```

```
boxplot(hospital.Weight,hospital.Sex)  
title('Weight by Gender')
```

The order of the box plots corresponds to the new level order.

### Concepts

- “Categorical Arrays” on page 2-41
- “Advantages of Using Categorical Arrays” on page 2-43

## Categorize Numeric Data

This example shows how to categorize numeric data into a categorical ordinal array using `ordinal`. This is useful for discretizing continuous data.

### Load sample data.

The dataset array, `hospital`, contains variables measured on a sample of patients. Compute the minimum, median, and maximum of the variable `Age`.

```
load('hospital')
quantile(hospital.Age,[0,.5,1])
```

```
ans =
    25    39    50
```

The patient ages range from 25 to 50.

### Convert a numeric array to an ordinal array.

Group patients into the age categories Under 30, 30-39, Over 40.

```
hospital.AgeCat = ordinal(hospital.Age,{'Under 30','30-39','Over 40'},...
                           [],[25,30,40,50]);
getlevels(hospital.AgeCat)
```

```
ans =
    Under 30    30-39    Over 40
```

The last input argument to `ordinal` has the endpoints for the categories. The first category begins at age 25, the second at age 30, and so on. The last category contains ages 40 and above, so begins at 40 and ends at 50 (the maximum age in the data set). To specify three categories, you must specify four endpoints (the last endpoint is the upper bound of the last category).

### Explore categories.

Display the age and age category for the second patient.

```
dataset({hospital.Age(2),'Age'},...
```

```
{hospital.AgeCat(2), 'AgeCategory'}  
  
ans =  
  
    Age    AgeCategory  
    43    Over 40
```

When you discretize a numeric array into categories, the categorical array loses all information about the actual numeric values. In this example, `AgeCat` is not numeric, and you cannot recover the raw data values from it.

### **Categorize a numeric array into quartiles.**

The variable `Weight` has weight measurements for the sample patients. Categorize the patient weights into four categories, by quartile.

```
p = 0:.25:1;  
breaks = quantile(hospital.Weight,p);  
hospital.WeightQ = ordinal(hospital.Weight,{'Q1','Q2','Q3','Q4'},...  
    [],breaks);  
getlevels(hospital.WeightQ)  
  
ans =  
  
    Q1    Q2    Q3    Q4
```

### **Explore categories.**

Display the weight and weight quartile for the second patient.

```
dataset({hospital.Weight(2), 'Weight'},...  
    {hospital.WeightQ(2), 'WeightQuartile'})  
  
ans =  
  
    Weight    WeightQuartile  
    163      Q3
```

### **Summary statistics grouped by category levels.**

Compute the mean systolic and diastolic blood pressure for each age and weight category.

```
grpstats(hospital, {'AgeCat', 'WeightQ'}, 'mean', 'DataVars', 'BloodPressure')
```

```
ans =
```

	AgeCat	WeightQ	GroupCount	mean_BloodPressure	
Under 30_Q1	Under 30	Q1	6	123.17	79.667
Under 30_Q2	Under 30	Q2	3	120.33	79.667
Under 30_Q3	Under 30	Q3	2	127.5	86.5
Under 30_Q4	Under 30	Q4	4	122	78
30-39_Q1	30-39	Q1	12	121.75	81.75
30-39_Q2	30-39	Q2	9	119.56	82.556
30-39_Q3	30-39	Q3	9	121	83.222
30-39_Q4	30-39	Q4	11	125.55	87.273
Over 40_Q1	Over 40	Q1	7	122.14	84.714
Over 40_Q2	Over 40	Q2	13	123.38	79.385
Over 40_Q3	Over 40	Q3	14	123.07	84.643
Over 40_Q4	Over 40	Q4	10	124.6	85.1

The variable `BloodPressure` is a matrix with two columns. The first column is systolic blood pressure, and the second column is diastolic blood pressure. The group in the sample with the highest mean diastolic blood pressure, 87.273, is aged 30–39 and in the highest weight quartile, 30-39\_Q4.

- “Advantages of Using Categorical Arrays” on page 2-43

## Merge Category Levels

This example shows how to merge categories in a categorical array using `mergelevels`. This is useful for collapsing categories with few observations.

### Load sample data.

```
load('carsmall')
```

### Create a nominal array.

The variable `Origin` is a character array containing the country of origin for 100 sample cars. Convert `Origin` to a nominal array.

```
Origin = nominal(Origin);  
getlevels(Origin)
```

```
ans =
```

```
      France      Germany      Italy      Japan      Sweden      USA
```

There are six unique countries of origin in the data.

### Tabulate category counts.

Explore the elements of the categorical array.

```
tabulate(Origin)
```

Value	Count	Percent
France	4	4.00%
Germany	9	9.00%
Italy	1	1.00%
Japan	15	15.00%
Sweden	2	2.00%
USA	69	69.00%

There are relatively few observations in each European country.

### Merge categories.

Merge the categories France, Germany, Italy, and Sweden into one category called Europe.

```
Origin = mergelevels(Origin,{'France','Germany','Italy','Sweden'},...
                    'Europe');
getlevels(Origin)

ans =
```

```
      Japan      USA      Europe
```

The variable `Origin` now has only three category levels.

#### **Tabulate category counts.**

Explore the elements of the merged categories.

```
tabulate(Origin)

      Value      Count      Percent
      Japan       15      15.00%
      USA         69      69.00%
      Europe      16      16.00%
```

The category `Europe` has the 16% of observations that were previously distributed across four countries.

## Add and Drop Category Levels

This example shows how to add and drop levels from a categorical array.

### Load sample data.

```
load('examgrades')
```

The array `grades` contains exam scores from 0 to 100 on five exams for a sample of 120 students.

### Create an ordinal array.

Assign letter grades to each student for each test using these categories.

Grade Range	Letter Grade
100	A+
90–99	A
80–89	B
70–79	C
60–69	D

```
letter = ordinal(grades,{'D','C','B','A','A+'},[],...
                 [60,70,80,90,100,100]);
getlevels(letter)
```

```
ans =
```

```
      D      C      B      A      A+
```

There are five grade categories, in the specified order  $D < C < B < A < A+$ .

### Check for undefined categories.

Check whether or not there are any exam scores that do not fall into the five letter categories.

```
any(isundefined(letter))
```

```
ans =
      1      0      1      1      0
```

Recall that there are five exam scores for each student. The previous command returns a logical value for each of the five exams, indicating whether there are any scores that are `<undefined>`. There are scores for the first, third, and fourth exams that are `<undefined>`, that is, missing a category level.

**Identify elements in undefined categories.**

You can find the exam scores that do not have a letter grade using the `isundefined` logical condition.

```
grades(isundefined(letter))
```

```
ans =
      55
      59
      58
      59
      54
      57
      56
      59
      59
      50
      59
      52
```

The exam scores that are in the 50s do not have a letter grade.

**Add a new category.**

Put all scores that are `<undefined>` into a new category labeled D-.

```
letter(isundefined(letter)) = 'D-';
getlevels(letter)
```

```
Warning: Categorical level 'D-' being added.
```

```
> In categorical.subsasgn at 55
```

```
ans =
```

```
      D      C      B      A      A+      D-
```

The ordinal variable, `letter`, has a new category added to the end.

### Reorder category levels.

Reorder the categories so that `D- < D`.

```
letter = reorderlevels(letter,{'D-', 'D', 'C', 'B', 'A', 'A+'});  
getlevels(letter)
```

```
ans =
```

```
      D-      D      C      B      A      A+
```

### Compare elements.

Now that all exam scores have a letter grade, count how many students received a higher letter grade on the second test than on the first test.

```
sum(letter(:,2) > letter(:,1))
```

```
ans =
```

```
32
```

Thirty-two students improved their letter grade between the first two exams.

### Explore categories.

Count the number of `A+` scores in each of the five exams.

```
sum(letter=='A+')
```

```
ans =
```

```
      0      0      0      0      0
```

There are no A+ scores on any of the five exams.

**Drop a category.**

Drop the category A+ from the ordinal variable, letter.

```
letter = droplevels(letter, 'A+');  
getlevels(letter)
```

```
ans =
```

```
      D-      D      C      B      A
```

Category A+ is no longer in the ordinal variable, letter.

## Plot Data Grouped by Category

This example shows how to plot data grouped by the levels of a categorical variable.

### **Load sample data.**

```
load('carsmall')
```

The variable `Acceleration` contains acceleration measurements on 100 sample cars. The variable `Origin` is a character array containing the country of origin for each car.

### **Create a nominal array.**

Convert `Origin` to a nominal array.

```
Origin = nominal(Origin);  
getlevels(Origin)
```

```
ans =
```

```
      France      Germany      Italy      Japan      Sweden      USA
```

There are six unique countries of origin in the sample. By default, `nominal` orders the countries in ascending alphabetical order.

### **Plot data grouped by category.**

Draw box plots for `Acceleration`, grouped by `Origin`.

```
figure()  
boxplot(Acceleration,Origin)  
title('Acceleration, Grouped by Country of Origin')
```

The box plots appear in the same order as the categorical levels (use `reorder(levels)` to change the order of the categories).

Few observations have Italy as the country of origin.

**Tabulate category counts.**

Tabulate the number of sample cars from each country.

```
tabulate(Origin)
```

Value	Count	Percent
France	4	4.00%
Germany	9	9.00%
Italy	1	1.00%
Japan	15	15.00%
Sweden	2	2.00%
USA	69	69.00%

Only one car is made in Italy.

**Drop a category.**

Delete the Italian car from the sample.

```
Acceleration2 = Acceleration(Origin~='Italy');  
Origin2 = Origin(Origin~='Italy');  
getlevels(Origin2)
```

```
ans =
```

```
      France      Germany      Italy      Japan      Sweden      USA
```

Even though the car from Italy is no longer in the sample, the nominal variable, `Origin2`, still has the category `Italy`. Note that this is intentional—the levels of a categorical array do not necessarily coincide with the values.

**Drop a category level.**

Use `droplevels` to remove the `Italy` category.

```
Origin2 = droplevels(Origin2, 'Italy');  
tabulate(Origin2)
```

```
tabulate(Origin2)  
  Value  Count  Percent  
  France    4    4.04%  
  Germany    9    9.09%  
  Japan   15   15.15%  
  Sweden    2    2.02%  
  USA     69   69.70%
```

The `Italy` category is no longer in the nominal array, `Origin2`.

**Plot data grouped by category.**

Draw box plots of `Acceleration2`, grouped by `Origin2`.

```
figure()  
boxplot(Acceleration2, Origin2)
```

```
title('Acceleration, Grouped by Country of Origin')
```

The plot no longer includes the car from Italy.

- “Grouping Variables” on page 2-51

## Test Differences Between Category Means

This example shows how to test for significant differences between category (group) means using a *t*-test, two-way ANOVA (analysis of variance), and ANOCOVA (analysis of covariance) analysis.

The goal is determining if the expected miles per gallon for a car depends on the decade in which it was manufactured, or the location where it was manufactured.

### Load sample data.

```
load('carsmall')
unique(Model_Year)
```

```
ans =
```

```
70
76
82
```

The variable MPG has miles per gallon measurements on a sample of 100 cars. The variables Model\_Year and Origin contain the model year and country of origin for each car.

The first factor of interest is the decade of manufacture. There are three manufacturing years in the data.

### Create a factor for the decade of manufacture.

Create an ordinal array named Decade by merging the observations from years 70 and 76 into a category labeled 1970s, and putting the observations from 82 into a category labeled 1980s.

```
Decade = ordinal(Model_Year,{'1970s','1980s'},[],[70 77 82]);
getlevels(Decade)
```

```
ans =
```

```
1970s    1980s
```

**Plot data grouped by category.**

Draw a box plot of miles per gallon, grouped by the decade of manufacture.

```
figure()
boxplot(MPG,Decade)
title('Miles per Gallon, Grouped by Decade of Manufacture')
```

The box plot suggests that miles per gallon is higher in cars manufactured during the 1980s compared to the 1970s.

**Compute summary statistics.**

Compute the mean and variance of miles per gallon for each decade.

```
[xbar,s2,grp] = grpstats(MPG,Decade,{'mean','var','gname'})
```

```
xbar =
```

```
19.7857
31.7097

s2 =

35.1429
29.0796

grp =

'1970s'
'1980s'
```

This output shows that the mean miles per gallon in the 1980s was 31.71, compared to 19.79 in the 1970s. The variances in the two groups are similar.

### **Conduct a two-sample *t*-test for equal group means.**

Conduct a two-sample *t*-test, assuming equal variances, to test for a significant difference between the group means. The hypothesis is

$$H_0 : \mu_{70} = \mu_{80}$$
$$H_A : \mu_{70} \neq \mu_{80}.$$

```
MPG70 = MPG(Decade=='1970s');
MPG80 = MPG(Decade=='1980s');
[h,p] = ttest2(MPG70,MPG80)
```

```
h =

1

p =

3.4809e-15
```

The logical value 1 indicates the null hypothesis is rejected at the default 0.05 significance level. The p-value for the test is very small. There is sufficient evidence that the mean miles per gallon in the 1980s differs from the mean miles per gallon in the 1970s.

**Create a factor for the location of manufacture.**

The second factor of interest is the location of manufacture. First, convert Origin to a nominal array.

```
Location = nominal(Origin);
tabulate(Location)
```

```
tabulate(Location)
  Value    Count   Percent
  France     4    4.00%
  Germany     9    9.00%
  Italy       1    1.00%
  Japan     15   15.00%
  Sweden     2    2.00%
  USA       69   69.00%
```

There are six different countries of manufacture. The European countries have relatively few observations.

**Merge categories.**

Combine the categories France, Germany, Italy, and Sweden into a new category named Europe.

```
Location = mergelevels(Location,{'France','Germany','Italy','Sweden'},...
                        'Europe');
tabulate(Location)
```

```
  Value    Count   Percent
  Japan     15   15.00%
  USA       69   69.00%
  Europe    16   16.00%
```

**Compute summary statistics.**

Compute the mean miles per gallon, grouped by the location of manufacture.

```
[xbar,grp] = grpstats(MPG,Location,{'mean','gname'})
```

```
xbar =
```

```
31.8000  
21.1328  
26.6667
```

```
grp =
```

```
'Japan'  
'USA'  
'Europe'
```

This result shows that average miles per gallon is lowest for the sample of cars manufactured in the U.S.

### **Conduct two-way ANOVA.**

Conduct a two-way ANOVA to test for differences in expected miles per gallon between factor levels for Decade and Location.

The statistical model is

$$MPG_{ij} = \mu + \alpha_i + \beta_j + \varepsilon_{ij}, \quad i = 1, 2; j = 1, 2, 3,$$

where  $MPG_{ij}$  is the response, miles per gallon, for cars made in decade  $i$  at location  $j$ . The treatment effects for the first factor, decade of manufacture, are the  $\alpha_i$  terms (constrained to sum to zero). The treatment effects for the second factor, location of manufacture, are the  $\beta_j$  terms (constrained to sum to zero). The  $\varepsilon_{ij}$  are uncorrelated, normally distributed noise terms.

The hypotheses to test are equality of decade effects,

$$H_0 : \alpha_1 = \alpha_2 = 0$$

$$H_A : \text{at least one } \alpha_i \neq 0,$$

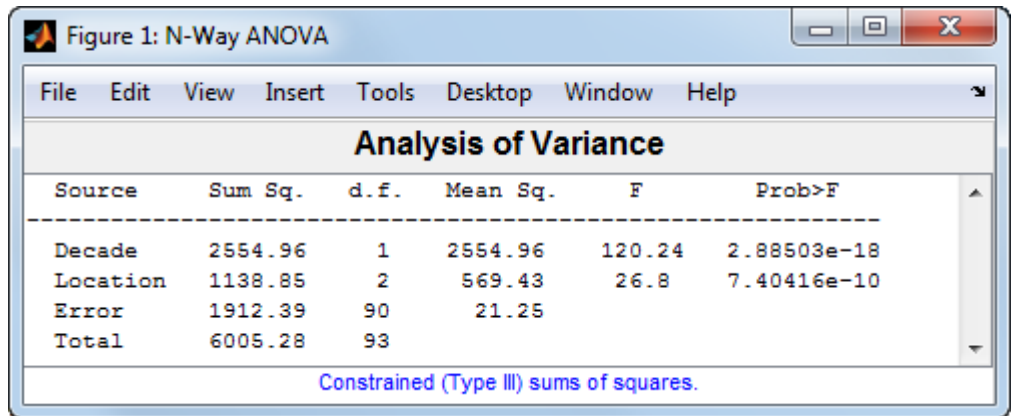

and equality of location effects,

$$H_0 : \beta_1 = \beta_2 = \beta_3 = 0$$

$$H_A : \text{at least one } \beta_j \neq 0.$$

You can conduct a multiple-factor ANOVA using `anovan`.

```
anovan(MPG, {Decade, Location}, 'varnames', {'Decade', 'Location'});
```

This output shows the results of the two-way ANOVA. The p-value for testing the equality of decade effects is  $2.88503e-18$ , so the null hypothesis is rejected at the 0.05 significance level. The p-value for testing the equality of location effects is  $7.40416e-10$ , so this null hypothesis is also rejected.

### Conduct ANOCOVA analysis.

A potential confounder in this analysis is car weight. Cars with greater weight are expected to have lower gas mileage. Include the variable `Weight` as a continuous covariate in the ANOVA; that is, conduct an ANOCOVA analysis.

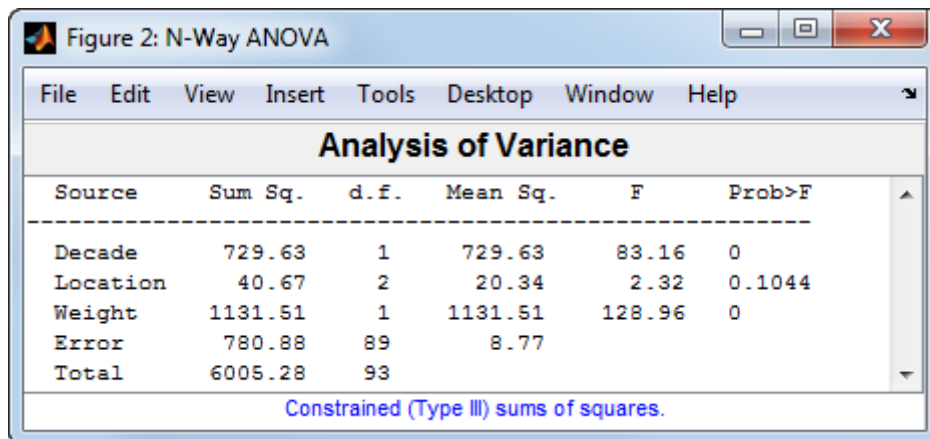

Assuming parallel lines, the statistical model is

$$MPG_{ijk} = \mu + \alpha_i + \beta_j + \gamma Weight_{ijk} + \varepsilon_{ijk}, \quad i = 1, 2; \quad j = 1, 2, 3; \quad k = 1, \dots, 100.$$

The difference between this model and the two-way ANOVA model is the inclusion of the continuous predictor,  $Weight_{ijk}$ , the weight for the  $k$ th car, which was made in the  $i$ th decade and in the  $j$ th location. The slope parameter is  $\gamma$ .

Add the continuous covariate as a third group in the second anovan input argument. Use the name-value pair argument `Continuous` to specify that `Weight` (the third group) is continuous.

```
anovan(MPG,{Decade,Location,Weight},'Continuous',3,...
       'varnames',{'Decade','Location','Weight'});
```

This output shows that when car weight is considered, there is insufficient evidence of a manufacturing location effect (p-value = 0.1044).

#### Use interactive tool.

You can use the interactive `aoctool` to explore this result.

```
aoctool(Weight,MPG,Location);
```

This command opens three dialog boxes. In the ANOCOVA Prediction Plot dialog box, select the **Separate Means** model.

This output shows that when you do not include **Weight** in the model, there are fairly large differences in the expected miles per gallon among the three manufacturing locations. Note that here the model does not adjust for the decade of manufacturing.

Now, select the **Parallel Lines** model.

When you include `Weight` in the model, the difference in expected miles per gallon among the three manufacturing locations is much smaller.

## Summary Statistics Grouped by Category

This example shows how to compute summary statistics grouped by levels of a categorical variable. You can compute group summary statistics for a numeric array or a dataset array using `grpstats`.

### Load sample data.

```
load('hospital')
```

The dataset array, `hospital`, has 7 variables (columns) and 100 observations (rows).

### Compute summary statistics by category.

The variable `Sex` is a nominal array with two levels, `Male` and `Female`. Compute the minimum and maximum weights for each gender.

```
stats = grpstats(hospital, 'Sex', {'min', 'max'}, 'DataVars', 'Weight')
```

```
stats =
```

	Sex	GroupCount	min_Weight	max_Weight
Female	Female	53	111	147
Male	Male	47	158	202

The dataset array, `stats`, has observations corresponding to the levels of the variable `Sex`. The variable `min_Weight` contains the minimum weight for each group, and the variable `max_Weight` contains the maximum weight for each group.

### Compute summary statistics by multiple categories.

The variable `Smoker` is a logical array with value 1 for smokers and value 0 for nonsmokers. Compute the minimum and maximum weights for each gender and smoking combination.

```
stats = grpstats(hospital, {'Sex', 'Smoker'}, {'min', 'max'}, ...
                'DataVars', 'Weight')
```

```
stats =
```

	Sex	Smoker	GroupCount	min_Weight	max_Weight
Female_0	Female	false	40	111	147
Female_1	Female	true	13	115	146
Male_0	Male	false	26	158	194
Male_1	Male	true	21	164	202

The dataset array, `stats`, has an observation row for each combination of levels of `Sex` and `Smoker` in the original data.

### See Also

`dataset | nominal | grpstats`

## Sort Ordinal Arrays

This example shows how to determine sorting order for ordinal arrays.

### Load sample data.

```
AllSizes = {'medium','large','small','small','medium',...  
           'large','medium','small'};
```

The created variable, `AllSizes`, is a cell array of strings containing size measurements on eight objects.

### Create an ordinal array.

Convert `AllSizes` to an ordinal array with levels `small < medium < large`.

```
AllSizes = ordinal(AllSizes, {}, {'small', 'medium', 'large'});  
getlevels(AllSizes)
```

```
ans =  
  
    small    medium    large
```

### Sort the ordinal array.

When you sort ordinal arrays, the sorted observations are in the same order as the category levels.

```
sizeSort = sort(AllSizes);  
sizeSort(:)
```

```
ans =  
  
    small  
    small  
    small  
    medium  
    medium  
    medium  
    large  
    large
```

The sorted ordinal array, `sizeSort`, contains the observations ordered from small to large.

## Categorical Arrays

### In this section...

“What Are Categorical Arrays?” on page 2-41

“Categorical Array Conversion” on page 2-41

### What Are Categorical Arrays?

*Categorical arrays* are Statistics Toolbox data types for storing categorical values. Categorical arrays store data that have a finite set of discrete levels, which might or might not have a natural order. There are two types of categorical arrays:

- **ordinal** arrays store categorical values with ordered levels. For example, an ordinal variable might have levels {small, medium, large}.
- **nominal** arrays store categorical values with unordered levels. For example, a nominal variable might have levels {red, blue, green}.

In experimental design, these variables are often called *factors*, with ordered or unordered *factor levels*.

Categorical arrays are convenient and memory efficient containers for storing categorical variables. In addition to storing information about which category each observation belongs to, categorical arrays store descriptive metadata including category labels and order.

Categorical arrays have associated methods that streamline common tasks such as merging categories, adding or dropping levels, and changing level labels.

### Categorical Array Conversion

You can easily convert to and from categorical arrays. To create a nominal or ordinal array, use `nominal` or `ordinal`, respectively. You can convert these data types to categorical arrays:

- Numeric array

- Logical array
- Character array
- Cell array of strings

### **See Also**

[ordinal](#) | [nominal](#) |

### **Related Examples**

- “Create Nominal and Ordinal Arrays” on page 2-3
- “Summary Statistics Grouped by Category” on page 2-37
- “Plot Data Grouped by Category” on page 2-24
- “Index and Search Using Categorical Arrays” on page 2-46

### **Concepts**

- “Advantages of Using Categorical Arrays” on page 2-43
- “Grouping Variables” on page 2-51

## Advantages of Using Categorical Arrays

In this section...
“Manipulate Category Levels” on page 2-43
“Analysis Using Categorical Arrays” on page 2-43
“Reduce Memory Requirements” on page 2-44

### Manipulate Category Levels

When working with categorical variables and their levels, you’ll encounter some typical challenges. This table summarizes the functions you can use with categorical arrays to manipulate category levels. For additional functions, type `methods nominal` or `methods ordinal` at the command line, or see the `nominal` and `ordinal` reference pages.

Task	Function
Add new category levels	<code>addlevels</code>
Drop category levels	<code>droplevels</code>
Combine category levels	<code>mergelevels</code>
Reorder category levels	<code>reorderlevels</code>
Count the number of observations in each category	<code>levelcounts</code>
Change the label or name of category levels	<code>setlabels</code>
Create an interaction factor	<code>times</code>
Find observations that are not in a defined category	<code>isundefined</code>

### Analysis Using Categorical Arrays

You can use categorical arrays in a variety of statistical analyses. For example, you might want to compute descriptive statistics for data grouped by the category levels, conduct statistical tests on differences between category means, or perform regression analysis using categorical predictors.

Statistics Toolbox functions that accept a grouping variable as an input argument accept categorical arrays. This includes descriptive functions such as:

- `grpstats`
- `gscatter`
- `boxplot`
- `gplotmatrix`

You can also use categorical arrays as input arguments to analysis functions and methods based on models, such as:

- `anovan`
- `fitlm`
- `fitglm`
- `fitnlm`

When you use a categorical array as a predictor in these functions, the fitting function automatically recognizes the categorical predictor, and constructs appropriate dummy indicator variables for analysis. Alternatively, you can construct your own dummy indicator variables using `dummyvar`.

### **Reduce Memory Requirements**

The levels of categorical variables are often defined as text strings, which can be costly to store and manipulate in a cell array of strings or `char` array. Categorical arrays separately store category membership and category labels, greatly reducing the amount of memory required to store the variable.

For example, load some sample data:

```
load('fisheriris')
```

The variable `species` is a cell array of strings requiring 19,300 bytes of memory.

Workspace		
Name ▲	Value	Bytes
 meas	150x4 double	4800
 species	150x1 cell	19300

Convert species to a nominal array:

```
species = nominal(species);
```

Workspace		
Name ▲	Value	Bytes
 meas	150x4 double	4800
 species	150x1 nominal	792

There is a 95% reduction in memory required to store the variable.

## Index and Search Using Categorical Arrays

### Index By Category

It is often useful to index and search data by its category, or group. If you store categories as string labels inside a cell array of strings or char array, it can be difficult to index and search the categories. When using categorical arrays, you can easily:

- **Index elements from particular categories.** For both nominal and ordinal arrays, you can use the logical operators `==` and `~=` to index the observations that are in, or not in, a particular category. For ordinal arrays, which have an encoded order, you can also use inequalities, `>`, `>=`, `<`, and `<=`, to find observations in categories above or below a particular category.
- **Search for members of a category.** In addition to the logical operator `==`, you can use `ismember` to find observations in a particular group.
- **Find elements that are not in a defined category.** Categorical arrays indicate which elements do not belong to a defined category by `<undefined>`. You can use `isundefined` to find observations missing a category.
- **Delete observations that are in a particular category.** You can use logical operators to include or exclude observations from particular categories. Even if you remove all observations from a category, the category level remains defined unless you remove it using `droplevels`.

### Common Indexing and Searching

The following brief examples illustrate several indexing and searching methods.

**Load sample data.**

```
load('carsmall')
```

Convert the char array, `Origin`, to a nominal array. This variable contains the country of origin, or manufacture, for each sample car.

```
Origin = nominal(Origin);
```

**Search for observations in a category.** Determine if there any cars in the sample that were manufactured in Canada.

```
any(Origin=='Canada')
```

```
ans =
```

```
0
```

There are no sample cars manufactured in Canada. List the countries that are levels of `Origin`.

```
getlevels(Origin)
```

```
ans =
```

```
France      Germany      Italy      Japan      Sweden      USA
```

**Index elements that are in a particular category.** Plot a histogram of the acceleration measurements for cars made in the U.S.

```
figure()
```

```
hist(Acceleration(Origin=='USA'))
```

```
title('Acceleration of Cars Made in the USA')
```

**Delete observations that are in a particular category.** Delete all cars made in Sweden from `Origin`.

```
Origin = Origin(Origin~='Sweden');  
any(ismember(Origin, 'Sweden'))
```

```
ans =
```

```
0
```

The cars made in Sweden are deleted from `Origin`, but Sweden is still a level of `Origin`.

```
getlevels(Origin)
```

```
ans =
```

```
France    Germany    Italy    Japan    Sweden    USA
```

Remove Sweden from the levels of `Origin`.

```
Origin = droplevels(Origin,'Sweden');
getlevels(Origin)
```

```
ans =
```

```
      France      Germany      Italy      Japan      USA
```

**Check for observations not in a defined category.** Get the indices for the cars made in France.

```
ix = find(Origin=='France')
```

```
ix =
```

```
    11
    27
    39
    61
```

There are four cars from France. Remove France from the levels of `Origin`.

```
Origin = droplevels(Origin,'France');
```

```
Warning: OLDLEVELS contains categorical levels that were present in the
input array A. As a result, the output array B contains array elements
that have undefined levels.
```

```
> In categorical.droplevels at 52
```

The warning indicates that you are dropping a category level that has elements in it. These observations are no longer in a defined category, indicated by `<undefined>`.

```
Origin(ix)
```

```
ans =
```

```
<undefined>
<undefined>
<undefined>
<undefined>
```

You can use `isundefined` to search for observations with an undefined category.

```
find(isundefined(Origin))
```

```
ans =
```

```
11  
27  
39  
61
```

These indices correspond to the observations that were in category `France`, before that category was dropped from `Origin`.

## Grouping Variables

### In this section...

“What Are Grouping Variables?” on page 2-51

“Group Definition” on page 2-52

“Analysis Using Grouping Variables” on page 2-52

“Missing Group Values” on page 2-53

### What Are Grouping Variables?

*Grouping variables* are utility variables used to group, or categorize, observations. Grouping variables are useful for summarizing or visualizing data by group. A grouping variable can be any of these data types:

- Numeric vector
- Logical vector
- String array (also called character arrays)
- Cell array of strings
- Categorical vector

A grouping variable must have the same number of observations (rows) as the dataset array or numeric array you are grouping. Observations that have the same grouping variable value belong to the same group.

For example, the following variables comprise the same groups. Each grouping variable divides five observations into two groups. The first group contains the first and fourth observations. The other three observations are in the second group.

Data Type	Grouping Variable
Numeric vector	[ 1 2 2 1 2 ]
Logical vector	[ 0 1 1 0 1 ]

Data Type	Grouping Variable
Cell array of strings	{'Male', 'Female', 'Female', 'Male', 'Female'}
Categorical vector	Male Female Female Male Female

Grouping variables with string labels give each group a meaningful name. A categorical array is an efficient and flexible choice of grouping variable.

### Group Definition

Typically, there are as many groups as unique values in the grouping variable. However, categorical arrays can have levels that are not represented in the data. The groups and the order of the groups depend on the data type of the grouping variable. Suppose **G** is a grouping variable.

- If **G** is a numeric or logical vector, then the groups correspond to the distinct values in **G**, in the sorted order of the unique values.
- If **G** is a string array or cell array of strings, then the groups correspond to the distinct strings in **G**, in the order of their first appearance.
- If **G** is a categorical vector, then the groups correspond to the unique category levels in **G**, in the order returned by `getlevels`.

Some functions, such as `grpstats`, accept multiple grouping variables specified as a cell array of grouping variables, for example, {**G1**, **G2**, **G3**}. In this case, the groups are defined by the unique combinations of values in the grouping variables. The order is decided first by the order of the first grouping variable, then by the order of the second grouping variable, and so on.

### Analysis Using Grouping Variables

This table lists common tasks you might want to perform using grouping variables.

Grouping Task	Function Accepting Grouping Variable
Draw side-by-side boxplots for data in different groups.	boxplot
Draw a scatter plot with markers colored by group.	gscatter
Draw a scatter plot matrix with markers colored by group.	gplotmatrix
Compute summary statistics by group.	grpstats
Test for differences between group means.	anovan
Create an index vector from a grouping variable.	grp2idx

## Missing Group Values

Grouping variables can have missing values provided you include a valid indicator.

Grouping Variable Data Type	Missing Value Indicator
Numeric vector	NaN
Logical vector	(Cannot be missing)
String array	Row of spaces
Cell array of strings	' '
Categorical vector	<undefined>

## Dummy Indicator Variables

### In this section...

“What Are Dummy Variables?” on page 2-55

“Creating Dummy Variables” on page 2-56

### What Are Dummy Variables?

When performing regression analysis, it is common to include both continuous and categorical (quantitative and qualitative) predictor variables. When including a categorical independent variable, it is important not to input the variable as a numeric array. Numeric arrays have both order and magnitude. A categorical variable might have order (for example, an ordinal variable), but it does not have magnitude. Using a numeric array implies a known “distance” between the categories.

The appropriate way to include categorical predictors is as dummy indicator variables. An indicator variable has values 0 and 1. A categorical variable with  $c$  categories can be represented by  $c - 1$  indicator variables.

For example, suppose you have a categorical variable with levels {Small,Medium,Large}. You can represent this variable using two dummy variables, as shown in this figure.

	X <sub>1</sub>	X <sub>2</sub>	
Small	0	0	Reference Group
Medium	1	0	
Large	0	1	

In this example,  $X_1$  is a dummy variable that has value 1 for the `Medium` group, and 0 otherwise.  $X_2$  is a dummy variable that has value 1 for the `Large` group, and 0 otherwise. Together, these two variables represent the three categories. Observations in the `Small` group have 0s for both dummy variables.

The category represented by all 0s is the *reference group*. When you include the dummy variables in a regression model, the coefficients of the dummy variables are interpreted with respect to the reference group.

## Creating Dummy Variables

### Automatic Creation of Dummy Variables

The regression fitting functions, `fitlm`, `fitglm`, and `fitnlm`, recognize categorical array inputs as categorical predictors. That is, if you input your categorical predictor as a `nominal` or `ordinal` array, the fitting function automatically creates the required dummy variables. The first level returned by `getlevels` is the reference group. To use a different reference group, use `reorderlevels` to change the level order.

If there are  $c$  unique levels in the categorical array, then the fitting function estimates  $c - 1$  regression coefficients for the categorical predictor.

---

**Note** The fitting functions use every level of the categorical array returned by `getlevels`, even if there are levels with no observations. To remove levels from the categorical array, use `droplevels`.

---

### Manual Creation of Dummy Variables

If you prefer to create your own dummy variable design matrix, use `dummyvar`. This function accepts a numeric or categorical column vector, and returns a matrix of indicator variables. The dummy variable design matrix has a column for every group, and a row for every observation.

For example,

```
gender = nominal({'Male'; 'Female'; 'Female'; 'Male'; 'Female'});  
dv = dummyvar(gender)
```

```

dv =
    0     1
    1     0
    1     0
    0     1
    1     0

```

There are five rows corresponding to the number of rows in `gender`, and two columns for the unique groups, `Female` and `Male`. Column order corresponds to the order of the levels in `gender`. For nominal arrays, the default order is ascending alphabetical.

To use these dummy variables in a regression model, you must either delete a column (to create a reference group), or fit a regression model with no intercept term. For the `gender` example, only one dummy variable is needed to represent two genders. Notice what happens if you add an intercept term to the complete design matrix, `dv`.

```
X = [ones(5,1) dv]
```

```

X =
    1     0     1
    1     1     0
    1     1     0
    1     0     1
    1     1     0

```

```
rank(X)
```

```

ans =
    2

```

The design matrix with an intercept term is not of full rank, and is not invertible. Because of this linear dependence, use only  $c - 1$  indicator variables to represent a categorical variable with  $c$  categories in a regression model with an intercept term.

`nominal` | `ordinal` | `fitlm` | `fitglm` | `fitnlm` | `dummyvar`

### **Related Examples**

- “Regression with Categorical Covariates” on page 2-59
- “Test Differences Between Category Means” on page 2-28

## Regression with Categorical Covariates

This example shows how to perform a regression with categorical covariates using categorical arrays and `fitlm`.

### **Load sample data.**

```
load('carsmall')
```

The variable `MPG` contains measurements on the miles per gallon of 100 sample cars. The model year of each car is in the variable `Model_Year`, and `Weight` contains the weight of each car.

### **Plot grouped data.**

Draw a scatter plot of `MPG` against `Weight`, grouped by model year.

```
figure()  
gscatter(Weight,MPG,Model_Year,'bgr','x.o')  
title('MPG vs. Weight, Grouped by Model Year')
```

The grouping variable, `Model_Year`, has three unique values, 70, 76, and 82, corresponding to model years 1970, 1976, and 1982.

### Create dataset and nominal arrays.

Create a dataset array that contains the variables `MPG`, `Weight`, and `Model_Year`. Convert the variable `Model_Year` to a nominal array.

```
cars = dataset(MPG,Weight,Model_Year);  
cars.Model_Year = nominal(cars.Model_Year);
```

### Fit a regression model.

Fit a regression model using `fitlm` with `MPG` as the dependent variable, and `Weight` and `Model_Year` as the independent variables. Because `Model_Year` is a categorical covariate with three levels, it should enter the model as two indicator variables.

The scatter plot suggests that the slope of MPG against Weight might differ for each model year. To assess this, include weight-year interaction terms.

The proposed model is

$$E(MPG) = \beta_0 + \beta_1 \text{Weight} + \beta_2 I[1976] + \beta_3 I[1982] + \beta_4 \text{Weight} \times I[1976] + \beta_5 \text{Weight} \times I[1982],$$

where  $I[1976]$  and  $I[1982]$  are dummy variables indicating the model years 1976 and 1982, respectively.  $I[1976]$  takes the value 1 if model year is 1976 and takes the value 0 if it is not.  $I[1982]$  takes the value 1 if model year is 1982 and takes the value 0 if it is not. In this model, 1970 is the reference year.

```
fit = fitlm(cars, 'MPG~Weight*Model_Year')
```

```
fit =
```

Linear regression model:

```
MPG ~ 1 + Weight*Model_Year
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	37.399	2.1466	17.423	2.8607
Weight	-0.0058437	0.00061765	-9.4612	4.6077
Model_Year_76	4.6903	2.8538	1.6435	0.1
Model_Year_82	21.051	4.157	5.0641	2.2364
Weight:Model_Year_76	-0.00082009	0.00085468	-0.95953	0.3
Weight:Model_Year_82	-0.0050551	0.0015636	-3.2329	0.001

Number of observations: 94, Error degrees of freedom: 88

Root Mean Squared Error: 2.79

R-squared: 0.886, Adjusted R-Squared 0.88

F-statistic vs. constant model: 137, p-value = 5.79e-40

The regression output shows:

- `fitlm` recognizes `Model_Year` as a nominal variable, and constructs the required indicator (dummy) variables. By default, the first level, 70, is the reference group (use `reorderlevels` to change the reference group).

- The model specification,  $MPG \sim Weight * Model\_Year$ , specifies the first-order terms for *Weight* and *Model\_Year*, and all interactions.
- The model  $R^2 = 0.886$ , meaning the variation in miles per gallon is reduced by 88.6% when you consider weight, model year, and their interactions.
- The fitted model is

$$\hat{MPG} = 37.4 - 0.006Weight + 4.7I[1976] + 21.1I[1982] - 0.0008Weight \times I[1976] - 0.005Weight \times I[1982].$$

Thus, the estimated regression equations for the model years are as follows.

Model Year	Predicted MPG Against Weight
1970	$\hat{MPG} = 37.4 - 0.006Weight$
1976	$\hat{MPG} = (37.4 + 4.7) - (0.006 + 0.0008)Weight$
1982	$\hat{MPG} = (37.4 + 21.1) - (0.006 + 0.005)Weight$

The relationship between MPG and Weight has an increasingly negative slope as the model year increases.

### Plot fitted regression lines.

Plot the data and fitted regression lines.

```
w = linspace(min(Weight),max(Weight));

figure()
gscatter(Weight,MPG,Model_Year,'bgr','x.o')
line(w,feval(fit,w,'70'),'Color','b','LineWidth',2)
line(w,feval(fit,w,'76'),'Color','g','LineWidth',2)
line(w,feval(fit,w,'82'),'Color','r','LineWidth',2)
title('Fitted Regression Lines by Model Year')
```

### Test for different slopes.

Test for significant differences between the slopes. This is equivalent to testing the hypothesis

$$H_0 : \beta_4 = \beta_5 = 0$$

$$H_A : \beta_i \neq 0 \text{ for at least one } i.$$

```
anova(fit)
```

```
ans =
```

	SumSq	DF	MeanSq	F	pValue
Weight	2050.2	1	2050.2	263.87	3.2055e-28
Model_Year	807.69	2	403.84	51.976	1.2494e-15
Weight:Model_Year	81.219	2	40.609	5.2266	0.0071637
Error	683.74	88	7.7698		

This output shows that the  $p$ -value for the test is 0.0072 (from the interaction row, `Weight:Model_Year`), so the null hypothesis is rejected at the 0.05 significance level. The value of the test statistic is 5.2266. The numerator degrees of freedom for the test is 2, which is the number of coefficients in the null hypothesis.

There is sufficient evidence that the slopes are not equal for all three model years.

## Create a Dataset Array from Workspace Variables

### In this section...

“Create a Dataset Array from a Numeric Array” on page 2-65

“Create Dataset Array from Heterogeneous Workspace Variables” on page 2-68

### Create a Dataset Array from a Numeric Array

This example shows how to create a dataset array from a numeric array existing in the MATLAB® workspace.

#### Load sample data.

```
load('fisheriris')
```

Two variables load into the workspace: `meas`, a 150-by-4 numeric array, and `species`, a 150-by-1 cell array of strings containing species labels.

#### Create a dataset array.

Use `mat2dataset` to convert the numeric array, `meas`, into a dataset array.

```
ds = mat2dataset(meas);
ds(1:10,:)
```

```
ans =
```

meas1	meas2	meas3	meas4
5.1	3.5	1.4	0.2
4.9	3	1.4	0.2
4.7	3.2	1.3	0.2
4.6	3.1	1.5	0.2
5	3.6	1.4	0.2
5.4	3.9	1.7	0.4
4.6	3.4	1.4	0.3
5	3.4	1.5	0.2
4.4	2.9	1.4	0.2
4.9	3.1	1.5	0.1

The array, `meas`, has four columns, so the dataset array, `ds`, has four variables. The default variable names are the array name, `meas`, with column numbers appended.

You can specify your own variable or observation names using the name-value pair arguments `VarNames` and `ObsNames`, respectively.

If you use `dataset` to convert a numeric array to a dataset array, by default, the resulting dataset array has one variable that is an array instead of separate variables for each column.

### **Examine the dataset array.**

Return the size of the dataset array, `ds`.

```
size(ds)
```

```
ans =
```

```
    150     4
```

The dataset array, `ds`, is the same size as the numeric array, `meas`. Variable names and observation names do not factor into the size of a dataset array.

### **Explore dataset array metadata.**

Return the metadata properties of the dataset array, `ds`.

```
ds.Properties
```

```
ans =
```

```
    Description: ''
  VarDescription: {}
         Units: {}
   DimNames: {'Observations' 'Variables'}
   UserData: []
   ObsNames: {}
   VarNames: {'meas1' 'meas2' 'meas3' 'meas4'}
```

You can also access the properties individually. For example, you can retrieve the variable names using `ds.Properties.VarNames`.

### Access data in a dataset array variable.

You can use variable names with dot indexing to access the data in a dataset array. For example, find the minimum value in the first variable, `meas1`.

```
min(ds.meas1)

ans =

    4.3000
```

### Change variable names.

The four variables in `ds` are actually measurements of sepal length, sepal width, petal length, and petal width. Modify the variable names to be more descriptive.

```
ds.Properties.VarNames = {'SLength', 'SWidth', 'PLength', 'PWidth'};
```

### Add description.

you can add a description for the dataset array.

```
ds.Properties.Description = 'Fisher iris data';
ds.Properties
```

```
ans =

    Description: 'Fisher iris data'
  VarDescription: {}
         Units: {}
   DimNames: {'Observations' 'Variables'}
   UserData: []
   ObsNames: {}
   VarNames: {'SLength' 'SWidth' 'PLength' 'PWidth'}
```

The dataset array properties are updated with the new variable names and description.

### Add a variable to the dataset array.

The variable `species` is a cell array of strings containing species labels. Add `species` to the dataset array, `ds`, as a nominal array named `Species`. Display the first five observations in the dataset array.

```
ds.Species = nominal(species);  
ds(1:5,:)
```

```
ans =
```

SLength	SWidth	PLength	PWidth	Species
5.1	3.5	1.4	0.2	setosa
4.9	3	1.4	0.2	setosa
4.7	3.2	1.3	0.2	setosa
4.6	3.1	1.5	0.2	setosa
5	3.6	1.4	0.2	setosa

The dataset array, `ds`, now has the fifth variable, `Species`.

## Create Dataset Array from Heterogeneous Workspace Variables

This example shows how to create a dataset array from heterogeneous variables existing in the MATLAB workspace.

### Load sample data.

```
load('carsmall')
```

### Create a dataset array.

Create a dataset array from a subset of the workspace variables.

```
ds = dataset(Origin,Acceleration,Cylinders,MPG);  
ds.Properties.VarNames(:)
```

```
ans =
```

```
'Origin'  
'Acceleration'
```

```
'Cylinders'
'MPG'
```

When creating the dataset array, you do not need to enter variable names. `dataset` automatically uses the name of each workspace variable.

Notice that the dataset array, `ds`, contains a collection of variables with heterogeneous data types. `Origin` is a character array, and the other variables are numeric.

### Examine a dataset array.

Display the first five observations in the dataset array.

```
ds(1:5,:)
```

```
ans =
```

Origin	Acceleration	Cylinders	MPG
USA	12	8	18
USA	11.5	8	15
USA	11	8	18
USA	12	8	16
USA	10.5	8	17

### Apply a function to a dataset array.

Use `datasetfun` to return the data type of each variable in `ds`.

```
varclass = datasetfun(@class,ds,'UniformOutput',false);
varclass(:)
```

```
ans =
```

```
'char'
'double'
'double'
'double'
```

You can get additional information about the variables using `summary(ds)`.

### Modify a dataset array.

`Cylinders` is a numeric variable that has values 4, 6, and 8 for the number of cylinders. Convert `Cylinders` to a nominal array with levels `four`, `six`, and `eight`.

Display the country of origin and number of cylinders for the first 15 cars.

```
ds.Cylinders = nominal(ds.Cylinders,{'four','six','eight'});  
ds(1:15,{'Origin','Cylinders'})
```

```
ans =
```

Origin	Cylinders
USA	eight
USA	eight
USA	eight
USA	eight
USA	eight
USA	eight
USA	eight
USA	eight
USA	eight
USA	eight
USA	eight
France	four
USA	eight
USA	eight
USA	eight
USA	eight

The variable `Cylinders` has a new data type.

## Create a Dataset Array from a File

### In this section...

“Create a Dataset Array from a Tab-Delimited Text File” on page 2-71

“Create a Dataset Array from a Comma-Separated Text File” on page 2-74

“Create a Dataset Array from an Excel File” on page 2-77

### Create a Dataset Array from a Tab-Delimited Text File

This example shows how to create a dataset array from the contents of a tab-delimited text file.

#### Create a dataset array using default settings.

Navigate to the folder containing sample data. Import the text file `hospitalSmall.txt` as a dataset array using the default settings.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
ds = dataset('File','hospitalSmall.txt')
```

```
ds =
```

name	sex	age	wgt	smoke
'SMITH'	'm'	38	176	1
'JOHNSON'	'm'	43	163	0
'WILLIAMS'	'f'	38	131	0
'JONES'	'f'	40	133	0
'BROWN'	'f'	49	119	0
'DAVIS'	'f'	46	142	0
'MILLER'	'f'	33	142	1
'WILSON'	'm'	40	180	0
'MOORE'	'm'	28	183	0
'TAYLOR'	'f'	31	132	0
'ANDERSON'	'f'	45	128	0
'THOMAS'	'f'	42	137	0
'JACKSON'	'm'	25	174	0
'WHITE'	'm'	39	202	1

By default, `dataset` uses the first row of the text file for variable names. If the first row does not contain variable names, you can specify the optional name-value pair argument `'ReadVarNames'`, `false` to change the default behavior.

The dataset array contains heterogeneous variables. The variables `id`, `name`, and `sex` are cell arrays of strings, and the other variables are numeric.

### Summarize the dataset array.

You can see the data type and other descriptive statistics for each variable by using `summary` to summarize the dataset array.

```
summary(ds)
```

```
name: [14x1 cell string]
```

```
sex: [14x1 cell string]
```

```
age: [14x1 double]
```

min	1st quartile	median	3rd quartile	max
25	33	39.5	43	49

```
wgt: [14x1 double]
```

min	1st quartile	median	3rd quartile	max
119	132	142	176	202

```
smoke: [14x1 double]
```

min	1st quartile	median	3rd quartile	max
0	0	0	0	1

### Import observation names.

Import the text file again, this time specifying that the first column contains observation names.

```
ds = dataset('File','hospitalSmall.txt','ReadObsNames',true)
```

```
ds =

      sex      age      wgt      smoke
SMITH      'm'      38      176      1
JOHNSON    'm'      43      163      0
WILLIAMS   'f'      38      131      0
JONES      'f'      40      133      0
BROWN      'f'      49      119      0
DAVIS      'f'      46      142      0
MILLER     'f'      33      142      1
WILSON     'm'      40      180      0
MOORE      'm'      28      183      0
TAYLOR     'f'      31      132      0
ANDERSON   'f'      45      128      0
THOMAS     'f'      42      137      0
JACKSON    'm'      25      174      0
WHITE      'm'      39      202      1
```

The elements of the first column in the text file, last names, are now observation names. Observation names and row names are dataset array properties. You can always add or change the observation names of an existing dataset array by modifying the property `ObsNames`.

### **Change dataset array properties.**

By default, the `DimNames` property of the dataset array has name as the descriptor of the observation (row) dimension. `dataset` got this name from the first row of the first column in the text file.

Change the first element of `DimNames` to `LastName`.

```
ds.Properties.DimNames{1} = 'LastName';
ds.Properties
```

```
ans =
```

```
      Description: ''
      VarDescription: {}
           Units: {}
      DimNames: {'LastName' 'Variables'}
      UserData: []
```

```
ObsNames: {14x1 cell}
VarNames: {'sex' 'age' 'wgt' 'smoke'}
```

### Index into dataset array.

You can use observation names to index into a dataset array. For example, return the data for the patient with last name BROWN.

```
ds('BROWN', :)
```

```
ans =
```

	sex	age	wgt	smoke
BROWN	'f'	49	119	0

Note that observation names must be unique.

## Create a Dataset Array from a Comma-Separated Text File

This example shows how to create a dataset array from the contents of a comma-separated text file.

### Create a dataset array.

Navigate to the folder containing sample data. Import the file `hospitalSmall.csv` as a dataset array, specifying the comma-delimited format.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
ds = dataset('File','hospitalSmall.csv','Delimiter',',',')
```

```
ds =
```

id	name	sex	age	wgt	smoke
'YPL-320'	'SMITH'	'm'	38	176	1
'GLI-532'	'JOHNSON'	'm'	43	163	0
'PNI-258'	'WILLIAMS'	'f'	38	131	0
'MIJ-579'	'JONES'	'f'	40	133	0
'XLK-030'	'BROWN'	'f'	49	119	0

'TFP-518'	'DAVIS'	'f'	46	142	0
'LPD-746'	'MILLER'	'f'	33	142	1
'ATA-945'	'WILSON'	'm'	40	180	0
'VNL-702'	'MOORE'	'm'	28	183	0
'LQW-768'	'TAYLOR'	'f'	31	132	0
'QFY-472'	'ANDERSON'	'f'	45	128	0
'UJG-627'	'THOMAS'	'f'	42	137	0
'XUE-826'	'JACKSON'	'm'	25	174	0
'TRW-072'	'WHITE'	'm'	39	202	1

By default, `dataset` uses the first row in the text file as variable names.

### Add observation names.

Use the unique identifiers in the variable `id` as observation names. Then, delete the variable `id` from the dataset array.

```
ds.Properties.ObsNames = ds.id;
ds.id = []
```

```
ds =
```

	name	sex	age	wgt	smoke
YPL-320	'SMITH'	'm'	38	176	1
GLI-532	'JOHNSON'	'm'	43	163	0
PNI-258	'WILLIAMS'	'f'	38	131	0
MIJ-579	'JONES'	'f'	40	133	0
XLK-030	'BROWN'	'f'	49	119	0
TFP-518	'DAVIS'	'f'	46	142	0
LPD-746	'MILLER'	'f'	33	142	1
ATA-945	'WILSON'	'm'	40	180	0
VNL-702	'MOORE'	'm'	28	183	0
LQW-768	'TAYLOR'	'f'	31	132	0
QFY-472	'ANDERSON'	'f'	45	128	0
UJG-627	'THOMAS'	'f'	42	137	0
XUE-826	'JACKSON'	'm'	25	174	0
TRW-072	'WHITE'	'm'	39	202	1

### Delete observations.

Delete any patients with the last name **BROWN**. You can use `strcmp` to match the string `'BROWN'` with the elements of the variable containing last names, `name`.

```
toDelete = strcmp(ds.name, 'BROWN');  
ds(toDelete, :) = []
```

```
ds =
```

	name	sex	age	wgt	smoke
YPL-320	'SMITH'	'm'	38	176	1
GLI-532	'JOHNSON'	'm'	43	163	0
PNI-258	'WILLIAMS'	'f'	38	131	0
MIJ-579	'JONES'	'f'	40	133	0
TFP-518	'DAVIS'	'f'	46	142	0
LPD-746	'MILLER'	'f'	33	142	1
ATA-945	'WILSON'	'm'	40	180	0
VNL-702	'MOORE'	'm'	28	183	0
LQW-768	'TAYLOR'	'f'	31	132	0
QFY-472	'ANDERSON'	'f'	45	128	0
UJG-627	'THOMAS'	'f'	42	137	0
XUE-826	'JACKSON'	'm'	25	174	0
TRW-072	'WHITE'	'm'	39	202	1

One patient having last name **BROWN** is deleted from the dataset array.

### **Return size of dataset array.**

The array now has 13 observations.

```
size(ds)
```

```
ans =
```

```
13    5
```

Note that the row and column corresponding to variable and observation names, respectively, are not included in the size of a dataset array.

## Create a Dataset Array from an Excel File

This example shows how to create a dataset array from the contents of an Excel® spreadsheet file.

### Create a dataset array.

Navigate to the folder containing sample data. Import the data from the first worksheet in the file `hospitalSmall.xlsx`, specifying that the data file is an Excel spreadsheet.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
ds = dataset('XLSFile','hospitalSmall.xlsx')
```

```
ds =
```

id	name	sex	age	wgt	smoke
'YPL-320'	'SMITH'	'm'	38	176	1
'GLI-532'	'JOHNSON'	'm'	43	163	0
'PNI-258'	'WILLIAMS'	'f'	38	131	0
'MIJ-579'	'JONES'	'f'	40	133	0
'XLK-030'	'BROWN'	'f'	49	119	0
'TFP-518'	'DAVIS'	'f'	46	142	0
'LPD-746'	'MILLER'	'f'	33	142	1
'ATA-945'	'WILSON'	'm'	40	180	0
'VNL-702'	'MOORE'	'm'	28	183	0
'LQW-768'	'TAYLOR'	'f'	31	132	0
'QFY-472'	'ANDERSON'	'f'	45	128	0
'UJG-627'	'THOMAS'	'f'	42	137	0
'XUE-826'	'JACKSON'	'm'	25	174	0
'TRW-072'	'WHITE'	'm'	39	202	1

By default, `dataset` creates variable names using the contents of the first row in the spreadsheet.

### Specify which worksheet to import.

Import the data from the second worksheet into a new dataset array.

```
ds2 = dataset('XLSFile','hospitalSmall.xlsx','Sheet',2)
```

ds2 =

id	name	sex	age	wgt	smoke
'TRW-072'	'WHITE'	'm'	39	202	1
'ELG-976'	'HARRIS'	'f'	36	129	0
'KOQ-996'	'MARTIN'	'm'	48	181	1
'YUZ-646'	'THOMPSON'	'm'	32	191	1
'XBR-291'	'GARCIA'	'f'	27	131	1
'KPW-846'	'MARTINEZ'	'm'	37	179	0
'XBA-581'	'ROBINSON'	'm'	50	172	0
'BKD-785'	'CLARK'	'f'	48	133	0

### Concepts

- “Dataset Arrays” on page 2-135

## Add and Delete Observations

This example shows how to add and delete observations in a dataset array. You can also edit dataset arrays using the Variables editor.

### Load sample data.

Navigate to the folder containing sample data. Import the data from the first worksheet in `hospitalSmall.xlsx` into a dataset array.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
ds = dataset('XLSFile','hospitalSmall.xlsx');
size(ds)
```

```
ans =
```

```
    14     6
```

The dataset array, `ds`, has 14 observations (rows) and 6 variables (columns).

### Add observations by concatenation.

The second worksheet in `hospitalSmall.xlsx` has additional patient data. Append the observations in this spreadsheet to the end of `ds`.

```
ds2 = dataset('XLSFile','hospitalSmall.xlsx','Sheet',2);
dsNew = [ds;ds2];
size(dsNew)
```

```
ans =
```

```
    22     6
```

The dataset array `dsNew` has 22 observations. In order to vertically concatenate two dataset arrays, both arrays must have the same number of variables, with the same variable names.

### Add observations from a cell array.

If you want to append new observations stored in a cell array, first convert the cell array to a dataset array, and then concatenate the dataset arrays.

```
cellObs = {'id', 'name', 'sex', 'age', 'wgt', 'smoke';  
          'YQR-965', 'BAKER', 'M', 36, 160, 0;  
          'LFG-497', 'WALL', 'F', 28, 125, 1;  
          'KSD-003', 'REED', 'M', 32, 187, 0};  
dsNew = [dsNew; cell2dataset(cellObs)];  
size(dsNew)
```

```
ans =  
  
    25     6
```

### **Add observations from a structure.**

You can also append new observations stored in a structure. Convert the structure to a dataset array, and then concatenate the dataset arrays.

```
structObs(1,1).id = 'GHK-842';  
structObs(1,1).name = 'GEORGE';  
structObs(1,1).sex = 'M';  
structObs(1,1).age = 45;  
structObs(1,1).wgt = 182;  
structObs(1,1).smoke = 1;  
  
structObs(2,1).id = 'QRH-308';  
structObs(2,1).name = 'BAILEY';  
structObs(2,1).sex = 'F';  
structObs(2,1).age = 29;  
structObs(2,1).wgt = 120;  
structObs(2,1).smoke = 0;  
  
dsNew = [dsNew; struct2dataset(structObs)];  
size(dsNew)
```

```
ans =  
  
    27     6
```

### **Delete duplicate observations.**

Use `unique` to delete any observations in a dataset array that are duplicated.

```
dsNew = unique(dsNew);  
size(dsNew)
```

```
ans =  
  
    21     6
```

One duplicated observation is deleted.

#### **Delete observations by observation number.**

Delete observations 18, 20, and 21 from the dataset array.

```
dsNew([18,20,21],:) = [];  
size(dsNew)
```

```
ans =  
  
    18     6
```

The dataset array has only 18 observations now.

#### **Delete observations by observation name.**

First, specify the variable of identifiers, `id`, as observation names. Then, delete the variable `id` from `dsNew`. You can use the observation name to index observations.

```
dsNew.Properties.ObsNames = dsNew.id;  
dsNew.id = [];  
dsNew('K0Q-996',:) = [];  
size(dsNew)
```

```
ans =  
  
    17     5
```

The dataset array now has one less observation and one less variable.

#### **Search for observations to delete.**

You can also search for observations in the dataset array. For example, delete observations for any patients with the last name WILLIAMS.

```
toDelete = strcmp(dsNew.name, 'WILLIAMS');  
dsNew(toDelete,:) = [];  
size(dsNew)
```

```
ans =
```

```
16    5
```

The dataset array now has one less observation.

### Concepts

- “Dataset Arrays” on page 2-135

## Add and Delete Variables

This example shows how to add and delete variables in a dataset array. You can also edit dataset arrays using the Variables editor.

### Load sample data.

Navigate to the folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Import the data from the first worksheet in `hospitalSmall.xlsx` into a dataset array.

```
ds = dataset('XLSFile','hospitalSmall.xlsx');
size(ds)
```

```
ans =
```

```
    14     6
```

The dataset array, `ds`, has 14 observations (rows) and 6 variables (columns).

### Add variables by concatenating dataset arrays.

The worksheet `Heights` in `hospitalSmall.xlsx` has heights for the patients on the first worksheet. Concatenate the data in this spreadsheet with `ds`.

```
ds2 = dataset('XLSFile','hospitalSmall.xlsx','Sheet','Heights');
ds = [ds ds2];
size(ds)
```

```
ans =
```

```
    14     7
```

The dataset array now has seven variables. You can only horizontally concatenate dataset arrays with observations in the same position, or with the same observation names.

```
ds.Properties.VarNames{end}
```

```
ans =
```

```
hgt
```

The name of the last variable in `ds` is `hgt`, which dataset read from the first row of the imported spreadsheet.

### Delete variables by variable name.

First, specify the unique identifiers in the variable `id` as observation names. Then, delete the variable `id` from the dataset array.

```
ds.Properties.ObsNames = ds.id;  
ds.id = [];  
size(ds)
```

```
ans =
```

```
14    6
```

The dataset array now has six variables. List the variable names.

```
ds.Properties.VarNames(:)
```

```
ans =
```

```
'name'  
'sex'  
'age'  
'wgt'  
'smoke'  
'hgt'
```

There is no longer a variable called `id`.

### Add a new variable by name.

Add a new variable, `bmi`—which contains the body mass index (BMI) for each patient—to the dataset array. BMI is a function of height and weight. Display the last name, gender, and BMI for each patient.

```
ds.bmi = ds.wgt*703./ds.hgt.^2;
```

```
ds(:, {'name', 'sex', 'bmi'})

ans =
```

	name	sex	bmi
YPL-320	'SMITH'	'm'	24.544
GLI-532	'JOHNSON'	'm'	24.068
PNI-258	'WILLIAMS'	'f'	23.958
MIJ-579	'JONES'	'f'	25.127
XLK-030	'BROWN'	'f'	21.078
TFP-518	'DAVIS'	'f'	27.729
LPD-746	'MILLER'	'f'	26.828
ATA-945	'WILSON'	'm'	24.41
VNL-702	'MOORE'	'm'	27.822
LQW-768	'TAYLOR'	'f'	22.655
QFY-472	'ANDERSON'	'f'	23.409
UJG-627	'THOMAS'	'f'	25.883
XUE-826	'JACKSON'	'm'	24.265
TRW-072	'WHITE'	'm'	29.827

The operators `./` and `.^` in the calculation of BMI indicate element-wise division and exponentiation, respectively.

### Delete variables by variable number.

Delete the variable `wgt`, the fourth variable in the dataset array.

```
ds(:,4) = [];
ds.Properties.VarNames(:)

ans =
```

```
'name'
'sex'
'age'
'smoke'
'hgt'
'bmi'
```

The variable `wgt` is deleted from the dataset array.

## Access Data in Dataset Array Variables

This example shows how to work with dataset array variables and their data.

### Access variables by name.

You can access variable data, or select a subset of variables, by using variable (column) names and dot indexing. Load a sample dataset array. Display the names of the variables in `hospital`.

```
load('hospital')
hospital.Properties.VarNames(:)
```

```
ans =
```

```
    'LastName'  
    'Sex'  
    'Age'  
    'Weight'  
    'Smoker'  
    'BloodPressure'  
    'Trials'
```

The dataset array has 7 variables (columns) and 100 observations (rows). You can double-click `hospital` in the Workspace window to view the dataset array in the Variables editor.

### Plot histogram.

Plot a histogram of the data in the variable `Weight`.

```
figure()  
hist(hospital.Weight)
```

The histogram shows that the weight distribution is bimodal.

**Plot data grouped by category.**

Draw box plots of `Weight` grouped by the values in `Sex` (Male and Female). That is, use the variable `Sex` as a grouping variable.

```
figure()  
boxplot(hospital.Weight,hospital.Sex)
```

The box plot suggests that gender accounts for the bimodality in weight.

**Select a subset of variables.**

Create a new dataset array with only the variables `LastName`, `Sex`, and `Weight`. You can access the variables by name or column number.

```
ds1 = hospital(:, {'LastName', 'Sex', 'Weight'});  
ds2 = hospital(:, [1, 2, 4]);
```

The dataset arrays `ds1` and `ds2` are equivalent. Use parentheses ( ) when indexing dataset arrays to preserve the data type; that is, to create a dataset array from a subset of a dataset array. You can also use the Variables editor to create a new dataset array from a subset of variables and observations.

**Convert the variable data type.**

Convert the data type of the variable `Smoker` from logical to nominal with labels `No` and `Yes`.

```
hospital.Smoker = nominal(hospital.Smoker,{'No','Yes'});  
class(hospital.Smoker)
```

```
ans =
```

```
nominal
```

### **Explore data.**

Display the first 10 elements of `Smoker`.

```
hospital.Smoker(1:10)
```

```
ans =
```

```
Yes
```

```
No
```

```
No
```

```
No
```

```
No
```

```
No
```

```
Yes
```

```
No
```

```
No
```

```
No
```

If you want to change the level labels in a nominal array, use `setlabels`.

### **Add variables.**

The variable `BloodPressure` is a 100-by-2 array. The first column corresponds to systolic blood pressure, and the second column to diastolic blood pressure. Separate this array into two new variables, `SysPressure` and `DiaPressure`.

```
hospital.SysPressure = hospital.BloodPressure(:,1);  
hospital.DiaPressure = hospital.BloodPressure(:,2);  
hospital.Properties.VarNames(:)
```

```
ans =
```

```

'LastName'
'Sex'
'Age'
'Weight'
'Smoker'
'BloodPressure'
'Trials'
'SysPressure'
'DiaPressure'

```

The dataset array, `hospital`, has two new variables.

### **Search for variables by name.**

Use `regexp` to find variables in `hospital` with the string 'Pressure' in their name. Create a new dataset array containing only these variables.

```

bp = regexp(hospital.Properties.VarNames, 'Pressure');
bpIdx = cellfun(@isempty, bp);
bpData = hospital(:, ~bpIdx);
bpData.Properties.VarNames(:)

```

```

ans =

    'BloodPressure'
    'SysPressure'
    'DiaPressure'

```

The new dataset array, `bpData`, contains only the blood pressure variables.

### **Delete variables.**

Delete the variable `BloodPressure` from the dataset array, `hospital`.

```

hospital.BloodPressure = [];
hospital.Properties.VarNames(:)

```

```

ans =

    'LastName'

```

```
'Sex '  
'Age '  
'Weight '  
'Smoker '  
'Trials '  
'SysPressure '  
'DiaPressure '
```

The variable `BloodPressure` is no longer in the dataset array.

**See Also** `dataset |`

## Select Subsets of Observations

This example shows how to select an observation or subset of observations from a dataset array.

### Load sample data.

Load the sample dataset array, `hospital`. Dataset arrays can have observation (row) names. This array has observation names corresponding to unique patient identifiers.

```
load('hospital')
hospital.Properties.ObsNames(1:10)
```

```
ans =
```

```
'YPL-320'
'GLI-532'
'PNI-258'
'MIJ-579'
'XLK-030'
'TFP-518'
'LPD-746'
'ATA-945'
'VNL-702'
'LQW-768'
```

These are the first 10 observation names.

### Index an observation by name.

You can use the observation names to index into the dataset array. For example, extract the last name, sex, and age for the patient with identifier `XLK-030`.

```
hospital('XLK-030',{'LastName','Sex','Age'})
```

```
ans =
```

	LastName	Sex	Age
XLK-030	'BROWN'	Female	49

### Index a subset of observations by number.

Create a new dataset array containing the first 50 patients.

```
ds50 = hospital(1:50,:);  
size(ds50)
```

```
ans =  
  
    50     7
```

### Search observations using a logical condition.

Create a new dataset array containing only male patients. To find the male patients, use a logical condition to search the variable containing gender information.

```
dsMale = hospital(hospital.Sex=='Male',:);  
dsMale(1:10,{'LastName','Sex'})
```

```
ans =  
  
          LastName      Sex  
YPL-320   'SMITH'      Male  
GLI-532   'JOHNSON'    Male  
ATA-945   'WILSON'      Male  
VNL-702   'MOORE'      Male  
XUE-826   'JACKSON'    Male  
TRW-072   'WHITE'      Male  
KOQ-996   'MARTIN'     Male  
YUZ-646   'THOMPSON'    Male  
KPW-846   'MARTINEZ'   Male  
XBA-581   'ROBINSON'   Male
```

### Search observations using multiple conditions.

You can use multiple conditions to search the dataset array. For example, create a new dataset array containing only female patients older than 40.

```
dsFemale = hospital(hospital.Sex=='Female' & hospital.Age > 40,:);  
dsFemale(1:10,{'LastName','Sex','Age'})
```

```
ans =
```

	LastName	Sex	Age
XLK-030	'BROWN'	Female	49
TFP-518	'DAVIS'	Female	46
QFY-472	'ANDERSON'	Female	45
UJG-627	'THOMAS'	Female	42
BKD-785	'CLARK'	Female	48
VWL-936	'LEWIS'	Female	41
AAX-056	'LEE'	Female	44
AFK-336	'WRIGHT'	Female	45
KKL-155	'ADAMS'	Female	48
RBA-579	'SANCHEZ'	Female	44

**Select a random subset of observations.**

Create a new dataset array containing a random subset of 20 patients from the dataset array hospital.

```
rng('default') % For reproducibility
dsRandom = hospital(randsample(length(hospital),20),:);
dsRandom.Properties.ObsNames
```

```
ans =
```

```
'DAU-529'
'AGR-528'
'RBO-332'
'Q00-305'
'RVS-253'
'QEQ-082'
'EHE-616'
'HVR-372'
'KOQ-996'
'REV-997'
'PUE-347'
'LQW-768'
'YLN-495'
'HJQ-495'
'ELG-976'
```

```
'XUE-826'  
'MEZ-469'  
'UDS-151'  
'MIJ-579'  
'DGC-290'
```

### Delete observations by name.

Delete the data for the patient with observation name HVR-372.

```
hospital('HVR-372',:) = [];  
size(hospital)
```

```
ans =
```

```
99      7
```

The dataset array has one less observation.

### See Also `dataset` |

### Concepts

- “Dataset Arrays” on page 2-135

## Sort Observations in Dataset Arrays

This example shows how to sort observations (rows) in a dataset array using the command line. You can also sort rows using the Variables editor.

### Sort observations in ascending order.

Load the sample dataset array, `hospital`. Sort the observations by the values in `Age`, in ascending order.

```
load('hospital')
dsAgeUp = sortrows(hospital,'Age');
dsAgeUp(1:10,{'LastName','Age'})
```

ans =

	LastName	Age
XUE-826	'JACKSON'	25
FZR-250	'HALL'	25
PUE-347	'YOUNG'	25
LIM-480	'HILL'	25
SCQ-914	'JAMES'	25
REV-997	'ALEXANDER'	25
XBR-291	'GARCIA'	27
VNL-702	'MOORE'	28
DTT-578	'WALKER'	28
XAX-646	'COOPER'	28

The youngest patients are age 25.

### Sort observations in descending order.

Sort the observations by `Age` in descending order.

```
dsAgeDown = sortrows(hospital,'Age','descend');
dsAgeDown(1:10,{'LastName','Age'})
```

ans =

	LastName	Age
XBA-581	'ROBINSON'	50

DAU-529	'REED'	50
XLK-030	'BROWN'	49
FLJ-908	'STEWART'	49
GGU-691	'HUGHES'	49
MEZ-469	'GRIFFIN'	49
KOQ-996	'MARTIN'	48
BKD-785	'CLARK'	48
KKL-155	'ADAMS'	48
NSK-403	'RAMIREZ'	48

The oldest patients are age 50.

### **Sort observations by the values of two variables.**

Sort the observations in `hospital` by `Age`, and then by `LastName`.

```
dsName = sortrows(hospital,{'Age','LastName'});  
dsName(1:10,{'LastName','Age'})
```

```
ans =
```

	LastName	Age
REV-997	'ALEXANDER'	25
FZR-250	'HALL'	25
LIM-480	'HILL'	25
XUE-826	'JACKSON'	25
SCQ-914	'JAMES'	25
PUE-347	'YOUNG'	25
XBR-291	'GARCIA'	27
XAX-646	'COOPER'	28
QEQ-082	'COX'	28
NSU-424	'JENKINS'	28

Now the names are sorted alphabetically within increasing age groups.

### **Sort observations in mixed order.**

Sort the observations in `hospital` by `Age` in an increasing order, and then by `Weight` in a decreasing order.

```
dsWeight = sortrows(hospital,{'Age','Weight'},{'ascend','descend'});
```

```
dsWeight(1:10,{'LastName','Age','Weight'})
```

```
ans =
```

	LastName	Age	Weight
FZR-250	'HALL'	25	189
SCQ-914	'JAMES'	25	186
XUE-826	'JACKSON'	25	174
REV-997	'ALEXANDER'	25	171
LIM-480	'HILL'	25	138
PUE-347	'YOUNG'	25	114
XBR-291	'GARCIA'	27	131
NSU-424	'JENKINS'	28	189
VNL-702	'MOORE'	28	183
XAX-646	'COOPER'	28	127

This shows that the maximum weight among patients that are age 25 is 189 lbs.

### Sort observations by observation name.

Sort the observations in hospital by the observation names.

```
dsObs = sortrows(hospital,'obsnames');
dsObs(1:10,{'LastName','Age'})
```

```
ans =
```

	LastName	Age
AAX-056	'LEE'	44
AFB-271	'PEREZ'	44
AFK-336	'WRIGHT'	45
AGR-528	'SIMMONS'	45
ATA-945	'WILSON'	40
BEZ-311	'DIAZ'	45
BKD-785	'CLARK'	48
DAU-529	'REED'	50
DGC-290	'BUTLER'	38
DTT-578	'WALKER'	28

The observations are sorted by observation name in ascending alphabetical order.

## Merge Dataset Arrays

This example shows how to merge dataset arrays using `join`.

### Load sample data.

Navigate to a folder containing sample data. Import the data from the first worksheet in `hospitalSmall.xlsx` into a dataset array, then keep only a few of the variables.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
ds1 = dataset('XLSFile','hospitalSmall.xlsx');
ds1 = ds1(:,{'id','name','sex','age'})
```

```
ds1 =
```

id	name	sex	age
'YPL-320'	'SMITH'	'm'	38
'GLI-532'	'JOHNSON'	'm'	43
'PNI-258'	'WILLIAMS'	'f'	38
'MIJ-579'	'JONES'	'f'	40
'XLK-030'	'BROWN'	'f'	49
'TFP-518'	'DAVIS'	'f'	46
'LPD-746'	'MILLER'	'f'	33
'ATA-945'	'WILSON'	'm'	40
'VNL-702'	'MOORE'	'm'	28
'LQW-768'	'TAYLOR'	'f'	31
'QFY-472'	'ANDERSON'	'f'	45
'UJG-627'	'THOMAS'	'f'	42
'XUE-826'	'JACKSON'	'm'	25
'TRW-072'	'WHITE'	'm'	39

The dataset array, `ds1`, has 14 observations (rows) and 4 variables (columns).

Import the data from the worksheet `Heights2` in `hospitalSmall.xlsx`.

```
ds2 = dataset('XLSFile','hospitalSmall.xlsx','Sheet','Heights2')
```

```
ds2 =
```

id	hgt
'LPD-746'	61
'PNI-258'	62
'XUE-826'	71
'ATA-945'	72
'XLK-030'	63

`ds2` has height measurements for a subset of five individuals from the first dataset array, `ds1`.

### **Merge only the matching subset of observations.**

Use `join` to merge the two dataset arrays, `ds1` and `ds2`, keeping only the subset of observations that are in `ds2`.

```
JoinSmall = join(ds2,ds1)
```

```
JoinSmall =
```

id	hgt	name	sex	age
'LPD-746'	61	'MILLER'	'f'	33
'PNI-258'	62	'WILLIAMS'	'f'	38
'XUE-826'	71	'JACKSON'	'm'	25
'ATA-945'	72	'WILSON'	'm'	40
'XLK-030'	63	'BROWN'	'f'	49

In `JoinSmall`, the variable `id` only appears once. This is because it is the key variable—the variable that links observations between the two dataset arrays—and has the same variable name in both `ds1` and `ds2`.

### **Include incomplete observations in the merge.**

Merge `ds1` and `ds2` keeping all observations in the larger `ds1`.

```
joinAll = join(ds2,ds1,'type','rightouter','mergekeys',true)
```

```
joinAll =
```

id	hgt	name	sex	age
'ATA-945'	72	'WILSON'	'm'	40
'GLI-532'	NaN	'JOHNSON'	'm'	43

'LPD-746'	61	'MILLER'	'f'	33
'LQW-768'	NaN	'TAYLOR'	'f'	31
'MIJ-579'	NaN	'JONES'	'f'	40
'PNI-258'	62	'WILLIAMS'	'f'	38
'QFY-472'	NaN	'ANDERSON'	'f'	45
'TFP-518'	NaN	'DAVIS'	'f'	46
'TRW-072'	NaN	'WHITE'	'm'	39
'UJG-627'	NaN	'THOMAS'	'f'	42
'VNL-702'	NaN	'MOORE'	'm'	28
'XLK-030'	63	'BROWN'	'f'	49
'XUE-826'	71	'JACKSON'	'm'	25
'YPL-320'	NaN	'SMITH'	'm'	38

Each observation in `ds1` without corresponding height measurements in `ds2` has height value `NaN`. Also, because there is no `id` value in `ds2` for each observation in `ds1`, you need to merge the keys using the option `'MergeKeys', true`. This merges the key variable, `id`.

### **Merge dataset arrays with different key variable names.**

When using `join`, it is not necessary for the key variable to have the same name in the dataset arrays to be merged. Import the data from the worksheet named `Heights3` in `hospitalSmall.xlsx`.

```
ds3 = dataset('XLSFile', 'hospitalSmall.xlsx', 'Sheet', 'Heights3')
```

```
ds3 =
```

identifier	hgt
'GLI-532'	69
'QFY-472'	62
'MIJ-579'	61
'VNL-702'	68
'XLK-030'	63
'LPD-746'	61
'TFP-518'	60
'YPL-320'	71
'ATA-945'	72
'LQW-768'	64
'PNI-258'	62
'UJG-627'	61

```
'XUE-826'      71
'TRW-072'      69
```

`ds3` has height measurements for each observation in `ds1`. This dataset array has the same patient identifiers as `ds1`, but they are under the variable name `identifier`, instead of `id` (and in a different order).

### Specify key variable.

You can easily change the variable name of the key variable in `ds3` by setting `d3.Properties.VarNames` or using the Variables editor, but it is not required to perform a merge. Instead, you can specify the name of the key variable in each dataset array using `LeftKeys` and `RightKeys`.

```
joinDiff = join(ds3,ds1,'LeftKeys','identifier','RightKeys','id')
```

```
joinDiff =
```

identifier	hgt	name	sex	age
'GLI-532'	69	'JOHNSON'	'm'	43
'QFY-472'	62	'ANDERSON'	'f'	45
'MIJ-579'	61	'JONES'	'f'	40
'VNL-702'	68	'MOORE'	'm'	28
'XLK-030'	63	'BROWN'	'f'	49
'LPD-746'	61	'MILLER'	'f'	33
'TFP-518'	60	'DAVIS'	'f'	46
'YPL-320'	71	'SMITH'	'm'	38
'ATA-945'	72	'WILSON'	'm'	40
'LQW-768'	64	'TAYLOR'	'f'	31
'PNI-258'	62	'WILLIAMS'	'f'	38
'UJG-627'	61	'THOMAS'	'f'	42
'XUE-826'	71	'JACKSON'	'm'	25
'TRW-072'	69	'WHITE'	'm'	39

The merged dataset array, `joinDiff`, has the same key variable order and name as the first dataset array input to `join`, `ds3`.

## Stack or Unstack Dataset Arrays

This example shows how to reformat dataset arrays between wide and tall (or long) format using `stack` and `unstack`.

### Load sample data.

Navigate to the folder containing sample data. Import the data from the comma-separated text file `testScores.csv`.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
ds = dataset('File','testScores.csv','Delimiter','');
```

```
ds =
```

LastName	Sex	Test1	Test2	Test3	Test4
'HOWARD'	'male'	90	87	93	92
'WARD'	'male'	87	85	83	90
'TORRES'	'male'	86	85	88	86
'PETERSON'	'female'	75	80	72	77
'GRAY'	'female'	89	86	87	90
'RAMIREZ'	'female'	96	92	98	95
'JAMES'	'male'	78	75	77	77
'WATSON'	'female'	91	94	92	90
'BROOKS'	'female'	86	83	85	89
'KELLY'	'male'	79	76	82	80

Each of the 10 students has 4 test scores, displayed here in wide format.

### Perform calculations on dataset array.

With the data in this format, you can, for example, calculate the average test score for each student. The test scores are in columns 3 to 6.

```
ds.TestAve = mean(double(ds(:,3:6)),2);
ds(:,{'LastName','Sex','TestAve'})
```

```
ans =
```

LastName	Sex	TestAve
----------	-----	---------

'HOWARD'	'male'	90.5
'WARD'	'male'	86.25
'TORRES'	'male'	86.25
'PETERSON'	'female'	76
'GRAY'	'female'	88
'RAMIREZ'	'female'	95.25
'JAMES'	'male'	76.75
'WATSON'	'female'	91.75
'BROOKS'	'female'	85.75
'KELLY'	'male'	79.25

A new variable with average test scores is added to the dataset array, ds.

**Reformat the dataset array into tall format.**

Stack the test score variables into a new variable, Scores.

```
dsTall = stack(ds, {'Test1', 'Test2', 'Test3', 'Test4'}, ...
              'newDataVarName', 'Scores')
```

```
dsTall =
```

LastName	Sex	TestAve	Scores_Indicator	Scores
'HOWARD'	'male'	90.5	Test1	90
'HOWARD'	'male'	90.5	Test2	87
'HOWARD'	'male'	90.5	Test3	93
'HOWARD'	'male'	90.5	Test4	92
'WARD'	'male'	86.25	Test1	87
'WARD'	'male'	86.25	Test2	85
'WARD'	'male'	86.25	Test3	83
'WARD'	'male'	86.25	Test4	90
'TORRES'	'male'	86.25	Test1	86
'TORRES'	'male'	86.25	Test2	85
'TORRES'	'male'	86.25	Test3	88
'TORRES'	'male'	86.25	Test4	86
'PETERSON'	'female'	76	Test1	75
'PETERSON'	'female'	76	Test2	80
'PETERSON'	'female'	76	Test3	72
'PETERSON'	'female'	76	Test4	77
'GRAY'	'female'	88	Test1	89
'GRAY'	'female'	88	Test2	86

'GRAY'	'female'	88	Test3	87
'GRAY'	'female'	88	Test4	90
'RAMIREZ'	'female'	95.25	Test1	96
'RAMIREZ'	'female'	95.25	Test2	92
'RAMIREZ'	'female'	95.25	Test3	98
'RAMIREZ'	'female'	95.25	Test4	95
'JAMES'	'male'	76.75	Test1	78
'JAMES'	'male'	76.75	Test2	75
'JAMES'	'male'	76.75	Test3	77
'JAMES'	'male'	76.75	Test4	77
'WATSON'	'female'	91.75	Test1	91
'WATSON'	'female'	91.75	Test2	94
'WATSON'	'female'	91.75	Test3	92
'WATSON'	'female'	91.75	Test4	90
'BROOKS'	'female'	85.75	Test1	86
'BROOKS'	'female'	85.75	Test2	83
'BROOKS'	'female'	85.75	Test3	85
'BROOKS'	'female'	85.75	Test4	89
'KELLY'	'male'	79.25	Test1	79
'KELLY'	'male'	79.25	Test2	76
'KELLY'	'male'	79.25	Test3	82
'KELLY'	'male'	79.25	Test4	80

The original test variable names, `Test1`, `Test2`, `Test3`, and `Test4`, appear as levels in the combined test scores indicator variable, `Scores_Indicator`.

### **Plot data grouped by category.**

With the data in this format, you can use `Scores_Indicator` as a grouping variable, and draw box plots of test scores grouped by test.

```
figure()  
boxplot(dsTall.Scores,dsTall.Scores_Indicator)
```

**Reformat the dataset array into wide format.**

Reformat dsTall back into its original wide format.

```
dsWide = unstack(dsTall, 'Scores', 'Scores_Indicator');
dsWide(:, {'LastName', 'Test1', 'Test2', 'Test3', 'Test4'})
```

ans =

LastName	Test1	Test2	Test3	Test4
'HOWARD'	90	87	93	92
'WARD'	87	85	83	90
'TORRES'	86	85	88	86
'PETERSON'	75	80	72	77
'GRAY'	89	86	87	90
'RAMIREZ'	96	92	98	95
'JAMES'	78	75	77	77
'WATSON'	91	94	92	90

'BROOKS'	86	83	85	89
'KELLY'	79	76	82	80

The dataset array is back in wide format. `unstack` reassigns the levels of the indicator variable, `Scores_Indicator`, as variable names in the unstacked dataset array.

## Calculations on Dataset Arrays

This example shows how to perform calculations on dataset arrays.

### Load sample data.

Navigate to the folder containing sample data. Import the data from the comma-separated text file `testScores.csv`.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
ds = dataset('File','testScores.csv','Delimiter','(',')')
```

```
ds =
```

LastName	Sex	Test1	Test2	Test3	Test4
'HOWARD'	'male'	90	87	93	92
'WARD'	'male'	87	85	83	90
'TORRES'	'male'	86	85	88	86
'PETERSON'	'female'	75	80	72	77
'GRAY'	'female'	89	86	87	90
'RAMIREZ'	'female'	96	92	98	95
'JAMES'	'male'	78	75	77	77
'WATSON'	'female'	91	94	92	90
'BROOKS'	'female'	86	83	85	89
'KELLY'	'male'	79	76	82	80

There are 4 test scores for each of 10 students, in wide format.

### Average dataset array variables.

Compute the average (mean) test score for each student in the dataset array, and store it in a new variable, `TestAvg`. Test scores are in columns 3 to 6.

Use `double` to convert the specified dataset array variables into a numeric array. Then, calculate the mean across the second dimension (across columns) to get the test average for each student.

```
ds.TestAvg = mean(double(ds(:,3:6)),2);
ds(:,{'LastName','TestAvg'})
```

```
ans =  
  
    LastName      TestAvg  
    'HOWARD'      90.5  
    'WARD'        86.25  
    'TORRES'      86.25  
    'PETERSON'    76  
    'GRAY'        88  
    'RAMIREZ'     95.25  
    'JAMES'       76.75  
    'WATSON'      91.75  
    'BROOKS'     85.75  
    'KELLY'      79.25
```

### Summarize the dataset array using a grouping variable.

Compute the mean and maximum average test scores for each gender.

```
stats = grpstats(ds,'Sex',{'mean','max'},'DataVars','TestAvg')
```

```
stats =
```

	Sex	GroupCount	mean_TestAvg	max_TestAvg
male	'male'	5	83.8	90.5
female	'female'	5	87.35	95.25

This returns a new dataset array containing the specified summary statistics for each level of the grouping variable, `Sex`.

### Replace data values.

The denominator for each test score is 100. Convert the test score denominator to 25.

```
scores = double(ds(:,3:6));  
newScores = scores*25/100;  
ds = replacedata(ds,newScores,3:6)
```

```
ds =
```

LastName	Sex	Test1	Test2	Test3	Test4	T
----------	-----	-------	-------	-------	-------	---

'HOWARD'	'male'	22.5	21.75	23.25	23	
'WARD'	'male'	21.75	21.25	20.75	22.5	8
'TORRES'	'male'	21.5	21.25	22	21.5	8
'PETERSON'	'female'	18.75	20	18	19.25	
'GRAY'	'female'	22.25	21.5	21.75	22.5	
'RAMIREZ'	'female'	24	23	24.5	23.75	9
'JAMES'	'male'	19.5	18.75	19.25	19.25	7
'WATSON'	'female'	22.75	23.5	23	22.5	9
'BROOKS'	'female'	21.5	20.75	21.25	22.25	8
'KELLY'	'male'	19.75	19	20.5	20	7

The first two lines of code extract the test data and perform the desired calculation. Then, `replacedata` inserts the new test scores back into the dataset array.

The variable of test score averages, `TestAvg`, is now the final score for each student.

### Change variable name.

Change the variable name to `Final`.

```
ds.Properties.VarNames{end} = 'Final';
ds
```

```
ds =
```

LastName	Sex	Test1	Test2	Test3	Test4	F
'HOWARD'	'male'	22.5	21.75	23.25	23	
'WARD'	'male'	21.75	21.25	20.75	22.5	8
'TORRES'	'male'	21.5	21.25	22	21.5	8
'PETERSON'	'female'	18.75	20	18	19.25	
'GRAY'	'female'	22.25	21.5	21.75	22.5	
'RAMIREZ'	'female'	24	23	24.5	23.75	9
'JAMES'	'male'	19.5	18.75	19.25	19.25	7
'WATSON'	'female'	22.75	23.5	23	22.5	9
'BROOKS'	'female'	21.5	20.75	21.25	22.25	8
'KELLY'	'male'	19.75	19	20.5	20	7

## Export Dataset Arrays

This example shows how to export a dataset array from the MATLAB workspace to a text or spreadsheet file.

### Load sample data.

```
load('hospital')
```

The dataset array has 100 observations and 7 variables.

### Export to a text file.

Export the dataset array, `hospital`, to a text file named `hospital.txt`. By default, `export` writes to a tab-delimited text file with the same name as the dataset array, appended by `.txt`.

```
export(hospital)
```

This creates the file `hospital.txt` in the current working folder, if it does not previously exist. If the file already exists in the current working folder, `export` overwrites the existing file.

By default, variable names are in the first line of the text file. Observation names, if present, are in the first column.

### Export without variable names.

Export `hospital` with variable names suppressed to a text file named `NoLabels.txt`.

```
export(hospital,'File','NoLabels.txt','WriteVarNames',false)
```

There are no variable names in the first line of the created text file, `NoLabels.txt`.

### Export to a comma-delimited format.

Export `hospital` to a comma-delimited text file, `hospital.csv`.

```
export(hospital,'File','hospital.csv','Delimiter',',')
```

### **Export to an Excel spreadsheet.**

Export `hospital` to an Excel spreadsheet named `hospital.xlsx`.

```
export(hospital, 'XLSFile', 'hospital.xlsx')
```

By default, the first row of `hospital.xlsx` has variable names, and the first column has observation names.

## Clean Messy and Missing Data

This example shows how to find, clean, and delete observations with missing data in a dataset array.

### Load sample data.

Navigate to the folder containing sample data. Import the data from the spreadsheet `messy.xlsx`.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
messyData = dataset('XLSFile','messy.xlsx')
```

```
messyData =
```

var1	var2	var3	var4	var5
'afe1'	'3'	'yes'	'3'	3
'egh3'	'.'	'no'	'7'	7
'wth4'	'3'	'yes'	'3'	3
'atn2'	'23'	'no'	'23'	23
'arg1'	'5'	'yes'	'5'	5
'jre3'	'34.6'	'yes'	'34.6'	34.6
'wen9'	'234'	'yes'	'234'	234
'ple2'	'2'	'no'	'2'	2
'dbo8'	'5'	'no'	'5'	5
'oii4'	'5'	'yes'	'5'	5
'wnk3'	'245'	'yes'	'245'	245
'abk6'	'563'	''	'563'	563
'pnj5'	'463'	'no'	'463'	463
'wnn3'	'6'	'no'	'6'	6
'oks9'	'23'	'yes'	'23'	23
'wba3'	''	'yes'	'NaN'	14
'pkn4'	'2'	'no'	'2'	2
'adw3'	'22'	'no'	'22'	22
'poj2'	'-99'	'yes'	'-99'	-99
'bas8'	'23'	'no'	'23'	23
'gry5'	'NA'	'yes'	'NaN'	21

When you import data from a spreadsheet, `dataset` reads any variables with nonnumeric elements as a cell array of strings. This is why the variable `var2` is a cell array of strings. When importing data from a text file, you have more flexibility to specify which nonnumeric expressions to treat as missing using the option `TreatAsEmpty`.

There are many different missing data indicators in `messy.xlsx`, such as:

- Empty cells
- A period (.)
- NA
- NaN
- -99

### **Find observations with missing values.**

Display the subset of observations that have at least one missing value using `ismissing`.

```
ix = ismissing(messyData, 'NumericTreatAsMissing', -99, ...  
             'StringTreatAsMissing', {'NaN', '.', 'NA'});  
messyData(any(ix,2),:)
```

ans =

var1	var2	var3	var4	var5
'egh3'	'.'	'no'	'7'	7
'abk6'	'563'	''	'563'	563
'wba3'	''	'yes'	'NaN'	14
'poj2'	'-99'	'yes'	'-99'	-99
'gry5'	'NA'	'yes'	'NaN'	21

By default, `ismissing` recognizes the following missing value indicators:

- NaN for numeric arrays
- '' for string arrays
- <undefined> for categorical arrays

Use the `NumericTreatAsMissing` and `StringTreatAsMissing` options to specify other values to treat as missing.

### Convert string arrays to double arrays.

You can convert the string variables that should be numeric using `str2double`.

```
messyData.var2 = str2double(messyData.var2);
messyData.var4 = str2double(messyData.var4)
```

```
messyData =
```

var1	var2	var3	var4	var5
'afe1'	3	'yes'	3	3
'egh3'	NaN	'no'	7	7
'wth4'	3	'yes'	3	3
'atn2'	23	'no'	23	23
'arg1'	5	'yes'	5	5
'jre3'	34.6	'yes'	34.6	34.6
'wen9'	234	'yes'	234	234
'ple2'	2	'no'	2	2
'dbo8'	5	'no'	5	5
'oii4'	5	'yes'	5	5
'wnk3'	245	'yes'	245	245
'abk6'	563	' '	563	563
'pnj5'	463	'no'	463	463
'wnn3'	6	'no'	6	6
'oks9'	23	'yes'	23	23
'wba3'	NaN	'yes'	NaN	14
'pkn4'	2	'no'	2	2
'adw3'	22	'no'	22	22
'poj2'	-99	'yes'	-99	-99
'bas8'	23	'no'	23	23
'gry5'	NaN	'yes'	NaN	21

Now, `var2` and `var4` are numeric arrays. During the conversion, `str2double` replaces the nonnumeric elements of the variables `var2` and `var4` with the value `NaN`. However, there are no changes to the numeric missing value indicator, `-99`.

When applying the same function to many dataset array variables, it can sometimes be more convenient to use `datasetfun`. For example, to convert both `var2` and `var4` to numeric arrays simultaneously, you can use:

```
messyData(:,[2,4]) = datasetfun(@str2double,messyData,'DataVars',[2,4],...  
                               'DatasetOutput',true);
```

### Replace missing value indicators.

Clean the data so that the missing values indicated by the code `-99` have the standard MATLAB numeric missing value indicator, `NaN`.

```
messyData = replaceWithMissing(messyData,'NumericValues',-99)
```

```
messyData =
```

var1	var2	var3	var4	var5
'afe1'	3	'yes'	3	3
'egh3'	NaN	'no'	7	7
'wth4'	3	'yes'	3	3
'atn2'	23	'no'	23	23
'arg1'	5	'yes'	5	5
'jre3'	34.6	'yes'	34.6	34.6
'wen9'	234	'yes'	234	234
'ple2'	2	'no'	2	2
'dbo8'	5	'no'	5	5
'oii4'	5	'yes'	5	5
'wnk3'	245	'yes'	245	245
'abk6'	563	' '	563	563
'pnj5'	463	'no'	463	463
'wnn3'	6	'no'	6	6
'oks9'	23	'yes'	23	23
'wba3'	NaN	'yes'	NaN	14
'pkn4'	2	'no'	2	2
'adw3'	22	'no'	22	22
'poj2'	NaN	'yes'	NaN	NaN
'bas8'	23	'no'	23	23
'gry5'	NaN	'yes'	NaN	21

### Create a dataset array with complete observations.

Create a new dataset array that contains only the complete observations—those without missing data.

```
ix = ismissing(messyData);
completeData = messyData(~any(ix,2),:)
```

```
completeData =
```

var1	var2	var3	var4	var5
'afe1'	3	'yes'	3	3
'wth4'	3	'yes'	3	3
'atn2'	23	'no'	23	23
'arg1'	5	'yes'	5	5
'jre3'	34.6	'yes'	34.6	34.6
'wen9'	234	'yes'	234	234
'ple2'	2	'no'	2	2
'dbo8'	5	'no'	5	5
'oii4'	5	'yes'	5	5
'wnk3'	245	'yes'	245	245
'pnj5'	463	'no'	463	463
'wnn3'	6	'no'	6	6
'oks9'	23	'yes'	23	23
'pkn4'	2	'no'	2	2
'adw3'	22	'no'	22	22
'bas8'	23	'no'	23	23

### Open Dataset Arrays in the Variables Editor

The MATLAB Variables editor provides a convenient interface for viewing, modifying, and plotting dataset arrays.

First, load the sample data set, `hospital`.

```
load('hospital')
```

The dataset array, `hospital`, is created in the MATLAB workspace.

The screenshot shows the MATLAB Workspace window with a table of variables. The table has two columns: 'Name' and 'Value'. The first row shows 'Description' with a value of 'Simulated hospital data'. The second row shows 'hospital' with a value of '<100x7 dataset>'. The 'hospital' row is highlighted with a blue background.

Name	Value
Description	'Simulated hospital data'
hospital	<100x7 dataset>

The dataset array has 100 observations and 7 variables.

To open `hospital` in the Variables editor, click **Open Variable**, and select `hospital`.

The Variables editor opens, displaying the contents of the dataset array (only the first 10 observations are shown here).

hospital <100x7 dataset>							
	1	2	3	4	5	6	7
	LastName	Sex	Age	Weight	Smoker	BloodPressure	Trials
1	YPL-320	'SMITH'	Male	38	176	1	124 93 18
2	GLI-532	'JOHNSON'	Male	43	163	0	109 77 [11,13,22]
3	PNI-258	'WILLIAMS'	Female	38	131	0	125 83 []
4	MIJ-579	'JONES'	Female	40	133	0	117 75 [6,12]
5	XLK-030	'BROWN'	Female	49	119	0	122 80 [14,23]
6	TFP-518	'DAVIS'	Female	46	142	0	121 70 19
7	LPD-746	'MILLER'	Female	33	142	1	130 88 13
8	ATA-945	'WILSON'	Male	40	180	0	115 82 []
9	VNL-702	'MOORE'	Male	28	183	0	115 78 2
10	LQW-768	'TAYLOR'	Female	31	132	0	118 86 11

In the Variables editor, you can see the names of the seven variables along the top row, and the observations names down the first column.

## Modify Variable and Observation Names

You can modify variable and observation names by double-clicking a name, and then typing new text.

	1	2
	LastName	Sex
1 YPL-320	'SMITH'	Male
2 GLI-532	'JOHNSON'	Male
3 PNI-258	'WILLIAMS'	Female

	1	2
	LastName	Gender
1 YPL-320	'SMITH'	Male
2 GLI-532	'JOHNSON'	Male
3 PNI-258	'WILLIAMS'	Female
4 MIJ-579	'JONES'	Female
5 XLK-030	'BROWN'	Female

All changes made in the Variables editor are also sent to the command line.

```
Command Window
>> hospital.Properties.VarNames{2} = 'Gender';
fx >>
```

The sixth variable in the data set, `BloodPressure`, is a numeric array with two columns. The first column shows systolic blood pressure, and the second column shows diastolic blood pressure. Click the arrow that appears on the right side of the variable name cell to see the units and description of the variable. You can type directly in the units and description fields to modify the text. The variable data type and size are shown under the variable description.

6	7	8	9
BloodPressure	Trials		
124	Ascending		
109	Descending		
125	UNITS		
117	mm Hg		
122	DESCRIPTION		
121	Systolic/Diastolic		
130			
115			
115			

## Reorder or Delete Variables

You can reorder variables in a dataset array using the Variables editor. Hover over the left side of a variable name cell until a four-headed arrow appears.

4	5
Weight	Smoker
176	1
163	0
131	0
133	0
119	0
142	0

After the arrow appears, click and drag the variable column to a new location.

4 Weight	5 Smoke	5 Smoker	6 BloodPressure
176	1	1	124
163	0	0	109
131	0	0	125
133	0	0	117
119	0	0	122
142	0	0	121
142	1	1	130
180	0	0	115
183	0	0	115
132	0	0	118
128	0	0	114
137	0	0	115
174	0	0	127

5 BloodPressure	6 Smoker	7 Trials
124	93	1 18
109	77	0 [11,13,22]
125	83	0 []
117	75	0 [6,12]
122	80	0 [14,23]
121	70	0 19
130	88	1 17

The command for the variable reordering appears in the command line.

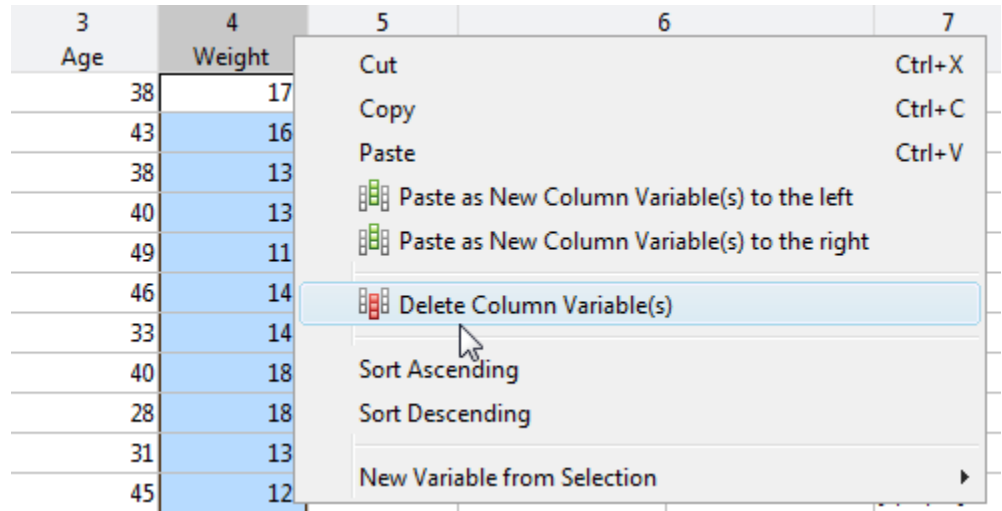

```

Command Window
>> hospital = hospital(:, [1:4 6 5 end]);
fx >>

```

You can delete a variable in the Variables editor by selecting the variable column, right-clicking, and selecting **Delete Column Variable(s)**.

The command for the variable deletion appears in the command line.

```
Command Window
>> hospital(:, 'Weight') = [];
fx >>
```

## Add New Data

You can enter new data values directly into the Variables editor. For example, you can add a new patient observation to the `hospital` data set. To enter a new last name, add a string to the end of the variable `LastName`.

100	ZZB-405	'HAYES'	Male	48	114	86
101		'JONES'				
102						

The variable `Gender` is a nominal array. The levels of the categorical variable appear in a drop-down list when you double-click a cell in the `Gender` column.

You can choose one of the levels previously used, or create a new level by selecting **New Item**.

100	ZZB-405	'HAYES'	Male
101	Obs101	'JONES'	Female
102			Female
103			Male
104			New item
105			

You can continue to add data for the remaining variables.

To change the observation name, click the observation name and type the new name.

100	ZZB-405	'HAYES'	Male	48
101	Obs101	'JONES'	Female	45
102				

The commands for entering the new data appear at the command line.

```

Command Window
>> hospital.LastName{101} = 'JONES';
Warning: Observations with default values added to dataset
variables.
> In dataset.subsasgn at 584
>> hospital.Sex(101) = 'Female';
>> hospital.Age(101) = 45;
>> hospital.BloodPressure(101,2) = 85;
>> hospital.BloodPressure(101,1) = 120;
>> hospital.Properties.ObsNames{101} = 'QPO-187';
fx >>
    
```

Notice the warning that appears after the first assignment. When you enter the first piece of data in the new observation row—here, the last name—default values are assigned to all other variables. Default assignments are:

- 0 for numeric variables
- <undefined> for categorical variables
- [ ] for cell arrays

You can also copy and paste data from one dataset array to another using the Variables editor.

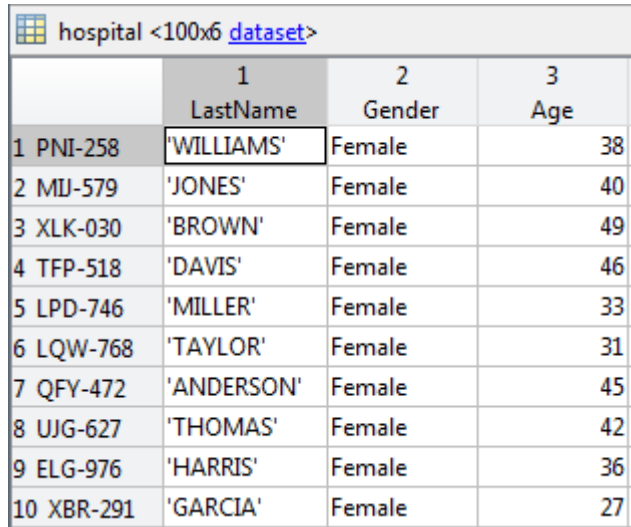

## Sort Observations

You can use the Variables editor to sort dataset array observations by the values of one or more variables. To sort by gender, for example, select the variable Gender. Then click **Sort**, and choose to sort rows by ascending or descending values of the selected variable.

The screenshot shows the Variables Editor interface with the 'VIEW' tab selected. The 'Sort' menu is open, showing options for 'Sort Ascending by Selected Columns' and 'Sort Descending by Selected Columns'. The data table below shows the 'hospital' dataset with columns: LastName, Gender, Age, BloodPressure, Smoker, and Trials. The rows are sorted by Gender, with females grouped together and males grouped together.

	1 LastName	2 Gender	3 Age	4 BloodPressure	5 Smoker	6 Trials		
1	YPL-320	'SMITH'	Male	38	124	93	1	18
2	GLI-532	'JOHNSON'	Male	43	109	77	0	[11,13,22]
3	PNI-258	'WILLIAMS'	Female	38	125	83	0	[]
4	MIJ-579	'JONES'	Female	40	117	75	0	[6,12]
5	XLK-030	'BROWN'	Female	49	122	80	0	[14,23]

When sorting by variables that are cell arrays of strings or of nominal data type, observations are sorted alphabetically. For ordinal variables, rows are sorted by the ordering of the levels. For example, when the observations of `hospital` are sorted by the values in `Gender`, the females are grouped together, followed by the males.

	1 LastName	2 Gender	3 Age	
1	PNI-258	'WILLIAMS'	Female	38
2	MU-579	'JONES'	Female	40
3	XLK-030	'BROWN'	Female	49
4	TFP-518	'DAVIS'	Female	46
5	LPD-746	'MILLER'	Female	33
6	LQW-768	'TAYLOR'	Female	31
7	QFY-472	'ANDERSON'	Female	45
8	UJG-627	'THOMAS'	Female	42
9	ELG-976	'HARRIS'	Female	36
10	XBR-291	'GARCIA'	Female	27

To sort by the values of multiple variables, press **Ctrl** while you select multiple variables.

When you use the Variables editor to sort rows, it is the same as calling `sortrows`. You can see this at the command line after executing the sorting.

```
Command Window
>> hospital = sortrows(hospital, 'Gender', 'ascend');
fx >>
```

### Select a Subset of Data

You can select a subset of data from a dataset array in the Variables editor, and create a new dataset array from the selection. For example, to create a dataset array containing only the variables `LastName` and `Age`:

- 1 Hold **Ctrl** while you click the variables `LastName` and `Age`.
- 2 Right-click, and select **New Variable from Selection > New Dataset Array**.

hospital <100x6 dataset>							
	1	2	3	4	5	6	7
	LastName	Gender	Age	BloodPressure	Smoker	Trials	
1	PNI-258	'WILLIAMS'	Female				
2	MJ-579	'JONES'	Female				
3	XLK-030	'BROWN'	Female				
4	TFP-518	'DAVIS'	Female				
5	LPD-746	'MILLER'	Female				
6	LQW-768	'TAYLOR'	Female				
7	QFY-472	'ANDERSON'	Female				
8	UJG-627	'THOMAS'	Female				
9	ELG-976	'HARRIS'	Female				
10	XBR-291	'GARCIA'	Female				
11	BKD-785	'CLARK'	Female				
12	JHV-416	'RODRIGUEZ'	Female				
13	VWL-936	'LEWIS'	Female	41	114	88	0 8
14	AAX-056	'LEE'	Female	44	128	90	1 []
15	DTT-578	'WALKER'	Female	28	129	96	17

The new dataset array appears in the Workspace window with the name LastName. The Command Window shows the commands that execute the selection.

Workspace		Command Window
Name	Value	
Description	'Simulated hospital data'	>> LastName = hospital(:, [1,3]);
LastName	<100x2 dataset>	fx >>
hospital	<100x6 dataset>	

You can use the same steps to select any subset of data. To select observations according to some logical condition, you can use a combination of sorting and selecting. For example, to create a new dataset array containing only males aged 45 and older:

- 1 Sort the observations of hospital by the values in Gender and Age, descending.
- 2 Select the male observations with age 45 and older.

hospital <100x6 dataset>

	1 LastName	2 Gender	3 Age	4 BloodPressure	5 Smoker	6 Trials
1 XBA-581	'ROBINSON'	Male	50	125	76	0 [20,26,30]
2 DAU-529	'REED'	Male	50	129	89	1 22
3 FLJ-908	'STEWART'	Male	49	129	95	1 15
4 MEZ-469	'GRIFFIN'	Male	49	119	74	0 9
5 KOQ-996	'MARTIN'	Male	48	130	92	1 [13,15,21,27]
6 FCD-425	'GONZALES'	Male	48	123	79	0 []
7 ZZB-405	'HAYES'	Male	48	114	86	0 28
8 YVY-570	'SCOTT'	Male	47	127	84	0 8
9 VDZ-577	'PHILLIPS'	Male	45	117	89	0 [10,15,17,19]
10 WCJ-997	'BELL'	Male	45	138	82	1 7
11 AGR-528	'SIMMONS'	Male	45	124	77	0 [8,18,25]
12 BEZ-311	'DIAZ'	Male	45	136	93	1 []
13 MSL-692	'GREEN'	Male	44	121	92	0 []

- 3** Right-click, and select **New Variables from Selection > New Dataset Array**. The new dataset array, LastName1, is created in the Workspace window.

Workspace

Name	Value
Description	'Simulated hospital data'
LastName	<100x2 dataset>
LastName1	<12x6 dataset>
hospital	<100x6 dataset>

Command Window

```
>> hospital = sortrows(hospital, {'Gender', 'Age'}, 'descend');
>> LastName1 = hospital(1:12, 1:6);
fx >>
```

- 4** You can rename the dataset array in the Workspace window.

Workspace

Name	Value
Description	'Simulated hospital data'
LastName	<100x2 dataset>
Male45	<12x6 dataset>
hospital	<100x6 dataset>

## Create Plots

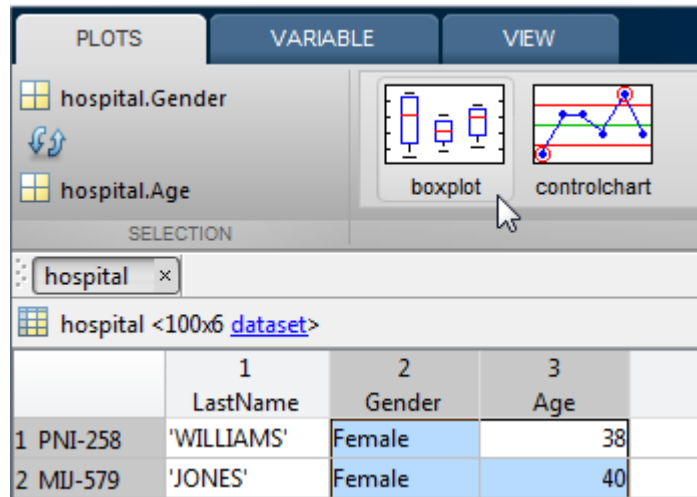

You can plot data from a dataset array using plotting options in the Variables editor. Available plot choices depend on the data types of variables to be plotted.

For example, if you select the variable **Age**, you can see in the **Plots** tab some plotting options that are appropriate for a univariate, numeric variable.

The screenshot shows the Variables Editor interface. The 'PLOTS' tab is active, displaying five plot options: 'plot' (line graph), 'bar' (bar chart), 'area' (area chart), 'pie' (pie chart), and 'hist' (histogram). Below the plot options is a 'SELECTION' area with a dropdown menu showing 'hospital' and a table view of the dataset. The table has columns for LastName, Gender, Age, BloodPressure, and Sm, with the Age column highlighted in blue.

	1	2	3	4		
	LastName	Gender	Age	BloodPressure	Sm	
1	PNI-258	'WILLIAMS'	Female	38	125	83
2	MJ-579	'JONES'	Female	40	117	75
3	XLK-030	'BROWN'	Female	49	122	80
4	TFP-518	'DAVIS'	Female	46	121	70
5	LPD-746	'MILLER'	Female	33	130	88

Sometimes, there are plot options for multiple variables, depending on their data types. For example, if you select both **Age** and **Gender**, you can draw box plots of age, grouped by gender.

The screenshot shows the SAS software interface. At the top, there are three tabs: 'PLOTS', 'VARIABLE', and 'VIEW'. Under the 'PLOTS' tab, two variables are listed: 'hospital.Gender' and 'hospital.Age'. To the right of these variables are two plot icons: a 'boxplot' icon and a 'controlchart' icon. Below the plot icons is a 'SELECTION' section with a search box containing 'hospital' and a dropdown menu showing 'hospital <100x6 dataset>'. At the bottom of the screenshot is a table view of the 'hospital' dataset with the following data:

	1	2	3	
	LastName	Gender	Age	
1	PNI-258	'WILLIAMS'	Female	38
2	MIJ-579	'JONES'	Female	40

## Dataset Arrays

### In this section...

“What Are Dataset Arrays?” on page 2-135

“Dataset Array Conversion” on page 2-135

“Dataset Array Properties” on page 2-136

### What Are Dataset Arrays?

Statistics Toolbox has *dataset arrays* for storing variables with heterogeneous data types. For example, you can combine numeric data, logical data, cell arrays of strings, and categorical arrays in one dataset array variable.

Within a dataset array, each variable (column) must be one homogeneous data type, but the different variables can be of heterogeneous data types. A dataset array is usually interpreted as a set of variables measured on many units of observation. That is, each row in a dataset array corresponds to an observation, and each column to a variable. In this sense, a dataset array organizes data like a typical spreadsheet.

Dataset arrays are a unique data type, with a corresponding set of valid operations. Even if a dataset array contains only numeric variables, you cannot operate on the dataset array like a numeric variable. The valid operations for dataset arrays are the methods of the `dataset` class.

### Dataset Array Conversion

You can create a dataset array by combining variables that exist in the MATLAB workspace, or directly importing data from a file, such as a text file or spreadsheet. This table summarizes the functions you can use to create dataset arrays.

Data Source	Conversion to Dataset Array
Data from a file	<code>dataset</code>
Heterogeneous collection of workspace variables	<code>dataset</code>

<b>Data Source</b>	<b>Conversion to Dataset Array</b>
Numeric array	mat2dataset
Cell array	cell2dataset
Structure array	struct2dataset
Table	table2dataset

You can export dataset arrays to text or spreadsheet files using `export`. To convert a dataset array to a cell array or structure array, use `dataset2cell` or `dataset2struct`. To convert a dataset array to a table, use `dataset2table`.

## **Dataset Array Properties**

In addition to storing data in a dataset array, you can store metadata such as:

- Variable and observation names
- Data descriptions
- Units of measurement
- Variable descriptions

This information is stored as dataset array properties. For a dataset array named `ds`, you can view the dataset array metadata by entering `ds.Properties` at the command line. You can access a specific property, such as variable names—property `VarNames`—using `ds.Properties.VarNames`. You can both retrieve and modify property values using this syntax.

Variable and observation names are included in the display of a dataset array. Variable names display across the top row, and observation names, if present, appear in the first column. Note that variable and observation names do not affect the size of a dataset array.

## Index and Search Dataset Arrays

### Ways To Index and Search

There are many ways to index into dataset arrays. For example, for a dataset array, `ds`, you can:

- Use `()` to create a new dataset array from a subset of `ds`. For example, `ds1 = ds(1:5, :)` creates a new dataset array, `ds1`, consisting of the first five rows of `ds`. Metadata, including variable and observation names, transfers to the new dataset array.
- Use variable names with dot notation to index individual variables in a dataset array. For example, `ds.Height` indexes the variable named `Height`.
- Use observation names to index individual observations in a dataset array. For example, `ds('Obs1', :)` gives data for the observation named `Obs1`.
- Use observation or variable numbers. For example, `ds(:, [1,3,5])` gives the data in the first, third, and fifth variables (columns) of `ds`.
- Use logical indexing to search for observations in `ds` that satisfy a logical condition. For example, `ds(ds.Gender=='Male', :)` gives the observations in `ds` where the variable named `Gender`, a nominal array, has the value `Male`.
- Use `ismissing` to find missing data in the dataset array.

### Common Indexing and Searching

The following brief examples illustrate several indexing and searching methods.

#### Load sample data.

```
load('hospital')  
size(hospital)
```

```
ans =
```

```
    100     7
```

The dataset array has 100 observations and 7 variables.

**Index a variable by name.** Return the minimum age in the dataset array.

```
min(hospital.Age)
```

```
ans =
```

```
    25
```

Delete the variable Trials.

```
hospital.Trials = [];
size(hospital)
```

```
ans =
```

```
    100     6
```

**Index an observation by name.** Display measurements on the first five variables for the observation named PUE-347.

```
hospital('PUE-347',1:5)
```

```
ans =
```

	LastName	Sex	Age	Weight	Smoker
PUE-347	'YOUNG'	Female	25	114	false

**Index variables by number.** Create a new dataset array containing the first four variables of hospital.

```
dsNew = hospital(:,1:4);
dsNew.Properties.VarNames(:)
```

```
ans =
```

```
'LastName'
'Sex'
'Age'
'Weight'
```

**Index observations by number.** Delete the last 10 observations.

```
hospital(end-9:end,:) = [];  
size(hospital)
```

```
ans =
```

```
90    7
```

**Search for observations by logical condition.** Create a new dataset array containing only females who smoke.

```
dsFS = hospital(hospital.Sex=='Female' & hospital.Smoker==true,:);  
dsFS(:,{'LastName','Sex','Smoker'})
```

```
ans =
```

	LastName	Sex	Smoker
LPD-746	'MILLER'	Female	true
XBR-291	'GARCIA'	Female	true
AAX-056	'LEE'	Female	true
DTT-578	'WALKER'	Female	true
AFK-336	'WRIGHT'	Female	true
RBA-579	'SANCHEZ'	Female	true
HAK-381	'MORRIS'	Female	true
NSK-403	'RAMIREZ'	Female	true
ILS-109	'WATSON'	Female	true
JDR-456	'SANDERS'	Female	true
HWZ-321	'PATTERSON'	Female	true
GGU-691	'HUGHES'	Female	true
WUS-105	'FLORES'	Female	true

- “Data with Missing Values” on page 3-21

## **Introduction to Descriptive Statistics**

You may need to summarize large, complex data sets—both numerically and visually—to convey their essence to the data analyst and to allow for further processing.

## Measures of Central Tendency

Measures of central tendency locate a distribution of data along an appropriate scale.

The following table lists the functions that calculate the measures of central tendency.

Function Name	Description
geomean	Geometric mean
harmmean	Harmonic mean
mean	Arithmetic average
median	50th percentile
mode	Most frequent value
trimmean	Trimmed mean

The average is a simple and popular estimate of location. If the data sample comes from a normal distribution, then the sample mean is also optimal (minimum variance unbiased estimator (MVUE) of  $\mu$ ).

Unfortunately, outliers, data entry errors, or glitches exist in almost all real data. The sample mean is sensitive to these problems. One bad data value can move the average away from the center of the rest of the data by an arbitrarily large distance.

The median and trimmed mean are two measures that are resistant (robust) to outliers. The median is the 50th percentile of the sample, which will only change slightly if you add a large perturbation to any value. The idea behind the trimmed mean is to ignore a small percentage of the highest and lowest values of a sample when determining the center of the sample.

The geometric mean and harmonic mean, like the average, are not robust to outliers. They are useful when the sample is distributed lognormal or heavily skewed.

The following example shows the behavior of the measures of location for a sample with one outlier.

```
x = [ones(1,6) 100]
```

```
x =  
    1    1    1    1    1    1   100
```

```
locate = [geomean(x) harmmean(x) mean(x) median(x)...  
          trimmean(x,25)]
```

```
locate =  
    1.9307    1.1647   15.1429    1.0000    1.0000
```

You can see that the mean is far from any data value because of the influence of the outlier. The median and trimmed mean ignore the outlying value and describe the location of the rest of the data values.

## Measures of Dispersion

The purpose of measures of dispersion is to find out how spread out the data values are on the number line. Another term for these statistics is measures of spread.

The table gives the function names and descriptions.

Function Name	Description
iqr	Interquartile range
mad	Mean absolute deviation
moment	Central moment of all orders
range	Range
std	Standard deviation
var	Variance

The range (the difference between the maximum and minimum values) is the simplest measure of spread. But if there is an outlier in the data, it will be the minimum or maximum value. Thus, the range is not robust to outliers.

The standard deviation and the variance are popular measures of spread that are optimal for normally distributed samples. The sample variance is the minimum variance unbiased estimator (MVUE) of the normal parameter  $\sigma^2$ . The standard deviation is the square root of the variance and has the desirable property of being in the same units as the data. That is, if the data is in meters, the standard deviation is in meters as well. The variance is in meters<sup>2</sup>, which is more difficult to interpret.

Neither the standard deviation nor the variance is robust to outliers. A data value that is separate from the body of the data can increase the value of the statistics by an arbitrarily large amount.

The mean absolute deviation (MAD) is also sensitive to outliers. But the MAD does not move quite as much as the standard deviation or variance in response to bad data.

The interquartile range (IQR) is the difference between the 75th and 25th percentile of the data. Since only the middle 50% of the data affects this measure, it is robust to outliers.

The following example shows the behavior of the measures of dispersion for a sample with one outlier.

```
x = [ones(1,6) 100]

x =
     1     1     1     1     1     1    100

stats = [iqr(x) mad(x) range(x) std(x)]

stats =
     0    24.2449    99.0000    37.4185
```

## Quantiles and Percentiles

This section explains how the Statistics Toolbox functions `quantile` and `prctile` compute quantiles and percentiles.

The `prctile` function calculates the percentiles in a similar way as `quantile` calculates quantiles. The following steps in the computation of quantiles are also true for percentiles, given the fact that, for the same data sample, the quantile at the value  $Q$  is the same as the percentile at the value  $P = 100 * Q$ .

**1** `quantile` initially assigns the sorted values in  $X$  to the  $(0.5/n)$ ,  $(1.5/n)$ , ...,  $([n - 0.5]/n)$  quantiles. For example:

- For a data vector of six elements such as {6, 3, 2, 10, 8, 1}, the sorted elements {1, 2, 3, 6, 8, 10} respectively correspond to the  $(0.5/6)$ ,  $(1.5/6)$ ,  $(2.5/6)$ ,  $(3.5/6)$ ,  $(4.5/6)$ , and  $(5.5/6)$  quantiles.
- For a data vector of five elements such as {2, 10, 5, 9, 13}, the sorted elements {2, 5, 9, 10, 13} respectively correspond to the 0.1, 0.3, 0.5, 0.7, and 0.9 quantiles.

The following figure illustrates this approach for data vector  $X = \{2, 10, 5, 9, 13\}$ . The first observation corresponds to the cumulative probability  $1/5 = 0.2$ , the second observation corresponds to the cumulative probability  $2/5 = 0.4$ , and so on. The step function in this figure shows these cumulative probabilities. `quantile` instead places the observations in midpoints, such that the first corresponds to  $0.5/5 = 0.1$ , the second corresponds to  $1.5/5 = 0.3$ , and so on, and then connects these midpoints. The red lines in the following figure connect the midpoints.

**Assigning Observations to Quantiles**

By switching the axes, as the next figure, you can see the values of the variable  $X$  that correspond to the  $p$  quantiles.

### Quantiles of X

- 2** quantile finds any quantiles between the data values using linear interpolation.

*Linear interpolation* uses linear polynomials to approximate a function  $f(x)$  and construct new data points within the range of a known set of data points. Algebraically, given the data points  $(x_1, y_1)$  and  $(x_2, y_2)$ , where  $y_1 = f(x_1)$  and  $y_2 = f(x_2)$ , linear interpolation finds  $y = f(x)$  for a given  $x$  between  $x_1$  and  $x_2$  as follows:

$$y = f(x) = y_1 + \frac{(x - x_1)}{(x_2 - x_1)}(y_2 - y_1).$$

Similarly, if the  $1.5/n$  quantile is  $y_{1.5/n}$  and the  $2.5/n$  quantile is  $y_{2.5/n}$ , then linear interpolation finds the  $2.3/n$  quantile  $y_{2.3/n}$  as

$$y_{\frac{2.3}{n}} = y_{\frac{1.5}{n}} + \frac{\left(\frac{2.3}{n} - \frac{1.5}{n}\right)}{\left(\frac{2.5}{n} - \frac{1.5}{n}\right)} \left( y_{\frac{2.5}{n}} - y_{\frac{1.5}{n}} \right).$$

**3** quantile assigns the first and last values of  $X$  to the quantiles for probabilities less than  $(0.5/n)$  and greater than  $([n-0.5]/n)$ , respectively.

**See Also**

quantile | prctile | median

## Exploratory Analysis of Data

This example shows how to explore the distribution of data using descriptive statistics.

### Generate sample data.

```
rng('default') % for reproducibility  
x = [normrnd(4,1,1,100) normrnd(6,0.5,1,200)];
```

### Create a histogram of data with normal density fit.

```
histfit(x)
```

The distribution of the data seems left skewed and normal distribution does not look like a good fit to this distribution.

**Obtain a normal probability plot.**

```
probplot('normal',x)
```

This probability plot also clearly shows the deviation of data from normality.

**Compute quantiles of data.**

```
p = 0:0.25:1;  
y = quantile(x,p);
```

```
z = [p;y]
```

```
z =
```

```
          0    0.2500    0.5000    0.7500    1.0000
1.0557    4.7375    5.6872    6.1526    7.5784
```

**Plot a box plot.**

A box plot helps to visualize the statistics.

```
boxplot(x)
```

You can also see the 0.25, 0.5, and 0.75 quantiles in the box plot. The long lower tail and plus signs also show the lack of symmetry in the sample values.

**Compute the mean and median of data.**

`y = [mean(x) median(x)]`

`y =`

```
5.3438    5.6872
```

The mean and median values seem close to each other, but a mean smaller than the median usually flags left skewness of the data.

**Compute the skewness and kurtosis of data.**

```
y = [skewness(x) kurtosis(x)]
```

```
y =
```

```
-1.0417    3.5895
```

A negative skewness value means the data is left skewed. The data has a larger peakedness than a normal distribution because the kurtosis value is greater than 3.

**Identify possible outliers.**

Compute z-scores. Find the z-scores that are greater than 3 or less than  $-3$ .

```
Z = zscore(x);
find(abs(Z)>3);
```

```
ans =
```

```
3    35
```

The 3rd and 35th observations might be outliers.

**See Also**

```
quantile | prctile | histfit | boxplot | mean | median | kurtosis
| skewness
```

## Resampling Statistics

In this section...
“Bootstrap” on page 3-16
“Jackknife” on page 3-19
“Parallel Computing Support for Resampling Methods” on page 3-20

### Bootstrap

The *bootstrap* procedure involves choosing random samples with replacement from a data set and analyzing each sample the same way. Sampling with replacement means that each observation is selected separately at random from the original dataset. So a particular data point from the original data set could appear multiple times in a given bootstrap sample. The number of elements in each bootstrap sample equals the number of elements in the original data set. The range of sample estimates you obtain enables you to establish the uncertainty of the quantity you are estimating.

This example from Efron and Tibshirani [33] compares Law School Admission Test (LSAT) scores and subsequent law school grade point average (GPA) for a sample of 15 law schools.

```
load lawdata
plot(lsat,gpa, '+')
lsline
```

The least-squares fit line indicates that higher LSAT scores go with higher law school GPAs. But how certain is this conclusion? The plot provides some intuition, but nothing quantitative.

You can calculate the correlation coefficient of the variables using the `corr` function.

```
rho_hat = corr(lsat, gpa)
rho_hat =
    0.7764
```

Now you have a number describing the positive connection between LSAT and GPA; though it may seem large, you still do not know if it is statistically significant.

Using the `bootstrp` function you can resample the `lsat` and `gpa` vectors as many times as you like and consider the variation in the resulting correlation coefficients.

Here is an example.

```
rhos1000 = bootstrp(1000, 'corr', lsat, gpa);
```

This command resamples the `lsat` and `gpa` vectors 1000 times and computes the `corr` function on each sample. Here is a histogram of the result.

```
hist(rhos1000, 30)  
set(get(gca, 'Children'), 'FaceColor', [.8 .8 1])
```

Nearly all the estimates lie on the interval  $[0.4 \ 1.0]$ .

It is often desirable to construct a confidence interval for a parameter estimate in statistical inferences. Using the `bootci` function, you can use bootstrapping to obtain a confidence interval. The confidence interval for the `lsat` and `gpa` data is computed as:

```
ci = bootci(5000,@corr,lsat,gpa)
```

```
ci =  
    0.3313  
    0.9427
```

Therefore, a 95% confidence interval for the correlation coefficient between LSAT and GPA is [0.33 0.94]. This is strong quantitative evidence that LSAT and subsequent GPA are positively correlated. Moreover, this evidence does not require any strong assumptions about the probability distribution of the correlation coefficient.

Although the `bootci` function computes the Bias Corrected and accelerated (BCa) interval as the default type, it is also able to compute various other types of bootstrap confidence intervals, such as the studentized bootstrap confidence interval.

## Jackknife

Similar to the bootstrap is the *jackknife*, which uses resampling to estimate the bias of a sample statistic. Sometimes it is also used to estimate standard error of the sample statistic. The jackknife is implemented by the Statistics Toolbox function `jackknife`.

The jackknife resamples systematically, rather than at random as the bootstrap does. For a sample with  $n$  points, the jackknife computes sample statistics on  $n$  separate samples of size  $n-1$ . Each sample is the original data with a single observation omitted.

In the previous bootstrap example you measured the uncertainty in estimating the correlation coefficient. You can use the jackknife to estimate the bias, which is the tendency of the sample correlation to over-estimate or under-estimate the true, unknown correlation. First compute the sample correlation on the data:

```
load lawdata
```

```
rhohat = corr(lsat,gpa)
```

```
rhohat =  
    0.7764
```

Next compute the correlations for jackknife samples, and compute their mean:

```
jackrho = jackknife(@corr,lsat,gpa);  
meanrho = mean(jackrho)
```

```
meanrho =  
    0.7759
```

Now compute an estimate of the bias:

```
n = length(lsat);  
biasrho = (n-1) * (meanrho-rhohat)
```

```
biasrho =  
   -0.0065
```

The sample correlation probably underestimates the true correlation by about this amount.

## **Parallel Computing Support for Resampling Methods**

For information on computing resampling statistics in parallel, see Parallel Computing Toolbox™.

## Data with Missing Values

Many data sets have one or more missing values. It is convenient to code missing values as NaN (Not a Number) to preserve the structure of data sets across multiple variables and observations.

For example:

```
X = magic(3);
X([1 5]) = [NaN NaN]
X =
     NaN     1     6
     3     NaN     7
     4     9     2
```

Normal MATLAB arithmetic operations yield NaN values when operands are NaN:

```
s1 = sum(X)
s1 =
     NaN     NaN    15
```

Removing the NaN values would destroy the matrix structure. Removing the rows containing the NaN values would discard data. Statistics Toolbox functions in the following table remove NaN values only for the purposes of computation.

Function	Description
nancov	Covariance matrix, ignoring NaN values
nanmax	Maximum, ignoring NaN values
nanmean	Mean, ignoring NaN values
nanmedian	Median, ignoring NaN values
nanmin	Minimum, ignoring NaN values
nanstd	Standard deviation, ignoring NaN values
nansum	Sum, ignoring NaN values
nanvar	Variance, ignoring NaN values

For example:

```
s2 = nansum(X)
s2 =
     7     10     15
```

Other Statistics Toolbox functions also ignore NaN values. These include `iqr`, `kurtosis`, `mad`, `prctile`, `range`, `skewness`, and `trimmean`.

# Statistical Visualization

---

- “Introduction to Statistical Visualization” on page 4-2
- “Create Scatter Plots Using Grouped Data” on page 4-3
- “Box Plots” on page 4-7
- “Distribution Plots” on page 4-9

## Introduction to Statistical Visualization

Statistics Toolbox data visualization functions add to the extensive graphics capabilities already in MATLAB.

- Scatter plots are a basic visualization tool for multivariate data. They are used to identify relationships among variables. Grouped versions of these plots use different plotting symbols to indicate group membership. The `gname` function is used to label points on these plots with a text label or an observation number.
- Box plots display a five-number summary of a set of data: the median, the two ends of the interquartile range (the box), and two extreme values (the whiskers) above and below the box. Because they show less detail than histograms, box plots are most useful for side-by-side comparisons of two distributions.
- Distribution plots help you identify an appropriate distribution family for your data. They include normal and Weibull probability plots, quantile-quantile plots, and empirical cumulative distribution plots.

Advanced Statistics Toolbox visualization functions are available for specialized statistical analyses.

## Create Scatter Plots Using Grouped Data

This example shows how to create scatter plots using grouped sample data.

A scatter plot is a simple plot of one variable against another. The MATLAB functions `plot` and `scatter` produce scatter plots. The MATLAB function `plotmatrix` can produce a matrix of such plots showing the relationship between several pairs of variables.

Statistics Toolbox functions `gscatter` and `gplotmatrix` produce grouped versions of these plots. These are useful for determining whether the values of two variables or the relationship between those variables is the same in each group.

Suppose you want to examine the weight and mileage of cars from three different model years.

```
load carsmall
gscatter(Weight,MPG,Model_Year,' ','xos')
```

This shows that not only is there a strong relationship between the weight of a car and its mileage, but also that newer cars tend to be lighter and have better gas mileage than older cars.

The default arguments for `gscatter` produce a scatter plot with the different groups shown with the same symbol but different colors. The last two arguments above request that all groups be shown in default colors and with different symbols.

The carsmall data set contains other variables that describe different aspects of cars. You can examine several of them in a single display by creating a grouped plot matrix.

```
xvars = [Weight Displacement Horsepower];
yvars = [MPG Acceleration];
gplotmatrix(xvars,yvars,Model_Year,' ','xos')
```

The upper right subplot displays MPG against Horsepower, and shows that over the years the horsepower of the cars has decreased but the gas mileage has improved.

The `gplotmatrix` function can also graph all pairs from a single list of variables, along with histograms for each variable. See MANOVA.

## Box Plots

The graph below, created with the `boxplot` command, compares petal lengths in samples from two species of iris.

```
load fisheriris
s1 = meas(51:100,3);
s2 = meas(101:150,3);
boxplot([s1 s2], 'notch', 'on', ...
        'labels', {'versicolor', 'virginica'})
```

This plot has the following features:

- The tops and bottoms of each “box” are the 25th and 75th percentiles of the samples, respectively. The distances between the tops and bottoms are the interquartile ranges.

- The line in the middle of each box is the sample median. If the median is not centered in the box, it shows sample skewness.
- The whiskers are lines extending above and below each box. Whiskers are drawn from the ends of the interquartile ranges to the furthest observations within the whisker length (the *adjacent values*).
- Observations beyond the whisker length are marked as outliers. By default, an outlier is a value that is more than 1.5 times the interquartile range away from the top or bottom of the box, but this value can be adjusted with additional input arguments. Outliers are displayed with a red + sign.
- Notches display the variability of the median between samples. The width of a notch is computed so that box plots whose notches do not overlap (as above) have different medians at the 5% significance level. The significance level is based on a normal distribution assumption, but comparisons of medians are reasonably robust for other distributions. Comparing box-plot medians is like a visual hypothesis test, analogous to the  $t$  test used for means.

## Distribution Plots

In this section...
“Normal Probability Plots” on page 4-9
“Quantile-Quantile Plots” on page 4-12
“Cumulative Distribution Plots” on page 4-15
“Other Probability Plots” on page 4-16

### Normal Probability Plots

Normal probability plots are used to assess whether data comes from a normal distribution. Many statistical procedures make the assumption that an underlying distribution is normal, so normal probability plots can provide some assurance that the assumption is justified, or else provide a warning of problems with the assumption. An analysis of normality typically combines normal probability plots with hypothesis tests for normality.

This example generates a data sample of 25 random numbers from a normal distribution with  $\mu = 10$  and  $\sigma = 1$ , and creates a normal probability plot of the data.

```
rng('default'); % For reproducibility
x = normrnd(10,1,25,1);
normplot(x)
```

The plus signs plot the empirical probability versus the data value for each point in the data. A solid line connects the 25th and 75th percentiles in the data, and a dashed line extends it to the ends of the data. The y-axis values are probabilities from zero to one, but the scale is not linear. The distance between tick marks on the y-axis matches the distance between the quantiles of a normal distribution. The quantiles are close together near the median (probability = 0.5) and stretch out symmetrically as you move away from the median.

In a normal probability plot, if all the data points fall near the line, an assumption of normality is reasonable. Otherwise, the points will curve away from the line, and an assumption of normality is not justified. For example, the following generates a data sample of 100 random numbers from an exponential distribution with  $\mu = 10$ , and creates a normal probability plot of the data.

```
x = exprnd(10,100,1);  
normplot(x)
```

The plot is strong evidence that the underlying distribution is not normal.

### Quantile-Quantile Plots

Quantile-quantile plots are used to determine whether two samples come from the same distribution family. They are scatter plots of quantiles computed from each sample, with a line drawn between the first and third quartiles. If the data falls near the line, it is reasonable to assume that the two samples come from the same distribution. The method is robust with respect to changes in the location and scale of either distribution.

To create a quantile-quantile plot, use the `qqplot` function.

The following example generates two data samples containing random numbers from Poisson distributions with different parameter values, and creates a quantile-quantile plot. The data in `x` is from a Poisson distribution with `lambda = 10`, and the data in `y` is from a Poisson distribution with `lambda = 5`.

```
x = poissrnd(10,50,1);  
y = poissrnd(5,100,1);  
qqplot(x,y);
```

Even though the parameters and sample sizes are different, the approximate linear relationship suggests that the two samples may come from the same distribution family. As with normal probability plots, hypothesis tests can provide additional justification for such an assumption. For statistical procedures that depend on the two samples coming from the same distribution, however, a linear quantile-quantile plot is often sufficient.

The following example shows what happens when the underlying distributions are not the same. Here, `x` contains 100 random numbers generated from a

normal distribution with  $\mu = 5$  and  $\sigma = 1$ , while  $y$  contains 100 random numbers generated from a Weibull distribution with  $A = 2$  and  $B = 0.5$ .

```
x = normrnd(5,1,100,1);  
y = wblrnd(2,0.5,100,1);  
qqplot(x,y);
```

These samples clearly are not from the same distribution family.

## Cumulative Distribution Plots

An empirical cumulative distribution function (cdf) plot shows the proportion of data less than each  $x$  value, as a function of  $x$ . The scale on the  $y$ -axis is linear; in particular, it is not scaled to any particular distribution. Empirical cdf plots are used to compare data cdfs to cdfs for particular distributions.

To create an empirical cdf plot, use the `cdfplot` function (or `ecdf` and `stairs`).

The following example compares the empirical cdf for a sample from an extreme value distribution with a plot of the cdf for the sampling distribution. In practice, the sampling distribution would be unknown, and would be chosen to match the empirical cdf.

```
y = evrnd(0,3,100,1);
cdfplot(y)
hold on
x = -20:0.1:10;
f = evcdf(x,0,3);
plot(x,f,'m')
legend('Empirical','Theoretical','Location','NW')
```

### Other Probability Plots

A probability plot, like the normal probability plot, is just an empirical cdf plot scaled to a particular distribution. The  $y$ -axis values are probabilities from zero to one, but the scale is not linear. The distance between tick marks is the distance between quantiles of the distribution. In the plot, a line is drawn between the first and third quartiles in the data. If the data falls near the line, it is reasonable to choose the distribution as a model for the data.

To create probability plots for different distributions, use the `probplot` function.

The following example assesses two samples, one from a Weibull distribution with  $A = 3$  and  $B = 3$ , and one from a Rayleigh distribution with  $B = 3$ , to see if either distribution may have come from a Weibull population.

```
x1 = wblrnd(3,3,100,1);  
x2 = raylrnd(3,100,1);  
probplot('weibull',[x1 x2])  
legend('Weibull Sample','Rayleigh Sample','Location','NW')
```

The plot gives justification for modeling the first sample with a Weibull distribution; much less so for the second sample.

A distribution analysis typically combines probability plots with hypothesis tests for a particular distribution.

## Working with Probability Distributions

In this section...
“Types of Probability Distributions” on page 5-3
“How to Work with Probability Distributions” on page 5-4

### Types of Probability Distributions

Probability distributions are theoretical distributions based on assumptions about a source population. The distributions assign probability to the event that a random variable has a specific, discrete value, or falls within a specified range of continuous values. The two main types of distributions are parametric and nonparametric.

Parametric distributions are probability distributions that you can describe using a finite set of parameters. You can choose a distribution model for your data based on a parametric family of probability distributions, and then adjust the parameters to fit the data. You can then perform further analyses by computing summary statistics, evaluating the probability density function (pdf) and cumulative distribution function (cdf), and assessing the fit of the distribution to your data.

Nonparametric and empirical distributions provide estimates of probability density functions (pdf) or cumulative distribution functions (cdf) based on sample data. You can use this approach when the data cannot be described accurately by the supported parametric distributions. Statistics Toolbox supports the following nonparametric and empirical techniques:

- Kernel distribution
- Piecewise linear distribution
- Empirical cumulative distribution function
- Piecewise distribution with Pareto tails
- Triangular distribution

### **How to Work with Probability Distributions**

Statistics Toolbox provides several ways to work with parametric and nonparametric probability distributions.

Apps and user interfaces provide an interactive approach to working with parametric and nonparametric probability distributions.

- Use the Distribution Fitting app to fit a distribution to your data and export a probability distribution object to your workspace for further analysis.
- Use the Probability Distribution Function user interface to visually explore probability distributions.
- Use the Random Number Generation user interface to generate random data from a specified distribution and export the results to your workspace.

Probability distribution objects provide a convenient way to explore and fit your data to a parametric or nonparametric distribution, save the results to a single entity, and generate random data from the resulting parameters.

Command-line functions let you further explore parametric and nonparametric distributions, fit relevant models to your data, and generate random data. You can use command-line functions to work with distributions that are not currently supported as probability distribution objects.

## Maximum Likelihood Estimation

The Statistics Toolbox function `mle` is a convenient front end to the individual distribution fitting functions, and more. The function computes maximum likelihood estimates (MLEs) for distributions beyond those for which Statistics Toolbox software provides specific pdf functions.

For some pdfs, MLEs can be given in closed form and computed directly. For other pdfs, a search for the maximum likelihood must be employed. The search can be controlled with an `options` input argument, created using the `statset` function. For efficient searches, it is important to choose a reasonable distribution model and set appropriate convergence tolerances.

MLEs can be heavily biased, especially for small samples. As sample size increases, however, MLEs become unbiased minimum variance estimators with approximate normal distributions. This is used to compute confidence bounds for the estimates.

For example, consider the following distribution of means from repeated random samples of an exponential distribution:

```
mu = 1; % Population parameter
n = 1e3; % Sample size
ns = 1e4; % Number of samples
samples = exprnd(mu,n,ns); % Population samples
means = mean(samples); % Sample means
```

The Central Limit Theorem says that the means will be approximately normally distributed, regardless of the distribution of the data in the samples. The `normfit` function can be used to find the normal distribution that best fits the means:

```
[muhat,sigmahat,muci,sigmaci] = normfit(means)
muhat =
    1.0003
sigmahat =
    0.0319
muci =
    0.9997
    1.0010
```

```
sigmaci =  
    0.0314  
    0.0323
```

The function returns MLEs for the mean and standard deviation and their 95% confidence intervals.

To visualize the distribution of sample means together with the fitted normal distribution, you must scale the fitted pdf, with area = 1, to the area of the histogram being used to display the means:

```
numbins = 50;  
hist(means,numbins)  
set(get(gca,'Children'),'FaceColor',[.8 .8 1])  
hold on  
[bincounts,binpositions] = hist(means,numbins);  
binwidth = binpositions(2) - binpositions(1);  
histarea = binwidth*sum(bincounts);  
x = binpositions(1):0.001:binpositions(end);  
y = normpdf(x,muhat,sigmahat);  
plot(x,histarea*y,'r','LineWidth',2)
```

## Negative Loglikelihood Functions

Negative loglikelihood functions for supported Statistics Toolbox distributions all end with `like`, as in `explike`. Each function represents a parametric family of distributions. Input arguments are lists of parameter values specifying a particular member of the distribution family followed by an array of data. Functions return the negative log-likelihood of the parameters, given the data.

Negative log-likelihood functions are used as objective functions in search algorithms such as the one implemented by the MATLAB function `fminsearch`. Additional search algorithms are implemented by Optimization Toolbox™ functions and Global Optimization Toolbox functions.

When used to compute maximum likelihood estimates (MLEs), negative log-likelihood functions allow you to choose a search algorithm and exercise low-level control over algorithm execution. By contrast, the functions discussed in “Maximum Likelihood Estimation” on page 5-5 use preset algorithms with options limited to those set by the `statset` function.

Likelihoods are conditional probability densities. A parametric family of distributions is specified by its pdf  $f(x,a)$ , where  $x$  and  $a$  represent the variables and parameters, respectively. When  $a$  is fixed, the pdf is used to compute the density at  $x$ ,  $f(x|a)$ . When  $x$  is fixed, the pdf is used to compute the *likelihood* of the parameters  $a$ ,  $f(a|x)$ . The joint likelihood of the parameters over an independent random sample  $X$  is

$$L(a) = \prod_{x \in X} f(a|x)$$

Given  $X$ , MLEs maximize  $L(a)$  over all possible  $a$ .

In numerical algorithms, the log-likelihood function,  $\log(L(a))$ , is (equivalently) optimized. The logarithm transforms the product of potentially small likelihoods into a sum of logs, which is easier to distinguish from 0 in computation. For convenience, Statistics Toolbox negative log-likelihood functions return the *negative* of this sum, since the optimization algorithms to which the values are passed typically search for minima rather than maxima.

For example, use `gamrnd` to generate a random sample from a specific gamma distribution:

```
a = [1,2];
X = gamrnd(a(1),a(2),1e3,1);
```

Given `X`, the `gamlike` function can be used to visualize the likelihood surface in the neighborhood of `a`:

```
mesh = 50;
delta = 0.5;
a1 = linspace(a(1)-delta,a(1)+delta,mesh);
a2 = linspace(a(2)-delta,a(2)+delta,mesh);
logL = zeros(mesh); % Preallocate memory
for i = 1:mesh
    for j = 1:mesh
        logL(i,j) = gamlike([a1(i),a2(j)],X);
    end
end
end
```

```
[A1,A2] = meshgrid(a1,a2);
surfc(A1,A2,logL)
```

The MATLAB function `fminsearch` is used to search for the minimum of the likelihood surface:

```
LL = @(u)gamlike([u(1),u(2)],X); % Likelihood given X
MLES = fminsearch(LL,[1,2])
MLES =
    1.0231    1.9729
```

These can be compared to the MLEs returned by the `gamfit` function, which uses a combination search and solve algorithm:

```
ahat = gamfit(X)
ahat =
    1.0231    1.9728
```

The MLEs can be added to the surface plot (rotated to show the minimum):

```
hold on
plot3(MLES(1),MLES(2),LL(MLES),...
      'ro','MarkerSize',5,...
      'MarkerFaceColor','r')
```

## Random Number Generation

The Statistics Toolbox supports the generation of random numbers from various distributions. Each RNG represents a parametric family of distributions. RNGs return random numbers from the specified distribution in an array of the specified dimensions.

Other random number generation functions which do not support specific distributions include:

- `cvpartition`
- `datasample`
- `hmmgenerate`
- `lhsdesign`
- `lhsnorm`
- `mhsample`
- `random`
- `randsample`
- `slicesample`

RNGs in Statistics Toolbox software depend on MATLAB's default random number stream via the `rand` and `randn` functions, each RNG uses one of the techniques discussed in “Common Generation Methods” on page 6-5 to generate random numbers from a given distribution.

By controlling the default random number stream and its state, you can control how the RNGs in Statistics Toolbox software generate random values. For example, to reproduce the same sequence of values from an RNG, you can save and restore the default stream's state, or reset the default stream. For details on managing the default random number stream, see “Managing the Global Stream”.

MATLAB initializes the default random number stream to the same state each time it starts up. Thus, RNGs in Statistics Toolbox software will generate the same sequence of values for each MATLAB session unless you

modify that state at startup. One simple way to do that is to add commands to `startup.m` such as

```
rng('shuffle');
```

that initialize MATLAB's default random number stream to a different state for each session.

The following table lists the dependencies of Statistics Toolbox RNGs on the MATLAB base RNGs `rand`, `randi`, and/or `randn`.

<b>RNG</b>	<b>MATLAB Base RNG</b>
<code>betarnd</code>	<code>rand</code> , <code>randn</code>
<code>binornd</code>	<code>rand</code>
<code>chi2rnd</code>	<code>rand</code> , <code>randn</code>
<code>evrnd</code>	<code>rand</code>
<code>exprnd</code>	<code>rand</code>
<code>datasample</code>	<code>rand</code> , <code>randi</code> , <code>randperm</code>
<code>frnd</code>	<code>rand</code> , <code>randn</code>
<code>gamrnd</code>	<code>rand</code> , <code>randn</code>
<code>geornd</code>	<code>rand</code>
<code>gevrnd</code>	<code>rand</code>
<code>gprnd</code>	<code>rand</code>
<code>hygernd</code>	<code>rand</code>
<code>iwishrnd</code>	<code>rand</code> , <code>randn</code>
<code>johnsrnd</code>	<code>randn</code>
<code>lhsdesign</code>	<code>rand</code>
<code>lhsnorm</code>	<code>rand</code>
<code>lognrnd</code>	<code>randn</code>

<b>RNG</b>	<b>MATLAB Base RNG</b>
mhsample	rand or randn, depending on the RNG given for the proposal distribution
mvnrnd	randn
mvtrnd	rand, randn
nbinrnd	rand, randn
ncfrnd	rand, randn
nctrnd	rand, randn
ncx2rnd	randn
normrnd	randn
pearsrnd	rand or randn, depending on the distribution type
poissrnd	rand, randn
random	rand or randn, depending on the specified distribution
randsample	rand
raylrnd	randn
slicesample	rand
trnd	rand, randn
unidrnd	rand
unifrnd	rand
wblrnd	rand
wishrnd	rand, randn

## Nonparametric and Empirical Probability Distributions

“Overview” on page 5-14
“Kernel Distribution” on page 5-14
“Piecewise Linear Distribution” on page 5-14
“Empirical Cumulative Distribution Function” on page 5-15
“Pareto Tails” on page 5-15
“Triangular Distribution” on page 5-15

### Overview

In some situations, you cannot accurately describe a data sample using a parametric distribution. Instead, the probability density function (pdf) or cumulative distribution function (cdf) must be estimated from the data. Several options exist in Statistics Toolbox for estimating the pdf or cdf from sample data.

### Kernel Distribution

“Kernel Distribution” on page B-67 produces a nonparametric probability density estimate that adapts itself to the data, rather than selecting a density with a particular parametric form and estimating the parameters. This distribution is defined by a kernel density estimator, a smoothing function that determines the shape of the curve used to generate the pdf, and a bandwidth value that controls the smoothness of the resulting density curve.

### Piecewise Linear Distribution

A piecewise distribution is a probability distribution formed by estimating the pdf or cdf in pieces from the sample data. “Piecewise Linear Distribution” on page B-115 estimates an overall cdf by computing the cdf value at each individual point in the sample data, and linearly connects these values to form a continuous curve.

## **Empirical Cumulative Distribution Function**

An empirical cumulative distribution function (ecdf) estimates the cdf of a random variable by assigning equal probability to each observation in a sample. It creates an exact match between the empirical cdf and the distribution of the sample data. However, the empirical cdf is not a smooth distribution, especially in the tails where data might be sparse. In this case, you can use Pareto tails to smooth the distribution in the tails.

For more information, see `ecdf`, `paretotails`, and `coxphfit`.

## **Pareto Tails**

Pareto tails use a piecewise approach to improve the fit of a nonparametric cdf or pdf by smoothing the tails of the distribution. You can fit a kernel distribution, piecewise linear distribution, or empirical cdf to the middle data values, then fit generalized Pareto distributions (GPDs) to the tails. This technique is especially useful when the sample data is sparse in the tails.

For more information, see `paretotails`.

## **Triangular Distribution**

“Triangular Distribution” on page B-127 provides a simplistic representation of the probability distribution when limited sample data is available. It uses the minimum, mode, and maximum value of the sample data as parameters, and linearly connects these points to estimate the pdf.

## Fit Kernel Distribution Object to Data

This example shows how to fit a kernel probability distribution object to sample data.

### **Step 1. Load sample data.**

Load the sample data.

```
load carsmall;
```

This data contains miles per gallon (MPG) measurements for different makes and models of cars, grouped by country of origin (**Origin**), model year (**Year**), and other vehicle characteristics.

### **Step 2. Fit a kernel distribution object.**

Use `fitdist` to fit a kernel probability distribution object to the miles per gallon (MPG) data for all makes of cars.

```
pd = fitdist(MPG,'Kernel')
```

```
pd =
```

```
KernelDistribution
```

```
Kernel = normal  
Bandwidth = 4.11428  
Support = unbounded
```

This creates a `prob.KernelDistribution` object. By default, `fitdist` uses a normal kernel smoothing function and chooses an optimal bandwidth for estimating normal densities, unless you specify otherwise. You can access information about the fit and perform further calculations using the related object functions.

### **Step 3. Compute descriptive statistics.**

Compute the mean, median, and standard deviation of the fitted kernel distribution.

```
m = mean(pd)
med = median(pd)
s = std(pd)
```

```
m =
    23.7181
```

```
med =
    23.4841
```

```
s =
    8.9896
```

#### **Step 4. Compute and plot the pdf.**

Compute and plot the pdf of the fitted kernel distribution.

```
figure;
x = 0:1:60;
y = pdf(pd,x);
plot(x,y,'LineWidth',2);
title('Miles per Gallon');
xlabel('MPG');
```

The plot shows the pdf of the kernel distribution fit to the MPG data across all makes of cars. The distribution is smooth and fairly symmetrical, although it is slightly skewed with a heavier right tail.

### **Step 5. Generate random numbers.**

Generate a vector of random numbers from the fitted kernel distribution.

```
rng('default') % For reproducibility
r = random(pd,1000,1);
figure;
hist(r);
set(get(gca,'Children'),'FaceColor',[.8 .8 1]);
```

```
hold on;  
y = y*5000; % Scale pdf to overlay on histogram  
plot(x,y,'LineWidth',2);  
title('Random Numbers Generated From Distribution');  
hold off;
```

The histogram has a similar shape to the pdf plot because the random numbers generate from the nonparametric kernel distribution fit to the sample data.

**See Also** `fitdist`

### **Related Examples**

- “Fit Kernel Distribution Using `ksdensity`” on page 5-21

### **Concepts**

- “Kernel Distribution” on page B-67

## Fit Kernel Distribution Using `ksdensity`

This example shows how to generate a kernel probability density estimate from sample data using the `ksdensity` function.

### **Step 1. Load sample data.**

Load the sample data.

```
load carsmall;
```

This data contains miles per gallon (MPG) measurements for different makes and models of cars, grouped by country of origin (`Origin`), model year (`Year`), and other vehicle characteristics.

### **Step 2. Generate a kernel probability density estimate.**

Use `ksdensity` to generate a kernel probability density estimate for the miles per gallon (MPG) data.

```
[f,xi] = ksdensity(MPG);
```

By default, `ksdensity` uses a normal kernel smoothing function and chooses an optimal bandwidth for estimating normal densities, unless you specify otherwise.

### **Step 3. Plot the kernel probability density estimate.**

Plot the kernel probability density estimate to visualize the |MPG| distribution.

```
figure;  
plot(xi,f,'LineWidth',2);  
title('Miles per Gallon');  
xlabel('MPG');
```

The plot shows the pdf of the kernel distribution fit to the MPG data across all makes of cars. The distribution is smooth and fairly symmetrical, although it is slightly skewed with a heavier right tail.

**See Also** `ksdensity`

### Related Examples

- “Fit Kernel Distribution Object to Data” on page 5-16

### Concepts

- “Kernel Distribution” on page B-67

## Fit Kernel Distributions to Grouped Data Using ksdensity

This example shows how to fit kernel distributions to grouped sample data using the ksdensity function.

### Step 1. Load sample data.

Load the sample data.

```
load carsmall;
```

The data contains miles per gallon (MPG) measurements for different makes and models of cars, grouped by country of origin (Origin), model year (Model\_Year), and other vehicle characteristics.

### Step 2. Group sample data by origin.

Group the MPG data by origin (Origin) for cars made in the USA, Japan, and Germany.

```
Origin = nominal(Origin);  
MPG_USA = MPG(Origin=='USA');  
MPG_Japan = MPG(Origin=='Japan');  
MPG_Germany = MPG(Origin=='Germany');
```

### Step 3. Compute and plot the pdf.

Compute and plot the pdf for each group.

```
figure;  
  
[fi,xi] = ksdensity(MPG_USA);  
plot(xi,fi,'r-');  
hold on;  
  
[fj,xj] = ksdensity(MPG_Japan);  
plot(xj,fj,'b-.');  
  
[fk,xk] = ksdensity(MPG_Germany);  
plot(xk,fk,'k:');
```

```
legend('USA', 'Japan', 'Germany')  
title('MPG by Origin');  
xlabel('MPG');  
hold off;
```

The plot shows how miles per gallon (MPG) performance differs by country of origin (Origin). Using this data, the USA has the widest distribution, and its peak is at the lowest MPG value of the three origins. Japan has the most regular distribution with a slightly heavier left tail, and its peak is at the highest MPG value of the three origins. The peak for Germany is between the USA and Japan, and the second bump near 44 miles per gallon suggests that there might be multiple modes in the data.

## Create and Plot Empirical Cumulative Distribution Functions

This example shows how to create and plot an empirical cumulative distribution function based on sample data.

### **Step 1. Load sample data.**

Load the sample data.

### **Step 2. Compute the empirical cumulative distribution.**

The empirical cdf assigns the probability  $1/n$  to each of  $n$  observations in a data sample. It returns the values of a function  $F$  such that  $F(x)$  represents the proportion of observations in a sample less than or equal to  $x$ . The empirical distributions computed by `ecdf` assign equal probability to each observation in a sample, providing an exact match of the sample distribution. However, the distributions are not smooth, especially in the tails where data may be sparse. In this situation, you can use Pareto tails to smooth the cdf in the tails.

### **Step 3. Plot the ecdf.**

The graph of an empirical cdf has a stair-step appearance. If a sample comes from a distribution in a parametric family (such as a normal distribution), its empirical cdf is likely to resemble the parametric distribution. If not, its empirical distribution still gives an estimate of the cdf for the distribution that generated the data.

## Fit a Nonparametric Distribution with Pareto Tails

This example shows how to fit a nonparametric probability distribution to sample data using Pareto tails to smooth the distribution in the tails.

### Step 1. Generate sample data.

Generate sample data that contains more outliers than expected from a standard normal distribution.

```
rng('default') % For reproducibility
left_tail = -exprnd(1,10,1);
right_tail = exprnd(5,10,1);
center = randn(80,1);
data = [left_tail;center;right_tail];
```

The data contains 80% values from a standard normal distribution, 10% from an exponential distribution with a mean of 5, and 10% from an exponential distribution with mean of -1. The data contains random numbers from an exponential distribution. Compared to a standard normal distribution, the exponential values are more likely to be outliers, especially in the upper tail.

### Step 2. Fit probability distributions to the data.

Fit a normal distribution and a  $t$  location-scale distribution to the data, and plot for a visual comparison.

```
figure;
probplot(data);
p = fitdist(data,'tlocation-scale');
h = probplot(gca,p);
set(h,'color','r','linestyle','-');
title('Probability Plot');
legend('Normal','Data','t location-scale','Location','SE');
```

Both distributions appear to fit reasonably well in the center, but neither the normal distribution nor the  $t$  location-scale distribution fit the tails very well.

**Step 3. Generate an empirical distribution.**

To obtain a better fit, use `ecdf` to generate an empirical cdf based on the sample data.

```
figure;  
ecdf(data)
```

The empirical distribution provides a perfect fit, but the outliers make the tails very discrete. Random samples generated from this distribution using the inversion method might include, for example, values near 4.33 and 9.25, but no values in between.

**Step 4. Fit a distribution using Pareto tails.**

Use `paretotails` to generate an empirical cdf for the middle 80% of the data and fit generalized Pareto distributions to the lower and upper 10%.

```
pfit = paretotails(data,0.1,0.9)
```

```
pfit =
```

```
Piecewise distribution with 3 segments
  -Inf < x < -1.24623    (0 < p < 0.1): lower tail, GPD(-0.334156,0.798
  -1.24623 < x < 1.48551 (0.1 < p < 0.9): interpolated empirical cdf
    1.48551 < x < Inf    (0.9 < p < 1): upper tail, GPD(1.23681,0.58186
```

To obtain a better fit, `paretotails` fits a distribution by piecing together an ecdf or kernel distribution in the center of the sample, and smooth generalized Pareto distributions (GPDs) in the tails. The `paretotails` function creates a `paretotails` probability distribution object. You can access information about the fit and perform further calculations on the object using the methods of the `paretotails` class. For example, you can evaluate the cdf or generate random numbers from the distribution.

### **Step 5. Compute and plot the cdf.**

Compute and plot the cdf of the fitted `paretotails` distribution.

```
x = -4:0.01:10;
plot(x,cdf(pfit,x));
```

The `paretotails` cdf closely fits the data but is smoother in the tails than the ecdf generated in Step 3.

## Generate Random Numbers Using the Triangular Distribution

This example shows how to create a triangular probability distribution object based on sample data, and generate random numbers for use in a simulation.

### Step 1. Input sample data.

Input the data vector `time`, which contains the observed length of time (in seconds) that 10 different cars stopped at a highway tollbooth.

```
time = [6 14 8 7 16 8 23 6 7 15];
```

The data shows that, while most cars stopped for 6 to 16 seconds, one outlier stopped for 23 seconds.

### Step 2. Estimate distribution parameters.

Estimate the triangular distribution parameters from the sample data.

```
lower = min(time);  
peak = median(time);  
upper = max(time);
```

A triangular distribution provides a simplistic representation of the probability distribution when sample data is limited. Estimate the lower and upper boundaries of the distribution by finding the minimum and maximum values of the sample data. For the peak parameter, the median might provide a better estimate of the mode than the mean, since the data includes an outlier.

### Step 3. Create a probability distribution object.

Create a triangular probability distribution object using the estimated parameter values.

```
pd = makedist('Triangular','a',lower,'b',peak,'c',upper)  
  
pd =  
  
TriangularDistribution
```

$A = 6, B = 8, C = 23$

Compute and plot the pdf of the triangular distribution.

```
figure;  
x = 0:.1:230;  
y = pdf(pd,x);  
plot(x,y);  
title('Time Spent at Tollbooth');  
xlabel('Time (seconds)');
```

The plot shows that this triangular distribution is skewed to the right. However, since the estimated peak value is the sample median, the distribution should be symmetrical about the peak. Because of its skew, this model might, for example, generate random numbers that seem unusually high when compared to the initial sample data.

### **Step 4. Generate random numbers.**

Generate random numbers from this distribution to simulate future traffic flow through the tollbooth.

```
rng('default'); % For reproducibility
r = random(pd,10,1)
```

```
r =
```

```
16.1265
18.0987
 8.0796
18.3001
13.3176
 7.8211
 9.4360
12.2508
19.7082
20.0078
```

The returned values in `r` are the time in seconds that the next 10 simulated cars spend at the tollbooth. These values seem high compared to the values in the original data vector `time` because the outlier skewed the distribution to the right. Using the second-highest value as the upper limit parameter might mitigate the effects of the outlier and generate a set of random numbers more similar to the initial sample data.

### **Step 5. Revise estimated parameters.**

Estimate the upper boundary of the distribution using the second largest value in the sample data.

```
sort_time = sort(time,'descend');
secondLargest = sort_time(2);
```

**Step 6. Create a new distribution object and plot the pdf.**

Create a new triangular probability distribution object using the revised estimated parameters, and plot its pdf.

```
figure;  
pd2 = makedist('Triangular','a',lower,'b',peak,'c',secondLargest);  
y2 = pdf(pd2,x);  
plot(x,y2,'LineWidth',2);  
title('Time Spent at Tollbooth');  
xlabel('Time (seconds)');
```

The plot shows that this triangular distribution is still slightly skewed to the right. However, it is much more symmetrical about the peak than the distribution that used the maximum sample data value to estimate the upper limit.

**Step 7. Generate new random numbers.**

Generate new random numbers from the revised distribution.

```
rng('default'); % For reproducibility
r2 = random(pd2,10,1)
```

```
r2 =
    12.1501
    13.2547
     7.5937
    13.3675
    10.5768
     7.3967
     8.4026
     9.9792
    14.1562
    14.3240
```

These new values more closely resemble those in the original data vector `time`. They are also closer to the sample median than the random numbers generated by the distribution that used the outlier to estimate its upper limit. This example does not remove the outlier from the sample data when computing the median. Other options for parameter estimation include removing outliers from the sample data altogether, or using the mean or mode of the sample data as the peak value.

## Explore the Probability Distribution Function UI

The Probability Distribution Function user interface (UI) interactively displays the influence of parameter changes on the shapes of the pdfs and cdfs of supported Statistics Toolbox distributions.

Run the user interface by typing `disttool` at the command line.

Start by selecting a distribution. Then choose the function type: probability density function (pdf) or cumulative distribution function (cdf).

After the plot appears, you can

- Calculate a new function value by
  - Typing a new  $x$  value in the text box on the  $x$ -axis
  - Dragging the vertical reference line.
  - Clicking in the figure where you want the line to be.The new function value appears in the text box to the left of the plot.
- For cdf plots, find critical values corresponding to a specific probability by typing the desired probability in the text box on the  $y$ -axis or by dragging the horizontal reference line.
- Use the controls at the bottom of the window to set parameter values for the distribution and to change their upper and lower bounds.

## Model Data Using the Distribution Fitting App

The Distribution Fitting app fits univariate distributions to data. This section describes how to use the Distribution Fitting app and covers the following topics:

<b>In this section...</b>
“Opening the Distribution Fitting App” on page 5-40
“Creating and Managing Data Sets” on page 5-43
“Creating a New Fit” on page 5-48
“Displaying Results” on page 5-53
“Managing Fits” on page 5-55
“Evaluating Fits” on page 5-57
“Excluding Data” on page 5-61
“Saving and Loading Sessions” on page 5-67
“Example: Fitting a Distribution” on page 5-68
“Generating a File to Fit and Plot Distributions” on page 5-75

### Opening the Distribution Fitting App

Open the Distribution Fitting app by entering:

```
dfittool
```

Alternatively, click Distribution Fitting on the Apps tab.

## Adjusting the Plot

Buttons at the top of the tool allow you to adjust the plot displayed in this window:

-  — Toggle the legend on (default) or off.
-  — Toggle grid lines on or off (default).
-  — Restore default axes limits.

### Displaying the Data

The **Display type** field specifies the type of plot displayed in the main window. Each type corresponds to a probability function, for example, a probability density function. The following display types are available:

- **Density (PDF)** — Display a probability density function (PDF) plot for the fitted distribution.
- **Cumulative probability (CDF)** — Display a cumulative probability plot of the data.
- **Quantile (inverse CDF)** — Display a quantile (inverse CDF) plot.
- **Probability plot** — Display a probability plot.
- **Survivor function** — Display a survivor function plot of the data.
- **Cumulative hazard** — Display a cumulative hazard plot of the data.

### Inputting and Fitting Data

The task buttons enable you to perform the tasks necessary to fit distributions to data. Each button opens a new dialog box in which you perform the task. The buttons include:

- **Data** — Import and manage data sets.
- **New Fit** — Create new fits.
- **Manage Fits** — Manage existing fits.
- **Evaluate** — Evaluate fits at any points you choose.
- **Exclude** — Create rules specifying which values to exclude when fitting a distribution.

The display pane displays plots of the data sets and fits you create. Whenever you make changes in one of the dialog boxes, the results in the display pane update.

### Saving and Customizing Distributions

The Distribution Fitting app menus contain items that enable you to do the following:

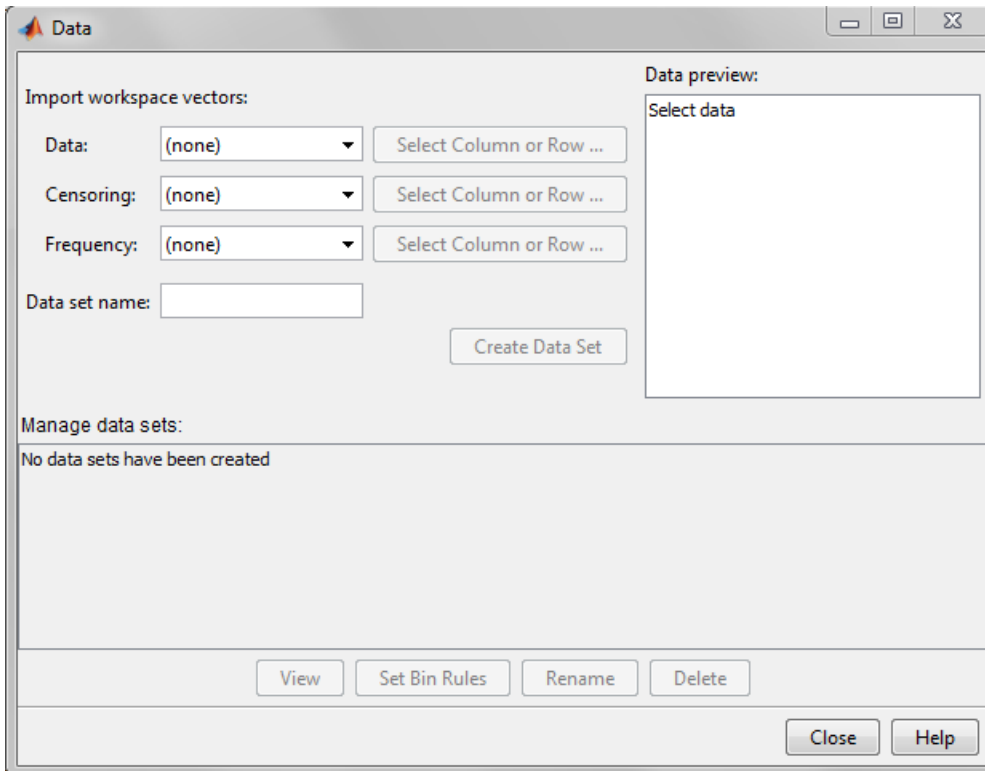

- Save and load sessions.
- Generate a file with which you can fit distributions to data and plot the results independently of the Distribution Fitting app.
- Define and import custom distributions.

## Creating and Managing Data Sets

This section describes how to create and manage data sets.

To begin, click the **Data** button in the Distribution Fitting app to open the Data dialog box shown in the following figure.

## Importing Data

The **Import workspace vectors** pane enables you to create a data set by importing a vector from the MATLAB workspace. The following sections describe the fields in this pane and give appropriate values for vectors imported from the MATLAB workspace:

- **Data** — The drop-down list in the **Data** field contains the names of all matrices and vectors, other than 1-by-1 matrices (scalars) in the MATLAB workspace. Select the array containing the data you want to fit. The actual data you import must be a vector. If you select a matrix in the **Data** field, the first column of the matrix is imported by default. To select a different column or row of the matrix, click **Select Column or Row**. This displays the matrix in the Variables editor, where you can select a row or column by highlighting it with the mouse.

Alternatively, you can enter any valid MATLAB expression in the **Data** field.

When you select a vector in the **Data** field, a histogram of the data appears in the **Data preview** pane.

- **Censoring** — If some of the points in the data set are censored, enter a Boolean vector, of the same size as the data vector, specifying the censored entries of the data. A 1 in the censoring vector specifies that the corresponding entry of the data vector is censored, while a 0 specifies that the entry is not censored. If you enter a matrix, you can select a column or row by clicking **Select Column or Row**. If you do not want to censor any data, leave the **Censoring** field blank.
- **Frequency** — Enter a vector of positive integers of the same size as the data vector to specify the frequency of the corresponding entries of the data vector. For example, a value of 7 in the 15th entry of frequency vector specifies that there are 7 data points corresponding to the value in the 15th entry of the data vector. If all entries of the data vector have frequency 1, leave the **Frequency** field blank.
- **Data set name** — Enter a name for the data set you import from the workspace, such as `My data`.

After you have entered the information in the preceding fields, click **Create Data Set** to create the data set `My data`.

## Managing Data Sets

The **Manage data sets** pane enables you to view and manage the data sets you create. When you create a data set, its name appears in the **Data sets** list. The following figure shows the **Manage data sets** pane after creating the data set **My data**.

For each data set in the **Data sets** list, you can:

- Select the **Plot** check box to display a plot of the data in the main Distribution Fitting app window. When you create a new data set, **Plot** is selected by default. Clearing the **Plot** check box removes the data from the plot in the main window. You can specify the type of plot displayed in the **Display type** field in the main window.
- If **Plot** is selected, you can also select **Bounds** to display confidence interval bounds for the plot in the main window. These bounds are pointwise confidence bounds around the empirical estimates of these functions. The bounds are only displayed when you set **Display Type** in the main window to one of the following:
  - Cumulative probability (CDF)
  - Survivor function
  - Cumulative hazard

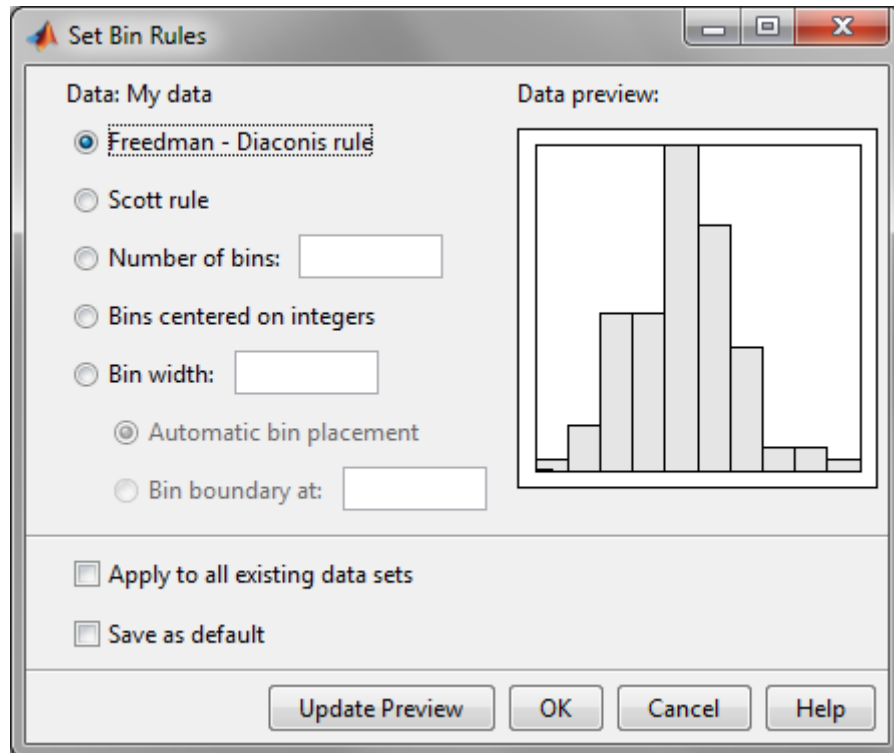

The Distribution Fitting app cannot display confidence bounds on density (PDF), quantile (inverse CDF), or probability plots. Clearing the **Bounds** check box removes the confidence bounds from the plot in the main window.

When you select a data set from the list, the following buttons are enabled:

- **View** — Display the data in a table in a new window.
- **Set Bin Rules** — Defines the histogram bins used in a density (PDF) plot.
- **Rename** — Rename the data set.
- **Delete** — Delete the data set.

### **Setting Bin Rules**

To set bin rules for the histogram of a data set, click **Set Bin Rules**. This opens the **Set Bin Width Rules** dialog box.

You can select from the following rules:

- **Freedman-Diaconis rule** — Algorithm that chooses bin widths and locations automatically, based on the sample size and the spread of the data. This rule, which is the default, is suitable for many kinds of data.
- **Scott rule** — Algorithm intended for data that are approximately normal. The algorithm chooses bin widths and locations automatically.
- **Number of bins** — Enter the number of bins. All bins have equal widths.
- **Bins centered on integers** — Specifies bins centered on integers.
- **Bin width** — Enter the width of each bin. If you select this option, you can also select:
  - **Automatic bin placement** — Place the edges of the bins at integer multiples of the **Bin width**.

- **Bin boundary at** — Enter a scalar to specify the boundaries of the bins. The boundary of each bin is equal to this scalar plus an integer multiple of the **Bin width**.

The Set Bin Width Rules dialog box also provides the following options:

- **Apply to all existing data sets** — Apply the rule to all data sets. Otherwise, the rule is only applied to the data set currently selected in the Data dialog box.
- **Save as default** — Apply the current rule to any new data sets that you create. You can also set default bin width rules by selecting **Set Default Bin Rules** from the **Tools** menu in the main window.

### Creating a New Fit

This section describes how to create a new fit. To begin, click the **New Fit** button at the top of the main window to open the New Fit dialog box. If you created the data set `My data`, it appears in the **Data** field.

New Fit

Fit name:

Data:

Distribution:

Exclusion rule:

Normal

Distribution parameters:

- mu (location)
- sigma (scale)

Apply

Results:

Click "Apply" to fit this distribution

Save to workspace... Manage Fits Close Help

<b>Field Name</b>	<b>Description</b>
Fit Name	Enter a name for the fit in the <b>Fit Name</b> field.
Data	The <b>Data</b> field contains a drop-down list of the data sets you have created. Select the data set to which you want to fit a distribution.
Distribution	<p>Select the type of distribution to fit from the <b>Distribution</b> drop-down list.</p> <p>Only the distributions that apply to the values of the selected data set appear in the <b>Distribution</b> field. For example, positive distributions are not displayed when the data include values that are zero or negative.</p> <p>You can specify either a parametric or a nonparametric distribution. When you select a parametric distribution from the drop-down list, a description of its parameters appears in the Normal pane. The Distribution Fitting Tool estimates these parameters to fit the distribution to the data set. When you select <b>Nonparametric fit</b>, options for the fit appear in the pane, as described in “Further Options for Nonparametric Fits” on page 5-52.</p>
Exclusion rule	Specify a rule to exclude some data in the <b>Exclusion rule</b> field. Create an exclusion rule by clicking <b>Exclude</b> in the Distribution Fitting app. For more information, see “Excluding Data” on page 5-61.

### **Apply the New Fit**

Click **Apply** to fit the distribution. For a parametric fit, the **Results** pane displays the values of the estimated parameters. For a nonparametric fit, the **Results** pane displays information about the fit.

When you click **Apply**, the Distribution Fitting app displays a plot of the distribution, along with the corresponding data.

---

**Note** When you click **Apply**, the title of the dialog box changes to **Edit Fit**. You can now make changes to the fit you just created and click **Apply** again to save them. After closing the **Edit Fit** dialog box, you can reopen it from the **Fit Manager** dialog box at any time to edit the fit.

---

After applying the fit, you can save the information to the workspace using probability distribution objects by clicking **Save to workspace**.

### Available Distributions

Most, but not all, of the distributions available in the Distribution Fitting app are supported elsewhere in Statistics Toolbox software, and have dedicated distribution fitting functions. These functions compute the majority of the fits in the Distribution Fitting app, and are referenced in the list below. Other fits are computed using functions internal to the Distribution Fitting app.

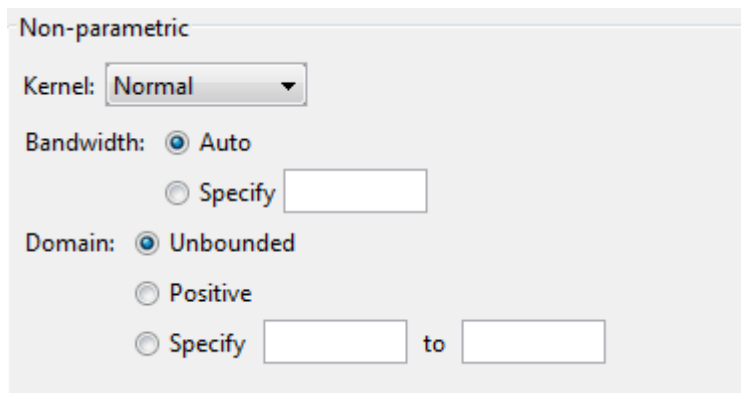

Not all of the distributions listed below are available for all data sets. The Distribution Fitting app determines the extent of the data (nonnegative, unit interval, etc.) and displays appropriate distributions in the **Distribution** drop-down list. Distribution data ranges are given parenthetically in the list below.

- Beta (unit interval values) distribution, fit using the function `betafit`.
- Binomial (nonnegative values) distribution, fit using the function `binopdf`.
- Birnbaum-Saunders (positive values) distribution.
- Burr Type XII (positive values) distribution.
- Exponential (nonnegative values) distribution, fit using the function `expfit`.
- Extreme value (all values) distribution, fit using the function `evfit`.
- Gamma (positive values) distribution, fit using the function `gamfit`.
- Generalized extreme value (all values) distribution, fit using the function `gevfit`.
- Generalized Pareto (all values) distribution, fit using the function `gpfit`.
- Inverse Gaussian (positive values) distribution.

- Logistic (all values) distribution.
- Loglogistic (positive values) distribution.
- Lognormal (positive values) distribution, fit using the function `lognfit`.
- Nakagami (positive values) distribution.
- Negative binomial (nonnegative values) distribution, fit using the function `nbinpdf`.
- Nonparametric (all values) distribution, fit using the function `ksdensity`.
- Normal (all values) distribution, fit using the function `normfit`.
- Poisson (nonnegative integer values) distribution, fit using the function `poisspdf`.
- Rayleigh (positive values) distribution using the function `raylfit`.
- Rician (positive values) distribution.
- *t* location-scale (all values) distribution.
- Weibull (positive values) distribution using the function `wblfit`.

### Further Options for Nonparametric Fits

When you select Non-parametric in the **Distribution** field, a set of options appears in the **Non-parametric** pane, as shown in the following figure.

The options for nonparametric distributions are:

- **Kernel** — Type of kernel function to use.
  - Normal
  - Box
  - Triangle
  - Epanechnikov
- **Bandwidth** — The bandwidth of the kernel smoothing window. Select **Auto** for a default value that is optimal for estimating normal densities. This value appears in the **Fit results** pane after you click **Apply**. Select **Specify** and enter a smaller value to reveal features such as multiple modes or a larger value to make the fit smoother.
- **Domain** — The allowed  $x$ -values for the density.
  - **Unbounded** — The density extends over the whole real line.
  - **Positive** — The density is restricted to positive values.
  - **Specify** — Enter lower and upper bounds for the domain of the density.

When you select **Positive** or **Specify**, the nonparametric fit has zero probability outside the specified domain.

## Displaying Results

This section explains the different ways to display results in the Distribution Fitting app window. This window displays plots of:

- The data sets for which you select **Plot** in the Data dialog box
- The fits for which you select **Plot** in the Fit Manager dialog box
- Confidence bounds for:
  - Data sets for which you select **Bounds** in the Data dialog box
  - Fits for which you select **Bounds** in the Fit Manager dialog box

The following fields are available.

## Display Type

The **Display Type** field in the main window specifies the type of plot displayed. Each type corresponds to a probability function, for example, a probability density function. The following display types are available:

- **Density (PDF)** — Display a probability density function (PDF) plot for the fitted distribution. The main window displays data sets using a probability histogram, in which the height of each rectangle is the fraction of data points that lie in the bin divided by the width of the bin. This makes the sum of the areas of the rectangles equal to 1.
- **Cumulative probability (CDF)** — Display a cumulative probability plot of the data. The main window displays data sets using a cumulative probability step function. The height of each step is the cumulative sum of the heights of the rectangles in the probability histogram.
- **Quantile (inverse CDF)** — Display a quantile (inverse CDF) plot.
- **Probability plot** — Display a probability plot of the data. You can specify the type of distribution used to construct the probability plot in the **Distribution** field, which is only available when you select **Probability plot**. The choices for the distribution are:
  - Exponential
  - Extreme value
  - Logistic
  - Log-Logistic
  - Lognormal
  - Normal
  - Rayleigh
  - Weibull

In addition to these choices, you can create a probability plot against a parametric fit that you create in the **New Fit** pane. These fits are added at the bottom of the **Distribution** drop-down list when you create them.

- **Survivor function** — Display survivor function plot of the data.
- **Cumulative hazard** — Display cumulative hazard plot of the data.

---

**Note** Some distributions are unavailable if the plotted data includes 0 or negative values.

---

## Confidence Bounds

You can display confidence bounds for data sets and fits when you set **Display Type** to **Cumulative probability (CDF)**, **Survivor function**, **Cumulative hazard**, or, for fits only, **Quantile (inverse CDF)**.

- To display bounds for a data set, select **Bounds** next to the data set in the **Data sets** pane of the Data dialog box.
- To display bounds for a fit, select **Bounds** next to the fit in the Fit Manager dialog box. Confidence bounds are not available for all fit types.

To set the confidence level for the bounds, select **Confidence Level** from the **View** menu in the main window and choose from the options.

## Managing Fits

This section describes how to manage fits that you have created. To begin, click the **Manage Fits** button in the Distribution Fitting app. This opens the Fit Manager dialog box as shown in the following figure.

The **Table of fits** displays a list of the fits you create, with the following options:

- **Plot** — Select **Plot** to display a plot of the fit in the main window of the Distribution Fitting app. When you create a new fit, **Plot** is selected by default. Clearing the **Plot** check box removes the fit from the plot in the main window.
- **Bounds** — If **Plot** is selected, you can also select **Bounds** to display confidence bounds in the plot. The bounds are displayed when you set **Display Type** in the main window to one of the following:
  - Cumulative probability (CDF)
  - Quantile (inverse CDF)
  - Survivor function

- **Cumulative hazard**

The Distribution Fitting app cannot display confidence bounds on density (PDF) or probability plots. In addition, bounds are not supported for nonparametric fits and some parametric fits.

Clearing the **Bounds** check box removes the confidence intervals from the plot in the main window.

When you select a fit in the **Table of fits**, the following buttons are enabled below the table:

- **New Fit** — Open a New Fit window.
- **Copy** — Create a copy of the selected fit.
- **Edit** — Open an Edit Fit dialog box, where you can edit the fit.

---

**Note** You can only edit the currently selected fit in the Edit Fit dialog box. To edit a different fit, select it in the **Table of fits** and click **Edit** to open another Edit Fit dialog box.

---

- **Save to workspace** — Save the selected fit as a distribution object.
- **Delete** — Delete the selected fit.

## Evaluating Fits

The Evaluate dialog box enables you to evaluate any fit at whatever points you choose. To open the dialog box, click the **Evaluate** button in the Distribution Fitting app. The following figure shows the Evaluate dialog box.

The Evaluate dialog box contains the following items:

- **Fit** pane — Display the names of existing fits. Select one or more fits that you want to evaluate. Using your platform specific functionality, you can select multiple fits.
- **Function** — Select the type of probability function you want to evaluate for the fit. The available functions are
  - Density (PDF) — Computes a probability density function.
  - Cumulative probability (CDF) — Computes a cumulative probability function.
  - Quantile (inverse CDF) — Computes a quantile (inverse CDF) function.

- Survivor function — Computes a survivor function.
- Cumulative hazard — Computes a cumulative hazard function.
- Hazard rate — Computes the hazard rate.
- **At  $\mathbf{x} =$**  — Enter a vector of points or the name of a workspace variable containing a vector of points at which you want to evaluate the distribution function. If you change **Function** to **Quantile (inverse CDF)**, the field name changes to **At  $\mathbf{p} =$**  and you enter a vector of probability values.
- **Compute confidence bounds** — Select this box to compute confidence bounds for the selected fits. The check box is only enabled if you set **Function** to one of the following:
  - Cumulative probability (CDF)
  - Quantile (inverse CDF)
  - Survivor function
  - Cumulative hazard

The Distribution Fitting app cannot compute confidence bounds for nonparametric fits and for some parametric fits. In these cases, it returns NaN for the bounds.

- **Level** — Set the level for the confidence bounds.
- **Plot function** — Select this box to display a plot of the distribution function, evaluated at the points you enter in the **At  $\mathbf{x} =$**  field, in a new window.

---

**Note** The settings for **Compute confidence bounds**, **Level**, and **Plot function** do not affect the plots that are displayed in the main window of the Distribution Fitting app. The settings only apply to plots you create by clicking **Plot function** in the Evaluate window.

---

Click **Apply** to apply these settings to the selected fit. The following figure shows the results of evaluating the cumulative density function for the fit `My fit`, at the points in the vector `-4:1:6`.

X	My fit		
	F(X)	LB	UB
-4	0.00268	0.00064	0.0094
-3	0.01498	0.00568	0.03518
-2	0.05984	0.03225	0.10321
-1	0.1732	0.11948	0.24022
0	0.37179	0.29863	0.44992
1	0.61309	0.53479	0.68703
2	0.81644	0.74822	0.87178
3	0.93529	0.89025	0.96446
4	0.98345	0.96201	0.99356
5	0.99698	0.98969	0.99925
6	0.99961	0.99782	0.99995

The window displays the following values in the columns of the table to the right of the **Fit** pane:

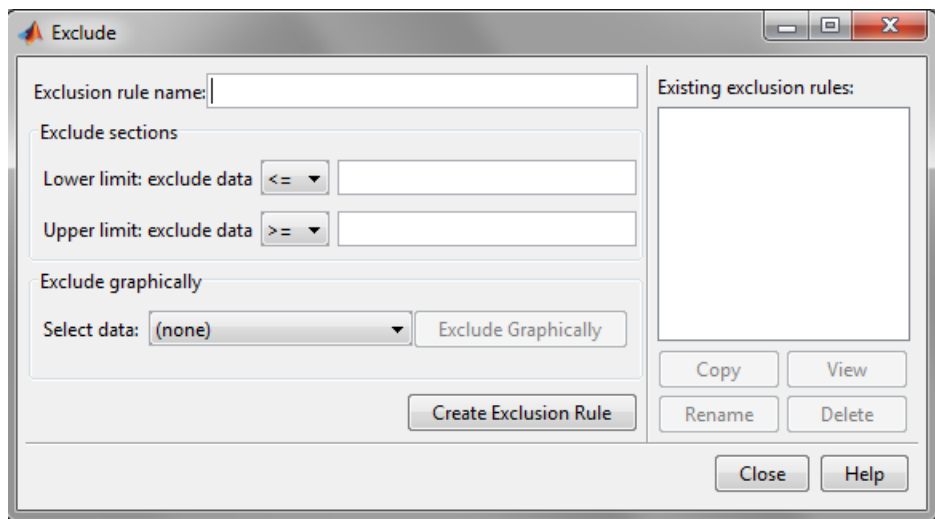

- X — The entries of the vector you enter in **At x =** field
- F(X)— The corresponding values of the CDF at the entries of X
- LB — The lower bounds for the confidence interval, if you select **Compute confidence bounds**

- UB — The upper bounds for the confidence interval, if you select **Compute confidence bounds**

To save the data displayed in the Evaluate window, click **Export to Workspace**. This saves the values in the table to a matrix in the MATLAB workspace.

## Excluding Data

To exclude values from fit, click the **Exclude** button in the main window of the Distribution Fitting app. This opens the Exclude window, in which you can create rules for excluding specified values. You can use these rules to exclude data when you create a new fit in the New Fit window. The following figure shows the Exclude window.

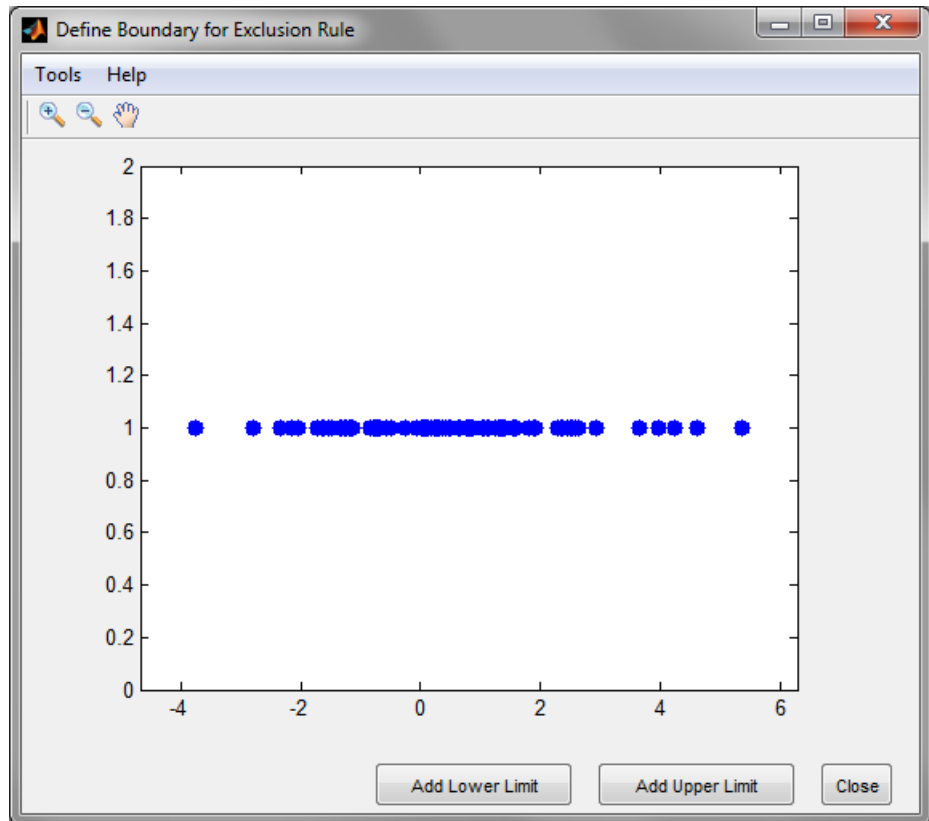

To create an exclusion rule:

- 1 Exclusion Rule Name**—Enter a name for the exclusion rule in the **Exclusion rule name** field.
- 2 Exclude Sections**—In the **Exclude sections** pane, you can specify bounds for the excluded data:

- In the **Lower limit: exclude Y** drop-down list, select  $\leq$  or  $<$  from the drop-down list and enter a scalar in the field to the right. This excludes values that are either less than or equal to or less than that scalar, respectively.
- In the **Upper limit: exclude Y** drop-down list, select  $\geq$  or  $>$  from the drop-down list and enter a scalar in the field to the right to exclude values that are either greater than or equal to or greater than the scalar, respectively.

**OR**

**Exclude Graphically**—The **Exclude Graphically** button enables you to define the exclusion rule by displaying a plot of the values in a data set and selecting the bounds for the excluded data with the mouse. For example, if you created the data set `My data`, described in *Creating and Managing Data Sets*, select it from the drop-down list next to **Exclude graphically** and then click the **Exclude graphically** button. This displays the values in `My data` in a new window as shown in the following figure.

To set a lower limit for the boundary of the excluded region, click **Add Lower Limit**. This displays a vertical line on the left side of the plot window. Move the line with the mouse to the point you where you want the lower limit, as shown in the following figure.

Moving the vertical line changes the value displayed in the **Lower limit: exclude data** field in the Exclude window, as shown in the following figure.

The value displayed corresponds to the  $x$ -coordinate of the vertical line.

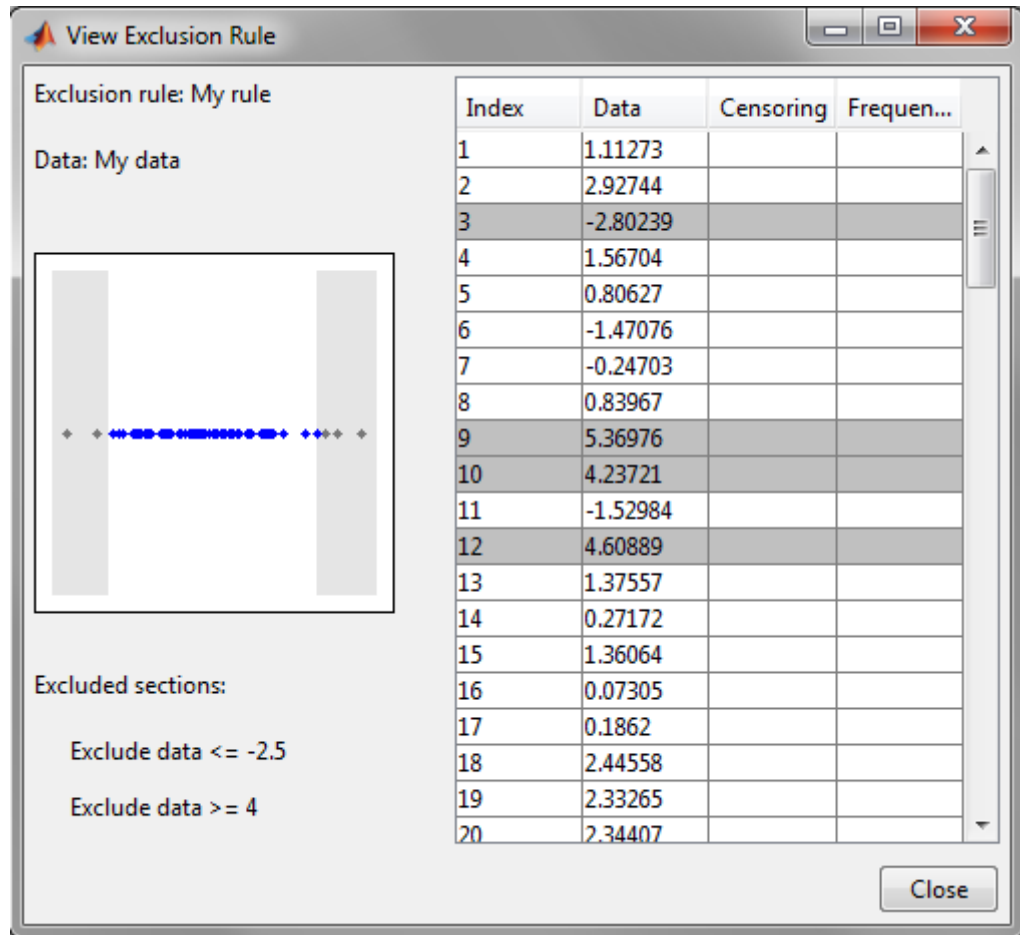

Similarly, you can set the upper limit for the boundary of the excluded region by clicking **Add Upper Limit** and moving the vertical line that

appears at the right side of the plot window. After setting the lower and upper limits, click **Close** and return to the Exclude window.

- 3 Create Exclusion Rule**—Once you have set the lower and upper limits for the boundary of the excluded data, click **Create Exclusion Rule** to create the new rule. The name of the new rule now appears in the **Existing exclusion rules** pane.

When you select an exclusion rule in the **Existing exclusion rules** pane, the following buttons are enabled:

- **Copy** — Creates a copy of the rule, which you can then modify. To save the modified rule under a different name, click **Create Exclusion Rule**.
- **View** — Opens a new window in which you can see which data points are excluded by the rule. The following figure shows a typical example.

The shaded areas in the plot graphically display which data points are excluded. The table to the right lists all data points. The shaded rows indicate excluded points:

- **Rename** — Renames the rule
- **Delete** — Deletes the rule

Once you define an exclusion rule, you can use it when you fit a distribution to your data. The rule does not exclude points from the display of the data set.

## Saving and Loading Sessions

This section explains how to save your work in the current Distribution Fitting app session and then load it in a subsequent session, so that you can continue working where you left off.

### Saving a Session

To save the current session, select **Save Session** from the **File** menu in the main window. This opens a dialog box that prompts you to enter a filename, such as `my_session.dfit`, for the session. Clicking **Save** saves the following items created in the current session:

- Data sets
- Fits
- Exclusion rules
- Plot settings
- Bin width rules

### Loading a Session

To load a previously saved session, select **Load Session** from the **File** menu in the main window and enter the name of a previously saved session. Clicking **Open** restores the information from the saved session to the current session of the Distribution Fitting app.

## Example: Fitting a Distribution

This section presents an example that illustrates how to use the Distribution Fitting app. The example involves the following steps:

- “Step 1: Generate Random Data” on page 5-68
- “Step 2: Import Data” on page 5-68
- “Step 3: Create a New Fit” on page 5-71

### Step 1: Generate Random Data

To try the example, first generate some random data to which you will fit a distribution. The following command generates a vector `data`, of length 100, whose entries are random numbers from a normal distribution with mean `.36` and standard deviation `1.4`.

```
rng('default')  
data = normrnd(.36, 1.4, 100, 1);
```

### Step 2: Import Data

Open the distribution fitting tool:

```
dfittool
```

To import the vector `data` into the Distribution Fitting app, click the **Data** button in main window. This opens the window shown in the following figure.

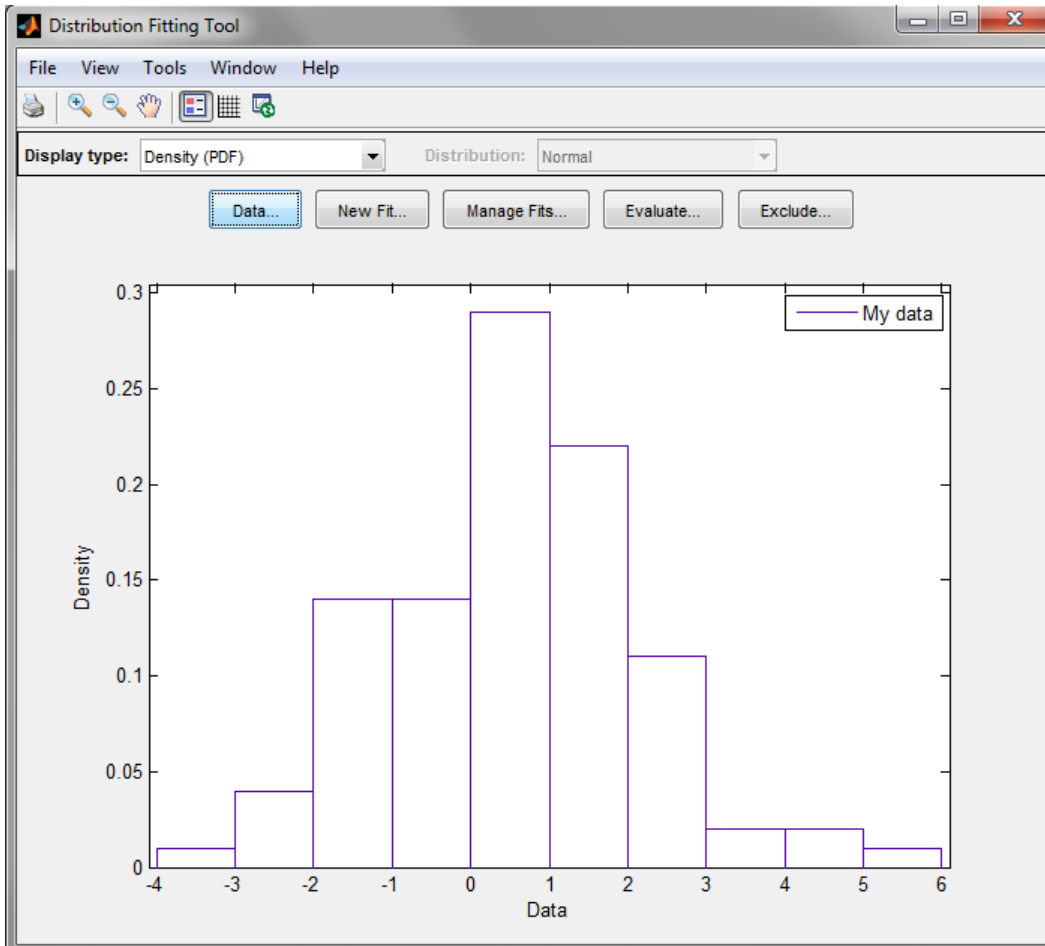

The **Data** field displays all numeric arrays in the MATLAB workspace. Select data from the drop-down list, as shown in the following figure.

This displays a histogram of the data in the **Data preview** pane.

In the **Data set name** field, type a name for the data set, such as **My data**, and click **Create Data Set** to create the data set. The main window of the Distribution Fitting app now displays a larger version of the histogram in the **Data preview** pane, as shown in the following figure.

---

**Note** Because the example uses random data, you might see a slightly different histogram if you try this example for yourself.

---

### **Step 3: Create a New Fit**

To fit a distribution to the data, click **New Fit** in the main window of the Distribution Fitting app. This opens the window shown in the following figure.

To fit a normal distribution, the default entry of the **Distribution** field, to My data:

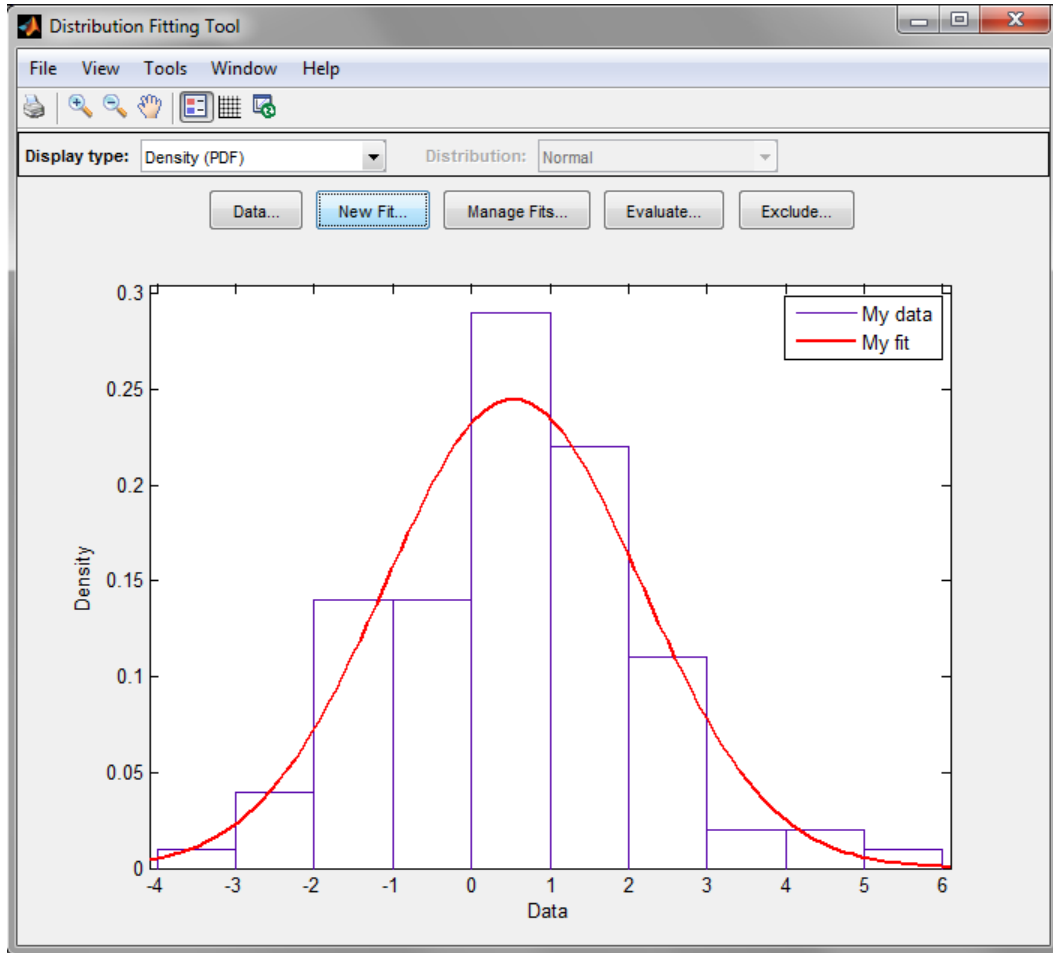

- 1 Enter a name for the fit, such as My fit, in the **Fit name** field.
- 2 Select My data from the drop-down list in the **Data** field.

**3** Click **Apply**.

The **Results** pane displays the mean and standard deviation of the normal distribution that best fits My data, as shown in the following figure.

The main window of the Distribution Fitting app displays a plot of the normal distribution with this mean and standard deviation, as shown in the following figure.

## Generating a File to Fit and Plot Distributions

The **Generate Code** option in the **File** menu enables you to create a file that

- Fits the distributions used in the current session to any data vector in the MATLAB workspace.
- Plots the data and the fits.

After you end the current session, you can use the file to create plots in a standard MATLAB figure window, without having to reopen the Distribution Fitting app.

As an example, assuming you created the fit described in “Creating a New Fit” on page 5-48, do the following steps:

- 1** Select **Generate Code** from the **File** menu.
- 2** Choose **File > Save as** in the MATLAB Editor window. Save the file as `normal_fit.m` in a folder on the MATLAB path.

You can then apply the function `normal_fit` to any vector of data in the MATLAB workspace. For example, the following commands

```
new_data = normrnd(4.1, 12.5, 100, 1);
newfit = normal_fit(new_data)
legend('New Data', 'My fit')
```

generate `newfit`, a fitted normal distribution of the data, and generates a plot of the data and the fit.

```
newfit =
normal distribution

    mu = 3.19148
    sigma = 12.5631
```

---

**Note** By default, the file labels the data in the legend using the same name as the data set in the Distribution Fitting app. You can change the label using the `legend` command, as illustrated by the preceding example.

---

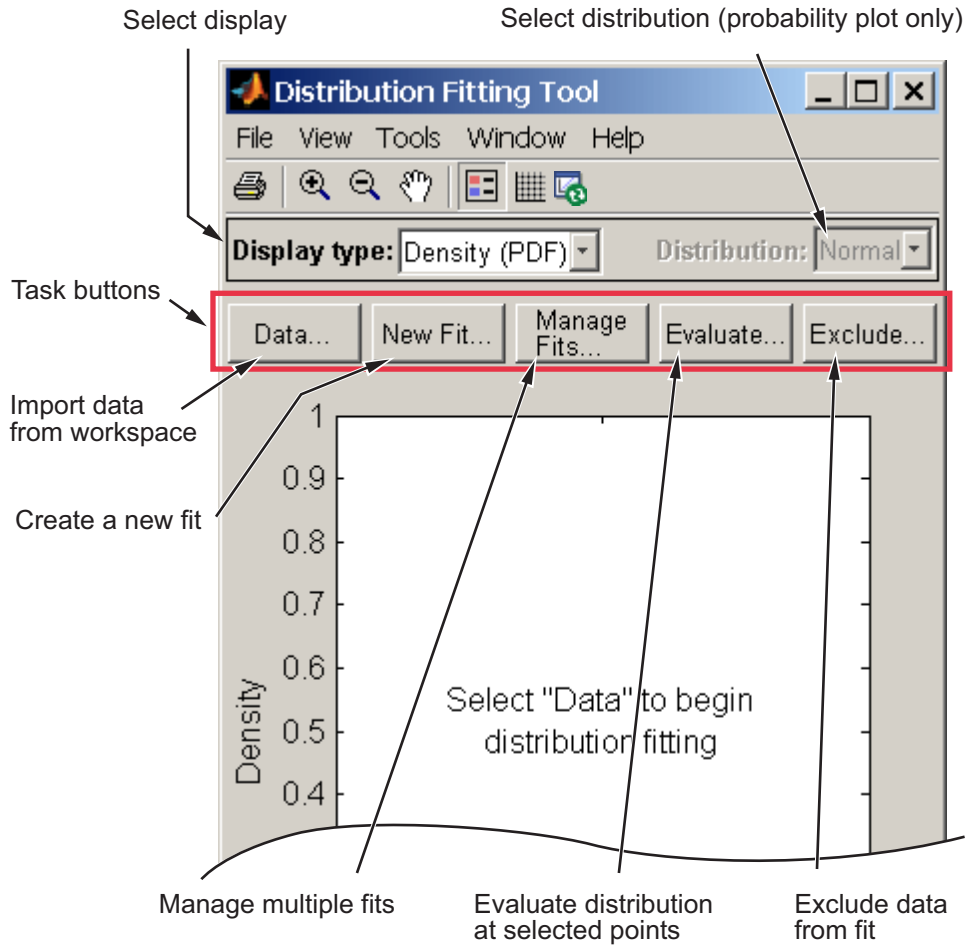

## Custom Distributions Using the Distribution Fitting App

You can use the Distribution Fitting app to fit distributions not supported by the Statistics Toolbox by defining a custom distribution.

### Opening the Distribution Fitting App

To open the Distribution Fitting app, enter the command

```
dfittool
```

Alternatively, click Distribution Fitting on the Apps tab.

## Defining Custom Distributions

To define a custom distribution, select **Define Custom Distribution** from the **File** menu. This opens a file template in the MATLAB editor. You then edit this file so that it computes the distribution you want.

The template includes example code that computes the Laplace distribution. Follow the instructions in the template to define your own custom distribution.

To save your custom distribution, create a directory called `+prob` on your path. Save the file in this directory using a name that matches your distribution name. If you save the template in a folder on the MATLAB path, under its default name `dfittooldists.m`, the Distribution Fitting app reads it in automatically when you start the tool. You can also save the template under a different name, such as `laplace.m`, and then import the custom distribution as described in the following section.

## Importing Custom Distributions

To import a custom distribution, select **Import Custom Distributions** from the **File** menu. This opens a dialog box in which you can select the file that defines the distribution. For example, if you created the file `laplace.m`, as described in the preceding section, you can enter `laplace.m` and select **Open** in the dialog box. The **Distribution** field of the New Fit window now contains the option **Laplace**.

### Explore the Random Number Generation UI

The Random Number Generation user interface (UI) generates random samples from specified probability distributions, and displays the samples as histograms. Use the interface to explore the effects of changing parameters and sample size on the distributions.

Run the user interface by typing `randtool` at the command line.

Start by selecting a distribution, then enter the desired sample size.

You can also

- Use the controls at the bottom of the window to set parameter values for the distribution and to change their upper and lower bounds.
- Draw another sample from the same distribution, with the same size and parameters.
- Export the current sample to your workspace. A dialog box enables you to provide a name for the sample.

## Compare Multiple Distribution Fits

This example shows how to fit multiple probability distribution objects to the same set of sample data, and obtain a visual comparison of how well each distribution fits the data.

### Step 1. Load sample data.

Load the sample data.

```
load carsmall;
```

This data contains miles per gallon (MPG) measurements for different makes and models of cars, grouped by country of origin (`Origin`), model year (`Model_Year`), and other vehicle characteristics.

### Step 2. Create a nominal array.

Transform `Origin` into a nominal array and remove the Italian car from the sample data.

```
Origin = nominal(Origin);
MPG2 = MPG(Origin~='Italy');
Origin2 = Origin(Origin~='Italy');
Origin2 = droplevels(Origin2, 'Italy');
```

Since there is only one Italian car, `fitdist` cannot fit a distribution to that group. Removing the Italian car from the sample data prevents `fitdist` from producing an error.

### Step 3. Fit multiple distributions by group.

Use `fitdist` to fit Weibull, normal, logistic, and kernel distributions to each country of origin group in the MPG data.

```
[WeiByOrig,Country] = fitdist(MPG2, 'weibull', 'by', Origin2);
[NormByOrig,Country] = fitdist(MPG2, 'normal', 'by', Origin2);
[LogByOrig,Country] = fitdist(MPG2, 'logistic', 'by', Origin2);
[KerByOrig,Country] = fitdist(MPG2, 'kernel', 'by', Origin2);
```

```
WeiByOrig
```

Country

WeiByOrig =

Column 1

[1x1 prob.WeibullDistribution]

Column 2

[1x1 prob.WeibullDistribution]

Column 3

[1x1 prob.WeibullDistribution]

Column 4

[1x1 prob.WeibullDistribution]

Column 5

[1x1 prob.WeibullDistribution]

Country =

'France'

'Germany'

'Japan'

'Sweden'

'USA'

Each country group now has four distribution objects associated with it. For example, the cell array `WeiByOrig` contains five Weibull distribution objects, one for each country represented in the sample data. Likewise, the cell array `NormByOrig` contains five normal distribution objects, and so on. Each object contains properties that hold information about the data, distribution, and parameters. The array `Country` lists the country of origin for each group in the same order as the distribution objects are stored in the cell arrays.

**Step 4. Compute the pdf for each distribution.**

Extract the four probability distribution objects for USA and compute the pdf for each distribution. As shown in Step 3, USA is in position 5 in each cell array.

```
WeiUSA = WeiByOrig{5};
NormUSA = NormByOrig{5};
LogUSA = LogByOrig{5};
KerUSA = KerByOrig{5};

x = 0:1:50;
pdf_Wei = pdf(WeiUSA,x);
pdf_Norm = pdf(NormUSA,x);
pdf_Log = pdf(LogUSA,x);
pdf_Ker = pdf(KerUSA,x);
```

**Step 5. Plot pdf the for each distribution.**

Plot the pdf for each distribution fit to the USA data, superimposed on a histogram of the sample data. Scale the density by the histogram area for easier display.

```
% Create a histogram of the USA sample data
data = MPG(Origin2=='USA');
figure;
[n,y] = hist(data,10);
b = bar(y,n,'hist');
set(b,'FaceColor',[1,0.8,0]);

% Scale the density by the histogram area for easier display
area = sum(n)*(y(2)-y(1));
time = 0:50;
pdfWei = pdf(WeiUSA,time);
pdfNorm = pdf(NormUSA,time);
pdfLog = pdf(LogUSA,time);
pdfKer = pdf(KerUSA,time);

% Plot the pdf of each fitted distribution
line(x,pdfWei*area,'LineStyle','-','Color','r');
hold on;
```

```

line(x,pdfNorm*area,'LineStyle','-.-','Color','b');
line(x,pdfLog*area,'LineStyle','--','Color','g');
line(x,pdfKer*area,'LineStyle',':','Color','k');
l = legend('Data','Weibull','Normal','Logistic','Kernel');
set(l,'Location','Best');
title('MPG for Cars from USA');
xlabel('MPG');
hold off;

```

Superimposing the pdf plots over a histogram of the sample data provides a visual comparison of how well each type of distribution fits the data. Only the nonparametric kernel distribution `KerUSA` comes close to revealing the two modes in the original data.

**Step 6. Further group USA data by year.**

To investigate the two modes revealed in Step 5, group the MPG data by both country of origin (`Origin`) and model year (`Model_Year`), and use `fitdist` to fit kernel distributions to each group.

```
[KerByYearOrig,Names] = fitdist(MPG,'Kernel','By',{Origin Model_Year});
```

Each unique combination of origin and model year now has a kernel distribution object associated with it.

**Step 7. Compute the pdf for each group.**

Extract the three probability distributions for each USA model year, which are in positions 12, 13, and 14 in the cell array `KerByYearOrig`. Compute each pdf.

```
USA70 = KerByYearOrig{12};
USA76 = KerByYearOrig{13};
USA82 = KerByYearOrig{14};
```

```
pdf70 = pdf(USA70,x);
pdf76 = pdf(USA76,x);
pdf82 = pdf(USA82,x);
```

**Step 8. Plot pdf for each group.**

Plot the pdf for each group on the same figure.

```
figure;
plot(x,pdf70,'r-');
hold on;
plot(x,pdf76,'b-.');
plot(x,pdf82,'k:');
legend({'1970','1976','1982'],'Location','NW');
title('MPG in USA Cars by Model Year');
xlabel('MPG');
hold off;
```

When further grouped by model year, the pdf plots reveal two distinct peaks in the MPG data for cars made in the USA — one for the model year 1970, and one for the model year 1982. This explains why the smooth curve produced by the kernel distribution for the combined USA miles per gallon data shows two peaks instead of one.

### Concepts

- “Grouping Variables” on page 2-51

## Fit Probability Distribution Objects to Grouped Data

This example shows how to fit probability distribution objects to grouped sample data, and create a plot to visually compare the pdf of each group.

### Step 1. Load sample data.

Load the sample data.

```
load carsmall;
```

The data contains miles per gallon (MPG) measurements for different makes and models of cars, grouped by country of origin (`Origin`), model year (`Model_Year`), and other vehicle characteristics.

### Step 2. Create a nominal array.

Transform `Origin` into a nominal array and remove the Italian car from the sample data. Since there is only one Italian car, `fitdist` cannot fit a distribution to that group. Removing the Italian car from the sample data prevents `fitdist` from returning an error.

```
Origin = nominal(Origin);
MPG2 = MPG(Origin~='Italy');
Origin2 = Origin(Origin~='Italy');
Origin2 = droplevels(Origin2,'Italy');
```

### Step 3. Fit kernel distributions to each group.

Use `fitdist` to fit kernel distributions to each country of origin group in the MPG data.

```
[KerByOrig,Country] = fitdist(MPG2,'Kernel','by',Origin2)
```

```
KerByOrig =
```

```
Column 1
```

```
[1x1 prob.KernelDistribution]
```

```
Column 2
```

```
[1x1 prob.KernelDistribution]

Column 3

[1x1 prob.KernelDistribution]

Column 4

[1x1 prob.KernelDistribution]

Column 5

[1x1 prob.KernelDistribution]

Country =

    'France'
    'Germany'
    'Japan'
    'Sweden'
    'USA'
```

The cell array `KerByOrig` contains five kernel distribution objects, one for each country represented in the sample data. Each object contains properties that hold information about the data, the distribution, and the parameters. The array `Country` lists the country of origin for each group in the same order as the distribution objects are stored in `KerByOrig`.

#### **Step 4. Compute the pdf for each group.**

Extract the probability distribution objects for Germany, Japan, and USA. Use the positions of each country in `KerByOrig` shown in Step 3, which indicates that Germany is the second country, Japan is the third country, and USA is the fifth country. Compute the pdf for each group.

```
Germany = KerByOrig{2};
Japan = KerByOrig{3};
USA = KerByOrig{5};
```

```
x = 0:1:50;

USA_pdf = pdf(USA,x);
Japan_pdf = pdf(Japan,x);
Germany_pdf = pdf(Germany,x);
```

**Step 5. Plot the pdf for each group.**

Plot the pdf for each group on the same figure.

```
figure;
plot(x,USA_pdf,'r-');
hold on;
plot(x,Japan_pdf,'b-.');
plot(x,Germany_pdf,'k:');
legend({'USA','Japan','Germany'},'Location','NW');
title('MPG by Country of Origin');
xlabel('MPG');
```

The resulting plot shows how miles per gallon (MPG) performance differs by country of origin (Origin). Using this data, the USA has the widest distribution, and its peak is at the lowest MPG value of the three origins. Japan has the most regular distribution with a slightly heavier left tail, and its peak is at the highest MPG value of the three origins. The peak for Germany is between the USA and Japan, and the second bump near 44 miles per gallon suggests that there might be multiple modes in the data.

## Multinomial Probability Distribution Objects

This example shows how to generate random numbers, compute and plot the pdf, and compute descriptive statistics of a multinomial distribution using probability distribution objects.

### Step 1. Define the distribution parameters.

Create a vector `p` containing the probability of each outcome. Outcome 1 has a probability of 1/2, outcome 2 has a probability of 1/3, and outcome 3 has a probability of 1/6. The number of trials `n` in each experiment is 5, and the number of repetitions `reps` of the experiment is 8.

```
p = [1/2 1/3 1/6];  
n = 5;  
reps = 8;
```

### Step 2. Create a multinomial probability distribution object.

Create a multinomial probability distribution object using the specified value `p` for the `Probabilities` parameter.

```
pd = makedist('Multinomial','Probabilities',p)
```

```
pd =  
  
    MultinomialDistribution  
  
    Probabilities:  
    0.5000    0.3333    0.1667
```

### Step 3. Generate one random number.

Generate one random number from the multinomial distribution, which is the outcome of a single trial.

```
rng('default') % For reproducibility  
r = random(pd)  
  
r =
```

2

This trial resulted in outcome 2.

**Step 4. Generate a matrix of random numbers.**

You can also generate a matrix of random numbers from the multinomial distribution, which reports the results of multiple experiments that each contain multiple trials. Generate a matrix that contains the outcomes of an experiment with  $n = 5$  trials and  $\text{reps} = 8$  repetitions.

```
r = random(pd, reps, n)
```

```
r =
```

```

3     3     3     2     1
1     1     2     2     1
3     3     3     1     2
2     3     2     2     2
1     1     1     1     1
1     2     3     2     3
2     1     3     1     1
3     1     2     1     1

```

Each element in the resulting matrix is the outcome of one trial. The columns correspond to the five trials in each experiment, and the rows correspond to the eight experiments. For example, in the first experiment (corresponding to the first row), one of the five trials resulted in outcome 1, one of the five trials resulted in outcome 2, and three of the five trials resulted in outcome 3.

**Step 5. Compute and plot the pdf.**

Compute the pdf of the distribution.

```

x = 1:3;
y = pdf(pd, x);
bar(x, y);
xlabel('Outcome');
ylabel('Probability Mass');
title('Trinomial Distribution');

```

The plot shows the probability mass for each  $k$  possible outcome. For this distribution, the pdf value for any  $x$  other than 1, 2, or 3 is 0.

**Step 6. Compute descriptive statistics.**

Compute the mean, median, and standard deviation of the distribution.

```
m = mean(pd)
med = median(pd)
s = std(pd)
```

```
m =
```

1.6667

med =

1

s =

0.7454

## Multinomial Probability Distribution Functions

This example shows how to generate random numbers and compute and plot the pdf of a multinomial distribution using probability distribution functions.

### Step 1. Define the distribution parameters.

Create a vector  $p$  containing the probability of each outcome. Outcome 1 has a probability of  $1/2$ , outcome 2 has a probability of  $1/3$ , and outcome 3 has a probability of  $1/6$ . The number of trials in each experiment  $n$  is 5, and the number of repetitions of the experiment  $reps$  is 8.

```
p = [1/2 1/3 1/6];  
n = 5;  
reps = 8;
```

### Step 2. Generate one random number.

Generate one random number from the multinomial distribution, which is the outcome of a single trial.

```
rng('default') % For reproducibility  
r = mnrnd(1,p,1)
```

```
r =  
  
    0     1     0
```

The returned vector  $r$  contains three elements, which show the counts for each possible outcome. This single trial resulted in outcome 2.

### Step 3. Generate a matrix of random numbers.

You can also generate a matrix of random numbers from the multinomial distribution, which reports the results of multiple experiments that each contain multiple trials. Generate a matrix that contains the outcomes of an experiment with  $n = 5$  trials and  $reps = 8$  repetitions.

```
r = mnrnd(n,p,reps)  
  
r =
```

1	1	3
3	2	0
1	1	3
0	4	1
5	0	0
1	2	2
3	1	1
3	1	1

Each row in the resulting matrix contains counts for each of the  $k$  multinomial bins. For example, in the first experiment (corresponding to the first row), one of the five trials resulted in outcome 1, one of the five trials resulted in outcome 2, and three of the five trials resulted in outcome 3.

#### Step 4. Compute the pdf.

Since multinomial functions work with bin counts, create a multidimensional array of all possible outcome combinations, and compute the pdf using `mnpdf`.

```
count1 = 1:n;
count2 = 1:n;
[x1,x2] = meshgrid(count1,count2);
x3 = n-(x1+x2);
y = mnpdf([x1(:),x2(:),x3(:)], repmat(p, (n)^2, 1));
```

#### Step 5. Plot the pdf.

Create a 3-D bar graph to visualize the pdf for each combination of outcome frequencies.

```
figure;
y = reshape(y,n,n);
bar3(y);
set(gca, 'XTickLabel', 1:n);
set(gca, 'YTickLabel', 1:n);
xlabel('x_1 Frequency');
ylabel('x_2 Frequency');
zlabel('Probability Mass');
```

The plot shows the probability mass for each possible combination of outcomes. It does not show  $x_3$ , which is determined by the constraint  $x_1 + x_2 + x_3 = n$ .

## Generate Random Numbers Using Uniform Distribution Inversion

This example shows how to generate random numbers using the uniform distribution inversion method. This is useful for distributions when it is possible to compute the inverse cumulative distribution function, but there is no support for sampling from the distribution directly.

### Step 1. Generate random numbers from the standard uniform distribution.

Use `rand` to generate 1000 random numbers from the uniform distribution on the interval (0,1).

```
rng('default') % For reproducibility
u = rand(1000,1);
```

The inversion method relies on the principle that continuous cumulative distribution functions (cdfs) range uniformly over the open interval (0,1). If  $u$  is a uniform random number on (0,1), then  $x = F^{-1}(u)$  generates a random number  $x$  from any continuous distribution with the specified cdf  $F$ .

### Step 2. Generate random numbers from the Weibull distribution.

Use the inverse cumulative distribution function to generate the random numbers from a Weibull distribution with parameters  $A = 1$  and  $B = 1$  that correspond to the probabilities in  $u$ . Plot the results.

```
figure;
x = wblinv(u,1,1);
hist(x,20);
```

The histogram shows that the random numbers generated using the Weibull inverse cdf function `wblinv` have a Weibull distribution.

**Step 3. Generate random numbers from the standard normal distribution.**

The same values in `u` can generate random numbers from any distribution, for example the standard normal, by following the same procedure using the inverse cdf of the desired distribution.

```
figure;
x_norm = norminv(u,1,0);
hist = (x_norm,20);
```

The histogram shows that, by using the standard normal inverse cdf `norminv`, the random numbers generated from `u` now have a standard normal distribution.

## Use $t$ Location-Scale to Represent Cauchy Distribution

This example shows how to use the  $t$  location-scale probability distribution object to work with a Cauchy distribution with nonstandard parameter values.

### Step 1. Create a probability distribution object.

Create a  $t$  location-scale probability distribution object with degrees of freedom `nu = 1`. Specify `mu = 3` to set the location parameter equal to 3, and `sigma = 1` to set the scale parameter equal to 1.

```
pd = makedist('tLocationScale','mu',3,'sigma',1,'nu',1)
```

```
pd =
```

```
tLocationScaleDistribution  
  
t Location-Scale distribution  
    mu = 3  
    sigma = 1  
    nu = 1
```

### Step 2. Compute descriptive statistics.

Use object functions to compute descriptive statistics for the Cauchy distribution.

```
med = median(pd)  
r = iqr(pd)  
m = mean(pd)  
s = std(pd)
```

```
med =
```

```
3
```

```
r =
```

```
2
```

```
m =
```

```
NaN
```

```
s =
```

```
Inf
```

The median of the Cauchy distribution is equal to its location parameter, and the interquartile range is equal to two times its scale parameter. Its mean and standard deviation are undefined.

**Step 3. Compute and plot the pdf.**

Compute and plot the pdf of the Cauchy distribution.

```
figure;  
x = -20:1:20;  
y = pdf(pd,x);  
plot(x,y,'LineWidth',2);
```

The peak of the pdf is centered at the location parameter  $\mu = 3$ .

**Step 4. Generate a vector of Cauchy random numbers.**

Generate a column vector containing 10 random numbers from the Cauchy distribution using the random function for the  $t$  location-scale probability distribution object.

```
rng('default'); % For reproducibility  
r = random(pd,10,1)
```

```
r =
```

3.2678  
 4.6547  
 2.0604  
 4.7322  
 3.1810  
 1.6649  
 1.8471  
 4.2466  
 5.4647  
 8.8874

**Step 5. Generate a matrix of Cauchy random numbers.**

Generate a 5-by-5 matrix of Cauchy random numbers.

```
r = random(pd,5,5)
```

```
r =
```

```
2.2867    2.9692   -1.7003    5.5949    1.9806
2.7421    2.7180    3.2210    2.4233    3.1394
3.5966    3.9806    1.0182    6.4180    5.1367
5.4791   15.6472    0.7558    2.8908    5.9031
1.6863    4.0985    2.9934   13.9506    4.8792
```

## Use Student's $t$ to Generate Standard Cauchy Random Numbers

This example shows how to use the Student's  $t$  distribution to generate random numbers from a standard Cauchy distribution.

### Step 1. Generate a vector of random numbers.

Generate a column vector containing 10 random numbers from a standard Cauchy distribution, which has a location parameter  $\mu = 0$  and scale parameter  $\sigma = 1$ . Use `trnd` with degrees of freedom  $V = 1$ .

```
rng('default'); % For reproducibility
r = trnd(1,10,1)
```

```
r =
    0.2678
    1.6547
   -0.9396
    1.7322
    0.1810
   -1.3351
   -1.1529
    1.2466
    2.4647
    5.8874
```

### Step 2. Generate a matrix of random numbers.

Generate a 5-by-5 matrix of random numbers from a standard Cauchy distribution.

```
r = trnd(1,5,5)
```

```
r =
   -0.7133   -0.0308   -4.7003    2.5949   -1.0194
   -0.2579   -0.2820    0.2210   -0.5767    0.1394
    0.5966    0.9806   -1.9818    3.4180    2.1367
```

2.4791	12.6472	-2.2442	-0.1092	2.9031
-1.3137	1.0985	-0.0066	10.9506	1.8792

## Probability Distributions Used for Multivariate Modeling

### In this section...

“Gaussian Mixture Models” on page 5-110

“Copulas: Generate Correlated Samples” on page 5-120

### Gaussian Mixture Models

- “Creating Gaussian Mixture Models” on page 5-110
- “Simulating Gaussian Mixtures” on page 5-118

Gaussian mixture models are formed by combining multivariate normal density components. In Statistics Toolbox software, use the `gmdistribution` class to fit data using an expectation maximization (EM) algorithm, which assigns posterior probabilities to each component density with respect to each observation. The fitting method uses an iterative algorithm that converges to a local optimum. Clustering using Gaussian mixture models is sometimes considered a soft clustering method. The posterior probabilities for each point indicate that each data point has some probability of belonging to each cluster.

For more information on clustering with Gaussian mixture models, see “Gaussian Mixture Models” on page 14-30. This section describes their creation.

### Creating Gaussian Mixture Models

- “Specifying a Model” on page 5-110
- “Fitting a Model to Data” on page 5-114

**Specifying a Model.** Use the `gmdistribution` constructor to create Gaussian mixture models with specified means, covariances, and mixture proportions.

First, define the means, covariances, and mixture proportions.

```
MU = [1 2; -3 -5]; % Means
```

```
SIGMA = cat(3,[2 0;0 .5],[1 0;0 1]); % Covariances
p = ones(1,2)/2; % Mixing proportions
```

Then, create an object of the `gmdistribution` class defining a two-component mixture of bivariate Gaussian distributions:

```
obj = gmdistribution(MU,SIGMA,p);
```

Display properties of the object with the MATLAB function `fieldnames`:

```
properties = fieldnames(obj)
```

```
properties =
    'NDimensions'
    'DistName'
    'NComponents'
    'PComponents'
    'mu'
    'Sigma'
    'NlogL'
    'AIC'
    'BIC'
    'Converged'
    'Iters'
    'SharedCov'
    'CovType'
    'RegV'
```

The `gmdistribution` reference page describes these properties. To access the value of a property, use dot indexing. For example, access the dimensions of the object.

```
dimension = obj.NDimensions
```

```
dimension =
```

2

Access the distribution name.

```
name = obj.DistName
```

```
name =
```

```
gaussian mixture distribution
```

Use the methods `pdf` and `cdf` to compute values and visualize the object:

```
figure
```

```
ezsurf(@(x,y)pdf(obj,[x y]),[-10 10],[-10 10])
```

```
figure  
ezsurf(@ (x,y) cdf(obj,[x y]), [-10 10], [-10 10])
```

**Fitting a Model to Data.** You can also create Gaussian mixture models by fitting a parametric model with a specified number of components to data. The `fit` method of the `gmdistribution` class uses the syntax `obj = gmdistribution.fit(X,k)`, where `X` is a data matrix and `k` is the specified number of components. Choosing a suitable number of components `k` is essential for creating a useful model of the data—too few components fails to model the data accurately; too many components leads to an over-fit model with singular covariance matrices.

The following example illustrates this approach.

First, create some data from a mixture of two bivariate Gaussian distributions using the `mvnrnd` function:

```
MU1 = [1 2];  
SIGMA1 = [2 0; 0 .5];  
MU2 = [-3 -5];  
SIGMA2 = [1 0; 0 1];  
X = [mvnrnd(MU1,SIGMA1,1000);  
mvnrnd(MU2,SIGMA2,1000)];  
figure  
scatter(X(:,1),X(:,2),10, '.')
```

Next, fit a two-component Gaussian mixture model:

```
options = statset('Display','final');  
obj = gmdistribution.fit(X,2,'Options',options);  
hold on  
h = ezcontour(@(x,y)pdf(obj,[x y]),[-8 6],[-8 6]);  
hold off
```

18 iterations, log-likelihood = -7058.35

Among the properties of the fit are the parameter estimates.

Display the estimates for mu, sigma, and mixture proportions

```
ComponentMeans = obj.mu  
ComponentCovariances = obj.Sigma  
MixtureProportions = obj.PComponents
```

```
ComponentMeans =
```

```
    -2.9617    -4.9727  
     0.9539     2.0261
```

```
ComponentCovariances(:, :, 1) =
```

```
    1.0100    0.0059  
    0.0059    0.9897
```

```
ComponentCovariances(:, :, 2) =
```

```
    1.9939   -0.0092  
   -0.0092    0.4981
```

```
MixtureProportions =
```

```
    0.5000    0.5000
```

The two-component model minimizes the Akaike information:

```
AIC = zeros(1,4);  
obj = cell(1,4);  
for k = 1:4  
    obj{k} = gmdistribution.fit(X,k);  
    AIC(k) = obj{k}.AIC;  
end  
  
[minAIC,numComponents] = min(AIC);
```

```
numComponents
```

```
numComponents =
```

```
2
```

Display the model.

```
model = obj{2}
```

```
model =
```

```
Gaussian mixture distribution with 2 components in 2 dimensions
```

```
Component 1:
```

```
Mixing proportion: 0.500000
```

```
Mean: -2.9617 -4.9727
```

```
Component 2:
```

```
Mixing proportion: 0.500000
```

```
Mean: 0.9539 2.0261
```

Both the Akaike and Bayes information are negative log-likelihoods for the data with penalty terms for the number of estimated parameters. You can use them to determine an appropriate number of components for a model when the number of components is unspecified.

### **Simulating Gaussian Mixtures**

Use the method `random` of the `gmdistribution` class to generate random data from a Gaussian mixture model created with `gmdistribution` or `fit`.

For example, the following specifies a `gmdistribution` object consisting of a two-component mixture of bivariate Gaussian distributions:

```
MU = [1 2; -3 -5];  
SIGMA = cat(3,[2 0;0 .5],[1 0;0 1]);  
p = ones(1,2)/2;  
obj = gmdistribution(MU,SIGMA,p);  
  
figure  
ezcontour(@(x,y)pdf(obj,[x y]),[-10 10],[-10 10])  
hold on
```

Use random (gmdistribution) to generate 1000 random values:

```
Y = random(obj,1000);  
scatter(Y(:,1),Y(:,2),10,'.')
```

## Copulas: Generate Correlated Samples

- “Archimedean Copulas” on page 5-145
- “Simulating Dependent Multivariate Data Using Copulas” on page 5-147
- “Fitting Copulas to Data” on page 5-153

*Copulas* are functions that describe dependencies among variables, and provide a way to create distributions that model correlated multivariate data. Using a copula, you can construct a multivariate distribution by specifying marginal univariate distributions, and then choose a copula to provide a correlation structure between variables. Bivariate distributions, as well as distributions in higher dimensions, are possible.

### **Determining Dependence Between Simulation Inputs**

One of the design decisions for a Monte Carlo simulation is a choice of probability distributions for the random inputs. Selecting a distribution for each individual variable is often straightforward, but deciding what dependencies should exist between the inputs may not be. Ideally, input data to a simulation should reflect what you know about dependence among the real quantities you are modeling. However, there may be little or no information on which to base any dependence in the simulation. In such cases, it is useful to experiment with different possibilities in order to determine the model’s sensitivity.

It can be difficult to generate random inputs with dependence when they have distributions that are not from a standard multivariate distribution. Further, some of the standard multivariate distributions can model only limited types of dependence. It is always possible to make the inputs independent, and while that is a simple choice, it is not always sensible and can lead to the wrong conclusions.

For example, a Monte-Carlo simulation of financial risk could have two random inputs that represent different sources of insurance losses. You could model these inputs as lognormal random variables. A reasonable question to ask is how dependence between these two inputs affects the results of the simulation. Indeed, you might know from real data that the same random

conditions affect both sources; ignoring that in the simulation could lead to the wrong conclusions.

**Example: Generate and Exponentiate Normal Random Variables.**

The `lognrnd` function simulates independent lognormal random variables. In the following example, the `mvnrnd` function generates  $n$  pairs of independent normal random variables, and then exponentiates them. Notice that the covariance matrix used here is diagonal:

```
n = 1000;

sigma = .5;
SigmaInd = sigma.^2 .* [1 0; 0 1]
SigmaInd =
    0.25    0
    0    0.25
ZInd = mvnrnd([0 0],SigmaInd,n);
XInd = exp(ZInd);

plot(XInd(:,1),XInd(:,2),'.')
axis([0 5 0 5])
axis equal
xlabel('X1')
ylabel('X2')
```

Dependent bivariate lognormal random variables are also easy to generate using a covariance matrix with nonzero off-diagonal terms:

```
rho = .7;

SigmaDep = sigma.^2 .* [1 rho; rho 1]
SigmaDep =
    0.25    0.175
    0.175    0.25

ZDep = mvnrnd([0 0],SigmaDep,n);
XDep = exp(ZDep);
```

A second scatter plot demonstrates the difference between these two bivariate distributions:

```
plot(XDep(:,1),XDep(:,2),'.')
axis([0 5 0 5])
axis equal
xlabel('X1')
ylabel('X2')
```

It is clear that there is a tendency in the second data set for large values of  $X_1$  to be associated with large values of  $X_2$ , and similarly for small values. The correlation parameter,  $\rho$ , of the underlying bivariate normal determines this dependence. The conclusions drawn from the simulation could well depend on whether you generate  $X_1$  and  $X_2$  with dependence. The bivariate lognormal distribution is a simple solution in this case; it easily generalizes to higher dimensions in cases where the marginal distributions are different lognormals.

Other multivariate distributions also exist. For example, the multivariate  $t$  and the Dirichlet distributions simulate dependent  $t$  and beta random variables, respectively. But the list of simple multivariate distributions is not long, and they only apply in cases where the marginals are all in the same family (or even the exact same distributions). This can be a serious limitation in many situations.

### Constructing Dependent Bivariate Distributions

Although the construction discussed in the previous section creates a bivariate lognormal that is simple, it serves to illustrate a method that is more generally applicable.

- 1 Generate pairs of values from a bivariate normal distribution. There is statistical dependence between these two variables, and each has a normal marginal distribution.
- 2 Apply a transformation (the exponential function) separately to each variable, changing the marginal distributions into lognormals. The transformed variables still have a statistical dependence.

If a suitable transformation can be found, this method can be generalized to create dependent bivariate random vectors with other marginal distributions. In fact, a general method of constructing such a transformation does exist, although it is not as simple as exponentiation alone.

By definition, applying the normal cumulative distribution function (cdf), denoted here by  $\Phi$ , to a standard normal random variable results in a random variable that is uniform on the interval  $[0,1]$ . To see this, if  $Z$  has a standard normal distribution, then the cdf of  $U = \Phi(Z)$  is

$$\Pr\{U \leq u\} = \Pr\{\Phi(Z) \leq u\} = \Pr\{Z \leq \Phi^{-1}(u)\} = u$$

and that is the cdf of a  $\text{Unif}(0,1)$  random variable. Histograms of some simulated normal and transformed values demonstrate that fact:

```
n = 1000;
rng('default') % for reproducibility
z = normrnd(0,1,n,1); % generate standard normal data
```

```
hist(z,-3.75:.5:3.75) % plot the histogram of data
xlim([-4 4])
title('1000 Simulated N(0,1) Random Values')
xlabel('Z')
ylabel('Frequency')
set(get(gca,'Children'),'FaceColor',[.8 .8 1])
```

```
u = normcdf(z); % compute the cdf values of the sample data

figure
hist(u,.05:.1:.95) % plot the histogram of the cdf values
```

```
title('1000 Simulated N(0,1) Values Transformed to Unif(0,1)')
xlabel('U')
ylabel('Frequency')
set(get(gca,'Children'),'FaceColor',[.8 .8 1])
```

Borrowing from the theory of univariate random number generation, applying the inverse cdf of any distribution,  $F$ , to a  $\text{Unif}(0,1)$  random variable results in a random variable whose distribution is exactly  $F$  (see “Inversion Methods” on page 6-7). The proof is essentially the opposite of the preceding proof for

the forward case. Another histogram illustrates the transformation to a gamma distribution:

```
x = gaminv(u,2,1); % transform to gamma values
```

```
figure  
hist(x,.25:.5:9.75) % plot the histogram of gamma values  
title('1000 Simulated N(0,1) Values Transformed to Gamma(2,1)')  
xlabel('X')  
ylabel('Frequency')  
set(get(gca,'Children'),'FaceColor',[.8 .8 1])
```

You can apply this two-step transformation to each variable of a standard bivariate normal, creating dependent random variables with arbitrary marginal distributions. Because the transformation works on each component separately, the two resulting random variables need not even have the same marginal distributions. The transformation is defined as:

$$Z = [Z_1, Z_2] \square N\left([0, 0], \begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix}\right)$$

$$U = [\Phi(Z_1), \Phi(Z_2)]$$

$$X = [G_1(U_1), G_2(U_2)]$$

where  $G_1$  and  $G_2$  are inverse cdfs of two possibly different distributions. For example, the following generates random vectors from a bivariate distribution with  $t_5$  and Gamma(2,1) marginals:

```
n = 1000; rho = .7;
Z = mvnrnd([0 0],[1 rho; rho 1],n);
U = normcdf(Z);
X = [gaminv(U(:,1),2,1) tinv(U(:,2),5)];

% draw the scatter plot of data with histograms
figure
scatterhist(X(:,1),X(:,2),'Direction','out')
```

This plot has histograms alongside a scatter plot to show both the marginal distributions, and the dependence.

### Using Rank Correlation Coefficients

The correlation parameter,  $\rho$ , of the underlying bivariate normal determines the dependence between  $X_1$  and  $X_2$  in this construction. However, the linear correlation of  $X_1$  and  $X_2$  is not  $\rho$ . For example, in the original lognormal case, a closed form for that correlation is:

$$\text{cor}(X1, X2) = \frac{e^{\rho\sigma^2} - 1}{e^{\sigma^2} - 1}$$

which is strictly less than  $\rho$ , unless  $\rho$  is exactly 1. In more general cases such as the Gamma/ $t$  construction, the linear correlation between  $X1$  and  $X2$  is difficult or impossible to express in terms of  $\rho$ , but simulations show that the same effect happens.

That is because the linear correlation coefficient expresses the linear dependence between random variables, and when nonlinear transformations are applied to those random variables, linear correlation is not preserved. Instead, a rank correlation coefficient, such as Kendall's  $\tau$  or Spearman's  $\rho$ , is more appropriate.

Roughly speaking, these rank correlations measure the degree to which large or small values of one random variable associate with large or small values of another. However, unlike the linear correlation coefficient, they measure the association only in terms of ranks. As a consequence, the rank correlation is preserved under any monotonic transformation. In particular, the transformation method just described preserves the rank correlation. Therefore, knowing the rank correlation of the bivariate normal  $Z$  exactly determines the rank correlation of the final transformed random variables,  $X$ . While the linear correlation coefficient,  $\rho$ , is still needed to parameterize the underlying bivariate normal, Kendall's  $\tau$  or Spearman's  $\rho$  are more useful in describing the dependence between random variables, because they are invariant to the choice of marginal distribution.

For the bivariate normal, there is a simple one-to-one mapping between Kendall's  $\tau$  or Spearman's  $\rho$ , and the linear correlation coefficient  $\rho$ :

$$\tau = \frac{2}{\pi} \arcsin(\rho) \quad \text{or} \quad \rho = \sin\left(\tau \frac{\pi}{2}\right)$$

$$\rho_s = \frac{6}{\pi} \arcsin\left(\frac{\rho}{2}\right) \quad \text{or} \quad \rho = 2\sin\left(\rho_s \frac{\pi}{6}\right)$$

The following plot shows the relationship:

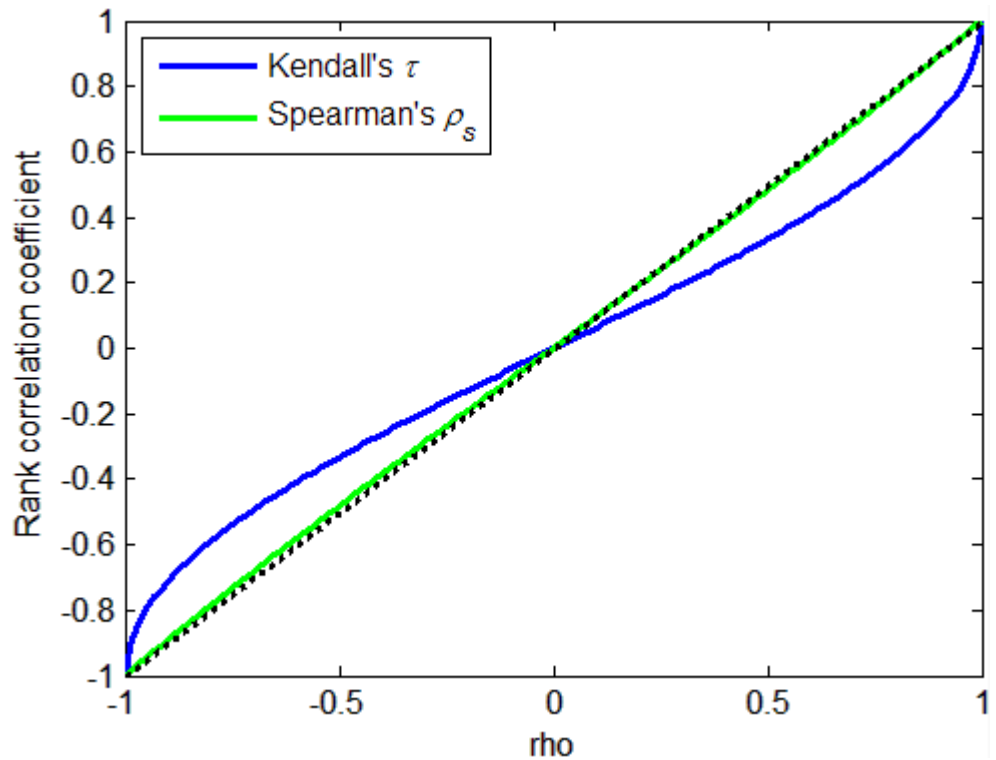

```
rho = -1:.01:1;
```

```

tau = 2.*asin(rho)./pi;
rho_s = 6.*asin(rho./2)./pi;

plot(rho,tau,'b-','LineWidth',2)
hold on
plot(rho,rho_s,'g-','LineWidth',2)
plot([-1 1],[-1 1],'k:','LineWidth',2)
axis([-1 1 -1 1])
xlabel('rho')
ylabel('Rank correlation coefficient')
legend('Kendall''s  $\tau$ ', ...
       'Spearman''s  $\rho_s$ ', ...
       'location','NW')

```

Thus, it is easy to create the desired rank correlation between  $X_1$  and  $X_2$ , regardless of their marginal distributions, by choosing the correct  $\rho$  parameter value for the linear correlation between  $Z_1$  and  $Z_2$ .

For the multivariate normal distribution, Spearman's rank correlation is almost identical to the linear correlation. However, this is not true once you transform to the final random variables.

### Using Bivariate Copulas

The first step of the construction described in the previous section defines what is known as a bivariate Gaussian copula. A copula is a multivariate probability distribution, where each random variable has a uniform marginal distribution on the unit interval  $[0,1]$ . These variables may be completely independent, deterministically related (e.g.,  $U_2 = U_1$ ), or anything in between. Because of the possibility for dependence among variables, you can use a copula to construct a new multivariate distribution for dependent variables. By transforming each of the variables in the copula separately using the inversion method, possibly using different cdfs, the resulting distribution can have arbitrary marginal distributions. Such multivariate distributions are often useful in simulations, when you know that the different random inputs are not independent of each other.

Statistics Toolbox functions compute:

- Probability density functions (`copulapdf`) and the cumulative distribution functions (`copulacdf`) for Gaussian copulas
- Rank correlations from linear correlations (`copulastat`) and vice versa (`copulaparam`)
- Random vectors (`copularnd`)
- Parameters for copulas fit to data (`copulafit`)

For example, use the `copularnd` function to create scatter plots of random values from a bivariate Gaussian copula for various levels of  $\rho$ , to illustrate the range of different dependence structures. The family of bivariate Gaussian copulas is parameterized by the linear correlation matrix:

$$P = \begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix}$$

$U_1$  and  $U_2$  approach linear dependence as  $\rho$  approaches  $\pm 1$ , and approach complete independence as  $\rho$  approaches zero:

```
n = 500;
```

```
rng('default') % for reproducibility
U = copularnd('Gaussian',[1 .8; .8 1],n);
subplot(2,2,1)
plot(U(:,1),U(:,2),'.')
title('\it\rho = 0.8')
xlabel('U1')
ylabel('U2')

U = copularnd('Gaussian',[1 .1; .1 1],n);
subplot(2,2,2)
plot(U(:,1),U(:,2),'.')
title('\it\rho = 0.1')
xlabel('U1')
ylabel('U2')

U = copularnd('Gaussian',[1 -.1; -.1 1],n);
subplot(2,2,3)
plot(U(:,1),U(:,2),'.')
title('\it\rho = -0.1')
xlabel('U1')
ylabel('U2')

U = copularnd('Gaussian',[1 -.8; -.8 1],n);
subplot(2,2,4)
plot(U(:,1),U(:,2),'.')
title('\it\rho = -0.8')
xlabel('U1')
ylabel('U2')
```

The dependence between  $U_1$  and  $U_2$  is completely separate from the marginal distributions of  $X_1 = G(U_1)$  and  $X_2 = G(U_2)$ .  $X_1$  and  $X_2$  can be given any marginal distributions, and still have the same rank correlation. This is one of the main appeals of copulas—they allow this separate specification of dependence and marginal distribution. You can also compute the pdf (`copulapdf`) and the cdf (`copulacdf`) for a copula. For example, these plots show the pdf and cdf for  $\rho = .8$ :

```
u1 = linspace(1e-3,1-1e-3,50);
u2 = linspace(1e-3,1-1e-3,50);
```

```
[U1,U2] = meshgrid(u1,u2);
Rho = [1 .8; .8 1];
f = copulapdf('t',[U1(:) U2(:)],Rho,5);
f = reshape(f,size(U1));

figure()
surf(u1,u2,log(f),'FaceColor','interp','EdgeColor','none')
view([-15,20])
xlabel('U1')
ylabel('U2')
zlabel('Probability Density')
```

```
u1 = linspace(1e-3,1-1e-3,50);  
u2 = linspace(1e-3,1-1e-3,50);  
[U1,U2] = meshgrid(u1,u2);  
F = copulacdf('t',[U1(:) U2(:)],Rho,5);  
F = reshape(F,size(U1));
```

```
figure()  
surf(u1,u2,F,'FaceColor','interp','EdgeColor','none')  
view([-15,20])  
xlabel('U1')
```

```
ylabel('U2')
zlabel('Cumulative Probability')
```

A different family of copulas can be constructed by starting from a bivariate  $t$  distribution and transforming using the corresponding  $t$  cdf. The bivariate  $t$  distribution is parameterized with  $P$ , the linear correlation matrix, and  $\nu$ , the degrees of freedom. Thus, for example, you can speak of a  $t_1$  or a  $t_5$  copula, based on the multivariate  $t$  with one and five degrees of freedom, respectively.

Just as for Gaussian copulas, Statistics Toolbox functions for  $t$  copulas compute:

- Probability density functions (`copulapdf`) and the cumulative distribution functions (`copulacdf`) for Gaussian copulas
- Rank correlations from linear correlations (`copulastat`) and vice versa (`copulaparam`)
- Random vectors (`copularnd`)
- Parameters for copulas fit to data (`copulafit`)

For example, use the `copularnd` function to create scatter plots of random values from a bivariate  $t_1$  copula for various levels of  $\rho$ , to illustrate the range of different dependence structures:

```
n = 500;
nu = 1;

rng('default') % for reproducibility
U = copularnd('t',[1 .8; .8 1],nu,n);
subplot(2,2,1)
plot(U(:,1),U(:,2),'.')
title('\it\rho = 0.8')
xlabel('U1')
ylabel('U2')

U = copularnd('t',[1 .1; .1 1],nu,n);
subplot(2,2,2)
plot(U(:,1),U(:,2),'.')
title('\it\rho = 0.1')
xlabel('U1')
ylabel('U2')

U = copularnd('t',[1 -.1; -.1 1],nu,n);
subplot(2,2,3)
plot(U(:,1),U(:,2),'.')
title('\it\rho = -0.1')
xlabel('U1')
ylabel('U2')
```

```

U = copularnd('t',[1 -.8; -.8 1],nu, n);
subplot(2,2,4)
plot(U(:,1),U(:,2),'.')
title('\it\rho = -0.8')
xlabel('U1')
ylabel('U2')

```

A  $t$  copula has uniform marginal distributions for  $U_1$  and  $U_2$ , just as a Gaussian copula does. The rank correlation  $\tau$  or  $\rho_s$  between components in a  $t$  copula is also the same function of  $\rho$  as for a Gaussian. However, as these plots

demonstrate, a  $t_1$  copula differs quite a bit from a Gaussian copula, even when their components have the same rank correlation. The difference is in their dependence structure. Not surprisingly, as the degrees of freedom parameter  $\nu$  is made larger, a  $t_\nu$  copula approaches the corresponding Gaussian copula.

As with a Gaussian copula, any marginal distributions can be imposed over a  $t$  copula. For example, using a  $t$  copula with 1 degree of freedom, you can again generate random vectors from a bivariate distribution with Gamma(2,1) and  $t_5$  marginals using `copularnd`:

```
n = 1000;
rho = .7;
nu = 1;

rng('default') % for reproducibility
U = copularnd('t',[1 rho; rho 1],nu,n);
X = [gaminv(U(:,1),2,1) tinv(U(:,2),5)];

figure()
scatterhist(X(:,1),X(:,2),'Direction','out')
```

Compared to the bivariate Gamma/ $t$  distribution constructed earlier, which was based on a Gaussian copula, the distribution constructed here, based on a  $t_1$  copula, has the same marginal distributions and the same rank correlation between variables but a very different dependence structure. This illustrates the fact that multivariate distributions are not uniquely defined by their marginal distributions, or by their correlations. The choice of a particular copula in an application may be based on actual observed data, or different copulas may be used as a way of determining the sensitivity of simulation results to the input distribution.

## Higher Dimension Copulas

The Gaussian and  $t$  copulas are known as elliptical copulas. It is easy to generalize elliptical copulas to a higher number of dimensions. For example, simulate data from a trivariate distribution with Gamma(2,1), Beta(2,2), and  $t_5$  marginals using a Gaussian copula and `copularnd`, as follows:

```
n = 1000;
Rho = [1 .4 .2; .4 1 -.8; .2 -.8 1];
rng('default') % for reproducibility
U = copularnd('Gaussian',Rho,n);
X = [gaminv(U(:,1),2,1) betainv(U(:,2),2,2) tinv(U(:,3),5)];
```

Plot the data.

```
subplot(1,1,1)
plot3(X(:,1),X(:,2),X(:,3),'.')
grid on
view([-55, 15])
xlabel('X1')
ylabel('X2')
zlabel('X3')
```

Notice that the relationship between the linear correlation parameter  $\rho$  and, for example, Kendall's  $\tau$ , holds for each entry in the correlation matrix  $P$  used here. You can verify that the sample rank correlations of the data are approximately equal to the theoretical values:

```
tauTheoretical = 2.*asin(Rho)./pi
```

```
tauTheoretical =
```

```

1.0000    0.2620    0.1282
0.2620    1.0000   -0.5903
0.1282   -0.5903    1.0000

```

```
tauSample = corr(X,'type','Kendall')
```

```
tauSample =
```

```

1.0000    0.2581    0.1414
0.2581    1.0000   -0.5790
0.1414   -0.5790    1.0000

```

## Archimedean Copulas

Statistics Toolbox functions are available for three bivariate Archimedean copula families:

- Clayton copulas
- Frank copulas
- Gumbel copulas

These are one-parameter families that are defined directly in terms of their cdfs, rather than being defined constructively using a standard multivariate distribution.

To compare these three Archimedean copulas to the Gaussian and  $t$  bivariate copulas, first use the `copulastat` function to find the rank correlation for a Gaussian or  $t$  copula with linear correlation parameter of 0.8, and then use the `copulaparam` function to find the Clayton copula parameter that corresponds to that rank correlation:

```
tau = copulastat('Gaussian',.8,'type','kendall')
```

```
tau =
```

```
0.5903
```

```
alpha = copulaparam('Clayton',tau,'type','kendall')
```

```
alpha =
```

```
2.8820
```

Finally, plot a random sample from the Clayton copula with `copularnd`. Repeat the same procedure for the Frank and Gumbel copulas:

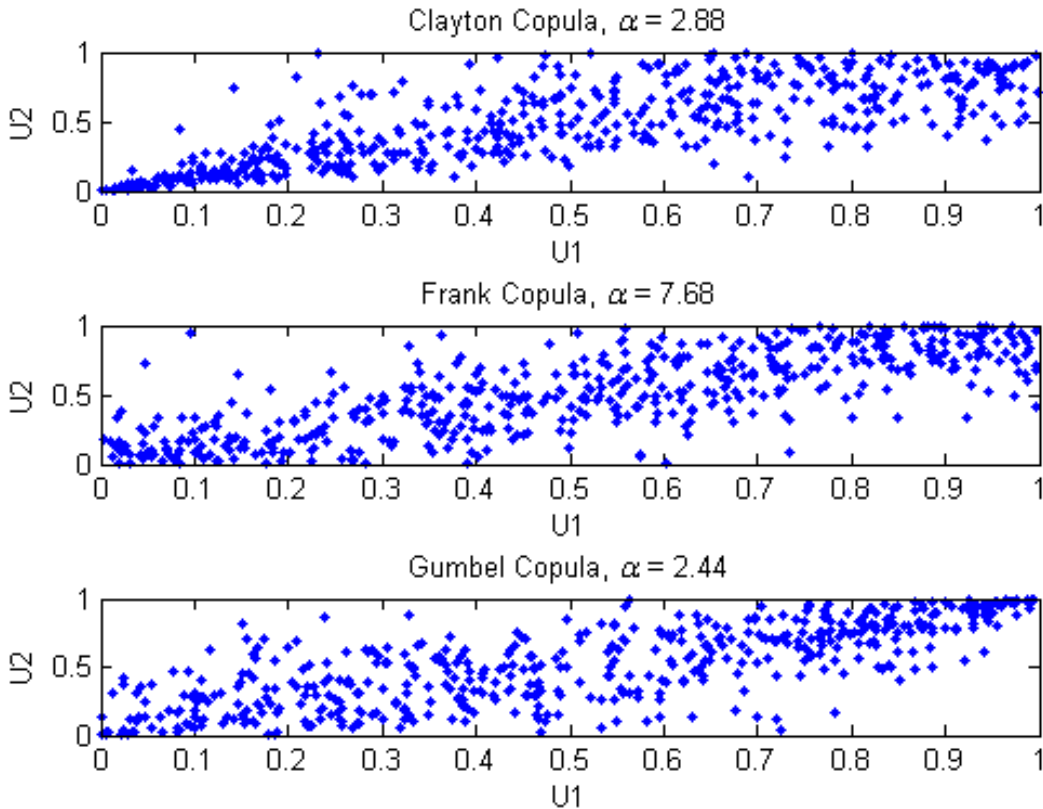

```
n = 500;
```

```
U = copularnd('Clayton',alpha,n);
subplot(3,1,1)
plot(U(:,1),U(:,2),'.');
title(['Clayton Copula, {\it\alpha} = ',sprintf('%0.2f',alpha)])
xlabel('U1')
ylabel('U2')
```

```
alpha = copulaparam('Frank',tau,'type','kendall');
U = copularnd('Frank',alpha,n);
subplot(3,1,2)
plot(U(:,1),U(:,2),'.');
title(['Frank Copula, {\it\alpha} = ',sprintf('%0.2f',alpha)])
xlabel('U1')
ylabel('U2')
```

```
alpha = copulaparam('Gumbel',tau,'type','kendall');
U = copularnd('Gumbel',alpha,n);
subplot(3,1,3)
plot(U(:,1),U(:,2),'.');
title(['Gumbel Copula, {\it\alpha} = ',sprintf('%0.2f',alpha)])
xlabel('U1')
ylabel('U2')
```

### Simulating Dependent Multivariate Data Using Copulas

To simulate dependent multivariate data using a copula, you must specify each of the following:

- The copula family (and any shape parameters)
- The rank correlations among variables
- Marginal distributions for each variable

Suppose you have return data for two stocks and want to run a Monte Carlo simulation with inputs that follow the same distributions as the data:

```
load stockreturns
nobs = size(stocks,1);

subplot(2,1,1)
hist(stocks(:,1),10)
xlim([-3.5 3.5])
xlabel('X1')
ylabel('Frequency')
set(get(gca,'Children'),'FaceColor',[.8 .8 1])

subplot(2,1,2)
hist(stocks(:,2),10)
xlim([-3.5 3.5])
xlabel('X2')
ylabel('Frequency')
set(get(gca,'Children'),'FaceColor',[.8 .8 1])
```

You could fit a parametric model separately to each dataset, and use those estimates as the marginal distributions. However, a parametric model may not be sufficiently flexible. Instead, you can use a nonparametric model to transform to the marginal distributions. All that is needed is a way to compute the inverse cdf for the nonparametric model.

The simplest nonparametric model is the empirical cdf, as computed by the `ecdf` function. For a discrete marginal distribution, this is appropriate. However, for a continuous distribution, use a model that is smoother than the step function computed by `ecdf`. One way to do that is to estimate

the empirical cdf and interpolate between the midpoints of the steps with a piecewise linear function. Another way is to use kernel smoothing with `ksdensity`. For example, compare the empirical cdf to a kernel smoothed cdf estimate for the first variable:

```
[Fi,xi] = ecdf(stocks(:,1));

figure()
stairs(xi,Fi,'b','LineWidth',2)
hold on

Fi_sm = ksdensity(stocks(:,1),xi,'function','cdf','width',.15);

plot(xi,Fi_sm,'r-','LineWidth',1.5)
xlabel('X1')
ylabel('Cumulative Probability')
legend('Empirical','Smoothed','Location','NW')
grid on
```

For the simulation, experiment with different copulas and correlations. Here, you will use a bivariate  $t$  copula with a fairly small degrees of freedom parameter. For the correlation parameter, you can compute the rank correlation of the data.

```
nu = 5;
tau = corr(stocks(:,1),stocks(:,2),'type','kendall')
```

```
tau =
```

```
0.5180
```

Find the corresponding linear correlation parameter for the  $t$  copula using `copulaparam`.

```
rho = copulaparam('t', tau, nu, 'type','kendall')
```

```
rho =
```

```
0.7268
```

Next, use `copularnd` to generate random values from the  $t$  copula and transform using the nonparametric inverse cdfs. The `ksdensity` function allows you to make a kernel estimate of distribution and evaluate the inverse cdf at the copula points all in one step:

```
n = 1000;
U = copularnd('t',[1 rho; rho 1],nu,n);

X1 = ksdensity(stocks(:,1),U(:,1),...
               'function','icdf','width',.15);
X2 = ksdensity(stocks(:,2),U(:,2),...
               'function','icdf','width',.15);
```

Alternatively, when you have a large amount of data or need to simulate more than one set of values, it may be more efficient to compute the inverse cdf over a grid of values in the interval (0,1) and use interpolation to evaluate it at the copula points:

```
p = linspace(0.00001,0.99999,1000);
G1 = ksdensity(stocks(:,1),p,'function','icdf','width',0.15);
X1 = interp1(p,G1,U(:,1),'spline');
G2 = ksdensity(stocks(:,2),p,'function','icdf','width',0.15);
X2 = interp1(p,G2,U(:,2),'spline');

scatterhist(X1,X2,'Direction','out')
```

The marginal histograms of the simulated data are a smoothed version of the histograms for the original data. The amount of smoothing is controlled by the bandwidth input to `ksdensity`.

### Fitting Copulas to Data

This example shows how to use `copulafit` to calibrate copulas with data. To generate data  $X_{\text{sim}}$  with a distribution "just like" (in terms of marginal distributions and correlations) the distribution of data in the matrix  $X$ , you need to fit marginal distributions to the columns of  $X$ , use appropriate cdf

functions to transform  $X$  to  $U$ , so that  $U$  has values between 0 and 1, use `copulafit` to fit a copula to  $U$ , generate new data  $U_{\text{sim}}$  from the copula, and use appropriate inverse cdf functions to transform  $U_{\text{sim}}$  to  $X_{\text{sim}}$ .

Load and plot the simulated stock return data.

```
load stockreturns
x = stocks(:,1);
y = stocks(:,2);

scatterhist(x,y,'Direction','out')
```

Transform the data to the copula scale (unit square) using a kernel estimator of the cumulative distribution function.

```
u = ksdensity(x,x,'function','cdf');
v = ksdensity(y,y,'function','cdf');
```

```
scatterhist(u,v,'Direction','out')
xlabel('u')
ylabel('v')
```

Fit a  $t$  copula.

```
[Rho,nu] = copulafit('t',[u v],'Method','ApproximateML')
```

```
Rho =
```

```
    1.0000    0.7220  
    0.7220    1.0000
```

```
nu =
```

```
    3.2763e+06
```

Generate a random sample from the  $t$  copula.

```
r = copularnd('t',Rho,nu,1000);
```

```
u1 = r(:,1);
```

```
v1 = r(:,2);
```

```
scatterhist(u1,v1,'Direction','out')
```

```
xlabel('u')
```

```
ylabel('v')
```

```
set(get(gca,'children'),'marker','.')
```

Transform the random sample back to the original scale of the data.

```
x1 = ksdensity(x,u1,'function','icdf');  
y1 = ksdensity(y,v1,'function','icdf');
```

```
scatterhist(x1,y1,'Direction','out')  
set(get(gca,'children'),'marker','.')
```

As the example illustrates, copulas integrate naturally with other distribution fitting functions.

# Random Number Generation

### Generating Random Data

*Pseudorandom* numbers are generated by deterministic algorithms. They are "random" in the sense that, on average, they pass statistical tests regarding their distribution and correlation. They differ from true random numbers in that they are generated by an algorithm, rather than a truly random process.

*Random number generators* (RNGs) like those in MATLAB are algorithms for generating pseudorandom numbers with a specified distribution.

For more information on the GUI for generating random numbers from supported distributions, see "Explore the Random Number Generation UI" on page 5-80.

## Random Number Generation Functions

The following table lists the supported distributions and their respective random number generation functions.

Distribution	Random Number Generation Function
Beta	betarnd, random, randtool
Binomial	binornd, random, randtool
Chi-square	chi2rnd, random, randtool
Clayton copula	copularnd
Exponential	exprnd, random, randtool
Extreme value	evrnd, random, randtool
$F$	frnd, random, randtool
Frank copula	copularnd
Gamma	gamrnd, randg, random, randtool
Gaussian copula	copularnd
Gaussian mixture	random
Generalized extreme value	gevrnd, random, randtool
Generalized Pareto	gprnd, random, randtool
Geometric	geornd, random, randtool
Gumbel copula	copularnd
Hypergeometric	hygernd, random
Inverse Wishart	iwishrnd
Johnson system	johnsrnd
Lognormal	lognrnd, random, randtool
Multinomial	mnrnd
Multivariate normal	mvnrnd
Multivariate $t$	mvtrnd

<b>Distribution</b>	<b>Random Number Generation Function</b>
Negative binomial	nbinrnd, random, randtool
Noncentral chi-square	ncx2rnd, random, randtool
Noncentral $F$	ncfrnd, random, randtool
Noncentral $t$	nctrnd, random, randtool
Normal (Gaussian)	normrnd, randn, random, randtool
Pearson system	pearsrnd
Piecewise	random
Poisson	poissrnd, random, randtool
Rayleigh	raylrnd, random, randtool
Student's $t$	trnd, random, randtool
$t$ copula	copularnd
Uniform (continuous)	unifrnd, rand, random
Uniform (discrete)	unidrnd, random, randtool
Weibull	wblrnd, random
Wishart	wishrnd

## Common Generation Methods

### In this section...

“Direct Methods” on page 6-5

“Inversion Methods” on page 6-7

“Acceptance-Rejection Methods” on page 6-9

Methods for generating pseudorandom numbers usually start with uniform random numbers, like the MATLAB `rand` function produces. The methods described in this section detail how to produce random numbers from other distributions.

### Direct Methods

Direct methods directly use the definition of the distribution.

For example, consider binomial random numbers. A binomial random number is the number of heads in  $N$  tosses of a coin with probability  $p$  of a heads on any single toss. If you generate  $N$  uniform random numbers on the interval  $(0,1)$  and count the number less than  $p$ , then the count is a binomial random number with parameters  $N$  and  $p$ .

This function is a simple implementation of a binomial RNG using the direct approach:

```
function X = directbinornd(N,p,m,n)

X = zeros(m,n); % Preallocate memory
for i = 1:m*n
    u = rand(N,1);
    X(i) = sum(u < p);
end
```

For example:

```
X = directbinornd(100,0.3,1e4,1);
hist(X,101)
set(get(gca, 'Children'), 'FaceColor', [.8 .8 1])
```

The Statistics Toolbox function `binornd` uses a modified direct method, based on the definition of a binomial random variable as the sum of Bernoulli random variables.

You can easily convert the previous method to a random number generator for the Poisson distribution with parameter  $\lambda$ . The Poisson distribution is the limiting case of the binomial distribution as  $N$  approaches infinity,  $p$  approaches zero, and  $Np$  is held fixed at  $\lambda$ . To generate Poisson random numbers, create a version of the previous generator that inputs  $\lambda$  rather than  $N$  and  $p$ , and internally sets  $N$  to some large number and  $p$  to  $\lambda/N$ .

The Statistics Toolbox function `poissrnd` actually uses two direct methods:

- A waiting time method for small values of  $\lambda$
- A method due to Ahrens and Dieter for larger values of  $\lambda$

## Inversion Methods

*Inversion methods* are based on the observation that continuous cumulative distribution functions (cdfs) range uniformly over the interval (0,1). If  $u$  is a uniform random number on (0,1), then using  $X = F^{-1}(U)$  generates a random number  $X$  from a continuous distribution with specified cdf  $F$ .

For example, the following code generates random numbers from a specific exponential distribution using the inverse cdf and the MATLAB uniform random number generator `rand`:

```
mu = 1;  
X = expinv(rand(1e4,1),mu);
```

Compare the distribution of the generated random numbers to the pdf of the specified exponential by scaling the pdf to the area of the histogram used to display the distribution:

```
numbins = 50;  
hist(X,numbins)  
set(get(gca,'Children'),'FaceColor',[.8 .8 1])  
hold on  
  
[bincounts,binpositions] = hist(X,numbins);  
binwidth = binpositions(2) - binpositions(1);  
histarea = binwidth*sum(bincounts);  
  
x = binpositions(1):0.001:binpositions(end);  
y = exppdf(x,mu);  
plot(x,histarea*y,'r','LineWidth',2)
```

Inversion methods also work for discrete distributions. To generate a random number  $X$  from a discrete distribution with probability mass vector  $P(X=x_i) = p_i$  where  $x_0 < x_1 < x_2 < \dots$ , generate a uniform random number  $u$  on  $(0,1)$  and then set  $X = x_i$  if  $F(x_{i-1}) < u < F(x_i)$ .

For example, the following function implements an inversion method for a discrete distribution with probability mass vector  $p$ :

```
function X = discreteinvrnd(p,m,n)

X = zeros(m,n); % Preallocate memory
for i = 1:m*n
    u = rand;
    I = find(u < cumsum(p));
    X(i) = min(I);
end
```

Use the function to generate random numbers from any discrete distribution:

```
p = [0.1 0.2 0.3 0.2 0.1 0.1]; % Probability mass vector
X = discreteinvrnd(p,1e4,1);
[n,x] = hist(X,length(p));
bar(1:length(p),n)
set(get(gca,'Children'),'FaceColor',[.8 .8 1])
```

## Acceptance-Rejection Methods

The functional form of some distributions makes it difficult or time-consuming to generate random numbers using direct or inversion methods.

Acceptance-rejection methods provide an alternative in these cases.

*Acceptance-rejection methods* begin with uniform random numbers, but require an additional random number generator. If your goal is to generate a random number from a continuous distribution with pdf  $f$ , acceptance-rejection methods first generate a random number from a continuous distribution with pdf  $g$  satisfying  $f(x) \leq cg(x)$  for some  $c$  and all  $x$ .

A continuous acceptance-rejection RNG proceeds as follows:

- 1** Chooses a density  $g$ .
- 2** Finds a constant  $c$  such that  $f(x)/g(x) \leq c$  for all  $x$ .
- 3** Generates a uniform random number  $u$ .
- 4** Generates a random number  $v$  from  $g$ .
- 5** If  $cu \leq f(v)/g(v)$ , accepts and returns  $v$ .
- 6** Otherwise, rejects  $v$  and goes to step 3.

For efficiency, a “cheap” method is necessary for generating random numbers from  $g$ , and the scalar  $c$  should be small. The expected number of iterations to produce a single random number is  $c$ .

The following function implements an acceptance-rejection method for generating random numbers from pdf  $f$ , given  $f$ ,  $g$ , the RNG `grnd` for  $g$ , and the constant  $c$ :

```

function X = accrejrnd(f,g,grnd,c,m,n)

X = zeros(m,n); % Preallocate memory
for i = 1:m*n
    accept = false;
    while accept == false
        u = rand();
        v = grnd();
        if c*u <= f(v)/g(v)
            X(i) = v;
            accept = true;
        end
    end
end
end

```

For example, the function  $f(x) = xe^{-x/2}$  satisfies the conditions for a pdf on  $[0, \infty)$  (nonnegative and integrates to 1). The exponential pdf with mean 1,  $f(x) = e^{-x}$ , dominates  $g$  for  $c$  greater than about 2.2. Thus, you can use `rand` and `exprnd` to generate random numbers from  $f$ :

```

f = @(x)x.*exp(-(x.^2)/2);
g = @(x)exp(-x);
grnd = @()exprnd(1);
X = accrejrnd(f,g,grnd,2.2,1e4,1);

```

The pdf  $f$  is actually a Rayleigh distribution with shape parameter 1. This example compares the distribution of random numbers generated by the acceptance-rejection method with those generated by `raylrnd`:

```

Y = raylrnd(1,1e4,1);
hist([X Y])
h = get(gca,'Children');
set(h(1),'FaceColor',[.8 .8 1])
legend('A-R RNG','Rayleigh RNG')

```

The Statistics Toolbox function `raylrnd` uses a transformation method, expressing a Rayleigh random variable in terms of a chi-square random variable, which you compute using `randn`.

Acceptance-rejection methods also work for discrete distributions. In this case, the goal is to generate random numbers from a distribution with probability mass  $P_p(X = i) = p_i$ , assuming that you have a method for generating random numbers from a distribution with probability mass  $P_q(X = i) = q_i$ . The RNG proceeds as follows:

- 1** Chooses a density  $P_q$ .
- 2** Finds a constant  $c$  such that  $p_i/q_i \leq c$  for all  $i$ .
- 3** Generates a uniform random number  $u$ .
- 4** Generates a random number  $v$  from  $P_q$ .
- 5** If  $cu \leq p_i/q_i$ , accepts and returns  $v$ .
- 6** Otherwise, rejects  $v$  and goes to step 3.

# Representing Sampling Distributions Using Markov Chain Samplers

## In this section...

“Using the Metropolis-Hastings Algorithm” on page 6-13

“Using Slice Sampling” on page 6-14

The methods in “Common Generation Methods” on page 6-5 might be inadequate when sampling distributions are difficult to represent in computations. Such distributions arise, for example, in Bayesian data analysis and in the large combinatorial problems of Markov chain Monte Carlo (MCMC) simulations. An alternative is to construct a Markov chain with a stationary distribution equal to the target sampling distribution, using the states of the chain to generate random numbers after an initial burn-in period in which the state distribution converges to the target.

## Using the Metropolis-Hastings Algorithm

The Metropolis-Hastings algorithm draws samples from a distribution that is only known up to a constant. Random numbers are generated from a distribution with a probability density function that is equal to or proportional to a proposal function.

To generate random numbers:

- 1 Assume an initial value  $x(t)$ .
- 2 Draw a sample,  $y(t)$ , from a proposal distribution  $q(y | x(t))$ .
- 3 Accept  $y(t)$  as the next sample  $x(t + 1)$  with probability  $r(x(t), y(t))$ , and keep  $x(t)$  as the next sample  $x(t + 1)$  with probability  $1 - r(x(t), y(t))$ , where:

$$r(x, y) = \min \left\{ \frac{f(y) q(x | y)}{f(x) q(y | x)}, 1 \right\}$$

- 4 Increment  $t \rightarrow t+1$ , and repeat steps 2 and 3 until you get the desired number of samples.

Generate random numbers using the Metropolis-Hastings method with the `mhsample` function. To produce quality samples efficiently with the Metropolis-Hastings algorithm, it is crucial to select a good proposal distribution. If it is difficult to find an efficient proposal distribution, use the slice sampling algorithm (`slicesample`) without explicitly specifying a proposal distribution.

## Using Slice Sampling

In instances where it is difficult to find an efficient Metropolis-Hastings proposal distribution, the slice sampling algorithm does not require an explicit specification. The slice sampling algorithm draws samples from the region under the density function using a sequence of vertical and horizontal steps. First, it selects a height at random from 0 to the density function  $f(x)$ . Then, it selects a new  $x$  value at random by sampling from the horizontal “slice” of the density above the selected height. A similar slice sampling algorithm is used for a multivariate distribution.

If a function  $f(x)$  proportional to the density function is given, then do the following to generate random numbers:

- 1** Assume an initial value  $x(t)$  within the domain of  $f(x)$ .
- 2** Draw a real value  $y$  uniformly from  $(0, f(x(t)))$ , thereby defining a horizontal “slice” as  $S = \{x: y < f(x)\}$ .
- 3** Find an interval  $I = (L, R)$  around  $x(t)$  that contains all, or much of the “slice”  $S$ .
- 4** Draw the new point  $x(t+1)$  within this interval.
- 5** Increment  $t \rightarrow t+1$  and repeat steps 2 through 4 until you get the desired number of samples.

Slice sampling can generate random numbers from a distribution with an arbitrary form of the density function, provided that an efficient numerical procedure is available to find the interval  $I = (L, R)$ , which is the “slice” of the density.

Generate random numbers using the slice sampling method with the `slicesample` function.

## Generating Quasi-Random Numbers

In this section...
“Quasi-Random Sequences” on page 6-15
“Quasi-Random Point Sets” on page 6-16
“Quasi-Random Streams” on page 6-24

### Quasi-Random Sequences

*Quasi-random number generators* (QRNGs) produce highly uniform samples of the unit hypercube. QRNGs minimize the *discrepancy* between the distribution of generated points and a distribution with equal proportions of points in each sub-cube of a uniform partition of the hypercube. As a result, QRNGs systematically fill the “holes” in any initial segment of the generated quasi-random sequence.

Unlike the pseudorandom sequences described in “Common Generation Methods” on page 6-5, quasi-random sequences fail many statistical tests for randomness. Approximating true randomness, however, is not their goal. Quasi-random sequences seek to fill space uniformly, and to do so in such a way that initial segments approximate this behavior up to a specified density.

QRNG applications include:

- **Quasi-Monte Carlo (QMC) integration.** Monte Carlo techniques are often used to evaluate difficult, multi-dimensional integrals without a closed-form solution. QMC uses quasi-random sequences to improve the convergence properties of these techniques.
- **Space-filling experimental designs.** In many experimental settings, taking measurements at every factor setting is expensive or infeasible. Quasi-random sequences provide efficient, uniform sampling of the design space.
- **Global optimization.** Optimization algorithms typically find a local optimum in the neighborhood of an initial value. By using a quasi-random sequence of initial values, searches for global optima uniformly sample the basins of attraction of all local minima.

**Example: Using Scramble, Leap, and Skip**

Imagine a simple 1-D sequence that produces the integers from 1 to 10. This is the basic sequence and the first three points are [1,2,3]:

1 2 3 4 5 6 7 8 9 10

Now look at how Scramble, Leap, and Skip work together:

- **Scramble** — Scrambling shuffles the points in one of several different ways. In this example, assume a scramble turns the sequence into 1,3,5,7,9,2,4,6,8,10. The first three points are now [1,3,5]:

1 3 5 7 9 2 4 6 8 10

- **Skip** — A Skip value specifies the number of initial points to ignore. In this example, set the Skip value to 2. The sequence is now 5,7,9,2,4,6,8,10 and the first three points are [5,7,9]:

1 3 5 7 9 2 4 6 8 10

- **Leap** — A Leap value specifies the number of points to ignore for each one you take. Continuing the example with the Skip set to 2, if you set the Leap to 1, the sequence uses every other point. In this example, the sequence is now 5,9,4,8 and the first three points are [5,9,4]:

1 3 5 7 9 2 4 6 8 10

**Quasi-Random Point Sets**

Statistics Toolbox functions support these quasi-random sequences:

- **Halton sequences.** Produced by the `haltonset` function. These sequences use different prime bases to form successively finer uniform partitions of the unit interval in each dimension.

- **Sobol sequences.** Produced by the `sobolset` function. These sequences use a base of 2 to form successively finer uniform partitions of the unit interval, and then reorder the coordinates in each dimension.
- **Latin hypercube sequences.** Produced by the `lhsdesign` function. Though not quasi-random in the sense of minimizing discrepancy, these sequences nevertheless produce sparse uniform samples useful in experimental designs.

Quasi-random sequences are functions from the positive integers to the unit hypercube. To be useful in application, an initial *point set* of a sequence must be generated. Point sets are matrices of size  $n$ -by- $d$ , where  $n$  is the number of points and  $d$  is the dimension of the hypercube being sampled. The functions `haltonset` and `sobolset` construct point sets with properties of a specified quasi-random sequence. Initial segments of the point sets are generated by the `net` method of the `grandset` class (parent class of the `haltonset` class and `sobolset` class), but points can be generated and accessed more generally using parenthesis indexing.

Because of the way in which quasi-random sequences are generated, they may contain undesirable correlations, especially in their initial segments, and especially in higher dimensions. To address this issue, quasi-random point sets often *skip*, *leap* over, or *scramble* values in a sequence. The `haltonset` and `sobolset` functions allow you to specify both a `Skip` and a `Leap` property of a quasi-random sequence, and the `scramble` method of the `grandset` class allows you apply a variety of scrambling techniques. Scrambling reduces correlations while also improving uniformity.

## Generate a Quasi-Random Point Set

This example shows how to use `haltonset` to construct a 2-D Halton quasi-random point set.

Create a `haltonset` object `p`, that skips the first 1000 values of the sequence and then retains every 101st point.

```
rng('default'); % For reproducibility
p = haltonset(2, 'Skip', 1e3, 'Leap', 1e2)
```

```
p =
```

```
Halton point set in 2 dimensions (89180190640991 points)
```

```
Properties:
```

```
    Skip : 1000  
    Leap : 100  
    ScrambleMethod : none
```

The object `p` encapsulates properties of the specified quasi-random sequence. The point set is finite, with a length determined by the `Skip` and `Leap` properties and by limits on the size of point set indices.

Use `scramble` to apply reverse-radix scrambling.

```
p = scramble(p, 'RR2')
```

```
p =
```

```
Halton point set in 2 dimensions (89180190640991 points)
```

```
Properties:
```

```
    Skip : 1000  
    Leap : 100  
    ScrambleMethod : RR2
```

Use `net` to generate the first 500 points.

```
X0 = net(p,500);
```

This is equivalent to

```
X0 = p(1:500,:);
```

Values of the point set `X0` are not generated and stored in memory until you access `p` using `net` or parenthesis indexing.

To appreciate the nature of quasi-random numbers, create a scatter plot of the two dimensions in  $X_0$ .

```
scatter(X0(:,1),X0(:,2),5,'r')  
axis square  
title('\bf Quasi-Random Scatter')
```

Compare this to a scatter of uniform pseudorandom numbers generated by the `rand` function.

```
X = rand(500,2);
```

```
scatter(X(:,1),X(:,2),5,'b')
axis square
title('{\bf Uniform Random Scatter}')
```

The quasi-random scatter appears more uniform, avoiding the clumping in the pseudorandom scatter.

In a statistical sense, quasi-random numbers are too uniform to pass traditional tests of randomness. For example, a Kolmogorov-Smirnov test, performed by `kstest`, is used to assess whether or not a point set has a

uniform random distribution. When performed repeatedly on uniform pseudorandom samples, such as those generated by `rand`, the test produces a uniform distribution of  $p$ -values.

```
nTests = 1e5;
sampSize = 50;
PVALS = zeros(nTests,1);
for test = 1:nTests
    x = rand(sampSize,1);
    [h,pval] = kstest(x,[x,x]);
    PVALS(test) = pval;
end

hist(PVALS,100)
set(get(gca,'Children'),'FaceColor',[.8 .8 1])
xlabel('\it p}-values')
ylabel('Number of Tests')
```

The results are quite different when the test is performed repeatedly on uniform quasi-random samples.

```
p = haltonset(1, 'Skip', 1e3, 'Leap', 1e2);  
p = scramble(p, 'RR2');
```

```
nTests = 1e5;  
sampSize = 50;  
PVALS = zeros(nTests, 1);  
for test = 1:nTests
```

```
x = p(test:test+(sampSize-1),:);  
[h,pval] = kstest(x,[x,x]);  
PVALS(test) = pval;  
end  
  
hist(PVALS,100)  
set(get(gca,'Children'),'FaceColor',[.8 .8 1])  
xlabel('\it p}-values')  
ylabel('Number of Tests')
```

Small  $p$ -values call into question the null hypothesis that the data are uniformly distributed. If the hypothesis is true, about 5% of the  $p$ -values are expected to fall below 0.05. The results are remarkably consistent in their failure to challenge the hypothesis.

## Quasi-Random Streams

Quasi-random *streams*, produced by the `grandstream` function, are used to generate sequential quasi-random outputs, rather than point sets of a specific size. Streams are used like pseudoRNGS, such as `rand`, when client applications require a source of quasi-random numbers of indefinite size that can be accessed intermittently. Properties of a quasi-random stream, such as its type (Halton or Sobol), dimension, skip, leap, and scramble, are set when the stream is constructed.

In implementation, quasi-random streams are essentially very large quasi-random point sets, though they are accessed differently. The *state* of a quasi-random stream is the scalar index of the next point to be taken from the stream. Use the `grand` method of the `grandstream` class to generate points from the stream, starting from the current state. Use the `reset` method to reset the state to 1. Unlike point sets, streams do not support parenthesis indexing.

## Generate a Quasi-Random Stream

This example shows how to generate samples from a quasi-random point set.

Use `haltonset` to create a quasi-random point set `p`, then repeatedly increment the index into the point set `test` to generate different samples.

```
p = haltonset(1, 'Skip', 1e3, 'Leap', 1e2);
p = scramble(p, 'RR2');

nTests = 1e5;
sampSize = 50;
PVALS = zeros(nTests,1);
for test = 1:nTests
    x = p(test:test+(sampSize-1),:);
    [h,pval] = kstest(x,[x,x]);
    PVALS(test) = pval;
```

```
end
```

The same results are obtained by using `grandstream` to construct a quasi-random stream `q` based on the point set `p` and letting the stream take care of increments to the index.

```
p = haltonset(1,'Skip',1e3,'Leap',1e2);  
p = scramble(p,'RR2');  
q = grandstream(p);
```

```
nTests = 1e5;  
sampSize = 50;  
PVALS = zeros(nTests,1);  
for test = 1:nTests  
    X = grand(q,sampSize);  
    [h,pval] = kstest(X,[X,X]);  
    PVALS(test) = pval;  
end
```

## Generating Data Using Flexible Families of Distributions

### In this section...

“Pearson and Johnson Systems” on page 6-26

“Generating Data Using the Pearson System” on page 6-28

“Generating Data Using the Johnson System” on page 6-30

### Pearson and Johnson Systems

As described in “Working with Probability Distributions” on page 5-3, choosing an appropriate parametric family of distributions to model your data can be based on *a priori* or *a posteriori* knowledge of the data-producing process, but the choice is often difficult. The *Pearson and Johnson systems* can make such a choice unnecessary. Each system is a flexible parametric family of distributions that includes a wide range of distribution shapes, and it is often possible to find a distribution within one of these two systems that provides a good match to your data.

#### Data Input

The following parameters define each member of the Pearson and Johnson systems

- Mean — Estimated by mean
- Standard deviation — Estimated by std
- Skewness — Estimated by skewness
- Kurtosis — Estimated by kurtosis

These statistics can also be computed with the `moment` function. The Johnson system, while based on these four parameters, is more naturally described using quantiles, estimated by the `quantile` function.

The Statistics Toolbox functions `pearsrnd` and `johnsrnd` take input arguments defining a distribution (parameters or quantiles, respectively) and return the type and the coefficients of the distribution in the corresponding system. Both functions also generate random numbers from the specified distribution.

As an example, load the data in `carbig.mat`, which includes a variable `MPG` containing measurements of the gas mileage for each car.

```
load carbig
MPG = MPG(~isnan(MPG));
[n,x] = hist(MPG,15);
bar(x,n)
set(get(gca,'Children'),'FaceColor',[.8 .8 1])
```

The following two sections model the distribution with members of the Pearson and Johnson systems, respectively.

## Generating Data Using the Pearson System

The statistician Karl Pearson devised a system, or family, of distributions that includes a unique distribution corresponding to every valid combination of mean, standard deviation, skewness, and kurtosis. If you compute sample values for each of these moments from data, it is easy to find the distribution in the Pearson system that matches these four moments and to generate a random sample.

The Pearson system embeds seven basic types of distribution together in a single parametric framework. It includes common distributions such as the normal and  $t$  distributions, simple transformations of standard distributions such as a shifted and scaled beta distribution and the inverse gamma distribution, and one distribution—the Type IV—that is not a simple transformation of any standard distribution.

For a given set of moments, there are distributions that are not in the system that also have those same first four moments, and the distribution in the Pearson system may not be a good match to your data, particularly if the data are multimodal. But the system does cover a wide range of distribution shapes, including both symmetric and skewed distributions.

To generate a sample from the Pearson distribution that closely matches the MPG data, simply compute the four sample moments and treat those as distribution parameters.

```
moments = {mean(MPG),std(MPG),skewness(MPG),kurtosis(MPG)};
rng('default'); % For reproducibility
[r,type] = pearsrnd(moments{:},10000,1);
```

The optional second output from `pearsrnd` indicates which type of distribution within the Pearson system matches the combination of moments.

```
type
```

```
type =
```

```
1
```

In this case, `pearsrnd` has determined that the data are best described with a Type I Pearson distribution, which is a shifted, scaled beta distribution.

Verify that the sample resembles the original data by overlaying the empirical cumulative distribution functions.

```
ecdf(MPG);  
[Fi,xi] = ecdf(r);  
hold on;  
stairs(xi,Fi,'r');  
hold off
```

## Generating Data Using the Johnson System

Statistician Norman Johnson devised a different system of distributions that also includes a unique distribution for every valid combination of mean, standard deviation, skewness, and kurtosis. However, since it is more natural to describe distributions in the Johnson system using quantiles, working with this system is different than working with the Pearson system.

The Johnson system is based on three possible transformations of a normal random variable, plus the identity transformation. The three nontrivial cases are known as SL, SU, and SB, corresponding to exponential, logistic, and hyperbolic sine transformations. All three can be written as

$$X = \gamma + \delta \cdot \Gamma\left(\frac{(Z-\xi)}{\lambda}\right)$$

where  $Z$  is a standard normal random variable,  $\Gamma$  is the transformation, and  $\gamma$ ,  $\delta$ ,  $\xi$ , and  $\lambda$  are scale and location parameters. The fourth case, SN, is the identity transformation.

To generate a sample from the Johnson distribution that matches the MPG data, first define the four quantiles to which the four evenly spaced standard normal quantiles of -1.5, -0.5, 0.5, and 1.5 should be transformed. That is, you compute the sample quantiles of the data for the cumulative probabilities of 0.067, 0.309, 0.691, and 0.933.

```
probs = normcdf([-1.5 -0.5 0.5 1.5])

probs =
    0.0668    0.3085    0.6915    0.9332

quantiles = quantile(MPG,probs)

quantiles =
    13.0000    18.0000    27.2000    36.0000
```

Then treat those quantiles as distribution parameters.

```
[r1,type] = johnsrnd(quantiles,10000,1);
```

The optional second output from `johnsrnd` indicates which type of distribution within the Johnson system matches the quantiles.

```
type
```

```
type =
```

```
SB
```

You can verify that the sample resembles the original data by overlaying the empirical cumulative distribution functions.

```
ecdf(MPG);  
[Fi,xi] = ecdf(r1);  
hold on;  
stairs(xi,Fi,'r');  
hold off
```

In some applications, it may be important to match the quantiles better in some regions of the data than in others. To do that, specify four evenly spaced standard normal quantiles at which you want to match the data, instead of the default -1.5, -0.5, 0.5, and 1.5. For example, you might care more about matching the data in the right tail than in the left, and so you specify standard normal quantiles that emphasizes the right tail.

```
qnorm = [-.5 .25 1 1.75];  
probs = normcdf(qnorm);  
qemp = quantile(MPG,probs);
```

```
r2 = johnsrnd([qnorm; qemp],10000,1);
```

However, while the new sample matches the original data better in the right tail, it matches much worse in the left tail.

```
[Fj,xj] = ecdf(r2);  
hold on;  
stairs(xj,Fj,'g');  
hold off
```

# Hypothesis Tests

---

- “Introduction to Hypothesis Tests” on page 7-2
- “Hypothesis Test Terminology” on page 7-3
- “Hypothesis Test Assumptions” on page 7-5
- “Hypothesis Testing” on page 7-7
- “Available Hypothesis Tests” on page 7-14

## Introduction to Hypothesis Tests

Hypothesis testing is a common method of drawing inferences about a population based on statistical evidence from a sample.

As an example, suppose someone says that at a certain time in the state of Massachusetts the average price of a gallon of regular unleaded gas was \$1.15. How could you determine the truth of the statement? You could try to find prices at every gas station in the state at the time. That approach would be definitive, but it could be time-consuming, costly, or even impossible.

A simpler approach would be to find prices at a small number of randomly selected gas stations around the state, and then compute the sample average.

Sample averages differ from one another due to chance variability in the selection process. Suppose your sample average comes out to be \$1.18. Is the \$0.03 difference an artifact of random sampling or significant evidence that the average price of a gallon of gas was in fact greater than \$1.15? Hypothesis testing is a statistical method for making such decisions.

## Hypothesis Test Terminology

All hypothesis tests share the same basic terminology and structure.

- A *null hypothesis* is an assertion about a population that you would like to test. It is “null” in the sense that it often represents a status quo belief, such as the absence of a characteristic or the lack of an effect. It may be formalized by asserting that a population parameter, or a combination of population parameters, has a certain value. In the example given in the “Introduction to Hypothesis Tests” on page 7-2, the null hypothesis would be that the average price of gas across the state was \$1.15. This is written  $H_0: \mu = 1.15$ .
- An *alternative hypothesis* is a contrasting assertion about the population that can be tested against the null hypothesis. In the example given in the “Introduction to Hypothesis Tests” on page 7-2, possible alternative hypotheses are:
  - $H_1: \mu \neq 1.15$  — State average was different from \$1.15 (two-tailed test)
  - $H_1: \mu > 1.15$  — State average was greater than \$1.15 (right-tail test)
  - $H_1: \mu < 1.15$  — State average was less than \$1.15 (left-tail test)
- To conduct a hypothesis test, a random sample from the population is collected and a relevant *test statistic* is computed to summarize the sample. This statistic varies with the type of test, but its distribution under the null hypothesis must be known (or assumed).
- The *p value* of a test is the probability, under the null hypothesis, of obtaining a value of the test statistic as extreme or more extreme than the value computed from the sample.
- The *significance level* of a test is a threshold of probability  $\alpha$  agreed to before the test is conducted. A typical value of  $\alpha$  is 0.05. If the *p* value of a test is less than  $\alpha$ , the test rejects the null hypothesis. If the *p* value is greater than  $\alpha$ , there is insufficient evidence to reject the null hypothesis. Note that lack of evidence for rejecting the null hypothesis is not evidence for accepting the null hypothesis. Also note that substantive “significance” of an alternative cannot be inferred from the statistical significance of a test.
- The significance level  $\alpha$  can be interpreted as the probability of rejecting the null hypothesis when it is actually true—a *type I error*. The distribution of the test statistic under the null hypothesis determines the probability

$\alpha$  of a type I error. Even if the null hypothesis is not rejected, it may still be false—a *type II error*. The distribution of the test statistic under the alternative hypothesis determines the probability  $\beta$  of a type II error. Type II errors are often due to small sample sizes. The *power* of a test,  $1 - \beta$ , is the probability of correctly rejecting a false null hypothesis.

- Results of hypothesis tests are often communicated with a *confidence interval*. A confidence interval is an estimated range of values with a specified probability of containing the true population value of a parameter. Upper and lower bounds for confidence intervals are computed from the sample estimate of the parameter and the known (or assumed) sampling distribution of the estimator. A typical assumption is that estimates will be normally distributed with repeated sampling (as dictated by the Central Limit Theorem). Wider confidence intervals correspond to poor estimates (smaller samples); narrow intervals correspond to better estimates (larger samples). If the null hypothesis asserts the value of a population parameter, the test rejects the null hypothesis when the hypothesized value lies outside the computed confidence interval for the parameter.

## Hypothesis Test Assumptions

Different hypothesis tests make different assumptions about the distribution of the random variable being sampled in the data. These assumptions must be considered when choosing a test and when interpreting the results.

For example, the  $z$ -test (`ztest`) and the  $t$ -test (`ttest`) both assume that the data are independently sampled from a normal distribution. Statistics Toolbox functions are available for testing this assumption, such as `chi2gof`, `jbtest`, `lillietest`, and `normplot`.

Both the  $z$ -test and the  $t$ -test are relatively robust with respect to departures from this assumption, so long as the sample size  $n$  is large enough. Both tests compute a sample mean  $\bar{x}$ , which, by the Central Limit Theorem, has an approximately normal sampling distribution with mean equal to the population mean  $\mu$ , regardless of the population distribution being sampled.

The difference between the  $z$ -test and the  $t$ -test is in the assumption of the standard deviation  $\sigma$  of the underlying normal distribution. A  $z$ -test assumes that  $\sigma$  is known; a  $t$ -test does not. As a result, a  $t$ -test must compute an estimate  $s$  of the standard deviation from the sample.

Test statistics for the  $z$ -test and the  $t$ -test are, respectively,

$$z = \frac{\bar{x} - \mu}{\sigma / \sqrt{n}}$$
$$t = \frac{\bar{x} - \mu}{s / \sqrt{n}}$$

Under the null hypothesis that the population is distributed with mean  $\mu$ , the  $z$ -statistic has a standard normal distribution,  $N(0,1)$ . Under the same null hypothesis, the  $t$ -statistic has Student's  $t$  distribution with  $n - 1$  degrees of freedom. For small sample sizes, Student's  $t$  distribution is flatter and wider than  $N(0,1)$ , compensating for the decreased confidence in the estimate  $s$ . As sample size increases, however, Student's  $t$  distribution approaches the standard normal distribution, and the two tests become essentially equivalent.

Knowing the distribution of the test statistic under the null hypothesis allows for accurate calculation of  $p$ -values. Interpreting  $p$ -values in the context of the test assumptions allows for critical analysis of test results.

Assumptions underlying Statistics Toolbox hypothesis tests are given in the reference pages for implementing functions.

## Hypothesis Testing

This example shows how to use hypothesis testing to analyze gas prices measured across the state of Massachusetts during two separate months.

This example uses the gas price data in the file `gas.mat`. The file contains two random samples of prices for a gallon of gas around the state of Massachusetts in 1993. The first sample, `price1`, contains 20 random observations around the state on a single day in January. The second sample, `price2`, contains 20 random observations around the state one month later.

```
load gas
prices = [price1 price2];
```

As a first step, you might want to test the assumption that the samples come from normal distributions. A normal probability plot gives a quick idea.

```
normplot(prices)
```

Both scatters approximately follow straight lines through the first and third quartiles of the samples, indicating approximate normal distributions. The February sample (the right-hand line) shows a slight departure from normality in the lower tail. A shift in the mean from January to February is evident. A hypothesis test is used to quantify the test of normality. Since each sample is relatively small, a Lilliefors test is recommended.

```
lillietest(price1)  
lillietest(price2)
```

```
ans =  
0
```

```
ans =  
0
```

The default significance level of `lillietest` is 5%. The logical 0 returned by each test indicates a failure to reject the null hypothesis that the samples are normally distributed. This failure may reflect normality in the population or it may reflect a lack of strong evidence against the null hypothesis due to the small sample size.

Now compute the sample means.

```
sample_means = mean(prices)
```

```
sample_means =  
115.1500 118.5000
```

You might want to test the null hypothesis that the mean price across the state on the day of the January sample was \$1.15. If you know that the standard deviation in prices across the state has historically, and consistently, been \$0.04, then a *z*-test is appropriate.

```
[h,pvalue,ci] = ztest(price1/100,1.15,0.04)
```

```
h =  
0
```

```
pvalue =  
  
    0.8668  
  
ci =  
  
    1.1340  
    1.1690
```

The logical output  $h = 0$  indicates a failure to reject the null hypothesis at the default significance level of 5%. This is a consequence of the high probability under the null hypothesis, indicated by the  $p$  value, of observing a value as extreme or more extreme of the  $z$ -statistic computed from the sample. The 95% confidence interval on the mean [1.1340 1.1690] includes the hypothesized population mean of \$1.15.

Does the later sample offer stronger evidence for rejecting a null hypothesis of a state-wide average price of \$1.15 in February? The shift shown in the probability plot and the difference in the computed sample means suggest this. The shift might indicate a significant fluctuation in the market, raising questions about the validity of using the historical standard deviation. If a known standard deviation cannot be assumed, a  $t$ -test is more appropriate.

```
[h,pvalue,ci] = ttest(price2/100,1.15)
```

```
h =  
  
    1  
  
pvalue =  
  
    4.9517e-04  
  
ci =
```

```
1.1675
1.2025
```

The logical output  $h = 1$  indicates a rejection of the null hypothesis at the default significance level of 5%. In this case, the 95% confidence interval on the mean does not include the hypothesized population mean of \$1.15.

You might want to investigate the shift in prices a little more closely. The function `ttest2` tests if two independent samples come from normal distributions with equal but unknown standard deviations and the same mean, against the alternative that the means are unequal.

```
[h,sig,ci] = ttest2(price1,price2)
```

```
h =
```

```
1
```

```
sig =
```

```
0.0083
```

```
ci =
```

```
-5.7845
```

```
-0.9155
```

The null hypothesis is rejected at the default 5% significance level, and the confidence interval on the difference of means does not include the hypothesized value of 0. A notched box plot is another way to visualize the shift.

```
boxplot(prices,1)
set(gca,'XTick',[1 2])
set(gca,'XtickLabel',{'January','February'})
```

The plot displays the distribution of the samples around their medians. The heights of the notches in each box are computed so that the side-by-side boxes have nonoverlapping notches when their medians are different at a default 5% significance level. The computation is based on an assumption of normality in the data, but the comparison is reasonably robust for other distributions. The side-by-side plots provide a kind of visual hypothesis test,

comparing medians rather than means. The plot above appears to barely reject the null hypothesis of equal medians.

The nonparametric Wilcoxon rank sum test, implemented by the function `ranksum`, can be used to quantify the test of equal medians. It tests if two independent samples come from identical continuous (not necessarily normal) distributions with equal medians, against the alternative that they do not have equal medians.

```
[p,h] = ranksum(price1,price2)
```

```
p =
```

```
0.0095
```

```
h =
```

```
1
```

The test rejects the null hypothesis of equal medians at the default 5% significance level.

## Available Hypothesis Tests

Function	Description
ansaribradley	Ansari-Bradley test. Tests if two independent samples come from the same distribution, against the alternative that they come from distributions that have the same median and shape but different variances.
barttest	Bartlett's test. Tests if the variances of the data values along each principal component are equal, against the alternative that the variances are not all equal.
chi2gof	Chi-square goodness-of-fit test. Tests if a sample comes from a specified distribution, against the alternative that it does not come from that distribution.
dwtest	Durbin-Watson test. Tests if the residuals from a linear regression are uncorrelated, against the alternative that there is autocorrelation among them.
friedman	Friedman's test. Tests if the column effects in a two-way layout are all the same, against the alternative that the column effects are not all the same.
jbtest	Jarque-Bera test. Tests if a sample comes from a normal distribution with unknown mean and variance, against the alternative that it does not come from a normal distribution.
kruskalwallis	Kruskal-Wallis test. Tests if multiple samples are all drawn from the same populations (or equivalently, from different populations with the same distribution), against the alternative that they are not all drawn from the same population.
kstest	One-sample Kolmogorov-Smirnov test. Tests if a sample comes from a continuous distribution with specified parameters, against the alternative that it does not come from that distribution.

<b>Function</b>	<b>Description</b>
<code>kstest2</code>	Two-sample Kolmogorov-Smirnov test. Tests if two samples come from the same continuous distribution, against the alternative that they do not come from the same distribution.
<code>lillietest</code>	Lilliefors test. Tests if a sample comes from a distribution in the normal family, against the alternative that it does not come from a normal distribution.
<code>linhypstest</code>	Linear hypothesis test. Tests if $H^*b = c$ for parameter estimates $b$ with estimated covariance $H$ and specified $c$ , against the alternative that $H^*b \neq c$ .
<code>ranksum</code>	Wilcoxon rank sum test. Tests if two independent samples come from identical continuous distributions with equal medians, against the alternative that they do not have equal medians.
<code>runstest</code>	Runs test. Tests if a sequence of values comes in random order, against the alternative that the ordering is not random.
<code>signrank</code>	One-sample or paired-sample Wilcoxon signed rank test. Tests if a sample comes from a continuous distribution symmetric about a specified median, against the alternative that it does not have that median.
<code>signtest</code>	One-sample or paired-sample sign test. Tests if a sample comes from an arbitrary continuous distribution with a specified median, against the alternative that it does not have that median.
<code>ttest</code>	One-sample or paired-sample $t$ -test. Tests if a sample comes from a normal distribution with unknown variance and a specified mean, against the alternative that it does not have that mean.

Function	Description
<code>ttest2</code>	Two-sample $t$ -test. Tests if two independent samples come from normal distributions with unknown but equal (or, optionally, unequal) variances and the same mean, against the alternative that the means are unequal.
<code>vartest</code>	One-sample chi-square variance test. Tests if a sample comes from a normal distribution with specified variance, against the alternative that it comes from a normal distribution with a different variance.
<code>vartest2</code>	Two-sample $F$ -test for equal variances. Tests if two independent samples come from normal distributions with the same variance, against the alternative that they come from normal distributions with different variances.
<code>vartestn</code>	Bartlett multiple-sample test for equal variances. Tests if multiple samples come from normal distributions with the same variance, against the alternative that they come from normal distributions with different variances.
<code>ztest</code>	One-sample $z$ -test. Tests if a sample comes from a normal distribution with known variance and specified mean, against the alternative that it does not have that mean.

---

**Note** In addition to the previous functions, Statistics Toolbox functions are available for analysis of variance (ANOVA), which perform hypothesis tests in the context of linear modeling.

## **Introduction to Analysis of Variance**

Analysis of variance (ANOVA) is a procedure for assigning sample variance to different sources and deciding whether the variation arises within or among different population groups. Samples are described in terms of variation around group means and variation of group means around an overall mean. If variations within groups are small relative to variations between groups, a difference in group means may be inferred. Hypothesis tests are used to quantify decisions.

### Introduction to One-Way ANOVA

The purpose of one-way ANOVA is to find out whether data from several groups have a common mean. That is, to determine whether the groups are actually different in the measured characteristic.

One-way ANOVA is a simple special case of the linear model. The one-way ANOVA form of the model is

$$y_{ij} = \alpha_{.j} + \varepsilon_{ij}$$

where:

- $y_{ij}$  is a matrix of observations in which each column represents a different group.

- $\alpha_j$  is a matrix whose columns are the group means. (The “dot  $j$ ” notation means that  $\alpha$  applies to all rows of column  $j$ . That is, the value  $\alpha_{ij}$  is the same for all  $i$ .)
- $\varepsilon_{ij}$  is a matrix of random disturbances.

The model assumes that the columns of  $y$  are a constant plus a random disturbance. You want to know if the constants are all the same.

### Example: One-Way ANOVA

The data below comes from a study by Hogg and Ledolter [48] of bacteria counts in shipments of milk. The columns of the matrix `hogg` represent different shipments. The rows are bacteria counts from cartons of milk chosen randomly from each shipment. Do some shipments have higher counts than others?

```
load hogg
hogg
hogg =
```

```
    24    14    11    7    19
    15     7     9    7    24
    21    12     7    4    19
    27    17    13    7    15
    33    14    12   12    10
    23    16    18   18    20
```

```
[p,tbl,stats] = anova1(hogg);
p
p =
    1.1971e-04
```

The standard ANOVA table has columns for the sums of squares, degrees of freedom, mean squares (SS/df),  $F$  statistic, and  $p$  value.

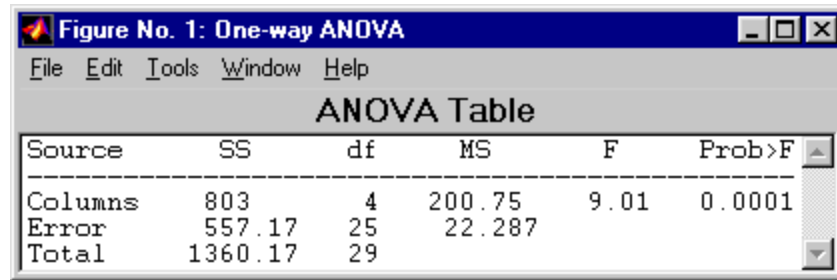

Figure No. 1: One-way ANOVA

File Edit Tools Window Help

ANOVA Table

Source	SS	df	MS	F	Prob>F
Columns	803	4	200.75	9.01	0.0001
Error	557.17	25	22.287		
Total	1360.17	29			

You can use the  $F$  statistic to do a hypothesis test to find out if the bacteria counts are the same. `anova1` returns the  $p$  value from this hypothesis test.

In this case the  $p$  value is about 0.0001, a very small value. This is a strong indication that the bacteria counts from the different shipments are not the same. An  $F$  statistic as extreme as the observed  $F$  would occur by chance only once in 10,000 times if the counts were truly equal.

The  $p$  value returned by `anova1` depends on assumptions about the random disturbances  $\varepsilon_{ij}$  in the model equation. For the  $p$  value to be correct, these disturbances need to be independent, normally distributed, and have constant variance.

You can get some graphical assurance that the means are different by looking at the box plots in the second figure window displayed by `anova1`. Note, however, that the notches are used for a comparison of medians, not a comparison of means. For more information on this display, see “Box Plots” on page 4-7.

### Multiple Comparisons

Sometimes you need to determine not just whether there are any differences among the means, but specifically which pairs of means are significantly different. It is tempting to perform a series of  $t$  tests, one for each pair of means, but this procedure has a pitfall.

In a  $t$  test, you compute a  $t$  statistic and compare it to a critical value. The critical value is chosen so that when the means are really the same (any apparent difference is due to random chance), the probability that the  $t$  statistic will exceed the critical value is small, say 5%. When the means are different, the probability that the statistic will exceed the critical value is larger.

In this example there are five means, so there are 10 pairs of means to compare. It stands to reason that if all the means are the same, and if there is a 5% chance of incorrectly concluding that there is a difference in one pair,

then the probability of making at least one incorrect conclusion among all 10 pairs is much larger than 5%.

Fortunately, there are procedures known as *multiple comparison procedures* that are designed to compensate for multiple tests.

### Example: Multiple Comparisons

You can perform a multiple comparison test using the `multcompare` function and supplying it with the `stats` output from `anova1`.

```
load hogg
[p,tbl,stats] = anova1(hogg);
[c,m] = multcompare(stats)
c =
    1.0000    2.0000    2.4953   10.5000   18.5047
    1.0000    3.0000    4.1619   12.1667   20.1714
    1.0000    4.0000    6.6619   14.6667   22.6714
    1.0000    5.0000   -2.0047    6.0000   14.0047
    2.0000    3.0000   -6.3381    1.6667    9.6714
    2.0000    4.0000   -3.8381    4.1667   12.1714
    2.0000    5.0000  -12.5047   -4.5000    3.5047
    3.0000    4.0000   -5.5047    2.5000   10.5047
    3.0000    5.0000  -14.1714   -6.1667    1.8381
    4.0000    5.0000  -16.6714   -8.6667   -0.6619
m =
    23.8333    1.9273
    13.3333    1.9273
    11.6667    1.9273
     9.1667    1.9273
    17.8333    1.9273
```

The first output from `multcompare` has one row for each pair of groups, with an estimate of the difference in group means and a confidence interval for that group. For example, the second row has the values

```
1.0000    3.0000    4.1619   12.1667   20.1714
```

indicating that the mean of group 1 minus the mean of group 3 is estimated to be 12.1667, and a 95% confidence interval for this difference is

[4.1619, 20.1714]. This interval does not contain 0, so you can conclude that the means of groups 1 and 3 are different.

The second output contains the mean and its standard error for each group.

It is easier to visualize the difference between group means by looking at the graph that `multcompare` produces.

There are five groups. The graph instructs you to **Click on the group you want to test**. Three groups have slopes significantly different from group one.

The graph shows that group 1 is significantly different from groups 2, 3, and 4. By using the mouse to select group 4, you can determine that it is also significantly different from group 5. Other pairs are not significantly different.

## Two-Way ANOVA

- “Introduction to Two-Way ANOVA” on page 8-9
- “Example: Two-Way ANOVA” on page 8-10

### Introduction to Two-Way ANOVA

The purpose of two-way ANOVA is to find out whether data from several groups have a common mean. One-way ANOVA and two-way ANOVA differ in that the groups in two-way ANOVA have two categories of defining characteristics instead of one.

Suppose an automobile company has two factories, and each factory makes the same three models of car. It is reasonable to ask if the gas mileage in the cars varies from factory to factory as well as from model to model. There are two predictors, factory and model, to explain differences in mileage.

There could be an overall difference in mileage due to a difference in the production methods between factories. There is probably a difference in the mileage of the different models (irrespective of the factory) due to differences in design specifications. These effects are called *additive*.

Finally, a factory might make high mileage cars in one model (perhaps because of a superior production line), but not be different from the other factory for other models. This effect is called an *interaction*. It is impossible to detect an interaction unless there are duplicate observations for some combination of factory and car model.

Two-way ANOVA is a special case of the linear model. The two-way ANOVA form of the model is

$$y_{ijk} = \mu + \alpha_{.j} + \beta_i + \gamma_{ij} + \varepsilon_{ijk}$$

where, with respect to the automobile example above:

- $y_{ijk}$  is a matrix of gas mileage observations (with row index  $i$ , column index  $j$ , and repetition index  $k$ ).
- $\mu$  is a constant matrix of the overall mean gas mileage.

- $\alpha_j$  is a matrix whose columns are the deviations of each car's gas mileage (from the mean gas mileage  $\mu$ ) that are attributable to the car's *model*. All values in a given column of  $\alpha_j$  are identical, and the values in each row of  $\alpha_j$  sum to 0.
- $\beta_i$  is a matrix whose rows are the deviations of each car's gas mileage (from the mean gas mileage  $\mu$ ) that are attributable to the car's *factory*. All values in a given row of  $\beta_i$  are identical, and the values in each column of  $\beta_i$  sum to 0.
- $\gamma_{ij}$  is a matrix of interactions. The values in each row of  $\gamma_{ij}$  sum to 0, and the values in each column of  $\gamma_{ij}$  sum to 0.
- $\varepsilon_{ijk}$  is a matrix of random disturbances.

### Example: Two-Way ANOVA

The purpose of the example is to determine the effect of car model and factory on the mileage rating of cars.

```
load mileage
mileage
```

```
mileage =
```

```

33.3000  34.5000  37.4000
33.4000  34.8000  36.8000
32.9000  33.8000  37.6000
32.6000  33.4000  36.6000
32.5000  33.7000  37.0000
33.0000  33.9000  36.7000
```

```
cars = 3;
[p,tbl,stats] = anova2(mileage,cars);
p
```

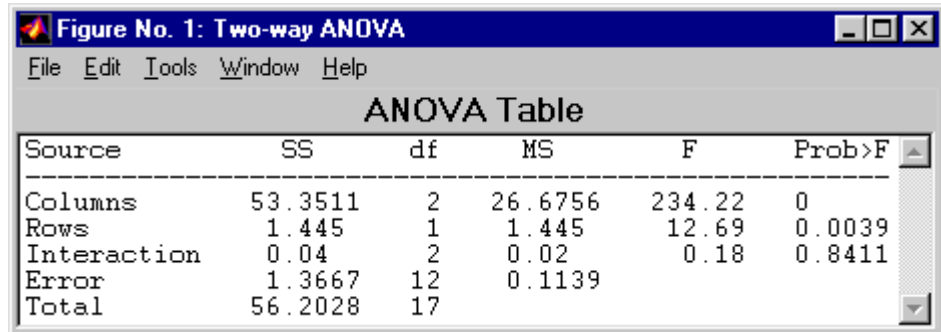

```
p =
0.0000    0.0039    0.8411
```

There are three models of cars (columns) and two factories (rows). The reason there are six rows in `mileage` instead of two is that each factory provides

three cars of each model for the study. The data from the first factory is in the first three rows, and the data from the second factory is in the last three rows.

The standard ANOVA table has columns for the sums of squares, degrees-of-freedom, mean squares (SS/df),  $F$  statistics, and  $p$ -values.

Source	SS	df	MS	F	Prob>F
Columns	53.3511	2	26.6756	234.22	0
Rows	1.445	1	1.445	12.69	0.0039
Interaction	0.04	2	0.02	0.18	0.8411
Error	1.3667	12	0.1139		
Total	56.2028	17			

You can use the  $F$  statistics to do hypotheses tests to find out if the mileage is the same across models, factories, and model-factory pairs (after adjusting for the additive effects). `anova2` returns the  $p$  value from these tests.

The  $p$  value for the model effect is zero to four decimal places. This is a strong indication that the mileage varies from one model to another. An  $F$  statistic as extreme as the observed  $F$  would occur by chance less than once in 10,000 times if the gas mileage were truly equal from model to model. If you used the `multcompare` function to perform a multiple comparison test, you would find that each pair of the three models is significantly different.

The  $p$  value for the factory effect is 0.0039, which is also highly significant. This indicates that one factory is out-performing the other in the gas mileage of the cars it produces. The observed  $p$  value indicates that an  $F$  statistic as extreme as the observed  $F$  would occur by chance about four out of 1000 times if the gas mileage were truly equal from factory to factory.

There does not appear to be any interaction between factories and models. The  $p$  value, 0.8411, means that the observed result is quite likely (84 out of 100 times) given that there is no interaction.

The  $p$ -values returned by `anova2` depend on assumptions about the random disturbances  $\varepsilon_{ijk}$  in the model equation. For the  $p$ -values to be correct these disturbances need to be independent, normally distributed, and have constant variance.

In addition, `anova2` requires that data be *balanced*, which in this case means there must be the same number of cars for each combination of model and factory. The next section discusses a function that supports unbalanced data with any number of predictors.

## N-Way ANOVA

- “Introduction to N-Way ANOVA” on page 8-12
- “N-Way ANOVA with a Small Data Set” on page 8-13
- “N-Way ANOVA with a Large Data Set” on page 8-15
- “ANOVA with Random Effects” on page 8-19

### Introduction to N-Way ANOVA

You can use N-way ANOVA to determine if the means in a set of data differ when grouped by multiple factors. If they do differ, you can determine which factors or combinations of factors are associated with the difference.

N-way ANOVA is a generalization of two-way ANOVA. For three factors, the model can be written

$$y_{ijkl} = \mu + \alpha_{.j.} + \beta_{i..} + \gamma_{..k} + (\alpha\beta)_{ij.} + (\alpha\gamma)_{i.k} + (\beta\gamma)_{.jk} + (\alpha\beta\gamma)_{ijk} + \varepsilon_{ijkl}$$

In this notation parameters with two subscripts, such as  $(\alpha\beta)_{ij.}$ , represent the interaction effect of two factors. The parameter  $(\alpha\beta\gamma)_{ijk}$  represents the three-way interaction. An ANOVA model can have the full set of parameters or any subset, but conventionally it does not include complex interaction terms unless it also includes all simpler terms for those factors. For example, one would generally not include the three-way interaction without also including all two-way interactions.

The `anovan` function performs N-way ANOVA. Unlike the `anova1` and `anova2` functions, `anovan` does not expect data in a tabular form. Instead, it expects a vector of response measurements and a separate vector (or text array) containing the values corresponding to each factor. This input data format is more convenient than matrices when there are more than two factors or when the number of measurements per factor combination is not constant.

### N-Way ANOVA with a Small Data Set

Consider the following two-way example using `anova2`.

```
m = [23 15 20;27 17 63;43 3 55;41 9 90]
m =
    23    15    20
    27    17    63
    43     3    55
    41     9    90
```

```
anova2(m,2)
```

```
ans =
    0.0197    0.2234    0.2663
```

The factor information is implied by the shape of the matrix `m` and the number of measurements at each factor combination (2). Although `anova2` does not actually require arrays of factor values, for illustrative purposes you could create them as follows.

```
cfactor = repmat(1:3,4,1)

cfactor =
     1     2     3
     1     2     3
     1     2     3
     1     2     3

rfactor = [ones(2,3); 2*ones(2,3)]

rfactor =
     1     1     1
```

```
1    1    1
2    2    2
2    2    2
```

The `cfactor` matrix shows that each column of `m` represents a different level of the column factor. The `rfactor` matrix shows that the top two rows of `m` represent one level of the row factor, and bottom two rows of `m` represent a second level of the row factor. In other words, each value `m(i, j)` represents an observation at column factor level `cfactor(i, j)` and row factor level `rfactor(i, j)`.

To solve the above problem with `anovan`, you need to reshape the matrices `m`, `cfactor`, and `rfactor` to be vectors.

```
m = m(:);
cfactor = cfactor(:);
rfactor = rfactor(:);
```

```
[m cfactor rfactor]
```

```
ans =
```

```
23    1    1
27    1    1
43    1    2
41    1    2
15    2    1
17    2    1
 3    2    2
 9    2    2
20    3    1
63    3    1
55    3    2
90    3    2
```

```
anovan(m, {cfactor rfactor}, 2)
```

```
ans =
```

```
0.0197
```

```
0.2234
0.2663
```

## N-Way ANOVA with a Large Data Set

The previous example used `anova2` to study a small data set measuring car mileage. This example illustrates how to analyze a larger set of car data with mileage and other information on 406 cars made between 1970 and 1982. First, load the data set and look at the variable names.

```
load carbig
whos
```

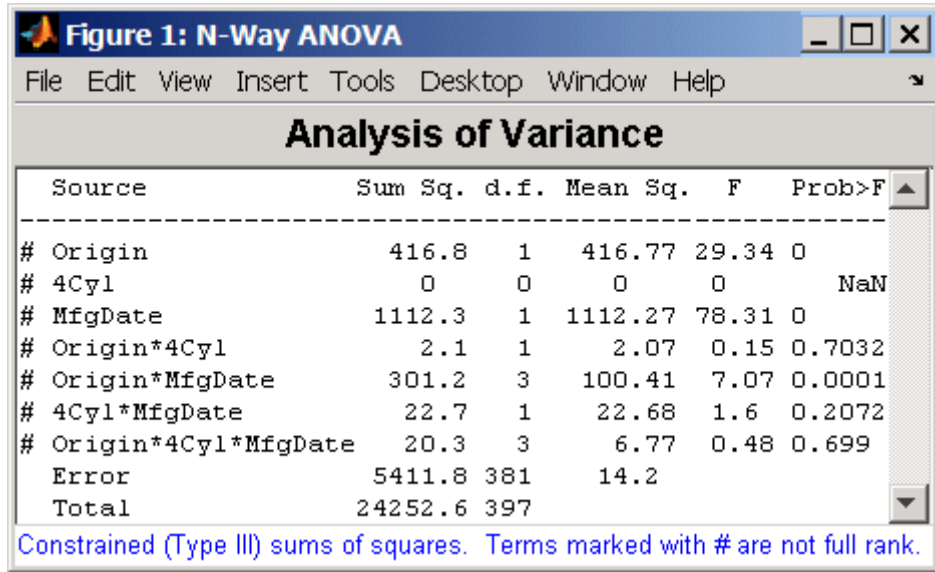

Name	Size	Bytes	Class
Acceleration	406x1	3248	double array
Cylinders	406x1	3248	double array
Displacement	406x1	3248	double array
Horsepower	406x1	3248	double array
MPG	406x1	3248	double array
Model	406x36	29232	char array
Model_Year	406x1	3248	double array
Origin	406x7	5684	char array
Weight	406x1	3248	double array
cyl4	406x5	4060	char array
org	406x7	5684	char array
when	406x5	4060	char array

The example focusses on four variables. MPG is the number of miles per gallon for each of 406 cars (though some have missing values coded as NaN). The other three variables are factors: `cyl4` (four-cylinder car or not), `org` (car originated in Europe, Japan, or the USA), and `when` (car was built early in the period, in the middle of the period, or late in the period).

First, fit the full model, requesting up to three-way interactions and Type 3 sums-of-squares.

```
varnames = {'Origin';'4Cyl';'MfgDate'};
anovan(MPG,{org cyl4 when},3,3,varnames)
ans =
    0.0000
```

NaN  
 0  
 0.7032  
 0.0001  
 0.2072  
 0.6990

Note that many terms are marked by a # symbol as not having full rank, and one of them has zero degrees of freedom and is missing a  $p$  value. This can happen when there are missing factor combinations and the model has higher-order terms. In this case, the cross-tabulation below shows that there are no cars made in Europe during the early part of the period with other than four cylinders, as indicated by the 0 in `table(2,1,1)`.

```
[table, chi2, p, factorvals] = crosstab(org,when,cyl4)
```

```
table(:, :, 1) =
```

```
82  75  25
 0   4   3
 3   3   4
```

```

table(:, :, 2) =
    12    22    38
    23    26    17
    12    25    32

chi2 =

    207.7689

p =

    0

factorvals =

    'USA'      'Early'    'Other'
    'Europe'  'Mid'      'Four'
    'Japan'   'Late'     []

```

Consequently it is impossible to estimate the three-way interaction effects, and including the three-way interaction term in the model makes the fit singular.

Using even the limited information available in the ANOVA table, you can see that the three-way interaction has a  $p$  value of 0.699, so it is not significant. So this time you examine only two-way interactions.

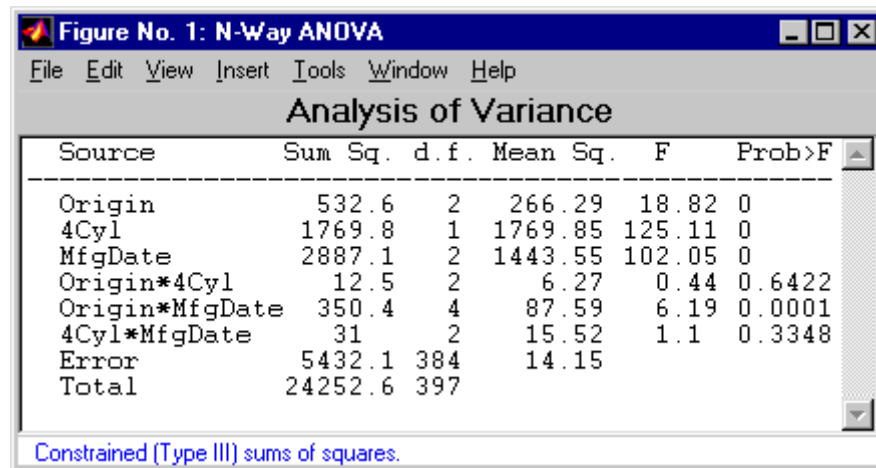

```

[p,tbl,stats,terms] = anovan(MPG,{org cyl4 when},2,3,varnames);
terms

terms =

    1     0     0
    0     1     0
    0     0     1
    1     1     0
    1     0     1
    0     1     1

```

Constrained (Type III) sums of squares.

Now all terms are estimable. The  $p$ -values for interaction term 4 (Origin\*4Cyl) and interaction term 6 (4Cyl\*MfgDate) are much larger than a typical cutoff value of 0.05, indicating these terms are not significant. You could choose to omit these terms and pool their effects into the error term. The output terms variable returns a matrix of codes, each of which is a bit pattern representing a term. You can omit terms from the model by deleting their entries from terms and running anovan again, this time supplying the resulting vector as the model argument.

```
terms([4 6],:) = []
```

```
terms =
```

```

1    0    0
0    1    0
0    0    1

Constrained (Type III) sums of squares.

Now you have a more parsimonious model indicating that the mileage of these cars seems to be related to all three factors, and that the effect of the manufacturing date depends on where the car was made.

## ANOVA with Random Effects

- “Introduction to ANOVA with Random Effects” on page 8-19
- “Setting Up the Model” on page 8-20
- “Fitting a Random Effects Model” on page 8-21
- “F Statistics for Models with Random Effects” on page 8-22
- “Variance Components” on page 8-24

**Introduction to ANOVA with Random Effects.** In an ordinary ANOVA model, each grouping variable represents a fixed factor. The levels of that factor are a fixed set of values. Your goal is to determine whether different factor levels lead to different response values. This section presents an example that shows how to use anovan to fit models where a factor’s levels represent a random selection from a larger (infinite) set of possible levels.

**Setting Up the Model.** To set up the example, first load the data, which is stored in a 6-by-3 matrix, `mileage`.

```
load mileage
```

The `anova2` function works only with balanced data, and it infers the values of the grouping variables from the row and column numbers of the input matrix. The `anovan` function, on the other hand, requires you to explicitly create vectors of grouping variable values. To create these vectors, do the following steps:

- 1 Create an array indicating the factory for each value in `mileage`. This array is 1 for the first column, 2 for the second, and 3 for the third.

```
factory = repmat(1:3,6,1);
```

- 2 Create an array indicating the car model for each mileage value. This array is 1 for the first three rows of `mileage`, and 2 for the remaining three rows.

```
carmod = [ones(3,3); 2*ones(3,3)];
```

- 3 Turn these matrices into vectors and display them.

```
mileage = mileage(:);  
factory = factory(:);  
carmod = carmod(:);  
[mileage factory carmod]
```

```
ans =
```

```
33.3000    1.0000    1.0000  
33.4000    1.0000    1.0000  
32.9000    1.0000    1.0000  
32.6000    1.0000    2.0000  
32.5000    1.0000    2.0000  
33.0000    1.0000    2.0000  
34.5000    2.0000    1.0000  
34.8000    2.0000    1.0000  
33.8000    2.0000    1.0000  
33.4000    2.0000    2.0000  
33.7000    2.0000    2.0000
```

33.9000	2.0000	2.0000
37.4000	3.0000	1.0000
36.8000	3.0000	1.0000
37.6000	3.0000	1.0000
36.6000	3.0000	2.0000
37.0000	3.0000	2.0000
36.7000	3.0000	2.0000

**Fitting a Random Effects Model.** Continuing the example from the preceding section, suppose you are studying a few factories but you want information about what would happen if you build these same car models in a different factory—either one that you already have or another that you might construct. To get this information, fit the analysis of variance model, specifying a model that includes an interaction term and that the factory factor is random.

```
[pvals,tbl,stats] = anovan(mileage, {factory carmod}, ...
    'model',2, 'random',1,'varnames',{'Factory' 'Car Model'});
```

Source	Sum Sq.	d.f.	Mean Sq.	F	Prob>F
Factory	53.3511	2	26.6756	1333.78	0.0007
Car Model	1.445	1	1.445	72.25	0.0136
Factory*Car Model	0.04	2	0.02	0.18	0.8411
Error	1.3667	12	0.1139		
Total	56.2028	17			

Constrained (Type III) sums of squares.

In the fixed effects version of this fit, which you get by omitting the inputs 'random', 1 in the preceding code, the effect of car model is significant, with a  $p$  value of 0.0039. But in this example, which takes into account the random variation of the effect of the variable 'Car Model' from one factory to another, the effect is still significant, but with a higher  $p$  value of 0.0136.

**F Statistics for Models with Random Effects.** The  $F$  statistic in a model having random effects is defined differently than in a model having all fixed effects. In the fixed effects model, you compute the  $F$  statistic for any term by taking the ratio of the mean square for that term with the mean square for error. In a random effects model, however, some  $F$  statistics use a different mean square in the denominator.

In the example described in “Setting Up the Model” on page 8-20, the effect of the variable 'Factory' could vary across car models. In this case, the interaction mean square takes the place of the error mean square in the  $F$  statistic. The  $F$  statistic for factory is:

$$F = 26.6756 / 0.02$$

$$F =$$

$$1333.78$$

The degrees of freedom for the statistic are the degrees of freedom for the numerator (2) and denominator (2) mean squares. Therefore the  $p$  value for the statistic is:

$$pval = 1 - fcdf(F,2,2)$$

$$pval =$$

$$7.4919e-04$$

With random effects, the expected value of each mean square depends not only on the variance of the error term, but also on the variances contributed by the random effects. You can see these dependencies by writing the expected values as linear combinations of contributions from the various model terms. To find the coefficients of these linear combinations, enter `stats.ems`, which returns the `ems` field of the `stats` structure:

```
stats.ems
```

```
ans =
```

```
6.0000    0.0000    3.0000    1.0000
0.0000    9.0000    3.0000    1.0000
```

```

0.0000    0.0000    3.0000    1.0000
      0          0          0    1.0000

```

To see text representations of the linear combinations, enter

```
stats.txtems
```

```
ans =
```

```

'6*V(Factory)+3*V(Factory*Car Model)+V(Error) '
'9*Q(Car Model)+3*V(Factory*Car Model)+V(Error) '
'3*V(Factory*Car Model)+V(Error) '
'V(Error) '

```

The expected value for the mean square due to car model (second term) includes contributions from a quadratic function of the car model effects, plus three times the variance of the interaction term's effect, plus the variance of the error term. Notice that if the car model effects were all zero, the expression would reduce to the expected mean square for the third term (the interaction term). That is why the  $F$  statistic for the car model effect uses the interaction mean square in the denominator.

In some cases there is no single term whose expected value matches the one required for the denominator of the  $F$  statistic. In that case, the denominator is a linear combination of mean squares. The `stats` structure contains fields giving the definitions of the denominators for each  $F$  statistic. The `txtdenom` field, `stats.txtdenom`, gives a text representation, and the `denom` field gives a matrix that defines a linear combination of the variances of terms in the model. For balanced models like this one, the `denom` matrix, `stats.denom`, contains zeros and ones, because the denominator is just a single term's mean square:

```
stats.txtdenom
```

```
ans =
```

```

'MS(Factory*Car Model) '
'MS(Factory*Car Model) '
'MS(Error) '

```

```
stats.denom
```

```
ans =  
  
-0.0000    1.0000    0.0000  
 0.0000    1.0000   -0.0000  
 0.0000         0    1.0000
```

**Variance Components.** For the model described in “Setting Up the Model” on page 8-20, consider the mileage for a particular car of a particular model made at a random factory. The variance of that car is the sum of components, or contributions, one from each of the random terms.

```
stats.rtnames
```

```
ans =  
  
  'Factory'  
  'Factory*Car Model'  
  'Error'
```

You do not know those variances, but you can estimate them from the data. Recall that the `ems` field of the `stats` structure expresses the expected value of each term’s mean square as a linear combination of unknown variances for random terms, and unknown quadratic forms for fixed terms. If you take the expected mean square expressions for the random terms, and equate those expected values to the computed mean squares, you get a system of equations that you can solve for the unknown variances. These solutions are the variance component estimates. The `varest` field contains a variance component estimate for each term. The `rtnames` field contains the names of the random terms.

```
stats.varest
```

```
ans =  
  
  4.4426  
 -0.0313  
  0.1139
```

Under some conditions, the variability attributed to a term is unusually low, and that term’s variance component estimate is negative. In those cases it

is common to set the estimate to zero, which you might do, for example, to create a bar graph of the components.

```
bar(max(0,stats.varest))
set(gca,'xtick',1:3,'xticklabel',stats.rtnames)
```

You can also compute confidence bounds for the variance estimate. The `anovan` function does this by computing confidence bounds for the variance expected mean squares, and finding lower and upper limits on each variance component containing all of these bounds. This procedure leads to a set of bounds that is conservative for balanced data. (That is, 95% confidence bounds will have a probability of at least 95% of containing the true variances if the number of observations for each combination of grouping variables is the same.) For unbalanced data, these are approximations that are not guaranteed to be conservative.

```
[{'Term' 'Estimate' 'Lower' 'Upper'};
 stats.rtnames, num2cell([stats.varest stats.varci])]
```

```
ans =
```

```
    'Term'                'Estimate'    'Lower'    'Upper'
```

```

'Factory'          [ 4.4426]    [1.0736]    [175.6038]
'Factory*Car Model' [ -0.0313]   [   NaN]    [   NaN]
'Error'           [ 0.1139]   [0.0586]    [ 0.3103]

```

## Other ANOVA Models

The `anovan` function also has arguments that enable you to specify two other types of model terms. First, the `'nested'` argument specifies a matrix that indicates which factors are nested within other factors. A nested factor is one that takes different values within each level its nested factor.

For example, the mileage data from the previous section assumed that the two car models produced in each factory were the same. Suppose instead, each factory produced two distinct car models for a total of six car models, and we numbered them 1 and 2 for each factory for convenience. Then, the car model is nested in factory. A more accurate and less ambiguous numbering of car model would be as follows:

<b>Factory</b>	<b>Car Model</b>
1	1
1	2
2	3
2	4
3	5
3	6

However, it is common with nested models to number the nested factor the same way in each nested factor.

Second, the `'continuous'` argument specifies that some factors are to be treated as continuous variables. The remaining factors are categorical variables. Although the `anovan` function can fit models with multiple continuous and categorical predictors, the simplest model that combines one predictor of each type is known as an *analysis of covariance* model. The next section describes a specialized tool for fitting this model.

## Analysis of Covariance

- “Introduction to Analysis of Covariance” on page 8-27
- “Analysis of Covariance Tool” on page 8-27
- “Confidence Bounds” on page 8-31
- “Multiple Comparisons” on page 8-34

### Introduction to Analysis of Covariance

Analysis of covariance is a technique for analyzing grouped data having a response ( $y$ , the variable to be predicted) and a predictor ( $x$ , the variable used to do the prediction). Using analysis of covariance, you can model  $y$  as a linear function of  $x$ , with the coefficients of the line possibly varying from group to group.

### Analysis of Covariance Tool

The `aocool` function opens an interactive graphical environment for fitting and prediction with analysis of covariance (ANOCOVA) models. It fits the following models for the  $i$ th group:

Same mean	$y = a + \varepsilon$
Separate means	$y = (a + a_i) + \varepsilon$
Same line	$y = a + \beta x + \varepsilon$
Parallel lines	$y = (a + a_i) + \beta x + \varepsilon$
Separate lines	$y = (a + a_i) + (\beta + \beta_i)x + \varepsilon$

For example, in the parallel lines model the intercept varies from one group to the next, but the slope is the same for each group. In the same mean model, there is a common intercept and no slope. In order to make the group coefficients well determined, the tool imposes the constraints

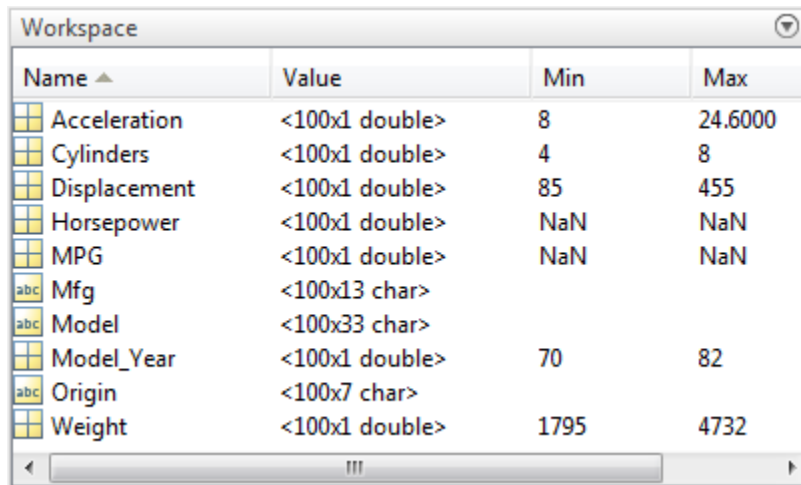

$$\sum \alpha_j = \sum \beta_j = 0$$

The following steps describe the use of `aocool`.

- 1 Load the data.** The Statistics Toolbox data set `carsmall.mat` contains information on cars from the years 1970, 1976, and 1982. This example studies the relationship between the weight of a car and its mileage, and whether this relationship has changed over the years. To start the demonstration, load the data set.

```
load carsmall
```

The Workspace Browser shows the variables in the data set.

Name	Value	Min	Max
Acceleration	<100x1 double>	8	24.6000
Cylinders	<100x1 double>	4	8
Displacement	<100x1 double>	85	455
Horsepower	<100x1 double>	NaN	NaN
MPG	<100x1 double>	NaN	NaN
Mfg	<100x13 char>		
Model	<100x33 char>		
Model_Year	<100x1 double>	70	82
Origin	<100x7 char>		
Weight	<100x1 double>	1795	4732

You can also use `aoctool` with your own data.

- 2 Start the tool.** The following command calls `aoctool` to fit a separate line to the column vectors `Weight` and `MPG` for each of the three model group defined in `Model_Year`. The initial fit models the  $y$  variable, `MPG`, as a linear function of the  $x$  variable, `Weight`.

```
[h,atab,ctab,stats] = aoctool(Weight,MPG,Model_Year);
```

See the `aoctool` function reference page for detailed information about calling `aoctool`.

- 3 Examine the output.** The graphical output consists of a main window with a plot, a table of coefficient estimates, and an analysis of variance table. In the plot, each `Model_Year` group has a separate line. The data

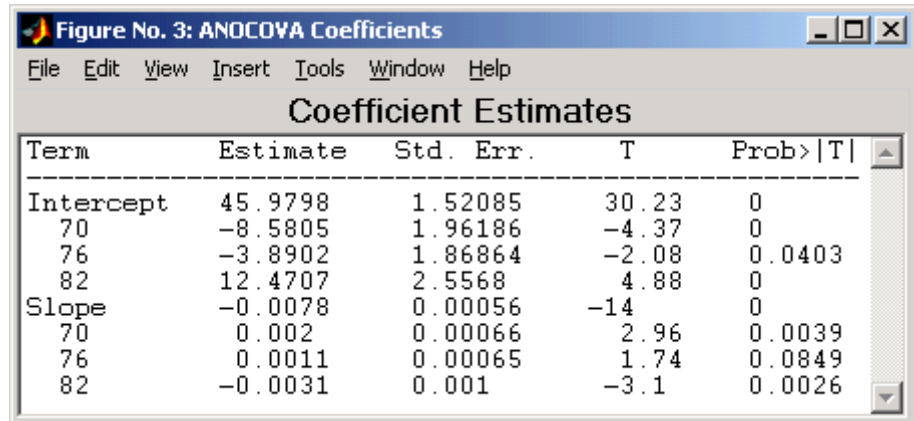

points for each group are coded with the same color and symbol, and the fit for each group has the same color as the data points.

The coefficients of the three lines appear in the figure titled ANCOVA Coefficients. You can see that the slopes are roughly  $-0.0078$ , with a small deviation for each group:

- Model year 1970:  $y = (45.9798 - 8.5805) + (-0.0078 + 0.002)x + \varepsilon$
- Model year 1976:  $y = (45.9798 - 3.8902) + (-0.0078 + 0.0011)x + \varepsilon$

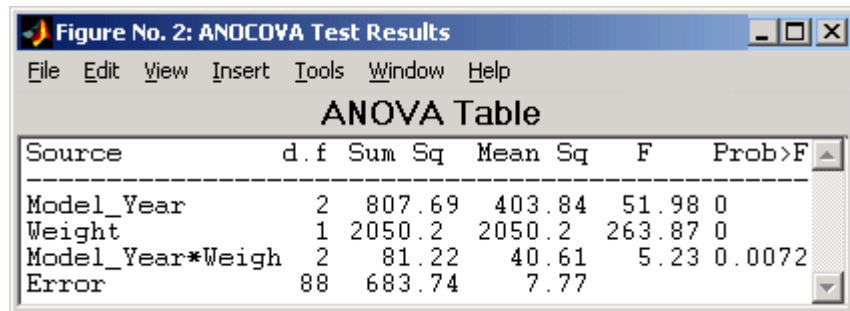

- Model year 1982:  $y = (45.9798 + 12.4707) + (-0.0078 - 0.0031)x + \varepsilon$

**Figure No. 3: ANCOVA Coefficients**

Term	Estimate	Std. Err.	T	Prob> T
Intercept	45.9798	1.52085	30.23	0
70	-8.5805	1.96186	-4.37	0
76	-3.8902	1.86864	-2.08	0.0403
82	12.4707	2.5568	4.88	0
Slope	-0.0078	0.00056	-14	0
70	0.002	0.00066	2.96	0.0039
76	0.0011	0.00065	1.74	0.0849
82	-0.0031	0.001	-3.1	0.0026

Because the three fitted lines have slopes that are roughly similar, you may wonder if they really are the same. The `Model_Year*Weight` interaction expresses the difference in slopes, and the ANOVA table shows a test for the significance of this term. With an  $F$  statistic of 5.23 and a  $p$  value of 0.0072, the slopes are significantly different.

**Figure No. 2: ANCOVA Test Results**

Source	d.f	Sum Sq	Mean Sq	F	Prob>F
Model_Year	2	807.69	403.84	51.98	0
Weight	1	2050.2	2050.2	263.87	0
Model_Year*Weigh	2	81.22	40.61	5.23	0.0072
Error	88	683.74	7.77		

- 4 Constrain the slopes to be the same.** To examine the fits when the slopes are constrained to be the same, return to the ANCOVA Prediction Plot window and use the **Model** pop-up menu to select a **Parallel Lines** model. The window updates to show the following graph.

Though this fit looks reasonable, it is significantly worse than the Separate Lines model. Use the **Model** pop-up menu again to return to the original model.

### Confidence Bounds

The example in “Analysis of Covariance Tool” on page 8-27 provides estimates of the relationship between MPG and Weight for each Model\_Year, but how accurate are these estimates? To find out, you can superimpose confidence bounds on the fits by examining them one group at a time.

- 1 In the **Model\_Year** menu at the lower right of the figure, change the setting from All Groups to 82. The data and fits for the other groups are dimmed, and confidence bounds appear around the 82 fit.

The dashed lines form an envelope around the fitted line for model year 82. Under the assumption that the true relationship is linear, these bounds provide a 95% confidence region for the true line. Note that the fits for the other model years are well outside these confidence bounds for Weight values between 2000 and 3000.

- 2 Sometimes it is more valuable to be able to predict the response value for a new observation, not just estimate the average response value. Use the

aoctool function **Bounds** menu to change the definition of the confidence bounds from Line to Observation. The resulting wider intervals reflect the uncertainty in the parameter estimates as well as the randomness of a new observation.

Like the polytool function, the aoctool function has cross hairs that you can use to manipulate the Weight and watch the estimate and confidence bounds along the y-axis update. These values appear only when a single group is selected, not when All Groups is selected.

## Multiple Comparisons

You can perform a multiple comparison test by using the `stats` output structure from `aocool` as input to the `multcompare` function. The `multcompare` function can test either slopes, intercepts, or population marginal means (the predicted MPG of the mean weight for each group). The example in “Analysis of Covariance Tool” on page 8-27 shows that the slopes are not all the same, but could it be that two are the same and only the other one is different? You can test that hypothesis.

```
multcompare(stats,0.05,'on',' ','s')
```

```
ans =  
    1.0000    2.0000   -0.0012    0.0008    0.0029  
    1.0000    3.0000    0.0013    0.0051    0.0088  
    2.0000    3.0000    0.0005    0.0042    0.0079
```

This matrix shows that the estimated difference between the intercepts of groups 1 and 2 (1970 and 1976) is 0.0008, and a confidence interval for the difference is  $[-0.0012, 0.0029]$ . There is no significant difference between the two. There are significant differences, however, between the intercept for 1982 and each of the other two. The graph shows the same information.

Note that the `stats` structure was created in the initial call to the `aocool` function, so it is based on the initial model fit (typically a separate-lines model). If you change the model interactively and want to base your multiple comparisons on the new model, you need to run `aocool` again to get another `stats` structure, this time specifying your new model as the initial model.

## Nonparametric Methods

- “Introduction to Nonparametric Methods” on page 8-36

- “Kruskal-Wallis Test” on page 8-36
- “Friedman’s Test” on page 8-37

## Introduction to Nonparametric Methods

Statistics Toolbox functions include nonparametric versions of one-way and two-way analysis of variance. Unlike classical tests, nonparametric tests make only mild assumptions about the data, and are appropriate when the distribution of the data is non-normal. On the other hand, they are less powerful than classical methods for normally distributed data.

Both of the nonparametric functions described here will return a `stats` structure that can be used as an input to the `multcompare` function for multiple comparisons.

## Kruskal-Wallis Test

The example “Example: One-Way ANOVA” on page 8-4 uses one-way analysis of variance to determine if the bacteria counts of milk varied from shipment to shipment. The one-way analysis rests on the assumption that the measurements are independent, and that each has a normal distribution with a common variance and with a mean that was constant in each column. You can conclude that the column means were not all the same. The following example repeats that analysis using a nonparametric procedure.

The Kruskal-Wallis test is a nonparametric version of one-way analysis of variance. The assumption behind this test is that the measurements come from a continuous distribution, but not necessarily a normal distribution. The test is based on an analysis of variance using the ranks of the data values, not the data values themselves. Output includes a table similar to an ANOVA table, and a box plot.

You can run this test as follows:

```
load hogg

p = kruskalwallis(hogg)
p =
    0.0020
```

The low  $p$  value means the Kruskal-Wallis test results agree with the one-way analysis of variance results.

### Friedman's Test

“Example: Two-Way ANOVA” on page 8-10 uses two-way analysis of variance to study the effect of car model and factory on car mileage. The example tests whether either of these factors has a significant effect on mileage, and whether there is an interaction between these factors. The conclusion of the example is there is no interaction, but that each individual factor has a significant effect. The next example examines whether a nonparametric analysis leads to the same conclusion.

Friedman's test is a nonparametric test for data having a two-way layout (data grouped by two categorical factors). Unlike two-way analysis of variance, Friedman's test does not treat the two factors symmetrically and it does not test for an interaction between them. Instead, it is a test for whether the columns are different after adjusting for possible row differences. The test is based on an analysis of variance using the ranks of the data across categories of the row factor. Output includes a table similar to an ANOVA table.

You can run Friedman's test as follows.

```
load mileage
p = friedman(mileage,3)
p =
    7.4659e-004
```

Recall the classical analysis of variance gave a  $p$  value to test column effects, row effects, and interaction effects. This  $p$  value is for column effects. Using either this  $p$  value or the  $p$  value from ANOVA ( $p < 0.0001$ ), you conclude that there are significant column effects.

In order to test for row effects, you need to rearrange the data to swap the roles of the rows in columns. For a data matrix  $x$  with no replications, you could simply transpose the data and type

```
p = friedman(x')
```

With replicated data it is slightly more complicated. A simple way is to transform the matrix into a three-dimensional array with the first dimension

representing the replicates, swapping the other two dimensions, and restoring the two-dimensional shape.

```
x = reshape(mileage, [3 2 3]);  
x = permute(x,[1 3 2]);  
x = reshape(x,[9 2])  
x =  
    33.3000    32.6000  
    33.4000    32.5000  
    32.9000    33.0000  
    34.5000    33.4000  
    34.8000    33.7000  
    33.8000    33.9000  
    37.4000    36.6000  
    36.8000    37.0000  
    37.6000    36.7000
```

```
friedman(x,3)  
ans =  
    0.0082
```

Again, the conclusion is similar to that of the classical analysis of variance. Both this  $p$  value and the one from ANOVA ( $p = 0.0039$ ) lead you to conclude that there are significant row effects.

You cannot use Friedman's test to test for interactions between the row and column factors.

# MANOVA

## In this section...

“Introduction to MANOVA” on page 8-39

“ANOVA with Multiple Responses” on page 8-39

## Introduction to MANOVA

The analysis of variance technique in “Example: One-Way ANOVA” on page 8-4 takes a set of grouped data and determine whether the mean of a variable differs significantly among groups. Often there are multiple response variables, and you are interested in determining whether the entire set of means is different from one group to the next. There is a multivariate version of analysis of variance that can address the problem.

## ANOVA with Multiple Responses

The carsmall data set has measurements on a variety of car models from the years 1970, 1976, and 1982. Suppose you are interested in whether the characteristics of the cars have changed over time.

Load the sample data.

```
load carsmall
whos
```

Name	Size	Bytes	Class	Attributes
Acceleration	100x1	800	double	
Cylinders	100x1	800	double	
Displacement	100x1	800	double	
Horsepower	100x1	800	double	
MPG	100x1	800	double	
Mfg	100x13	2600	char	
Model	100x33	6600	char	
Model_Year	100x1	800	double	
Origin	100x7	1400	char	
Weight	100x1	800	double	

Four of these variables (Acceleration, Displacement, Horsepower, and MPG) are continuous measurements on individual car models. The variable Model\_Year indicates the year in which the car was made. You can create a grouped plot matrix of these variables using the `gplotmatrix` function.

Create a grouped plot matrix of these variables using the `gplotmatrix` function.

```
x = [MPG Horsepower Displacement Weight];  
gplotmatrix(x,[],Model_Year,[],'+xo')
```

(When the second argument of `gplotmatrix` is empty, the function graphs the columns of the `x` argument against each other, and places histograms along the diagonals. The empty fourth argument produces a graph with the default colors. The fifth argument controls the symbols used to distinguish between groups.)

It appears the cars do differ from year to year. The upper right plot, for example, is a graph of MPG versus Weight. The 1982 cars appear to have higher mileage than the older cars, and they appear to weigh less on average. But as a group, are the three years significantly different from one another? The `manova1` function can answer that question.

```
[d,p,stats] = manova1(x,Model_Year)
```

```
d =
```

```
2
```

```
p =
```

```
1.0e-06 *
```

```
0.0000
```

```
0.1141
```

```
stats =
```

```
W: [4x4 double]
```

```
B: [4x4 double]
```

```
T: [4x4 double]
```

```
dfW: 90
```

```
dfB: 2
```

```
dfT: 92
```

```
lambda: [2x1 double]
```

```
chisq: [2x1 double]
```

```
chisqdf: [2x1 double]
```

```
eigenval: [4x1 double]
```

```
eigenvec: [4x4 double]
  canon: [100x4 double]
  mdist: [1x100 double]
  gmdist: [3x3 double]
  gnames: {3x1 cell}
```

The `manova1` function produces three outputs:

- The first output, `d`, is an estimate of the dimension of the group means. If the means were all the same, the dimension would be 0, indicating that the means are at the same point. If the means differed but fell along a line, the dimension would be 1. In the example the dimension is 2, indicating that the group means fall in a plane but not along a line. This is the largest possible dimension for the means of three groups.
- The second output, `p`, is a vector of  $p$ -values for a sequence of tests. The first  $p$  value tests whether the dimension is 0, the next whether the dimension is 1, and so on. In this case both  $p$ -values are small. That's why the estimated dimension is 2.
- The third output, `stats`, is a structure containing several fields, described in the following section.

### The Fields of the `stats` Structure

The `W`, `B`, and `T` fields are matrix analogs to the within, between, and total sums of squares in ordinary one-way analysis of variance. The next three fields are the degrees of freedom for these matrices. Fields `lambda`, `chisq`, and `chisqdf` are the ingredients of the test for the dimensionality of the group means. (The  $p$ -values for these tests are the first output argument of `manova1`.)

The next three fields are used to do a canonical analysis. Recall that in principal components analysis (“Principal Component Analysis (PCA)” on page 13-80) you look for the combination of the original variables that has the largest possible variation. In multivariate analysis of variance, you instead look for the linear combination of the original variables that has the largest separation between groups. It is the single variable that would give the most significant result in a univariate one-way analysis of variance. Having found that combination, you next look for the combination with the second highest separation, and so on.

The `eigenvec` field is a matrix that defines the coefficients of the linear combinations of the original variables. The `eigenval` field is a vector measuring the ratio of the between-group variance to the within-group variance for the corresponding linear combination. The `canon` field is a matrix of the canonical variable values. Each column is a linear combination of the mean-centered original variables, using coefficients from the `eigenvec` matrix.

```
c1 = stats.canon(:,1);  
c2 = stats.canon(:,2);
```

Plot the grouped scatter plot of the first two canonical variables.

```
figure()  
gscatter(c2,c1,Model_Year,[],'oxs')
```

A grouped scatter plot of the first two canonical variables shows more separation between groups than a grouped scatter plot of any pair of original variables. In this example, it shows three clouds of points, overlapping but with distinct centers. One point in the bottom right sits apart from the others. You can mark this point on the plot using the `gname` function.

Roughly speaking, the first canonical variable,  $c_1$ , separates the 1982 cars (which have high values of  $c_1$ ) from the older cars. The second canonical variable,  $c_2$ , reveals some separation between the 1970 and 1976 cars.

The final two fields of the `stats` structure are Mahalanobis distances. The `mdist` field measures the distance from each point to its group mean. Points with large values may be outliers. In this data set, the largest outlier is the one in the scatter plot, the Buick Estate station wagon. (Note that you could have supplied the model name to the `gname` function above if you wanted to label the point with its model name rather than its row number.)

Find the largest distance from the group mean.

```
max(stats.mdist)
```

```
ans =
```

```
31.5273
```

Find the point that has the largest distance from the group mean.

```
find(stats.mdist == ans)
```

```
ans =
```

```
20
```

Find the car model that corresponds to the largest distance from the group mean.

```
Model(20,:)
```

```
ans =
```

```
buick estate wagon (sw)
```

The `gmdist` field measures the distances between each pair of group means. Examine the group means using `grpstats`.

```
grpstats(x, Model_Year)
```

```
ans =
```

```
1.0e+03 *
```

```
0.0177    0.1489    0.2869    3.4413
0.0216    0.1011    0.1978    3.0787
0.0317    0.0815    0.1289    2.4535
```

Find the distances between the each pair of group means.

```
stats.gmdist
```

```
ans =
```

```
0    3.8277    11.1106
3.8277    0    6.1374
11.1106    6.1374    0
```

As might be expected, the multivariate distance between the extreme years 1970 and 1982 (11.1) is larger than the difference between more closely spaced years (3.8 and 6.1). This is consistent with the scatter plots, where the points seem to follow a progression as the year changes from 1970 through 1976 to 1982. If you had more groups, you might find it instructive to use the `manovacluster` function to draw a diagram that presents clusters of the groups, formed using the distances between their means.

## Parametric Regression Analysis

### In this section...

“What Is Parametric Regression?” on page 9-3

“Choose a Regression Function” on page 9-3

“Update Legacy Code with New Fitting Methods” on page 9-4

### What Is Parametric Regression?

Regression is the process of fitting models to data. The models must have numerical responses. For models with categorical responses, see “Parametric Classification” on page 15-2 or “Supervised Learning (Machine Learning) Workflow and Algorithms” on page 16-2. The regression process depends on the model. If a model is parametric, regression estimates the parameters from the data. If a model is linear in the parameters, estimation is based on methods from linear algebra that minimize the norm of a residual vector. If a model is nonlinear in the parameters, estimation is based on search methods from optimization that minimize the norm of a residual vector.

### Choose a Regression Function

You have:	You want:	Use this:
Continuous or categorical predictors, continuous response, linear model	Fitted model coefficients	<code>fitlm</code> . See “Linear Regression” on page 9-12.
Continuous or categorical predictors, continuous response, linear model of unknown complexity	Fitted model and fitted coefficients	<code>stepwiselm</code> . See “Stepwise Regression” on page 9-119.
Continuous or categorical predictors, response possibly with restrictions such as nonnegative or integer-valued, generalized linear model	Fitted generalized linear model coefficients	<code>fitglm</code> or <code>stepwiseglm</code> . See “Generalized Linear Models” on page 10-12.

<b>You have:</b>	<b>You want:</b>	<b>Use this:</b>
Continuous predictors with a continuous nonlinear response, parametrized nonlinear model	Fitted nonlinear model coefficients	<code>fitnlm</code> . See “Nonlinear Regression” on page 11-2.
Continuous predictors, continuous response, linear model	Set of models from ridge, lasso, or elastic net regression	<code>lasso</code> or <code>ridge</code> See “Lasso and Elastic Net” on page 9-132 or “Ridge Regression” on page 9-128.
Correlated continuous predictors, continuous response, linear model	Fitted model and fitted coefficients	<code>plsregress</code> See “Partial Least Squares” on page 9-147.
Continuous or categorical predictors, continuous response, unknown model	Nonparametric model	<code>RegressionTree.fit</code> or <code>fitensemble</code> See “Classification Trees and Regression Trees” on page 16-31 or “Ensemble Methods” on page 16-59.
Categorical predictors only	ANOVA	<code>anova</code> , <code>anova1</code> , <code>anova2</code> , <code>anovan</code>
Continuous predictors, multivariable response, linear model	Fitted multivariate regression model coefficients	<code>mvregress</code>
Continuous predictors, continuous response, mixed-effects model	Fitted mixed-effects model coefficients	<code>nlmefit</code> or <code>nlmefitsa</code> See “Mixed-Effects Models” on page 11-23.

## Update Legacy Code with New Fitting Methods

There are several Statistics Toolbox functions for performing regression. The following sections describe how to replace calls to older functions to new versions:

- “regress into `fitlm`” on page 9-5
- “regstats into `fitlm`” on page 9-5

- “robustfit into fitlm” on page 9-6
- “stepwisefit into stepwiselm” on page 9-6
- “glmfit into fitglm” on page 9-7
- “nlinfit into fitnlm” on page 9-7

## **regress into fitlm**

### **Previous Syntax.**

```
[b,bint,r,rint,stats] = regress(y,X)
```

where  $X$  contains a column of ones.

### **Current Syntax.**

```
mdl = fitlm(X,y)
```

where you do not add a column of ones to  $X$ .

Equivalent values of the previous outputs:

- $b$  — `mdl.Coefficients.Estimate`
- $bint$  — `coefCI(mdl)`
- $r$  — `mdl.Residuals.Raw`
- $rint$  — There is no exact equivalent. Try examining `mdl.Residuals.Studentized` to find outliers.
- $stats$  — `mdl` contains various properties that replace components of `stats`.

## **regstats into fitlm**

### **Previous Syntax.**

```
stats = regstats(y,X,model,whichstats)
```

### **Current Syntax.**

```
mdl = fitlm(X,y,model)
```

Obtain statistics from the properties and methods of `mdl`. For example, see the `mdl.Diagnostics` and `mdl.Residuals` properties.

### **robustfit into fitlm**

#### **Previous Syntax.**

```
[b,stats] = robustfit(X,y,wfun,tune,const)
```

#### **Current Syntax.**

```
mdl = fitlm(X,y,'robust','on') % bisquare
```

Or to use the *wfun* weight and the *tune* tuning parameter:

```
opt.RobustWgtFun = 'wfun';  
opt.Tune = tune; % optional  
mdl = fitlm(X,y,'robust',opt)
```

Obtain statistics from the properties and methods of `mdl`. For example, see the `mdl.Diagnostics` and `mdl.Residuals` properties.

### **stepwisefit into stepwiselm**

#### **Previous Syntax.**

```
[b,se,pval,inmodel,stats,nextstep,history] = stepwisefit(X,y,Name,Value)
```

#### **Current Syntax.**

```
mdl = stepwiselm(ds,modelspec,Name,Value)
```

or

```
mdl = stepwiselm(X,y,modelspec,Name,Value)
```

Obtain statistics from the properties and methods of `mdl`. For example, see the `mdl.Diagnostics` and `mdl.Residuals` properties.

## glmfit into fitglm

### Previous Syntax.

```
[b,dev,stats] = glmfit(X,y,distr,param1,val1,...)
```

### Current Syntax.

```
mdl = fitglm(X,y,distr,...)
```

Obtain statistics from the properties and methods of `mdl`. For example, the deviance is `mdl.Deviance`, and to compare `mdl` against a constant model, use `devianceTest(mdl)`.

## nlinfit into fitnlm

### Previous Syntax.

```
[beta,r,J,COVB,mse] = nlinfit(X,y,fun,beta0,options)
```

### Current Syntax.

```
mdl = fitnlm(X,y,fun,beta0,'Options',options)
```

Equivalent values of the previous outputs:

- `beta` — `mdl.Coefficients.Estimate`
- `r` — `mdl.Residuals.Raw`
- `covb` — `mdl.CoefficientCovariance`
- `mse` — `mdl.mse`

`mdl` does not provide the Jacobian (`J`) output. The primary purpose of `J` was to pass it into `nlparci` or `nlpredci` to obtain confidence intervals for the estimated coefficients (parameters) or predictions. Obtain those confidence intervals as:

```
parci = coefCI(mdl)  
[pred,predci] = predict(mdl)
```

## What Are Linear Regression Models?

Regression models describe the relationship between a *dependent variable*,  $y$ , and *independent variable* or variables,  $X$ . The dependent variable is also called the *response variable*. Independent variables are also called *explanatory* or *predictor variables*. Continuous predictor variables might be called *covariates*, whereas categorical predictor variables might be also referred to as *factors*. The matrix,  $X$ , of observations on predictor variables is usually called the *design matrix*.

A multiple linear regression model is

$$y_i = \beta_0 + \beta_1 X_{i1} + \beta_2 X_{i2} + \cdots + \beta_p X_{ip} + \varepsilon_i, \quad i = 1, \dots, n,$$

where

- $y_i$  is the  $i$ th response.
- $\beta_k$  is the  $k$ th coefficient, where  $\beta_0$  is the constant term in the model. Sometimes, design matrices might include information about the constant term. However, `fitlm` or `stepwiselm` by default includes a constant term in the model, so you must not enter a column of 1s into your design matrix  $X$ .
- $X_{ij}$  is the  $i$ th observation on the  $j$ th predictor variable,  $j = 1, \dots, p$ .
- $\varepsilon_i$  is the  $i$ th noise term, that is, random error.

In general, a linear regression model can be a model of the form

$$y_i = \beta_0 + \sum_{k=1}^K \beta_k f_k(X_{i1}, X_{i2}, \dots, X_{ip}) + \varepsilon_i, \quad i = 1, \dots, n,$$

where  $f(\cdot)$  is a scalar-valued function of the independent variables,  $X_{ij}$ s. The functions,  $f(X)$ , might be in any form including nonlinear functions or polynomials. The linearity, in the linear regression models, refers to the linearity of the coefficients  $\beta_k$ . That is, the response variable,  $y$ , is a linear function of the coefficients,  $\beta_k$ .

Some examples of linear models are:

$$y_i = \beta_0 + \beta_1 X_{1i} + \beta_2 X_{2i} + \beta_3 X_{3i} + \varepsilon_i$$

$$y_i = \beta_0 + \beta_1 X_{1i} + \beta_2 X_{2i} + \beta_3 X_{1i}^3 + \beta_4 X_{2i}^2 + \varepsilon_i$$

$$y_i = \beta_0 + \beta_1 X_{1i} + \beta_2 X_{2i} + \beta_3 X_{1i} X_{2i} + \beta_4 \log X_{3i} + \varepsilon_i$$

The following, however, are not linear models since they are not linear in the unknown coefficients,  $\beta_k$ .

$$\log y_i = \beta_0 + \beta_1 X_{1i} + \beta_2 X_{2i} + \varepsilon_i$$

$$y_i = \beta_0 + \beta_1 X_{1i} + \frac{1}{\beta_2 X_{2i}} + e^{\beta_3 X_{1i} X_{2i}} + \varepsilon_i$$

The usual assumptions for linear regression models are:

- The noise terms,  $\varepsilon_i$ , are uncorrelated.
- The noise terms,  $\varepsilon_i$ , have independent and identical normal distributions with mean zero and constant variance,  $\sigma^2$ . Thus

$$\begin{aligned} E(y_i) &= E\left(\sum_{k=0}^K \beta_k f_k(X_{i1}, X_{i2}, \dots, X_{ip}) + \varepsilon_i\right) \\ &= \sum_{k=0}^K \beta_k f_k(X_{i1}, X_{i2}, \dots, X_{ip}) + E(\varepsilon_i) \\ &= \sum_{k=0}^K \beta_k f_k(X_{i1}, X_{i2}, \dots, X_{ip}) \end{aligned}$$

and

$$V(y_i) = V\left(\sum_{k=0}^K \beta_k f_k(X_{i1}, X_{i2}, \dots, X_{ip}) + \varepsilon_i\right) = V(\varepsilon_i) = \sigma^2$$

So the variance of  $y_i$  is the same for all levels of  $X_{ij}$ .

- The responses  $y_i$  are uncorrelated.

The fitted linear function is

$$\hat{y}_i = b_0 + \sum_{k=1}^K b_k f_k(X_{i1}, X_{i2}, \dots, X_{ip}), \quad i = 1, \dots, n,$$

where  $\hat{y}_i$  is the estimated response and  $b_k$ s are the fitted coefficients. The coefficients are estimated so as to minimize the mean squared difference between the prediction vector  $bf(X)$  and the true response vector  $y$ , that is  $\hat{y} - y$ . This method is called the *method of least squares*. Under the assumptions on the noise terms, these coefficients also maximize the likelihood of the prediction vector.

In a linear regression model of the form  $y = \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_p X_p$ , the coefficient  $\beta_k$  expresses the impact of a one-unit change in predictor variable,  $X_j$ , on the mean of the response,  $E(y)$  provided that all other variables are held constant. The sign of the coefficient gives the direction of the effect. For example, if the linear model is  $E(y) = 1.8 - 2.35X_1 + X_2$ , then  $-2.35$  indicates a 2.35 unit decrease in the mean response with a one-unit increase in  $X_1$ , given  $X_2$  is held constant. If the model is  $E(y) = 1.1 + 1.5X_1^2 + X_2$ , the coefficient of  $X_1^2$  indicates a 1.5 unit increase in the mean of  $Y$  with a one-unit increase in  $X_1^2$  given all else held constant. However, in the case of  $E(y) = 1.1 + 2.1X_1 + 1.5X_1^2$ , it is difficult to interpret the coefficients similarly, since it is not possible to hold  $X_1$  constant when  $X_1^2$  changes or vice versa.

“Predict or Simulate Responses to New Data” on page 9-40

“Share Fitted Models” on page 9-43

“Linear Regression Workflow” on page 9-44

### Prepare Data

To begin fitting a regression, put your data into a form that fitting functions expect. All regression techniques begin with input data in an array  $X$  and response data in a separate vector  $y$ , or input data in a dataset array  $ds$  and response data as a column in  $ds$ . Each row of the input data represents one observation. Each column represents one predictor (variable).

For a dataset array  $ds$ , indicate the response variable with the 'ResponseVar' name-value pair:

```
mdl = fitlm(ds, 'ResponseVar', 'BloodPressure');  
% or  
mdl = fitglm(ds, 'ResponseVar', 'BloodPressure');
```

The response variable is the last column by default.

You can use numeric *categorical* predictors. A categorical predictor is one that takes values from a fixed set of possibilities.

- For a numeric array  $X$ , indicate the categorical predictors using the 'Categorical' name-value pair. For example, to indicate that predictors 2 and 3 out of six are categorical:

```
mdl = fitlm(X,y,'Categorical',[2,3]);
% or
mdl = fitglm(X,y,'Categorical',[2,3]);
% or equivalently
mdl = fitlm(X,y,'Categorical',logical([0 1 1 0 0 0]));
```

- For a dataset array `ds`, fitting functions assume that these data types are categorical:
  - Logical
  - Categorical (nominal or ordinal)
  - String or character array

If you want to indicate that a numeric predictor is categorical, use the 'Categorical' name-value pair.

Represent missing numeric data as NaN. To represent missing data for other data types, see “Missing Group Values” on page 2-53.

### **Dataset Array for Input and Response Data**

For example, to create a dataset array from an Excel spreadsheet:

```
ds = dataset('XLSFile','hospital.xls',...
            'ReadObsNames',true);
```

To create a dataset array from workspace variables:

```
load carsmall
ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);
```

### **Numeric Matrix for Input Data, Numeric Vector for Response**

For example, to create numeric arrays from workspace variables:

```
load carsmall
X = [Weight Horsepower Cylinders Model_Year];
y = MPG;
```

To create numeric arrays from an Excel spreadsheet:

```
[X Xnames] = xlsread('hospital.xls');  
y = X(:,4); % response y is systolic pressure  
X(:,4) = []; % remove y from the X matrix
```

Notice that the nonnumeric entries, such as `sex`, do not appear in `X`.

## Choose a Fitting Method

There are three ways to fit a model to data:

- “Least-Squares Fit” on page 9-14
- “Robust Fit” on page 9-14
- “Stepwise Fit” on page 9-14

### Least-Squares Fit

Use `fitlm` to construct a least-squares fit of a model to the data. This method is best when you are reasonably certain of the model’s form, and mainly need to find its parameters. This method is also useful when you want to explore a few models. The method requires you to examine the data manually to discard outliers, though there are techniques to help (see “Residuals — Model Quality for Training Data” on page 9-25).

### Robust Fit

Use `fitlm` with the `RobustOpts` name-value pair to create a model that is little affected by outliers. Robust fitting saves you the trouble of manually discarding outliers. However, `step` does not work with robust fitting. This means that when you use robust fitting, you cannot search stepwise for a good model.

### Stepwise Fit

Use `stepwiselm` to find a model, and fit parameters to the model. `stepwiselm` starts from one model, such as a constant, and adds or subtracts terms one at a time, choosing an optimal term each time in a greedy fashion, until it cannot improve further. Use stepwise fitting to find a good model, which is one that has only relevant terms.

The result depends on the starting model. Usually, starting with a constant model leads to a small model. Starting with more terms can lead to a more complex model, but one that has lower mean squared error. See “Compare large and small stepwise models” on page 9-119.

You cannot use robust options along with stepwise fitting. So after a stepwise fit, examine your model for outliers (see “Residuals — Model Quality for Training Data” on page 9-25).

## Choose a Model or Range of Models

There are several ways of specifying a model for linear regression. Use whichever you find most convenient.

- “Brief String” on page 9-16
- “Terms Matrix” on page 9-16
- “Formula” on page 9-20

For `fitlm`, the model specification you give is the model that is fit. If you do not give a model specification, the default is `'linear'`.

For `stepwiselm`, the model specification you give is the starting model, which the stepwise procedure tries to improve. If you do not give a model specification, the default starting model is `'constant'`, and the default upper bounding model is `'interactions'`. Change the upper bounding model using the `Upper` name-value pair.

---

**Note** There are other ways of selecting models, such as using `lasso`, `lassoglm`, `sequentialfs`, or `plsregress`.

---

**Brief String**

String	Model Type
'constant'	Model contains only a constant (intercept) term.
'linear'	Model contains an intercept and linear terms for each predictor.
'interactions'	Model contains an intercept, linear terms, and all products of pairs of distinct predictors (no squared terms).
'purequadratic'	Model contains an intercept, linear terms, and squared terms.
'quadratic'	Model contains an intercept, linear terms, interactions, and squared terms.
'polyijk'	Model is a polynomial with all terms up to degree $i$ in the first predictor, degree $j$ in the second predictor, etc. Use numerals 0 through 9. For example, 'poly2111' has a constant plus all linear and product terms, and also contains terms with predictor 1 squared.

For example, to specify an interaction model using `fitlm` with matrix predictors:

```
mdl = fitlm(X,y,'interactions');
```

To specify a model using `stepwiselm` and a dataset array `ds` of predictors, suppose you want to start from a constant and have a linear model upper bound. Assume the response variable in `ds` is in the third column.

```
mdl2 = stepwiselm(ds,'constant',...
    'Upper','linear','ResponseVar',3);
```

**Terms Matrix**

A terms matrix is a  $t$ -by- $(p + 1)$  matrix specifying terms in a model, where  $t$  is the number of terms,  $p$  is the number of predictor variables, and plus one is for the response variable. The value of  $T(i, j)$  is the exponent of variable  $j$  in term  $i$ . Suppose there are three predictor variables A, B, and C:

```
[0 0 0 0] % Constant term or intercept
[0 1 0 0] % B; equivalently, A^0 * B^1 * C^0
[1 0 1 0] % A*C
[2 0 0 0] % A^2
[0 1 2 0] % B*(C^2)
```

The 0 at the end of each term represents the response variable. In general,

- If you have the variables in a dataset array, then 0 must represent the response variable depending on the position of the response variable in the dataset array. The following example illustrates this.

Load the sample data and define the dataset array.

```
load hospital
ds = dataset(hospital.Sex,hospital.BloodPressure(:,1),hospital.Age,...
hospital.Smoker,'VarNames',{'Sex','BloodPressure','Age','Smoker'});
```

Represent the linear model 'BloodPressure ~ 1 + Sex + Age + Smoker' in a terms matrix. The response variable is in the second column of the dataset array, so there must be a column of 0s for the response variable in the second column of the terms matrix.

```
T = [0 0 0 0;1 0 0 0;0 0 1 0;0 0 0 1]
```

```
T =
```

```

0     0     0     0
1     0     0     0
0     0     1     0
0     0     0     1
```

Redefine the dataset array.

```
ds = dataset(hospital.BloodPressure(:,1),hospital.Sex,hospital.Age,...
hospital.Smoker,'VarNames',{'BloodPressure','Sex','Age','Smoker'});
```

Now, the response variable is the first term in the dataset array. Specify the same linear model, 'BloodPressure ~ 1 + Sex + Age + Smoker', using a terms matrix.

```
T = [0 0 0 0;0 1 0 0;0 0 1 0;0 0 0 1]
```

```
T =  
  
    0    0    0    0  
    0    1    0    0  
    0    0    1    0  
    0    0    0    1
```

- If you have the predictor and response variables in a matrix and column vector, then you must include 0 for the response variable at the end of each term. The following example illustrates this.

Load the sample data and define the matrix of predictors.

```
load carsmall  
X = [Acceleration,Weight];
```

Specify the model 'MPG ~ Acceleration + Weight + Acceleration:Weight + Weight^2' using a term matrix and fit the model to the data. This model includes the main effect and two-way interaction terms for the variables, Acceleration and Weight, and a second-order term for the variable, Weight.

```
T = [0 0 0;1 0 0;0 1 0;1 1 0;0 2 0]
```

```
T =  
  
    0    0    0  
    1    0    0  
    0    1    0  
    1    1    0  
    0    2    0
```

Fit a linear model.

```
mdl = fitlm(X,MPG,T)
```

```
mdl =
```

```
Linear regression model:  
y ~ 1 + x1*x2 + x2^2
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	48.906	12.589	3.8847	0.00019665
x1	0.54418	0.57125	0.95261	0.34337
x2	-0.012781	0.0060312	-2.1192	0.036857
x1:x2	-0.00010892	0.00017925	-0.6076	0.545
x2^2	9.7518e-07	7.5389e-07	1.2935	0.19917

Number of observations: 94, Error degrees of freedom: 89

Root Mean Squared Error: 4.1

R-squared: 0.751, Adjusted R-Squared 0.739

F-statistic vs. constant model: 67, p-value = 4.99e-26

Only the intercept and x2 term, which correspond to the Weight variable, are significant at the 5% significance level.

Now, perform a stepwise regression with a constant model as the starting model and a linear model with interactions as the upper model.

```
T = [0 0 0;1 0 0;0 1 0;1 1 0];
mdl = stepwiselm(X,MPG,[0 0 0],'upper',T)
```

1. Adding x2, FStat = 259.3087, pValue = 1.643351e-28

```
mdl =
```

Linear regression model:

$$y \sim 1 + x2$$

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	49.238	1.6411	30.002	2.7015e-49
x2	-0.0086119	0.0005348	-16.103	1.6434e-28

Number of observations: 94, Error degrees of freedom: 92

Root Mean Squared Error: 4.13

R-squared: 0.738, Adjusted R-Squared 0.735

F-statistic vs. constant model: 259, p-value = 1.64e-28

The results of the stepwise regression are consistent with the results of `fitlm` in the previous step.

## Formula

A formula for a model specification is a string of the form

`'Y ~ terms'`,

- *Y* is the response name.
- *terms* contains
  - Variable names
  - + to include the next variable
  - - to exclude the next variable
  - : to define an interaction, a product of terms
  - \* to define an interaction and all lower-order terms
  - ^ to raise the predictor to a power, exactly as in \* repeated, so ^ includes lower order terms as well
  - () to group terms

---

**Tip** Formulas include a constant (intercept) term by default. To exclude a constant term from the model, include -1 in the formula.

---

Examples:

`'Y ~ A + B + C'` is a three-variable linear model with intercept.

`'Y ~ A + B + C - 1'` is a three-variable linear model without intercept.

`'Y ~ A + B + C + B^2'` is a three-variable model with intercept and a  $B^2$  term.

`'Y ~ A + B^2 + C'` is the same as the previous example, since  $B^2$  includes a B term.

`'Y ~ A + B + C + A:B'` includes an  $A*B$  term.

`'Y ~ A*B + C'` is the same as the previous example, since  $A*B = A + B + A:B$ .

`'Y ~ A*B*C - A:B:C'` has all interactions among A, B, and C, except the three-way interaction.

`'Y ~ A*(B + C + D)'` has all linear terms, plus products of A with each of the other variables.

For example, to specify an interaction model using `fitlm` with matrix predictors:

```
mdl = fitlm(X,y,'y ~ x1*x2*x3 - x1:x2:x3');
```

To specify a model using `stepwiselm` and a dataset array `ds` of predictors, suppose you want to start from a constant and have a linear model upper bound. Assume the response variable in `ds` is named `'y'`, and the predictor variables are named `'x1'`, `'x2'`, and `'x3'`.

```
mdl2 = stepwiselm(ds,'y ~ 1','Upper','y ~ x1 + x2 + x3');
```

## Fit Model to Data

The most common optional arguments for fitting:

- For robust regression in `fitlm`, set the `'RobustOpts'` name-value pair to `'on'`.
- Specify an appropriate upper bound model in `stepwiselm`, such as set `'Upper'` to `'linear'`.
- Indicate which variables are categorical using the `'CategoricalVars'` name-value pair. Provide a vector with column numbers, such as `[1 6]` to specify that predictors 1 and 6 are categorical. Alternatively, give a logical vector the same length as the data columns, with a 1 entry indicating that variable is categorical. If there are seven predictors, and predictors 1 and 6 are categorical, specify `logical([1,0,0,0,0,1,0])`.
- For a dataset array, specify the response variable using the `'ResponseVar'` name-value pair. The default is the last column in the array.

For example,

```
mdl = fitlm(X,y,'linear',...
    'RobustOpts','on','CategoricalVars',3);
mdl2 = stepwiselm(ds,'constant',...
    'ResponseVar','MPG','Upper','quadratic');
```

## Examine Quality and Adjust the Fitted Model

After fitting a model, examine the result.

- “Model Display” on page 9-22

- “ANOVA” on page 9-23
- “Diagnostic Plots” on page 9-24
- “Residuals — Model Quality for Training Data” on page 9-25
- “Plots to Understand Predictor Effects” on page 9-30
- “Plots to Understand Terms Effects” on page 9-35
- “Change Models” on page 9-37

### Model Display

A linear regression model shows several diagnostics when you enter its name or enter `disp mdl`. This display gives some of the basic information to check whether the fitted model represents the data adequately.

For example, fit a linear model to data constructed with two out of five predictors not present and with no intercept term:

```
X = randn(100,5);
y = X*[1;0;3;0;-1]+randn(100,1);
mdl = fitlm(X,y)
```

```
mdl =
```

Linear regression model:

$$y \sim 1 + x_1 + x_2 + x_3 + x_4 + x_5$$

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	0.038164	0.099458	0.38372	0.70205
x1	0.92794	0.087307	10.628	8.5494e-18
x2	-0.075593	0.10044	-0.75264	0.45355
x3	2.8965	0.099879	29	1.1117e-48
x4	0.045311	0.10832	0.41831	0.67667
x5	-0.99708	0.11799	-8.4504	3.593e-13

Number of observations: 100, Error degrees of freedom: 94

Root Mean Squared Error: 0.972

R-squared: 0.93, Adjusted R-Squared 0.926

F-statistic vs. constant model: 248, p-value = 1.5e-52

Notice that:

- The display contains the estimated values of each coefficient in the Estimate column. These values are reasonably near the true values `[0;1;0;3;0;-1]`.
- There is a standard error column for the coefficient estimates.
- The reported pValue (which are derived from the  $t$  statistics under the assumption of normal errors) for predictors 1, 3, and 5 are extremely small. These are the three predictors that were used to create the response data  $y$ .
- The pValue for (Intercept),  $x_2$  and  $x_4$  are much larger than 0.01. These three predictors were not used to create the response data  $y$ .
- The display contains  $R^2$ , adjusted  $R^2$ , and  $F$  statistics.

## ANOVA

To examine the quality of the fitted model, consult an ANOVA table. For example, use `anova` on a linear model with five predictors:

```
X = randn(100,5);
y = X*[1;0;3;0;-1]+randn(100,1);
mdl = fitlm(X,y);
tbl = anova(mdl)
```

```
tbl =
```

	SumSq	DF	MeanSq	F	pValue
x1	106.62	1	106.62	112.96	8.5494e-18
x2	0.53464	1	0.53464	0.56646	0.45355
x3	793.74	1	793.74	840.98	1.1117e-48
x4	0.16515	1	0.16515	0.17498	0.67667
x5	67.398	1	67.398	71.41	3.593e-13
Error	88.719	94	0.94382		

This table gives somewhat different results than the default display (see “Model Display” on page 9-22). The table clearly shows that the effects of  $x_2$  and  $x_4$  are not significant. Depending on your goals, consider removing  $x_2$  and  $x_4$  from the model.

## Diagnostic Plots

Diagnostic plots help you identify outliers, and see other problems in your model or fit. For example, load the `carsmall` data, and make a model of MPG as a function of `Cylinders` (nominal) and `Weight`:

```
load carsmall
ds = dataset(Weight,MPG,Cylinders);
ds.Cylinders = ordinal(ds.Cylinders);
mdl = fitlm(ds,'MPG ~ Cylinders*Weight + Weight^2');
```

Make a leverage plot of the data and model.

```
plotDiagnostics(mdl)
```

There are a few points with high leverage. But this plot does not reveal whether the high-leverage points are outliers.

Look for points with large Cook's distance.

```
plotDiagnostics(md1, 'cookd')
```

There is one point with large Cook's distance. Identify it and remove it from the model. You can use the Data Cursor to click the outlier and identify it, or identify it programmatically:

```
[~,larg] = max(md1.Diagnostics.CooksDistance);
md12 = fitlm(ds,'MPG ~ Cylinders*Weight + Weight^2',...
    'Exclude',larg);
```

## Residuals – Model Quality for Training Data

There are several residual plots to help you discover errors, outliers, or correlations in the model or data. The simplest residual plots are the default histogram plot, which shows the range of the residuals and their frequencies,

and the probability plot, which shows how the distribution of the residuals compares to a normal distribution with matched variance.

Load the `carsmall` data, and make a model of MPG as a function of Cylinders (nominal) and Weight:

```
load carsmall
ds = dataset(Weight,MPG,Cylinders);
ds.Cylinders = ordinal(ds.Cylinders);
mdl = fitlm(ds,'MPG ~ Cylinders*Weight + Weight^2');
```

Examine the residuals:

```
plotResiduals(mdl)
```

The observations above 12 are potential outliers.

```
plotResiduals mdl, 'probability'
```

The two potential outliers appear on this plot as well. Otherwise, the probability plot seems reasonably straight, meaning a reasonable fit to normally distributed residuals.

You can identify the two outliers and remove them from the data:

```
out1 = find(mdl.Residuals.Raw > 12)
```

```
out1 =
```

```
90
```

```
97
```

To remove the outliers, use the Exclude name-value pair:

```
md12 = fitlm(ds,'MPG ~ Cylinders*Weight + Weight^2',...  
            'Exclude',out1);
```

Examine a residuals plot of md12:

```
plotResiduals(md12)
```

The new residuals plot looks fairly symmetric, without obvious problems. However, there might be some serial correlation among the residuals. Create a new plot to see if such an effect exists.

```
plotResiduals(md12,'lagged')
```

The scatter plot shows many more crosses in the upper-right and lower-left quadrants than in the other two quadrants, indicating positive serial correlation among the residuals.

Another potential issue is when residuals are large for large observations. See if the current model has this issue.

```
plotResiduals(md12, 'fitted')
```

There is some tendency for larger fitted values to have larger residuals. Perhaps the model errors are proportional to the measured values.

### Plots to Understand Predictor Effects

This example shows how to understand the effect each predictor has on a regression model using a variety of available plots.

- 1 Create a model of mileage from some predictors in the carsmall data.

```
load carsmall
ds = dataset(Weight,MPG,Cylinders);
ds.Cylinders = ordinal(ds.Cylinders);
mdl = fitlm(ds,'MPG ~ Cylinders*Weight + Weight^2');
```

- 2** Examine a slice plot of the responses. This displays the effect of each predictor separately.

```
plotSlice mdl
```

You can drag the individual predictor values, which are represented by dashed blue vertical lines. You can also choose between simultaneous and non-simultaneous confidence bounds, which are represented by dashed red curves.

- 3 Use an effects plot to show another view of the effect of predictors on the response.

```
plotEffects mdl
```

This plot shows that changing Weight from about 2500 to 4732 lowers MPG by about 30 (the location of the upper blue circle). It also shows that changing the number of cylinders from 8 to 4 raises MPG by about 10 (the lower blue circle). The horizontal blue lines represent confidence intervals for these predictions. The predictions come from averaging over one predictor as the other is changed. In cases such as this, where the two predictors are correlated, be careful when interpreting the results.

- 4 Instead of viewing the effect of averaging over a predictor as the other is changed, examine the joint interaction in an interaction plot.

```
plotInteraction(md1, 'Weight', 'Cylinders')
```

The interaction plot shows the effect of changing one predictor with the other held fixed. In this case, the plot is much more informative. It shows, for example, that lowering the number of cylinders in a relatively light car

(Weight = 1795) leads to an increase in mileage, but lowering the number of cylinders in a relatively heavy car (Weight = 4732) leads to a decrease in mileage.

- For an even more detailed look at the interactions, look at an interaction plot with predictions. This plot holds one predictor fixed while varying the other, and plots the effect as a curve. Look at the interactions for various fixed numbers of cylinders.

```
plotInteraction(md1, 'Cylinders', 'Weight', 'predictions')
```

Now look at the interactions with various fixed levels of weight.

```
plotInteraction(md1, 'Weight', 'Cylinders', 'predictions')
```

### Plots to Understand Terms Effects

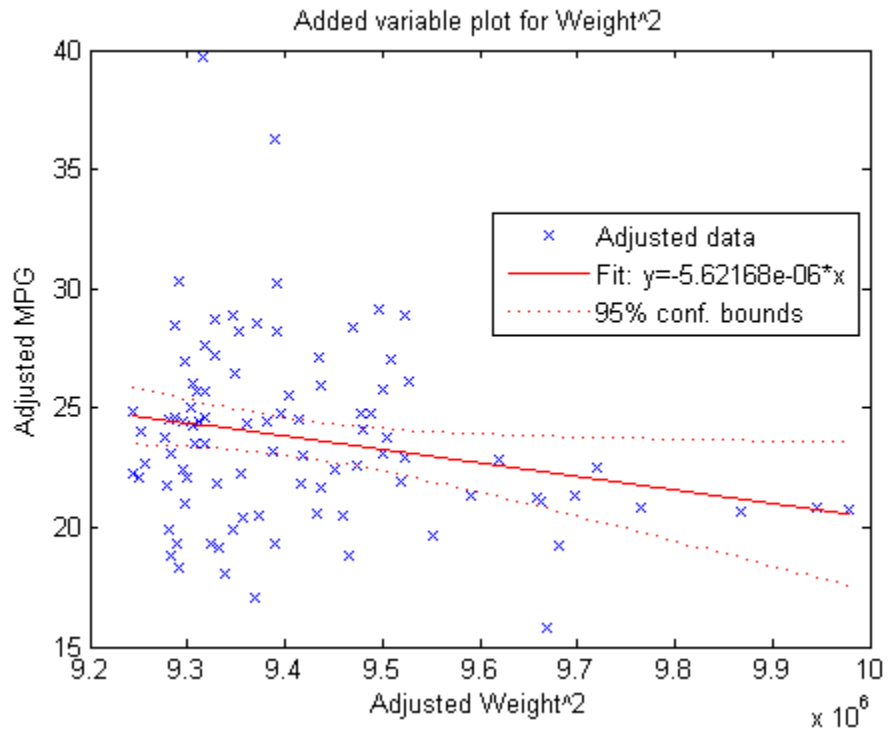

This example shows how to understand the effect of each term in a regression model using a variety of available plots.

- 1 Create a model of mileage from some predictors in the carsmall data.

```
load carsmall
ds = dataset(Weight,MPG,Cylinders);
ds.Cylinders = ordinal(ds.Cylinders);
mdl = fitlm(ds,'MPG ~ Cylinders*Weight + Weight^2');
```

- 2 Create an added variable plot with  $\text{Weight}^2$  as the added variable.

```
plotAdded(mdl, 'Weight^2')
```

This plot shows the results of fitting both  $\text{Weight}^2$  and MPG to the terms other than  $\text{Weight}^2$ . The reason to use `plotAdded` is to understand what additional improvement in the model you get by adding  $\text{Weight}^2$ . The coefficient of a line fit to these points is the coefficient of  $\text{Weight}^2$  in the full model. The  $\text{Weight}^2$  predictor is just over the edge of significance ( $p\text{Value} < 0.05$ ) as you can see in the coefficients table display. You can see that in the plot as well. The confidence bounds look like they could not contain a horizontal line (constant  $y$ ), so a zero-slope model is not consistent with the data.

- 3 Create an added variable plot for the model as a whole.

```
plotAdded(md1)
```

The model as a whole is very significant, so the bounds don't come close to containing a horizontal line. The slope of the line is the slope of a fit to the predictors projected onto their best-fitting direction, or in other words, the norm of the coefficient vector.

## Change Models

There are two ways to change a model:

- `step` — Add or subtract terms one at a time, where `step` chooses the most important term to add or remove.
- `addTerms` and `removeTerms` — Add or remove specified terms. Give the terms in any of the forms described in "Choose a Model or Range of Models" on page 9-15.

If you created a model using `stepwiselm`, `step` can have an effect only if you give different upper or lower models. `step` does not work when you fit a model using `RobustOpts`.

For example, start with a linear model of mileage from the `carbig` data:

```
load carbig
ds = dataset(Acceleration,Displacement,Horsepower,Weight,MPG);
mdl = fitlm(ds,'linear','ResponseVar','MPG')
```

```
mdl =
```

Linear regression model:

```
MPG ~ 1 + Acceleration + Displacement + Horsepower + Weight
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	45.251	2.456	18.424	7.0721e-55
Acceleration	-0.023148	0.1256	-0.1843	0.85388
Displacement	-0.0060009	0.0067093	-0.89441	0.37166
Horsepower	-0.043608	0.016573	-2.6312	0.008849
Weight	-0.0052805	0.00081085	-6.5123	2.3025e-10

Number of observations: 392, Error degrees of freedom: 387

Root Mean Squared Error: 4.25

R-squared: 0.707, Adjusted R-Squared 0.704

F-statistic vs. constant model: 233, p-value = 9.63e-102

Try to improve the model using `step` for up to 10 steps:

```
mdl1 = step(mdl,'NSteps',10)
```

```
1. Adding Displacement:Horsepower, FStat = 87.4802, pValue = 7.05273e-19
```

```
mdl1 =
```

Linear regression model:

```
MPG ~ 1 + Acceleration + Weight + Displacement*Horsepower
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	61.285	2.8052	21.847	1.8593e-69
Acceleration	-0.34401	0.11862	-2.9	0.0039445
Displacement	-0.081198	0.010071	-8.0623	9.5014e-15
Horsepower	-0.24313	0.026068	-9.3265	8.6556e-19
Weight	-0.0014367	0.00084041	-1.7095	0.088166
Displacement:Horsepower	0.00054236	5.7987e-05	9.3531	7.0527e-19

Number of observations: 392, Error degrees of freedom: 386

Root Mean Squared Error: 3.84

R-squared: 0.761, Adjusted R-Squared 0.758

F-statistic vs. constant model: 246, p-value = 1.32e-117

**step stopped after just one change.**

To try to simplify the model, remove the Acceleration and Weight terms from mdl1:

```
mdl2 = removeTerms(mdl1, 'Acceleration + Weight')
```

```
mdl2 =
```

Linear regression model:

```
MPG ~ 1 + Displacement*Horsepower
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	53.051	1.526	34.765	3.0201e-121
Displacement	-0.098046	0.0066817	-14.674	4.3203e-39
Horsepower	-0.23434	0.019593	-11.96	2.8024e-28
Displacement:Horsepower	0.00058278	5.193e-05	11.222	1.6816e-25

Number of observations: 392, Error degrees of freedom: 388

Root Mean Squared Error: 3.94

R-squared: 0.747, Adjusted R-Squared 0.745

F-statistic vs. constant model: 381, p-value = 3e-115

mdl2 uses just Displacement and Horsepower, and has nearly as good a fit to the data as mdl1 in the Adjusted R-Squared metric.

### Predict or Simulate Responses to New Data

There are three ways to use a linear model to predict or simulate the response to new data:

- “predict” on page 9-40
- “feval” on page 9-41
- “random” on page 9-42

#### predict

This example shows how to predict and obtain confidence intervals on the predictions using the predict method.

- 1 Load the carbig data and make a default linear model of the response MPG to the Acceleration, Displacement, Horsepower, and Weight predictors.

```
load carbig
X = [Acceleration,Displacement,Horsepower,Weight];
mdl = fitlm(X,MPG);
```

- 2 Create a three-row array of predictors from the minimal, mean, and maximal values. There are some NaN values, so use functions that ignore NaN values.

```
Xnew = [nanmin(X);nanmean(X);nanmax(X)]; % new data
```

- 3 Find the predicted model responses and confidence intervals on the predictions.

```
[NewMPG NewMPGCI] = predict(mdl,Xnew)
```

```
NewMPG =
    34.1345
    23.4078
     4.7751
```

```
NewMPGCI =
    31.6115    36.6575
    22.9859    23.8298
     0.6134     8.9367
```

The confidence bound on the mean response is narrower than those for the minimum or maximum responses, which is quite sensible.

## feval

When you construct a model from a dataset array, `feval` is often more convenient for predicting mean responses than `predict`. However, `feval` does not provide confidence bounds.

This example shows how to predict mean responses using the `feval` method.

- 1 Load the `carbig` data and make a default linear model of the response MPG to the Acceleration, Displacement, Horsepower, and Weight predictors.

```
load carbig
ds = dataset(Acceleration,Displacement,Horsepower,Weight,MPG);
mdl = fitlm(ds,'linear','ResponseVar','MPG');
```

- 2 Create a three-row array of predictors from the minimal, mean, and maximal values. There are some NaN values, so use functions that ignore NaN values.

```
X = [Acceleration,Displacement,Horsepower,Weight];
Xnew = [nanmin(X);nanmean(X);nanmax(X)]; % new data
```

The `Xnew` array is not a dataset array. It has the right number of columns for prediction, so `feval` can use it for predictions.

- 3 Find the predicted model responses.

```
NewMPG = feval(mdl,Xnew)
```

```
NewMPG =
    34.1345
    23.4078
     4.7751
```

**random**

The `random` method simulates new random response values, equal to the mean prediction plus a random disturbance with the same variance as the training data.

This example shows how to simulate responses using the `random` method.

- 1 Load the `carbig` data and make a default linear model of the response MPG to the Acceleration, Displacement, Horsepower, and Weight predictors.

```
load carbig
X = [Acceleration,Displacement,Horsepower,Weight];
mdl = fitlm(X,MPG);
```

- 2 Create a three-row array of predictors from the minimal, mean, and maximal values. There are some NaN values, so use functions that ignore NaN values.

```
Xnew = [nanmin(X);nanmean(X);nanmax(X)]; % new data
```

- 3 Generate new predicted model responses including some randomness.

```
rng('default') % for reproducibility
NewMPG = random(mdl,Xnew)
```

```
NewMPG =

    36.4178
    31.1958
    -4.8176
```

- 4 Because a negative value of MPG does not seem sensible, try predicting two more times.

```
NewMPG = random(mdl,Xnew)
```

```
NewMPG =

    37.7959
    24.7615
    -0.7783
```

```
NewMPG = random(md1,Xnew)
```

```
NewMPG =
```

```
32.2931
24.8628
19.9715
```

Clearly, the predictions for the third (maximal) row of `Xnew` are not reliable.

## Share Fitted Models

Suppose you have a linear regression model, such as `mdl` from the following commands:

```
load carbig
ds = dataset(Acceleration,Displacement,Horsepower,Weight,MPG);
mdl = fitlm(ds,'linear','ResponseVar','MPG');
```

To share the model with other people, you can:

- Provide the model display.

```
mdl
```

```
mdl =
```

```
Linear regression model:
```

```
MPG ~ 1 + Acceleration + Displacement + Horsepower + Weight
```

```
Estimated Coefficients:
```

	Estimate	SE	tStat	pValue
(Intercept)	45.251	2.456	18.424	7.0721e-55
Acceleration	-0.023148	0.1256	-0.1843	0.85388
Displacement	-0.0060009	0.0067093	-0.89441	0.37166
Horsepower	-0.043608	0.016573	-2.6312	0.008849
Weight	-0.0052805	0.00081085	-6.5123	2.3025e-10

```
Number of observations: 392, Error degrees of freedom: 387
```

```
Root Mean Squared Error: 4.25
```

```
R-squared: 0.707, Adjusted R-Squared 0.704  
F-statistic vs. constant model: 233, p-value = 9.63e-102
```

- Provide just the model definition and coefficients.

```
mdl.CoefficientNames
```

```
ans =
```

```
      '(Intercept)'      'Acceleration'      'Displacement'      'Horsepower'
```

```
mdl.Coefficients.Estimate
```

```
ans =
```

```
45.2511  
-0.0231  
-0.0060  
-0.0436  
-0.0053
```

```
mdl.Formula
```

```
ans =
```

```
MPG ~ 1 + Acceleration + Displacement + Horsepower + Weight
```

### Linear Regression Workflow

This example shows how to fit a linear regression model. A typical workflow involves the following: import data, fit a regression, test its quality, modify it to improve the quality, and share it.

#### Step 1. Import the data into a dataset array.

hospital.xls is an Excel spreadsheet containing patient names, sex, age, weight, blood pressure, and dates of treatment in an experimental protocol. First read the data into a dataset array.

```
patients = dataset('XLSFile','hospital.xls',...  
                  'ReadObsNames',true);
```

Examine the first row of data.

```
patients(1,:)
```

```
ans =
      name      sex      age      wgt      smoke
YPL-320 'SMITH'    'm'      38      176      1

      sys      dia      trial1      trial2      trial3      trial4
YPL-320  124      93      18      -99      -99      -99
```

The sex and smoke fields seem to have two choices each. So change these fields to nominal.

```
patients.smoke = nominal(patients.smoke,{'No','Yes'});
patients.sex = nominal(patients.sex);
```

### Step 2. Create a fitted model.

Your goal is to model the systolic pressure as a function of a patient's age, weight, sex, and smoking status. Create a linear formula for 'sys' as a function of 'age', 'wgt', 'sex', and 'smoke'.

```
modelspec = 'sys ~ age + wgt + sex + smoke';
mdl = fitlm(patients,modelspec)
```

```
mdl =
```

Linear regression model:

```
sys ~ 1 + sex + age + wgt + smoke
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	118.28	7.6291	15.504	9.1557e-28
sex_m	0.88162	2.9473	0.29913	0.76549
age	0.08602	0.06731	1.278	0.20438
wgt	-0.016685	0.055714	-0.29947	0.76524
smoke_Yes	9.884	1.0406	9.498	1.9546e-15

Number of observations: 100, Error degrees of freedom: 95  
Root Mean Squared Error: 4.81  
R-squared: 0.508, Adjusted R-Squared 0.487  
F-statistic vs. constant model: 24.5, p-value = 5.99e-14

The sex, age, and weight predictors have rather high  $p$ -values, indicating that some of these predictors might be unnecessary.

**Step 3. Locate and remove outliers.**

See if there are outliers in the data that should be excluded from the fit. Plot the residuals.

```
plotResiduals(md1)
```

There is one possible outlier, with a value greater than 12. This is probably not truly an outlier. For demonstration, here is how to find and remove it.

Find the outlier.

```
outlier = mdl.Residuals.Raw > 12;
find(outlier)
```

```
ans =
     84
```

Remove the outlier.

```
mdl = fitlm(patients,modelspec,...
    'Exclude',84);
```

```
mdl.ObservationInfo(84,:)
```

```
ans =
           WXM-486      Weights      Excluded      Missing      Subset
           1           1           true           false           false
```

Observation 84 is no longer in the model.

#### Step 4. Simplify the model.

Try to obtain a simpler model, one with fewer predictors but the same predictive accuracy. `step` looks for a better model by adding or removing one term at a time. Allow `step` take up to 10 steps.

```
mdl1 = step(mdl,'NSteps',10)
```

1. Removing wgt, FStat = 4.6001e-05, pValue = 0.9946
2. Removing sex, FStat = 0.063241, pValue = 0.80199

```
mdl1 =
```

```
Linear regression model:
    sys ~ 1 + age + smoke
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	115.11	2.5364	45.383	1.1407e-66
age	0.10782	0.064844	1.6628	0.09962

```
smoke_Yes      10.054      0.97696      10.291      3.5276e-17
```

```
Number of observations: 99, Error degrees of freedom: 96  
Root Mean Squared Error: 4.61  
R-squared: 0.536, Adjusted R-Squared 0.526  
F-statistic vs. constant model: 55.4, p-value = 1.02e-16
```

step took two steps. This means it could not improve the model further by adding or subtracting a single term.

Plot the effectiveness of the simpler model on the training data.

```
plotResiduals(md11)
```

The residuals look about as small as those of the original model.

**Step 5. Predict responses to new data.**

Suppose you have four new people, aged 25, 30, 40, and 65, and the first and third smoke. Predict their systolic pressure using `mdl1`.

```
ages = [25;30;40;65];
smoker = {'Yes';'No';'Yes';'No'};
systolicnew = feval(mdl1,ages,smoker)
```

```
systolicnew =
```

```
127.8561
118.3412
129.4734
122.1149
```

To make predictions, you need only the variables that `mdl1` uses.

**Step 6. Share the model.**

You might want others to be able to use your model for prediction. Access the terms in the linear model.

```
coefnames = mdl1.CoefficientNames
```

```
coefnames =
```

```
 '(Intercept)'      'age'      'smoke_Yes'
```

View the model formula.

```
mdl1.Formula
```

```
ans =
```

```
sys ~ 1 + age + smoke
```

Access the coefficients of the terms.

```
coefvals = mdl1.Coefficients(:,1); % dataset array
coefvals = double(coefvals)
```

```
coefvals =
```

```
115.1066
```

```
0.1078
```

```
10.0540
```

The model is  $\text{sys} = 115.1066 + 0.1078 \cdot \text{age} + 10.0540 \cdot \text{smoke}$ , where  $\text{smoke}$  is 1 for a smoker, and 0 otherwise.

## Regression Using Dataset Arrays

This example shows how to perform linear and stepwise regression analyses using dataset arrays.

### Load sample data.

```
load imports-85
```

### Store predictor and response variables in dataset array.

```
ds = dataset(X(:,7),X(:,8),X(:,9),X(:,15),'Varnames',...
{'curb_weight','engine_size','bore','price'});
```

### Fit linear regression model.

Fit a linear regression model that explains the price of a car in terms of its curb weight, engine size, and bore.

```
fitlm(ds,'price~curb_weight+engine_size+bore')
```

```
ans =
```

```
Linear regression model:
```

```
price ~ 1 + curb_weight + engine_size + bore
```

```
Estimated Coefficients:
```

	Estimate	SE	tStat	pValue
(Intercept)	64.095	3.703	17.309	2.0481e-41
curb_weight	-0.0086681	0.0011025	-7.8623	2.42e-13
engine_size	-0.015806	0.013255	-1.1925	0.23452
bore	-2.6998	1.3489	-2.0015	0.046711

```
Number of observations: 201, Error degrees of freedom: 197
```

```
Root Mean Squared Error: 3.95
```

```
R-squared: 0.674, Adjusted R-Squared 0.669
```

```
F-statistic vs. constant model: 136, p-value = 1.14e-47
```

The command `fitlm(ds)` also returns the same result because `fitlm`, by default, assumes the predictor variable is in the last column of the dataset array `ds`.

### Recreate dataset array and repeat analysis.

This time, put the response variable in the first column of the dataset array.

```
ds = dataset(X(:,15),X(:,7),X(:,8),X(:,9), 'Varnames', ...
{'price', 'curb_weight', 'engine_size', 'bore'});
```

When the response variable is in the first column of `ds`, define its location. For example, `fitlm`, by default, assumes that `bore` is the response variable. You can define the response variable in the model using either:

```
fitlm(ds, 'ResponseVar', 'price');
```

or

```
fitlm(ds, 'ResponseVar', logical([1 0 0 0]));
```

### Perform stepwise regression.

```
stepwiselm(ds, 'quadratic', 'lower', 'price~1', ...
'ResponseVar', 'price')
```

1. Removing `bore^2`, `FStat` = 0.01282, `pValue` = 0.90997
2. Removing `engine_size^2`, `FStat` = 0.078043, `pValue` = 0.78027
3. Removing `curb_weight:bore`, `FStat` = 0.70558, `pValue` = 0.40195

```
ans =
```

Linear regression model:

```
price ~ 1 + curb_weight*engine_size + engine_size*bore + curb_weight^2
```

Estimated Coefficients:

	Estimate	SE	tStat	pVal
(Intercept)	131.13	14.273	9.1873	6.23
curb_weight	-0.043315	0.0085114	-5.0891	8.46
engine_size	-0.17102	0.13844	-1.2354	0
bore	-12.244	4.999	-2.4493	0.

curb_weight:engine_size	-6.3411e-05	2.6577e-05	-2.386	0.
engine_size:bore	0.092554	0.037263	2.4838	0.
curb_weight^2	8.0836e-06	1.9983e-06	4.0451	7.54

Number of observations: 201, Error degrees of freedom: 194

Root Mean Squared Error: 3.59

R-squared: 0.735, Adjusted R-Squared 0.726

F-statistic vs. constant model: 89.5, p-value = 3.58e-53

The initial model is a quadratic formula, and the lowest model considered is the constant. Here, `stepwiselm` performs a backward elimination technique to determine the terms in the model. The final model is `price ~ 1 + curb_weight*engine_size + engine_size*bore + curb_weight^2`, which corresponds to

$$P = \beta_0 + \beta_C C + \beta_E E + \beta_B B + \beta_{CE} CE + \beta_{EB} EB + \beta_{C^2} C^2 + \varepsilon$$

where  $P$  is price,  $C$  is curb weight,  $E$  is engine size,  $B$  is bore,  $\beta_i$  is the coefficient for the corresponding term in the model, and  $\varepsilon$  is the error term. The final model includes all three main effects, the interaction effects for curb weight and engine size and engine size and bore, and the second-order term for curb weight.

## Linear Regression with Interaction Effects

This example shows how to construct and analyze a linear regression model with interaction effects and interpret the results.

### Load sample data.

```
load hospital
```

To retain only the first column of blood pressure, store data in a new dataset array.

```
ds = dataset(hospital.Sex,hospital.Age,hospital.Weight,hospital.Smoker,...
hospital.BloodPressure(:,1),'Varnames',{'Sex','Age','Weight','Smoker',...
'BloodPressure'});
```

### Perform stepwise linear regression.

For the initial model, use the full model with all terms and their pairwise interactions.

```
mdl = stepwiselm(ds,'interactions')
```

1. Removing Sex:Smoker, FStat = 0.050738, pValue = 0.8223
2. Removing Weight:Smoker, FStat = 0.07758, pValue = 0.78124
3. Removing Age:Weight, FStat = 1.9717, pValue = 0.16367
4. Removing Sex:Age, FStat = 0.32389, pValue = 0.57067
5. Removing Age:Smoker, FStat = 2.4939, pValue = 0.11768

```
mdl =
```

Linear regression model:

```
BloodPressure ~ 1 + Age + Smoker + Sex*Weight
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	133.17	10.337	12.883	1.76e-22
Sex_Male	-35.269	17.524	-2.0126	0.047015
Age	0.11584	0.067664	1.712	0.090198
Weight	-0.1393	0.080211	-1.7367	0.085722

Smoker_1	9.8307	1.0229	9.6102	1.2391e-15
Sex_Male:Weight	0.2341	0.11192	2.0917	0.039162

Number of observations: 100, Error degrees of freedom: 94  
 Root Mean Squared Error: 4.72  
 R-squared: 0.53, Adjusted R-Squared 0.505  
 F-statistic vs. constant model: 21.2, p-value = 4e-14

The final model in formula form is **BloodPressure ~ 1 + Age + Smoker + Sex\*Weight**. This model includes all four main effects (Age, Smoker, Sex, Weight) and the two-way interaction between Sex and Weight. This model corresponds to

$$BP = \beta_0 + \beta_A X_A + \beta_{Sm} I_{Sm} + \beta_S I_S + \beta_W X_W + \beta_{SW} X_W I_S + \varepsilon,$$

where

- $BP$  is the blood pressure
- $\beta_i$ s are the coefficients
- $I_{Sm}$  is the indicator variable for smoking;  $I_{Sm} = 1$  indicates a smoking patient whereas  $I_{Sm} = 0$  indicates a nonsmoking patient
- $I_S$  is the indicator variable for sex;  $I_S = 1$  indicates a male patient whereas  $I_S = 0$  indicates a female patient
- $X_A$  is the Age variable
- $X_W$  is the Weight variable
- $\varepsilon$  is the error term

The following table shows the fitted linear model for each gender and smoking combination.

$I_{Sm}$	$I_S$	Linear Model
1 (Male)	1 (Smoker)	$BP = (\beta_0 + \beta_{Sm} + \beta_S) + \beta_A X_A + (\beta_W + \beta_{SW}) X_W$ $\hat{BP} = 107.5617 + 0.11584 X_A + 0.11826 X_W$
1 (Male)	0 (Nonsmoker)	$BP = (\beta_0 + \beta_{Sm}) + \beta_A X_A + \beta_W X_W$
0 (Female)	1 (Smoker)	$BP = (\beta_0 + \beta_S) + \beta_A X_A + (\beta_W + \beta_{SW}) X_W$ $\hat{BP} = 97.901 + 0.11584 X_A + 0.11826 X_W$
0 (Female)	0 (Nonsmoker)	$BP = \beta_0 + \beta_A X_A + \beta_W X_W$ $\hat{BP} = 133.17 + 0.11584 X_A - 0.1393 X_W$

As seen from these models,  $\beta_{Sm}$  and  $\beta_S$  show how much the intercept of the response function changes when the indicator variable takes the value 1 compared to when it takes the value 0.  $\beta_{SW}$ , however, shows the effect of the Weight variable on the response variable when the indicator variable for sex takes the value 1 compared to when it takes the value 0. You can explore the main and interaction effects in the final model using the methods of the `LinearModel` class as follows.

**Plot prediction slice plots.**

```
figure()
plotSlice mdl
```

This plot shows the main effects for all predictor variables. The green line in each panel shows the change in the response variable as a function of the predictor variable when all other predictor variables are held constant. For example, for a smoking male patient aged 37.5, the expected blood pressure increases as the weight of the patient increases, given all else the same.

The dashed red curves in each panel show the 95% confidence bounds for the predicted response values.

The horizontal dashed blue line in each panel shows the predicted response for the specific value of the predictor variable corresponding to the vertical dashed blue line. You can drag these lines to get the predicted response values at other predictor values, as shown next.

For example, the predicted value of the response variable is 118.3497 when a patient is female, nonsmoking, age 40.3788, and weighs 139.9545 pounds. The values in the square brackets, [114.621, 122.079], show the lower and upper limits of a 95% confidence interval for the estimated response. Note that, for a nonsmoking female patient, the expected blood pressure decreases as the weight increases, given all else is held constant.

**Plot main effects.**

```
figure()  
plotEffects mdl
```

This plot displays the main effects. The circles show the magnitude of the effect and the blue lines show the upper and lower confidence limits for the main effect. For example, being a smoker increases the expected blood pressure by 10 units, compared to being a nonsmoker, given all else is held constant. Expected blood pressure increases about two units for males compared to females, again, given other predictors held constant. An increase in age from 25 to 50 causes an expected increase of 4 units, whereas a change in weight from 111 to 202 causes about a 4-unit decrease in the expected blood pressure, given all else held constant.

**Plot interaction effects.**

```
figure()
plotInteraction mdl, 'Sex', 'Weight'
```

This plot displays the impact of a change in one factor given the other factor is fixed at a value.

Be cautious while interpreting the interaction effects. When there is not enough data on all factor combinations or the data is highly correlated, it might be difficult to determine the interaction effect of changing one factor while keeping the other fixed. In such cases, the estimated interaction effect is an extrapolation from the data.

The blue circles show the main effect of a specific term, as in the main effects plot. The red circles show the impact of a change in one term for fixed values of the other term. For example, in the bottom half of this plot, the red circles show the impact of a weight change in female and male patients, separately. You can see that an increase in a female's weight from 111 to 202 pounds causes about a 14-unit decrease in the expected blood pressure, while an increase of the same amount in the weight of a male patient causes about a 5-unit increase in the expected blood pressure, again given other predictors are held constant.

**Plot prediction effects.**

```
figure()  
plotInteraction(md1, 'Sex', 'Weight', 'predictions')
```

This plot shows the effect of changing one variable as the other predictor variable is held constant. In this example, the last figure shows the response variable, blood pressure, as a function of weight, when the variable sex is fixed at males and females. The lines for males and females are crossing which indicates a strong interaction between weight and sex. You can see that the expected blood pressure increases as the weight of a male patient increases, but decreases as the weight of a female patient increases.

```

```
R-squared: 0.752, Adjusted R-Squared 0.744
```

```
F-statistic vs. constant model: 90, p-value = 7.38e-27
```

This linear regression outputs display shows the following.

$y \sim 1 + x_1 + x_2 + x_3$	Linear regression model in the formula form using Wilkinson notation. Here it corresponds to:  $y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \varepsilon.$
First column (under Estimated Coefficients)	Terms included in the model.
Estimate	Coefficient estimates for each corresponding term in the model. For example, the estimate for the constant term (intercept) is 47.977.
SE	Standard error of the coefficients.
tStat	<i>t</i> -statistic for each coefficient to test the null hypothesis that the corresponding coefficient is zero against the alternative that it is different from zero, given the other predictors in the model. Note that $tStat = Estimate/SE$ . For example, the <i>t</i> -statistic for the intercept is $47.977/3.8785 = 12.37$ .
pValue	<i>p</i> -value for the F statistic of the hypotheses test that the corresponding coefficient is equal to zero or not. For example, the <i>p</i> -value of the F-statistic for $x_2$ is greater than 0.05, so this term is not significant at the 5% significance level given the other terms in the model.
Number of observations	Number of rows without any NaN values. For example, Number of observations is 93 because the MPG data vector has 6 NaN values and one of the data vectors, Horsepower, has one NaN value for a different observation.
Error degrees of freedom	$n - p$ , where $n$ is the number of observations, and $p$ is the number of coefficients in the model, including the intercept. For example, the model has four predictors, so the Error degrees of freedom is $93 - 4 = 89$ .
Root mean squared error	Square root of the mean squared error, which estimates the standard deviation of the error distribution.

R-squared and Adjusted R-squared	Coefficient of determination and adjusted coefficient of determination, respectively. For example, the R-squared value suggests that the model explains approximately 75% of the variability in the response variable MPG.
F-statistic vs. constant model	Test statistic for the F-test on the regression model. It tests for a significant linear regression relationship between the response variable and the predictor variables.
p-value	<i>p</i> -value for the F-test on the model. For example, the model is significant with a <i>p</i> -value of 7.3816e-27.

You can request this display by using `disp`. For example, if you name your model `lm`, then you can display the outputs using `disp(lm)`.

**Perform analysis of variance (ANOVA) for the model.**

```
anova(lm, 'summary')
```

```
ans =
```

	SumSq	DF	MeanSq	F	pValue
Total	6004.8	92	65.269		
Model	4516	3	1505.3	89.987	7.3816e-27
Residual	1488.8	89	16.728		

This ANOVA display shows the following.

SumSq	Sum of squares for the regression model, Model, the error term, Residual, and the total, Total.
DF	Degrees of freedom for each term. Degrees of freedom is $n - 1$ for the total, $p - 1$ for the model, and $n - p$ for the error term, where $n$ is the number of observations, and $p$ is the number of coefficients in the model, including the intercept. For example, MPG data vector has six NaN values and one of the data vectors, Horsepower, has one NaN value for a different observation, so the total degrees of freedom is $93 - 1 = 92$ . There are four coefficients in the model, so the model DF is $4 - 1 = 3$ , and the DF for error term is $93 - 4 = 89$ .
MeanSq	Mean squared error for each term. Note that $\text{MeanSq} = \text{SumSq}/\text{DF}$ . For example, the mean squared error for the error term is $1488.8/89 = 16.728$ . The square root of this value is the root mean squared error in the linear regression display, or 4.09.
F	F-statistic value, which is the same as F-statistic vs. constant model in the linear regression display. In this example, it is 89.987, and in the linear regression display this F-statistic value is rounded up to 90.
pValue	p-value for the F-test on the model. In this example, it is 7.3816e-27.

If there are higher-order terms in the regression model, anova partitions the model SumSq into the part explained by the higher-order terms and the rest. The corresponding F-statistics are for testing the significance of the linear terms and higher-order terms as separate groups.

If the data includes replicates, or multiple measurements at the same predictor values, then the anova partitions the error SumSq into the part for the replicates and the rest. The corresponding F-statistic is for testing the lack-of-fit by comparing the model residuals with the model-free variance estimate computed on the replicates.

See the anova method for details.

**Decompose ANOVA table for model terms.**

```
anova(lm)
```

```
ans =
```

	SumSq	DF	MeanSq	F	pValue
x1	563.18	1	563.18	33.667	9.8742e-08
x2	52.187	1	52.187	3.1197	0.08078
x3	0.060046	1	0.060046	0.0035895	0.95236
Error	1488.8	89	16.728		

This anova display shows the following:

First column	Terms included in the model.
SumSq	Sum of squared error for each term except for the constant.
DF	Degrees of freedom. In this example, DF is 1 for each term in the model and $n - p$ for the error term, where $n$ is the number of observations, and $p$ is the number of coefficients in the model, including the intercept. For example, the DF for the error term in this model is $93 - 4 = 89$ . If any of the variables in the model is a categorical variable, the DF for that variable is the number of indicator variables created for its categories (number of categories - 1).
MeanSq	Mean squared error for each term. Note that $\text{MeanSq} = \text{SumSq}/\text{DF}$ . For example, the mean squared error for the error term is $1488.8/89 = 16.728$ .
F	F-values for each coefficient. The F-value is the ratio of the mean squared of each term and mean squared error, that is, $F = \text{MeanSq}(x_i) / \text{MeanSq}(\text{Error})$ . Each F-statistic has an F distribution, with the numerator degrees of freedom, DF value for the corresponding term, and the denominator degrees of freedom, $n - p$ . $n$ is the number of observations, and $p$ is the number of coefficients in the model. In this example, each F-statistic has an $F_{(1, 89)}$ distribution.
pValue	$p$ -value for each hypothesis test on the coefficient of the corresponding term in the linear model. For example, the $p$ -value for the F-statistic coefficient of $x_2$ is 0.08078, and is not

significant at the 5% significance level given the other terms in the model.

### Display coefficient confidence intervals.

```
coefCI(lm)
```

```
ans =
```

```

40.2702  55.6833
-0.0088 -0.0043
-0.0913  0.0054
-0.3957  0.3726

```

The values in each row are the lower and upper confidence limits, respectively, for the default 95% confidence intervals for the coefficients. For example, the first row shows the lower and upper limits, 40.2702 and 55.6833, for the intercept,  $\beta_0$ . Likewise, the second row shows the limits for  $\beta_1$  and so on. Confidence intervals provide a measure of precision for linear regression coefficient estimates. A  $100(1-\alpha)\%$  confidence interval gives the range the corresponding regression coefficient will be in with  $100(1-\alpha)\%$  confidence.

You can also change the confidence level. Find the 99% confidence intervals for the coefficients.

```
coefCI(lm,0.01)
```

```
ans =
```

```

37.7677  58.1858
-0.0095 -0.0036
-0.1069  0.0211
-0.5205  0.4973

```

### Perform hypothesis test on coefficients.

Test the null hypothesis that all predictor variable coefficients are equal to zero versus the alternate hypothesis that at least one of them is different from zero.

```
[p,F,d] = coefTest(lm)
```

```
p =  
7.3816e-27
```

```
F =  
89.9874
```

```
d =  
3
```

Here, `coefTest` performs an F-test for the hypothesis that all regression coefficients (except for the intercept) are zero versus at least one differs from zero, which essentially is the hypothesis on the model. It returns  $p$ , the  $p$ -value,  $F$ , the F-statistic, and  $d$ , the numerator degrees of freedom. The F-statistic and  $p$ -value are the same as the ones in the linear regression display and ANOVA for the model. The degrees of freedom is  $4 - 1 = 3$  because there are four predictors (including the intercept) in the model.

Now, perform a hypothesis test on the coefficients of the first and second predictor variables.

```
H = [0 1 0 0; 0 0 1 0];  
[p,F,d] = coefTest(lm,H)
```

```
p =  
5.1702e-23
```

```
F =  
96.4873
```

```
d =
```

2

The numerator degrees of freedom is the number of coefficients tested, which is 2 in this example. The results indicate that at least one of  $\beta_2$  and  $\beta_3$  differs from zero.

## Cook's Distance

### Purpose

Cook's distance is useful for identifying outliers in the  $X$  values (observations for predictor variables). It also shows the influence of each observation on the fitted response values. An observation with Cook's distance larger than three times the mean Cook's distance might be an outlier.

### Definition

Cook's distance is the scaled change in fitted values. Each element in `CooksDistance` is the normalized change in the vector of coefficients due to the deletion of an observation. The Cook's distance,  $D_i$ , of observation  $i$  is

$$D_i = \frac{\sum_{j=1}^n (\hat{y}_j - \hat{y}_{j(i)})^2}{pMSE},$$

where

- $\hat{y}_j$  is the  $j$ th fitted response value.
- $\hat{y}_{j(i)}$  is the  $j$ th fitted response value, where the fit does not include observation  $i$ .
- $MSE$  is the mean squared error.
- $p$  is the number of coefficients in the regression model.

Cook's distance is algebraically equivalent to the following expression:

$$D_i = \frac{r_i^2}{pMSE} \left( \frac{h_{ii}}{(1-h_{ii})^2} \right),$$

where  $r_i$  is the  $i$ th residual, and  $h_{ii}$  is the  $i$ th leverage value.

`CooksDistance` is an  $n$ -by-1 column vector in the `Diagnostics` dataset array of the `LinearModel` object.

## How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Display the Cook's distance values by indexing into the property using dot notation,

```
mdl.Diagnostics.CooksDistance
```

- Plot the Cook's distance values using

```
plotDiagnostics(mdl, 'cookd')
```

For details, see the `plotDiagnostics` method of the `LinearModel` class.

## Example

This example shows how to use Cook's Distance to determine the outliers in the data.

Load the sample data and define the independent and response variables.

```
load hospital
X = double(hospital(:,2:5));
y = hospital.BloodPressure(:,1);
```

Fit the linear regression model.

```
mdl = fitlm(X,y);
```

Plot the Cook's distance values.

```
plotDiagnostics(mdl, 'cookd')
```

The dashed line in the figure corresponds to the recommended threshold value,  $3 \cdot \text{mean}(\text{mdl.Diagnostics.CooksDistance})$ . The plot has some observations with Cook's distance values greater than the threshold value, which for this example is  $3 \cdot (0.0108) = 0.0324$ . In particular, there are two Cook's distance values that are relatively higher than the others, which exceed the threshold value. You might want to find and omit these from your data and rebuild your model.

Find the observations with Cook's distance values that exceed the threshold value.

```
find((mdl.Diagnostics.CooksDistance)>3*mean(mdl.Diagnostics.CooksDistance))
```

```
ans =  
    2  
   13  
   28  
   44  
   58  
   70  
   71  
   84  
   93  
   95
```

Find the observations with Cook's distance values that are relatively larger than the other observations with Cook's distances exceeding the threshold value.

```
find((mdl.Diagnostics.CooksDistance)>5*mean(mdl.Diagnostics.CooksDistance))
```

```
ans =  
    2  
   84
```

## Coefficient Standard Errors and Confidence Intervals

### In this section...

“Coefficient Covariance and Standard Errors” on page 9-76

“Compute Coefficient Covariance and Standard Errors” on page 9-76

“Coefficient Confidence Intervals” on page 9-77

“Compute Coefficient Confidence Intervals” on page 9-78

## Coefficient Covariance and Standard Errors

### Purpose

Estimated coefficient variances and covariances capture the precision of regression coefficient estimates. The coefficient variances and their square root, the standard errors, are useful in testing hypotheses for coefficients.

### Definition

The estimated covariance matrix is

$$\Sigma = MSE(XX)^{-1},$$

where  $MSE$  is the mean squared error, and  $X$  is the matrix of observations on the predictor variables. `CoefficientCovariance`, a property of the fitted model, is a  $p$ -by- $p$  covariance matrix of regression coefficient estimates.  $p$  is the number of coefficients in the regression model. The diagonal elements are the variances of the individual coefficients.

### How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can display the coefficient covariances using

```
mdl.CoefficientCovariance
```

## Compute Coefficient Covariance and Standard Errors

This example shows how to compute the covariance matrix and standard errors of the coefficients.

Load the sample data and define the predictor and response variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = fitlm(X,y);
```

Display the coefficient covariance matrix.

```
CM = mdl.CoefficientCovariance
```

```
CM =

    27.5113    11.0027   -0.1542   -0.2444    0.2702
    11.0027     8.6864    0.0021   -0.1547   -0.0838
   -0.1542     0.0021    0.0045   -0.0001   -0.0029
   -0.2444   -0.1547   -0.0001    0.0031   -0.0026
    0.2702   -0.0838   -0.0029   -0.0026    1.0829
```

Compute the coefficient standard errors.

```
SE = diag(sqrt(CM))
```

```
SE =

    5.2451
    2.9473
    0.0673
    0.0557
    1.0406
```

## Coefficient Confidence Intervals

### Purpose

The coefficient confidence intervals provide a measure of precision for linear regression coefficient estimates. A  $100(1-\alpha)\%$  confidence interval gives the range that the corresponding regression coefficient will be in with  $100(1-\alpha)\%$  confidence.

**Definition**

The  $100*(1-\alpha)\%$  confidence intervals for linear regression coefficients are

$$b_i \pm t_{(1-\alpha/2, n-p)} SE(b_i),$$

where  $b_i$  is the coefficient estimate,  $SE(b_i)$  is the standard error of the coefficient estimate, and  $t_{(1-\alpha/2, n-p)}$  is the  $100(1-\alpha/2)$  percentile of  $t$ -distribution with  $n - p$  degrees of freedom.  $n$  is the number of observations and  $p$  is the number of regression coefficients.

**How To**

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can obtain the default 95% confidence intervals for coefficients using

```
coefCI(mdl)
```

You can also change the confidence level using

```
coefCI(mdl, alpha)
```

For details, see the `coefCI` and `coefTest` methods of `LinearModel` class.

**Compute Coefficient Confidence Intervals**

This example shows how to compute coefficient confidence intervals.

Load the sample data and fit a linear regression model.

```
load hald  
mdl = fitlm(ingredients, heat);
```

Display the 95% coefficient confidence intervals.

```
coefCI(mdl)  
  
ans =  
  
-99.1786  223.9893  
-0.1663   3.2685  
-1.1589   2.1792
```

```
-1.6385    1.8423
-1.7791    1.4910
```

The values in each row are the lower and upper confidence limits, respectively, for the default 95% confidence intervals for the coefficients. For example, the first row shows the lower and upper limits,  $-99.1786$  and  $223.9893$ , for the intercept,  $\beta_0$ . Likewise, the second row shows the limits for  $\beta_1$  and so on.

Display the 90% confidence intervals for the coefficients ( $\alpha = 0.1$ ).

```
coefCI mdl, 0.1)
```

```
ans =
```

```
-67.8949  192.7057
  0.1662   2.9360
-0.8358   1.8561
-1.3015   1.5053
-1.4626   1.1745
```

The confidence interval limits become narrower as the confidence level decreases.

## Coefficient of Determination (R-Squared)

### Purpose

Coefficient of determination (R-squared) indicates the proportionate amount of variation in the response variable  $y$  explained by the independent variables  $X$  in the linear regression model. The larger the R-squared is, the more variability is explained by the linear regression model.

### Definition

R-squared is the proportion of the total sum of squares explained by the model. Rsquared, a property of the fitted model, is a structure with two fields:

- Ordinary — Ordinary (unadjusted) R-squared

$$R^2 = \frac{SSR}{SST} = 1 - \frac{SSE}{SST}.$$

- Adjusted — R-squared adjusted for the number of coefficients

$$R_{adj}^2 = 1 - \left( \frac{n-1}{n-p} \right) \frac{SSE}{SST}.$$

$SSE$  is the sum of squared error,  $SSR$  is the sum of squared regression,  $SST$  is the sum of squared total,  $n$  is the number of observations, and  $p$  is the number of regression coefficients (including the intercept). Because R-squared increases with added predictor variables in the regression model, the adjusted R-squared adjusts for the number of predictor variables in the model. This makes it more useful for comparing models with a different number of predictors.

### How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can obtain either R-squared value as a scalar by indexing into the property using dot notation, for example,

```
mdl.Rsquared.Ordinary  
mdl.Rsquared.Adjusted
```

You can also obtain the SSE, SSR, and SST using the properties with the same name.

```
mdl.SSE
mdl.SSR
mdl.SST
```

## Example

This example shows how to display Rsquared (coefficient of determination) and adjusted R-squared.

Load the sample data and define the response and independent variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = fitlm(X,y)
```

```
mdl =
```

```
Linear regression model:
y ~ 1 + x1 + x2 + x3 + x4
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	117.4	5.2451	22.383	1.1667e-39
x1	0.88162	2.9473	0.29913	0.76549
x2	0.08602	0.06731	1.278	0.20438
x3	-0.016685	0.055714	-0.29947	0.76524
x4	9.884	1.0406	9.498	1.9546e-15

Number of observations: 100, Error degrees of freedom: 95

Root Mean Squared Error: 4.81

R-squared: 0.508, Adjusted R-Squared 0.487

F-statistic vs. constant model: 24.5, p-value = 5.99e-14

The R-squared and adjusted R-squared values are 0.508 and 0.487, respectively. Model explains about 50% of the variability in the response variable.

Access the R-squared and adjusted R-squared values using the property of the fitted `LinearModel` object.

```
mdl.Rsquared.Ordinary
```

```
ans =
```

```
0.5078
```

```
mdl.Rsquared.Adjusted
```

```
ans =
```

```
0.4871
```

The adjusted R-squared value is smaller than the ordinary R-squared value.

“Delete-1 Variance (S2\_i)” on page 9-90

“Delete-1 Variance Example” on page 9-91

## Delete-1 Change in Covariance (covratio)

### Purpose

Delete-1 change in covariance (covratio) identifies the observations that are influential in the regression fit. An influential observation is one where its exclusion from the model might significantly alter the regression function. Values of covratio larger than  $1 + 3*p/n$  or smaller than  $1 - 3*p/n$  indicate influential points, where  $p$  is the number of regression coefficients, and  $n$  is the number of observations.

### Definition

The covratio statistic is the ratio of the determinant of the coefficient covariance matrix with observation  $i$  deleted to the determinant of the covariance matrix for the full model:

$$\text{covratio} = \frac{\det\{MSE(i)[X'(i)X(i)]^{-1}\}}{\det[MSE(XX)^{-1}]}$$

CovRatio is an  $n$ -by-1 vector in the Diagnostics dataset array of the fitted LinearModel object. Each element is the ratio of the generalized variance of

the estimated coefficients when the corresponding element is deleted to the generalized variance of the coefficients using all the data.

### How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Display the `CovRatio` by indexing into the property using dot notation

```
mdl.Diagnostics.CovRatio
```

- Plot the delete-1 change in covariance using

```
plotDiagnostics(mdl, 'CovRatio')
```

For details, see the `plotDiagnostics` method of the `LinearModel` class.

### CovRatio Example

This example shows how to use the `CovRatio` statistics to determine the influential points in data.

Load the sample data and define the response and predictor variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = fitlm(X,y);
```

Plot the `CovRatio` statistics.

```
plotDiagnostics(mdl, 'CovRatio')
```

For this example, the threshold limits are  $1 + 3*5/100 = 1.15$  and  $1 - 3*5/100 = 0.85$ . There are a few points beyond the limits, which might be influential points.

Find the observations that are beyond the limits.

```
find((mdl.Diagnostics.CovRatio)>1.15|(mdl.Diagnostics.CovRatio)<0.85)
```

```
ans =
```

```
2  
14  
84
```

93

## Delete-1 Scaled Difference in Coefficient Estimates (Dfbetas)

### Purpose

The sign of a delete-1 scaled difference in coefficient estimate (Dfbetas) for coefficient  $j$  and observation  $i$  indicates whether that observation causes an increase or decrease in the estimate of the regression coefficient. The absolute value of a Dfbetas indicates the magnitude of the difference relative to the estimated standard deviation of the regression coefficient. A Dfbetas value larger than  $3/\sqrt{n}$  in absolute value indicates that the observation has a large influence on the corresponding coefficient.

### Definition

Dfbetas for coefficient  $j$  and observation  $i$  is the ratio of the difference in the estimate of coefficient  $j$  using all observations and the one obtained by removing observation  $i$ , and the standard error of the coefficient estimate obtained by removing observation  $i$ . The Dfbetas for coefficient  $j$  and observation  $i$  is

$$Dfbetas_{ij} = \frac{b_j - b_{j(i)}}{\sqrt{MSE_{(i)}(1 - h_{ii})}},$$

where  $b_j$  is the estimate for coefficient  $j$ ,  $b_{j(i)}$  is the estimate for coefficient  $j$  by removing observation  $i$ ,  $MSE_{(i)}$  is the mean squared error of the regression fit by removing observation  $i$ , and  $h_{ii}$  is the leverage value for observation  $i$ . Dfbetas is an  $n$ -by- $p$  matrix in the `Diagnostics` dataset array of the fitted `LinearModel` object. Each cell of Dfbetas corresponds to the Dfbetas value for the corresponding coefficient obtained by removing the corresponding observation.

### How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can obtain the Dfbetas values as an  $n$ -by- $p$  matrix by indexing into the property using dot notation,

```
mdl.Diagnostics.Dfbetas
```

## Dfbetas Example

This example shows how to determine the observations that have large influence on coefficients using Dfbetas.

Load the sample data and define the response and independent variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = fitlm(X,y);
```

Find the Dfbetas values that are high in absolute value.

```
[row,col] = find(abs(mdl.Diagnostics.Dfbetas)>3/sqrt(100));
disp([row col])
```

```

 2     1
28     1
84     1
93     1
 2     2
13     3
84     3
 2     4
84     4
```

## Delete-1 Scaled Change in Fitted Values (Dffits)

### Purpose

The delete-1 scaled change in fitted values (Dffits) show the influence of each observation on the fitted response values. Dffits values with an absolute value larger than  $2\sqrt{p/n}$  might be influential.

**Definition**

Dffits for observation  $i$  is

$$Dffits_i = sr_i \sqrt{\frac{h_{ii}}{1-h_{ii}}},$$

where  $sr_i$  is the studentized residual, and  $h_{ii}$  is the leverage value of the fitted `LinearModel` object. `Dffits` is an  $n$ -by-1 column vector in the `Diagnostics` dataset array of the fitted `LinearModel` object. Each element in `Dffits` is the change in the fitted value caused by deleting the corresponding observation and scaling by the standard error.

**How To**

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Display the `Dffits` values by indexing into the property using dot notation

```
mdl.Diagnostics.Dffits
```

- Plot the delete-1 scaled change in fitted values using

```
plotDiagnostics(mdl, 'Dffits')
```

For details, see the `plotDiagnostics` method of the `LinearModel` class for details.

**Dffits Example**

This example shows how to determine the observations that are influential on the fitted response values using `Dffits` values.

Load the sample data and define the response and independent variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = fitlm(X,y);
```

Plot the Dffits values.

```
plotDiagnostics mdl, 'Dffits')
```

The influential threshold limit for the absolute value of Dffits in this example is  $2\sqrt{5/100} = 0.45$ . Again, there are some observations with Dffits values beyond the recommended limits.

Find the Dffits values that are large in absolute value.

```
find(abs(mdl.Diagnostics.Dffits)>2*sqrt(4/100))
```

```
ans =
```

## Delete-1 Variance (S2\_i)

### Purpose

The delete-1 variance (S2\_i) shows how the mean squared error changes when an observation is removed from the data set. You can compare the S2\_i values with the value of the mean squared error.

### Definition

S2\_i is a set of residual variance estimates obtained by deleting each observation in turn. The S2\_i value for observation  $i$  is

$$S2\_i = MSE_{(i)} = \frac{\sum_{j \neq i}^n [y_j - y_{j(i)}]^2}{n - p - 1},$$

where  $y_j$  is the  $j$ th observed response value. S2\_i is an  $n$ -by-1 vector in the Diagnostics dataset array of the fitted LinearModel object. Each element in S2\_i is the mean squared error of the regression obtained by deleting that observation.

### How To

After obtaining a fitted model, say, mdl, using fitlm or stepwiselm, you can:

- Display the S2\_i vector by indexing into the property using dot notation

```
mdl.Diagnostics.S2_i
```

- Plot the delete-1 variance values using

```
plotDiagnostics mdl, 'S2_i' )
```

For details, see the `plotDiagnostics` method of the `LinearModel` class.

## Delete-1 Variance Example

This example shows how to compute and plot `S2_i` values to examine the change in the mean squared error when an observation is removed from the data.

Load the sample data and define the response and independent variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = fitlm(X,y);
```

Display the MSE value for the model.

```
mdl.MSE
```

```
ans =
```

```
23.1140
```

Plot the `S2_i` values.

```
plotDiagnostics(mdl, 'S2_i' )
```

This plot makes it easy to compare the  $S^2_i$  values to the MSE value of 23.114, indicated by the horizontal dashed lines. You can see how deleting one observation changes the error variance.

## Durbin-Watson Test

### Purpose

The Durbin-Watson test assesses whether there is autocorrelation among the residuals or not.

### Definition

The Durbin-Watson test statistic,  $DW$ , is

$$DW = \frac{\sum_{i=1}^{n-1} (r_{i+1} - r_i)^2}{\sum_{i=1}^n r_i^2}.$$

Here,  $r_i$  is the  $i$ th raw residual, and  $n$  is the number of observations.

### How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can perform the Durbin-Watson test using

```
dwtest(mdl)
```

For details, see the `dwtest` method of the `LinearModel` class.

### Example

This example shows how to test for autocorrelation among the residuals of a linear regression model.

Load the sample data and fit a linear regression model.

```
load hald
mdl = fitlm(ingredients,heat);
```

Perform a two-sided Durbin-Watson test to determine if there is any autocorrelation among the residuals of the linear model, `mdl`.

```
[p,DW] = dwtest mdl,'exact','both')
```

```
p =
```

```
0.6285
```

```
DW =
```

```
2.0526
```

The value of the Durbin-Watson test statistic is 2.0526. The  $p$ -value of 0.6285 suggest that the residuals are not autocorrelated.

“t-statistic Example” on page 9-99

## F-statistic

### Purpose

In linear regression, the F-statistic is the test statistic for the analysis of variance (ANOVA) approach to test the significance of the model or the components in the model.

### Definition

The F-statistic in the linear model output display is the test statistic for testing the statistical significance of the model. The F-statistic values in the anova display are for assessing the significance of the terms or components in the model.

### How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Find the F-statistic vs. constant model in the output display or by using

```
disp(mdl)
```

- Display the ANOVA for the model using

```
anova(mdl, 'summary')
```

- Obtain the F-statistic values for the components, except for the constant term using

```
anova mdl)
```

For details, see the `anova` method of the `LinearModel` class.

## F-statistic Example

This example shows how to use assess the fit of the model and the significance of the regression coefficients using F-statistic.

Load the sample data.

```
load carbig
ds = dataset(Acceleration,Cylinders,Weight,MPG);
ds.Cylinders = ordinal(Cylinders);
```

Fit a linear regression model.

```
mdl = fitlm(ds,'MPG~Acceleration*Weight+Cylinders+Weight^2')
```

```
mdl =
```

Linear regression model:

```
MPG ~ 1 + Cylinders + Acceleration*Weight + Weight^2
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	50.816	7.5669	6.7156	6.661e-
Acceleration	0.023343	0.33931	0.068796	0.945
Cylinders_4	7.167	2.0596	3.4798	0.00055
Cylinders_5	10.963	3.1299	3.5028	0.000513
Cylinders_6	4.7415	2.1257	2.2306	0.0262
Cylinders_8	5.057	2.2981	2.2005	0.0283
Weight	-0.017497	0.0034674	-5.0461	6.9371e-
Acceleration:Weight	7.0745e-05	0.00011171	0.6333	0.526
Weight^2	1.5767e-06	3.6909e-07	4.2719	2.4396e-

Number of observations: 398, Error degrees of freedom: 389

Root Mean Squared Error: 4.02

R-squared: 0.741, Adjusted R-Squared 0.736

F-statistic vs. constant model: 139, p-value = 2.94e-109

The F-statistic of the linear fit versus the constant model is 139, with a  $p$ -value of 2.94e-109. The model is significant at the 5% significance level. The R-squared value of 0.741 means the model explains about 74% of the variability in the response.

Display the ANOVA table for the fitted model.

```
anova(md1, 'summary')
```

```
ans =
```

	SumSq	DF	MeanSq	F	pValue
Total	24253	397	61.09		
Model	17981	8	2247.6	139.41	2.9432e-109
. Linear	17667	6	2944.4	182.63	7.5446e-110
. Nonlinear	314.36	2	157.18	9.7492	7.3906e-05
Residual	6271.6	389	16.122		
. Lack of fit	6267.1	387	16.194	7.1973	0.12968
. Pure error	4.5	2	2.25		

This display separates the variability in the model into linear and nonlinear terms. Since there are two non-linear terms ( $Weight^2$  and the interaction between *Weight* and *Acceleration*), the nonlinear degrees of freedom in the DF column is 2. There are six linear terms in the model (four *Cylinders* indicator variables, *Weight*, and *Acceleration*). The corresponding F-statistics in the F column are for testing the significance of the linear and nonlinear terms as separate groups.

The residual term is also separated into two parts; first is the error due to the lack of fit, and second is the pure error independent from the model, obtained from the replicated observations. The corresponding F-statistics in the F column are for testing the lack of fit, that is, whether the proposed model is an adequate fit or not.

Display the ANOVA table for the model terms.

```
anova(md1)
```

```
ans =
```

	SumSq	DF	MeanSq	F	pValue
Acceleration	104.99	1	104.99	6.5122	0.011095
Cylinders	408.94	4	102.23	6.3412	5.9573e-05
Weight	2187.5	1	2187.5	135.68	4.1974e-27
Acceleration:Weight	6.4662	1	6.4662	0.40107	0.52691
Weight^2	294.22	1	294.22	18.249	2.4396e-05
Error	6271.6	389	16.122		

This display decomposes the ANOVA table into the model terms. The corresponding F-statistics in the F column are for assessing the statistical significance of each term. The F-test for Cylinders test whether at least one of the coefficients of indicator variables for cylinders categories is different from zero or not. That is, whether different numbers of cylinders have a significant effect on MPG or not. The degrees of freedom for each model term is the numerator degrees of freedom for the corresponding F-test. Most of the terms have 1 degree of freedom, but the degrees of freedom for Cylinders is 4. Because there are four indicator variables for this term.

## t-statistic

### Purpose

In linear regression, the  $t$ -statistic is useful for making inferences about the regression coefficients. The hypothesis test on coefficient  $i$  tests the null hypothesis that it is equal to zero – meaning the corresponding term is not significant – versus the alternate hypothesis that the coefficient is different from zero.

### Definition

For a hypotheses test on coefficient  $i$ , with

$$H_0 : \beta_i = 0$$

$$H_1 : \beta_i \neq 0,$$

the  $t$ -statistic is:

$$t = \frac{b_i}{SE(b_i)},$$

where  $SE(b_i)$  is the standard error of the estimated coefficient  $b_i$ .

## How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Find the coefficient estimates, the standard errors of the estimates (SE), and the  $t$ -statistic values of hypothesis tests for the corresponding coefficients (`tStat`) in the output display.
- Call for the display using

```
display(mdl)
```

## t-statistic Example

This example shows how to test for the significance of the regression coefficients using  $t$ -statistic.

Load the sample data and fit the linear regression model.

```
load hald
mdl = fitlm(ingredients,heat)
```

```
mdl =
```

```
Linear regression model:
y ~ 1 + x1 + x2 + x3 + x4
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	62.405	70.071	0.8906	0.39913
x1	1.5511	0.74477	2.0827	0.070822
x2	0.51017	0.72379	0.70486	0.5009
x3	0.10191	0.75471	0.13503	0.89592
x4	-0.14406	0.70905	-0.20317	0.84407

Number of observations: 13, Error degrees of freedom: 8

```

Root Mean Squared Error: 2.45
R-squared: 0.982, Adjusted R-Squared 0.974
F-statistic vs. constant model: 111, p-value = 4.76e-07

```

You can see that for each coefficient,  $tStat = Estimate/SE$ . The  $p$ -values for the hypotheses tests are in the `pValue` column. Each  $t$ -statistic tests for the significance of each term given other terms in the model. According to these results, none of the coefficients seem significant at the 5% significance level, although the R-squared value for the model is really high at 0.97. This often indicates possible multicollinearity among the predictor variables.

Use stepwise regression to decide which variables to include in the model.

```

load hald
mdl = stepwiselm(ingredients,heat)

1. Adding x4, FStat = 22.7985, pValue = 0.000576232
2. Adding x1, FStat = 108.2239, pValue = 1.105281e-06

mdl =

```

```

Linear regression model:
y ~ 1 + x1 + x4

```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	103.1	2.124	48.54	3.3243e-13
x1	1.44	0.13842	10.403	1.1053e-06
x4	-0.61395	0.048645	-12.621	1.8149e-07

```

Number of observations: 13, Error degrees of freedom: 10
Root Mean Squared Error: 2.73
R-squared: 0.972, Adjusted R-Squared 0.967
F-statistic vs. constant model: 177, p-value = 1.58e-08

```

In this example, `stepwiselm` starts with the constant model (default) and uses forward selection to incrementally add `x4` and `x1`. Each predictor variable in the final model is significant given the other one is in the model. The algorithm stops when adding none of the other predictor variables

significantly improves in the model. For details on stepwise regression, see `stepwiselm`.

## Hat Matrix and Leverage

**In this section...**

“Hat Matrix” on page 9-102

“Leverage” on page 9-103

“Determine High Leverage Observations” on page 9-104

### Hat Matrix

**Purpose**

The hat matrix provides a measure of leverage. It is useful for investigating whether one or more observations are outlying with regard to their  $X$  values, and therefore might be excessively influencing the regression results.

**Definition**

The hat matrix is also known as the *projection matrix* because it projects the vector of observations,  $y$ , onto the vector of predictions,  $\hat{y}$ , thus putting the "hat" on  $y$ . The hat matrix  $H$  is defined in terms of the data matrix  $X$ :

$$H = X(X^T X)^{-1} X^T$$

and determines the fitted or predicted values since

$$\hat{y} = Hy = Xb.$$

The diagonal elements of  $H$ ,  $h_{ii}$ , are called leverages and satisfy

$$0 \leq h_{ii} \leq 1$$

$$\sum_{i=1}^n h_{ii} = p,$$

where  $p$  is the number of coefficients, and  $n$  is the number of observations (rows of  $X$ ) in the regression model. `HatMatrix` is an  $n$ -by- $n$  matrix in the `Diagnostics` dataset array.

## How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Display the `HatMatrix` by indexing into the property using dot notation

```
mdl.Diagnostics.HatMatrix
```

When  $n$  is large, `HatMatrix` might be computationally expensive. In those cases, you can obtain the diagonal values directly, using

```
mdl.Diagnostics.Leverage
```

## Leverage

### Purpose

Leverage is a measure of the effect of a particular observation on the regression predictions due to the position of that observation in the space of the inputs. In general, the farther a point is from the center of the input space, the more leverage it has. Because the sum of the leverage values is  $p$ , an observation  $i$  can be considered as an outlier if its leverage substantially exceeds the mean leverage value,  $p/n$ , for example, a value larger than  $2^*p/n$ .

### Definition

The leverage of observation  $i$  is the value of the  $i$ th diagonal term,  $h_{ii}$ , of the hat matrix,  $H$ , where

$$H = X(X^T X)^{-1} X^T.$$

The diagonal terms satisfy

$$0 \leq h_{ii} \leq 1$$

$$\sum_{i=1}^n h_{ii} = p,$$

where  $p$  is the number of coefficients in the regression model, and  $n$  is the number of observations. The minimum value of  $h_{ii}$  is  $1/n$  for a model with a constant term. If the fitted model goes through the origin, then the minimum leverage value is 0 for an observation at  $x = 0$ .

It is possible to express the fitted values,  $\hat{y}$ , by the observed values,  $y$ , since

$$\hat{y} = Hy = Xb.$$

Hence,  $h_{ii}$  expresses how much the observation  $y_i$  has impact on  $\hat{y}_i$ . A large value of  $h_{ii}$  indicates that the  $i$ th case is distant from the center of all X values for all  $n$  cases and has more leverage. Leverage is an  $n$ -by-1 column vector in the Diagnostics dataset array.

### How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Display the Leverage vector by indexing into the property using dot notation

```
mdl.Diagnostics.Leverage
```

- Plot the leverage for the values fitted by your model using

```
plotDiagnostics(mdl)
```

See the `plotDiagnostics` method of the `LinearModel` class for details.

### Determine High Leverage Observations

This example shows how to compute Leverage values and assess high leverage observations.

Load the sample data and define the response and independent variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = fitlm(X,y);
```

Plot the leverage values.

```
plotDiagnostics(mdl)
```

For this example, the recommended threshold value is  $2*5/100 = 0.1$ . There is no indication of high leverage observations.

# Residuals

## Purpose

Residuals are useful for detecting outlying  $y$  values and checking the linear regression assumptions with respect to the error term in the regression model. High-leverage observations have smaller residuals because they often shift the regression line or surface closer to them. You can also use residuals to detect some forms of heteroscedasticity and autocorrelation.

## Definition

The Residuals matrix is an  $n$ -by-4 dataset array containing a table of four types of residuals, with one row for each observation.

## Raw Residuals

Observed minus fitted values, that is,

$$r_i = y_i - \hat{y}_i.$$

## Pearson Residuals

Raw residuals divided by the root mean squared error, that is,

$$pr_i = \frac{r_i}{\sqrt{MSE}},$$

where  $r_i$  is the raw residual and  $MSE$  is the mean squared error.

## Standardized Residuals

Standardized residuals are raw residuals divided by their estimated standard deviation. The standardized residual for observation  $i$  is

$$st_i = \frac{r_i}{\sqrt{MSE(1 - h_{ii})}},$$

where  $MSE$  is the mean squared error and  $h_{ii}$  is the leverage value for observation  $i$ .

## Studentized Residuals

Studentized residuals are the raw residuals divided by an independent estimate of the residual standard deviation. The residual for observation  $i$  is divided by an estimate of the error standard deviation based on all observations except for observation  $i$ .

$$sr_i = \frac{r_i}{\sqrt{MSE_{(i)}(1 - h_{ii})}},$$

where  $MSE_{(i)}$  is the mean squared error of the regression fit calculated by removing observation  $i$ , and  $h_{ii}$  is the leverage value for observation  $i$ . The studentized residual  $sr_i$  has a  $t$ -distribution with  $n - p - 1$  degrees of freedom.

## How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Find the `Residuals` dataset array under `mdl` object.
- Obtain any of these columns as a vector by indexing into the property using dot notation, for example,

```
mdl.Residuals.Raw
```

- Plot any of the residuals for the values fitted by your model using

```
plotResiduals(mdl)
```

For details, see the `plotResiduals` method of the `LinearModel` class.

## Example

This example shows how to assess the model assumptions by examining the residuals of a fitted linear regression model.

Load the sample data and store the independent and response variables in a dataset array.

```
load imports-85
ds = dataset(X(:,7),X(:,8),X(:,9),X(:,15),'VarNames',...
{'curb_weight','engine_size','bore','price'});
```

Fit a linear regression model.

```
mdl = fitlm(ds)
```

```
mdl =
```

Linear regression model:

price ~ 1 + curb\_weight + engine\_size + bore

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	64.095	3.703	17.309	2.0481e-41
curb_weight	-0.0086681	0.0011025	-7.8623	2.42e-13
engine_size	-0.015806	0.013255	-1.1925	0.23452
bore	-2.6998	1.3489	-2.0015	0.046711

Number of observations: 201, Error degrees of freedom: 197

Root Mean Squared Error: 3.95

R-squared: 0.674, Adjusted R-Squared 0.669

F-statistic vs. constant model: 136, p-value = 1.14e-47

Plot the histogram of raw residuals.

```
plotResiduals(mdl)
```

The histogram shows that the residuals are slightly right skewed.

Plot the box plot of all four types of residuals.

```
Res = double mdl.Residuals;
```

You can see the right-skewed structure of the residuals in the box plot as well.

Plot the normal probability plot of the raw residuals.

```
plotResiduals mdl, 'probability'  
boxplot(Res)
```

This normal probability plot also shows the deviation from normality and the skewness on the right tail of the distribution of residuals.

Plot the residuals versus lagged residuals.

```
plotResiduals mdl, 'lagged'
```

This graph shows a trend, which indicates a possible correlation among the residuals. You can further check this using `dwtest(mdl)`. Serial correlation among residuals usually means that the model can be improved.

Plot the symmetry plot of residuals.

```
plotResiduals(mdl, 'symmetry')
```

This plot also suggests that the residuals are not distributed equally around their median, as would be expected for normal distribution.

Plot the residuals versus the fitted values.

```
plotResiduals mdl, 'fitted'
```

The increase in the variance as the fitted values increase suggests possible heteroscedasticity.

“Compare large and small stepwise models” on page 9-119

### Stepwise Regression to Select Appropriate Models

`stepwiselm` creates a linear model and automatically adds to or trims the model. To create a small model, start from a constant model. To create a large model, start with a model containing many terms. A large model usually has lower error as measured by the fit to the original data, but might not have any advantage in predicting new data.

`stepwiselm` can use all the name-value options from `fitlm`, with additional options relating to the starting and bounding models. In particular:

- For a small model, start with the default lower bounding model: 'constant' (a model that has no predictor terms).
- The default upper bounding model has linear terms and interaction terms (products of pairs of predictors). For an upper bounding model that also includes squared terms, set the Upper name-value pair to 'quadratic'.

### Compare large and small stepwise models

This example shows how to compare models that `stepwiselm` returns starting from a constant model and starting from a full interaction model.

Load the `carbig` data and create a dataset array from some of the data.

```
load carbig
ds = dataset(Acceleration,Displacement,Horsepower,Weight,MPG);
```

Create a mileage model stepwise starting from the constant model.

```
mdl1 = stepwiselm(ds,'constant','ResponseVar','MPG')
```

1. Adding Weight, FStat = 888.8507, pValue = 2.9728e-103
2. Adding Horsepower, FStat = 3.8217, pValue = 0.00049608

3. Adding Horsepower:Weight, FStat = 64.8709, pValue = 9.93362e-15

mdl1 =

Linear regression model:

MPG ~ 1 + Horsepower\*Weight

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	63.558	2.3429	27.127	1.2343e-91
Horsepower	-0.25084	0.027279	-9.1952	2.3226e-18
Weight	-0.010772	0.00077381	-13.921	5.1372e-36
Horsepower:Weight	5.3554e-05	6.6491e-06	8.0542	9.9336e-15

Number of observations: 392, Error degrees of freedom: 388

Root Mean Squared Error: 3.93

R-squared: 0.748, Adjusted R-Squared 0.746

F-statistic vs. constant model: 385, p-value = 7.26e-116

Create a mileage model stepwise starting from the full interaction model.

`mdl2 = stepwiselm(ds,'interactions','ResponseVar','MPG')`

1. Removing Acceleration:Displacement, FStat = 0.024186, pValue = 0.8765

2. Removing Displacement:Weight, FStat = 0.33103, pValue = 0.56539

3. Removing Acceleration:Horsepower, FStat = 1.7334, pValue = 0.18876

4. Removing Acceleration:Weight, FStat = 0.93269, pValue = 0.33477

5. Removing Horsepower:Weight, FStat = 0.64486, pValue = 0.42245

mdl2 =

Linear regression model:

MPG ~ 1 + Acceleration + Weight + Displacement\*Horsepower

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	61.285	2.8052	21.847	1.8593e-69

Acceleration	-0.34401	0.11862	-2.9	0.0039445
Displacement	-0.081198	0.010071	-8.0623	9.5014e-15
Horsepower	-0.24313	0.026068	-9.3265	8.6556e-19
Weight	-0.0014367	0.00084041	-1.7095	0.088166
Displacement:Horsepower	0.00054236	5.7987e-05	9.3531	7.0527e-19

Number of observations: 392, Error degrees of freedom: 386

Root Mean Squared Error: 3.84

R-squared: 0.761, Adjusted R-Squared 0.758

F-statistic vs. constant model: 246, p-value = 1.32e-117

Notice that:

- `mdl1` has four coefficients (the Estimate column), and `mdl2` has six coefficients.
- The adjusted R-squared of `mdl1` is 0.746, which is slightly less (worse) than that of `mdl2`, 0.758.

Create a mileage model stepwise with a full quadratic model as the upper bound, starting from the full quadratic model:

```
mdl3 = stepwiselm(ds,'quadratic',...
    'ResponseVar','MPG','Upper','quadratic');
```

Compare the three model complexities by examining their formulas.

`mdl1`.Formula

```
ans =
MPG ~ 1 + Horsepower*Weight
```

`mdl2`.Formula

```
ans =
MPG ~ 1 + Acceleration + Weight + Displacement*Horsepower
```

`mdl3`.Formula

```
ans =
MPG ~ 1 + Weight + Acceleration*Displacement
```

```
+ Displacement*Horsepower + Acceleration^2
```

The adjusted  $R^2$  values improve slightly as the models become more complex:

```
RSquared = [mdl1.Rsquared.Adjusted, ...  
            mdl2.Rsquared.Adjusted, mdl3.Rsquared.Adjusted]
```

```
RSquared =  
    0.7465    0.7580    0.7599
```

Compare residual plots of the three models.

```
subplot(3,1,1)  
plotResiduals(mdl1)  
subplot(3,1,2)  
plotResiduals(mdl2)  
subplot(3,1,3)  
plotResiduals(mdl3)
```

The models have similar residuals. It is not clear which fits the data better.

Interestingly, the more complex models have larger maximum deviations of the residuals:

```

Range1 = [min(md11.Residuals.Raw),max(md11.Residuals.Raw)];
Range2 = [min(md12.Residuals.Raw),max(md12.Residuals.Raw)];
Range3 = [min(md13.Residuals.Raw),max(md13.Residuals.Raw)];
Ranges = [range1;range2;range3]

```

```

Ranges =
    -10.7725    14.7314
    -11.4407    16.7562

```

## Robust Regression — Reduce Outlier Effects

### In this section...

“What Is Robust Regression?” on page 9-125

“Robust Regression versus Standard Least-Squares Fit” on page 9-125

### What Is Robust Regression?

The models described in “What Are Linear Regression Models?” on page 9-8 are based on certain assumptions, such as a normal distribution of errors in the observed responses. If the distribution of errors is asymmetric or prone to outliers, model assumptions are invalidated, and parameter estimates, confidence intervals, and other computed statistics become unreliable. Use `fitlm` with the `RobustOpts` name-value pair to create a model that is not much affected by outliers. The robust fitting method is less sensitive than ordinary least squares to large changes in small parts of the data.

Robust regression works by assigning a weight to each data point. Weighting is done automatically and iteratively using a process called *iteratively reweighted least squares*. In the first iteration, each point is assigned equal weight and model coefficients are estimated using ordinary least squares. At subsequent iterations, weights are recomputed so that points farther from model predictions in the previous iteration are given lower weight. Model coefficients are then recomputed using weighted least squares. The process continues until the values of the coefficient estimates converge within a specified tolerance.

### Robust Regression versus Standard Least-Squares Fit

This example shows how to use robust regression. It compares the results of a robust fit to a standard least-squares fit.

#### Step 1. Prepare data.

Load the moore data. The data is in the first five columns, and the response in the sixth.

```
load moore
X = [moore(:,1:5)];
```

```
y = moore(:,6);
```

**Step 2. Fit robust and nonrobust models.**

Fit two linear models to the data, one using robust fitting, one not.

```
mdl = fitlm(X,y); % not robust  
mdlr = fitlm(X,y,'RobustOpts','on');
```

**Step 3. Examine model residuals.**

Examine the residuals of the two models.

```
subplot(1,2,1);plotResiduals(mdl,'probability')  
subplot(1,2,2);plotResiduals(mdlr,'probability')
```

The residuals from the robust fit (right half of the plot) are nearly all closer to the straight line, except for the one obvious outlier.

#### 4. Remove the outlier from the standard model

Find the index of the outlier. Examine the weight of the outlier in the robust fit.

```
[~,outlier] = max mdlr.Residuals.Raw);  
mdlr.Robust.Weights(outlier)
```

```
ans =
```

```
0.0246
```

Check the median weight.

```
median(mdlr.Robust.Weights)
```

```
ans =
```

```
0.9718
```

This weight of the outlier in the robust fit is much less than a typical weight of an observation.

## Ridge Regression

### In this section...

“Introduction to Ridge Regression” on page 9-128

“Ridge Regression” on page 9-128

### Introduction to Ridge Regression

Coefficient estimates for the models described in “Linear Regression” on page 9-12 rely on the independence of the model terms. When terms are correlated and the columns of the design matrix  $X$  have an approximate linear dependence, the matrix  $(X^T X)^{-1}$  becomes close to singular. As a result, the least-squares estimate

$$\hat{\beta} = (X^T X)^{-1} X^T y$$

becomes highly sensitive to random errors in the observed response  $y$ , producing a large variance. This situation of *multicollinearity* can arise, for example, when data are collected without an experimental design.

*Ridge regression* addresses the problem by estimating regression coefficients using

$$\hat{\beta} = (X^T X + kI)^{-1} X^T y$$

where  $k$  is the *ridge parameter* and  $I$  is the identity matrix. Small positive values of  $k$  improve the conditioning of the problem and reduce the variance of the estimates. While biased, the reduced variance of ridge estimates often result in a smaller mean square error when compared to least-squares estimates.

The Statistics Toolbox function `ridge` carries out ridge regression.

### Ridge Regression

For example, load the data in `acetylene.mat`, with observations of the predictor variables `x1`, `x2`, `x3`, and the response variable `y`:

```
load acetylene
```

Plot the predictor variables against each other:

```
subplot(1,3,1)
plot(x1,x2,'. ')
xlabel('x1'); ylabel('x2'); grid on; axis square
```

```
subplot(1,3,2)
plot(x1,x3,'. ')
xlabel('x1'); ylabel('x3'); grid on; axis square
```

```
subplot(1,3,3)
plot(x2,x3,'. ')
xlabel('x2'); ylabel('x3'); grid on; axis square
```

Note the correlation between  $x_1$  and the other two predictor variables.

Use `ridge` and `x2fx` to compute coefficient estimates for a multilinear model with interaction terms, for a range of ridge parameters:

```
X = [x1 x2 x3];
D = x2fx(X,'interaction');
D(:,1) = []; % No constant term
k = 0:1e-5:5e-3;
betahat = ridge(y,D,k);
```

Plot the ridge trace:

```
figure
```

```
plot(k,betahat,'LineWidth',2)
ylim([-100 100])
grid on
xlabel('Ridge Parameter')
ylabel('Standardized Coefficient')
title('{\bf Ridge Trace}')
legend('x1','x2','x3','x1x2','x1x3','x2x3')
```

The estimates stabilize to the right of the plot. Note that the coefficient of the  $x_2x_3$  interaction term changes sign at a value of the ridge parameter  $\approx 5 \times 10^{-4}$ .

## Lasso and Elastic Net

### In this section...

“What Are Lasso and Elastic Net?” on page 9-132

“Lasso Regularization” on page 9-132

“Lasso and Elastic Net with Cross Validation” on page 9-135

“Wide Data via Lasso and Parallel Computing” on page 9-138

“Lasso and Elastic Net Details” on page 9-144

“References” on page 9-145

### What Are Lasso and Elastic Net?

Lasso is a regularization technique. Use lasso to:

- Reduce the number of predictors in a regression model.
- Identify important predictors.
- Select among redundant predictors.
- Produce shrinkage estimates with potentially lower predictive errors than ordinary least squares.

Elastic net is a related technique. Use elastic net when you have several highly correlated variables. `lasso` provides elastic net regularization when you set the Alpha name-value pair to a number strictly between 0 and 1.

See “Lasso and Elastic Net Details” on page 9-144.

For lasso regularization of regression ensembles, see `regularize`.

### Lasso Regularization

To see how `lasso` identifies and discards unnecessary predictors:

- 1 Generate 200 samples of five-dimensional artificial data  $X$  from exponential distributions with various means:

```

rng(3,'twister') % for reproducibility
X = zeros(200,5);
for ii = 1:5
    X(:,ii) = exprnd(ii,200,1);
end

```

- 2** Generate response data  $Y = X*r + \text{eps}$  where  $r$  has just two nonzero components, and the noise  $\text{eps}$  is normal with standard deviation 0.1:

```

r = [0;2;0;-3;0];
Y = X*r + randn(200,1)*.1;

```

- 3** Fit a cross-validated sequence of models with `lasso`, and plot the result:

```

[b fitinfo] = lasso(X,Y,'CV',10);
lassoPlot(b,fitinfo,'PlotType','Lambda','XScale','log');

```

The plot shows the nonzero coefficients in the regression for various values of the Lambda regularization parameter. Larger values of Lambda appear on the left side of the graph, meaning more regularization, resulting in fewer nonzero regression coefficients.

The dashed vertical lines represent the Lambda value with minimal mean squared error (on the right), and the Lambda value with minimal mean squared error plus one standard deviation. This latter value is a recommended setting for Lambda. These lines appear only when you perform cross validation. Cross validate by setting the 'CV' name-value pair. This example uses 10-fold cross validation.

The upper part of the plot shows the degrees of freedom (df), meaning the number of nonzero coefficients in the regression, as a function of Lambda. On the left, the large value of Lambda causes all but one coefficient to be 0. On the right all five coefficients are nonzero, though the plot shows only two clearly. The other three coefficients are so small that you cannot visually distinguish them from 0.

For small values of Lambda (toward the right in the plot), the coefficient values are close to the least-squares estimate. See step 5 on page 9-135.

- 4 Find the Lambda value of the minimal cross-validated mean squared error plus one standard deviation. Examine the MSE and coefficients of the fit at that Lambda:

```
lam = fitinfo.Index1SE;  
fitinfo.MSE(lam)
```

```
ans =  
    0.1398
```

```
b(:,lam)
```

```
ans =  
     0  
    1.8855  
     0  
   -2.9367  
     0
```

lasso did a good job finding the coefficient vector  $\mathbf{r}$ .

- 5** For comparison, find the least-squares estimate of  $\mathbf{r}$ :

```
rhat = X\Y
```

```
rhat =
```

```
-0.0038
 1.9952
 0.0014
-2.9993
 0.0031
```

The estimate  $\mathbf{b}(:, \lambda)$  has slightly more mean squared error than the mean squared error of  $\mathbf{rhat}$ :

```
res = X*rhat - Y; % calculate residuals
MSEmin = res'*res/200 % b(:,lam) value is 0.1398
```

```
MSEmin =
 0.0088
```

But  $\mathbf{b}(:, \lambda)$  has only two nonzero components, and therefore can provide better predictive estimates on new data.

## Lasso and Elastic Net with Cross Validation

Consider predicting the mileage (MPG) of a car based on its weight, displacement, horsepower, and acceleration. The `carbig` data contains these measurements. The data seem likely to be correlated, making elastic net an attractive choice.

- 1** Load the data:

```
load carbig
```

- 2** Extract the continuous (noncategorical) predictors (lasso does not handle categorical predictors):

```
X = [Acceleration Displacement Horsepower Weight];
```

3 Perform a lasso fit with 10-fold cross validation:

```
[b fitinfo] = lasso(X,MPG,'CV',10);
```

4 Plot the result:

```
lassoPlot(b,fitinfo,'PlotType','Lambda','XScale','log');
```

5 Calculate the correlation of the predictors:

```
% Eliminate NaNs so corr runs
nonan = ~any(isnan([X MPG]),2);
Xnonan = X(nonan,:);
MPGnonan = MPG(nonan,:);
corr(Xnonan)

ans =
```

1.0000	-0.5438	-0.6892	-0.4168
-0.5438	1.0000	0.8973	0.9330
-0.6892	0.8973	1.0000	0.8645
-0.4168	0.9330	0.8645	1.0000

- 6** Because some predictors are highly correlated, perform elastic net fitting. Use Alpha = 0.5:

```
[ba fitinfoa] = lasso(X,MPG,'CV',10,'Alpha',.5);
```

- 7** Plot the result. Name each predictor so you can tell which curve is which:

```
pnames = {'Acceleration','Displacement',...
          'Horsepower','Weight'};
lassoPlot(ba,fitinfoa,'PlotType','Lambda',...
          'XScale','log','PredictorNames',pnames);
```

When you activate the data cursor

and click the plot, you see the name of the predictor, the coefficient, the value of  $\text{Lambda}$ , and the index of that point, meaning the column in  $\mathbf{b}$  associated with that fit.

Here, the elastic net and lasso results are not very similar. Also, the elastic net plot reflects a notable qualitative property of the elastic net technique. The elastic net retains three nonzero coefficients as  $\text{Lambda}$  increases (toward the left of the plot), and these three coefficients reach 0 at about the same  $\text{Lambda}$  value. In contrast, the lasso plot shows two of the three coefficients becoming 0 at the same value of  $\text{Lambda}$ , while another coefficient remains nonzero for higher values of  $\text{Lambda}$ .

This behavior exemplifies a general pattern. In general, elastic net tends to retain or drop groups of highly correlated predictors as  $\text{Lambda}$  increases. In contrast, lasso tends to drop smaller groups, or even individual predictors.

## Wide Data via Lasso and Parallel Computing

Lasso and elastic net are especially well suited to *wide* data, meaning data with more predictors than observations. Obviously, there are redundant predictors in this type of data. Use lasso along with cross validation to identify important predictors.

Cross validation can be slow. If you have a Parallel Computing Toolbox license, speed the computation using parallel computing.

### 1 Load the spectra data:

```
load spectra
Description

Description =

== Spectral and octane data of gasoline ==
```

NIR spectra and octane numbers of 60 gasoline samples

NIR: NIR spectra, measured in 2 nm intervals from 900 nm to 1700 nm

octane: octane numbers

spectra: a dataset array containing variables for NIR and octane

Reference:

Kalivas, John H., "Two Data Sets of Near Infrared Spectra," *Chemometrics and Intelligent Laboratory Systems*, v.37 (1997) pp.255-259

**2** Compute the default lasso fit:

```
[b fitinfo] = lasso(NIR,octane);
```

**3** Plot the number of predictors in the fitted lasso regularization as a function of Lambda, using a logarithmic  $x$ -axis:

```
lassoPlot(b,fitinfo,'PlotType','Lambda','XScale','log');
```

- 4 It is difficult to tell which value of Lambda is appropriate. To determine a good value, try fitting with cross validation:

```
tic
[b fitinfo] = lasso(NIR,octane,'CV',10);
% A time-consuming operation
toc
```

Elapsed time is 226.876926 seconds.

- 5 Plot the result:

```
lassoPlot(b,fitinfo,'PlotType','Lambda','XScale','log');
```

You can see the suggested value of Lambda is over  $1e-2$ , and the Lambda with minimal MSE is under  $1e-2$ . These values are in the `fitinfo` structure:

```
fitinfo.LambdaMinMSE
```

```
ans =  
    0.0057
```

```
fitinfo.Lambda1SE
```

```
ans =  
    0.0190
```

- 6 Examine the quality of the fit for the suggested value of Lambda:

```
lambdaindex = fitinfo.Index1SE;  
fitinfo.MSE(lambdaindex)
```

```
ans =
    0.0532
```

```
fitinfo.DF(lambdaindex)
```

```
ans =
    11
```

The fit uses just 11 of the 401 predictors, and achieves a cross-validated MSE of 0.0532.

**7** Examine the plot of cross-validated MSE:

```
lassoPlot(b,fitinfo,'PlotType','CV');
% Use a log scale for MSE to see small MSE values better
set(gca,'YScale','log');
```

As `Lambda` increases (toward the left), MSE increases rapidly. The coefficients are reduced too much and they do not adequately fit the responses.

As `Lambda` decreases, the models are larger (have more nonzero coefficients). The increasing MSE suggests that the models are overfitted.

The default set of `Lambda` values does not include values small enough to include all predictors. In this case, there does not appear to be a reason to look at smaller values. However, if you want smaller values than the default, use the `LambdaRatio` parameter, or supply a sequence of `Lambda` values using the `Lambda` parameter. For details, see the `lasso` reference page.

- 8 To compute the cross-validated lasso estimate faster, use parallel computing (available with a Parallel Computing Toolbox license):

```
parpool()
Starting parpool using the 'local' profile ... connected to 2 workers.

ans =

    Pool with properties:

        AttachedFiles: {0x1 cell}
           NumWorkers: 2
        IdleTimeout: 30
           Cluster: [1x1 parallel.cluster.Local]
    RequestQueue: [1x1 parallel.RequestQueue]
        SpmdEnabled: 1

opts = statset('UseParallel',true);
tic;
[b fitinfo] = lasso(NIR,octane,'CV',10,'Options',opts);
toc
Elapsed time is 114.712260 seconds.
```

Computing in parallel using two workers is faster on this problem.

## Lasso and Elastic Net Details

### Overview of Lasso and Elastic Net

Lasso is a regularization technique for performing linear regression. Lasso includes a penalty term that constrains the size of the estimated coefficients. Therefore, it resembles ridge regression. Lasso is a *shrinkage estimator*: it generates coefficient estimates that are biased to be small. Nevertheless, a lasso estimator can have smaller mean squared error than an ordinary least-squares estimator when you apply it to new data.

Unlike ridge regression, as the penalty term increases, lasso sets more coefficients to zero. This means that the lasso estimator is a smaller model, with fewer predictors. As such, lasso is an alternative to stepwise regression and other model selection and dimensionality reduction techniques.

Elastic net is a related technique. Elastic net is a hybrid of ridge regression and lasso regularization. Like lasso, elastic net can generate reduced models by generating zero-valued coefficients. Empirical studies have suggested that the elastic net technique can outperform lasso on data with highly correlated predictors.

### Definition of Lasso

The *lasso* technique solves this regularization problem. For a given value of  $\lambda$ , a nonnegative parameter, lasso solves the problem

$$\min_{\beta_0, \beta} \left( \frac{1}{2N} \sum_{i=1}^N (y_i - \beta_0 - x_i^T \beta)^2 + \lambda \sum_{j=1}^p |\beta_j| \right),$$

where

- $N$  is the number of observations.
- $y_i$  is the response at observation  $i$ .
- $x_i$  is data, a vector of  $p$  values at observation  $i$ .
- $\lambda$  is a positive regularization parameter corresponding to one value of Lambda.

- The parameters  $\beta_0$  and  $\beta$  are scalar and  $p$ -vector respectively.

As  $\lambda$  increases, the number of nonzero components of  $\beta$  decreases.

The lasso problem involves the  $L^1$  norm of  $\beta$ , as contrasted with the elastic net algorithm.

### Definition of Elastic Net

The *elastic net* technique solves this regularization problem. For an  $\alpha$  strictly between 0 and 1, and a nonnegative  $\lambda$ , elastic net solves the problem

$$\min_{\beta_0, \beta} \left( \frac{1}{2N} \sum_{i=1}^N (y_i - \beta_0 - x_i^T \beta)^2 + \lambda P_\alpha(\beta) \right),$$

where

$$P_\alpha(\beta) = \frac{(1-\alpha)}{2} \|\beta\|_2^2 + \alpha \|\beta\|_1 = \sum_{j=1}^p \left( \frac{(1-\alpha)}{2} \beta_j^2 + \alpha |\beta_j| \right).$$

Elastic net is the same as lasso when  $\alpha = 1$ . As  $\alpha$  shrinks toward 0, elastic net approaches ridge regression. For other values of  $\alpha$ , the penalty term  $P_\alpha(\beta)$  interpolates between the  $L^1$  norm of  $\beta$  and the squared  $L^2$  norm of  $\beta$ .

## Partial Least Squares

In this section...
“Introduction to Partial Least Squares” on page 9-147
“Partial Least Squares” on page 9-148

### Introduction to Partial Least Squares

*Partial least-squares (PLS)* regression is a technique used with data that contain correlated predictor variables. This technique constructs new predictor variables, known as *components*, as linear combinations of the original predictor variables. PLS constructs these components while considering the observed response values, leading to a parsimonious model with reliable predictive power.

The technique is something of a cross between multiple linear regression and principal component analysis:

- Multiple linear regression finds a combination of the predictors that best fit a response.
- Principal component analysis finds combinations of the predictors with large variance, reducing correlations. The technique makes no use of response values.
- PLS finds combinations of the predictors that have a large covariance with the response values.

PLS therefore combines information about the variances of both the predictors and the responses, while also considering the correlations among them.

PLS shares characteristics with other regression and feature transformation techniques. It is similar to ridge regression in that it is used in situations with correlated predictors. It is similar to stepwise regression (or more general feature selection techniques) in that it can be used to select a smaller set of model terms. PLS differs from these methods, however, by transforming the original predictor space into the new component space.

The Statistics Toolbox function `pplsregress` carries out PLS regression.

## Partial Least Squares

For example, consider the data on biochemical oxygen demand in `moore.mat`, padded with noisy versions of the predictors to introduce correlations:

```
load moore
y = moore(:,6);           % Response
X0 = moore(:,1:5);       % Original predictors
X1 = X0+10*randn(size(X0)); % Correlated predictors
X = [X0,X1];
```

Use `plsregress` to perform PLS regression with the same number of components as predictors, then plot the percentage variance explained in the response as a function of the number of components:

```
[XL,y1,XS,YS,beta,PCTVAR] = plsregress(X,y,10);

plot(1:10,cumsum(100*PCTVAR(2,:)),'-bo');
xlabel('Number of PLS components');
ylabel('Percent Variance Explained in y');
```

Choosing the number of components in a PLS model is a critical step. The plot gives a rough indication, showing nearly 80% of the variance in  $y$  explained by the first component, with as many as five additional components making significant contributions.

The following computes the six-component model:

```
[XL,y1,XS,YS,beta,PCTVAR,MSE,stats] = plsregress(X,y,6);  
yfit = [ones(size(X,1),1) X]*beta;  
  
plot(y,yfit,'o')
```

The scatter shows a reasonable correlation between fitted and observed responses, and this is confirmed by the  $R^2$  statistic:

```
TSS = sum((y-mean(y)).^2);  
RSS = sum((y-yfit).^2);  
Rsquared = 1 - RSS/TSS  
Rsquared =  
    0.8421
```

A plot of the weights of the ten predictors in each of the six components shows that two of the components (the last two computed) explain the majority of the variance in  $X$ :

```
plot(1:10,stats.W,'o-');  
legend({'c1','c2','c3','c4','c5','c6'},'Location','NW')  
xlabel('Predictor');  
ylabel('Weight');
```

A plot of the mean-squared errors suggests that as few as two components may provide an adequate model:

```
[axes,h1,h2] = plotyy(0:6,MSE(1,:),0:6,MSE(2,:));
set(h1,'Marker','o')
set(h2,'Marker','o')
legend('MSE Predictors','MSE Response')
xlabel('Number of Components')
```

The calculation of mean-squared errors by `plsregress` is controlled by optional parameter name/value pairs specifying cross-validation type and the number of Monte Carlo repetitions.

## Linear Mixed-Effects Models

Linear mixed-effects models are extensions of linear regression models for data that are collected and summarized in groups. These models describe the relationship between a response variable and independent variables, with coefficients that can vary with respect to one or more grouping variables. A mixed-effects model consists of two parts, fixed effects and random effects. Fixed-effects terms are usually the conventional linear regression part, and the random effects are associated with individual experimental units drawn at random from a population. The random effects have prior distributions whereas fixed effects do not. Mixed-effects models can represent the covariance structure related to the grouping of data by associating the common random effects to observations that have the same level of a grouping variable. The standard form of a linear mixed-effects model is

$$y = \underbrace{X\beta}_{\text{fixed}} + \underbrace{Zb}_{\text{random}} + \underbrace{\varepsilon}_{\text{error}},$$

where

- $y$  is the  $n$ -by-1 response vector, and  $n$  is the number of observations.
- $X$  is an  $n$ -by- $p$  fixed-effects design matrix.
- $\beta$  is a  $p$ -by-1 fixed-effects vector.
- $Z$  is an  $n$ -by- $q$  random-effects design matrix.
- $b$  is a  $q$ -by-1 random-effects vector.
- $\varepsilon$  is the  $n$ -by-1 observation error vector

The assumptions for the linear mixed-effects model are:

- Random-effects vector,  $b$ , and the error vector,  $\varepsilon$ , have the following prior distributions:

$$b \sim N(0, \sigma^2 D(\theta)),$$

$$\varepsilon \sim N(0, \sigma^2 I),$$

where  $D$  is a symmetric and positive semidefinite matrix, parameterized by a variance component vector  $\theta$ ,  $I$  is an  $n$ -by- $n$  identity matrix, and  $\sigma^2$  is the error variance.

- Random-effects vector,  $b$ , and the error vector,  $\varepsilon$ , are independent from each other.

Mixed-effects models are also called *multilevel models* or *hierarchical models* depending on the context. Mixed-effects models is a more general term than the latter two. Mixed-effects models might include factors that are not necessarily multilevel or hierarchical, for example crossed factors. That is why mixed-effects is the terminology preferred here. Sometimes mixed-effects models are expressed as multilevel regression models (first level and grouping level models) that are fit simultaneously. For example, a varying or random intercept model, with one continuous predictor variable  $x$  and one grouping variable with  $M$  levels, can be expressed as

$$y_{im} = \beta_{0m} + \beta_1 x_{im} + \varepsilon_{im}, \quad i = 1, 2, \dots, n, \quad m = 1, 2, \dots, M, \quad \varepsilon_{im} \sim N(0, \sigma^2),$$

$$\beta_{0m} = \beta_{00} + b_{0m}, \quad b_{0m} \sim N(0, \sigma_0^2),$$

where  $y_{im}$  corresponds to data for observation  $i$  and group  $m$ ,  $n$  is the total number of observations, and  $b_{0m}$  and  $\varepsilon_{im}$  are independent of each other. After substituting the group-level parameters in the first-level model, the model for the response vector becomes

$$y_{im} = \underbrace{\beta_{00} + \beta_1 x_{im}}_{\text{fixed effects}} + \underbrace{b_{0m}}_{\text{random effects}} + \varepsilon_{im}.$$

A random intercept and slope model with one continuous predictor variable  $x$ , where both the intercept and slope vary independently by a grouping variable with  $M$  levels is

$$y_{im} = \beta_{0m} + \beta_{1m} x_{im} + \varepsilon_{im}, \quad i = 1, 2, \dots, n, \quad m = 1, 2, \dots, M, \quad \varepsilon_{im} \sim N(0, \sigma^2),$$

$$\beta_{0m} = \beta_{00} + b_{0m}, \quad b_{0m} \sim N(0, \sigma_0^2),$$

$$\beta_{1m} = \beta_{10} + b_{1m}, \quad b_{1m} \sim N(0, \sigma_1^2),$$

or

$$b_m = \begin{pmatrix} b_{0m} \\ b_{1m} \end{pmatrix} \sim N \left( 0, \begin{pmatrix} \sigma_0^2 & 0 \\ 0 & \sigma_1^2 \end{pmatrix} \right).$$

You might also have correlated random effects. In general, for a model with a random intercept and slope, the distribution of the random effects is

$$b_m = \begin{pmatrix} b_{0m} \\ b_{1m} \end{pmatrix} \sim N \left( 0, \sigma^2 D(\theta) \right),$$

where  $D$  is a 2-by-2 symmetric and positive semidefinite matrix, parameterized by a variance component vector  $\theta$ .

After substituting the group-level parameters in the first-level model, the model for the response vector is

$$y_{im} = \underbrace{\beta_{00} + \beta_{10}x_{im}}_{\text{fixed effects}} + \underbrace{b_{0m} + b_{1m}x_{im}}_{\text{random effects}} + \varepsilon_{im}, \quad i = 1, 2, \dots, n, \quad m = 1, 2, \dots, M.$$

If you express the group-level variable,  $x_{im}$ , in the random-effects term by  $z_{im}$ , this model is

$$y_{im} = \underbrace{\beta_{00} + \beta_{10}x_{im}}_{\text{fixed effects}} + \underbrace{b_{0m} + b_{1m}z_{im}}_{\text{random effects}} + \varepsilon_{im}, \quad i = 1, 2, \dots, n, \quad m = 1, 2, \dots, M.$$

In this case, the same terms appear in both the fixed-effects design matrix and random-effects design matrix.  $z$  includes as many columns as the levels of the grouping variable. Each column of  $z$  is formed by taking parts of  $x$  that correspond to a level of the grouping variable.

It is also possible to explain more of the group-level variations by adding more group-level predictor variables. A random-intercept and random-slope model with one continuous predictor variable  $x$ , where both the intercept and slope vary independently by a grouping variable with  $M$  levels, and one group-level predictor variable  $v_m$  is

$$\begin{aligned}
 y_{im} &= \beta_{0im} + \beta_{1im}x_{im} + \varepsilon_{im}, \quad i = 1, 2, \dots, n, \quad m = 1, 2, \dots, M, \quad \varepsilon_{im} \sim N(0, \sigma^2), \\
 \beta_{0im} &= \beta_{00} + \beta_{01}v_{im} + b_{0m}, \quad b_{0m} \sim N(0, \sigma_0^2), \\
 \beta_{1im} &= \beta_{10} + \beta_{11}v_{im} + b_{1m}, \quad b_{1m} \sim N(0, \sigma_1^2).
 \end{aligned}$$

This model results in main effects of the group-level predictor and an interaction term between the first-level and group-level predictor variables in the model for the response variable as

$$\begin{aligned}
 y_{im} &= \beta_{00} + \beta_{01}v_{im} + b_{0m} + (\beta_{10} + \beta_{11}v_{im} + b_{1m})x_{im} + \varepsilon_{im}, \quad i = 1, 2, \dots, n, \quad m = 1, 2, \dots, M, \\
 &= \underbrace{\beta_{00} + \beta_{10}x_{im} + \beta_{01}v_{im} + \beta_{11}v_{im}x_{im}}_{\text{fixed effects}} + \underbrace{b_{0m} + b_{1m}x_{im}}_{\text{random effects}} + \varepsilon_{im}.
 \end{aligned}$$

The term  $\beta_{11}v_{im}x_{im}$  is often called a cross-level interaction in many textbooks on multilevel models. The model for the response variable  $y$  can be expressed as

$$y_{im} = \begin{bmatrix} 1 & x_{1im} & v_{im} & v_{im}x_{1im} \end{bmatrix} \begin{bmatrix} \beta_{00} \\ \beta_{10} \\ \beta_{01} \\ \beta_{11} \end{bmatrix} + \begin{bmatrix} 1 & x_{1im} \end{bmatrix} \begin{bmatrix} b_{0m} \\ b_{1m} \end{bmatrix} + \varepsilon_{im}, \quad i = 1, 2, \dots, n, \quad m = 1, 2, \dots, M,$$

which corresponds to the standard form given earlier,

$$y = X\beta + Zb + \varepsilon.$$

In general, if there are  $R$  grouping variables, and  $m(r, i)$  shows the level of grouping variable  $r$ , for observation  $i$ , then the model for the response variable for observation  $i$  is

$$y_i = x_i^T \beta + \sum_{r=1}^R z_{ir} b_{m(r, i)}^{(r)} + \varepsilon_i, \quad i = 1, 2, \dots, n,$$

where  $\beta$  is a  $p$ -by-1 fixed-effects vector,  $b^{(r)}_{m(r,i)}$  is a  $q(r)$ -by-1 random-effects vector for the  $r$ th grouping variable and level  $m(r,i)$ , and  $\varepsilon_i$  is a 1-by-1 error term for observation  $i$ .

### Dataset Arrays

To fit a linear-mixed effects model, you must store your data in a dataset array. In your dataset array, you must have a column for each variable including the response variable. More specifically, the dataset array, say  $ds$ , must contain the following:

- A response variable  $y$
- Predictive variables  $X_j$  which can be continuous or grouping variables
- Grouping variables  $g_1, g_2, \dots, g_R$ ,

where the grouping variables in  $X_j$  and  $g_r$  can be categorical, logical, character arrays, or a cell arrays of strings,  $r = 1, 2, \dots, R$ .

You must organize your data so that each row represents an observation. And each row should contain the value of variables and the levels of grouping variables corresponding to that observation. For example, if you have data from an experiment with four treatment options, on five different types of individuals chosen randomly from a population of individuals (blocks), the dataset array must look like this.

Block	Treatment	Response
1	1	y11
1	2	y12
1	3	y13
1	4	y14
...	...	...

Block	Treatment	Response
5	1	y51
5	2	y52
5	3	y53
5	4	y54

Now, consider a split-plot experiment, where the effect of four different types of fertilizers on the yield of tomato plants is studied. The soil where the tomato plants are planted is divided into three blocks based on the soil type: sandy, silty, and loamy. Each block is divided into five plots, where five types of tomato plants, (cherry, heirloom, grape, vine, and plum) are randomly assigned to these plots. Then, the tomato plants in the plots are divided into subplots, where each subplot is treated by one of the four fertilizers. The data from this experiment looks like:

Soil	Tomato	Fertilizer	Yield
'Sandy'	'Plum'	1	104
'Sandy'	'Plum'	2	136
'Sandy'	'Plum'	3	158
'Sandy'	'Plum'	4	174
'Sandy'	'Cherry'	1	57
'Sandy'	'Cherry'	2	86
...	...	...	...
'Sandy'	'Vine'	3	99
'Sandy'	'Vine'	4	117
'Silty'	'Plum'	1	120
'Silty'	'Plum'	2	115
...	...	...	...
'Loamy'	'Vine'	3	111
'Loamy'	'Vine'	4	105

You must specify the model you want to fit using the formula input argument to `fitlme`.

In general, a formula for model specification is a string of the term 'y ~ terms'. For linear mixed-effects models, this formula is in the form 'y ~ fixed + (random1|grouping1) + ... + (randomR|groupingR)', where `fixed` contains the fixed-effects terms and `random1`, ..., `randomR` contain the random-effects terms. For example, for the previous fertilizer experiment, consider the following mixed-effects model

$$y_{imjk} = \beta_0 + \sum_{m=2}^4 \beta_{1m} I[F]_{im} + \sum_{j=2}^5 \beta_{2j} I[T]_{ij} + b_{0k} S_k + b_{0jk} (S * T)_{jk} + \varepsilon_{imjk},$$

where  $i = 1, 2, \dots, 60$ , the index  $m$  corresponds to the fertilizer types,  $j$  corresponds to the tomato types, and  $k = 1, 2, 3$  corresponds to the blocks (soil).  $S_k$  represents the  $k$ th soil type, and  $I[F]_{im}$  is the dummy variable representing level  $m$  of the fertilizer. Similarly,  $I[T]_{ij}$  is the dummy variable representing the level  $j$  of the tomato type.

You can fit this model using the formula 'Yield ~ 1 + Fertilizer + Tomato + (1|Soil)+(1|Soil:Tomato)'

For detailed information on how to specify your model using formula, see "Relationship Between Formula and Design Matrices" on page 9-164.

## Design Matrices

If you cannot easily describe your model using a formula, you can create design matrices to define the fixed and random effects, and fit the model using `fitlmematrix(X,y,Z,G)`. You must create your design matrices as follows.

Fixed-effects and random-effects design matrices X and Z:

- Enter a column of 1s for the intercept using `ones(n,1)`, where  $n$  is the total number of observations.
- If X1 is a continuous variable, then enter X1 as it is in a separate column.
- If X1 is a categorical variable with  $m$  levels, then there must be  $m - 1$  dummy variables for  $m - 1$  levels of X1 in X.

For example, consider an experiment where you want to study the impact of quality of raw materials from four different providers on the productivity of a production line. If you fit a linear mixed-effects model with intercept and provider as the fixed-effects terms, intercept is the random-effects term, and you use reference contrasts coding, then you must construct your fixed- and random-effects design matrices as follows.

```
D = dummyvar(provider); % Create dummy variables
X = [ones(n,1) D(:,2) D(:,3) D(:,4)];
Z = [ones(n,1)];
```

Because reference contrast coding uses the first provider as the reference, and the model has an intercept, you must use the dummy variables for only the last three providers.

- If there is an interaction term of predictor variables X1 and X2, then you must enter a column that you form by elementwise product of the vectors X1 and X2.

For example, if you want to fit a model, where there is an intercept, a continuous treatment factor, a continuous time factor, and their interaction as the fixed-effects in a longitudinal study, and time is the random-effects term, then your fixed- and random-effects design matrices should look like

```
X = [ones(n,1), treatment, time, treatment.*time];
y = response;
Z = [time];
```

Grouping variables G:

There is one column for each grouping variable and a column of elementwise product of the grouping variables in case of a nesting.

For example, if you want to group plots (plot) within blocks (block), then you must add a column of elementwise product of plot by block. More specifically, if you want to fit a model where there is intercept and a continuous treatment factor as the fixed-effects in a split-block experiment, and the intercept and treatment are grouped by the plots nested within blocks, then the design matrices should look like this.

```
X = [ones(n,1), treatment];
y = response;
```

```
Z = [ones(n,1),treatment];
G = [block.*plot];
```

Suppose in the earlier quality of raw materials example, the raw materials arrive in bulks, and the bulks are nested within providers. If you want to fit a linear mixed-effects model, where intercept is grouped by the bulks within providers, then your design matrices should look like this.

```
D = dummyvar(provider);
X = [ones(n,1) D(:,2) D(:,3) D(:,4)];
y = response;
Z = ones(n,1);
G = [provider.*bulks];
```

In the earlier longitudinal study example, if you want to add random effects for intercept and time grouped by subjects that participated in the study, then your design matrices should look like

```
X = [ones(n,1),treatment,time, treatment.*time];
y = response;
Z = [ones(n,1),time];
G = subject;
```

## Relation of Matrix Form to Dataset Arrays

`fitlme(ds,formula)` and `fitlmematrix(X,y,Z,G)` are equivalent in functionality, such that

- $y$  is the  $n$ -by-1 response vector.
- $X$  is an  $n$ -by- $p$  fixed-effects design matrix. `fitlme` constructs this from the expression `fixed` in `formula`.
- $Z$  is an  $R$ -by-1 cell array with  $Z\{r\}$  being an  $n$ -by- $q(r)$  random-effects design matrix constructed from the  $r$ th expression in `random` in `formula`,  $r = 1, 2, \dots, R$ .
- $G$  is an  $R$ -by-1 cell array with  $G\{r\}$  being an  $n$ -by-1 grouping variable,  $g_r$ , in `formula` with  $M(r)$  levels or groups.

For example, if `ds` is a dataset array containing the response variable `y`, the continuous variables `X1` and `X2`, and the grouping variable `g`, then to fit a linear mixed-effects model that corresponds to the formula expression `'y ~`

$X1 + X2 + (X1 * X2 | g)$  using `fitlmematrix(X,y,Z,G)` the input arguments must correspond to the following:

```
y = ds.y
X = [ones(n,1), ds.X1, ds.X2]
Z = [ones(n,1), ds.X1, ds.X2, ds.X1.*ds.X2]
G = ds.g
```

## Relationship Between Formula and Design Matrices

### In this section...

“Formula” on page 9-164

“Design Matrices for Fixed and Random Effects” on page 9-166

“Grouping Variables” on page 9-169

### Formula

In general, a formula for model specification is a string of the form `'y ~ terms'`. For the linear mixed-effects models, this formula is in the form `'y ~ fixed + (random1|grouping1) + ... + (randomR|groupingR)'`, where `fixed` and `random` contain the fixed-effects and the random-effects terms. Suppose a dataset array `ds` contains the following:

- A response variable, `y`
- Predictor variables, `Xj`, which can be continuous or grouping variables
- Grouping variables, `g1, g2, ..., gR`,

where the grouping variables in `Xj` and `gr` can be categorical, logical, character arrays, or cell arrays of strings.

Then, in a formula of the form, `'y ~ fixed + (random1|g1) + ... + (randomR|gR)'`, the term `fixed` corresponds to a specification of the fixed-effects design matrix `X`, `random1` is a specification of the random-effects design matrix `Z1` corresponding to grouping variable `g1`, and similarly `randomR` is a specification of the random-effects design matrix `ZR` corresponding to grouping variable `gR`. You can express the `fixed` and `random` terms using Wilkinson notation.

Wilkinson notation describes the factors present in models. The notation relates to factors present in models, not to the multipliers (coefficients) of those factors.

Wilkinson Notation	Factors in Standard Notation
1	Constant (intercept) term
$X^k$ , where $k$ is a positive integer	$X, X^2, \dots, X^k$
$X1 + X2$	$X1, X2$
$X1 * X2$	$X1, X2, X1.*X2$ (elementwise multiplication of $X1$ and $X2$ )
$X1:X2$	$X1.*X2$ only
$- X2$	Do not include $X2$
$X1 * X2 + X3$	$X1, X2, X3, X1 * X2$
$X1 + X2 + X3 + X1:X2$	$X1, X2, X3, X1 * X2$
$X1 * X2 * X3 - X1:X2:X3$	$X1, X2, X3, X1 * X2, X1 * X3, X2 * X3$
$X1 * (X2 + X3)$	$X1, X2, X3, X1 * X2, X1 * X3$

Statistics Toolbox notation always includes a constant term unless you explicitly remove the term using `-1`. Here are some examples for linear mixed-effects model specification.

Formula	Description
'y ~ X1 + X2'	Fixed effects for the intercept, $X1$ and $X2$ . This is equivalent to 'y ~ 1 + X1 + X2'.
'y ~ -1 + X1 + X2'	Fixed effects for $X1$ and $X2$ . The implicit intercept term is suppressed by including <code>-1</code> .
'y ~ 1 + (1   g1)'	Intercept plus random effect for each level of the grouping variable $g1$ .
'y ~ X1 + (1   g1)'	Random intercept model with a fixed slope.
'y ~ X1 + (X1   g1)'	Random intercept and slope, with possible correlation between them.

Formula	Description
'y ~ X1 + (1   g1) + (-1 + X1   g1)'	Independent random intercept and slope.
'y ~ 1 + (1   g1) + (1   g2) + (1   g1:g2)'	Random intercept model with independent main effects for g1 and g2, plus an independent interaction effect.

### Design Matrices for Fixed and Random Effects

fitlme converts the expressions in the fixed and random parts (not grouping variables) of a formula into design matrices as follows:

- Each term in a formula adds one or more columns to the corresponding design matrix.
- A term containing a single continuous variable adds one column to the design matrix.
- A fixed term containing a categorical variable X with  $k$  levels adds  $(k - 1)$  dummy variables to the design matrix.

For example, if the variable `Supplier` represents three different suppliers a manufacturer receives parts from, i.e. a categorical variable with three levels, and out of six batches of parts, the first two batches come from supplier 1 (level 1), the second two batches come from supplier 2 (level 2), and the last two batches come from supplier 3 (level 3), such as

Supplier =

1  
1  
2  
2  
3  
3

Then, adding `Supplier` to the formula as a fixed-effects or random-effects term adds the following two dummy variables to the corresponding design matrix, using the 'reference' contrast:

```
0 0
0 0
1 0
1 0
0 1
0 1
```

For more details on dummy variables, see “Dummy Indicator Variables” on page 2-55. For other contrast options, see the 'DummyVarCoding' name-value pair argument of `fitlme`.

- If  $X1$  and  $X2$  are continuous variables, the product term  $X1:X2$  adds one column obtained by elementwise multiplication of  $X1$  and  $X2$  to the design matrix.
- If  $X1$  is continuous and  $X2$  is categorical with  $k$  levels, the product term  $X1:X2$  multiplies elementwise  $X1$  with the  $(k - 1)$  dummy variables representing  $X2$ , and adds these  $(k - 1)$  columns to the design matrix.

For example, if `Drug` is the amount of a drug given to patients, a continuous treatment, and `Time` is three distinct points in time when the health measures are taken, a categorical variable with three levels, and out of nine observations, the first three are observed at time point 1, the second three are observed at time point 2, and the last three are observed at time point 3 so that

```
[Drug Time] =
0.1000 1.0000
0.2000 1.0000
0.5000 2.0000
0.6000 2.0000
0.3000 3.0000
0.8000 3.0000
```

Then, the product term `Drug:Time` adds the following two variables to the design matrix:

```

      0      0
      0      0
0.5000      0
0.6000      0
      0    0.3000
      0    0.8000
    
```

- If  $X_1$  and  $X_2$  are categorical variables with  $k$  and  $m$  levels respectively, the product term  $X_1:X_2$  adds  $(k - 1)*(m - 1)$  dummy variables to the design matrix formed by taking the elementwise product of each dummy variable representing  $X_1$  with each dummy variable representing  $X_2$ .

For example, in an experiment to determine the impact of the type of corn and the popping method on the yield, suppose there are three types of Corn and two types of Method as follows:

```

1   oil
1   oil
1   air
1   air
2   oil
2   oil
2   air
2   air
3   oil
3   oil
3   air
3   air
    
```

Then, the interaction term  $\text{Corn:Method}$  adds the following to the design matrix:

```

      0      0
      0      0
      0      0
      0      0
      1      0
      1      0
      0      0
      0      0
      0      1
    
```

$$\begin{array}{cc} 0 & 1 \\ 0 & 0 \\ 0 & 0 \end{array}$$

- The term  $X1*X2$  adds the necessary number of columns for  $X1$ ,  $X2$ , and  $X1:X2$  to the design matrix.
- The term  $X1^2$  adds the necessary number of columns for  $X1$  and  $X1:X1$  to the design matrix.
- The symbol 1 (one) in the formula stands for a column of all 1s. By default a column of 1s is included in the design matrix. To exclude a column of ones from the design matrix, you must explicitly specify `1` as a term in the expression.

## Grouping Variables

`fitlme` handles the grouping variables in the `(. | group)` part of a formula as follows:

- If a grouping variable has  $k$  levels, then  $k$  dummy variables represent this grouping.

For example, suppose `District` is a categorical grouping variable with three levels, showing the three types of districts, and out of six schools, the first two are in district 1, the second two are in district 2, and the last two are in district 3, so that

District =

$$\begin{array}{c} 1 \\ 1 \\ 2 \\ 2 \\ 3 \\ 3 \end{array}$$

Then, the dummy variables that represent this grouping are:

$$\begin{array}{ccc} 1 & 0 & 0 \end{array}$$

1	0	0
0	1	0
0	1	0
0	0	1
0	0	1

- If  $X_1$  is a continuous random-effects variable and  $X_2$  is a grouping variable with  $k$  levels, then the random term  $(X_1 \quad 1 | X_2)$  multiplies elementwise  $X_1$  with the  $k$  dummy variables representing  $X_2$  and adds these  $k$  columns to the random-effects design matrix.

For example, suppose `Score` is a continuous variable showing the scores of students from a math exam in a school, and `Class` is a categorical variable with three levels, showing the three different classes in a school. Also, suppose out of nine observations first three correspond to the scores of students in the first class, the second three correspond to scores of students in the second class, and the last three correspond to the scores of students in the third class, such as

[Score Class] =

78.0000	1.0000
68.0000	1.0000
81.0000	2.0000
53.0000	2.0000
85.0000	3.0000
72.0000	3.0000

Then, the random term  $(\text{Score} \quad 1 | \text{Class})$  adds the following three columns to the random-effects design matrix:

78.0000	0	0
68.0000	0	0
0	81.0000	0
0	53.0000	0
0	0	85.0000
0	0	72.0000

- If  $X_1$  is a continuous predictor variable and  $X_2$  and  $X_3$  are grouping variables with  $k$  and  $m$  levels respectively, the term  $(X_1 | X_2 : X_3)$  represents this grouping of  $X_1$  with  $k*m$  dummy variables formed by taking the

elementwise product of each dummy variable representing X2 with each dummy variable representing X3.

For example, suppose `Treatment` is a continuous predictor variable, and there are three levels of `Block` and two levels of `Plot` nested within the block as follows:

0.1000	1	a
0.2000	1	b
0.5000	2	a
0.6000	2	b
0.3000	3	a
0.8000	3	b

Then, the random term (`Treatment`  $\times$  `1|Block:Plot`) adds the following to the random-effects design matrix:

0.1000	0	0	0	0	0
0	0.2000	0	0	0	0
0	0	0.5000	0	0	0
0	0	0	0.6000	0	0
0	0	0	0	0.3000	0
0	0	0	0	0	0.8000

## Estimating Parameters in Linear Mixed-Effects Models

### In this section...

“Maximum Likelihood (ML)” on page 9-173

“Restricted Maximum Likelihood (REML)” on page 9-174

A linear mixed-effects model is of the form

$$y = \underbrace{X\beta}_{\text{fixed}} + \underbrace{Zb}_{\text{random}} + \underbrace{\varepsilon}_{\text{error}},$$

where

- $y$  is the  $n$ -by-1 response vector, and  $n$  is the number of observations.
- $X$  is an  $n$ -by- $p$  fixed-effects design matrix.
- $\beta$  is a  $p$ -by-1 fixed-effects vector.
- $Z$  is an  $n$ -by- $q$  random-effects design matrix.
- $b$  is a  $q$ -by-1 random-effects vector.
- $\varepsilon$  is the  $n$ -by-1 observation error vector.

The random-effects vector,  $b$ , and the error vector,  $\varepsilon$ , are assumed to have the following independent prior distributions:

$$b \sim N(0, \sigma^2 D(\theta)),$$

$$\varepsilon \sim N(0, \sigma^2 I),$$

where  $D$  is a symmetric and positive semidefinite matrix, parameterized by a variance component vector  $\theta$ ,  $I$  is an  $n$ -by- $n$  identity matrix, and  $\sigma^2$  is the error variance.

In this model, the parameters to estimate are the fixed-effects coefficients  $\beta$ , and the variance components  $\theta$  and  $\varepsilon$ . The two most commonly used approaches to parameter estimation in linear mixed-effects models are maximum likelihood and restricted maximum likelihood methods.

## Maximum Likelihood (ML)

The maximum likelihood estimation includes both regression coefficients and the variance components, that is, both fixed-effects and random-effects terms in the likelihood function.

For a linear mixed-effects model defined above, the conditional response of the response variable  $y$  given  $\beta$ ,  $b$ ,  $\theta$ , and  $\sigma^2$  is

$$y | b, \beta, \theta, \sigma^2 \sim N(X\beta + Zb, \sigma^2 I_n).$$

The likelihood of  $y$  given  $\beta$ ,  $\theta$ , and  $\sigma^2$  is

$$P(y | \beta, \theta, \sigma^2) = \int P(y | b, \beta, \theta, \sigma^2) P(b | \theta, \sigma^2) db,$$

where

$$P(b | \theta, \sigma^2) = \frac{1}{(2\pi\sigma^2)^{q/2}} \frac{1}{|D(\theta)|^{1/2}} \exp\left\{-\frac{1}{2\sigma^2} b^T D^{-1} b\right\} \quad \text{and}$$

$$P(y | b, \beta, \theta, \sigma^2) = \frac{1}{(2\pi\sigma^2)^{n/2}} \exp\left\{-\frac{1}{2\sigma^2} (y - X\beta - Zb)^T (y - X\beta - Zb)\right\}.$$

Suppose  $\Lambda(\theta)$  is the lower triangular Cholesky factor of  $D(\theta)$  and  $\Delta(\theta)$  is the inverse of  $\Lambda(\theta)$ . Then,

$$D(\theta)^{-1} = \Delta(\theta)^T \Delta(\theta).$$

Define

$$r^2(\beta, b, \theta) = b^T \Delta(\theta)^T \Delta(\theta) b + (y - X\beta - Zb)^T (y - X\beta - Zb),$$

and suppose  $b^*$  is the value of  $b$  that satisfies

$$\left. \frac{\partial r^2(\beta, b, \theta)}{\partial b} \right|_{b^*} = 0$$

for given  $\beta$  and  $\theta$ . Then, the likelihood function is

$$P(y | \beta, \theta, \sigma^2) = (2\pi\sigma^2)^{-n/2} |D(\theta)|^{-1/2} \exp\left\{-\frac{1}{2\sigma^2} r^2(\beta, b^*(\beta), \theta)\right\} \frac{1}{|\Delta^T \Delta + Z^T Z|^{1/2}}.$$

$P(y | \beta, \theta, \sigma^2)$  is first maximized with respect to  $\beta$  and  $\sigma^2$  for a given  $\theta$ .

Thus the optimized solutions  $\hat{\beta}(\theta)$  and  $\hat{\sigma}^2(\theta)$  are obtained as functions of  $\theta$ . Substituting these solutions into the likelihood function produces

$P(y | \beta(\theta), \theta, \sigma^2(\theta))$ . This expression is called a profiled likelihood where  $\beta$

and  $\sigma^2$  have been profiled out.  $P(y | \beta(\theta), \theta, \sigma^2(\theta))$  is a function of  $\theta$ , and the algorithm then optimizes it with respect to  $\theta$ . Once it finds the optimal estimate of  $\theta$ , the estimates of  $\beta$  and  $\sigma^2$  are given by  $\hat{\beta}(\theta)$ .

The ML method treats  $\beta$  as fixed but unknown quantities when the variance components are estimated, but does not take into account the degrees of freedom lost by estimating the fixed effects. This causes ML estimates to be biased with smaller variances. However, one advantage of ML over REML is that it is possible to compare two models in terms of their fixed- and random-effects terms. On the other hand, if you use REML to estimate the parameters, you can only compare two models, that are nested in their random-effects terms, with the same fixed-effects design.

### Restricted Maximum Likelihood (REML)

Restricted maximum likelihood estimation includes only the variance components, that is, the parameters that parameterize the random-effects terms in the linear mixed-effects model.  $\beta$  is estimated in a second step. Assuming a uniform improper prior distribution for  $\beta$  and integrating the likelihood  $P(y | \beta, \theta, \sigma^2)$  with respect to  $\beta$  results in the restricted likelihood  $P(y | \theta, \sigma^2)$ . That is,

$$P(y | \theta, \sigma^2) = \int P(y | \beta, \theta, \sigma^2) P(\beta) d\beta = \int P(y | \beta, \theta, \sigma^2) d\beta.$$

The algorithm first profiles out  $\hat{\sigma}_R^2$  and maximizes remaining objective function with respect to  $\theta$  to find  $\hat{\theta}_R$ . The restricted likelihood is then maximized with respect to  $\sigma^2$  to find  $\hat{\sigma}_R^2$ . Then, it estimates  $\beta$  by finding its expected value with respect to the posterior distribution

$$P(\beta | y, \theta_R, \sigma_R^2).$$

REML accounts for the degrees of freedom lost by estimating the fixed effects, and makes a less biased estimation of random effects variances. The estimates of  $\theta$  and  $\sigma^2$  are invariant to the value of  $\beta$  and less sensitive to outliers in the data compared to ML estimates. However, if you use REML to estimate the parameters, you can only compare two models that have the identical fixed-effects design matrices and are nested in their random-effects terms.

## Multinomial Models for Nominal Responses

The outcome of a response variable might be one of a restricted set of possible values. If there are only two possible outcomes, such as a yes or no answer to a question, these responses are called binary responses. If there are multiple outcomes, then they are called polytomous responses. Some examples include the degree of a disease (mild, medium, severe), preferred districts to live in a city, and so on. When the response variable is *nominal*, there is no natural order among the response variable categories. Nominal response models explain and predict the probability that an observation is in each category of a categorical response variable.

A nominal response model is one of several natural extensions of the binary logit model and is also called a *multinomial logit* model. The multinomial logit model explains the relative risk of being in one category versus being in the reference category,  $k$ , using a linear combination of predictor variables. Consequently, the probability of each outcome is expressed as a nonlinear function of  $p$  predictor variables. The 'interactions', 'on' name-value pair argument in `mnrfit` corresponds to this multinomial model with separate intercept and slopes among categories. `mnrfit` uses the default logit link function for multinomial models. You cannot specify a different link function for multinomial responses.

The multinomial logit model is

$$\begin{aligned}\ln\left(\frac{\pi_1}{\pi_k}\right) &= \alpha_1 + \beta_{11}X_1 + \beta_{12}X_2 + \cdots + \beta_{1p}X_p, \\ \ln\left(\frac{\pi_2}{\pi_k}\right) &= \alpha_2 + \beta_{21}X_1 + \beta_{22}X_2 + \cdots + \beta_{2p}X_p, \\ &\vdots \\ \ln\left(\frac{\pi_{k-1}}{\pi_k}\right) &= \alpha_{(k-1)} + \beta_{(k-1)1}X_1 + \beta_{(k-1)2}X_2 + \cdots + \beta_{(k-1)p}X_p,\end{aligned}$$

where  $\pi_j = P(y = j)$  is the probability of an outcome being in category  $j$ ,  $k$  is the number of response categories, and  $p$  is the number of predictor variables. Theoretically, any category can be the reference category, but `mnrfit` chooses the last one,  $k$ , as the reference category. Thus, `mnrfit` assumes the coefficients of the  $k$ th category are zero. The total of  $j - 1$  equations are

solved simultaneously to estimate the coefficients. `mnrfit` uses the iteratively weighted least squares algorithm to find the maximum likelihood estimates.

The coefficients in the model express the effects of the predictor variables on the relative risk or the log odds of being in category  $j$  versus the reference category, here  $k$ . For example, the coefficient  $\beta_{23}$  indicates that the probability of the response variable being in category 2 compared to the probability of being in category  $k$  increases  $\exp(\beta_{23})$  times for each unit increase in  $X_3$ , given all else is held constant. Or it indicates that the relative log odds of the response variable being category 2 versus in category  $k$  increases  $\beta_{23}$  times with a one-unit increase in  $X_3$ , given all else equal.

Based on the nominal response model, and the assumption that the coefficients for the last category are zero, the probability of being in each category is

$$\pi_j = P(y = j) = \frac{e^{\sum_{l=1}^p \beta_{jl} x_l}}{1 + \sum_{j=1}^{k-1} e^{\sum_{l=1}^p \beta_{jl} x_l}}, \quad j = 1, \dots, k-1.$$

The probability of the  $k$ th category becomes

$$\pi_k = P(y = k) = \frac{1}{1 + \sum_{j=1}^{k-1} e^{\sum_{l=1}^p \beta_{jl} x_l}},$$

which is simply equal to  $1 - \pi_1 - \pi_2 - \dots - \pi_{k-1}$ .

After estimating the model coefficients using `mnrfit`, you can estimate the category probabilities or the number in each category using `mnrval` (the default name-value pair is 'type', 'category'). This function accepts the coefficient estimates and the model statistics `mnrfit` returns and estimates the categorical probabilities or the number in each category and their confidence bounds. You can also specify the cumulative or conditional probabilities or numbers to estimate using the 'type' name-value pair argument in `mnrval`.

## Multinomial Models for Ordinal Responses

The outcome of a response variable might be one of a restricted set of possible values. If there are only two possible outcomes, such as male and female for gender, these responses are called binary responses. If there are multiple outcomes, then they are called polytomous responses. Some examples of polytomous responses include levels of a disease (mild, medium, severe), preferred districts to live in a city, the species for a certain flower type, and so on. Sometimes there might be a natural order among the response categories. These responses are called *ordinal responses*.

The ordering might be inherent in the category choices, such as an individual being not satisfied, satisfied, or very satisfied with an online customer service. The ordering might also be introduced by categorization of a latent (continuous) variable, such as in the case of an individual being in the low risk, medium risk, or high risk group for developing a certain disease, based on a quantitative medical measure such as blood pressure.

You can specify a multinomial regression model that uses the natural ordering among the response categories. This ordinal model describes the relationship between the cumulative probabilities of the categories and predictor variables.

Different link functions can describe this relationship with logit and probit being the most used.

- **Logit:** The default link function `mnrfit` uses for ordinal categories is the *logit* link function. This models the *log cumulative odds*. The `'link', 'logit'` name-value pair specifies this in `mnrfit`. Log cumulative odds is the logarithm of the ratio of the probability that a response belongs to a category with a value less than or equal to category  $j$ ,  $P(y \leq c_j)$ , and the probability that a response belongs to a category with a value greater than category  $j$ ,  $P(y > c_j)$ .

Ordinal models are usually based on the assumption that the effects of predictor variables are the same for all categories on the logarithmic scale. That is, the model has different intercepts but common slopes (coefficients) among categories. This model is called *parallel regression* or the *proportional odds* model. It is the default for ordinal responses, and the `'interactions', 'off'` name-value pair specifies this model in `mnrfit`.

The proportional odds model is

$$\begin{aligned}\ln\left(\frac{P(y \leq c_1)}{P(y > c_1)}\right) &= \ln\left(\frac{\pi_1}{\pi_2 + \dots + \pi_k}\right) = \alpha_1 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_p X_p, \\ \ln\left(\frac{P(y \leq c_2)}{P(y > c_2)}\right) &= \ln\left(\frac{\pi_1 + \pi_2}{\pi_3 + \dots + \pi_k}\right) = \alpha_2 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_p X_p, \\ &\vdots \\ \ln\left(\frac{P(y \leq c_{k-1})}{P(y > c_{k-1})}\right) &= \ln\left(\frac{\pi_1 + \pi_2 + \dots + \pi_{k-1}}{\pi_k}\right) = \alpha_{k-1} + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_p X_p,\end{aligned}$$

where  $\pi_j, j = 1, 2, \dots, k$ , are the category probabilities.

For example, for a response variable with three categories, there are  $3 - 1 = 2$  equations as follows:

$$\begin{aligned}\ln\left(\frac{\pi_1}{\pi_2 + \pi_3}\right) &= \alpha_1 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_p X_p, \\ \ln\left(\frac{\pi_1 + \pi_2}{\pi_3}\right) &= \alpha_2 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_p X_p.\end{aligned}$$

Under the proportional odds assumption, the partial effect of a predictor variable  $X$  is invariant to the choice of the response variable category,  $j$ . For example, if there are three categories, then the coefficients express the impact of a predictor variable on the relative risk or log odds of the response value being in category 1 versus categories 2 or 3, or in category 1 or 2 versus category 3.

Thus, a unit change in variable  $X_2$  would mean a change in the cumulative odds of the response value being in category 1 versus categories 2 or 3, or category 1 or 2 versus category 3 by a factor of  $\exp(\beta_2)$ , given all else equal.

You can alternatively fit a model with different intercept and slopes among the categories by using the 'interactions', 'on' name-value pair argument. However, using this option for ordinal models when the equal slopes model is true causes a loss of efficiency (you lose the advantage of estimating fewer parameters).

- **Probit:** The 'link', 'probit' name-value pair argument uses the *probit* link function which is based on a normally distributed latent variable assumption. For ordinal response variables this is also called an *ordered probit* model. Consider the regression model that describes the relationship

of a latent variable  $y^*$  of an ordinal process and a vector of predictor variables,  $X$ ,

$$y = \beta X + \varepsilon,$$

where the error term  $\varepsilon$  has a standard normal distribution. Suppose there is the following relationship between the latent variable  $y^*$  and the observed variable  $y$ :

$$\begin{aligned} y = c_1 & \text{ if } \alpha_0 < y^* \leq \alpha_1, \\ y = c_2 & \text{ if } \alpha_1 < y^* \leq \alpha_2, \\ & \vdots \\ y = c_k & \text{ if } \alpha_{k-1} < y^* \leq \alpha_k, \end{aligned}$$

where  $\alpha_0 = -\infty$  and  $\alpha_k = \infty$ . Then, the cumulative probability of  $y$  being in category  $j$  or one of earlier categories,  $P(y \leq c_j)$ , is equal to

$$P(y \leq c_j) = P(y^* < \alpha_j) = P(\beta X + \varepsilon < \alpha_j) = P(\varepsilon < \alpha_j - \beta X) = \Phi(\alpha_j - \beta X),$$

where  $\Phi$  is standard normal cumulative distribution function. Thus,

$$\Phi^{-1}(P(y \leq c_j)) = \alpha_j - \beta X,$$

where  $\alpha_j$  corresponds to the cut points of the latent variable and the intercept in the regression model. This only holds under the assumptions of a normal latent variable and parallel regression. More generally, for a response variable with  $k$  categories and multiple predictors, the ordered probit model is

$$\begin{aligned} \Phi^{-1}(P(y \leq c_1)) &= \alpha_1 + \beta_1 X_1 + \cdots + \beta_p X_p, \\ \Phi^{-1}(P(y \leq c_2)) &= \alpha_2 + \beta_1 X_1 + \cdots + \beta_p X_p, \\ & \vdots \\ \Phi^{-1}(P(y \leq c_{k-1})) &= \alpha_{k-1} + \beta_1 X_1 + \cdots + \beta_p X_p, \end{aligned}$$

where  $P(y \leq c_j) = \pi_1 + \pi_2 + \dots + \pi_j$ .

The coefficients indicate the impact of a unit change in the predictor variable on the likelihood of a state. A positive coefficient,  $\beta_1$ , for example, indicates an increase in the underlying latent variable with an increase in the corresponding predictor variable,  $X_1$ . Hence, it causes a decrease in  $P(y \leq c_1)$  and an increase in  $P(y \leq c_k)$ .

After estimating the model coefficients using `mnrfit`, you can estimate the cumulative probabilities or the cumulative number in each category using `mnrval` with the 'type', 'cumulative' name-value pair option. `mnrval` accepts the coefficient estimates and the model statistics `mnrfit` returns, and estimates the categorical probabilities or the number in each category and their confidence intervals. You can specify which category or conditional probabilities or numbers to estimate by changing the value of the 'type' name-value pair argument.

## Hierarchical Multinomial Models

The outcome of a response variable might sometimes be one of a restricted set of possible values. If there are only two possible outcomes, such as male and female for gender, these responses are called binary responses. If there are multiple outcomes, then they are called polytomous responses. These responses are usually qualitative rather than quantitative, such as preferred districts to live in a city, the severity level of a disease, the species for a certain flower type, and so on. Polytomous responses might also have categories which are not independent of each other. Instead the response happens in a sequential manner, or one category is nested in the previous one. These types of responses are called *hierarchical*, or *sequential*, or *nested multinomial responses*.

For example, if the response is the number of cigarettes a person smokes in a given day, the first level is whether the person is a smoker or not. Given that he or she is a smoker, the number of cigarettes he or she smokes can be from one to five or more than five a day. Given that it is more than 5, this person might be smoking from 6 to 10 or more than 10 cigarettes a day, and so on. The risk group at each level changes accordingly. At level one, the risk group is all of the individuals of interest (smoker or not), say  $m$ . If out of  $m$  individuals,  $y_1$  of them are not smokers, then at level two, the risk group is the number of all smoking individuals,  $m - y_1$ . If  $y_2$  of these  $m - y_1$  individuals smoke from one to five cigarettes a day, then at level three, the risk group is  $m - y_1 - y_2$ . So, at each level, the number of people in that category becomes a conditional binomial observation.

The hierarchical multinomial regression models are extensions of binary regression models based on conditional binary observations. The default is a model with different intercept and slopes (coefficients) among categories, in which case `mnrfit` fits a sequence of conditional binomial models. The 'interactions', 'on' name-value pair specifies this in `mnrfit`. The default link function is logit and the 'link', 'logit' name-value pair specifies this model in `mnrfit`.

Suppose the probability that an individual is in category  $j$  given that he or she is not in the previous categories is  $\pi_j$ , and the cumulative probability that a response belongs to a category  $j$  or a previous category is  $P(y \leq c_j)$ . Then the hierarchical model with a logit link function and different slopes assumption is

$$\begin{aligned} \ln\left(\frac{\pi_1}{1 - P(y \leq c_1)}\right) &= \ln\left(\frac{\pi_1}{1 - \pi_1}\right) = \alpha_1 + \beta_{11}X_1 + \beta_{12}X_2 + \cdots + \beta_{1p}X_p, \\ \ln\left(\frac{\pi_2}{1 - P(y \leq c_2)}\right) &= \ln\left(\frac{\pi_2}{1 - (\pi_1 + \pi_2)}\right) = \alpha_2 + \beta_{21}X_1 + \beta_{22}X_2 + \cdots + \beta_{2p}X_p, \\ &\vdots \\ \ln\left(\frac{\pi_{k-1}}{1 - P(y \leq c_{k-1})}\right) &= \ln\left(\frac{\pi_{k-1}}{1 - (\pi_1 + \cdots + \pi_{k-1})}\right) = \alpha_{k-1} + \beta_{(k-1)1}X_1 + \beta_{(k-1)2}X_2 + \cdots + \beta_{(k-1)p}X_p. \end{aligned}$$

For example, for a response variable with four sequential categories, there are  $4 - 1 = 3$  equations as follows:

$$\begin{aligned} \ln\left(\frac{\pi_1}{\pi_2 + \pi_3 + \pi_4}\right) &= \alpha_1 + \beta_{11}X_1 + \beta_{12}X_2 + \cdots + \beta_{1p}X_p, \\ \ln\left(\frac{\pi_2}{\pi_3 + \pi_4}\right) &= \alpha_2 + \beta_{21}X_1 + \beta_{22}X_2 + \cdots + \beta_{2p}X_p, \\ \ln\left(\frac{\pi_3}{\pi_4}\right) &= \alpha_3 + \beta_{31}X_1 + \beta_{32}X_2 + \cdots + \beta_{3p}X_p. \end{aligned}$$

The coefficients  $\beta_{ij}$  are interpreted within each level. For example, for the previous smoking example,  $\beta_{12}$  shows the impact of  $X_2$  on the log odds of a person being a smoker versus a nonsmoker, provided that everything else is held constant. Alternatively,  $\beta_{22}$  shows the impact of  $X_2$  on the log odds of a person smoking one to five cigarettes versus more than five cigarettes a day, given that he or she is a smoker, provided that everything else is held constant. Similarly,  $\beta_{33}$  shows the effect of  $X_2$  on the log odds of a person smoking 6 to 10 cigarettes versus more than 10 cigarettes a day, given that he or she smokes more than 5 cigarettes a day, provided that everything else is held constant.

You can specify other link functions for hierarchical models. The 'link', 'probit' name-value pair argument uses the probit link function. With the separate slopes assumption, the model becomes

$$\begin{aligned}\Phi^{-1}(\pi_1) &= \alpha_1 + \beta_{11}X_1 + \cdots + \beta_{1p}X_p, \\ \Phi^{-1}(\pi_2) &= \alpha_2 + \beta_{21}X_1 + \cdots + \beta_{2p}X_p, \\ &\vdots \\ \Phi^{-1}(\pi_k) &= \alpha_k + \beta_{k1}X_1 + \cdots + \beta_{kp}X_p,\end{aligned}$$

where  $\pi_j$  is the conditional probability of being in category  $j$ , given that it is not in categories previous to category  $j$ . And  $\Phi^{-1}(\cdot)$  is the inverse of the standard normal cumulative distribution function.

After estimating the model coefficients using `mnrfit`, you can estimate the cumulative probabilities or the cumulative number in each category using `mnrval` with the 'type', 'conditional' name-value pair argument. The function `mnrval` accepts the coefficient estimates and the model statistics `mnrfit` returns, and estimates the categorical probabilities or the number in each category and their confidence bounds. You can specify which category or cumulative probabilities or numbers to estimate by changing the value of the 'type' name-value pair argument in `mnrval`.

### What Are Generalized Linear Models?

Linear regression models describe a linear relationship between a response and one or more predictive terms. Many times, however, a nonlinear relationship exists. “Nonlinear Regression” on page 11-2 describes general nonlinear models. A special class of nonlinear models, called *generalized linear models*, uses linear methods.

Recall that linear models have these characteristics:

- At each set of values for the predictors, the response has a normal distribution with mean  $\mu$ .
- A coefficient vector  $b$  defines a linear combination  $Xb$  of the predictors  $X$ .
- The model is  $\mu = Xb$ .

In generalized linear models, these characteristics are generalized as follows:

- At each set of values for the predictors, the response has a distribution that can be normal, binomial, Poisson, gamma, or inverse Gaussian, with parameters including a mean  $\mu$ .
- A coefficient vector  $b$  defines a linear combination  $Xb$  of the predictors  $X$ .

- A *link function*  $f$  defines the model as  $f(\mu) = Xb$ .

## Prepare Data

To begin fitting a regression, put your data into a form that fitting functions expect. All regression techniques begin with input data in an array  $X$  and response data in a separate vector  $y$ , or input data in a dataset array  $ds$  and response data as a column in  $ds$ . Each row of the input data represents one observation. Each column represents one predictor (variable).

For a dataset array  $ds$ , indicate the response variable with the 'ResponseVar' name-value pair:

```
mdl = fitlm(ds,'ResponseVar','BloodPressure');
% or
mdl = fitglm(ds,'ResponseVar','BloodPressure');
```

The response variable is the last column by default.

You can use numeric *categorical* predictors. A categorical predictor is one that takes values from a fixed set of possibilities.

- For a numeric array  $X$ , indicate the categorical predictors using the 'Categorical' name-value pair. For example, to indicate that predictors 2 and 3 out of six are categorical:

```
mdl = fitlm(X,y,'Categorical',[2,3]);
% or
mdl = fitglm(X,y,'Categorical',[2,3]);
% or equivalently
mdl = fitlm(X,y,'Categorical',logical([0 1 1 0 0 0]));
```

- For a dataset array  $ds$ , fitting functions assume that these data types are categorical:
  - Logical
  - Categorical (nominal or ordinal)
  - String or character array

If you want to indicate that a numeric predictor is categorical, use the 'Categorical' name-value pair.

Represent missing numeric data as NaN. To represent missing data for other data types, see “Missing Group Values” on page 2-53.

- For a 'binomial' model with data matrix  $X$ , the response  $y$  can be:
  - Binary column vector — Each entry represents success (1) or failure (0).
  - Two-column matrix of integers — The first column is the number of successes in each observation, the second column is the number of trials in that observation.
- For a 'binomial' model with dataset  $ds$ :
  - Use the `ResponseVar` name-value pair to specify the column of  $ds$  that gives the number of successes in each observation.
  - Use the `BinomialSize` name-value pair to specify the column of  $ds$  that gives the number of trials in each observation.

### **Dataset Array for Input and Response Data**

For example, to create a dataset array from an Excel spreadsheet:

```
ds = dataset('XLSFile','hospital.xls',...  
            'ReadObsNames',true);
```

To create a dataset array from workspace variables:

```
load carsmall  
ds = dataset(MPG,Weight);  
ds.Year = ordinal(Model_Year);
```

### **Numeric Matrix for Input Data, Numeric Vector for Response**

For example, to create numeric arrays from workspace variables:

```
load carsmall  
X = [Weight Horsepower Cylinders Model_Year];  
y = MPG;
```

To create numeric arrays from an Excel spreadsheet:

```
[X Xnames] = xlsread('hospital.xls');  
y = X(:,4); % response y is systolic pressure
```

```
X(:,4) = []; % remove y from the X matrix
```

Notice that the nonnumeric entries, such as `sex`, do not appear in `X`.

## Choose Generalized Linear Model and Link Function

Often, your data suggests the distribution type of the generalized linear model.

Response Data Type	Suggested Model Distribution Type
Any real number	'normal'
Any positive number	'gamma' or 'inverse gaussian'
Any nonnegative integer	'poisson'
Integer from 0 to $n$ , where $n$ is a fixed positive value	'binomial'

Set the model distribution type with the `Distribution` name-value pair. After selecting your model type, choose a link function to map between the mean  $\mu$  and the linear predictor  $Xb$ .

Value	Description
'comloglog'	$\log(-\log((1-\mu))) = Xb$
'identity', default for the distribution 'normal'	$\mu = Xb$
'log', default for the distribution 'poisson'	$\log(\mu) = Xb$
'logit', default for the distribution 'binomial'	$\log(\mu/(1-\mu)) = Xb$
'loglog'	$\log(-\log(\mu)) = Xb$
'probit'	$\Phi^{-1}(\mu) = Xb$ , where $\Phi$ is the normal (Gaussian) CDF function
'reciprocal', default for the distribution 'gamma'	$\mu^{-1} = Xb$

Value	Description
p (a number), default for the distribution 'inverse gaussian' (with $p = -2$ )	$\mu^p = Xb$
Cell array of the form {FL FD FI}, containing three function handles, created using @, that define the link (FL), the derivative of the link (FD), and the inverse link (FI). Equivalently, can be a structure of function handles with field Link containing FL, field Derivative containing FD, and field Inverse containing FI.	User-specified link function (see “Custom Link Function” on page 10-16)

The nondefault link functions are mainly useful for binomial models. These nondefault link functions are 'comloglog', 'loglog', and 'probit'.

### Custom Link Function

The link function defines the relationship  $f(\mu) = Xb$  between the mean response  $\mu$  and the linear combination  $Xb = X*b$  of the predictors. You can choose one of the built-in link functions or define your own by specifying the link function FL, its derivative FD, and its inverse FI:

- The link function FL calculates  $f(\mu)$ .
- The derivative of the link function FD calculates  $df(\mu)/d\mu$ .
- The inverse function FI calculates  $g(Xb) = \mu$ .

You can specify a custom link function in either of two equivalent ways. Each way contains function handles that accept a single array of values representing  $\mu$  or  $Xb$ , and returns an array the same size. The function handles are either in a cell array or a structure:

- Cell array of the form {FL FD FI}, containing three function handles, created using @, that define the link (FL), the derivative of the link (FD), and the inverse link (FI).
- Structure `s` with three fields, each containing a function handle created using @:
  - `s.Link` — Link function
  - `s.Derivative` — Derivative of the link function
  - `s.Inverse` — Inverse of the link function

For example, to fit a model using the 'probit' link function:

```
x = [2100 2300 2500 2700 2900 ...
     3100 3300 3500 3700 3900 4100 4300]';
n = [48 42 31 34 31 21 23 23 21 16 17 21]';
y = [1 2 0 3 8 8 14 17 19 15 17 21]';
g = fitglm(x,[y n],...
           'linear','distr','binomial','link','probit')
```

```
g =
```

Generalized Linear regression model:

```
probit(y) ~ 1 + x1
Distribution = Binomial
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	-7.3628	0.66815	-11.02	3.0701e-28
x1	0.0023039	0.00021352	10.79	3.8274e-27

12 observations, 10 error degrees of freedom

Dispersion: 1

Chi^2-statistic vs. constant model: 241, p-value = 2.25e-54

You can perform the same fit using a custom link function that performs identically to the 'probit' link function:

```
s = {@norminv,@(x)1./normpdf(norminv(x)),@normcdf};
g = fitglm(x,[y n],...
           'linear','distr','binomial','link',s)
```

```

g =

Generalized Linear regression model:
  link(y) ~ 1 + x1
  Distribution = Binomial

Estimated Coefficients:

```

	Estimate	SE	tStat	pValue
(Intercept)	-7.3628	0.66815	-11.02	3.0701e-28
x1	0.0023039	0.00021352	10.79	3.8274e-27

```

12 observations, 10 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 241, p-value = 2.25e-54

```

The two models are the same.

Equivalently, you can write `s` as a structure instead of a cell array of function handles:

```

s.Link = @norminv;
s.Derivative = @(x) 1./normpdf(norminv(x));
s.Inverse = @normcdf;
g = fitglm(x,[y n],...
  'linear','distr','binomial','link',s)

g =

Generalized Linear regression model:
  link(y) ~ 1 + x1
  Distribution = Binomial

Estimated Coefficients:

```

	Estimate	SE	tStat	pValue
(Intercept)	-7.3628	0.66815	-11.02	3.0701e-28
x1	0.0023039	0.00021352	10.79	3.8274e-27

```

12 observations, 10 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 241, p-value = 2.25e-54

```

## Choose Fitting Method and Model

There are two ways to create a fitted model.

- Use `fitglm` when you have a good idea of your generalized linear model, or when you want to adjust your model later to include or exclude certain terms.
- Use `stepwiseglm` when you want to fit your model using stepwise regression. `stepwiseglm` starts from one model, such as a constant, and adds or subtracts terms one at a time, choosing an optimal term each time in a greedy fashion, until it cannot improve further. Use stepwise fitting to find a good model, one that has only relevant terms.

The result depends on the starting model. Usually, starting with a constant model leads to a small model. Starting with more terms can lead to a more complex model, but one that has lower mean squared error.

In either case, provide a model to the fitting function (which is the starting model for `stepwiseglm`).

Specify a model using one of these methods.

- “Brief String” on page 10-19
- “Terms Matrix” on page 10-20
- “Formula” on page 10-23

### Brief String

String	Model Type
'constant'	Model contains only a constant (intercept) term.
'linear'	Model contains an intercept and linear terms for each predictor.
'interactions'	Model contains an intercept, linear terms, and all products of pairs of distinct predictors (no squared terms).
'purequadratic'	Model contains an intercept, linear terms, and squared terms.

String	Model Type
'quadratic'	Model contains an intercept, linear terms, interactions, and squared terms.
'polyijk'	Model is a polynomial with all terms up to degree $i$ in the first predictor, degree $j$ in the second predictor, etc. Use numerals 0 through 9. For example, 'poly2111' has a constant plus all linear and product terms, and also contains terms with predictor 1 squared.

### Terms Matrix

A terms matrix is a  $t$ -by- $(p + 1)$  matrix specifying terms in a model, where  $t$  is the number of terms,  $p$  is the number of predictor variables, and plus one is for the response variable. The value of  $T(i, j)$  is the exponent of variable  $j$  in term  $i$ . Suppose there are three predictor variables A, B, and C:

```
[0 0 0 0] % Constant term or intercept
[0 1 0 0] % B; equivalently, A^0 * B^1 * C^0
[1 0 1 0] % A*C
[2 0 0 0] % A^2
[0 1 2 0] % B*(C^2)
```

The 0 at the end of each term represents the response variable. In general,

- If you have the variables in a dataset array, then 0 must represent the response variable depending on the position of the response variable in the dataset array. The following example illustrates this.

Load the sample data and define the dataset array.

```
load hospital
ds = dataset(hospital.Sex,hospital.BloodPressure(:,1),hospital.Age,...
hospital.Smoker,'VarNames',{'Sex','BloodPressure','Age','Smoker'});
```

Represent the linear model 'BloodPressure ~ 1 + Sex + Age + Smoker' in a terms matrix. The response variable is in the second column of the dataset array, so there must be a column of 0s for the response variable in the second column of the terms matrix.

```
T = [0 0 0 0;1 0 0 0;0 0 1 0;0 0 0 1]
```

```
T =
```

```

0     0     0     0
1     0     0     0
0     0     1     0
0     0     0     1
```

Redefine the dataset array.

```
ds = dataset(hospital.BloodPressure(:,1),hospital.Sex,hospital.Age,...
hospital.Smoker,'VarNames',{'BloodPressure','Sex','Age','Smoker'});
```

Now, the response variable is the first term in the dataset array. Specify the same linear model, 'BloodPressure ~ 1 + Sex + Age + Smoker', using a terms matrix.

```
T = [0 0 0 0;0 1 0 0;0 0 1 0;0 0 0 1]
```

```
T =
```

```

0     0     0     0
0     1     0     0
0     0     1     0
0     0     0     1
```

- If you have the predictor and response variables in a matrix and column vector, then you must include 0 for the response variable at the end of each term. The following example illustrates this.

Load the sample data and define the matrix of predictors.

```
load carsmall
X = [Acceleration,Weight];
```

Specify the model 'MPG ~ Acceleration + Weight + Acceleration:Weight + Weight^2' using a term matrix and fit the model to the data. This model includes the main effect and two-way interaction terms for the variables, Acceleration and Weight, and a second-order term for the variable, Weight.

```
T = [0 0 0;1 0 0;0 1 0;1 1 0;0 2 0]
```

```
T =
```

```

0    0    0
1    0    0
0    1    0
1    1    0
0    2    0
```

Fit a linear model.

```
mdl = fitlm(X,MPG,T)
```

```
mdl =
```

Linear regression model:

```
y ~ 1 + x1*x2 + x2^2
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	48.906	12.589	3.8847	0.00019665
x1	0.54418	0.57125	0.95261	0.34337
x2	-0.012781	0.0060312	-2.1192	0.036857
x1:x2	-0.00010892	0.00017925	-0.6076	0.545
x2^2	9.7518e-07	7.5389e-07	1.2935	0.19917

Number of observations: 94, Error degrees of freedom: 89

Root Mean Squared Error: 4.1

R-squared: 0.751, Adjusted R-Squared 0.739

F-statistic vs. constant model: 67, p-value = 4.99e-26

Only the intercept and x2 term, which correspond to the Weight variable, are significant at the 5% significance level.

Now, perform a stepwise regression with a constant model as the starting model and a linear model with interactions as the upper model.

```
T = [0 0 0;1 0 0;0 1 0;1 1 0];
mdl = stepwiselm(X,MPG,[0 0 0],'upper',T)
```

1. Adding x2, FStat = 259.3087, pValue = 1.643351e-28

mdl =

Linear regression model:

$$y \sim 1 + x2$$

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	49.238	1.6411	30.002	2.7015e-49
x2	-0.0086119	0.0005348	-16.103	1.6434e-28

Number of observations: 94, Error degrees of freedom: 92

Root Mean Squared Error: 4.13

R-squared: 0.738, Adjusted R-Squared 0.735

F-statistic vs. constant model: 259, p-value = 1.64e-28

The results of the stepwise regression are consistent with the results of fitlm in the previous step.

## Formula

A formula for a model specification is a string of the form

`'Y ~ terms'`,

- Y is the response name.
- *terms* contains
  - Variable names
  - + to include the next variable
  - - to exclude the next variable
  - : to define an interaction, a product of terms
  - \* to define an interaction and all lower-order terms
  - ^ to raise the predictor to a power, exactly as in \* repeated, so ^ includes lower order terms as well
  - () to group terms

---

**Tip** Formulas include a constant (intercept) term by default. To exclude a constant term from the model, include `-1` in the formula.

---

Examples:

`'Y ~ A + B + C'` is a three-variable linear model with intercept.

`'Y ~ A + B + C - 1'` is a three-variable linear model without intercept.

`'Y ~ A + B + C + B^2'` is a three-variable model with intercept and a  $B^2$  term.

`'Y ~ A + B^2 + C'` is the same as the previous example, since  $B^2$  includes a  $B$  term.

`'Y ~ A + B + C + A:B'` includes an  $A*B$  term.

`'Y ~ A*B + C'` is the same as the previous example, since  $A*B = A + B + A:B$ .

`'Y ~ A*B*C - A:B:C'` has all interactions among  $A$ ,  $B$ , and  $C$ , except the three-way interaction.

`'Y ~ A*(B + C + D)'` has all linear terms, plus products of  $A$  with each of the other variables.

## Fit Model to Data

Create a fitted model using `fitglm` or `stepwiseglm`. Choose between them as in “Choose Fitting Method and Model” on page 10-19. For generalized linear models other than those with a normal distribution, give a `Distribution` name-value pair as in “Choose Generalized Linear Model and Link Function” on page 10-15. For example,

```
mdl = fitglm(X,y,'linear','Distribution','poisson')
% or
mdl = fitglm(X,y,'quadratic',...
            'Distribution','binomial')
```

## Examine Quality and Adjust the Fitted Model

After fitting a model, examine the result.

- “Model Display” on page 10-25
- “Diagnostic Plots” on page 10-26

- “Residuals — Model Quality for Training Data” on page 10-29
- “Plots to Understand Predictor Effects and How to Modify a Model” on page 10-32

## Model Display

A linear regression model shows several diagnostics when you enter its name or enter `disp mdl`. This display gives some of the basic information to check whether the fitted model represents the data adequately.

For example, fit a Poisson model to data constructed with two out of five predictors not affecting the response, and with no intercept term:

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[.4;.2;.3]);
y = poissrnd(mu);
mdl = fitglm(X,y,...
    'linear','Distribution','poisson')
```

```
mdl =
```

Generalized Linear regression model:

```
log(y) ~ 1 + x1 + x2 + x3 + x4 + x5
Distribution = Poisson
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	0.039829	0.10793	0.36901	0.71212
x1	0.38551	0.076116	5.0647	4.0895e-07
x2	-0.034905	0.086685	-0.40266	0.6872
x3	-0.17826	0.093552	-1.9054	0.056722
x4	0.21929	0.09357	2.3436	0.019097
x5	0.28918	0.1094	2.6432	0.0082126

100 observations, 94 error degrees of freedom

Dispersion: 1

Chi<sup>2</sup>-statistic vs. constant model: 44.9, p-value = 1.55e-08

Notice that:

- The display contains the estimated values of each coefficient in the Estimate column. These values are reasonably near the true values [0; .4; 0; 0; .2; .3], except possibly the coefficient of `x3` is not terribly near 0.
- There is a standard error column for the coefficient estimates.
- The reported `pValue` (which are derived from the  $t$  statistics under the assumption of normal errors) for predictors 1, 4, and 5 are small. These are the three predictors that were used to create the response data `y`.
- The `pValue` for (Intercept), `x2` and `x3` are larger than 0.01. These three predictors were not used to create the response data `y`. The `pValue` for `x3` is just over .05, so might be regarded as possibly significant.
- The display contains the Chi-square statistic.

### Diagnostic Plots

Diagnostic plots help you identify outliers, and see other problems in your model or fit. To illustrate these plots, consider binomial regression with a logistic link function.

The *logistic model* is useful for proportion data. It defines the relationship between the proportion  $p$  and the weight  $w$  by:

$$\log[p/(1 - p)] = b_1 + b_2w$$

This example fits a binomial model to data. The data are derived from `carbig.mat`, which contains measurements of large cars of various weights. Each weight in `w` has a corresponding number of cars in `total` and a corresponding number of poor-mileage cars in `poor`.

It is reasonable to assume that the values of `poor` follow binomial distributions, with the number of trials given by `total` and the percentage of successes depending on `w`. This distribution can be accounted for in the context of a logistic model by using a generalized linear model with link function  $\log(\mu/(1 - \mu)) = Xb$ . This link function is called 'logit'.

`w = [2100 2300 2500 2700 2900 3100 ...`

```
3300 3500 3700 3900 4100 4300]';  
total = [48 42 31 34 31 21 23 23 21 16 17 21]';  
poor = [1 2 0 3 8 8 14 17 19 15 17 21]';  
mdl = fitglm(w,[poor total],...  
            'linear','Distribution','binomial','link','logit')
```

```
mdl =
```

Generalized Linear regression model:

logit(y) ~ 1 + x1

Distribution = Binomial

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	-13.38	1.394	-9.5986	8.1019e-22
x1	0.0041812	0.00044258	9.4474	3.4739e-21

12 observations, 10 error degrees of freedom

Dispersion: 1

Chi^2-statistic vs. constant model: 242, p-value = 1.3e-54

See how well the model fits the data.

```
plotSlice(mdl)
```

The fit looks reasonably good, with fairly wide confidence bounds.

To examine further details, create a leverage plot.

```
plotDiagnostics(md1)
```

This is typical of a regression with points ordered by the predictor variable. The leverage of each point on the fit is higher for points with relatively extreme predictor values (in either direction) and low for points with average predictor values. In examples with multiple predictors and with points not ordered by predictor value, this plot can help you identify which observations have high leverage because they are outliers as measured by their predictor values.

### **Residuals – Model Quality for Training Data**

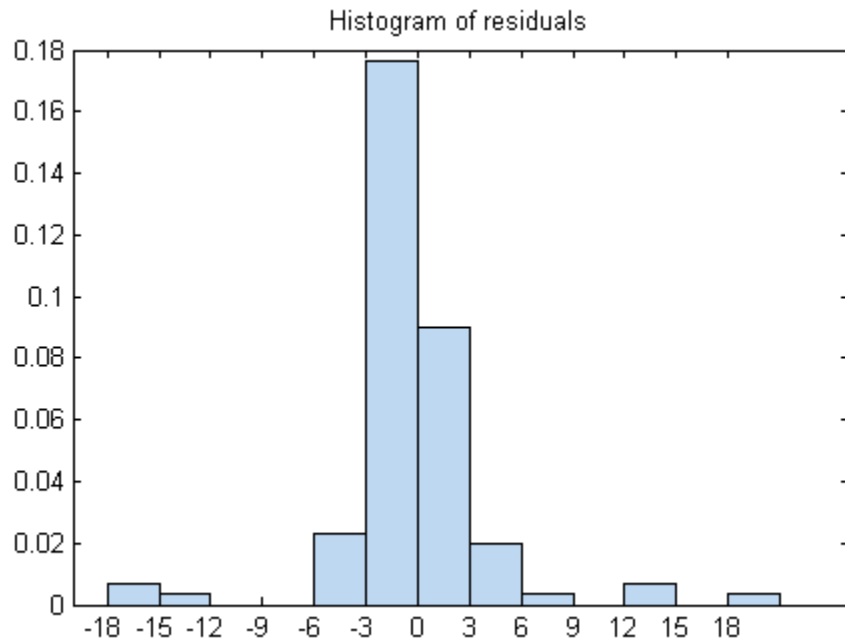

There are several residual plots to help you discover errors, outliers, or correlations in the model or data. The simplest residual plots are the default histogram plot, which shows the range of the residuals and their frequencies, and the probability plot, which shows how the distribution of the residuals compares to a normal distribution with matched variance.

This example shows residual plots for a fitted Poisson model. The data construction has two out of five predictors not affecting the response, and no intercept term:

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = fitglm(X,y,...
            'linear','Distribution','poisson');
```

Examine the residuals:

```
plotResiduals(mdl)
```

While most residuals cluster near 0, there are several near  $\pm 18$ . So examine a different residuals plot.

```
plotResiduals mdl, 'fitted'
```

The large residuals don't seem to have much to do with the sizes of the fitted values.

Perhaps a probability plot is more informative.

```
plotResiduals mdl, 'probability'
```

Now it is clear. The residuals do not follow a normal distribution. Instead, they have fatter tails, much as an underlying Poisson distribution.

### Plots to Understand Predictor Effects and How to Modify a Model

This example shows how to understand the effect each predictor has on a regression model, and how to modify the model to remove unnecessary terms.

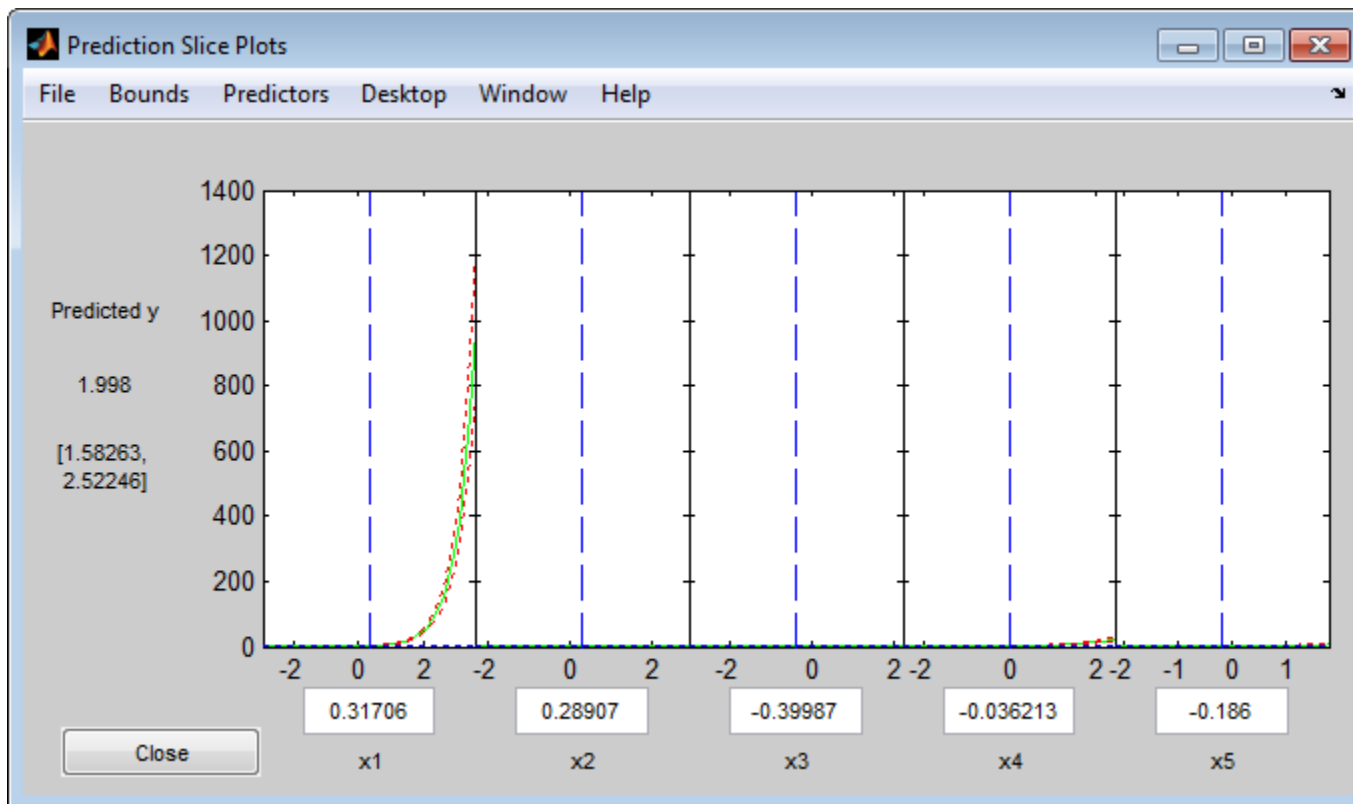

- 1 Create a model from some predictors in artificial data. The data do not use the second and third columns in  $X$ . So you expect the model not to show much dependence on those predictors.

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = fitglm(X,y,...
```

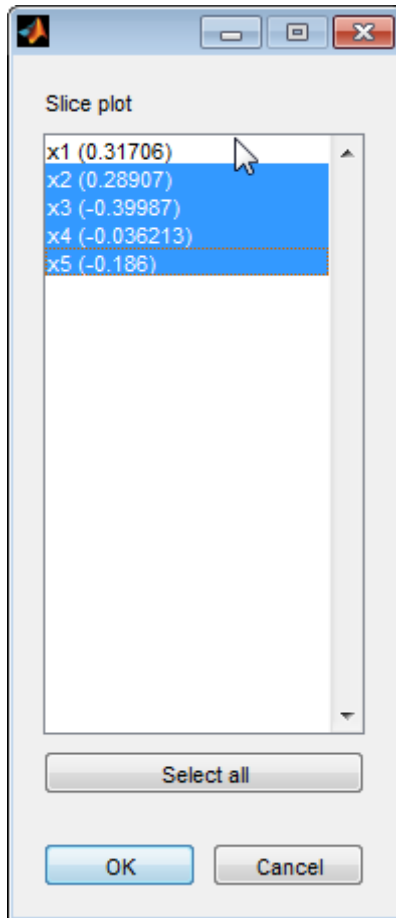

```
'linear', 'Distribution', 'poisson');
```

- 2 Examine a slice plot of the responses. This displays the effect of each predictor separately.

```
plotSlice mdl
```

The scale of the first predictor is overwhelming the plot. Disable it using the **Predictors** menu.

Now it is clear that predictors 2 and 3 have little to no effect.

You can drag the individual predictor values, which are represented by dashed blue vertical lines. You can also choose between simultaneous and non-simultaneous confidence bounds, which are represented by dashed red curves. Dragging the predictor lines confirms that predictors 2 and 3 have little to no effect.

- Remove the unnecessary predictors using either `removeTerms` or `step`. Using `step` can be safer, in case there is an unexpected importance to a term that becomes apparent after removing another term. However, sometimes `removeTerms` can be effective when `step` does not proceed. In this case, the two give identical results.

```
mdl1 = removeTerms(mdl, 'x2 + x3')
```

```
mdl1 =
```

Generalized Linear regression model:

$\log(y) \sim 1 + x1 + x4 + x5$

Distribution = Poisson

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	0.17604	0.062215	2.8295	0.004662
x1	1.9122	0.024638	77.614	0
x4	0.98521	0.026393	37.328	5.6696e-305
x5	0.61321	0.038435	15.955	2.6473e-57

100 observations, 96 error degrees of freedom

Dispersion: 1

Chi<sup>2</sup>-statistic vs. constant model: 4.97e+04, p-value = 0

```
mdl1 = step(mdl, 'NSteps', 5, 'Upper', 'linear')
```

1. Removing x3, Deviance = 93.856, Chi2Stat = 0.00075551, PValue = 0.97807

2. Removing x2, Deviance = 96.333, Chi2Stat = 2.4769, PValue = 0.11553

```
mdl1 =
```

Generalized Linear regression model:

$\log(y) \sim 1 + x1 + x4 + x5$

Distribution = Poisson

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	0.17604	0.062215	2.8295	0.004662
x1	1.9122	0.024638	77.614	0
x4	0.98521	0.026393	37.328	5.6696e-305
x5	0.61321	0.038435	15.955	2.6473e-57

```

100 observations, 96 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 4.97e+04, p-value = 0

```

## Predict or Simulate Responses to New Data

There are three ways to use a linear model to predict the response to new data:

- “predict” on page 10-37
- “feval” on page 10-38
- “random” on page 10-39

### predict

The `predict` method gives a prediction of the mean responses and, if requested, confidence bounds.

This example shows how to predict and obtain confidence intervals on the predictions using the `predict` method.

- 1 Create a model from some predictors in artificial data. The data do not use the second and third columns in  $X$ . So you expect the model not to show much dependence on these predictors. Construct the model stepwise to include the relevant predictors automatically.

```

rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = stepwiseglm(X,y,...
    'constant','upper','linear','Distribution','poisson');

```

```

1. Adding x1, Deviance = 2515.02869, Chi2Stat = 47242.9622, PValue = 0
2. Adding x4, Deviance = 328.39679, Chi2Stat = 2186.6319, PValue = 0
3. Adding x5, Deviance = 96.3326, Chi2Stat = 232.0642, PValue = 2.114384e-52

```

- 2 Generate some new data, and evaluate the predictions from the data.

```

Xnew = randn(3,5) + repmat([1 2 3 4 5],[3,1]); % new data
[ynew,ynewci] = predict(mdl,Xnew)

```

```

ynew =

    1.0e+04 *

    0.1130
    1.7375
    3.7471

ynewci =

    1.0e+04 *

    0.0821    0.1555
    1.2167    2.4811
    2.8419    4.9407

```

## feval

When you construct a model from a dataset array, `feval` is often more convenient for predicting mean responses than `predict`. However, `feval` does not provide confidence bounds.

This example shows how to predict mean responses using the `feval` method.

- 1 Create a model from some predictors in artificial data. The data do not use the second and third columns in  $X$ . So you expect the model not to show much dependence on these predictors. Construct the model stepwise to include the relevant predictors automatically.

```

rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[2;1;.5]);
y = poissrnd(mu);
ds = dataset({X,'x1','x2','x3','x4','x5'},{y,'y'});
mdl = stepwiseglm(ds,...
    'constant','upper','linear','Distribution','poisson');

```

1. Adding x1, Deviance = 2515.02869, Chi2Stat = 47242.9622, PValue = 0
2. Adding x4, Deviance = 328.39679, Chi2Stat = 2186.6319, PValue = 0
3. Adding x5, Deviance = 96.3326, Chi2Stat = 232.0642, PValue = 2.114384e-52

**2** Generate some new data, and evaluate the predictions from the data.

```
Xnew = randn(3,5) + repmat([1 2 3 4 5],[3,1]); % new data
ynew = feval mdl,Xnew(:,1),Xnew(:,4),Xnew(:,5)) % only need predictors 1,
```

```
ynew =

    1.0e+04 *

    0.1130
    1.7375
    3.7471
```

Equivalently,

```
ynew = feval(mdl,Xnew(:,[1 4 5])) % only need predictors 1,4,5
```

```
ynew =

    1.0e+04 *

    0.1130
    1.7375
    3.7471
```

## random

The `random` method generates new random response values for specified predictor values. The distribution of the response values is the distribution used in the model. `random` calculates the mean of the distribution from the predictors, estimated coefficients, and link function. For distributions such as normal, the model also provides an estimate of the variance of the response. For the binomial and Poisson distributions, the variance of the response is determined by the mean; `random` does not use a separate “dispersion” estimate.

This example shows how to simulate responses using the `random` method.

**1** Create a model from some predictors in artificial data. The data do not use the second and third columns in `X`. So you expect the model not to show

much dependence on these predictors. Construct the model stepwise to include the relevant predictors automatically.

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = stepwiseglm(X,y,...
    'constant','upper','linear','Distribution','poisson');
```

1. Adding x1, Deviance = 2515.02869, Chi2Stat = 47242.9622, PValue = 0
2. Adding x4, Deviance = 328.39679, Chi2Stat = 2186.6319, PValue = 0
3. Adding x5, Deviance = 96.3326, Chi2Stat = 232.0642, PValue = 2.114384e-52

## 2 Generate some new data, and evaluate the predictions from the data.

```
Xnew = randn(3,5) + repmat([1 2 3 4 5],[3,1]); % new data
ysim = random(mdl,Xnew)
```

```
ysim =

    1111
    17121
    37457
```

The predictions from random are Poisson samples, so are integers.

## 3 Evaluate the random method again, the result changes.

```
ysim = random(mdl,Xnew)
```

```
ysim =

    1175
    17320
    37126
```

## Share Fitted Models

The model display contains enough information to enable someone else to recreate the model in a theoretical sense. For example,

```
rng('default') % for reproducibility
```

```
X = randn(100,5);
mu = exp(X(:, [1 4 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = stepwiseglm(X,y,...
    'constant','upper','linear','Distribution','poisson')
```

1. Adding x1, Deviance = 2515.02869, Chi2Stat = 47242.9622, PValue = 0
2. Adding x4, Deviance = 328.39679, Chi2Stat = 2186.6319, PValue = 0
3. Adding x5, Deviance = 96.3326, Chi2Stat = 232.0642, PValue = 2.114384e-52

```
mdl =
```

Generalized Linear regression model:

```
log(y) ~ 1 + x1 + x4 + x5
Distribution = Poisson
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	0.17604	0.062215	2.8295	0.004662
x1	1.9122	0.024638	77.614	0
x4	0.98521	0.026393	37.328	5.6696e-305
x5	0.61321	0.038435	15.955	2.6473e-57

100 observations, 96 error degrees of freedom

Dispersion: 1

Chi^2-statistic vs. constant model: 4.97e+04, p-value = 0

You can access the model description programmatically, too. For example,

```
mdl.Coefficients.Estimate
```

```
ans =
```

```
0.1760
1.9122
0.9852
0.6132
```

```
mdl.Formula
```

```
ans =

log(y) ~ 1 + x1 + x4 + x5
```

## Generalized Linear Model Workflow

This example shows how to fit a generalized linear model and analyze the results. A typical workflow involves the following: import data, fit a generalized linear model, test its quality, modify it to improve the quality, and make predictions based on the model. It computes the probability that a flower is in one of two classes, based on the Fisher iris data.

### Step 1. Load the data.

Load the Fisher iris data. Extract the rows that have classification `versicolor` or `virginica`. These are rows 51 to 150. Create logical response variables that are true for `versicolor` flowers.

```
load fisheriris
X = meas(51:end,:); % versicolor and virginica
y = strcmp('versicolor',species(51:end));
```

### Step 2. Fit a generalized linear model.

Fit a binomial generalized linear model to the data.

```
mdl = fitglm(X,y,'linear',...
            'distr','binomial')
```

```
mdl =
```

```
Generalized Linear regression model:
logit(y) ~ 1 + x1 + x2 + x3 + x4
Distribution = Binomial
```

```
Estimated Coefficients:
```

	Estimate	SE	tStat	pValue
(Intercept)	42.638	25.708	1.6586	0.097204
x1	2.4652	2.3943	1.0296	0.30319
x2	6.6809	4.4796	1.4914	0.13585
x3	-9.4294	4.7372	-1.9905	0.046537
x4	-18.286	9.7426	-1.8769	0.060529

```

100 observations, 95 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 127, p-value = 1.95e-26

```

### Step 3. Examine the result, consider alternative models.

Some  $p$ -values in the `pValue` column are not very small. Perhaps the model can be simplified.

See if some 95% confidence intervals for the coefficients include 0. If so, perhaps these model terms could be removed.

```
confint = coefCI mdl
```

```

confint =
   -8.3984   93.6740
   -2.2881    7.2185
   -2.2122   15.5739
  -18.8339   -0.0248
  -37.6277    1.0554

```

Only two of the predictors have coefficients whose confidence intervals do not include 0.

The coefficients of 'x1' and 'x2' have the largest  $p$ -values. Test whether both coefficients could be zero.

```

M = [0 1 0 0 0      % picks out coefficient for column 1
      0 0 1 0 0];  % picks out coefficient for column 2
p = coefTest(mdl,M)

```

```
p =
```

```
0.1442
```

The  $p$ -value of about 0.14 is not very small. Drop those terms from the model.

```
mdl1 = removeTerms(mdl, 'x1 + x2')
```

```
mdl1 =
```

Generalized Linear regression model:

logit(y) ~ 1 + x3 + x4  
 Distribution = Binomial

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	45.272	13.612	3.326	0.00088103
x3	-5.7545	2.3059	-2.4956	0.012576
x4	-10.447	3.7557	-2.7816	0.0054092

100 observations, 97 error degrees of freedom

Dispersion: 1

Chi^2-statistic vs. constant model: 118, p-value = 2.3e-26

Perhaps it would have been better to have `stepwiseglm` identify the model initially.

```
mdl2 = stepwiseglm(X,y,...
    'constant','Distribution','binomial','upper','linear')
```

1. Adding x4, Deviance = 33.4208, Chi2Stat = 105.2086, PValue = 1.099298e-24
2. Adding x3, Deviance = 20.5635, Chi2Stat = 12.8573, PValue = 0.000336166
3. Adding x2, Deviance = 13.2658, Chi2Stat = 7.29767, PValue = 0.00690441

mdl2 =

Generalized Linear regression model:

logit(y) ~ 1 + x2 + x3 + x4  
 Distribution = Binomial

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	50.527	23.995	2.1057	0.035227
x2	8.3761	4.7612	1.7592	0.078536
x3	-7.8745	3.8407	-2.0503	0.040334
x4	-21.43	10.707	-2.0014	0.04535

100 observations, 96 error degrees of freedom

Dispersion: 1

Chi^2-statistic vs. constant model: 125, p-value = 5.4e-27

stepwiseglm included 'x2' in the model, because it neither adds nor removes terms with  $p$ -values between 0.05 and 0.10.

**Step 4. Look for outliers and exclude them.**

Examine a leverage plot to look for influential outliers.

```
plotDiagnostics(md12, 'leverage')
```

There is one observation with a leverage close to one. Using the Data Cursor, click the point, and find it has index 69.

See if the model coefficients change when you fit a model excluding this point.

```
oldCoeffs = mdl2.Coefficients.Estimate;  
mdl3 = fitglm(X,y,'linear',...  
    'distr','binomial','pred',2:4,'exclude',69);  
newCoeffs = mdl3.Coefficients.Estimate;  
disp([oldCoeffs newCoeffs])
```

```
50.5268    50.5268  
8.3761     8.3761  
-7.8745    -7.8745  
-21.4296   -21.4296
```

The model coefficients do not change, suggesting that the response at the high-leverage point is consistent with the predicted value from the reduced model.

#### **Step 5. Predict the probability that a new flower is versicolor.**

Use `mdl2` to predict the probability that a flower with average measurements is versicolor. Generate confidence intervals for your prediction.

```
[newf newc] = predict(mdl2,mean(X))
```

```
newf =  
0.5086
```

```
newc =  
0.1863    0.8239
```

The model gives almost a 50% probability that the average flower is versicolor, with a wide confidence interval about this estimate.

“References” on page 10-67

### What is Generalized Linear Model Lasso Regularization?

Lasso is a regularization technique. Use `lasso1m` to:

- Reduce the number of predictors in a generalized linear model.
- Identify important predictors.
- Select among redundant predictors.
- Produce shrinkage estimates with potentially lower predictive errors than ordinary least squares.

Elastic net is a related technique. Use it when you have several highly correlated variables. `lasso1m` provides elastic net regularization when you set the `Alpha` name-value pair to a number strictly between 0 and 1.

For details about lasso and elastic net computations and algorithms, see “Generalized Linear Model Lasso and Elastic Net” on page 10-65. For a discussion of generalized linear models, see “What Are Generalized Linear Models?” on page 10-12.

### Regularize Poisson Regression

This example shows how to identify and remove redundant predictors from a generalized linear model.

Create data with 20 predictors, and Poisson responses using just three of the predictors, plus a constant.

```
rng('default') % for reproducibility
X = randn(100,20);
mu = exp(X(:, [5 10 15]) * [.4; .2; .3] + 1);
y = poissrnd(mu);
```

Construct a cross-validated lasso regularization of a Poisson regression model of the data.

```
[B FitInfo] = lassoglm(X,y,'poisson','CV',10);
```

Examine the cross-validation plot to see the effect of the Lambda regularization parameter.

```
lassoPlot(B,FitInfo,'plottype','CV');
```

The green circle and dashed line locate the Lambda with minimal cross-validation error. The blue circle and dashed line locate the point with minimal cross-validation error plus one standard deviation.

Find the nonzero model coefficients corresponding to the two identified points.

```
minpts = find(B(:,FitInfo.IndexMinDeviance))
```

```
minpts =
     3
     5
     6
```

```

10
11
15
16

```

```
min1pts = find(B(:,FitInfo.Index1SE))
```

```
min1pts =
```

```

5
10
15

```

The coefficients from the minimal plus one standard error point are exactly those coefficients used to create the data.

Find the values of the model coefficients at the minimal plus one standard error point.

```
B(min1pts,FitInfo.Index1SE)
```

```
ans =
```

```

0.2903
0.0789
0.2081

```

The values of the coefficients are, as expected, smaller than the original  $[0.4, 0.2, 0.3]$ . Lasso works by “shrinkage,” which biases predictor coefficients toward zero.

The constant term is in the `FitInfo.Intercept` vector.

```
FitInfo.Intercept(FitInfo.Index1SE)
```

```
ans =
```

```
1.0879
```

The constant term is near 1, which is the value used to generate the data.

## Regularize Logistic Regression

This example shows how to regularize binomial regression. The default (canonical) link function for binomial regression is the logistic function.

### Step 1. Prepare the data.

Load the `ionosphere` data. The response `Y` is a cell array of 'g' or 'b' strings. Convert the cells to logical values, with `true` representing 'g'. Remove the first two columns of `X` because they have some awkward statistical properties, which are beyond the scope of this discussion.

```
load ionosphere
Ybool = strcmp(Y, 'g');
X = X(:,3:end);
```

### Step 2. Create a cross-validated fit.

Construct a regularized binomial regression using 25 Lambda values and 10-fold cross validation. This process can take a few minutes.

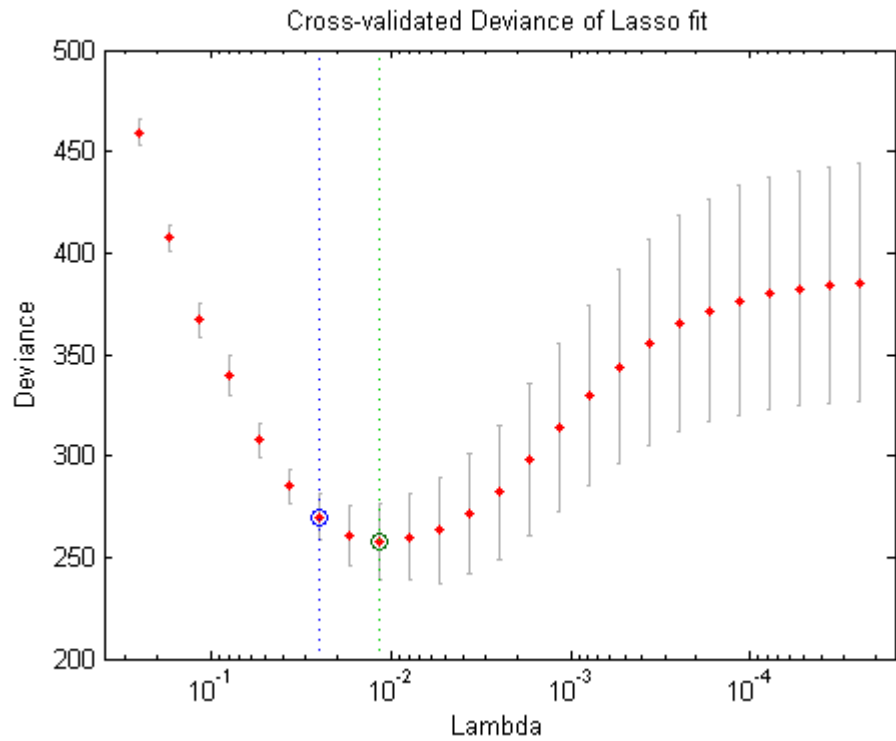

```
rng('default') % for reproducibility
[B,FitInfo] = lassoglm(X,Ybool,'binomial',...
    'NumLambda',25,'CV',10);
```

### Step 3. Examine plots to find appropriate regularization.

`lassoPlot` can give both a standard trace plot and a cross-validated deviance plot. Examine both plots.

```
lassoPlot(B,FitInfo,'PlotType','CV');
```

The plot identifies the minimum-deviance point with a green circle and dashed line as a function of the regularization parameter  $\lambda$ . The blue circled point has minimum deviance plus no more than one standard deviation.

```
lassoPlot(B,FitInfo,'PlotType','Lambda','XScale','log');
```

The trace plot shows nonzero model coefficients as a function of the regularization parameter  $\text{Lambda}$ . Because there are 32 predictors and a linear model, there are 32 curves. As  $\text{Lambda}$  increases to the left, `lasso1m` sets various coefficients to zero, removing them from the model.

The trace plot is somewhat compressed. Zoom in to see more detail.

```
xlim([.01 .1])
ylim([-3 3])
```

As Lambda increases toward the left side of the plot, fewer nonzero coefficients remain.

Find the number of nonzero model coefficients at the Lambda value with minimum deviance plus one standard deviation point. The regularized model coefficients are in column `FitInfo.Index1SE` of the B matrix.

```
indx = FitInfo.Index1SE;
B0 = B(:,indx);
nonzeros = sum(B0 ~= 0)
```

```
nonzeros =
```

```
14
```

When you set `Lambda` to `FitInfo.Index1SE`, `lassoglm` removes over half of the 32 original predictors.

**Step 4. Create a regularized model.**

The constant term is in the `FitInfo.Index1SE` entry of the `FitInfo.Intercept` vector. Call that value `cnst`.

The model is  $\text{logit}(\mu) = \log(\mu/(1 - \mu))X*B0 + \text{cnst}$ . Therefore, for predictions,  $\mu = \exp(X*B0 + \text{cnst}) / (1 + \exp(x*B0 + \text{cnst}))$ .

The `glmval` function evaluates model predictions. It assumes that the first model coefficient relates to the constant term. Therefore, create a coefficient vector with the constant term first.

```
cnst = FitInfo.Intercept(indx);  
B1 = [cnst;B0];
```

**Step 5. Examine residuals.**

Plot the training data against the model predictions for the regularized `lassoglm` model.

```
preds = glmval(B1,X,'logit');  
hist(Ybool - preds) % plot residuals  
title('Residuals from lassoglm model')
```

**Step 6. Alternative: Use identified predictors in a least-squares generalized linear model.**

Instead of using the biased predictions from the model, you can make an unbiased model using just the identified predictors.

```
predictors = find(B0); % indices of nonzero predictors
mdl = fitglm(X,Ybool,'linear',...
    'Distribution','binomial','PredictorVars',predictors)

mdl =
```

Generalized Linear regression model:

```
y ~ [Linear formula with 15 terms in 14 predictors]
Distribution = Binomial
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	-2.9367	0.50926	-5.7666	8.0893e-09
x1	2.492	0.60795	4.099	4.1502e-05
x3	2.5501	0.63304	4.0284	5.616e-05
x4	0.48816	0.50336	0.9698	0.33215
x5	0.6158	0.62192	0.99015	0.3221
x6	2.294	0.5421	4.2317	2.3198e-05
x7	0.77842	0.57765	1.3476	0.1778
x12	1.7808	0.54316	3.2786	0.0010432
x16	-0.070993	0.50515	-0.14054	0.88823
x20	-2.7767	0.55131	-5.0365	4.7402e-07
x24	2.0212	0.57639	3.5067	0.00045372
x25	-2.3796	0.58274	-4.0835	4.4363e-05
x27	0.79564	0.55904	1.4232	0.15467
x29	1.2689	0.55468	2.2876	0.022162
x32	-1.5681	0.54336	-2.8859	0.0039035

351 observations, 336 error degrees of freedom

Dispersion: 1

Chi<sup>2</sup>-statistic vs. constant model: 262, p-value = 1e-47

Plot the residuals of the model.

`plotResiduals(md1)`

As expected, residuals from the least-squares model are slightly smaller than those of the regularized model. However, this does not mean that `mdl` is a better predictor for new data.

## Regularize Wide Data in Parallel

This example shows how to regularize a model with many more predictors than observations. *Wide data* is data with more predictors than observations. Typically, with wide data you want to identify important predictors. Use `lasso glm` as an exploratory or screening tool to select a smaller set of variables to prioritize your modeling and research. Use parallel computing to speed up cross validation.

Load the `ovariancancer` data. This data has 216 observations and 4000 predictors in the `obs` workspace variable. The responses are binary, either

'Cancer' or 'Normal', in the grp workspace variable. Convert the responses to binary for use in `lassoglm`.

```
load ovariancancer
y = strcmp(grp,'Cancer');
```

Set options to use parallel computing. Prepare to compute in parallel using `parpool`.

```
opt = statset('UseParallel',true);
parpool()
```

Starting `parpool` using the 'local' profile ... connected to 2 workers.

```
ans =
```

```
Pool with properties:
```

```
AttachedFiles: {0x1 cell}
NumWorkers: 2
IdleTimeout: 30
Cluster: [1x1 parallel.cluster.Local]
RequestQueue: [1x1 parallel.RequestQueue]
SpmEnabled: 1
```

Fit a cross-validated set of regularized models. Use the Alpha parameter to favor retaining groups of highly correlated predictors, as opposed to eliminating all but one member of the group. Commonly, you use a relatively large value of Alpha.

```
rng('default') % for reproducibility
tic
[B,S] = lassoglm(obs,y,'binomial','NumLambda',100, ...
'Alpha',0.9,'LambdaRatio',1e-4,'CV',10,'Options',opt);
toc
```

```
Elapsed time is 398.635386 seconds.
```

Examine cross-validation plot.

```
lassoPlot(B,S,'PlotType','CV');
```

Examine trace plot.

```
lassoPlot(B,S,'PlotType','Lambda','XScale','log')
```

The right (green) vertical dashed line represents the Lambda providing the smallest cross-validated deviance. The left (blue) dashed line has the minimal deviance plus no more than one standard deviation. This blue line has many fewer predictors:

```
[S.DF(S.Index1SE) S.DF(S.IndexMinDeviance)]
```

```
ans =
```

```
50 86
```

You asked `lasso1m` to fit using 100 different Lambda values. How many did it use?

```
size(B)
```

```
ans =
      4000      84
```

`lassoglm` stopped after 84 values because the deviance was too small for small Lambda values. To avoid overfitting, `lassoglm` halts when the deviance of the fitted model is too small compared to the deviance in the binary responses, ignoring the predictor variables.

You can force `lassoglm` to include more terms by explicitly providing a set of Lambda values.

```
minLambda = min(S.Lambda);
explicitLambda = [minLambda*.1 .01 .001] S.Lambda];
[B2,S2] = lassoglm(obs,y,'binomial','Lambda',explicitLambda,...
    'LambdaRatio',1e-4, 'CV',10,'Options',opt);
length(S2.Lambda)
```

```
ans =
      87
```

`lassoglm` used the three smaller values in fitting.

To save time, you can use:

- Fewer Lambda, meaning fewer fits
- Fewer cross-validation folds
- A larger value for LambdaRatio

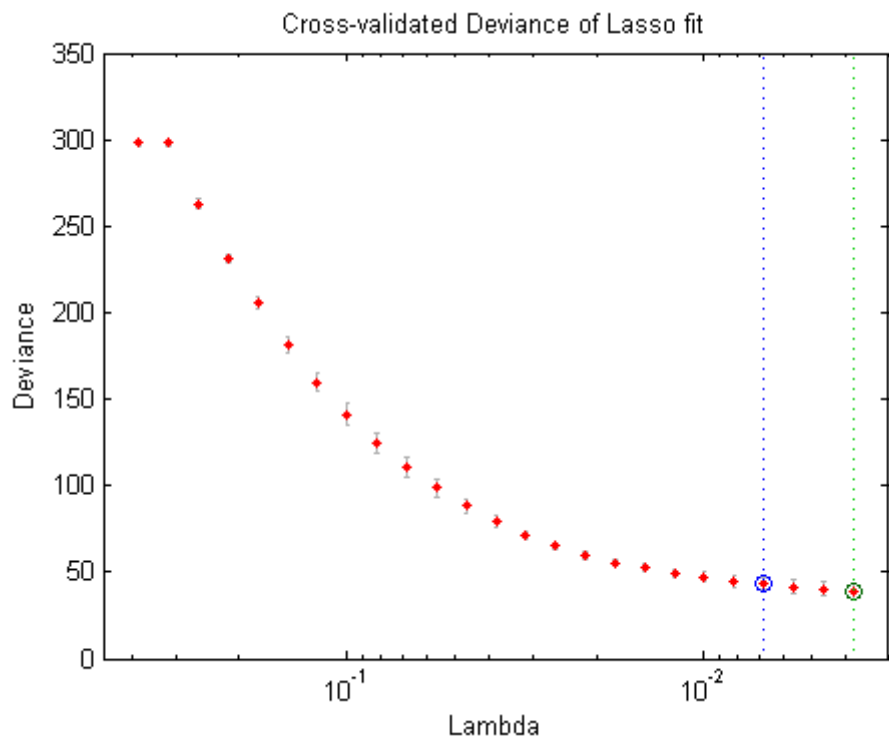

Use serial computation and all three of these time-saving methods:

```
tic
[Bquick,Squick] = lassoglm(obs,y,'binomial','NumLambda',25,...
    'LambdaRatio',1e-2,'CV',5);
toc
```

Elapsed time is 51.708074 seconds.

Graphically compare the new results to the first results.

```
lassoPlot(Bquick,Squick,'PlotType','CV');
```

```
lassoPlot(Bquick,Squick,'PlotType','Lambda','XScale','log')
```

The number of nonzero coefficients in the lowest plus one standard deviation model is around 50, similar to the first computation.

## Generalized Linear Model Lasso and Elastic Net

### Overview of Lasso and Elastic Net

*Lasso* is a regularization technique for estimating generalized linear models. Lasso includes a penalty term that constrains the size of the estimated coefficients. Therefore, it resembles ridge regression. Lasso is a *shrinkage estimator*: it generates coefficient estimates that are biased to be small. Nevertheless, a lasso estimator can have smaller error than an ordinary maximum likelihood estimator when you apply it to new data.

Unlike ridge regression, as the penalty term increases, the lasso technique sets more coefficients to zero. This means that the lasso estimator is a smaller

model, with fewer predictors. As such, lasso is an alternative to stepwise regression and other model selection and dimensionality reduction techniques.

*Elastic net* is a related technique. Elastic net is akin to a hybrid of ridge regression and lasso regularization. Like lasso, elastic net can generate reduced models by generating zero-valued coefficients. Empirical studies suggest that the elastic net technique can outperform lasso on data with highly correlated predictors.

### Definition of Lasso for Generalized Linear Models

For a nonnegative value of  $\lambda$ , lasso solves the problem

$$\min_{\beta_0, \beta} \left( \frac{1}{N} \text{Deviance}(\beta_0, \beta) + \lambda \sum_{j=1}^p |\beta_j| \right),$$

where

- Deviance is the deviance of the model fit to the responses using intercept  $\beta_0$  and predictor coefficients  $\beta$ . The formula for Deviance depends on the `distr` parameter you supply to `lasso glm`. Minimizing the  $\lambda$ -penalized deviance is equivalent to maximizing the  $\lambda$ -penalized log likelihood.
- $N$  is the number of observations.
- $\lambda$  is a nonnegative regularization parameter corresponding to one value of `Lambda`.
- Parameters  $\beta_0$  and  $\beta$  are scalar and  $p$ -vector respectively.

As  $\lambda$  increases, the number of nonzero components of  $\beta$  decreases.

The lasso problem involves the  $L^1$  norm of  $\beta$ , as contrasted with the elastic net algorithm.

### Definition of Elastic Net for Generalized Linear Models

For an  $\alpha$  strictly between 0 and 1, and a nonnegative  $\lambda$ , elastic net solves the problem

$$\min_{\beta_0, \beta} \left( \frac{1}{N} \text{Deviance}(\beta_0, \beta) + \lambda P_\alpha(\beta) \right),$$

where

$$P_\alpha(\beta) = \frac{(1-\alpha)}{2} \|\beta\|_2^2 + \alpha \|\beta\|_1 = \sum_{j=1}^p \left( \frac{(1-\alpha)}{2} \beta_j^2 + \alpha |\beta_j| \right).$$

Elastic net is the same as lasso when  $\alpha = 1$ . For other values of  $\alpha$ , the penalty term  $P_\alpha(\beta)$  interpolates between the  $L^1$  norm of  $\beta$  and the squared  $L^2$  norm of  $\beta$ . As  $\alpha$  shrinks toward 0, elastic net approaches ridge regression.

“Examine Quality and Adjust the Fitted Model” on page 11-8

“Predict or Simulate Responses to New Data” on page 11-12

“Nonlinear Regression Workflow” on page 11-16

### What Are Parametric Nonlinear Regression Models?

Parametric nonlinear models represent the relationship between a continuous response variable and one or more continuous predictor variables in the form

$$y = f(X, \beta) + \varepsilon,$$

where

- $y$  is an  $n$ -by-1 vector of observations of the response variable.
- $f$  is any function of  $X$  and  $\beta$  that evaluates each row of  $X$  along with the vector  $\beta$  to compute the prediction for the corresponding row of  $y$ .
- $X$  is an  $n$ -by- $p$  matrix of predictors, with one row for each observation, and one column for each predictor.
- $\beta$  is a  $p$ -by-1 vector of unknown parameters to be estimated.
- $\varepsilon$  is an  $n$ -by-1 vector of independent, identically distributed random disturbances.

In contrast, nonparametric models do not attempt to characterize the relationship between predictors and response with model parameters. Descriptions are often graphical, as in the case of “Classification Trees and Regression Trees” on page 16-31.

`fitnlm` attempts to find values of the parameters  $\beta$  that minimize the mean squared differences between the observed responses  $y$  and the predictions of the model  $f(X,\beta)$ . To do so, it needs a starting value `beta0` before iteratively modifying the vector  $\beta$  to a vector with minimal mean squared error.

## Prepare Data

To begin fitting a regression, put your data into a form that fitting functions expect. All regression techniques begin with input data in an array  $X$  and response data in a separate vector  $y$ , or input data in a dataset array `ds` and response data as a column in `ds`. Each row of the input data represents one observation. Each column represents one predictor (variable).

For a dataset array `ds`, indicate the response variable with the 'ResponseVar' name-value pair:

```
mdl = fitlm(ds,'ResponseVar','BloodPressure');
```

The response variable is the last column by default.

You cannot use numeric *categorical* predictors for nonlinear regression. A categorical predictor is one that takes values from a fixed set of possibilities.

Represent missing data as NaN for both input data and response data.

## Dataset Array for Input and Response Data

For example, to create a dataset array from an Excel spreadsheet:

```
ds = dataset('XLSFile','hospital.xls',...
            'ReadObsNames',true);
```

To create a dataset array from workspace variables:

```
load carsmall
ds = dataset(Weight,Model_Year,MPG);
```

## Numeric Matrix for Input Data and Numeric Vector for Response

For example, to create numeric arrays from workspace variables:

```
load carsmall
X = [Weight Horsepower Cylinders Model_Year];
y = MPG;
```

To create numeric arrays from an Excel spreadsheet:

```
[X Xnames] = xlsread('hospital.xls');
y = X(:,4); % response y is systolic pressure
X(:,4) = []; % remove y from the X matrix
```

Notice that the nonnumeric entries, such as `sex`, do not appear in `X`.

## Represent the Nonlinear Model

There are several ways to represent a nonlinear model. Use whichever is most convenient.

The nonlinear model is a required input to `fitnlm`, in the `modelfun` input.

`fitnlm` assumes that the response function  $f(X, \beta)$  is smooth in the parameters  $\beta$ . If your function is not smooth, `fitnlm` can fail to provide optimal parameter estimates.

- “Function Handle to Anonymous Function or Function File” on page 11-4
- “String Representation of Formula” on page 11-5

### Function Handle to Anonymous Function or Function File

The function handle `@modelfun(b, x)` accepts a vector `b` and matrix or dataset array `x`. The function handle should return a vector `f` with the same number of rows as `x`. For example, the function file `hougen.m` computes

$$\text{hougen}(b, x) = \frac{b(1)x(2) - x(3) / b(5)}{1 + b(2)x(1) + b(3)x(2) + b(4)x(3)}.$$

Examine the function by entering type `hougen` at the MATLAB command line.

```
function yhat = hougen(beta, x)
%HOUGEN Hougen-Watson model for reaction kinetics.
```

```

%   YHAT = HOUGEN(BETA,X) gives the predicted values of the
%   reaction rate, YHAT, as a function of the vector of
%   parameters, BETA, and the matrix of data, X.
%   BETA must have 5 elements and X must have three
%   columns.
%
%   The model form is:
%    $y = (b1*x2 - x3/b5) ./ (1+b2*x1+b3*x2+b4*x3)$ 
%
%   Reference:
%   [1] Bates, Douglas, and Watts, Donald, "Nonlinear
%   Regression Analysis and Its Applications", Wiley
%   1988 p. 271-272.
%
%   Copyright 1993-2004 The MathWorks, Inc.
%   $Revision: 1.1.6.4.2.1 $ $Date: 2013/07/08 16:23:10 $
%   B.A. Jones 1-06-95.

```

```

b1 = beta(1);
b2 = beta(2);
b3 = beta(3);
b4 = beta(4);
b5 = beta(5);

```

```

x1 = x(:,1);
x2 = x(:,2);
x3 = x(:,3);

```

```

yhat = (b1*x2 - x3/b5) ./ (1+b2*x1+b3*x2+b4*x3);

```

You can write an anonymous function that performs the same calculation as `hougen.m`.

```

modelfun = @(b,x)(b(1)*x(:,2) - x(:,3)/b(5))./...
(1 + b(2)*x(:,1) + b(3)*x(:,2) + b(4)*x(:,3));

```

### String Representation of Formula

For data in a matrix  $X$  and response in a vector  $y$ :

- Represent the formula using 'x1' as the first predictor (column) in X, 'x2' as the second predictor, etc.
- Represent the vector of parameters to optimize as 'b1', 'b2', etc.
- Write the formula as 'y ~ (mathematical expressions)'.

For example, to represent the response to the reaction data:

```
modelfun = 'y ~ (b1*x2 - x3/b5)/(1 + b2*x1 + b3*x2 + b4*x3)';
```

For data in a dataset array, you can use formulas represented as strings with the variable names from the dataset array. Put the response variable name at the left of the formula, followed by a ~, followed by a string representing the response formula.

This example shows how to create a string to represent the response to the reaction data that is in a dataset array.

- 1 Load the reaction data.

```
load reaction
```

- 2 Put the data into a dataset array, where each variable has a name given in the xn or yn strings.

```
ds = dataset({reactants,xn(1,:),xn(2,:),xn(3,:)},...
            {rate,yn});
```

- 3 Examine the first row of the dataset array.

```
ds(1,:)
```

```
ans =
```

Hydrogen	n_Pentane	Isopentane	ReactionRate
470	300	10	8.55

- 4 Write the hougén formula using names in the dataset array.

```
modelfun = ['ReactionRate ~ (b1*n_Pentane - Isopentane/b5) /'...
            '(1 + Hydrogen*b2 + n_Pentane*b3 + Isopentane*b4)']
```

```

modelfun =
ReactionRate ~ (b1*n_Pentane - Isopentane/b5) / ...
              (1 + Hydrogen*b2 + n_Pentane*b3 + Isopentane*b4)

```

## Choose Initial Vector beta0

The initial vector for the fitting iterations, `beta0`, can greatly influence the quality of the resulting fitted model. `beta0` gives the dimensionality of the problem, meaning it needs the correct length. A good choice of `beta0` leads to a quick, reliable model, while a poor choice can lead to a long computation, or to an inadequate model.

It is difficult to give advice on choosing a good `beta0`. If you believe certain components of the vector should be positive or negative, set your `beta0` to have those characteristics. If you know the approximate value of other components, include them in `beta0`. However, if you don't know good values, try a random vector, such as

```

beta0 = randn(nVars,1);
% or
beta0 = 10*rand(nVars,1);

```

## Fit Nonlinear Model to Data

The syntax for fitting a nonlinear regression model using a dataset array `ds` is

```
mdl = fitnlm(ds,modelfun,beta0)
```

The syntax for fitting a nonlinear regression model using a numeric array `X` and numeric response vector `y` is

```
mdl = fitnlm(X,y,modelfun,beta0)
```

For information on representing the input parameters, see “Prepare Data” on page 11-3, “Represent the Nonlinear Model” on page 11-4, and “Choose Initial Vector `beta0`” on page 11-7.

`fitnlm` assumes that the response variable in a dataset array `ds` is the last column. To change this, use the `ResponseVar` name-value pair to name the response column.

## Examine Quality and Adjust the Fitted Model

There are diagnostic plots to help you examine the quality of a model.

- `plotDiagnostics mdl` gives a variety of plots, including leverage and Cook's distance plots.
- `plotResiduals mdl` gives the difference between the fitted model and the data.

There are also properties of `mdl` that relate to the model quality.

- `mdl.RMSE` gives the root mean square error between the data and the fitted model.
- `mdl.Residuals.Raw` gives the raw residuals.
- `mdl.Diagnostics` contains several fields, such as `Leverage` and `CooksDistance`, that can help you identify particularly interesting observations.

This example shows how to examine a fitted nonlinear model using diagnostic, residual, and slice plots.

- 1 Load the reaction data.

```
load reaction
```

- 2 Create a nonlinear model of `rate` as a function of `reactants` using the `hougen.m` function, starting from `beta0 = ones(5,1);`.

```
beta0 = ones(5,1);  
mdl = fitnlm(reactants,...  
            rate,@hougen,beta0);
```

- 3 Make a leverage plot of the data and model.

```
plotDiagnostics(mdl)
```

**4** There is one point that has high leverage. Locate the point:

```
[-,max1] = max mdl.Diagnostics.Leverage)
```

```
max1 =
```

```
6
```

**5** Examine a residuals plot.

```
plotResiduals(mdl, 'fitted')
```

Nothing stands out as an outlier.

- 6 Use a slice plot to show the effect of each predictor on the model.

```
plotSlice mdl)
```

You can drag the vertical dashed blue lines to see the effect of a change in one predictor on the response. For example, drag the X2 line to the right, and notice that the slope of the X3 line changes.

## Predict or Simulate Responses to New Data

There are three ways to use a linear model to predict or simulate the response to new data:

- “predict” on page 11-14
- “feval” on page 11-15
- “random” on page 11-15

The prediction method examples use the following synthetic data and model. The problem is to fit a nonlinear curve of known form, with unknown center and scale parameters.

- 1 Generate synthetic data from a Cauchy distribution.

```
rng('default')
X = rand(100,1);
X = tan(pi*X - pi/2);
```

- 2 Generate the response according to the model

$$y = b_1 * (\pi/2 + \text{atan}((x - b_2) / b_3)).$$

Add noise to the response.

```
modelfun = @(b,x) b(1) * ...
    (pi/2 + atan((x - b(2))/b(3)));
y = modelfun([12 5 10],X) + randn(100,1);
```

**3** Fit a model starting from the arbitrary parameters  $b = [1,1,1]$ .

```
beta0 = [1 1 1]; % an arbitrary guess
mdl = fitnlm(X,y,modelfun,beta0)
```

```
mdl =
```

```
Nonlinear regression model:
```

```
y ~ b1*(pi/2 + atan((x - b2)/b3))
```

```
Estimated Coefficients:
```

	Estimate	SE	tStat	pValue
b1	12.082	0.80028	15.097	3.3151e-27
b2	5.0603	1.0825	4.6747	9.5063e-06
b3	9.64	0.46499	20.732	2.0382e-37

```
Number of observations: 100, Error degrees of freedom: 97
```

```
Root Mean Squared Error: 1.02
```

```
R-Squared: 0.92, Adjusted R-Squared 0.918
```

```
F-statistic vs. constant model: 558, p-value = 6.11e-54
```

The fitted values are within a few percent of the parameters [12,5,10].

**4** Examine the fit:

```
plotSlice(mdl)
```

## predict

The predict method predicts the mean responses and, if requested, gives confidence bounds. For example, to find the predicted response values and predicted confidence intervals about the response at X values [-15;5;12]:

```
Xnew = [-15;5;12];
[ynew,ynewci] = predict mdl,Xnew
```

```
ynew =
```

```
5.4122
18.9022
26.5161
```

```
ynewci =
```

```

    4.8233    6.0010
   18.4555   19.3490
   25.0170   28.0151

```

The confidence intervals are reflected in the slice plot.

## feval

The `feval` method predicts the mean responses. `feval` is often more convenient to use than `predict` when you construct a model from a dataset array. For example,

- 1 Create the nonlinear model from a dataset array.

```

ds = dataset({X,'X'},{y,'y'});
mdl2 = fitnlm(ds,modelfun,beta0);

```

- 2 Find the predicted model responses (CDF) at X values [-15;5;12].

```

Xnew = [-15;5;12];
ynew = feval(mdl2,Xnew)

```

```

ynew =

    5.4122
   18.9022
   26.5161

```

## random

The `random` method simulates new random response values, equal to the mean prediction plus a random disturbance with the same variance as the training data. For example,

```

Xnew = [-15;5;12];
ysim = random(mdl,Xnew)

```

```

ysim =

    6.0505
   19.0893
   25.4647

```

Rerun the random method. The results change.

```
ysim = random mdl, Xnew)
```

```
ysim =
```

```
6.3813
```

```
19.2157
```

```
26.6541
```

## Nonlinear Regression Workflow

This example shows how to do a typical nonlinear regression workflow: import data, fit a nonlinear regression, test its quality, modify it to improve the quality, and make predictions based on the model.

### Step 1. Prepare the data.

Load the reaction data

```
load reaction
```

Examine the data in the workspace. `reactants` is a matrix with 13 rows and 3 columns. Each row corresponds to one observation, and each column corresponds to one variable. The variable names are in `xn`:

```
xn
```

```
xn =
```

```
Hydrogen
```

```
n-Pentane
```

```
Isopentane
```

Similarly, `rate` is a vector of 13 responses, with the variable name in `yn`:

```
yn
```

```
yn =
```

```
Reaction Rate
```

The `hougen.m` file contains a nonlinear model of reaction rate as a function of the three predictor variables. For a 5-D vector  $b$  and 3-D vector  $x$ ,

$$\text{hougen}(b,x) = \frac{b(1)x(2) - x(3) / b(5)}{1 + b(2)x(1) + b(3)x(2) + b(4)x(3)}.$$

As a start point for the solution, take  $b$  as a vector of ones.

```
beta0 = ones(5,1);
```

### Step 2. Fit a nonlinear model to the data.

```
mdl = fitnlm(reactants,...
            rate,@hougen,beta0)
```

```
mdl =
```

```
Nonlinear regression model:
```

```
y ~ hougen(b,X)
```

```
Estimated Coefficients:
```

	Estimate	SE	tStat	pValue
b1	1.2526	0.86702	1.4447	0.18654
b2	0.062776	0.043562	1.4411	0.18753
b3	0.040048	0.030885	1.2967	0.23089
b4	0.11242	0.075158	1.4957	0.17309
b5	1.1914	0.83671	1.4239	0.1923

```
Number of observations: 13, Error degrees of freedom: 8
```

```
Root Mean Squared Error: 0.193
```

```
R-Squared: 0.999, Adjusted R-Squared 0.998
```

```
F-statistic vs. constant model: 1.81e+03, p-value = 7.36e-12
```

### Step 3. Examine the quality of the model.

The root mean squared error is fairly low compared to the range of observed values.

```
[mdl.RMSE min(rate) max(rate)]
```

```
ans =
```

0.1933 0.0200 14.3900

Examine a residuals plot.

```
plotResiduals(md1)
```

The model seems adequate for the data.

Examine a diagnostic plot to look for outliers.

```
plotDiagnostics(md1, 'cookd')
```

Observation 6 seems out of line.

**Step 4. Remove the outlier.**

Remove the outlier from the fit using the `Exclude` name-value pair.

```
mdl1 = fitnlm(reactants,...
    rate,@hougen,ones(5,1),'Exclude',6)
```

```
mdl1 =
```

```
Nonlinear regression model:
y ~ hougen(b,X)
```

```
Estimated Coefficients:
```

	Estimate	SE	tStat	pValue
b1	0.619	0.4552	1.3598	0.21605

b2	0.030377	0.023061	1.3172	0.22924
b3	0.018927	0.01574	1.2024	0.26828
b4	0.053411	0.041084	1.3	0.23476
b5	2.4125	1.7903	1.3475	0.2198

Number of observations: 12, Error degrees of freedom: 7  
 Root Mean Squared Error: 0.198  
 R-Squared: 0.999, Adjusted R-Squared 0.998  
 F-statistic vs. constant model: 1.24e+03, p-value = 4.73e-10

The model coefficients changed quite a bit from those in mdl.

### Step 5. Examine slice plots of both models.

To see the effect of each predictor on the response, make a slice plot using `plotSlice(mdl)`.

```
plotSlice(mdl)
```

```
plotSlice(mdl1)
```

The plots look very similar, with slightly wider confidence bounds for mdl1. This difference is understandable, since there is one less data point in the fit, representing over 7% fewer observations.

#### Step 6. Predict for new data.

Create some new data and predict the response from both models.

```
Xnew = [200,200,200;100,200,100;500,50,5];
[ypred yci] = predict(mdl,Xnew)
```

```
ypred =
```

```
1.8762
6.2793
1.6718
```

```
yci =
```

```
1.6283    2.1242
5.9789    6.5797
1.5589    1.7846
```

```
[ypred1 yci1] = predict(mdl1,Xnew)
```

```
ypred1 =
```

1.8984  
6.2555  
1.6594

yci1 =

1.6260 2.1708  
5.9323 6.5787  
1.5345 1.7843

Even though the model coefficients are dissimilar, the predictions are nearly identical.

### Introduction to Mixed-Effects Models

In statistics, an *effect* is anything that influences the value of a response variable at a particular setting of the predictor variables. Effects are translated into model parameters. In linear models, effects become coefficients, representing the proportional contributions of model terms. In nonlinear models, effects often have specific physical interpretations, and appear in more general nonlinear combinations.

*Fixed effects* represent population parameters, assumed to be the same each time data is collected. Estimating fixed effects is the traditional domain of regression modeling. *Random effects*, by comparison, are sample-dependent random variables. In modeling, random effects act like additional error terms, and their distributions and covariances must be specified.

For example, consider a model of the elimination of a drug from the bloodstream. The model uses time  $t$  as a predictor and the concentration of the drug  $C$  as the response. The nonlinear model term  $C_0 e^{-rt}$  combines parameters  $C_0$  and  $r$ , representing, respectively, an initial concentration and an elimination rate. If data is collected across multiple individuals, it is reasonable to assume that the elimination rate is a random variable  $r_i$  depending on individual  $i$ , varying around a population mean  $\bar{r}$ . The term  $C_0 e^{-rt}$  becomes

$$C_0 e^{-[\bar{r} + (r_i - \bar{r})]t} = C_0 e^{-(\beta + b_i)t},$$

where  $\beta = \bar{r}$  is a fixed effect and  $b_i = r_i - \bar{r}$  is a random effect.

Random effects are useful when data falls into natural groups. In the drug elimination model, the groups are simply the individuals under study. More sophisticated models might group data by an individual's age, weight, diet, etc. Although the groups are not the focus of the study, adding random effects to a model extends the reliability of inferences beyond the specific sample of individuals.

*Mixed-effects models* account for both fixed and random effects. As with all regression models, their purpose is to describe a response variable as a function of the predictor variables. Mixed-effects models, however, recognize correlations within sample subgroups. In this way, they provide a compromise between ignoring data groups entirely and fitting each group with a separate model.

## Mixed-Effects Model Hierarchy

Suppose data for a nonlinear regression model falls into one of  $m$  distinct groups  $i = 1, \dots, m$ . To account for the groups in a model, write response  $j$  in group  $i$  as:

$$y_{ij} = f(\varphi, x_{ij}) + \varepsilon_{ij}$$

$y_{ij}$  is the response,  $x_{ij}$  is a vector of predictors,  $\varphi$  is a vector of model parameters, and  $\varepsilon_{ij}$  is the measurement or process error. The index  $j$  ranges from 1 to  $n_i$ , where  $n_i$  is the number of observations in group  $i$ . The function  $f$  specifies the form of the model. Often,  $x_{ij}$  is simply an observation time  $t_{ij}$ . The errors are usually assumed to be independent and identically, normally distributed, with constant variance.

Estimates of the parameters in  $\varphi$  describe the population, assuming those estimates are the same for all groups. If, however, the estimates vary by group, the model becomes

$$y_{ij} = f(\varphi_i, x_{ij}) + \varepsilon_{ij}$$

In a mixed-effects model,  $\varphi_i$  may be a combination of a fixed and a random effect:

$$\varphi_i = \beta + b_i$$

The random effects  $b_i$  are usually described as multivariate normally distributed, with mean zero and covariance  $\Psi$ . Estimating the fixed effects  $\beta$  and the covariance of the random effects  $\Psi$  provides a description of the population that does not assume the parameters  $\varphi_i$  are the same across groups. Estimating the random effects  $b_i$  also gives a description of specific groups within the data.

Model parameters do not have to be identified with individual effects. In general, *design matrices*  $A$  and  $B$  are used to identify parameters with linear combinations of fixed and random effects:

$$\varphi_i = A\beta + Bb_i$$

If the design matrices differ among groups, the model becomes

$$\varphi_i = A_i\beta + B_i b_i$$

If the design matrices also differ among observations, the model becomes

$$\begin{aligned}\varphi_{ij} &= A_{ij}\beta + B_{ij}b_i \\ y_{ij} &= f(\varphi_{ij}, x_{ij}) + \varepsilon_{ij}\end{aligned}$$

Some of the group-specific predictors in  $x_{ij}$  may not change with observation  $j$ . Calling those  $v_i$ , the model becomes

$$y_{ij} = f(\varphi_{ij}, x_{ij}, v_i) + \varepsilon_{ij}$$

## Specifying Mixed-Effects Models

Suppose data for a nonlinear regression model falls into one of  $m$  distinct groups  $i = 1, \dots, m$ . (Specifically, suppose that the groups are not nested.) To specify a general nonlinear mixed-effects model for this data:

- 1** Define group-specific model parameters  $\varphi_i$  as linear combinations of fixed effects  $\beta$  and random effects  $b_i$ .
- 2** Define response values  $y_i$  as a nonlinear function  $f$  of the parameters and group-specific predictor variables  $X_i$ .

The model is:

$$\begin{aligned}\varphi_i &= A_i\beta + B_ib_i \\ y_i &= f(\varphi_i, X_i) + \varepsilon_i \\ b_i &\square N(0, \Psi) \\ \varepsilon_i &\square N(0, \sigma^2)\end{aligned}$$

This formulation of the nonlinear mixed-effects model uses the following notation:

$\varphi_i$	A vector of group-specific model parameters
$\beta$	A vector of fixed effects, modeling population parameters
$b_i$	A vector of multivariate normally distributed group-specific random effects
$A_i$	A group-specific design matrix for combining fixed effects
$B_i$	A group-specific design matrix for combining random effects
$X_i$	A data matrix of group-specific predictor values
$y_i$	A data vector of group-specific response values
$f$	A general, real-valued function of $\varphi_i$ and $X_i$
$\varepsilon_i$	A vector of group-specific errors, assumed to be independent, identically, normally distributed, and independent of $b_i$
$\Psi$	A covariance matrix for the random effects
$\sigma^2$	The error variance, assumed to be constant across observations

For example, consider a model of the elimination of a drug from the bloodstream. The model incorporates two overlapping phases:

- An initial phase  $p$  during which drug concentrations reach equilibrium with surrounding tissues
- A second phase  $q$  during which the drug is eliminated from the bloodstream

For data on multiple individuals  $i$ , the model is

$$y_{ij} = C_{pi}e^{-r_{pi}t_{ij}} + C_{qi}e^{-r_{qi}t_{ij}} + \varepsilon_{ij},$$

where  $y_{ij}$  is the observed concentration in individual  $i$  at time  $t_{ij}$ . The model allows for different sampling times and different numbers of observations for different individuals.

The elimination rates  $r_{pi}$  and  $r_{qi}$  must be positive to be physically meaningful. Enforce this by introducing the log rates  $R_{pi} = \log(r_{pi})$  and  $R_{qi} = \log(r_{qi})$  and reparametrizing the model:

$$y_{ij} = C_{pi}e^{-\exp(R_{pi})t_{ij}} + C_{qi}e^{-\exp(R_{qi})t_{ij}} + \varepsilon_{ij}$$

Choosing which parameters to model with random effects is an important consideration when building a mixed-effects model. One technique is to add random effects to all parameters, and use estimates of their variances to determine their significance in the model. An alternative is to fit the model separately to each group, without random effects, and look at the variation of the parameter estimates. If an estimate varies widely across groups, or if confidence intervals for each group have minimal overlap, the parameter is a good candidate for a random effect.

To introduce fixed effects  $\beta$  and random effects  $b_i$  for all model parameters, reexpress the model as follows:

$$\begin{aligned} y_{ij} &= [\bar{C}_p + (C_{pi} - \bar{C}_p)]e^{-\exp[\bar{R}_p + (R_{pi} - \bar{R}_p)]t_{ij}} + \\ &\quad [\bar{C}_q + (C_{qi} - \bar{C}_q)]e^{-\exp[\bar{R}_q + (R_{qi} - \bar{R}_q)]t_{ij}} + \varepsilon_{ij} \\ &= (\beta_1 + b_{1i})e^{-\exp(\beta_2 + b_{2i})t_{ij}} + \\ &\quad (\beta_3 + b_{3i})e^{-\exp(\beta_4 + b_{4i})t_{ij}} + \varepsilon_{ij} \end{aligned}$$

In the notation of the general model:

$$\beta = \begin{pmatrix} \beta_1 \\ \vdots \\ \beta_4 \end{pmatrix}, b_i = \begin{pmatrix} b_{i1} \\ \vdots \\ b_{i4} \end{pmatrix}, y_i = \begin{pmatrix} y_{i1} \\ \vdots \\ y_{in_i} \end{pmatrix}, X_i = \begin{pmatrix} t_{i1} \\ \vdots \\ t_{in_i} \end{pmatrix},$$

where  $n_i$  is the number of observations of individual  $i$ . In this case, the design matrices  $A_i$  and  $B_i$  are, at least initially, 4-by-4 identity matrices. Design matrices may be altered, as necessary, to introduce weighting of individual effects, or time dependency.

Fitting the model and estimating the covariance matrix  $\Psi$  often leads to further refinements. A relatively small estimate for the variance of a random effect suggests that it can be removed from the model. Likewise, relatively small estimates for covariances among certain random effects suggests that a full covariance matrix is unnecessary. Since random effects are unobserved,  $\Psi$  must be estimated indirectly. Specifying a diagonal or block-diagonal covariance pattern for  $\Psi$  can improve convergence and efficiency of the fitting algorithm.

Statistics Toolbox functions `nlmefit` and `nlmefitsa` fit the general nonlinear mixed-effects model to data, estimating the fixed and random effects. The functions also estimate the covariance matrix  $\Psi$  for the random effects. Additional diagnostic outputs allow you to assess tradeoffs between the number of model parameters and the goodness of fit.

## Specifying Covariate Models

If the model in “Specifying Mixed-Effects Models” on page 11-25 assumes a group-dependent covariate such as weight ( $w$ ) the model becomes:

$$\begin{pmatrix} \varphi_1 \\ \varphi_2 \\ \varphi_3 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & w_i \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} \beta_1 \\ \beta_2 \\ \beta_3 \\ \beta_4 \end{pmatrix} + \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} b_1 \\ b_2 \\ b_3 \end{pmatrix}$$

Thus, the parameter  $\varphi_i$  for any individual in the  $i$ th group is:

$$\begin{pmatrix} \varphi_{1_i} \\ \varphi_{2_i} \\ \varphi_{3_i} \end{pmatrix} = \begin{pmatrix} \beta_1 + \beta_4 * w_i \\ \beta_2 \\ \beta_3 \end{pmatrix} + \begin{pmatrix} b_{1_i} \\ b_{2_i} \\ b_{3_i} \end{pmatrix}$$

To specify a covariate model, use the 'FEGroupDesign' option.

'FEGroupDesign' is a p-by-q-by-m array specifying a different p-by-q fixed-effects design matrix for each of the m groups. Using the previous example, the array resembles the following:

$$\begin{bmatrix} \begin{bmatrix} 1 & 0 & 0 & W_1 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \\ \begin{bmatrix} 1 & 0 & 0 & W_2 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \\ \begin{bmatrix} 1 & 0 & 0 & W_3 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \\ \dots & \dots \\ \begin{bmatrix} 1 & 0 & 0 & W_m \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \end{bmatrix}$$

**1** Create the array.

```
% Number of parameters in the model (Phi)
num_params = 3;
% Number of covariates
num_cov = 1;
% Assuming number of groups in the data set is 7
num_groups = 7;
% Array of covariate values
covariates = [75; 52; 66; 55; 70; 58; 62 ];
A = repmat(eye(num_params, num_params+num_cov), ...
[1,1,num_groups]);
A(1,num_params+1,1:num_groups) = covariates(:,1)
```

**2** Create a struct with the specified design matrix.

```
options.FEGroupDesign = A;
```

- 3 Specify the arguments for `nlmefit` (or `nlmefitsa`) as shown in “Mixed-Effects Models Using `nlmefit` and `nlmefitsa`” on page 11-38.

## Choosing `nlmefit` or `nlmefitsa`

Statistics Toolbox provides two functions, `nlmefit` and `nlmefitsa` for fitting nonlinear mixed-effects models. Each function provides different capabilities, which may help you decide which to use.

- “Approximation Methods” on page 11-30
- “Parameters Specific to `nlmefitsa`” on page 11-31
- “Model and Data Requirements” on page 11-32

## Approximation Methods

`nlmefit` provides the following four approximation methods for fitting nonlinear mixed-effects models:

- 'LME' — Use the likelihood for the linear mixed-effects model at the current conditional estimates of `beta` and `B`. This is the default.
- 'RELME' — Use the restricted likelihood for the linear mixed-effects model at the current conditional estimates of `beta` and `B`.
- 'FO' — First-order Laplacian approximation without random effects.
- 'FOCE' — First-order Laplacian approximation at the conditional estimates of `B`.

`nlmefitsa` provides an additional approximation method, Stochastic Approximation Expectation-Maximization (SAEM) [24] with three steps :

- 1 Simulation: Generate simulated values of the random effects  $b$  from the posterior density  $p(b | \Sigma)$  given the current parameter estimates.
- 2 Stochastic approximation: Update the expected value of the log likelihood function by taking its value from the previous step, and moving part way toward the average value of the log likelihood calculated from the simulated random effects.

- 3 Maximization step: Choose new parameter estimates to maximize the log likelihood function given the simulated values of the random effects.

Both `nlmefit` and `nlmefitsa` attempt to find parameter estimates to maximize a likelihood function, which is difficult to compute. `nlmefit` deals with the problem by approximating the likelihood function in various ways, and maximizing the approximate function. It uses traditional optimization techniques that depend on things like convergence criteria and iteration limits.

`nlmefitsa`, on the other hand, simulates random values of the parameters in such a way that in the long run they converge to the values that maximize the exact likelihood function. The results are random, and traditional convergence tests don't apply. Therefore `nlmefitsa` provides options to plot the results as the simulation progresses, and to restart the simulation multiple times. You can use these features to judge whether the results have converged to the accuracy you desire.

### Parameters Specific to `nlmefitsa`

The following parameters are specific to `nlmefitsa`. Most control the stochastic algorithm.

- `Cov0` — Initial value for the covariance matrix `PSI`. Must be an  $r$ -by- $r$  positive definite matrix. If empty, the default value depends on the values of `BETA0`.
- `ComputeStdErrors` — `true` to compute standard errors for the coefficient estimates and store them in the output `STATS` structure, or `false` (default) to omit this computation.
- `LogLikMethod` — Specifies the method for approximating the log likelihood.
- `NBurnIn` — Number of initial burn-in iterations during which the parameter estimates are not recomputed. Default is 5.
- `NIterations` — Controls how many iterations are performed for each of three phases of the algorithm.
- `NMCMCIterations` — Number of Markov Chain Monte Carlo (MCMC) iterations.

## Model and Data Requirements

There are some differences in the capabilities of `nlmefit` and `nlmefitsa`. Therefore some data and models are usable with either function, but some may require you to choose just one of them.

- **Error models** — `nlmefitsa` supports a variety of error models. For example, the standard deviation of the response can be constant, proportional to the function value, or a combination of the two. `nlmefit` fits models under the assumption that the standard deviation of the response is constant. One of the error models, 'exponential', specifies that the log of the response has a constant standard deviation. You can fit such models using `nlmefit` by providing the log response as input, and by rewriting the model function to produce the log of the nonlinear function value.
- **Random effects** — Both functions fit data to a nonlinear function with parameters, and the parameters may be simple scalar values or linear functions of covariates. `nlmefit` allows any coefficients of the linear functions to have both fixed and random effects. `nlmefitsa` supports random effects only for the constant (intercept) coefficient of the linear functions, but not for slope coefficients. So in the example in “Specifying Covariate Models” on page 11-28, `nlmefitsa` can treat only the first three beta values as random effects.
- **Model form** — `nlmefit` supports a very general model specification, with few restrictions on the design matrices that relate the fixed coefficients and the random effects to the model parameters. `nlmefitsa` is more restrictive:
  - The fixed effect design must be constant in every group (for every individual), so an observation-dependent design is not supported.
  - The random effect design must be constant for the entire data set, so neither an observation-dependent design nor a group-dependent design is supported.
  - As mentioned under **Random Effects**, the random effect design must not specify random effects for slope coefficients. This implies that the design must consist of zeros and ones.
  - The random effect design must not use the same random effect for multiple coefficients, and cannot use more than one random effect for any single coefficient.

- The fixed effect design must not use the same coefficient for multiple parameters. This implies that it can have at most one nonzero value in each column.

If you want to use `nlmefitsa` for data in which the covariate effects are random, include the covariates directly in the nonlinear model expression. Don't include the covariates in the fixed or random effect design matrices.

- **Convergence** — As described in the **Model form**, `nlmefit` and `nlmefitsa` have different approaches to measuring convergence. `nlmefit` uses traditional optimization measures, and `nlmefitsa` provides diagnostics to help you judge the convergence of a random simulation.

In practice, `nlmefitsa` tends to be more robust, and less likely to fail on difficult problems. However, `nlmefit` may converge faster on problems where it converges at all. Some problems may benefit from a combined strategy, for example by running `nlmefitsa` for a while to get reasonable parameter estimates, and using those as a starting point for additional iterations using `nlmefit`.

## Using Output Functions with Mixed-Effects Models

The `OutputFcn` field of the options structure specifies one or more functions that the solver calls after each iteration. Typically, you might use an output function to plot points at each iteration or to display optimization quantities from the algorithm. To set up an output function:

- 1 Write the output function as a MATLAB file function or local function.
- 2 Use `statset` to set the value of `OutputFcn` to be a function handle, that is, the name of the function preceded by the `@` sign. For example, if the output function is `outfun.m`, the command

```
options = statset('OutputFcn', @outfun);
```

specifies `OutputFcn` to be the handle to `outfun`. To specify multiple output functions, use the syntax:

```
options = statset('OutputFcn',{@outfun, @outfun2});
```

- 3 Call the optimization function with options as an input argument.

For an example of an output function, see “Sample Output Function” on page 11-38.

## Structure of the Output Function

The function definition line of the output function has the following form:

```
stop = outfun(beta,status,state)
```

where

- *beta* is the current fixed effects.
- *status* is a structure containing data from the current iteration. “Fields in status” on page 11-34 describes the structure in detail.
- *state* is the current state of the algorithm. “States of the Algorithm” on page 11-35 lists the possible values.
- *stop* is a flag that is true or false depending on whether the optimization routine should quit or continue. See “Stop Flag” on page 11-36 for more information.

The solver passes the values of the input arguments to `outfun` at each iteration.

## Fields in status

The following table lists the fields of the `status` structure:

Field	Description
procedure	<ul style="list-style-type: none"> <li>• 'ALT' — alternating algorithm for the optimization of the linear mixed effects or restricted linear mixed effects approximations</li> <li>• 'LAP' — optimization of the Laplacian approximation for first order or first order conditional estimation</li> </ul>
iteration	An integer starting from 0.

Field	Description
inner	<p>A structure describing the status of the inner iterations within the ALT and LAP procedures, with the fields:</p> <ul style="list-style-type: none"> <li>• procedure — When procedure is 'ALT': <ul style="list-style-type: none"> <li>▪ 'PNLS' (penalized nonlinear least squares)</li> <li>▪ 'LME' (linear mixed-effects estimation)</li> <li>▪ 'none'</li> </ul> When procedure is 'LAP', <ul style="list-style-type: none"> <li>▪ 'PNLS' (penalized nonlinear least squares)</li> <li>▪ 'PLM' (profiled likelihood maximization)</li> <li>▪ 'none'</li> </ul> </li> <li>• state — one of the following: <ul style="list-style-type: none"> <li>▪ 'init'</li> <li>▪ 'iter'</li> <li>▪ 'done'</li> <li>▪ 'none'</li> </ul> </li> <li>• iteration — an integer starting from 0, or NaN. For nlme fits with burn-in iterations, the output function is called after each of those iterations with a negative value for STATUS.iteration.</li> </ul>
fval	The current log likelihood
Psi	The current random-effects covariance matrix
theta	The current parameterization of Psi
mse	The current error variance

### States of the Algorithm

The following table lists the possible values for state:

state	Description
'init'	The algorithm is in the initial state before the first iteration.
'iter'	The algorithm is at the end of an iteration.
'done'	The algorithm is in the final state after the last iteration.

The following code illustrates how the output function might use the value of `state` to decide which tasks to perform at the current iteration:

```
switch state
    case 'iter'
        % Make updates to plot or guis as needed
    case 'init'
        % Setup for plots or guis
    case 'done'
        % Cleanup of plots, guis, or final plot
otherwise
end
```

### Stop Flag

The output argument `stop` is a flag that is true or false. The flag tells the solver whether it should quit or continue. The following examples show typical ways to use the stop flag.

**Stopping an Optimization Based on Intermediate Results.** The output function can stop the estimation at any iteration based on the values of arguments passed into it. For example, the following code sets `stop` to true based on the value of the log likelihood stored in the `'fval'` field of the status structure:

```
stop = outfun(beta,status,state)
stop = false;
% Check if loglikelihood is more than 132.
if status.fval > -132
    stop = true;
end
```

**Stopping an Iteration Based on GUI Input.** If you design a GUI to perform `nlmefit` iterations, you can make the output function stop when a user clicks a **Stop** button on the GUI. For example, the following code implements a dialog to cancel calculations:

```
function retval = stop_outfcn(beta,str,status)
persistent h stop;
if isequal(str.inner.state,'none')
    switch(status)
        case 'init'
            % Initialize dialog
            stop = false;
            h = msgbox('Press STOP to cancel calculations.',...
                'NLMEFIT: Iteration 0 ');
            button = findobj(h,'type','uicontrol');
            set(button,'String','STOP','Callback',@stopper)
            pos = get(h,'Position');
            pos(3) = 1.1 * pos(3);
            set(h,'Position',pos)
            drawnow
        case 'iter'
            % Display iteration number in the dialog title
            set(h,'Name',sprintf('NLMEFIT: Iteration %d',...
                str.iteration))
            drawnow;
        case 'done'
            % Delete dialog
            delete(h);
    end
end
if stop
    % Stop if the dialog button has been pressed
    delete(h)
end
retval = stop;

function stopper(varargin)
    % Set flag to stop when button is pressed
    stop = true;
    disp('Calculation stopped.')
```

```
        end
    end
```

### Sample Output Function

`nlmefitoutputfcn` is the sample Statistics Toolbox output function for `nlmefit` and `nlmefitsa`. It initializes or updates a plot with the fixed-effects (BETA) and variance of the random effects (`diag(STATUS.Psi)`). For `nlmefit`, the plot also includes the log-likelihood (`STATUS.fval`).

`nlmefitoutputfcn` is the default output function for `nlmefitsa`. To use it with `nlmefit`, specify a function handle for it in the options structure:

```
opt = statset('OutputFcn', @nlmefitoutputfcn, )
beta = nlmefit( , 'Options', opt, )
```

To prevent `nlmefitsa` from using of this function, specify an empty value for the output function:

```
opt = statset('OutputFcn', [], )
beta = nlmefitsa( , 'Options', opt, )
```

`nlmefitoutputfcn` stops `nlmefit` or `nlmefitsa` if you close the figure that it produces.

## Mixed-Effects Models Using `nlmefit` and `nlmefitsa`

Load the sample data.

```
load indomethacin
```

The data in `indomethacin.mat` records concentrations of the drug indomethacin in the bloodstream of six subjects over eight hours.

Plot the scatter plot of indomethacin in the bloodstream grouped by subject.

```
gscatter(time, concentration, subject)
xlabel('Time (hours)')
ylabel('Concentration (mcg/ml)')
title('{\bf Indomethacin Elimination}')
```

hold on

Specifying Mixed-Effects Models page discusses a useful model for this type of data.

Construct the model via an anonymous function.

```
model = @(phi,t)(phi(1)*exp(-exp(phi(2))*t) + ...
              phi(3)*exp(-exp(phi(4))*t));
```

Use the `nlinfit` function to fit the model to all of the data, ignoring subject-specific effects.

```
phi0 = [1 2 1 1];  
[phi,res] = nlinfit(time,concentration,model,phi0);
```

Compute the mean squared error.

```
numObs = length(time);  
numParams = 4;  
df = numObs-numParams;  
mse = (res'*res)/df
```

```
mse =
```

```
0.0304
```

Super impose the model on the scatter plot of data.

```
tplot = 0:0.01:8;  
plot(tplot,model(phi,tplot),'k','LineWidth',2)  
hold off
```

Draw the box-plot of residuals by subject.

```

colors = 'rygcbm';
h = boxplot(res,subject,'colors',colors,'symbol','o');
set(h(~isnan(h)),'LineWidth',2)
hold on
boxplot(res,subject,'colors','k','symbol','ko')
grid on
xlabel('Subject')
ylabel('Residual')

```

The box plot of residuals by subject shows that the boxes are mostly above or below zero, indicating that the model has failed to account for subject-specific effects.

To account for subject-specific effects, fit the model separately to the data for each subject.

```
phi0 = [1 2 1 1];  
PHI = zeros(4,6);
```

```

RES = zeros(11,6);
for I = 1:6
    tI = time(subject == I);
    cI = concentration(subject == I);
    [PHI(:,I),RES(:,I)] = nlinfit(tI,cI,model,phi0);
end
PHI

```

PHI =

2.0293	2.8277	5.4683	2.1981	3.5661	3.0023
0.5794	0.8013	1.7498	0.2423	1.0408	1.0882
0.1915	0.4989	1.6757	0.2545	0.2915	0.9685
-1.7878	-1.6354	-0.4122	-1.6026	-1.5069	-0.8731

Compute the mean squared error.

```

numParams = 24;
df = numObs-numParams;
mse = (RES(:)'*RES(:))/df

```

mse =

0.0057

Plot the scatter plot of the data and superimpose the model for each subject.

```

gscatter(time,concentration,subject)
xlabel('Time (hours)')
ylabel('Concentration (mcg/ml)')
title('{\bf Indomethacin Elimination}')
hold on
for I = 1:6
    plot(tplot,model(PHI(:,I),tplot),'Color',colors(I))
end
axis([0 8 0 3.5])

```

hold off

PHI gives estimates of the four model parameters for each of the six subjects. The estimates vary considerably, but taken as a 24-parameter model of the data, the mean-squared error of 0.0057 is a significant reduction from 0.0304 in the original four-parameter model.

Draw the box plot of residuals by subject.

```
h = boxplot(RES,'colors',colors,'symbol','o');
set(h(~isnan(h)),'LineWidth',2)
```

```
hold on
boxplot(RES, 'colors', 'k', 'symbol', 'ko')
grid on
xlabel('Subject')
ylabel('Residual')
hold off
```

Now the box plot shows that the larger model accounts for most of the subject-specific effects. The spread of the residuals (the vertical scale of the

box plot) is much smaller than in the previous box plot, and the boxes are now mostly centered on zero.

While the 24-parameter model successfully accounts for variations due to the specific subjects in the study, it does not consider the subjects as representatives of a larger population. The sampling distribution from which the subjects are drawn is likely more interesting than the sample itself. The purpose of mixed-effects models is to account for subject-specific variations more broadly, as random effects varying around population means.

Use the `nlmefit` function to fit a mixed-effects model to the data. You can also use `nlmefitsa` in place of `nlmefit`.

The following anonymous function, `nlme_model`, adapts the four-parameter model used by `nlmefit` to the calling syntax of `nlmefit` by allowing separate parameters for each individual. By default, `nlmefit` assigns random effects to all the model parameters. Also by default, `nlmefit` assumes a diagonal covariance matrix (no covariance among the random effects) to avoid overparametrization and related convergence issues.

```
nlme_model = @(PHI,t)(PHI(:,1).*exp(-exp(PHI(:,2)).*t) + ...
                    PHI(:,3).*exp(-exp(PHI(:,4)).*t));
```

```
phi0 = [1 2 1 1];
```

```
[phi,PSI,stats] = nlmefit(time,concentration,subject, ...
                        [],nlme_model,phi0)
```

```
phi =
```

```
2.8277
0.7729
0.4606
-1.3459
```

```
PSI =
```

```
0.3264    0    0    0
    0    0.0250    0    0
    0    0    0.0124    0
```

```

0          0          0    0.0000

stats =

    dfe: 57
    logl: 54.5882
    mse: 0.0066
    rmse: 0.0787
    errorparam: 0.0815
    aic: -91.1765
    bic: -93.0506
    covb: [4x4 double]
    sebeta: [0.2558 0.1066 0.1092 0.2244]
    ires: [66x1 double]
    pres: [66x1 double]
    iwres: [66x1 double]
    pwres: [66x1 double]
    cwres: [66x1 double]

```

The mean-squared error of 0.0066 is comparable to the 0.0057 of the 24-parameter model without random effects, and significantly better than the 0.0304 of the four-parameter model without random effects.

The estimated covariance matrix PSI shows that the variance of the fourth random effect is essentially zero, suggesting that you can remove it to simplify the model. To do this, use the 'REParamsSelect' name-value pair to specify the indices of the parameters to be modeled with random effects in `nlmefit`.

```

[phi,PSI,stats] = nlmefit(time,concentration,subject, ...
                        [],nlme_model,phi0, ...
                        'REParamsSelect',[1 2 3])

```

```

phi =

    2.8277
    0.7728
    0.4605

```

```
-1.3460
```

```
PSI =
```

```
0.3270      0      0
      0 0.0250      0
      0      0 0.0124
```

```
stats =
```

```
    dfe: 58
    logl: 54.5875
    mse: 0.0066
    rmse: 0.0780
errorparam: 0.0815
    aic: -93.1750
    bic: -94.8410
    covb: [4x4 double]
sebeta: [0.2560 0.1066 0.1092 0.2244]
    ires: [66x1 double]
    pres: [66x1 double]
    iwres: [66x1 double]
    pwres: [66x1 double]
    cwres: [66x1 double]
```

The log-likelihood `logl` is almost identical to what it was with random effects for all of the parameters, the Akaike information criterion `aic` is reduced from -91.1765 to -93.1750, and the Bayesian information criterion `bic` is reduced from -93.0506 to -94.8410. These measures support the decision to drop the fourth random effect.

Refitting the simplified model with a full covariance matrix allows for identification of correlations among the random effects. To do this, use the `CovPattern` parameter to specify the pattern of nonzero elements in the covariance matrix.

```
[phi,PSI,stats] = nlmefit(time,concentration,subject, ...
```

```
[ ],nlme_model,phi0, ...
'REParamsSelect',[1 2 3], ...
'CovPattern',ones(3))

phi =

    2.8149
    0.8292
    0.5613
   -1.1409

PSI =

    0.4767    0.1151    0.0499
    0.1151    0.0321    0.0032
    0.0499    0.0032    0.0236

stats =

    dfe: 55
    logl: 58.4726
    mse: 0.0061
    rmse: 0.0782
    errorparam: 0.0781
    aic: -94.9451
    bic: -97.2358
    covb: [4x4 double]
    sebeta: [0.3028 0.1103 0.1179 0.1662]
    ires: [66x1 double]
    pres: [66x1 double]
    iwres: [66x1 double]
    pwres: [66x1 double]
    cwres: [66x1 double]
```

The estimated covariance matrix PSI shows that the random effects on the first two parameters have a relatively strong correlation, and both have a

relatively weak correlation with the last random effect. This structure in the covariance matrix is more apparent if you convert PSI to a correlation matrix using `corrcoef`.

```
RHO = corrcoef(PSI)
clf;
imagesc(RHO)
set(gca,'XTick',[1 2 3],'YTick',[1 2 3])
title('\bf Random Effect Correlation')
h = colorbar;
set(get(h,'YLabel'),'String','Correlation');
```

```
RHO =
    1.0000    0.9315    0.4706
    0.9315    1.0000    0.1175
    0.4706    0.1175    1.0000
```

Incorporate this structure into the model by changing the specification of the covariance pattern to block-diagonal.

```
P = [1 1 0;1 1 0;0 0 1] % Covariance pattern
[phi,PSI,stats,b] = nlmeFit(time,concentration,subject, ...
    [],nlme_model,phi0, ...
    'REParamsSelect',[1 2 3], ...
    'CovPattern',P)
```

P =

1	1	0
1	1	0
0	0	1

phi =

2.7830  
0.8981  
0.6581  
-1.0000

PSI =

0.5180	0.1069	0
0.1069	0.0221	0
0	0	0.0454

stats =

dfc: 57  
logl: 58.0804  
mse: 0.0061  
rmse: 0.0768  
errorparam: 0.0782  
aic: -98.1608  
bic: -100.0350  
covb: [4x4 double]  
sebeta: [0.3171 0.1073 0.1384 0.1453]  
ires: [66x1 double]  
pres: [66x1 double]  
iwres: [66x1 double]  
pwres: [66x1 double]  
cwres: [66x1 double]

b =

-0.8507	-0.1563	1.0427	-0.7559	0.5652	0.1550
-0.1756	-0.0323	0.2152	-0.1560	0.1167	0.0320
-0.2756	0.0519	0.2620	0.1064	-0.2835	0.1389

The block-diagonal covariance structure reduces `aic` from -94.9462 to -98.1608 and `bic` from -97.2368 to -100.0350 without significantly affecting the log-likelihood. These measures support the covariance structure used in the final model. The output `b` gives predictions of the three random effects for each of the six subjects. These are combined with the estimates of the fixed effects in `phi` to produce the mixed-effects model.

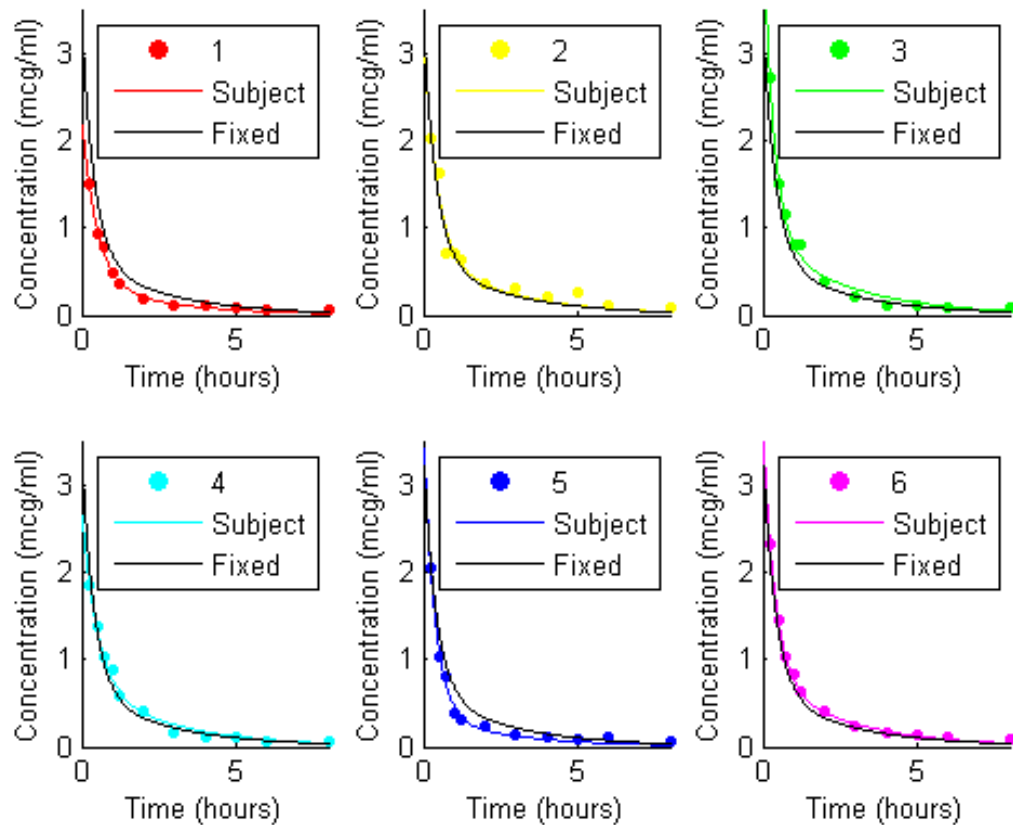

Plot the mixed-effects model for each of the six subjects. For comparison, the model without random effects is also shown.

```

PHI = repmat(phi,1,6) + ...           % Fixed effects
      [b(1,:);b(2,:);b(3,:);zeros(1,6)]; % Random effects
RES = zeros(11,6); % Residuals
colors = 'rygcbm';
for I = 1:6
    fitted_model = @(t)(PHI(1,I)*exp(-exp(PHI(2,I))*t) + ...
                        PHI(3,I)*exp(-exp(PHI(4,I))*t));
    tI = time(subject == I);
    cI = concentration(subject == I);
    RES(:,I) = cI - fitted_model(tI);

    subplot(2,3,I)
    scatter(tI,cI,20,colors(I),'filled')
    hold on
    plot(tplot,fitted_model(tplot),'Color',colors(I))
    plot(tplot,model(phi,tplot),'k')
    axis([0 8 0 3.5])
    xlabel('Time (hours)')
    ylabel('Concentration (mcg/ml)')
    legend(num2str(I),'Subject','Fixed')
end

```

If obvious outliers in the data (visible in previous box plots) are ignored, a normal probability plot of the residuals shows reasonable agreement with model assumptions on the errors.

```
clf; normplot(RES(:))
```

## Examining Residuals for Model Verification

You can examine the `stats` structure, which is returned by both `nlmeFit` and `nlmeFitSA`, to determine the quality of your model. The `stats` structure contains fields with conditional weighted residuals (`cwres` field) and individual weighted residuals (`iwres` field). Since the model assumes that residuals are normally distributed, you can examine the residuals to see how well this assumption holds.

This example generates synthetic data using normal distributions. It shows how the fit statistics look:

- Good when testing against the same type of model as generates the data
- Poor when tested against incorrect data models

**1** Initialize a 2-D model with 100 individuals:

```
nGroups = 100; % 100 Individuals
nlmefun = @(PHI,t)(PHI(:,1)*5 + PHI(:,2)^2.*t); % Regression fcn
REParamSelect = [1 2]; % Both Parameters have random effect
errorParam = .03;
beta0 = [ 1.5 5]; % Parameter means
psi = [ 0.35 0; ... % Covariance Matrix
       0 0.51 ];
time =[0.25;0.5;0.75;1;1.25;2;3;4;5;6];
nParameters = 2;
rng(0,'twister') % for reproducibility
```

**2** Generate the data for fitting with a proportional error model:

```
b_i = mvnrnd(zeros(1, numel(REParamSelect)), psi, nGroups);
individualParameters = zeros(nGroups,nParameters);
individualParameters(:, REParamSelect) = ...
    bsxfun(@plus,beta0(REParamSelect), b_i);

groups = repmat(1:nGroups,numel(time),1);
groups = vertcat(groups(:));

y = zeros(numel(time)*nGroups,1);
x = zeros(numel(time)*nGroups,1);
for i = 1:nGroups
    idx = groups == i;
    f = nlmefun(individualParameters(i,:), time);
    % Make a proportional error model for y:
    y(idx) = f + errorParam*f.*randn(numel(f),1);
    x(idx) = time;
end

P = [ 1 0 ; 0 1 ];
```

- 3** Fit the data using the same regression function and error model as the model generator:

```
[~,~,stats] = nlmefit(x,y,groups, ...
    [],nlmefun,[1 1], 'REParamsSelect', REParamSelect, ...
    'ErrorModel', 'Proportional', 'CovPattern', P);
```

- 4** Create a plotting routine by copying the following function definition, and creating a file `plotResiduals.m` on your MATLAB path:

```
function plotResiduals(stats)
pwres = stats.pwres;
iwres = stats.iwres;
cwres = stats.cwres;
figure
subplot(2,3,1);
normplot(pwres); title('PWRES')
subplot(2,3,4);
createhistplot(pwres);

subplot(2,3,2);
normplot(cwres); title('CWRES')
subplot(2,3,5);
createhistplot(cwres);

subplot(2,3,3);
normplot(iwres); title('IWRES')
subplot(2,3,6);
createhistplot(iwres); title('IWRES')

function createhistplot(pwres)
[x, n] = hist(pwres);
d = n(2)- n(1);
x = x/sum(x*d);
bar(n,x);
ylim([0 max(x)*1.05]);
hold on;
x2 = -4:0.1:4;
f2 = normpdf(x2,0,1);
plot(x2,f2, 'r');
end
```

end

5 Plot the residuals using the plotResiduals function:

```
plotResiduals(stats);
```

The upper probability plots look straight, meaning the residuals are normally distributed. The bottom histogram plots match the superimposed normal density plot. So you can conclude that the error model matches the data.

6 For comparison, fit the data using a constant error model, instead of the proportional model that created the data:

```

[~,~,stats] = nlmeFit(x,y,groups, ...
    [],nlmeFun,[0 0], 'REParamsSelect',REParamSelect,...
    'ErrorModel', 'Constant', 'CovPattern',P);
plotResiduals(stats);

```

The upper probability plots are not straight, indicating the residuals are not normally distributed. The bottom histogram plots are fairly close to the superimposed normal density plots.

- 7 For another comparison, fit the data to a different structural model than created the data:

```
nlmeFun2 = @(PHI,t)(PHI(:,1)*5 + PHI(:,2).*t.^4);
```

```
[~,~,stats] = nlmefit(x,y,groups, ...
    [],nlmefun2,[0 0], 'REParamsSelect',REParamSelect,...
    'ErrorModel','constant', 'CovPattern',P);
plotResiduals(stats);
```

Not only are the upper probability plots not straight, but the histogram plot is quite skewed compared to the superimposed normal density. These residuals are not normally distributed, and do not match the model.

## Pitfalls in Fitting Nonlinear Models by Transforming to Linearity

This example shows pitfalls that can occur when fitting a nonlinear model by transforming to linearity. Imagine that we have collected measurements on two variables,  $x$  and  $y$ , and we want to model  $y$  as a function of  $x$ . Assume that  $x$  is measured exactly, while measurements of  $y$  are affected by additive, symmetric, zero-mean errors.

```
x = [5.72 4.22 5.72 3.59 5.04 2.66 5.02 3.11 0.13 2.26 ...
      5.39 2.57 1.20 1.82 3.23 5.46 3.15 1.84 0.21 4.29 ...
      4.61 0.36 3.76 1.59 1.87 3.14 2.45 5.36 3.44 3.41]';
y = [2.66 2.91 0.94 4.28 1.76 4.08 1.11 4.33 8.94 5.25 ...
      0.02 3.88 6.43 4.08 4.90 1.33 3.63 5.49 7.23 0.88 ...
      3.08 8.12 1.22 4.24 6.21 5.48 4.89 2.30 4.13 2.17]';
```

Let's also assume that theory tells us that these data should follow a model of exponential decay,  $y = p_1 \exp(p_2 x)$ , where  $p_1$  is positive and  $p_2$  is negative. To fit this model, we could use nonlinear least squares.

```
modelFun = @(p,x) p(1)*exp(p(2)*x);
```

But the nonlinear model can also be transformed to a linear one by taking the log on both sides, to get  $\log(y) = \log(p_1) + p_2 x$ . That's tempting, because we can fit that linear model by ordinary linear least squares. The coefficients we'd get from a linear least squares would be  $\log(p_1)$  and  $p_2$ .

```
paramEstsLin = [ones(size(x)), x] \ log(y);
paramEstsLin(1) = exp(paramEstsLin(1))
```

```
paramEstsLin =
```

```
11.9312
-0.4462
```

How did we do? We can superimpose the fit on the data to find out.

```
xx = linspace(min(x), max(x));
```

```
yyLin = modelFun(paramEstsLin, xx);  
plot(x,y,'o', xx,yyLin,'-');  
xlabel('x'); ylabel('y');  
legend({'Raw data','Linear fit on the log scale'},'location','NE');
```

Something seems to have gone wrong, because the fit doesn't really follow the trend that we can see in the raw data. What kind of fit would we get if we used `nlinfit` to do nonlinear least squares instead? We'll use the previous fit as a rough starting point, even though it's not a great fit.

```
paramEsts = nlinfit(x, y, modelFun, paramEstsLin)
```

```
paramEsts =  
  
    8.8145  
   -0.2885  
  
yy = modelFun(paramEsts,xx);  
plot(x,y,'o', xx,yyLin,'-', xx,yy,'-');  
xlabel('x'); ylabel('y');  
legend({'Raw data','Linear fit on the log scale', ...  
       'Nonlinear fit on the original scale'},'location','NE');
```

The fit using `nlinfit` more or less passes through the center of the data point scatter. A residual plot shows something approximately like an even scatter about zero.

```
r = y-modelFun(paramEsts,x);
plot(x,r,'+', [min(x) max(x)], [0 0], 'k:');
xlabel('x'); ylabel('residuals');
```

So what went wrong with the linear fit? The problem is in log transform. If we plot the data and the two fits on the log scale, we can see that there's an extreme outlier.

```
plot(x,log(y),'o', xx,log(yyLin),'- ', xx,log(yy),'- ');
xlabel('x'); ylabel('log(y)');
ylim([-5,3]);
legend({'Raw data', 'Linear fit on the log scale', ...
       'Nonlinear fit on the original scale'},'location','SW');
```

That observation is not an outlier in the original data, so what happened to make it one on the log scale? The log transform is exactly the right thing to straighten out the trend line. But the log is a very nonlinear transform, and so symmetric measurement errors on the original scale have become asymmetric on the log scale. Notice that the outlier had the smallest y value on the original scale -- close to zero. The log transform has "stretched out" that smallest y value more than its neighbors. We made the linear fit on the log scale, and so it is very much affected by that outlier.

Had the measurement at that one point been slightly different, the two fits might have been much more similar. For example,

```
y(11) = 1;
paramEsts = nlinfit(x, y, modelFun, [10;-.3])

paramEsts =

    8.7618
   -0.2833

paramEstsLin = [ones(size(x)), x] \ log(y);
paramEstsLin(1) = exp(paramEstsLin(1))

paramEstsLin =

    9.6357
   -0.3394

yy = modelFun(paramEsts,xx);
yyLin = modelFun(paramEstsLin, xx);
plot(x,y,'o', xx,yyLin,'-', xx,yy,'-');
xlabel('x'); ylabel('y');
legend({'Raw data', 'Linear fit on the log scale', ...
       'Nonlinear fit on the original scale'},'location','NE');
```

Still, the two fits are different. Which one is "right"? To answer that, suppose that instead of additive measurement errors, measurements of  $y$  were affected by multiplicative errors. These errors would not be symmetric, and least squares on the original scale would not be appropriate. On the other hand, the log transform would make the errors symmetric on the log scale, and the linear least squares fit on that scale is appropriate.

So, which method is "right" depends on what assumptions you are willing to make about your data. In practice, when the noise term is small relative to the trend, the log transform is "locally linear" in the sense that  $y$  values

near the same  $x$  value will not be stretched out too asymmetrically. In that case, the two methods lead to essentially the same fit. But when the noise term is not small, you should consider what assumptions are realistic, and choose an appropriate fitting method.

## What Is Survival Analysis?

In this section...
“Introduction” on page 12-2
“Censoring” on page 12-2
“Data” on page 12-3
“Survivor Function” on page 12-5
“Hazard Function” on page 12-7

### Introduction

Survival analysis is time-to-event analysis, that is, when the outcome of interest is the time until an event occurs. Examples of time-to-events are the time until infection, reoccurrence of a disease, or recovery in health sciences, duration of unemployment in economics, time until the failure of a machine part or lifetime of light bulbs in engineering, and so on. Survival analysis is a part of reliability studies in engineering. In this case, it is usually used to study the lifetime of industrial components. In reliability analyses, survival times are usually called failure times as the variable of interest is how much time a component functions properly before it fails.

Survival analysis consists of parametric, semiparametric, and nonparametric methods. You can use these to estimate the most commonly used measures in survival studies, survivor and hazard functions, compare them for different groups, and assess the relationship of predictor variables to survival time. Some statistical probability distributions describe survival times well. Commonly used distributions are exponential, Weibull, lognormal, Burr, and Birnbaum-Saunders distributions. Statistics Toolbox functions `ecdf` and `ksdensity` compute the empirical and kernel density estimates of the cdf, cumulative hazard, and survivor functions. `coxphfit` fits the Cox proportional hazards model to the data.

### Censoring

One important concept in survival analysis is censoring. The survival times of some individuals might not be fully observed due to different reasons. In life sciences, this might happen when the survival study (e.g., the clinical trial)

stops before the full survival times of all individuals can be observed, or a person drops out of a study, or for long-term studies, when the patient is lost to follow up. In the industrial context, not all components might have failed before the end of the reliability study. In such cases, the individual survives beyond the time of the study, and the exact survival time is unknown. This is called right censoring.

During a survival study either the individual is observed to fail at time  $T$ , or the observation on that individual ceases at time  $c$ . Then the observation is  $\min(T, c)$  and an indicator variable  $I_c$  shows if the individual is censored or not. The calculations for hazard and survivor functions must be adjusted to account for censoring. Statistics Toolbox functions such as `ecdf`, `ksdensity`, `coxphfit`, `mle` account for censoring.

## Data

Survival data usually consists of the time until an event of interest occurs and the censoring information for each individual or component. The following table shows the fictitious unemployment time of individuals in a 6-month study. Two individuals are right censored (indicated by a censoring value of 1). One individual was still unemployed after the 24th week, when the study ended. Contact with the other censored individual was lost at the end of the 21st week.

Unemployment Time (Weeks)	Censoring
14	0
23	0
7	0
21	1
19	0
16	0
24	1
8	0

Survival data might also include the number of failures at a certain time (the number of times a particular survival or failure time was observed). The

following table shows the simulated time until a light-emitting diodes drops to 70% of its full light output level, in hours, in an accelerated life test.

<b>Failure Time (hrs)</b>	<b>Frequency</b>
8600	6
15300	19
22000	11
28600	20
35300	17
42000	14
48700	8
55400	2
62100	0
68800	2

Data might also have information on the predictor variables, to use in semi-parametric regression-like methods such as Cox proportional hazards regression.

<b>Time Until Recovery (weeks)</b>	<b>Censoring</b>	<b>Gender</b>	<b>Systolic Blood Pressure</b>	<b>Diastolic Blood Pressure</b>
12	1	Male	124	93
20	0	Female	109	77
7	0	Female	125	83
13	0	Male	117	75
9	1	Male	122	80
15	0	Female	121	70
17	1	Male	130	88
8	0	Female	115	82
14	0	Male	118	86

## Survivor Function

The survivor function is the probability of survival as a function of time. It is also called the survival function. It gives the probability that the survival time of an individual exceeds a certain value. Since the cumulative distribution function,  $F(t)$ , is the probability that the survival time is less than or equal to a given point in time, the survival function for a continuous distribution,  $S(t)$ , is the complement of the cumulative distribution function:

$$S(t) = 1 - F(t).$$

For example, for data coming from a Burr distribution with parameters 50, 3, and 1, you can calculate and plot the survivor function.

```
x = 0:0.1:200;
figure()
plot(x,1-cdf('Burr',x,50,3,1))
xlabel('Failure time');
ylabel('Survival probability');
```

The survivor function is also related to the hazard function. If the data has the hazard function,  $h(t)$ , then the survivor function is

$$S(t) = \exp\left(-\int_0^t h(u) du\right),$$

which corresponds to

$$S(t) = \exp(-H(t)),$$

where  $H(t)$  is the cumulative hazard function.

## Hazard Function

The hazard function gives the instantaneous failure rate of an individual conditioned on the fact that the individual survived until a given time. That is,

$$h(t) = \lim_{\Delta t \rightarrow 0} \frac{P(t \leq T < t + \Delta t \mid T \geq t)}{\Delta t},$$

where  $\Delta t$  is a very small time interval. The hazard rate, therefore, is sometimes called the conditional failure rate. The hazard function always takes a positive value. However, these values do not correspond to probabilities and might be greater than 1.

The hazard function is related to the probability density function,  $f(t)$ , cumulative distribution function,  $F(t)$ , and survivor function,  $S(t)$ , as follows:

$$h(t) = \frac{f(t)}{S(t)} = \frac{f(t)}{1 - F(t)},$$

which is also equivalent to

$$h(t) = -\frac{d}{dt} \ln S(t).$$

So, if you know the shape of the survival function, you can also derive the corresponding hazard function.

For example, for data coming from a Burr distribution with parameters 50, 3, and 1, you can calculate and plot the hazard function.

```
x = 0:1:200;
Burrhazard = pdf('Burr',x,50,3,1) ./ (1-cdf('Burr',x,50,3,1));
figure()
plot(x,Burrhazard)
xlabel('Failure time');
ylabel('Hazard rate');
```

There are different types of hazard functions. The previous figure shows a situation when the hazard rate increases for the early time periods and then gradually decreases. The hazard rate might also be monotonically decreasing, increasing, or constant over time. The following figure shows examples of different types of hazard functions for data coming from different Weibull distributions.

```
ax1 = subplot(3,1,1);
x1 = 0:0.5:30;
hazard1 = pdf('wbl',x1,3,0.6)./(1-cdf('wbl',x1,3,0.6));
plot(x1,hazard1)

ax2 = subplot(3,1,2);
x2 = 0:0.05:2;
```

```

hazard2 = pdf('wbl',x2,0.9,4)./(1-cdf('wbl',x2,0.9,4));
plot(x2,hazard2,'color','r')

ax3 = subplot(3,1,3);
x3 = 0:0.05:5;
hazard3 = pdf('wbl',x3,2.5,1)./(1-cdf('wbl',x3,2.5,1));
plot(x3,hazard3)

set(ax1,'Ylim',[0 0.4]);
legend(ax1,'a=3, b=0.6');
legend(ax2,'a=0.9, b=4','location','northwest');
legend(ax3,'a=2.5, b=1');

```

In the third case, the Weibull distribution has a shape parameter value of 1, which corresponds to the exponential distribution. The exponential distribution always has a constant hazard rate over time.

## Concepts

- “Kaplan-Meier Method” on page 12-11
- “Cox Proportional Hazards Regression” on page 12-31

## Kaplan-Meier Method

Use the Kaplan-Meier nonparametric method to estimate the empirical hazard, survivor, and cumulative distribution functions. The Statistics Toolbox function `ecdf` produces the empirical cumulative hazard, survivor, and cumulative distribution functions. The Kaplan-Meier estimator for the survivor function is also called the *product-limit estimator*.

The Kaplan-Meier method uses survival data summarized in life tables. Life tables order data according to ascending failure times, but you don't have to enter the failure/survival times in an ordered manner to use `ecdf`.

A life table usually consists of:

- Failure times
- Number of items failed at a time/time period
- Number of items censored at a time/time period
- Number of items at risk at the beginning of a time/time period

The number at risk is the total number of survivors at the beginning of each period. The number at risk at the beginning of the first period is all individuals in the lifetime study. At the beginning of each remaining period, the number at risk is reduced by the number of failures plus individuals censored at the end of the previous period.

This life table shows fictitious survival data. At the beginning of the first failure time, there are seven items at risk. At time 4, three fail. So at the beginning of time 7, there are four items at risk. Only one fails at time 7, so the number at risk at the beginning of time 11 is three. Two fail at time 11, so at the beginning of time 12, the number at risk is one. The remaining item fails at time 12.

Failure Time (t)	Number Failed	Number at Risk
4	3	7
7	1	4

Failure Time ( $t$ )	Number Failed	Number at Risk
11	2	3
12	1	1

You can estimate the hazard, cumulative hazard, survival, and cumulative distribution functions using the life tables as described next.

**Cumulative Hazard Rate (Failure Rate)**

The hazard rate at each period is the number of failures in the given period divided by the number of surviving individuals at the beginning of the period (number at risk).

Failure Time ( $t$ )	Hazard Rate ( $h(t)$ )	Cumulative Hazard Rate
0	0	0
$t_1$	$d_1/r_1$	$d_1/r_1$
$t_2$	$d_2/r_2$	$h(t_1) + d_2/r_2$
...	...	...
$t_n$	$d_n/r_n$	$h(t_{n-1}) + d_n/r_n$

**Survival Probability**

For each period, the survival probability is the product of the complement of hazard rates. The initial survival probability at the beginning of the first time period is 1. If the hazard rate for the each period is  $h(t_i)$ , then the survivor probability is as shown.

Time ( $t$ )	Survival Probability ( $S(t)$ )
0	1
$t_1$	$1*(1 - h(t_1))$
$t_2$	$S(t_1)*(1 - h(t_2))$

Time ( $t$ )	Survival Probability ( $S(t)$ )
...	...
$t_n$	$S(t_{n-1}) * (1 - h(t_n))$

### Cumulative Distribution Function

Because the cumulative distribution function (cdf) and the survivor function are complements of each other, you can find the cdf from the life tables using  $F(t) = 1 - S(t)$ .

You can compute the cumulative hazard rate, survival rate, and cumulative distribution function for the simulated data in the first table on this page as follows.

$t$	Number Failed ( $d$ )	Number at Risk ( $r$ )	Hazard Rate	Survival Probability	Cumulative Distribution Function
4	3	7	3/7	$1 - 3/7 = 4/7 = 0.5714$	0.4286
7	1	4	1/4	$4/7 * (1 - 1/4) = 3/7 = .4286$	0.5714
11	2	3	2/3	$3/7 * (1 - 2/3) = 1/7 = 0.1429$	0.8571
12	1	1	1/1	$1/7 * (1 - 1) = 0$	1

This rates in this example are based on the discrete failure times, and hence the calculations do not necessarily follow the derivative-based definition in “What Is Survival Analysis?” on page 12-2

Here is how you can enter the data and calculate these measures using `ecdf`. The data does not necessarily have to be in ascending order. Suppose the failure times are stored in an array `y`.

```
y = [4 7 11 12];
freq = [3 1 2 1];
[f,x] = ecdf(y, 'frequency', freq)
```

```
f =
```

```
0
0.4286
0.5714
0.8571
1.0000
```

```
x =
```

```
4
4
7
11
12
```

When you have censored data, the life table might look like the following:

Time (t)	Number failed (d)	Censoring	Number at Risk (r)	Hazard Rate	Survival Probability	Cumulative Distribution Function
4	2	1	7	2/7	$1 - 2/7 = 0.7143$	0.2857
7	1	0	4	1/4	$0.7143 * (1 - 1/4) = 0.5357$	0.4643
11	1	1	3	2/3	$0.5357 * (1 - 1/3) = 0.3571$	0.6429
12	1	0	1	1/1	$0.3571 * (1 - 1) = 0$	1.0000

At any given time, the censored items are also considered in the total of number at risk, and the hazard rate formula is based on the number failed and the total number at risk. While updating the number at risk at the beginning of each period, the total number failed and censored in the previous period is reduced from the number at risk at the beginning of that period.

While using `ecdf`, you must also enter the censoring information using an array of binary variables. Enter 1 for censored data, and enter 0 for exact failure time.

```
y = [4 4 4 7 11 11 12];  
cens = [0 1 0 0 1 0 0];  
[f,x] = ecdf(y,'censoring',cens)
```

```
f =  
  
      0  
0.2857  
0.4643  
0.6429  
1.0000
```

```
x =  
  
      4  
      4  
      7  
     11  
     12
```

`ecdf`, by default, produces the cumulative distribution function values. You have to specify the survivor function or the hazard function using optional name-value pair arguments. You can also plot the results as follows.

```
figure()  
ecdf(y,'censoring',cens,'function','survivor');
```

```
figure()  
ecdf(y,'censoring',cens,'function','cumulative hazard');
```

## Hazard and Survivor Functions for Different Groups

This example shows how to estimate and plot the cumulative hazard and survivor functions for different groups.

### Step 1. Load and organize sample data.

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load readmissiontimes
```

The data has readmission times of patients with information on their gender, age, weight, smoking status, and censorship. This is simulated data.

Create a matrix of readmission times and censoring for each gender.

```
female = [ReadmissionTime(Sex==1),Censored(Sex==1)];
male = [ReadmissionTime(Sex==0),Censored(Sex==0)];
```

### Step 2. Estimate and plot cumulative distribution function for each gender.

Plot the Kaplan-Meier estimate of the cumulative distribution function for female and male patients.

```
figure()
ecdf(gca,female(:,1),'Censoring',female(:,2));
hold on
[f,x] = ecdf(male(:,1),'Censoring',male(:,2));
stairs(x,f,'--r')
hold off
legend('female','male','Location','SouthEast')
```

### Step 3. Plot survivor functions.

Compare the survivor functions for female and male patients.

```
figure()
ax1 = gca;
ecdf(ax1,female(:,1),'Censoring',female(:,2),'function','survivor');
hold on
[f,x] = ecdf(male(:,1),'Censoring',male(:,2),'function','survivor');
stairs(x,f,'--r')
legend('female','male')
```

This figure shows that readmission times are shorter for male patients than female patients.

**Step 4. Fit Weibull survivor functions.**

Fit Weibull distributions to readmission times of female and male patients.

```
pd = fitdist(female(:,1),'wbl','Censoring',female(:,2))
```

```
pd =
```

```
weibull distribution
```

```
a = 12.5593
b = 1.99834

pd2 = fitdist(male(:,1), 'wbl', 'Censoring', male(:,2))

pd2 =

weibull distribution

a = 4.63991
b = 1.94422

pd2 = fitdist(male(:,1), 'wbl', 'Censoring', male(:,2))

pd2 =

weibull distribution

a = 4.63991
b = 1.94422
```

Plot the Weibull survivor functions for female and male patients on estimated survivor functions.

```
plot(0:1:25, 1-cdf('wbl', 0:1:25, 12.5593, 1.99834), '-. ')
plot(0:1:25, 1-cdf('wbl', 0:1:25, 4.63991, 1.94422), ':r')
hold off
legend('Festimated', 'Mestimated', 'FWeibull', 'MWeibull')
```

Weibull distribution provides a good fit for the data.

**Step 5. Estimate cumulative hazard and fit Weibull cumulative hazard functions.**

Estimate the cumulative hazard function for the genders and fit Weibull cumulative hazard functions.

```
figure()
[f,x] = ecdf(female(:,1),'Censoring',female(:,2),...
'function','cumhazard');
plot(x,f)
hold on
plot(x,cumsum(pdf(pd,x)./(1-cdf(pd,x))),'-.-')
```

```
[f,x] = ecdf(male(:,1),'Censoring',male(:,2),...
'function','cumhazard');
plot(x,f,'--r')
plot(x,cumsum(pdf(pd2,x)./(1-cdf(pd2,x))),':r')
legend('Festimated','FWeibull','Mestimated','MWeibull',...
'Location','North')
```

## Survivor Functions for Two Groups

This example shows how to find the empirical survivor functions and the parametric survivor functions using the Burr type XII distribution fit to data for two groups.

### Step 1. Load and prepare sample data.

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data

```
load lightbulb
```

The first column of the data has the lifetime (in hours) of two types of light bulbs. The second column has information about the type of light bulb. 1 indicates fluorescent bulbs whereas 0 indicates the incandescent bulb. The third column has censoring information. 1 indicates censored data, and 0 indicates the exact failure time. This is simulated data.

Create a variable for each light bulb type and also include the censorship information.

```
fluo = [lightbulb(lightbulb(:,2)==0,1),...
        lightbulb(lightbulb(:,2)==0,3)];
insec = [lightbulb(lightbulb(:,2)==1,1),...
         lightbulb(lightbulb(:,2)==1,3)];
```

### Step 2. Plot estimated survivor functions.

Plot the estimated survivor functions for the two different types of light bulbs.

```
figure()
[f,x,flow,fup] = ecdf(fluc(:,1),'censoring',fluc(:,2),...
    'function','survivor');
ax1 = stairs(x,f);
hold on
stairs(x,flow,':')
```

```

stairs(x,fup,':')
[f,x,flow,fup] = ecdf(incsc(:,1),'censoring',incsc(:,2),...
    'function','survivor');
ax2 = stairs(x,f,'color','r');
stairs(x,flow,':r')
stairs(x,fup,':r')
legend([ax1,ax2],{'Fluorescent','Incandescent'})
xlabel('Lifetime (hours)')
ylabel('Survival probability')

```

You can see that the survival probability of incandescent light bulbs is much smaller than that of fluorescent light bulbs.

**Step 3. Fit Burr Type XII distribution.**

Fit Burr distribution to the lifetime data of fluorescent and incandescent type bulbs.

```
pd = fitdist(fluo(:,1), 'burr', 'Censoring', fluo(:,2))
```

```
pd =
```

```
burr distribution
```

```
alpha = 29143.5
```

```
c = 3.44582
```

```
k = 33.704
```

```
pd2 = fitdist(incsc(:,1), 'burr', 'Censoring', incsc(:,2))
```

```
pd2 =
```

```
burr distribution
```

```
alpha = 2650.76
```

```
c = 3.41898
```

```
k = 4.5891
```

Superimpose Burr type XII survivor functions.

```
ax3 = plot(0:500:15000, 1-cdf('burr', 0:500:15000, 29143.5, ...  
3.44582, 33.704), 'm');
```

```
ax4 = plot(0:500:5000, 1-cdf('burr', 0:500:5000, 2650.76, ...  
3.41898, 4.5891), 'g');
```

```
legend([ax1;ax2;ax3;ax4], 'Festimate', 'Iestimate', 'FBurr', 'IBurr')
```

Burr distribution provides a good fit for the lifetime of light bulbs in this example.

#### Step 4. Fit a Cox proportional hazards model.

Fit a Cox proportional hazards regression where the type of the bulb is the explanatory variable.

```
[b,logl,H,stats] = coxphfit(lightbulb(:,2),lightbulb(:,1),...
    'Censoring',lightbulb(:,3));
stats
```

```
stats =
```

```
covb: 1.0757  
beta: 4.7262  
se: 1.0372  
z: 4.5568  
p: 5.1936e-06
```

The  $p$ -value,  $p$ , indicates that the type of light bulb is statistically significant. The estimate of the hazard ratio is  $\exp(b) = 112.8646$ . This means that the hazard for the incandescent bulbs is 112.86 times the hazard for the fluorescent bulbs.

## Cox Proportional Hazards Regression

Cox proportional hazards regression is a semiparametric method for adjusting survival rate estimates to quantify the effect of predictor variables. The method represents the effects of explanatory variables as a multiplier of a common baseline hazard function,  $h_0(t)$ . The hazard function is the nonparametric part of the Cox proportional hazards regression function, whereas the impact of the predictor variables is a loglinear regression. For a baseline relative to 0, this model corresponds to

$$h_X(t) = h_0(t)e^{\sum_i X_i b_i},$$

where  $h_X(t)$  is the hazard rate at  $X$  and  $h_0(t)$  is the baseline hazard rate function.

The Cox proportional hazards model relates the hazard rate for individuals or items at the value  $X$ , to the hazard rate for individuals or items at the baseline value. It produces an estimate for the hazard ratio,  $HR = h_X(t)/h_0(t)$ . The model is based on the assumption that the baseline hazard function depends on time,  $t$ , but the predictor variables do not. This is also called the proportional hazards assumption, which states that the hazard rate does not change over time for any individual. The hazard ratio represents the relative risk of instant failure for individuals or items having the predictive variable value  $X$  compared to the ones having the baseline values. For example, if the predictive variable is smoking status, where nonsmoking is the baseline category, the hazard ratio shows the relative instant failure rate of smokers compared to the baseline category, that is, nonsmokers.

For a baseline relative to  $X^*$  and the predictor variable value  $X$ , the hazard ratio is

$$HR = \frac{h_X(t)}{h_{X^*}(t)} = \exp\left[\sum_i (X_i - X_i^*) b_i\right].$$

For example, if the baseline is the mean values of the predictor variables ( $\text{mean}(X)$ ), then the hazard rate model becomes

$$h_X(t) = h_{\bar{X}}(t) \exp \left[ \sum_i (X_i - \bar{X}) b_i \right].$$

Hazard rates are related to survival rates, such that the survival rate at time  $t$  for an individual with the explanatory variable value  $x$  is

$$S_X(t) = S_0(t)^{HR_x(t)},$$

where  $S_0(t)$  is the survivor function with the baseline hazard rate function  $h_0(t)$ , and  $HR_x(t)$  is the hazard ratio of the predictor variable value  $x$  relative to the baseline value.

A point estimate of the effect of each explanatory variable, that is, the estimated hazard ratio for the effect of each explanatory variable is  $\exp(b)$ , given all other variables are held constant, where  $b$  is the coefficient estimate for that variable. The coefficient estimates are found by maximizing the likelihood function of the model. The likelihood function for the proportional hazards regression model is based on the observed order of events. It is the product of likelihood of a failure estimated for each failure time. If there are  $n$  failures at  $n$  distinct failure times, then the likelihood is

$$L = \left[ \frac{h(t_1)}{\sum_{i=1}^n h(t_i)} \right] \times \left[ \frac{h(t_2)}{\sum_{i=2}^n h(t_i)} \right] \times \dots \times \left[ \frac{h(t_n)}{h(t_n)} \right].$$

You can use a likelihood ratio test to assess the significance of adding a term or terms in a model. Consider the two models where the first model has  $p$  predictive variables and the second model has  $p + r$  predictive variables. Then, comparing the two models,  $-2 \ln(L_1/L_2)$  has a chi-square distribution with  $r$  degrees of freedom (the number of terms being tested).

## Cox Proportional Hazards Model for Censored Data

This example shows how to construct a Cox proportional hazards model, and assess the significance of the predictor variables.

### Step 1. Load sample data.

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load readmissiontimes
```

The response variable is `Readmission Time`, which shows the readmission times for 100 patients. The predictor variables are `Age`, `Sex`, `Weight`, and the smoking status of each patient, `Smoker`. 1 indicates the patient is a smoker, and 0 indicates that the patient does not smoke. The column vector `Censored` has the censorship information for each patient, where 1 indicates censored data, and 0 indicates the exact readmission times are observed. This is simulated data.

### Step 2. Fit Cox proportional hazards function.

Fit a Cox proportional hazard function with the variable `Sex` as the predictor variable, taking the censoring into account.

```
X = Sex;
[b,logl,H,stats] = coxphfit(X,ReadmissionTime,...
'censoring',Censored);
```

Assess the statistical significance of the term `Sex`.

```
stats

stats =

    covb: 0.1016
    beta: -1.7642
```

```

se: 0.3188
z: -5.5335
p: 3.1392e-08

```

The  $p$ -value,  $p$ , indicates that the term Sex is statistically significant.

Save the loglikelihood value with a different name. You will use this to assess the significance of the extended models.

```

loglSex = logl
loglSex =
-262.1365

```

### Step 3. Add Age and Weight to the model.

Fit a Cox proportional hazards model with the variables Sex, Age, and Weight.

```

X = [Sex Age Weight];
[b,logl,H,stats] = coxphfit(X,ReadmissionTime,...
'censoring',Censored);

```

Assess the significance of the terms.

```

stats.beta
ans =
-0.5441
0.0143
0.0250

```

```

stats.p
ans =
0.4953
0.3842
0.0960

```

None of the terms, adjusted for others, is statistically significant.

Assess the significance of the terms using the log likelihood ratio. You can assess the significance of the new model using the likelihood ratio statistic. First find the difference between the log-likelihood statistic of the model without the terms Age and Weight and the log-likelihood of the model with Sex, Age, and Weight.

```
-2*[loglSex - logl]
```

```
ans =
```

```
3.6705
```

Now, compute the  $p$ -value for the likelihood ratio statistic. The likelihood ratio statistic has a Chi-square distribution with a degrees of freedom equal to the number of predictor variables being assessed. In this case, the degrees of freedom is 2.

```
p = 1 - cdf('chi2',3.6705,2)
```

```
p =
```

```
0.1596
```

The  $p$ -value of 0.1596 indicates that the terms Age and Weight are not statistically significant, given the term Sex in the model.

#### **Step 4. Add Smoker to the model.**

Fit a Cox proportional hazards model with the variables Sex and Smoker.

```
X = [Sex Smoker];  
[b,logl,H,stats] = coxphfit(X,ReadmissionTime,...  
'censoring',Censored);
```

Assess the significance of the terms in the model.

```
stats.p
```

```
ans =
```

```
0.0000
```

```
0.0148
```

Compare this model to the first model where Sex is the only term.

```
-2*[loglSex - logl]
```

```
ans =
```

```
5.5789
```

Compute the  $p$ -value for the likelihood ratio statistic. The likelihood ratio statistic has a Chi-square distribution with a degree of freedom of 1.

```
p = 1 - cdf('chi2',5.5789,1)
```

```
p =
```

```
0.0182
```

The  $p$ -value of 0.0182 indicates that Sex and Smoker are statistically significant given the other is in the model. The model with Sex and Smoker is a better fit compared to the model with only Sex.

Request the coefficient estimates.

```
stats.beta
```

```
ans =
```

```
-1.7165
```

```
0.6338
```

The default baseline is the mean of  $X$ , so the final model for the hazard ratio is

$$HR = \frac{h_X(t)}{h_{\bar{X}}(t)} = \exp\left[\beta_s (X_s - \bar{X}_s) + \beta_a (X_a - \bar{X}_a)\right].$$

Fit a Cox ph model with a baseline of 0.

```
X = [Sex Smoker];
```

```
[b,logl,H,stats] = coxphfit(X,ReadmissionTime,...
```

```
'censoring',Censored,'baseline',0);
```

The model for the hazard ratio is

$$HR = \frac{h_X(t)}{h_0(t)} = \exp[\beta_s X_s + \beta_a X_a].$$

Request the coefficient estimates.

```
stats.beta
```

```
ans =
```

```
-1.7165  
0.6338
```

The coefficients are not affected, but the hazard rate differs from when the baseline is the mean of  $X$ .

## Introduction to Multivariate Methods

Large, high-dimensional data sets are common in the modern era of computer-based instrumentation and electronic data storage. High-dimensional data present many challenges for statistical visualization, analysis, and modeling.

Data visualization, of course, is impossible beyond a few dimensions. As a result, pattern recognition, data preprocessing, and model selection must rely heavily on numerical methods.

A fundamental challenge in high-dimensional data analysis is the so-called *curse of dimensionality*. Observations in a high-dimensional space are necessarily sparser and less representative than those in a low-dimensional space. In higher dimensions, data over-represent the edges of a sampling distribution, because regions of higher-dimensional space contain the majority of their volume near the surface. (A  $d$ -dimensional spherical shell has a volume, relative to the total volume of the sphere, that approaches 1 as  $d$  approaches infinity.) In high dimensions, typical data points at the interior of a distribution are sampled less frequently.

Often, many of the dimensions in a data set—the measured features—are not useful in producing a model. Features may be irrelevant or redundant. Regression and classification algorithms may require large amounts of storage and computation time to process raw data, and even if the algorithms are successful the resulting models may contain an incomprehensible number of terms.

Because of these challenges, multivariate statistical methods often begin with some type of *dimension reduction*, in which data are approximated by points in a lower-dimensional space. Dimension reduction is the goal of the methods presented in this chapter. Dimension reduction often leads to simpler models and fewer measured variables, with consequent benefits when measurements are expensive and visualization is important.

## Multivariate Linear Regression

### In this section...

“Multivariate Linear Regression Model” on page 13-3

“Solving Multivariate Regression Problems” on page 13-4

### Multivariate Linear Regression Model

The multivariate linear regression model expresses a  $d$ -dimensional continuous response vector as a linear combination of predictor terms plus a vector of error terms with a multivariate normal distribution. Let

$\mathbf{y}_i = (y_{i1}, \dots, y_{id})'$  denote the response vector for observation  $i$ ,  $i = 1, \dots, n$ . In the most general case, given the  $d$ -by- $K$  design matrix  $\mathbf{X}_i$  and the  $K$ -by-1 vector of coefficients  $\beta$ , the multivariate linear regression model is

$$\mathbf{y}_i = \mathbf{X}_i \beta + \varepsilon_i,$$

where the  $d$ -dimensional vector of error terms follows a multivariate normal distribution,

$$\varepsilon_i \square MVN_d(\mathbf{0}, \Sigma).$$

The model assumes independence between observations, meaning the error variance-covariance matrix for the  $n$  stacked  $d$ -dimensional response vectors is

$$\mathbf{I}_n \otimes \Sigma = \begin{pmatrix} \Sigma & & \mathbf{0} \\ & \ddots & \\ \mathbf{0} & & \Sigma \end{pmatrix}.$$

If  $\mathbf{Y}$  denotes the  $nd$ -by-1 vector of stacked  $d$ -dimensional responses, and  $\mathbf{X}$  denotes the  $nd$ -by- $K$  matrix of stacked design matrices, then the distribution of the response vector is

$$\mathbf{y} \square MVN_{nd}(\mathbf{X}\beta, \mathbf{I}_n \otimes \Sigma).$$

## Solving Multivariate Regression Problems

To fit multivariate linear regression models of the form

$$\mathbf{y}_i = \mathbf{X}_i\boldsymbol{\beta} + \boldsymbol{\varepsilon}_i, \boldsymbol{\varepsilon}_i \sim MVN_d(\mathbf{0}, \boldsymbol{\Sigma})$$

in Statistics Toolbox, use `mvregress`. This function fits multivariate regression models with a diagonal (heteroscedastic) or unstructured (heteroscedastic and correlated) error variance-covariance matrix,  $\boldsymbol{\Sigma}$ , using least squares or maximum likelihood estimation.

Many variations of multivariate regression might not initially appear to be of the form supported by `mvregress`, such as:

- Multivariate general linear model
- Multivariate analysis of variance (MANOVA)
- Longitudinal analysis
- Panel data analysis
- Seemingly unrelated regression (SUR)
- Vector autoregressive (VAR) model

In many cases, you can frame these problems in the form used by `mvregress` (but `mvregress` does not support parameterized error variance-covariance matrices). For the special case of one-way MANOVA, you can alternatively use `manova1`. Econometrics Toolbox™ has functions for VAR estimation.

---

**Note** The multivariate linear regression model is distinct from the multiple linear regression model, which models a *univariate* continuous response as a linear combination of exogenous terms plus an independent and identically distributed error term. To fit a multiple linear regression model, use `LinearModel.fit`.

- “Error Covariance Estimation” on page 13-8
- “Feasible Generalized Least Squares” on page 13-9
- “Panel Corrected Standard Errors” on page 13-10

### Ordinary Least Squares

When you fit multivariate linear regression models using `mvregress`, you can use the optional name-value pair `'algorithm'`, `'cwlsl'` to choose least squares estimation. In this case, by default, `mvregress` returns ordinary least squares (OLS) estimates using  $\Sigma = \mathbf{I}_d$ . Alternatively, if you specify a covariance matrix for weighting, you can return covariance-weighted least squares (CWLS) estimates. If you combine OLS and CWLS, you can get feasible generalized least squares (FGLS) estimates.

The OLS estimate for the coefficient vector is the vector  $\mathbf{b}$  that minimizes

$$\sum_{i=1}^n (\mathbf{y}_i - \mathbf{X}_i \mathbf{b})' (\mathbf{y}_i - \mathbf{X}_i \mathbf{b}).$$

Let  $\mathbf{y}$  denote the  $nd$ -by-1 vector of stacked  $d$ -dimensional responses, and  $\mathbf{X}$  denote the  $nd$ -by- $K$  matrix of stacked design matrices. The  $K$ -by-1 vector of OLS regression coefficient estimates is

$$\mathbf{b}_{OLS} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}.$$

This is the first `mvregress` output.

Given  $\Sigma = \mathbf{I}_d$  (the `mvregress` OLS default), the variance-covariance matrix of the OLS estimates is

$$V(\mathbf{b}_{OLS}) = (\mathbf{X}'\mathbf{X})^{-1}.$$

This is the fourth `mvregress` output. The standard errors of the OLS regression coefficients are the square root of the diagonal of this variance-covariance matrix.

If your data is not scaled such that  $\Sigma = \sigma^2\mathbf{I}_d$ , then you can multiply the `mvregress` variance-covariance matrix by the mean squared error (MSE), an unbiased estimate of  $\sigma^2$ . To compute the MSE, return the  $n$ -by- $d$  matrix of residuals,  $\mathbf{E}$  (the third `mvregress` output). Then,

$$\text{MSE} = \frac{\sum_{i=1}^n \mathbf{e}_i \mathbf{e}_i'}{n - K},$$

where  $\mathbf{e}_i = (\mathbf{y}_i - \mathbf{X}_i\boldsymbol{\beta})'$  is the  $i$ th row of  $\mathbf{E}$ .

### Covariance-Weighted Least Squares

For most multivariate problems, an identity error covariance matrix is insufficient, and leads to inefficient or biased standard error estimates. You can specify a matrix for CWLS estimation using the optional name-value pair argument `covar0`, for example, an invertible  $d$ -by- $d$  matrix named  $\mathbf{C}_0$ .

Usually,  $\mathbf{C}_0$  is a diagonal matrix such that the inverse matrix  $\mathbf{C}_0^{-1}$  contains weights for each dimension to model heteroscedasticity. However,  $\mathbf{C}_0$  can also be a nondiagonal matrix that models correlation.

Given  $\mathbf{C}_0$ , the CWLS solution is the vector  $\mathbf{b}$  that minimizes

$$\sum_{i=1}^n (\mathbf{y}_i - \mathbf{X}_i \mathbf{b})' \mathbf{C}_0 (\mathbf{y}_i - \mathbf{X}_i \mathbf{b}).$$

In this case, the  $K$ -by-1 vector of CWLS regression coefficient estimates is

$$\mathbf{b}_{CWLS} = \left( \mathbf{X}' (\mathbf{I}_n \otimes \mathbf{C}_0)^{-1} \mathbf{X} \right)^{-1} \mathbf{X}' (\mathbf{I}_n \otimes \mathbf{C}_0)^{-1} \mathbf{y}.$$

This is the first `mvregress` output.

If  $\Sigma = \mathbf{C}_0$ , this is the generalized least squares (GLS) solution. The corresponding variance-covariance matrix of the CWLS estimates is

$$V(\mathbf{b}_{CWLS}) = \left( \mathbf{X}' (\mathbf{I}_n \otimes \mathbf{C}_0)^{-1} \mathbf{X} \right)^{-1}.$$

This is the fourth `mvregress` output. The standard errors of the CWLS regression coefficients are the square root of the diagonal of this variance-covariance matrix.

If you only know the error covariance matrix up to a proportion, that is,

$\Sigma = \sigma^2 \mathbf{C}_0$ , you can multiply the `mvregress` variance-covariance matrix by the MSE, as described in “Ordinary Least Squares” on page 13-6.

### Error Covariance Estimation

Regardless of which least squares method you use, the estimate for the error variance-covariance matrix is

$$\hat{\Sigma} = \begin{pmatrix} \hat{\sigma}_1^2 & \hat{\sigma}_{12} & \cdots & \hat{\sigma}_{1d} \\ \hat{\sigma}_{12} & \hat{\sigma}_2^2 & \cdots & \hat{\sigma}_{2d} \\ \vdots & \vdots & \ddots & \vdots \\ \hat{\sigma}_{1d} & \hat{\sigma}_{2d} & \cdots & \hat{\sigma}_d^2 \end{pmatrix} = \frac{\mathbf{E}' \mathbf{E}}{n},$$

where  $\mathbf{E}$  is the  $n$ -by- $d$  matrix of residuals. The  $i$ th row of  $\mathbf{E}$  is

$$\mathbf{e}_i = (\mathbf{y}_i - \mathbf{X}_i \mathbf{b})'.$$

The error covariance estimate,  $\hat{\Sigma}$ , is the second `mvregress` output, and the matrix of residuals,  $\mathbf{E}$ , is the third output. If you specify the optional name-value pair 'covtype', 'diagonal', then `mvregress` returns  $\hat{\Sigma}$  with zeros in the off-diagonal entries,

$$\hat{\Sigma} = \begin{pmatrix} \hat{\sigma}_1^2 & & \mathbf{0} \\ & \ddots & \\ \mathbf{0} & & \hat{\sigma}_d^2 \end{pmatrix}.$$

### Feasible Generalized Least Squares

The generalized least squares estimate is the CWLS estimate with a known covariance matrix. That is, given  $\Sigma$  is known, the GLS solution is

$$\mathbf{b}_{GLS} = \left( \mathbf{X}'(\mathbf{I}_n \otimes \Sigma)^{-1} \mathbf{X} \right)^{-1} \mathbf{X}'(\mathbf{I}_n \otimes \Sigma)^{-1} \mathbf{y},$$

with variance-covariance matrix

$$V(\mathbf{b}_{GLS}) = \left( \mathbf{X}'(\mathbf{I}_n \otimes \Sigma)^{-1} \mathbf{X} \right)^{-1}.$$

In most cases, the error covariance is unknown. The feasible generalized least squares (FGLS) estimate uses  $\hat{\Sigma}$  in place of  $\Sigma$ . You can obtain two-step FGLS estimates as follows:

- 1 Perform OLS regression, and return an estimate  $\hat{\Sigma}$ .
- 2 Perform CWLS regression, using  $\mathbf{C}_0 = \hat{\Sigma}$ .

You can also iterate between these two steps until convergence is reached.

For some data, the OLS estimate  $\hat{\Sigma}$  is positive semidefinite, and has no unique inverse. In this case, you cannot get the FGLS estimate using `mvregress`. As an alternative, you can use `lscov`, which uses a generalized inverse to return weighted least squares solutions for positive semidefinite covariance matrices.

### Panel Corrected Standard Errors

An alternative to FGLS is to use OLS coefficient estimates (which are consistent) and make a standard error correction to improve efficiency. One such standard error adjustment—which does not require inversion of the covariance matrix—is panel corrected standard errors (PCSE) [1]. The panel corrected variance-covariance matrix for OLS estimates is

$$V_{pcse}(\mathbf{b}_{OLS}) = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'(\mathbf{I}_n \otimes \Sigma)\mathbf{X}(\mathbf{X}'\mathbf{X}).$$

The PCSE are the square root of the diagonal of this variance-covariance matrix. “Fixed Effects Panel Model with Concurrent Correlation” on page 13-35 illustrates PCSE computation.

### Maximum Likelihood Estimation

- “Maximum Likelihood Estimates” on page 13-10
- “Standard Errors” on page 13-11

### Maximum Likelihood Estimates

The default estimation algorithm used by `mvregress` is maximum likelihood estimation (MLE). The loglikelihood function for the multivariate linear regression model is

$$\begin{aligned} \log L(\beta, \Sigma | \mathbf{y}, \mathbf{X}) &= \frac{1}{2}nd \log(2\pi) + \frac{1}{2}n \log(\det(\Sigma)) \\ &+ \frac{1}{2} \sum_{i=1}^n (\mathbf{y}_i - \mathbf{X}_i\beta)' \Sigma^{-1} (\mathbf{y}_i - \mathbf{X}_i\beta). \end{aligned}$$

The MLEs for  $\beta$  and  $\Sigma$  are the values that maximize the loglikelihood objective function.

`mvregress` finds the MLEs using an iterative two-stage algorithm. At iteration  $m + 1$ , the estimates are

$$\mathbf{b}_{MLE}^{(m+1)} = \left( \mathbf{X}' (\mathbf{I}_n \otimes \Sigma^{(m)})^{-1} \mathbf{X} \right)^{-1} \mathbf{X}' (\mathbf{I}_n \otimes \Sigma^{(m)})^{-1} \mathbf{y}$$

and

$$\hat{\Sigma}^{(m+1)} = \frac{1}{n} \sum_{i=1}^n (\mathbf{y}_i - \mathbf{X}_i \mathbf{b}_{MLE}^{(m+1)}) (\mathbf{y}_i - \mathbf{X}_i \mathbf{b}_{MLE}^{(m+1)})'.$$

The algorithm terminates when the changes in the coefficient estimates and loglikelihood objective function are less than a specified tolerance, or when the specified maximum number of iterations is reached. The optional name-value pair arguments for changing these convergence criteria are `tolbeta`, `tolobj`, and `maxiter`, respectively.

### Standard Errors

The variance-covariance matrix of the MLEs is an optional `mvregress` output. By default, `mvregress` returns the variance-covariance matrix for only the regression coefficients, but you can also get the variance-covariance matrix of  $\hat{\Sigma}$  using the optional name-value pair `'vartype', 'full'`. In this case, `mvregress` returns the variance-covariance matrix for all  $K$  regression coefficients, and  $d$  or  $d(d+1)/2$  covariance terms (depending on whether the error covariance is diagonal or full).

By default, the variance-covariance matrix is the inverse of the observed Fisher information matrix (the `'hessian'` option). You can request the expected Fisher information matrix using the optional name-value pair `'vartype', 'fisher'`. Provided there is no missing response data, the observed and expected Fisher information matrices are the same. If response data is missing, the observed Fisher information accounts for the added uncertainty due to the missing values, whereas the expected Fisher information matrix does not.

The variance-covariance matrix for the regression coefficient MLEs is

$$V(\mathbf{b}_{MLE}) = \left( \mathbf{X}' (\mathbf{I}_n \otimes \Sigma)^{-1} \mathbf{X} \right)^{-1},$$

evaluated at the MLE of the error covariance matrix. This is the fourth `mvregress` output. The standard errors of the MLEs are the square root of the diagonal of this variance-covariance matrix.

For  $\hat{\Sigma}$ , let  $\theta$  denote the vector of parameters in the estimated error variance-covariance matrix. For example, if  $d = 2$ , then:

- If the estimated covariance matrix is diagonal, then  $\theta = (\sigma_1^2, \sigma_2^2)$ .
- If the estimated covariance matrix is full, then  $\theta = (\sigma_1^2, \sigma_{12}, \sigma_2^2)$ .

The Fisher information matrix for  $\theta$ ,  $I(\theta)$ , has elements

$$I(\theta)_{u,v} = \frac{1}{2} \text{tr} \left( \Sigma^{-1} \frac{\partial \Sigma}{\partial \theta_u} \Sigma^{-1} \frac{\partial \Sigma}{\partial \theta_v} \right), \quad u, v = 1, \dots, n_\theta,$$

where  $n_\theta$  is the length of  $\theta$  (either  $d$  or  $d(d + 1)/2$ ). The resulting variance-covariance matrix is

$$V(\theta) = I(\theta)^{-1}.$$

When you request the full variance-covariance matrix, `mvregress` returns (as the fourth output) the block diagonal matrix

$$\begin{pmatrix} V(\mathbf{b}_{MLE}) & \mathbf{0} \\ \mathbf{0} & V(\theta) \end{pmatrix}.$$

## Missing Response Data

- “Expectation/Conditional Maximization” on page 13-12
- “Observed Information Matrix” on page 13-14

### Expectation/Conditional Maximization

If any response values are missing, indicated by NaN, `mvregress` uses an expectation/conditional maximization (ECM) algorithm for estimation (if

enough data is available). In this case, the algorithm is iterative for both least squares and maximum likelihood estimation. During each iteration, `mvregress` imputes missing response values using their conditional expectation.

Consider organizing the data so that the joint distribution of the missing and observed responses, denoted  $\tilde{\mathbf{y}}$  and  $\mathbf{y}$  respectively, can be written as

$$\begin{pmatrix} \tilde{\mathbf{y}} \\ \mathbf{y} \end{pmatrix} \square MVN \left\{ \begin{pmatrix} \tilde{\mathbf{X}}\beta \\ \mathbf{X}\beta \end{pmatrix}, \begin{pmatrix} \Sigma_{\tilde{y}} & \Sigma_{\tilde{y}y} \\ \Sigma_{y\tilde{y}} & \Sigma_y \end{pmatrix} \right\}.$$

Using properties of the multivariate normal distribution, the conditional expectation of the missing responses given the observed responses is

$$E(\tilde{\mathbf{y}}|\mathbf{y}) = \tilde{\mathbf{X}}\beta + \Sigma_{\tilde{y}y}\Sigma_y^{-1}(\mathbf{y} - \mathbf{X}\beta).$$

Also, the variance-covariance matrix of the conditional distribution is

$$\text{COV}(\tilde{\mathbf{y}}|\mathbf{y}) = \Sigma_{\tilde{y}} - \Sigma_{\tilde{y}y}\Sigma_y^{-1}\Sigma_{y\tilde{y}}.$$

At each iteration of the ECM algorithm, `mvregress` uses the parameter values from the previous iteration to:

- Update the regression coefficients using the combined vector of observed responses and conditional expectations of missing responses.
- Update the variance-covariance matrix, adjusting for missing responses using the variance-covariance matrix of the conditional distribution.

Finally, the residuals that `mvregress` returns for missing responses are the difference between the conditional expectation and the fitted value, both evaluated at the final parameter estimates.

If you prefer to ignore any observations that have missing response values, use the name-value pair `'algorithm', 'mvm'`. Note that `mvregress` always ignores observations that have missing predictor values.

### Observed Information Matrix

By default, `mvregress` uses the observed Fisher information matrix (the 'hessian' option) to compute the variance-covariance matrix of the regression parameters. This accounts for the additional uncertainty due to missing response values.

The observed information matrix includes contributions from only the observed responses. That is, the observed Fisher information matrix for the parameters in the error variance-covariance matrix has elements

$$I(\theta)_{u,v} = \frac{1}{2} \sum_{i=1}^n \text{tr} \left( \Sigma_i^{-1} \frac{\partial \Sigma_i}{\partial \theta_u} \Sigma_i^{-1} \frac{\partial \Sigma_i}{\partial \theta_v} \right), \quad u, v = 1, \dots, n_\theta,$$

where  $\hat{\Sigma}_i$  is the subset of  $\hat{\Sigma}$  corresponding to the observed responses in  $\mathbf{Y}_i$ .

For example, if  $d = 3$ , but  $y_{i2}$  is missing, then

$$\hat{\Sigma}_i = \begin{pmatrix} \hat{\sigma}_1^2 & \hat{\sigma}_{13} \\ \hat{\sigma}_{13} & \hat{\sigma}_3^2 \end{pmatrix}.$$

The observed Fisher information for the regression coefficients has similar contributions from the design and covariance matrices.

## Set Up Multivariate Regression Problems

In this section...
“Response Matrix” on page 13-16
“Design Matrices” on page 13-21
“Common Multivariate Regression Problems” on page 13-22

### Response Matrix

To fit a multivariate linear regression model using `mvregress`, you must set up your response matrix and design matrices in a particular way. Given properly formatted inputs, `mvregress` can handle a variety of multivariate regression problems.

`mvregress` expects the  $n$  observations of potentially correlated  $d$ -dimensional responses to be in an  $n$ -by- $d$  matrix, named  $Y$ , for example. That is, set up your responses so that the dependency structure is between observations in the same *row*. If you specify  $Y$  as a vector of length  $n$  (either a row or column vector), then `mvregress` assumes that  $d = 1$ , and treats the elements as  $n$  independent observations. It does *not* model the vector as one realization of a correlated series (such as a time series).

To illustrate how to set up a response matrix, suppose that your multivariate responses are repeated measurements made on subjects at multiple time points, as in the following figure.

Suppose that observations within a subject are correlated.

In this case, set up the response matrix  $Y$  such that each row corresponds to a subject, and each column corresponds to a time point.

$d = \text{Number of Time Points}$  $n = \text{Number of Subjects}$ 

	Y

Then again, suppose that observations made on subjects at the same time are correlated (concurrent correlation).

In this case, set up the response matrix  $Y$  such that each row corresponds to a time point, and each column corresponds to a subject.

## Design Matrices

In the multivariate linear regression model, each  $d$ -dimensional response has a corresponding design matrix. Depending on the model, the design matrix might be comprised of exogenous predictor variables, dummy variables, lagged responses, or a combination of these and other covariate terms.

- If  $d > 1$  and all  $d$  dimensions have the same design matrix, then specify one  $n$ -by- $p$  design matrix, where  $p$  is the number of predictor variables. To determine an intercept for each dimension, add a column of ones to the design matrix. In this case, `mvregress` applies the design matrix to all  $d$  dimensions.
- If  $d > 1$  and all  $d$  dimensions do not have the same design matrix, then specify the design matrices using a length- $n$  cell array of  $d$ -by- $K$  arrays, named  $X$ , for example.  $K$  is the total number of regression coefficients in

the model. Note that the rows of the arrays in  $X$  correspond to the columns of the response matrix,  $Y$ .

$$X = \left\{ \begin{array}{c} \overleftarrow{K} \\ \boxed{\mathbf{X}_1} \\ \overrightarrow{d} \end{array} , \begin{array}{c} \overleftarrow{K} \\ \boxed{\mathbf{X}_2} \\ \overrightarrow{d} \end{array} , \dots , \begin{array}{c} \overleftarrow{K} \\ \boxed{\mathbf{X}_n} \\ \overrightarrow{d} \end{array} \right\}$$

If all  $n$  observations have the same design matrix, you can specify a cell array containing one  $d$ -by- $K$  design matrix. In this case, `mvregress` applies the design matrix to all  $n$  observations. For example, this situation might arise if the predictors are functions of time, and all observations were measured at the same time points.

- In the special case that  $d = 1$ , you can specify one  $n$ -by- $K$  design matrix (not in a cell array). However, you should consider using `fitlm` to fit regression models to univariate, continuous responses.

The following sections illustrate how to set up the some common multivariate regression problems for estimation using `mvregress`.

## Common Multivariate Regression Problems

### Multivariate General Linear Model

The multivariate general linear model is of the form

$$\mathbf{Y}_{n \times d} = \mathbf{X}_{n \times (p+1)} \mathbf{B}_{(p+1) \times d} + \mathbf{E}_{n \times d}.$$

In expanded form,

$$\begin{bmatrix} y_{11} & y_{12} & \cdots & y_{1d} \\ y_{21} & y_{22} & \cdots & y_{2d} \\ \vdots & \vdots & \ddots & \vdots \\ y_{n1} & y_{n2} & \cdots & y_{nd} \end{bmatrix} = \begin{bmatrix} 1 & x_{11} & x_{12} & \cdots & x_{1p} \\ 1 & x_{21} & x_{22} & \cdots & x_{2p} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & x_{n1} & x_{n2} & \cdots & x_{np} \end{bmatrix} \begin{bmatrix} \beta_{01} & \beta_{02} & \cdots & \beta_{0d} \\ \beta_{11} & \beta_{12} & \cdots & \beta_{1d} \\ \vdots & \vdots & \ddots & \vdots \\ \beta_{p1} & \beta_{p2} & \cdots & \beta_{pd} \end{bmatrix} + \begin{bmatrix} \varepsilon_{11} & \varepsilon_{12} & \cdots & \varepsilon_{1d} \\ \varepsilon_{21} & \varepsilon_{22} & \cdots & \varepsilon_{2d} \\ \vdots & \vdots & \ddots & \vdots \\ \varepsilon_{n1} & \varepsilon_{n2} & \cdots & \varepsilon_{nd} \end{bmatrix}.$$

That is, each  $d$ -dimensional response has an intercept and  $p$  predictor variables, and each dimension has its own set of regression coefficients. In this form, the least squares solution is  $\mathbf{B} = \mathbf{X} \backslash \mathbf{Y}$ . To estimate this model using `mvregress`, use the  $n$ -by- $d$  matrix of responses, as above.

If all  $d$  dimensions have the same design matrix, use the  $n$ -by- $(p+1)$  design matrix, as above. Adding a column of ones to the  $p$  predictor variables computes the intercept for each dimension.

If all  $d$  dimensions do not have the same design matrix, reformat the  $n$ -by- $(p+1)$  design matrix into a length- $n$  cell array of  $d$ -by- $K$  matrices. Here,  $K = (p+1)d$  for an intercept and slopes for each dimension.

For example, suppose  $n = 4$ ,  $d = 3$ , and  $p = 2$  (two predictor terms in addition to an intercept). This figure shows how to format the  $i$ th element in the cell array.

$$\begin{bmatrix} y_{11} & y_{12} & y_{13} \\ y_{21} & y_{22} & y_{23} \\ y_{31} & y_{32} & y_{33} \\ y_{41} & y_{42} & y_{43} \end{bmatrix} = \begin{bmatrix} 1 & x_{11} & x_{12} \\ 1 & x_{21} & x_{22} \\ 1 & x_{31} & x_{32} \\ 1 & x_{41} & x_{42} \end{bmatrix} \begin{bmatrix} \beta_{01} & \beta_{02} & \beta_{03} \\ \beta_{11} & \beta_{12} & \beta_{13} \\ \beta_{21} & \beta_{22} & \beta_{23} \end{bmatrix} + \begin{bmatrix} \varepsilon_{11} & \varepsilon_{12} & \varepsilon_{13} \\ \varepsilon_{21} & \varepsilon_{22} & \varepsilon_{23} \\ \varepsilon_{31} & \varepsilon_{32} & \varepsilon_{33} \\ \varepsilon_{41} & \varepsilon_{42} & \varepsilon_{43} \end{bmatrix}$$

$$\begin{bmatrix} 1 & 0 & 0 & x_{i1} & 0 & 0 & x_{i2} & 0 & 0 \\ 0 & 1 & 0 & 0 & x_{i1} & 0 & 0 & x_{i2} & 0 \\ 0 & 0 & 1 & 0 & 0 & x_{i1} & 0 & 0 & x_{i2} \end{bmatrix} \begin{bmatrix} \beta_{01} \\ \beta_{02} \\ \beta_{03} \\ \beta_{11} \\ \beta_{12} \\ \beta_{13} \\ \beta_{21} \\ \beta_{22} \\ \beta_{23} \end{bmatrix}$$

$X\{i\}$

If you prefer, you can reshape the  $K$ -by-1 vector of coefficients back into a  $(p + 1)$ -by- $d$  matrix after estimation.

To put constraints on the model parameters, adjust the design matrix accordingly. For example, suppose that the three dimensions in the previous example have a common slope. That is,  $\beta_{11} = \beta_{12} = \beta_{13} = \beta_1$  and  $\beta_{21} = \beta_{22} = \beta_{23} = \beta_2$ . In this case, each design matrix is 3-by-5, as shown in the following figure.

$$\underbrace{\begin{bmatrix} 1 & 0 & 0 & x_{i1} & x_{i2} \\ 0 & 1 & 0 & x_{i1} & x_{i2} \\ 0 & 0 & 1 & x_{i1} & x_{i2} \end{bmatrix}}_{X\{i\}} \begin{bmatrix} \beta_{01} \\ \beta_{02} \\ \beta_{03} \\ \beta_1 \\ \beta_2 \end{bmatrix}$$

### Longitudinal Analysis

In a longitudinal analysis, you might measure responses on  $n$  subjects at  $d$  time points, with correlation between observations made on the same subject. For example, suppose that you measure responses  $y_{ij}$  at times  $t_{ij}$ ,  $i = 1, \dots, n$  and  $j = 1, \dots, d$ . In addition, suppose that each subject is in one of two groups (such as male or female), specified by the indicator variable  $G_i$ . You could model  $y_{ij}$  as a function of  $G_i$  and  $t_{ij}$ , with group-specific intercepts and slopes, as follows:

$$y_{ij} = \beta_0 + \beta_1 G_i + \beta_2 t_{ij} + \beta_3 G_i \times t_{ij} + \varepsilon_{ij}, \quad i = 1, \dots, n; j = 1, \dots, d,$$

where

$$\varepsilon_i = (\varepsilon_{i1}, \dots, \varepsilon_{id})' \square MVN(\mathbf{0}, \Sigma).$$

Most longitudinal models include time as an explicit predictor.

To fit this model using `mvregress`, arrange the responses in an  $n$ -by- $d$  matrix, where  $n$  is the number of subjects and  $d$  is the number of time points. Specify the design matrices in an  $n$ -length cell array of  $d$ -by- $K$  matrices, where here  $K = 4$  for the four regression coefficients.

For example, suppose  $d = 5$  (five observations per subject). The  $i$ th design matrix and corresponding parameter vector for the specified model are shown in the following figure.

$$\underbrace{\begin{bmatrix} 1 & G_i & t_{i1} & G_i * t_{i1} \\ 1 & G_i & t_{i2} & G_i * t_{i2} \\ 1 & G_i & t_{i3} & G_i * t_{i3} \\ 1 & G_i & t_{i4} & G_i * t_{i4} \\ 1 & G_i & t_{i5} & G_i * t_{i5} \end{bmatrix}}_{X\{i\}} \begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \beta_3 \end{bmatrix}$$

### Panel Analysis

In a panel analysis, you might measure responses and covariates on  $d$  subjects (such as individuals or countries) at  $n$  time points. For example, suppose you measure responses  $y_{tj}$  and covariates  $x_{tj}$  on subjects  $j = 1, \dots, d$  at times  $t = 1, \dots, n$ . A fixed effects panel model, with subject-specific fixed effects, and concurrent correlation might look like:

$$y_{tj} = \alpha_j + \beta x_{tj} + \varepsilon_{tj},$$

where

$$\varepsilon_t = (\varepsilon_{t1}, \dots, \varepsilon_{td})' \square MVN(\mathbf{0}, \Sigma).$$

In contrast to longitudinal models, the panel analysis model typically includes covariates measured at each time point, instead of using time as an explicit predictor.

To fit this model using `mvregress`, arrange the responses in an  $n$ -by- $d$  matrix, such that each column corresponds to a subject. Specify the design matrices in an  $n$ -length cell array of  $d$ -by- $K$  matrices, where here  $K = d + 1$  for the  $d$  intercepts and a slope term.

For example, suppose  $d = 4$  (four subjects). The  $t$ th design matrix and corresponding parameter vector are shown in the following figure.

$$\underbrace{\begin{bmatrix} 1 & 0 & 0 & 0 & x_{t1} \\ 0 & 1 & 0 & 0 & x_{t2} \\ 0 & 0 & 1 & 0 & x_{t3} \\ 0 & 0 & 0 & 1 & x_{t4} \end{bmatrix}}_{X\{t\}} \begin{bmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_3 \\ \alpha_4 \\ \beta \end{bmatrix}$$

### Seemingly Unrelated Regression

In a seemingly unrelated regression (SUR), you model  $d$  separate regressions, each with its own intercept and slope, but a common error variance-covariance matrix. For example, suppose you measure responses  $y_{ij}$  and covariates  $x_{ij}$  for regression models  $j = 1, \dots, d$ , with  $i = 1, \dots, n$  observations to fit each regression. The SUR model might look like:

$$y_{ij} = \beta_{0j} + \beta_j x_{ij} + \varepsilon_{ij},$$

where

$$\varepsilon_i = (\varepsilon_{i1}, \dots, \varepsilon_{id})' \square MVN(\mathbf{0}, \Sigma).$$

This model is very similar to the multivariate general linear model, except that it has different covariates for each dimension.

To fit this model using `mvregress`, arrange the responses in an  $n$ -by- $d$  matrix, such that each column has the data for the  $j$ th regression model. Specify the design matrices in an  $n$ -length cell array of  $d$ -by- $K$  matrices, where here  $K = 2d$  for  $d$  intercepts and  $d$  slopes.

For example, suppose  $d = 3$  (three regressions). The  $i$ th design matrix and corresponding parameter vector are shown in the following figure.

$$\underbrace{\begin{bmatrix} 1 & 0 & 0 & x_{i1} & 0 & 0 \\ 0 & 1 & 0 & 0 & x_{i2} & 0 \\ 0 & 0 & 1 & 0 & 0 & x_{i3} \end{bmatrix}}_{X\{i\}} \begin{bmatrix} \beta_{01} \\ \beta_{02} \\ \beta_{03} \\ \beta_1 \\ \beta_2 \\ \beta_3 \end{bmatrix}$$

### Vector Autoregressive Model

The VAR( $p$ ) vector autoregressive model expresses  $d$ -dimensional time series responses as a linear function of  $p$  lagged  $d$ -dimensional responses from previous times. For example, suppose you measure responses  $y_{ij}$  for time series  $j = 1, \dots, d$  at times  $t = 1, \dots, n$ . The VAR( $p$ ) model might look like:

$$\begin{bmatrix} y_{t1} \\ y_{t2} \\ \vdots \\ y_{td} \end{bmatrix} = \begin{bmatrix} c_1 \\ c_2 \\ \vdots \\ c_d \end{bmatrix} + \begin{bmatrix} \varphi_{11}^{(1)} & \varphi_{12}^{(1)} & \dots & \varphi_{1d}^{(1)} \\ \vdots & \vdots & \ddots & \vdots \\ \varphi_{d1}^{(1)} & \varphi_{d2}^{(1)} & \dots & \varphi_{dd}^{(1)} \end{bmatrix} \begin{bmatrix} y_{t-1,1} \\ y_{t-1,2} \\ \vdots \\ y_{t-1,d} \end{bmatrix} + \dots + \begin{bmatrix} \varphi_{11}^{(p)} & \varphi_{12}^{(p)} & \dots & \varphi_{1d}^{(p)} \\ \vdots & \vdots & \ddots & \vdots \\ \varphi_{d1}^{(p)} & \varphi_{d2}^{(p)} & \dots & \varphi_{dd}^{(p)} \end{bmatrix} \begin{bmatrix} y_{t-p,1} \\ y_{t-p,2} \\ \vdots \\ y_{t-p,d} \end{bmatrix} + \begin{bmatrix} \varepsilon_{t1} \\ \varepsilon_{t2} \\ \vdots \\ \varepsilon_{td} \end{bmatrix},$$

where

$$\varepsilon_t = (\varepsilon_{t1}, \dots, \varepsilon_{td})' \square MVN(\mathbf{0}, \Sigma).$$

When estimating vector autoregressive models, you typically need to use the first  $p$  observations to initiate the model, or provide some other presample response values.

To fit this model using `mvregress`, arrange the responses in an  $n$ -by- $d$  matrix, such that each column corresponds to a time series. Specify the design matrices in an  $n$ -length cell array of  $d$ -by- $K$  matrices, where here  $K = d + pd^2$ .

For example, suppose  $d = 2$  (two time series) and  $p = 1$  (one lag). The  $t$ th design matrix and corresponding parameter vector are shown in the following figure.

$$\begin{bmatrix} 1 & 0 & y_{t-1,1} & 0 & y_{t-1,2} & 0 \\ 0 & 1 & 0 & y_{t-1,1} & 0 & y_{t-1,2} \end{bmatrix} \begin{bmatrix} c_1 \\ c_2 \\ \phi_{11}^{(1)} \\ \phi_{21}^{(1)} \\ \phi_{12}^{(1)} \\ \phi_{22}^{(1)} \end{bmatrix}$$

$\underbrace{\hspace{10em}}_{X\{t\}}$

Alternatively, Econometrics Toolbox has functions for fitting and forecasting VAR( $p$ ) models, including the option to specify exogenous predictor variables.

## Multivariate General Linear Model

This example shows how to set up a multivariate general linear model for estimation using `mvregress`.

### **Load sample data.**

This data contains measurements on a sample of 205 auto imports from 1985.

Here, model the bivariate response of city and highway MPG (columns 14 and 15).

For predictors, use wheel base (column 3), curb weight (column 7), and fuel type (column 18). The first two predictors are continuous, and for this example are centered and scaled. Fuel type is a categorical variable with two categories (11 and 20), so a dummy indicator variable is needed for the regression.

```
load('imports-85')
Y = X(:,14:15);
[n,d] = size(Y);

X1 = zscore(X(:,3));
X2 = zscore(X(:,7));
X3 = X(:,18)==20;

Xmat = [ones(n,1) X1 X2 X3];
```

The variable `X3` is coded to have value 1 for the fuel type 20, and value 0 otherwise.

For convenience, the three predictors (wheel base, curb weight, and fuel type indicator) are combined into one design matrix, with an added intercept term.

### **Set up design matrices.**

Given these predictors, the multivariate general linear model for the bivariate MPG response is

$$\begin{bmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \\ \vdots & \vdots \\ y_{n1} & y_{n2} \end{bmatrix} = \begin{bmatrix} 1 & x_{11} & x_{12} & x_{13} \\ 1 & x_{21} & x_{22} & x_{23} \\ \vdots & \vdots & \vdots & \vdots \\ 1 & x_{n1} & x_{n2} & x_{n3} \end{bmatrix} \begin{bmatrix} \beta_{01} & \beta_{02} \\ \beta_{11} & \beta_{12} \\ \beta_{21} & \beta_{22} \\ \beta_{31} & \beta_{32} \end{bmatrix} + \begin{bmatrix} \varepsilon_{11} & \varepsilon_{12} \\ \varepsilon_{21} & \varepsilon_{22} \\ \vdots & \vdots \\ \varepsilon_{n1} & \varepsilon_{n2} \end{bmatrix},$$

where  $\varepsilon_i = (\varepsilon_{i1}, \varepsilon_{i2})' \square MVN(\mathbf{0}, \Sigma)$ . There are  $K = 8$  regression coefficients in total.

Create a length  $n = 205$  cell array of 2-by-8 ( $d$ -by- $K$ ) matrices for use with `mvregress`. The  $i$ th matrix in the cell array is

$$X\{i\} = \begin{bmatrix} 1 & 0 & x_{i1} & 0 & x_{i2} & 0 & x_{i3} & 0 \\ 0 & 1 & 0 & x_{i1} & 0 & x_{i2} & 0 & x_{i3} \end{bmatrix}.$$

```
Xcell = cell(1,n);
for i = 1:n
    Xcell{i} = [kron([Xmat(i,:)],eye(d))];
end
```

Given this specification of the design matrices, the corresponding parameter vector is

$$\beta = \begin{bmatrix} \beta_{01} \\ \beta_{02} \\ \beta_{11} \\ \beta_{12} \\ \beta_{21} \\ \beta_{22} \\ \beta_{31} \\ \beta_{32} \end{bmatrix}.$$

**Estimate regression coefficients.**

Fit the model using maximum likelihood estimation.

```
[beta,sigma,E,V] = mvregress(Xcell,Y);
```

```
beta
beta =
  33.5476
  38.5720
   0.9723
   0.3950
  -6.3064
  -6.3584
  -9.2284
  -8.6663
```

These coefficient estimates show:

- The expected city and highway MPG for cars of average wheel base, curb weight, and fuel type 11 are 33.5 and 38.6, respectively. For fuel type 20, the expected city and highway MPG are  $33.5476 - 9.2284 = 24.3192$  and  $38.5720 - 8.6663 = 29.9057$ .
- An increase of one standard deviation in curb weight has almost the same effect on expected city and highway MPG. Given all else is equal, the expected MPG decreases by about 6.3 with each one standard deviation increase in curb weight, for both city and highway MPG.
- For each one standard deviation increase in wheel base, the expected city MPG increases 0.972, while the expected highway MPG increases by only 0.395, given all else is equal.

**Compute standard errors.**

The standard errors for the regression coefficients are the square root of the diagonal of the variance-covariance matrix,  $V$ .

```
se = sqrt(diag(V))
se =
  0.7365
  0.7599
  0.3589
  0.3702
```

```

0.3497
0.3608
0.7790
0.8037

```

### Reshape coefficient matrix.

You can easily reshape the regression coefficients into the original 4-by-2 matrix.

```
B = reshape(beta,2,4)'
```

```
B =
```

```

33.5476  38.5720
 0.9723   0.3950
-6.3064 -6.3584
-9.2284 -8.6663

```

### Check model assumptions.

Under the model assumptions,  $\mathbf{z} = \mathbf{E}\Sigma^{-1/2}$  should be independent, with a bivariate standard normal distribution. In this 2-D case, you can assess the validity of this assumption using a scatter plot.

```

z = E/chol(sigma);
figure()
plot(z(:,1),z(:,2),'.')
title('Standardized Residuals')
hold on

% Overlay standard normal contours
z1 = linspace(-5,5);
z2 = linspace(-5,5);
[zx,zy] = meshgrid(z1,z2);
zgrid = [reshape(zx,100^2,1),reshape(zy,100^2,1)];
zn = reshape(mvnpdf(zgrid),100,100);
[c,h] = contour(zx,zy,zn);
clabel(c,h)

```

Several residuals are larger than expected, but overall, there is little evidence against the multivariate normality assumption.

## Fixed Effects Panel Model with Concurrent Correlation

This example shows how to perform panel data analysis using `mvregress`. First, a fixed effects model with concurrent correlation is fit by ordinary least squares (OLS) to some panel data. Then, the estimated error covariance matrix is used to get panel corrected standard errors for the regression coefficients.

### Load sample data.

Navigate to the folder containing sample data. Load the sample panel data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
load('panelData')
```

The dataset array, `panelData`, contains yearly observations on eight cities for 6 years. This is simulated data.

### Define variables.

The first variable, `Growth`, measures economic growth (the response variable). The second and third variables are `city` and `year` indicators, respectively. The last variable, `Employ`, measures employment (the predictor variable).

```
y = panelData.Growth;
city = panelData.City;
year = panelData.Year;
x = panelData.Employ;
```

### Plot data grouped by category.

To look for potential city-specific fixed effects, create a box plot of the response grouped by city.

```
figure()
boxplot(y,city)
xlabel('City')
```

There does not appear to be any systematic differences in the mean response among cities.

**Plot data grouped by a different category.**

To look for potential year-specific fixed effects, create a box plot of the response grouped by year.

```
figure()  
boxplot(y,year)  
xlabel('Year')
```

Some evidence of systematic differences in the mean response between years seems to exist.

#### Format response data.

Let  $y_{ij}$  denote the response for city  $j = 1, \dots, d$ , in year  $i = 1, \dots, n$ . Similarly,  $x_{ij}$  is the corresponding value of the predictor variable. In this example,  $n = 6$  and  $d = 8$ .

Consider fitting a year-specific fixed effects model with a constant slope and concurrent correlation among cities in the same year,

$$y_{ij} = \alpha_i + \beta_1 x_{ij} + \varepsilon_{ij}, \quad i = 1, \dots, n, j = 1, \dots, d,$$

where  $\varepsilon_i = (\varepsilon_{i1}, \dots, \varepsilon_{id})' \square MVN(\mathbf{0}, \Sigma)$ . The concurrent correlation accounts for any unmeasured, time-static factors that might impact growth similarly for some cities. For example, cities with close spatial proximity might be more likely to have similar economic growth.

To fit this model using `mvregress`, reshape the response data into an  $n$ -by- $d$  matrix.

```
n = 6; d = 8;
Y = reshape(y,n,d);
```

**Format design matrices.**

Create a length- $n$  cell array of  $d$ -by- $K$  design matrices. For this model, there are  $K = 7$  parameters ( $d = 6$  intercept terms and a slope).

Suppose the vector of parameters is arranged as

$$\beta = \begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \vdots \\ \alpha_6 \\ \beta_1 \end{pmatrix}.$$

In this case, the first design matrix for year 1 looks like

$$X\{1\} = \begin{pmatrix} 1 & 0 & \cdots & 0 & x_{11} \\ 1 & 0 & \cdots & 0 & x_{12} \\ \vdots & \vdots & \cdots & 0 & \vdots \\ 1 & 0 & \cdots & 0 & x_{18} \end{pmatrix},$$

and the second design matrix for year 2 looks like

$$X\{2\} = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 & x_{21} \\ 0 & 1 & 0 & \cdots & 0 & x_{22} \\ \vdots & \vdots & 0 & \cdots & 0 & \vdots \\ 0 & 1 & 0 & \cdots & 0 & x_{28} \end{pmatrix}.$$

The design matrices for the remaining 4 years are similar.

```
K = 7; N = n*d;
X = cell(n,1);
for i = 1:n
    x0 = zeros(d,K-1);
```

```

    x0(:,i) = 1;
    X{i} = [x0,x(i:n:N)];
end

```

### Fit the model.

Fit the model using ordinary least squares (OLS).

```

[b,sig,E,V] = mvregress(X,Y,'algorithm','cqls');
b

```

b =

```

    41.6878
    26.1864
   -64.5107
    11.0924
   -59.1872
    71.3313
     4.9525

```

### Plot fitted model.

```

xx = linspace(min(x),max(x));
axx = repmat(b(1:K-1),1,length(xx));
bxx = repmat(b(K)*xx,n,1);
yhat = axx + bxx;

figure()
hPoints = gscatter(x,y,year);
hold on
hLines = plot(xx,yhat);
for i=1:n
    set(hLines(i),'color',get(hPoints(i),'color'));
end
hold off

```

The model with year-specific intercepts and common slope appears to fit the data quite well.

**Residual correlation.**

Plot the residuals, grouped by year.

```
figure()  
gscatter(year,E(:),city)  
ylabel('Residuals')
```

The residual plot suggests concurrent correlation is present. For examples, cities 1, 2, 3, and 4 are consistently above or below average as a group in any given year. The same is true for the collection of cities 5, 6, 7, and 8. As seen in the exploratory plots, there are no systematic city-specific effects.

### Panel corrected standard errors.

Use the estimated error variance-covariance matrix to compute panel corrected standard errors for the regression coefficients.

```
XX = cell2mat(X);
S = kron(eye(n), sig);
Vpcse = inv(XX'*XX)*XX'*S*XX*inv(XX'*XX);
se = sqrt(diag(Vpcse))
```

se =

9.3750

8.6698  
9.3406  
9.4286

## Longitudinal Analysis

This example shows how to perform longitudinal analysis using `mvregress`.

### Load sample data.

Navigate to the folder containing sample data. Load the sample longitudinal data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
load('longitudinalData')
```

The matrix `Y` contains response data for 16 individuals. The response is the blood level of a drug measured at five time points ( $t = 0, 2, 4, 6,$  and  $8$ ). Each row of `Y` corresponds to an individual, and each column corresponds to a time point. The first eight subjects are female, and the second eight subjects are male. This is simulated data.

### Plot data.

Plot the data for all 16 subjects.

```
figure()
t = [0,2,4,6,8];
plot(t,Y)
hold on

hf = plot(t,Y(1:8,:), '^');
hm = plot(t,Y(9:16,:), 'o');
legend([hf(1),hm(1)], 'Female', 'Male', 'Location', 'NorthEast')

title('Longitudinal Response')
ylabel('Blood Drug Level')
xlabel('Time')
hold off
```

**Define design matrices.**

Let  $y_{ij}$  denote the response for individual  $i = 1, \dots, n$  measured at times  $t_{ij}$ ,  $j = 1, \dots, d$ . In this example,  $n = 16$  and  $d = 5$ . Let  $G_i$  denote the gender of individual  $i$ , where  $G_i = 1$  for males and 0 for females.

Consider fitting a quadratic longitudinal model, with a separate slope and intercept for each gender,

$$y_{ij} = \beta_0 + \beta_1 G_i + \beta_2 t_{ij} + \beta_3 t_{ij}^2 + \beta_4 G_i \times t_{ij} + \beta_5 G_i \times t_{ij}^2 + \varepsilon_{ij},$$

where  $\varepsilon_i = (\varepsilon_{i1}, \dots, \varepsilon_{id})' \square MVN(\mathbf{0}, \Sigma)$ . The error correlation accounts for clustering within an individual.

To fit this model using `mvregress`, the response data should be in an  $n$ -by- $d$  matrix.  $Y$  is already in the proper format.

Next, create a length- $n$  cell array of  $d$ -by- $K$  design matrices. For this model, there are  $K = 6$  parameters.

For individual  $i$ , the 5-by-6 design matrix is

$$X\{i\} = \begin{pmatrix} 1 & G_i & t_{i1} & t_{i1}^2 & G_i \times t_{i1} & G_i \times t_{i1}^2 \\ 1 & G_i & t_{i2} & t_{i2}^2 & G_i \times t_{i2} & G_i \times t_{i2}^2 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & G_i & t_{i5} & t_{i5}^2 & G_i \times t_{i5} & G_i \times t_{i5}^2 \end{pmatrix},$$

corresponding to the parameter vector

$$\beta = \begin{pmatrix} \beta_0 \\ \beta_1 \\ \vdots \\ \beta_5 \end{pmatrix}.$$

The matrix X1 has the design matrix for a female, and X2 has the design matrix for a male.

Create a cell array of design matrices. The first eight individuals are females, and the second eight are males.

```
X = cell(8,1);
X(1:8) = {X1};
X(9:16) = {X2};
```

**Fit the model.**

Fit the model using maximum likelihood estimation. Display the estimated coefficients and standard errors.

```
[b,sig,E,V,loglikF] = mvregress(X,Y);
[b sqrt(diag(V))]
```

ans =

```
18.8619    0.7432
13.0942    1.0511
```

```
2.5968    0.2845
-0.3771    0.0398
-0.5929    0.4023
0.0290    0.0563
```

The coefficients on the interaction terms (in the last two rows of  $b$ ) do not appear significant. You can use the value of the loglikelihood objective function for this fit, `loglikF`, to compare this model to one without the interaction terms using a likelihood ratio test.

**Plot fitted model.**

Plot the fitted lines for females and males.

```
Yhatf = X1*b;
Yhatm = X2*b;

figure()
plot(t,Y)
hold on

plot(t,Y(1:8,:), '^', t, Y(9:16,:), 'o')

hf = plot(t, Yhatf, 'k--', 'LineWidth', 3);
hm = plot(t, Yhatm, 'k', 'LineWidth', 3);
legend([hf, hm], 'Females', 'Males', 'Location', 'NorthEast')

title('Longitudinal Response')
ylabel('Blood Drug Level')
xlabel('Time')
hold off
```

**Define a reduced model.**

Fit the model without interaction terms,

$$y_{ij} = \beta_0 + \beta_1 G_i + \beta_2 t_{ij} + \beta_3 t_{ij}^2 + \varepsilon_{ij},$$

where  $\varepsilon_i = (\varepsilon_{i1}, \dots, \varepsilon_{id})' \square MVN(\mathbf{0}, \Sigma)$ .

This model has four coefficients, which correspond to the first four columns of the design matrices X1 and X2 (for females and males, respectively).

```
X1R = X1(:, 1:4);
```

```
X2R = X2(:, 1:4);
```

```
XR = cell(8, 1);
```

```
XR(1:8) = {X1R};
```

```
XR(9:16) = {X2R};
```

**Fit the reduced model.**

Fit this model using maximum likelihood estimation. Display the estimated coefficients and their standard errors.

```
[bR,sigR,ER,VR,loglikR] = mvregress(XR,Y);
[bR,sqrt(diag(VR))]
```

```
ans =
```

```
    19.3765    0.6898
    12.0936    0.8591
     2.2919    0.2139
    -0.3623    0.0283
```

**Conduct a likelihood ratio test.**

Compare the two models using a likelihood ratio test. The null hypothesis is that the reduced model is sufficient. The alternative is that the reduced model is inadequate (compared to the full model with the interaction terms).

The likelihood ratio test statistic is compared to a chi-squared distribution with two degrees of freedom (for the two coefficients being dropped).

```
LR = 2*(loglikF-loglikR);
pval = 1 - chi2cdf(LR,2)
```

```
pval =
```

```
    0.0803
```

The  $p$ -value 0.0803 indicates that the null hypothesis is not rejected at the 5% significance level. Therefore, there is insufficient evidence that the extra terms improve the fit.

## Multidimensional Scaling

### In this section...

“Introduction to Multidimensional Scaling” on page 13-50

“Classical Multidimensional Scaling” on page 13-50

“Nonclassical Multidimensional Scaling” on page 13-56

“Nonmetric Multidimensional Scaling” on page 13-58

### Introduction to Multidimensional Scaling

One of the most important goals in visualizing data is to get a sense of how near or far points are from each other. Often, you can do this with a scatter plot. However, for some analyses, the data that you have might not be in the form of points at all, but rather in the form of pairwise similarities or dissimilarities between cases, observations, or subjects. There are no points to plot.

Even if your data are in the form of points rather than pairwise distances, a scatter plot of those data might not be useful. For some kinds of data, the relevant way to measure how near two points are might not be their Euclidean distance. While scatter plots of the raw data make it easy to compare Euclidean distances, they are not always useful when comparing other kinds of inter-point distances, city block distance for example, or even more general dissimilarities. Also, with a large number of variables, it is very difficult to visualize distances unless the data can be represented in a small number of dimensions. Some sort of dimension reduction is usually necessary.

Multidimensional scaling (MDS) is a set of methods that address all these problems. MDS allows you to visualize how near points are to each other for many kinds of distance or dissimilarity metrics and can produce a representation of your data in a small number of dimensions. MDS does not require raw data, but only a matrix of pairwise distances or dissimilarities.

### Classical Multidimensional Scaling

- “Introduction to Classical Multidimensional Scaling” on page 13-51

- “Example: Multidimensional Scaling” on page 13-53

## Introduction to Classical Multidimensional Scaling

This example shows how to use `cmdscale` to perform classical (metric) multidimensional scaling, also known as principal coordinates analysis.

`cmdscale` takes as an input a matrix of inter-point distances and creates a configuration of points. Ideally, those points are in two or three dimensions, and the Euclidean distances between them reproduce the original distance matrix. Thus, a scatter plot of the points created by `cmdscale` provides a visual representation of the original distances.

As a very simple example, you can reconstruct a set of points from only their inter-point distances. First, create some four dimensional points with a small component in their fourth coordinate, and reduce them to distances.

```
rng('default'); % For reproducibility
X = [normrnd(0,1,10,3),normrnd(0,.1,10,1)];
D = pdist(X,'euclidean');
```

Next, use `cmdscale` to find a configuration with those inter-point distances. `cmdscale` accepts distances as either a square matrix, or, as in this example, in the vector upper-triangular form produced by `pdist`.

```
[Y,eigvals] = cmdscale(D);
```

`cmdscale` produces two outputs. The first output, `Y`, is a matrix containing the reconstructed points. The second output, `eigvals`, is a vector containing the sorted eigenvalues of what is often referred to as the "scalar product matrix," which, in the simplest case, is equal to  $Y*Y'$ . The relative magnitudes of those eigenvalues indicate the relative contribution of the corresponding columns of `Y` in reproducing the original distance matrix `D` with the reconstructed points.

```
format short g
[eigvals eigvals/max(abs(eigvals))]
```

```
ans =
```

```
35.41
```

```
1
```

```

11.158      0.31511
 1.6894     0.04771
 0.1436     0.0040553
7.5802e-15  2.1407e-16
 6.299e-15  1.7789e-16
 2.1747e-15  6.1415e-17
-4.8934e-17 -1.3819e-18
-5.9631e-16 -1.684e-17
-2.8339e-15 -8.0032e-17

```

If `eigvals` contains only positive and zero (within round-off error) eigenvalues, the columns of `Y` corresponding to the positive eigenvalues provide an exact reconstruction of `D`, in the sense that their inter-point Euclidean distances, computed using `pdist`, for example, are identical (within round-off) to the values in `D`.

```
maxerr4 = max(abs(D - pdist(Y))) % Exact reconstruction
```

```
maxerr4 =
```

```
5.9952e-15
```

If two or three of the eigenvalues in `eigvals` are much larger than the rest, then the distance matrix based on the corresponding columns of `Y` nearly reproduces the original distance matrix `D`. In this sense, those columns form a lower-dimensional representation that adequately describes the data. However it is not always possible to find a good low-dimensional reconstruction.

```
maxerr3 = max(abs(D - pdist(Y(:,1:3)))) % Good reconstruction in 3D
```

```
maxerr2 = max(abs(D - pdist(Y(:,1:2)))) % Poor reconstruction in 2D
```

```
maxerr3 =
```

```
0.043142
```

```
maxerr2 =
    0.98315
```

The reconstruction in three dimensions reproduces  $D$  very well, but the reconstruction in two dimensions has errors that are of the same order of magnitude as the largest values in  $D$ .

```
max(max(D))
```

```
ans =
    5.8974
```

Often, `eigvals` contains some negative eigenvalues, indicating that the distances in  $D$  cannot be reproduced exactly. That is, there might not be any configuration of points whose inter-point Euclidean distances are given by  $D$ . If the largest negative eigenvalue is small in magnitude relative to the largest positive eigenvalues, then the configuration returned by `cmdscale` might still reproduce  $D$  well.

### Example: Multidimensional Scaling

This example shows how to construct a map of 10 US cities based on the distances between those cities, using `cmdscale`.

First, create the distance matrix and pass it to `cmdscale`. In this example,  $D$  is a full distance matrix: it is square and symmetric, has positive entries off the diagonal, and has zeros on the diagonal.

```
cities = ...
{'Atl', 'Chi', 'Den', 'Hou', 'LA', 'Mia', 'NYC', 'SF', 'Sea', 'WDC'};
D = [
    0  587 1212  701 1936  604  748 2139 2182  543;
    587  0  920  940 1745 1188  713 1858 1737  597;
    1212 920  0  879  831 1726 1631  949 1021 1494;
    701  940  879  0 1374  968 1420 1645 1891 1220;
```

```

1936 1745 831 1374 0 2339 2451 347 959 2300;
604 1188 1726 968 2339 0 1092 2594 2734 923;
748 713 1631 1420 2451 1092 0 2571 2408 205;
2139 1858 949 1645 347 2594 2571 0 678 2442;
2182 1737 1021 1891 959 2734 2408 678 0 2329;
543 597 1494 1220 2300 923 205 2442 2329 0];
[Y,eigvals] = cmdscale(D);

```

Next, look at the eigenvalues returned by `cmdscale`. Some of these are negative, indicating that the original distances are not Euclidean. This is because of the curvature of the earth.

```

format short g
[eigvals eigvals/max(abs(eigvals))]

```

```
ans =
```

```

9.5821e+06      1
1.6868e+06      0.17604
8157.3          0.0008513
1432.9          0.00014954
508.67         5.3085e-05
25.143         2.624e-06
4.0575e-10     4.2344e-17
-897.7         -9.3685e-05
-5467.6        -0.0005706
-35479         -0.0037026

```

However, in this case, the two largest positive eigenvalues are much larger in magnitude than the remaining eigenvalues. So, despite the negative eigenvalues, the first two coordinates of `Y` are sufficient for a reasonable reproduction of `D`.

```

Dtriu = D(find(tril(ones(10),-1)))';
maxrelerr = max(abs(Dtriu-pdist(Y(:,1:2))))./max(Dtriu)

```

```
maxrelerr =
```

0.0075371

Here is a plot of the reconstructed city locations as a map. The orientation of the reconstruction is arbitrary.

```
plot(Y(:,1),Y(:,2),'.')
text(Y(:,1)+25,Y(:,2),cities)
xlabel('Miles')
ylabel('Miles')
```

## Nonclassical Multidimensional Scaling

The function `mdscale` performs nonclassical multidimensional scaling. As with `cmdscale`, you use `mdscale` either to visualize dissimilarity data for which no “locations” exist, or to visualize high-dimensional data by reducing its dimensionality. Both functions take a matrix of dissimilarities as an input and produce a configuration of points. However, `mdscale` offers a choice of different criteria to construct the configuration, and allows missing data and weights.

For example, the cereal data include measurements on 10 variables describing breakfast cereals. You can use `mdscale` to visualize these data in two dimensions. First, load the data. For clarity, this example code selects a subset of 22 of the observations.

```
load cereal.mat
X = [Calories Protein Fat Sodium Fiber ...
     Carbo Sugars Shelf Potass Vitamins];
% Take a subset from a single manufacturer
mfg1 = strcmp('G',cellstr(Mfg));
X = X(mfg1,:);
size(X)
ans =
    22 10
```

Then use `pdist` to transform the 10-dimensional data into dissimilarities. The output from `pdist` is a symmetric dissimilarity matrix, stored as a vector containing only the  $(23 \times 22/2)$  elements in its upper triangle.

```
dissimilarities = pdist(zscore(X),'cityblock');
size(dissimilarities)
ans =
    1 231
```

This example code first standardizes the cereal data, and then uses city block distance as a dissimilarity. The choice of transformation to dissimilarities is application-dependent, and the choice here is only for simplicity. In some applications, the original data are already in the form of dissimilarities.

Next, use `mdscale` to perform metric MDS. Unlike `cmdscale`, you must specify the desired number of dimensions, and the method to use to construct

the output configuration. For this example, use two dimensions. The metric STRESS criterion is a common method for computing the output; for other choices, see the `mdscale` reference page in the online documentation. The second output from `mdscale` is the value of that criterion evaluated for the output configuration. It measures the how well the inter-point distances of the output configuration approximate the original input dissimilarities:

```
[Y, stress] = ...
mdscale(dissimilarities, 2, 'criterion', 'metricstress');
stress
stress =
    0.1856
```

A scatterplot of the output from `mdscale` represents the original 10-dimensional data in two dimensions, and you can use the `gname` function to label selected points:

```
plot(Y(:,1), Y(:,2), 'o', 'LineWidth', 2);
gname(Name(mfg1))
```

### Nonmetric Multidimensional Scaling

Metric multidimensional scaling creates a configuration of points whose inter-point distances approximate the given dissimilarities. This is sometimes too strict a requirement, and non-metric scaling is designed to relax it a bit. Instead of trying to approximate the dissimilarities themselves, non-metric scaling approximates a nonlinear, but monotonic, transformation of them. Because of the monotonicity, larger or smaller distances on a plot of the output will correspond to larger or smaller dissimilarities, respectively. However, the nonlinearity implies that `mdscale` only attempts to preserve the ordering of dissimilarities. Thus, there may be contractions or expansions of distances at different scales.

You use `mdscale` to perform nonmetric MDS in much the same way as for metric scaling. The nonmetric STRESS criterion is a common method for computing the output; for more choices, see the `mdscale` reference page in the online documentation. As with metric scaling, the second output from `mdscale` is the value of that criterion evaluated for the output configuration. For nonmetric scaling, however, it measures the how well the inter-point distances of the output configuration approximate the disparities. The disparities are returned in the third output. They are the transformed values of the original dissimilarities:

```
[Y, stress, disparities] = ...
mdscale(dissimilarities, 2, 'criterion', 'stress');
stress
stress =
    0.1562
```

To check the fit of the output configuration to the dissimilarities, and to understand the disparities, it helps to make a Shepard plot:

```
distances = pdist(Y);
[dum, ord] = sortrows([disparities(:) dissimilarities(:)]);
plot(dissimilarities, distances, 'bo', ...
     dissimilarities(ord), disparities(ord), 'r.-', ...
     [0 25], [0 25], 'k-')
xlabel('Dissimilarities')
ylabel('Distances/Disparities')
legend({'Distances' 'Disparities' '1:1 Line'}, ...
     'Location', 'NorthWest');
```

This plot shows that `mdscale` has found a configuration of points in two dimensions whose inter-point distances approximates the disparities, which in turn are a nonlinear transformation of the original dissimilarities. The concave shape of the disparities as a function of the dissimilarities indicates that fit tends to contract small distances relative to the corresponding dissimilarities. This may be perfectly acceptable in practice.

`mdscale` uses an iterative algorithm to find the output configuration, and the results can often depend on the starting point. By default, `mdscale` uses `cmdscale` to construct an initial configuration, and this choice often leads to a globally best solution. However, it is possible for `mdscale` to stop at a configuration that is a local minimum of the criterion. Such

cases can be diagnosed and often overcome by running `mdscale` multiple times with different starting points. You can do this using the `'start'` and `'replicates'` parameters. The following code runs five replicates of MDS, each starting at a different randomly-chosen initial configuration. The criterion value is printed out for each replication; `mdscale` returns the configuration with the best fit.

```
opts = statset('Display','final');  
[Y, stress] = ...  
mdscale(dissimilarities,2,'criterion','stress',...  
'start','random','replicates',5,'Options',opts);
```

```
35 iterations, Final stress criterion = 0.156209  
31 iterations, Final stress criterion = 0.156209  
48 iterations, Final stress criterion = 0.171209  
33 iterations, Final stress criterion = 0.175341  
32 iterations, Final stress criterion = 0.185881
```

Notice that `mdscale` finds several different local solutions, some of which do not have as low a stress value as the solution found with the `cmdscale` starting point.

## Procrustes Analysis

### In this section...

“Compare Landmark Data” on page 13-62

“Data Input” on page 13-62

“Preprocess Data for Accurate Results” on page 13-63

“Compare Handwritten Shapes” on page 13-64

### Compare Landmark Data

The `procrustes` function analyzes the distribution of a set of shapes using Procrustes analysis. This analysis method matches landmark data (geometric locations representing significant features in a given shape) to calculate the best shape-preserving Euclidian transformations. These transformations minimize the differences in location between compared landmark data.

Procrustes analysis is also useful in conjunction with multidimensional scaling. In “Example: Multidimensional Scaling” on page 13-53 there is an observation that the orientation of the reconstructed points is arbitrary. Two different applications of multidimensional scaling could produce reconstructed points that are very similar in principle, but that look different because they have different orientations. The `procrustes` function transforms one set of points to make them more comparable to the other.

### Data Input

The `procrustes` function takes two matrices as input:

- The target shape matrix  $X$  has dimension  $n \times p$ , where  $n$  is the number of landmarks in the shape and  $p$  is the number of measurements per landmark.
- The comparison shape matrix  $Y$  has dimension  $n \times q$  with  $q \leq p$ . If there are fewer measurements per landmark for the comparison shape than the target shape ( $q < p$ ), the function adds columns of zeros to  $Y$ , yielding an  $n \times p$  matrix.

The equation to obtain the transformed shape,  $Z$ , is

$$Z = bYT + c \quad (13-1)$$

where:

- $b$  is a scaling factor that stretches ( $b > 1$ ) or shrinks ( $b < 1$ ) the points.
- $T$  is the orthogonal rotation and reflection matrix.
- $c$  is a matrix with constant values in each column, used to shift the points.

The `procrustes` function chooses  $b$ ,  $T$ , and  $c$  to minimize the distance between the target shape  $X$  and the transformed shape  $Z$  as measured by the least squares criterion:

$$\sum_{i=1}^n \sum_{j=1}^p (X_{ij} - Z_{ij})^2$$

## Preprocess Data for Accurate Results

Procrustes analysis is appropriate when all  $p$  measurement dimensions have similar scales. The analysis would be inaccurate, for example, if the columns of  $Z$  had different scales:

- The first column is measured in milliliters ranging from 2,000 to 6,000.
- The second column is measured in degrees Celsius ranging from 10 to 25.
- The third column is measured in kilograms ranging from 50 to 230.

In such cases, standardize your variables by:

- 1 Subtracting the sample mean from each variable.
- 2 Dividing each resultant variable by its sample standard deviation.

Use the `zscore` function to perform this standardization.

## Compare Handwritten Shapes

In this example, use Procrustes analysis to compare two handwritten number threes. Visually and analytically explore the effects of forcing size and reflection changes as follows:

- “Step 1: Load and Display the Original Data” on page 13-64
- “Step 2: Calculate the Best Transformation” on page 13-65
- “Step 3: Examine the Similarity of the Two Shapes” on page 13-66
- “Step 4: Restrict the Form of the Transformations” on page 13-68

### Step 1: Load and Display the Original Data

Input landmark data for two handwritten number threes:

```
A = [11 39;17 42;25 42;25 40;23 36;19 35;30 34;35 29;...
30 20;18 19];
B = [15 31;20 37;30 40;29 35;25 29;29 31;31 31;35 20;...
29 10;25 18];
```

Create X and Y from A and B, moving B to the side to make each shape more visible:

```
X = A;
Y = B + repmat([25 0], 10,1);
```

Plot the shapes, using letters to designate the landmark points. Lines in the figure join the points to indicate the drawing path of each shape.

```
plot(X(:,1), X(:,2), 'r-', Y(:,1), Y(:,2), 'b-');
text(X(:,1), X(:,2), ('abcdefghij'))
text(Y(:,1), Y(:,2), ('abcdefghij'))
legend('X = Target', 'Y = Comparison', 'location', 'SE')
set(gca, 'YLim', [0 55], 'XLim', [0 65]);
```

## Step 2: Calculate the Best Transformation

Use Procrustes analysis to find the transformation that minimizes distances between landmark data points.

Call `procrustes` as follows:

```
[d, Z, tr] = procrustes(X,Y);
```

The outputs of the function are:

- `d` – A standardized dissimilarity measure.)
- `Z` – A matrix of the transformed landmarks.
- `tr` – A structure array of the computed transformation with fields `T`, `b`, and `c` which correspond to the transformation equation, Equation 13-1.

Visualize the transformed shape, Z, using a dashed blue line:

```
plot(X(:,1), X(:,2), 'r-', Y(:,1), Y(:,2), 'b-', ...
     Z(:,1), Z(:,2), 'b:');
text(X(:,1), X(:,2), ('abcdefghij'))
text(Y(:,1), Y(:,2), ('abcdefghij'))
text(Z(:,1), Z(:,2), ('abcdefghij'))
legend('X = Target', 'Y = Comparison', ...
       'Z = Transformed', 'location', 'SW')
set(gca, 'YLim', [0 55], 'XLim', [0 65]);
```

**Step 3: Examine the Similarity of the Two Shapes**

Use two different numerical values to assess the similarity of the target shape and the transformed shape.

**Dissimilarity Measure d.** The dissimilarity measure  $d$  gives a number between 0 and 1 describing the difference between the target shape and the transformed shape. Values near 0 imply more similar shapes, while values near 1 imply dissimilarity. For this example:

```
d =
    0.1502
```

The small value of  $d$  in this case shows that the two shapes are similar.

`procrustes` calculates  $d$  by comparing the sum of squared deviations between the set of points with the sum of squared deviations of the original points from their column means:

```
numerator = sum(sum((X-Z).^2))
numerator =

    166.5321

denominator = sum(sum(bsxfun(@minus,X,mean(X)).^2))
denominator =

    1.1085e+003

ratio = numerator/denominator
ratio =

    0.1502
```

---

**Note** The resulting measure  $d$  is independent of the scale of the size of the shapes and takes into account only the similarity of landmark data. “Examine the Scaling Measure  $b$ ” on page 13-67 shows how to examine the size similarity of the shapes.

---

**Examine the Scaling Measure  $b$ .** The target and comparison threes in the previous figure visually show that the two numbers are of a similar size. The closeness of calculated value of the scaling factor  $b$  to 1 supports this observation as well:

```
tr.b
ans =
    0.9291
```

The sizes of the target and comparison shapes appear similar. This visual impression is reinforced by the value of  $b = 0.93$ , which implies that the best transformation results in shrinking the comparison shape by a factor .93 (only 7%).

#### Step 4: Restrict the Form of the Transformations

Explore the effects of manually adjusting the scaling and reflection coefficients.

**Fix the Scaling Factor  $b = 1$ .** Force  $b$  to equal 1 (set 'Scaling' to false) to examine the amount of dissimilarity in size of the target and transformed figures:

```
ds = procrustes(X,Y,'Scaling',false)
ds =
    0.1552
```

In this case, setting 'Scaling' to false increases the calculated value of  $d$  only 0.0049, which further supports the similarity in the size of the two number threes. A larger increase in  $d$  would have indicated a greater size discrepancy.

**Force a Reflection in the Transformation.** This example requires only a rotation, not a reflection, to align the shapes. You can show this by observing that the determinant of the matrix  $T$  is 1 in this analysis:

```
det(tr.T)
ans =
    1.0000
```

If you need a reflection in the transformation, the determinant of  $T$  is -1. You can force a reflection into the transformation as follows:

```
[dr,Zr,trr] = procrustes(X,Y,'Reflection',true);
dr
dr =
```

0.8130

The  $d$  value increases dramatically, indicating that a forced reflection leads to a poor transformation of the landmark points. A plot of the transformed shape shows a similar result:

- The landmark data points are now further away from their target counterparts.
- The transformed three is now an undesirable mirror image of the target three.

```
plot(X(:,1), X(:,2), 'r-', Y(:,1), Y(:,2), 'b-', ...  
Zr(:,1), Zr(:,2), 'b:');  
text(X(:,1), X(:,2), ('abcdefghij'))  
text(Y(:,1), Y(:,2), ('abcdefghij'))  
text(Zr(:,1), Zr(:,2), ('abcdefghij'))  
legend('X = Target', 'Y = Comparison', ...  
'Z = Transformed', 'location', 'SW')  
set(gca, 'YLim', [0 55], 'XLim', [0 65]);
```

It appears that the shapes might be better matched if you flipped the transformed shape upside down. Flipping the shapes would make the transformation even worse, however, because the landmark data points would be further away from their target counterparts. From this example, it is clear that manually adjusting the scaling and reflection parameters is generally not optimal.

## Feature Selection

In this section...
“Introduction to Feature Selection” on page 13-71
“Sequential Feature Selection” on page 13-71

### Introduction to Feature Selection

*Feature selection* reduces the dimensionality of data by selecting only a subset of measured features (predictor variables) to create a model. Selection criteria usually involve the minimization of a specific measure of predictive error for models fit to different subsets. Algorithms search for a subset of predictors that optimally model measured responses, subject to constraints such as required or excluded features and the size of the subset.

Feature selection is preferable to feature transformation when the original units and meaning of features are important and the modeling goal is to identify an influential subset. When categorical features are present, and numerical transformations are inappropriate, feature selection becomes the primary means of dimension reduction.

### Sequential Feature Selection

- “Introduction to Sequential Feature Selection” on page 13-71
- “Example: Sequential Feature Selection” on page 13-72

### Introduction to Sequential Feature Selection

A common method of feature selection is *sequential feature selection*. This method has two components:

- An objective function, called the *criterion*, which the method seeks to minimize over all feasible feature subsets. Common criteria are mean squared error (for regression models) and misclassification rate (for classification models).
- A sequential search algorithm, which adds or removes features from a candidate subset while evaluating the criterion. Since an exhaustive

comparison of the criterion value at all  $2^n$  subsets of an  $n$ -feature data set is typically infeasible (depending on the size of  $n$  and the cost of objective calls), sequential searches move in only one direction, always growing or always shrinking the candidate set.

The method has two variants:

- *Sequential forward selection (SFS)*, in which features are sequentially added to an empty candidate set until the addition of further features does not decrease the criterion.
- *Sequential backward selection (SBS)*, in which features are sequentially removed from a full candidate set until the removal of further features increase the criterion.

Stepwise regression is a sequential feature selection technique designed specifically for least-squares fitting. The functions `stepwise` and `stepwisefit` make use of optimizations that are only possible with least-squares criteria. Unlike generalized sequential feature selection, stepwise regression may remove features that have been added or add features that have been removed.

The Statistics Toolbox function `sequentialfs` carries out sequential feature selection. Input arguments include predictor and response data and a function handle to a file implementing the criterion function. Optional inputs allow you to specify SFS or SBS, required or excluded features, and the size of the feature subset. The function calls `cvpartition` and `crossval` to evaluate the criterion at different candidate sets.

### **Example: Sequential Feature Selection**

For example, consider a data set with 100 observations of 10 predictors. The following generates random data from a logistic model, with a binomial distribution of responses at each set of values for the predictors. Some coefficients are set to zero so that not all of the predictors affect the response:

```
n = 100;  
m = 10;  
X = rand(n,m);  
b = [1 0 0 2 .5 0 0 0.1 0 1];  
Xb = X*b';  
p = 1./(1+exp(-Xb));
```

```
N = 50;  
y = binornd(N,p);
```

The `glmfit` function fits a logistic model to the data:

```
Y = [y N*ones(size(y))];  
[b0,dev0,stats0] = glmfit(X,Y,'binomial');
```

% Display coefficient estimates and their standard errors:

```
model0 = [b0 stats0.se]  
model0 =
```

0.3115	0.2596
0.9614	0.1656
-0.1100	0.1651
-0.2165	0.1683
1.9519	0.1809
0.5683	0.2018
-0.0062	0.1740
0.0651	0.1641
-0.1034	0.1685
0.0017	0.1815
0.7979	0.1806

% Display the deviance of the fit:

```
dev0  
dev0 =  
101.2594
```

This is the full model, using all of the features (and an initial constant term). Sequential feature selection searches for a subset of the features in the full model with comparative predictive power.

First, you must specify a criterion for selecting the features. The following function, which calls `glmfit` and returns the deviance of the fit (a generalization of the residual sum of squares) is a useful criterion in this case:

```
function dev = critfun(X,Y)  
  
[b,dev] = glmfit(X,Y,'binomial');
```

You should create this function as a file on the MATLAB path.

The function `sequentialfs` performs feature selection, calling the criterion function via a function handle:

```
maxdev = chi2inv(.95,1);
opt = statset('display','iter',...
             'TolFun',maxdev,...
             'TolTypeFun','abs');

inmodel = sequentialfs(@critfun,X,Y,...
                       'cv','none',...
                       'nullmodel',true,...
                       'options',opt,...
                       'direction','forward');
```

Start forward sequential feature selection:

```
Initial columns included: none
Columns that can not be included: none
Step 1, used initial columns, criterion value 309.118
Step 2, added column 4, criterion value 180.732
Step 3, added column 1, criterion value 138.862
Step 4, added column 10, criterion value 114.238
Step 5, added column 5, criterion value 103.503
Final columns included: 1 4 5 10
```

The iterative display shows a decrease in the criterion value as each new feature is added to the model. The final result is a reduced model with only four of the original ten features: columns 1, 4, 5, and 10 of  $X$ . These features are indicated in the logical vector `inmodel` returned by `sequentialfs`.

The deviance of the reduced model is higher than for the full model, but the addition of any other single feature would not decrease the criterion by more than the absolute tolerance, `maxdev`, set in the options structure. Adding a feature with no effect reduces the deviance by an amount that has a chi-square distribution with one degree of freedom. Adding a significant feature results in a larger change. By setting `maxdev` to `chi2inv(.95,1)`, you instruct `sequentialfs` to continue adding features so long as the change in deviance is more than would be expected by random chance.

The reduced model (also with an initial constant term) is:

```
[b,dev,stats] = glmfit(X(:,inmodel),Y,'binomial');
```

```
% Display coefficient estimates and their standard errors:  
model = [b stats.se]  
model =  
    0.0784    0.1642  
    1.0040    0.1592  
    1.9459    0.1789  
    0.6134    0.1872  
    0.8245    0.1730
```

## Feature Transformation

### In this section...

“Introduction to Feature Transformation” on page 13-76

“Nonnegative Matrix Factorization” on page 13-76

“Principal Component Analysis (PCA)” on page 13-80

“Quality of Life in U.S. Cities” on page 13-81

“Factor Analysis” on page 13-94

### Introduction to Feature Transformation

*Feature transformation* is a group of methods that create new features (predictor variables). The methods are useful for dimension reduction when the transformed features have a descriptive power that is more easily ordered than the original features. In this case, less descriptive features can be dropped from consideration when building models.

Feature transformation methods are contrasted with the methods presented in “Feature Selection” on page 13-71, where dimension reduction is achieved by computing an optimal subset of predictive features measured in the original data.

The methods presented in this section share some common methodology. Their goals, however, are essentially different:

- Nonnegative matrix factorization is used when model terms must represent nonnegative quantities, such as physical quantities.
- Principal component analysis is used to summarize data in fewer dimensions, for example, to visualize it.
- Factor analysis is used to build explanatory models of data correlations.

### Nonnegative Matrix Factorization

- “Introduction to Nonnegative Matrix Factorization” on page 13-77
- “Example: Nonnegative Matrix Factorization” on page 13-77

## Introduction to Nonnegative Matrix Factorization

*Nonnegative matrix factorization (NMF)* is a dimension-reduction technique based on a low-rank approximation of the feature space. Besides providing a reduction in the number of features, NMF guarantees that the features are nonnegative, producing additive models that respect, for example, the nonnegativity of physical quantities.

Given a nonnegative  $m$ -by- $n$  matrix  $X$  and a positive integer  $k < \min(m, n)$ , NMF finds nonnegative  $m$ -by- $k$  and  $k$ -by- $n$  matrices  $W$  and  $H$ , respectively, that minimize the norm of the difference  $X - WH$ .  $W$  and  $H$  are thus approximate nonnegative factors of  $X$ .

The  $k$  columns of  $W$  represent transformations of the variables in  $X$ ; the  $k$  rows of  $H$  represent the coefficients of the linear combinations of the original  $n$  variables in  $X$  that produce the transformed variables in  $W$ . Since  $k$  is generally smaller than the rank of  $X$ , the product  $WH$  provides a compressed approximation of the data in  $X$ . A range of possible values for  $k$  is often suggested by the modeling context.

The Statistics Toolbox function `nnmf` carries out nonnegative matrix factorization. `nnmf` uses one of two iterative algorithms that begin with random initial values for  $W$  and  $H$ . Because the norm of the residual  $X - WH$  may have local minima, repeated calls to `nnmf` may yield different factorizations. Sometimes the algorithm converges to a solution of lower rank than  $k$ , which may indicate that the result is not optimal.

### Example: Nonnegative Matrix Factorization

For example, consider the five predictors of biochemical oxygen demand in the data set `moore.mat`.

```
load moore
X = moore(:,1:5);
rng('default'); % For reproducibility
```

The following uses `nnmf` to compute a rank-two approximation of  $X$  with a multiplicative update algorithm that begins from five random initial values for  $W$  and  $H$ .

```
opt = statset('MaxIter',10,'Display','final');
```

```
[W0,H0] = nnmf(X,2,'replicates',5,'options',opt,'algorithm','mult');
```

```

      rep   iteration   rms resid   |delta x|
      1      10      358.296   0.00190554
      2      10      78.3556   0.000351747
      3      10      230.962   0.0172839
      4      10      326.347   0.00739552
      5      10      361.547   0.00705539

```

```
Final root mean square residual = 78.3556
```

The 'mult' algorithm is sensitive to initial values, which makes it a good choice when using 'replicates' to find W and H from multiple random starting values.

Now perform the factorization using an alternating least-squares algorithm, which converges faster and more consistently. Run 100 times more iterations, beginning from the initial W0 and H0 identified above.

```
opt = statset('Maxiter',1000,'Display','final');
[W,H] = nnmf(X,2,'w0',W0,'h0',H0,'options',opt,'algorithm','als');
```

```

      rep   iteration   rms resid   |delta x|
      1      2      77.5315   0.000830334

```

```
Final root mean square residual = 77.5315
```

The two columns of W are the transformed predictors. The two rows of H give the relative contributions of each of the five predictors in X to the predictors in W.

H

H =

```

      0.0835   0.0190   0.1782   0.0072   0.9802
      0.0559   0.0250   0.9969   0.0085   0.0497

```

The fifth predictor in  $X$  (weight 0.9802) strongly influences the first predictor in  $W$ . The third predictor in  $X$  (weight 0.9969) strongly influences the second predictor in  $W$ .

Visualize the relative contributions of the predictors in  $X$  with a biplot, showing the data and original variables in the column space of  $W$ .

```
biplot(H', 'scores', W, 'varlabels', {'', '', 'v3', '', 'v5'});  
axis([0 1.1 0 1.1])  
xlabel('Column 1')  
ylabel('Column 2')
```

## Principal Component Analysis (PCA)

One of the difficulties inherent in multivariate statistics is the problem of visualizing data that has many variables. The MATLAB function `plot` displays a graph of the relationship between two variables. The `plot3` and `surf` commands display different three-dimensional views. But when there are more than three variables, it is more difficult to visualize their relationships.

Fortunately, in data sets with many variables, groups of variables often move together. One reason for this is that more than one variable might be measuring the same driving principle governing the behavior of the system. In many systems there are only a few such driving forces. But an abundance of instrumentation enables you to measure dozens of system variables. When this happens, you can take advantage of this redundancy of information. You can simplify the problem by replacing a group of variables with a single new variable.

Principal component analysis is a quantitatively rigorous method for achieving this simplification. The method generates a new set of variables, called *principal components*. Each principal component is a linear combination of the original variables. All the principal components are orthogonal to each other, so there is no redundant information. The principal components as a whole form an orthogonal basis for the space of the data.

There are an infinite number of ways to construct an orthogonal basis for several columns of data. What is so special about the principal component basis?

The first principal component is a single axis in space. When you project each observation on that axis, the resulting values form a new variable. And the variance of this variable is the maximum among all possible choices of the first axis.

The second principal component is another axis in space, perpendicular to the first. Projecting the observations on this axis generates another new variable. The variance of this variable is the maximum among all possible choices of this second axis.

The full set of principal components is as large as the original set of variables. But it is commonplace for the sum of the variances of the first few principal

components to exceed 80% of the total variance of the original data. By examining plots of these few new variables, researchers often develop a deeper understanding of the driving forces that generated the original data.

You can use the function `pca` to find the principal components. To use `pca`, you need to have the actual measured data you want to analyze. However, if you lack the actual data, but have the sample covariance or correlation matrix for the data, you can still use the function `pcacov` to perform a principal components analysis. See the reference page for `pcacov` for a description of its inputs and outputs.

## Quality of Life in U.S. Cities

This example shows how to perform a weighted principal components analysis and interpret the results.

### Load sample data.

Load the sample data. The data includes ratings for 9 different indicators of the quality of life in 329 U.S. cities. These are climate, housing, health, crime, transportation, education, arts, recreation, and economics. For each category, a higher rating is better. For example, a higher rating for crime means a lower crime rate.

Display the `categories` variable.

```
load cities
categories

categories =
  climate
  housing
  health
  crime
  transportation
  education
  arts
  recreation
  economics
```

In total, the `cities` data set contains three variables:

- categories, a string matrix containing the names of the indices
- names, a string matrix containing the 329 city names
- ratings, the data matrix with 329 rows and 9 columns

**Plot data.**

Make a boxplot to look at the distribution of the ratings data.

```
figure()  
boxplot(ratings, 'orientation', 'horizontal', 'labels', categories)
```

There is more variability in the ratings of the arts and housing than in the ratings of crime and climate.

**Check pairwise correlation.**

Check the pairwise correlation between the variables.

```
C = corr(ratings,ratings);
```

The correlation among some variables is as high as 0.85. Principal components analysis constructs independent new variables which are linear combinations of the original variables.

**Compute principal components.**

When all variables are in the same unit, it is appropriate to compute principal components for raw data. When the variables are in different units or the difference in the variance of different columns is substantial (as in this case), scaling of the data or use of weights is often preferable.

Perform the principal component analysis by using the inverse variances of the ratings as weights.

```
w = 1./var(ratings);
[wcoeff,score,latent,tsquared,explained] = pca(ratings,...
'VariableWeights',w);
```

Or equivalently:

```
[wcoeff,score,latent,tsquared,explained] = pca(ratings,...
'VariableWeights','variance');
```

The following sections explain the five outputs of `pca`.

**Component coefficients.**

The first output, `wcoeff`, contains the coefficients of the principal components.

The first three principal component coefficient vectors are:

```
c3 = wcoeff(:,1:3)
```

```
c3 = wcoeff(:,1:3)
c3 =
```

```
1.0e+03 *  
0.0249 -0.0263 -0.0834  
0.8504 -0.5978 -0.4965  
0.4616 0.3004 -0.0073  
0.1005 -0.1269 0.0661  
0.5096 0.2606 0.2124  
0.0883 0.1551 0.0737  
2.1496 0.9043 -0.1229  
0.2649 -0.3106 -0.0411  
0.1469 -0.5111 0.6586
```

These coefficients are weighted, hence the coefficient matrix is not orthonormal.

#### **Transform coefficients.**

Transform the coefficients so that they are orthonormal.

```
coefforth = inv(diag(std(ratings)))*wcoeff;
```

Note that if you use a weights vector,  $w$ , while conducting the pca, then

```
coefforth = diag(sqrt(w))*wcoeff;
```

#### **Check coefficients are orthonormal.**

The transformed coefficients are now orthonormal.

```
I = c3'*c3
```

```
I =  
1.0000 -0.0000 -0.0000  
-0.0000 1.0000 -0.0000  
-0.0000 -0.0000 1.0000
```

#### **Component scores.**

The second output, `score`, contains the coordinates of the original data in the new coordinate system defined by the principal components. The `score`

matrix is the same size as the input data matrix. You can also obtain the component scores using the orthonormal coefficients and the standardized ratings as follows.

```
cscores = zscore(ratings)*coefforth;
```

cscores and score are identical matrices.

**Plot component scores.**

Create a plot of the first two columns of score.

```
figure()  
plot(score(:,1),score(:,2),'+')  
xlabel('1st Principal Component')  
ylabel('2nd Principal Component')
```

This plot shows the centered and scaled ratings data projected onto the first two principal components. `pca` computes the scores to have mean zero.

**Explore plot interactively.**

Note the outlying points in the right half of the plot. You can graphically identify these points as follows.

```
gname
```

Move your cursor over the plot and click once near the rightmost seven points. This labels the points by their row numbers as in the following figure.

After labeling points, press **Return**.

**Extract observation names.**

Create an index variable containing the row numbers of all the cities you chose and get the names of the cities.

```
metro = [43 65 179 213 234 270 314];
names(metro,:)
```

```
ans =
    Boston, MA
    Chicago, IL
```

```
Los Angeles, Long Beach, CA
New York, NY
Philadelphia, PA-NJ
San Francisco, CA
Washington, DC-MD-VA
```

These labeled cities are some of the biggest population centers in the United States and they appear more extreme than the remainder of the data.

**Component variances.**

The third output, `latent`, is a vector containing the variance explained by the corresponding principal component. Each column of `score` has a sample variance equal to the corresponding row of `latent`.

```
latent
```

```
latent =
```

```
3.4083
1.2140
1.1415
0.9209
0.7533
0.6306
0.4930
0.3180
0.1204
```

**Percent variance explained.**

The fifth output, `explained`, is a vector containing the percent variance explained by the corresponding principal component.

```
explained
```

```
explained =
```

```
37.8699
13.4886
12.6831
```

```
10.2324
 8.3698
 7.0062
 5.4783
 3.5338
 1.3378
```

**Create scree plot.**

Make a scree plot of the percent variability explained by each principal component.

```
figure()
pareto(explained)
xlabel('Principal Component')
ylabel('Variance Explained (%)')
```

This scree plot only shows the first seven (instead of the total nine) components that explain 95% of the total variance. The only clear break in the amount of variance accounted for by each component is between the first and second components. However, the first component by itself explains less than 40% of the variance, so more components might be needed. You can see that the first three principal components explain roughly two-thirds of the total variability in the standardized ratings, so that might be a reasonable way to reduce the dimensions.

**Hotelling's T-squared statistic.**

The last output from `pca` is `tsquared`, which is Hotelling's  $T^2$ , a statistical measure of the multivariate distance of each observation from the center of the data set. This is an analytical way to find the most extreme points in the data.

```
[st2,index] = sort(tsquared,'descend'); % sort in descending order
extreme = index(1);
names(extreme,:)
```

```
ans =
```

```
New York, NY
```

The ratings for New York are the furthest from the average U.S. city.

### **Visualize the results.**

Visualize both the orthonormal principal component coefficients for each variable and the principal component scores for each observation in a single plot.

```
biplot(coefforth(:,1:2), 'scores', score(:,1:2), 'varlabels', categories);
axis([-0.26 0.6 -0.51 0.51]);
```

All nine variables are represented in this bi-plot by a vector, and the direction and length of the vector indicate how each variable contributes to the two principal components in the plot. For example, the first principal component, on the horizontal axis, has positive coefficients for all nine variables. That is why the nine vectors are directed into the right half of the plot. The largest coefficients in the first principal component are the third and seventh elements, corresponding to the variables health and arts.

The second principal component, on the vertical axis, has positive coefficients for the variables education, health, arts, and transportation, and negative coefficients for the remaining five variables. This indicates that the

second component distinguishes among cities that have high values for the first set of variables and low for the second, and cities that have the opposite.

The variable labels in this figure are somewhat crowded. You can either exclude the `VarLabels` parameter when making the plot, or select and drag some of the labels to better positions using the `Edit Plot` tool from the figure window toolbar.

This 2-D bi-plot also includes a point for each of the 329 observations, with coordinates indicating the score of each observation for the two principal components in the plot. For example, points near the left edge of this plot have the lowest scores for the first principal component. The points are scaled with respect to the maximum score value and maximum coefficient length, so only their relative locations can be determined from the plot.

You can identify items in the plot by selecting **Tools>Data Cursor** from the figure window. By clicking a variable (vector), you can read that variable's coefficients for each principal component. By clicking an observation (point), you can read that observation's scores for each principal component.

### **Create a three-dimensional bi-plot.**

You can also make a bi-plot in three dimensions.

```
figure()  
biplot(coefforth(:,1:3), 'scores', score(:,1:3), 'obslabels', names);  
axis([-0.26 0.8 -0.51 0.51 -0.61 0.81]);  
view([30 40]);
```

This graph is useful if the first two principal coordinates do not explain enough of the variance in your data. You can also rotate the figure to see it from different angles by selecting the **Tools**> Rotate 3D.

## Factor Analysis

- “Introduction to Factor Analysis” on page 13-95
- “Example: Factor Analysis” on page 13-95

## Introduction to Factor Analysis

Multivariate data often includes a large number of measured variables, and sometimes those variables overlap, in the sense that groups of them might be dependent. For example, in a decathlon, each athlete competes in 10 events, but several of them can be thought of as speed events, while others can be thought of as strength events, etc. Thus, you can think of a competitor's 10 event scores as largely dependent on a smaller set of three or four types of athletic ability.

Factor analysis is a way to fit a model to multivariate data to estimate just this sort of interdependence. In a factor analysis model, the measured variables depend on a smaller number of unobserved (latent) factors. Because each factor might affect several variables in common, they are known as *common factors*. Each variable is assumed to be dependent on a linear combination of the common factors, and the coefficients are known as *loadings*. Each measured variable also includes a component due to independent random variability, known as *specific variance* because it is specific to one variable.

Specifically, factor analysis assumes that the covariance matrix of your data is of the form

$$\Sigma_x = \Lambda\Lambda^T + \Psi$$

where  $\Lambda$  is the matrix of loadings, and the elements of the diagonal matrix  $\Psi$  are the specific variances. The function `factoran` fits the Factor Analysis model using maximum likelihood.

### Example: Factor Analysis

- “Factor Loadings” on page 13-96
- “Factor Rotation” on page 13-98
- “Factor Scores” on page 13-101
- “Visualize the Results” on page 13-103

**Factor Loadings.** Over the course of 100 weeks, the percent change in stock prices for ten companies has been recorded. Of the ten companies, the first four can be classified as primarily technology, the next three as financial, and the last three as retail. It seems reasonable that the stock prices for companies that are in the same sector might vary together as economic conditions change. Factor Analysis can provide quantitative evidence that companies within each sector do experience similar week-to-week changes in stock price.

In this example, you first load the data, and then call `factoran`, specifying a model fit with three common factors. By default, `factoran` computes rotated estimates of the loadings to try and make their interpretation simpler. But in this example, you specify an unrotated solution.

```
load stockreturns
```

```
[Loadings,specificVar,T,stats] = factoran(stocks,3,'rotate','none');
```

The first two `factoran` return arguments are the estimated loadings and the estimated specific variances. Each row of the loadings matrix represents one of the ten stocks, and each column corresponds to a common factor. With unrotated estimates, interpretation of the factors in this fit is difficult because most of the stocks contain fairly large coefficients for two or more factors.

Loadings

```
Loadings =
```

0.8885	0.2367	-0.2354
0.7126	0.3862	0.0034
0.3351	0.2784	-0.0211
0.3088	0.1113	-0.1905
0.6277	-0.6643	0.1478
0.4726	-0.6383	0.0133
0.1133	-0.5416	0.0322
0.6403	0.1669	0.4960
0.2363	0.5293	0.5770
0.1105	0.1680	0.5524

---

**Note** “Factor Rotation” on page 13-98 helps to simplify the structure in the Loadings matrix, to make it easier to assign meaningful interpretations to the factors.

---

From the estimated specific variances, you can see that the model indicates that a particular stock price varies quite a lot beyond the variation due to the common factors.

```
specificVar
```

```
specificVar =
```

```
0.0991
0.3431
0.8097
0.8559
0.1429
0.3691
0.6928
0.3162
0.3311
0.6544
```

A specific variance of 1 would indicate that there is *no* common factor component in that variable, while a specific variance of 0 would indicate that the variable is *entirely* determined by common factors. These data seem to fall somewhere in between.

The  $p$  value returned in the `stats` structure fails to reject the null hypothesis of three common factors, suggesting that this model provides a satisfactory explanation of the covariation in these data.

```
stats.p
```

```
ans =
```

```
0.8144
```

To determine whether fewer than three factors can provide an acceptable fit, you can try a model with two common factors. The  $p$  value for this second fit is highly significant, and rejects the hypothesis of two factors, indicating that the simpler model is not sufficient to explain the pattern in these data.

```
[Loadings2,specificVar2,T2,stats2] = factoran(stocks, 2, 'rotate', 'none');
```

```
stats2.p
```

```
ans =
```

```
3.5610e-06
```

**Factor Rotation.** As the results illustrate, the estimated loadings from an unrotated factor analysis fit can have a complicated structure. The goal of factor rotation is to find a parameterization in which each variable has only a small number of large loadings. That is, each variable is affected by a small number of factors, preferably only one. This can often make it easier to interpret what the factors represent.

If you think of each row of the loadings matrix as coordinates of a point in  $M$ -dimensional space, then each factor corresponds to a coordinate axis. Factor rotation is equivalent to rotating those axes and computing new loadings in the rotated coordinate system. There are various ways to do this. Some methods leave the axes orthogonal, while others are oblique methods that change the angles between them. For this example, you can rotate the estimated loadings by using the promax criterion, a common oblique method.

```
[LoadingsPM,specVarPM] = factoran(stocks,3,'rotate','promax');  
LoadingsPM
```

```
LoadingsPM =
```

0.9452	0.1214	-0.0617
0.7064	-0.0178	0.2058
0.3885	-0.0994	0.0975
0.4162	-0.0148	-0.1298
0.1021	0.9019	0.0768
0.0873	0.7709	-0.0821
-0.1616	0.5320	-0.0888
0.2169	0.2844	0.6635
0.0016	-0.1881	0.7849
-0.2289	0.0636	0.6475

Promax rotation creates a simpler structure in the loadings, one in which most of the stocks have a large loading on only one factor. To see this structure more clearly, you can use the `biplot` function to plot each stock using its factor loadings as coordinates.

```
biplot(LoadingsPM, 'varlabels', num2str((1:10)'));  
axis square  
view(155,27);
```

This plot shows that promax has rotated the factor loadings to a simpler structure. Each stock depends primarily on only one factor, and it is possible to describe each factor in terms of the stocks that it affects. Based on which companies are near which axes, you could reasonably conclude that the first factor axis represents the financial sector, the second retail, and the third technology. The original conjecture, that stocks vary primarily within sector, is apparently supported by the data.

**Factor Scores.** Sometimes, it is useful to be able to classify an observation based on its factor scores. For example, if you accepted the three-factor model and the interpretation of the rotated factors, you might want to categorize each week in terms of how favorable it was for each of the three stock sectors, based on the data from the 10 observed stocks.

Because the data in this example are the raw stock price changes, and not just their correlation matrix, you can have `factoran` return estimates of the value of each of the three rotated common factors for each week. You can then plot the estimated scores to see how the different stock sectors were affected during each week.

```
[LoadingsPM,specVarPM,TPM,stats,F] = factoran(stocks, 3, 'rotate', 'promax');  
  
plot3(F(:,1),F(:,2),F(:,3), 'b. ')  
line([-4 4 NaN 0 0 NaN 0 0], [0 0 NaN -4 4 NaN 0 0],[0 0 NaN 0 0 NaN -4 4],  
xlabel('Financial Sector')  
ylabel('Retail Sector')  
zlabel('Technology Sector')  
grid on  
axis square  
view(-22.5, 8)
```

Oblique rotation often creates factors that are correlated. This plot shows some evidence of correlation between the first and third factors, and you can investigate further by computing the estimated factor correlation matrix.

```
inv(TPM' * TPM)
```

```
ans =
```

```
1.0000    0.1559    0.4082
```

```
0.1559    1.0000   -0.0559
0.4082   -0.0559    1.0000
```

**Visualize the Results.** You can use the `biplot` function to help visualize both the factor loadings for each variable and the factor scores for each observation in a single plot. For example, the following command plots the results from the factor analysis on the stock data and labels each of the 10 stocks.

```
biplot(LoadingsPM,'scores',F,'varlabels',num2str((1:10)))
xlabel('Financial Sector')
ylabel('Retail Sector')
zlabel('Technology Sector')
axis square
view(155,27)
```

In this case, the factor analysis includes three factors, and so the biplot is three-dimensional. Each of the 10 stocks is represented in this plot by a vector, and the direction and length of the vector indicates how each stock depends on the underlying factors. For example, you have seen that after promax rotation, the first four stocks have positive loadings on the first factor, and unimportant loadings on the other two factors. That first factor, interpreted as a financial sector effect, is represented in this biplot as one of the horizontal axes. The dependence of those four stocks on that factor corresponds to the four vectors directed approximately along that axis. Similarly, the dependence

of stocks 5, 6, and 7 primarily on the second factor, interpreted as a retail sector effect, is represented by vectors directed approximately along that axis.

Each of the 100 observations is represented in this plot by a point, and their locations indicate the score of each observation for the three factors. For example, points near the top of this plot have the highest scores for the technology sector factor. The points are scaled to fit within the unit square, so only their relative locations can be determined from the plot.

You can use the **Data Cursor** tool from the **Tools** menu in the figure window to identify the items in this plot. By clicking a stock (vector), you can read off that stock's loadings for each factor. By clicking an observation (point), you can read off that observation's scores for each factor.

## Partial Least Squares Regression and Principal Components Regression

This example shows how to apply Partial Least Squares Regression (PLSR) and Principal Components Regression (PCR), and discusses the effectiveness of the two methods. PLSR and PCR are both methods to model a response variable when there are a large number of predictor variables, and those predictors are highly correlated or even collinear. Both methods construct new predictor variables, known as components, as linear combinations of the original predictor variables, but they construct those components in different ways. PCR creates components to explain the observed variability in the predictor variables, without considering the response variable at all. On the other hand, PLSR does take the response variable into account, and therefore often leads to models that are able to fit the response variable with fewer components. Whether or not that ultimately translates into a more parsimonious model, in terms of its practical use, depends on the context.

### Loading the Data

Load a data set comprising spectral intensities of 60 samples of gasoline at 401 wavelengths, and their octane ratings. These data are described in Kalivas, John H., "Two Data Sets of Near Infrared Spectra," *Chemometrics and Intelligent Laboratory Systems*, v.37 (1997) pp.255-259.

```
load spectra
whos NIR octane
```

Name	Size	Bytes	Class	Attributes
NIR	60x401	192480	double	
octane	60x1	480	double	

```
[dummy,h] = sort(octane);
oldorder = get(gcf,'DefaultAxesColorOrder');
set(gcf,'DefaultAxesColorOrder',jet(60));
plot3(repmat(1:401,60,1)',repmat(octane(h),1,401)',NIR(h,:));
set(gcf,'DefaultAxesColorOrder',oldorder);
xlabel('Wavelength Index'); ylabel('Octane'); axis('tight');
grid on
```

### Fitting the Data with Two Components

Use the `plsregress` function to fit a PLSR model with ten PLS components and one response.

```
X = NIR;  
y = octane;  
[n,p] = size(X);  
[Xloadings,Yloadings,Xscores,Yscores,betaPLS10,PLSPctVar] = plsregress(...  
X,y,10);
```

Ten components may be more than will be needed to adequately fit the data, but diagnostics from this fit can be used to make a choice of a simpler model with fewer components. For example, one quick way to choose the number of components is to plot the percent of variance explained in the response variable as a function of the number of components.

```
plot(1:10,cumsum(100*PLSPctVar(2,:)),'-bo');  
xlabel('Number of PLS components');  
ylabel('Percent Variance Explained in Y');
```

In practice, more care would probably be advisable in choosing the number of components. Cross-validation, for instance, is a widely-used method that will be illustrated later in this example. For now, the above plot suggests that PLSR with two components explains most of the variance in the observed  $y$ . Compute the fitted response values for the two-component model.

```
[Xloadings,Yloadings,Xscores,Yscores,betaPLS] = plsregress(X,y,2);
yfitPLS = [ones(n,1) X]*betaPLS;
```

Next, fit a PCR model with two principal components. The first step is to perform Principal Components Analysis on  $X$ , using the `pca` function, and retaining two principal components. PCR is then just a linear regression of the response variable on those two components. It often makes sense to normalize each variable first by its standard deviation when the variables have very different amounts of variability, however, that is not done here.

```
[PCALoadings,PCAScores,PCAVar] = pca(X,'Economy',false);
betaPCR = regress(y-mean(y), PCAScores(:,1:2));
```

To make the PCR results easier to interpret in terms of the original spectral data, transform to regression coefficients for the original, uncentered variables.

```
betaPCR = PCALoadings(:,1:2)*betaPCR;
betaPCR = [mean(y) - mean(X)*betaPCR; betaPCR];
yfitPCR = [ones(n,1) X]*betaPCR;
```

Plot fitted vs. observed response for the PLSR and PCR fits.

```
plot(y,yfitPLS,'bo',y,yfitPCR,'r^');
xlabel('Observed Response');
ylabel('Fitted Response');
legend({'PLSR with 2 Components' 'PCR with 2 Components'}, ...
      'location','NW');
```

In a sense, the comparison in the plot above is not a fair one -- the number of components (two) was chosen by looking at how well a two-component PLSR model predicted the response, and there's no reason why the PCR model should be restricted to that same number of components. With the same number of components, however, PLSR does a much better job at fitting  $y$ . In fact, looking at the horizontal scatter of fitted values in the plot above, PCR with two components is hardly better than using a constant model. The  $r$ -squared values from the two regressions confirm that.

$$\text{TSS} = \text{sum}((y - \text{mean}(y)).^2);$$

```
RSS_PLS = sum((y-yfitPLS).^2);  
rsquaredPLS = 1 - RSS_PLS/TSS
```

```
rsquaredPLS =
```

```
0.9466
```

```
RSS_PCR = sum((y-yfitPCR).^2);  
rsquaredPCR = 1 - RSS_PCR/TSS
```

```
rsquaredPCR =
```

```
0.1962
```

Another way to compare the predictive power of the two models is to plot the response variable against the two predictors in both cases.

```
plot3(Xscores(:,1),Xscores(:,2),y-mean(y),'bo');  
legend('PLSR');  
grid on; view(-30,30);
```

It's a little hard to see without being able to interactively rotate the figure, but the PLSR plot above shows points closely scattered about a plane. On the other hand, the PCR plot below shows a cloud of points with little indication of a linear relationship.

```
plot3(PCAScores(:,1),PCAScores(:,2),y-mean(y),'r^');  
legend('PCR');  
grid on; view(-30,30);
```

Notice that while the two PLS components are much better predictors of the observed  $y$ , the following figure shows that they explain somewhat less variance in the observed  $X$  than the first two principal components used in the PCR.

```
plot(1:10,100*cumsum(PLSPctVar(1,:)), 'b-o', 1:10, ...
     100*cumsum(PCAVar(1:10))/sum(PCAVar(1:10)), 'r-^');
xlabel('Number of Principal Components');
ylabel('Percent Variance Explained in X');
legend({'PLSR' 'PCR'}, 'location', 'SE');
```

The fact that the PCR curve is uniformly higher suggests why PCR with two components does such a poor job, relative to PLSR, in fitting  $y$ . PCR constructs components to best explain  $X$ , and as a result, those first two components ignore the information in the data that is important in fitting the observed  $y$ .

#### **Fitting with More Components**

As more components are added in PCR, it will necessarily do a better job of fitting the original data  $y$ , simply because at some point most of the important

predictive information in  $X$  will be present in the principal components. For example, the following figure shows that the difference in residuals for the two methods is much less dramatic when using ten components than it was for two components.

```
yfitPLS10 = [ones(n,1) X]*betaPLS10;
betaPCR10 = regress(y-mean(y), PCAScores(:,1:10));
betaPCR10 = PCALoadings(:,1:10)*betaPCR10;
betaPCR10 = [mean(y) - mean(X)*betaPCR10; betaPCR10];
yfitPCR10 = [ones(n,1) X]*betaPCR10;
plot(y,yfitPLS10,'bo',y,yfitPCR10,'r^');
xlabel('Observed Response');
ylabel('Fitted Response');
legend({'PLSR with 10 components' 'PCR with 10 Components'}, ...
       'location','NW');
```

Both models fit  $y$  fairly accurately, although PLSR still makes a slightly more accurate fit. However, ten components is still an arbitrarily-chosen number for either model.

#### **Choosing the Number of Components with Cross-Validation**

It's often useful to choose the number of components to minimize the expected error when predicting the response from future observations on the predictor variables. Simply using a large number of components will do a good job in fitting the current observed data, but is a strategy that leads to overfitting.

Fitting the current data too well results in a model that does not generalize well to other data, and gives an overly-optimistic estimate of the expected error.

Cross-validation is a more statistically sound method for choosing the number of components in either PLSR or PCR. It avoids overfitting data by not reusing the same data to both fit a model and to estimate prediction error. Thus, the estimate of prediction error is not optimistically biased downwards.

`plsregress` has an option to estimate the mean squared prediction error (MSEP) by cross-validation, in this case using 10-fold C-V.

```
[X1,Y1,Xs,Ys,beta,pctVar,PLSmsep] = plsregress(X,y,10,'CV',10);
```

For PCR, `crossval` combined with a simple function to compute the sum of squared errors for PCR, can estimate the MSEP, again using 10-fold cross-validation.

```
PCRmsep = sum(crossval(@pcrsse,X,y,'KFold',10),1) / n;
```

The MSEP curve for PLSR indicates that two or three components does about as good a job as possible. On the other hand, PCR needs four components to get the same prediction accuracy.

```
plot(0:10,PLSmsep(2,:), 'b-o',0:10,PCRmsep, 'r-^');  
xlabel('Number of components');  
ylabel('Estimated Mean Squared Prediction Error');  
legend({'PLSR' 'PCR'}, 'location', 'NE');
```

In fact, the second component in PCR *increases* the prediction error of the model, suggesting that the combination of predictor variables contained in that component is not strongly correlated with  $y$ . Again, that's because PCR constructs components to explain variation in  $X$ , not  $y$ .

### Model Parsimony

So if PCR requires four components to get the same prediction accuracy as PLSR with three components, is the PLSR model more parsimonious? That depends on what aspect of the model you consider.

The PLS weights are the linear combinations of the original variables that define the PLS components, i.e., they describe how strongly each component in the PLSR depends on the original variables, and in what direction.

```
[X1,Y1,Xs,Ys,beta,pctVar,mse,stats] = plsregress(X,y,3);  
plot(1:401,stats.W,'-');  
xlabel('Variable');  
ylabel('PLS Weight');  
legend({'1st Component' '2nd Component' '3rd Component'}, ...  
       'location','NW');
```

Similarly, the PCA loadings describe how strongly each component in the PCR depends on the original variables.

```
plot(1:401,PCALoadings(:,1:4),'-');  
xlabel('Variable');  
ylabel('PCA Loading');  
legend({'1st Component' '2nd Component' '3rd Component' ...  
      '4th Component'},'location','NW');
```

For either PLSR or PCR, it may be that each component can be given a physically meaningful interpretation by inspecting which variables it weights

most heavily. For instance, with these spectral data it may be possible to interpret intensity peaks in terms of compounds present in the gasoline, and then to observe that weights for a particular component pick out a small number of those compounds. From that perspective, fewer components are simpler to interpret, and because PLSR often requires fewer components to predict the response adequately, it leads to more parsimonious models.

On the other hand, both PLSR and PCR result in one regression coefficient for each of the original predictor variables, plus an intercept. In that sense, neither is more parsimonious, because regardless of how many components are used, both models depend on all predictors. More concretely, for these data, both models need 401 spectral intensity values in order to make a prediction.

However, the ultimate goal may be to reduce the original set of variables to a smaller subset still able to predict the response accurately. For example, it may be possible to use the PLS weights or the PCA loadings to select only those variables that contribute most to each component. As shown earlier, some components from a PCR model fit may serve primarily to describe the variation in the predictor variables, and may include large weights for variables that are not strongly correlated with the response. Thus, PCR can lead to retaining variables that are unnecessary for prediction.

For the data used in this example, the difference in the number of components needed by PLSR and PCR for accurate prediction is not great, and the PLS weights and PCA loadings seem to pick out the same variables. That may not be true for other data.

# Cluster Analysis

- “k-Means Clustering” on page 14-22
- “Gaussian Mixture Models” on page 14-30

## Introduction to Cluster Analysis

*Cluster analysis*, also called *segmentation analysis* or *taxonomy analysis*, creates groups, or *clusters*, of data. Clusters are formed in such a way that objects in the same cluster are very similar and objects in different clusters are very distinct. Measures of similarity depend on the application.

“Hierarchical Clustering” on page 14-3 groups data over a variety of scales by creating a cluster tree or *dendrogram*. The tree is not a single set of clusters, but rather a multilevel hierarchy, where clusters at one level are joined as clusters at the next level. This allows you to decide the level or scale of clustering that is most appropriate for your application. The Statistics Toolbox function `clusterdata` performs all of the necessary steps for you. It incorporates the `pdist`, `linkage`, and `cluster` functions, which may be used separately for more detailed analysis. The `dendrogram` function plots the cluster tree.

“k-Means Clustering” on page 14-22 is a partitioning method. The function `kmeans` partitions data into  $k$  mutually exclusive clusters, and returns the index of the cluster to which it has assigned each observation. Unlike hierarchical clustering, k-means clustering operates on actual observations (rather than the larger set of dissimilarity measures), and creates a single level of clusters. The distinctions mean that k-means clustering is often more suitable than hierarchical clustering for large amounts of data.

“Gaussian Mixture Models” on page 14-30 form clusters by representing the probability density function of observed variables as a mixture of multivariate normal densities. Mixture models of the `gmdistribution` class use an expectation maximization (EM) algorithm to fit data, which assigns posterior probabilities to each component density with respect to each observation. Clusters are assigned by selecting the component that maximizes the posterior probability. Clustering using Gaussian mixture models is sometimes considered a soft clustering method. The posterior probabilities for each point indicate that each data point has some probability of belonging to each cluster. Like k-means clustering, Gaussian mixture modeling uses an iterative algorithm that converges to a local optimum. Gaussian mixture modeling may be more appropriate than k-means clustering when clusters have different sizes and correlation within them.

# Hierarchical Clustering

## Introduction to Hierarchical Clustering

Hierarchical clustering groups data over a variety of scales by creating a cluster tree or *dendrogram*. The tree is not a single set of clusters, but rather a multilevel hierarchy, where clusters at one level are joined as clusters at the next level. This allows you to decide the level or scale of clustering that is most appropriate for your application. The Statistics Toolbox function `clusterdata` supports agglomerative clustering and performs all of the necessary steps for you. It incorporates the `pdist`, `linkage`, and `cluster` functions, which you can use separately for more detailed analysis. The `dendrogram` function plots the cluster tree.

## Algorithm Description

To perform agglomerative hierarchical cluster analysis on a data set using Statistics Toolbox functions, follow this procedure:

- 1 Find the similarity or dissimilarity between every pair of objects in the data set.** In this step, you calculate the *distance* between objects using the `pdist` function. The `pdist` function supports many different ways to compute this measurement. See “Similarity Measures” on page 14-4 for more information.
- 2 Group the objects into a binary, hierarchical cluster tree.** In this step, you link pairs of objects that are in close proximity using the `linkage`

function. The `linkage` function uses the distance information generated in step 1 to determine the proximity of objects to each other. As objects are paired into binary clusters, the newly formed clusters are grouped into larger clusters until a hierarchical tree is formed. See “Linkages” on page 14-6 for more information.

**3 Determine where to cut the hierarchical tree into clusters.** In this step, you use the `cluster` function to prune branches off the bottom of the hierarchical tree, and assign all the objects below each cut to a single cluster. This creates a partition of the data. The `cluster` function can create these clusters by detecting natural groupings in the hierarchical tree or by cutting off the hierarchical tree at an arbitrary point.

The following sections provide more information about each of these steps.

---

**Note** The Statistics Toolbox function `clusterdata` performs all of the necessary steps for you. You do not need to execute the `pdist`, `linkage`, or `cluster` functions separately.

---

## Similarity Measures

You use the `pdist` function to calculate the distance between every pair of objects in a data set. For a data set made up of  $m$  objects, there are  $m*(m - 1)/2$  pairs in the data set. The result of this computation is commonly known as a distance or dissimilarity matrix.

There are many ways to calculate this distance information. By default, the `pdist` function calculates the Euclidean distance between objects; however, you can specify one of several other options. See `pdist` for more information.

---

**Note** You can optionally normalize the values in the data set before calculating the distance information. In a real world data set, variables can be measured against different scales. For example, one variable can measure Intelligence Quotient (IQ) test scores and another variable can measure head circumference. These discrepancies can distort the proximity calculations. Using the `zscore` function, you can convert all the values in the data set to use the same proportional scale. See `zscore` for more information.

---

For example, consider a data set,  $X$ , made up of five objects where each object is a set of  $x,y$  coordinates.

- **Object 1:** 1, 2
- **Object 2:** 2.5, 4.5
- **Object 3:** 2, 2
- **Object 4:** 4, 1.5
- **Object 5:** 4, 2.5

You can define this data set as a matrix

and pass it to `pdist`. The `pdist` function calculates the distance between object 1 and object 2, object 1 and object 3, and so on until the distances between all the pairs have been calculated. The following figure plots these objects in a graph. The Euclidean distance between object 2 and object 3 is shown to illustrate one interpretation of distance.

### Distance Information

The `pdist` function returns this distance information in a vector,  $Y$ , where each element contains the distance between a pair of objects.

$Y = \text{pdist}(X)$

```

Y =

Columns 1 through 7

    2.9155    1.0000    3.0414    3.0414    2.5495    3.3541    2.5000

Columns 8 through 10

    2.0616    2.0616    1.0000

```

To make it easier to see the relationship between the distance information generated by `pdist` and the objects in the original data set, you can reformat the distance vector into a matrix using the `squareform` function. In this matrix, element  $i,j$  corresponds to the distance between object  $i$  and object  $j$  in the original data set. In the following example, element 1,1 represents the distance between object 1 and itself (which is zero). Element 1,2 represents the distance between object 1 and object 2, and so on.

```
squareform(Y)
```

```

ans =

    0    2.9155    1.0000    3.0414    3.0414
  2.9155    0    2.5495    3.3541    2.5000
  1.0000    2.5495    0    2.0616    2.0616
  3.0414    3.3541    2.0616    0    1.0000
  3.0414    2.5000    2.0616    1.0000    0

```

## Linkages

Once the proximity between objects in the data set has been computed, you can determine how objects in the data set should be grouped into clusters, using the `linkage` function. The `linkage` function takes the distance information generated by `pdist` and links pairs of objects that are close together into binary clusters (clusters made up of two objects). The `linkage` function then links these newly formed clusters to each other and to other

objects to create bigger clusters until all the objects in the original data set are linked together in a hierarchical tree.

For example, given the distance vector `Y` generated by `pdist` from the sample data set of  $x$ - and  $y$ -coordinates, the `linkage` function generates a hierarchical cluster tree, returning the linkage information in a matrix, `Z`.

```
Z = linkage(Y)
```

```
Z =
```

```

4.0000    5.0000    1.0000
1.0000    3.0000    1.0000
6.0000    7.0000    2.0616
2.0000    8.0000    2.5000
```

In this output, each row identifies a link between objects or clusters. The first two columns identify the objects that have been linked. The third column contains the distance between these objects. For the sample data set of  $x$ - and  $y$ -coordinates, the `linkage` function begins by grouping objects 4 and 5, which have the closest proximity (distance value = 1.0000). The `linkage` function continues by grouping objects 1 and 3, which also have a distance value of 1.0000.

The third row indicates that the `linkage` function grouped objects 6 and 7. If the original sample data set contained only five objects, what are objects 6 and 7? Object 6 is the newly formed binary cluster created by the grouping of objects 4 and 5. When the `linkage` function groups two objects into a new cluster, it must assign the cluster a unique index value, starting with the value  $m+1$ , where  $m$  is the number of objects in the original data set. (Values 1 through  $m$  are already used by the original data set.) Similarly, object 7 is the cluster formed by grouping objects 1 and 3.

`linkage` uses distances to determine the order in which it clusters objects. The distance vector `Y` contains the distances between the original objects 1 through 5. But `linkage` must also be able to determine distances involving clusters that it creates, such as objects 6 and 7. By default, `linkage` uses a

method known as single linkage. However, there are a number of different methods available. See the `linkage` reference page for more information.

As the final cluster, the `linkage` function grouped object 8, the newly formed cluster made up of objects 6 and 7, with object 2 from the original data set. The following figure graphically illustrates the way `linkage` groups the objects into a hierarchy of clusters.

## Dendrograms

The hierarchical, binary cluster tree created by the `linkage` function is most easily understood when viewed graphically. The Statistics Toolbox function `dendrogram` plots the tree as follows.

```
dendrogram(Z)
```

In the figure, the numbers along the horizontal axis represent the indices of the objects in the original data set. The links between objects are represented as upside-down U-shaped lines. The height of the U indicates the distance between the objects. For example, the link representing the cluster containing objects 1 and 3 has a height of 1. The link representing the cluster that groups object 2 together with objects 1, 3, 4, and 5, (which are already clustered as object 8) has a height of 2.5. The height represents the distance linkage computes between objects 2 and 8. For more information about creating a dendrogram diagram, see the `dendrogram` reference page.

## Verify the Cluster Tree

After linking the objects in a data set into a hierarchical cluster tree, you might want to verify that the distances (that is, heights) in the tree reflect the original distances accurately. In addition, you might want to investigate natural divisions that exist among links between objects. Statistics Toolbox functions are available for both of these tasks, as described in the following sections.

- “Verify Dissimilarity” on page 14-10
- “Verify Consistency” on page 14-11

### Verify Dissimilarity

In a hierarchical cluster tree, any two objects in the original data set are eventually linked together at some level. The height of the link represents the distance between the two clusters that contain those two objects. This height is known as the *cophenetic distance* between the two objects. One way to measure how well the cluster tree generated by the `linkage` function reflects your data is to compare the cophenetic distances with the original distance data generated by the `pdist` function. If the clustering is valid, the linking of objects in the cluster tree should have a strong correlation with the distances between objects in the distance vector. The `cophenet` function compares these two sets of values and computes their correlation, returning a value called the *cophenetic correlation coefficient*. The closer the value of the cophenetic correlation coefficient is to 1, the more accurately the clustering solution reflects your data.

You can use the cophenetic correlation coefficient to compare the results of clustering the same data set using different distance calculation methods or clustering algorithms. For example, you can use the `cophenet` function to evaluate the clusters created for the sample data set.

```
c = cophenet(Z,Y)
```

```
c =
```

```
0.8615
```

Z is the matrix output by the linkage function and Y is the distance vector output by the pdist function.

Execute pdist again on the same data set, this time specifying the city block metric. After running the linkage function on this new pdist output using the average linkage method, call cophenet to evaluate the clustering solution.

```
Y = pdist(X, 'cityblock');  
Z = linkage(Y, 'average');  
c = cophenet(Z,Y)
```

```
c =  
  
    0.9047
```

The cophenetic correlation coefficient shows that using a different distance and linkage method creates a tree that represents the original distances slightly better.

### **Verify Consistency**

One way to determine the natural cluster divisions in a data set is to compare the height of each link in a cluster tree with the heights of neighboring links below it in the tree.

A link that is approximately the same height as the links below it indicates that there are no distinct divisions between the objects joined at this level of the hierarchy. These links are said to exhibit a high level of consistency, because the distance between the objects being joined is approximately the same as the distances between the objects they contain.

On the other hand, a link whose height differs noticeably from the height of the links below it indicates that the objects joined at this level in the cluster tree are much farther apart from each other than their components were when they were joined. This link is said to be inconsistent with the links below it.

In cluster analysis, inconsistent links can indicate the border of a natural division in a data set. The `cluster` function uses a quantitative measure of inconsistency to determine where to partition your data set into clusters.

The following dendrogram illustrates inconsistent links. Note how the objects in the dendrogram fall into two groups that are connected by links at a much higher level in the tree. These links are inconsistent when compared with the links below them in the hierarchy.

These links show inconsistency when compared to the links below them.

These links show consistency.

The relative consistency of each link in a hierarchical cluster tree can be quantified and expressed as the *inconsistency coefficient*. This value compares the height of a link in a cluster hierarchy with the average height of links below it. Links that join distinct clusters have a high inconsistency coefficient; links that join indistinct clusters have a low inconsistency coefficient.

To generate a listing of the inconsistency coefficient for each link in the cluster tree, use the `inconsistent` function. By default, the `inconsistent` function compares each link in the cluster hierarchy with adjacent links that are less than two levels below it in the cluster hierarchy. This is called the *depth* of the comparison. You can also specify other depths. The objects at the bottom of the cluster tree, called leaf nodes, that have no further objects below them, have an inconsistency coefficient of zero. Clusters that join two leaves also have a zero inconsistency coefficient.

For example, you can use the `inconsistent` function to calculate the inconsistency values for the links created by the `linkage` function in “Linkages” on page 14-6.

First, recompute the distance and linkage values using the default settings.

```
Y = pdist(X);
Z = linkage(Y);
```

Next, use `inconsistent` to calculate the inconsistency values.

```
I = inconsistent(Z)
```

```
I =
```

1.0000	0	1.0000	0
1.0000	0	1.0000	0
1.3539	0.6129	3.0000	1.1547
2.2808	0.3100	2.0000	0.7071

The `inconsistent` function returns data about the links in an  $(m-1)$ -by-4 matrix, whose columns are described in the following table.

Column	Description
1	Mean of the heights of all the links included in the calculation
2	Standard deviation of all the links included in the calculation
3	Number of links included in the calculation
4	Inconsistency coefficient

In the sample output, the first row represents the link between objects 4 and 5. This cluster is assigned the index 6 by the `linkage` function. Because both 4 and 5 are leaf nodes, the inconsistency coefficient for the cluster is zero. The second row represents the link between objects 1 and 3, both of which are also leaf nodes. This cluster is assigned the index 7 by the `linkage` function.

The third row evaluates the link that connects these two clusters, objects 6 and 7. (This new cluster is assigned index 8 in the `linkage` output). Column 3 indicates that three links are considered in the calculation: the link itself and the two links directly below it in the hierarchy. Column 1 represents the mean of the heights of these links. The `inconsistent` function uses the height information output by the `linkage` function to calculate the mean. Column 2 represents the standard deviation between the links. The last column contains the inconsistency value for these links, 1.1547. It is the difference between the current link height and the mean, normalized by the standard deviation.

$$(2.0616 - 1.3539) / .6129$$

ans =

$$1.1547$$

The following figure illustrates the links and heights included in this calculation.

---

**Note** In the preceding figure, the lower limit on the y-axis is set to 0 to show the heights of the links. To set the lower limit to 0, select **Axes Properties** from the **Edit** menu, click the **Y Axis** tab, and enter 0 in the field immediately to the right of **Y Limits**.

---

Row 4 in the output matrix describes the link between object 8 and object 2. Column 3 indicates that two links are included in this calculation: the link itself and the link directly below it in the hierarchy. The inconsistency coefficient for this link is 0.7071.

The following figure illustrates the links and heights included in this calculation.

### Create Clusters

After you create the hierarchical tree of binary clusters, you can prune the tree to partition your data into clusters using the `cluster` function. The `cluster` function lets you create clusters in two ways, as discussed in the following sections:

- “Find Natural Divisions in Data” on page 14-17

- “Specify Arbitrary Clusters” on page 14-18

### Find Natural Divisions in Data

The hierarchical cluster tree may naturally divide the data into distinct, well-separated clusters. This can be particularly evident in a dendrogram diagram created from data where groups of objects are densely packed in certain areas and not in others. The inconsistency coefficient of the links in the cluster tree can identify these divisions where the similarities between objects change abruptly. (See “Verify the Cluster Tree” on page 14-10 for more information about the inconsistency coefficient.) You can use this value to determine where the `cluster` function creates cluster boundaries.

For example, if you use the `cluster` function to group the sample data set into clusters, specifying an inconsistency coefficient threshold of 1.2 as the value of the `cutoff` argument, the `cluster` function groups all the objects in the sample data set into one cluster. In this case, none of the links in the cluster hierarchy had an inconsistency coefficient greater than 1.2.

```
T = cluster(Z, 'cutoff', 1.2)
```

```
T =
```

```

1
1
1
1
1
```

The `cluster` function outputs a vector, `T`, that is the same size as the original data set. Each element in this vector contains the number of the cluster into which the corresponding object from the original data set was placed.

If you lower the inconsistency coefficient threshold to 0.8, the `cluster` function divides the sample data set into three separate clusters.

```
T = cluster(Z, 'cutoff', 0.8)
```

```
T =  
  
    3  
    2  
    3  
    1  
    1
```

This output indicates that objects 1 and 3 were placed in cluster 1, objects 4 and 5 were placed in cluster 2, and object 2 was placed in cluster 3.

When clusters are formed in this way, the cutoff value is applied to the inconsistency coefficient. These clusters may, but do not necessarily, correspond to a horizontal slice across the dendrogram at a certain height. If you want clusters corresponding to a horizontal slice of the dendrogram, you can either use the `criterion` option to specify that the cutoff should be based on distance rather than inconsistency, or you can specify the number of clusters directly as described in the following section.

### Specify Arbitrary Clusters

Instead of letting the `cluster` function create clusters determined by the natural divisions in the data set, you can specify the number of clusters you want created.

For example, you can specify that you want the `cluster` function to partition the sample data set into two clusters. In this case, the `cluster` function creates one cluster containing objects 1, 3, 4, and 5 and another cluster containing object 2.

```
T = cluster(Z, 'maxclust', 2)
```

```
T =  
  
    2  
    1  
    2
```

2  
2

To help you visualize how the `cluster` function determines these clusters, the following figure shows the dendrogram of the hierarchical cluster tree. The horizontal dashed line intersects two lines of the dendrogram, corresponding to setting `'maxclust'` to 2. These two lines partition the objects into two clusters: the objects below the left-hand line, namely 1, 3, 4, and 5, belong to one cluster, while the object below the right-hand line, namely 2, belongs to the other cluster.

On the other hand, if you set 'maxclust' to 3, the cluster function groups objects 4 and 5 in one cluster, objects 1 and 3 in a second cluster, and object 2 in a third cluster. The following command illustrates this.

```
T = cluster(Z, 'maxclust', 3)
```

```
T =
```

```
2  
3  
2  
1  
1
```

This time, the cluster function cuts off the hierarchy at a lower point, corresponding to the horizontal line that intersects three lines of the dendrogram in the following figure.

## k-Means Clustering

### In this section...

“Introduction to k-Means Clustering” on page 14-22

“Create Clusters and Determine Separation” on page 14-23

“Determine the Correct Number of Clusters” on page 14-25

“Avoid Local Minima” on page 14-28

### Introduction to k-Means Clustering

k-means clustering is a partitioning method. The function `kmeans` partitions data into  $k$  mutually exclusive clusters, and returns the index of the cluster to which it has assigned each observation. Unlike hierarchical clustering, k-means clustering operates on actual observations (rather than the larger set of dissimilarity measures), and creates a single level of clusters. The distinctions mean that k-means clustering is often more suitable than hierarchical clustering for large amounts of data.

`kmeans` treats each observation in your data as an object having a location in space. It finds a partition in which objects within each cluster are as close to each other as possible, and as far from objects in other clusters as possible. You can choose from five different distance measures, depending on the kind of data you are clustering.

Each cluster in the partition is defined by its member objects and by its centroid, or center. The centroid for each cluster is the point to which the sum of distances from all objects in that cluster is minimized. `kmeans` computes cluster centroids differently for each distance measure, to minimize the sum with respect to the measure that you specify.

`kmeans` uses an iterative algorithm that minimizes the sum of distances from each object to its cluster centroid, over all clusters. This algorithm moves objects between clusters until the sum cannot be decreased further. The result is a set of clusters that are as compact and well-separated as possible. You can control the details of the minimization using several optional input parameters to `kmeans`, including ones for the initial values of the cluster centroids, and for the maximum number of iterations.

## Create Clusters and Determine Separation

The following example explores possible clustering in four-dimensional data by analyzing the results of partitioning the points into three, four, and five clusters.

---

**Note** Because each part of this example generates random numbers sequentially, i.e., without setting a new state, you must perform all steps in sequence to duplicate the results shown. If you perform the steps out of sequence, the answers will be essentially the same, but the intermediate results, number of iterations, or ordering of the silhouette plots may differ.

---

First, load some data:

```
rng('default'); % For reproducibility
load kmeansdata;
size(X)
```

```
ans =
```

```
560    4
```

Even though these data are four-dimensional, and cannot be easily visualized, `kmeans` enables you to investigate whether a group structure exists in them. Call `kmeans` with `k`, the desired number of clusters, equal to 3. For this example, specify the city block distance measure, and use the default starting method of initializing centroids from randomly selected data points.

```
idx3 = kmeans(X,3,'distance','city');
```

To get an idea of how well-separated the resulting clusters are, you can make a silhouette plot using the cluster indices output from `kmeans`. The silhouette plot displays a measure of how close each point in one cluster is to points in the neighboring clusters. This measure ranges from +1, indicating points that are very distant from neighboring clusters, through 0, indicating points that are not distinctly in one cluster or another, to -1, indicating points that are

probably assigned to the wrong cluster. `silhouette` returns these values in its first output.

```
[silh3,h] = silhouette(X,idx3,'city');  
set(get(gca,'Children'),'FaceColor',[.8 .8 1])  
xlabel('Silhouette Value')  
ylabel('Cluster')
```

From the silhouette plot, you can see that most points in the second cluster have a large silhouette value, greater than 0.6, indicating that the cluster is somewhat separated from neighboring clusters. However, the third cluster

contains many points with low silhouette values, and the first contains a few points with negative values, indicating that those two clusters are not well separated.

## Determine the Correct Number of Clusters

Increase the number of clusters to see if `kmeans` can find a better grouping of the data. This time, use the optional `'display'` parameter to print information about each iteration.

```
idx4 = kmeans(X,4, 'dist','city', 'display','iter');
```

```

iter phase      num      sum
   1     1      560    2077.43
   2     1       51    1778.64
   3     1        3    1771.1
   4     2         0    1771.1
Best total sum of distances = 1771.1
```

Notice that the total sum of distances decreases at each iteration as `kmeans` reassigns points between clusters and recomputes cluster centroids. In this case, the second phase of the algorithm did not make any reassignments, indicating that the first phase reached a minimum after five iterations. In some problems, the first phase might not reach a minimum, but the second phase always will.

A silhouette plot for this solution indicates that these four clusters are better separated than the three in the previous solution.

```
[silh4,h] = silhouette(X,idx4,'city');
set(get(gca,'Children'),'FaceColor',[.8 .8 1])
xlabel('Silhouette Value')
ylabel('Cluster')
```

A more quantitative way to compare the two solutions is to look at the average silhouette values for the two cases.

```
cluster3 = mean(silh3)
cluster4 = mean(silh4)
```

```
cluster3 =
    0.5352
```

```
cluster4 =
```

```
    0.6400
```

Finally, try clustering the data using five clusters.

```
idx5 = kmeans(X,5,'dist','city','replicates',5);  
[silh5,h] = silhouette(X,idx5,'city');  
set(get(gca,'Children'),'FaceColor',[.8 .8 1])  
xlabel('Silhouette Value')  
ylabel('Cluster')  
mean(silh5)
```

```
ans =
```

```
    0.5266
```

This silhouette plot indicates that this is probably not the right number of clusters, since two of the clusters contain points with mostly low silhouette values. Without some knowledge of how many clusters are really in the data, it is a good idea to experiment with a range of values for  $k$ .

### **Avoid Local Minima**

Like many other types of numerical minimizations, the solution that  $k$ means reaches often depends on the starting points. It is possible for  $k$ means to reach a local minimum, where reassigning any one point to a new cluster

would increase the total sum of point-to-centroid distances, but where a better solution does exist. However, you can use the optional 'replicates' parameter to overcome that problem.

For four clusters, specify five replicates, and use the 'display' parameter to print out the final sum of distances for each of the solutions.

```
[idx4,cent4,sumdist] = kmeans(X,4,'dist','city',...  
                             'display','final','replicates',5);
```

```
Replicate 1, 4 iterations, total sum of distances = 1771.1.  
Replicate 2, 7 iterations, total sum of distances = 1771.1.  
Replicate 3, 8 iterations, total sum of distances = 1771.1.  
Replicate 4, 5 iterations, total sum of distances = 1771.1.  
Replicate 5, 6 iterations, total sum of distances = 1771.1.  
Best total sum of distances = 1771.1
```

In this example, `kmeans` found the same minimum in all five replications. However, even for relatively simple problems, nonglobal minima do exist. Each of these five replicates began from a different randomly selected set of initial centroids, so sometimes `kmeans` finds more than one local minimum. However, the final solution that `kmeans` returns is the one with the lowest total sum of distances, over all replicates.

```
sum(sumdist)
```

```
ans =
```

```
1.7711e+03
```

## Gaussian Mixture Models

### In this section...

“Introduction to Gaussian Mixture Models” on page 14-30

“Cluster with Gaussian Mixtures” on page 14-30

### Introduction to Gaussian Mixture Models

Gaussian mixture models are formed by combining multivariate normal density components.

In Statistics Toolbox software, use the `gmdistribution` class to fit data using an expectation maximization (EM) algorithm, which assigns posterior probabilities to each component density with respect to each observation.

Gaussian mixture models are often used for data clustering. Clusters are assigned by selecting the component that maximizes the posterior probability. Like k-means clustering, Gaussian mixture modeling uses an iterative algorithm that converges to a local optimum. Gaussian mixture modeling may be more appropriate than k-means clustering when clusters have different sizes and correlation within them. Clustering using Gaussian mixture models is sometimes considered a soft clustering method. The posterior probabilities for each point indicate that each data point has some probability of belonging to each cluster.

### Cluster with Gaussian Mixtures

Gaussian mixture distributions can be used for clustering data, by realizing that the multivariate normal components of the fitted model can represent clusters.

- 1 To demonstrate the process, first generate some simulated data from a mixture of two bivariate Gaussian distributions using the `mvnrnd` function.

```
rng('default') % For reproducibility
mu1 = [1 2];
sigma1 = [3 .2; .2 2];
mu2 = [-1 -2];
```

```
sigma2 = [2 0; 0 1];  
X = [mvnrnd(mu1,sigma1,200);mvnrnd(mu2,sigma2,100)];  
  
scatter(X(:,1),X(:,2),10,'ko')
```

- 2** Fit a two-component Gaussian mixture distribution. Here, you know the correct number of components to use. In practice, with real data, this decision would require comparing models with different numbers of components.

```
options = statset('Display','final');
```

```
gm = gmdistribution.fit(X,2,'Options',options);
```

```
33 iterations, log-likelihood = -1210.59
```

- 3** Plot the estimated probability density contours for the two-component mixture distribution. The two bivariate normal components overlap, but their peaks are distinct. This suggests that the data could reasonably be divided into two clusters.

```
hold on  
ezcontour(@(x,y)pdf(gm,[x y]),[-8 6],[-8 6]);  
hold off
```

- 4** Partition the data into clusters using the `cluster` method for the fitted mixture distribution. The `cluster` method assigns each point to one of the two components in the mixture distribution.

```
idx = cluster(gm,X);  
cluster1 = (idx == 1);  
cluster2 = (idx == 2);  
  
scatter(X(cluster1,1),X(cluster1,2),10,'r+');  
hold on  
scatter(X(cluster2,1),X(cluster2,2),10,'bo');
```

Each cluster corresponds to one of the bivariate normal components in the mixture distribution. `cluster` assigns points to clusters based on the estimated posterior probability that a point came from a component; each point is assigned to the cluster corresponding to the highest posterior probability. The posterior method returns those posterior probabilities. For example, plot the posterior probability of the first component for each point.

```
P = posterior(gm,X);  
  
scatter(X(cluster1,1),X(cluster1,2),10,P(cluster1,1),'+')  
hold on  
scatter(X(cluster2,1),X(cluster2,2),10,P(cluster2,1),'o')  
hold off  
legend('Cluster 1','Cluster 2','Location','NW')  
clrmmap = jet(80); colormap(clrmmap(9:72,:))  
ylabel(colorbar,'Component 1 Posterior Probability')
```

### **Soft Clustering Using Gaussian Mixture Distributions**

An alternative to the previous example is to use the posterior probabilities for "soft clustering". Each point is assigned a membership score to each cluster. Membership scores are simply the posterior probabilities, and describe how similar each point is to each cluster's archetype, i.e., the mean of the corresponding component. The points can be ranked by their membership score in a given cluster.

```
[~,order] = sort(P(:,1));  
plot(1:size(X,1),P(order,1),'r-',1:size(X,1),P(order,2),'b-');  
legend({'Cluster 1 Score' 'Cluster 2 Score'},'location','NW');  
ylabel('Cluster Membership Score');  
xlabel('Point Ranking');
```

Although a clear separation of the data is hard to see in a scatter plot of the data, plotting the membership scores indicates that the fitted distribution does a good job of separating the data into groups. Very few points have scores close to 0.5.

Soft clustering using a Gaussian mixture distribution is similar to fuzzy k-means clustering, which also assigns each point to each cluster with a membership score. The fuzzy k-means algorithm assumes that clusters are roughly spherical in shape, and all of roughly equal size. This is comparable to a Gaussian mixture distribution with a single covariance matrix that is

shared across all components, and is a multiple of the identity matrix. In contrast, `gmdistribution` allows you to specify different covariance options. The default is to estimate a separate, unconstrained covariance matrix for each component. A more restricted option, closer to k-means, would be to estimate a shared, diagonal covariance matrix.

```
gm2 = gmdistribution.fit(X,2,'CovType','Diagonal',...  
    'SharedCov',true);
```

This covariance option is similar to fuzzy k-means clustering, but provides more flexibility by allowing unequal variances for different variables.

You can compute the soft cluster membership scores without computing hard cluster assignments, using `posterior`, or as part of hard clustering, as the second output from `cluster`.

```
P2 = posterior(gm2,X); % equivalently [idx,P2] = cluster(gm2,X)  
[~,order] = sort(P2(:,1));  
plot(1:size(X,1),P2(order,1),'r-',1:size(X,1),P2(order,2),'b-');  
legend({'Cluster 1 Score' 'Cluster 2 Score'},'location','NW');  
ylabel('Cluster Membership Score');  
xlabel('Point Ranking');
```

### Assign New Data to Clusters

In the previous example, fitting the mixture distribution to data using `fit`, and clustering those data using `cluster`, are separate steps. However, the same data are used in both steps. You can also use the `cluster` method to assign new data points to the clusters (mixture components) found in the original data.

- 1 Given a data set  $X$ , first fit a Gaussian mixture distribution. The previous code has already done that.

```
gm
```

```
gm =
```

```
Gaussian mixture distribution with 2 components in 2 dimensions
```

```
Component 1:
```

```
Mixing proportion: 0.629379
```

```
Mean:    1.0758    2.0426
```

```
Component 2:
```

```
Mixing proportion: 0.370621
```

```
Mean:   -0.8292   -1.8482
```

- 2** You can then use `cluster` to assign each point in a new data set, `Y`, to one of the clusters defined for the original data.

```
Y = [mvnrnd(mu1,sigma1,50);mvnrnd(mu2,sigma2,25)];
```

```
idx = cluster(gm,Y);
```

```
cluster1 = (idx == 1);
```

```
cluster2 = (idx == 2);
```

```
scatter(Y(cluster1,1),Y(cluster1,2),10,'r+');
```

```
hold on
```

```
scatter(Y(cluster2,1),Y(cluster2,2),10,'bo');
```

```
hold off
```

```
legend('Class 1','Class 2','Location','NW')
```

As with the previous example, the posterior probabilities for each point can be treated as membership scores rather than determining "hard" cluster assignments.

For cluster to provide meaningful results with new data,  $Y$  should come from the same population as  $X$ , the original data used to create the mixture distribution. In particular, the estimated mixing probabilities for the Gaussian mixture distribution fitted to  $X$  are used when computing the posterior probabilities for  $Y$ .

# Parametric Classification

---

- “Parametric Classification” on page 15-2
- “Discriminant Analysis” on page 15-3
- “Naive Bayes Classification” on page 15-38
- “Performance Curves” on page 15-41

## Parametric Classification

Models of data with a categorical response are called *classifiers*. A classifier is built from *training data*, for which classifications are known. The classifier assigns new *test data* to one of the categorical levels of the response.

Parametric methods, like “Discriminant Analysis” on page 15-3, fit a parametric model to the training data and interpolate to classify test data.

Nonparametric methods, like classification and regression trees, use other means to determine classifications.

## Discriminant Analysis

### In this section...

“What Is Discriminant Analysis?” on page 15-3

“Create Discriminant Analysis Classifiers” on page 15-3

“Regularize a Discriminant Analysis Classifier” on page 15-23

“Examine the Gaussian Mixture Assumption” on page 15-29

“Bibliography” on page 15-37

### What Is Discriminant Analysis?

Discriminant analysis is a classification method. It assumes that different classes generate data based on different Gaussian distributions.

- To train (create) a classifier, the fitting function estimates the parameters of a Gaussian distribution for each class (see “Creating a Classifier Using ClassificationDiscriminant.fit” on page 15-4).
- To predict the classes of new data, the trained classifier finds the class with the smallest misclassification cost (see “How the predict Method Classifies” on page 15-6).

Linear discriminant analysis is also known as the Fisher discriminant, named for its inventor, Sir R. A. Fisher [2].

### Create Discriminant Analysis Classifiers

To create the basic types of discriminant analysis classifiers for the Fisher iris data:

- 1 Load the data:

```
load fisheriris;
```

- 2 Create a default (linear) discriminant analysis classifier:

```
linclass = ClassificationDiscriminant.fit(meas,species);
```

To visualize the classification boundaries of a 2-D linear classification of the data, see “Create and Visualize Discriminant Analysis Classifier” on page 15-9.

- 3 Classify an iris with average measurements:

```
meanmeas = mean(meas);  
meanclass = predict(linclass,meanmeas)
```

```
meanclass =  
    'versicolor'
```

- 4 Create a quadratic classifier:

```
quadclass = ClassificationDiscriminant.fit(meas,species,...  
    'discrimType','quadratic');
```

To visualize the classification boundaries of a 2-D quadratic classification of the data, see “Create and Visualize Discriminant Analysis Classifier” on page 15-9.

- 5 Classify an iris with average measurements using the quadratic classifier:

```
meanclass2 = predict(quadclass,meanmeas)
```

```
meanclass2 =  
    'versicolor'
```

## **Creating a Classifier Using ClassificationDiscriminant.fit**

The model for discriminant analysis is:

- Each class (Y) generates data (X) using a multivariate normal distribution. In other words, the model assumes X has a Gaussian mixture distribution (gmdistribution).

- For linear discriminant analysis, the model has the same covariance matrix for each class; only the means vary.
- For quadratic discriminant analysis, both means and covariances of each class vary.

Under this modeling assumption, `ClassificationDiscriminant.fit` infers the mean and covariance parameters of each class.

- For linear discriminant analysis, it computes the sample mean of each class. Then it computes the sample covariance by first subtracting the sample mean of each class from the observations of that class, and taking the empirical covariance matrix of the result.
- For quadratic discriminant analysis, it computes the sample mean of each class. Then it computes the sample covariances by first subtracting the sample mean of each class from the observations of that class, and taking the empirical covariance matrix of each class.

The `fit` method does not use prior probabilities or costs for fitting.

### Weighted Observations

The `fit` method constructs weighted classifiers using the following scheme. Suppose  $M$  is an  $N$ -by- $K$  class membership matrix:

$$\begin{aligned} M_{nk} &= 1 \text{ if observation } n \text{ is from class } k \\ M_{nk} &= 0 \text{ otherwise.} \end{aligned}$$

The estimate of the class mean for unweighted data is

$$\hat{\mu}_k = \frac{\sum_{n=1}^N M_{nk} x_n}{\sum_{n=1}^N M_{nk}}.$$

For weighted data with positive weights  $w_n$ , the natural generalization is

$$\hat{\mu}_k = \frac{\sum_{n=1}^N M_{nk} w_n x_n}{\sum_{n=1}^N M_{nk} w_n}.$$

The unbiased estimate of the pooled-in covariance matrix for unweighted data is

$$\hat{\Sigma} = \frac{\sum_{n=1}^N \sum_{k=1}^K M_{nk} (x_n - \hat{\mu}_k)(x_n - \hat{\mu}_k)^T}{N - K}.$$

For quadratic discriminant analysis, the `fit` method uses  $K = 1$ .

For weighted data, assuming the weights sum to 1, the unbiased estimate of the pooled-in covariance matrix is

$$\hat{\Sigma} = \frac{\sum_{n=1}^N \sum_{k=1}^K M_{nk} w_n (x_n - \hat{\mu}_k)(x_n - \hat{\mu}_k)^T}{1 - \sum_{k=1}^K \frac{W_k^{(2)}}{W_k}},$$

where

- $W_k = \sum_{n=1}^N M_{nk} w_n$  is the sum of the weights for class  $k$ .
- $W_k^{(2)} = \sum_{n=1}^N M_{nk} w_n^2$  is the sum of squared weights per class.

## How the predict Method Classifies

There are three elements in the `predict` classification algorithm:

- “Posterior Probability” on page 15-7
- “Prior Probability” on page 15-8
- “Cost” on page 15-8

`predict` classifies so as to minimize the expected classification cost:

$$\hat{y} = \arg \min_{y=1, \dots, K} \sum_{k=1}^K \hat{P}(k | x) C(y | k),$$

where

- $\hat{y}$  is the predicted classification.
- $K$  is the number of classes.
- $\hat{P}(k | x)$  is the posterior probability of class  $k$  for observation  $x$ .
- $C(y | k)$  is the cost of classifying an observation as  $y$  when its true class is  $k$ .

The space of  $X$  values divides into regions where a classification  $Y$  is a particular value. The regions are separated by straight lines for linear discriminant analysis, and by conic sections (ellipses, hyperbolas, or parabolas) for quadratic discriminant analysis. For a visualization of these regions, see “Create and Visualize Discriminant Analysis Classifier” on page 15-9.

### Posterior Probability

The posterior probability that a point  $x$  belongs to class  $k$  is the product of the prior probability and the multivariate normal density. The density function of the multivariate normal with mean  $\mu_k$  and covariance  $\Sigma_k$  at a point  $x$  is

$$P(x | k) = \frac{1}{(2\pi |\Sigma_k|)^{1/2}} \exp\left(-\frac{1}{2}(x - \mu_k)^T \Sigma_k^{-1} (x - \mu_k)\right),$$

where  $|\Sigma_k|$  is the determinant of  $\Sigma_k$ , and  $\Sigma_k^{-1}$  is the inverse matrix.

Let  $P(k)$  represent the prior probability of class  $k$ . Then the posterior probability that an observation  $x$  is of class  $k$  is

$$\hat{P}(k | x) = \frac{P(x | k)P(k)}{P(x)},$$

where  $P(x)$  is a normalization constant, namely, the sum over  $k$  of  $P(x|k)P(k)$ .

### Prior Probability

The prior probability is one of three choices:

- 'uniform' — The prior probability of class  $k$  is 1 over the total number of classes.
- 'empirical' — The prior probability of class  $k$  is the number of training samples of class  $k$  divided by the total number of training samples.
- A numeric vector — The prior probability of class  $k$  is the  $j$ th element of the prior vector. See `ClassificationDiscriminant.fit`.

After creating a classifier `obj`, you can set the prior using dot addressing:

```
obj.Prior = v;
```

where  $v$  is a vector of positive elements representing the frequency with which each element occurs. You do not need to retrain the classifier when you set a new prior.

### Cost

There are two costs associated with discriminant analysis classification: the true misclassification cost per class, and the expected misclassification cost per observation.

**True Misclassification Cost per Class.**  $\text{Cost}(i, j)$  is the cost of classifying an observation into class  $j$  if its true class is  $i$ . By default,  $\text{Cost}(i, j)=1$  if  $i \neq j$ , and  $\text{Cost}(i, j)=0$  if  $i=j$ . In other words, the cost is 0 for correct classification, and 1 for incorrect classification.

You can set any cost matrix you like when creating a classifier. Pass the cost matrix in the `Cost` name-value pair in `ClassificationDiscriminant.fit`.

After you create a classifier `obj`, you can set a custom cost using dot addressing:

```
obj.Cost = B;
```

$B$  is a square matrix of size  $K$ -by- $K$  when there are  $K$  classes. You do not need to retrain the classifier when you set a new cost.

**Expected Misclassification Cost per Observation.** Suppose you have  $N_{\text{obs}}$  observations that you want to classify with a trained discriminant analysis classifier `obj`. Suppose you have  $K$  classes. You place the observations into a matrix  $X_{\text{new}}$  with one observation per row. The command

```
[label,score,cost] = predict(obj,Xnew)
```

returns, among other outputs, a cost matrix of size  $N_{\text{obs}}$ -by- $K$ . Each row of the cost matrix contains the expected (average) cost of classifying the observation into each of the  $K$  classes. `cost(n,k)` is

$$\sum_{i=1}^K \hat{P}(i | X_{\text{new}}(n)) C(k | i),$$

where

- $K$  is the number of classes.
- $\hat{P}(i | X_{\text{new}}(n))$  is the posterior probability of class  $i$  for observation  $X_{\text{new}}(n)$ .
- $C(k | i)$  is the cost of classifying an observation as  $k$  when its true class is  $i$ .

## Create and Visualize Discriminant Analysis Classifier

This example shows how to perform linear and quadratic classification of Fisher iris data.

Load the sample data.

```
load fisheriris
```

The column vector, `species`, consists of iris flowers of three different species, `setosa`, `versicolor`, `virginica`. The double matrix `meas` consists of four types of measurements on the flowers, the length and width of sepals and petals in centimeters, respectively.

Use petal length (third column in `meas`) and petal width (fourth column in `meas`) measurements. Save these as variables `PL` and `PW`, respectively.

```
PL = meas(:,3);  
PW = meas(:,4);
```

Plot the data, showing the classification, that is, create a scatter plot of the measurements, grouped by species.

```
h1 = gscatter(PL,PW,species,'krb','ov^',[],'off');  
set(h1,'LineWidth',2)  
legend('Setosa','Versicolor','Virginica','Location','best')  
hold on
```

Create a linear classifier.

```
X = [PL,PW];
cls = ClassificationDiscriminant.fit(X,species);
```

Plot the classification boundaries.

```
K = cls.Coeffs(2,3).Const; % First retrieve the coefficients for the linear
L = cls.Coeffs(2,3).Linear;% boundary between the second and third classes
% (versicolor and virginica).
```

```
% Plot the curve  $K + [x,y]*L = 0$ .
f = @(x1,x2) K + L(1)*x1 + L(2)*x2;
h2 = ezplot(f,[.9 7.1 0 2.5]);
set(h2,'Color','r','LineWidth',2)

% Now, retrieve the coefficients for the linear boundary between the first
% and second classes (setosa and versicolor).
K = cls.Coeffs(1,2).Const;
L = cls.Coeffs(1,2).Linear;

% Plot the curve  $K + [x1,x2]*L = 0$ :
f = @(x1,x2) K + L(1)*x1 + L(2)*x2;
h3 = ezplot(f,[.9 7.1 0 2.5]);
set(h3,'Color','k','LineWidth',2)
axis([.9 7.1 0 2.5])
xlabel('Petal Length')
ylabel('Petal Width')
title('\bf Linear Classification with Fisher Training Data')
```

Create a quadratic discriminant classifier.

```
cqs = ClassificationDiscriminant.fit(X,species,...
    'DiscrimType','quadratic');
```

Plot the classification boundaries similarly.

```
delete(h2); delete(h3) % First, remove the linear boundaries from the plot.
```

```
% Now, retrieve the coefficients for the quadratic boundary between the
% second and third classes (versicolor and virginica).
```

```

K = cqs.Coeffs(2,3).Const;
L = cqs.Coeffs(2,3).Linear;
Q = cqs.Coeffs(2,3).Quadratic;

% Plot the curve  $K + [x_1, x_2]*L + [x_1, x_2]*Q*[x_1, x_2]' = 0$ .
f = @(x1,x2) K + L(1)*x1 + L(2)*x2 + Q(1,1)*x1.^2 + ...
    (Q(1,2)+Q(2,1))*x1.*x2 + Q(2,2)*x2.^2;
h2 = ezplot(f,[.9 7.1 0 2.5]);
set(h2,'Color','r','LineWidth',2)

% Now, retrieve the coefficients for the quadratic boundary between the
% first and second classes (setosa and versicolor).
K = cqs.Coeffs(1,2).Const;
L = cqs.Coeffs(1,2).Linear;
Q = cqs.Coeffs(1,2).Quadratic;

% Plot the curve  $K + [x_1, x_2]*L + [x_1, x_2]*Q*[x_1, x_2]' = 0$ :
f = @(x1,x2) K + L(1)*x1 + L(2)*x2 + Q(1,1)*x1.^2 + ...
    (Q(1,2)+Q(2,1))*x1.*x2 + Q(2,2)*x2.^2;
h3 = ezplot(f,[.9 7.1 0 1.02]); % Plot the relevant portion of the curve.

set(h3,'Color','k','LineWidth',2)
axis([.9 7.1 0 2.5])
xlabel('Petal Length')
ylabel('Petal Width')
title('{\bf Quadratic Classification with Fisher Training Data}')
hold off

```

## Improve a Discriminant Analysis Classifier

- “Deal with Singular Data” on page 15-16
- “Choose a Discriminant Type” on page 15-17
- “Examine the Resubstitution Error and Confusion Matrix” on page 15-18
- “Cross Validation” on page 15-19
- “Change Costs and Priors” on page 15-21

## Deal with Singular Data

Discriminant analysis needs data sufficient to fit Gaussian models with invertible covariance matrices. If your data is not sufficient to fit such a model uniquely, `ClassificationDiscriminant.fit` fails. This section shows methods for handling failures.

---

**Tip** To obtain a discriminant analysis classifier without failure, set the `DiscrimType` name-value pair to `'pseudoLinear'` or `'pseudoQuadratic'` in `ClassificationDiscriminant.fit`.

“Pseudo” discriminants never fail, because they use the pseudoinverse of the covariance matrix  $\Sigma_k$  (see `pinv`).

---

**Example: Singular Covariance Matrix.** When the covariance matrix of the fitted classifier is singular, `ClassificationDiscriminant.fit` can fail:

```
load popcorn
X = popcorn(:,[1 2]);
X(:,3) = 0; % a zero-variance column
Y = popcorn(:,3);
ppcrn = ClassificationDiscriminant.fit(X,Y);

Error using ClassificationDiscriminant (line 635)
Predictor x3 has zero variance. Either exclude this predictor or set 'discrimType' to
'pseudoLinear' or 'diagLinear'.

Error in classreg.learning.FitTemplate/fit (line 243)
    obj = this.MakeFitObject(X,Y,W,this.ModelParams,fitArgs{:});

Error in ClassificationDiscriminant.fit (line 296)
    this = fit(temp,X,Y);
```

To proceed with linear discriminant analysis, use a `pseudoLinear` or `diagLinear` discriminant type:

```
ppcrn = ClassificationDiscriminant.fit(X,Y,...
    'discrimType','pseudoLinear');
meanpredict = predict(ppcrn,mean(X))
```

```
meanpredict =  
    3.5000
```

## Choose a Discriminant Type

There are six types of discriminant analysis classifiers: linear and quadratic, with *diagonal* and *pseudo* variants of each type.

---

**Tip** To see if your covariance matrix is singular, set `discrimType` to 'linear' or 'quadratic'. If the matrix is singular, the `ClassificationDiscriminant.fit` method fails for 'quadratic', and the `Gamma` property is nonzero for 'linear'.

To obtain a quadratic classifier even when your covariance matrix is singular, set `discrimType` to 'pseudoQuadratic' or 'diagQuadratic'.

```
obj = ClassificationDiscriminant.fit(X,Y,...  
    'discrimType','pseudoQuadratic') % or 'diagQuadratic'
```

---

Choose a classifier type by setting the `discrimType` name-value pair to one of:

- 'linear' (default) — Estimate one covariance matrix for all classes.
- 'quadratic' — Estimate one covariance matrix for each class.
- 'diagLinear' — Use the diagonal of the 'linear' covariance matrix, and use its pseudoinverse if necessary.
- 'diagQuadratic' — Use the diagonals of the 'quadratic' covariance matrices, and use their pseudoinverses if necessary.
- 'pseudoLinear' — Use the pseudoinverse of the 'linear' covariance matrix if necessary.
- 'pseudoQuadratic' — Use the pseudoinverses of the 'quadratic' covariance matrices if necessary.

`ClassificationDiscriminant.fit` can fail for the 'linear' and 'quadratic' classifiers. When it fails, it returns an explanation, as shown in “Deal with Singular Data” on page 15-16.

`ClassificationDiscriminant.fit` always succeeds with the diagonal and pseudo variants. For information about pseudoinverses, see `pinv`.

You can set the discriminant type using dot addressing after constructing a classifier:

```
obj.DiscrimType = 'discrimType'
```

You can change between linear types or between quadratic types, but cannot change between a linear and a quadratic type.

### **Examine the Resubstitution Error and Confusion Matrix**

The *resubstitution error* is the difference between the response training data and the predictions the classifier makes of the response based on the input training data. If the resubstitution error is high, you cannot expect the predictions of the classifier to be good. However, having low resubstitution error does not guarantee good predictions for new data. Resubstitution error is often an overly optimistic estimate of the predictive error on new data.

The *confusion matrix* shows how many errors, and which types, arise in resubstitution. When there are  $K$  classes, the confusion matrix  $R$  is a  $K$ -by- $K$  matrix with

$R(i, j)$  = the number of observations of class  $i$  that the classifier predicts to be of class  $j$ .

#### **Example: Resubstitution Error of a Discriminant Analysis Classifier.**

Examine the resubstitution error of the default discriminant analysis classifier for the Fisher iris data:

```
load fisheriris
obj = ClassificationDiscriminant.fit(meas,species);
resuberror = resubLoss(obj)

resuberror =
    0.0200
```

The resubstitution error is very low, meaning `obj` classifies nearly all the Fisher iris data correctly. The total number of misclassifications is:

```
resuberror * obj.NObservations  
  
ans =  
    3.0000
```

To see the details of the three misclassifications, examine the confusion matrix:

```
R = confusionmat(obj.Y,resubPredict(obj))  
  
R =  
    50     0     0  
     0    48     2  
     0     1    49
```

```
obj.ClassNames
```

```
ans =  
    'setosa'  
    'versicolor'  
    'virginica'
```

- $R(1,:) = [50 \ 0 \ 0]$  means `obj` classifies all 50 setosa irises correctly.
- $R(2,:) = [0 \ 48 \ 2]$  means `obj` classifies 48 versicolor irises correctly, and misclassifies two versicolor irises as virginica.
- $R(3,:) = [0 \ 1 \ 49]$  means `obj` classifies 49 virginica irises correctly, and misclassifies one virginica iris as versicolor.

## Cross Validation

Typically, discriminant analysis classifiers are robust and do not exhibit overtraining when the number of predictors is much less than the number of observations. Nevertheless, it is good practice to cross validate your classifier to ensure its stability.

### **Cross Validating a Discriminant Analysis Classifier.**

This example shows how to perform five-fold cross validation of a quadratic discriminant analysis classifier.

Load the sample data.

```
load fisheriris
```

Create a quadratic discriminant analysis classifier for the data.

```
quadisc = ClassificationDiscriminant.fit(meas,species,'DiscrimType','quadra
```

Find the resubstitution error of the classifier.

```
qerror = resubLoss(quadisc)
```

```
qerror =
```

```
    0.0200
```

The classifier does an excellent job. Nevertheless, resubstitution error can be an optimistic estimate of the error when classifying new data. So proceed to cross validation.

Create a cross-validation model.

```
cvmodel = crossval(quadisc,'kfold',5);
```

Find the cross-validation loss for the model, meaning the error of the out-of-fold observations.

```
cverror = kfoldLoss(cvmodel)
```

```
cverror =
```

```
    0.0200
```

The cross-validated loss is as low as the original resubstitution loss. Therefore, you can have confidence that the classifier is reasonably accurate.

### Change Costs and Priors

Sometimes you want to avoid certain misclassification errors more than others. For example, it might be better to have oversensitive cancer detection instead of undersensitive cancer detection. Oversensitive detection gives more false positives (unnecessary testing or treatment). Undersensitive detection gives more false negatives (preventable illnesses or deaths). The consequences of underdetection can be high. Therefore, you might want to set costs to reflect the consequences.

Similarly, the training data  $Y$  can have a distribution of classes that does not represent their true frequency. If you have a better estimate of the true frequency, you can include this knowledge in the classification prior property.

**Example: Setting Custom Misclassification Costs.** Consider the Fisher iris data. Suppose that the cost of classifying a versicolor iris as virginica is 10 times as large as making any other classification error. Create a classifier from the data, then incorporate this cost and then view the resulting classifier.

- 1 Load the Fisher iris data and create a default (linear) classifier as in “Example: Resubstitution Error of a Discriminant Analysis Classifier” on page 15-18:

```
load fisheriris
obj = ClassificationDiscriminant.fit(meas,species);
resuberror = resubLoss(obj)

resuberror =
    0.0200

R = confusionmat(obj.Y,resubPredict(obj))

R =
    50     0     0
     0    48     2
     0     1    49
```

```
obj.ClassNames
```

```
ans =  
    'setosa'  
    'versicolor'  
    'virginica'
```

`R(2,:) = [0 48 2]` means `obj` classifies 48 versicolor irises correctly, and misclassifies two versicolor irises as virginica.

- 2 Change the cost matrix to make fewer mistakes in classifying versicolor irises as virginica:

```
obj.Cost(2,3) = 10;  
R2 = confusionmat(obj.Y,resubPredict(obj))
```

```
R2 =  
    50     0     0  
     0    50     0  
     0     7    43
```

`obj` now classifies all versicolor irises correctly, at the expense of increasing the number of misclassifications of virginica irises from 1 to 7.

**Example: Setting Alternative Priors.** Consider the Fisher iris data. There are 50 irises of each kind in the data. Suppose that, in a particular region, you have historical data that shows virginica are five times as prevalent as the other kinds. Create a classifier that incorporates this information.

- 1 Load the Fisher iris data and make a default (linear) classifier as in “Example: Resubstitution Error of a Discriminant Analysis Classifier” on page 15-18:

```
load fisheriris  
obj = ClassificationDiscriminant.fit(meas,species);  
resuberror = resubLoss(obj)  
  
resuberror =  
    0.0200  
  
R = confusionmat(obj.Y,resubPredict(obj))
```

```
R =
  50    0    0
   0   48    2
   0    1   49
```

```
obj.ClassNames
```

```
ans =
  'setosa'
  'versicolor'
  'virginica'
```

`R(3,:) = [0 1 49]` means `obj` classifies 49 virginica irises correctly, and misclassifies one virginica iris as versicolor.

- 2 Change the prior to match your historical data, and examine the confusion matrix of the new classifier:

```
obj.Prior = [1 1 5];
R2 = confusionmat(obj.Y, resubPredict(obj))
```

```
R2 =
  50    0    0
   0   46    4
   0    0   50
```

The new classifier classifies all virginica irises correctly, at the expense of increasing the number of misclassifications of versicolor irises from 2 to 4.

## Regularize a Discriminant Analysis Classifier

This example shows how to make a more robust and simpler model by trying to remove predictors without hurting the model's predictive power. This is especially important when you have many predictors in your data. Linear discriminant analysis uses the two regularization parameters, `Gamma` and `Delta`, to identify and remove redundant predictors. The `cvshrink` method helps you identify appropriate settings for these parameters.

1. Load data and create a classifier.

Create a linear discriminant analysis classifier for the ovariancancer data. Set the `SaveMemory` and `FillCoeffs` options to keep the resulting model reasonably small.

```
load ovariancancer
obj = ClassificationDiscriminant.fit(obs,grp,...
    'SaveMemory','on','FillCoeffs','off');
```

### **2. Cross validate the classifier.**

Use 30 levels of `Gamma` and 30 levels of `Delta` to search for good parameters. This search is time consuming. Set `Verbose` to 1 to view the progress.

```
rng(8000,'twister') % for reproducibility
[err,gamma,delta,numpred] = cvshrink(obj,...
    'NumGamma',29,'NumDelta',29,'Verbose',1);
```

```
Done building cross-validated model.
Processing Gamma step 1 out of 30.
Processing Gamma step 2 out of 30.
Processing Gamma step 3 out of 30.
%%% (many lines removed) %%%
Processing Gamma step 28 out of 30.
Processing Gamma step 29 out of 30.
Processing Gamma step 30 out of 30.
```

### **3. Examine the quality of the regularized classifiers.**

Plot the number of predictors against the error.

```
figure;
plot(err,numpred,'k.')
xlabel('Error rate');
ylabel('Number of predictors');
```

Examine the lower-left part of the plot more closely.

```
axis([0 .1 0 1000])
```

There is a clear tradeoff between lower number of predictors and lower error.

**4. Choose an optimal tradeoff between model size and accuracy.**

Find the values of Gamma and Delta that give minimal error.

```
minerr = min(min(err));
[p,q] = find(err == minerr)
```

```
p =
    24
    25
```

```
q =
     8
     8
```

Two points have the same minimal error: [24,8] and [25,8], which correspond to

```
[gamma(p(1)),delta(p(1),q(1)); gamma(p(2)),delta(p(2),q(2))]
```

```
ans =
    0.8436    0.1463
    0.8697    0.1425
```

These points correspond to about a quarter of the total predictors having nonzero coefficients in the model.

```
[numpred(p(1),q(1)); numpred(p(2),q(2))]
```

```
ans =
    957
    960
```

To further lower the number of predictors, you must accept larger error rates. For example, to choose the Gamma and Delta that give the lowest error rate with 250 or fewer predictors:

```
low250 = min(min(err(numpred <= 250)));
lownum = min(min(numpred(err == low250)));
[low250 lownum]
```

```
ans =

    [0.0278 243]
```

You need 243 predictors to achieve an error rate of 0.0278, and this is the lowest error rate among those that have 250 predictors or fewer.

The Gamma and Delta that achieve this error/number of predictors:

```
[r,s] = find((err == low250) & (numpred == lownum));
[gamma(r); delta(r,s)]
```

```
ans =

    0.7133
    0.2960
```

**5. Set the regularization parameters.**

To set the classifier with these values of Gamma and Delta, use dot addressing.

```
obj.Gamma = gamma(r);  
obj.Delta = delta(r,s);
```

**6. Heat map plot.**

To compare the `cvshrink` calculation to that in Guo, Hastie, and Tibshirani [3], plot heat maps of error and number of predictors against Gamma and the index of the Delta parameter. (The Delta parameter range depends on the value of the Gamma parameter. So to get a rectangular plot, use the Delta index, not the parameter itself.)

```
% First create the Delta index matrix  
indx = repmat(1:size(delta,2),size(delta,1),1);  
figure  
subplot(1,2,1)  
imagesc(err);  
colorbar;  
title('Classification error');  
xlabel('Delta index');  
ylabel('Gamma index');  
  
subplot(1,2,2)  
imagesc(numpred);  
colorbar;  
title('Number of predictors in the model');  
xlabel('Delta index');  
ylabel('Gamma index');
```

You see the best classification error when Delta is small, but fewest predictors when Delta is large.

## Examine the Gaussian Mixture Assumption

Discriminant analysis assumes that the data comes from a Gaussian mixture model (see “Creating a Classifier Using ClassificationDiscriminant.fit” on page 15-4). If the data appears to come from a Gaussian mixture model, you can expect discriminant analysis to be a good classifier. Furthermore, the default linear discriminant analysis assumes that all class covariance matrices are equal. This section shows methods to check these assumptions:

- “Bartlett Test of Equal Covariance Matrices for Linear Discriminant Analysis” on page 15-30
- “Q-Q Plot” on page 15-31
- “Mardia Kurtosis Test of Multivariate Normality” on page 15-35

### **Bartlett Test of Equal Covariance Matrices for Linear Discriminant Analysis**

The Bartlett test (see Box [1]) checks equality of the covariance matrices of the various classes. If the covariance matrices are equal, the test indicates that linear discriminant analysis is appropriate. If not, consider using quadratic discriminant analysis, setting the `DiscrimType` name-value pair to 'quadratic' in `ClassificationDiscriminant.fit`.

The Bartlett test assumes normal (Gaussian) samples, where neither the means nor covariance matrices are known. To determine whether the covariances are equal, compute the following quantities:

- Sample covariance matrices per class  $\sigma_i$ ,  $1 \leq i \leq k$ , where  $k$  is the number of classes.
- Pooled-in covariance matrix  $\sigma$ .
- Test statistic  $V$ :

$$V = (n - k) \log(|\Sigma|) - \sum_{i=1}^k (n_i - 1) \log(|\Sigma_i|)$$

where  $n$  is the total number of observations, and  $n_i$  is the number of observations in class  $i$ , and  $|\Sigma|$  means the determinant of the matrix  $\Sigma$ .

- Asymptotically, as the number of observations in each class  $n_i$  become large,  $V$  is distributed approximately  $\chi^2$  with  $kd(d + 1)/2$  degrees of freedom, where  $d$  is the number of predictors (number of dimensions in the data).

The Bartlett test is to check whether  $V$  exceeds a given percentile of the  $\chi^2$  distribution with  $kd(d + 1)/2$  degrees of freedom. If it does, then reject the hypothesis that the covariances are equal.

**Example: Bartlett Test for Equal Covariance Matrices.** Check whether the Fisher iris data is well modeled by a single Gaussian covariance, or whether it would be better to model it as a Gaussian mixture.

```
load fisheriris;
prednames = {'SepalLength','SepalWidth','PetalLength','PetalWidth'};
L = ClassificationDiscriminant.fit(meas,species,'PredictorNames',prednames)
Q = ClassificationDiscriminant.fit(meas,species,'PredictorNames',prednames,
D = 4; % Number of dimensions of X
Nclass = [50 50 50];
N = L.NObservations;
K = numel(L.ClassNames);
SigmaQ = Q.Sigma;
SigmaL = L.Sigma;
logV = (N-K)*log(det(SigmaL));
for k=1:K
    logV = logV - (Nclass(k)-1)*log(det(SigmaQ(:,:,k)));
end
nu = (K-1)*D*(D+1)/2;
pval = 1 - chi2cdf(logV,nu)

pval =

    0
```

The Bartlett test emphatically rejects the hypothesis of equal covariance matrices. If `pval` had been greater than 0.05, the test would not have rejected the hypothesis. The result indicates to use quadratic discriminant analysis, as opposed to linear discriminant analysis.

### Q-Q Plot

A Q-Q plot graphically shows whether an empirical distribution is close to a theoretical distribution. If the two are equal, the Q-Q plot lies on a 45° line. If not, the Q-Q plot strays from the 45° line.

**Check Q-Q Plots for Linear and Quadratic Discriminants.** For linear discriminant analysis, use a single covariance matrix for all classes.

```
load fisheriris;
prednames = {'SepalLength', 'SepalWidth', 'PetalLength', 'PetalWidth'};
L = ClassificationDiscriminant.fit(meas, species, 'PredictorNames', prednames);
N = L.NObservations;
K = numel(L.ClassNames);
mahL = mahal(L, L.X, 'ClassLabels', L.Y);
D = 4;
expQ = chi2inv(((1:N)-0.5)/N, D); % expected quantiles
[mahL, sorted] = sort(mahL); % sorted observed quantiles
figure;
gscatter(expQ, mahL, L.Y(sorted), 'bgr', [], [], 'off');
legend('virginica', 'versicolor', 'setosa', 'Location', 'NW');
xlabel('Expected quantile');
ylabel('Observed quantile');
line([0 20], [0 20], 'color', 'k');
```

Overall, the agreement between the expected and observed quantiles is good. Look at the right half of the plot. The deviation of the plot from the 45° line upward indicates that the data has tails heavier than a normal distribution. There are three possible outliers on the right: two observations from class 'setosa' and one observation from class 'virginica'.

As shown in “Bartlett Test of Equal Covariance Matrices for Linear Discriminant Analysis” on page 15-30, the data does not match a single covariance matrix. Redo the calculations for a quadratic discriminant.

```
load fisheriris;
prednames = {'SepalLength', 'SepalWidth', 'PetalLength', 'PetalWidth'};
Q = ClassificationDiscriminant.fit(meas, species, 'PredictorNames', prednames,
Nclass = [50 50 50];
N = L.NObservations;
K = numel(L.ClassNames);
mahQ = mahal(Q, Q.X, 'ClassLabels', Q.Y);
expQ = chi2inv((1:N)-0.5)/N, D);
[mahQ, sorted] = sort(mahQ);
figure;
gscatter(expQ, mahQ, Q.Y(sorted), 'bgr', [], [], 'off');
legend('virginica', 'versicolor', 'setosa', 'Location', 'NW');
xlabel('Expected quantile');
ylabel('Observed quantile for QDA');
line([0 20], [0 20], 'color', 'k');
```

The Q-Q plot shows a better agreement between the observed and expected quantiles. There is only one outlier candidate, from class 'setosa'.

### **Mardia Kurtosis Test of Multivariate Normality**

The Mardia kurtosis test (see Mardia [4]) is an alternative to examining a Q-Q plot. It gives a numeric approach to deciding if data matches a Gaussian mixture model.

In the Mardia kurtosis test you compute  $M$ , the mean of the fourth power of the Mahalanobis distance of the data from the class means. If the data is normally distributed with constant covariance matrix (and is thus suitable for linear discriminant analysis),  $M$  is asymptotically distributed as normal with mean  $d(d + 2)$  and variance  $8d(d + 2)/n$ , where

- $d$  is the number of predictors (number of dimensions in the data).
- $n$  is the total number of observations.

The Mardia test is two sided: check whether  $M$  is close enough to  $d(d + 2)$  with respect to a normal distribution of variance  $8d(d + 2)/n$ .

**Example: Mardia Kurtosis Test for Linear and Quadratic Discriminants.**

Check whether the Fisher iris data is approximately normally distributed for both linear and quadratic discriminant analysis. According to “Bartlett Test of Equal Covariance Matrices for Linear Discriminant Analysis” on page 15-30, the data is not normal for linear discriminant analysis (the covariance matrices are different). “Check Q-Q Plots for Linear and Quadratic Discriminants” on page 15-31 indicates that the data is well modeled by a Gaussian mixture model with different covariances per class. Check these conclusions with the Mardia kurtosis test:

```
load fisheriris;
prednames = {'SepalLength', 'SepalWidth', 'PetalLength', 'PetalWidth'};
L = ClassificationDiscriminant.fit(meas, species, 'PredictorNames', prednames)
mahL = mahal(L, L.X, 'ClassLabels', L.Y);
D = 4;
N = L.NObservations;
obsKurt = mean(mahL.^2);
expKurt = D*(D+2);
varKurt = 8*D*(D+2)/N;
[~, pval] = ztest(obsKurt, expKurt, sqrt(varKurt))
```

```
pval =
    0.0208
```

The Mardia test indicates to reject the hypothesis that the data is normally distributed.

Continuing the example with quadratic discriminant analysis:

```
Q = ClassificationDiscriminant.fit(meas,species,'PredictorNames',prednames,
mahQ = mahal(Q,Q.X,'ClassLabels',Q.Y);
obsKurt = mean(mahQ.^2);
[~,pval] = ztest(obsKurt,expKurt,sqrt(varKurt))
```

```
pval =
```

```
0.7230
```

Because `pval` is high, you conclude the data are consistent with the multivariate normal distribution.

## Naive Bayes Classification

The Naive Bayes classifier is designed for use when features are independent of one another within each class, but it appears to work well in practice even when that independence assumption is not valid. It classifies data in two steps:

- 1 Training step: Using the training samples, the method estimates the parameters of a probability distribution, assuming features are conditionally independent given the class.
- 2 Prediction step: For any unseen test sample, the method computes the posterior probability of that sample belonging to each class. The method then classifies the test sample according to the largest posterior probability.

The class-conditional independence assumption greatly simplifies the training step since you can estimate the one-dimensional class-conditional density for each feature individually. While the class-conditional independence between features is not true in general, research shows that this optimistic assumption works well in practice. This assumption of class independence allows the Naive Bayes classifier to better estimate the parameters required for accurate classification while using less training data than many other classifiers. This makes it particularly effective for datasets containing many predictors or features.

### Supported Distributions

Naive Bayes classification is based on estimating  $P(X|Y)$ , the probability or probability density of features  $X$  given class  $Y$ . The Naive Bayes classification object `NaiveBayes` provides support for normal (Gaussian), kernel, multinomial, and multivariate multinomial distributions. It is possible to use different distributions for different features.

### Normal (Gaussian) Distribution

The 'normal' distribution is appropriate for features that have normal distributions in each class. For each feature you model with a normal distribution, the Naive Bayes classifier estimates a separate normal

distribution for each class by computing the mean and standard deviation of the training data in that class.

### **Kernel Distribution**

The 'kernel' distribution is appropriate for features that have a continuous distribution. It does not require a strong assumption such as a normal distribution and you can use it in cases where the distribution of a feature may be skewed or have multiple peaks or modes. It requires more computing time and more memory than the normal distribution. For each feature you model with a kernel distribution, the Naive Bayes classifier computes a separate kernel density estimate for each class based on the training data for that class. By default the kernel is the normal kernel, and the classifier selects a width automatically for each class and feature. It is possible to specify different kernels for each feature, and different widths for each feature or class.

### **Multinomial Distribution**

The multinomial distribution (specify with the 'mn' keyword) is appropriate when all features represent counts of a set of words or tokens. This is sometimes called the "bag of words" model. For example, an email spam classifier might be based on features that count the number of occurrences of various tokens in an email. One feature might count the number of exclamation points, another might count the number of times the word "money" appears, and another might count the number of times the recipient's name appears. This is a Naive Bayes model under the further assumption that the total number of tokens (or the total document length) is independent of response class.

For the multinomial option, each feature represents the count of one token. The classifier counts the set of relative token probabilities separately for each class. The classifier defines the multinomial distribution for each row by the vector of probabilities for the corresponding class, and by  $N$ , the total token count for that row.

Classification is based on the relative frequencies of the tokens. For a row in which no token appears,  $N$  is 0 and no classification is possible. This classifier is not appropriate when the total number of tokens provides information about the response class.

### **Multivariate Multinomial Distribution**

The multivariate multinomial distribution (specify with the 'mvmn' keyword) is appropriate for categorical features. For example, you could fit a feature describing the weather in categories such as rain/sun/snow/clouds using the multivariate multinomial model. The feature categories are sometimes called the feature levels, and differ from the class levels for the response variable.

For each feature you model with a multivariate multinomial distribution, the Naive Bayes classifier computes a separate set of probabilities for the set of feature levels for each class.

## Performance Curves

### In this section...

“Introduction to Performance Curves” on page 15-41

“What are ROC Curves?” on page 15-41

“Evaluate Classifier Performance Using `perfcurve`” on page 15-41

### Introduction to Performance Curves

After a classification algorithm such as `NaiveBayes` or `TreeBagger` has trained on data, you may want to examine the performance of the algorithm on a specific test dataset. One common way of doing this would be to compute a gross measure of performance such as quadratic loss or accuracy, averaged over the entire test dataset.

### What are ROC Curves?

You may want to inspect the classifier performance more closely, for example, by plotting a Receiver Operating Characteristic (ROC) curve. By definition, a ROC curve [1,2] shows true positive rate versus false positive rate (equivalently, sensitivity versus  $1 - \text{specificity}$ ) for different thresholds of the classifier output. You can use it, for example, to find the threshold that maximizes the classification accuracy or to assess, in more broad terms, how the classifier performs in the regions of high sensitivity and high specificity.

### Evaluate Classifier Performance Using `perfcurve`

`perfcurve` computes measures for a plot of classifier performance. You can use this utility to evaluate classifier performance on test data after you train the classifier. Various measures such as mean squared error, classification error, or exponential loss can summarize the predictive power of a classifier in a single number. However, a performance curve offers more information as it lets you explore the classifier performance across a range of thresholds on its output.

You can use `perfcurve` with any classifier or, more broadly, with any method that returns a numeric score for an instance of input data. By convention adopted here,

- A high score returned by a classifier for any given instance signifies that the instance is likely from the positive class.
- A low score signifies that the instance is likely from the negative classes.

For some classifiers, you can interpret the score as the posterior probability of observing an instance of the positive class at point  $X$ . An example of such a score is the fraction of positive observations in a leaf of a decision tree. In this case, scores fall into the range from 0 to 1 and scores from positive and negative classes add up to unity. Other methods can return scores ranging between minus and plus infinity, without any obvious mapping from the score to the posterior class probability.

`perfcurve` does not impose any requirements on the input score range. Because of this lack of normalization, you can use `perfcurve` to process scores returned by any classification, regression, or fit method. `perfcurve` does not make any assumptions about the nature of input scores or relationships between the scores for different classes. As an example, consider a problem with three classes, A, B, and C, and assume that the scores returned by some classifier for two instances are as follows:

	A	B	C
instance 1	0.4	0.5	0.1
instance 2	0.4	0.1	0.5

If you want to compute a performance curve for separation of classes A and B, with C ignored, you need to address the ambiguity in selecting A over B. You could opt to use the score ratio,  $s(A)/s(B)$ , or score difference,  $s(A) - s(B)$ ; this choice could depend on the nature of these scores and their normalization. `perfcurve` always takes one score per instance. If you only supply scores for class A, `perfcurve` does not distinguish between observations 1 and 2. The performance curve in this case may not be optimal.

`perfcurve` is intended for use with classifiers that return scores, not those that return only predicted classes. As a counter-example, consider a decision tree that returns only hard classification labels, 0 or 1, for data with two classes. In this case, the performance curve reduces to a single point because classified instances can be split into positive and negative categories in one way only.

For input, `perfcurve` takes true class labels for some data and scores assigned by a classifier to these data. By default, this utility computes a Receiver Operating Characteristic (ROC) curve and returns values of 1-specificity, or false positive rate, for  $X$  and sensitivity, or true positive rate, for  $Y$ . You can choose other criteria for  $X$  and  $Y$  by selecting one out of several provided criteria or specifying an arbitrary criterion through an anonymous function. You can display the computed performance curve using `plot(X, Y)`.

`perfcurve` can compute values for various criteria to plot either on the  $x$ - or the  $y$ -axis. All such criteria are described by a 2-by-2 confusion matrix, a 2-by-2 cost matrix, and a 2-by-1 vector of scales applied to class counts.

The confusion matrix,  $C$ , is defined as

$$\begin{pmatrix} TP & FN \\ FP & TN \end{pmatrix}$$

where

- $P$  stands for "positive".
- $N$  stands for "negative".
- $T$  stands for "true".
- $F$  stands for "false".

For example, the first row of the confusion matrix defines how the classifier identifies instances of the positive class:  $C(1, 1)$  is the count of correctly identified positive instances and  $C(1, 2)$  is the count of positive instances misidentified as negative.

The cost matrix defines the cost of misclassification for each category:

$$\begin{pmatrix} Cost(P | P) & Cost(N | P) \\ Cost(P | N) & Cost(N | N) \end{pmatrix}$$

where  $Cost(I | J)$  is the cost of assigning an instance of class  $J$  to class  $I$ . Usually  $Cost(I | J) = 0$  for  $I = J$ . For flexibility, `perfcurve` allows you to specify nonzero costs for correct classification as well.

The two scales include prior information about class probabilities. `perfcurve` computes these scales by taking  $\text{scale}(P) = \text{prior}(P) * N$  and  $\text{scale}(N) = \text{prior}(N) * P$  and normalizing the sum  $\text{scale}(P) + \text{scale}(N)$  to 1.  $P = TP + FN$  and  $N = TN + FP$  are the total instance counts in the positive and negative class, respectively. The function then applies the scales as multiplicative factors to the counts from the corresponding class: `perfcurve` multiplies counts from the positive class by  $\text{scale}(P)$  and counts from the negative class by  $\text{scale}(N)$ . Consider, for example, computation of positive predictive value,  $PPV = TP / (TP + FP)$ . TP counts come from the positive class and FP counts come from the negative class. Therefore, you need to scale TP by  $\text{scale}(P)$  and FP by  $\text{scale}(N)$ , and the modified formula for PPV with prior probabilities taken into account is now:

$$PPV = \frac{\text{scale}(P) * TP}{\text{scale}(P) * TP + \text{scale}(N) * FP}$$

If all scores in the data are above a certain threshold, `perfcurve` classifies all instances as 'positive'. This means that TP is the total number of instances in the positive class and FP is the total number of instances in the negative class. In this case, PPV is simply given by the prior:

$$PPV = \frac{\text{prior}(P)}{\text{prior}(P) + \text{prior}(N)}$$

The `perfcurve` function returns two vectors, X and Y, of performance measures. Each measure is some function of `confusion`, `cost`, and `scale` values. You can request specific measures by name or provide a function handle to compute a custom measure. The function you provide should take `confusion`, `cost`, and `scale` as its three inputs and return a vector of output values.

The criterion for X must be a monotone function of the positive classification count, or equivalently, threshold for the supplied scores. If `perfcurve` cannot perform a one-to-one mapping between values of the X criterion and score thresholds, it exits with an error message.

By default, `perfcurve` computes values of the X and Y criteria for all possible score thresholds. Alternatively, it can compute a reduced number of specific X values supplied as an input argument. In either case, for M requested values, `perfcurve` computes M+1 values for X and Y. The first value out of these M+1 values is special. `perfcurve` computes it by setting the TP instance count

to zero and setting TN to the total count in the negative class. This value corresponds to the 'reject all' threshold. On a standard ROC curve, this translates into an extra point placed at (0,0).

If there are NaN values among input scores, `perfcurve` can process them in either of two ways:

- It can discard rows with NaN scores.
- It can add them to false classification counts in the respective class.

That is, for any threshold, instances with NaN scores from the positive class are counted as false negative (FN), and instances with NaN scores from the negative class are counted as false positive (FP). In this case, the first value of X or Y is computed by setting TP to zero and setting TN to the total count minus the NaN count in the negative class. For illustration, consider an example with two rows in the positive and two rows in the negative class, each pair having a NaN score:

<b>Class</b>	<b>Score</b>
Negative	0.2
Negative	NaN
Positive	0.7
Positive	NaN

If you discard rows with NaN scores, then as the score cutoff varies, `perfcurve` computes performance measures as in the following table. For example, a cutoff of 0.5 corresponds to the middle row where rows 1 and 3 are classified correctly, and rows 2 and 4 are omitted.

TP	FN	FP	TN
0	1	0	1
1	0	0	1
1	0	1	0

If you add rows with NaN scores to the false category in their respective classes, `perfcurve` computes performance measures as in the following table. For example, a cutoff of 0.5 corresponds to the middle row where now rows

2 and 4 are counted as incorrectly classified. Notice that only the FN and FP columns differ between these two tables.

TP	FN	FP	TN
0	2	1	1
1	1	1	1
1	1	2	0

For data with three or more classes, `perfcurve` takes one positive class and a list of negative classes for input. The function computes the X and Y values using counts in the positive class to estimate TP and FN, and using counts in all negative classes to estimate TN and FP. `perfcurve` can optionally compute Y values for each negative class separately and, in addition to Y, return a matrix of size M-by-C, where M is the number of elements in X or Y and C is the number of negative classes. You can use this functionality to monitor components of the negative class contribution. For example, you can plot TP counts on the X-axis and FP counts on the Y-axis. In this case, the returned matrix shows how the FP component is split across negative classes.

You can also use `perfcurve` to estimate confidence intervals. `perfcurve` computes confidence bounds using either cross-validation or bootstrap. If you supply cell arrays for `labels` and `scores`, `perfcurve` uses cross-validation and treats elements in the cell arrays as cross-validation folds. If you set input parameter `NBoot` to a positive integer, `perfcurve` generates `nboot` bootstrap replicas to compute pointwise confidence bounds.

`perfcurve` estimates the confidence bounds using one of two methods:

- Vertical averaging (VA) — estimate confidence bounds on Y and T at fixed values of X. Use the `XVals` input parameter to use this method for computing confidence bounds.
- Threshold averaging (TA) — estimate confidence bounds for X and Y at fixed thresholds for the positive class score. Use the `TVals` input parameter to use this method for computing confidence bounds.

To use observation weights instead of observation counts, you can use the `'Weights'` parameter in your call to `perfcurve`. When you use this parameter, to compute X, Y and T or to compute confidence bounds by cross-validation, `perfcurve` uses your supplied observation weights instead of

observation counts. To compute confidence bounds by bootstrap, perfcurve samples  $N$  out of  $N$  with replacement using your weights as multinomial sampling probabilities.

## Supervised Learning (Machine Learning) Workflow and Algorithms

### In this section...

“Steps in Supervised Learning (Machine Learning)” on page 16-2

“Characteristics of Algorithms” on page 16-7

### Steps in Supervised Learning (Machine Learning)

Supervised learning (machine learning) takes a known set of input data and known responses to the data, and seeks to build a predictor model that generates reasonable predictions for the response to new data.

Suppose you want to predict if someone will have a heart attack within a year. You have a set of data on previous people, including age, weight, height, blood pressure, etc. You know if the previous people had heart attacks within a year of their data measurements. So the problem is combining all the existing data into a model that can predict whether a new person will have a heart attack within a year.

Supervised learning splits into two broad categories:

- Classification for responses that can have just a few known values, such as 'true' or 'false'. Classification algorithms apply to nominal, not ordinal response values.

- Regression for responses that are a real number, such as miles per gallon for a particular car.

You can have trouble deciding whether you have a classification problem or a regression problem. In that case, create a regression model first, because they are often more computationally efficient.

While there are many Statistics Toolbox algorithms for supervised learning, most use the same basic workflow for obtaining a predictor model. (Detailed instruction on the steps for ensemble learning is in “Framework for Ensemble Learning” on page 16-59.) The steps for supervised learning are:

- 1 “Prepare Data” on page 16-3
- 2 “Choose an Algorithm” on page 16-4
- 3 “Fit a Model” on page 16-4
- 4 “Choose a Validation Method” on page 16-5
- 5 “Examine Fit and Update Until Satisfied” on page 16-6
- 6 “Use Fitted Model for Predictions” on page 16-6

### **Prepare Data**

All supervised learning methods start with an input data matrix, usually called  $X$  here. Each row of  $X$  represents one observation. Each column of  $X$  represents one variable, or predictor. Represent missing entries with NaN values in  $X$ . Statistics Toolbox supervised learning algorithms can handle NaN values, either by ignoring them or by ignoring any row with a NaN value.

You can use various data types for response data  $Y$ . Each element in  $Y$  represents the response to the corresponding row of  $X$ . Observations with missing  $Y$  data are ignored.

- For regression,  $Y$  must be a numeric vector with the same number of elements as the number of rows of  $X$ .
- For classification,  $Y$  can be any of these data types. This table also contains the method of including missing entries.

Data Type	Missing Entry
Numeric vector	NaN
Categorical vector	<undefined>
Character array	Row of spaces
Cell array of strings	' '
Logical vector	(Cannot represent)

## Choose an Algorithm

There are tradeoffs between several characteristics of algorithms, such as:

- Speed of training
- Memory usage
- Predictive accuracy on new data
- Transparency or interpretability, meaning how easily you can understand the reasons an algorithm makes its predictions

Details of the algorithms appear in “Characteristics of Algorithms” on page 16-7. More detail about ensemble algorithms is in “Choose an Applicable Ensemble Method” on page 16-62.

## Fit a Model

The fitting function you use depends on the algorithm you choose.

Algorithm	Fitting Function
Classification Trees	<code>ClassificationTree.fit</code>
Regression Trees	<code>RegressionTree.fit</code>
Discriminant Analysis (classification)	<code>ClassificationDiscriminant.fit</code>
<i>K</i> -Nearest Neighbors (classification)	<code>ClassificationKNN.fit</code>
Naive Bayes (classification)	<code>NaiveBayes.fit</code>

Algorithm	Fitting Function
Classification or Regression Ensembles	fitensemble
Classification or Regression Ensembles in Parallel	TreeBagger

### Choose a Validation Method

The three main methods to examine the accuracy of the resulting fitted model are:

- Examine the resubstitution error. For examples, see:
  - “Example: Resubstitution Error of a Classification Tree” on page 16-39
  - “Example: Cross Validating a Regression Tree” on page 16-40
  - “Example: Test Ensemble Quality” on page 16-72
  - “Example: Resubstitution Error of a Discriminant Analysis Classifier” on page 15-18
- Examine the cross-validation error. For examples, see:
  - “Example: Cross Validating a Regression Tree” on page 16-40
  - “Example: Test Ensemble Quality” on page 16-72
  - “Classification with Many Categorical Levels” on page 16-91
  - “Cross Validating a Discriminant Analysis Classifier” on page 15-20
- Examine the out-of-bag error for bagged decision trees. For examples, see:
  - “Example: Test Ensemble Quality” on page 16-72
  - “Workflow Example: Regression of Insurance Risk Rating for Car Imports with TreeBagger” on page 16-125
  - “Workflow Example: Classifying Radar Returns for Ionosphere Data with TreeBagger” on page 16-134

## Examine Fit and Update Until Satisfied

After validating the model, you might want to change it for better accuracy, better speed, or to use less memory.

- Change fitting parameters to try to get a more accurate model. For examples, see:
  - “Tuning RobustBoost” on page 16-115
  - “Example: Unequal Classification Costs” on page 16-85
  - “Improve a Discriminant Analysis Classifier” on page 15-15
- Change fitting parameters to try to get a smaller model. This sometimes gives a model with more accuracy. For examples, see:
  - “Example: Selecting Appropriate Tree Depth” on page 16-41
  - “Example: Pruning a Classification Tree” on page 16-44
  - “Surrogate Splits” on page 16-95
  - “Example: Regularizing a Regression Ensemble” on page 16-105
  - “Workflow Example: Regression of Insurance Risk Rating for Car Imports with TreeBagger” on page 16-125
  - “Workflow Example: Classifying Radar Returns for Ionosphere Data with TreeBagger” on page 16-134
- Try a different algorithm. For applicable choices, see:
  - “Characteristics of Algorithms” on page 16-7
  - “Choose an Applicable Ensemble Method” on page 16-62

When satisfied with a model of some types, you can trim it using the appropriate `compact` method (`compact` for classification trees, `compact` for classification ensembles, `compact` for regression trees, `compact` for regression ensembles, `compact` for discriminant analysis). `compact` removes training data and pruning information, so the model uses less memory.

## Use Fitted Model for Predictions

To predict classification or regression response for most fitted models, use the `predict` method:

```
Ypredicted = predict(obj,Xnew)
```

- obj is the fitted model object.
- Xnew is the new input data.
- Ypredicted is the predicted response, either classification or regression.

For classtree, use the eval method instead of predict.

## Characteristics of Algorithms

This table shows typical characteristics of the various supervised learning algorithms. The characteristics in any particular case can vary from the listed ones. Use the table as a guide for your initial choice of algorithms, but be aware that the table can be inaccurate for some problems.

### Characteristics of Supervised Learning Algorithms

Algorithm	Predictive Accuracy	Fitting Speed	Prediction Speed	Memory Usage	Easy to Interpret	Handles Categorical Predictors
Trees	Low	Fast	Fast	Low	Yes	Yes
SVM	High	Medium	*	*	*	No
Naive Bayes	Low	**	**	**	Yes	Yes
Nearest Neighbor	***	Fast***	Medium	High	No	Yes***
Discriminant Analysis	****	Fast	Fast	Low	Yes	No
Ensembles	See “Suggestions for Choosing an Appropriate Ensemble Algorithm” on page 16-64 and “General Characteristics of Ensemble Algorithms” on page 16-65					

\* — SVM prediction speed and memory usage are good if there are few support vectors, but can be poor if there are many support vectors. When you use a kernel function, it can be difficult to interpret how SVM classifies data, though the default linear scheme is easy to interpret.

\*\* — Naive Bayes speed and memory usage are good for simple distributions, but can be poor for kernel distributions and large data sets.

\*\*\* — Nearest Neighbor usually has good predictions in low dimensions, but can have poor predictions in high dimensions. For linear search, Nearest Neighbor does not perform any fitting. For  $k$ d-trees, Nearest Neighbor does perform fitting. Nearest Neighbor can have either continuous or categorical predictors, but not both.

\*\*\*\* — Discriminant Analysis is accurate when the modeling assumptions are satisfied (multivariate normal by class). Otherwise, the predictive accuracy varies.

## Classification Using Nearest Neighbors

### In this section...

“Pairwise Distance” on page 16-9

“ $k$ -Nearest Neighbor Search and Radius Search” on page 16-12

“ $K$ -Nearest Neighbor Classification for Supervised Learning” on page 16-26

“Construct a KNN Classifier” on page 16-27

“Examine the Quality of a KNN Classifier” on page 16-27

“Predict Classification Based on a KNN Classifier” on page 16-28

“Modify a KNN Classifier” on page 16-29

### Pairwise Distance

Categorizing query points based on their distance to points in a training dataset can be a simple yet effective way of classifying new points. You can use various metrics to determine the distance, described next. Use `pdist2` to find the distance between a set of data and query points.

### Distance Metrics

Given an  $m \times n$  data matrix  $X$ , which is treated as  $m \times (1 \text{-by-} n)$  row vectors  $x_1, x_2, \dots, x_m$ , and  $m \times n$  data matrix  $Y$ , which is treated as  $m \times (1 \text{-by-} n)$  row vectors  $y_1, y_2, \dots, y_m$ , the various distances between the vector  $x_s$  and  $y_t$  are defined as follows:

- Euclidean distance

$$d_{st}^2 = (x_s - y_t)(x_s - y_t)'$$

The Euclidean distance is a special case of the Minkowski metric, where  $p = 2$ .

- Standardized Euclidean distance

$$d_{st}^2 = (x_s - y_t)V^{-1}(x_s - y_t)'$$

where  $V$  is the  $n$ -by- $n$  diagonal matrix whose  $j$ th diagonal element is  $S(j)^2$ , where  $S$  is the vector containing the inverse weights.

- Mahalanobis distance

$$d_{st}^2 = (x_s - y_t)C^{-1}(x_s - y_t)'$$

where  $C$  is the covariance matrix.

- City block metric

$$d_{st} = \sum_{j=1}^n |x_{sj} - y_{tj}|$$

The city block distance is a special case of the Minkowski metric, where  $p = 1$ .

- Minkowski metric

$$d_{st} = \sqrt[p]{\sum_{j=1}^n |x_{sj} - y_{tj}|^p}$$

For the special case of  $p = 1$ , the Minkowski metric gives the city block metric, for the special case of  $p = 2$ , the Minkowski metric gives the Euclidean distance, and for the special case of  $p = \infty$ , the Minkowski metric gives the Chebychev distance.

- Chebychev distance

$$d_{st} = \max_j \{|x_{sj} - y_{tj}|\}$$

The Chebychev distance is a special case of the Minkowski metric, where  $p = \infty$ .

- Cosine distance

$$d_{st} = \left( 1 - \frac{x_s y_t'}{\sqrt{(x_s x_s')(y_t y_t')}} \right)$$

- Correlation distance

$$d_{st} = 1 - \frac{(x_s - \bar{x}_s)(y_t - \bar{y}_t)'}{\sqrt{(x_s - \bar{x}_s)(x_s - \bar{x}_s)' (y_t - \bar{y}_t)(y_t - \bar{y}_t)'}}$$

where

$$\bar{x}_s = \frac{1}{n} \sum_j x_{sj}$$

and

$$\bar{y}_t = \frac{1}{n} \sum_j y_{tj}$$

- Hamming distance

$$d_{st} = (\#(x_{sj} \neq y_{tj}) / n)$$

- Jaccard distance

$$d_{st} = \frac{\#[(x_{sj} \neq y_{tj}) \cap ((x_{sj} \neq 0) \cup (y_{tj} \neq 0))]}{\#[(x_{sj} \neq 0) \cup (y_{tj} \neq 0)]}$$

- Spearman distance

$$d_{st} = 1 - \frac{(r_s - \bar{r}_s)(r_t - \bar{r}_t)'}{\sqrt{(r_s - \bar{r}_s)(r_s - \bar{r}_s)' (r_t - \bar{r}_t)(r_t - \bar{r}_t)'}}$$

where

- $r_{sj}$  is the rank of  $x_{sj}$  taken over  $x_{1j}, x_{2j}, \dots, x_{mj}$ , as computed by tiedrank.
- $r_{tj}$  is the rank of  $y_{tj}$  taken over  $y_{1j}, y_{2j}, \dots, y_{mj}$ , as computed by tiedrank.
- $r_s$  and  $r_t$  are the coordinate-wise rank vectors of  $x_s$  and  $y_t$ , i.e.,  $r_s = (r_{s1}, r_{s2}, \dots, r_{sn})$  and  $r_t = (r_{t1}, r_{t2}, \dots, r_{tn})$ .

$$\bar{r}_s = \frac{1}{n} \sum_j r_{sj} = \frac{(n+1)}{2}.$$

$$\bar{r}_t = \frac{1}{n} \sum_j r_{tj} = \frac{(n+1)}{2}.$$

### ***k*-Nearest Neighbor Search and Radius Search**

Given a set  $X$  of  $n$  points and a distance function,  $k$ -nearest neighbor ( $k$ NN) search lets you find the  $k$  closest points in  $X$  to a query point or set of points  $Y$ . The  $k$ NN search technique and  $k$ NN-based algorithms are widely used as benchmark learning rules. The relative simplicity of the  $k$ NN search technique makes it easy to compare the results from other classification techniques to  $k$ NN results. The technique has been used in various areas such as:

- bioinformatics
- image processing and data compression
- document retrieval
- computer vision
- multimedia database
- marketing data analysis

You can use  $k$ NN search for other machine learning algorithms, such as:

- $k$ NN classification
- local weighted regression
- missing data imputation and interpolation
- density estimation

You can also use  $k$ NN search with many distance-based learning functions, such as K-means clustering.

In contrast, for a positive real value  $r$ , `rangesearch` finds all points in  $X$  that are within a distance  $r$  of each point in  $Y$ . This fixed-radius search is closely

related to  $k$ NN search, as it supports the same distance metrics and search classes, and uses the same search algorithms.

### ***k*-Nearest Neighbor Search Using Exhaustive Search**

When your input data meets any of the following criteria, `knnsearch` uses the exhaustive search method by default to find the  $k$ -nearest neighbors:

- The number of columns of  $X$  is more than 10.
- $X$  is sparse.
- The distance measure is either:
  - 'seuclidean'
  - 'mahalanobis'
  - 'cosine'
  - 'correlation'
  - 'spearman'
  - 'hamming'
  - 'jaccard'
  - A custom distance function

`knnsearch` also uses the exhaustive search method if your search object is an `ExhaustiveSearcher` object. The exhaustive search method finds the distance from each query point to every point in  $X$ , ranks them in ascending order, and returns the  $k$  points with the smallest distances. For example, this diagram shows the  $k = 3$  nearest neighbors.

### ***k*-Nearest Neighbor Search Using a *kd*-Tree**

When your input data meets all of the following criteria, `knnsearch` creates a *kd*-tree by default to find the *k*-nearest neighbors:

- The number of columns of *X* is less than 10.
- *X* is not sparse.
- The distance measure is either:
  - 'euclidean' (default)
  - 'cityblock'
  - 'minkowski'
  - 'chebychev'

`knnsearch` also uses a *kd*-tree if your search object is a `KDTreeSearcher` object.

*kd*-trees divide your data into nodes with at most `BucketSize` (default is 50) points per node, based on coordinates (as opposed to categories). The following diagrams illustrate this concept using patch objects to color code the different “buckets.”

When you want to find the  $k$ -nearest neighbors to a given query point, `knnsearch` does the following:

- 1 Determines the node to which the query point belongs. In the following example, the query point (32,90) belongs to Node 4.

- 2 Finds the closest  $k$  points within that node and its distance to the query point. In the following example, the points in red circles are equidistant from the query point, and are the closest points to the query point within Node 4.
- 3 Chooses all other nodes having any area that is within the same distance, in any direction, from the query point to the  $k$ th closest point. In this example, only Node 3 overlaps the solid black circle centered at the query point with radius equal to the distance to the closest points within Node 4.
- 4 Searches nodes within that range for any points closer to the query point. In the following example, the point in a red square is slightly closer to the query point than those within Node 4.

Using a *kd*-tree for large datasets with fewer than 10 dimensions (columns) can be much more efficient than using the exhaustive search method, as `knnsearch` needs to calculate only a subset of the distances. To maximize the efficiency of *kd*-trees, use a `KDTreeSearcher` object.

## What Are Search Objects?

Basically, objects are a convenient way of storing information. Classes of related objects (for example, all search objects) have the same properties with values and types relevant to a specified search method. In addition to storing information within objects, you can perform certain actions (called *methods*) on objects.

All search objects have a `knnsearch` method specific to that class. This lets you efficiently perform a *k*-nearest neighbors search on your object for that specific object type. In addition, there is a generic `knnsearch` function that searches without creating or using an object.

To determine which type of object and search method is best for your data, consider the following:

- Does your data have many columns, say more than 10? The `ExhaustiveSearcher` object may perform better.
- Is your data sparse? Use the `ExhaustiveSearcher` object.
- Do you want to use one of these distance measures to find the nearest neighbors? Use the `ExhaustiveSearcher` object.
  - `'seuclidean'`
  - `'mahalanobis'`
  - `'cosine'`
  - `'correlation'`
  - `'spearman'`
  - `'hamming'`
  - `'jaccard'`
  - A custom distance function

- Is your dataset huge (but with fewer than 10 columns)? Use the `KDTreeSearcher` object.
- Are you searching for the nearest neighbors for a large number of query points? Use the `KDTreeSearcher` object.

### **Classifying Query Data Using `knnsearch`**

This example shows how to classify query data using `knnsearch` .

Classify a new point based on the last two columns of the Fisher iris data. Using only the last two columns makes it easier to plot.

```
load fisheriris
x = meas(:,3:4);
gscatter(x(:,1),x(:,2),species)
set(legend,'location','best')
```

Plot the new point.

```
newpoint = [5 1.45];  
line(newpoint(1),newpoint(2),'marker','x','color','k',...  
      'markersize',10,'linewidth',2)
```

Find the 10 sample points closest to the new point.

```
[n,d] = knnsearch(x,newpoint,'k',10);  
line(x(n,1),x(n,2),'color',[.5 .5 .5],'marker','o',...  
      'linestyle','none','markersize',10)
```

It appears that `knnsearch` has found only the nearest eight neighbors. In fact, this particular dataset contains duplicate values.

```
x(n, :)
```

```
ans =
```

```
5.0000    1.5000
4.9000    1.5000
```

4.9000	1.5000
5.1000	1.5000
5.1000	1.6000
4.8000	1.4000
5.0000	1.7000
4.7000	1.4000
4.7000	1.4000
4.7000	1.5000

Make the axes equal so the calculated distances correspond to the apparent distances on the plot axis equal and zoom in to see the neighbors better.

```
set(gca,'xlim',[4.5 5.5],'ylim',[1 2]); axis square
```

Find the species of the 10 neighbors.

```
tabulate(species(n))
```

Value	Count	Percent
virginica	2	20.00%
versicolor	8	80.00%

Using a rule based on the majority vote of the 10 nearest neighbors, you can classify this new point as a versicolor.

Visually identify the neighbors by drawing a circle around the group of them. Define the center and diameter of a circle, based on the location of the new point.

```
ctr = newpoint - d(end);
diameter = 2*d(end);
% Draw a circle around the 10 nearest neighbors.
h = rectangle('position',[ctr,diameter,diameter],...
    'curvature',[1 1]);
set(h,'linestyle',':')
```

Using the same dataset, find the 10 nearest neighbors to three new points.

```
figure
newpoint2 = [5 1.45;6 2;2.75 .75];
gscatter(x(:,1),x(:,2),species)
legend('location','best')
[n2,d2] = knnsearch(x,newpoint2,'k',10);
line(x(n2,1),x(n2,2),'color',[.5 .5 .5],'marker','o',...
     'linestyle','none','markersize',10)
line(newpoint2(:,1),newpoint2(:,2),'marker','x','color','k',...
     'markersize',10,'linewidth',2,'linestyle','none')
```

Find the species of the 10 nearest neighbors for each new point.

```
tabulate(species(n2(1, :)))
```

Value	Count	Percent
virginica	2	20.00%
versicolor	8	80.00%

```
tabulate(species(n2(2, :)))
```

Value	Count	Percent
virginica	10	100.00%

```
tabulate(species(n2(3, :)))
```

Value	Count	Percent
versicolor	7	70.00%
setosa	3	30.00%

For more examples using `knnsearch` methods and function, see the individual reference pages.

## **K-Nearest Neighbor Classification for Supervised Learning**

The `ClassificationKNN` class lets you:

- “Construct a KNN Classifier” on page 16-27
- “Examine the Quality of a KNN Classifier” on page 16-27
- “Predict Classification Based on a KNN Classifier” on page 16-28
- “Modify a KNN Classifier” on page 16-29

Work with the classifier as you would with `ClassificationTree` or `ClassificationDiscriminant`. In particular, prepare your data for classification according to the procedure in “Steps in Supervised Learning (Machine Learning)” on page 16-2. Then construct the classifier using `ClassificationKNN.fit`.

## Construct a KNN Classifier

This example shows how to construct a  $k$ -nearest neighbor classifier for the Fisher iris data.

Load the Fisher iris data.

```
load fisheriris
X = meas; % use all data for fitting
Y = species; % response data
```

Construct the classifier using `ClassificationKNN.fit`.

```
mdl = ClassificationKNN.fit(X,Y)
```

```
mdl =
```

```
ClassificationKNN
  PredictorNames: {'x1' 'x2' 'x3' 'x4'}
  ResponseName: 'Y'
  ClassNames: {'setosa' 'versicolor' 'virginica'}
  ScoreTransform: 'none'
  NObservations: 150
  Distance: 'euclidean'
  NumNeighbors: 1
```

Properties, Methods

A default  $k$ -nearest neighbor classifier uses just the single nearest neighbor. Often, a classifier is more robust with more neighbors than that. Change the neighborhood size of `mdl` to 4, meaning `mdl` classifies using the four nearest neighbors:

```
mdl.NumNeighbors = 4;
```

## Examine the Quality of a KNN Classifier

This example shows how to examine the quality of a  $k$ -nearest neighbor classifier using resubstitution and cross validation.

Construct a KNN classifier for the Fisher iris data as in “Construct a KNN Classifier” on page 16-27.

```
load fisheriris
X = meas; % use all data for fitting
Y = species; % response data
mdl = ClassificationKNN.fit(X,Y,'NumNeighbors',4);
```

Examine the resubstitution loss, which, by default, is the fraction of misclassifications from the predictions of mdl. (For nondefault cost, weights, or priors, see `ClassificationKNN.loss`.)

```
rloss = resubLoss(mdl)
```

```
rloss =
```

```
0.0400
```

The classifier predicts incorrectly for 4% of the training data.

Construct a cross-validated classifier from the model.

```
cvmdl = crossval(mdl);
```

Examine the cross-validation loss, which is the average loss of each cross-validation model when predicting on data that is not used for training.

```
kloss = kfoldLoss(cvmdl)
```

```
kloss =
```

```
0.0600
```

The cross-validated classification accuracy resembles the resubstitution accuracy. Therefore, you can expect mdl to misclassify approximately 5% of new data, assuming that the new data has about the same distribution as the training data.

## **Predict Classification Based on a KNN Classifier**

This example shows how to predict classification for a  $k$ -nearest neighbor classifier.

Construct a default KNN classifier for the Fisher iris data as in “Construct a KNN Classifier” on page 16-27.

```
load fisheriris
X = meas; % use all data for fitting
Y = species; % response data
mdl = ClassificationKNN.fit(X,Y);
```

Predict the classification of an average flower.

```
flwr = mean(X); % an average flower
flwrClass = predict(mdl,flwr)
```

```
flwrClass =
    'versicolor'
```

## Modify a KNN Classifier

This example shows how to modify a  $k$ -nearest neighbor classifier.

Construct a default KNN classifier for the Fisher iris data as in “Construct a KNN Classifier” on page 16-27.

```
load fisheriris
X = meas; % use all data for fitting
Y = species; % response data
mdl = ClassificationKNN.fit(X,Y);
```

Modify the model to use the three nearest neighbors, rather than the default one nearest neighbor.

```
mdl.NumNeighbors = 3;
```

Compare the resubstitution predictions and cross-validation loss with the new number of neighbors.

```
rloss = resubLoss(mdl)
```

```
rloss =
    0.0400
```

```
rng('default')
cvmdl = crossval mdl, 'kfold', 5);
kloss = kfoldLoss(cvmdl)
```

```
kloss =

    0.0333
```

The model with three neighbors has lower cross-validated loss than a model with four neighbors (see “Examine the Quality of a KNN Classifier” on page 16-27).

Modify the model to use cosine distance instead of the default, and examine the loss. To use cosine distance, you must recreate the model using the exhaustive search method.

```
cmd1 = ClassificationKNN.fit(X,Y,'NSMethod','exhaustive',...
    'Distance','cosine');
cmd1.NumNeighbors = 3;
closs = resubLoss(cmd1)
```

```
closs =

    0.0200
```

The classifier now has lower resubstitution error than before.

Check the quality of a cross-validated version of the new model.

```
cvcmd1 = crossval(cmd1);
kcloss = kfoldLoss(cvcmd1)
```

```
kcloss =

    0.0333
```

The cross-validated loss is the same as before. The lesson is that improving the resubstitution error does not necessarily produce a model with better predictions.

## Classification Trees and Regression Trees

### In this section...

“What Are Classification Trees and Regression Trees?” on page 16-31

“Improving Classification Trees and Regression Trees” on page 16-39

“Alternative: classregtree” on page 16-48

### What Are Classification Trees and Regression Trees?

Classification trees and regression trees predict responses to data. To predict a response, follow the decisions in the tree from the root (beginning) node down to a leaf node. The leaf node contains the response. Classification trees give responses that are nominal, such as 'true' or 'false'. Regression trees give numeric responses.

Statistics Toolbox trees are binary. Each step in a prediction involves checking the value of one predictor (variable). For example, here is a simple classification tree:

This tree predicts classifications based on two predictors,  $x_1$  and  $x_2$ . To predict, start at the top node, represented by a triangle ( $\Delta$ ). The first decision is whether  $x_1$  is smaller than 0.5. If so, follow the left branch, and see that the tree classifies the data as type 0.

If, however,  $x_1$  exceeds 0.5, then follow the right branch to the lower-right triangle node. Here the tree asks if  $x_2$  is smaller than 0.5. If so, then follow the left branch to see that the tree classifies the data as type 0. If not, then follow the right branch to see that the that the tree classifies the data as type 1.

To learn how to prepare your data for classification or regression using decision trees, see “Steps in Supervised Learning (Machine Learning)” on page 16-2.

## Creating a Classification Tree

To create a classification tree for the ionosphere data:

```
load ionosphere % contains X and Y variables
ctree = ClassificationTree.fit(X,Y)
```

```
ctree =
```

```
ClassificationTree
    PredictorNames: {1x34 cell}
    ResponseName: 'Y'
    ClassNames: {'b' 'g'}
    ScoreTransform: 'none'
    CategoricalPredictors: []
    NObservations: 351
```

```
Properties, Methods
```

## Creating a Regression Tree

To create a regression tree for the carsmall data based on the Horsepower and Weight vectors for data, and MPG vector for response:

```
load carsmall % contains Horsepower, Weight, MPG
```

```
X = [Horsepower Weight];
rtree = RegressionTree.fit(X,MPG)

rtree =

    RegressionTree
      PredictorNames: {'x1' 'x2'}
      ResponseName: 'Y'
      ResponseTransform: 'none'
      CategoricalPredictors: []
      NObservations: 94
```

Properties, Methods

## Viewing a Classification or Regression Tree

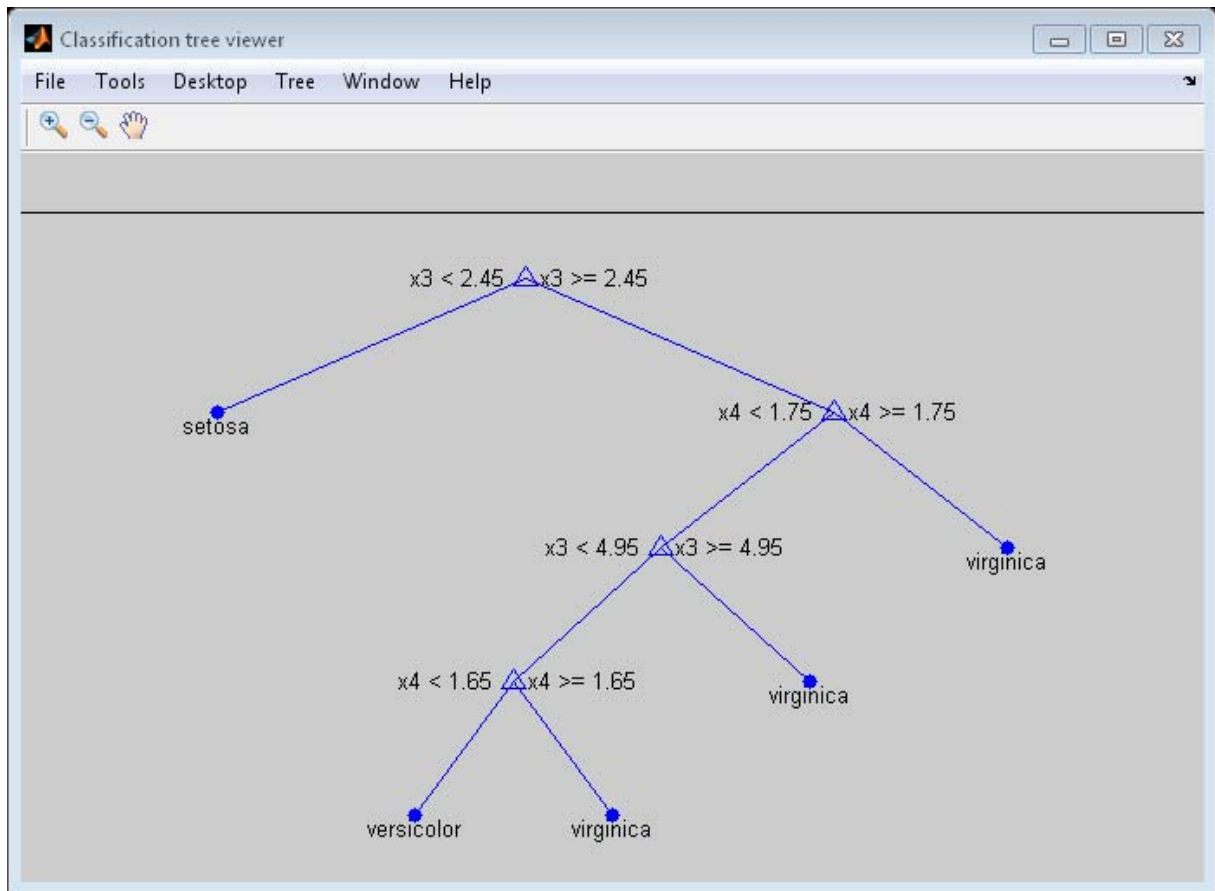

This example shows how to view a classification or a regression tree. There are two ways to view a tree: `view(tree)` returns a text description and `view(tree, 'mode', 'graph')` returns a graphic description of the tree.

Create and view a classification tree.

```
load fisheriris % load the sample data
ctree = ClassificationTree.fit(meas,species); % create classification tree
view(ctree) % text description
```

```
Decision tree for classification
1  if x3<2.45 then node 2 elseif x3>=2.45 then node 3 else setosa
2  class = setosa
3  if x4<1.75 then node 4 elseif x4>=1.75 then node 5 else versicolor
4  if x3<4.95 then node 6 elseif x3>=4.95 then node 7 else versicolor
5  class = virginica
6  if x4<1.65 then node 8 elseif x4>=1.65 then node 9 else versicolor
7  class = virginica
8  class = versicolor
9  class = virginica
```

```
view(ctree, 'mode', 'graph') % graphic description
```

Now, create and view a regression tree.

```

load carsmall % load the sample data, contains Horsepower, Weight, MPG
X = [Horsepower Weight];
rtree = RegressionTree.fit(X,MPG,'MinParent',30); % create classification t
view(rtree) % text description
  
```

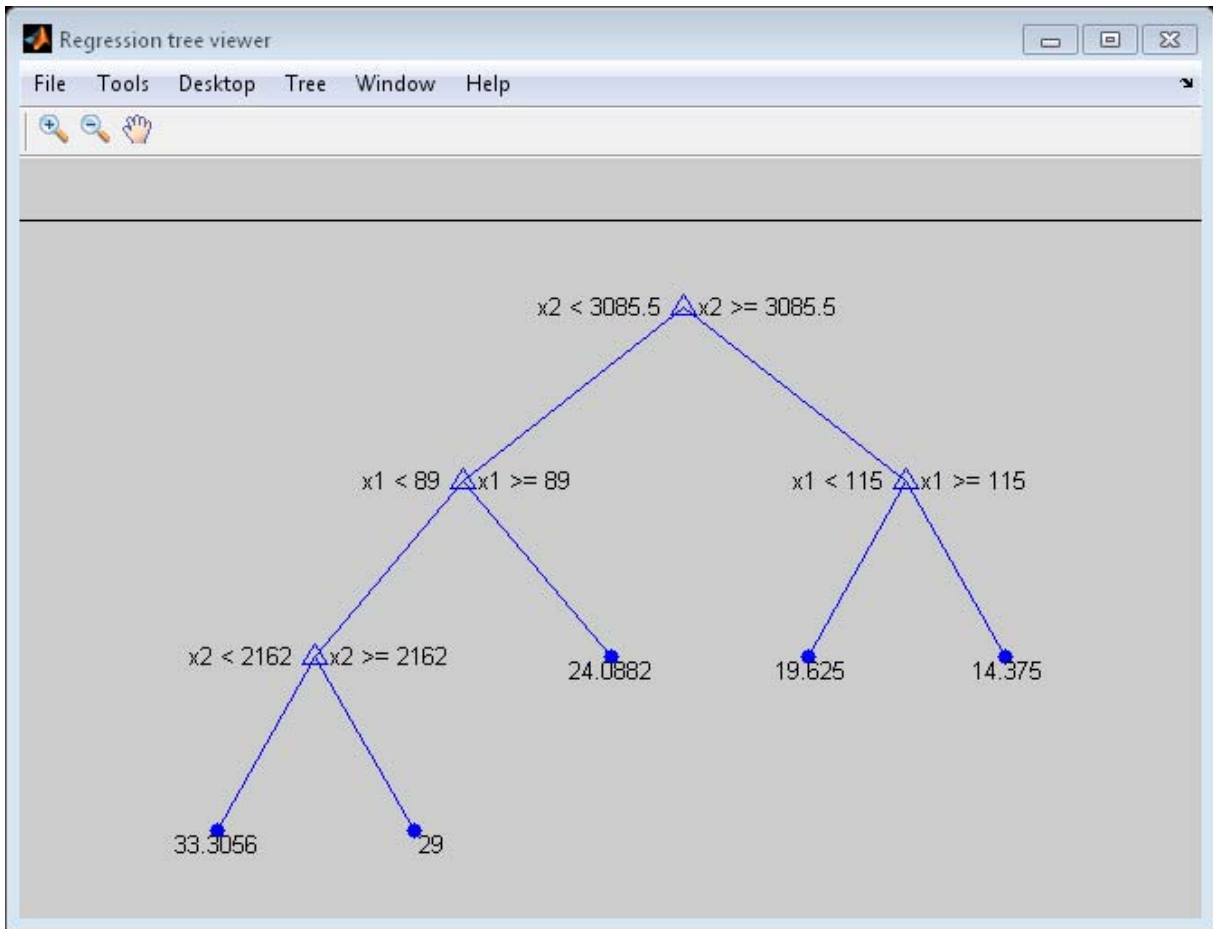

Decision tree for regression

```

1 if x2<3085.5 then node 2 elseif x2>=3085.5 then node 3 else 23.7181
  
```

```
2 if x1<89 then node 4 elseif x1>=89 then node 5 else 28.7931
3 if x1<115 then node 6 elseif x1>=115 then node 7 else 15.5417
4 if x2<2162 then node 8 elseif x2>=2162 then node 9 else 30.9375
5 fit = 24.0882
6 fit = 19.625
7 fit = 14.375
8 fit = 33.3056
9 fit = 29
```

```
view(rtree,'mode','graph') % graphic description
```

### How the Fit Methods Create Trees

The `ClassificationTree.fit` and `RegressionTree.fit` methods perform the following steps to create decision trees:

- 1 Start with all input data, and examine all possible binary splits on every predictor.
- 2 Select a split with best optimization criterion.

- If the split leads to a child node having too few observations (less than the `MinLeaf` parameter), select a split with the best optimization criterion subject to the `MinLeaf` constraint.

**3** Impose the split.

**4** Repeat recursively for the two child nodes.

The explanation requires two more items: description of the optimization criterion, and stopping rule.

**Stopping rule:** Stop splitting when any of the following hold:

- The node is *pure*.
  - For classification, a node is pure if it contains only observations of one class.
  - For regression, a node is pure if the mean squared error (MSE) for the observed response in this node drops below the MSE for the observed response in the entire data multiplied by the tolerance on quadratic error per node (`qetoler` parameter).
- There are fewer than `MinParent` observations in this node.
- Any split imposed on this node would produce children with fewer than `MinLeaf` observations.

**Optimization criterion:**

- Regression: mean-squared error (MSE). Choose a split to minimize the MSE of predictions compared to the training data.
- Classification: One of three measures, depending on the setting of the `SplitCriterion` name-value pair:
  - `'gdi'` (Gini's diversity index, the default)
  - `'twoing'`
  - `'deviance'`

For details, see `ClassificationTree` “Definitions” on page 21-326.

For a continuous predictor, a tree can split halfway between any two adjacent unique values found for this predictor. For a categorical predictor with  $L$  levels, a classification tree needs to consider  $2^{L-1}-1$  splits to find the optimal split. Alternatively, you can choose a heuristic algorithm to find a good split, as described in “Splitting Categorical Predictors” on page 16-56.

## Predicting Responses With Classification and Regression Trees

After creating a tree, you can easily predict responses for new data. Suppose  $X_{\text{new}}$  is new data that has the same number of columns as the original data  $X$ . To predict the classification or regression based on the tree and the new data, enter

```
Ynew = predict(tree,Xnew);
```

For each row of data in  $X_{\text{new}}$ , `predict` runs through the decisions in `tree` and gives the resulting prediction in the corresponding element of  $Y_{\text{new}}$ . For more information for classification, see the classification `predict` reference page; for regression, see the regression `predict` reference page.

For example, to find the predicted classification of a point at the mean of the ionosphere data:

```
load ionosphere % contains X and Y variables
ctree = ClassificationTree.fit(X,Y);
Ynew = predict(ctree,mean(X))
```

```
Ynew =
```

```
    'g'
```

To find the predicted MPG of a point at the mean of the `carsmall` data:

```
load carsmall % contains Horsepower, Weight, MPG
X = [Horsepower Weight];
rtree = RegressionTree.fit(X,MPG);
Ynew = predict(rtree,mean(X))
```

```
Ynew =
```

28.7931

## Improving Classification Trees and Regression Trees

You can tune trees by setting name-value pairs in `ClassificationTree.fit` and `RegressionTree.fit`. The remainder of this section describes how to determine the quality of a tree, how to decide which name-value pairs to set, and how to control the size of a tree:

- “Examining Resubstitution Error” on page 16-39
- “Cross Validation” on page 16-39
- “Control Depth or “Leafiness”” on page 16-40
- “Pruning” on page 16-44

### Examining Resubstitution Error

*Resubstitution error* is the difference between the response training data and the predictions the tree makes of the response based on the input training data. If the resubstitution error is high, you cannot expect the predictions of the tree to be good. However, having low resubstitution error does not guarantee good predictions for new data. Resubstitution error is often an overly optimistic estimate of the predictive error on new data.

**Example: Resubstitution Error of a Classification Tree.** Examine the resubstitution error of a default classification tree for the Fisher iris data:

```
load fisheriris
ctree = ClassificationTree.fit(meas,species);
resuberror = resubLoss(ctree)

resuberror =

    0.0200
```

The tree classifies nearly all the Fisher iris data correctly.

### Cross Validation

To get a better sense of the predictive accuracy of your tree for new data, cross validate the tree. By default, cross validation splits the training data

into 10 parts at random. It trains 10 new trees, each one on nine parts of the data. It then examines the predictive accuracy of each new tree on the data not included in training that tree. This method gives a good estimate of the predictive accuracy of the resulting tree, since it tests the new trees on new data.

**Example: Cross Validating a Regression Tree.** Examine the resubstitution and cross-validation accuracy of a regression tree for predicting mileage based on the carsmall data:

```
load carsmall
X = [Acceleration Displacement Horsepower Weight];
rtree = RegressionTree.fit(X,MPG);
resuberror = resubLoss(rtree)

resuberror =
    4.7188
```

The resubstitution loss for a regression tree is the mean-squared error. The resulting value indicates that a typical predictive error for the tree is about the square root of 4.7, or a bit over 2.

Now calculate the error by cross validating the tree:

```
rng('default')
cvrtree = crossval(rtree);
cvloss = kfoldLoss(cvrtree)

cvloss =
    23.8065
```

The cross-validated loss is almost 25, meaning a typical predictive error for the tree on new data is about 5. This demonstrates that cross-validated loss is usually higher than simple resubstitution loss.

### **Control Depth or “Leafiness”**

When you grow a decision tree, consider its simplicity and predictive power. A deep tree with many leaves is usually highly accurate on the training data. However, the tree is not guaranteed to show a comparable accuracy on an

independent test set. A leafy tree tends to overtrain, and its test accuracy is often far less than its training (resubstitution) accuracy. In contrast, a shallow tree does not attain high training accuracy. But a shallow tree can be more robust — its training accuracy could be close to that of a representative test set. Also, a shallow tree is easy to interpret.

If you do not have enough data for training and test, estimate tree accuracy by cross validation.

For an alternative method of controlling the tree depth, see “Pruning” on page 16-44.

**Example: Selecting Appropriate Tree Depth.** This example shows how to control the depth of a decision tree, and how to choose an appropriate depth.

- 1 Load the ionosphere data:

```
load ionosphere
```

- 2 Generate minimum leaf occupancies for classification trees from 10 to 100, spaced exponentially apart:

```
leafs = logspace(1,2,10);
```

- 3 Create cross validated classification trees for the ionosphere data with minimum leaf occupancies from leafs:

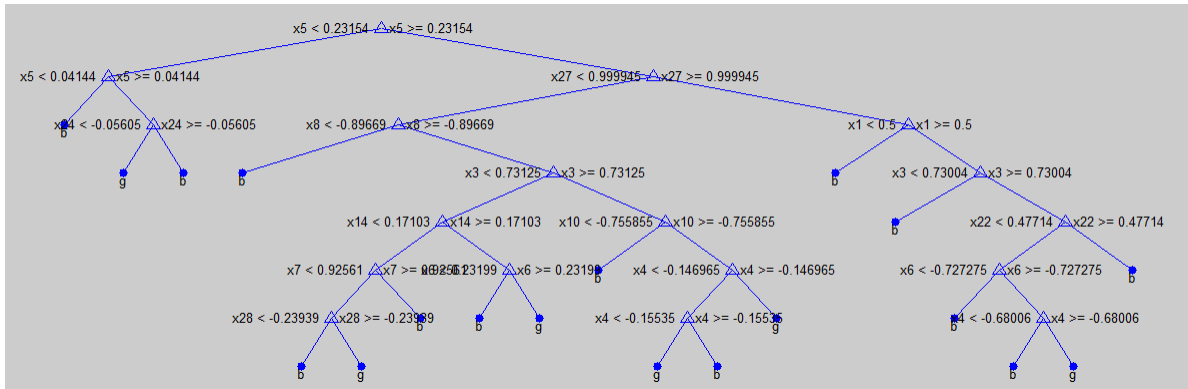

```
rng('default')
N = numel(leafs);
err = zeros(N,1);
for n=1:N
    t = ClassificationTree.fit(X,Y,'crossval','on',...
        'minleaf',leafs(n));
    err(n) = kfoldLoss(t);
end
plot(leafs,err);
xlabel('Min Leaf Size');
ylabel('cross-validated error');
```

The best leaf size is between about 20 and 50 observations per leaf.

- 4 Compare the near-optimal tree with at least 40 observations per leaf with the default tree, which uses 10 observations per parent node and 1 observation per leaf.

```
DefaultTree = ClassificationTree.fit(X,Y);  
view(DefaultTree,'mode','graph')
```

```
OptimalTree = ClassificationTree.fit(X,Y,'minleaf',40);
view(OptimalTree,'mode','graph')
```

```
resubOpt = resubLoss(OptimalTree);
lossOpt = kfoldLoss(crossval(OptimalTree));
resubDefault = resubLoss(DefaultTree);
lossDefault = kfoldLoss(crossval(DefaultTree));
resubOpt,resubDefault,lossOpt,lossDefault
```

```
resubOpt =
```

```
0.0883
resubDefault =
0.0114
lossOpt =
0.1054
lossDefault =
0.1111
```

The near-optimal tree is much smaller and gives a much higher resubstitution error. Yet it gives similar accuracy for cross-validated data.

### **Pruning**

Pruning optimizes tree depth (leafiness) is by merging leaves on the same tree branch. “Control Depth or “Leafiness”” on page 16-40 describes one method for selecting the optimal depth for a tree. Unlike in that section, you do not need to grow a new tree for every node size. Instead, grow a deep tree, and prune it to the level you choose.

Prune a tree at the command line using the `prune` method (classification) or `prune` method (regression). Alternatively, prune a tree interactively with the tree viewer:

```
view(tree, 'mode', 'graph')
```

To prune a tree, the tree must contain a pruning sequence. By default, both `ClassificationTree.fit` and `RegressionTree.fit` calculate a pruning sequence for a tree during construction. If you construct a tree with the 'Prune' name-value pair set to 'off', or if you prune a tree to a smaller level, the tree does not contain the full pruning sequence. Generate the full pruning sequence with the `prune` method (classification) or `prune` method (regression).

**Example: Pruning a Classification Tree.** This example creates a classification tree for the ionosphere data, and prunes it to a good level.

**1** Load the ionosphere data:

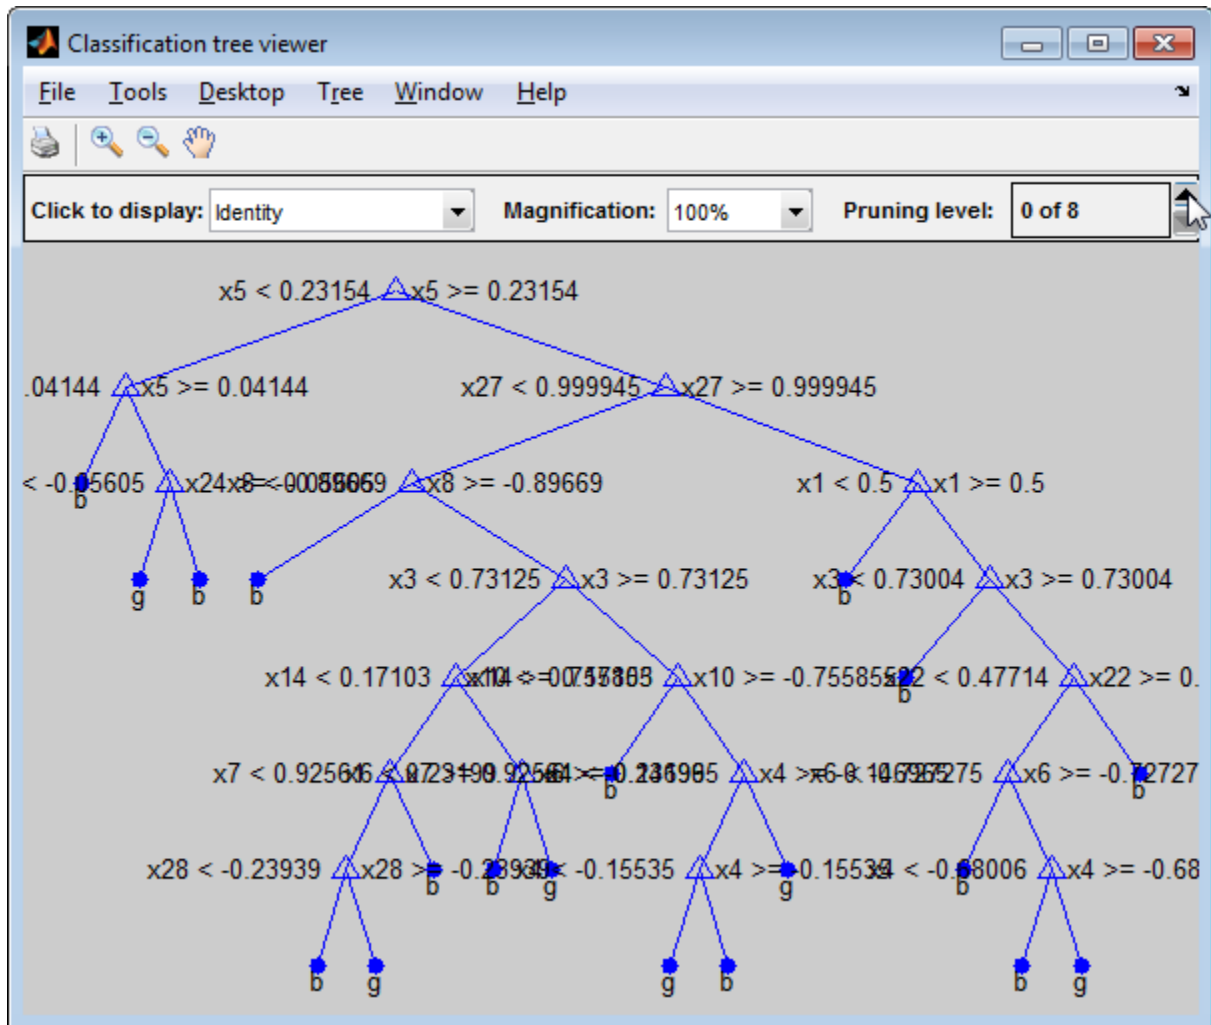

```
load ionosphere
```

**2** Construct a default classification tree for the data:

```
tree = ClassificationTree.fit(X,Y);
```

**3** View the tree in the interactive viewer:

```
view(tree, 'mode', 'graph')
```

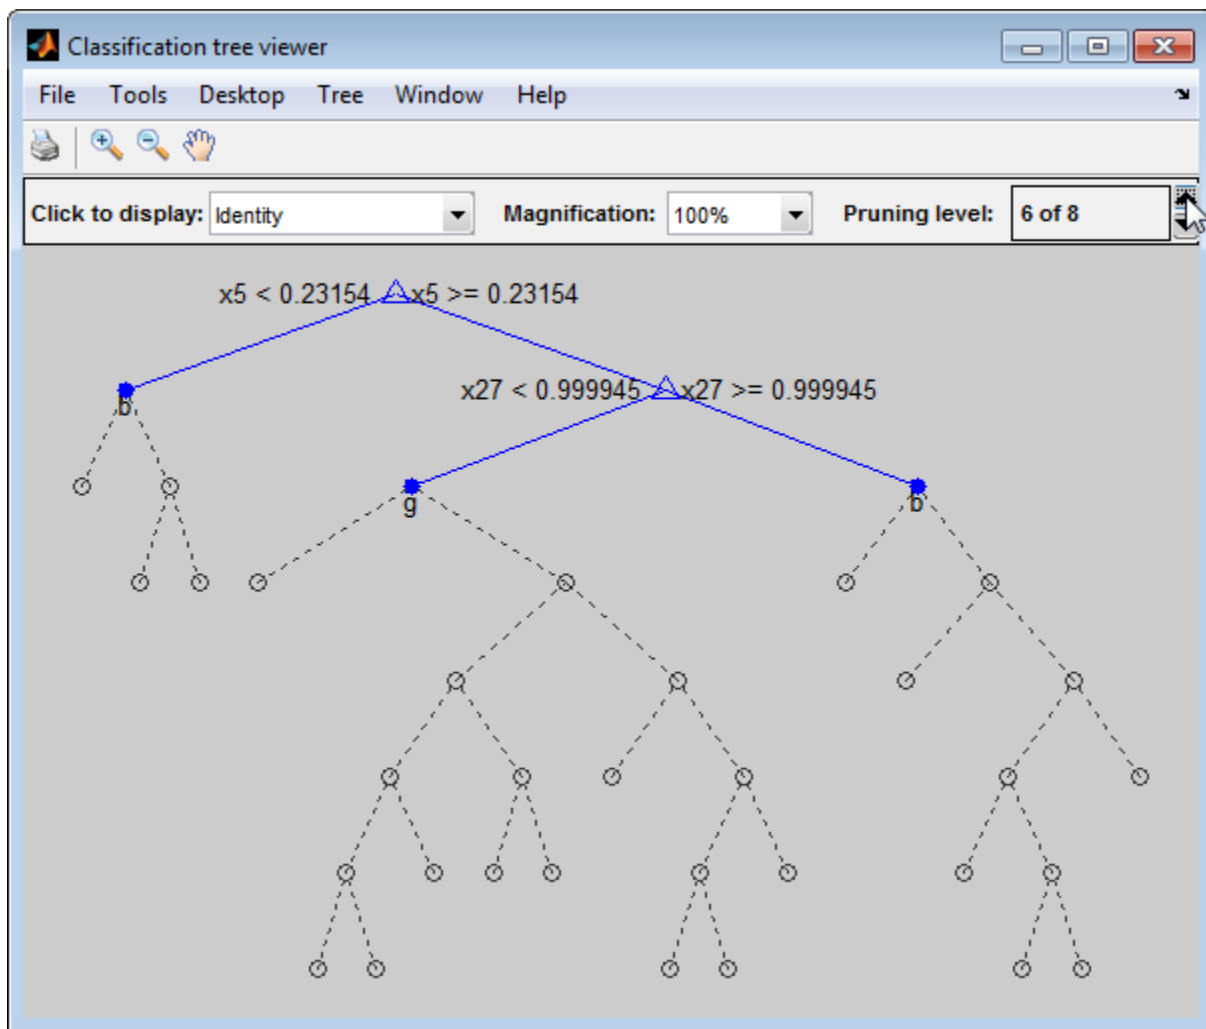

4 Find the optimal pruning level by minimizing cross-validated loss:

```
[~,~,~,bestlevel] = cvLoss(tree,...
    'subtrees','all','treesize','min')
```

```
bestlevel =
```

6

5 Prune the tree to level 6 in the interactive viewer:

The pruned tree is the same as the near-optimal tree in “Example: Selecting Appropriate Tree Depth” on page 16-41.

- 6 Set 'treesize' to 'se' (default) to find the maximal pruning level for which the tree error does not exceed the error from the best level plus one standard deviation:

```
[~,~,~,bestlevel] = cvLoss(tree,'subtrees','all')
```

```
bestlevel =
```

```
6
```

In this case the level is the same for either setting of 'treesize'.

- 7 Prune the tree to use it for other purposes:

```
tree = prune(tree,'Level',6);  
view(tree,'mode','graph')
```

### Alternative: classregtree

The ClassificationTree and RegressionTree classes are new in MATLAB R2011a. Previously, you represented both classification trees and regression trees with a classregtree object. The new classes provide all the functionality of the classregtree class, and are more convenient when used in conjunction with “Ensemble Methods” on page 16-59.

Before the `classregtree` class, there were `treefit`, `treedisp`, `treeval`, `treeprune`, and `treetest` functions. Statistics Toolbox software maintains these only for backward compatibility.

### Example: Creating Classification Trees Using `classregtree`

This example uses Fisher's iris data in `fisheriris.mat` to create a classification tree for predicting species using measurements of sepal length, sepal width, petal length, and petal width as predictors. Here, the predictors are continuous and the response is categorical.

- 1 Load the data and use the `classregtree` constructor of the `classregtree` class to create the classification tree:

```
load fisheriris

t = classregtree(meas,species,...
                'names',{'SL' 'SW' 'PL' 'PW'})

t =
Decision tree for classification
1  if PL<2.45 then node 2 elseif PL>=2.45 then node 3 else setosa
2  class = setosa
3  if PW<1.75 then node 4 elseif PW>=1.75 then node 5 else versicolor
4  if PL<4.95 then node 6 elseif PL>=4.95 then node 7 else versicolor
5  class = virginica
6  if PW<1.65 then node 8 elseif PW>=1.65 then node 9 else versicolor
7  class = virginica
8  class = versicolor
9  class = virginica
```

`t` is a `classregtree` object and can be operated on with any class method.

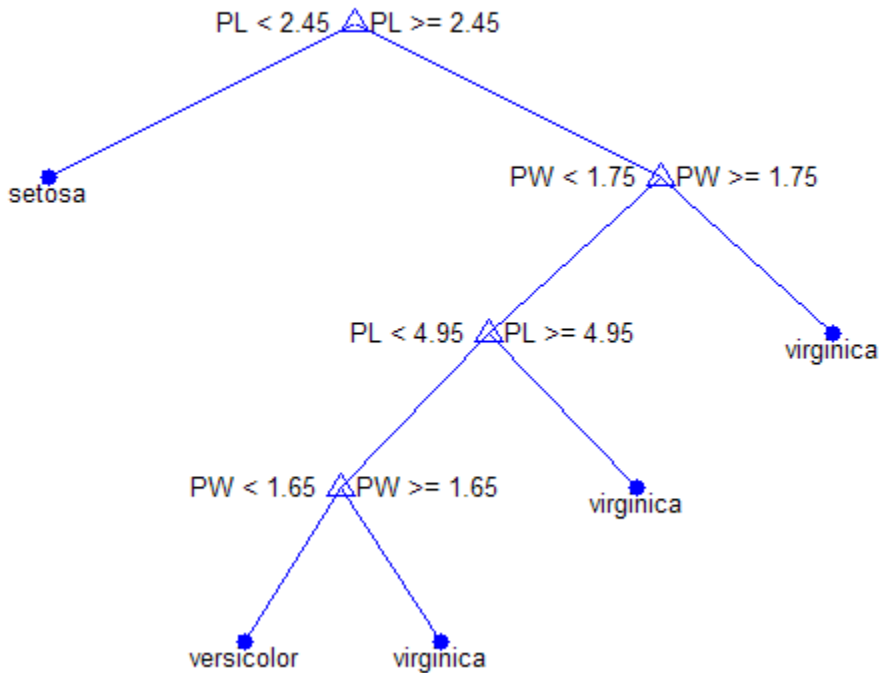

- 2 Use the `type` method of the `classregtree` class to show the type of the tree:

```
treetype = type(t)
treetype =
classification
```

`classregtree` creates a classification tree because `species` is a cell array of strings, and the response is assumed to be categorical.

**3** To view the tree, use the view method of the `classregtree` class:

```
view(t)
```

The tree predicts the response values at the circular leaf nodes based on a series of questions about the iris at the triangular branching nodes. A true answer to any question follows the branch to the left. A false follows the branch to the right.

**4** The tree does not use sepal measurements for predicting species. These can go unmeasured in new data, and you can enter them as NaN values for predictions. For example, to use the tree to predict the species of an iris with petal length 4.8 and petal width 1.6, type:

```

predicted = t([NaN NaN 4.8 1.6])
predicted =
    'versicolor'

```

The object allows for functional evaluation, of the form  $t(X)$ . This is a shorthand way of calling the `eval` method of the `classregtree` class. The predicted species is the left leaf node at the bottom of the tree in the previous view.

- 5** You can use a variety of methods of the `classregtree` class, such as `cutvar` and `cuttype` to get more information about the split at node 6 that makes the final distinction between `versicolor` and `virginica`:

```

var6 = cutvar(t,6) % What variable determines the split?
var6 =
    'PW'

```

```

type6 = cuttype(t,6) % What type of split is it?
type6 =
    'continuous'

```

- 6** Classification trees fit the original (training) data well, but can do a poor job of classifying new values. Lower branches, especially, can be strongly affected by outliers. A simpler tree often avoids overfitting. You can use the `prune` method of the `classregtree` class to find the next largest tree from an optimal pruning sequence:

```

pruned = prune(t,'level',1)
pruned =
Decision tree for classification
1  if PL<2.45 then node 2 elseif PL>=2.45 then node 3 else setosa
2  class = setosa
3  if PW<1.75 then node 4 elseif PW>=1.75 then node 5 else versicolor
4  if PL<4.95 then node 6 elseif PL>=4.95 then node 7 else versicolor
5  class = virginica
6  class = versicolor
7  class = virginica

view(pruned)

```

To find the best classification tree, employing the techniques of resubstitution and cross validation, use the test method of the `classregtree` class.

### Example: Creating Regression Trees Using `classregtree`

This example uses the data on cars in `carsmall.mat` to create a regression tree for predicting mileage using measurements of weight and the number of cylinders as predictors. Here, one predictor (weight) is continuous and the other (cylinders) is categorical. The response (mileage) is continuous.

- 1 Load the data and use the `classregtree` constructor of the `classregtree` class to create the regression tree:

```

load carsmall

t = classregtree([Weight, Cylinders],MPG,...
                'cat',2,'splitmin',20,...
                'names',{'W','C'})

t =

Decision tree for regression
1  if W<3085.5 then node 2 elseif W>=3085.5 then node 3 else 23.7181
2  if W<2371 then node 4 elseif W>=2371 then node 5 else 28.7931
3  if C=8 then node 6 elseif C in {4 6} then node 7 else 15.5417
4  if W<2162 then node 8 elseif W>=2162 then node 9 else 32.0741
5  if C=6 then node 10 elseif C=4 then node 11 else 25.9355
6  if W<4381 then node 12 elseif W>=4381 then node 13 else 14.2963
7  fit = 19.2778
8  fit = 33.3056
9  fit = 29.6111
10 fit = 23.25
11 if W<2827.5 then node 14 elseif W>=2827.5 then node 15 else 27.2143
12 if W<3533.5 then node 16 elseif W>=3533.5 then node 17 else 14.8696
13 fit = 11
14 fit = 27.6389
15 fit = 24.6667
16 fit = 16.6
17 fit = 14.3889

```

t is a `classregtree` object and can be operated on with any of the methods of the class.

- 2** Use the `type` method of the `classregtree` class to show the type of the tree:

```

treetype = type(t)
treetype =
regression

```

`classregtree` creates a regression tree because `MPG` is a numerical vector, and the response is assumed to be continuous.

- 3** To view the tree, use the `view` method of the `classregtree` class:

view(t)

Click to display:  Magnification:  Pruning level:

The tree predicts the response values at the circular leaf nodes based on a series of questions about the car at the triangular branching nodes. A true answer to any question follows the branch to the left; a false follows the branch to the right.

- 4 Use the tree to predict the mileage for a 2000-pound car with either 4, 6, or 8 cylinders:

```

mileage2K = t([2000 4; 2000 6; 2000 8])
mileage2K =
  33.3056
  33.3056
  33.3056
  
```

The object allows for functional evaluation, of the form `t(X)`. This is a shorthand way of calling the `eval` method of the `classregtree` class.

- 5 The predicted responses computed above are all the same. This is because they follow a series of splits in the tree that depend only on weight, terminating

at the leftmost leaf node in the view above. A 4000-pound car, following the right branch from the top of the tree, leads to different predicted responses:

```
mileage4K = t([4000 4; 4000 6; 4000 8])
mileage4K =
    19.2778
    19.2778
    14.3889
```

- 6 You can use a variety of other methods of the `classregtree` class, such as `cutvar`, `cuttype`, and `cutcategories`, to get more information about the split at node 3 that distinguishes the 8-cylinder car:

```
var3 = cutvar(t,3) % What variable determines the split?
var3 =
    'C'

type3 = cuttype(t,3) % What type of split is it?
type3 =
    'categorical'

c = cutcategories(t,3) % Which classes are sent to the left
                        % child node, and which to the right?
c =
    [8]    [1x2 double]
c{1}
ans =
    8
c{2}
ans =
    4    6
```

Regression trees fit the original (training) data well, but may do a poor job of predicting new values. Lower branches, especially, may be strongly affected by outliers. A simpler tree often avoids overfitting. To find the best regression tree, employing the techniques of resubstitution and cross validation, use the `test` method of the `classregtree` class.

## Splitting Categorical Predictors

### Challenges in Splitting Multilevel Predictors

When growing a classification tree, finding an optimal binary split for a categorical predictor with many levels is significantly more computationally challenging than finding a split for a continuous predictor. For a continuous predictor, a tree can split halfway between any two adjacent unique values of this predictor.

In contrast, to find an exact optimal binary split for a categorical predictor with  $L$  levels, a classification tree needs to consider  $2^{L-1}-1$  splits. To obtain this formula, observe that you can assign  $L$  distinct values to the left and right nodes in  $2^L$  ways. Two out of these  $2^L$  configurations leave either the left or right node empty, and therefore should be discarded. Now, divide by 2 because left and right can be swapped.

For regression and binary classification problems, with  $K = 2$  response classes, there is a computational shortcut [1]. The tree can order the categories by mean response (for regression) or class probability for one of the classes (for classification). Then, the optimal split is one of the  $L - 1$  splits for the ordered list. When  $K = 2$ , `ClassificationTree.fit` always uses an exact search.

Therefore, computational challenges really only arise when growing classification trees for data with  $K \geq 3$  classes. To reduce computation, there are several heuristic algorithms for finding a good split. When using `ClassificationTree.fit` to grow a classification tree, you can choose an algorithm for splitting categorical predictors using the `AlgorithmForCategorical` name-value pair argument. You can also set this algorithm when creating a classification template.

If you do not specify an algorithm, `ClassificationTree.fit` splits categorical predictors using the exact search algorithm, provided the predictor has at most `MaxCat` levels (the default is 10 levels, and, depending on your platform, you cannot perform an exact search on categorical predictors with more than 32 or 64 levels). Otherwise, `ClassificationTree.fit` chooses a good inexact search algorithm based on the number of classes and levels.

The available heuristic algorithms are: pull left by purity, a principle component-based partitioning, and one versus all by class.

### **Pull Left By Purity**

This algorithm starts with all  $L$  categorical levels on the right branch. Inspect the  $K$  categories that have the largest class probabilities for each class. Move the category with the maximum value of the split criterion to the left branch. Continue moving categories from right to left, recording the split criterion at each move, until the right child has only one category remaining. Out of this sequence, the chosen split is the one that maximizes the split criterion.

Select this pull left by purity algorithm by using the 'AlgorithmForCategorical', 'PullLeft' name-value pair in `ClassificationTree.fit`.

### **Principle Component-Based Partitioning**

This algorithm was developed by Coppersmith, Hong, and Hosking [2]. It finds a close-to-optimal binary partition of the  $L$  predictor levels by searching for a separating hyperplane that is perpendicular to the first principal component of the weighted covariance matrix of the centered class probability matrix.

The algorithm assigns a score to each of the  $L$  categories, computed as the inner product between the found principal component and the vector of class probabilities for that category. Then, the chosen split is the one of the  $L - 1$  splits of the scores that maximizes the split criterion.

Select this principle component-based partitioning by using the 'AlgorithmForCategorical', 'PCA' name-value pair in `ClassificationTree.fit`.

## One Versus All By Class

This algorithm starts with all  $L$  categorical levels on the right branch. For each of the  $K$  classes, order the categories based on their probability for that class.

For the first class, move each category to the left branch in order, recording the split criterion at each move. Repeat for the remaining classes. Out of this sequence, the chosen split is the one that maximizes the split criterion.

Select this one versus all by class algorithm by using the 'AlgorithmForCategorical', 'OVAByClass' name-value pair in `ClassificationTree.fit`.

### Framework for Ensemble Learning

You have several methods for melding results from many weak learners into one high-quality ensemble predictor. These methods closely follow the same syntax, so you can try different methods with minor changes in your commands.

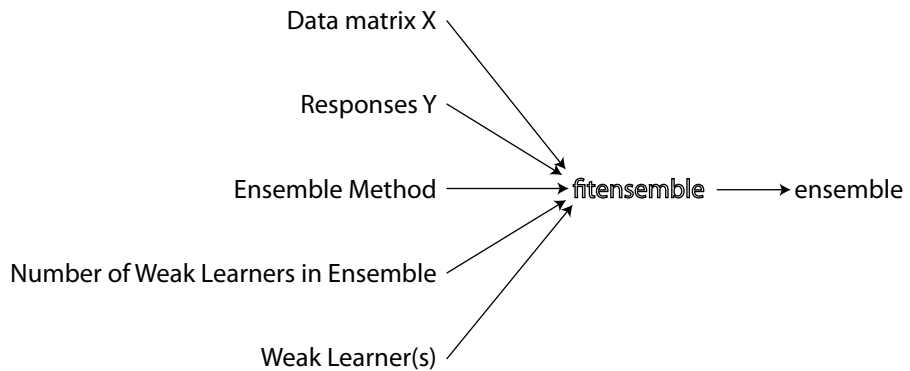

Create an ensemble with the `fitensemble` function. Its syntax is

```
ens = fitensemble(X,Y,model,numberens,learners)
```

- X is the matrix of data. Each row contains one observation, and each column contains one predictor variable.
- Y is the vector of responses, with the same number of observations as the rows in X.

- `model` is a string naming the type of ensemble.
- `numberens` is the number of weak learners in `ens` from each element of `learners`. So the number of elements in `ens` is `numberens` times the number of elements in `learners`.
- `learners` is either a string naming a weak learner, a weak learner template, or a cell array of such templates.

Pictorially, here is the information you need to create an ensemble:

For all classification or nonlinear regression problems, follow these steps to create an ensemble:

- 1** “Put Predictor Data in a Matrix” on page 16-61
- 2** “Prepare the Response Data” on page 16-61
- 3** “Choose an Applicable Ensemble Method” on page 16-62
- 4** “Set the Number of Ensemble Members” on page 16-65
- 5** “Prepare the Weak Learners” on page 16-66
- 6** “Call `fitensemble`” on page 16-68

## Put Predictor Data in a Matrix

All supervised learning methods start with a data matrix, usually called  $X$  in this documentation. Each row of  $X$  represents one observation. Each column of  $X$  represents one variable, or predictor.

## Prepare the Response Data

You can use a wide variety of data types for response data.

- For regression ensembles,  $Y$  must be a numeric vector with the same number of elements as the number of rows of  $X$ .
- For classification ensembles,  $Y$  can be any of the following data types. This table also contains the method of including missing entries.

Data Type	Missing Entry
Numeric vector	NaN
Categorical vector	<undefined>
Character array	Row of spaces
Cell array of strings	' '
Logical vector	(not possible to represent)

`fitensemble` ignores missing values in  $Y$  when creating an ensemble.

For example, suppose your response data consists of three observations in the following order: `true`, `false`, `true`. You could express  $Y$  as:

- `[1;0;1]` (numeric vector)
- `nominal({'true','false','true'})` (categorical vector)
- `[true;false;true]` (logical vector)
- `['true ','false ','true ']` (character array, padded with spaces so each row has the same length)
- `{'true','false','true'}` (cell array of strings)

Use whichever data type is most convenient. Because you cannot represent missing values with logical entries, do not use logical entries when you have missing values in  $Y$ .

### **Choose an Applicable Ensemble Method**

`fitensemble` uses one of these algorithms to create an ensemble.

- For classification with two classes:
  - 'AdaBoostM1'
  - 'LogitBoost'
  - 'GentleBoost'
  - 'RobustBoost' (requires an Optimization Toolbox license)
  - 'LPBoost' (requires an Optimization Toolbox license)
  - 'TotalBoost' (requires an Optimization Toolbox license)
  - 'RUSBoost'
  - 'Subspace'
  - 'Bag'
- For classification with three or more classes:
  - 'AdaBoostM2'
  - 'LPBoost' (requires an Optimization Toolbox license)
  - 'TotalBoost' (requires an Optimization Toolbox license)
  - 'RUSBoost'
  - 'Subspace'
  - 'Bag'
- For regression:
  - 'LSBoost'
  - 'Bag'

'Bag' applies to all methods. When using 'Bag', indicate whether you want a classifier or regressor with the type name-value pair set to 'classification' or 'regression'.

For descriptions of the various algorithms, see “Ensemble Algorithms” on page 16-146.

See “Suggestions for Choosing an Appropriate Ensemble Algorithm” on page 16-64.

This table lists characteristics of the various algorithms. In the table titles:

- **Regress.** — Regression
- **Classif.** — Classification
- **Preds.** — Predictors
- **Imbalance** — Good for imbalanced data (one class has many more observations than the other)
- **Stop** — Algorithm self-terminates
- **Sparse** — Requires fewer weak learners than other ensemble algorithms

<b>Algorithm</b>	<b>Regress.</b>	<b>Binary Classif.</b>	<b>Binary Classif. Multi- Level Preds.</b>	<b>Classif. 3+ Classes</b>	<b>Class Imbalance</b>	<b>Stop</b>	<b>Sparse</b>
Bag	×	×		×			
AdaBoostM1		×					
AdaBoostM2				×			
LogitBoost		×	×				
GentleBoost		×	×				
RobustBoost		×					
LPBoost		×		×		×	×
TotalBoost		×		×		×	×

Algorithm	Regress.	Binary Classif.	Binary Classif. Multi-Level Preds.	Classif. 3+ Classes	Class Imbalance	Stop	Sparse
RUSBoost		×		×	×		
LSBoost	×						
Subspace		×		×			

RobustBoost, LPBoost, and TotalBoost require an Optimization Toolbox license. Try TotalBoost before LPBoost, as TotalBoost can be more robust.

### Suggestions for Choosing an Appropriate Ensemble Algorithm.

- **Regression** — Your choices are LSBoost or Bag. See “General Characteristics of Ensemble Algorithms” on page 16-65 for the main differences between boosting and bagging.
- **Binary Classification** — Try AdaBoostM1 first, with these modifications:

Data Characteristic	Recommended Algorithm
Many predictors	Subspace
Skewed data (many more observations of one class)	RUSBoost
Categorical predictors with over 31 levels	LogitBoost or GentleBoost
Label noise (some training data has the wrong class)	RobustBoost
Many observations	Avoid LPBoost, TotalBoost, and Bag

- **Multiclass Classification** — Try AdaBoostM2 first, with these modifications:

<b>Data Characteristic</b>	<b>Recommended Algorithm</b>
Many predictors	Subspace
Skewed data (many more observations of one class)	RUSBoost
Many observations	Avoid LPBoost, TotalBoost, and Bag

For details of the algorithms, see “Ensemble Algorithms” on page 16-146.

### **General Characteristics of Ensemble Algorithms.**

- Bag generally constructs deep trees. This construction is both time consuming and memory-intensive. This also leads to relatively slow predictions.
- Boost algorithms generally use very shallow trees. This construction uses relatively little time or memory. However, for effective predictions, boosted trees might need more ensemble members than bagged trees. Therefore it is not always clear which class of algorithms is superior.
- Bag can estimate the generalization error without additional cross validation. See `oobLoss`.
- Except for Subspace, all boosting and bagging algorithms are based on tree learners. Subspace can use either discriminant analysis or  $k$ -nearest neighbor learners.

For details of the characteristics of individual ensemble members, see “Characteristics of Algorithms” on page 16-7.

### **Set the Number of Ensemble Members**

Choosing the size of an ensemble involves balancing speed and accuracy.

- Larger ensembles take longer to train and to generate predictions.
- Some ensemble algorithms can become overtrained (inaccurate) when too large.

To set an appropriate size, consider starting with several dozen to several hundred members in an ensemble, training the ensemble, and then checking the ensemble quality, as in “Example: Test Ensemble Quality” on page 16-72. If it appears that you need more members, add them using the `resume` method (classification) or the `resume` method (regression). Repeat until adding more members does not improve ensemble quality.

---

**Tip** For classification, the `LPBoost` and `TotalBoost` algorithms are self-terminating, meaning you do not have to investigate the appropriate ensemble size. Try setting `numberens` to 500. The algorithms usually terminate with fewer members.

---

## Prepare the Weak Learners

Currently the weak learner types are:

- 'Discriminant' (for Subspace ensemble)
- 'KNN' (for Subspace ensemble)
- 'Tree' (for any ensemble except Subspace)

There are two ways to set the weak learner type in the ensemble:

- To create an ensemble with default weak learner options, pass in the string as the weak learner. For example,

```
ens = fitensemble(X,Y,'AdaBoostM2',50,'Tree');  
% or  
ens = fitensemble(X,Y,'Subspace',50,'KNN');
```

- To create an ensemble with nondefault weak learner options, create a nondefault weak learner using the appropriate `template` method. For example, if you have missing data, and want to use trees with surrogate splits for better accuracy:

```
templ = ClassificationTree.template('Surrogate','all');  
ens = fitensemble(X,Y,'AdaBoostM2',50,templ);
```

To grow trees with roughly 10 leaf nodes per tree:

```
templ = ClassificationTree.template('MinLeaf',size(X,1)/10);
ens = fitensemble(X,Y,'AdaBoostM2',50,templ);
```

While you can give `fitensemble` a cell array of learner templates, the most common usage is to give just one weak learner template.

For examples using a template, see “Example: Unequal Classification Costs” on page 16-85 and “Surrogate Splits” on page 16-95.

Decision trees can handle NaN values in  $X$ . Such values are called “missing.” If you have some missing values in a row of  $X$ , a decision tree finds optimal splits using nonmissing values only. If an entire row consists of NaN, `fitensemble` ignores that row. If you have data with a large fraction of missing values in  $X$ , use surrogate decision splits. For examples of surrogate splits, see “Example: Unequal Classification Costs” on page 16-85 and “Surrogate Splits” on page 16-95.

### Common Settings for Tree Weak Learners.

- The depth of a weak learner tree makes a difference for training time, memory usage, and predictive accuracy. You control the depth with two parameters:
  - `MinLeaf` — Each leaf has at least `MinLeaf` observations. Set small values of `MinLeaf` to get a deep tree.
  - `MinParent` — Each branch node in the tree has at least `MinParent` observations. Set small values of `MinParent` to get a deep tree.

If you supply both `MinParent` and `MinLeaf`, the learner uses the setting that gives larger leaves:

$$\text{MinParent} = \max(\text{MinParent}, 2 * \text{MinLeaf})$$

- `Surrogate` — Grow decision trees with surrogate splits when `Surrogate` is 'on'. Use surrogate splits when your data has missing values.

---

**Note** Surrogate splits cause training to be slower and use more memory.

---

### Call `fitensemble`

The syntax of `fitensemble` is

```
ens = fitensemble(X,Y,model,numberens,learners)
```

- `X` is the matrix of data. Each row contains one observation, and each column contains one predictor variable.
- `Y` is the responses, with the same number of observations as rows in `X`.
- `model` is a string naming the type of ensemble.
- `numberens` is the number of weak learners in `ens` from each element of `learners`. So the number of elements in `ens` is `numberens` times the number of elements in `learners`.
- `learners` is a string naming a weak learner, a weak learner template, or a cell array of such strings and templates.

The result of `fitensemble` is an ensemble object, suitable for making predictions on new data. For a basic example of creating a classification ensemble, see “Create a Classification Ensemble” on page 16-69. For a basic example of creating a regression ensemble, see “Creating a Regression Ensemble” on page 16-70.

**Where to Set Name-Value Pairs.** There are several name-value pairs you can pass to `fitensemble`, and several that apply to the weak learners (`ClassificationDiscriminant.template`, `ClassificationKNN.template`, `ClassificationTree.template` and `RegressionTree.template`). To determine which option (name-value pair) is appropriate, the ensemble or the weak learner:

- Use template name-value pairs to control the characteristics of the weak learners.
- Use `fitensemble` name-value pairs to control the ensemble as a whole, either for algorithms or for structure.

For example, to have an ensemble of boosted classification trees with each tree deeper than the default, set the `ClassificationTree.template` name-value pairs (`MinLeaf` and `MinParent`) to smaller values than the defaults. This causes the trees to be leafier (deeper).

To name the predictors in the ensemble (part of the structure of the ensemble), use the `PredictorNames` name-value pair in `fitensemble`.

## Basic Ensemble Examples

### Create a Classification Ensemble

Create a classification tree ensemble for the Fisher iris data, and use it to predict the classification of a flower with average measurements.

- 1 Load the data:

```
load fisheriris
```

- 2 The predictor data `X` is the `meas` matrix.

- 3 The response data `Y` is the `species` cell array.

- 4 For classification trees with three or more classes, “Suggestions for Choosing an Appropriate Ensemble Algorithm” on page 16-64 suggests using an `'AdaBoostM2'` ensemble.

- 5 For this example, arbitrarily take an ensemble of 100 trees.

- 6 Use a default tree template.

- 7 Create the ensemble:

```
ens = fitensemble(meas,species,'AdaBoostM2',100,'Tree')
```

```
ens =
```

```
classreg.learning.classif.ClassificationEnsemble
  PredictorNames: {'x1' 'x2' 'x3' 'x4'}
  ResponseName: 'Y'
  ClassNames: {'setosa' 'versicolor' 'virginica'}
  ScoreTransform: 'none'
  NObservations: 150
  NTrained: 100
  Method: 'AdaBoostM2'
  LearnerNames: {'Tree'}
```

```
ReasonForTermination: [1x77 char]
                   FitInfo: [100x1 double]
                   FitInfoDescription: {2x1 cell}
```

Properties, Methods

- 8** Predict the classification of a flower with average measurements:

```
flower = predict(ens,mean(meas))

flower =

    'versicolor'
```

### **Creating a Regression Ensemble**

Create a regression ensemble to predict mileage of cars based on their horsepower and weight, trained on the `carsmall` data. Use the resulting ensemble to predict the mileage of a car with 150 horsepower weighing 2750 lbs.

- 1** Load the data:

```
load carsmall
```

- 2** Prepare the input data.

```
X = [Horsepower Weight];
```

- 3** The response data `Y` is MPG.

- 4** The only boosted regression ensemble type is `'LSBoost'`.

- 5** For this example, arbitrarily take an ensemble of 100 trees.

- 6** Use a default tree template.

- 7** Create the ensemble:

```
ens = fitensemble(X,MPG,'LSBoost',100,'Tree')

ens =
```

```

classreg.learning.regr.RegressionEnsemble
    PredictorNames: {'x1' 'x2'}
    ResponseName: 'Y'
    ResponseTransform: 'none'
    NObservations: 94
    NTrained: 100
    Method: 'LSBoost'
    LearnerNames: {'Tree'}
    ReasonForTermination: [1x77 char]
    FitInfo: [100x1 double]
    FitInfoDescription: {2x1 cell}
    Regularization: []

```

Properties, Methods

- 8** Predict the mileage of a car with 150 horsepower weighing 2750 lbs:

```
mileage = ens.predict([150 2750])
```

```
mileage =
```

```
22.4180
```

## Test Ensemble Quality

Usually you cannot evaluate the predictive quality of an ensemble based on its performance on training data. Ensembles tend to “overtrain,” meaning they produce overly optimistic estimates of their predictive power. This means the result of `resubLoss` for classification (`resubLoss` for regression) usually indicates lower error than you get on new data.

To obtain a better idea of the quality of an ensemble, use one of these methods:

- Evaluate the ensemble on an independent test set (useful when you have a lot of training data).
- Evaluate the ensemble by cross validation (useful when you don’t have a lot of training data).

- Evaluate the ensemble on out-of-bag data (useful when you create a bagged ensemble with `fitensemble`).

### Example: Test Ensemble Quality

This example uses a bagged ensemble so it can use all three methods of evaluating ensemble quality.

- 1 Generate an artificial dataset with 20 predictors. Each entry is a random number from 0 to 1. The initial classification:

$$Y = 1 \text{ when } X(1) + X(2) + X(3) + X(4) + X(5) > 2.5$$
$$Y = 0 \text{ otherwise.}$$

```
rng(1,'twister') % for reproducibility
X = rand(2000,20);
Y = sum(X(:,1:5),2) > 2.5;
```

In addition, to add noise to the results, randomly switch 10% of the classifications:

```
idx = randsample(2000,200);
Y(idx) = ~Y(idx);
```

### 2 Independent Test Set

Create independent training and test sets of data. Use 70% of the data for a training set by calling `cvpartition` using the `holdout` option:

```
cvpart = cvpartition(Y,'holdout',0.3);
Xtrain = X(training(cvpart),:);
Ytrain = Y(training(cvpart),:);
Xtest = X(test(cvpart),:);
Ytest = Y(test(cvpart),:);
```

- 3 Create a bagged classification ensemble of 200 trees from the training data:

```
bag = fitensemble(Xtrain,Ytrain,'Bag',200,'Tree',...
    'type','classification')

bag =
```

```
classreg.learning.classif.ClassificationBaggedEnsemble
    PredictorNames: {1x20 cell}
    ResponseName: 'Y'
    ClassNames: [0 1]
    ScoreTransform: 'none'
    NObservations: 1400
    NTrained: 200
    Method: 'Bag'
    LearnerNames: {'Tree'}
    ReasonForTermination: [1x77 char]
    FitInfo: []
    FitInfoDescription: 'None'
    FResample: 1
    Replace: 1
    UseObsForLearner: [1400x200 logical]
```

Properties, Methods

- 4 Plot the loss (misclassification) of the test data as a function of the number of trained trees in the ensemble:

```
figure;
plot(loss(bag,Xtest,Ytest,'mode','cumulative'));
xlabel('Number of trees');
ylabel('Test classification error');
```

### 5 Cross Validation

Generate a five-fold cross-validated bagged ensemble:

```
cv = fitensemble(X,Y,'Bag',200,'Tree',...
    'type','classification','kfold',5)
```

```
cv =
```

```
classreg.learning.partition.ClassificationPartitionedEnsemble
    CrossValidatedModel: 'Bag'
        PredictorNames: {1x20 cell}
    CategoricalPredictors: []
```

```
ResponseName: 'Y'  
NObservations: 2000  
KFold: 5  
Partition: [1x1 cvpartition]  
NTrainedPerFold: [200 200 200 200 200]  
ClassNames: [0 1]  
ScoreTransform: 'none'
```

### Properties, Methods

- 6 Examine the cross-validation loss as a function of the number of trees in the ensemble:

```
figure;  
plot(loss(bag,Xtest,Ytest,'mode','cumulative'));  
hold on;  
plot(kfoldLoss(cv,'mode','cumulative'),'r.');
```

hold off;  
xlabel('Number of trees');  
ylabel('Classification error');  
legend('Test','Cross-validation','Location','NE');

Cross validating gives comparable estimates to those of the independent set.

### 7 Out-of-Bag Estimates

Generate the loss curve for out-of-bag estimates, and plot it along with the other curves:

```
figure;
plot(loss(bag,Xtest,Ytest,'mode','cumulative'));
hold on;
plot(kfoldLoss(cv,'mode','cumulative'),'r. ');
plot(oobLoss(bag,'mode','cumulative'),'k--');
```

```

hold off;
xlabel('Number of trees');
ylabel('Classification error');
legend('Test','Cross-validation','Out of bag','Location','NE');

```

The out-of-bag estimates are again comparable to those of the other methods.

## Classification with Imbalanced Data

This example shows how to classify when one class has many more observations than another. Try the RUSBoost algorithm first, because it is designed to handle this case.

This example uses the “Cover type” data from the UCI machine learning archive, described in <http://archive.ics.uci.edu/ml/datasets/Covertype>. The data classifies types of forest (ground cover), based on predictors such as elevation, soil type, and distance to water. The data has over 500,000 observations and over 50 predictors, so training and using a classifier is time consuming.

Blackard and Dean [1] describe a neural net classification of this data. They quote a 70.6% classification accuracy. RUSBoost obtains over 76% classification accuracy; see steps 6 and 7.

**Step 1. Obtain the data.**

```
urlwrite('http://archive.ics.uci.edu/ml/machine-learning-databases/covtype/
```

Then, extract the data from the `forestcover.gz` file. The data is in the `covtype.data` file.

**Step 2. Import the data and prepare it for classification.**

Import the data into your workspace. Extract the last data column into a variable named `Y`.

```
load covtype.data
Y = covtype(:,end);
covtype(:,end) = [];
```

**Step 3. Examine the response data.**

```
tabulate(Y)
```

Value	Count	Percent
1	211840	36.46%
2	283301	48.76%
3	35754	6.15%
4	2747	0.47%
5	9493	1.63%
6	17367	2.99%
7	20510	3.53%

There are hundreds of thousands of data points. Those of class 4 are less than 0.5% of the total. This imbalance indicates that RUSBoost is an appropriate algorithm.

#### Step 4. Partition the data for quality assessment.

Use half the data to fit a classifier, and half to examine the quality of the resulting classifier.

```
part = cvpartition(Y,'holdout',0.5);
istrain = training(part); % data for fitting
istest = test(part); % data for quality assessment
tabulate(Y(istrain))
```

Value	Count	Percent
1	105920	36.46%
2	141651	48.76%
3	17877	6.15%
4	1374	0.47%
5	4746	1.63%
6	8683	2.99%
7	10255	3.53%

#### Step 5. Create the ensemble.

Use deep trees for higher ensemble accuracy. To do so, set the trees to have minimal leaf size of 5. Set `LearnRate` to 0.1 in order to achieve higher accuracy as well. The data is large, and, with deep trees, creating the ensemble is time consuming.

```
t = ClassificationTree.template('minleaf',5);
tic
rusTree = fitensemble(covtype(istrain,:),Y(istrain),'RUSBoost',1000,t,...
    'LearnRate',0.1,'nprint',100);
toc
```

```
Training RUSBoost...
Grown weak learners: 100
Grown weak learners: 200
Grown weak learners: 300
Grown weak learners: 400
```

```
Grown weak learners: 500
Grown weak learners: 600
Grown weak learners: 700
Grown weak learners: 800
Grown weak learners: 900
Grown weak learners: 1000
Elapsed time is 918.258401 seconds.
```

### **Step 6. Inspect the classification error.**

Plot the classification error against the number of members in the ensemble.

```
figure;
tic
plot(loss(rusTree,covtype(istest,:),Y(istest),'mode','cumulative'));
toc
grid on;
xlabel('Number of trees');
ylabel('Test classification error');
```

```
Elapsed time is 775.646935 seconds.
```

The ensemble achieves a classification error of under 24% using 150 or more trees. It achieves the lowest error for 400 or more trees.

Examine the confusion matrix for each class as a percentage of the true class.

```
tic
Yfit = predict(rusTree,covtype(istest,:));
toc
tab = tabulate(Y(istest));
bsxfun(@rdivide,confusionmat(Y(istest),Yfit),tab(:,2))*100
```

Elapsed time is 427.293168 seconds.

```
ans =

Columns 1 through 6

83.3771    7.4056    0.0736         0    1.7051    0.2681
18.3156   66.4652    2.1193    0.0162    9.3435    2.8239
         0    0.0839   90.8038    2.3885    0.6545    6.0693
         0         0    2.4763   95.8485         0    1.6752
         0    0.2739    0.6530         0   98.6518    0.4213
         0    0.1036    3.8346    1.1400    0.4030   94.5187
0.2340         0         0         0    0.0195         0

Column 7

7.1705
0.9163
0
0
0
0
99.7465
```

All classes except class 2 have over 80% classification accuracy, and classes 3 through 7 have over 90% accuracy. But class 2 makes up close to half the data, so the overall accuracy is not that high.

### Step 7. Compact the ensemble.

The ensemble is large. Remove the data using the compact method.

```
cmpctRus = compact(rusTree);
```

```
sz(1) = whos('rusTree');
sz(2) = whos('cmpctRus');
[sz(1).bytes sz(2).bytes]
```

```
ans =

1.0e+09 *

1.6947    0.9790
```

The compacted ensemble is about half the size of the original.

Remove half the trees from `cmpctRus`. This action is likely to have minimal effect on the predictive performance, based on the observation that 400 out of 1000 trees give nearly optimal accuracy.

```
cmpctRus = removeLearners(cmpctRus, [500:1000]);
```

```
sz(3) = whos('cmpctRus');
sz(3).bytes
```

```
ans =
```

```
475495669
```

The reduced compact ensemble takes about a quarter the memory of the full ensemble. Its overall loss rate is under 24%:

```
L = loss(cmpctRus, covtype(istest,:), Y(istest))
```

```
L =
```

```
0.2326
```

The predictive accuracy on new data might differ, because the ensemble accuracy might be biased. The bias arises because the same data used for assessing the ensemble was used for reducing the ensemble size. To obtain an unbiased estimate of requisite ensemble size, you should use cross validation. However, that procedure is time consuming.

## **Classification: Imbalanced Data or Unequal Misclassification Costs**

In many real-world applications, you might prefer to treat classes in your data asymmetrically. For example, you might have data with many more observations of one class than of any other. Or you might work on a problem in which misclassifying observations of one class has more severe consequences than misclassifying observations of another class. In such situations, you can use two optional parameters for `fitensemble`: `prior` and `cost`.

By using `prior`, you set prior class probabilities (that is, class probabilities used for training). Use this option if some classes are under- or overrepresented in your training set. For example, you might obtain your training data by simulation. Because simulating class A is more expensive than class B, you opt to generate fewer observations of class A and more observations of class B. You expect, however, that class A and class B are mixed in a different proportion in the real world. In this case, set prior probabilities for class A and B approximately to the values you expect to observe in the real world. `fitensemble` normalizes prior probabilities to make them add up to 1; multiplying all prior probabilities by the same positive factor does not affect the result of classification.

If classes are adequately represented in the training data but you want to treat them asymmetrically, use the `cost` parameter. Suppose you want to classify benign and malignant tumors in cancer patients. Failure to identify a malignant tumor (false negative) has far more severe consequences than misidentifying benign as malignant (false positive). You should assign high cost to misidentifying malignant as benign and low cost to misidentifying benign as malignant.

You must pass misclassification costs as a square matrix with nonnegative elements. Element  $C(i, j)$  of this matrix is the cost of classifying an observation into class  $j$  if the true class is  $i$ . The diagonal elements  $C(i, i)$  of the cost matrix must be 0. For the previous example, you can choose malignant tumor to be class 1 and benign tumor to be class 2. Then you can set the cost matrix to

$$\begin{bmatrix} 0 & c \\ 1 & 0 \end{bmatrix}$$

where  $c > 1$  is the cost of misidentifying a malignant tumor as benign. Costs are relative—multiplying all costs by the same positive factor does not affect the result of classification.

If you have only two classes, `fitensemble` adjusts their prior probabilities using  $\tilde{P}_i = C_{ij}P_i$  for class  $i = 1, 2$  and  $j \neq i$ .  $P_i$  are prior probabilities either passed into `fitensemble` or computed from class frequencies in the training

data, and  $\tilde{P}_i$  are adjusted prior probabilities. Then `fitensemble` uses the default cost matrix

$$\begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$$

and these adjusted probabilities for training its weak learners. Manipulating the cost matrix is thus equivalent to manipulating the prior probabilities.

If you have three or more classes, `fitensemble` also converts input costs into adjusted prior probabilities. This conversion is more complex. First, `fitensemble` attempts to solve a matrix equation described in Zhou and Liu [20]. If it fails to find a solution, `fitensemble` applies the “average cost” adjustment described in Breiman et al. [6]. For more information, see Zadrozny, Langford, and Abe [19].

### Example: Unequal Classification Costs

This example uses data on patients with hepatitis to see if they live or die as a result of the disease. The data is described at <http://archive.ics.uci.edu/ml/datasets/Hepatitis>.

- 1 Load the data into a file named `hepatitis.txt`:

```
s = urlread(['http://archive.ics.uci.edu/ml/' ...
            'machine-learning-databases/hepatitis/hepatitis.data']);
fid = fopen('hepatitis.txt','w');
fwrite(fid,s);
fclose(fid);
```

- 2 Load the data `hepatitis.txt` into a dataset, with variable names describing the fields in the data:

```
VarNames = {'die_or_live' 'age' 'sex' 'steroid' 'antivirals' 'fatigue' ...  
            'malaise' 'anorexia' 'liver_big' 'liver_firm' 'spleen_palpable' ...  
            'spiders' 'ascites' 'varices' 'bilirubin' 'alk_phosphate' 'sgot' ...  
            'albumin' 'protime' 'histology'};  
ds = dataset('file','hepatitis.txt','VarNames',VarNames,...  
            'Delimiter',' ',' ','ReadVarNames',false,'TreatAsEmpty','?',...  
            'Format','%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f%f');
```

ds is a dataset with 155 observations and 20 variables:

```
size(ds)
```

```
ans =
```

```
    155    20
```

- 3 Convert the data in the dataset to the format for ensembles: a numeric matrix of predictors, and a cell array with outcome names: 'Die' or 'Live'. The first field in the dataset has the outcomes.

```
X = double(ds(:,2:end));  
ClassNames = {'Die' 'Live'};  
Y = ClassNames(ds.die_or_live);
```

- 4 Inspect the data for missing values:

```
figure;  
bar(sum(isnan(X),1)/size(X,1));  
xlabel('Predictor');  
ylabel('Fraction of missing values');
```

Most predictors have missing values, and one has nearly 45% of missing values. Therefore, use decision trees with surrogate splits for better accuracy. Because the dataset is small, training time with surrogate splits should be tolerable.

- 5** Create a classification tree template that uses surrogate splits:

```
rng(0,'twister') % for reproducibility
t = ClassificationTree.template('surrogate','all');
```

- 6** Examine the data or the description of the data to see which predictors are categorical:

```
X(1:5,:)
```

```
ans =
```

```
Columns 1 through 6
```

```

30.0000    2.0000    1.0000    2.0000    2.0000    2.0000
50.0000    1.0000    1.0000    2.0000    1.0000    2.0000
78.0000    1.0000    2.0000    2.0000    1.0000    2.0000
31.0000    1.0000         NaN    1.0000    2.0000    2.0000
34.0000    1.0000    2.0000    2.0000    2.0000    2.0000

```

Columns 7 through 12

```

2.0000    1.0000    2.0000    2.0000    2.0000    2.0000
2.0000    1.0000    2.0000    2.0000    2.0000    2.0000
2.0000    2.0000    2.0000    2.0000    2.0000    2.0000
2.0000    2.0000    2.0000    2.0000    2.0000    2.0000
2.0000    2.0000    2.0000    2.0000    2.0000    2.0000

```

Columns 13 through 18

```

2.0000    1.0000    85.0000    18.0000    4.0000         NaN
2.0000    0.9000   135.0000    42.0000    3.5000         NaN
2.0000    0.7000    96.0000    32.0000    4.0000         NaN
2.0000    0.7000    46.0000    52.0000    4.0000    80.0000
2.0000    1.0000         NaN   200.0000    4.0000         NaN

```

Column 19

```

1.0000
1.0000
1.0000
1.0000
1.0000

```

It appears that predictors 2 through 13 are categorical, as well as predictor 19. You can confirm this inference with the dataset description at <http://archive.ics.uci.edu/ml/datasets/Hepatitis>.

**7** List the categorical variables:

```
ncat = [2:13,19];
```

**8** Create a cross-validated ensemble using 150 learners and the GentleBoost algorithm:

```

a = fitensemble(X,Y,'GentleBoost',150,t,...
    'PredictorNames',VarNames(2:end),'LearnRate',0.1,...
    'CategoricalPredictors',ncat,'kfold',5);
figure;
plot(kfoldLoss(a,'mode','cumulative','lossfun','exponential'));
xlabel('Number of trees');
ylabel('Cross-validated exponential loss');

```

- 9 Inspect the confusion matrix to see which people the ensemble predicts correctly:

```

[Yfit,Sfit] = kfoldPredict(a); %
confusionmat(Y,Yfit,'order',ClassNames)

```

```
ans =
    18    14
    11   112
```

Of the 123 people who live, the ensemble predicts correctly that 112 will live. But for the 32 people who die of hepatitis, the ensemble only predicts correctly that about half will die of hepatitis.

**10** There are two types of error in the predictions of the ensemble:

- Predicting that the patient lives, but the patient dies
- Predicting that the patient dies, but the patient lives

Suppose you believe that the first error is five times worse than the second. Make a new classification cost matrix that reflects this belief:

```
cost.ClassNames = ClassNames;
cost.ClassificationCosts = [0 5; 1 0];
```

**11** Create a new cross-validated ensemble using `cost` as misclassification cost, and inspect the resulting confusion matrix:

```
aC = fitensemble(X,Y,'GentleBoost',150,t,...
    'PredictorNames',VarNames(2:end),'LearnRate',0.1,...
    'CategoricalPredictors',ncat,'kfold',5,...
    'cost',cost);
[YfitC,SfitC] = kfoldPredict(aC);
confusionmat(Y,YfitC,'order',ClassNames)
```

```
ans =
    19    13
     8   115
```

As expected, the new ensemble does a better job classifying the people who die. Somewhat surprisingly, the new ensemble also does a better job classifying the people who live, though the result is not statistically significantly better. The results of the cross validation are random, so this result is simply a statistical fluctuation. The result seems to indicate that the classification of people who live is not very sensitive to the cost.

## Classification with Many Categorical Levels

Generally, you cannot use classification with more than 31 levels in any categorical predictor. However, two boosting algorithms can classify data with many categorical predictor levels and binary responses: `LogitBoost` and `GentleBoost`. For details, see “`LogitBoost`” on page 16-153 and “`GentleBoost`” on page 16-153.

This example uses demographic data from the U.S. Census, available at <http://archive.ics.uci.edu/ml/machine-learning-databases/adult/>. The objective of the researchers who posted the data is predicting whether an individual makes more than \$50,000/year, based on a set of characteristics. You can see details of the data, including predictor names, in the `adult.names` file at the site.

- 1 Load the 'adult.data' file from the UCI Machine Learning Repository:

```
s = urlread(['http://archive.ics.uci.edu/ml/' ...
            'machine-learning-databases/adult/adult.data']);
```

- 2 'adult.data' represents missing data as '?'. Replace instances of missing data with the blank string '':

```
s = strrep(s, '?', '');
```

- 3 Put the data into a MATLAB dataset array:

```
fid = fopen('adult.txt','w');
fwrite(fid,s);
fclose(fid);
clear s;
VarNames = {'age' 'workclass' 'fnlwtg' 'education' 'education_num' ...
            'marital_status' 'occupation' 'relationship' 'race' ...
            'sex' 'capital_gain' 'capital_loss' ...
            'hours_per_week' 'native_country' 'income'};
ds = dataset('file','adult.txt','VarNames',VarNames,...
            'Delimiter',',','ReadVarNames',false,'Format',...
            '%u%s%u%s%u%s%%s%%s%%s%u%u%u%s%');
cat = ~datasetfun(@isnumeric,ds(:,1:end-1)); % Logical indices
%                                         of categorical variables
```

```
catcol = find(cat); % indices of categorical variables
```

- 4** Many predictors in the data are categorical. Convert those fields in the dataset array to nominal:

```
ds.workclass = nominal(ds.workclass);  
ds.education = nominal(ds.education);  
ds.marital_status = nominal(ds.marital_status);  
ds.occupation = nominal(ds.occupation);  
ds.relationship = nominal(ds.relationship);  
ds.race = nominal(ds.race);  
ds.sex = nominal(ds.sex);  
ds.native_country = nominal(ds.native_country);  
ds.income = nominal(ds.income);
```

- 5** Convert the dataset array into numerical variables for `fitensemble`:

```
X = double(ds(:,1:end-1));  
Y = ds.income;
```

- 6** Some variables have many levels. Plot the number of levels of each predictor:

```
ncat = zeros(1,numel(catcol));  
for c=1:numel(catcol)  
    [~,gn] = grp2idx(X(:,catcol(c)));  
    ncat(c) = numel(gn);  
end  
figure;  
bar(catcol,ncat);  
xlabel('Predictor');  
ylabel('Number of categories');
```

Predictor 14 ('native\_country') has more than 40 categorical levels. For binary classification, `ClassificationTree.fit` uses a computational shortcut to find an optimal split for categorical predictors with many categories. For classification with more than two classes, you can choose a heuristic algorithm for finding a good split. See “Splitting Categorical Predictors” on page 16-56.

**7** Create classification ensembles using both `LogitBoost` and `GentleBoost`:

```
lb = fitensemble(X,Y,'LogitBoost',300,'Tree','CategoricalPredictors',cat,...
    'PredictorNames',VarNames(1:end-1),'ResponseName','income');
gb = fitensemble(X,Y,'GentleBoost',300,'Tree','CategoricalPredictors',cat,...
    'PredictorNames',VarNames(1:end-1),'ResponseName','income');
```

**8** Examine the resubstitution error for the two ensembles:

```
figure;
plot(resubLoss(lb,'mode','cumulative'));
hold on
plot(resubLoss(gb,'mode','cumulative'),'r--');
hold off
xlabel('Number of trees');
ylabel('Resubstitution error');
```

```
legend('LogitBoost','GentleBoost','Location','NE');
```

The GentleBoost algorithm has slightly smaller resubstitution error.

- 9 Estimate the generalization error for the two algorithms by cross validation.

```
lbcv = crossval(lb,'kfold',5);
gbcv = crossval(gb,'kfold',5);
figure;
plot(kfoldLoss(lbcv,'mode','cumulative'));
hold on
plot(kfoldLoss(gbcv,'mode','cumulative'),'r--');
hold off
```

```
xlabel('Number of trees');  
ylabel('Cross-validated error');  
legend('LogitBoost', 'GentleBoost', 'Location', 'NE');
```

The cross-validated loss is nearly the same as the resubstitution error.

## Surrogate Splits

When you have missing data, trees and ensembles of trees give better predictions when they include surrogate splits. Furthermore, estimates of predictor importance are often different with surrogate splits. Eliminating unimportant predictors can save time and memory for predictions, and can make predictions easier to understand.

This example shows the effects of surrogate splits for predictions for data containing missing entries in the test set.

- 1** Load sample data. Partition it into a training and test set.

```
load ionosphere;

rng(10) % for reproducibility
cv = cvpartition(Y,'holdout',0.3);
Xtrain = X(training(cv),:);
Ytrain = Y(training(cv));
Xtest = X(test(cv),:);
Ytest = Y(test(cv));
```

- 2** Bag decision trees with and without surrogate splits.

```
b = fitensemble(Xtrain,Ytrain,'Bag',50,'Tree',...
    'type','class');

templS = ClassificationTree.template('surrogate','on');
bs = fitensemble(Xtrain,Ytrain,'Bag',50,templS,...
    'type','class');
```

- 3** Suppose half of the values in the test set are missing.

```
Xtest(rand(size(Xtest))>0.5) = NaN;
```

- 4** Test accuracy with and without surrogate splits.

```
figure;
plot(loss(b,Xtest,Ytest,'mode','cumulative'));
hold on;
plot(loss(bs,Xtest,Ytest,'mode','cumulative'),'r--');
legend('Regular trees','Trees with surrogate splits');
xlabel('Number of trees');
ylabel('Test classification error');
```

- 5** Check the statistical significance of the difference in results with the McNemar test. Convert the labels to a nominal data type to make it easier to check for equality.

```

Yfit = nominal(predict(b,Xtest));
YfitS = nominal(predict(bs,Xtest));
N10 = sum(Yfit==nominal(Ytest) & YfitS~=nominal(Ytest));
N01 = sum(Yfit~=nominal(Ytest) & YfitS==nominal(Ytest));
mcnemar = (abs(N10-N01) - 1)^2/(N10+N01);
pval = 1 - chi2cdf(mcnemar,1)

```

```
pval =
```

1.7683e-04

The extremely low  $p$ -value indicates that the ensemble with surrogate splits is better in a statistically significant manner.

## LPBoost and TotalBoost for Small Ensembles

This example shows how to obtain the benefits of the LPBoost and TotalBoost algorithms. These algorithms share two beneficial characteristics:

They are self-terminating, so you don't have to guess how many members to include.

They produce ensembles with some very small weights, so you can safely remove ensemble members.

Note that the algorithms in this example require an Optimization Toolbox license.

### Step 1. Load the data.

Load the ionosphere data.

```
load ionosphere
```

### Step 2. Create the classification ensembles.

Create ensembles for classifying the ionosphere data using the LPBoost, TotalBoost, and, for comparison, AdaBoostM1 algorithms. It is hard to know how many members to include in an ensemble. For LPBoost and TotalBoost, try using 500. For comparison, also use 500 for AdaBoostM1.

```
rng default % for reproducibility
T = 500;
adaStump = fitensemble(X,Y,'AdaBoostM1',T,'Tree');
totalStump = fitensemble(X,Y,'TotalBoost',T,'Tree');
lpStump = fitensemble(X,Y,'LPBoost',T,'Tree');
figure;
plot(resubLoss(adaStump,'mode','cumulative'));
hold on
plot(resubLoss(totalStump,'mode','cumulative'),'r');
```

```

plot(resubLoss(lpStump,'mode','cumulative'),'g');
hold off
xlabel('Number of stumps');
ylabel('Training error');
legend('AdaBoost','TotalBoost','LPBoost','Location','NE');

```

All three algorithms achieve perfect prediction on the training data after a while. Examine the number of members in all three ensembles.

```
[adaStump.NTrained totalStump.NTrained lpStump.NTrained]
```

ans =

500 52 67

AdaBoostM1 trained all 500 members. The other two algorithms stopped training early.

**Step 3. Cross validate the ensembles.**

Cross validate the ensembles to better determine ensemble accuracy.

```
cvlp = crossval(lpStump, 'kfold', 5);
cvtotal = crossval(totalStump, 'kfold', 5);
cvada = crossval(adaStump, 'kfold', 5);

figure;
plot(kfoldLoss(cvada, 'mode', 'cumulative'));
hold on
plot(kfoldLoss(cvtotal, 'mode', 'cumulative'), 'r');
plot(kfoldLoss(cvlp, 'mode', 'cumulative'), 'g');
hold off
xlabel('Ensemble size');
ylabel('Cross-validated error');
legend('AdaBoost', 'TotalBoost', 'LPBoost', 'Location', 'NE');
```

It appears that each boosting algorithms achieves 10% or lower loss with 50 ensemble members, and AdaBoostM1 achieves near 6% error with 150 or more ensemble members.

#### Step 4. Compact and remove ensemble members.

To reduce the ensemble sizes, compact them, and then use the `removeLearners` method. The question is, how many learners should you remove? The cross-validated loss curves give you one measure. For another, examine the learner weights for LPBoost and TotalBoost after compacting.

```
cada = compact(adaStump);
c1p = compact(lpStump);
```

```

ctotal = compact(totalStump);

figure
subplot(2,1,1)
plot(clp.TrainedWeights)
title('LPBoost weights')
subplot(2,1,2)
plot(ctotal.TrainedWeights)
title('TotalBoost weights')

```

Both LPBoost and TotalBoost show clear points where the ensemble member weights become negligible.

Remove the unimportant ensemble members.

```
cada = removeLearners(cada,150:cada.NTrained);
clp = removeLearners(clp,60:clp.NTrained);
ctotal = removeLearners(ctotal,40:ctotal.NTrained);
```

Check that removing these learners does not affect ensemble accuracy on the training data.

```
[loss(cada,X,Y) loss(clp,X,Y) loss(ctotal,X,Y)]
```

```
ans =
     0     0     0
```

Check the resulting compact ensemble sizes.

```
s(1) = whos('cada');
s(2) = whos('clp');
s(3) = whos('ctotal');
s.bytes
```

```
ans =
    605605
```

```
ans =
    241375
```

```
ans =
    160435
```

The sizes of the compact ensembles are approximately proportional to the number of members in each.

## Ensemble Regularization

Regularization is a process of choosing fewer weak learners for an ensemble in a way that does not diminish predictive performance. Currently you can regularize regression ensembles. (You can also regularize a discriminant analysis classifier in a non-ensemble context; see “Regularize a Discriminant Analysis Classifier” on page 15-23.)

The `regularize` method finds an optimal set of learner weights  $a_t$  that minimize

$$\sum_{n=1}^N w_n g \left( \left( \sum_{t=1}^T \alpha_t h_t(x_n) \right), y_n \right) + \lambda \sum_{t=1}^T |\alpha_t|.$$

Here

- $\lambda \geq 0$  is a parameter you provide, called the lasso parameter.
- $h_t$  is a weak learner in the ensemble trained on  $N$  observations with predictors  $x_n$ , responses  $y_n$ , and weights  $w_n$ .
- $g(f, y) = (f - y)^2$  is the squared error.

The ensemble is regularized on the same  $(x_n, y_n, w_n)$  data used for training, so

$$\sum_{n=1}^N w_n g \left( \left( \sum_{t=1}^T \alpha_t h_t(x_n) \right), y_n \right)$$

is the ensemble resubstitution error. The error is measured by mean squared error (MSE).

If you use  $\lambda = 0$ , `regularize` finds the weak learner weights by minimizing the resubstitution MSE. Ensembles tend to overtrain. In other words, the resubstitution error is typically smaller than the true generalization error. By making the resubstitution error even smaller, you are likely to make the ensemble accuracy worse instead of improving it. On the other hand, positive values of  $\lambda$  push the magnitude of the  $\alpha_t$  coefficients to 0. This often improves the generalization error. Of course, if you choose  $\lambda$  too large, all the optimal coefficients are 0, and the ensemble does not have any accuracy. Usually you can find an optimal range for  $\lambda$  in which the accuracy of the regularized ensemble is better or comparable to that of the full ensemble without regularization.

A nice feature of lasso regularization is its ability to drive the optimized coefficients precisely to 0. If a learner's weight  $\alpha_t$  is 0, this learner can be

excluded from the regularized ensemble. In the end, you get an ensemble with improved accuracy and fewer learners.

### **Example: Regularizing a Regression Ensemble**

This example uses data for predicting the insurance risk of a car based on its many attributes.

- 1** Load the `imports-85` data into the MATLAB workspace:

```
load imports-85;
```

- 2** Look at a description of the data to find the categorical variables and predictor names:

#### **Description**

```
Description =  
1985 Auto Imports Database from the UCI repository  
http://archive.ics.uci.edu/ml/machine-learning-databases/autos/imports-85.names  
Variables have been reordered to place variables with numeric values (referred  
to as "continuous" on the UCI site) to the left and categorical values to the  
right. Specifically, variables 1:16 are: symboling, normalized-losses,  
wheel-base, length, width, height, curb-weight, engine-size, bore, stroke,  
compression-ratio, horsepower, peak-rpm, city-mpg, highway-mpg, and price.  
Variables 17:26 are: make, fuel-type, aspiration, num-of-doors, body-style,  
drive-wheels, engine-location, engine-type, num-of-cylinders, and fuel-system.
```

The objective of this process is to predict the “symboling,” the first variable in the data, from the other predictors. “symboling” is an integer from -3 (good insurance risk) to 3 (poor insurance risk). You could use a classification ensemble to predict this risk instead of a regression ensemble. As stated in “Steps in Supervised Learning (Machine Learning)” on page 16-2, when you have a choice between regression and classification, you should try regression first. Furthermore, this example is to show regularization, which currently works only for regression.

- 3** Prepare the data for ensemble fitting:

```

Y = X(:,1);
X(:,1) = [];
VarNames = {'normalized-losses' 'wheel-base' 'length' 'width' 'height' ...
            'curb-weight' 'engine-size' 'bore' 'stroke' 'compression-ratio' ...
            'horsepower' 'peak-rpm' 'city-mpg' 'highway-mpg' 'price' 'make' ...
            'fuel-type' 'aspiration' 'num-of-doors' 'body-style' 'drive-wheels' ...
            'engine-location' 'engine-type' 'num-of-cylinders' 'fuel-system'};
catidx = 16:25; % indices of categorical predictors

```

**4** Create a regression ensemble from the data using 300 default trees:

```

ls = fitensemble(X,Y,'LSBoost',300,'Tree','LearnRate',0.1,...
                'PredictorNames',VarNames,'ResponseName','symboling',...
                'CategoricalPredictors',catidx)

```

```
ls =
```

```

classreg.learning.regr.RegressionEnsemble
    PredictorNames: {1x25 cell}
    ResponseName: 'symboling'
    ResponseTransform: 'none'
    NObservations: 205
    NTrained: 300
    Method: 'LSBoost'
    LearnerNames: {'Tree'}
    ReasonForTermination: [1x77 char]
    FitInfo: [300x1 double]
    FitInfoDescription: {2x1 cell}
    Regularization: []

```

Properties, Methods

The final line, `Regularization`, is empty (`[]`). To regularize the ensemble, you have to use the `regularize` method.

**5** Cross validate the ensemble, and inspect its loss curve.

```

cv = crossval(ls,'kfold',5);
figure;

```

```

plot(kfoldLoss(cv,'mode','cumulative'));
xlabel('Number of trees');
ylabel('Cross-validated MSE');
ylim([0.2,2])

```

It appears you might obtain satisfactory performance from a smaller ensemble, perhaps one containing from 50 to 100 trees.

- 6 Call the `regularize` method to try to find trees that you can remove from the ensemble. By default, `regularize` examines 10 values of the lasso (Lambda) parameter spaced exponentially.

```
ls = regularize(ls)
```

```
ls =
```

```

classreg.learning.regr.ReggressionEnsemble
    PredictorNames: {1x25 cell}

```

```

        ResponseName: 'symboling'
    ResponseTransform: 'none'
        NObservations: 205
        NTrained: 300
        Method: 'LSBoost'
        LearnerNames: {'Tree'}
    ReasonForTermination: [1x77 char]
        FitInfo: [300x1 double]
    FitInfoDescription: {2x1 cell}
        Regularization: [1x1 struct]

```

Properties, Methods

The Regularization property is no longer empty.

- 7 Plot the resubstitution mean-squared error (MSE) and number of learners with nonzero weights against the lasso parameter. Separately plot the value at  $\text{Lambda}=0$ . Use a logarithmic scale because the values of  $\text{Lambda}$  are exponentially spaced.

```

figure;
semilogx(ls.Regularization.Lambda,ls.Regularization.ResubstitutionMSE);
line([1e-3 1e-3],[ls.Regularization.ResubstitutionMSE(1) ...
    ls.Regularization.ResubstitutionMSE(1)],...
    'marker','x','markersize',12,'color','b');
r0 = resubLoss(ls);
line([ls.Regularization.Lambda(2) ls.Regularization.Lambda(end)],...
    [r0 r0],'color','r','LineStyle','--');
xlabel('Lambda');
ylabel('Resubstitution MSE');
annotation('textbox',[0.5 0.22 0.5 0.05],'String','unregularized ensemble',...
    'color','r','FontSize',14,'LineStyle','none');

```

```

figure;
loglog(ls.Regularization.Lambda,sum(ls.Regularization.TrainedWeights>0,1));
line([1e-3 1e-3],...
    [sum(ls.Regularization.TrainedWeights(:,1)>0) ...
    sum(ls.Regularization.TrainedWeights(:,1)>0)],...

```

```
'marker','x','markersize',12,'color','b');  
line([ls.Regularization.Lambda(2) ls.Regularization.Lambda(end)],...  
      [ls.NTrained ls.NTrained],...  
      'color','r','LineStyle','--');  
xlabel('Lambda');  
ylabel('Number of learners');  
annotation('textbox',[0.3 0.8 0.5 0.05],'String','unregularized ensemble',...  
           'color','r','FontSize',14,'LineStyle','none');
```

- 8 The resubstitution MSE values are likely to be overly optimistic. To obtain more reliable estimates of the error associated with various values of Lambda, cross validate the ensemble using `cvshrink`. Plot the resulting cross-validation loss (MSE) and number of learners against Lambda.

```
rng(0,'Twister') % for reproducibility
[mse,nlearn] = cvshrink(ls,'lambda',ls.Regularization.Lambda,'kfold',5);

figure;
semilogx(ls.Regularization.Lambda,ls.Regularization.ResubstitutionMSE);
hold;
semilogx(ls.Regularization.Lambda,mse,'r--');
hold off;
xlabel('Lambda');
ylabel('Mean squared error');
legend('resubstitution','cross-validation','Location','NW');
```

```
line([1e-3 1e-3],[ls.Regularization.ResubstitutionMSE(1) ...
    ls.Regularization.ResubstitutionMSE(1)],...
    'marker','x','markersize',12,'color','b');
line([1e-3 1e-3],[mse(1) mse(1)],'marker','o',...
    'markersize',12,'color','r','LineStyle','--');

figure;
loglog(ls.Regularization.Lambda,sum(ls.Regularization.TrainedWeights>0,1));
hold;
loglog(ls.Regularization.Lambda,nlearn,'r--');
hold off;
xlabel('Lambda');
ylabel('Number of learners');
legend('resubstitution','cross-validation','Location','NE');
line([1e-3 1e-3],...
    [sum(ls.Regularization.TrainedWeights(:,1)>0) ...
    sum(ls.Regularization.TrainedWeights(:,1)>0)],...
    'marker','x','markersize',12,'color','b');
line([1e-3 1e-3],[nlearn(1) nlearn(1)],'marker','o',...
```

```
'markersize',12,'color','r','LineStyle','--');
```

Examining the cross-validated error shows that the cross-validation MSE is almost flat for Lambda up to a bit over  $1e-2$ .

- 9 Examine `ls.Regularization.Lambda` to find the highest value that gives MSE in the flat region (up to a bit over  $1e-2$ ):

```
jj = 1:length(ls.Regularization.Lambda);
[jj;ls.Regularization.Lambda]
```

```
ans =
```

```
Columns 1 through 6
```

1.0000	2.0000	3.0000	4.0000	5.0000	6.0000
0	0.0014	0.0033	0.0077	0.0183	0.0435

```
Columns 7 through 10
```

```

7.0000    8.0000    9.0000   10.0000
0.1031    0.2446    0.5800    1.3754

```

Element 5 of `ls.Regularization.Lambda` has value 0.0183, the largest in the flat range.

- 10** Reduce the ensemble size using the `shrink` method. `shrink` returns a compact ensemble with no training data. The generalization error for the new compact ensemble was already estimated by cross validation in `mse(5)`.

```

cmp = shrink(ls,'weightcolumn',5)

cmp =

classreg.learning.regr.CompactRegressionEnsemble
    PredictorNames: {1x25 cell}
    ResponseName: 'symboling'
    ResponseTransform: 'none'
    NTrained: 15

```

Properties, Methods

There are only 15 trees in the new ensemble, notably reduced from the 300 in `ls`.

- 11** Compare the sizes of the ensembles:

```

sz(1) = whos('cmp'); sz(2) = whos('ls');
[sz(1).bytes sz(2).bytes]

ans =

    84544    1775691

```

The reduced ensemble is about 5% the size of the original.

- 12** Compare the MSE of the reduced ensemble to that of the original ensemble:

```

figure;
plot(kfoldLoss(cv,'mode','cumulative'));
hold on

```

```
plot(cmp.NTrained,mse(5),'ro','MarkerSize',12);
xlabel('Number of trees');
ylabel('Cross-validated MSE');
legend('unregularized ensemble','regularized ensemble',...
      'Location','NE');
hold off
```

The reduced ensemble gives low loss while using many fewer trees.

## Tuning RobustBoost

The RobustBoost algorithm can make good classification predictions even when the training data has noise. However, the default RobustBoost parameters can produce an ensemble that does not predict well. This example shows one way of tuning the parameters for better predictive accuracy.

---

**Note** RobustBoost requires an Optimization Toolbox license.

---

- 1 Generate data with label noise. This example has twenty uniform random numbers per observation, and classifies the observation as 1 if the sum of the first five numbers exceeds 2.5 (so is larger than average), and 0 otherwise:

```
rng(0,'twister') % for reproducibility
Xtrain = rand(2000,20);
Ytrain = sum(Xtrain(:,1:5),2) > 2.5;
```

- 2 To add noise, randomly switch 10% of the classifications:

```
idx = randsample(2000,200);
Ytrain(idx) = ~Ytrain(idx);
```

- 3 Create an ensemble with AdaBoostM1 for comparison purposes:

```
ada = fitensemble(Xtrain,Ytrain,'AdaBoostM1',...
    300,'Tree','LearnRate',0.1);
```

- 4 Create an ensemble with RobustBoost. Because the data has 10% incorrect classification, perhaps an error goal of 15% is reasonable.

```
rb1 = fitensemble(Xtrain,Ytrain,'RobustBoost',300,...
    'Tree','RobustErrorGoal',0.15,'RobustMaxMargin',1);
```

- 5 Try setting a high value of the error goal, 0.6. You get an error:

```
rb2 = fitensemble(Xtrain,Ytrain,'RobustBoost',300,'Tree','RobustErrorGoal',0.6)
```

Error using RobustBoost>RobustBoost.RobustBoost

For the chosen values of 'RobustMaxMargin' and 'RobustMarginSigma', you must set 'RobustErrorGoal' to a value between 0 and 0.5.

- 6 Create an ensemble with very optimistic error goal, 0.01:

```
rb2 = fitensemble(Xtrain,Ytrain,'RobustBoost',300,...
    'Tree','RobustErrorGoal',0.01);
```

**7** Compare the resubstitution error of the four ensembles:

```
figure
plot(resubLoss(rb1,'mode','cumulative'));
hold on
plot(resubLoss(rb2,'mode','cumulative'),'r--');
plot(resubLoss(ada,'mode','cumulative'),'g. ');
hold off;
xlabel('Number of trees');
ylabel('Resubstitution error');
legend('ErrorGoal=0.15','ErrorGoal=0.01',...
      'AdaBoostM1','Location','NE');
```

All the RobustBoost curves show lower resubstitution error than the AdaBoostM1 curve. The error goal of 0.15 curve shows the lowest resubstitution error over most of the range.

- 8 Generate test data to see the predictive power of the ensembles. Test the four ensembles:

```
Xtest = rand(2000,20);
Ytest = sum(Xtest(:,1:5),2) > 2.5;
idx = randsample(2000,200);
Ytest(idx) = -Ytest(idx);
figure;
plot(loss(rb1,Xtest,Ytest,'mode','cumulative'));
hold on
plot(loss(rb2,Xtest,Ytest,'mode','cumulative'),'r--');
plot(loss(ada,Xtest,Ytest,'mode','cumulative'),'g. ');
hold off;
xlabel('Number of trees');
ylabel('Test error');
legend('ErrorGoal=0.15','ErrorGoal=0.01',...
      'AdaBoostM1','Location','NE');
```

The error curve for error goal 0.15 is lowest (best) in the plotted range. AdaBoostM1 has higher error than the curve for error goal 0.15. The curve for the too-optimistic error goal 0.01 remains substantially higher (worse) than the other algorithms for most of the plotted range.

## Random Subspace Classification

This example shows how to use a random subspace ensemble to increase the accuracy of classification. It also shows how to use cross validation to determine good parameters for both the weak learner template and the ensemble.

### 1. Load the data.

Load the ionosphere data. This data has 351 binary responses to 34 predictors.

```
load ionosphere;  
[N,D] = size(X)
```

```
N =  
    351
```

```
D =  
    34
```

```
resp = unique(Y)
```

```
resp =  
    'b'  
    'g'
```

## **2. Choose the number of nearest neighbors.**

Find a good choice for  $k$ , the number of nearest neighbors in the classifier, by cross validation. Choose the number of neighbors approximately evenly spaced on a logarithmic scale.

```
rng(8000,'twister') % for reproducibility  
K = round(logspace(0,log10(N),10)); % number of neighbors  
cvloss = zeros(numel(K),1);  
for k=1:numel(K)  
    knn = ClassificationKNN.fit(X,Y,...  
        'NumNeighbors',K(k),'crossval','on');  
    cvloss(k) = kfoldLoss(knn);  
end  
figure; % plot the accuracy versus k  
semilogx(K,cvloss);  
xlabel('Number of nearest neighbors');  
ylabel('10 fold classification error');  
title('k-NN classification');
```

The lowest cross-validation error occurs for  $k = 2$ .

### 3. Create the ensembles.

Create ensembles for 2-nearest neighbor classification with various numbers of dimensions, and examine the cross-validated loss of the resulting ensembles.

This step takes a long time. To keep track of the progress, print a message as each dimension finishes.

```
NPredToSample = round(linspace(1,D,10)); % linear spacing of dimensions
cvloss = zeros(numel(NPredToSample),1);
learner = ClassificationKNN.template('NumNeighbors',2);
```

```
for npred=1:numel(NPredToSample)
    subspace = fitensemble(X,Y,'subspace',200,learner,...
        'npredtosample',NPredToSample(npred),'crossval','on');
    cvloss(npred) = kfoldLoss(subspace);
    fprintf('Random Subspace %i done.\n',npred);
end
figure; % plot the accuracy versus dimension
plot(NPredToSample,cvloss);
xlabel('Number of predictors selected at random');
ylabel('10 fold classification error');
title('k-NN classification with Random Subspace');
```

```
Random Subspace 1 done.
Random Subspace 2 done.
Random Subspace 3 done.
Random Subspace 4 done.
Random Subspace 5 done.
Random Subspace 6 done.
Random Subspace 7 done.
Random Subspace 8 done.
Random Subspace 9 done.
Random Subspace 10 done.
```

The ensemble with five predictors per learner has the lowest cross-validated error. The error rate, about 0.06, is about half the amount for the individual learners, which was over 0.10.

#### 4. Find a good ensemble size.

Find the smallest number of learners in the ensemble that still give good classification.

```
ens = fitensemble(X,Y,'subspace',200,learner,...
    'npredtosample',5,'crossval','on');
figure; % plot the accuracy versus number in ensemble
plot(kfoldLoss(ens,'mode','cumulative'))
xlabel('Number of learners in ensemble');
```

```
ylabel('10 fold classification error');  
title('k-NN classification with Random Subspace');
```

There seems to be no advantage in an ensemble with more than 150 or so learners. It is not clear whether there is any advantage with more than 50 learners. It is possible that 25 learners gives good predictions.

##### 5. Create a final ensemble.

Construct a final ensemble with 50 learners. Compact the ensemble and see if the compacted version saves an appreciable amount of memory.

```
ens = fitensemble(X,Y,'subspace',50,learner,...  
    'npretdosample',5);
```

```

cens = compact(ens);
s1 = whos('ens');s2 = whos('cens');
[s1.bytes s2.bytes] % si.bytes = size in bytes

ans =
    2317803    2087370

```

The compact ensemble is about 10% smaller than the full ensemble. Both give the same predictions.

## TreeBagger Examples

TreeBagger ensembles have more functionality than those constructed with `fitensemble`; see [TreeBagger Features Not in fitensemble](#) on page 16-151. Also, some property and method names differ from their `fitensemble` counterparts. This section contains examples of workflow for regression and classification that use this extra TreeBagger functionality.

### Workflow Example: Regression of Insurance Risk Rating for Car Imports with TreeBagger

In this example, use a database of 1985 car imports with 205 observations, 25 input variables, and one response variable, insurance risk rating, or “symboling.” The first 15 variables are numeric and the last 10 are categorical. The symboling index takes integer values from  $-3$  to  $3$ .

- 1 Load the dataset and split it into predictor and response arrays:

```

load imports-85;
Y = X(:,1);
X = X(:,2:end);

```

- 2 Because bagging uses randomized data drawings, its exact outcome depends on the initial random seed. To reproduce the exact results in this example, use the random stream settings:

```

rng(1945,'twister')

```

**Finding the Optimal Leaf Size.** For regression, the general rule is to set leaf size to 5 and select one third of input features for decision splits at random. In the following step, verify the optimal leaf size by comparing mean-squared errors obtained by regression for various leaf sizes. `oobError` computes MSE versus the number of grown trees. You must set `oobpred` to 'on' to obtain out-of-bag predictions later.

```
leaf = [1 5 10 20 50 100];
col = 'rgbcmy';
figure(1);
for i=1:length(leaf)
    b = TreeBagger(50,X,Y,'method','r','oobpred','on',...
        'cat',16:25,'minleaf',leaf(i));
    plot(oobError(b),col(i));
    hold on;
end
xlabel('Number of Grown Trees');
ylabel('Mean Squared Error');
legend({'1' '5' '10' '20' '50' '100'},'Location','NorthEast');
hold off;
```

The red (leaf size 1) curve gives the lowest MSE values.

## Estimating Feature Importance.

- 1 In practical applications, you typically grow ensembles with hundreds of trees. Only 50 trees were used in “Finding the Optimal Leaf Size” on page 16-126 for faster processing. Now that you have estimated the optimal leaf size, grow a larger ensemble with 100 trees and use it for estimation of feature importance:

```
b = TreeBagger(100,X,Y,'method','r','oobvarimp','on',...
'cat',16:25,'minleaf',1);
```

- 2 Inspect the error curve again to make sure nothing went wrong during training:

```
figure(2);
plot(oobError(b));
xlabel('Number of Grown Trees');
ylabel('Out-of-Bag Mean Squared Error');
```

Prediction ability should depend more on important features and less on unimportant features. You can use this idea to measure feature importance.

For each feature, you can permute the values of this feature across all of the observations in the data set and measure how much worse the mean-squared

error (MSE) becomes after the permutation. You can repeat this for each feature.

- 1 Using the following code, plot the increase in MSE due to permuting out-of-bag observations across each input variable. The `OOBPermutedVarDeltaError` array stores the increase in MSE averaged over all trees in the ensemble and divided by the standard deviation taken over the trees, for each variable. The larger this value, the more important the variable. Imposing an arbitrary cutoff at 0.65, you can select the five most important features.

```
figure(3);
bar(b.OOBPermutedVarDeltaError);
xlabel('Feature Number');
ylabel('Out-Of-Bag Feature Importance');
idxvar = find(b.OOBPermutedVarDeltaError>0.65)

idxvar =

     1     2     4    16    19
```

- 2** The `OOBIndices` property of `TreeBagger` tracks which observations are out of bag for what trees. Using this property, you can monitor the fraction of observations in the training data that are in bag for all trees. The curve starts at approximately  $2/3$ , the fraction of unique observations selected by one bootstrap replica, and goes down to 0 at approximately 10 trees.

```

finbag = zeros(1,b.NTrees);
for t=1:b.NTrees
    finbag(t) = sum(all(~b.OOBIndices(:,1:t),2));
end
finbag = finbag / size(X,1);
figure(4);
plot(finbag);

```

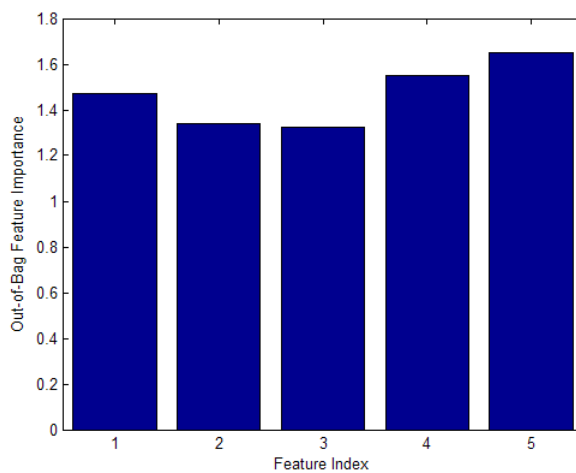

```
xlabel('Number of Grown Trees');  
ylabel('Fraction of in-Bag Observations');
```

**Growing Trees on a Reduced Set of Features.** Using just the five most powerful features selected in “Estimating Feature Importance” on page 16-127, determine if it is possible to obtain a similar predictive power. To begin, grow 100 trees on these features only. The first three of the five selected features are numeric and the last two are categorical.

```
b5v = TreeBagger(100,X(:,idxvar),Y,'method','r',...  
'oobvarimp','on','cat',4:5,'minleaf',1);  
figure(5);  
plot(oobError(b5v));
```

```
xlabel('Number of Grown Trees');  
ylabel('Out-of-Bag Mean Squared Error');  
figure(6);  
bar(b5v.00BPermutedVarDeltaError);  
xlabel('Feature Index');  
ylabel('Out-of-Bag Feature Importance');
```

These five most powerful features give the same MSE as the full set, and the ensemble trained on the reduced set ranks these features similarly to each other. Features 1 and 2 from the reduced set perhaps could be removed without a significant loss in the predictive power.

**Finding Outliers.** To find outliers in the training data, compute the proximity matrix using `fillProximities`:

```
b5v = fillProximities(b5v);
```

The method normalizes this measure by subtracting the mean outlier measure for the entire sample, taking the magnitude of this difference and dividing the result by the median absolute deviation for the entire sample:

```
figure(7);  
hist(b5v.OutlierMeasure);  
xlabel('Outlier Measure');  
ylabel('Number of Observations');
```

**Discovering Clusters in the Data.** By applying multidimensional scaling to the computed matrix of proximities, you can inspect the structure of the input data and look for possible clusters of observations. The `mdsProx` method returns scaled coordinates and eigenvalues for the computed proximity matrix. If run with the `colors` option, this method makes a scatter plot of two scaled coordinates, first and second by default.

```
figure(8);  
[~,e] = mdsProx(b5v,'colors','k');  
xlabel('1st Scaled Coordinate');  
ylabel('2nd Scaled Coordinate');
```

Assess the relative importance of the scaled axes by plotting the first 20 eigenvalues:

```
figure(9);  
bar(e(1:20));  
xlabel('Scaled Coordinate Index');  
ylabel('Eigenvalue');
```

**Saving the Ensemble Configuration for Future Use.** To use the trained ensemble for predicting the response on unseen data, store the ensemble to disk and retrieve it later. If you do not want to compute predictions for out-of-bag data or reuse training data in any other way, there is no need to store the ensemble object itself. Saving the compact version of the ensemble would be enough in this case. Extract the compact object from the ensemble:

```
c = compact(b5v)
```

```
c =
```

```
Ensemble with 100 decision trees:
```

```
Method:          regression
```

```
Nvars:          5
```

This object can be now saved in a \*.mat file as usual.

### Workflow Example: Classifying Radar Returns for Ionosphere Data with TreeBagger

You can also use ensembles of decision trees for classification. For this example, use ionosphere data with 351 observations and 34 real-valued predictors. The response variable is categorical with two levels:

- 'g' for good radar returns
- 'b' for bad radar returns

The goal is to predict good or bad returns using a set of 34 measurements. The workflow resembles that for “Workflow Example: Regression of Insurance Risk Rating for Car Imports with TreeBagger” on page 16-125.

- 1 Fix the initial random seed, grow 50 trees, inspect how the ensemble error changes with accumulation of trees, and estimate feature importance. For classification, it is best to set the minimal leaf size to 1 and select the square root of the total number of features for each decision split at random. These are the default settings for a TreeBagger used for classification.

```
load ionosphere;
rng(1945, 'twister')
b = TreeBagger(50,X,Y, 'oobvarimp', 'on');
figure(10);
plot(oobError(b));
xlabel('Number of Grown Trees');
ylabel('Out-of-Bag Classification Error');
```

- 2 The method trains ensembles with few trees on observations that are in bag for all trees. For such observations, it is impossible to compute the true

out-of-bag prediction, and `TreeBagger` returns the most probable class for classification and the sample mean for regression. You can change the default value returned for in-bag observations using the `DefaultYfit` property. If you set the default value to an empty string for classification, the method excludes in-bag observations from computation of the out-of-bag error. In this case, the curve is more variable when the number of trees is small, either because some observations are never out of bag (and are therefore excluded) or because their predictions are based on few trees.

```
b.DefaultYfit = '';
figure(11);
plot(oobError(b));
xlabel('Number of Grown Trees');
ylabel('Out-of-Bag Error Excluding in-Bag Observations');
```

- 3** The `OOBIndices` property of `TreeBagger` tracks which observations are out of bag for what trees. Using this property, you can monitor the fraction of observations in the training data that are in bag for all trees. The curve starts at approximately  $2/3$ , the fraction of unique observations selected by one bootstrap replica, and goes down to 0 at approximately 10 trees.

```
finbag = zeros(1,b.NTrees);
for t=1:b.NTrees
    finbag(t) = sum(all(~b.OOBIndices(:,1:t),2));
```

```

end
finbag = finbag / size(X,1);
figure(12);
plot(finbag);
xlabel('Number of Grown Trees');
ylabel('Fraction of in-Bag Observations');

```

#### 4 Estimate feature importance:

```

figure(13);
bar(b.OOBPermutedVarDeltaError);
xlabel('Feature Index');
ylabel('Out-of-Bag Feature Importance');
idxvar = find(b.OOBPermutedVarDeltaError>0.8)

idxvar =

```

```

    3     4     5     7     8

```

- 5 Having selected the five most important features, grow a larger ensemble on the reduced feature set. Save time by not permuting out-of-bag observations to obtain new estimates of feature importance for the reduced feature set (set `oobvarimp` to `'off'`). You would still be interested in obtaining out-of-bag estimates of classification error (set `oobpred` to `'on'`).

```
b5v = TreeBagger(100,X(:,idxvar),Y,'oobpred','on');  
figure(14);  
plot(oobError(b5v));  
xlabel('Number of Grown Trees');  
ylabel('Out-of-Bag Classification Error');
```

- 6 For classification ensembles, in addition to classification error (fraction of misclassified observations), you can also monitor the average classification margin. For each observation, the *margin* is defined as the difference between the score for the true class and the maximal score for other classes predicted by this tree. The cumulative classification margin uses the scores averaged over all trees and the mean cumulative classification margin is the cumulative margin averaged over all observations. The `oobMeanMargin` method with the `'mode'` argument set to `'cumulative'` (default) shows how the mean cumulative margin changes as the ensemble grows: every new element in the returned array represents the cumulative margin obtained by including a new tree in the ensemble. If training is successful, you would expect to see a gradual increase in the mean classification margin.

For decision trees, a classification score is the probability of observing an instance of this class in this tree leaf. For example, if the leaf of a grown decision tree has five 'good' and three 'bad' training observations in it, the scores returned by this decision tree for any observation fallen on this leaf are  $5/8$  for the 'good' class and  $3/8$  for the 'bad' class. These probabilities are called 'scores' for consistency with other classifiers that might not have an obvious interpretation for numeric values of returned predictions.

```
figure(15);
plot(oobMeanMargin(b5v));
```

```
xlabel('Number of Grown Trees');  
ylabel('Out-of-Bag Mean Classification Margin');
```

- 7** Compute the matrix of proximities and look at the distribution of outlier measures. Unlike regression, outlier measures for classification ensembles are computed within each class separately.

```
b5v = fillProximities(b5v);  
figure(16);  
hist(b5v.OutlierMeasure);  
xlabel('Outlier Measure');  
ylabel('Number of Observations');
```

- 8 All extreme outliers for this dataset come from the 'good' class:

```
b5v.Y(b5v.OutlierMeasure>40)
```

```
ans =
```

```
'g'
'g'
'g'
'g'
'g'
```

- 9 As for regression, you can plot scaled coordinates, displaying the two classes in different colors using the `colors` argument of `mdsProx`. This argument takes a string in which every character represents a color. To find the order of classes used by the ensemble, look at the `ClassNames` property:

```
b5v.ClassNames
```

```
ans =
```

```
'g'
'b'
```

The 'good' class is first and the 'bad' class is second. Display scaled coordinates using red for 'good' and blue for 'bad' observations:

```
figure(17);  
[s,e] = mdsProx(b5v,'colors','rb');  
xlabel('1st Scaled Coordinate');  
ylabel('2nd Scaled Coordinate');
```

- 10** Plot the first 20 eigenvalues obtained by scaling. The first eigenvalue in this case clearly dominates and the first scaled coordinate is most important.

```
figure(18);  
bar(e(1:20));  
xlabel('Scaled Coordinate Index');  
ylabel('Eigenvalue');
```

**Plotting a Classification Performance Curve.** Another way of exploring the performance of a classification ensemble is to plot its Receiver Operating Characteristic (ROC) curve or another performance curve suitable for the current problem. First, obtain predictions for out-of-bag observations. For a classification ensemble, the `oobPredict` method returns a cell array of classification labels ('g' or 'b' for ionosphere data) as the first output argument and a numeric array of scores as the second output argument. The returned array of scores has two columns, one for each class. In this case, the first column is for the 'good' class and the second column is for the 'bad' class. One column in the score matrix is redundant because the scores represent class probabilities in tree leaves and by definition add up to 1.

```
[Yfit,Sfit] = oobPredict(b5v);
```

Use the `perfcurve` utility (see “Performance Curves” on page 15-41) to compute a performance curve. By default, `perfcurve` returns the standard ROC curve, which is the true positive rate versus the false positive rate. `perfcurve` requires true class labels, scores, and the positive class label for input. In this case, choose the 'good' class as positive. The scores for this class are in the first column of `Sfit`.

```
[fpr,tpr] = perfcurve(b5v.Y,Sfit(:,1),'g');
figure(19);
plot(fpr,tpr);
```

```
xlabel('False Positive Rate');
ylabel('True Positive Rate');
```

Instead of the standard ROC curve, you might want to plot, for example, ensemble accuracy versus threshold on the score for the 'good' class. The `ycrit` input argument of `perfcurve` lets you specify the criterion for the  $y$ -axis, and the third output argument of `perfcurve` returns an array of thresholds for the positive class score. Accuracy is the fraction of correctly classified observations, or equivalently, 1 minus the classification error.

```
[fpr,accu,thre] = perfcurve(b5v.Y,Sfit(:,1),'g','ycrit','accu');
figure(20);
plot(thre,accu);
xlabel('Threshold for ''good'' Returns');
ylabel('Classification Accuracy');
```

The curve shows a flat region indicating that any threshold from 0.2 to 0.6 is a reasonable choice. By default, the function assigns classification labels using 0.5 as the boundary between the two classes. You can find exactly what accuracy this corresponds to:

```
i50 = find(accu>=0.50,1,'first')
accu(abs(thre-0.5)<eps)
```

```
returns
```

```
i50 =
     2
```

```
ans =
     0.9430
```

The maximal accuracy is a little higher than the default one:

```
[maxaccu,iaccu] = max(accu)
```

```
returns
```

```
maxaccu =
     0.9459
```

```
iaccu =  
    91
```

The optimal threshold is therefore:

```
thre(iaccu)
```

```
ans =  
    0.5056
```

## Ensemble Algorithms

### AdaBoostM1

AdaBoostM1 is a very popular boosting algorithm for binary classification. The algorithm trains learners sequentially. For every learner with index  $t$ , AdaBoostM1 computes the weighted classification error

$$\varepsilon_t = \sum_{n=1}^N d_n^{(t)} \mathbb{I}(y_n \neq h_t(x_n)),$$

where

- $x_n$  is a vector of predictor values for observation  $n$ .
- $y_n$  is the true class label.
- $h_t$  is the prediction of learner (hypothesis) with index  $t$ .
- $\mathbb{I}$  is the indicator function.
- $d_n^{(t)}$  is the weight of observation  $n$  at step  $t$ .

AdaBoostM1 then increases weights for observations misclassified by learner  $t$  and reduces weights for observations correctly classified by learner  $t$ . The next learner  $t + 1$  is then trained on the data with updated weights  $d_n^{(t+1)}$ .

After training finishes, AdaBoostM1 computes prediction for new data using

$$f(x) = \sum_{t=1}^T \alpha_t h_t(x),$$

where

$$\alpha_t = \frac{1}{2} \log \frac{1 - \varepsilon_t}{\varepsilon_t}$$

are weights of the weak hypotheses in the ensemble.

Training by AdaBoostM1 can be viewed as stagewise minimization of the exponential loss

$$\sum_{n=1}^N w_n \exp(-y_n f(x_n)),$$

where

- $y_n \in \{-1, +1\}$  is the true class label.

- $w_n$  are observation weights normalized to add up to 1.
- $f(x_n) \in (-\infty, +\infty)$  is the predicted classification score.

The observation weights  $w_n$  are the original observation weights you passed to `fitensemble`.

The second output from the `predict` method of an `AdaBoostM1` classification ensemble is an  $N$ -by-2 matrix of classification scores for the two classes and  $N$  observations. The second column in this matrix is always equal to minus the first column. `predict` returns two scores to be consistent with multiclass models, though this is redundant because the second column is always the negative of the first.

Most often `AdaBoostM1` is used with decision stumps (default) or shallow trees. If boosted stumps give poor performance, try setting the minimal parent node size to one quarter of the training data.

By default, the learning rate for boosting algorithms is 1. If you set the learning rate to a lower number, the ensemble learns at a slower rate, but can converge to a better solution. 0.1 is a popular choice for the learning rate. Learning at a rate less than 1 is often called “shrinkage”.

For examples using `AdaBoostM1`, see “Tuning `RobustBoost`” on page 16-115.

For references related to `AdaBoostM1`, see Freund and Schapire [9], Schapire et al. [15], Friedman, Hastie, and Tibshirani [11], and Friedman [10].

## AdaBoostM2

`AdaBoostM2` is an extension of `AdaBoostM1` for multiple classes. Instead of weighted classification error, `AdaBoostM2` uses weighted pseudo-loss for  $N$  observations and  $K$  classes

$$\varepsilon_t = \frac{1}{2} \sum_{n=1}^N \sum_{k \neq y_n} d_{n,k}^{(t)} (1 - h_t(x_n, y_n) + h_t(x_n, k)),$$

where

- $h_t(x_n, k)$  is the confidence of prediction by learner at step  $t$  into class  $k$  ranging from 0 (not at all confident) to 1 (highly confident).
- $d_{n,k}^{(t)}$  are observation weights at step  $t$  for class  $k$ .
- $y_n$  is the true class label taking one of the  $K$  values.
- The second sum is over all classes other than the true class  $y_n$ .

Interpreting the pseudo-loss is harder than classification error, but the idea is the same. Pseudo-loss can be used as a measure of the classification accuracy from any learner in an ensemble. Pseudo-loss typically exhibits the same behavior as a weighted classification error for AdaBoostM1: the first few learners in a boosted ensemble give low pseudo-loss values. After the first few training steps, the ensemble begins to learn at a slower pace, and the pseudo-loss value approaches 0.5 from below.

For examples using AdaBoostM2, see “Create a Classification Ensemble” on page 16-69.

For references related to AdaBoostM2, see Freund and Schapire [9].

## Bag

*Bagging*, which stands for “bootstrap aggregation,” is a type of ensemble learning. To bag a weak learner such as a decision tree on a dataset, generate many bootstrap replicas of this dataset and grow decision trees on these replicas. Obtain each bootstrap replica by randomly selecting  $N$  observations out of  $N$  with replacement, where  $N$  is the dataset size. To find the predicted response of a trained ensemble, take an average over predictions from individual trees.

Bagged decision trees were introduced in MATLAB R2009a as `TreeBagger`. The `fitensemble` function lets you bag in a manner consistent with boosting. An ensemble of bagged trees, either `ClassificationBaggedEnsemble` or `RegressionBaggedEnsemble`, returned by `fitensemble` offers almost the same functionality as `TreeBagger`. Discrepancies between `TreeBagger` and the new framework are described in detail in `TreeBagger Features Not in fitensemble` on page 16-151.

Bagging works by training learners on resampled versions of the data. This resampling is usually done by bootstrapping observations, that is, selecting  $N$  out of  $N$  observations with replacement for every new learner. In addition, every tree in the ensemble can randomly select predictors for decision splits—a technique known to improve the accuracy of bagged trees.

By default, the minimal leaf sizes for bagged trees are set to 1 for classification and 5 for regression. Trees grown with the default leaf size are usually very deep. These settings are close to optimal for the predictive power of an ensemble. Often you can grow trees with larger leaves without losing predictive power. Doing so reduces training and prediction time, as well as memory usage for the trained ensemble.

Another important parameter is the number of predictors selected at random for every decision split. This random selection is made for every split, and every deep tree involves many splits. By default, this parameter is set to a square root of the number of predictors for classification, and one third of predictors for regression.

Several features of bagged decision trees make them a unique algorithm. Drawing  $N$  out of  $N$  observations with replacement omits on average 37% of observations for each decision tree. These are “out-of-bag” observations. You can use them to estimate the predictive power and feature importance. For each observation, you can estimate the out-of-bag prediction by averaging over predictions from all trees in the ensemble for which this observation is out of bag. You can then compare the computed prediction against the observed response for this observation. By comparing the out-of-bag predicted responses against the observed responses for all observations used for training, you can estimate the average out-of-bag error. This out-of-bag average is an unbiased estimator of the true ensemble error. You can also obtain out-of-bag estimates of feature importance by randomly permuting out-of-bag data across one variable or column at a time and estimating the increase in the out-of-bag error due to this permutation. The larger the increase, the more important the feature. Thus, you need not supply test data for bagged ensembles because you obtain reliable estimates of the predictive power and feature importance in the process of training, which is an attractive feature of bagging.

Another attractive feature of bagged decision trees is the proximity matrix. Every time two observations land on the same leaf of a tree, their proximity

increases by 1. For normalization, sum these proximities over all trees in the ensemble and divide by the number of trees. The resulting matrix is symmetric with diagonal elements equal to 1 and off-diagonal elements ranging from 0 to 1. You can use this matrix for finding outlier observations and discovering clusters in the data through multidimensional scaling.

For examples using bagging, see:

- “Example: Test Ensemble Quality” on page 16-72
- “Surrogate Splits” on page 16-95
- “Workflow Example: Regression of Insurance Risk Rating for Car Imports with TreeBagger” on page 16-125
- “Workflow Example: Classifying Radar Returns for Ionosphere Data with TreeBagger” on page 16-134

For references related to bagging, see Breiman [3], [4], and [5].

**Comparison of TreeBagger and Bagged Ensembles.** `fitensemble` produces bagged ensembles that have most, but not all, of the functionality of TreeBagger objects. Additionally, some functionality has different names in the new bagged ensembles.

### TreeBagger Features Not in `fitensemble`

Feature	TreeBagger Property	TreeBagger Method
Computation of proximity matrix	Proximity	<code>fillProximities</code> , <code>mdsProx</code>
Computation of outliers	OutlierMeasure	N/A
Out-of-bag estimates of predictor importance	<code>OOBPermutedVarDeltaError</code> , <code>OOBPermutedVarDeltaMeanMargin</code> , <code>OOBPermutedVarCountRaiseMargin</code>	N/A
Merging two ensembles trained separately	N/A	<code>append</code>
Parallel computation for creating ensemble	Set the <code>UseParallel</code> name-value pair to <code>true</code>	N/A

### Differing Names Between TreeBagger and Bagged Ensembles

Feature	TreeBagger	Bagged Ensembles
Split criterion contributions for each predictor	DeltaCritDecisionSplit property	First output of predictorImportance (classification) or predictorImportance (regression)
Predictor associations	VarAssoc property	Second output of predictorImportance (classification) or predictorImportance (regression)
Error (misclassification probability or mean-squared error)	error and oobError methods	loss and oobLoss methods (classification); loss and oobLoss methods (regression)
Train additional trees and add to ensemble	growTrees method	resume method (classification); resume method (regression)
Mean classification margin per tree	meanMargin and oobMeanMargin methods	edge and oobEdge methods (classification)

In addition, two important changes were made to training and prediction for bagged classification ensembles:

- If you pass a misclassification cost matrix to `TreeBagger`, it passes this matrix along to the trees. If you pass a misclassification cost matrix to `fitensemble`, it uses this matrix to adjust the class prior probabilities. `fitensemble` then passes the adjusted prior probabilities and the default cost matrix to the trees. The default cost matrix is `ones(K) - eye(K)` for  $K$  classes.
- Unlike the `loss` and `edge` methods in the new framework, the `TreeBagger` `error` and `meanMargin` methods do not normalize input observation weights of the prior probabilities in the respective class.

## GentleBoost

GentleBoost (also known as Gentle AdaBoost) combines features of AdaBoostM1 and LogitBoost. Like AdaBoostM1, GentleBoost minimizes the exponential loss. But its numeric optimization is set up differently. Like LogitBoost, every weak learner fits a regression model to response values  $y_n \in \{-1, +1\}$ . This makes GentleBoost another good candidate for binary classification of data with multilevel categorical predictors.

`fitensemble` computes and stores the mean-squared error in the `FitInfo` property of the ensemble object. The mean-squared error is

$$\sum_{n=1}^N d_n^{(t)} (\tilde{y}_n - h_t(x_n))^2,$$

where

- $d_n^{(t)}$  are observation weights at step  $t$  (the weights add up to 1).
- $h_t(x_n)$  are predictions of the regression model  $h_t$  fitted to response values  $y_n$ .

As the strength of individual learners weakens, the weighted mean-squared error approaches 1.

For examples using GentleBoost, see “Example: Unequal Classification Costs” on page 16-85 and “Classification with Many Categorical Levels” on page 16-91.

For references related to GentleBoost, see Friedman, Hastie, and Tibshirani [11].

## LogitBoost

LogitBoost is another popular algorithm for binary classification. LogitBoost works similarly to AdaBoostM1, except it minimizes binomial deviance

$$\sum_{n=1}^N w_n \log(1 + \exp(-2y_n f(x_n))),$$

where

- $y_n \in \{-1, +1\}$  is the true class label.
- $w_n$  are observation weights normalized to add up to 1.
- $f(x_n) \in (-\infty, +\infty)$  is the predicted classification score.

Binomial deviance assigns less weight to badly misclassified observations (observations with large negative values of  $y_n f(x_n)$ ). `LogitBoost` can give better average accuracy than `AdaBoostM1` for data with poorly separable classes.

Learner  $t$  in a `LogitBoost` ensemble fits a regression model to response values

$$\tilde{y}_n = \frac{y_n^* - p_t(x_n)}{p_t(x_n)(1 - p_t(x_n))},$$

where

- $y_n^* \in \{0, +1\}$  are relabeled classes (0 instead of  $-1$ ).
- $p_t(x_n)$  is the current ensemble estimate of the probability for observation  $x_n$  to be of class 1.

Fitting a regression model at each boosting step turns into a great computational advantage for data with multilevel categorical predictors. Take a categorical predictor with  $L$  levels. To find the optimal decision split on such a predictor, classification tree needs to consider  $2^{L-1} - 1$  splits. A regression tree needs to consider only  $L - 1$  splits, so the processing time can be much shorter. `LogitBoost` is recommended for categorical predictors with many levels.

`fitensemble` computes and stores the mean-squared error in the `FitInfo` property of the ensemble object. The mean-squared error is

$$\sum_{n=1}^N a_n^{(t)} (\tilde{y}_n - h_t(x_n))^2,$$

where

- $d_n^{(t)}$  are observation weights at step  $t$  (the weights add up to 1).
- $h_t(x_n)$  are predictions of the regression model  $h_t$  fitted to response values  $\tilde{y}_n$ .

Values  $y_n$  can range from  $-\infty$  to  $+\infty$ , so the mean-squared error does not have well-defined bounds.

For examples using **LogitBoost**, see “Classification with Many Categorical Levels” on page 16-91.

For references related to **LogitBoost**, see Friedman, Hastie, and Tibshirani [11].

## LPBoost

**LPBoost** (linear programming boost), like **TotalBoost**, performs multiclass classification by attempting to maximize the minimal *margin* in the training set. This attempt uses optimization algorithms, namely linear programming for **LPBoost**. So you need an Optimization Toolbox license to use **LPBoost** or **TotalBoost**.

The margin of a classification is the difference between the predicted soft classification *score* for the true class, and the largest score for the false classes. For trees, the *score* of a classification of a leaf node is the posterior probability of the classification at that node. The posterior probability of the classification at a node is the number of training sequences that lead to that node with the classification, divided by the number of training sequences that lead to that node. For more information, see “Definitions” on page 21-1868 in *margin*.

Why maximize the minimal margin? For one thing, the generalization error (the error on new data) is the probability of obtaining a negative margin. Schapire and Singer [16] establish this inequality on the probability of obtaining a negative margin:

$$P_{\text{test}}(m \leq 0) \leq P_{\text{train}}(m \leq \theta) + O\left(\frac{1}{\sqrt{N}} \sqrt{\frac{V \log^2(N/V)}{\theta^2} + \log(1/\delta)}\right).$$

Here  $m$  is the margin,  $\theta$  is any positive number,  $V$  is the Vapnik-Chervonenkis dimension of the classifier space,  $N$  is the size of the training set, and  $\delta$  is a small positive number. The inequality holds with probability  $1-\delta$  over many i.i.d. training and test sets. This inequality says: To obtain a low generalization error, minimize the number of observations below margin  $\theta$  in the training set.

LPBoost iteratively maximizes the minimal margin through a sequence of linear programming problems. Equivalently, by duality, LPBoost minimizes the maximal *edge*, where edge is the weighted mean margin (see “Definitions” on page 21-765). At each iteration, there are more constraints in the problem. So, for large problems, the optimization problem becomes increasingly constrained, and slow to solve.

LPBoost typically creates ensembles with many learners having weights that are orders of magnitude smaller than those of other learners. Therefore, to better enable you to remove the unimportant ensemble members, the compact method reorders the members of an LPBoost ensemble from largest weight to smallest. Therefore, you can easily remove the least important members of the ensemble using the `removeLearners` method.

For examples using LPBoost, see “LPBoost and TotalBoost for Small Ensembles” on page 16-98.

For references related to LPBoost, see Warmuth, Liao, and Ratsch [18].

## LSBoost

LSBoost (least squares boosting) fits regression ensembles. At every step, the ensemble fits a new learner to the difference between the observed response and the aggregated prediction of all learners grown previously. The ensemble fits to minimize mean-squared error.

You can use LSBoost with shrinkage by passing in the `LearnRate` parameter. By default this parameter is set to 1, and the ensemble learns at the maximal speed. If you set `LearnRate` to a value from 0 to 1, the ensemble fits every new learner to  $y_n - \eta f(x_n)$ , where

- $y_n$  is the observed response.

- $f(x_n)$  is the aggregated prediction from all weak learners grown so far for observation  $x_n$ .
- $\eta$  is the learning rate.

For examples using `LSBoost`, see “Creating a Regression Ensemble” on page 16-70 and “Example: Regularizing a Regression Ensemble” on page 16-105.

For references related to `LSBoost`, see Hastie, Tibshirani, and Friedman [12], Chapters 7 (Model Assessment and Selection) and 15 (Random Forests).

## RobustBoost

Boosting algorithms such as `AdaBoostM1` and `LogitBoost` increase weights for misclassified observations at every boosting step. These weights can become very large. If this happens, the boosting algorithm sometimes concentrates on a few misclassified observations and neglects the majority of training data. Consequently the average classification accuracy suffers.

In this situation, you can try using `RobustBoost`. This algorithm does not assign almost the entire data weight to badly misclassified observations. It can produce better average classification accuracy.

Unlike `AdaBoostM1` and `LogitBoost`, `RobustBoost` does not minimize a specific loss function. Instead, it maximizes the number of observations with the classification margin above a certain threshold.

`RobustBoost` trains based on time evolution. The algorithm starts at  $t = 0$ . At every step, `RobustBoost` solves an optimization problem to find a positive step in time  $\Delta t$  and a corresponding positive change in the average margin for training data  $\Delta m$ . `RobustBoost` stops training and exits if at least one of these three conditions is true:

- Time  $t$  reaches 1.
- `RobustBoost` cannot find a solution to the optimization problem with positive updates  $\Delta t$  and  $\Delta m$ .
- `RobustBoost` grows as many learners as you requested.

Results from `RobustBoost` can be usable for any termination condition. Estimate the classification accuracy by cross validation or by using an independent test set.

To get better classification accuracy from `RobustBoost`, you can adjust three parameters in `fitensemble`: `RobustErrorGoal`, `RobustMaxMargin`, and `RobustMarginSigma`. Start by varying values for `RobustErrorGoal` from 0 to 1. The maximal allowed value for `RobustErrorGoal` depends on the two other parameters. If you pass a value that is too high, `fitensemble` produces an error message showing the allowed range for `RobustErrorGoal`.

For examples using `RobustBoost`, see “Tuning `RobustBoost`” on page 16-115.

For references related to `RobustBoost`, see Freund [8].

### **RUSBoost**

`RUSBoost` is especially effective at classifying imbalanced data, meaning some class in the training data has many fewer members than another. `RUS` stands for Random Under Sampling. The algorithm takes  $N$ , the number of members in the class with the fewest members in the training data, as the basic unit for sampling. Classes with more members are under sampled by taking only  $N$  observations of every class. In other words, if there are  $K$  classes, then, for each weak learner in the ensemble, `RUSBoost` takes a subset of the data with  $N$  observations from each of the  $K$  classes. The boosting procedure follows the procedure in “`AdaBoostM2`” on page 16-148 for reweighting and constructing the ensemble.

When you construct a `RUSBoost` ensemble, there is an optional name-value pair called `RatioToSmallest`. Give a vector of  $K$  values, each value representing the multiple of  $N$  to sample for the associated class. For example, if the smallest class has  $N = 100$  members, then `RatioToSmallest = [2,3,4]` means each weak learner has 200 members in class 1, 300 in class 2, and 400 in class 3. If `RatioToSmallest` leads to a value that is larger than the number of members in a particular class, then `RUSBoost` samples the members with replacement. Otherwise, `RUSBoost` samples the members without replacement.

For examples using `RUSBoost`, see “Classification with Imbalanced Data” on page 16-77.

For references related to RUSBoost, see Seiffert et al. [17].

## Subspace

Use random subspace ensembles (`Subspace`) to improve the accuracy of discriminant analysis (`ClassificationDiscriminant`) or  $k$ -nearest neighbor (`ClassificationKNN`) classifiers. `Subspace` ensembles also have the advantage of using less memory than ensembles with all predictors, and can handle missing values (NaNs).

The basic random subspace algorithm uses these parameters.

- $m$  is the number of dimensions (variables) to sample in each learner. Set  $m$  using the `NPredToSample` name-value pair.
- $d$  is the number of dimensions in the data, which is the number of columns (predictors) in the data matrix  $X$ .
- $n$  is the number of learners in the ensemble. Set  $n$  using the `NLearn` input.

The basic random subspace algorithm performs the following steps:

- 1** Choose without replacement a random set of  $m$  predictors from the  $d$  possible values.
- 2** Train a weak learner using just the  $m$  chosen predictors.
- 3** Repeat steps 1 and 2 until there are  $n$  weak learners.
- 4** Predict by taking an average of the score prediction of the weak learners, and classify the category with the highest average score.

You can choose to create a weak learner for every possible set of  $m$  predictors from the  $d$  dimensions. To do so, set  $n$ , the number of learners, to `'AllPredictorCombinations'`. In this case, there are `nchoosek(size(X,2),NPredToSample)` weak learners in the ensemble.

`fitensemble` downweights predictors after choosing them for a learner, so subsequent learners have a lower chance of using a predictor that was previously used. This weighting tends to make predictors more evenly distributed among learners than in uniform weighting.

For examples using `Subspace`, see “Random Subspace Classification” on page 16-119.

For references related to random subspace ensembles, see Ho [13].

### TotalBoost

`TotalBoost`, like linear programming boost (`LPBoost`), performs multiclass classification by attempting to maximize the minimal *margin* in the training set. This attempt uses optimization algorithms, namely quadratic programming for `TotalBoost`. So you need an Optimization Toolbox license to use `LPBoost` or `TotalBoost`.

The margin of a classification is the difference between the predicted soft classification *score* for the true class, and the largest score for the false classes. For trees, the *score* of a classification of a leaf node is the posterior probability of the classification at that node. The posterior probability of the classification at a node is the number of training sequences that lead to that node with the classification, divided by the number of training sequences that lead to that node. For more information, see “Definitions” on page 21-1868 in `margin`.

Why maximize the minimal margin? For one thing, the generalization error (the error on new data) is the probability of obtaining a negative margin. Schapire and Singer [16] establish this inequality on the probability of obtaining a negative margin:

$$P_{\text{test}}(m \leq 0) \leq P_{\text{train}}(m \leq \theta) + O\left(\frac{1}{\sqrt{N}} \sqrt{\frac{V \log^2(N/V)}{\theta^2} + \log(1/\delta)}\right).$$

Here  $m$  is the margin,  $\theta$  is any positive number,  $V$  is the Vapnik-Chervonenkis dimension of the classifier space,  $N$  is the size of the training set, and  $\delta$  is a small positive number. The inequality holds with probability  $1-\delta$  over many i.i.d. training and test sets. This inequality says: To obtain a low generalization error, minimize the number of observations below margin  $\theta$  in the training set.

`TotalBoost` minimizes a proxy of the Kullback-Leibler divergence between the current weight distribution and the initial weight distribution, subject to

the constraint that the *edge* (the weighted margin) is below a certain value. The proxy is a quadratic expansion of the divergence:

$$D(W, W_0) = \sum_{n=1}^N \log \frac{W(n)}{W_0(n)} \approx \sum_{n=1}^N \left( 1 + \frac{W(n)}{W_0(n)} \right) \Delta + \frac{1}{2W(n)} \Delta^2,$$

where  $\Delta$  is the difference between  $W(n)$ , the weights at the current and next iteration, and  $W_0$ , the initial weight distribution, which is uniform. This optimization formulation keeps weights from becoming zero. At each iteration, there are more constraints in the problem. So, for large problems, the optimization problem becomes increasingly constrained, and slow to solve.

TotalBoost typically creates ensembles with many learners having weights that are orders of magnitude smaller than those of other learners. Therefore, to better enable you to remove the unimportant ensemble members, the compact method reorders the members of a TotalBoost ensemble from largest weight to smallest. Therefore you can easily remove the least important members of the ensemble using the `removeLearners` method.

For examples using TotalBoost, see “LPBoost and TotalBoost for Small Ensembles” on page 16-98.

For references related to TotalBoost, see Warmuth, Liao, and Ratsch [18].

## Support Vector Machines (SVM)

In this section...

### Understanding Support Vector Machines

- “Separable Data” on page 16-162
- “Nonseparable Data” on page 16-165
- “Nonlinear Transformation with Kernels” on page 16-167

#### Separable Data

You can use a support vector machine (SVM) when your data has exactly two classes. An SVM classifies data by finding the best hyperplane that separates all data points of one class from those of the other class. The *best* hyperplane for an SVM means the one with the largest *margin* between the two classes. Margin means the maximal width of the slab parallel to the hyperplane that has no interior data points.

The *support vectors* are the data points that are closest to the separating hyperplane; these points are on the boundary of the slab. The following figure illustrates these definitions, with + indicating data points of type 1, and – indicating data points of type –1.

**Mathematical Formulation: Primal.** This discussion follows Hastie, Tibshirani, and Friedman [12] and Christianini and Shawe-Taylor [7].

The data for training is a set of points (vectors)  $x_i$  along with their categories  $y_i$ . For some dimension  $d$ , the  $x_i \in R^d$ , and the  $y_i = \pm 1$ . The equation of a hyperplane is

$$\langle w, x \rangle + b = 0,$$

where  $w \in R^d$ ,  $\langle w, x \rangle$  is the inner (dot) product of  $w$  and  $x$ , and  $b$  is real.

The following problem defines the *best* separating hyperplane. Find  $w$  and  $b$  that minimize  $\|w\|$  such that for all data points  $(x_i, y_i)$ ,

$$y_i(\langle w, x_i \rangle + b) \geq 1.$$

The support vectors are the  $x_i$  on the boundary, those for which  $y_i(\langle w, x_i \rangle + b) = 1$ .

For mathematical convenience, the problem is usually given as the equivalent problem of minimizing  $\langle w, w \rangle / 2$ . This is a quadratic programming problem. The optimal solution  $w, b$  enables classification of a vector  $z$  as follows:

$$\text{class}(z) = \text{sign}(\langle w, z \rangle + b).$$

**Mathematical Formulation: Dual.** It is computationally simpler to solve the dual quadratic programming problem. To obtain the dual, take positive Lagrange multipliers  $\alpha_i$  multiplied by each constraint, and subtract from the objective function:

$$L_P = \frac{1}{2} \langle w, w \rangle - \sum_i \alpha_i (y_i (\langle w, x_i \rangle + b) - 1),$$

where you look for a stationary point of  $L_P$  over  $w$  and  $b$ . Setting the gradient of  $L_P$  to 0, you get

$$\begin{aligned} w &= \sum_i \alpha_i y_i x_i \\ 0 &= \sum_i \alpha_i y_i. \end{aligned} \tag{16-1}$$

Substituting into  $L_P$ , you get the dual  $L_D$ :

$$L_D = \sum_i \alpha_i - \frac{1}{2} \sum_i \sum_j \alpha_i \alpha_j y_i y_j \langle x_i, x_j \rangle,$$

which you maximize over  $\alpha_i \geq 0$ . In general, many  $\alpha_i$  are 0 at the maximum. The nonzero  $\alpha_i$  in the solution to the dual problem define the hyperplane, as seen in Equation 16-1, which gives  $w$  as the sum of  $\alpha_i y_i x_i$ . The data points  $x_i$  corresponding to nonzero  $\alpha_i$  are the *support vectors*.

The derivative of  $L_D$  with respect to a nonzero  $\alpha_i$  is 0 at an optimum. This gives

$$y_i (\langle w, x_i \rangle + b) - 1 = 0.$$

In particular, this gives the value of  $b$  at the solution, by taking any  $i$  with nonzero  $\alpha_i$ .

The dual is a standard quadratic programming problem. For example, the Optimization Toolbox quadprog solver solves this type of problem.

## Nonseparable Data

Your data might not allow for a separating hyperplane. In that case, SVM can use a *soft margin*, meaning a hyperplane that separates many, but not all data points.

There are two standard formulations of soft margins. Both involve adding slack variables  $s_i$  and a penalty parameter  $C$ .

- The  $L^1$ -norm problem is:

$$\min_{w,b,s} \left( \frac{1}{2} \langle w, w \rangle + C \sum_i s_i \right)$$

such that

$$\begin{aligned} y_i (\langle w, x_i \rangle + b) &\geq 1 - s_i \\ s_i &\geq 0. \end{aligned}$$

The  $L^1$ -norm refers to using  $s_i$  as slack variables instead of their squares. The SMO `svmtrain` method minimizes the  $L^1$ -norm problem.

- The  $L^2$ -norm problem is:

$$\min_{w,b,s} \left( \frac{1}{2} \langle w, w \rangle + C \sum_i s_i^2 \right)$$

subject to the same constraints. The QP `svmtrain` method minimizes the  $L^2$ -norm problem.

In these formulations, you can see that increasing  $C$  places more weight on the slack variables  $s_i$ , meaning the optimization attempts to make a stricter separation between classes. Equivalently, reducing  $C$  towards 0 makes misclassification less important.

**Mathematical Formulation: Dual.** For easier calculations, consider the  $L^1$  dual problem to this soft-margin formulation. Using Lagrange multipliers  $\mu_i$ , the function to minimize for the  $L^1$ -norm problem is:

$$L_P = \frac{1}{2} \langle w, w \rangle + C \sum_i s_i - \sum_i \alpha_i (y_i (\langle w, x_i \rangle + b) - (1 - s_i)) - \sum_i \mu_i s_i,$$

where you look for a stationary point of  $L_P$  over  $w$ ,  $b$ , and positive  $s_i$ . Setting the gradient of  $L_P$  to 0, you get

$$\begin{aligned} b &= \sum_i \alpha_i y_i x_i \\ \sum_i \alpha_i y_i &= 0 \\ \alpha_i &= C - \mu_i \\ \alpha_i, \mu_i, s_i &\geq 0. \end{aligned}$$

These equations lead directly to the dual formulation:

$$\max_{\alpha} \sum_i \alpha_i - \frac{1}{2} \sum_i \sum_j \alpha_i \alpha_j y_i y_j \langle x_i, x_j \rangle$$

subject to the constraints

$$\begin{aligned} \sum_i y_i \alpha_i &= 0 \\ 0 \leq \alpha_i &\leq C. \end{aligned}$$

The final set of inequalities,  $0 \leq \alpha_i \leq C$ , shows why  $C$  is sometimes called a *box constraint*.  $C$  keeps the allowable values of the Lagrange multipliers  $\alpha_i$  in a “box”, a bounded region.

The gradient equation for  $b$  gives the solution  $b$  in terms of the set of nonzero  $\alpha_i$ , which correspond to the support vectors.

You can write and solve the dual of the  $L^2$ -norm problem in an analogous manner. For details, see Christianini and Shawe-Taylor [7], Chapter 6.

**svmtrain Implementation.** Both dual soft-margin problems are quadratic programming problems. Internally, `svmtrain` has several different algorithms for solving the problems. The default Sequential Minimal Optimization (SMO) algorithm minimizes the one-norm problem. SMO is a relatively fast algorithm. If you have an Optimization Toolbox license, you can choose to use `quadprog` as the algorithm. `quadprog` minimizes the  $L^2$ -norm problem. `quadprog` uses a good deal of memory, but solves quadratic programs to a high degree of precision (see Bottou and Lin [2]). For details, see the `svmtrain` function reference page.

## Nonlinear Transformation with Kernels

Some binary classification problems do not have a simple hyperplane as a useful separating criterion. For those problems, there is a variant of the mathematical approach that retains nearly all the simplicity of an SVM separating hyperplane.

This approach uses these results from the theory of reproducing kernels:

- There is a class of functions  $K(x,y)$  with the following property. There is a linear space  $S$  and a function  $\varphi$  mapping  $x$  to  $S$  such that

$$K(x,y) = \langle \varphi(x), \varphi(y) \rangle.$$

The dot product takes place in the space  $S$ .

- This class of functions includes:
  - Polynomials: For some positive integer  $d$ ,

$$K(x,y) = (1 + \langle x,y \rangle)^d.$$

- Radial basis function: For some positive number  $\sigma$ ,

$$K(x,y) = \exp(-\langle (x-y), (x-y) \rangle / (2\sigma^2)).$$

- Multilayer perceptron (neural network): For a positive number  $p_1$  and a negative number  $p_2$ ,

$$K(x,y) = \tanh(p_1 \langle x,y \rangle + p_2).$$

---

**Note** Not every set of  $p_1$  and  $p_2$  gives a valid reproducing kernel.

---

The mathematical approach using kernels relies on the computational method of hyperplanes. All the calculations for hyperplane classification use nothing more than dot products. Therefore, nonlinear kernels can use identical calculations and solution algorithms, and obtain classifiers that are nonlinear. The resulting classifiers are hypersurfaces in some space  $S$ , but the space  $S$  does not have to be identified or examined.

## Using Support Vector Machines

As with any supervised learning model, you first train a support vector machine, then use the trained machine to classify (predict) new data. In addition, to obtain satisfactory predictive accuracy, you can use various SVM kernel functions, and you must tune the parameters of the kernel functions.

- “Training an SVM Classifier” on page 16-168
- “Classifying New Data with an SVM Classifier” on page 16-169
- “Tuning an SVM Classifier” on page 16-169

### Training an SVM Classifier

Train an SVM classifier with the `svmtrain` function. The most common syntax is:

```
SVMstruct = svmtrain(data,groups,'Kernel_Function','rbf');
```

The inputs are:

- `data` — Matrix of data points, where each row is one observation, and each column is one feature.
- `groups` — Column vector with each row corresponding to the value of the corresponding row in `data`. `groups` should have only two types of entries. So `groups` can have logical entries, or can be a double vector or cell array with two values.

- `Kernel_Function` — The default value of `'linear'` separates the data by a hyperplane. The value `'rbf'` uses a Gaussian radial basis function. Hsu, Chang, and Lin [14] suggest using `'rbf'` as your first try.

The resulting structure, `SVMstruct`, contains the optimized parameters from the SVM algorithm, enabling you to classify new data.

For more name-value pairs you can use to control the training, see the `svmtrain` reference page.

### Classifying New Data with an SVM Classifier

Classify new data with the `svmclassify` function. The syntax for classifying new data with a `SVMstruct` structure is:

```
newClasses = svmclassify(SVMstruct,newData)
```

The resulting vector, `newClasses`, represents the classification of each row in `newData`.

### Tuning an SVM Classifier

Hsu, Chang, and Lin [14] recommend tuning parameters of your classifier according to this scheme:

- Start with `Kernel_Function` set to `'rbf'` and default parameters.
- Try different parameters for training, and check via cross validation to obtain the best parameters.

The most important parameters to try changing are:

- `boxconstraint` — One strategy is to try a geometric sequence of the box constraint parameter. For example, take 11 values, from  $1e-5$  to  $1e5$  by a factor of 10.
- `rbf_sigma` — One strategy is to try a geometric sequence of the RBF sigma parameter. For example, take 11 values, from  $1e-5$  to  $1e5$  by a factor of 10.

For the various parameter settings, try cross validating the resulting classifier. Use `crossval` with 5-way or the default 10-way cross validation.

After obtaining a reasonable initial parameter, you might want to refine your parameters to obtain better accuracy. Start with your initial parameters and perform another cross validation step, this time using a factor of 1.2. Alternatively, optimize your parameters with `fminsearch`, as shown in “SVM Classification with Cross Validation” on page 16-174.

## Nonlinear Classifier with Gaussian Kernel

This example shows how to generate a nonlinear classifier with Gaussian kernel function. First, generate one class of points inside the unit disk in two dimensions, and another class of points in the annulus from radius 1 to radius 2. Then, generates a classifier based on the data with the Gaussian radial basis function kernel. The default linear classifier is obviously unsuitable for this problem, since the model is circularly symmetric. Set the box constraint parameter to `Inf` to make a strict classification, meaning no misclassified training points. Other kernel functions might not work with this strict box constraint, since they might be unable to provide a strict classification. Even though the `rbf` classifier can separate the classes, the result can be overtrained.

Generate 100 points uniformly distributed in the unit disk. To do so, generate a radius  $r$  as the square root of a uniform random variable, generate an angle  $t$  uniformly in  $(0, 2\pi)$ , and put the point at  $(r \cos(t), r \sin(t))$ .

```
r = sqrt(rand(100,1)); % radius
t = 2*pi*rand(100,1); % angle
data1 = [r.*cos(t), r.*sin(t)]; % points
```

Generate 100 points uniformly distributed in the annulus. The radius is again proportional to a square root, this time a square root of the uniform distribution from 1 through 4.

```
r2 = sqrt(3*rand(100,1)+1); % radius
t2 = 2*pi*rand(100,1); % angle
data2 = [r2.*cos(t2), r2.*sin(t2)]; % points
```

Plot the points, and plot circles of radii 1 and 2 for comparison.

```
plot(data1(:,1),data1(:,2),'r.')
hold on
plot(data2(:,1),data2(:,2),'b.')
```

```
ezpolar(@(x)1);ezpolar(@(x)2);  
axis equal  
hold off
```

Put the data in one matrix, and make a vector of classifications.

```
data3 = [data1;data2];  
theclass = ones(200,1);  
theclass(1:100) = -1;
```

Train an SVM classifier with `Kernel_Function` set to `'rbf'` and `boxconstraint` set to `Inf`.

```
c1 = svmtrain(data3,theclass,'Kernel_Function','rbf',...  
    'boxconstraint',Inf,'showplot',true);  
hold on  
axis equal  
ezpolar(@(x)1)  
hold off
```

svmtrain generates a classifier that is close to a circle of radius 1. The difference is due to the random training data.

Training with the default parameters makes a more nearly circular classification boundary, but one that misclassifies some training data.

```
c1 = svmtrain(data3,theclass,'Kernel_Function','rbf',...  
             'showplot',true);  
hold on  
axis equal  
ezpolar(@(x)1)  
hold off
```

### SVM Classification with Cross Validation

This example classifies points from a Gaussian mixture model. The model is described in Hastie, Tibshirani, and Friedman [12], page 17. It begins with generating 10 base points for a “green” class, distributed as 2-D independent normals with mean (1,0) and unit variance. It also generates 10 base points for a “red” class, distributed as 2-D independent normals with mean (0,1) and unit variance. For each class (green and red), generate 100 random points as follows:

- 1 Choose a base point  $m$  of the appropriate color uniformly at random.
- 2 Generate an independent random point with 2-D normal distribution with mean  $m$  and variance  $I/5$ , where  $I$  is the 2-by-2 identity matrix.

After generating 100 green and 100 red points, classify them using `svmtrain`, and tune the classification using cross validation.

To generate the points and classifier:

- 1 Generate the 10 base points for each class:

```
grnpop = mvnrnd([1,0],eye(2),10);  
redpop = mvnrnd([0,1],eye(2),10);
```

- 2 View the base points:

```
plot(grnpop(:,1),grnpop(:,2),'go')  
hold on  
plot(redpop(:,1),redpop(:,2),'ro')  
hold off
```

Since many red base points are close to green base points, it is difficult to classify the data points.

**3** Generate the 100 data points of each class:

```
redpts = zeros(100,2);grnpts = redpts;  
for i = 1:100  
    grnpts(i,:) = mvnrnd(grnpop(randi(10),:),eye(2)*0.2);  
    redpts(i,:) = mvnrnd(redpop(randi(10),:),eye(2)*0.2);  
end
```

**4** View the data points:

```
figure  
plot(grnpts(:,1),grnpts(:,2),'go')  
hold on
```

```
plot(redpts(:,1),redpts(:,2),'ro')
hold off
```

- 5** Put the data into one matrix, and make a vector `grp` that labels the class of each point:

```
cdata = [grnpts;redpts];
grp = ones(200,1);
% green label 1, red label -1
grp(101:200) = -1;
```

- 6** Check the basic classification of all the data using the default parameters:

```
svmStruct = svmtrain(cdata,grp,'Kernel_Function','rbf',...
```

```
'showplot',true);
```

- 7 Write a function called `crossfun` to calculate the predicted classification `yfit` from a test vector `xtest`, when the SVM is trained on a sample `xtrain` that has classification `ytrain`. Since you want to find the best parameters `rbf_sigma` and `boxconstraint`, include those in the function.

```
function yfit = ...
    crossfun(xtrain,ytrain,xtest,rbf_sigma,boxconstraint)

% Train the model on xtrain, ytrain,
% and get predictions of class of xtest
svmStruct = svmtrain(xtrain,ytrain,'Kernel_Function','rbf',...
```

```
'rbf_sigma',rbf_sigma,'boxconstraint',boxconstraint);
yfit = svmclassify(svmStruct,xtest);
```

- 8** Set up a partition for cross validation. This step causes the cross validation to be fixed. Without this step, the cross validation is random, so a minimization procedure can find a spurious local minimum.

```
c = cvpartition(200,'kfold',10);
```

- 9** Set up a function that takes an input  $z=[\text{rbf\_sigma},\text{boxconstraint}]$ , and returns the cross-validation value of  $\exp(z)$ . The reason to take  $\exp(z)$  is twofold:

- `rbf_sigma` and `boxconstraint` must be positive.
- You should look at points spaced approximately exponentially apart.

This function handle computes the cross validation at parameters  $\exp([\text{rbf\_sigma},\text{boxconstraint}])$ :

```
minfn = @(z)crossval('mcr',cdata,grp,'Predfun', ...
    @(xtrain,ytrain,xtest)crossfun(xtrain,ytrain,...
    xtest,exp(z(1)),exp(z(2))),'partition',c);
```

- 10** Search for the best parameters  $[\text{rbf\_sigma},\text{boxconstraint}]$  with `fminsearch`, setting looser tolerances than the defaults.

---

**Tip** If you have a Global Optimization Toolbox license, use `patternsearch` for faster, more reliable minimization. Give bounds on the components of  $z$  to keep the optimization in a sensible region, such as  $[-5,5]$ , and give a relatively loose `TolMesh` tolerance.

---

```
opts = optimset('TolX',5e-4,'TolFun',5e-4);
[searchmin fval] = fminsearch(minfn,randn(2,1),opts)
```

```
searchmin =
    0.9758
   -0.1569
```

```
fval =  
    0.3350
```

The best parameters [rbf\_sigma;boxconstraint] in this run are:

```
z = exp(searchmin)  
z =  
    2.6534  
    0.8548
```

- 11** Since the result of `fminsearch` can be a local minimum, not a global minimum, try again with a different starting point to check that your result is meaningful:

```
[searchmin fval] = fminsearch(minfn,randn(2,1),opts)
```

```
searchmin =  
    0.2778  
    0.6395
```

```
fval =  
    0.3100
```

The best parameters [rbf\_sigma;boxconstraint] in this run are:

```
z = exp(searchmin)  
z =  
    1.3202  
    1.8956
```

- 12** Try another search:

```
[searchmin fval] = fminsearch(minfn,randn(2,1),opts)
```

```
searchmin =  
   -0.0749  
    0.6085
```

```
fval =  
    0.2850
```

The third search obtains the lowest function value. The final parameters are:

```
z = exp(searchmin)
z =
    0.9278
    1.8376
```

The default parameters [1,1] are close to optimal for this data and partition.

**13** Use the z parameters to train a new SVM classifier:

```
svmStruct = svmtrain(cdata,grp,'Kernel_Function','rbf',...
    'rbf_sigma',z(1),'boxconstraint',z(2),'showplot',true);
```

**14** Generate and classify some new data points:

```

grnobj = gmdistribution(grnpop,.2*eye(2));
redobj = gmdistribution(redpop,.2*eye(2));

newData = random(grnobj,10);
newData = [newData;random(redobj,10)];
grpData = ones(20,1);
grpData(11:20) = -1; % red = -1

v = svmclassify(svmStruct,newData,'showplot',true);

```

**15** See which new data points are correctly classified. Circle the correctly classified points in red, and the incorrectly classified points in black.

```
mydiff = (v == grpData); % classified correctly
hold on
for ii = mydiff % plot red circles around correct pts
    plot(newData(ii,1),newData(ii,2),'ro','MarkerSize',12)
end

for ii = not(mydiff) % plot black circles around incorrect pts
    plot(newData(ii,1),newData(ii,2),'ko','MarkerSize',12)
end
hold off
```

- “Markov Chains” on page 17-3
- “Hidden Markov Models (HMM)” on page 17-5

## Introduction to Markov Models

Markov processes are examples of stochastic processes—processes that generate random sequences of outcomes or *states* according to certain probabilities. Markov processes are distinguished by being memoryless—their next state depends only on their current state, not on the history that led them there. Models of Markov processes are used in a wide variety of applications, from daily stock prices to the positions of genes in a chromosome.

## Markov Chains

A Markov model is given visual representation with a *state diagram*, such as the one below.

### State Diagram for a Markov Model

The rectangles in the diagram represent the possible states of the process you are trying to model, and the arrows represent transitions between states. The label on each arrow represents the probability of that transition. At each step of the process, the model may generate an output, or *emission*, depending on which state it is in, and then make a transition to another state. An important characteristic of Markov models is that the next state depends only on the current state, and not on the history of transitions that lead to the current state.

For example, for a sequence of coin tosses the two states are heads and tails. The most recent coin toss determines the current state of the model and each subsequent toss determines the transition to the next state. If the coin is fair, the transition probabilities are all  $1/2$ . The emission might simply be the current state. In more complicated models, random processes at each state will generate emissions. You could, for example, roll a die to determine the emission at any step.

*Markov chains* are mathematical descriptions of Markov models with a discrete set of states. Markov chains are characterized by:

- A set of states  $\{1, 2, \dots, M\}$
- An  $M$ -by- $M$  *transition matrix*  $T$  whose  $i,j$  entry is the probability of a transition from state  $i$  to state  $j$ . The sum of the entries in each row of  $T$  must be 1, because this is the sum of the probabilities of making a transition from a given state to each of the other states.
- A set of possible outputs, or *emissions*,  $\{s_1, s_2, \dots, s_N\}$ . By default, the set of emissions is  $\{1, 2, \dots, N\}$ , where  $N$  is the number of possible emissions, but you can choose a different set of numbers or symbols.
- An  $M$ -by- $N$  *emission matrix*  $E$  whose  $i,k$  entry gives the probability of emitting symbol  $s_k$  given that the model is in state  $i$ .

Markov chains begin in an *initial state*  $i_0$  at step 0. The chain then transitions to state  $i_1$  with probability  $T_{1i_1}$ , and emits an output  $s_{k_1}$  with probability  $E_{i_1k_1}$ . Consequently, the probability of observing the sequence of states  $i_1i_2\dots i_r$  and the sequence of emissions  $s_{k_1}s_{k_2}\dots s_{k_r}$  in the first  $r$  steps, is

$$T_{1i_1} E_{i_1k_1} T_{i_1i_2} E_{i_2k_2} \dots T_{i_{r-1}i_r} E_{i_rk_r}$$

## Hidden Markov Models (HMM)

In this section...
“Introduction to Hidden Markov Models (HMM)” on page 17-5
“Analyzing Hidden Markov Models” on page 17-7

### Introduction to Hidden Markov Models (HMM)

A *hidden Markov model* (HMM) is one in which you observe a sequence of emissions, but do not know the sequence of states the model went through to generate the emissions. Analyses of hidden Markov models seek to recover the sequence of states from the observed data.

As an example, consider a Markov model with two states and six possible emissions. The model uses:

- A red die, having six sides, labeled 1 through 6.
- A green die, having twelve sides, five of which are labeled 2 through 6, while the remaining seven sides are labeled 1.
- A weighted red coin, for which the probability of heads is .9 and the probability of tails is .1.
- A weighted green coin, for which the probability of heads is .95 and the probability of tails is .05.

The model creates a sequence of numbers from the set {1, 2, 3, 4, 5, 6} with the following rules:

- Begin by rolling the red die and writing down the number that comes up, which is the emission.
- Toss the red coin and do one of the following:
  - If the result is heads, roll the red die and write down the result.
  - If the result is tails, roll the green die and write down the result.
- At each subsequent step, you flip the coin that has the same color as the die you rolled in the previous step. If the coin comes up heads, roll the same die as in the previous step. If the coin comes up tails, switch to the other die.

The state diagram for this model has two states, red and green, as shown in the following figure.

You determine the emission from a state by rolling the die with the same color as the state. You determine the transition to the next state by flipping the coin with the same color as the state.

The transition matrix is:

$$T = \begin{bmatrix} 0.9 & 0.1 \\ 0.05 & 0.95 \end{bmatrix}$$

The emissions matrix is:

$$E = \begin{bmatrix} \frac{1}{6} & \frac{1}{6} & \frac{1}{6} & \frac{1}{6} & \frac{1}{6} & \frac{1}{6} \\ \frac{7}{12} & \frac{1}{12} & \frac{1}{12} & \frac{1}{12} & \frac{1}{12} & \frac{1}{12} \end{bmatrix}$$

The model is not hidden because you know the sequence of states from the colors of the coins and dice. Suppose, however, that someone else is generating

the emissions without showing you the dice or the coins. All you see is the sequence of emissions. If you start seeing more 1s than other numbers, you might suspect that the model is in the green state, but you cannot be sure because you cannot see the color of the die being rolled.

Hidden Markov models raise the following questions:

- Given a sequence of emissions, what is the most likely state path?
- Given a sequence of emissions, how can you estimate transition and emission probabilities of the model?
- What is the *forward probability* that the model generates a given sequence?
- What is the *posterior probability* that the model is in a particular state at any point in the sequence?

## Analyzing Hidden Markov Models

- “Generating a Test Sequence” on page 17-8
- “Estimating the State Sequence” on page 17-8
- “Estimating Transition and Emission Matrices” on page 17-9
- “Estimating Posterior State Probabilities” on page 17-11
- “Changing the Initial State Distribution” on page 17-12

Statistics Toolbox functions related to hidden Markov models are:

- `hmmgenerate` — Generates a sequence of states and emissions from a Markov model
- `hmmestimate` — Calculates maximum likelihood estimates of transition and emission probabilities from a sequence of emissions and a known sequence of states
- `hmmtrain` — Calculates maximum likelihood estimates of transition and emission probabilities from a sequence of emissions
- `hmmviterbi` — Calculates the most probable state path for a hidden Markov model

- `hmmdecode` — Calculates the posterior state probabilities of a sequence of emissions

This section shows how to use these functions to analyze hidden Markov models.

### Generating a Test Sequence

The following commands create the transition and emission matrices for the model described in the “Introduction to Hidden Markov Models (HMM)” on page 17-5:

```
TRANS = [.9 .1; .05 .95];  
  
EMIS = [1/6, 1/6, 1/6, 1/6, 1/6, 1/6;...  
7/12, 1/12, 1/12, 1/12, 1/12, 1/12];
```

To generate a random sequence of states and emissions from the model, use `hmmgenerate`:

```
[seq,states] = hmmgenerate(1000,TRANS,EMIS);
```

The output `seq` is the sequence of emissions and the output `states` is the sequence of states.

`hmmgenerate` begins in state 1 at step 0, makes the transition to state  $i_1$  at step 1, and returns  $i_1$  as the first entry in `states`. To change the initial state, see “Changing the Initial State Distribution” on page 17-12.

### Estimating the State Sequence

Given the transition and emission matrices `TRANS` and `EMIS`, the function `hmmviterbi` uses the Viterbi algorithm to compute the most likely sequence of states the model would go through to generate a given sequence `seq` of emissions:

```
likelystates = hmmviterbi(seq, TRANS, EMIS);
```

`likelystates` is a sequence the same length as `seq`.

To test the accuracy of `hmmviterbi`, compute the percentage of the actual sequence `states` that agrees with the sequence `likelystates`.

```
sum(states==likelystates)/1000
ans =
    0.8200
```

In this case, the most likely sequence of states agrees with the random sequence 82% of the time.

## Estimating Transition and Emission Matrices

- “Using `hmmestimate`” on page 17-9
- “Using `hmmtrain`” on page 17-10

The functions `hmmestimate` and `hmmtrain` estimate the transition and emission matrices `TRANS` and `EMIS` given a sequence `seq` of emissions.

**Using `hmmestimate`.** The function `hmmestimate` requires that you know the sequence of states `states` that the model went through to generate `seq`.

The following takes the emission and state sequences and returns estimates of the transition and emission matrices:

```
[TRANS_EST, EMIS_EST] = hmmestimate(seq, states)

TRANS_EST =
    0.8989    0.1011
    0.0585    0.9415

EMIS_EST =
    0.1721    0.1721    0.1749    0.1612    0.1803    0.1393
    0.5836    0.0741    0.0804    0.0789    0.0726    0.1104
```

You can compare the outputs with the original transition and emission matrices, `TRANS` and `EMIS`:

```
TRANS
TRANS =
    0.9000    0.1000
    0.0500    0.9500

EMIS
```

```
EMIS =
0.1667    0.1667    0.1667    0.1667    0.1667    0.1667
0.5833    0.0833    0.0833    0.0833    0.0833    0.0833
```

**Using hmmtrain.** If you do not know the sequence of states `states`, but you have initial guesses for `TRANS` and `EMIS`, you can still estimate `TRANS` and `EMIS` using `hmmtrain`.

Suppose you have the following initial guesses for `TRANS` and `EMIS`.

```
TRANS_GUESS = [.85 .15; .1 .9];
EMIS_GUESS = [.17 .16 .17 .16 .17 .17;.6 .08 .08 .08 .08 08];
```

You estimate `TRANS` and `EMIS` as follows:

```
[TRANS_EST2, EMIS_EST2] = hmmtrain(seq, TRANS_GUESS, EMIS_GUESS)
```

```
TRANS_EST2 =
0.2286    0.7714
0.0032    0.9968
```

```
EMIS_EST2 =
0.1436    0.2348    0.1837    0.1963    0.2350    0.0066
0.4355    0.1089    0.1144    0.1082    0.1109    0.1220
```

`hmmtrain` uses an iterative algorithm that alters the matrices `TRANS_GUESS` and `EMIS_GUESS` so that at each step the adjusted matrices are more likely to generate the observed sequence, `seq`. The algorithm halts when the matrices in two successive iterations are within a small tolerance of each other.

If the algorithm fails to reach this tolerance within a maximum number of iterations, whose default value is 100, the algorithm halts. In this case, `hmmtrain` returns the last values of `TRANS_EST` and `EMIS_EST` and issues a warning that the tolerance was not reached.

If the algorithm fails to reach the desired tolerance, increase the default value of the maximum number of iterations with the command:

```
hmmtrain(seq,TRANS_GUESS,EMIS_GUESS,'maxiterations',maxiter)
```

where `maxiter` is the maximum number of steps the algorithm executes.

Change the default value of the tolerance with the command:

```
hmmtrain(seq, TRANS_GUESS, EMIS_GUESS, 'tolerance', tol)
```

where `tol` is the desired value of the tolerance. Increasing the value of `tol` makes the algorithm halt sooner, but the results are less accurate.

Two factors reduce the reliability of the output matrices of `hmmtrain`:

- The algorithm converges to a local maximum that does not represent the true transition and emission matrices. If you suspect this, use different initial guesses for the matrices `TRANS_EST` and `EMIS_EST`.
- The sequence `seq` may be too short to properly train the matrices. If you suspect this, use a longer sequence for `seq`.

### Estimating Posterior State Probabilities

The posterior state probabilities of an emission sequence `seq` are the conditional probabilities that the model is in a particular state when it generates a symbol in `seq`, given that `seq` is emitted. You compute the posterior state probabilities with `hmmdecode`:

```
PSTATES = hmmdecode(seq, TRANS, EMIS)
```

The output `PSTATES` is an  $M$ -by- $L$  matrix, where  $M$  is the number of states and  $L$  is the length of `seq`. `PSTATES(i, j)` is the conditional probability that the model is in state  $i$  when it generates the  $j$ th symbol of `seq`, given that `seq` is emitted.

`hmmdecode` begins with the model in state 1 at step 0, prior to the first emission. `PSTATES(i, 1)` is the probability that the model is in state  $i$  at the following step 1. To change the initial state, see “Changing the Initial State Distribution” on page 17-12.

To return the logarithm of the probability of the sequence `seq`, use the second output argument of `hmmdecode`:

```
[PSTATES, logpseq] = hmmdecode(seq, TRANS, EMIS)
```

The probability of a sequence tends to 0 as the length of the sequence increases, and the probability of a sufficiently long sequence becomes less

than the smallest positive number your computer can represent. `hmmdecode` returns the logarithm of the probability to avoid this problem.

### Changing the Initial State Distribution

By default, Statistics Toolbox hidden Markov model functions begin in state 1. In other words, the distribution of initial states has all of its probability mass concentrated at state 1. To assign a different distribution of probabilities,  $p = [p_1, p_2, \dots, p_M]$ , to the  $M$  initial states, do the following:

- 1 Create an  $M+1$ -by- $M+1$  augmented transition matrix,  $\hat{T}$  of the following form:

$$\hat{T} = \begin{bmatrix} 0 & p \\ 0 & T \end{bmatrix}$$

where  $T$  is the true transition matrix. The first column of  $\hat{T}$  contains  $M+1$  zeros.  $p$  must sum to 1.

- 2 Create an  $M+1$ -by- $N$  augmented emission matrix,  $\hat{E}$ , that has the following form:

$$\hat{E} = \begin{bmatrix} 0 \\ E \end{bmatrix}$$

If the transition and emission matrices are `TRANS` and `EMIS`, respectively, you create the augmented matrices with the following commands:

```
TRANS_HAT = [0 p; zeros(size(TRANS,1),1) TRANS];
```

```
EMIS_HAT = [zeros(1,size(EMIS,2)); EMIS];
```

# Design of Experiments

---

- “Design of Experiments” on page 18-2
- “Full Factorial Designs” on page 18-3
- “Fractional Factorial Designs” on page 18-5
- “Response Surface Designs” on page 18-9
- “D-Optimal Designs” on page 18-15

## Design of Experiments

Passive data collection leads to a number of problems in statistical modeling. Observed changes in a response variable may be correlated with, but not caused by, observed changes in individual *factors* (process variables). Simultaneous changes in multiple factors may produce interactions that are difficult to separate into individual effects. Observations may be dependent, while a model of the data considers them to be independent.

Designed experiments address these problems. In a designed experiment, the data-producing process is actively manipulated to improve the quality of information and to eliminate redundant data. A common goal of all experimental designs is to collect data as parsimoniously as possible while providing sufficient information to accurately estimate model parameters.

For example, a simple model of a response  $y$  in an experiment with two controlled factors  $x_1$  and  $x_2$  might look like this:

$$y = \beta_0 + \beta_1x_1 + \beta_2x_2 + \beta_3x_1x_2 + \varepsilon$$

Here  $\varepsilon$  includes both experimental error and the effects of any uncontrolled factors in the experiment. The terms  $\beta_1x_1$  and  $\beta_2x_2$  are *main effects* and the term  $\beta_3x_1x_2$  is a two-way *interaction effect*. A designed experiment would systematically manipulate  $x_1$  and  $x_2$  while measuring  $y$ , with the objective of accurately estimating  $\beta_0$ ,  $\beta_1$ ,  $\beta_2$ , and  $\beta_3$ .

## Full Factorial Designs

### In this section...

“Multilevel Designs” on page 18-3

“Two-Level Designs” on page 18-4

### Multilevel Designs

To systematically vary experimental factors, assign each factor a discrete set of *levels*. Full factorial designs measure response variables using every *treatment* (combination of the factor levels). A full factorial design for  $n$  factors with  $N_1, \dots, N_n$  levels requires  $N_1 \times \dots \times N_n$  experimental runs—one for each treatment. While advantageous for separating individual effects, full factorial designs can make large demands on data collection.

As an example, suppose a machine shop has three machines and four operators. If the same operator always uses the same machine, it is impossible to determine if a machine or an operator is the cause of variation in production. By allowing every operator to use every machine, effects are separated. A full factorial list of treatments is generated by the Statistics Toolbox function `fullfact`:

```
dFF = fullfact([3,4])
```

```
dFF =
```

```

1     1
2     1
3     1
1     2
2     2
3     2
1     3
2     3
3     3
1     4
2     4
3     4
```

Each of the  $3 \times 4 = 12$  rows of `dFF` represent one machine/operator combination.

## Two-Level Designs

Many experiments can be conducted with two-level factors, using *two-level designs*. For example, suppose the machine shop in the previous example always keeps the same operator on the same machine, but wants to measure production effects that depend on the composition of the day and night shifts. The Statistics Toolbox function `ff2n` generates a full factorial list of treatments:

```
dFF2 = ff2n(4)
dFF2 =
     0     0     0     0
     0     0     0     1
     0     0     1     0
     0     0     1     1
     0     1     0     0
     0     1     0     1
     0     1     1     0
     0     1     1     1
     1     0     0     0
     1     0     0     1
     1     0     1     0
     1     0     1     1
     1     1     0     0
     1     1     0     1
     1     1     1     0
     1     1     1     1
```

Each of the  $2^4 = 16$  rows of `dFF2` represent one schedule of operators for the day (0) and night (1) shifts.

## Fractional Factorial Designs

### In this section...

“Introduction to Fractional Factorial Designs” on page 18-5

“Plackett-Burman Designs” on page 18-5

“General Fractional Designs” on page 18-6

### Introduction to Fractional Factorial Designs

Two-level designs are sufficient for evaluating many production processes. Factor levels of  $\pm 1$  can indicate categorical factors, normalized factor extremes, or simply “up” and “down” from current factor settings. Experimenters evaluating process *changes* are interested primarily in the factor directions that lead to process improvement.

For experiments with many factors, two-level full factorial designs can lead to large amounts of data. For example, a two-level full factorial design with 10 factors requires  $2^{10} = 1024$  runs. Often, however, individual factors or their interactions have no distinguishable effects on a response. This is especially true of higher order interactions. As a result, a well-designed experiment can use fewer runs for estimating model parameters.

Fractional factorial designs use a fraction of the runs required by full factorial designs. A subset of experimental treatments is selected based on an evaluation (or assumption) of which factors and interactions have the most significant effects. Once this selection is made, the experimental design must separate these effects. In particular, significant effects should not be *confounded*, that is, the measurement of one should not depend on the measurement of another.

### Plackett-Burman Designs

*Plackett-Burman designs* are used when only main effects are considered significant. Two-level Plackett-Burman designs require a number of experimental runs that are a multiple of 4 rather than a power of 2. The MATLAB function `hadamard` generates these designs:

`dPB = hadamard(8)`

```

dPB =
  1  1  1  1  1  1  1  1
  1 -1  1 -1  1 -1  1 -1
  1  1 -1 -1  1  1 -1 -1
  1 -1 -1  1  1 -1 -1  1
  1  1  1  1 -1 -1 -1 -1
  1 -1  1 -1 -1  1 -1  1
  1  1 -1 -1 -1 -1  1  1
  1 -1 -1  1 -1  1  1 -1

```

Binary factor levels are indicated by  $\pm 1$ . The design is for eight runs (the rows of dPB) manipulating seven two-level factors (the last seven columns of dPB). The number of runs is a fraction  $8/2^7 = 0.0625$  of the runs required by a full factorial design. Economy is achieved at the expense of confounding main effects with any two-way interactions.

## General Fractional Designs

At the cost of a larger fractional design, you can specify which interactions you wish to consider significant. A design of *resolution R* is one in which no  $n$ -factor interaction is confounded with any other effect containing less than  $R - n$  factors. Thus, a resolution III design does not confound main effects with one another but may confound them with two-way interactions (as in “Plackett-Burman Designs” on page 18-5), while a resolution IV design does not confound either main effects or two-way interactions but may confound two-way interactions with each other.

Specify general fractional factorial designs using a full factorial design for a selected subset of *basic factors* and *generators* for the remaining factors. Generators are products of the basic factors, giving the levels for the remaining factors. Use the Statistics Toolbox function `fracfact` to generate these designs:

```

dfF = fracfact('a b c d bcd acd')
dfF =
  -1  -1  -1  -1  -1  -1
  -1  -1  -1  1  1  1
  -1  -1  1  -1  1  1
  -1  -1  1  1  -1  -1
  -1  1  -1  -1  1  -1

```

-1	1	-1	1	-1	1
-1	1	1	-1	-1	1
-1	1	1	1	1	-1
1	-1	-1	-1	-1	1
1	-1	-1	1	1	-1
1	-1	1	-1	1	-1
1	-1	1	1	-1	1
1	1	-1	-1	1	1
1	1	-1	1	-1	-1
1	1	1	-1	-1	-1
1	1	1	1	1	1

This is a six-factor design in which four two-level basic factors (a, b, c, and d in the first four columns of `dfF`) are measured in every combination of levels, while the two remaining factors (in the last three columns of `dfF`) are measured only at levels defined by the generators `bcd` and `acd`, respectively. Levels in the generated columns are products of corresponding levels in the columns that make up the generator.

The challenge of creating a fractional factorial design is to choose basic factors and generators so that the design achieves a specified resolution in a specified number of runs. Use the Statistics Toolbox function `fracfactgen` to find appropriate generators:

```
generators = fracfactgen('a b c d e f',4,4)
generators =
    'a'
    'b'
    'c'
    'd'
    'bcd'
    'acd'
```

These are generators for a six-factor design with factors a through f, using  $2^4 = 16$  runs to achieve resolution IV. The `fracfactgen` function uses an efficient search algorithm to find generators that meet the requirements.

An optional output from `fracfact` displays the *confounding pattern* of the design:

```
[dfF,confounding] = fracfact(generators);
```

```

confounding
confounding =
  'Term'      'Generator'  'Confounding'
  'X1'        'a'          'X1'
  'X2'        'b'          'X2'
  'X3'        'c'          'X3'
  'X4'        'd'          'X4'
  'X5'        'bcd'       'X5'
  'X6'        'acd'       'X6'
  'X1*X2'     'ab'        'X1*X2 + X5*X6'
  'X1*X3'     'ac'        'X1*X3 + X4*X6'
  'X1*X4'     'ad'        'X1*X4 + X3*X6'
  'X1*X5'     'abcd'      'X1*X5 + X2*X6'
  'X1*X6'     'cd'        'X1*X6 + X2*X5 + X3*X4'
  'X2*X3'     'bc'        'X2*X3 + X4*X5'
  'X2*X4'     'bd'        'X2*X4 + X3*X5'
  'X2*X5'     'cd'        'X1*X6 + X2*X5 + X3*X4'
  'X2*X6'     'abcd'      'X1*X5 + X2*X6'
  'X3*X4'     'cd'        'X1*X6 + X2*X5 + X3*X4'
  'X3*X5'     'bd'        'X2*X4 + X3*X5'
  'X3*X6'     'ad'        'X1*X4 + X3*X6'
  'X4*X5'     'bc'        'X2*X3 + X4*X5'
  'X4*X6'     'ac'        'X1*X3 + X4*X6'
  'X5*X6'     'ab'        'X1*X2 + X5*X6'
  
```

The confounding pattern shows that main effects are effectively separated by the design, but two-way interactions are confounded with various other two-way interactions.

## Response Surface Designs

“Introduction to Response Surface Designs” on page 18-9
“Central Composite Designs” on page 18-9
“Box-Behnken Designs” on page 18-13

### Introduction to Response Surface Designs

Quadratic response surfaces are simple models that provide a maximum or minimum without making additional assumptions about the form of the response. Quadratic models can be calibrated using full factorial designs with three or more levels for each factor, but these designs generally require more runs than necessary to accurately estimate model parameters. This section discusses designs for calibrating quadratic models that are much more efficient, using three or five levels for each factor, but not using all combinations of levels.

### Central Composite Designs

Central composite designs (CCDs), also known as Box-Wilson designs, are appropriate for calibrating full quadratic models. There are three types of CCDs—circumscribed, inscribed, and faced—pictured below:

Each design consists of a factorial design (the corners of a cube) together with *center* and *star* points that allow for estimation of second-order effects. For a full quadratic model with  $n$  factors, CCDs have enough design points to estimate the  $(n+2)(n+1)/2$  coefficients in a full quadratic model with  $n$  factors.

The type of CCD used (the position of the factorial and star points) is determined by the number of factors and by the desired properties of the design. The following table summarizes some important properties. A design is *rotatable* if the prediction variance depends only on the distance of the design point from the center of the design.

<b>Design</b>	<b>Rotatable</b>	<b>Factor Levels</b>	<b>Uses Points Outside <math>\pm 1</math></b>	<b>Accuracy of Estimates</b>
Circumscribed (CCC)	Yes	5	Yes	Good over entire design space
Inscribed (CCI)	Yes	5	No	Good over central subset of design space
Faced (CCF)	No	3	No	Fair over entire design space; poor for pure quadratic coefficients

Generate CCDs with the Statistics Toolbox function `ccdesign`:

```
dCC = ccdesign(3,'type','circumscribed')
```

```
dCC =
-1.0000 -1.0000 -1.0000
-1.0000 -1.0000  1.0000
-1.0000  1.0000 -1.0000
-1.0000  1.0000  1.0000
 1.0000 -1.0000 -1.0000
 1.0000 -1.0000  1.0000
 1.0000  1.0000 -1.0000
 1.0000  1.0000  1.0000
-1.6818         0         0
 1.6818         0         0
         0 -1.6818         0
         0  1.6818         0
         0         0 -1.6818
         0         0  1.6818
         0         0         0
         0         0         0
         0         0         0
         0         0         0
         0         0         0
         0         0         0
         0         0         0
         0         0         0
         0         0         0
         0         0         0
         0         0         0
```

0            0            0

The repeated center point runs allow for a more uniform estimate of the prediction variance over the entire design space.

## Box-Behnken Designs

Like the designs described in “Central Composite Designs” on page 18-9, Box-Behnken designs are used to calibrate full quadratic models. Box-Behnken designs are rotatable and, for a small number of factors (four or less), require fewer runs than CCDs. By avoiding the corners of the design space, they allow experimenters to work around extreme factor combinations. Like an inscribed CCD, however, extremes are then poorly estimated.

The geometry of a Box-Behnken design is pictured in the following figure.

Design points are at the midpoints of edges of the design space and at the center, and do not contain an embedded factorial design.

Generate Box-Behnken designs with the Statistics Toolbox function `bbdesign`:

```
dBB = bbdesign(3)
```

```
dBB =  
    -1    -1     0  
    -1     1     0  
     1    -1     0  
     1     1     0  
    -1     0    -1  
    -1     0     1  
     1     0    -1  
     1     0     1  
     0    -1    -1  
     0    -1     1  
     0     1    -1  
     0     1     1  
     0     0     0  
     0     0     0  
     0     0     0
```

Again, the repeated center point runs allow for a more uniform estimate of the prediction variance over the entire design space.

## D-Optimal Designs

### Introduction to D-Optimal Designs

Traditional experimental designs (“Full Factorial Designs” on page 18-3, “Fractional Factorial Designs” on page 18-5, and “Response Surface Designs” on page 18-9) are appropriate for calibrating linear models in experimental settings where factors are relatively unconstrained in the region of interest. In some cases, however, models are necessarily nonlinear. In other cases, certain treatments (combinations of factor levels) may be expensive or infeasible to measure. *D-optimal designs* are model-specific designs that address these limitations of traditional designs.

A D-optimal design is generated by an iterative search algorithm and seeks to minimize the covariance of the parameter estimates for a specified model. This is equivalent to maximizing the determinant  $D = |X^T X|$ , where  $X$  is the design matrix of model terms (the columns) evaluated at specific treatments in the design space (the rows). Unlike traditional designs, D-optimal designs do not require orthogonal design matrices, and as a result, parameter estimates may be correlated. Parameter estimates may also be locally, but not globally, D-optimal.

There are several Statistics Toolbox functions for generating D-optimal designs:

Function	Description
candexch	Uses a row-exchange algorithm to generate a D-optimal design with a specified number of runs for a specified model and a specified candidate set. This is the second component of the algorithm used by rowexch.
candgen	Generates a candidate set for a specified model. This is the first component of the algorithm used by rowexch.
cordexch	Uses a coordinate-exchange algorithm to generate a D-optimal design with a specified number of runs for a specified model.
daugment	Uses a coordinate-exchange algorithm to augment an existing D-optimal design with additional runs to estimate additional model terms.
dcovary	Uses a coordinate-exchange algorithm to generate a D-optimal design with fixed covariate factors.
rowexch	Uses a row-exchange algorithm to generate a D-optimal design with a specified number of runs for a specified model. The algorithm calls candgen and then candexch. (Call candexch separately to specify a candidate set.)

The following sections explain how to use these functions to generate D-optimal designs.

---

**Note** The Statistics Toolbox function `rsmdemo` generates simulated data for experimental settings specified by either the user or by a D-optimal design generated by `cordexch`. It uses the `rstool` interface to visualize response surface models fit to the data, and it uses the `nlintool` interface to visualize a nonlinear model fit to the data.

---

## Generate D-Optimal Designs

Two Statistics Toolbox algorithms generate D-optimal designs:

- The `cordexch` function uses a coordinate-exchange algorithm
- The `rowexch` function uses a row-exchange algorithm

Both `cordexch` and `rowexch` use iterative search algorithms. They operate by incrementally changing an initial design matrix  $X$  to increase  $D = |X^T X|$  at each step. In both algorithms, there is randomness built into the selection of the initial design and into the choice of the incremental changes. As a result, both algorithms may return locally, but not globally, D-optimal designs. Run each algorithm multiple times and select the best result for your final design. Both functions have a 'tries' parameter that automates this repetition and comparison.

At each step, the row-exchange algorithm exchanges an entire row of  $X$  with a row from a design matrix  $C$  evaluated at a *candidate set* of feasible treatments. The `rowexch` function automatically generates a  $C$  appropriate for a specified model, operating in two steps by calling the `candgen` and `candexch` functions in sequence. Provide your own  $C$  by calling `candexch` directly. In either case, if  $C$  is large, its static presence in memory can affect computation.

The coordinate-exchange algorithm, by contrast, does not use a candidate set. (Or rather, the candidate set is the entire design space.) At each step, the coordinate-exchange algorithm exchanges a single element of  $X$  with a new element evaluated at a neighboring point in design space. The absence of a candidate set reduces demands on memory, but the smaller scale of the search means that the coordinate-exchange algorithm is more likely to become trapped in a local minimum than the row-exchange algorithm.

For example, suppose you want a design to estimate the parameters in the following three-factor, seven-term interaction model:

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_{12} x_1 x_2 + \beta_{13} x_1 x_3 + \beta_{23} x_2 x_3 + \varepsilon$$

Use `cordexch` to generate a D-optimal design with seven runs:

```
nfactors = 3;
nruns = 7;
[dCE,X] = cordexch(nfactors,nruns,'interaction','tries',10)
dCE =
    -1     1     1
    -1    -1    -1
     1     1     1
    -1     1    -1
     1    -1     1
```

$$X = \begin{matrix} & 1 & -1 & -1 \\ & -1 & -1 & 1 \\ & 1 & -1 & 1 & 1 & -1 & -1 & 1 \\ & 1 & -1 & -1 & -1 & 1 & 1 & 1 \\ & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ & 1 & -1 & 1 & -1 & -1 & 1 & -1 \\ & 1 & 1 & -1 & 1 & -1 & 1 & -1 \\ & 1 & 1 & -1 & -1 & -1 & -1 & 1 \\ & 1 & -1 & -1 & 1 & 1 & -1 & -1 \end{matrix}$$

Columns of the design matrix  $X$  are the model terms evaluated at each row of the design  $dCE$ . The terms appear in order from left to right:

- 1** Constant term
- 2** Linear terms (1, 2, 3)
- 3** Interaction terms (12, 13, 23)

Use  $X$  in a linear regression model fit to response data measured at the design points in  $dCE$ .

Use `rowexch` in a similar fashion to generate an equivalent design:

```
[dRE,X] = rowexch(nfactors,nruns,'interaction','tries',10)
dRE =
```

$$\begin{matrix} -1 & -1 & 1 \\ 1 & -1 & 1 \\ 1 & -1 & -1 \\ 1 & 1 & 1 \\ -1 & -1 & -1 \\ -1 & 1 & -1 \\ -1 & 1 & 1 \end{matrix}$$

$$X = \begin{matrix} 1 & -1 & -1 & 1 & 1 & -1 & -1 \\ 1 & 1 & -1 & 1 & -1 & 1 & -1 \\ 1 & 1 & -1 & -1 & -1 & -1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & -1 & -1 & -1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 & -1 & 1 & -1 \end{matrix}$$

```
1 -1 1 1 -1 -1 1
```

## Augment D-Optimal Designs

In practice, you may want to add runs to a completed experiment to learn more about a process and estimate additional model coefficients. The `daugment` function uses a coordinate-exchange algorithm to augment an existing D-optimal design.

For example, the following eight-run design is adequate for estimating main effects in a four-factor model:

```
dCEmain = cordexch(4,8)
dCEmain =
    1 -1 -1 1
   -1 -1 1 1
   -1 1 -1 1
    1 1 1 -1
    1 1 1 1
   -1 1 -1 -1
    1 -1 -1 -1
   -1 -1 1 -1
```

To estimate the six interaction terms in the model, augment the design with eight additional runs:

```
dCEinteraction = daugment(dCEmain,8,'interaction')
dCEinteraction =
    1 -1 -1 1
   -1 -1 1 1
   -1 1 -1 1
    1 1 1 -1
    1 1 1 1
   -1 1 -1 -1
    1 -1 -1 -1
   -1 -1 1 -1
   -1 1 1 1
   -1 -1 -1 -1
    1 -1 1 -1
    1 1 -1 1
   -1 1 1 -1
```

```

1      1      -1     -1
1      -1     1      1
1      1      1      -1

```

The augmented design is full factorial, with the original eight runs in the first eight rows.

The 'start' parameter of the `candexch` function provides the same functionality as `daugment`, but uses a row exchange algorithm rather than a coordinate-exchange algorithm.

## Specify Fixed Covariate Factors

In many experimental settings, certain factors and their covariates are constrained to a fixed set of levels or combinations of levels. These cannot be varied when searching for an optimal design. The `dcovary` function allows you to specify fixed covariate factors in the coordinate exchange algorithm.

For example, suppose you want a design to estimate the parameters in a three-factor linear additive model, with eight runs that necessarily occur at different times. If the process experiences temporal linear drift, you may want to include the run time as a variable in the model. Produce the design as follows:

```

time = linspace(-1,1,8)';
[dCV,X] = dcovary(3,time,'linear')
dCV =
-1.0000    1.0000    1.0000   -1.0000
 1.0000   -1.0000   -1.0000   -0.7143
-1.0000   -1.0000   -1.0000   -0.4286
 1.0000   -1.0000    1.0000   -0.1429
 1.0000    1.0000   -1.0000    0.1429
-1.0000    1.0000   -1.0000    0.4286
 1.0000    1.0000    1.0000    0.7143
-1.0000   -1.0000    1.0000    1.0000
X =
 1.0000   -1.0000    1.0000    1.0000   -1.0000
 1.0000    1.0000   -1.0000   -1.0000   -0.7143
 1.0000   -1.0000   -1.0000   -1.0000   -0.4286
 1.0000    1.0000   -1.0000    1.0000   -0.1429

```

1.0000	1.0000	1.0000	-1.0000	0.1429
1.0000	-1.0000	1.0000	-1.0000	0.4286
1.0000	1.0000	1.0000	1.0000	0.7143
1.0000	-1.0000	-1.0000	1.0000	1.0000

The column vector `time` is a fixed factor, normalized to values between  $\pm 1$ . The number of rows in the fixed factor specifies the number of runs in the design. The resulting design `dCV` gives factor settings for the three controlled model factors at each time.

## Specify Categorical Factors

Categorical factors take values in a discrete set of levels. Both `cordexch` and `rowexch` have a `'categorical'` parameter that allows you to specify the indices of categorical factors and a `'levels'` parameter that allows you to specify a number of levels for each factor.

For example, the following eight-run design is for a linear additive model with five factors in which the final factor is categorical with three levels:

```
dCEcat = cordexch(5,8,'linear','categorical',5,'levels',3)
dCEcat =
    -1    -1     1     1     2
    -1    -1    -1    -1     3
     1     1     1     1     3
     1     1    -1    -1     2
     1    -1    -1     1     3
    -1     1    -1     1     1
    -1     1     1    -1     3
     1    -1     1    -1     1
```

## Specify Candidate Sets

The row-exchange algorithm exchanges rows of an initial design matrix  $X$  with rows from a design matrix  $C$  evaluated at a candidate set of feasible treatments. The `rowexch` function automatically generates a  $C$  appropriate for a specified model, operating in two steps by calling the `candgen` and `candexch` functions in sequence. Provide your own  $C$  by calling `candexch` directly.

For example, the following uses `rowexch` to generate a five-run design for a two-factor pure quadratic model using a candidate set that is produced internally:

```
dRE1 = rowexch(2,5,'purequadratic','tries',10)
dRE1 =
    -1     1
     0     0
     1    -1
     1     0
     1     1
```

The same thing can be done using `candgen` and `candexch` in sequence:

```
[dC,C] = candgen(2,'purequadratic') % Candidate set, C
dC =
    -1    -1
     0    -1
     1    -1
    -1     0
     0     0
     1     0
    -1     1
     0     1
     1     1
C =
     1    -1    -1     1     1
     1     0    -1     0     1
     1     1    -1     1     1
     1    -1     0     1     0
     1     0     0     0     0
     1     1     0     1     0
     1    -1     1     1     1
     1     0     1     0     1
     1     1     1     1     1
treatments = candexch(C,5,'tries',10) % D-opt subset
treatments =
     2
     1
     7
     3
```

```

      4
dRE2 = dC(treatments,:) % Display design
dRE2 =
      0     -1
     -1     -1
     -1      1
      1     -1
     -1      0

```

You can replace `C` in this example with a design matrix evaluated at your own candidate set. For example, suppose your experiment is constrained so that the two factors cannot have extreme settings simultaneously. The following produces a restricted candidate set:

```

constraint = sum(abs(dC),2) < 2; % Feasible treatments
my_dC = dC(constraint,:)
my_dC =
      0     -1
     -1      0
      0      0
      1      0
      0      1

```

Use the `x2fx` function to convert the candidate set to a design matrix:

```

my_C = x2fx(my_dC, 'purequadratic')
my_C =
      1      0     -1      0      1
      1     -1      0      1      0
      1      0      0      0      0
      1      1      0      1      0
      1      0      1      0      1

```

Find the required design in the same manner:

```

my_treatments = candexch(my_C,5,'tries',10) % D-opt subset
my_treatments =
      2
      4
      5
      1

```

```
      3
my_dRE = my_dC(my_treatments,:) % Display design
my_dRE =
    -1     0
     1     0
     0     1
     0    -1
     0     0
```

# Statistical Process Control

---

- “Introduction to Statistical Process Control” on page 19-2
- “Control Charts” on page 19-3
- “Capability Studies” on page 19-7

## **Introduction to Statistical Process Control**

Statistical process control (SPC) refers to a number of different methods for monitoring and assessing the quality of manufactured goods. Combined with methods from the design of experiments, SPC is used in programs that define, measure, analyze, improve, and control development and production processes. These programs are often implemented using “Design for Six Sigma” methodologies.

## Control Charts

A control chart displays measurements of process samples over time. The measurements are plotted together with user-defined *specification limits* and process-defined *control limits*. The process can then be compared with its specifications—to see if it is *in control* or *out of control*.

The chart is just a monitoring tool. Control activity might occur if the chart indicates an undesirable, systematic change in the process. The control chart is used to discover the variation, so that the process can be adjusted to reduce it.

Control charts are created with the `controlchart` function. Any of the following chart types may be specified:

- Xbar or mean
- Standard deviation
- Range
- Exponentially weighted moving average
- Individual observation
- Moving range of individual observations
- Moving average of individual observations
- Proportion defective
- Number of defectives
- Defects per unit
- Count of defects

Control rules are specified with the `controlrules` function. The following example illustrates how to use Western Electric rules to mark out of control measurements on an Xbar chart.

First load the sample data.

```
load parts;
```

Construct the Xbar control chart using the Western Electric 2 rule (2 of 3 points at least 2 standard errors above the center line) to mark the out of control measurements.

```
st = controlchart(runout,'rules','we2');
```

For a better understanding of the Western Electric 2 rule, calculate and plot the 2 standard errors line on the chart.

```
x = st.mean;  
cl = st.mu;
```

```

se = st.sigma./sqrt(st.n);
hold on
plot(c1+2*se, 'm')

```

Identify the measurements that violate the control rule.

```

R = controlrules('we2',x,c1,se);
I = find(R)

```

I =

21  
23  
24  
25  
26  
27

## Capability Studies

Before going into production, many manufacturers run a *capability study* to determine if their process will run within specifications enough of the time. *Capability indices* produced by such a study are used to estimate expected percentages of defective parts.

Capability studies are conducted with the `capability` function. The following capability indices are produced:

- `mu` — Sample mean
- `sigma` — Sample standard deviation
- `P` — Estimated probability of being within the lower (L) and upper (U) specification limits
- `P1` — Estimated probability of being below L
- `Pu` — Estimated probability of being above U
- `Cp` —  $(U-L)/(6*\text{sigma})$
- `Cp1` —  $(\text{mu}-L)/(3.*\text{sigma})$
- `Cpu` —  $(U-\text{mu})/(3.*\text{sigma})$
- `Cpk` —  $\min(\text{Cp1}, \text{Cpu})$

As an example, simulate a sample from a process with a mean of 3 and a standard deviation of 0.005:

```
data = normrnd(3,0.005,100,1);
```

Compute capability indices if the process has an upper specification limit of 3.01 and a lower specification limit of 2.99:

```
S = capability(data,[2.99 3.01])
```

```
S =
```

```
    mu: 3.0006
   sigma: 0.0047
      P: 0.9669
     P1: 0.0116
     Pu: 0.0215
      Cp: 0.7156
```

Cp1: 0.7567  
Cpu: 0.6744  
Cpk: 0.6744

Visualize the specification and process widths:

```
capaplot(data,[2.99 3.01]);  
grid on
```

# Parallel Statistics

---

- “Quick Start Parallel Computing for Statistics Toolbox” on page 20-2
- “Concepts of Parallel Computing in Statistics Toolbox” on page 20-6
- “When to Run Statistical Functions in Parallel” on page 20-7
- “Working with parfor” on page 20-9
- “Reproducibility in Parallel Statistical Computations” on page 20-12
- “Examples of Parallel Statistical Functions” on page 20-18

## Quick Start Parallel Computing for Statistics Toolbox

---

**Note** To use parallel computing as described in this chapter, you must have a Parallel Computing Toolbox license.

---

In this section...
“What Is Parallel Statistics Functionality?” on page 20-2
“How To Compute in Parallel” on page 20-3
“Parallel Treebagger” on page 20-4

### What Is Parallel Statistics Functionality?

You can use any of the Statistics Toolbox functions with Parallel Computing Toolbox constructs such as `parfor` and `spmd`. However, some functions, such as those with interactive displays, can lose functionality in parallel. In particular, displays and interactive usage are not effective on workers (see “Vocabulary for Parallel Computation” on page 20-6).

Additionally, the following functions are enhanced to use parallel computing internally. These functions use `parfor` internally to parallelize calculations.

- `bootci`
- `bootstrp`
- `candexch`
- `cordexch`
- `crossval`
- `daugment`
- `dcovary`
- `jackknife`
- `kmeans`
- `lasso`

- `lassoglm`
- `nmmf`
- `plsregress`
- `rowexch`
- `sequentialfs`
- `TreeBagger`
- `TreeBagger.growTrees`

This chapter gives the simplest way to use these enhanced functions in parallel. For more advanced topics, including the issues of reproducibility and nested `parfor` loops, see the other sections in this chapter.

For information on parallel statistical computing at the command line, enter

```
help parallelstats
```

## How To Compute in Parallel

To have a function compute in parallel:

- 1 “Set Up a Parallel Environment” on page 20-3
- 2 “Set the UseParallel Option to true” on page 20-4
- 3 “Call the Function Using the Options Structure” on page 20-4

### Set Up a Parallel Environment

To run a statistical computation in parallel, first set up a parallel environment.

---

**Note** Setting up a parallel environment can take several seconds.

---

For a multicore machine, enter the following at the MATLAB command line:

```
parpool(n)
```

*n* is the number of workers you want to use.

### Set the UseParallel Option to true

Create an options structure with the `statset` function. To run in parallel, set the `UseParallel` option to true:

```
paroptions = statset('UseParallel',true);
```

### Call the Function Using the Options Structure

Call your function with syntax that uses the options structure. For example:

```
% Run crossval in parallel
cvMse = crossval('mse',x,y,'predfun',regf,'Options',paroptions);

% Run bootstrp in parallel
sts = bootstrp(100,@(x)[mean(x) std(x)],y,'Options',paroptions);

% Run TreeBagger in parallel
b = TreeBagger(50,meas,spec,'OOBPred','on','Options',paroptions);
```

For more complete examples of parallel statistical functions, see “Parallel Treebagger” on page 20-4 and “Examples of Parallel Statistical Functions” on page 20-18.

After you have finished computing in parallel, close the parallel environment:

```
delete mypool
```

---

**Tip** To save time, keep the pool open if you expect to compute in parallel again soon.

---

## Parallel Treebagger

To run the example “Workflow Example: Regression of Insurance Risk Rating for Car Imports with TreeBagger” on page 16-125 in parallel:

- 1 Set up the parallel environment to use two cores:

```
mypool = parpool(2)
Starting parpool using the 'local' profile ... connected to 2 workers.
```

```
mypool =
```

```
Pool with properties:
```

```
AttachedFiles: {0x1 cell}
NumWorkers: 2
Cluster: [1x1 parallel.cluster.Local]
SpmEnabled: 1
```

- 2** Set the options to use parallel processing:

```
paroptions = statset('UseParallel',true);
```

- 3** Load the problem data and separate it into input and response:

```
load imports-85;
Y = X(:,1);
X = X(:,2:end);
```

- 4** Estimate feature importance using leaf size 1 and 1000 trees in parallel. Time the function for comparison purposes:

```
tic
b = TreeBagger(1000,X,Y,'Method','r','OOBVarImp','on',...
'cat',16:25,'MinLeaf',1,'Options',paroptions);
toc
```

Elapsed time is 16.696336 seconds.

- 5** Perform the same computation in serial for timing comparison:

```
tic
b = TreeBagger(1000,X,Y,'Method','r','OOBVarImp','on',...
'cat',16:25,'MinLeaf',1); % No options gives serial
toc
```

Elapsed time is 21.747950 seconds.

Computing in parallel took about 75% of the time of computing serially.

## Concepts of Parallel Computing in Statistics Toolbox

### In this section...

“Subtleties in Parallel Computing” on page 20-6

“Vocabulary for Parallel Computation” on page 20-6

### Subtleties in Parallel Computing

There are two main subtleties in parallel computations:

- Nested parallel evaluations (see “No Nested `parfor` Loops” on page 20-10). Only the outermost `parfor` loop runs in parallel, the others run serially.
- Reproducible results when using random numbers (see “Reproducibility in Parallel Statistical Computations” on page 20-12). How can you get exactly the same results when repeatedly running a parallel computation that uses random numbers?

### Vocabulary for Parallel Computation

- *worker* — An independent MATLAB session that runs code distributed by the *client*.
- *client* — The MATLAB session with which you interact, and that distributes jobs to workers.
- `parfor` — A Parallel Computing Toolbox function that distributes independent code segments to workers (see “Working with `parfor`” on page 20-9).
- *random stream* — A pseudorandom number generator, and the sequence of values it generates. MATLAB implements random streams with the `RandStream` class.
- *reproducible computation* — A computation that can be exactly replicated, even in the presence of random numbers (see “Reproducibility in Parallel Statistical Computations” on page 20-12).

## When to Run Statistical Functions in Parallel

In this section...
“Why Run in Parallel?” on page 20-7
“Factors Affecting Speed” on page 20-7
“Factors Affecting Results” on page 20-8

### Why Run in Parallel?

The main reason to run statistical computations in parallel is to gain speed, meaning to reduce the execution time of your program or functions. “Factors Affecting Speed” on page 20-7 discusses the main items affecting the speed of programs or functions. “Factors Affecting Results” on page 20-8 discusses details that can cause a parallel run to give different results than a serial run.

### Factors Affecting Speed

Some factors that can affect the speed of execution of parallel processing are:

- Parallel environment setup. It takes time to run `parpool` to begin computing in parallel. If your computation is fast, the setup time can exceed any time saved by computing in parallel.
- Parallel overhead. There is overhead in communication and coordination when running in parallel. If function evaluations are fast, this overhead could be an appreciable part of the total computation time. Thus, solving a problem in parallel can be slower than solving the problem serially. For an example, see *Improving Optimization Performance with Parallel Computing* in *MATLAB Digest*, March 2009.
- No nested `parfor` loops. This is described in “Working with `parfor`” on page 20-9. `parfor` does not work in parallel when called from within another `parfor` loop. If you have programmed your custom functions to take advantage of parallel processing, the limitation of no nested `parfor` loops can cause a parallel function to run slower than expected.
- When executing serially, `parfor` loops run slightly slower than `for` loops.
- Passing parameters. Parameters are automatically passed to worker sessions during the execution of parallel computations. If there are many

parameters, or they take a large amount of memory, passing parameters can slow the execution of your computation.

- Contention for resources: network and computing. If the pool of workers has low bandwidth or high latency, parallel computation can be slow.

## **Factors Affecting Results**

Some factors can affect results when using parallel processing. There are several caveats related to `parfor` listed in “Limitations” in the Parallel Computing Toolbox documentation. Some important factors are:

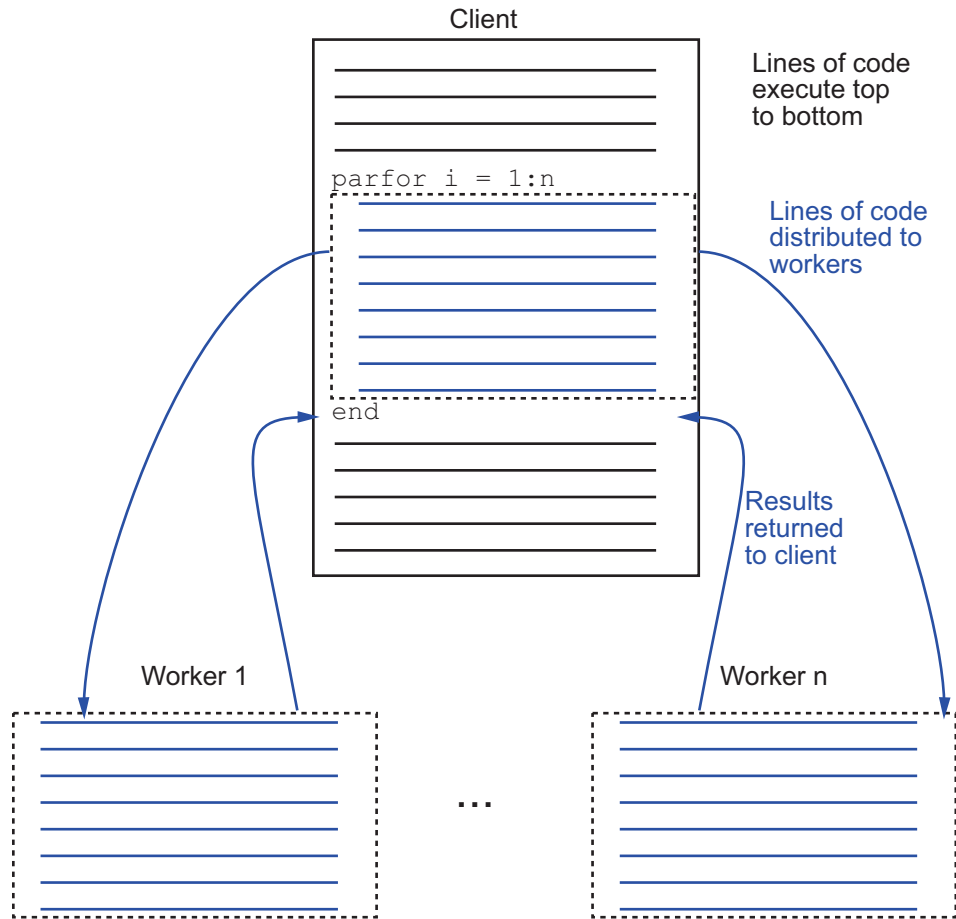

- Persistent or global variables. If any functions use persistent or global variables, these variables can take different values on different worker processors. Furthermore, they might not be cleared properly on the worker processors.
- Accessing external files. External files can be accessed unpredictably during a parallel computation. The order of computations is not guaranteed during parallel processing, so external files can be accessed in unpredictable order, leading to unpredictable results. Furthermore, if multiple processors try to read an external file simultaneously, the file can become locked, leading to a read error, and halting function execution.
- Noncomputational functions, such as `input`, `plot`, and `keyboard`, can behave badly when used in your custom functions. When called in a `parfor` loop, these functions are executed on worker machines. This can cause a worker to become nonresponsive, since it is waiting for input.
- `parfor` does not allow `break` or `return` statements.
- The random numbers you use can affect the results of your computations. See “Reproducibility in Parallel Statistical Computations” on page 20-12.

## Working with parfor

In this section...
“How Statistical Functions Use parfor” on page 20-9
“Characteristics of parfor” on page 20-10

### How Statistical Functions Use parfor

parfor is a Parallel Computing Toolbox function similar to a for loop. Parallel statistical functions call parfor internally. parfor distributes computations to worker processors.

## Characteristics of parfor

More caveats related to `parfor` appear in “Limitations” in the Parallel Computing Toolbox documentation.

### No Nested parfor Loops

`parfor` does not work in parallel when called from within another `parfor` loop, or from an `spmd` block. Parallelization occurs only at the outermost level.

Suppose, for example, you want to apply `jackknife` to your function `userfcn`, which calls `parfor`, and you want to call `jackknife` in a loop. The following figure shows three cases:

- 1 The outermost loop is `parfor`. Only that loop runs in parallel.
- 2 The outermost `parfor` loop is in `jackknife`. Only `jackknife` runs in parallel.
- 3 The outermost `parfor` loop is in `userfcn`. `userfcn` uses `parfor` in parallel.

**Bold** indicates the function that runs in parallel

① 

```
...
parfor i=1:10
    x(i)=jackknife(@userfcn,...)
...
end
```

← Only the outermost `parfor` loop runs in parallel

② 

```
...
for i=1:10
    x(i)=jackknife(@userfcn,...)
...
end
```

← If `UseParallel` = 'always' `jackknife` runs in parallel

③ 

```
...
for i=1:10
    x(i)=jackknife(@userfcn,...)
...
end
```

← If `UseParallel` = 'never' `userfcn` can use `parfor` in parallel

### When `parfor` Runs in Parallel

## Reproducibility in Parallel Statistical Computations

### In this section...

“Issues and Considerations in Reproducing Parallel Computations” on page 20-12

“Running Reproducible Parallel Computations” on page 20-13

“Parallel Statistical Computation Using Random Numbers” on page 20-14

### Issues and Considerations in Reproducing Parallel Computations

A *reproducible* computation is one that gives the same results every time it runs. Reproducibility is important for:

- Debugging — To correct an anomalous result, you need to reproduce the result.
- Confidence — When you can reproduce results, you can investigate and understand them.
- Modifying existing code — When you change existing code, you want to ensure that you do not break anything.

Generally, you do not need to ensure reproducibility for your computation. Often, when you want reproducibility, the simplest technique is to run in serial instead of in parallel. In serial computation you can simply call the `rng` function as follows:

```
s = rng % Obtain the current state of the random stream
% run the statistical function
rng(s) % Reset the stream to the previous state
% run the statistical function again, obtain identical results
```

This section addresses the case when your function uses random numbers, and you want reproducible results in parallel. This section also addresses the case when you want the same results in parallel as in serial.

## Running Reproducible Parallel Computations

To run a Statistics Toolbox function reproducibly:

- 1 Set the `UseSubstreams` option to `true`.
- 2 Set the `Streams` option to a type that supports substreams: `'mlfg6331_64'` or `'mrg32k3a'`. For information on these streams, see “Choosing a Random Number Generator” in the MATLAB Mathematics documentation.
- 3 To compute in parallel, set the `UseParallel` option to `true`.
- 4 Call the function with the options structure.
- 5 To reproduce the computation, reset the stream, then call the function again.

To understand why this technique gives reproducibility, see “How Substreams Enable Reproducible Parallel Computations” on page 20-14.

For example, to use the `'mlfg6331_64'` stream for reproducible computation:

- 1 Create an appropriate options structure:

```
s = RandStream('mlfg6331_64');
options = statset('UseParallel',true, ...
    'Streams',s,'UseSubstreams',true);
```
- 2 Run your parallel computation. For instructions, see “Quick Start Parallel Computing for Statistics Toolbox” on page 20-2.
- 3 Reset the random stream:

```
reset(s);
```
- 4 Rerun your parallel computation. You obtain identical results.

For an example of a parallel computation run this reproducible way, see “Reproducible Parallel Bootstrap” on page 20-24.

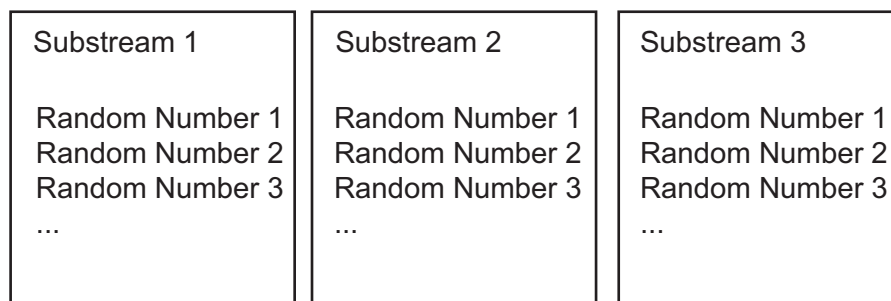

## Parallel Statistical Computation Using Random Numbers

### What Are Substreams?

A *substream* is a portion of a random stream that `RandStream` can access quickly. There is a number  $M$  such that for any positive integer  $k$ , `RandStream` can go the  $kM$ th pseudorandom number in the stream. From that point, `RandStream` can generate the subsequent entries in the stream. Currently, `RandStream` has  $M = 2^{72}$ , about  $5e21$ , or more.

The entries in different substreams have good statistical properties, similar to the properties of entries in a single stream: independence, and lack of  $k$ -way correlation at various lags. The substreams are so long that you can view the substreams as being independent streams, as in the following picture.

Two `RandStream` stream types support substreams: `'mlfg6331_64'` and `'mrg32k3a'`.

### How Substreams Enable Reproducible Parallel Computations

When MATLAB performs computations in parallel with `parfor`, each worker receives loop iterations in an unpredictable order. Therefore, you cannot

predict which worker gets which iteration, so cannot determine the random numbers associated with each iteration.

Substreams allow MATLAB to tie each iteration to a particular sequence of random numbers. `parfor` gives each iteration an index. The iteration uses the index as the substream number. Since the random numbers are associated with the iterations, not with the workers, the entire computation is reproducible.

To obtain reproducible results, simply reset the stream, and all the substreams generate identical random numbers when called again. This method succeeds when all the workers use the same stream, and the stream supports substreams. This concludes the discussion of how the procedure in “Running Reproducible Parallel Computations” on page 20-13 gives reproducible parallel results.

### **Random Numbers on the Client or Workers**

A few functions generate random numbers on the client before distributing them to parallel workers. The workers do not use random numbers, so operate purely deterministically. For these functions, you can run a parallel computation reproducibly using any random stream type.

The functions that operate this way include:

- `crossval`
- `plsregress`
- `sequentialfs`

To obtain identical results, reset the random stream on the client, or the random stream you pass to the client. For example:

```
s = rng % Obtain the current state of the random stream
% run the statistical function
rng(s) % Reset the stream to the previous state
% run the statistical function again, obtain identical results
```

While this method enables you to run reproducibly in parallel, the results can differ from a serial computation. The reason for the difference is `parfor` loops run in reverse order from `for` loops. Therefore, a serial computation can

generate random numbers in a different order than a parallel computation. For unequivocal reproducibility, use the technique in “Running Reproducible Parallel Computations” on page 20-13.

### Distributing Streams Explicitly

For testing or comparison using particular random number algorithms, you must set the random number generators. How do you set these generators in parallel, or initialize streams on each worker in a particular way? Or you might want to run a computation using a different sequence of random numbers than any other you have run. How can you ensure the sequence you use is statistically independent?

Parallel Statistics Toolbox functions allow you to set random streams on each worker explicitly. For information on *creating* multiple streams, enter `help RandStream/create` at the command line. To create four independent streams using the 'mrg32k3a' generator:

```
s = RandStream.create('mrg32k3a','NumStreams',4,...  
    'CellOutput',true);
```

Pass these streams to a statistical function using the `Streams` option. For example:

```
parpool(4) % if you have at least 4 cores  
s = RandStream.create('mrg32k3a','NumStreams',4,...  
    'CellOutput',true); % create 4 independent streams  
paroptions = statset('UseParallel',true,...  
    'Streams',s); % set the 4 different streams  
x = [randn(700,1); 4 + 2*randn(300,1)];  
latt = -4:0.01:12;  
myfun = @(X) ksdensity(X,latt);  
pdfestimate = myfun(x);  
B = bootstrp(200,myfun,x,'Options',paroptions);
```

This method of distributing streams gives each worker a different stream for the computation. However, it does not allow for a reproducible computation, because the workers perform the 200 bootstraps in an unpredictable order. If you want to perform a reproducible computation, use substreams as described in “Running Reproducible Parallel Computations” on page 20-13.

If you set the `UseSubstreams` option to `true`, then set the `Streams` option to a single random stream of the type that supports substreams (`'m1fg6331_64'` or `'mrg32k3a'`). This setting gives reproducible computations.

## Examples of Parallel Statistical Functions

### In this section...

“Parallel Jackknife” on page 20-18

“Parallel Cross Validation” on page 20-19

“Parallel Bootstrap” on page 20-21

### Parallel Jackknife

This example is from the jackknife function reference page, but runs in parallel.

```
mypool=parpool()
Starting parpool using the 'local' profile ... connected to 2 workers.
```

```
mypool =
```

```
Pool with properties:
```

```
AttachedFiles: {0x1 cell}
  NumWorkers: 2
  IdleTimeout: 30
  Cluster: [1x1 parallel.cluster.Local]
  RequestQueue: [1x1 parallel.RequestQueue]
  SpmdEnabled: 1
```

```
opts = statset('UseParallel',true);
sigma = 5;
rng('default')
y = normrnd(0,sigma,100,1);
m = jackknife(@var, y,1,'Options',opts);
n = length(y);
bias = -sigma^2 / n % known bias formula
jbias = (n - 1)*(mean(m)-var(y,1)) % jackknife bias estimate
```

```
bias =
```

```
-0.2500
```

```
jbias =
    -0.3378
```

This simple example is not a good candidate for parallel computation:

```
% How long to compute in serial?
tic;m = jackknife(@var,y,1);toc
Elapsed time is 0.022771 seconds.
```

```
% How long to compute in parallel?
tic;m = jackknife(@var,y,1,'Options',opts);toc
Elapsed time is 0.299066 seconds.
```

jackknife does not use random numbers, so gives the same results every time, whether run in parallel or serial.

## Parallel Cross Validation

- “Simple Parallel Cross Validation” on page 20-19
- “Reproducible Parallel Cross Validation” on page 20-20

### Simple Parallel Cross Validation

This example is the same as the first in the `crossval` function reference page, but runs in parallel.

```
mypool = parpool()
Starting parpool using the 'local' profile ... connected to 2 workers.

mypool =
```

Pool with properties:

```
AttachedFiles: {0x1 cell}
NumWorkers: 2
IdleTimeout: 30
Cluster: [1x1 parallel.cluster.Local]
```

```
RequestQueue: [1x1 parallel.RequestQueue]
SpmEnabled: 1opts = statset('UseParallel',true);

load('fisheriris');
y = meas(:,1);
X = [ones(size(y,1),1),meas(:,2:4)];
regf=@(XTRAIN,ytrain,XTEST)(XTEST*regress(ytrain,XTRAIN));

cvMse = crossval('mse',X,y,'Predfun',regf,'Options',opts)

cvMse =

    0.1028
```

This simple example is not a good candidate for parallel computation:

```
% How long to compute in serial?
tic;cvMse = crossval('mse',X,y,'Predfun',regf);toc
Elapsed time is 0.073438 seconds.

% How long to compute in parallel?
tic;cvMse = crossval('mse',X,y,'Predfun',regf,...
    'Options',opts);toc
Elapsed time is 0.289585 seconds.
```

### Reproducible Parallel Cross Validation

To run `crossval` in parallel in a reproducible fashion, set the options and reset the random stream appropriately (see “Running Reproducible Parallel Computations” on page 20-13).

```
mypool = parpool()
```

Starting `parpool` using the 'local' profile ... connected to 2 workers.

```
mypool =
```

```
Pool with properties:
```

```
AttachedFiles: {0x1 cell}
```

```

        NumWorkers: 2
        IdleTimeout: 30
            Cluster: [1x1 parallel.cluster.Local]
        RequestQueue: [1x1 parallel.RequestQueue]
        SpmdEnabled: 1

s = RandStream('mlfg6331_64');
opts = statset('UseParallel',true,...
    'Streams',s,'UseSubstreams',true);

load('fisheriris');
y = meas(:,1);
X = [ones(size(y,1),1),meas(:,2:4)];
regf=@(XTRAIN,ytrain,XTEST)(XTEST*regress(ytrain,XTRAIN));

cvMse = crossval('mse',X,y,'Predfun',regf,'Options',opts)

cvMse =

    0.1020

Reset the stream:

reset(s)
cvMse = crossval('mse',X,y,'Predfun',regf,'Options',opts)

cvMse =

    0.1020

```

## Parallel Bootstrap

- “Bootstrap in Serial and Parallel” on page 20-21
- “Reproducible Parallel Bootstrap” on page 20-24

### Bootstrap in Serial and Parallel

Here is an example timing a bootstrap in parallel versus in serial. The example generates data from a mixture of two Gaussians, constructs a

nonparametric estimate of the resulting data, and uses a bootstrap to get a sense of the sampling variability.

**1** Generate the data:

```
% Generate a random sample of size 1000,  
% from a mixture of two Gaussian distributions  
x = [randn(700,1); 4 + 2*randn(300,1)];
```

**2** Construct a nonparametric estimate of the density from the data:

```
latt = -4:0.01:12;  
myfun = @(X) ksdensity(X,latt);  
pdfestimate = myfun(x);
```

**3** Bootstrap the estimate to get a sense of its sampling variability. Run the bootstrap in serial for timing comparison.

```
tic;B = bootstrp(200,myfun,x);toc
```

Elapsed time is 10.878654 seconds.

**4** Run the bootstrap in parallel for timing comparison:

```
mypool = parpool()  
Starting parpool using the 'local' profile ... connected to 2 workers.
```

```
mypool =
```

```
Pool with properties:
```

```
AttachedFiles: {0x1 cell}  
NumWorkers: 2  
IdleTimeout: 30  
Cluster: [1x1 parallel.cluster.Local]  
RequestQueue: [1x1 parallel.RequestQueue]  
SpmEnabled: 1
```

```
opt = statset('UseParallel',true);  
tic;B = bootstrp(200,myfun,x,'Options',opt);toc
```

Elapsed time is 6.304077 seconds.

Computing in parallel is nearly twice as fast as computing in serial for this example.

Overlay the `ksdensity` density estimate with the 200 bootstrapped estimates obtained in the parallel bootstrap. You can get a sense of how to assess the accuracy of the density estimate from this plot.

```
hold on
for i=1:size(B,1),
    plot(latt,B(i,:), 'c: ')
end
plot(latt,pdfestimate);
xlabel('x');ylabel('Density estimate')
```

### Reproducible Parallel Bootstrap

To run the example in parallel in a reproducible fashion, set the options appropriately (see “Running Reproducible Parallel Computations” on page 20-13). First set up the problem and parallel environment as in “Bootstrap in Serial and Parallel” on page 20-21. Then set the options to use substreams along with a stream that supports substreams.

```
s = RandStream('mlfg6331_64'); % has substreams
opts = statset('UseParallel',true,...
    'Streams',s,'UseSubstreams',true);
B2 = bootstrp(200,myfun,x,'Options',opts);
```

To rerun the bootstrap and get the same result:

```
reset(s) % set the stream to initial state  
B3 = bootstrp(200,myfun,x,'Options',opts);  
isequal(B2,B3) % check if same results
```

```
ans =  
    1
```

# Functions — Alphabetical List

---

# addedvarplot

---

**Purpose** Added variable plot

**Syntax** `addedvarplot(X,y,num,inmodel)`  
`addedvarplot(X,y,num,inmodel,stats)`

**Description** `addedvarplot(X,y,num,inmodel)` displays an added variable plot using the predictive terms in  $X$ , the response values in  $y$ , the added term in column `num` of  $X$ , and the model with current terms specified by `inmodel`.  $X$  is an  $n$ -by- $p$  matrix of  $n$  observations of  $p$  predictive terms.  $y$  is vector of  $n$  response values. `num` is a scalar index specifying the column of  $X$  with the term to be added. `inmodel` is a logical vector of  $p$  elements specifying the columns of  $X$  in the current model. By default, all elements of `inmodel` are `false`.

---

**Note** `addedvarplot` automatically includes a constant term in all models. Do not enter a column of 1s directly into  $X$ .

---

`addedvarplot(X,y,num,inmodel,stats)` uses the `stats` output from the `stepwisefit` function to improve the efficiency of repeated calls to `addedvarplot`. Otherwise, this syntax is equivalent to the previous syntax.

Added variable plots are used to determine the unique effect of adding a new term to a multilinear model. The plot shows the relationship between the part of the response unexplained by terms already in the model and the part of the new term unexplained by terms already in the model. The “unexplained” parts are measured by the residuals of the respective regressions. A scatter of the residuals from the two regressions forms the added variable plot.

In addition to the scatter of residuals, the plot produced by `addedvarplot` shows 95% confidence intervals on predictions from the fitted line. The fitted line has intercept zero because, under typical linear model assumptions, both of the plotted variables have mean zero. The slope of the fitted line is the coefficient that the new term would have if it were added to the model with terms `inmodel`.

Added variable plots are sometimes known as partial regression leverage plots.

## Examples

Load the data in `hald.mat`, which contains observations of the heat of reaction of various cement mixtures:

```
load hald
whos
```

Name	Size	Bytes	Class	Attributes
Description	22x58	2552	char	
hald	13x5	520	double	
heat	13x1	104	double	
ingredients	13x4	416	double	

Create an added variable plot to investigate the addition of the third column of `ingredients` to a model consisting of the first two columns:

```
inmodel = [true true false false];
addedvarplot(ingredients,heat,3,inmodel)
```

# addedvarplot

The wide scatter and the low slope of the fitted line are evidence against the statistical significance of adding the third column to the model.

## See Also

`stepwisefit` | `stepwise`

**Purpose** Add levels to categorical array

**Syntax** `B = addlevels(A,newlevels)`

**Description** `B = addlevels(A,newlevels)` adds new levels to the categorical array `A`. `newlevels` is a cell array of strings or a 2-D character matrix that specifies the levels to add. `addlevels` adds the new levels at the end of the list of possible categorical levels in `A`, but does not modify the value of any element. `B` does not contain elements at the new levels.

## Examples **Example 1**

Add levels for additional species in Fisher's iris data:

```
load fisheriris
species = nominal(species,...
                  {'Species1','Species2','Species3'},...
                  {'setosa','versicolor','virginica'});
species = addlevels(species,{'Species4','Species5'});
getlabels(species)
ans =
    'Species1' 'Species2' 'Species3' 'Species4' 'Species5'
```

## Example 2

- 1 Load patient data from the CSV file `hospital.dat` and store the information in a dataset array with observation names given by the first column in the data (patient identification):

```
patients = dataset('file','hospital.dat',...
                  'delimiter',';',...
                  'ReadObsNames',true);
```

- 2 Make the `{0,1}`-valued variable `smoke` nominal, and change the labels to 'No' and 'Yes':

```
patients.smoke = nominal(patients.smoke,{'No','Yes'});
```

## categorical.addlevels

---

- 3** Add new levels to `smoke` as placeholders for more detailed histories of smokers:

```
patients.smoke = addlevels(patients.smoke,...
                           {'0-5 Years', '5-10 Years', 'LongTerm'});
```

- 4** Assuming the nonsmokers have never smoked, relabel the 'No' level:

```
patients.smoke = setlabels(patients.smoke, 'Never', 'No');
```

- 5** Drop the undifferentiated 'Yes' level from `smoke`:

```
patients.smoke = droplevels(patients.smoke, 'Yes');
```

Warning: `OLDLEVELS` contains categorical levels that were present in `A`, caused some array elements to have undefined levels.

Note that smokers now have an undefined level.

- 6** Set each smoker to one of the new levels, by observation name:

```
patients.smoke('YPL-320') = '5-10 Years';
```

### See Also

**Purpose**

Add listener for event

**Syntax**

```
e1 = addlistener(hsource, 'eventname', callback)
e1 = addlistener(hsource, property, 'eventname', callback)
```

**Description**

`e1 = addlistener(hsource, 'eventname', callback)` creates a listener for the event named `eventname`, the source of which is handle object `hsource`. If `hsource` is an array of source handles, the listener responds to the named event on any handle in the array. `callback` is a function handle that is invoked when the event is triggered.

`e1 = addlistener(hsource, property, 'eventname', callback)` adds a listener for a property event. `eventname` must be one of the strings `'PreGet'`, `'PostGet'`, `'PreSet'`, and `'PostSet'`. `property` must be either a property name or cell array of property names, or a `meta.property` or array of `meta.property`. The properties must belong to the class of `hsource`. If `hsource` is scalar, `property` can include dynamic properties.

For all forms, `addlistener` returns an `event.listener`. To remove a listener, delete the object returned by `addlistener`. For example, `delete(e1)` calls the handle class `delete` method to remove the listener and delete it from the workspace.

# GeneralizedLinearModel.addTerms

---

<b>Purpose</b>	Add terms to generalized linear model
<b>Syntax</b>	<code>mdl1 = addTerms(mdl, terms)</code>
<b>Description</b>	<code>mdl1 = addTerms(mdl, terms)</code> returns a generalized linear model the same as <code>mdl</code> but with additional terms.
<b>Input Arguments</b>	<p><b>mdl</b></p> <p>Generalized linear model, as constructed by <code>fitglm</code> or <code>stepwiseglm</code>.</p> <p><b>terms</b></p> <p>Terms to add to the <code>mdl</code> regression model. Specify as either a:</p> <ul style="list-style-type: none"><li>• Text string representing one or more terms to add. For details, see “Wilkinson Notation” on page 21-8.</li><li>• Row or rows in the terms matrix (see <code>modelspec</code> in <code>fitglm</code>). For example, if there are three variables A, B, and C:  <code>[0 0 0]</code> represents a constant term or intercept <code>[0 1 0]</code> represents B; equivalently, <math>A^0 * B^1 * C^0</math> <code>[1 0 1]</code> represents <math>A * C</math> <code>[2 0 0]</code> represents <math>A^2</math> <code>[0 1 2]</code> represents <math>B * (C^2)</math></li></ul>
<b>Output Arguments</b>	<p><b>mdl1</b></p> <p>Generalized linear model, the same as <code>mdl</code> but with additional terms given in <code>terms</code>. You can set <code>mdl1</code> equal to <code>mdl</code> to overwrite <code>mdl</code>.</p>
<b>Definitions</b>	<p><b>Wilkinson Notation</b></p> <p>Wilkinson notation describes the factors present in models. The notation relates to factors present in models, not to the multipliers (coefficients) of those factors.</p>

Wilkinson Notation	Factors in Standard Notation
1	Constant (intercept) term
$A^k$ , where $k$ is a positive integer	$A, A^2, \dots, A^k$
$A + B$	$A, B$
$A*B$	$A, B, A*B$
$A:B$	$A*B$ only
$-B$	Do not include $B$
$A*B + C$	$A, B, C, A*B$
$A + B + C + A:B$	$A, B, C, A*B$
$A*B*C - A:B:C$	$A, B, C, A*B, A*C, B*C$
$A*(B + C)$	$A, B, C, A*B, A*C$

Statistics Toolbox notation always includes a constant term unless you explicitly remove the term using `-1`.

For details, see Wilkinson and Rogers [1].

## Examples

### Add a term to a generalized linear regression model

Create a model using just one predictor, then add a second.

Generate artificial data for the model, Poisson random numbers with two underlying predictors  $X(1)$  and  $X(2)$ .

```
rng('default') % for reproducibility
rndvars = randn(100,2);
X = [2+rndvars(:,1),rndvars(:,2)];
mu = exp(1 + X*[1;2]);
y = poissrnd(mu);
```

Create a generalized linear regression model of Poisson data. Use just the first predictor in the model.

```
mdl = fitglm(X,y,...
```

# GeneralizedLinearModel.addTerms

---

```
'y ~ x1', 'distr', 'poisson')

mdl =

Generalized Linear regression model:
  log(y) ~ 1 + x1
  Distribution = Poisson

Estimated Coefficients:
              Estimate    SE          tStat    pValue
(Intercept)  2.7784      0.014043   197.85    0
x1           1.1732      0.0033653  348.6    0

100 observations, 98 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 1.25e+05, p-value = 0

Add the second predictor to the model.

mdl1 = addTerms(mdl, 'x2')

mdl1 =

Generalized Linear regression model:
  log(y) ~ 1 + x1 + x2
  Distribution = Poisson

Estimated Coefficients:
              Estimate    SE          tStat    pValue
(Intercept)  1.0405      0.022122   47.034    0
x1           0.9968      0.003362   296.49    0
x2           1.987       0.0063433  313.24    0

100 observations, 97 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 2.95e+05, p-value = 0
```

## Concepts

- “Generalized Linear Models” on page 10-12

# LinearModel.addTerms

---

<b>Purpose</b>	Add terms to linear regression model
<b>Syntax</b>	<code>mdl1 = addTerms(mdl, terms)</code>
<b>Description</b>	<code>mdl1 = addTerms(mdl, terms)</code> returns a linear model the same as <code>mdl</code> but with additional terms.
<b>Input Arguments</b>	<p><b>mdl</b></p> <p>Linear model, as constructed by <code>fitlm</code> or <code>stepwiselm</code>.</p> <p><b>terms</b></p> <p>Terms to add to the <code>mdl</code> regression model. Specify as either a:</p> <ul style="list-style-type: none"><li>• Text string representing one or more terms to add. For details, see “Wilkinson Notation” on page 21-12.</li><li>• Row or rows in the terms matrix (see <code>modelspec</code> in <code>fitlm</code>). For example, if there are three variables A, B, and C:  <code>[0 0 0]</code> represents a constant term or intercept <code>[0 1 0]</code> represents B; equivalently, <math>A^0 * B^1 * C^0</math> <code>[1 0 1]</code> represents <math>A * C</math> <code>[2 0 0]</code> represents <math>A^2</math> <code>[0 1 2]</code> represents <math>B * (C^2)</math></li></ul>
<b>Output Arguments</b>	<p><b>mdl1</b></p> <p>Linear model, the same as <code>mdl</code> but with additional terms given in terms. You can set <code>mdl1</code> equal to <code>mdl</code> to overwrite <code>mdl</code>.</p>
<b>Definitions</b>	<p><b>Wilkinson Notation</b></p> <p>Wilkinson notation describes the factors present in models. The notation relates to factors present in models, not to the multipliers (coefficients) of those factors.</p>

Wilkinson Notation	Factors in Standard Notation
1	Constant (intercept) term
$A^k$ , where $k$ is a positive integer	$A, A^2, \dots, A^k$
$A + B$	$A, B$
$A*B$	$A, B, A*B$
$A:B$	$A*B$ only
$-B$	Do not include $B$
$A*B + C$	$A, B, C, A*B$
$A + B + C + A:B$	$A, B, C, A*B$
$A*B*C - A:B:C$	$A, B, C, A*B, A*C, B*C$
$A*(B + C)$	$A, B, C, A*B, A*C$

Statistics Toolbox notation always includes a constant term unless you explicitly remove the term using `-1`.

For details, see Wilkinson and Rogers [1].

## Examples

### Add a Term to a Model

Create a model of the `carsmall` data without any interactions, then add an interaction term.

Load the `carsmall` data and make a model of the MPG as a function of weight and model year.

```
load carsmall
ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);
mdl = fitlm(ds,'MPG ~ Year + Weight^2');
```

Add an interaction term to `mdl`.

```
terms = 'Year*Weight';
mdl1 = addTerms(mdl,terms)
```

# LinearModel.addTerms

---

```
mdl1 =
```

```
Linear regression model:
```

```
MPG ~ 1 + Weight*Year + Weight^2
```

```
Estimated Coefficients:
```

	Estimate	SE	tStat	pValue
(Intercept)	48.045	6.779	7.0874	3.3967e-10
Weight	-0.012624	0.0041455	-3.0454	0.0030751
Year_76	2.7768	3.0538	0.90931	0.3657
Year_82	16.416	4.9802	3.2962	0.0014196
Weight:Year_76	-0.00020693	0.00092403	-0.22394	0.82333
Weight:Year_82	-0.0032574	0.0018919	-1.7217	0.088673
Weight^2	1.0121e-06	6.12e-07	1.6538	0.10177

```
Number of observations: 94, Error degrees of freedom: 87
```

```
Root Mean Squared Error: 2.76
```

```
R-squared: 0.89, Adjusted R-Squared 0.882
```

```
F-statistic vs. constant model: 117, p-value = 1.88e-39
```

## References

[1] Wilkinson, G. N., and C. E. Rogers. *Symbolic description of factorial models for analysis of variance*. J. Royal Statistics Society 22, pp. 392–399, 1973.

## Alternatives

Use `stepwiselm` to select a model from a starting model, continuing until no single step is beneficial.

Use `removeTerms` to remove particular terms.

Use `step` to optimally improve the model by adding or removing terms.

## See Also

`LinearModel` | `removeTerms` | `step` | `stepwiselm`

## How To

- “Linear Regression” on page 9-12

<b>Purpose</b>	Anderson-Darling test
<b>Syntax</b>	<pre>h = adtest(x) h = adtest(x,Name,Value) [h,p] = adtest( ___ ) [h,p,adstat,cv] = adtest( ___ )</pre>
<b>Description</b>	<p><code>h = adtest(x)</code> returns a test decision for the null hypothesis that the data in vector <code>x</code> is from a population with a normal distribution, using the Anderson-Darling test. The alternative hypothesis is that <code>x</code> is not from a population with a normal distribution. The result <code>h</code> is 1 if the test rejects the null hypothesis at the 5% significance level, or 0 otherwise.</p> <p><code>h = adtest(x,Name,Value)</code> returns a test decision for the Anderson-Darling test with additional options specified by one or more name-value pair arguments. For example, you can specify a null distribution other than normal, or select an alternative method for calculating the <i>p</i>-value.</p> <p><code>[h,p] = adtest( ___ )</code> also returns the <i>p</i>-value, <code>p</code>, of the Anderson-Darling test, using any of the input arguments from the previous syntaxes.</p> <p><code>[h,p,adstat,cv] = adtest( ___ )</code> also returns the test statistic, <code>adstat</code>, and the critical value, <code>cv</code>, for the Anderson-Darling test.</p>
<b>Input Arguments</b>	<p><b>x - Sample data</b> vector</p> <p>Sample data, specified as a vector. Missing observations in <code>x</code>, indicated by NaN, are ignored.</p> <p><b>Data Types</b> single   double</p>

## Name-Value Pair Arguments

Specify optional comma-separated pairs of `Name`, `Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( `' '`). You can specify several name and value pair arguments in any order as `Name1, Value1, . . . , NameN, ValueN`.

**Example:** `'Alpha', 0.01, 'MCTol', 0.01` conducts the hypothesis test at the 1% significance level, and determines the p-value,  $p$ , using a Monte Carlo simulation with a maximum Monte Carlo standard error for  $p$  of 0.01.

## 'Distribution' - Hypothesized distribution

`'norm'` (default) | `'exp'` | `'ev'` | `'logn'` | `'weibull'` | probability distribution object

Hypothesized distribution of data vector  $x$ , specified as the comma-separated pair consisting of `'Distribution'` and one of the following.

<code>'norm'</code>	Normal distribution
<code>'exp'</code>	Exponential distribution
<code>'ev'</code>	Extreme value distribution
<code>'logn'</code>	Lognormal distribution
<code>'weibull'</code>	Weibull distribution

In this case, you do not need to specify population parameters. Instead, `adtest` estimates the distribution parameters from the sample data and tests  $x$  against a composite hypothesis that it comes from the selected distribution family with parameters unspecified.

Alternatively, you can specify any continuous probability distribution object for the null distribution. In this case, you must specify all the distribution parameters, and `adtest` tests  $x$  against a simple hypothesis that it comes from the given distribution with its specified parameters.

**Example:** 'Distribution','exp'

### **'Alpha' - Significance level**

0.05 (default) | scalar value in the range (0,1)

Significance level of the hypothesis test, specified as the comma-separated pair consisting of 'Alpha' and a scalar value in the range (0,1).

**Example:** 'Alpha',0.01

### **Data Types**

single | double

### **'MCTol' - Maximum Monte Carlo standard error**

positive scalar value

Maximum Monte Carlo standard error for the  $p$ -value,  $p$ , specified as the comma-separated pair consisting of 'MCTol' and a positive scalar value. If you use MCTol, adtest determines  $p$  using a Monte Carlo simulation, and the name-value pair argument Asymptotic must have the value false.

**Example:** 'MCTol',0.01

### **Data Types**

single | double

### **'Asymptotic' - Method for calculating $p$ -value**

false (default) | true

Method for calculating the  $p$ -value of the Anderson-Darling test, specified as the comma-separated pair consisting of 'Asymptotic' and either true or false. If you specify 'true', adtest estimates the  $p$ -value using the limiting distribution of the Anderson-Darling test statistic. If you specify false, adtest calculates the  $p$ -value based on an analytical formula. For sample sizes greater than 120, the limiting distribution estimate is likely to be more accurate than the small sample size approximation method.

## Output Arguments

- If you specify a distribution family with unknown parameters for the Distribution name-value pair, `Asymptotic` must be `false`.
- If you use `MCTol` to calculate the  $p$ -value using a Monte Carlo simulation, `Asymptotic` must be `false`.

**Example:** `'Asymptotic',true`

### Data Types

logical

### **h** - Hypothesis test result

1 | 0

Hypothesis test result, returned as a logical value.

- If  $h = 1$ , this indicates the rejection of the null hypothesis at the Alpha significance level.
- If  $h = 0$ , this indicates a failure to reject the null hypothesis at the Alpha significance level.

### **p** - $p$ -value

scalar value in the range [0,1]

$p$ -value of the Anderson-Darling test, returned as a scalar value in the range [0,1].  $p$  is the probability of observing a test statistic as extreme as, or more extreme than, the observed value under the null hypothesis.  $p$  is calculated using one of these methods:

- If the hypothesized distribution is a fully specified probability distribution object, `adtest` calculates  $p$  analytically. If `'Asymptotic'` is `true`, `adtest` uses the asymptotic distribution of the test statistic. If you specify a value for `'MCTol'`, `adtest` uses a Monte Carlo simulation.
- If the hypothesized distribution is specified as a distribution family with unknown parameters, `adtest` retrieves the critical value from a table and uses inverse interpolation to determine the  $p$ -value. If you specify a value for `'MCTol'`, `adtest` uses a Monte Carlo simulation.

**adstat - Test statistic**

scalar value

Test statistic for the Anderson-Darling test, returned as a scalar value.

- If the hypothesized distribution is a fully specified probability distribution object, `adtest` computes `adstat` using specified parameters.
- If the hypothesized distribution is specified as a distribution family with unknown parameters, `adtest` computes `adstat` using parameters estimated from the sample data.

**cv - Critical value**

scalar value

Critical value for the Anderson-Darling test at the significance level Alpha, returned as a scalar value. `adtest` determines `cv` by interpolating into a table based on the specified Alpha significance level.

**Examples****Test for a Normal Distribution**

Load the data set. Create a vector containing the first column of the students' exam grades data.

```
load examgrades;  
x = grades(:,1);
```

Test the null hypothesis that the exam grades come from a normal distribution. You do not need to specify values for the population parameters.

```
[h,p,adstat,cv] = adtest(x);
```

```
h =  
    0
```

```
p =  
    0.1854
```

```
adstat =  
    0.5194  
  
cv =  
    0.7470
```

The returned value of  $h = 0$  indicates that `adtest` fails to reject the null hypothesis at the default 5% significance level.

## Test for an Extreme Value Distribution

Load the data set. Create a vector containing the first column of the students' exam grades data.

```
load examgrades;  
x = grades(:,1);
```

Test the null hypothesis that the exam grades come from an extreme value distribution. You do not need to specify values for the population parameters.

```
[h,p] = adtest(x,'Distribution','ev')  
  
h =  
    0  
  
p =  
    0.0714
```

The returned value of  $h = 0$  indicates that `adtest` fails to reject the null hypothesis at the default 5% significance level.

## Specify the Hypothesized Distribution Using a Probability Distribution Object

Load the data set. Create a vector containing the first column of the students' exam grades data.

```
load examgrades;
```

```
x = grades(:,1);
```

Create a normal probability distribution object with mean  $\mu = 75$  and standard deviation  $\sigma = 10$ .

```
dist = makedist('normal','mu',75,'sigma',10)
```

```
dist =
```

```
prob.NormalDistribution  
Package: prob
```

```
Normal distribution  
mu = 75  
sigma = 10
```

```
Properties, Methods
```

Test the null hypothesis that  $x$  comes from the hypothesized normal distribution.

```
[h,p] = adtest(x,'Distribution',dist)
```

```
h =  
    0
```

```
p =  
    0.4687
```

The returned value of  $h = 0$  indicates that `adtest` fails to reject the null hypothesis at the default 5% significance level.

## Definitions

### Anderson-Darling Test

The Anderson-Darling test is commonly used to test whether a data sample comes from a normal distribution. However, it can be used to test for another hypothesized distribution, even if you do not fully specify the distribution parameters. Instead, the test estimates any unknown parameters from the data sample.

The test statistic belongs to the family of quadratic empirical distribution function statistics, which measure the distance between the hypothesized distribution,  $F(x)$  and the empirical cdf,  $F_n(x)$  as

$$n \int_{-\infty}^{\infty} (F_n(x) - F(x))^2 w(x) dF(x),$$

over the ordered sample values  $x_1 < x_2 < \dots < x_n$ , where  $w(x)$  is a weight function and  $n$  is the number of data points in the sample.

The weight function for the Anderson-Darling test is

$$w(x) = [F(x)(1 - F(x))]^{-1},$$

which places greater weight on the observations in the tails of the distribution, thus making the test more sensitive to outliers and better at detecting departure from normality in the tails of the distribution.

The Anderson-Darling test statistic is

$$A_n^2 = -n - \sum_{i=1}^n \frac{2i-1}{n} [\ln(F(X_i)) + \ln(1 - F(X_{n+1-i}))],$$

where  $\{X_1 < \dots < X_n\}$  are the ordered sample data points and  $n$  is the number of data points in the sample.

In `adtest`, the decision to reject or not reject the null hypothesis is based on comparing the  $p$ -value for the hypothesis test with the specified significance level, not on comparing the test statistic with the critical value.

## Monte Carlo Standard Error

The Monte Carlo standard error is the error due to simulating the  $p$ -value.

The Monte Carlo standard error is calculated as

$$SE = \sqrt{\frac{(\hat{p})(1-\hat{p})}{\text{mcreps}}},$$

where  $\hat{p}$  is the estimated  $p$ -value of the hypothesis test, and `mcreps` is the number of Monte Carlo replications performed.

`adtest` chooses the number of Monte Carlo replications, `mcreps`, large enough to make the Monte Carlo standard error for  $\hat{p}$  less than the value specified for `MCTol`.

# gmdistribution.AIC property

---

**Purpose** Akaike Information Criterion

**Description** The Akaike Information Criterion:  $2 \cdot N \log L + 2 \cdot m$ , where  $m$  is the number of estimated parameters.

---

**Note** This property applies only to gmdistribution objects constructed with `fit`.

---

**Purpose**

Andrews plot

**Syntax**

```
andrewsplot(X)
andrewsplot(X, ..., 'Standardize', standopt)
andrewsplot(X, ..., 'Quantile', alpha)
andrewsplot(X, ..., 'Group', group)
andrewsplot(X, ..., 'PropName', PropVal, ...)
h = andrewsplot(X, ...)
```

**Description**

`andrewsplot(X)` creates an Andrews plot of the multivariate data in the matrix  $X$ . The rows of  $X$  correspond to observations, the columns to variables. Andrews plots represent each observation by a function  $f(t)$  of a continuous dummy variable  $t$  over the interval  $[0, 1]$ .  $f(t)$  is defined for the  $i$ th observation in  $X$  as

$$f(t) = X(i,1) / \sqrt{2} + X(i,2) \sin(2\pi t) + X(i,3) \cos(2\pi t) + \dots$$

`andrewsplot` treats NaN values in  $X$  as missing values and ignores the corresponding rows.

`andrewsplot(X, ..., 'Standardize', standopt)` creates an Andrews plot where *standopt* is one of the following:

- 'on' — scales each column of  $X$  to have mean 0 and standard deviation 1 before making the plot.
- 'PCA' — creates an Andrews plot from the principal component scores of  $X$ , in order of decreasing eigenvalue. (See `pca`.)
- 'PCAStd' — creates an Andrews plot using the standardized principal component scores. (See `pca`.)

`andrewsplot(X, ..., 'Quantile', alpha)` plots only the median and the  $\alpha$  and  $(1 - \alpha)$  quantiles of  $f(t)$  at each value of  $t$ . This is useful if  $X$  contains many observations.

`andrewsplot(X, ..., 'Group', group)` plots the data in different groups with different colors. Groups are defined by `group`, a numeric array containing a group index for each observation. `group` can also be a

# andrewsplot

---

categorical array, character matrix, or cell array of strings containing a group name for each observation.

`andrewsplot(X,...,'PropName',PropVal,...)` sets optional lineseries object properties to the specified values for all lineseries objects created by `andrewsplot`. (See `lineseriesproperties`.)

`h = andrewsplot(X,...)` returns a column vector of handles to the lineseries objects created by `andrewsplot`, one handle per row of `X`. If you use the `'Quantile'` input parameter, `h` contains one handle for each of the three lineseries objects created. If you use both the `'Quantile'` and the `'Group'` input parameters, `h` contains three handles for each group.

## Examples

### Create Andrews Plot to Visualize Grouped Data

This example shows how to create an Andrews plot to visualize grouped sample data.

Load the sample data.

```
load fisheriris
```

Create an Andrews plot, grouping the sample data by species.

```
andrewsplot(meas,'group',species)
```

Create a second, simplified Andrews plot that only displays the median and quartiles of each group.

```
andrewsplot(meas, 'group', species, 'quantile', .25)
```

# andrewsplot

---

**See Also**      [parallelcoords](#) | [glyphplot](#)

**How To**      • “Grouping Variables” on page 2-51

## Purpose

Analysis of variance for linear model

## Syntax

```
tbl = anova mdl
tbl = anova mdl, anovatype
tbl = anova mdl, anovatype, sstype
```

## Description

`tbl = anova(mdl)` returns a dataset array with summary ANOVA statistics.

`tbl = anova(mdl, anovatype)` returns ANOVA statistics of the chosen type.

`tbl = anova(mdl, anovatype, sstype)` computes ANOVA statistics using the chosen type of sum of squares.

## Input Arguments

### **mdl**

Linear model, as constructed by `fitlm` or `stepwiselm`.

### **anovatype**

ANOVA type:

- 'component' — `tbl` displays a 'components' ANOVA table, with sums of squares and  $F$  tests attributable to each term in the model except the constant term.
- 'summary' — `tbl` displays a summary ANOVA table with an  $F$  test for the model as a whole.
  - If there are both linear and higher-order terms, there is also an  $F$  test for the higher-order terms as a group.
  - If there are replications (multiple observations sharing the same predictor values), there is also an  $F$  test for lack-of-fit computed by decomposing the residual sum of squares into a sum of squares for the replicated observations and the remaining sum of squares.

**Default:** 'component'

## **sstype**

When anovatype is 'component', choose the sum of squares type:

- 1
- 2
- 3
- 'h'

For details, see “Sum of Squares” on page 21-58.

**Default:** 'h'

## **Output Arguments**

### **tbl**

Dataset array containing summary ANOVA statistics. `tbl` depends on `anovatype`:

- 'component':
  - Sum of squares
  - Degrees of freedom
  - Mean squares
  - $F$  statistic
  - $p$ -value
  - Formula used for model
- 'summary':
  - Total Sum of Squares
  - Model Sum of Squares
    - Linear Sum of Squares (present if model has powers or interactions)

- Nonlinear Sum of Squares (present if model has powers or interactions)
- Residual Sum of Squares
  - Lack-of-fit Sum of Squares (present if model has replicates)
  - Pure error Sum of Squares (present if model has replicates)

## Examples

### Component ANOVA Table

Create a component ANOVA table from a model of the `carsmall` data.

Load the `carsmall` data and make a model of the MPG as a function of weight and model year.

```
load carsmall
ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);
mdl = fitlm(ds,'MPG ~ Year + Weight^2');
```

Create an ANOVA table.

```
tbl = anova(mdl)
```

```
tbl =
```

	SumSq	DF	MeanSq	F	pValue
Weight	2050.2	1	2050.2	265.11	1.9885e-28
Year	849.55	2	424.77	54.927	2.9042e-16
Weight^2	76.688	1	76.688	9.9164	0.0022303
Error	688.27	89	7.7334		

### Summary ANOVA Table

Create a summary ANOVA table from a model of the `carsmall` data.

Load the `carsmall` data and make a model of the MPG as a function of weight and model year.

# LinearModel.anova

---

```
load carsmall
ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);
mdl = fitlm(ds,'MPG ~ Year + Weight^2');
```

Create a summary ANOVA table.

```
tbl = anova(mdl,'summary')
```

```
tbl =
```

	SumSq	DF	MeanSq	F	pValue
Total	6005.3	93	64.573		
Model	5317	4	1329.3	171.88	5.5208e-41
. Linear	5240.3	3	1746.8	225.87	1.7302e-41
. Nonlinear	76.688	1	76.688	9.9164	0.0022303
Residual	688.27	89	7.7334		
. Lack of fit	663.77	86	7.7183	0.9451	0.62874
. Pure error	24.5	3	8.1667		

The summary ANOVA table shows tests for groups of terms. The nonlinear group consists of just the  $\text{Weight}^2$  term, so it has the same  $p$ -value as that term in “Component ANOVA Table” on page 21-31. The  $F$  statistic comparing the residual sum of squares to a “pure error” estimate from replicated observations shows no evidence of lack of fit.

## Alternatives

More complete ANOVA statistics are available in the `anova1`, `anova2`, and `anovan` functions.

## Tutorials

- “ANOVA” on page 9-23

## How To

- “Linear Regression” on page 9-12

## Purpose

Analysis of variance for linear mixed-effects model

## Syntax

```
stats = anova(lme)
stats = anova(lme,Name,Value)
```

## Description

`stats = anova(lme)` returns the dataset array `stats` that includes the results of the  $F$ -tests for each fixed-effects term in the linear mixed-effects model `lme`.

`stats = anova(lme,Name,Value)` also returns the dataset array `stats` with additional options specified by one or more `Name,Value` pair arguments.

## Tips

- For each fixed-effects term, `anova` performs an  $F$ -test (marginal test), that all coefficients representing the fixed-effects term are 0. To perform tests for type III hypotheses, you must set the 'DummyVarCoding' name-value pair argument to 'effects' contrasts while fitting your linear mixed-effects model.

## Input Arguments

### **lme - Linear mixed-effects model**

`LinearMixedModel` object

Linear mixed-effects model, returned as a `LinearMixedModel` object.

For properties and methods of this object, see `LinearMixedModel`.

### **Name-Value Pair Arguments**

Specify optional comma-separated pairs of `Name,Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as `Name1,Value1,...,NameN,ValueN`.

### **'DFMethod' - Method for computing approximate degrees of freedom**

'Residual' (default) | 'Satterthwaite' | 'None'

# LinearMixedModel.anova

---

Method for computing approximate degrees of freedom to use in the  $F$ -test, specified as the comma-separated pair consisting of 'DFMethod' and one of the following.

'Residual'	Default. The degrees of freedom are assumed to be constant and equal to $n - p$ , where $n$ is the number of observations and $p$ is the number of fixed effects.
'Satterthwaite'	Satterthwaite approximation.
'None'	All degrees of freedom are set to infinity.

For example, you can specify the Satterthwaite approximation as follows.

**Example:** 'DFMethod', 'Satterthwaite'

## Output Arguments

### **stats** - Results of $F$ -tests for fixed-effects terms

dataset array

Results of  $F$ -tests for fixed-effects terms, returned as a dataset array with the following columns.

Term	Name of the fixed effects term
Fstat	$F$ -statistic for the term
DF1	Numerator degrees of freedom for the $F$ -statistic
DF2	Denominator degrees of freedom for the $F$ -statistic
pValue	$p$ -value of the test for the term

There is one row for each fixed-effects term. Each term is a continuous variable, a grouping variable, or an interaction

between two or more continuous or grouping variables. For each fixed-effects term, `anova` performs an  $F$ -test (marginal test) to determine if all coefficients representing the fixed-effects term are 0. To perform tests for the type III hypothesis, you must use the 'effects' contrasts while fitting the linear mixed-effects model.

## Examples

### F-Tests for Fixed Effects

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load shift
```

The data shows the deviations from the target quality characteristic measured from the products that five operators manufacture during three shifts: morning, evening, and night. This is a randomized block design, where the operators are the blocks. The experiment is designed to study the impact of the time of shift on the performance. The performance measure is the deviation of the quality characteristics from the target value. This is simulated data.

Shift and Operator are nominal variables.

```
shift.Shift = nominal(shift.Shift);
shift.Operator = nominal(shift.Operator);
```

Fit a linear mixed-effects model with a random intercept grouped by operator to assess if performance significantly differs according to the time of the shift. Use the restricted maximum likelihood method and 'effects' contrasts.

'effects' contrasts indicate that the coefficients sum to 0, and `fitlme` creates two contrast-coded variables in the fixed-effects design matrix,  $X_1$  and  $X_2$ , where

# LinearMixedModel.anova

$$\text{Shift\_Evening} = \begin{cases} 0, & \text{if Morning} \\ 1, & \text{if Evening} \\ -1, & \text{if Night} \end{cases} \quad \text{and} \quad \text{Shift\_Morning} = \begin{cases} 1, & \text{if Morning} \\ 0, & \text{if Evening} \\ -1, & \text{if Night} \end{cases}.$$

The model corresponds to

$$\text{Morning Shift: } QCDev_{im} = \beta_0 + \beta_2 \text{Shift} - \text{Morning}_i + b_{0m} + \varepsilon_{im}, \quad m = 1, 2, \dots, 5,$$

$$\text{Evening Shift: } QCDev_{im} = \beta_0 + \beta_1 \text{Shift} - \text{Evening}_i + b_{0m} + \varepsilon_{im},$$

$$\text{Night Shift: } QCDev_{im} = \beta_0 - \beta_1 \text{Shift} - \text{Evening}_i - \beta_2 \text{Shift} - \text{Morning}_i + b_{0m} + \varepsilon_{im},$$

where  $b \sim N(0, \sigma^2_b)$  and  $\varepsilon \sim N(0, \sigma^2)$ .

```
lme = fitlme(shift, 'QCDev ~ Shift + (1|Operator)', ...  
'FitMethod', 'REML', 'DummyVarCoding', 'effects')
```

```
lme =
```

```
Linear mixed-effects model fit by REML
```

```
Model information:
```

Number of observations	15
Fixed effects coefficients	3
Random effects coefficients	5
Covariance parameters	2

```
Formula:
```

```
QCDev ~ 1 + Shift + (1 | Operator)
```

```
Model fit statistics:
```

AIC	BIC	LogLikelihood	Deviance
58.913	61.337	-24.456	48.913

```
Fixed effects coefficients (95% CIs):
```

Name	Estimate	SE	tStat	DF	pValue
'(Intercept)'	3.6525	0.94109	3.8812	12	0.0021
'Shift_Evening'	-0.53293	0.31206	-1.7078	12	0.11

```
'Shift_Morning'          -0.91973    0.31206    -2.9473    12    0
```

Random effects covariance parameters (95% CIs):

Group: Operator (5 Levels)

Name1	Name2	Type	Estimate
'(Intercept)'	'(Intercept)'	'std'	2.0457

Group: Error

Name	Estimate	Lower	Upper
'Res Std'	0.85462	0.52357	1.395

Perform an  $F$ -test to determine if all fixed-effects coefficients are 0.

```
anova(lme)
```

```
ans =
```

```
ANOVA marginal tests: DFMethod = 'Residual'
```

Term	FStat	DF1	DF2	pValue
'(Intercept)'	15.063	1	12	0.0021832
'Shift'	11.091	2	12	0.0018721

The  $p$ -value for the constant term, 0.0021832, is the same as in the coefficient table in the `lme` display. The  $p$ -value of 0.0018721 for `Shift` measures the combined significance for both coefficients representing `Shift`.

## Split-Plot Experiment

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load fertilizer
```

# LinearMixedModel.anova

---

The dataset array includes data from a split-plot experiment, where soil is divided into three blocks based on the soil type: sandy, silty, and loamy. Each block is divided into five plots, where five types of tomato plants (cherry, heirloom, grape, vine, and plum) are randomly assigned to these plots. The tomato plants in the plots are then divided into subplots, where each subplot is treated by one of four fertilizers. This is simulated data.

Store the data in a dataset array called `ds`, for practical purposes, and define `Tomato`, `Soil`, and `Fertilizer` as categorical variables.

```
ds = fertilizer;  
ds.Tomato = nominal(ds.Tomato);  
ds.Soil = nominal(ds.Soil);  
ds.Fertilizer = nominal(ds.Fertilizer);
```

Fit a linear mixed-effects model, where `Fertilizer` and `Tomato` are the fixed-effects variables, and the mean yield varies by the block (soil type) and the plots within blocks (tomato types within soil types) independently. Use the 'effects' contrasts when fitting the data for the type III sum of squares.

```
lme = fitlme(ds, 'Yield ~ Fertilizer * Tomato + (1|Soil) + (1|Soil:Tomato)  
'DummyVarCoding', 'effects')
```

```
lme =
```

```
Linear mixed-effects model fit by ML
```

```
Model information:
```

Number of observations	60
Fixed effects coefficients	20
Random effects coefficients	18
Covariance parameters	3

```
Formula:
```

```
Yield ~ 1 + Tomato*Fertilizer + (1 | Soil) + (1 | Soil:Tomato)
```

# LinearMixedModel.anova

Group: Soil:Tomato (15 Levels)

Name1	Name2	Type	Estimate
'(Intercept)'	'(Intercept)'	'std'	10.225

# LinearMixedModel.anova

---

```
Group: Error
      Name      Estimate    Lower    Upper
  'Res Std'    10.499      8.5389   12.908
```

Perform an analysis of variance to test for the fixed-effects.

```
anova(lme)
```

```
ans =
```

```
ANOVA marginal tests: DFMethod = 'Residual'
```

Term	FStat	DF1	DF2	pValue
'(Intercept)'	1004.2	1	40	5.9086e-30
'Tomato'	7.1663	4	40	0.00018935
'Fertilizer'	58.833	3	40	1.0024e-14
'Tomato:Fertilizer'	1.4182	12	40	0.19804

The  $p$ -value for the constant term,  $5.9086e-30$ , is the same as in the coefficient table in the `lme` display. The  $p$ -values of  $0.00018935$ ,  $1.0024e-14$ , and  $0.19804$  for `Tomato`, `Fertilizer`, and `Tomato:Fertilizer` represent the combined significance for all tomato coefficients, fertilizer coefficients, and coefficients representing the interaction between the tomato and fertilizer, respectively. The  $p$ -value of  $0.19804$  indicates that the interaction between tomato and fertilizer is not significant.

## Satterthwaite Approximation for Degrees of Freedom

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load weight
```

weight contains data from a longitudinal study, where 20 subjects are randomly assigned 4 exercise programs, and their weight loss is recorded over six 2-week time periods. This is simulated data.

Store the data in a dataset array. Define Subject and Program as categorical variables.

```
ds = dataset(InitialWeight,Program,Subject,Week,y);  
ds.Subject = nominal(ds.Subject);  
ds.Program = nominal(ds.Program);
```

Fit the model using the 'effects' contrasts.

```
lme = fitlme(ds,'y ~ InitialWeight + Program*Week + (Week|Subject)', 'D'  
  
lme =
```

Linear mixed-effects model fit by ML

'Week'	'Week'	'std'	0.15033	C

Group: Error

Name	Estimate	Lower	Upper
'Res Std'	0.10261	0.087882	0.11981

The  $p$ -values 0.022863 and 4.1099e-08 indicate significant effects of the initial weights of the subjects and the time factor in the amount of weight lost. The weight loss of subjects who are in program B is significantly different relative to the weight loss of subjects that are in program A. The lower and upper limits of the covariance parameters for the random effects do not include zero, thus they are significant.

Perform an F-test that all fixed-effects coefficients are zero.

```
anova(lme)
```

```
ans =
```

ANOVA marginal tests: DFMethod = 'Residual'

Term	FStat	DF1	DF2	pValue
'(Intercept)'	10.065	1	111	0.0019549
'InitialWeight'	5.326	1	111	0.022863
'Program'	3.6798	3	111	0.014286

'Week'	34.747	1	111	4.1099e-08
'Program:Week'	0.066648	3	111	0.97748

The  $p$ -values for the constant term, initial weight, and week are the same as in the coefficient table in the previous `lme` output display. The  $p$ -value of 0.014286 for `Program` represents the combined significance for all program coefficients. Similarly, the  $p$ -value for the interaction between program and week (`Program:Week`) measures the combined significance for all coefficients representing this interaction.

Now, use the Satterthwaite method to compute the degrees of freedom.

```
anova(lme, 'DFMethod', 'Satterthwaite')
```

```
ans =
```

```
ANOVA marginal tests: DFMethod = 'Satterthwaite'
```

Term	FStat	DF1	DF2	pValue
'(Intercept)'	10.065	1	20.445	0.004695
'InitialWeight'	5.326	1	20	0.031827
'Program'	3.6798	3	19.14	0.030233
'Week'	34.747	1	20	9.1347e-06
'Program:Week'	0.066648	3	20	0.97697

The Satterthwaite method produces smaller denominator degrees of freedom and slightly larger  $p$ -values.

# anova1

---

**Purpose** One-way analysis of variance

**Syntax**

```
p = anova1(X)
p = anova1(X,group)
p = anova1(X,group,displayopt)
[p,table] = anova1(...)
[p,table,stats] = anova1(...)
```

**Description** `p = anova1(X)` performs balanced one-way ANOVA for comparing the means of two or more columns of data in the matrix `X`, where each column represents an independent sample containing mutually independent observations. The function returns the  $p$ -value under the null hypothesis that all samples in `X` are drawn from populations with the same mean.

If `p` is near zero, it casts doubt on the null hypothesis and suggests that at least one sample mean is significantly different than the other sample means. Common significance levels are 0.05 or 0.01.

The `anova1` function displays two figures, the standard ANOVA table and a box plot of the columns of `X`.

The standard ANOVA table divides the variability of the data into two parts:

- Variability due to the differences among the column means (variability *between* groups)
- Variability due to the differences between the data in each column and the column mean (variability *within* groups)

The standard ANOVA table has six columns:

- 1 The source of the variability.
- 2 The sum of squares (SS) due to each source.
- 3 The degrees of freedom (df) associated with each source.
- 4 The mean squares (MS) for each source, which is the ratio  $SS/df$ .

5 The  $F$ -statistic, which is the ratio of the mean squares.

6 The  $p$ -value, which is derived from the cdf of  $F$ .

The box plot of the columns of  $X$  suggests the size of the  $F$ -statistic and the  $p$ -value. Large differences in the center lines of the boxes correspond to large values of  $F$  and correspondingly small values of  $p$ .

anova1 treats NaN values as missing, and disregards them.

`p = anova1(X,group)` performs ANOVA by group. For more information on grouping variables, see “Grouping Variables” on page 2-51.

If  $X$  is a matrix, anova1 treats each column as a separate group, and evaluates whether the population means of the columns are equal. This form of anova1 is appropriate when each group has the same number of elements (balanced ANOVA). `group` can be a character array or a cell array of strings, with one row per column of  $X$ , containing group names. Enter an empty array (`[]`) or omit this argument if you do not want to specify group names.

If  $X$  is a vector, `group` must be a categorical variable, vector, string array, or cell array of strings with one name for each element of  $X$ .  $X$  values corresponding to the same value of `group` are placed in the same group. This form of anova1 is appropriate when groups have different numbers of elements (unbalanced ANOVA).

If `group` contains empty or NaN-valued cells or strings, the corresponding observations in  $X$  are disregarded.

`p = anova1(X,group,displayopt)` enables the ANOVA table and box plot displays when `displayopt` is 'on' (default) and suppresses the displays when `displayopt` is 'off'. Notches in the boxplot provide a test of group medians (see `boxplot`) different from the  $F$  test for means in the ANOVA table.

`[p,table] = anova1(...)` returns the ANOVA table (including column and row labels) in the cell array `table`. Copy a text version of the ANOVA table to the clipboard using the Copy Text item on the **Edit** menu.

`[p,table,stats] = anova1(...)` returns a structure `stats` used to perform a follow-up multiple comparison test. `anova1` evaluates the hypothesis that the samples all have the same mean against the alternative that the means are not all the same. Sometimes it is preferable to perform a test to determine which pairs of means are significantly different, and which are not. Use the `multcompare` function to perform such tests by supplying the `stats` structure as input.

## Assumptions

The ANOVA test makes the following assumptions about the data in `X`:

- All sample populations are normally distributed.
- All sample populations have equal variance.
- All observations are mutually independent.

The ANOVA test is known to be robust with respect to modest violations of the first two assumptions.

## Examples

### Example 1

Create `X` with columns that are constants plus random normal disturbances with mean zero and standard deviation one:

```
X = meshgrid(1:5)
```

```
X =  
  1  2  3  4  5  
  1  2  3  4  5  
  1  2  3  4  5  
  1  2  3  4  5  
  1  2  3  4  5
```

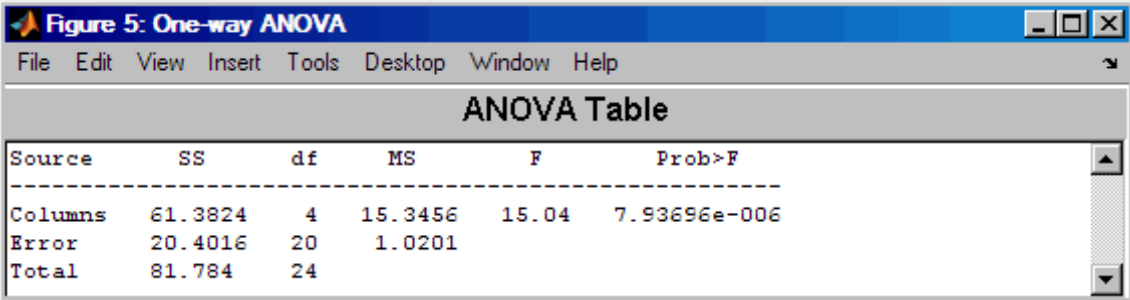

```
X = X + normrnd(0,1,5,5)
```

```
X =  
  1.3550    2.0662    2.4688    5.9447    5.4897  
  2.0693    1.7611    1.4864    4.8826    6.3222  
  2.1919    0.7276    3.1905    4.8768    4.6841  
  2.7620    1.8179    3.9506    4.4678    4.9291  
 -0.3626    1.1685    3.5742    2.1945    5.9465
```

Perform one-way ANOVA:

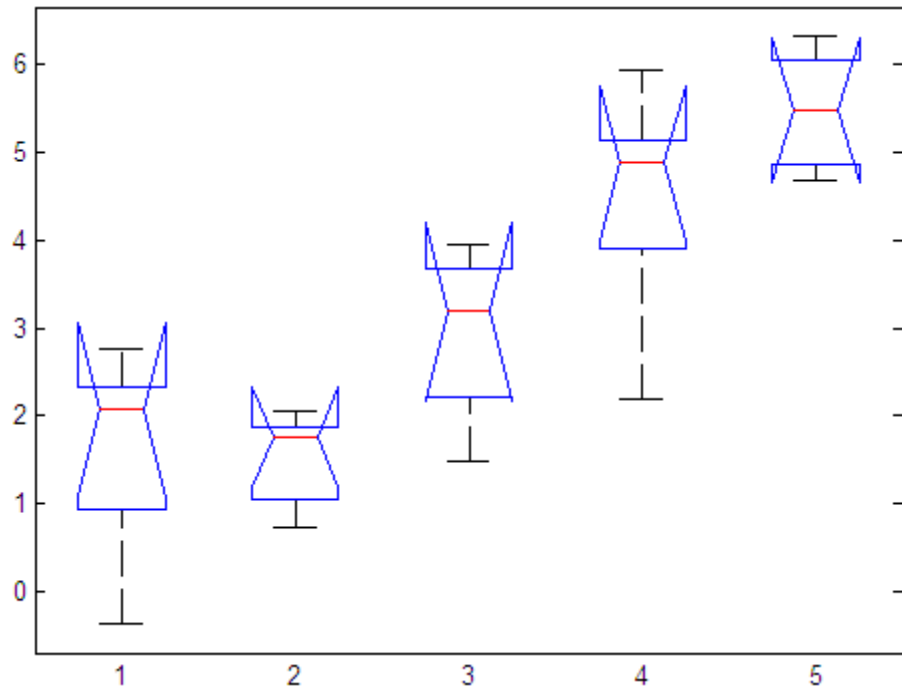

```
p = anova1(X)
```

```
p =  
7.9370e-006
```

The screenshot shows a software window titled "Figure 5: One-way ANOVA" with a menu bar containing "File", "Edit", "View", "Insert", "Tools", "Desktop", "Window", and "Help". The main content is an "ANOVA Table" with the following data:

Source	SS	df	MS	F	Prob>F
Columns	61.3824	4	15.3456	15.04	7.93696e-006
Error	20.4016	20	1.0201		
Total	81.784	24			

The very small  $p$  value indicates that differences between column means are highly significant. The probability of this outcome under the null hypothesis (that samples drawn from the same population would have means differing by the amounts seen in  $X$ ) is equal to the  $p$ -value.

## Example 2

The following example is from a study of the strength of structural beams in Hogg. The vector `strength` measures deflections of beams in thousandths of an inch under 3,000 pounds of force. The vector `alloy` identifies each beam as steel ('st'), alloy 1 ('a11'), or alloy 2 ('a12'). (Although `alloy` is sorted in this example, grouping variables do not need to be sorted.) The null hypothesis is that steel beams are equal in strength to beams made of the two more expensive alloys.

```
strength = [82 86 79 83 84 85 86 87 74 82 ...
```

```

78 75 76 77 79 79 77 78 82 79];

alloy = {'st','st','st','st','st','st','st','st',...
        'al1','al1','al1','al1','al1','al1',...
        'al2','al2','al2','al2','al2','al2'};

p = anova1(strength,alloy)
p =
1.5264e-004

```

Source	SS	df	MS	F	Prob>F
Columns	184.8	2	92.4	15.4	0.0002
Error	102	17	6		
Total	286.8	19			

# anova1

The  $p$ -value suggests rejection of the null hypothesis. The box plot shows that steel beams deflect more than beams made of the more expensive alloys.

## How To

- “Grouping Variables” on page 2-51

**Purpose** Two-way analysis of variance

**Syntax**

```
p = anova2(X, reps)
p = anova2(X, reps, displayopt)
[p, table] = anova2(...)
[p, table, stats] = anova2(...)
```

**Description** `p = anova2(X, reps)` performs a balanced two-way ANOVA for comparing the means of two or more columns and two or more rows of the observations in  $X$ . The data in different columns represent changes in factor  $A$ . The data in different rows represent changes in factor  $B$ . If there is more than one observation for each combination of factors, input `reps` indicates the number of replicates in each position, which must be constant. (For unbalanced designs, use `anovan`.)

The matrix below shows the format for a set-up where column factor  $A$  has two levels, row factor  $B$  has three levels, and there are two replications (`reps = 2`). The subscripts indicate row, column, and replicate, respectively.

$$\begin{array}{cc}
 A = 1 & A = 2 \\
 \left[ \begin{array}{cc}
 x_{111} & x_{121} \\
 x_{112} & x_{122} \\
 x_{211} & x_{221} \\
 x_{212} & x_{222} \\
 x_{311} & x_{321} \\
 x_{312} & x_{322}
 \end{array} \right] \left. \begin{array}{l} \\ \\ \\ \\ \\ \\ \end{array} \right\} \begin{array}{l} B = 1 \\ \\ B = 2 \\ \\ B = 3 \end{array}
 \end{array}$$

When `reps` is 1 (default), `anova2` returns two  $p$ -values in vector `p`:

- 1 The  $p$  value for the null hypothesis,  $H_{0A}$ , that all samples from factor  $A$  (i.e., all column-samples in  $X$ ) are drawn from the same population
- 2 The  $p$  value for the null hypothesis,  $H_{0B}$ , that all samples from factor  $B$  (i.e., all row-samples in  $X$ ) are drawn from the same population

When `reps` is greater than 1, `anova2` returns a third  $p$  value in vector `p`:

- 3 The  $p$  value for the null hypothesis,  $H_{0AB}$ , that the effects due to factors A and B are *additive* (i.e., that there is no interaction between factors A and B)

If any  $p$  value is near zero, this casts doubt on the associated null hypothesis. A sufficiently small  $p$  value for  $H_{0A}$  suggests that at least one column-sample mean is significantly different than the other column-sample means; i.e., there is a main effect due to factor A. A sufficiently small  $p$  value for  $H_{0B}$  suggests that at least one row-sample mean is significantly different than the other row-sample means; i.e., there is a main effect due to factor B. A sufficiently small  $p$  value for  $H_{0AB}$  suggests that there is an interaction between factors A and B. The choice of a limit for the  $p$  value to determine whether a result is “statistically significant” is left to the researcher. It is common to declare a result significant if the  $p$  value is less than 0.05 or 0.01.

`anova2` also displays a figure showing the standard ANOVA table, which divides the variability of the data in  $X$  into three or four parts depending on the value of `reps`:

- The variability due to the differences among the column means
- The variability due to the differences among the row means
- The variability due to the interaction between rows and columns (if `reps` is greater than its default value of one)
- The remaining variability not explained by any systematic source

The ANOVA table has five columns:

- The first shows the source of the variability.
- The second shows the Sum of Squares (SS) due to each source.
- The third shows the degrees of freedom (df) associated with each source.
- The fourth shows the Mean Squares (MS), which is the ratio SS/df.

- The fifth shows the  $F$  statistics, which is the ratio of the mean squares.

`p = anova2(X, reps, displayopt)` enables the ANOVA table display when `displayopt` is 'on' (default) and suppresses the display when `displayopt` is 'off'.

`[p, table] = anova2(...)` returns the ANOVA table (including column and row labels) in cell array `table`. (Copy a text version of the ANOVA table to the clipboard by using the Copy Text item on the **Edit** menu.)

`[p, table, stats] = anova2(...)` returns a `stats` structure that you can use to perform a follow-up multiple comparison test.

The `anova2` test evaluates the hypothesis that the row, column, and interaction effects are all the same, against the alternative that they are not all the same. Sometimes it is preferable to perform a test to determine *which pairs* of effects are significantly different, and which are not. Use the `multcompare` function to perform such tests by supplying the `stats` structure as input.

## Examples

The data below come from a study of popcorn brands and popper type (Hogg 1987). The columns of the matrix `popcorn` are brands (Gourmet, National, and Generic). The rows are popper type (Oil and Air.) The study popped a batch of each brand three times with each popper. The values are the yield in cups of popped popcorn.

```
load popcorn
```

```
popcorn
popcorn =
    5.5000    4.5000    3.5000
    5.5000    4.5000    4.0000
    6.0000    4.0000    3.0000
    6.5000    5.0000    4.0000
    7.0000    5.5000    5.0000
    7.0000    5.0000    4.5000
```

## anova2

```
p = anova2(popcorn,3)
p =
    0.0000    0.0001    0.7462
```

Source	SS	df	MS	F	Prob>F
Columns	15.75	2	7.875	56.7	0
Rows	4.5	1	4.5	32.4	0.0001
Interaction	0.0833	2	0.04167	0.3	0.7462
Error	1.6667	12	0.13889		
Total	22	17			

The vector `p` shows the  $p$ -values for the three brands of popcorn, 0.0000, the two popper types, 0.0001, and the interaction between brand and popper type, 0.7462. These values indicate that both popcorn brand and popper type affect the yield of popcorn, but there is no evidence of a synergistic (interaction) effect of the two.

The conclusion is that you can get the greatest yield using the Gourmet brand and an Air popper (the three values `popcorn(4:6,1)`).

`anova1` | `anovan`

**Purpose** *N*-way analysis of variance

**Syntax**

```
p = anovan(y,group)
p = anovan(y,group,param,val)
[p,table] = anovan(y,group,param,val)
[p,table,stats] = anovan(y,group,param,val)
[p,table,stats,terms] = anovan(y,group,param,val)
```

**Description** `p = anovan(y,group)` performs multiway (n-way) analysis of variance (ANOVA) for testing the effects of multiple factors on the mean of the vector `y`. This test compares the variance explained by factors to the left over variance that cannot be explained. The factors and factor levels of the observations in `y` are assigned by the cell array `group`. Each of the cells in the cell array `group` contains a list of factor levels identifying the observations in `y` with respect to one of the factors. The list within each cell can be a categorical array, numeric vector, character matrix, or single-column cell array of strings, and must have the same number of elements as `y`. The fitted ANOVA model includes the main effects of each grouping variable. All grouping variables are treated as fixed effects by default. The result `p` is a vector of *p*-values, one per term. For an example, see “Example of Three-Way ANOVA” on page 21-59.

`p = anovan(y,group,param,val)` specifies one or more of the parameter name/value pairs described in the following table.

Parameter	Value
'alpha'	A number between 0 and 1 requesting 100(1 – <i>alpha</i> )% confidence bounds (default 0.05 for 95% confidence)
'continuous'	A vector of indices indicating which grouping variables should be treated as continuous predictors rather than as categorical predictors.
'display'	'on' displays an ANOVA table (the default) 'off' omits the display

Parameter	Value
'model'	The type of model used. See “Model Type” on page 21-57 for a description of this parameter.
'nested'	A matrix M of 0's and 1's specifying the nesting relationships among the grouping variables. M(i,j) is 1 if variable i is nested in variable j.
'random'	A vector of indices indicating which grouping variables are random effects (all are fixed by default). See “ANOVA with Random Effects” on page 8-19 for an example of how to use 'random'.
'sstype'	1, 2, 3 (default), or h specifies the type of sum of squares. See “Sum of Squares” on page 21-58 for a description of this parameter.
'varnames'	A character matrix or a cell array of strings specifying names of grouping variables, one per grouping variable. When you do not specify 'varnames', the default labels 'X1', 'X2', 'X3', ..., 'XN' are used. See “ANOVA with Random Effects” on page 8-19 for an example of how to use 'varnames'.

`[p,table] = anovan(y,group,param,val)` returns the ANOVA table (including factor labels) in cell array `table`. (Copy a text version of the ANOVA table to the clipboard by using the Copy Text item on the **Edit** menu.)

`[p,table,stats] = anovan(y,group,param,val)` returns a `stats` structure that you can use to perform a follow-up multiple comparison test with the `multcompare` function. See “The Stats Structure” on page 21-62The Stats Structure for more information.

`[p,table,stats,terms] = anovan(y,group,param,val)` returns the main and interaction terms used in the ANOVA computations. The terms are encoded in the output matrix `terms` using the same format described above for input 'model'. When you specify 'model' itself in this matrix format, the matrix returned in `terms` is identical.

## Model Type

This section explains how to use the argument 'model' with the syntax:

```
[...] = anovan(y,group,'model',modeltype)
```

The argument *modeltype*, which specifies the type of model the function uses, can be any one of the following:

- 'linear' — The default 'linear' model computes only the *p*-values for the null hypotheses on the *N* main effects.
- 'interaction' — The 'interaction' model computes the *p*-values

for null hypotheses on the *N* main effects and the  $\binom{N}{2}$  two-factor interactions.

- 'full' — The 'full' model computes the *p*-values for null hypotheses on the *N* main effects and interactions at all levels.
- An integer — For an integer value of *modeltype*, *k* ( $k \leq N$ ), *anovan* computes all interaction levels through the *k*th level. For example, the value 3 means main effects plus two- and three-factor interactions. The values *k* = 1 and *k* = 2 are equivalent to the 'linear' and 'interaction' specifications, respectively, while the value *k* = *N* is equivalent to the 'full' specification.
- A matrix of term definitions having the same form as the input to the *x2fx* function. All entries must be 0 or 1 (no higher powers).

For more precise control over the main and interaction terms that *anovan* computes, *modeltype* can specify a matrix containing one row for each main or interaction term to include in the ANOVA model. Each row defines one term using a vector of *N* zeros and ones. The table below illustrates the coding for a 3-factor ANOVA.

Matrix Row	ANOVA Term
[1 0 0]	Main term A
[0 1 0]	Main term B

<b>Matrix Row</b>	<b>ANOVA Term</b>
[0 0 1]	Main term C
[1 1 0]	Interaction term AB
[1 0 1]	Interaction term AC
[0 1 1]	Interaction term BC
[1 1 1]	Interaction term ABC

For example, if *modeltype* is the matrix [0 1 0;0 0 1;0 1 1], the output vector *p* contains the *p*-values for the null hypotheses on the main effects B and C and the interaction effect BC, in that order. A simple way to generate the *modeltype* matrix is to modify the *terms* output, which codes the terms in the current model using the format described above. If *anovan* returns [0 1 0;0 0 1;0 1 1] for *terms*, for example, and there is no significant result for interaction BC, you can recompute the ANOVA on just the main effects B and C by specifying [0 1 0;0 0 1] for *modeltype*.

### Sum of Squares

This section explains how to use the argument '*sstype*' with the syntax:

```
[...] = anovan(y,group, 'sstype', type)
```

This syntax computes the ANOVA using the type of sum of squares specified by *type*, which can be 1, 2, 3, or h. While the numbers 1 – 3 designate Type 1, Type 2, or Type 3 sum of squares, respectively, h represents a hierarchical model similar to type 2, but with continuous as well as categorical factors used to determine the hierarchy of terms. The default value is 3. For a model containing main effects but no interactions, the value of *type* only influences computations on unbalanced data.

The sum of squares for any term is determined by comparing two models. The Type 1 sum of squares for a term is the reduction in residual sum of squares obtained by adding that term to a fit that already includes the terms listed before it. The Type 2 sum of squares is

the reduction in residual sum of squares obtained by adding that term to a model consisting of all other terms that do not contain the term in question. The Type 3 sum of squares is the reduction in residual sum of squares obtained by adding that term to a model containing all other terms, but with their effects constrained to obey the usual “sigma restrictions” that make models estimable.

Suppose you are fitting a model with two factors and their interaction, and that the terms appear in the order  $A, B, AB$ . Let  $R(\cdot)$  represent the residual sum of squares for a model, so for example  $R(A, B, AB)$  is the residual sum of squares fitting the whole model,  $R(A)$  is the residual sum of squares fitting just the main effect of  $A$ , and  $R(1)$  is the residual sum of squares fitting just the mean. The three types of sums of squares are as follows:

Term	Type 1 Sum of Squares	Type 2 Sum of Squares	Type 3 Sum of Squares
$A$	$R(1) - R(A)$	$R(B) - R(A, B)$	$R(B, AB) - R(A, B, AB)$
$B$	$R(A) - R(A, B)$	$R(A) - R(A, B)$	$R(A, AB) - R(A, B, AB)$
$AB$	$R(A, B) - R(A, B, AB)$	$R(A, B) - R(A, B, AB)$	$R(A, B) - R(A, B, AB)$

The models for Type 3 sum of squares have sigma restrictions imposed. This means, for example, that in fitting  $R(B, AB)$ , the array of  $AB$  effects is constrained to sum to 0 over  $A$  for each value of  $B$ , and over  $B$  for each value of  $A$ .

### Example of Three-Way ANOVA

As an example of three-way ANOVA, consider the vector  $y$  and group inputs below.

```

y = [52.7 57.5 45.9 44.5 53.0 57.0 45.9 44.0]';
g1 = [1 2 1 2 1 2 1 2];
g2 = {'hi'; 'hi'; 'lo'; 'lo'; 'hi'; 'hi'; 'lo'; 'lo'};
g3 = {'may'; 'may'; 'may'; 'may'; 'june'; 'june'; 'june'; 'june'};

```

This defines a three-way ANOVA with two levels of each factor. Every observation in  $y$  is identified by a combination of factor levels. If the factors are A, B, and C, then observation  $y(1)$  is associated with

- Level 1 of factor A
- Level 'hi' of factor B
- Level 'may' of factor C

Similarly, observation  $y(6)$  is associated with

- Level 2 of factor A
- Level 'hi' of factor B
- Level 'june' of factor C

To compute the ANOVA, enter

```
p = anovan(y, {g1 g2 g3})
p =
    0.4174
    0.0028
    0.9140
```

Output vector  $p$  contains  $p$ -values for the null hypotheses on the  $N$  main effects. Element  $p(1)$  contains the  $p$  value for the null hypotheses,  $H_{0A}$ , that samples at all levels of factor A are drawn from the same population; element  $p(2)$  contains the  $p$  value for the null hypotheses,  $H_{0B}$ , that samples at all levels of factor B are drawn from the same population; and so on.

If any  $p$  value is near zero, this casts doubt on the associated null hypothesis. For example, a sufficiently small  $p$  value for  $H_{0A}$  suggests that at least one A-sample mean is significantly different from the other A-sample means; that is, there is a main effect due to factor A. You need to choose a bound for the  $p$  value to determine whether a result is statistically significant. It is common to declare a result significant if the  $p$  value is less than 0.05 or 0.01.

anovan also displays a figure showing the standard ANOVA table, which by default divides the variability of the data in  $x$  into

- The variability due to differences between the levels of each factor accounted for in the model (one row for each factor)
- The remaining variability not explained by any systematic source

The ANOVA table has six columns:

- The first shows the source of the variability.
- The second shows the sum of squares (SS) due to each source.
- The third shows the degrees of freedom (df) associated with each source.
- The fourth shows the mean squares (MS), which is the ratio  $SS/df$ .
- The fifth shows the  $F$  statistics, which are the ratios of the mean squares.
- The sixth shows the  $p$ -values for the  $F$  statistics.

The table is shown in the following figure:

Source	Sum Sq.	d.f.	Mean Sq.	F	Prob>F
X1	3.781	1	3.781	0.82	0.4174
X2	199.001	1	199.001	42.95	0.0028
X3	0.061	1	0.061	0.01	0.914
Error	18.535	4	4.634		
Total	221.379	7			

Constrained (Type III) sums of squares.

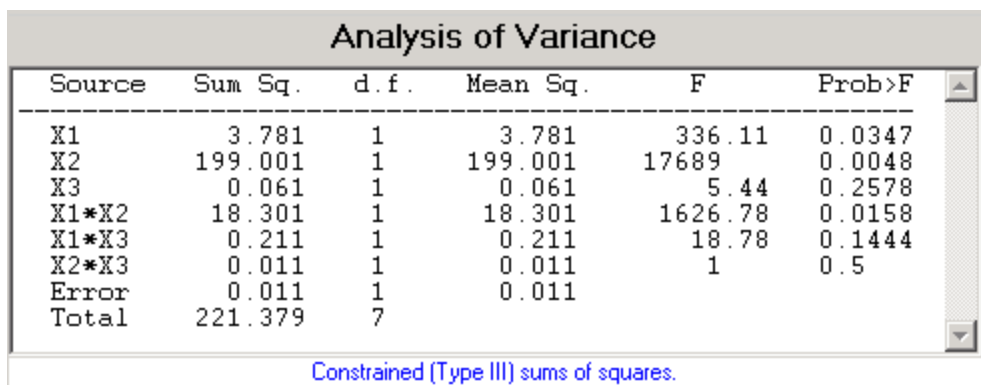

### Two-Factor Interactions

By default, anovan computes  $p$ -values just for the three main effects. To also compute  $p$ -values for the two-factor interactions,  $X1*X2$ ,  $X1*X3$ , and  $X2*X3$ , add the name/value pair 'model', 'interaction' as input arguments.

## anovan

```
p = anovan(y,{g1 g2 g3},'model','interaction')
p =
    0.0347
    0.0048
    0.2578
    0.0158
    0.1444
    0.5000
```

The first three entries of  $p$  are the  $p$ -values for the main effects. The last three entries are the  $p$ -values for the two-factor interactions. You can determine the order in which the two-factor interactions occur from the ANOVAN table shown in the following figure.

Source	Sum Sq.	d. f.	Mean Sq.	F	Prob>F
X1	3.781	1	3.781	336.11	0.0347
X2	199.001	1	199.001	17689	0.0048
X3	0.061	1	0.061	5.44	0.2578
X1*X2	18.301	1	18.301	1626.78	0.0158
X1*X3	0.211	1	0.211	18.78	0.1444
X2*X3	0.011	1	0.011	1	0.5
Error	0.011	1	0.011		
Total	221.379	7			

Constrained (Type III) sums of squares.

### The Stats Structure

The `anovan` test evaluates the hypothesis that the different levels of a factor (or more generally, a term) have the same effect, against the alternative that they do not all have the same effect. Sometimes it is preferable to perform a test to determine which pairs of levels are significantly different, and which are not. Use the `multcompare` function to perform such tests by supplying the `stats` structure as input.

The `stats` structure contains the fields listed below, in addition to a number of other fields required for doing multiple comparisons using the `multcompare` function:

Field	Description
<code>coeffs</code>	Estimated coefficients
<code>coeffnames</code>	Name of term for each coefficient
<code>vars</code>	Matrix of grouping variable values for each term
<code>resid</code>	Residuals from the fitted model

The `stats` structure also contains the following fields if there are random effects:

Field	Description
<code>ems</code>	Expected mean squares
<code>denom</code>	Denominator definition
<code>rtnames</code>	Names of random terms
<code>varest</code>	Variance component estimates (one per random term)
<code>varci</code>	Confidence intervals for variance components

## Examples

“Example: Two-Way ANOVA” on page 8-10 shows how to use `anova2` to analyze the effects of two factors on a response in a balanced design. For a design that is not balanced, use `anovan` instead.

The data in `carbig.mat` gives measurements on 406 cars. Use `anovan` to study how the mileage depends on where and when the cars were made:

```
load carbig

p = anovan(MPG,{org when},'model',2,'sstype',3,...
           'varnames',{'Origin';'Mfg date'})
p =
```

0  
0  
0.3059

Source	Sum Sq.	d.f.	Mean Sq.	F	Prob>F
Origin	5727.2	2	2863.58	115.09	0
Mfg date	4710.3	2	2355.15	94.65	0
Origin*Mfg date	120.5	4	30.12	1.21	0.3059
Error	9679.1	389	24.88		
Total	24252.6	397			

Constrained (Type III) sums of squares.

The  $p$  value for the interaction term is not small, indicating little evidence that the effect of the year or manufacture (when) depends on where the car was made (org). The linear effects of those two factors, however, are significant.

**Purpose**

Ansari-Bradley test

**Syntax**

```
h = ansaribradley(x,y)
h = ansaribradley(x,y,Name,Value)
[h,p] = ansaribradley( ___ )
[h,p,stats] = ansaribradley( ___ )
```

**Description**

`h = ansaribradley(x,y)` returns a test decision for the null hypothesis that the data in vectors `x` and `y` comes from the same distribution, using the Ansari-Bradley test. The alternative hypothesis is that the data in `x` and `y` comes from distributions with the same median and shape but different dispersions (e.g., variances). The result `h` is 1 if the test rejects the null hypothesis at the 5% significance level, or 0 otherwise.

`h = ansaribradley(x,y,Name,Value)` returns a test decision for the Ansari-Bradley test with additional options specified by one or more name-value pair arguments. For example, you can change the significance level, conduct a one-sided test, or use a normal approximation to calculate the value of the test statistic.

`[h,p] = ansaribradley( ___ )` also returns the *p*-value, `p`, of the test, using any of the input arguments in the previous syntaxes.

`[h,p,stats] = ansaribradley( ___ )` also returns the structure `stats` containing information about the test statistic.

**Input Arguments****x - Sample data**

vector | matrix | multidimensional array

Sample data, specified as a vector, matrix, or multidimensional array.

- If `x` and `y` are specified as vectors, they do not need to be the same length.

- If `x` and `y` are specified as matrices, they must have the same number of columns. `ansaribradley` performs separate tests along each column and returns a vector of results.
- If `x` and `y` are specified as multidimensional arrays, `ansaribradley` works along the first nonsingleton dimension. `x` and `y` must have the same size along all remaining dimensions.

## Data Types

single | double

## **y** - Sample data

vector | matrix | multidimensional array

Sample data, specified as a vector, matrix, or multidimensional array.

- If `x` and `y` are specified as vectors, they do not need to be the same length.
- If `x` and `y` are specified as matrices, they must have the same number of columns. `ansaribradley` performs separate tests along each column and returns a vector of results.
- If `x` and `y` are specified as multidimensional arrays, `ansaribradley` works along the first nonsingleton dimension. `x` and `y` must have the same size along all remaining dimensions.

## Data Types

single | double

## Name-Value Pair Arguments

Specify optional comma-separated pairs of `Name`, `Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( ' '). You can specify several name and value pair arguments in any order as `Name1, Value1, ..., NameN, ValueN`.

**Example:** `'Tail', 'right', 'Alpha', 0.01` specifies a right-tailed hypothesis test at the 1% significance level.

## 'Alpha' - Significance level

0.05 (default) | scalar value in the range (0,1)

Significance level of the hypothesis test, specified as the comma-separated pair consisting of 'Alpha' and a scalar value in the range (0,1).

**Example:** 'Alpha',0.01

### **Data Types**

single | double

### **'Dim' - Dimension**

first nonsingleton dimension (default) | positive integer value

Dimension of the input matrix along which to test the means, specified as the comma-separated pair consisting of 'Dim' and a positive integer value. For example, specifying 'Dim',1 tests the column means, while 'Dim',2 tests the row means.

**Example:** 'Dim',2

### **Data Types**

single | double

### **'Tail' - Type of alternative hypothesis**

'both' (default) | 'left' | 'right'

Type of alternative hypothesis to evaluate, specified as the comma-separated pair consisting of 'Tail' and one of the following.

- |         |   |
|---------|---|
| 'both'  | Test the alternative hypothesis that the dispersion parameters of x and y are not equal.      |
| 'right' | Test the alternative hypothesis that the dispersion parameter of x is greater than that of y. |
| 'left'  | Test the alternative hypothesis that the dispersion parameter of x is less than that of y.    |

**Example:** 'Tail','right'

### **'Method' - Computation method**

'exact' | 'approximate'

Computation method for the test statistic, specified as the comma-separated pair consisting of 'Method' and one of the following.

'exact' Compute  $p$  using an exact calculation of the distribution of the test statistic  $W$ . This is the default if  $n$ , the total number of rows in  $x$  and  $y$ , is 25 or less. Note that  $n$  is computed before any NaN values (representing missing data) are removed.

'approximate' Compute  $p$  using a normal approximation for the statistic  $W^*$ . This is the default if  $n$ , the total number of rows in  $x$  and  $y$ , is greater than 25.

**Example:** 'Method', 'exact'

## Output Arguments

### **h** - Hypothesis test result

1 | 0

Hypothesis test result, returned as a logical value.

- If  $h = 1$ , this indicates the rejection of the null hypothesis at the Alpha significance level.
- If  $h = 0$ , this indicates a failure to reject the null hypothesis at the Alpha significance level.

### **p** - **p-value**

scalar value in the range [0,1]

$p$ -value of the test, returned as a scalar value in the range [0,1].  $p$  is the probability of observing a test statistic as extreme as, or more extreme than, the observed value under the null hypothesis. Small values of  $p$  cast doubt on the validity of the null hypothesis.

### **stats** - Test statistics

structure

Test statistics for the Ansari-Bradley test, returned as a structure containing:

- `W` — Value of the test statistic, which is the sum of the Ansari-Bradley ranks for the `x` sample.
- `Wstar` — Approximate normal statistic  $W^*$ .

## Examples

### Test for Equal Variances

Load the sample data. Create data vectors of miles per gallon (MPG) measurements for the model years 1982 and 1976.

```
load carsmall;
x = MPG(Model_Year==82);
y = MPG(Model_Year==76);
```

Test the null hypothesis that the miles per gallon measured in cars from 1982 and 1976 have equal variances.

```
[h,p,stats] = ansaribradley(x,y)
```

```
h =
    0

p =
    0.8426

stats =
    W: 526.9000
   Wstar: 0.1986
```

The returned value of `h = 0` indicates that `ansaribradley` does not reject the null hypothesis at the default 5% significance level.

### One-Sided Hypothesis Test

Load the sample data. Create data vectors of miles per gallon (MPG) measurements for the model years 1982 and 1976.

```
load carsmall;
x = MPG(Model_Year==82);
y = MPG(Model_Year==76);
```

Test the null hypothesis that the miles per gallon measured in cars from 1982 and 1976 have equal variances, against the alternative hypothesis that the variance of cars from 1982 is greater than that of cars from 1976.

```
[h,p,stats] = ansaribradley(x,y,'Tail','right')
```

```
h =
    0
```

```
p =
    0.5787
```

```
stats =
    W: 526.9000
    Wstar: 0.1986
```

The returned value of  $h = 0$  indicates that `ansaribradley` does not reject the null hypothesis that the variance in miles per gallon is the same for the two model years, when the alternative is that the variance of cars from 1982 is greater than that of cars from 1976.

## Definitions

### Ansari-Bradley Test

The Ansari-Bradley test is a nonparametric alternative to the two-sample  $F$ -test of equal variances. It does not require the assumption that  $x$  and  $y$  come from normal distributions. The dispersion of a distribution is generally measured by its variance or standard deviation, but the Ansari-Bradley test can be used with samples from distributions that do not have finite variances.

This test requires that the samples have equal medians. Under that assumption, and if the distributions of the samples are continuous and identical, the test is independent of the distributions. If the samples

do not have the same medians, the results can be misleading. In that case, Ansari and Bradley recommend subtracting the median, but then the distribution of the resulting test under the null hypothesis is no longer independent of the common distribution of  $x$  and  $y$ . If you want to perform the tests with medians subtracted, you should subtract the medians from  $x$  and  $y$  before calling `ansaribradley`.

### **Multidimensional Array**

A multidimensional array has more than two dimensions. For example, if  $x$  is a 1-by-3-by-4 array, then  $x$  is a three-dimensional array.

### **First Nonsingleton Dimension**

The first nonsingleton dimension is the first dimension of an array whose size is not equal to 1. For example, if  $x$  is a 1-by-2-by-3-by-4 array, then the second dimension is the first nonsingleton dimension of  $x$ .

### **See Also**

`vartest2` | `vartestn` | `ttest2`

**Purpose** Interactive analysis of covariance

**Syntax**

```
aoctool(x,y,group)
aoctool(x,y,group,alpha)
aoctool(x,y,group,alpha,xname,yname,gname)
aoctool(x,y,group,alpha,xname,yname,gname,displayopt)
aoctool(x,y,group,alpha,xname,yname,gname,displayopt,model)
h = aoctool(...)
[h,atab,ctab] = aoctool(...)
[h,atab,ctab,stats] = aoctool(...)
```

**Description** `aoctool(x,y,group)` fits a separate line to the column vectors, `x` and `y`, for each group defined by the values in the array `group`. `group` may be a categorical variable, vector, character array, or cell array of strings. These types of models are known as one-way analysis of covariance (ANOCOVA) models. The output consists of three figures:

- An interactive graph of the data and prediction curves
- An ANOVA table
- A table of parameter estimates

You can use the figures to change models and to test different parts of the model. More information about interactive use of the `aoctool` function appears in “Analysis of Covariance Tool” on page 8-27.

`aoctool(x,y,group,alpha)` determines the confidence levels of the prediction intervals. The confidence level is  $100(1-\alpha)\%$ . The default value of `alpha` is 0.05.

`aoctool(x,y,group,alpha,xname,yname,gname)` specifies the name to use for the `x`, `y`, and `g` variables in the graph and tables. If you enter simple variable names for the `x`, `y`, and `g` arguments, the `aoctool` function uses those names. If you enter an expression for one of these arguments, you can specify a name to use in place of that expression by supplying these arguments. For example, if you enter `m(:,2)` as the `x` argument, you might choose to enter `'Col 2'` as the `xname` argument.

`aocool(x,y,group,alpha,xname,yname,gname,displayopt)` enables the graph and table displays when `displayopt` is 'on' (default) and suppresses those displays when `displayopt` is 'off'.

`aocool(x,y,group,alpha,xname,yname,gname,displayopt,model)` specifies the initial model to fit. The value of `model` can be any of the following:

- 'same mean' — Fit a single mean, ignoring grouping
- 'separate means' — Fit a separate mean to each group
- 'same line' — Fit a single line, ignoring grouping
- 'parallel lines' — Fit a separate line to each group, but constrain the lines to be parallel
- 'separate lines' — Fit a separate line to each group, with no constraints

`h = aocool(...)` returns a vector of handles to the line objects in the plot.

`[h,atab,ctab] = aocool(...)` returns cell arrays containing the entries in ANOVA table (`atab`) and the table of coefficient estimates (`ctab`). (You can copy a text version of either table to the clipboard by using the Copy Text item on the **Edit** menu.)

`[h,atab,ctab,stats] = aocool(...)` returns a `stats` structure that you can use to perform a follow-up multiple comparison test. The ANOVA table output includes tests of the hypotheses that the slopes or intercepts are all the same, against a general alternative that they are not all the same. Sometimes it is preferable to perform a test to determine which pairs of values are significantly different, and which are not. You can use the `multcompare` function to perform such tests by supplying the `stats` structure as input. You can test either the slopes, the intercepts, or population marginal means (the heights of the curves at the mean x value).

## Examples

This example illustrates how to fit different models non-interactively. After loading the smaller car data set and fitting a separate-slopes model, you can examine the coefficient estimates.

```
load carsmall
[h,a,c,s] = aoctool(Weight,MPG,Model_Year,0.05,...
                   ' ',' ',' ','off','separate lines');
c(:,1:2)
ans =
    'Term'          'Estimate'
    'Intercept'    [45.97983716833132]
    ' 70'          [-8.58050531454973]
    ' 76'          [-3.89017396094922]
    ' 82'          [12.47067927549897]
    'Slope'        [-0.00780212907455]
    ' 70'          [ 0.00195840368824]
    ' 76'          [ 0.00113831038418]
    ' 82'          [-0.00309671407243]
```

Roughly speaking, the lines relating MPG to Weight have an intercept close to 45.98 and a slope close to -0.0078. Each group's coefficients are offset from these values somewhat. For instance, the intercept for the cars made in 1970 is  $45.98 - 8.58 = 37.40$ .

Next, try a fit using parallel lines. (The ANOVA table shows that the parallel-lines fit is significantly worse than the separate-lines fit.)

```
[h,a,c,s] = aoctool(Weight,MPG,Model_Year,0.05,...
                   ' ',' ',' ','off','parallel lines');
c(:,1:2)
ans =
    'Term'          'Estimate'
    'Intercept'    [43.38984085130596]
    ' 70'          [-3.27948192983761]
    ' 76'          [-1.35036234809006]
```

```
' 82'      [ 4.62984427792768]
'Slope'    [-0.00664751826198]
```

Again, there are different intercepts for each group, but this time the slopes are constrained to be the same.

# TreeBagger.append

---

**Purpose** Append new trees to ensemble

**Syntax** `B = append(B, other)`

**Description** `B = append(B, other)` appends the trees from the `other` ensemble to those in `B`. This method checks for consistency of the `X` and `Y` properties of the two ensembles, as well as consistency of their compact objects and out-of-bag indices, before appending the trees. The output ensemble `B` takes training parameters such as `FBoot`, `Prior`, `Cost`, and `other` from the `B` input. There is no attempt to check if these training parameters are consistent between the two objects.

**See Also** `CompactTreeBagger.combine`

# ProbDistKernel.BandWidth property

---

<b>Purpose</b>	Read-only value specifying bandwidth of kernel smoothing function for ProbDistKernel object
<b>Description</b>	BandWidth is a read-only property of the ProbDistKernel class. BandWidth is a value specifying the width of the kernel smoothing function used to compute a nonparametric estimate of the probability distribution when creating a ProbDistKernel object.
<b>Values</b>	<p>For a distribution specified to cover only the positive numbers or only a finite interval, the data are transformed before the kernel density is applied, and the bandwidth is on the scale of the transformed data.</p> <p>Use this information to view and compare the width of the kernel smoothing function used to create distributions.</p>
<b>See Also</b>	<code>ksdensity</code>

# barttest

---

**Purpose** Bartlett's test

**Syntax**  
`ndim = barttest(X,alpha)`  
`[ndim,prob,chisquare] = barttest(X,alpha)`

**Description** `ndim = barttest(X,alpha)` returns the number of dimensions necessary to explain the nonrandom variation in the data matrix  $X$ , using the significance probability  $\alpha$ . The dimension is determined by a series of hypothesis tests. The test for `ndim=1` tests the hypothesis that the variances of the data values along each principal component are equal, the test for `ndim=2` tests the hypothesis that the variances along the second through last components are equal, and so on.

`[ndim,prob,chisquare] = barttest(X,alpha)` returns the number of dimensions, the significance values for the hypothesis tests, and the  $\chi^2$  values associated with the tests.

## **Examples** **Determine Dimensions Needed to Explain Nonrandom Data Variation**

This example shows how to determine the number of dimensions needed to explain nonrandom data variation, using Bartlett's test.

Generate a 20-by-6 matrix of sample data from a multinomial distribution.

```
rng('default'); % For reproducibility
X = mvnrnd([0 0],[1 0.99; 0.99 1],20);
X(:,3:4) = mvnrnd([0 0],[1 0.99; 0.99 1],20);
X(:,5:6) = mvnrnd([0 0],[1 0.99; 0.99 1],20);
```

Determine the number of dimensions necessary to explain the nonrandom variation in data matrix  $X$ . Report the significance values for the hypothesis tests.

```
[ndim, prob] = barttest(X,0.05)
```

```
ndim =  
      3  
  
prob =  
      0.0000  
      0.0000  
      0.0000  
      0.5148  
      0.3370
```

The results indicate that three dimensions are necessary to explain the nonrandom variation in X.

[pca](#) | [pcacov](#) | [pcares](#)

# bbdesign

---

**Purpose** Box-Behnken design

**Syntax**  
`dBB = bbdesign(n)`  
`[dBB,blocks] = bbdesign(n)`  
`[...] = bbdesign(n,param,val)`

**Description** `dBB = bbdesign(n)` generates a Box-Behnken design for  $n$  factors.  $n$  must be an integer 3 or larger. The output matrix `dBB` is  $m$ -by- $n$ , where  $m$  is the number of runs in the design. Each row represents one run, with settings for all factors represented in the columns. Factor values are normalized so that the cube points take values between -1 and 1.

`[dBB,blocks] = bbdesign(n)` requests a blocked design. The output `blocks` is an  $m$ -by-1 vector of block numbers for each run. Blocks indicate runs that are to be measured under similar conditions to minimize the effect of inter-block differences on the parameter estimates.

`[...] = bbdesign(n,param,val)` specifies one or more optional parameter/value pairs for the design. The following table lists valid parameter/value pairs.

Parameter	Description	Values
'center'	Number of center points.	Integer. The default depends on $n$ .
'blocksize'	Maximum number of points per block.	Integer. The default is Inf.

## Examples

The following creates a 3-factor Box-Behnken design:

```
dBB = bbdesign(3)
dBB =
    -1    -1     0
    -1     1     0
     1    -1     0
```

```

1      1      0
-1     0     -1
-1     0      1
1      0     -1
1      0      1
0     -1     -1
0     -1      1
0      1     -1
0      1      1
0      0      0
0      0      0
0      0      0

```

The center point is run 3 times to allow for a more uniform estimate of the prediction variance over the entire design space.

Visualize the design as follows:

```

plot3(dBB(:,1),dBB(:,2),dBB(:,3),'ro',...
      'MarkerFaceColor','b')
X = [1 -1 -1 -1 1 -1 -1 -1 1 1 -1 -1; ...
     1 1 1 -1 1 1 1 -1 1 1 -1 -1];
Y = [-1 -1 1 -1 -1 -1 1 -1 1 -1 1 -1; ...
     1 -1 1 1 1 -1 1 1 1 -1 1 -1];
Z = [1 1 1 1 -1 -1 -1 -1 -1 -1 -1 -1; ...
     1 1 1 1 -1 -1 -1 -1 1 1 1 1];
line(X,Y,Z,'Color','b')
axis square equal

```

`ccdesign`

**Superclasses** ToolboxFittableParametricDistribution

**Purpose** Beta probability distribution object

**Description** `prob.BetaDistribution` is an object consisting of parameters, a model description, and sample data for a beta probability distribution.

Create a probability distribution object with specified parameter values using `makedist`. Alternatively, fit a distribution to data using `fitdist` or the Distribution Fitting app.

**Construction** `pd = makedist('Beta')` creates a beta probability distribution object using the default parameter values.

`pd = makedist('Beta','a',a,'b',b)` creates a beta probability distribution object using the specified parameter values.

### Input Arguments

#### **a** - First shape parameter

1 (default) | positive scalar value

First shape parameter of the beta distribution, specified as a positive scalar value.

#### Data Types

single | double

#### **b** - Second shape parameter

1 (default) | positive scalar value

Second shape parameter of the beta distribution, specified as a positive scalar value.

#### Data Types

single | double

**Properties** **a**

First shape parameter of the beta distribution, stored as a positive scalar value.

# prob.BetaDistribution

---

## Data Types

single | double

## **b**

Second shape parameter of the beta distribution, stored as a positive scalar value.

## Data Types

single | double

## DistributionName

Name of the probability distribution, stored as a valid probability distribution name string. This property is read-only.

## Data Types

char

## InputData

Data used for distribution fitting, stored as a structure containing the following:

- data: Data vector used for distribution fitting.
- cens: Censoring vector, or empty if none.
- freq: Frequency vector, or empty if none.

This property is read-only.

## Data Types

single | double

## IsTruncated

Logical flag for truncated distribution, stored as a logical value. If IsTruncated equals 0, the distribution is not truncated. If IsTruncated equals 1, the distribution is truncated. This property is read-only.

## Data Types

logical

## **NumParameters**

Number of parameters for the probability distribution, stored as a positive integer value. This property is read-only.

## **Data Types**

single | double

## **ParameterCovariance**

Covariance matrix of the parameter estimates, stored as a  $p$ -by- $p$  matrix, where  $p$  is the number of parameters in the distribution. The  $(i,j)$  element is the covariance between the estimates of the  $i$ th parameter and the  $j$ th parameter. The  $(i,i)$  element is the estimated variance of the  $i$ th parameter. If parameter  $i$  is fixed rather than estimated by fitting the distribution to data, then the  $(i,i)$  elements of the covariance matrix are 0. This property is read-only.

## **Data Types**

single | double

## **ParameterDescription**

Descriptions of distribution parameters, stored as a cell array of strings. Each cell contains a short description of one distribution parameter. This property is read-only.

## **Data Types**

char

## **ParameterIsFixed**

Logical flag for fixed parameters, stored as an array of logical values. If 0, the corresponding parameter in the `ParameterNames` array is not fixed. If 1, the corresponding parameter in the `ParameterNames` array is fixed. This property is read-only.

## **Data Types**

logical

## **ParameterNames**

# prob.BetaDistribution

---

Names of distribution parameters, stored as a cell array of strings.  
This property is read-only.

## Data Types

char

## ParameterValues

Values of distribution parameters, stored as a vector. This  
property is read-only.

## Data Types

single | double

## Truncation

Truncation interval for the probability distribution, stored as a  
vector containing the lower and upper truncation boundaries.  
This property is read-only.

## Data Types

single | double

### Beta Distribution

The beta distribution describes a family of curves that are unique in that they are nonzero only on the interval (0,1). A more general version of the distribution assigns parameters to the endpoints of the interval.

The beta distribution uses the following parameters.

Parameter	Description	Support
a	First shape parameter	$a > 0$
b	Second shape parameter	$b > 0$

The probability density function (pdf) is

# prob.BetaDistribution

---

$$f(x|a,b) = \frac{1}{B(a,b)} x^{a-1} (1-x)^{b-1} \quad ; \quad 0 < x < 1,$$

where  $B(\cdot)$  is the beta function.

## Examples

### Create a Beta Distribution Object Using Default Parameters

Create a beta distribution object using the default parameter values.

```
pd = makedist('Beta')
```

```
pd =
```

```
BetaDistribution
```

```
Beta distribution
```

```
a = 1
```

```
b = 1
```

### Create a Beta Distribution Object Using Specified Parameters

Create a beta distribution object by specifying the parameter values.

```
pd = makedist('Beta','a',2,'b',4)
```

```
pd =
```

```
BetaDistribution
```

```
Beta distribution
```

```
a = 2
```

```
b = 4
```

Compute the mean of the distribution.

```
m = mean(pd)
```

```
m =
```

- Class Attributes
- Property Attributes

# betacdf

---

**Purpose** Beta cumulative distribution function

**Syntax**  
`p = betacdf(x,a,b)`  
`p = betacdf(x,a,b,'upper')`

**Description** `p = betacdf(x,a,b)` returns the beta cdf at each of the values in `x` using the corresponding parameters in `a` and `b`. `x`, `a`, and `b` can be vectors, matrices, or multidimensional arrays that all have the same size. A scalar input is expanded to a constant array with the same dimensions as the other inputs. The parameters in `a` and `b` must all be positive, and the values in `x` must lie on the interval `[0,1]`.

`p = betacdf(x,a,b,'upper')` returns the complement of the beta cdf at each of the values in `x`, using an algorithm that more accurately computes the extreme upper tail probabilities.

The beta cdf for a given value `x` and given pair of parameters `a` and `b` is

$$p = F(x | a, b) = \frac{1}{B(a, b)} \int_0^x t^{a-1} (1-t)^{b-1} dt$$

where  $B(\cdot)$  is the Beta function.

## Examples **Compute Beta Distribution CDF**

Compute the cdf for a beta distribution with parameters `a = 2` and `b = 2`.

```
x = 0.1:0.2:0.9;  
a = 2;  
b = 2;  
p = betacdf(x,a,b)
```

```
p =  
    0.0280    0.2160    0.5000    0.7840    0.9720
```

```
a = [1 2 3];
```

```
p = betacdf(0.5,a,a)
```

```
p =  
    0.5000  0.5000  0.5000
```

**How To**

- “Beta Distribution” on page B-5

# betafit

---

**Purpose** Beta parameter estimates

**Syntax**  
`phat = betafit(data)`  
`[phat,pci] = betafit(data,alpha)`

**Description** `phat = betafit(data)` computes the maximum likelihood estimates of the beta distribution parameters  $a$  and  $b$  from the data in the vector `data` and returns a column vector containing the  $a$  and  $b$  estimates, where the beta cdf is given by

$$F(x | a, b) = \frac{1}{B(a, b)} \int_0^x t^{a-1} (1-t)^{b-1} dt$$

and  $B(\cdot)$  is the Beta function. The elements of `data` must lie in the open interval  $(0, 1)$ , where the beta distribution is defined. However, it is sometimes also necessary to fit a beta distribution to data that include exact zeros or ones. For such data, the beta likelihood function is unbounded, and standard maximum likelihood estimation is not possible. In that case, `betafit` maximizes a modified likelihood that incorporates the zeros or ones by treating them as if they were values that have been left-censored at `sqrt(realmin)` or right-censored at `1-eps/2`, respectively.

`[phat,pci] = betafit(data,alpha)` returns confidence intervals on the  $a$  and  $b$  parameters in the 2-by-2 matrix `pci`. The first column of the matrix contains the lower and upper confidence bounds for parameter  $a$ , and the second column contains the confidence bounds for parameter  $b$ . The optional input argument `alpha` is a value in the range  $[0, 1]$  specifying the width of the confidence intervals. By default, `alpha` is 0.05, which corresponds to 95% confidence intervals. The confidence intervals are based on a normal approximation for the distribution of the logs of the parameter estimates.

**Examples** This example generates 100 beta distributed observations. The true  $a$  and  $b$  parameters are 4 and 3, respectively. Compare these to the

values returned in `p` by the beta fit. Note that the columns of `ci` both bracket the true parameters.

```
data = betarnd(4,3,100,1);
[p,ci] = betafit(data,0.01)
p =
    5.5328    3.8097
ci =
    3.6538    2.6197
    8.3781    5.5402
```

## How To

- “Beta Distribution” on page B-5

# betainv

---

**Purpose** Beta inverse cumulative distribution function

**Syntax** `X = betainv(P,A,B)`

**Description** `X = betainv(P,A,B)` computes the inverse of the beta cdf with parameters specified by A and B for the corresponding probabilities in P. P, A, and B can be vectors, matrices, or multidimensional arrays that are all the same size. A scalar input is expanded to a constant array with the same dimensions as the other inputs. The parameters in A and B must all be positive, and the values in P must lie on the interval [0, 1].

The inverse beta cdf for a given probability  $p$  and a given pair of parameters  $a$  and  $b$  is

$$x = F^{-1}(p | a, b) = \{x : F(x | a, b) = p\}$$

where

$$p = F(x | a, b) = \frac{1}{B(a, b)} \int_0^x t^{a-1} (1-t)^{b-1} dt$$

and  $B(\cdot)$  is the Beta function. Each element of output X is the value whose cumulative probability under the beta cdf defined by the corresponding parameters in A and B is specified by the corresponding value in P.

**Algorithms** The `betainv` function uses Newton's method with modifications to constrain steps to the allowable range for  $x$ , i.e., [0 1].

**Examples**

```
p = [0.01 0.5 0.99];  
x = betainv(p,10,5)  
x =  
    0.3726    0.6742    0.8981
```

According to this result, for a beta cdf with  $a = 10$  and  $b = 5$ , a value less than or equal to 0.3726 occurs with probability 0.01. Similarly,

values less than or equal to 0.6742 and 0.8981 occur with respective probabilities 0.5 and 0.99.

**How To**

- “Beta Distribution” on page B-5

# betalike

---

**Purpose** Beta negative log-likelihood

**Syntax**  
`nlogL = betalike(params,data)`  
`[nlogL,AVAR] = betalike(params,data)`

**Description** `nlogL = betalike(params,data)` returns the negative of the beta log-likelihood function for the beta parameters  $a$  and  $b$  specified in vector `params` and the observations specified in the column vector `data`.

The elements of `data` must lie in the open interval  $(0, 1)$ , where the beta distribution is defined. However, it is sometimes also necessary to fit a beta distribution to data that include exact zeros or ones. For such data, the beta likelihood function is unbounded, and standard maximum likelihood estimation is not possible. In that case, `betalike` computes a modified likelihood that incorporates the zeros or ones by treating them as if they were values that have been left-censored at `sqrt(realmin)` or right-censored at `1-eps/2`, respectively.

`[nlogL,AVAR] = betalike(params,data)` also returns `AVAR`, which is the asymptotic variance-covariance matrix of the parameter estimates if the values in `params` are the maximum likelihood estimates. `AVAR` is the inverse of Fisher's information matrix. The diagonal elements of `AVAR` are the asymptotic variances of their respective parameters.

`betalike` is a utility function for maximum likelihood estimation of the beta distribution. The likelihood assumes that all the elements in the data sample are mutually independent. Since `betalike` returns the negative beta log-likelihood function, minimizing `betalike` using `fminsearch` is the same as maximizing the likelihood.

**Examples** This example continues the `betafit` example, which calculates estimates of the beta parameters for some randomly generated beta distributed data.

```
r = betarnd(4,3,100,1);  
[nlogl,AVAR] = betalike(betafit(r),r)  
nlogl =
```

**How To**

- “Beta Distribution” on page B-5

# betapdf

---

**Purpose** Beta probability density function

**Syntax** `Y = betapdf(X,A,B)`

**Description** `Y = betapdf(X,A,B)` computes the beta pdf at each of the values in `X` using the corresponding parameters in `A` and `B`. `X`, `A`, and `B` can be vectors, matrices, or multidimensional arrays that all have the same size. A scalar input is expanded to a constant array with the same dimensions of the other inputs. The parameters in `A` and `B` must all be positive, and the values in `X` must lie on the interval `[0, 1]`.

The beta probability density function for a given value  $x$  and given pair of parameters  $a$  and  $b$  is

$$y = f(x | a, b) = \frac{1}{B(a, b)} x^{a-1} (1-x)^{b-1} I_{(0,1)}(x)$$

where  $B(\cdot)$  is the Beta function. The indicator function  $I_{(0,1)}(x)$  ensures that only values of  $x$  in the range  $(0, 1)$  have nonzero probability. The uniform distribution on  $(0, 1)$  is a degenerate case of the beta pdf where  $a = 1$  and  $b = 1$ .

A *likelihood function* is the pdf viewed as a function of the parameters. Maximum likelihood estimators (MLEs) are the values of the parameters that maximize the likelihood function for a fixed value of  $x$ .

**Examples**

```
a = [0.5 1; 2 4]
a =
    0.5000    1.0000
    2.0000    4.0000
y = betapdf(0.5, a, a)
y =
    0.6366    1.0000
    1.5000    2.1875
```

**How To**

- “Beta Distribution” on page B-5

# betarnd

---

**Purpose** Beta random numbers

**Syntax**  
R = betarnd(A,B)  
R = betarnd(A,B,m,n,...)  
R = betarnd(A,B,[m,n,...])

**Description** R = betarnd(A,B) generates random numbers from the beta distribution with parameters specified by A and B. A and B can be vectors, matrices, or multidimensional arrays that have the same size, which is also the size of R. A scalar input for A or B is expanded to a constant array with the same dimensions as the other input.

R = betarnd(A,B,m,n,...) or R = betarnd(A,B,[m,n,...]) generates an m-by-n-by-... array containing random numbers from the beta distribution with parameters A and B. A and B can each be scalars or arrays of the same size as R.

**Examples**

```
a = [1 1;2 2];  
b = [1 2;1 2];  
  
r = betarnd(a,b)  
r =  
    0.6987    0.6139  
    0.9102    0.8067  
  
r = betarnd(10,10,[1 5])  
r =  
    0.5974    0.4777    0.5538    0.5465    0.6327  
  
r = betarnd(4,2,2,3)  
r =  
    0.3943    0.6101    0.5768  
    0.5990    0.2760    0.5474
```

**See Also** random | betapdf | betafit | betainv | betastat | betalike | betacdf

**How To**

- “Beta Distribution” on page B-5

# betastat

---

**Purpose** Beta mean and variance

**Syntax** `[M,V] = betastat(A,B)`

**Description** `[M,V] = betastat(A,B)`, with  $A > 0$  and  $B > 0$ , returns the mean of and variance for the beta distribution with parameters specified by  $A$  and  $B$ .  $A$  and  $B$  can be vectors, matrices, or multidimensional arrays that have the same size, which is also the size of  $M$  and  $V$ . A scalar input for  $A$  or  $B$  is expanded to a constant array with the same dimensions as the other input.

The mean of the beta distribution with parameters  $a$  and  $b$  is  $a / (a + b)$  and the variance is

$$\frac{ab}{(a+b+1)(a+b)^2}$$

**Examples** If parameters  $a$  and  $b$  are equal, the mean is  $1/2$ .

```
a = 1:6;
[m,v] = betastat(a,a)
m =
    0.5000    0.5000    0.5000    0.5000    0.5000    0.5000
v =
    0.0833    0.0500    0.0357    0.0278    0.0227    0.0192
```

# prob.BinomialDistribution

---

**Superclasses**    `ToolboxFittableParametricDistribution`

**Purpose**            Binomial probability distribution object

**Description**     `prob.BinomialDistribution` is an object consisting of parameters, a model description, and sample data for a binomial probability distribution.

Create a probability distribution object with specified parameter values using `makedist`. Alternatively, fit a distribution to data using `fitdist` or the Distribution Fitting app.

**Construction**    `pd = makedist('Binomial')` creates a binomial probability distribution object using the default parameter values.

`pd = makedist('Binomial','N',n,'p',p)` creates a binomial probability distribution object using the specified parameter values.

## Input Arguments

### **n - Number of trials**

1 (default) | positive integer value

Number of trials for the binomial distribution, specified as a positive integer value.

### **Data Types**

single | double

### **p - Probability of success**

0.5 (default) | positive scalar value in the range [0,1]

Probability of success of any individual trial for the binomial distribution, specified as a positive scalar value in the range [0,1].

### **Data Types**

single | double

## Properties

### **N**

Number of trials for the binomial distribution, stored as a positive integer value.

#### **Data Types**

single | double

### **p**

Probability of success of any individual trial for the binomial distribution, stored as a positive scalar value in the range [0,1].

#### **Data Types**

single | double

### **DistributionName**

Name of the probability distribution, stored as a valid probability distribution name string. This property is read-only.

#### **Data Types**

char

### **InputData**

Data used for distribution fitting, stored as a structure containing the following:

- data: Data vector used for distribution fitting.
- cens: Censoring vector, or empty if none.
- freq: Frequency vector, or empty if none.

This property is read-only.

#### **Data Types**

single | double

### **IsTruncated**

Logical flag for truncated distribution, stored as a logical value. If IsTruncated equals 0, the distribution is not truncated.

# prob.BinomialDistribution

---

If `IsTruncated` equals 1, the distribution is truncated. This property is read-only.

## Data Types

logical

## NumParameters

Number of parameters for the probability distribution, stored as a positive integer value. This property is read-only.

## Data Types

single | double

## ParameterCovariance

Covariance matrix of the parameter estimates, stored as a  $p$ -by- $p$  matrix, where  $p$  is the number of parameters in the distribution. The  $(i,j)$  element is the covariance between the estimates of the  $i$ th parameter and the  $j$ th parameter. The  $(i,i)$  element is the estimated variance of the  $i$ th parameter. If parameter  $i$  is fixed rather than estimated by fitting the distribution to data, then the  $(i,i)$  elements of the covariance matrix are 0. This property is read-only.

## Data Types

single | double

## ParameterDescription

Descriptions of distribution parameters, stored as a cell array of strings. Each cell contains a short description of one distribution parameter. This property is read-only.

## Data Types

char

## ParameterIsFixed

Logical flag for fixed parameters, stored as an array of logical values. If 0, the corresponding parameter in the `ParameterNames` array is not fixed. If 1, the corresponding parameter in the `ParameterNames` array is fixed. This property is read-only.

## Data Types

logical

## ParameterNames

Names of distribution parameters, stored as a cell array of strings. This property is read-only.

## Data Types

char

## ParameterValues

Values of distribution parameters, stored as a vector. This property is read-only.

## Data Types

single | double

## Truncation

Truncation interval for the probability distribution, stored as a vector containing the lower and upper truncation boundaries. This property is read-only.

## Data Types

single | double

### Binomial Distribution

The binomial distribution models the total number of successes in repeated trials from an infinite population under the following conditions:

- Only two outcomes are possible for each of  $n$  trials.
- The probability of success for each trial is constant.
- All trials are independent of each other.

The binomial distribution uses the following parameters.

Parameter	Description	Support
N	Number of trials	positive integer
p	Probability of success	$0 \leq p \leq 1$

The probability density function (pdf) is

$$f(x | n, p) = \binom{n}{x} p^x (1-p)^{n-x} \quad ; \quad x = 0, 1, 2, \dots, n,$$

where  $x$  is the number of successes in  $n$  trials of a Bernoulli process with probability of success  $p$ .

## Examples

## Concepts

- “Binomial Distribution” on page B-9
- “Bernoulli Distribution” on page B-3
- Class Attributes
- Property Attributes

**Purpose** Binomial cumulative distribution function

**Syntax**  
`y = binocdf(x,N,p)`  
`y = binocdf(x,N,p,'upper')`

**Description** `y = binocdf(x,N,p)` computes a binomial cdf at each of the values in `x` using the corresponding number of trials in `N` and probability of success for each trial in `p`. `x`, `N`, and `p` can be vectors, matrices, or multidimensional arrays that are all the same size. A scalar input is expanded to a constant array with the same dimensions of the other inputs. The values in `N` must all be positive integers, the values in `x` must lie on the interval  $[0, N]$ , and the values in `p` must lie on the interval  $[0, 1]$ .

`y = binocdf(x,N,p,'upper')` returns the complement of the binomial cdf at each value in `x`, using an algorithm that more accurately computes the extreme upper tail probabilities.

The binomial cdf for a given value  $x$  and a given pair of parameters  $n$  and  $p$  is

$$y = F(x | n, p) = \sum_{i=0}^x \binom{n}{i} p^i (1-p)^{(n-i)} I_{(0,1,\dots,n)}(i).$$

The result,  $y$ , is the probability of observing up to  $x$  successes in  $n$  independent trials, where the probability of success in any given trial is

$p$ . The indicator function  $I_{(0,1,\dots,n)}(i)$  ensures that  $x$  only adopts values of  $0, 1, \dots, n$ .

## Examples **Compute Binomial CDF**

If a baseball team plays 162 games in a season and has a 50-50 chance of winning any game, then the probability of that team winning more than 100 games in a season is:

```
1 - binocdf(100,162,0.5)
```

# binocdf

---

```
ans =
```

```
0.0010
```

The result is 0.001 (i.e.,  $1 - 0.999$ ). If a team wins 100 or more games in a season, this result suggests that it is likely that the team's true probability of winning any game is greater than 0.5.

## How To

- “Binomial Distribution” on page B-9

**Purpose**

Binomial parameter estimates

**Syntax**

```
phat = binofit(x,n)
[phat,pci] = binofit(x,n)
[phat,pci] = binofit(x,n,alpha)
```

**Description**

`phat = binofit(x,n)` returns a maximum likelihood estimate of the probability of success in a given binomial trial based on the number of successes, `x`, observed in `n` independent trials. If `x = (x(1), x(2), ... x(k))` is a vector, `binofit` returns a vector of the same size as `x` whose `i`th entry is the parameter estimate for `x(i)`. All `k` estimates are independent of each other. If `n = (n(1), n(2), ..., n(k))` is a vector of the same size as `x`, the binomial fit, `binofit`, returns a vector whose `i`th entry is the parameter estimate based on the number of successes `x(i)` in `n(i)` independent trials. A scalar value for `x` or `n` is expanded to the same size as the other input.

`[phat,pci] = binofit(x,n)` returns the probability estimate, `phat`, and the 95% confidence intervals, `pci`. `binofit` uses the Clopper-Pearson method to calculate confidence intervals.

`[phat,pci] = binofit(x,n,alpha)` returns the  $100(1 - \alpha)\%$  confidence intervals. For example, `alpha = 0.01` yields 99% confidence intervals.

---

**Note** `binofit` behaves differently than other Statistics Toolbox functions that compute parameter estimates, in that it returns independent estimates for each entry of `x`. By comparison, `expfit` returns a single parameter estimate based on all the entries of `x`.

---

Unlike most other distribution fitting functions, the `binofit` function treats its input `x` vector as a collection of measurements from separate samples. If you want to treat `x` as a single sample and compute a single parameter estimate for it, you can use `binofit(sum(x),sum(n))` when `n` is a vector, and `binofit(sum(X),N*length(X))` when `n` is a scalar.

## Examples

This example generates a binomial sample of 100 elements, where the probability of success in a given trial is 0.6, and then estimates this probability from the outcomes in the sample.

```
r = binornd(100,0.6);  
[phat,pci] = binofit(r,100)  
phat =  
    0.5800  
pci =  
    0.4771    0.6780
```

The 95% confidence interval, `pci`, contains the true value, 0.6.

## How To

- “Binomial Distribution” on page B-9

**Purpose** Binomial inverse cumulative distribution function

**Syntax** `X = binoinv(Y,N,P)`

**Description** `X = binoinv(Y,N,P)` returns the smallest integer  $X$  such that the binomial cdf evaluated at  $X$  is equal to or exceeds  $Y$ . You can think of  $Y$  as the probability of observing  $X$  successes in  $N$  independent trials where  $P$  is the probability of success in each trial. Each  $X$  is a positive integer less than or equal to  $N$ .

$Y$ ,  $N$ , and  $P$  can be vectors, matrices, or multidimensional arrays that all have the same size. A scalar input is expanded to a constant array with the same dimensions as the other inputs. The parameters in  $N$  must be positive integers, and the values in both  $P$  and  $Y$  must lie on the interval  $[0\ 1]$ .

**Examples** If a baseball team has a 50-50 chance of winning any game, what is a reasonable range of games this team might win over a season of 162 games?

```
binoinv([0.05 0.95],162,0.5)
ans =
    71    91
```

This result means that in 90% of baseball seasons, a .500 team should win between 71 and 91 games.

**See Also** `icdf` | `binopdf` | `binocdf` | `binofit` | `binostat` | `binornd`

**How To** • “Binomial Distribution” on page B-9

# binopdf

---

**Purpose** Binomial probability density function

**Syntax** `Y = binopdf(X,N,P)`

**Description** `Y = binopdf(X,N,P)` computes the binomial pdf at each of the values in `X` using the corresponding number of trials in `N` and probability of success for each trial in `P`. `Y`, `N`, and `P` can be vectors, matrices, or multidimensional arrays that all have the same size. A scalar input is expanded to a constant array with the same dimensions of the other inputs.

The parameters in `N` must be positive integers, and the values in `P` must lie on the interval `[0, 1]`.

The binomial probability density function for a given value  $x$  and given pair of parameters  $n$  and  $p$  is

$$y = f(x | n, p) = \binom{n}{x} p^x q^{(n-x)} I_{(0,1,\dots,n)}(x)$$

where  $q = 1 - p$ . The result,  $y$ , is the probability of observing  $x$  successes in  $n$  independent trials, where the probability of success in any *given* trial is  $p$ . The indicator function  $I_{(0,1,\dots,n)}(x)$  ensures that  $x$  only adopts values of  $0, 1, \dots, n$ .

**Examples** A Quality Assurance inspector tests 200 circuit boards a day. If 2% of the boards have defects, what is the probability that the inspector will find no defective boards on any given day?

```
binopdf(0,200,0.02)
ans =
    0.0176
```

What is the most likely number of defective boards the inspector will find?

```
defects=0:200;
y = binopdf(defects,200,.02);
```

```
[x,i]=max(y);  
defects(i)  
ans =  
    4
```

**How To**

- “Binomial Distribution” on page B-9

# binornd

---

**Purpose** Binomial random numbers

**Syntax**  
`R = binornd(N,P)`  
`R = binornd(N,P,m,n,...)`  
`R = binornd(N,P,[m,n,...])`

**Description** `R = binornd(N,P)` generates random numbers from the binomial distribution with parameters specified by the number of trials, `N`, and probability of success for each trial, `P`. `N` and `P` can be vectors, matrices, or multidimensional arrays that have the same size, which is also the size of `R`. A scalar input for `N` or `P` is expanded to a constant array with the same dimensions as the other input.

`R = binornd(N,P,m,n,...)` or `R = binornd(N,P,[m,n,...])` generates an `m`-by-`n`-by-... array containing random numbers from the binomial distribution with parameters `N` and `P`. `N` and `P` can each be scalars or arrays of the same size as `R`.

**Algorithms** The `binornd` function uses the direct method using the definition of the binomial distribution as a sum of Bernoulli random variables.

**Examples**

```
n = 10:10:60;  
  
r1 = binornd(n,1./n)  
r1 =  
    2    1    0    1    1    2  
  
r2 = binornd(n,1./n,[1 6])  
r2 =  
    0    1    2    1    3    1  
  
r3 = binornd(n,1./n,1,6)  
r3 =  
    0    1    1    1    0    3
```

**See Also** `random` | `binoinv` | `binocdf` | `binofit` | `binostat` | `binopdf`

**How To**

- “Binomial Distribution” on page B-9

# binostat

---

**Purpose** Binomial mean and variance

**Syntax** `[M,V] = binostat(N,P)`

**Description** `[M,V] = binostat(N,P)` returns the mean of and variance for the binomial distribution with parameters specified by the number of trials,  $N$ , and probability of success for each trial,  $P$ .  $N$  and  $P$  can be vectors, matrices, or multidimensional arrays that have the same size, which is also the size of  $M$  and  $V$ . A scalar input for  $N$  or  $P$  is expanded to a constant array with the same dimensions as the other input.

The mean of the binomial distribution with parameters  $n$  and  $p$  is  $np$ . The variance is  $npq$ , where  $q = 1-p$ .

## Examples

```
n = logspace(1,5,5)
n =
    10    100   1000  10000 100000
```

```
[m,v] = binostat(n,1./n)
m =
    1    1    1    1    1
v =
    0.9000    0.9900    0.9990    0.9999    1.0000
```

```
[m,v] = binostat(n,1/2)
m =
    5    50   500   5000  50000
v =
    1.0e+04 *
    0.0003    0.0025    0.0250    0.2500    2.5000
```

**How To** • “Binomial Distribution” on page B-9

**Purpose**

Biplot

**Syntax**

```
biplot(coefs)
h = biplot(coefs, 'Name', Value)
```

**Description**

`biplot(coefs)` creates a biplot of the coefficients in the matrix `coefs`. The biplot is 2-D if `coefs` has two columns or 3-D if it has three columns. `coefs` usually contains principal component coefficients created with `pca`, `pcacov`, or factor loadings estimated with `factoran`. The axes in the biplot represent the principal components or latent factors (columns of `coefs`), and the observed variables (rows of `coefs`) are represented as vectors.

A biplot allows you to visualize the magnitude and sign of each variable's contribution to the first two or three principal components, and how each observation is represented in terms of those components.

`biplot` imposes a sign convention, forcing the element with largest magnitude in each column of `coefs` to be positive. This flips some of the vectors in `coefs` to the opposite direction, but often makes the plot easier to read. Interpretation of the plot is unaffected, because changing the sign of a coefficient vector does not change its meaning.

`biplot` scales the scores so that they fit on the plot: It divides each score by the maximum absolute value of all scores, and multiplies by the maximum coefficient length of `coefs`. Then `biplot` changes the sign of score coordinates according to the sign convention for the `coefs`.

`h = biplot(coefs, 'Name', Value)` specifies one or more name/value input pairs and returns a column vector of handles to the graphics objects created by `biplot`. The `h` contains, in order, handles corresponding to variables (line handles, followed by marker handles, followed by text handles), to observations (if present, marker handles followed by text handles), and to the axis lines.

**Input Arguments****Name-Value Pair Arguments****'Scores'**

# biplot

---

Plots both `coefs` and the `scores` in the matrix `scores` in the biplot. `scores` usually contains principal component scores created with `pca` or factor scores estimated with `factoran`. Each observation (row of `scores`) is represented as a point in the biplot.

## 'VarLabels'

Labels each vector (variable) with the text in the character array or cell array `varlabels`.

## 'ObsLabels'

Uses the text in the character array or cell array `obslabels` as observation names when displaying data cursors.

## 'Positive'

- 'true' — restricts the biplot to the positive quadrant (in 2-D) or octant (in 3-D).
- 'false' — makes the biplot over the range  $\pm \max(\text{coefs}(:))$  for all coordinates.

**Default:** false

## 'PropertyName'

Specifies optional property name/value pairs for all line graphics objects created by `biplot`.

## Examples

Perform a principal component analysis of the data in `carsmall.mat`:

```
load carsmall
x = [Acceleration Displacement Horsepower MPG Weight];
x = x(all(~isnan(x),2),:);

[coefs,score] = pca(zscore(x));
```

View the data and the original variables in the space of the first three principal components:

```
vbls = {'Accel','Disp','HP','MPG','Wgt'};  
biplot(coefs(:,1:3),'scores',score(:,1:3),...  
       'varlabels',vbls);
```

# prob.BirnbaumSaundersDistribution

---

**Superclasses** ToolboxFittableParametricDistribution

**Purpose** Birnbaum-Saunders probability distribution object

**Description** `prob.BirnbaumSaundersDistribution` is an object consisting of parameters, a model description, and sample data for a Birnbaum-Saunders probability distribution.

Create a probability distribution object with specified parameter values using `makedist`. Alternatively, fit a distribution to data using `fitdist` or the Distribution Fitting app.

**Construction** `pd = makedist('BirnbaumSaunders')` creates a Birnbaum-Saunders probability distribution object using the default parameter values.

`pd = makedist('BirnbaumSaunders', 'beta', beta, 'gamma', gamma)` creates a Birnbaum-Saunders distribution object using the specified parameter values.

## Input Arguments

### **beta** - Scale parameter

1 (default) | positive scalar value

Scale parameter of the Birnbaum-Saunders distribution, specified as a positive scalar value.

### **Data Types**

single | double

### **gamma** - Shape parameter

1 (default) | nonnegative scalar value

Shape parameter of the Birnbaum-Saunders distribution, specified as a nonnegative scalar value.

### **Data Types**

single | double

## Properties

### **beta**

Scale parameter of the Birnbaum-Saunders distribution, stored as a positive scalar value.

### **Data Types**

single | double

### **gamma**

Shape parameter of the Birnbaum-Saunders distribution, stored as a nonnegative scalar value.

### **Data Types**

single | double

### **DistributionName**

Name of the probability distribution, stored as a valid probability distribution name string. This property is read-only.

### **Data Types**

char

### **InputData**

Data used for distribution fitting, stored as a structure containing the following:

- data: Data vector used for distribution fitting.
- cens: Censoring vector, or empty if none.
- freq: Frequency vector, or empty if none.

This property is read-only.

### **Data Types**

single | double

### **IsTruncated**

Logical flag for truncated distribution, stored as a logical value. If IsTruncated equals 0, the distribution is not truncated.

# prob.BirnbaumSaundersDistribution

---

If `IsTruncated` equals 1, the distribution is truncated. This property is read-only.

## Data Types

logical

## NumParameters

Number of parameters for the probability distribution, stored as a positive integer value. This property is read-only.

## Data Types

single | double

## ParameterCovariance

Covariance matrix of the parameter estimates, stored as a  $p$ -by- $p$  matrix, where  $p$  is the number of parameters in the distribution. The  $(i,j)$  element is the covariance between the estimates of the  $i$ th parameter and the  $j$ th parameter. The  $(i,i)$  element is the estimated variance of the  $i$ th parameter. If parameter  $i$  is fixed rather than estimated by fitting the distribution to data, then the  $(i,i)$  elements of the covariance matrix are 0. This property is read-only.

## Data Types

single | double

## ParameterDescription

Descriptions of distribution parameters, stored as a cell array of strings. Each cell contains a short description of one distribution parameter. This property is read-only.

## Data Types

char

## ParameterIsFixed

Logical flag for fixed parameters, stored as an array of logical values. If 0, the corresponding parameter in the `ParameterNames` array is not fixed. If 1, the corresponding parameter in the `ParameterNames` array is fixed. This property is read-only.

## Data Types

logical

## ParameterNames

Names of distribution parameters, stored as a cell array of strings. This property is read-only.

## Data Types

char

## ParameterValues

Values of distribution parameters, stored as a vector. This property is read-only.

## Data Types

single | double

## Truncation

Truncation interval for the probability distribution, stored as a vector containing the lower and upper truncation boundaries. This property is read-only.

## Data Types

single | double

## Methods

### Inherited Methods

cdf	Cumulative distribution function of probability distribution object
icdf	Inverse cumulative distribution function of probability distribution object
iqr	Interquartile range of probability distribution object
median	Median of probability distribution object

# prob.BirnbaumSaundersDistribution

---

pdf	Probability density function of probability distribution object
random	Generate random numbers from probability distribution object
truncate	Truncate probability distribution object
mean	Mean of probability distribution object
negloglik	Negative loglikelihood of probability distribution object
paramci	Confidence intervals for probability distribution parameters
proflik	Profile likelihood function for probability distribution object
std	Standard deviation of probability distribution object
var	Variance of probability distribution object

## Definitions

### Birnbaum-Saunders Distribution

The Birnbaum-Saunders distribution was originally proposed as a lifetime model for materials subject to cyclic patterns of stress and strain, where the ultimate failure of the material comes from the growth of a prominent flaw. It is also called the fatigue life distribution.

The Birnbaum-Saunders distribution uses the following parameters.

# prob.BirnbaumSaundersDistribution

Parameter	Description	Support
beta	Scale parameter	$\beta > 0$
gamma	Shape parameter	$\gamma \geq 0$

The probability density function (pdf) is

$$f(x | \beta, \gamma) = \frac{1}{\sqrt{2\pi}} \exp \left\{ -\frac{\left( \sqrt{\frac{x}{\beta}} - \sqrt{\frac{\beta}{x}} \right)^2}{2\gamma^2} \right\} \left( \frac{\sqrt{\frac{x}{\beta}} - \sqrt{\frac{\beta}{x}}}{2\gamma x} \right) ; \quad x > 0.$$

## Examples

### Create a Birnbaum-Saunders Distribution Object Using Default Parameters

Create a Birnbaum-Saunders distribution object using the default parameter values.

```
pd = makedist('BirnbaumSaunders')
```

```
pd =
```

```
BirnbaumSaundersDistribution
```

```
Birnbaum-Saunders distribution
```

```
beta = 1
```

```
gamma = 1
```

### Create a Birnbaum-Saunders Distribution Object Using Specified Parameter Values

Create a Birnbaum-Saunders distribution object by specifying the parameter values.

```
pd = makedist('BirnbaumSaunders','beta',2,'gamma',5)
```

# prob.BirnbaumSaundersDistribution

---

```
pd =
```

```
    BirnbaumSaundersDistribution
```

```
    Birnbaum-Saunders distribution
```

```
        beta = 2
```

```
        gamma = 5
```

Compute the mean of the distribution.

```
m = mean(pd)
```

```
m =
```

```
    27
```

## Concepts

- “Birnbaum-Saunders Distribution” on page B-13
- Class Attributes
- Property Attributes

**Purpose**

Bootstrap confidence interval

**Syntax**

```
ci = bootci(nboot,bootfun,...)
ci = bootci(nboot,{bootfun,...},'alpha',alpha)
ci = bootci(nboot,{bootfun,...},...,'type',type)
ci = bootci(nboot,{bootfun,...},...,'type','student',
    'nbootstd',nbootstd)
ci = bootci(nboot,{bootfun,...},...,'type','student','stderr',
    stderr)
ci = bootci(nboot,{bootfun,...},...,'Weights',weights)
ci = bootci(nboot,{bootfun,...},...,'Options',options)
[ci,bootstat] = bootci(...)
```

**Description**

`ci = bootci(nboot,bootfun,...)` computes the 95% bootstrap confidence interval of the statistic computed by the function `bootfun`. `nboot` is a positive integer indicating the number of bootstrap samples used in the computation. `bootfun` is a function handle specified with `@`. The third and later input arguments to `bootci` are data (scalars, column vectors, or matrices) that are used to create inputs to `bootfun`. `bootci` creates each bootstrap sample by sampling with replacement from the rows of the non-scalar data arguments (these must have the same number of rows). Scalar data are passed to `bootfun` unchanged.

If `bootfun` returns a scalar, `ci` is a vector containing the lower and upper bounds of the confidence interval. If `bootfun` returns a vector of length  $m$ , `ci` is an array of size 2-by- $m$ , where `ci(1,:)` are lower bounds and `ci(2,:)` are upper bounds. If `bootfun` returns an array of size  $m$ -by- $n$ -by- $p$ -by-..., `ci` is an array of size 2-by- $m$ -by- $n$ -by- $p$ -by-..., where `ci(1,:,:,:,...)` is an array of lower bounds and `ci(2,:,:,:,...)` is an array of upper bounds.

`ci = bootci(nboot,{bootfun,...},'alpha',alpha)` computes the  $100*(1-\alpha)$  bootstrap confidence interval of the statistic defined by the function `bootfun`. `bootfun` and the data that `bootci` passes to it are contained in a single cell array. `alpha` is a scalar between 0 and 1. The default value of `alpha` is 0.05.

`ci = bootci(nboot, {bootfun, ...}, ..., 'type', type)` computes the bootstrap confidence interval of the statistic defined by the function `bootfun`. `type` is the confidence interval type, chosen from among the following strings:

- `'norm'` or `'normal'` — Normal approximated interval with bootstrapped bias and standard error.
- `'per'` or `'percentile'` — Basic percentile method.
- `'cper'` or `'corrected percentile'` — Bias corrected percentile method.
- `'bca'` — Bias corrected and accelerated percentile method. This is the default.
- `'stud'` or `'student'` — Studentized confidence interval.

`ci = bootci(nboot, {bootfun, ...}, ..., 'type', 'student', 'nbootstd', nbootstd)` computes the studentized bootstrap confidence interval of the statistic defined by the function `bootfun`. The standard error of the bootstrap statistics is estimated using bootstrap, with `nbootstd` bootstrap data samples. `nbootstd` is a positive integer value. The default value of `nbootstd` is 100.

`ci = bootci(nboot, {bootfun, ...}, ..., 'type', 'student', 'stderr', stderr)` computes the studentized bootstrap confidence interval of statistics defined by the function `bootfun`. The standard error of the bootstrap statistics is evaluated by the function `stderr`. `stderr` is a function handle. `stderr` takes the same arguments as `bootfun` and returns the standard error of the statistic computed by `bootfun`.

`ci = bootci(nboot, {bootfun, ...}, ..., 'Weights', weights)` specifies observation weights. `weights` must be a vector of non-negative numbers with at least one positive element. The number of elements in `weights` must be equal to the number of rows in non-scalar input arguments to `bootfun`. To obtain one bootstrap replicate, `bootstrp` samples  $N$  out of  $N$  with replacement using these weights as multinomial sampling probabilities.

`ci = bootci(nboot,{bootfun,...},...,'Options',options)` specifies options that govern the computation of bootstrap iterations. One option requests that `bootci` perform bootstrap iterations using multiple processors, if the Parallel Computing Toolbox is available. Two options specify the random number streams to be used in bootstrap resampling. This argument is a struct that you can create with a call to `statset`. You can retrieve values of the individual fields with a call to `statget`. Applicable `statset` parameters are:

- `'UseParallel'` — If `true` and if a `parpool` of the Parallel Computing Toolbox is open, compute bootstrap iterations in parallel. If the Parallel Computing Toolbox is not installed, or a `parpool` is not open, computation occurs in serial mode. Default is `false`, or serial computation.
- `UseSubstreams` — Set to `true` to compute in parallel in a reproducible fashion. Default is `false`. To compute reproducibly, set `Streams` to a type allowing substreams: `'mlfg6331_64'` or `'mrg32k3a'`.
- `Streams` — A `RandStream` object or cell array of such objects. If you do not specify `Streams`, `bootci` uses the default stream or streams. If you choose to specify `Streams`, use a single object except in the case
  - You have an open Parallel pool
  - `UseParallel` is `true`
  - `UseSubstreams` is `false`
 In that case, use a cell array the same size as the Parallel pool.

`[ci,bootstat] = bootci(...)` also returns the bootstrapped statistic computed for each of the `nboot` bootstrap replicate samples. Each row of `bootstat` contains the results of applying `bootfun` to one bootstrap sample. If `bootfun` returns a matrix or array, then this output is converted to a row vector for storage in `bootstat`.

## Examples

Compute the confidence interval for the capability index in statistical process control:

```
y = normrnd(1,1,30,1);           % Simulated process data
```

# bootci

---

```
LSL = -3; USL = 3; % Process specifications
capable = @(x)(USL-LSL)./(6* std(x)); % Process capability
ci = bootci(2000, capable, y) % BCa confidence interval
ci =
    0.8122
    1.2657

sci = bootci(2000, {capable, y}, 'type', 'student') % Studentized ci
sci =
    0.7739
    1.2707
```

## See Also

**Purpose**

Bootstrap sampling

**Syntax**

```
bootstat = bootstrap(nboot,bootfun,d1,...)
[bootstat,bootsam] = bootstrap(...)
bootstat = bootstrap(...,'Name',Value)
```

**Description**

`bootstat = bootstrap(nboot,bootfun,d1,...)` draws `nboot` bootstrap data samples, computes statistics on each sample using `bootfun`, and returns the results in the matrix `bootstat`. `nboot` must be a positive integer. `bootfun` is a function handle specified with `@`. Each row of `bootstat` contains the results of applying `bootfun` to one bootstrap sample. If `bootfun` returns a matrix or array, then this output is converted to a row vector for storage in `bootstat`.

The third and later input arguments (`d1,...`) are data (scalars, column vectors, or matrices) used to create inputs to `bootfun`. `bootstrap` creates each bootstrap sample by sampling with replacement from the rows of the non-scalar data arguments (these must have the same number of rows). `bootfun` accepts scalar data unchanged.

`[bootstat,bootsam] = bootstrap(...)` returns an `n`-by-`nboot` matrix of bootstrap indices, `bootsam`. Each column in `bootsam` contains indices of the values that were drawn from the original data sets to constitute the corresponding bootstrap sample. For example, if `d1,...` each contain 16 values, and `nboot = 4`, then `bootsam` is a 16-by-4 matrix. The first column contains the indices of the 16 values drawn from `d1,...`, for the first of the four bootstrap samples, the second column contains the indices for the second of the four bootstrap samples, and so on. (The bootstrap indices are the same for all input data sets.) To get the output samples `bootsam` without applying a function, set `bootfun` to empty (`[]`).

`bootstat = bootstrap(...,'Name',Value)` uses additional arguments specified by one or more `Name,Value` pair arguments. The name-value pairs must appear after the data arguments. The available name-value pairs:

- `'Weights'` — Observation weights. The `weights` value must be a vector of nonnegative numbers with at least one positive element.

The number of elements in `weights` must be equal to the number of rows in non-scalar input arguments to `bootstrap`. To obtain one bootstrap replicate, `bootstrap` samples  $N$  out of  $N$  with replacement using these weights as multinomial sampling probabilities.

- 'Options' — The value is a structure that contains options specifying whether to compute bootstrap iterations in parallel, and specifying how to use random numbers during the bootstrap sampling. Create the options structure with `statset`. Applicable `statset` parameters are:
  - 'UseParallel' — If true and if a `parpool` of the Parallel Computing Toolbox is open, compute bootstrap iterations in parallel. If the Parallel Computing Toolbox is not installed, or a `parpool` is not open, computation occurs in serial mode. Default is false, meaning serial computation.
  - UseSubstreams — Set to true to compute in parallel in a reproducible fashion. Default is false. To compute reproducibly, set `Streams` to a type allowing substreams: 'mlfg6331\_64' or 'mrg32k3a'.
  - Streams — A `RandStream` object or cell array of such objects. If you do not specify `Streams`, `bootstrap` uses the default stream or streams. If you choose to specify `Streams`, use a single object except in the case
    - You have an open Parallel pool
    - UseParallel is true
    - UseSubstreams is falseIn that case, use a cell array the same size as the Parallel pool.

## Examples

### Bootstrapping a Correlation Coefficient Standard Error

Load a data set containing the LSAT scores and law-school GPA for 15 students. These 15 data points are resampled to create 1000 different data sets, and the correlation between the two variables is computed for each data set.

```
load lawdata
[bootstat,bootsam] = bootstrp(1000,@corr,lsat,gpa);
```

Display the first 5 bootstrapped correlation coefficients.

```
bootstat(1:5,:)
ans =
    0.6600
    0.7969
    0.5807
    0.8766
    0.9197
```

Display the indices of the data selected for the first 5 bootstrap samples.

```
bootsam(:,1:5)
ans =
     9     8    15    11    15
    14     7     6     7    14
     4     6    10     3    11
     3    10    11     9     2
    15     4    13     4    14
     9     4     5     2    10
     8     5     4     3    13
     1     9     1    15    11
    10     8     6    12     3
     1     4     5     2     8
     1     1    10     6     2
     3    10    15    10     8
    14     6    10     3     8
    13    12     1     2     4
    12     6     4     9     8
hist(bootstat)
```

# bootstrap

The histogram shows the variation of the correlation coefficient across all the bootstrap samples. The sample minimum is positive, indicating that the relationship between LSAT score and GPA is not accidental.

Finally, compute a bootstrap standard of error for the estimated correlation coefficient.

```
se = std(bootstat)
se =
    0.1327
```

### Estimating the Density of Bootstrapped Statistic

Compute a sample of 100 bootstrapped means of random samples taken from the vector Y, and plot an estimate of the density of these bootstrapped means:

```
y = exprnd(5,100,1);  
m = bootstrp(100,@mean,y);  
[fi,xi] = ksdensity(m);  
plot(xi,fi);
```

## Bootstrapping More Than One Statistic

Compute a sample of 100 bootstrapped means and standard deviations of random samples taken from the vector Y, and plot the bootstrap estimate pairs:

```
y = exprnd(5,100,1);  
stats = bootstrap(100,@(x)[mean(x) std(x)],y);  
plot(stats(:,1),stats(:,2),'o')
```

### Bootstrapping a Regression Model

Estimate the standard errors for a coefficient vector in a linear regression by bootstrapping residuals:

```
load hald
x = [ones(size(heat)),ingredients];
y = heat;
b = regress(y,x);
yfit = x*b;
resid = y - yfit;
se = std(bootstrp(...
    1000,@(bootr)regress(yfit+bootr,x),resid));
```

# boxplot

---

**Purpose** Box plot

**Syntax**  
`boxplot(X)`  
`boxplot(X,G)`  
`boxplot(axes,X,...)`  
`boxplot(...,'Name',value)`

**Description** `boxplot(X)` produces a box plot of the data in *X*. If *X* is a matrix, there is one box per column; if *X* is a vector, there is just one box. On each box, the central mark is the median, the edges of the box are the 25th and 75th percentiles, the whiskers extend to the most extreme data points not considered outliers, and outliers are plotted individually. For controlling how much the whiskers extend, see the 'whiskers' name-value pair argument.

`boxplot(X,G)` specifies one or more grouping variables *G*, producing a separate box for each set of *X* values sharing the same *G* value or values. Grouping variables must have one row per element of *X*, or one row per column of *X*. Specify a single grouping variable in *G* using a vector, a character array, a cell array of strings, or a vector categorical array; specify multiple grouping variables in *G* using a cell array of these variable types, such as {*G1 G2 G3*}, or by using a matrix. If multiple grouping variables are used, they must all be the same length. Groups that contain a NaN value or an empty string in a grouping variable are omitted, and are not counted in the number of groups considered by other parameters.

By default, character and string grouping variables are sorted in the order they initially appear in the data, categorical grouping variables are sorted by the order of their levels, and numeric grouping variables are sorted in numeric order. To control the order of groups, do one of the following:

- Use categorical variables in *G* and specify the order of their levels.
- Use the 'grouporder' parameter described below.
- Pre-sort your data.

`boxplot(axes,X,...)` creates the plot in the axes with handle axes.

`boxplot(..., 'Name', value)` specifies one or more optional parameter name/value pairs, as described in the following table. Specify *Name* in single quotes.

Name	Value
'plotstyle'	<ul style="list-style-type: none"> <li>'traditional' — Traditional box style. This is the default.</li> <li>'compact' — Box style designed for plots with many groups. This style changes the defaults for some other parameters, as described in the following table.</li> </ul>
'boxstyle'	<ul style="list-style-type: none"> <li>'outline' — Draws an unfilled box with dashed whiskers. This is the default.</li> <li>'filled' — Draws a narrow filled box with lines for whiskers.</li> </ul>
'colorgroup'	One or more grouping variables, of the same type as permitted for <code>G</code> , specifying that the box color should change when the specified variables change. The default is <code>[]</code> for no box color change.
'colors'	Colors for boxes, specified as a single color (such as 'r' or <code>[1 0 0]</code> ) or multiple colors (such as 'rgbm' or a three-column matrix of RGB values). The sequence is replicated or truncated as required, so for example 'rb' gives boxes that alternate in color. The default when no 'colorgroup' is specified is to use the same color scheme for all boxes. The default when 'colorgroup' is specified is a modified hsv colormap.

# boxplot

---

Name	Value
'datalim'	A two-element vector containing lower and upper limits, used by 'extrememode' to determine which points are extreme. The default is [-Inf Inf].
'extrememode'	<ul style="list-style-type: none"><li>• 'clip' — Moves data outside the <code>datalim</code> limits to the limit. This is the default.</li><li>• 'compress' — Evenly distributes data outside the <code>datalim</code> limits in a region just outside the limit, retaining the relative order of the points.</li></ul> <p>A dotted line marks the limit if any points are outside it, and two gray lines mark the compression region if any points are compressed. Values at +/-Inf can be clipped or compressed, but NaN values still do not appear on the plot. Box notches are drawn to scale and may extend beyond the bounds if the median is inside the limit; they are not drawn if the median is outside the limits.</p>
'factordirection'	<ul style="list-style-type: none"><li>• 'data' — Arranges factors with the first value next to the origin. This is the default.</li><li>• 'list' — Arranges factors left-to-right if on the <i>x</i> axis or top-to-bottom if on the <i>y</i> axis.</li><li>• 'auto' — Uses 'data' for numeric grouping variables and 'list' for strings.</li></ul>

Name	Value
'fullfactors'	<ul style="list-style-type: none"> <li>• 'off' — One group for each unique row of G. This is the default.</li> <li>• 'on' — Create a group for each possible combination of group variable values, including combinations that do not appear in the data.</li> </ul>
'factorseparator'	<p>Specifies which factors should have their values separated by a grid line. The value may be 'auto' or a vector of grouping variable numbers. For example, [1 2] adds a separator line when the first or second grouping variable changes value. 'auto' is [] for one grouping variable and [1] for two or more grouping variables. The default is [].</p>
'factorgap'	<p>Specifies an extra gap to leave between boxes when the corresponding grouping factor changes value, expressed as a percentage of the width of the plot. For example, with [3 1], the gap is 3% of the width of the plot between groups with different values of the first grouping variable, and 1% between groups with the same value of the first grouping variable but different values for the second. 'auto' specifies that boxplot should choose a gap automatically. The default is [].</p>
'grouporder'	<p>Order of groups for plotting, specified as a cell array of strings. With multiple grouping variables, separate values within each string with a comma. Using categorical arrays as grouping variables is an easier way to control the order of the boxes. The default is [], which does not reorder the boxes.</p>

# boxplot

Name	Value
'jitter'	Maximum distance $d$ to displace outliers along the factor axis by a uniform random amount, in order to make duplicate points visible. A $d$ of 1 makes the jitter regions just touch between the closest adjacent groups. The default is 0.
'labels'	<p>A character array, cell array of strings, or numeric vector of box labels. There may be one label per group or one label per X value. Multiple label variables may be specified via a numeric matrix or a cell array containing any of these types.</p> <hr/> <p><b>Tip</b> To remove labels from a plot, use the following command:</p> <pre>set(gca,'XTickLabel',{' '})</pre> <hr/>
'labelorientation'	<ul style="list-style-type: none"><li>• 'inline' — Rotates the labels to be vertical. This is the default when <code>plotstyle</code> is 'compact'.</li><li>• 'horizontal' — Leaves the labels horizontal. This is the default when <code>plotstyle</code> has the default value of 'traditional'.</li></ul> <p>When the labels are on the y axis, both settings leave the labels horizontal.</p>

Name	Value
'labelverbosity'	<ul style="list-style-type: none"> <li>• 'all' — Displays every label. This is the default.</li> <li>• 'minor' — Displays a label for a factor only when that factor has a different value from the previous group.</li> <li>• 'majorminor' — Displays a label for a factor when that factor or any factor major to it has a different value from the previous group.</li> </ul>
'medianstyle'	<ul style="list-style-type: none"> <li>• 'line' — Draws a line for the median. This is the default.</li> <li>• 'target' — Draws a black dot inside a white circle for the median.</li> </ul>
'notch'	<ul style="list-style-type: none"> <li>• 'on' — Draws comparison intervals using notches when plotstyle is 'traditional', or triangular markers when plotstyle is 'compact'.</li> <li>• 'marker' — Draws comparison intervals using triangular markers.</li> <li>• 'off' — Omits notches. This is the default.</li> </ul> <p>Two medians are significantly different at the 5% significance level if their intervals do not overlap. Interval endpoints are the extremes of the notches or the centers of the triangular markers. The extremes correspond to <math>q_2 - 1.57(q_3 - q_1)/\sqrt{n}</math> and <math>q_2 + 1.57(q_3 - q_1)/\sqrt{n}</math>, where <math>q_2</math> is the median (50th percentile), <math>q_1</math> and <math>q_3</math> are the 25th and 75th percentiles, respectively, and <math>n</math> is the number of observations without any NaN values. When</p>

# boxplot

Name	Value
	the sample size is small, notches may extend beyond the end of the box.
'orientation'	<ul style="list-style-type: none"><li>'vertical' — Plots <math>X</math> on the <math>y</math> axis. This is the default.</li><li>'horizontal' — Plots <math>X</math> on the <math>x</math> axis.</li></ul>
'outliersize'	Size of the marker used for outliers, in points. The default is 6 (6/72 inch).
'positions'	Box positions specified as a numeric vector with one entry per group or $X$ value. The default is $1:\text{numGroups}$ , where $\text{numGroups}$ is the number of groups.
'symbol'	Symbol and color to use for outliers, using the same values as the <code>LineStyle</code> parameter in <code>plot</code> . The default is 'r+'. If the symbol is omitted then the outliers are invisible; if the color is omitted then the outliers have the same color as their corresponding box.
'whisker'	Maximum whisker length $w$ . The default is a $w$ of 1.5. Points are drawn as outliers if they are larger than $q_3 + w(q_3 - q_1)$ or smaller than $q_1 - w(q_3 - q_1)$ , where $q_1$ and $q_3$ are the 25th and 75th percentiles, respectively. The default of 1.5 corresponds to approximately $\pm 2.7\sigma$ and 99.3 coverage if the data are normally distributed. The plotted whisker extends to the <i>adjacent value</i> , which is the most extreme data value that is not an outlier. Set <code>whisker</code> to 0 to give no whiskers and to make every point outside of $q_1$ and $q_3$ an outlier.
'widths'	A scalar or vector of box widths for when <code>boxstyle</code> is 'outline'. The default is half of the minimum separation between boxes,

Name	Value
	which is 0.5 when the <code>positions</code> argument takes its default value. The list of values is replicated or truncated as necessary.

When the `plotstyle` parameter takes the value `'compact'`, the following default values for other parameters apply.

Parameter	Default when <code>plotstyle</code> is <code>'compact'</code>
<code>'boxstyle'</code>	<code>'filled'</code>
<code>'factorseparator'</code>	<code>'auto'</code>
<code>'factorgap'</code>	<code>'auto'</code>
<code>'jitter'</code>	0.5
<code>'labelorientation'</code>	<code>'inline'</code>
<code>'labelverbosity'</code>	<code>'majorminor'</code>
<code>'medianstyle'</code>	<code>'target'</code>
<code>'outliersize'</code>	4
<code>'symbol'</code>	<code>'o'</code>

You can see data values and group names using the data cursor in the figure window. The cursor shows the original values of any points affected by the `datalim` parameter. You can label the group to which an outlier belongs using the `gname` function.

To modify graphics properties of a box plot component, use `findobj` with the `Tag` property to find the component's handle. `Tag` values for box plot components depend on parameter settings, and are listed in the table below.

# boxplot

---

Parameter Settings	Tag Values
All settings	<ul style="list-style-type: none"><li>'Box'</li><li>'Outliers'</li></ul>
When 'plotstyle' is 'traditional'	<ul style="list-style-type: none"><li>'Median'</li><li>'Upper Whisker'</li><li>'Lower Whisker'</li><li>'Upper Adjacent Value'</li><li>'Lower Adjacent Value'</li></ul>
When 'plotstyle' is 'compact'	<ul style="list-style-type: none"><li>'Whisker'</li><li>'MedianOuter'</li><li>'MedianInner'</li></ul>
When 'notch' is 'marker'	<ul style="list-style-type: none"><li>'NotchLo'</li><li>'NotchHi'</li></ul>

## Examples

### Create Box Plots for Grouped Data

This example shows how to create box plots for grouped sample data.

Load the sample data.

```
load carsmall
```

Create a box plot of the miles per gallon (MPG) measurements from the sample data, grouped by the vehicles' country of origin, `Origin`.

```
boxplot(MPG,Origin)
```

## Create Notched Box Plots

This example shows how to create notched box plots.

Generate two sets of sample data. The first sample, `x1`, contains random numbers generated from a normal distribution with  $\mu = 5$  and  $\sigma = 1$ . The second sample, `x2`, contains random numbers generated from a normal distribution with  $\mu = 6$  and  $\sigma = 1$ .

```
rng('default'); % For reproducibility
```

# boxplot

---

```
x1 = normrnd(5,1,100,1);  
x2 = normrnd(6,1,100,1);
```

Create notched box plots of x1 and x2.

```
boxplot([x1,x2], 'notch', 'on')
```

The difference between the medians of the two groups is approximately 1. Since the notches in the box plot do not overlap, you can conclude, with 95% confidence, that the true medians do differ.

The following figure shows the box plot for the same data with the length of the whiskers specified as 1.0 times the interquartile range. Points beyond the whiskers are displayed using +.

```
boxplot([x1,x2], 'notch', 'on', 'whisker', 1)
```

## Create Compact Box Plots

This example shows how to create box plots using compact formatting, which is useful when the sample data contains many groups.

# boxplot

---

Create a 100-by-25 matrix of random numbers generated from a standard normal distribution to use as sample data.

```
rng('default'); % For reproducibility  
X = randn(100,25);
```

Create two box plots for the data in  $X$  on the same figure. The top plot uses the default box plot formatting. The bottom plot uses compact formatting.

```
subplot(2,1,1)  
boxplot(X)
```

```
subplot(2,1,2)  
boxplot(X,'plotstyle','compact')
```

[anova1](#) | [axes\\_props](#) | [kruskalwallis](#) | [multcompare](#)

**Purpose**

Piecewise distribution boundaries

**Syntax**

```
[p,q] = boundary(obj)  
[p,q] = boundary(obj,i)
```

**Description**

[p,q] = boundary(obj) returns the boundary points between segments of the piecewise distribution object, obj. p is a vector of cumulative probabilities at each boundary. q is a vector of quantiles at each boundary.

[p,q] = boundary(obj,i) returns p and q for the *i*th boundary.

**Examples**

Fit Pareto tails to a *t* distribution at cumulative probabilities 0.1 and 0.9:

```
t = trnd(3,100,1);  
obj = paretotails(t,0.1,0.9);  
[p,q] = boundary(obj)  
p =  
    0.1000  
    0.9000  
q =  
   -1.7766  
    1.8432
```

# prob.BurrDistribution

---

**Superclasses** ToolboxFittableParametricDistribution

**Purpose** Burr probability distribution object

**Description** `prob.BurrDistribution` is an object consisting of parameters, a model description, and sample data for a Burr probability distribution.

Create a probability distribution object with specified parameter values using `makedist`. Alternatively, fit a distribution to data using `fitdist` or the Distribution Fitting app.

**Construction** `pd = makedist('Burr')` creates a Burr probability distribution object using the default parameter values.

`pd = makedist('Burr','alpha',alpha,'c',c,'k',k)` creates a Burr probability distribution object using the specified parameter values.

## Input Arguments

### **alpha - Scale parameter**

1 (default) | positive scalar value

Scale parameter of the Burr distribution, specified as a positive scalar value.

### **Data Types**

single | double

### **c - First shape parameter**

1 (default) | positive scalar value

First shape parameter of the Burr distribution, specified as a positive scalar value.

### **Data Types**

single | double

### **k - Second shape parameter**

1 (default) | positive scalar value

Second shape parameter of the Burr distribution, specified as a positive scalar value.

**Data Types**

single | double

**Properties****alpha**

Scale parameter of the Burr distribution, stored as a positive scalar value.

**Data Types**

single | double

**c**

First shape parameter of the Burr distribution, stored as a positive scalar value.

**Data Types**

single | double

**k**

Second shape parameter of the Burr distribution, stored as a positive scalar value.

**Data Types**

single | double

**DistributionName**

Name of the probability distribution, stored as a valid probability distribution name string. This property is read-only.

**Data Types**

char

**InputData**

Data used for distribution fitting, stored as a structure containing the following:

- data: Data vector used for distribution fitting.

# prob.BurrDistribution

---

- cens: Censoring vector, or empty if none.
- freq: Frequency vector, or empty if none.

This property is read-only.

## Data Types

single | double

## IsTruncated

Logical flag for truncated distribution, stored as a logical value.

If IsTruncated equals 0, the distribution is not truncated.

If IsTruncated equals 1, the distribution is truncated. This property is read-only.

## Data Types

logical

## NumParameters

Number of parameters for the probability distribution, stored as a positive integer value. This property is read-only.

## Data Types

single | double

## ParameterCovariance

Covariance matrix of the parameter estimates, stored as a  $p$ -by- $p$  matrix, where  $p$  is the number of parameters in the distribution.

The  $(i,j)$  element is the covariance between the estimates of the  $i$ th parameter and the  $j$ th parameter. The  $(i,i)$  element is the estimated variance of the  $i$ th parameter. If parameter  $i$  is fixed rather than estimated by fitting the distribution to data, then the  $(i,i)$  elements of the covariance matrix are 0. This property is read-only.

## Data Types

single | double

## ParameterDescription

Descriptions of distribution parameters, stored as a cell array of strings. Each cell contains a short description of one distribution parameter. This property is read-only.

## Data Types

char

## ParameterIsFixed

Logical flag for fixed parameters, stored as an array of logical values. If 0, the corresponding parameter in the ParameterNames array is not fixed. If 1, the corresponding parameter in the ParameterNames array is fixed. This property is read-only.

## Data Types

logical

## ParameterNames

Names of distribution parameters, stored as a cell array of strings. This property is read-only.

## Data Types

char

## ParameterValues

Values of distribution parameters, stored as a vector. This property is read-only.

## Data Types

single | double

## Truncation

Truncation interval for the probability distribution, stored as a vector containing the lower and upper truncation boundaries. This property is read-only.

## Data Types

single | double

# prob.BurrDistribution

negloglik	Negative loglikelihood of probability distribution object
paramci	Confidence intervals for probability distribution parameters
proflik	Profile likelihood function for probability distribution object
std	Standard deviation of probability distribution object
var	Variance of probability distribution object

## Definitions

### Burr Distribution

The Burr distribution is a three-parameter family of distributions on the positive real line. It can fit a wide range of empirical data, and is used in various fields such as finance, hydrology, and reliability to model a variety of data types.

The Burr distribution uses the following parameters.

Parameter	Description	Support
alpha	Scale parameter	$\alpha > 0$
c	First shape parameter	$c > 0$
k	Second shape parameter	$k > 0$

The probability density function (pdf) is

$$f(x | \alpha, c, k) = \frac{\frac{kc}{\alpha} \left(\frac{x}{\alpha}\right)^{c-1}}{\left(1 + \left(\frac{x}{\alpha}\right)^c\right)^{k+1}} ; \quad x > 0.$$

## Examples

### Create a Burr Distribution Object Using Default Parameters

Create a Burr distribution object using the default parameter values.

```
pd = makedist('Burr')
```

```
pd =
```

```
BurrDistribution
```

# prob.BurrDistribution

---

```
Burr distribution
alpha = 1
c = 1
k = 1
```

## Create a Burr Distribution Object Using Specified Parameters

Create a Burr distribution object by specifying parameter values.

```
pd = makedist('Burr','alpha',1,'c',2,'k',5)
```

```
pd =
```

```
BurrDistribution

Burr distribution
alpha = 1
c = 2
k = 5
```

Compute the mean of the distribution.

```
m = mean(pd)
```

```
m =
```

```
0.4295
```

# clustering.evaluation.CalinskiHarabaszEvaluation

---

**Superclasses** ClusterCriterion

**Purpose** Calinski-Harabasz criterion clustering evaluation object

**Description** clustering.evaluation.CalinskiHarabaszEvaluation is an object consisting of sample data, clustering data, and Calinski-Harabasz criterion values used to evaluate the optimal number of clusters. Create a Calinski-Harabasz criterion clustering evaluation object using evalclusters.

**Construction** `eva = evalclusters(x,clust,'CalinskiHarabasz')` creates a Calinski-Harabasz criterion clustering evaluation object.

`eva = evalclusters(x,clust,'CalinskiHarabasz',Name,Value)` creates a Calinski-Harabasz criterion clustering evaluation object using additional options specified by one or more name-value pair arguments.

## Input Arguments

### **x - Input data**

matrix

Input data, specified as an  $N$ -by- $P$  matrix.  $N$  is the number of observations, and  $P$  is the number of variables.

### **Data Types**

single | double

### **clust - Clustering algorithm**

'kmeans' | 'linkage' | 'gmdistribution' | matrix of clustering solutions | function handle

Clustering algorithm, specified as one of the following.

# clustering.evaluation.CalinskiHarabaszEvaluation

---

'kmeans'	Cluster the data in $X$ using the kmeans clustering algorithm, with 'EmptyAction' set to 'singleton' and 'Replicates' set to 5.
'linkage'	Cluster the data in $X$ using the clusterdata agglomerative clustering algorithm, with 'Linkage' set to 'ward'.
'gmdistribution'	Cluster the data in $X$ using the gmdistribution Gaussian mixture distribution algorithm, with 'SharedCov' set to true and 'Replicates' set to 5.

If Criterion is 'CalinskHarabasz', 'DaviesBouldin', or 'silhouette', you can specify a clustering algorithm using the function\_handle (@) operator. The function must be of the form

```
C = clustfun(DATA,K)
```

where DATA is the data to be clustered, and K is the number of clusters. The output of clustfun must be one of the following:

- A vector of integers representing the cluster index for each observation in DATA. There must be K unique values in this vector.
- A numeric  $n$ -by- $K$  matrix of score for  $n$  observations and  $K$  classes. In this case, the cluster index for each observation is determined by taking the largest score value in each row.

If Criterion is 'CalinskHarabasz', 'DaviesBouldin', or 'silhouette', you can also specify clust as a  $n$ -by- $K$  matrix containing the proposed clustering solutions.  $n$  is the number of observations in the sample data, and  $K$  is the number of proposed clustering solutions. Column  $j$  contains the cluster indices for each of the  $N$  points in the  $j$ th clustering solution.

## Name-Value Pair Arguments

Specify optional comma-separated pairs of `Name`, `Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( ' '). You can specify several name and value pair arguments in any order as `Name1,Value1,...,NameN,ValueN`.

**Example:** `'KList',[1:6]` specifies to test 1, 2, 3, 4, 5, and 6 clusters to find the optimal number.

## **KList** - List of number of clusters to evaluate

vector

List of number of clusters to evaluate, specified as the comma-separated pair consisting of `'KList'` and a vector of positive integer values. You must specify `KList` when `clust` is a clustering algorithm name string or a function handle. When `criterion` is `'gap'`, `clust` must be a string or a function handle, and you must specify `KList`.

**Example:** `'KList',[1:6]`

## Properties

### **ClusteringFunction**

Clustering algorithm used to cluster the input data, stored as a valid clustering algorithm name string or function handle. If the clustering solutions are provided in the input, `ClusteringFunction` is empty.

### **CriterionName**

Name of the criterion used for clustering evaluation, stored as a valid criterion name string.

### **CriterionValues**

Criterion values corresponding to each proposed number of clusters in `InspectedK`, stored as a vector of numerical values.

### **Distance**

# clustering.evaluation.CalinskiHarabaszEvaluation

---

Distance measure used for clustering data, stored as a valid distance measure name string.

## **InspectedK**

List of the number of proposed clusters for which to compute criterion values, stored as a vector of positive integer values.

## **Missing**

Logical flag for excluded data, stored as a column vector of logical values. If `Missing` equals `true`, then the corresponding value in the data matrix `x` is not used in the clustering solution.

## **NumObservations**

Number of observations in the data matrix `X`, minus the number of missing (NaN) values in `X`, stored as a positive integer value.

## **OptimalK**

Optimal number of clusters, stored as a positive integer value.

## **OptimalY**

Optimal clustering solution corresponding to `OptimalK`, stored as a column vector of positive integer values. If the clustering solutions are provided in the input, `OptimalY` is empty.

## **X**

Data used for clustering, stored as a matrix of numerical values.

## **Methods**

### **Inherited Methods**

<code>compact</code>	Compact clustering evaluation object
<code>plot</code>	Plot clustering evaluation object criterion values

## Definitions

### Calinski-Harabasz Criterion

The Calinski-Harabasz criterion is sometimes called the variance ratio criterion (VRC). The Calinski-Harabasz index is defined as

$$VRC_k = \frac{SS_B}{SS_W} \times \frac{(N - k)}{(k - 1)},$$

, where  $SS_B$  is the overall between-cluster variance,  $SS_W$  is the overall within-cluster variance,  $k$  is the number of clusters, and  $N$  is the number of observations.

The overall between-cluster variance  $SS_B$  is defined as

$$SS_B = \sum_{i=1}^k n_i \|m_i - m\|^2,$$

where  $k$  is the number of clusters,  $m_i$  is the centroid of cluster  $i$ , and  $m$  is the overall mean of the sample data.

The overall within-cluster variance  $SS_W$  is defined as

$$SS_W = \sum_{i=1}^k \sum_{x \in c_i} \|x - m_i\|^2,$$

where  $k$  is the number of clusters,  $x$  is a data point,  $c_i$  is the  $i$ th cluster, and  $m_i$  is the centroid of cluster  $i$ .

Well-defined clusters have a large between-cluster variance ( $SS_B$ ) and a small within-cluster variance ( $SS_W$ ). The larger the  $VRC_k$  ratio, the better the data partition. To determine the optimal number of clusters, maximize  $VRC_k$  with respect to  $k$ . The optimal number of clusters is the solution with the highest Calinski-Harabasz index value.

The Calinski-Harabasz criterion is best suited for  $k$ -means clustering solutions with squared Euclidean distances.

# clustering.evaluation.CalinskiHarabaszEvaluation

---

## Examples

### Evaluate the Clustering Solution Using Calinski-Harabasz Criterion

Evaluate the optimal number of clusters using the Calinski-Harabasz clustering evaluation criterion.

Load the sample data.

```
load fisheriris;
```

The data contains length and width measurements from the sepals and petals of three species of iris flowers.

Evaluate the optimal number of clusters using the Calinski-Harabasz criterion. Cluster the data using kmeans.

```
rng('default'); % For reproducibility  
eva = evalclusters(meas,'kmeans','CalinskiHarabasz','KList',[1:6])
```

```
eva =
```

```
CalinskiHarabaszEvaluation with properties:
```

```
NumObservations: 150  
  InspectedK: [1 2 3 4 5 6]  
 CriterionValues: [1x6 double]  
   OptimalK: 3
```

The OptimalK value indicates that, based on the Calinski-Harabasz criterion, the optimal number of clusters is three.

Plot the Calinski-Harabasz criterion values for each number of clusters tested.

```
figure;  
plot(eva);
```

# clustering.evaluation.CalinskiHarabaszEvaluation

The plot shows that the highest Calinski-Harabasz value occurs at three clusters, suggesting that the optimal number of clusters is three.

Create a grouped scatter plot to examine the relationship between petal length and width. Group the data by suggested clusters.

```
PetalLength = meas(:,3);  
PetalWidth = meas(:,4);  
ClusterGroup = eva.OptimalY;  
figure;
```

# clustering.evaluation.CalinskiHarabaszEvaluation

```
gscatter(PetalLength,PetalWidth,ClusterGroup,'rbg','xod');
```

The plot shows cluster 1 in the lower-left corner, completely separated from the other two clusters. Cluster 1 contains flowers with the smallest petal widths and lengths. Cluster 3 is in the upper-right corner, and contains flowers with the largest petal widths and lengths. Cluster 2 is near the center of the plot, and contains flowers with measurements between these two extremes.

# candexch

---

**Purpose** *D*-optimal design from candidate set using row exchanges

**Syntax**  
`rlist = candexch(C,nrows)`  
`rlist = candexch(C,nrows,Name,Value)`

**Description**  
`rlist = candexch(C,nrows)` uses a row-exchange algorithm to select a *D*-optimal design from the candidate set *C*.  
`rlist = candexch(C,nrows,Name,Value)` generates a *D*-optimal design with additional options specified by one or more *Name,Value* pair arguments.

**Input Arguments**  
**C**  
N-by-P matrix containing the values of P model terms at each of N points.

**nrows**

The desired number of rows in the design.

**Name-Value Pair Arguments**

Specify optional comma-separated pairs of *Name,Value* arguments. *Name* is the argument name and *Value* is the corresponding value. *Name* must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as *Name1,Value1,...,NameN,ValueN*.

**'display'**

When 'on', displays iteration number. Disable the display by setting to 'off'.

**Default:** 'on', except when the `UseParallel` option is true

**'init'**

nrows-by-P matrix giving an initial design.

**Default:** A random subset of the rows of *C*

**'maxiter'**

Maximum number of iterations, a positive integer.

**Default:** 10

**'options'**

A structure that specifies whether to run in parallel, and specifies the random stream or streams. Create the options structure with `statset`. Option fields:

- `UseParallel` — Set to `true` to compute in parallel. Default is `false`.
- `UseSubstreams` — Set to `true` to compute in parallel in a reproducible fashion. Default is `false`. To compute reproducibly, set `Streams` to a type allowing substreams: `'mlfg6331_64'` or `'mrg32k3a'`.
- `Streams` — A `RandStream` object or cell array of such objects. If you do not specify `Streams`, `candexch` uses the default stream or streams. If you choose to specify `Streams`, use a single object except in the case
  - You have an open Parallel pool
  - `UseParallel` is `true`
  - `UseSubstreams` is `false`In that case, use a cell array the same size as the Parallel pool.

**Default:** []

**'start'**

An `nobs-by-p` matrix of factor settings, specifying a set of `nobs` fixed design points to include in the design. `candexch` finds `nrows` additional rows to add to the `start` design. The parameter provides the same functionality as the `daugment` function, using a row-exchange algorithm rather than a coordinate-exchange algorithm.

**Default:** []

## 'tries'

Number of times to try to generate a design from a new starting point. The algorithm uses random points for each try, except possibly the first.

**Default:** 1

## Output Arguments

### rlist

Vector of length nrows listing the selected rows.

## Examples

This example shows how to generate a  $D$ -optimal design when there is a restriction on the candidate set, so the rowexch function isn't appropriate.

```
F = (fullfact([5 5 5])-1)/4; % factor settings in unit cube
T = sum(F,2)<=1.51;        % find rows matching a restriction
F = F(T,:);               % take only those rows
C = [ones(size(F,1),1) F F.^2];
                           % compute model terms including
                           % a constant and all squared terms
R = candexch(C,12);       % find a D-optimal 12-point subset
X = F(R,:);               % get factor settings
```

## Algorithms

candexch selects a starting design  $X$  at random, and uses a row-exchange algorithm to iteratively replace rows of  $X$  by rows of  $C$  in an attempt to improve the determinant of  $X' * X$ .

## Alternatives

The rowexch function also generates  $D$ -optimal designs using a row-exchange algorithm, but it automatically generates a candidate set that is appropriate for a specified model. The daugment function augments a set of fixed design points using a coordinate-exchange algorithm; the 'start' parameter provides the same functionality using the row exchange algorithm.

**Tutorials**

- “Specify Candidate Sets” on page 18-21

**How To**

- “D-Optimal Designs” on page 18-15

**Purpose** Candidate set generation

**Syntax**

```
dC = candgen(nfactors, 'model')  
[dC,C] = candgen(nfactors, 'model')  
[...] = candgen(nfactors, 'model', 'Name', value)
```

**Description** `dC = candgen(nfactors, 'model')` generates a candidate set `dC` of treatments appropriate for estimating the parameters in the `model` with `nfactors` factors. `dC` has `nfactors` columns and one row for each candidate treatment. `model` is one of the following strings, specified inside single quotes:

- `linear` — Constant and linear terms. This is the default.
- `interaction` — Constant, linear, and interaction terms
- `quadratic` — Constant, linear, interaction, and squared terms
- `purequadratic` — Constant, linear, and squared terms

Alternatively, `model` can be a matrix specifying polynomial terms of arbitrary order. In this case, `model` should have one column for each factor and one row for each term in the model. The entries in any row of `model` are powers for the factors in the columns. For example, if a model has factors `X1`, `X2`, and `X3`, then a row `[0 1 2]` in `model` specifies the term  $(X1.^0) .* (X2.^1) .* (X3.^2)$ . A row of all zeros in `model` specifies a constant term, which can be omitted.

`[dC,C] = candgen(nfactors, 'model')` also returns the design matrix `C` evaluated at the treatments in `dC`. The order of the columns of `C` for a full quadratic model with `n` terms is:

- 1 The constant term
- 2 The linear terms in order 1, 2, ...,  $n$
- 3 The interaction terms in order (1, 2), (1, 3), ..., (1,  $n$ ), (2, 3), ..., ( $n-1$ ,  $n$ )
- 4 The squared terms in order 1, 2, ...,  $n$

Other models use a subset of these terms, in the same order.

Pass `C` to `candexch` to generate a  $D$ -optimal design using a coordinate-exchange algorithm.

`[...] = candgen(nfactors, 'model', 'Name', value)` specifies one or more optional name/value pairs for the design. Valid parameters and their values are listed in the following table. Specify *Name* inside single quotes.

Name	Value
bounds	Lower and upper bounds for each factor, specified as a 2-by- <code>nfactors</code> matrix. Alternatively, this value can be a cell array containing <code>nfactors</code> elements, each element specifying the vector of allowable values for the corresponding factor.
categorical	Indices of categorical predictors.
levels	Vector of number of levels for each factor.

---

**Note** The `rowexch` function automatically generates a candidate set using `candgen`, and then creates a  $D$ -optimal design from that candidate set using `candexch`. Call `candexch` separately to specify your own candidate set to the row-exchange algorithm.

---

## Examples

The following example uses `rowexch` to generate a five-run design for a two-factor pure quadratic model using a candidate set that is produced internally:

```
dRE1 = rowexch(2,5,'purequadratic','tries',10)
dRE1 =
    -1     1
     0     0
     1    -1
     1     0
```

# candgen

---

```
1 1
```

The same thing can be done using `candgen` and `candexch` in sequence:

```
[dC,C] = candgen(2,'purequadratic') % Candidate set, C
dC =
-1 -1
 0 -1
 1 -1
-1  0
 0  0
 1  0
-1  1
 0  1
 1  1
C =
 1 -1 -1  1  1
 1  0 -1  0  1
 1  1 -1  1  1
 1 -1  0  1  0
 1  0  0  0  0
 1  1  0  1  0
 1 -1  1  1  1
 1  0  1  0  1
 1  1  1  1  1
treatments = candexch(C,5,'tries',10) % Find D-opt subset
treatments =
 2
 1
 7
 3
 4
dRE2 = dC(treatments,:) % Display design
dRE2 =
 0 -1
-1 -1
-1  1
```

$$\begin{array}{cc} 1 & -1 \\ -1 & 0 \end{array}$$

## Purpose

Canonical correlation

## Syntax

```
[A,B] = canoncorr(X,Y)
[A,B,r] = canoncorr(X,Y)
[A,B,r,U,V] = canoncorr(X,Y)
[A,B,r,U,V,stats] = canoncorr(X,Y)
```

## Description

[A,B] = canoncorr(X,Y) computes the sample canonical coefficients for the n-by-d1 and n-by-d2 data matrices X and Y. X and Y must have the same number of observations (rows) but can have different numbers of variables (columns). A and B are d1-by-d and d2-by-d matrices, where  $d = \min(\text{rank}(X), \text{rank}(Y))$ . The jth columns of A and B contain the canonical coefficients, i.e., the linear combination of variables making up the jth canonical variable for X and Y, respectively. Columns of A and B are scaled to make the covariance matrices of the canonical variables the identity matrix (see U and V below). If X or Y is less than full rank, canoncorr gives a warning and returns zeros in the rows of A or B corresponding to dependent columns of X or Y.

[A,B,r] = canoncorr(X,Y) also returns a 1-by-d vector containing the sample canonical correlations. The jth element of r is the correlation between the jth columns of U and V (see below).

[A,B,r,U,V] = canoncorr(X,Y) also returns the canonical variables, scores. U and V are n-by-d matrices computed as

```
U = (X-repmat(mean(X),N,1))*A
V = (Y-repmat(mean(Y),N,1))*B
```

[A,B,r,U,V,stats] = canoncorr(X,Y) also returns a structure stats containing information relating to the sequence of d null

hypotheses  $H_0^{(k)}$ , that the (k+1)st through dth correlations are all zero, for  $k = 0:(d-1)$ . stats contains seven fields, each a 1-by-d vector with elements corresponding to the values of k, as described in the following table:

Field	Description
Wilks	Wilks' lambda (likelihood ratio) statistic
df1	Degrees of freedom for the chi-squared statistic, and the numerator degrees of freedom for the $F$ statistic
df2	Denominator degrees of freedom for the $F$ statistic
F	Rao's approximate $F$ statistic for $H_0^{(k)}$
pF	Right-tail significance level for F
chisq	Bartlett's approximate chi-squared statistic for $H_0^{(k)}$ with Lawley's modification
pChisq	Right-tail significance level for chisq

stats has two other fields (dfe and p) which are equal to df1 and pChisq, respectively, and exist for historical reasons.

### Examples

```
load carbig;
X = [Displacement Horsepower Weight Acceleration MPG];
nans = sum(isnan(X),2) > 0;
[A B r U V] = canoncorr(X(~nans,1:3),X(~nans,4:5));

plot(U(:,1),V(:,1),'.')
xlabel('0.0025*Disp+0.020*HP-0.000025*Wgt')
ylabel('-0.17*Accel-0.092*MPG')
```

manova1 | pca

**Purpose** Process capability indices

**Syntax** `S = capability(data,specs)`

**Description** `S = capability(data,specs)` estimates capability indices for measurements in `data` given the specifications in `specs`. `data` can be either a vector or a matrix of measurements. If `data` is a matrix, indices are computed for the columns. `specs` can be either a two-element vector of the form `[L,U]` containing lower and upper specification limits, or (if `data` is a matrix) a two-row matrix with the same number of columns as `data`. If there is no lower bound, use `-Inf` as the first element of `specs`. If there is no upper bound, use `Inf` as the second element of `specs`.

The output `S` is a structure with the following fields:

- `mu` — Sample mean
- `sigma` — Sample standard deviation
- `P` — Estimated probability of being within limits
- `P1` — Estimated probability of being below `L`
- `Pu` — Estimated probability of being above `U`
- `Cp` —  $(U-L)/(6*\text{sigma})$
- `Cp1` —  $(\text{mu}-L)/(3.*\text{sigma})$
- `Cpu` —  $(U-\text{mu})/(3.*\text{sigma})$
- `Cpk` —  $\min(\text{Cp1},\text{Cpu})$

Indices are computed under the assumption that data values are independent samples from a normal population with constant mean and variance.

Indices divide a “specification width” (between specification limits) by a “process width” (between control limits). Higher ratios indicate a process with fewer measurements outside of specification.

## Examples

### Compute Capability Indices

Simulate a sample from a process with a mean of 3 and a standard deviation of 0.005.

```
rng('default') % for reproducibility
data = normrnd(3,0.005,100,1);
```

Compute capability indices if the process has an upper specification limit of 3.01 and a lower specification limit of 2.99.

```
S = capability(data,[2.99 3.01])
```

```
S =
```

```
    mu: 3.0006
   sigma: 0.0058
      P: 0.9129
     Pl: 0.0339
     Pu: 0.0532
      Cp: 0.5735
     Cpl: 0.6088
     Cpu: 0.5382
     Cpk: 0.5382
```

Visualize the specification and process widths.

```
capaplot(data,[2.99 3.01]);
grid on
```

capaplot | histfit

# capaplot

---

**Purpose** Process capability plot

**Syntax** `p = capaplot(data,specs)`  
`[p,h] = capaplot(data,specs)`

**Description** `p = capaplot(data,specs)` estimates the mean and variance for the observations in input vector `data`, and plots the pdf of the resulting T distribution. The observations in `data` are assumed to be normally distributed. The output, `p`, is the probability that a new observation from the estimated distribution will fall within the range specified by the two-element vector `specs`. The portion of the distribution between the lower and upper bounds specified in `specs` is shaded in the plot.

`[p,h] = capaplot(data,specs)` additionally returns handles to the plot elements in `h`.

`capaplot` treats NaN values in `data` as missing, and ignores them.

**Examples** Simulate a sample from a process with a mean of 3 and a standard deviation of 0.005:

```
data = normrnd(3,0.005,100,1);
```

Compute capability indices if the process has an upper specification limit of 3.01 and a lower specification limit of 2.99:

```
S = capability(data,[2.99 3.01])
```

```
S =  
    mu: 3.0006  
   sigma: 0.0047  
    P: 0.9669  
   Pl: 0.0116  
   Pu: 0.0215  
    Cp: 0.7156  
   Cpl: 0.7567  
   Cpu: 0.6744  
   Cpk: 0.6744
```

Visualize the specification and process widths:

```
capaplot(data,[2.99 3.01]);  
grid on
```

# caseread

---

**Purpose** Read case names from file

**Syntax** `names = caseread('filename')`  
`names = caseread`

**Description** `names = caseread('filename')` reads the contents of *filename* and returns a string matrix of names. *filename* is the name of a file in the current folder, or the complete path name of any file elsewhere. `caseread` treats each line as a separate case.

`names = caseread` displays the **Select File to Open** dialog box for interactive selection of the input file.

**Examples** Read the file `months.dat` created using the `casewrite` function.

```
type months.dat
```

```
January  
February  
March  
April  
May
```

```
names = caseread('months.dat')  
names =  
January  
February  
March  
April  
May
```

**See Also** `casewrite` | `gname` | `tdfread` | `tblread`

---

<b>Purpose</b>	Write case names to file
<b>Syntax</b>	<pre>casewrite(strmat, 'filename') casewrite(strmat)</pre>
<b>Description</b>	<p><code>casewrite(strmat, 'filename')</code> writes the contents of string matrix <code>strmat</code> to <code>filename</code>. Each row of <code>strmat</code> represents one case name. <code>filename</code> is the name of a file in the current folder, or the complete path name of any file elsewhere. <code>casewrite</code> writes each name to a separate line in <code>filename</code>.</p> <p><code>casewrite(strmat)</code> displays the <b>Select File to Write</b> dialog box for interactive specification of the output file.</p>
<b>Examples</b>	<pre>strmat = char('January', 'February', ...               'March', 'April', 'May')  strmat = January February March April May  casewrite(strmat, 'months.dat') type months.dat  January February March April May</pre>
<b>See Also</b>	<code>gname</code>   <code>caseread</code>   <code>tblwrite</code>   <code>tdfread</code>

# categorical.cat

---

**Purpose** Concatenate categorical arrays

**Syntax** `c = cat(dim,A,B,...)`

**Description** `c = cat(dim,A,B,...)` concatenates the categorical arrays `A,B,...` along dimension `dim`. All inputs must have the same size except along dimension `dim`. The set of categorical levels for `C` is the sorted union of the sets of levels of the inputs, as determined by their labels.

**See Also** `cat` | `horzcat` | `vertcat`

**Purpose** Arrays for categorical data

**Description** In Statistics Toolbox, `categorical` is an abstract class, and you cannot create instances of it directly. You must create `nominal` or `ordinal` arrays. For the MATLAB categorical data type, see `categorical`.

Categorical arrays store data with values in a discrete set of levels. Each level is meant to capture a single, defining characteristic of an observation. If you do not encode ordering in the levels, the data and the array are `nominal`. If you do encode an ordering, the data and the array are `ordinal`.

## Methods

<code>addlevels</code>	Add levels to categorical array
<code>cat</code>	Concatenate categorical arrays
<code>cellstr</code>	Convert categorical array to cell array of strings
<code>char</code>	Convert categorical array to character array
<code>circshift</code>	Shift categorical array circularly
<code>ctranspose</code>	Transpose categorical matrix
<code>disp</code>	Display categorical array
<code>display</code>	Display categorical array
<code>double</code>	Convert categorical array to double array
<code>droplevels</code>	Drop levels
<code>end</code>	Last index in indexing expression for categorical array
<code>flipdim</code>	Flip categorical array along specified dimension

# categorical

---

<code>fliplr</code>	Flip categorical matrix in left/right direction
<code>flipud</code>	Flip categorical matrix in up/down direction
<code>getlabels</code>	Access categorical array labels
<code>getlevels</code>	Get categorical array levels
<code>hist</code>	Plot histogram of categorical data
<code>horzcat</code>	Horizontal concatenation for categorical arrays
<code>int16</code>	Convert categorical array to signed 16-bit integer array
<code>int32</code>	Convert categorical array to signed 32-bit integer array
<code>int64</code>	Convert categorical array to signed 64-bit integer array
<code>int8</code>	Convert categorical array to signed 8-bit integer array
<code>intersect</code>	Set intersection for categorical arrays
<code>ipermute</code>	Inverse permute dimensions of categorical array
<code>isempty</code>	True for empty categorical array
<code>isequal</code>	True if categorical arrays are equal
<code>islevel</code>	Test for levels
<code>ismember</code>	True for elements of categorical array in set
<code>isscalar</code>	True if categorical array is scalar
<code>isundefined</code>	Test for undefined elements

<code>isvector</code>	True if categorical array is vector
<code>length</code>	Length of categorical array
<code>levelcounts</code>	Element counts by level
<code>mergelevels</code>	Merge levels
<code>ndims</code>	Number of dimensions of categorical array
<code>numel</code>	Number of elements in categorical array
<code>permute</code>	Permute dimensions of categorical array
<code>reorderlevels</code>	Reorder levels
<code>repmat</code>	Replicate and tile categorical array
<code>reshape</code>	Resize categorical array
<code>rot90</code>	Rotate categorical matrix 90 degrees
<code>setdiff</code>	Set difference for categorical arrays
<code>setlabels</code>	Label levels
<code>setxor</code>	Set exclusive-or for categorical arrays
<code>shiftdim</code>	Shift dimensions of categorical array
<code>single</code>	Convert categorical array to single array
<code>size</code>	Size of categorical array
<code>squeeze</code>	Squeeze singleton dimensions from categorical array

# categorical

---

<code>subsasgn</code>	Subscripted assignment for categorical array
<code>subsindex</code>	Subscript index for categorical array
<code>subref</code>	Subscripted reference for categorical array
<code>times</code>	Product of categorical arrays
<code>transpose</code>	Transpose categorical matrix
<code>uint16</code>	Convert categorical array to unsigned 16-bit integers
<code>uint32</code>	Convert categorical array to unsigned 32-bit integers
<code>uint64</code>	Convert categorical array to unsigned 64-bit integers
<code>uint8</code>	Convert categorical array to unsigned 8-bit integers
<code>union</code>	Set union for categorical arrays
<code>unique</code>	Unique values in categorical array
<code>vertcat</code>	Vertical concatenation for categorical arrays

## Properties

<code>labels</code>	Text labels for levels
<code>undeflabel</code>	Text label for undefined levels

## Copy Semantics

Value. To learn how this affects your use of the class, see [Comparing Handle and Value Classes in the MATLAB Object-Oriented Programming documentation](#).

**How To**

- “Categorical Arrays” on page 2-41

# categorical

---

**Purpose** Create categorical array

**Description** In Statistics Toolbox, `categorical` is an abstract class, and you cannot create instances of it directly. You must create `nominal` or `ordinal` arrays. For the MATLAB categorical data type, see `categorical`.

**See Also** `nominal` | `ordinal` | `categorical`

# clustering.evaluation.DaviesBouldinEvaluation

---

**Superclasses** ClusterCriterion

**Purpose** Davies-Bouldin criterion clustering evaluation object

**Description** clustering.evaluation.DaviesBouldinEvaluation is an object consisting of sample data, clustering data, and Davies-Bouldin criterion values used to evaluate the optimal number of clusters. Create a Davies-Bouldin criterion clustering evaluation object using evalclusters.

**Construction** `eva = evalclusters(x,clust,'DaviesBouldin')` creates a Davies-Bouldin criterion clustering evaluation object.

`eva = evalclusters(x,clust,'DaviesBouldin',Name,Value)` creates a Davies-Bouldin criterion clustering evaluation object using additional options specified by one or more name-value pair arguments.

## Input Arguments

### **x - Input data**

matrix

Input data, specified as an  $N$ -by- $P$  matrix.  $N$  is the number of observations, and  $P$  is the number of variables.

### **Data Types**

single | double

### **clust - Clustering algorithm**

'kmeans' | 'linkage' | 'gmdistribution' | matrix of clustering solutions | function handle

Clustering algorithm, specified as one of the following.

# clustering.evaluation.DaviesBouldinEvaluation

---

'kmeans'	Cluster the data in $X$ using the kmeans clustering algorithm, with 'EmptyAction' set to 'singleton' and 'Replicates' set to 5.
'linkage'	Cluster the data in $X$ using the clusterdata agglomerative clustering algorithm, with 'Linkage' set to 'ward'.
'gmdistribution'	Cluster the data in $X$ using the gmdistribution Gaussian mixture distribution algorithm, with 'SharedCov' set to true and 'Replicates' set to 5.

If Criterion is 'CalinskHarabasz', 'DaviesBouldin', or 'silhouette', you can specify a clustering algorithm using the function\_handle (@) operator. The function must be of the form

```
C = clustfun(DATA,K)
```

where DATA is the data to be clustered, and K is the number of clusters. The output of clustfun must be one of the following:

- A vector of integers representing the cluster index for each observation in DATA. There must be K unique values in this vector.
- A numeric  $n$ -by- $K$  matrix of score for  $n$  observations and  $K$  classes. In this case, the cluster index for each observation is determined by taking the largest score value in each row.

If Criterion is 'CalinskHarabasz', 'DaviesBouldin', or 'silhouette', you can also specify clust as a  $n$ -by- $K$  matrix containing the proposed clustering solutions.  $n$  is the number of observations in the sample data, and  $K$  is the number of proposed clustering solutions. Column  $j$  contains the cluster indices for each of the  $N$  points in the  $j$ th clustering solution.

## **Name-Value Pair Arguments**

Specify optional comma-separated pairs of `Name`, `Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( ' '). You can specify several name and value pair arguments in any order as `Name1,Value1,...,NameN,ValueN`.

**Example:** `'KList',[1:5]` specifies to test 1, 2, 3, 4, and 5 clusters to find the optimal number.

## **KList - List of number of clusters to evaluate**

vector

List of number of clusters to evaluate, specified as the comma-separated pair consisting of `'KList'` and a vector of positive integer values. You must specify `KList` when `clust` is a clustering algorithm name string or a function handle. When `criterion` is `'gap'`, `clust` must be a string or a function handle, and you must specify `KList`.

**Example:** `'KList',[1:6]`

## **Properties**

### **ClusteringFunction**

Clustering algorithm used to cluster the input data, stored as a valid clustering algorithm name string or function handle. If the clustering solutions are provided in the input, `ClusteringFunction` is empty.

### **CriterionName**

Name of the criterion used for clustering evaluation, stored as a valid criterion name string.

### **CriterionValues**

Criterion values corresponding to each proposed number of clusters in `InspectedK`, stored as a vector of numerical values.

### **InspectedK**

# clustering.evaluation.DaviesBouldinEvaluation

---

List of the number of proposed clusters for which to compute criterion values, stored as a vector of positive integer values.

## Missing

Logical flag for excluded data, stored as a column vector of logical values. If `Missing` equals `true`, then the corresponding value in the data matrix `x` is not used in the clustering solution.

## NumObservations

Number of observations in the data matrix `X`, minus the number of missing (NaN) values in `X`, stored as a positive integer value.

## OptimalK

Optimal number of clusters, stored as a positive integer value.

## OptimalY

Optimal clustering solution corresponding to `OptimalK`, stored as a column vector of positive integer values. If the clustering solutions are provided in the input, `OptimalY` is empty.

## X

Data used for clustering, stored as a matrix of numerical values.

## Methods

### Inherited Methods

<code>compact</code>	Compact clustering evaluation object
<code>plot</code>	Plot clustering evaluation object criterion values

## Definitions

### Davies-Bouldin Criterion

The Davies-Bouldin criterion is based on a ratio of within-cluster and between-cluster distances. The Davies-Bouldin index is defined as

$$DB = \frac{1}{k} \sum_{i=1}^k \max_{j \neq i} \{D_{i,j}\},$$

where  $D_{i,j}$  is the within-to-between cluster distance ratio for the  $i$ th and  $j$ th clusters. In mathematical terms,

$$D_{i,j} = \frac{(\bar{d}_i + \bar{d}_j)}{d_{i,j}}.$$

$\bar{d}_i$  is the average distance between each point in the  $i$ th cluster and the centroid of the  $i$ th cluster.  $\bar{d}_j$  is the average distance between each point in the  $i$ th cluster and the centroid of the  $j$ th cluster.  $d_{i,j}$  is the Euclidean distance between the centroids of the  $i$ th and  $j$ th clusters.

The maximum value of  $D_{i,j}$  represents the worst-case within-to-between cluster ratio for cluster  $i$ . The optimal clustering solution has the smallest Davies-Bouldin index value.

## Examples

### Evaluate the Clustering Solution Using Davies-Bouldin Criterion

Evaluate the optimal number of clusters using the Davies-Bouldin clustering evaluation criterion.

Generate sample data containing random numbers from three multivariate distributions with different parameter values.

```
rng('default'); % For reproducibility
mu1 = [2 2];
sigma1 = [0.9 -0.0255; -0.0255 0.9];

mu2 = [5 5];
sigma2 = [0.5 0 ; 0 0.3];

mu3 = [-2, -2];
```

# clustering.evaluation.DaviesBouldinEvaluation

---

```
sigma3 = [1 0 ; 0 0.9];
```

```
N = 200;
```

```
X = [mvnrnd(mu1,sigma1,N);...  
     mvnrnd(mu2,sigma2,N);...  
     mvnrnd(mu3,sigma3,N)];
```

Evaluate the optimal number of clusters using the Davies-Bouldin criterion. Cluster the data using kmeans.

```
E = evalclusters(X,'kmeans','DaviesBouldin','klist',[1:6])
```

```
E =
```

```
DaviesBouldinEvaluation with properties:
```

```
NumObservations: 600
```

```
InspectedK: [1 2 3 4 5 6]
```

```
CriterionValues: [NaN 0.4663 0.4454 0.8300 0.7283 0.9199]
```

```
OptimalK: 3
```

The `OptimalK` value indicates that, based on the Davies-Bouldin criterion, the optimal number of clusters is three.

Plot the Davies-Bouldin criterion values for each number of clusters tested.

```
figure;  
plot(E)
```

# clustering.evaluation.DaviesBouldinEvaluation

The plot shows that the lowest Davies-Bouldin value occurs at three clusters, suggesting that the optimal number of clusters is three.

Create a grouped scatter plot to visually examine the suggested clusters.

```
figure;  
gscatter(X(:,1),X(:,2),E.OptimalY,'rbg','xod')
```

# clustering.evaluation.DaviesBouldinEvaluation

---

The plot shows three distinct clusters within the data: Cluster 1 is in the lower-left corner, cluster 2 is near the center of the plot, and cluster 3 is in the upper-right corner.

# dataset.cat

---

**Purpose** Concatenate dataset arrays

**Syntax** `ds = cat(dim, ds1, ds2, ...)`

**Description** `ds = cat(dim, ds1, ds2, ...)` concatenates the dataset arrays `ds1`, `ds2`, ... along dimension `dim` by calling the `dataset/horzcat` or `dataset/vertcat` method. `dim` must be 1 or 2.

**See Also** `horzcat` | `vertcat`

<b>Purpose</b>	Categorical splits used for branches in decision tree
<b>Syntax</b>	<code>v=catsplit(t)</code> <code>v=catsplit(t,j)</code>
<b>Description</b>	<p><code>v=catsplit(t)</code> returns an n-by-2 cell array <code>v</code>. Each row in <code>v</code> gives left and right values for a categorical split. For each branch node <code>j</code> based on a categorical predictor variable <code>z</code>, the left child is chosen if <code>z</code> is in <code>v(j,1)</code> and the right child is chosen if <code>z</code> is in <code>v(j,2)</code>. The splits are in the same order as nodes of the tree. Nodes for these splits can be found by running <code>cuttype</code> and selecting 'categorical' cuts from top to bottom.</p> <p><code>v=catsplit(t,j)</code> takes an array <code>j</code> of rows and returns the splits for the specified rows.</p>
<b>See Also</b>	<code>classregtree</code>

# gmdistribution.cdf

---

**Purpose** Cumulative distribution function for Gaussian mixture distribution

**Syntax** `y = cdf(obj,X)`

**Description** `y = cdf(obj,X)` returns a vector `y` of length  $n$  containing the values of the cumulative distribution function (`cdf`) for the `gmdistribution` object `obj`, evaluated at the  $n$ -by- $d$  data matrix `X`, where  $n$  is the number of observations and  $d$  is the dimension of the data. `obj` is an object created by `gmdistribution` or `fit`. `y(I)` is the cdf of observation `I`.

**Examples** Create a `gmdistribution` object defining a two-component mixture of bivariate Gaussian distributions:

```
MU = [1 2; -3 -5];
SIGMA = cat(3,[2 0; 0 .5],[1 0; 0 1]);
p = ones(1,2)/2;
obj = gmdistribution(MU,SIGMA,p);

ezsurf(@(x,y)cdf(obj,[x y]),[-10 10],[-10 10])
```

## See Also

# ccdesign

**Purpose** Central composite design

**Syntax**  
`dCC = ccdesign(n)`  
`[dCC,blocks] = ccdesign(n)`  
`[...] = ccdesign(n,'Name',value)`

**Description** `dCC = ccdesign(n)` generates a central composite design for  $n$  factors.  $n$  must be an integer 2 or larger. The output matrix `dCC` is  $m$ -by- $n$ , where  $m$  is the number of runs in the design. Each row represents one run, with settings for all factors represented in the columns. Factor values are normalized so that the cube points take values between -1 and 1.

`[dCC,blocks] = ccdesign(n)` requests a blocked design. The output `blocks` is an  $m$ -by-1 vector of block numbers for each run. Blocks indicate runs that are to be measured under similar conditions to minimize the effect of inter-block differences on the parameter estimates.

`[...] = ccdesign(n,'Name',value)` specifies one or more optional name/value pairs for the design. Valid parameters and their values are listed in the following table. Specify *Name* in single quotes.

Parameter	Description	Values	Value Description
center	Number of center points.	Integer	Number of center points to include.
		'uniform'	Select number of center points to give uniform precision.
		'orthogonal'	Select number of center points to give an orthogonal design. This is the default.

Parameter	Description	Values	Value Description
fraction	Fraction of full-factorial cube, expressed as an exponent of 1/2.	0	Whole design. Default when $n \leq 4$ .
		1	1/2 fraction. Default when $4 < n \leq 7$ or $n > 11$ .
		2	1/4 fraction. Default when $7 < n \leq 9$ .
		3	1/8 fraction. Default when $n = 10$ .
		4	1/16 fraction. Default when $n = 11$ .
type	Type of CCD.	'circumscribed'	Circumscribed (CCC). This is the default.
		'inscribed'	Inscribed (CCI).
		'faced'	Faced (CCF).
blocksize	Maximum number of points per block.	Integer	The default is Inf.

### Examples

The following creates a 2-factor CCC:

```
dCC = ccdesign(2,'type','circumscribed')
dCC =
    -1.0000    -1.0000
```

```
-1.0000    1.0000
 1.0000   -1.0000
 1.0000    1.0000
-1.4142     0
 1.4142     0
     0   -1.4142
     0    1.4142
     0     0
     0     0
     0     0
     0     0
     0     0
     0     0
     0     0
     0     0
     0     0
```

The center point is run 8 times to reduce the correlations among the coefficient estimates.

Visualize the design as follows:

```
plot(dCC(:,1),dCC(:,2),'ro','MarkerFaceColor','b')
X = [1 -1 -1 -1; 1 1 1 -1];
Y = [-1 -1 1 -1; 1 -1 1 1];
line(X,Y,'Color','b')
axis square equal
```

**See Also**

`bbdesign`

**Purpose** Cumulative distribution functions

**Syntax**

```
y = cdf('name',x,A)
y = cdf('name',x,A,B)
y = cdf('name',x,A,B,C)
y = cdf( __ , 'upper' )
```

**Description** `y = cdf('name',x,A)` returns the cumulative distribution function for the one-parameter family of distributions specified by `name`. `a` contains parameter values for the distribution. The cumulative distribution function is evaluated at the values in `x` and its values are returned in `y`. If `x` and `A` are arrays, they must be the same size. If `x` is a scalar, it is expanded to a constant matrix the same size as `A`. If `a` is a scalar, it is expanded to a constant matrix the same size as `x`. `y` is the common size of `x` and `A` after any necessary scalar expansion.

`y = cdf('name',x,A,B)` returns the cumulative distribution function for two-parameter families of distributions, where parameter values are given in `A` and `B`. If `x`, `A`, and `B` are arrays, they must be the same size. If `x` is a scalar, it is expanded to a constant matrix the same size as `A` and `B`. If either `A` or `B` are scalars, they are expanded to constant matrices the same size as `x`. `y` is the common size of `x`, `A`, and `B` after any necessary scalar expansion.

`y = cdf('name',x,A,B,C)` returns the cumulative distribution function for three-parameter families of distributions, where parameter values are given in `A`, `B`, and `C`. If `x`, `A`, `B`, and `C` are arrays, they must be the same size. If `x` is a scalar, it is expanded to a constant matrix the same size as `A`, `B`, and `C`. If any of `A`, `B` or `C` are scalars, they are expanded to constant matrices the same size as `x`. `y` is the common size of `x`, `A`, `B`, and `C` after any necessary scalar expansion.

`y = cdf( __ , 'upper' )` returns the complement of the cumulative distribution function for the specified distribution, using an algorithm that more accurately computes the extreme upper tail probabilities. You can use the `'upper'` argument with any of the previous syntaxes.

## Examples

### Compute Normal Distribution cdf

Compute the cdf of the normal distribution with mean 0 and standard deviation 1 at inputs -2, -1, 0, 1, 2.

```
p = cdf('Normal', -2:2, 0, 1)
```

```
p =
    0.0228    0.1587    0.5000    0.8413    0.9772
```

The order of the parameters is the same as for `normcdf`.

### Compute Poisson Distribution cdf

Compute the cdfs of Poisson distributions with rate parameters 1, 2, ... 5, at inputs 0, 1, ... 4, respectively.

```
p = cdf('Poisson', 0:4, 1:5)
```

```
p =
    0.3679    0.4060    0.4232    0.4335    0.4405
```

The order of the parameters is the same as for `poisscdf`.

# prob.TruncatableDistribution.cdf

---

## Output Arguments

### **y - Cumulative distribution function**

array

Cumulative distribution function of the specified probability distribution, evaluated at the values in **x**, returned as a array. **y** has the same dimensions as **x**.

## Examples

### **Plot Standard Normal Distribution cdf**

Create a standard normal distribution object.

```
pd = makedist('Normal')
```

```
pd =
```

```
NormalDistribution
```

```
Normal distribution
```

```
mu = 0
```

```
sigma = 1
```

Specify the **x** values and compute the cdf.

```
x = -3:.1:3;  
cdf_normal = cdf(pd,x);
```

Plot the cdf of the standard normal distribution.

```
plot(x,cdf_normal,'LineWidth',2)
```

## Plot Gamma Distribution cdf

Create three gamma distribution objects. The first uses the default parameter values. The second specifies  $a = 1$  and  $b = 2$ . The third specifies  $a = 2$  and  $b = 1$ .

```
pd_gamma = makedist('Gamma')
```

```
pd_gamma =
```

# prob.TruncatableDistribution.cdf

---

```
GammaDistribution
```

```
Gamma distribution
```

```
a = 1
```

```
b = 1
```

```
pd_12 = makedist('Gamma','a',1,'b',2)
```

```
pd_12 =
```

```
GammaDistribution
```

```
Gamma distribution
```

```
a = 1
```

```
b = 2
```

```
pd_21 = makedist('Gamma','a',2,'b',1)
```

```
pd_21 =
```

```
GammaDistribution
```

```
Gamma distribution
```

```
a = 2
```

```
b = 1
```

Specify the x values and compute the cdf for each distribution.

```
x = 0:.1:5;
```

```
cdf_gamma = cdf(pd_gamma,x);
```

```
cdf_12 = cdf(pd_12,x);
```

```
cdf_21 = cdf(pd_21,x);
```

Create a plot to visualize how the cdf of the gamma distribution changes when you specify different values for the shape parameters a and b.

```
figure;
```

```
J = plot(x,cdf_gamma)
```

```
hold on;  
K = plot(x,cdf_gamma_12,'r--')  
L = plot(x,cdf_gamma_21,'k-.')  
set(J,'LineWidth',2);  
set(K,'LineWidth',2);  
legend([J K L], 'a = 1, b = 1', 'a = 1, b = 2', 'a = 2, b = 1', 'Location  
hold off;
```

# cdfplot

---

**Purpose** Empirical cumulative distribution function plot

**Syntax**

```
cdfplot(X)
h = cdfplot(X)
[h,stats] = cdfplot(X)
```

**Description** `cdfplot(X)` displays a plot of the empirical cumulative distribution function (cdf) for the data in the vector `X`. The empirical cdf  $F(x)$  is defined as the proportion of `X` values less than or equal to `x`.

This plot, like those produced by `hist` and `normplot`, is useful for examining the distribution of a sample of data. You can overlay a theoretical cdf on the same plot to compare the empirical distribution of the sample to the theoretical distribution.

The `kstest`, `kstest2`, and `lillietest` functions compute test statistics that are derived from the empirical cdf. You may find the empirical cdf plot produced by `cdfplot` useful in helping you to understand the output from those functions.

`h = cdfplot(X)` returns a handle to the cdf curve.

`[h,stats] = cdfplot(X)` also returns a `stats` structure with the following fields.

Field	Description
<code>stats.min</code>	Minimum value
<code>stats.max</code>	Maximum value
<code>stats.mean</code>	Sample mean
<code>stats.median</code>	Sample median (50th percentile)
<code>stats.std</code>	Sample standard deviation

**Examples** The following example compares the empirical cdf for a sample from an extreme value distribution with a plot of the cdf for the sampling distribution. In practice, the sampling distribution would be unknown, and would be chosen to match the empirical cdf.

```
y = evrnd(0,3,100,1);  
cdfplot(y)  
hold on  
x = -20:0.1:10;  
f = evcdf(x,0,3);  
plot(x,f,'m')  
legend('Empirical','Theoretical','Location','NW')
```

# cell2dataset

---

**Purpose** Convert cell array to dataset array

**Syntax**  
`ds = cell2dataset(C)`  
`ds = cell2dataset(C,Name,Value)`

**Description** `ds = cell2dataset(C)` converts a cell array to a dataset array.

`ds = cell2dataset(C,Name,Value)` performs the conversion using additional options specified by one or more `Name, Value` pair arguments.

## Input Arguments

### **C - Input cell array**

cell array

Input cell array to convert to a dataset array, specified as an  $M$ -by- $N$  cell array. Each column of `C` becomes a variable in the output dataset array, `ds`. By default, `cell2dataset` assumes that the first row of `C` contains variable names.

### **Data Types**

cell

### **Name-Value Pair Arguments**

Specify optional comma-separated pairs of `Name, Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( ' '). You can specify several name and value pair arguments in any order as `Name1, Value1, ..., NameN, ValueN`.

**Example:** `'ReadVarNames', false, 'ReadObsNames', true` specifies that the first row of the cell array does not contain variable names, but the first column contains observation names.

### **'ReadVarNames' - Indicator for whether or not to read variable names**

true (default) | false

Indicator for whether or not to read variable names from the first row of the input cell array, specified as the comma-separated pair consisting of 'ReadVarNames' and either true or false. The default value is true, unless variable names are specified using the name-value pair argument VarNames. When ReadVarNames is false, cell2dataset creates default variable names if you do not provide any.

**Example:** 'ReadVarNames',false

### **'VarNames' - Variable names for output dataset array**

cell array of strings

Variable names for the output dataset array, specified as the comma-separated pair consisting of 'VarNames' and a cell array of strings. You must provide a variable name for each variable in ds. The names must be valid MATLAB identifiers, and must be unique.

**Example:** 'VarNames',{ 'myVar1', 'myVar2', 'myVar3' }

### **'ReadObsNames' - Indicator for whether or not to read observation names**

false (default) | true

Indicator for whether or not to read observation names from the input cell array, specified as the comma-separated pair consisting of 'ReadObsNames' and either true or false. When ReadObsNames has the value true, cell2dataset creates observation names in ds using the first column of C, and sets ds.Properties.DimNames equal to {C{1,1}, 'Variables'}.

**Example:** 'ReadObsNames',true

### **'ObsNames' - Observation names for output dataset array**

cell array of strings

Observation names for the output dataset array, specified as the comma-separated pair consisting of 'ObsNames' and a cell array of strings. The names do not need to be valid MATLAB identifiers, but they must be unique.

## **'NumCols' - Number of columns for each variable**

vector of nonnegative integers

Number of columns for each variable in `ds`, specified as the comma-separated pair consisting of `'NumCols'` and a vector of nonnegative integers. When the number of columns for a variable is greater than one, `cell2dataset` combines multiple columns in `C` into a single variable in `ds`. The vector you assign to `NumCols` must sum to `size(C,2)`, or `size(C,1)` of `ReadObsNames` is equal to `true`.

For example, to convert a cell array with eight columns into a dataset array with five variables, specify a vector with five elements that sum to eight, such as `'NumCols', [1,1,3,1,2]`.

## **Output Arguments**

### **`ds` - Output dataset array**

dataset array

Output dataset array, returned by default with a variable for each column of `C`, an observation for each row of `C` (except for the first row), and variable names corresponding to the first row of `C`.

- If you set `ReadVarNames` equal to `false` (or specify `VarNames`), then there is an observation in `ds` for each row of `C`, and `cell2dataset` creates default variable names (or uses the names in `VarNames`).
- If you set `ReadObsNames` equal to `true`, then `cell2dataset` uses the first column of `C` as observation names.
- If you specify `NumCols`, then the number of variables in `ds` is equal to the length of the specified vector of column numbers.

## **Examples**

### **Convert Cell Array to Dataset Array**

Convert a cell array to a dataset array using the default options.

Create a cell array to convert.

```
C = {'Name', 'Gender', 'SystolicBP', 'DiastolicBP';  
    'CLARK', 'M', 124, 93;  
    'BROWN', 'F', 122, 80;  
    'MARTIN', 'M', 130, 92}
```

```
C =
      'Name'      'Gender'      'SystolicBP'      'DiastolicBP'
      'CLARK'     'M'          [      124]      [      93]
      'BROWN'     'F'          [      122]      [      80]
      'MARTIN'    'M'          [      130]      [      92]
```

Convert the cell array to a dataset array.

```
ds = cell2dataset(C)
```

```
ds =
      Name          Gender      SystolicBP      DiastolicBP
      'CLARK'      'M'          124              93
      'BROWN'      'F'          122              80
      'MARTIN'     'M'          130              92
```

The first row of `C` become the variable names in the output dataset array, `ds`.

### Create a Dataset Array with Multicolumn Variables

Convert a cell array to a dataset array containing multicolumn variables.

Create a cell array to convert.

```
C = {'Name', 'Gender', 'SystolicBP', 'DiastolicBP';
     'CLARK', 'M', 124, 93;
     'BROWN', 'F', 122, 80;
     'MARTIN', 'M', 130, 92}
```

```
C =
      'Name'      'Gender'      'SystolicBP'      'DiastolicBP'
      'CLARK'     'M'          [      124]      [      93]
      'BROWN'     'F'          [      122]      [      80]
      'MARTIN'    'M'          [      130]      [      92]
```

# cell2dataset

---

Convert the cell array to a dataset array, combining the systolic and diastolic blood pressure measurements into one variable named `BloodPressure`.

```
ds = cell2dataset(C, 'NumCols', [1,1,2]);  
ds.Properties.VarNames{3} = 'BloodPressure';  
ds
```

```
ds =
```

Name	Gender	BloodPressure
'CLARK'	'M'	124 93
'BROWN'	'F'	122 80
'MARTIN'	'M'	130 92

The output dataset array has three observations and three variables.

- “Create a Dataset Array from a File” on page 2-71

## Concepts

- “Dataset Arrays” on page 2-135

**Purpose** Convert categorical array to cell array of strings

**Syntax** `B = cellstr(A)`

**Description** `B = cellstr(A)` converts the categorical array `A` to a cell array of strings. Each element of `B` contains the categorical level label for the corresponding element of `A`.

**See Also** `char` | `getlabels`

# dataset.cellstr

---

**Purpose** Create cell array of strings from dataset array

**Syntax** B = cellstr(A)  
B = cellstr(A, VARS)

**Description** B = cellstr(A) returns the contents of the dataset A, converted to a cell array of strings. The variables in the dataset must support the conversion and must have compatible sizes.

B = cellstr(A, VARS) returns the contents of the dataset variables specified by VARS. VARS is a positive integer, a vector of positive integers, a variable name, a cell array containing one or more variable names, or a logical vector.

**See Also** dataset.double | dataset.replacdata

**Purpose** Convert categorical array to character array

**Syntax** `B = char(A)`

**Description** `B = char(A)` converts the categorical array `A` to a 2-D character matrix. `char` does not preserve the shape of `A`. `B` contains `numel(A)` rows, and each row of `B` contains the categorical level label for the corresponding element of `A(:)`.

**See Also** `cellstr` | `getlabels`

# chi2cdf

---

**Purpose** Chi-square cumulative distribution function

**Syntax**  
`p = chi2cdf(x,v)`  
`p = chi2cdf(x,v,'upper')`

**Description** `p = chi2cdf(x,v)` computes the chi-square cdf at each of the values in `x` using the corresponding degrees of freedom in `v`. `x` and `v` can be vectors, matrices, or multidimensional arrays that have the same size. The degrees of freedom parameters in `v` must be positive integers, and the values in `x` must lie on the interval `[0 Inf]`. A scalar input is expanded to a constant array with the same dimensions as the other input.

`p = chi2cdf(x,v,'upper')` returns the complement of the chi-square cdf at each value in `x`, using an algorithm that more accurately computes the extreme upper tail probabilities.

The  $\chi^2$  cdf for a given value  $x$  and degrees-of-freedom  $v$  is

$$p = F(x | v) = \int_0^x \frac{t^{(v-2)/2} e^{-t/2}}{2^{v/2} \Gamma(v/2)} dt$$

where  $\Gamma(\cdot)$  is the Gamma function.

The chi-square density function with  $v$  degrees-of-freedom is the same as the gamma density function with parameters  $v/2$  and 2.

## Examples

### Compute Chi-Square CDF

```
probability = chi2cdf(5,1:5)
```

```
probability =  
    0.9747    0.9179    0.8282    0.7127    0.5841
```

```
probability = chi2cdf(1:5,1:5)
```

```
probability =  
    0.6827    0.6321    0.6084    0.5940    0.5841
```

**See Also**      `cdf` | `chi2pdf` | `chi2inv` | `chi2stat` | `chi2rnd`

**How To**      • “Chi-Square Distribution” on page B-28

# chi2gof

---

**Purpose** Chi-square goodness-of-fit test

**Syntax**

```
h = chi2gof(x)
h = chi2gof(x,Name,Value)
[h,p] = chi2gof( ___ )
[h,p,stats] = chi2gof( ___ )
```

**Description** `h = chi2gof(x)` returns a test decision for the null hypothesis that the data in vector `x` comes from a normal distribution with a mean and variance estimated from `x`, using the chi-square goodness-of-fit test. The alternative hypothesis is that the data does not come from such a distribution. The result `h` is 1 if the test rejects the null hypothesis at the 5% significance level, and 0 otherwise.

`h = chi2gof(x,Name,Value)` returns a test decision for the chi-square goodness-of-fit test with additional options specified by one or more name-value pair arguments. For example, you can test for a distribution other than normal, or change the significance level of the test.

`[h,p] = chi2gof( ___ )` also returns the *p*-value `p` of the hypothesis test, using any of the input arguments from the previous syntaxes.

`[h,p,stats] = chi2gof( ___ )` also returns the structure `stats`, containing information about the test statistic.

## Input Arguments

### **x - Sample data**

vector

Sample data for the hypothesis test, specified as a vector.

### **Name-Value Pair Arguments**

Specify optional comma-separated pairs of `Name,Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( ' '). You can

specify several name and value pair arguments in any order as `Name1,Value1,...,NameN,ValueN`.

**Example:** `'NBins',8,'Alpha',0.01` pools the data into eight bins and conducts the hypothesis test at the 1% significance level.

### **'NBins' - Number of bins**

10 (default) | positive integer value

Number of bins to use for the data pooling, specified as the comma-separated pair consisting of `'NBins'` and a positive integer value. If you specify a value for `NBins`, do not specify a value for `Ctrs` or `Edges`.

**Example:** `'NBins',8`

### **Data Types**

single | double

### **'Ctrs' - Bin centers**

vector

Bin centers, specified as the comma-separated pair consisting of `'Ctrs'` and a vector of center values for each bin. If you specify a value for `Ctrs`, do not specify a value for `NBins` or `Edges`.

**Example:** `'Ctrs',[1 2 3 4 5]`

### **Data Types**

single | double

### **'Edges' - Bin edges**

vector

Bin edges, specified as the comma-separated pair consisting of `'Edges'` and a vector of edge values for each bin. If you specify a value for `Edges`, do not specify a value for `NBins` or `Ctrs`.

**Example:** `'Edges',[-2.5 -1.5 -0.5 0.5 1.5 2.5]`

### **Data Types**

single | double

## **'CDF' - cdf of hypothesized distribution**

probability distribution object | function handle | cell array

The cdf of the hypothesized distribution, specified as the comma-separated pair consisting of 'CDF' and a probability distribution object, function handle, or cell array.

- If CDF is a probability distribution object, the degrees of freedom account for whether you estimate the parameters using `fitdist` or specify them using `makedist`.
- If CDF is a function handle, the distribution function must take `x` as its only argument.
- If CDF is a cell array, the first element must be a function handle, and the remaining elements must be parameter values, one per cell. The function must take `x` as its first argument, and the other parameters in the array as later arguments.

If you specify a value for CDF, do not specify a value for Expected.

**Example:** 'CDF',pd\_object

### **Data Types**

single | double

## **'Expected' - Expected counts**

vector of nonnegative values

Expected counts for each bin, specified as the comma-separated pair of 'Expected' and a vector of nonnegative values. If Expected depends on estimated parameters, use `NParams` to ensure that `chi2gof` correctly calculates the degrees of freedom. If you specify a value for Expected, do not specify a value for CDF.

**Example:** 'Expected',[19.1446 18.3789 12.3224 8.2432 4.1378]

### **Data Types**

single | double

## **'NParams' - Number of estimated parameters**

positive integer value

Number of estimated parameters used to describe the null distribution, specified as the comma-separated pair consisting of 'NParams' and a positive integer value. This value adjusts the degrees of freedom of the test based on the number of estimated parameters used to compute the cdf or expected counts.

The default value for NParams depends on how you specify the null distribution:

- If you specify CDF as a probability distribution object, NParams is equal to the number of estimated parameters used to create the object.
- If you specify CDF as a function name or handle, the default value of NParams is 0.
- If you specify CDF as a cell array, the default value of NParams is the number of parameters in the array.
- If you specify Expected, the default value of NParams is 0.

**Example:** 'NParams',1

### Data Types

single | double

### 'EMin' - Minimum expected count per bin

5 (default) | nonnegative integer value

Minimum expected count per bin, specified as the comma-separated pair consisting of 'EMin' and a nonnegative integer value. If the bin at the extreme end of either tail has an expected value less than EMin, it is combined with a neighboring bin until the count in each extreme bin is at least 5. If any interior bins have a count less than 5, chi2gof displays a warning, but does not combine the interior bins. In that case, you should use fewer bins, or provide bin centers or edges, to increase the expected counts in all bins. Specify EMin as 0 to prevent the combining of bins.

**Example:** 'EMin',0

## Data Types

single | double

## 'Frequency' - Frequency

vector of nonnegative integer values

Frequency of data values, specified as the comma-separated pair consisting of 'Frequency' and a vector of nonnegative integer values that is the same length as the vector  $x$ .

**Example:** 'Frequency',[20 16 13 10 8]

## Data Types

single | double

## 'Alpha' - Significance level

0.05 (default) | scalar value in the range (0,1)

Significance level of the hypothesis test, specified as the comma-separated pair consisting of 'Alpha' and a scalar value in the range (0,1).

**Example:** 'Alpha',0.01

## Data Types

single | double

## Output Arguments

### **h** - Hypothesis test result

1 | 0

Hypothesis test result, returned as a logical value.

- If  $h = 1$ , this indicates the rejection of the null hypothesis at the Alpha significance level.
- If  $h = 0$ , this indicates a failure to reject the null hypothesis at the Alpha significance level.

### **p** - p-value

scalar value in the range [0,1]

$p$ -value of the test, returned as a scalar value in the range [0,1].  $p$  is the probability of observing a test statistic as extreme as, or more extreme than, the observed value under the null hypothesis. Small values of  $p$  cast doubt on the validity of the null hypothesis.

### **stats - Test statistics**

structure

Test statistics, returned as a structure containing the following:

- `chi2stat` — Value of the test statistic.
- `df` — Degrees of freedom of the test.
- `edges` — Vector of bin edges after pooling.
- `O` — Vector of observed counts for each bin.
- `E` — Vector of expected counts for each bin.

## **Examples**

### **Test for a Normal Distribution**

Create a standard normal probability distribution object. Generate a data vector `x` using random numbers from the distribution.

```
pd = makedist('Normal');  
rng('default') % for reproducibility  
x = random(pd,100,1);
```

Test the null hypothesis that the data in `x` comes from a population with a normal distribution.

```
h = chi2gof(x)
```

```
h =
```

```
0
```

The returned value `h = 0` indicates that `chi2gof` does not reject the null hypothesis at the default 5% significance level.

## Test the Hypothesis at a Different Significance Level

Create a standard normal probability distribution object. Generate a data vector  $x$  using random numbers from the distribution.

```
pd = makedist('Normal');  
rng('default') % for reproducibility  
x = random(pd,100,1);
```

Test the null hypothesis that the data in  $x$  comes from a population with a normal distribution at the 1% significance level.

```
[h,p] = chi2gof(x,'Alpha',0.01)
```

```
h =
```

```
0
```

```
p =
```

```
0.3775
```

The returned value  $h = 0$  indicates that `chi2gof` does not reject the null hypothesis at the 1% significance level.

## Test for a Weibull Distribution Using a Probability Distribution Object

Navigate to the appropriate folder and load the lightbulb lifetime sample data.

```
cd('matlabroot');  
cd('help/toolbox/stats/examples');  
load lightbulb;
```

Create a vector from the first column of the data matrix, which contains the lifetime in hours of the lightbulbs.

```
x = lightbulb(:,1);
```

Test the null hypothesis that the data in `x` comes from a population with a Weibull distribution. Use `fitdist` to create a probability distribution object with `A` and `B` parameters estimated from the data.

```
pd = fitdist(x, 'Weibull');
h = chi2gof(x, 'CDF', pd)
```

```
h =
```

```
1
```

The returned value `h = 1` indicates that `chi2gof` rejects the null hypothesis at the default 5% significance level.

### Test for a Poisson Distribution

Create six bins, numbered 0 through 5, to use for data pooling.

```
bins = 0:5;
```

Create a vector containing the observed counts for each bin and compute the total number of observations.

```
obsCounts = [6 16 10 12 4 2];
n = sum(obsCounts);
```

Fit a Poisson probability distribution object to the data and compute the expected count for each bin.

```
pd = fitdist(bins, 'Poisson', 'Frequency', obsCounts);
expCounts = n*pdf(pd, bins);
```

Test the null hypothesis that the data in `obsCounts` comes from a Poisson distribution with a `lambda` parameter equal to `lambdaHat`.

```
[h,p,st] = chi2gof(bins, 'Ctrs', bins, ...
                  'Frequency', obsCounts, ...
                  'Expected', expCounts, ...
```

```
                                'NParams',1)

h =

    0

p =

    0.4654

st =

    chi2stat: 2.5550
           df: 3
          edges: [1x6 double]
                0: [6 16 10 12 6]
                E: [7.0429 13.8041 13.5280 8.8383 6.0284]
```

The returned value `h = 0` indicates that `chi2gof` does not reject the null hypothesis at the default 5% significance level. The vector `E` contains the expected counts for each bin under the null hypothesis, and `0` contains the observed counts for each bin.

## Definitions

### Chi-Square Goodness-of-Fit Test

The chi-square goodness-of-fit test determines if a data sample comes from a specified probability distribution, with parameters estimated from the data.

The test groups the data into bins, calculating the observed and expected counts for those bins, and computing the chi-square test statistic

$$\chi^2 = \sum_{i=1}^N (O_i - E_i)^2 / E_i ,$$

where  $O_i$  are the observed counts and  $E_i$  are the expected counts based on the hypothesized distribution. The test statistic has an approximate chi-square distribution when the counts are sufficiently large.

**Algorithms**

`chi2gof` compares the value of the test statistic to a chi-square distribution with degrees of freedom equal to  $n_{bins} - 1 - n_{params}$ , where  $n_{bins}$  is the number of bins used for the data pooling and  $n_{params}$  is the number of estimated parameters used to determine the expected counts. If there are not enough degrees of freedom to conduct the test, `chi2gof` returns the  $p$ -value as NaN.

**See Also**

`kstest` | `lillietest`

**Concepts**

- “Chi-Square Distribution” on page B-28

# chi2inv

---

**Purpose** Chi-square inverse cumulative distribution function

**Syntax** `X = chi2inv(P,V)`

**Description** `X = chi2inv(P,V)` computes the inverse of the chi-square cdf with degrees of freedom specified by `V` for the corresponding probabilities in `P`. `P` and `V` can be vectors, matrices, or multidimensional arrays that have the same size. A scalar input is expanded to a constant array with the same dimensions as the other inputs.

The degrees of freedom parameters in `V` must be positive integers, and the values in `P` must lie in the interval `[0 1]`.

The inverse chi-square cdf for a given probability  $p$  and  $v$  degrees of freedom is

$$x = F^{-1}(p | v) = \{x : F(x | v) = p\}$$

where

$$p = F(x | v) = \int_0^x \frac{t^{(v-2)/2} e^{-t/2}}{2^{v/2} \Gamma(v/2)} dt$$

and  $\Gamma(\cdot)$  is the Gamma function. Each element of output `X` is the value whose cumulative probability under the chi-square cdf defined by the corresponding degrees of freedom parameter in `V` is specified by the corresponding value in `P`.

**Examples** Find a value that exceeds 95% of the samples from a chi-square distribution with 10 degrees of freedom.

```
x = chi2inv(0.95,10)
x =
    18.3070
```

You would observe values greater than 18.3 only 5% of the time by chance.

**See Also**      `icdf` | `chi2cdf` | `chi2pdf` | `chi2stat` | `chi2rnd`

**How To**      • “Chi-Square Distribution” on page B-28

# chi2pdf

---

**Purpose** Chi-square probability density function

**Syntax** `Y = chi2pdf(X,V)`

**Description** `Y = chi2pdf(X,V)` computes the chi-square pdf at each of the values in `X` using the corresponding degrees of freedom in `V`. `X` and `V` can be vectors, matrices, or multidimensional arrays that have the same size, which is also the size of the output `Y`. A scalar input is expanded to a constant array with the same dimensions as the other input.

The degrees of freedom parameters in `V` must be positive integers, and the values in `X` must lie on the interval `[0 Inf]`.

The chi-square pdf for a given value  $x$  and  $\nu$  degrees of freedom is

$$y = f(x | \nu) = \frac{x^{(\nu-2)/2} e^{-x/2}}{2^{\nu/2} \Gamma(\nu / 2)}$$

where  $\Gamma(\cdot)$  is the Gamma function.

If  $x$  is standard normal, then  $x^2$  is distributed chi-square with one degree of freedom. If  $x_1, x_2, \dots, x_n$  are  $n$  independent standard normal observations, then the sum of the squares of the  $x$ 's is distributed chi-square with  $n$  degrees of freedom (and is equivalent to the gamma density function with parameters  $\nu/2$  and  $2$ ).

## Examples

```
nu = 1:6;  
x = nu;  
y = chi2pdf(x,nu)  
y =  
    0.2420    0.1839    0.1542    0.1353    0.1220    0.1120
```

The mean of the chi-square distribution is the value of the degrees of freedom parameter, `nu`. The above example shows that the probability density of the mean falls as `nu` increases.

**How To**

- “Chi-Square Distribution” on page B-28

# chi2rnd

---

**Purpose** Chi-square random numbers

**Syntax**  
R = chi2rnd(V)  
R = chi2rnd(V,m,n,...)  
R = chi2rnd(V,[m,n,...])

**Description** R = chi2rnd(V) generates random numbers from the chi-square distribution with degrees of freedom parameters specified by V. V can be a vector, a matrix, or a multidimensional array. R is the same size as V.  
R = chi2rnd(V,m,n,...) or R = chi2rnd(V,[m,n,...]) generates an m-by-n-by-... array containing random numbers from the chi-square distribution with degrees of freedom parameter V. V can be a scalar or an array of the same size as R.

**Examples** Note that the first and third commands are the same, but are different from the second command.

```
r = chi2rnd(1:6)
r =
    0.0037    3.0377    7.8142    0.9021    3.2019    9.0729

r = chi2rnd(6,[1 6])
r =
    6.5249    2.6226   12.2497    3.0388    6.3133    5.0388

r = chi2rnd(1:6,1,6)
r =
    0.7638    6.0955    0.8273    3.2506    1.5469   10.9197
```

**See Also** random | chi2cdf | chi2pdf | chi2inv | chi2stat

**How To** • “Chi-Square Distribution” on page B-28

**Purpose** Chi-square mean and variance

**Syntax** `[M,V] = chi2stat(NU)`

**Description** `[M,V] = chi2stat(NU)` returns the mean of and variance for the chi-square distribution with degrees of freedom parameters specified by NU.

The mean of the chi-square distribution is  $v$ , the degrees of freedom parameter, and the variance is  $2v$ .

### Examples

```

nu = 1:10;
nu = nu'*nu;
[m,v] = chi2stat(nu)
m =
    1     2     3     4     5     6     7     8     9    10
    2     4     6     8    10    12    14    16    18    20
    3     6     9    12    15    18    21    24    27    30
    4     8    12    16    20    24    28    32    36    40
    5    10    15    20    25    30    35    40    45    50
    6    12    18    24    30    36    42    48    54    60
    7    14    21    28    35    42    49    56    63    70
    8    16    24    32    40    48    56    64    72    80
    9    18    27    36    45    54    63    72    81    90
   10    20    30    40    50    60    70    80    90   100

v =
    2     4     6     8    10    12    14    16    18    20
    4     8    12    16    20    24    28    32    36    40
    6    12    18    24    30    36    42    48    54    60
    8    16    24    32    40    48    56    64    72    80
   10    20    30    40    50    60    70    80    90   100
   12    24    36    48    60    72    84    96   108   120
   14    28    42    56    70    84    98   112   126   140
   16    32    48    64    80    96   112   128   144   160
   18    36    54    72    90   108   126   144   162   180
   20    40    60    80   100   120   140   160   180   200

```

# chi2stat

**How To**

- “Chi-Square Distribution” on page B-28

## Purpose

Child nodes

## Syntax

```
C = children(t)
C = children(t,nodes)
```

## Description

`C = children(t)` returns an  $n$ -by-2 array `C` containing the numbers of the child nodes for each node in the tree `t`, where  $n$  is the number of nodes. Leaf nodes have child node 0.

`C = children(t,nodes)` takes a vector `nodes` of node numbers and returns the children for the specified nodes.

## Examples

Create a classification tree for Fisher's iris data:

```
load fisheriris;

t = classregtree(meas,species,...
                'names',{'SL' 'SW' 'PL' 'PW'})
t =
Decision tree for classification
1  if PL<2.45 then node 2 elseif PL>=2.45 then node 3 else setosa
2  class = setosa
3  if PW<1.75 then node 4 elseif PW>=1.75 then node 5 else versicolor
4  if PL<4.95 then node 6 elseif PL>=4.95 then node 7 else versicolor
5  class = virginica
6  if PW<1.65 then node 8 elseif PW>=1.65 then node 9 else versicolor
7  class = virginica
8  class = versicolor
9  class = virginica

view(t)
```

# classregtree.children

`classregtree` | `numnodes` | `parent`

# cholcov

---

**Purpose** Cholesky-like covariance decomposition

**Syntax**  
`T = cholcov(SIGMA)`  
`[T,num] = cholcov(SIGMA)`  
`[T,num] = cholcov(SIGMA,0)`

**Description** `T = cholcov(SIGMA)` computes `T` such that `SIGMA = T'*T`. `SIGMA` must be square, symmetric, and positive semi-definite. If `SIGMA` is positive definite, then `T` is the square, upper triangular Cholesky factor. If `SIGMA` is not positive definite, `T` is computed from an eigenvalue decomposition of `SIGMA`. `T` is not necessarily triangular or square in this case. Any eigenvectors whose corresponding eigenvalue is close to zero (within a small tolerance) are omitted. If any remaining eigenvalues are negative, `T` is empty.

`[T,num] = cholcov(SIGMA)` returns the number `num` of negative eigenvalues of `SIGMA`, and `T` is empty if `num` is positive. If `num` is zero, `SIGMA` is positive semi-definite. If `SIGMA` is not square and symmetric, `num` is NaN and `T` is empty.

`[T,num] = cholcov(SIGMA,0)` returns `num` equal to zero if `SIGMA` is positive definite, and `T` is the Cholesky factor. If `SIGMA` is not positive definite, `num` is a positive integer and `T` is empty. `[...] = cholcov(SIGMA,1)` is equivalent to `[...] = cholcov(SIGMA)`.

## Examples

The following 4-by-4 covariance matrix is rank-deficient:

```
C1 = [2 1 1 2;1 2 1 2;1 1 2 2;2 2 2 3]
```

```
C1 =
```

```
     2     1     1     2
     1     2     1     2
     1     1     2     2
     2     2     2     3
```

```
rank(C1)
```

```
ans =
```

```
     3
```

Use `cholcov` to factor `C1`:

```
T = cholcov(C1)
T =
    -0.2113    0.7887   -0.5774         0
     0.7887   -0.2113   -0.5774         0
     1.1547    1.1547    1.1547    1.7321
```

```
C2 = T'*T
C2 =
    2.0000    1.0000    1.0000    2.0000
    1.0000    2.0000    1.0000    2.0000
    1.0000    1.0000    2.0000    2.0000
    2.0000    2.0000    2.0000    3.0000
```

Use T to generate random data with the specified covariance:

```
C3 = cov(randn(1e6,3)*T)
C3 =
    1.9973    0.9982    0.9995    1.9975
    0.9982    1.9962    0.9969    1.9956
    0.9995    0.9969    1.9980    1.9972
    1.9975    1.9956    1.9972    2.9951
```

## See Also

chol | cov

# categorical.circshift

---

**Purpose** Shift categorical array circularly

**Syntax** `B = circshift(A, shiftsize)`

**Description** `B = circshift(A, shiftsize)` circularly shifts the values in the categorical array `A` by `shiftsize` elements. `shiftsize` is a vector of integer scalars where the `n`-th element specifies the shift amount for the `n`-th dimension of array `A`. If an element in `shiftsize` is positive, the values of `A` are shifted down (or to the right). If it is negative, the values of `A` are shifted up (or to the left).

**See Also** `permute` | `shiftdim`

# NaiveBayes.CIsNonEmpty property

---

**Purpose**

Flag for non-empty classes

**Description**

The `CIsNonEmpty` property is a logical vector of length `NClasses` specifying which classes are not empty. When the grouping variable is categorical, it may contain categorical levels that don't appear in the elements of the grouping variable. Those levels are empty and `NaiveBayes` ignores them for the purposes of training the classifier.

# classregtree.classcount

---

**Purpose** Class counts

**Syntax** `P = classcount(t)`  
`P = classcount(t,nodes)`

**Description** `P = classcount(t)` returns an  $n$ -by- $m$  array  $P$  of class counts for the nodes in the classification tree  $t$ , where  $n$  is the number of nodes and  $m$  is the number of classes. For any node number  $i$ , the class counts  $P(i,:)$  are counts of observations (from the data used in fitting the tree) from each class satisfying the conditions for node  $i$ .

`P = classcount(t,nodes)` takes a vector `nodes` of node numbers and returns the class counts for the specified nodes.

**Examples** Create a classification tree for Fisher's iris data:

```
load fisheriris;

t = classregtree(meas,species,...
                'names',{'SL' 'SW' 'PL' 'PW'})
t =
Decision tree for classification
1  if PL<2.45 then node 2 elseif PL>=2.45 then node 3 else setosa
2  class = setosa
3  if PW<1.75 then node 4 elseif PW>=1.75 then node 5 else versicolor
4  if PL<4.95 then node 6 elseif PL>=4.95 then node 7 else versicolor
5  class = virginica
6  if PW<1.65 then node 8 elseif PW>=1.65 then node 9 else versicolor
7  class = virginica
8  class = versicolor
9  class = virginica

view(t)
```

Click to display:  Magnification:  Pruning level:

P = classcount(t)

P =

# ClassificationBaggedEnsemble

---

<b>Purpose</b>	Classification ensemble grown by resampling
<b>Description</b>	ClassificationBaggedEnsemble combines a set of trained weak learner models and data on which these learners were trained. It can predict ensemble response for new data by aggregating predictions from its weak learners.
<b>Construction</b>	<code>ens = fitensemble(X,Y,'bag',nlearn,learners,'type','classification')</code> creates a bagged classification ensemble. For syntax details, see the <code>fitensemble</code> reference page.
<b>Properties</b>	<p><b>CategoricalPredictors</b></p> <p>List of categorical predictors. <code>CategoricalPredictors</code> is a numeric vector with indices from 1 to <code>p</code>, where <code>p</code> is the number of columns of <code>X</code>.</p> <p><b>CombineWeights</b></p> <p>String describing how <code>ens</code> combines weak learner weights, either <code>'WeightedSum'</code> or <code>'WeightedAverage'</code>.</p> <p><b>FitInfo</b></p> <p>Numeric array of fit information. The <code>FitInfoDescription</code> property describes the content of this array.</p> <p><b>FitInfoDescription</b></p> <p>String describing the meaning of the <code>FitInfo</code> array.</p> <p><b>FResample</b></p> <p>Numeric scalar between 0 and 1. <code>FResample</code> is the fraction of training data <code>fitensemble</code> resampled at random for every weak learner when constructing the ensemble.</p> <p><b>Method</b></p> <p>String describing the method that creates <code>ens</code>.</p> <p><b>ModelParams</b></p>

# ClassificationBaggedEnsemble

---

Parameters used in training `ens`.

## **NTrained**

Number of trained weak learners in `ens`, a scalar.

## **PredictorNames**

Cell array of names for the predictor variables, in the order in which they appear in `X`.

## **ReasonForTermination**

String describing the reason `fitensemble` stopped adding weak learners to the ensemble.

## **Replace**

Logical value indicating if the ensemble was trained with replacement (`true`) or without replacement (`false`).

## **ResponseName**

String with the name of the response variable `Y`.

## **ScoreTransform**

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means `@(x)x`. For a list of built-in transformation functions and the syntax of custom transformation functions, see `ClassificationTree.fit`.

Add or change a `ScoreTransform` function by dot addressing:

```
ens.ScoreTransform = 'function'
```

or

```
ens.ScoreTransform = @function
```

## **Trained**

Trained learners, a cell array of compact classification models.

## TrainedWeights

Numeric vector of trained weights for the weak learners in `ens`. `TrainedWeights` has `T` elements, where `T` is the number of weak learners in `learners`.

## UseObsForLearner

Logical matrix of size `N`-by-`NTrained`, where `N` is the number of observations in the training data and `NTrained` is the number of trained weak learners. `UseObsForLearner(I,J)` is `true` if observation `I` was used for training learner `J`, and is `false` otherwise.

## W

Scaled `weights`, a vector with length `n`, the number of rows in `X`. The sum of the elements of `W` is 1.

## X

Matrix of predictor values that trained the ensemble. Each column of `X` represents one variable, and each row represents one observation.

## Y

Numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. Each row of `Y` represents the classification of the corresponding row of `X`.

## Methods

<code>oobEdge</code>	Out-of-bag classification edge
<code>oobLoss</code>	Out-of-bag classification error
<code>oobMargin</code>	Out-of-bag classification margins
<code>oobPredict</code>	Predict out-of-bag response of ensemble

# ClassificationBaggedEnsemble

---

## Inherited Methods

<code>compact</code>	Compact classification ensemble
<code>crossval</code>	Cross validate ensemble
<code>resubEdge</code>	Classification edge by resubstitution
<code>resubLoss</code>	Classification error by resubstitution
<code>resubMargin</code>	Classification margins by resubstitution
<code>resubPredict</code>	Predict ensemble response by resubstitution
<code>resume</code>	Resume training ensemble
<code>edge</code>	Classification edge
<code>loss</code>	Classification error
<code>margin</code>	Classification margins
<code>predict</code>	Predict classification
<code>predictorImportance</code>	Estimates of predictor importance
<code>removeLearners</code>	Remove members of compact classification ensemble

## Copy Semantics

Value. To learn how value classes affect copy operations, see Copying Objects in the MATLAB documentation.

## Examples

Construct a bagged ensemble for the ionosphere data, and examine its resubstitution loss:

```
load ionosphere
rng(0,'twister') % for reproducibility
ens = fitensemble(X,Y,'bag',100,'Tree',...
```

```
        'type', 'classification');  
L = resubLoss(ens)  
  
L =  
    0
```

The ensemble does a perfect job classifying its training data.

## How To

- “Ensemble Methods” on page 16-59

# ClassificationDiscriminant

---

**Superclasses** CompactClassificationDiscriminant

**Purpose** Discriminant analysis classification

**Description** A ClassificationDiscriminant object encapsulates a discriminant analysis classifier, which is a Gaussian mixture model for data generation. A ClassificationDiscriminant object can predict responses for new data using the predict method. The object contains the data used for training, so can compute resubstitution predictions.

**Construction** `obj = ClassificationDiscriminant.fit(X,Y)` creates a discriminant classification object based on the input variables (also known as predictors, features, or attributes) `X` and output (response) `Y`. For syntax details, see `ClassificationDiscriminant.fit`.

`obj = ClassificationDiscriminant.fit(X,Y,Name,Value)` creates a classifier with additional options specified by one or more `Name, Value` pair arguments. If you use one of the following five options, `obj` is of class `ClassificationPartitionedModel`: `'crossval'`, `'kfold'`, `'holdout'`, `'leaveout'`, or `'cvpartition'`. Otherwise, `obj` is of class `ClassificationDiscriminant`.

## Input Arguments

### X

Matrix of numeric predictor values. Each column of `X` represents one variable, and each row represents one observation.

NaN values in `X` are considered missing values. Observations with missing values for `X` are not used in the fit.

### Y

Numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. Each row of `Y` represents the classification of the corresponding row of `X`. NaN values in `Y` are considered missing values.

Observations with missing values for `Y` are not used in the fit.

## Properties

### BetweenSigma

p-by-p matrix, the between-class covariance, where p is the number of predictors.

### CategoricalPredictors

List of categorical predictors, always empty ([]) for discriminant analysis.

### ClassNames

List of the elements in the training data Y with duplicates removed. `ClassNames` can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. `ClassNames` has the same data type as the data in the argument Y.

### Coeffs

k-by-k structure of coefficient matrices, where k is the number of classes. `Coeffs(i, j)` contains coefficients of the linear or quadratic boundaries between classes i and j. Fields in `Coeffs(i, j)`:

- `DiscrimType`
- `Class1` — `ClassNames(i)`
- `Class2` — `ClassNames(j)`
- `Const` — A scalar
- `Linear` — A vector with p components, where p is the number of columns in X
- `Quadratic` — p-by-p matrix, exists for quadratic `DiscrimType`

The equation of the boundary between class i and class j is

$$\text{Const} + \text{Linear} * x + x' * \text{Quadratic} * x = 0,$$

where x is a column vector of length p.

# ClassificationDiscriminant

---

If `ClassificationDiscriminant.fit` had the `FillCoeffs` name-value pair set to `'off'` when constructing the classifier, `Coeffs` is empty (`[]`).

## Cost

Square matrix, where `Cost(i, j)` is the cost of classifying a point into class `j` if its true class is `i`. `Cost` is `K-by-K`, where `K` is the number of classes.

Change a `Cost` matrix using dot addressing:

```
obj.Cost = costMatrix
```

## Delta

Value of the `Delta` threshold for a linear discriminant model, a nonnegative scalar. If a coefficient of `obj` has magnitude smaller than `Delta`, `obj` sets this coefficient to 0, and so you can eliminate the corresponding predictor from the model. Set `Delta` to a higher value to eliminate more predictors.

`Delta` must be 0 for quadratic discriminant models.

Change `Delta` by dot addressing:

```
obj.Delta = newDelta
```

## DeltaPredictor

Row vector of length equal to the number of predictors in `obj`. If `DeltaPredictor(i) < Delta` then coefficient `i` of the model is 0.

If `obj` is a quadratic discriminant model, all elements of `DeltaPredictor` are 0.

## DiscrimType

String specifying the discriminant type. One of:

- `'linear'`
- `'quadratic'`

- 'diagLinear'
- 'diagQuadratic'
- 'pseudoLinear'
- 'pseudoQuadratic'

Change `DiscrimType` using dot addressing:

```
obj.DiscrimType = newDiscrimType
```

You can change between linear types, or between quadratic types, but cannot change between linear and quadratic types.

## **Gamma**

Value of the Gamma regularization parameter, a scalar from 0 to 1. Change Gamma using dot addressing:

```
obj.Gamma = newGamma
```

- If you set 1 for linear discriminant, the discriminant sets its type to 'diagLinear'.
- If you set a value between `MinGamma` and 1 for linear discriminant, the discriminant sets its type to 'linear'.
- You cannot set values below the value of the `MinGamma` property.
- For quadratic discriminant, you can set either 0 (for `DiscrimType 'quadratic'`) or 1 (for `DiscrimType 'diagQuadratic'`).

## **LogDetSigma**

Logarithm of the determinant of the within-class covariance matrix. The type of `LogDetSigma` depends on the discriminant type:

- Scalar for linear discriminant analysis

# ClassificationDiscriminant

---

- Vector of length  $K$  for quadratic discriminant analysis, where  $K$  is the number of classes

## **MinGamma**

Nonnegative scalar, the minimal value of the Gamma parameter so that the correlation matrix is invertible. If the correlation matrix is not singular, MinGamma is 0.

## **ModelParams**

Parameters used in training obj.

## **Mu**

Matrix of class means of size  $K$ -by- $p$ , where  $K$  is the number of classes, and  $p$  is the number of predictors. Each row of Mu represents the mean of the multivariate normal distribution of the corresponding class. The class indices are in the **ClassNames** attribute.

## **NObservations**

Number of observations in the training data, a numeric scalar. NObservations can be less than the number of rows of input data  $X$  when there are missing values in  $X$  or response  $Y$ .

## **PredictorNames**

Cell array of names for the predictor variables, in the order in which they appear in the training data  $X$ .

## **Prior**

Prior probabilities for each class. Prior is a numeric vector whose entries relate to the corresponding **ClassNames** property.

Add or change a Prior vector using dot addressing:

```
obj.Prior = priorVector
```

## **ResponseName**

String describing the response variable  $Y$ .

## ScoreTransform

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means  $@(x)x$ . For a list of built-in transformation functions and the syntax of custom transformation functions, see `ClassificationDiscriminant.fit`.

Add or change a ScoreTransform function by dot addressing:

```
cobj.ScoreTransform = 'function'
```

or

```
cobj.ScoreTransform = @function
```

## Sigma

Within-class covariance matrix or matrices. The dimensions depend on `DiscrimType`:

- 'linear' (default) — Matrix of size p-by-p, where p is the number of predictors
- 'quadratic' — Array of size p-by-p-by-K, where K is the number of classes
- 'diagLinear' — Row vector of length p
- 'diagQuadratic' — Array of size 1-by-p-by-K
- 'pseudoLinear' — Matrix of size p-by-p
- 'pseudoQuadratic' — Array of size p-by-p-by-K

## W

Scaled weights, a vector with length n, the number of rows in X.

## X

Matrix of predictor values. Each column of X represents one predictor (variable), and each row represents one observation.

# ClassificationDiscriminant

---

## **Xcentered**

X data with class means subtracted. If  $Y(i)$  is of class  $j$ ,

$$Xcentered(i,:) = X(i,:) - Mu(j,:),$$

where  $Mu$  is the class mean property.

## **Y**

Numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. Each row of  $Y$  represents the classification of the corresponding row of  $X$ .

## **Methods**

compact	Compact discriminant analysis classifier
crossval	Cross-validated discriminant analysis classifier
cvshrink	Cross-validate regularization of linear discriminant
fit	Fit discriminant analysis classifier
make	Construct discriminant analysis classifier from parameters
resubEdge	Classification edge by resubstitution
resubLoss	Classification error by resubstitution
resubMargin	Classification margins by resubstitution

resubPredict	Predict resubstitution response of classifier
template	Discriminant analysis classifier template for ensemble

## Inherited Methods

edge	Classification edge
logP	Log of the unconditional probability density
loss	Classification error
mahal	Mahalanobis distance to class means
margin	Classification margins
nLinearCoeffs	Number of nonzero linear coefficients
predict	Predict classification

## Definitions

### Discriminant Classification

The model for discriminant analysis is:

- Each class ( $Y$ ) generates data ( $X$ ) using a multivariate normal distribution. That is, the model assumes  $X$  has a Gaussian mixture distribution (`gmdistribution`).
  - For linear discriminant analysis, the model has the same covariance matrix for each class, only the means vary.
  - For quadratic discriminant analysis, both means and covariances of each class vary.

`predict` classifies so as to minimize the expected classification cost:

# Classification Discriminant

---

$$\hat{y} = \arg \min_{y=1, \dots, K} \sum_{k=1}^K \hat{P}(k | x) C(y | k),$$

where

- $\hat{y}$  is the predicted classification.
- $K$  is the number of classes.
- $\hat{P}(k | x)$  is the posterior probability of class  $k$  for observation  $x$ .
- $C(y | k)$  is the cost of classifying an observation as  $y$  when its true class is  $k$ .

For details, see “How the predict Method Classifies” on page 15-6.

## Regularization

Regularization is the process of finding a small set of predictors that yield an effective predictive model. For linear discriminant analysis, there are two parameters,  $\gamma$  and  $\delta$ , that control regularization as follows. `cvshrink` helps you select appropriate values of the parameters.

Let  $\Sigma$  represent the covariance matrix of the data  $X$ , and let  $\hat{X}$  be the centered data (the data  $X$  minus the mean by class). Define

$$D = \text{diag}(\hat{X}^T * \hat{X}).$$

The regularized covariance matrix  $\tilde{\Sigma}$  is

$$\tilde{\Sigma} = (1 - \gamma)\Sigma + \gamma D.$$

Whenever  $\gamma \geq \text{MinGamma}$ ,  $\tilde{\Sigma}$  is nonsingular.

Let  $\mu_k$  be the mean vector for those elements of  $X$  in class  $k$ , and let  $\mu_0$  be the global mean vector (the mean of the rows of  $X$ ). Let  $C$  be

the correlation matrix of the data  $X$ , and let  $\tilde{C}$  be the regularized correlation matrix:

$$\tilde{C} = (1 - \gamma)C + \gamma I,$$

where  $I$  is the identity matrix.

The linear term in the regularized discriminant analysis classifier for a data point  $x$  is

$$(x - \mu_0)^T \tilde{\Sigma}^{-1} (\mu_k - \mu_0) = \left[ (x - \mu_0)^T D^{-1/2} \right] \left[ \tilde{C}^{-1} D^{-1/2} (\mu_k - \mu_0) \right].$$

The parameter  $\delta$  enters into this equation as a threshold on the final term in square brackets. Each component of the vector

$\left[ \tilde{C}^{-1} D^{-1/2} (\mu_k - \mu_0) \right]$  is set to zero if it is smaller in magnitude than the threshold  $\delta$ . Therefore, for class  $k$ , if component  $j$  is thresholded to zero, component  $j$  of  $x$  does not enter into the evaluation of the posterior probability.

The `DeltaPredictor` property is a vector related to this threshold. When  $\delta \geq \text{DeltaPredictor}(i)$ , all classes  $k$  have

$$\left| \tilde{C}^{-1} D^{-1/2} (\mu_k - \mu_0) \right| \leq \delta.$$

Therefore, when  $\delta \geq \text{DeltaPredictor}(i)$ , the regularized classifier does not use predictor  $i$ .

## Copy Semantics

Value. To learn how value classes affect copy operations, see `Copying Objects` in the MATLAB documentation.

## Examples

Create a discriminant analysis classifier for the Fisher iris data:

```
load fisheriris
obj = ClassificationDiscriminant.fit(meas,species)
```

# ClassificationDiscriminant

---

```
obj =  
ClassificationDiscriminant:  
  PredictorNames: {'x1' 'x2' 'x3' 'x4'}  
  ResponseName: 'Y'  
  ClassNames: {'setosa' 'versicolor' 'virginica'}  
  ScoreTransform: 'none'  
  NObservations: 150  
  DiscrimType: 'linear'  
    Mu: [3x4 double]  
    Coeffs: [3x3 struct]
```

## How To

• “Discriminant Analysis” on page 15-3

<b>Superclasses</b>	CompactClassificationEnsemble
<b>Purpose</b>	Ensemble classifier
<b>Description</b>	ClassificationEnsemble combines a set of trained weak learner models and data on which these learners were trained. It can predict ensemble response for new data by aggregating predictions from its weak learners. It also stores data used for training and can compute resubstitution predictions. It can resume training if desired.
<b>Construction</b>	<p><code>ens = fitensemble(X,Y,method,nlearn,learners)</code> returns an ensemble model that can predict responses to data. The ensemble consists of models listed in <code>learners</code>. For more information on the syntax, see the <code>fitensemble</code> function reference page.</p> <p><code>ens = fitensemble(X,Y,method,nlearn,learners,Name,Value)</code> returns an ensemble model with additional options specified by one or more <code>Name,Value</code> pair arguments. For more information on the syntax, see the <code>fitensemble</code> function reference page.</p>
<b>Properties</b>	<p><b>CategoricalPredictors</b></p> <p>List of categorical predictors. <code>CategoricalPredictors</code> is a numeric vector with indices from 1 to <code>p</code>, where <code>p</code> is the number of columns of <code>X</code>.</p> <p><b>ClassNames</b></p> <p>List of the elements in <code>Y</code> with duplicates removed. <code>ClassNames</code> can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. <code>ClassNames</code> has the same data type as the data in the argument <code>Y</code>.</p> <p><b>CombineWeights</b></p> <p>String describing how <code>ens</code> combines weak learner weights, either <code>'WeightedSum'</code> or <code>'WeightedAverage'</code>.</p> <p><b>Cost</b></p>

# ClassificationEnsemble

---

Square matrix where  $\text{Cost}(i, j)$  is the cost of classifying a point into class  $j$  if its true class is  $i$ .

## **FitInfo**

Numeric array of fit information. The `FitInfoDescription` property describes the content of this array.

## **FitInfoDescription**

String describing the meaning of the `FitInfo` array.

## **LearnerNames**

Cell array of strings with names of weak learners in the ensemble. The name of each learner appears just once. For example, if you have an ensemble of 100 trees, `LearnerNames` is `{'Tree'}`.

## **Method**

String describing the method that creates `ens`.

## **ModelParams**

Parameters used in training `ens`.

## **NObservations**

Numeric scalar containing the number of observations in the training data.

## **NTrained**

Number of trained weak learners in `ens`, a scalar.

## **PredictorNames**

Cell array of names for the predictor variables, in the order in which they appear in  $X$ .

## **Prior**

Prior probabilities for each class. `Prior` is a numeric vector whose entries relate to the corresponding `ClassNames` property.

## **ReasonForTermination**

String describing the reason `fitensemble` stopped adding weak learners to the ensemble.

## ResponseName

String with the name of the response variable `Y`.

## ScoreTransform

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means `@(x)x`. For a list of built-in transformation functions and the syntax of custom transformation functions, see `ClassificationTree.fit`.

Add or change a `ScoreTransform` function by dot addressing:

```
ens.ScoreTransform = 'function'
```

or

```
ens.ScoreTransform = @function
```

## Trained

Trained learners, a cell array of compact classification models.

## TrainedWeights

Numeric vector of trained weights for the weak learners in `ens`. `TrainedWeights` has `T` elements, where `T` is the number of weak learners in `learners`.

## UsePredForLearner

Logical matrix of size `P`-by-`NTrained`, where `P` is the number of predictors (columns) in the training data `X`. `UsePredForLearner(i, j)` is true when learner `j` uses predictor `i`, and is false otherwise. For each learner, the predictors have the same order as the columns in the training data `X`.

If the ensemble is not of type `Subspace`, all entries in `UsePredForLearner` are true.

# ClassificationEnsemble

---

## **W**

Scaled **w**eight**s**, a vector with length  $n$ , the number of rows in  $X$ . The sum of the elements of  $W$  is 1.

## **X**

Matrix of predictor values that trained the ensemble. Each column of  $X$  represents one variable, and each row represents one observation.

## **Y**

Numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. Each row of  $Y$  represents the classification of the corresponding row of  $X$ .

## **Methods**

compact	Compact classification ensemble
crossval	Cross validate ensemble
resubEdge	Classification edge by resubstitution
resubLoss	Classification error by resubstitution
resubMargin	Classification margins by resubstitution
resubPredict	Predict ensemble response by resubstitution
resume	Resume training ensemble

## **Inherited Methods**

edge	Classification edge
loss	Classification error

margin	Classification margins
predict	Predict classification
predictorImportance	Estimates of predictor importance
removeLearners	Remove members of compact classification ensemble

## Copy Semantics

Value. To learn how value classes affect copy operations, see Copying Objects in the MATLAB documentation.

## Examples

Construct a boosted classification ensemble for the ionosphere data, using the `AdaBoostM1` method:

```
load ionosphere
ens = fitensemble(X,Y,'AdaBoostM1',100,'Tree')

ens =
classreg.learning.classif.ClassificationEnsemble:
    PredictorNames: {1x34 cell}
    CategoricalPredictors: []
    ResponseName: 'Response'
    ClassNames: {'b' 'g'}
    ScoreTransform: 'none'
    NObservations: 351
    NTrained: 100
    Method: 'AdaBoostM1'
    LearnerNames: {'Tree'}
    ReasonForTermination: [1x77 char]
    FitInfo: [100x1 double]
    FitInfoDescription: [2x83 char]
```

Predict the classification of the mean of X:

```
ypredict = predict(ens,mean(X))

ypredict =
```

# ClassificationEnsemble

ClassificationTree | fitensemble | RegressionEnsemble |  
CompactClassificationEnsemble

<b>Purpose</b>	<i>k</i> -nearest neighbor classification
<b>Description</b>	A nearest-neighbor classification object, where both distance metric (“nearest”) and number of neighbors can be altered. The object classifies new observations using the <code>predict</code> method. The object contains the data used for training, so can compute resubstitution predictions.
<b>Construction</b>	<code>mdl = ClassificationKNN.fit(X,Y)</code> creates a <i>k</i> -nearest neighbor classification model. For details, see <code>ClassificationKNN.fit</code> . <code>mdl = ClassificationKNN.fit(X,Y,Name,Value)</code> creates a classifier with additional options specified by one or more <code>Name,Value</code> pair arguments. For details, see <code>ClassificationKNN.fit</code> .
	<b>Input Arguments</b>
	<b>X</b> Matrix of predictor values. Each column of <i>X</i> represents one variable, and each row represents one observation.
	<b>Y</b> A numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings, with the same number of rows as <i>X</i> . Each row of <i>Y</i> represents the classification of the corresponding row of <i>X</i> .
<b>Properties</b>	<b>BreakTies</b> String specifying the method <code>predict</code> uses to break ties if multiple classes have the same smallest cost. By default, ties occur when multiple classes have the same number of nearest points among the <i>K</i> nearest neighbors. <ul style="list-style-type: none"><li>• 'nearest' — Use the class with the nearest neighbor among tied groups.</li><li>• 'random' — Use a random tiebreaker among tied groups.</li></ul>

# ClassificationKNN

---

- 'smallest' — Use the smallest index among tied groups.

'BreakTies' applies when 'IncludeTies' is false.

Change BreakTies using dot addressing:

```
mdl.BreakTies = newBreakTies
```

## CategoricalPredictors

Specification of which predictors are categorical.

- 'all' — All predictors are categorical.
- [] — No predictors are categorical.

## ClassNames

List of elements in the training data Y with duplicates removed. ClassNames can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. ClassNames has the same data type as the data in the argument Y.

Change ClassNames using dot addressing:

```
mdl.ClassNames = newClassNames
```

## Cost

Square matrix, where  $Cost(i, j)$  is the cost of classifying a point into class  $j$  if its true class is  $i$ . Cost is K-by-K, where K is the number of classes.

Change a Cost matrix using dot addressing:

```
mdl.Cost = costMatrix
```

## Distance

String or function handle specifying the distance metric. The allowable strings depend on the NSMethod parameter, which you

set in `ClassificationKNN.fit`, and which exists as a field in `ModelParams`.

<b>NSMethod</b>	<b>Distance Metric Names</b>
exhaustive	Any distance metric of <code>ExhaustiveSearcher</code>
kdtree	'cityblock', 'chebychev', 'euclidean', or 'minkowski'

For definitions, see “Distance Metrics” on page 16-9.

The distance metrics of `ExhaustiveSearcher`:

<b>Value</b>	<b>Description</b>
'cityblock'	City block distance.
'chebychev'	Chebychev distance (maximum coordinate difference).
'correlation'	One minus the sample linear correlation between observations (treated as sequences of values).
'cosine'	One minus the cosine of the included angle between observations (treated as vectors).
'euclidean'	Euclidean distance.
'hamming'	Hamming distance, percentage of coordinates that differ.
'jaccard'	One minus the Jaccard coefficient, the percentage of nonzero coordinates that differ.

# ClassificationKNN

Value	Description
'mahalanobis'	Mahalanobis distance, computed using a positive definite covariance matrix <b>C</b> . The default value of <b>C</b> is the sample covariance matrix of <b>X</b> , as computed by <code>nancov(X)</code> . To specify a different value for <b>C</b> , use the 'Cov' name-value pair.
'minkowski'	Minkowski distance. The default exponent is 2. To specify a different exponent, use the 'P' name-value pair.
'seuclidean'	Standardized Euclidean distance. Each coordinate difference between <b>X</b> and a query point is scaled, meaning divided by a scale value <b>S</b> . The default value of <b>S</b> is the standard deviation computed from <b>X</b> , <code>S = nanstd(X)</code> . To specify another value for <b>S</b> , use the <code>Scale</code> name-value pair.
'spearman'	One minus the sample Spearman's rank correlation between observations (treated as sequences of values).
@ <i>distfun</i>	Distance function handle. <i>distfun</i> has the form  <pre>function D2 = DISTFUN(ZI,ZJ) % calculation of distance ...</pre> where <ul style="list-style-type: none"><li>• <b>ZI</b> is a 1-by-N vector containing one row of <b>X</b> or <b>Y</b>.</li><li>• <b>ZJ</b> is an M2-by-N matrix containing multiple rows of <b>X</b> or <b>Y</b>.</li></ul>

Value	Description
	<ul style="list-style-type: none"> <li>D2 is an M2-by-1 vector of distances, and D2(k) is the distance between observations ZI and ZJ (J, :).</li> </ul>

Change Distance using dot addressing:

```
mdl.Distance = newDistance
```

If NSMethod is kdtree, you can use dot addressing to change Distance only among the types 'cityblock', 'chebychev', 'euclidean', or 'minkowski'.

### DistanceWeight

String or function handle specifying the distance weighting function.

DistanceWeight	Meaning
'equal'	No weighting
'inverse'	Weight is 1/distance
'inversesquared'	Weight is 1/distance <sup>2</sup>
@fcn	<i>fcn</i> is a function that accepts a matrix of nonnegative distances, and returns a matrix the same size containing nonnegative distance weights. For example, 'inversesquared' is equivalent to @(d)d.^(-2).

Change DistanceWeight using dot addressing:

```
mdl.DistanceWeight = newDistanceWeight
```

### DistParameter

Additional parameter for the distance metric.

# ClassificationKNN

---

Distance Metric	Parameter
'mahalanobis'	Positive definite covariance matrix C.
'minkowski'	Minkowski distance exponent, a positive scalar.
'seuclidean'	Vector of positive scale values with length equal to the number of columns of X.

For values of the distance metric other than those in the table, `DistParameter` must be []. Change `DistParameter` using dot addressing:

```
mdl.DistParameter = newDistParameter
```

## IncludeTies

Logical value indicating whether `predict` includes all the neighbors whose distance values are equal to the Kth smallest distance. If `IncludeTies` is true, `predict` includes all these neighbors. Otherwise, `predict` uses exactly K neighbors (see 'BreakTies').

Change `IncludeTies` using dot addressing:

```
mdl.IncludeTies = newIncludeTies
```

## ModelParams

Parameters used in training `mdl`.

## NObservations

Number of observations used in training `mdl`. This can be less than the number of rows in the training data, because data rows containing NaN values are not part of the fit.

## NumNeighbors

Positive integer specifying the number of nearest neighbors in X to find for classifying each point when predicting. Change `NumNeighbors` using dot addressing:

```
mdl.NumNeighbors = newNumNeighbors
```

## **PredictorNames**

Cell array of names for the predictor variables, in the order in which they appear in the training data X. Change PredictorNames using dot addressing:

```
mdl.PredictorNames = newPredictorNames
```

## **Prior**

Prior probabilities for each class. Prior is a numeric vector whose entries relate to the corresponding ClassNames property.

Add or change a Prior vector using dot addressing:

```
obj.Prior = priorVector
```

## **ResponseName**

String describing the response variable Y. Change ResponseName using dot addressing:

```
mdl.ResponseName = newResponseName
```

## **W**

Numeric vector of nonnegative weights with the same number of rows as Y. Each entry in W specifies the relative importance of the corresponding observation in Y. Change W using dot addressing:

```
mdl.W = newW
```

## **X**

Numeric matrix of predictor values. Each column of X represents one predictor (variable), and each row represents one observation.

## **Y**

# ClassificationKNN

---

A numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings, with the same number of rows as  $X$ .

$Y$  is of the same type as the passed-in  $Y$  data.

## Methods

crossval	Cross-validated $k$ -nearest neighbor classifier
edge	Edge of $k$ -nearest neighbor classifier
fit	Fit $k$ -nearest neighbor classifier
loss	Loss of $k$ -nearest neighbor classifier
margin	Margin of $k$ -nearest neighbor classifier
predict	Predict $k$ -nearest neighbor classification
resubEdge	Edge of $k$ -nearest neighbor classifier by resubstitution
resubLoss	Loss of $k$ -nearest neighbor classifier by resubstitution
resubMargin	Margin of $k$ -nearest neighbor classifier by resubstitution
resubPredict	Predict resubstitution response of $k$ -nearest neighbor classifier
template	$k$ -nearest neighbor classifier template for ensemble

## Definitions

### Prediction

ClassificationKNN predicts the classification of a point  $X_{new}$  using a procedure equivalent to this:

- 1 Find the NumNeighbors points in the training set  $X$  that are nearest to  $X_{new}$ .
- 2 Find the NumNeighbors response values  $Y$  to those nearest points.
- 3 Assign the classification label  $Y_{new}$  that has smallest expected misclassification cost among the values in  $Y$ .

For details, see “Posterior Probability” on page 21-2608 and “Expected Cost” on page 21-2609 in the predict documentation.

## Copy Semantics

Value. To learn how value classes affect copy operations, see Copying Objects in the MATLAB documentation.

## Examples

### Construct a KNN Classifier

Construct a  $k$ -nearest neighbor classifier for the Fisher iris data, where  $k = 5$ .

Load the data.

```
load fisheriris
X = meas;
Y = species;
```

Construct a classifier for 5-nearest neighbors.

```
mdl = ClassificationKNN.fit(X,Y,'NumNeighbors',5)
```

```
mdl =
```

```
ClassificationKNN:
  PredictorNames: {'x1' 'x2' 'x3' 'x4'}
  ResponseName: 'Y'
```

# ClassificationKNN

---

```
      ClassNames: {'setosa' 'versicolor' 'virginica'}
ScoreTransform: 'none'
NObservations: 150
      Distance: 'euclidean'
      NumNeighbors: 5
```

## Alternatives

`knnsearch` finds the  $k$ -nearest neighbors of points. `rangesearch` finds all the points within a fixed distance. You can use these functions for classification, as shown in “Classifying Query Data Using `knnsearch`” on page 16-18. If you want to perform classification, `ClassificationKNN` can be more convenient, in that you can construct a classifier in one step and classify in other steps. Also, `ClassificationKNN` has cross-validation options.

## Concepts

- “Classification Using Nearest Neighbors” on page 16-9

## Purpose

Cross-validated classification ensemble

## Description

`ClassificationPartitionedEnsemble` is a set of classification ensembles trained on cross-validated folds. Estimate the quality of classification by cross validation using one or more “kfold” methods: `kfoldPredict`, `kfoldLoss`, `kfoldMargin`, `kfoldEdge`, and `kfoldfun`.

Every “kfold” method uses models trained on in-fold observations to predict response for out-of-fold observations. For example, suppose you cross validate using five folds. In this case, every training fold contains roughly 4/5 of the data and every test fold contains roughly 1/5 of the data. The first model stored in `Trained{1}` was trained on `X` and `Y` with the first 1/5 excluded, the second model stored in `Trained{2}` was trained on `X` and `Y` with the second 1/5 excluded, and so on. When you call `kfoldPredict`, it computes predictions for the first 1/5 of the data using the first model, for the second 1/5 of data using the second model, and so on. In short, response for every observation is computed by `kfoldPredict` using the model trained without this observation.

## Construction

`cvens = crossval(ens)` creates a cross-validated ensemble from `ens`, a classification ensemble. For syntax details, see the `crossval` method reference page.

`cvens = fitensemble(X,Y,method,nlearn,learners,name,value)` creates a cross-validated ensemble when `name` is one of `'crossval'`, `'kfold'`, `'holdout'`, `'leaveout'`, or `'cvpartition'`. For syntax details, see the `fitensemble` function reference page.

## Properties

### CategoricalPredictors

List of categorical predictors. `CategoricalPredictors` is a numeric vector with indices from 1 to `p`, where `p` is the number of columns of `X`.

### ClassNames

List of the elements in `Y` with duplicates removed. `ClassNames` can be a numeric vector, vector of categorical variables (nominal

# ClassificationPartitionedEnsemble

---

or ordinal), logical vector, character array, or cell array of strings. `ClassNames` has the same data type as the data in the argument `Y`.

## **Combiner**

Cell array of combiners across all folds.

## **Cost**

Square matrix, where `Cost(i, j)` is the cost of classifying a point into class `j` if its true class is `i`.

## **CrossValidatedModel**

Name of the cross-validated model, a string.

## **Kfold**

Number of folds used in a cross-validated ensemble, a positive integer.

## **ModelParams**

Object holding parameters of `cvens`.

## **NObservations**

Number of data points used in training the ensemble, a positive integer.

## **NTrainedPerFold**

Number of data points used in training each fold of the ensemble, a positive integer.

## **Partition**

Partition of class `cvpartition` used in creating the cross-validated ensemble.

## **PredictorNames**

Cell array of names for the predictor variables, in the order in which they appear in `X`.

## **Prior**

Prior probabilities for each class. `Prior` is a numeric vector whose entries relate to the corresponding `ClassNames` property.

## **ResponseName**

Name of the response variable `Y`, a string.

## **ScoreTransform**

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means  $@(x)x$ . For a list of built-in transformation functions and the syntax of custom transformation functions, see `ClassificationTree.fit`.

Add or change a `ScoreTransform` function by dot addressing:

```
ens.ScoreTransform = 'function'
```

or

```
ens.ScoreTransform = @function
```

## **Trainable**

Cell array of ensembles trained on cross-validation folds. Every ensemble is full, meaning it contains its training data and weights.

## **Trained**

Cell array of compact ensembles trained on cross-validation folds.

## **W**

Scaled `weights`, a vector with length `n`, the number of rows in `X`.

## **X**

A matrix of predictor values. Each column of `X` represents one variable, and each row represents one observation.

## **Y**

A numeric column vector with the same number of rows as `X`. Each entry in `Y` is the response to the data in the corresponding row of `X`.

# ClassificationPartitionedEnsemble

---

## Methods

kfoldEdge	Classification edge for observations not used for training
kfoldLoss	Classification loss for observations not used for training
resume	Resume training learners on cross-validation folds

## Inherited Methods

kfoldEdge	Classification edge for observations not used for training
kfoldfun	Cross validate function
kfoldLoss	Classification loss for observations not used for training
kfoldMargin	Classification margins for observations not used for training
kfoldPredict	Predict response for observations not used for training

## Copy Semantics

Value. To learn how value classes affect copy operations, see Copying Objects in the MATLAB documentation.

## Examples

Evaluate the k-fold cross-validation error for a classification ensemble that models the Fisher iris data:

```
load fisheriris
ens = fitensemble(meas,species,'AdaBoostM2',100,'Tree');
cvens = crossval(ens);
L = kfoldLoss(cvens)
```

L =  
0.0533

# ClassificationPartitionedModel

---

**Purpose** Cross-validated classification model

**Description** ClassificationPartitionedModel is a set of classification models trained on cross-validated folds. Estimate the quality of classification by cross validation using one or more “kfold” methods: `kfoldPredict`, `kfoldLoss`, `kfoldMargin`, `kfoldEdge`, and `kfoldfun`.

Every “kfold” method uses models trained on in-fold observations to predict response for out-of-fold observations. For example, suppose you cross validate using five folds. In this case, every training fold contains roughly 4/5 of the data and every test fold contains roughly 1/5 of the data. The first model stored in `Trained{1}` was trained on `X` and `Y` with the first 1/5 excluded, the second model stored in `Trained{2}` was trained on `X` and `Y` with the second 1/5 excluded, and so on. When you call `kfoldPredict`, it computes predictions for the first 1/5 of the data using the first model, for the second 1/5 of data using the second model, and so on. In short, response for every observation is computed by `kfoldPredict` using the model trained without this observation.

**Construction** `cvmodel = crossval(obj)` creates a cross-validated classification model from a classification model.

`cvmodel = ClassificationTree.fit(X,Y,name,value)` or `cvmodel = ClassificationDiscriminant.fit(X,Y,name,value)` creates a cross-validated model when `name` is one of `'crossval'`, `'kfold'`, `'holdout'`, `'leaveout'`, or `'cvpartition'`. For syntax details, see the `ClassificationTree.fit` or `ClassificationDiscriminant.fit` function reference pages.

## Input Arguments

### **obj**

A classification model. `obj` can be a classification tree constructed using `ClassificationTree.fit`, or a discriminant analysis classifier constructed using `ClassificationDiscriminant.fit`.

## Properties

### CategoricalPredictors

List of categorical predictors. `CategoricalPredictors` is a numeric vector with indices from 1 to  $p$ , where  $p$  is the number of columns of  $X$ .

### ClassNames

List of the elements in  $Y$  with duplicates removed. `ClassNames` can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. `ClassNames` has the same data type as the data in the argument  $Y$ .

### Cost

Square matrix, where `Cost(i, j)` is the cost of classifying a point into class  $j$  if its true class is  $i$ .

If `cvmodel` is a cross-validated `ClassificationDiscriminant` model, you can change a `Cost` matrix by dot addressing:

```
cvmodel.Cost = costMatrix
```

### CrossValidatedModel

Name of the cross-validated model, a string.

### Kfold

Number of folds used in cross-validated model, a positive integer.

### ModelParams

Object holding parameters of `cvmodel`.

### Partition

The partition of class `cvpartition` used in creating the cross-validated model.

### PredictorNames

A cell array of names for the predictor variables, in the order in which they appear in  $X$ .

# ClassificationPartitionedModel

---

## Prior

Prior probabilities for each class. Prior is a numeric vector whose entries relate to the corresponding ClassNames property.

If cvmodel is a cross-validated ClassificationDiscriminant model, you can change a Prior vector by dot addressing:

```
cvmodel.Prior = priorVector
```

## ResponseName

Name of the response variable Y, a string.

## ScoreTransform

Function handle for transforming scores, or string representing a built-in transformation function.

String	Formula
'symmetric'	$2x - 1$
'invlogit'	$\log(x / (1-x))$
'ismax'	Set score for the class with the largest score to 1, and scores for all other classes to 0.
'symmetricismax'	Set score for the class with the largest score to 1, and scores for all other classes to -1.
'none'	$x$
'logit'	$1/(1 + e^{-x})$
'doublelogit'	$1/(1 + e^{-2x})$
'symmetriclogit'	$2/(1 + e^{-x}) - 1$
'sign'	-1 for $x < 0$ 0 for $x = 0$ 1 for $x > 0$

You can include your own function handle for transforming scores. Your function should accept a matrix (the original scores) and return a matrix of the same size (the transformed scores).

Add or change a ScoreTransform function by dot addressing:

```
cvmodel.ScoreTransform = 'function'  
or  
cvmodel.ScoreTransform = @function
```

## Trained

The trained learners, a cell array of compact classification models.

## W

The scaled **w**eight, a vector with length  $n$ , the number of rows in  $X$ .

## X

A matrix of predictor values. Each column of  $X$  represents one variable, and each row represents one observation.

## Y

A numeric column vector with the same number of rows as  $X$ . Each entry in  $Y$  is the response to the data in the corresponding row of  $X$ .

## Methods

kfoldEdge	Classification edge for observations not used for training
kfoldfun	Cross validate function
kfoldLoss	Classification loss for observations not used for training

# ClassificationPartitionedModel

---

kfoldMargin	Classification margins for observations not used for training
kfoldPredict	Predict response for observations not used for training

## Copy Semantics

Value. To learn how value classes affect copy operations, see Copying Objects in the MATLAB documentation.

## Examples

Evaluate the k-fold cross-validation error for a classification tree model of the Fisher iris data:

```
load fisheriris
tree = ClassificationTree.fit(meas,species);
cvtree = crossval(tree);
L = kfoldLoss(cvtree)
```

```
L =
    0.0600
```

## How To

- “Cross Validating a Discriminant Analysis Classifier” on page 15-20

**Superclasses** CompactClassificationTree

**Purpose** Binary decision tree for classification

**Description** A decision tree with binary splits for classification. An object of class `ClassificationTree` can predict responses for new data with the `predict` method. The object contains the data used for training, so can compute resubstitution predictions.

**Construction** `tree = ClassificationTree.fit(X,Y)` returns a classification tree based on the input variables (also known as predictors, features, or attributes) `X` and output (response) `Y`. `tree` is a binary tree, where each branching node is split based on the values of a column of `X`.

`tree = ClassificationTree.fit(X,Y,Name,Value)` fits a tree with additional options specified by one or more `Name,Value` pair arguments. If you use one of the following five options, `tree` is of class `ClassificationPartitionedModel`: `'crossval'`, `'kfold'`, `'holdout'`, `'leaveout'`, or `'cvpartition'`. Otherwise, `tree` is of class `ClassificationTree`.

## Input Arguments

### X

A matrix of numeric predictor values. Each column of `X` represents one variable, and each row represents one observation.

NaN values in `X` are taken to be missing values. Observations with all missing values for `X` are not used in the fit. Observations with some missing values for `X` are used to find splits on variables for which these observations have valid values.

### Y

A numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. Each row of `Y` represents the classification of the corresponding

# ClassificationTree

---

row of  $X$ . For numeric  $Y$ , consider using `RegressionTree.fit` instead of `ClassificationTree.fit`.

NaN values in  $Y$  are taken to be missing values. Observations with missing values for  $Y$  are not used in the fit.

## Name-Value Pair Arguments

Specify optional comma-separated pairs of `Name`, `Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as `Name1, Value1, ..., NameN, ValueN`.

## AlgorithmForCategorical

Algorithm to find the best split on a categorical predictor with  $L$  levels for data with  $K \geq 3$  classes. The available algorithms are:

'Exact'	Consider all $2^{L-1} - 1$ combinations
'PullLeft'	Pull left by purity
'PCA'	Principle component-based partition[1]
'OVAbyClass'	One versus all by class

Descriptions of the algorithms are in “Splitting Categorical Predictors” on page 16-56.

**Default:** `ClassificationTree.fit` selects the optimal subset of algorithms for each split using the known number of classes and levels of a categorical predictor. For  $K = 2$  classes, `ClassificationTree.fit` always performs the exact search.

## CategoricalPredictors

List of categorical predictors. Pass `CategoricalPredictors` as one of:

- A numeric vector with indices from 1 to  $p$ , where  $p$  is the number of columns of  $X$ .
- A logical vector of length  $p$ , where a true entry means that the corresponding column of  $X$  is a categorical variable.
- 'all', meaning all predictors are categorical.
- A cell array of strings, where each element in the array is the name of a predictor variable. The names must match entries in PredictorNames values.
- A character matrix, where each row of the matrix is a name of a predictor variable. The names must match entries in PredictorNames values. Pad the names with extra blanks so each row of the character matrix has the same length.

**Default:** []

## **ClassNames**

Array of class names. Use the data type that exists in  $Y$ .

Use ClassNames to order the classes or to select a subset of classes for training.

**Default:** The class names that exist in  $Y$

## **Cost**

Square matrix, where  $Cost(i, j)$  is the cost of classifying a point into class  $j$  if its true class is  $i$ . Alternatively, Cost can be a structure  $S$  having two fields:  $S.ClassNames$  containing the group names as a variable of the same type as  $Y$ , and  $S.ClassificationCosts$  containing the cost matrix.

**Default:**  $Cost(i, j) = 1$  if  $i \neq j$ , and  $Cost(i, j) = 0$  if  $i = j$

## **crossval**

# ClassificationTree

---

Flag to grow a cross-validated decision tree. Possible values are 'on' or 'off'.

If 'on', `ClassificationTree.fit` grows a cross-validated decision tree with 10 folds. You can override this cross-validation setting using one of the 'kfold', 'holdout', 'leaveout', or 'cvpartition' name-value pair arguments. Note that you can only use one of these four options ('kfold', 'holdout', 'leaveout', or 'cvpartition') at a time when creating a cross-validated tree.

Alternatively, cross validate `tree` later using the `crossval` method.

**Default:** 'off'

## **cvpartition**

Partition created with `cvpartition` to use in a cross-validated tree.

Note that if you use 'cvpartition', you cannot use any of the 'kfold', 'holdout', or 'leaveout' name-value pair arguments.

## **holdout**

Holdout validation tests the specified fraction of the data, and uses the rest of the data for training. Specify a numeric scalar from 0 to 1.

Note that if you use 'holdout', you cannot use any of the 'cvpartition', 'kfold', or 'leaveout' name-value pair arguments.

## **kfold**

Number of folds to use in a cross-validated tree, a positive integer.

Note that if you use 'kfold', you cannot use any of the 'cvpartition', 'holdout', or 'leaveout' name-value pair arguments.

**Default:** 10

## **leaveout**

Use leave-one-out cross validation by setting to 'on'.

Note that if you use 'leaveout', you cannot use any of the 'cvpartition', 'holdout', or 'kfold' name-value pair arguments.

## **MaxCat**

`ClassificationTree.fit` splits a categorical predictor using the exact search algorithm if the predictor has at most `MaxCat` levels in the split node. Otherwise, `ClassificationTree.fit` finds the best categorical split using one of the inexact algorithms.

Specify `MaxCat` as a numeric nonnegative scalar value. Passing a small value can lead to loss of accuracy and passing a large value can lead to long computation time and memory overload.

**Default:** 10

## **MergeLeaves**

When 'on', `ClassificationTree.fit` merges leaves that originate from the same parent node, and that give a sum of risk values greater or equal to the risk associated with the parent node. When 'off', `ClassificationTree.fit` does not merge leaves.

**Default:** 'on'

## **MinLeaf**

Each leaf has at least `MinLeaf` observations per tree leaf. If you supply both `MinParent` and `MinLeaf`, `ClassificationTree.fit` uses the setting that gives larger leaves: `MinParent=max(MinParent,2*MinLeaf)`.

**Default:** 1

# ClassificationTree

---

## **MinParent**

Each branch node in the tree has at least `MinParent` observations. If you supply both `MinParent` and `MinLeaf`, `ClassificationTree.fit` uses the setting that gives larger leaves: `MinParent=max(MinParent,2*MinLeaf)`.

**Default:** 10

## **NVarToSample**

Number of predictors to select at random for each split. Can be a positive integer or 'all', which means use all available predictors.

**Default:** 'all'

## **PredictorNames**

A cell array of names for the predictor variables, in the order in which they appear in `X`.

**Default:** {'x1', 'x2', ...}

## **prior**

Prior probabilities for each class. Specify as one of:

- A string:
  - 'empirical' determines class probabilities from class frequencies in `Y`. If you pass observation weights, they are used to compute the class probabilities.
  - 'uniform' sets all class probabilities equal.
- A vector (one scalar value for each class)
- A structure `S` with two fields:

- `S.ClassNames` containing the class names as a variable of the same type as `Y`
- `S.ClassProbs` containing a vector of corresponding probabilities

If you set values for both `weights` and `prior`, the weights are renormalized to add up to the value of the prior probability in the respective class.

**Default:** `'empirical'`

## **Prune**

When `'on'`, `ClassificationTree.fit` grows the classification tree, and computes the optimal sequence of pruned subtrees. When `'off'` `ClassificationTree.fit` grows the classification tree without pruning.

**Default:** `'on'`

## **PruneCriterion**

String with the pruning criterion, either `'error'` or `'impurity'`.

**Default:** `'error'`

## **ResponseName**

Name of the response variable `Y`, a string.

**Default:** `'Response'`

## **ScoreTransform**

Function handle for transforming scores, or string representing a built-in transformation function.

# ClassificationTree

String	Formula
'symmetric'	$2x - 1$
'invlogit'	$\log(x / (1-x))$
'ismax'	Set score for the class with the largest score to 1, and scores for all other classes to 0.
'symmetricismax'	Set score for the class with the largest score to 1, and scores for all other classes to -1.
'none'	$x$
'logit'	$1/(1 + e^{-x})$
'doublelogit'	$1/(1 + e^{-2x})$
'symmetriclogit'	$2/(1 + e^{-x}) - 1$
'sign'	-1 for $x < 0$ 0 for $x = 0$ 1 for $x > 0$

You can include your own function handle for transforming scores. Your function should accept a matrix (the original scores) and return a matrix of the same size (the transformed scores).

**Default:** 'none'

## SplitCriterion

Criterion for choosing a split. One of 'gdi' (Gini's diversity index), 'twoing' for the twoing rule, or 'deviance' for maximum deviance reduction (also known as cross entropy).

**Default:** 'gdi'

## Surrogate

String describing whether to find surrogate decision splits at each branch node. Specify as 'on', 'off', 'all', or a positive scalar value.

- When 'on', `ClassificationTree.fit` finds at most 10 surrogate splits at each branch node.
- When set to a positive integer value, `ClassificationTree.fit` finds at most the specified number of surrogate splits at each branch node.
- When set to 'all', `ClassificationTree.fit` finds all surrogate splits at each branch node. The 'all' setting can use much time and memory.

Use surrogate splits to improve the accuracy of predictions for data with missing values. The setting also enables you to compute measures of predictive association between predictors.

**Default:** 'off'

## **weights**

Vector of observation weights. The length of `weights` is the number of rows in `X`. `ClassificationTree.fit` normalizes the weights in each class to add up to the value of the prior probability of the class.

**Default:** `ones(size(X,1),1)`

## **Properties**

### **CategoricalPredictors**

List of categorical predictors, a numeric vector with indices from 1 to `p`, where `p` is the number of columns of `X`.

### **CatSplit**

An  $n$ -by-2 cell array, where  $n$  is the number of categorical splits in `tree`. Each row in `CatSplit` gives left and right values for a categorical split. For each branch node with categorical split  $j$

# ClassificationTree

---

based on a categorical predictor variable  $z$ , the left child is chosen if  $z$  is in `CatSplit(j,1)` and the right child is chosen if  $z$  is in `CatSplit(j,2)`. The splits are in the same order as nodes of the tree. Find the nodes for these splits by selecting 'categorical' cuts from top to bottom in the `CutType` property.

## Children

An  $n$ -by-2 array containing the numbers of the child nodes for each node in `tree`, where  $n$  is the number of nodes. Leaf nodes have child node 0.

## ClassCount

An  $n$ -by- $k$  array of class counts for the nodes in `tree`, where  $n$  is the number of nodes and  $k$  is the number of classes. For any node number  $i$ , the class counts `ClassCount(i,:)` are counts of observations (from the data used in fitting the tree) from each class satisfying the conditions for node  $i$ .

## ClassNames

List of the elements in  $Y$  with duplicates removed. `ClassNames` can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. `ClassNames` has the same data type as the data in the argument  $Y$ .

## ClassProb

An  $n$ -by- $k$  array of class probabilities for the nodes in `tree`, where  $n$  is the number of nodes and  $k$  is the number of classes. For any node number  $i$ , the class probabilities `ClassProb(i,:)` are the estimated probabilities for each class for a point satisfying the conditions for node  $i$ .

## Cost

Square matrix, where `Cost(i,j)` is the cost of classifying a point into class  $j$  if its true class is  $i$ .

## CutCategories

An  $n$ -by-2 cell array of the categories used at branches in `tree`, where  $n$  is the number of nodes. For each branch node  $i$  based on a categorical predictor variable  $x$ , the left child is chosen if  $x$  is among the categories listed in `CutCategories{i,1}`, and the right child is chosen if  $x$  is among those listed in `CutCategories{i,2}`. Both columns of `CutCategories` are empty for branch nodes based on continuous predictors and for leaf nodes.

`CutPoint` contains the cut points for 'continuous' cuts, and `CutCategories` contains the set of categories.

## **CutPoint**

An  $n$ -element vector of the values used as cut points in `tree`, where  $n$  is the number of nodes. For each branch node  $i$  based on a continuous predictor variable  $x$ , the left child is chosen if  $x < \text{CutPoint}(i)$  and the right child is chosen if  $x \geq \text{CutPoint}(i)$ . `CutPoint` is NaN for branch nodes based on categorical predictors and for leaf nodes.

`CutPoint` contains the cut points for 'continuous' cuts, and `CutCategories` contains the set of categories.

## **CutType**

An  $n$ -element cell array indicating the type of cut at each node in `tree`, where  $n$  is the number of nodes. For each node  $i$ , `CutType{i}` is:

- 'continuous' — If the cut is defined in the form  $x < v$  for a variable  $x$  and cut point  $v$ .
- 'categorical' — If the cut is defined by whether a variable  $x$  takes a value in a set of categories.
- '' — If  $i$  is a leaf node.

`CutPoint` contains the cut points for 'continuous' cuts, and `CutCategories` contains the set of categories.

## **CutVar**

# ClassificationTree

---

An  $n$ -element cell array of the names of the variables used for branching in each node in `tree`, where  $n$  is the number of nodes. These variables are sometimes known as *cut variables*. For leaf nodes, `CutVar` contains an empty string.

`CutPoint` contains the cut points for 'continuous' cuts, and `CutCategories` contains the set of categories.

## **IsBranch**

An  $n$ -element logical vector that is true for each branch node and false for each leaf node of `tree`.

## **ModelParams**

Parameters used in training `tree`.

## **NObservations**

Number of observations in the training data, a numeric scalar. `NObservations` can be less than the number of rows of input data  $X$  when there are missing values in  $X$  or response  $Y$ .

## **NodeClass**

An  $n$ -element cell array with the names of the most probable classes in each node of `tree`, where  $n$  is the number of nodes in the tree. Every element of this array is a string equal to one of the class names in `ClassNames`.

## **NodeErr**

An  $n$ -element vector of the errors of the nodes in `tree`, where  $n$  is the number of nodes. `NodeErr(i)` is the misclassification probability for node  $i$ .

## **NodeProb**

An  $n$ -element vector of the probabilities of the nodes in `tree`, where  $n$  is the number of nodes. The probability of a node is computed as the proportion of observations from the original data that satisfy the conditions for the node. This proportion is adjusted for any prior probabilities assigned to each class.

## **NodeRisk**

An  $n$ -element vector of the risk of the nodes in the tree, where  $n$  is the number of nodes. The risk for each node is the measure of impurity (Gini index or deviance) for this node weighted by the node probability. If the tree is grown by twining, the risk for each node is zero.

## **NodeSize**

An  $n$ -element vector of the sizes of the nodes in `tree`, where  $n$  is the number of nodes. The size of a node is defined as the number of observations from the data used to create the tree that satisfy the conditions for the node.

## **NumNodes**

The number of nodes in `tree`.

## **Parent**

An  $n$ -element vector containing the number of the parent node for each node in `tree`, where  $n$  is the number of nodes. The parent of the root node is 0.

## **PredictorNames**

A cell array of names for the predictor variables, in the order in which they appear in `X`.

## **Prior**

Prior probabilities for each class. `Prior` is a numeric vector whose entries relate to the corresponding `ClassNames` property.

## **PruneAlpha**

Numeric vector with one element per pruning level. If the pruning level ranges from 0 to  $M$ , then `PruneAlpha` has  $M + 1$  elements sorted in ascending order. `PruneAlpha(1)` is for pruning level 0 (no pruning), `PruneAlpha(2)` is for pruning level 1, and so on.

## **PruneList**

An  $n$ -element numeric vector with the pruning levels in each node of `tree`, where  $n$  is the number of nodes. The pruning levels range from 0 (no pruning) to  $M$ , where  $M$  is the distance between the deepest leaf and the root node.

## **ResponseName**

String describing the response variable  $Y$ .

## **ScoreTransform**

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means  $@(x)x$ .

Add or change a `ScoreTransform` function by dot addressing:

```
tree.ScoreTransform = 'function'  
or  
tree.ScoreTransform = @function
```

## **SurrCutCategories**

An  $n$ -element cell array of the categories used for surrogate splits in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrCutCategories{k}` is a cell array. The length of `SurrCutCategories{k}` is equal to the number of surrogate predictors found at this node. Every element of `SurrCutCategories{k}` is either an empty string for a continuous surrogate predictor, or is a two-element cell array with categories for a categorical surrogate predictor. The first element of this two-element cell array lists categories assigned to the left child by this surrogate split, and the second element of this two-element cell array lists categories assigned to the right child by this surrogate split. The order of the surrogate split variables at each node is matched to the order of variables in `SurrCutVar`. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrCutCategories` contains an empty cell.

## **SurrCutFlip**

An  $n$ -element cell array of the numeric cut assignments used for surrogate splits in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrCutFlip{k}` is a numeric vector. The length of `SurrCutFlip{k}` is equal to the number of surrogate predictors found at this node. Every element of `SurrCutFlip{k}` is either zero for a categorical surrogate predictor, or a numeric cut assignment for a continuous surrogate predictor. The numeric cut assignment can be either  $-1$  or  $+1$ . For every surrogate split with a numeric cut  $C$  based on a continuous predictor variable  $Z$ , the left child is chosen if  $Z < C$  and the cut assignment for this surrogate split is  $+1$ , or if  $Z \geq C$  and the cut assignment for this surrogate split is  $-1$ . Similarly, the right child is chosen if  $Z \geq C$  and the cut assignment for this surrogate split is  $+1$ , or if  $Z < C$  and the cut assignment for this surrogate split is  $-1$ . The order of the surrogate split variables at each node is matched to the order of variables in `SurrCutVar`. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrCutFlip` contains an empty array.

## **SurrCutPoint**

An  $n$ -element cell array of the numeric values used for surrogate splits in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrCutPoint{k}` is a numeric vector. The length of `SurrCutPoint{k}` is equal to the number of surrogate predictors found at this node. Every element of `SurrCutPoint{k}` is either NaN for a categorical surrogate predictor, or a numeric cut for a continuous surrogate predictor. For every surrogate split with a numeric cut  $C$  based on a continuous predictor variable  $Z$ , the left child is chosen if  $Z < C$  and `SurrCutFlip` for this surrogate split is  $-1$ . Similarly, the right child is chosen if  $Z \geq C$  and `SurrCutFlip` for this surrogate split is  $+1$ , or if  $Z < C$  and `SurrCutFlip` for this surrogate split is  $-1$ . The order of the surrogate split variables at each node is matched to the order of variables returned by `SurrCutVar`. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrCutPoint` contains an empty cell.

## **SurrCutType**

An  $n$ -element cell array indicating types of surrogate splits at each node in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrCutType{k}` is a cell array with the types of the surrogate split variables at this node. The variables are sorted by the predictive measure of association with the optimal predictor in the descending order, and only variables with the positive predictive measure are included. The order of the surrogate split variables at each node is matched to the order of variables in `SurrCutVar`. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrCutType` contains an empty cell. A surrogate split type can be either 'continuous' if the cut is defined in the form  $Z < V$  for a variable  $Z$  and cut point  $V$  or 'categorical' if the cut is defined by whether  $Z$  takes a value in a set of categories.

## **SurrCutVar**

An  $n$ -element cell array of the names of the variables used for surrogate splits in each node in `tree`, where  $n$  is the number of nodes in `tree`. Every element of `SurrCutVar` is a cell array with the names of the surrogate split variables at this node. The variables are sorted by the predictive measure of association with the optimal predictor in the descending order, and only variables with the positive predictive measure are included. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrCutVar` contains an empty cell.

## **SurrVarAssoc**

An  $n$ -element cell array of the predictive measures of association for surrogate splits in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrVarAssoc{k}` is a numeric vector. The length of `SurrVarAssoc{k}` is equal to the number of surrogate predictors found at this node. Every element of `SurrVarAssoc{k}` gives the predictive measure of association between the optimal split and this surrogate split. The order of the surrogate split variables at each node is the order of variables in `SurrCutVar`.

The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrVarAssoc` contains an empty cell.

## **W**

The scaled `weights`, a vector with length `n`, the number of rows in `X`.

## **X**

A matrix of predictor values. Each column of `X` represents one variable, and each row represents one observation.

## **Y**

A numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. Each row of `Y` represents the classification of the corresponding row of `X`.

## **Methods**

<code>compact</code>	Compact tree
<code>crossval</code>	Cross-validated decision tree
<code>cvloss</code>	Classification error by cross validation
<code>fit</code>	Fit classification tree
<code>prune</code>	Produce sequence of subtrees by pruning
<code>resubEdge</code>	Classification edge by resubstitution
<code>resubLoss</code>	Classification error by resubstitution
<code>resubMargin</code>	Classification margins by resubstitution

# ClassificationTree

---

resubPredict	Predict resubstitution response of tree
template	Create classification template

## Inherited Methods

edge	Classification edge
loss	Classification error
margin	Classification margins
meanSurrVarAssoc	Mean predictive measure of association for surrogate splits in decision tree
predict	Predict classification
predictorImportance	Estimates of predictor importance
view	View tree

## Definitions

### Impurity and Node Error

`ClassificationTree` splits nodes based on either *impurity* or *node error*. Impurity means one of several things, depending on your choice of the `SplitCriterion` name-value pair:

- Gini's Diversity Index (`gdi`) — The Gini index of a node is

$$1 - \sum_i p^2(i),$$

where the sum is over the classes  $i$  at the node, and  $p(i)$  is the observed fraction of classes with class  $i$  that reach the node. A node with just one class (a *pure* node) has Gini index 0; otherwise the Gini index is positive. So the Gini index is a measure of node impurity.

- Deviance ('`deviance`') — With  $p(i)$  defined as for the Gini index, the deviance of a node is

$$-\sum_i p(i) \log p(i).$$

A pure node has deviance 0; otherwise, the deviance is positive.

- Twoing rule ('twoing') — Twoing is not a purity measure of a node, but is a different measure for deciding how to split a node. Let  $L(i)$  denote the fraction of members of class  $i$  in the left child node after a split, and  $R(i)$  denote the fraction of members of class  $i$  in the right child node after a split. Choose the split criterion to maximize

$$P(L)P(R) \left( \sum_i |L(i) - R(i)| \right)^2,$$

where  $P(L)$  and  $P(R)$  are the fractions of observations that split to the left and right respectively. If the expression is large, the split made each child node purer. Similarly, if the expression is small, the split made each child node similar to each other, and hence similar to the parent node, and so the split did not increase node purity.

- Node error — The node error is the fraction of misclassified classes at a node. If  $j$  is the class with largest number of training samples at a node, the node error is

$$1 - p(j).$$

## Copy Semantics

Value. To learn how value classes affect copy operations, see Copying Objects in the MATLAB documentation.

## Examples

Construct a classification tree for the data in `ionosphere.mat`:

```
load ionosphere
tc = ClassificationTree.fit(X,Y)

tc =

ClassificationTree
```

# ClassificationTree

---

```
PredictorNames: {1x34 cell}
  ResponseName: 'Y'
    ClassNames: {'b' 'g'}
  ScoreTransform: 'none'
CategoricalPredictors: []
NObservations: 351
```

Properties, Methods

## How To

- “Classification Trees and Regression Trees” on page 16-31

**Purpose**

Discriminant analysis

**Syntax**

```
class = classify(sample,training,group)
class = classify(sample,training,group,'type')
class = classify(sample,training,group,'type',prior)
[class,err] = classify(...)
[class,err,POSTERIOR] = classify(...)
[class,err,POSTERIOR,logp] = classify(...)
[class,err,POSTERIOR,logp,coeff] = classify(...)
```

**Description**

`class = classify(sample,training,group)` classifies each row of the data in `sample` into one of the groups in `training`. `sample` and `training` must be matrices with the same number of columns. `group` is a grouping variable for `training`. Its unique values define groups; each element defines the group to which the corresponding row of `training` belongs. `group` can be a categorical variable, a numeric vector, a string array, or a cell array of strings. `training` and `group` must have the same number of rows. `classify` treats NaNs or empty strings in `group` as missing values, and ignores the corresponding rows of `training`. The output `class` indicates the group to which each row of `sample` has been assigned, and is of the same type as `group`.

`class = classify(sample,training,group,'type')` allows you to specify the type of discriminant function. Specify `type` inside single quotes. `type` is one of:

- `linear` — Fits a multivariate normal density to each group, with a pooled estimate of covariance. This is the default.
- `diaglinear` — Similar to `linear`, but with a diagonal covariance matrix estimate (naive Bayes classifiers).
- `quadratic` — Fits multivariate normal densities with covariance estimates stratified by group.
- `diagquadratic` — Similar to `quadratic`, but with a diagonal covariance matrix estimate (naive Bayes classifiers).
- `mahalanobis` — Uses Mahalanobis distances with stratified covariance estimates.

# classify

---

`class = classify(sample, training, group, 'type', prior)` allows you to specify prior probabilities for the groups. *prior* is one of:

- A numeric vector the same length as the number of unique values in `group` (or the number of levels defined for `group`, if `group` is categorical). If `group` is numeric or categorical, the order of *prior* must correspond to the ordered values in `group`, or, if `group` contains strings, to the order of first occurrence of the values in `group`.
- A 1-by-1 structure with fields:
  - `prob` — A numeric vector.
  - `group` — Of the same type as `group`, containing unique values indicating the groups to which the elements of `prob` correspond.

As a structure, *prior* can contain groups that do not appear in `group`. This can be useful if `training` is a subset a larger training set. `classify` ignores any groups that appear in the structure but not in the `group` array.

- The string 'empirical', indicating that group prior probabilities should be estimated from the group relative frequencies in `training`.

*prior* defaults to a numeric vector of equal probabilities, i.e., a uniform distribution. *prior* is not used for discrimination by Mahalanobis distance, except for error rate calculation.

`[class, err] = classify(...)` also returns an estimate `err` of the misclassification error rate based on the `training` data. `classify` returns the apparent error rate, i.e., the percentage of observations in `training` that are misclassified, weighted by the prior probabilities for the groups.

`[class, err, POSTERIOR] = classify(...)` also returns a matrix `POSTERIOR` of estimates of the posterior probabilities that the *j*th training group was the source of the *i*th sample observation, i.e.,  $Pr(\text{group } j | \text{obs } i)$ . `POSTERIOR` is not computed for Mahalanobis discrimination.

`[class, err, POSTERIOR, logp] = classify(...)` also returns a vector `logp` containing estimates of the logarithms of the unconditional

predictive probability density of the sample observations,  $p(\text{obs } i) = \sum p(\text{obs } i | \text{group } j) Pr(\text{group } j)$  over all groups. `logp` is not computed for Mahalanobis discrimination.

`[class,err,POSTERIOR,logp,coeff] = classify(...)` also returns a structure array `coeff` containing coefficients of the boundary curves between pairs of groups. Each element `coeff(I,J)` contains information for comparing group I to group J in the following fields:

- `type` — Type of discriminant function, from the `type` input.
- `name1` — Name of the first group.
- `name2` — Name of the second group.
- `const` — Constant term of the boundary equation (K)
- `linear` — Linear coefficients of the boundary equation (L)
- `quadratic` — Quadratic coefficient matrix of the boundary equation (Q)

For the `linear` and `diaglinear` types, the `quadratic` field is absent, and a row `x` from the sample array is classified into group I rather than group J if  $0 < K+x*L$ . For the other types, `x` is classified into group I if  $0 < K+x*L+x*Q*x'$ .

## Examples

For training data, use Fisher's sepal measurements for iris versicolor and virginica:

```
load fisheriris
SL = meas(51:end,1);
SW = meas(51:end,2);
group = species(51:end);
h1 = gscatter(SL,SW,group,'rb','v^',[],'off');
set(h1,'LineWidth',2)
legend('Fisher versicolor','Fisher virginica',...
      'Location','NW')
```

# classify

Classify a grid of measurements on the same scale:

```
[X,Y] = meshgrid(linspace(4.5,8),linspace(2,4));  
X = X(:); Y = Y(:);  
[C,err,P,logp,coeff] = classify([X Y],[SL SW],...  
                               group,'quadratic');
```

Visualize the classification:

```
hold on;  
gscatter(X,Y,C,'rb','.',1,'off');  
K = coeff(1,2).const;  
L = coeff(1,2).linear;
```

```

Q = coeff(1,2).quadratic;
% Function to compute K + L*v + v'*Q*v for multiple vectors
% v=[x;y]. Accepts x and y as scalars or column vectors.
f = @(x,y) K + [x y]*L + sum(([x y]*Q) .* [x y], 2);

h2 = ezplot(f,[4.5 8 2 4]);
set(h2,'Color','m','LineWidth',2)
axis([4.5 8 2 4])
xlabel('Sepal Length')
ylabel('Sepal Width')
title('\bf Classification with Fisher Training Data')

```

# classify

---

# TreeBagger.ClassNames property

---

**Purpose** Names of classes

**Description** The `ClassNames` property is a cell array containing the class names for the response variable  $Y$ . This property is empty for regression trees.

## Purpose

Class probabilities

## Syntax

```
P = classprob(t)
P = classprob(t,nodes)
```

## Description

`P = classprob(t)` returns an  $n$ -by- $m$  array  $P$  of class probabilities for the nodes in the classification tree  $t$ , where  $n$  is the number of nodes and  $m$  is the number of classes. For any node number  $i$ , the class probabilities  $P(i, :)$  are the estimated probabilities for each class for a point satisfying the conditions for node  $i$ .

`P = classprob(t,nodes)` takes a vector `nodes` of node numbers and returns the class probabilities for the specified nodes.

## Examples

Create a classification tree for Fisher's iris data:

```
load fisheriris;

t = classregtree(meas,species,...
                'names',{'SL' 'SW' 'PL' 'PW'})
t =
Decision tree for classification
1  if PL<2.45 then node 2 elseif PL>=2.45 then node 3 else setosa
2  class = setosa
3  if PW<1.75 then node 4 elseif PW>=1.75 then node 5 else versicolor
4  if PL<4.95 then node 6 elseif PL>=4.95 then node 7 else versicolor
5  class = virginica
6  if PW<1.65 then node 8 elseif PW>=1.65 then node 9 else versicolor
7  class = virginica
8  class = versicolor
9  class = virginica

view(t)
```

## Properties

Objects of the `classregtree` class have no properties accessible by dot indexing, `get` methods, or `set` methods. To obtain information about a `classregtree` object, use the appropriate method.

## Copy Semantics

Value. To learn how this affects your use of the class, see [Comparing Handle and Value Classes in the MATLAB Object-Oriented Programming documentation](#).

## How To

- “Ensemble Methods” on page 16-59
- “Classification Trees and Regression Trees” on page 16-31
- “Grouping Variables” on page 2-51

**Purpose** Construct classification and regression trees

---

**Note** Use `ClassificationTree.fit` or `RegressionTree.fit` instead.

---

**Syntax**

```
t = classregtree(X,y)
t = classregtree(X,y, 'Name',value)
```

**Description**

---

**Note** This function is superseded by `ClassificationTree.fit` and `RegressionTree.fit` of `ClassificationTree` and `RegressionTree` classes. It is maintained only for backwards compatibility.

---

`t = classregtree(X,y)` creates a decision tree `t` for predicting the response `y` as a function of the predictors in the columns of `X`. `X` is an  $n$ -by- $m$  matrix of predictor values. If `y` is a vector of  $n$  response values, `classregtree` performs regression. If `y` is a categorical variable, character array, or cell array of strings, `classregtree` performs classification. Either way, `t` is a binary tree where each branching node is split based on the values of a column of `X`. NaN values in `X` or `y` are taken to be missing values. Observations with all missing values for `X` or missing values for `y` are not used in the fit. Observations with some missing values for `X` are used to find splits on variables for which these observations have valid values.

`t = classregtree(X,y, 'Name',value)` specifies one or more optional parameter name/value pairs. Specify *Name* in single quotes. The following options are available:

For all trees:

- `categorical` — Vector of indices of the columns of  $X$  that are to be treated as unordered categorical variables
- `method` — Either 'classification' (default if  $y$  is text or a categorical variable) or 'regression' (default if  $y$  is numeric).
- `names` — A cell array of names for the predictor variables, in the order in which they appear in the  $X$  from which the tree was created.
- `prune` — 'on' (default) to compute the full tree and the optimal sequence of pruned subtrees, or 'off' for the full tree without pruning.
- `minparent` — A number  $k$  such that impure nodes must have  $k$  or more observations to be split (default is 10).
- `minleaf` — A minimal number of observations per tree leaf (default is 1). If you supply both 'minparent' and 'minleaf', `classregtree` uses the setting which results in larger leaves: `minparent = max(minparent, 2*minleaf)`
- `mergeleaves` — 'on' (default) to merge leaves that originate from the same parent node and give the sum of risk values greater or equal to the risk associated with the parent node. If 'off', `classregtree` does not merge leaves.
- `nvartosample` — Number of predictor variables randomly selected for each split. By default all variables are considered for each decision split.
- `stream` — Random number stream. Default is the MATLAB default random number stream.
- `surrogate` — 'on' to find surrogate splits at each branch node. Default is 'off'. If you set this parameter to 'on', `classregtree` can run significantly slower and consume significantly more memory.
- `weights` — Vector of observation weights. By default the weight of every observation is 1. The length of this vector must be equal to the number of rows in  $X$ .

For regression trees only:

- `qetoler` — Defines tolerance on quadratic error per node for regression trees. Splitting nodes stops when quadratic error per node drops below `qetoler*qed`, where `qed` is the quadratic error for the entire data computed before the decision tree is grown: `qed = norm(y-ybar)` with `ybar` estimated as the average of the input array `Y`. Default value is `1e-6`.

For classification trees only:

- `cost` — Square matrix `C`, where `C(i,j)` is the cost of classifying a point into class `j` if its true class is `i` (default has `C(i,j)=1` if `i~j`, and `C(i,j)=0` if `i=j`). Alternatively, this value can be a structure `S` having two fields: `S.group` containing the group names as a categorical variable, character array, or cell array of strings; and `S.cost` containing the cost matrix `C`.
- `splitcriterion` — Criterion for choosing a split. One of `'gdi'` (default) or Gini's diversity index, `'twoing'` for the twoing rule, or `'deviance'` for maximum deviance reduction.
- `priorprob` — Prior probabilities for each class, specified as a string (`'empirical'` or `'equal'`) or as a vector (one value for each distinct group name) or as a structure `S` with two fields:
  - `S.group` containing the group names as a categorical variable, character array, or cell array of strings
  - `S.prob` containing a vector of corresponding probabilities.
 If the input value is `'empirical'` (default), class probabilities are determined from class frequencies in `Y`. If the input value is `'equal'`, all class probabilities are set equal. If both observation weights and class prior probabilities are supplied, the weights are renormalized to add up to the value of the prior probability in the respective class.

## Examples

Create a classification tree for Fisher's iris data:

```
load fisheriris;
```

# classregtree

---

```
t = classregtree(meas,species,...
                'names',{'SL' 'SW' 'PL' 'PW'})
t =
Decision tree for classification
1  if PL<2.45 then node 2 elseif PL>=2.45 then node 3 else setosa
2  class = setosa
3  if PW<1.75 then node 4 elseif PW>=1.75 then node 5 else versicolor
4  if PL<4.95 then node 6 elseif PL>=4.95 then node 7 else versicolor
5  class = virginica
6  if PW<1.65 then node 8 elseif PW>=1.65 then node 9 else versicolor
7  class = virginica
8  class = versicolor
9  class = virginica

view(t)
```

Click to display:  Magnification:  Pruning level:

- “Ensemble Methods” on page 16-59

## NaiveBayes.ClassLevels property

---

**Purpose** Class levels

**Description** The `ClassLevels` property is a vector of the same type as the grouping variable, containing the unique levels of the grouping variable.

**Purpose**

Construct agglomerative clusters from linkages

**Syntax**

```
T = cluster(Z, 'cutoff', c)
T = cluster(Z, 'cutoff', c, 'depth', d)
T = cluster(Z, 'cutoff', c, 'criterion', criterion)
T = cluster(Z, 'maxclust', n)
```

**Description**

`T = cluster(Z, 'cutoff', c)` constructs clusters from the agglomerative hierarchical cluster tree, `Z`, as generated by the linkage function. `Z` is a matrix of size  $(m - 1)$ -by-3, where  $m$  is the number of observations in the original data. `c` is a threshold for cutting `Z` into clusters. Clusters are formed when a node and all of its subnodes have inconsistent value less than `c`. All leaves at or below the node are grouped into a cluster. `t` is a vector of size  $m$  containing the cluster assignments of each observation.

If `c` is a vector, `T` is a matrix of cluster assignments with one column per cutoff value.

`T = cluster(Z, 'cutoff', c, 'depth', d)` evaluates inconsistent values by looking to a depth `d` below each node. The default depth is 2.

`T = cluster(Z, 'cutoff', c, 'criterion', criterion)` uses the specified criterion for forming clusters, where `criterion` is one of the strings `'inconsistent'` (default) or `'distance'`. The `'distance'` criterion uses the distance between the two subnodes merged at a node to measure node height. All leaves at or below a node with height less than `c` are grouped into a cluster.

`T = cluster(Z, 'maxclust', n)` constructs a maximum of  $n$  clusters using the `'distance'` criterion. `cluster` finds the smallest height at which a horizontal cut through the tree leaves  $n$  or fewer clusters.

If `n` is a vector, `T` is a matrix of cluster assignments with one column per maximum value.

**Examples**

Compare clusters from Fisher iris data with species:

```
load fisheriris
```

# cluster

---

```
d = pdist(meas);  
Z = linkage(d);  
c = cluster(Z, 'maxclust',3:5);
```

```
crosstab(c(:,1),species)
```

```
ans =  
    0    0    2  
    0   50   48  
   50    0    0
```

```
crosstab(c(:,2),species)
```

```
ans =  
    0    0    1  
    0   50   47  
    0    0    2  
   50    0    0
```

```
crosstab(c(:,3),species)
```

```
ans =  
    0    4    0  
    0   46   47  
    0    0    1  
    0    0    2  
   50    0    0
```

## See Also

[clusterdata](#) | [cophenet](#) | [inconsistent](#) | [linkage](#) | [pdist](#)

**Purpose** Construct clusters from Gaussian mixture distribution

**Syntax**

```
idx = cluster(obj,X)
[idx,nlogl] = cluster(obj,X)
[idx,nlogl,P] = cluster(obj,X)
[idx,nlogl,P,logpdf] = cluster(obj,X)
[idx,nlogl,P,logpdf,M] = cluster(obj,X)
```

**Description** `idx = cluster(obj,X)` partitions data in the  $n$ -by- $d$  matrix  $X$ , where  $n$  is the number of observations and  $d$  is the dimension of the data, into  $k$  clusters determined by the  $k$  components of the Gaussian mixture distribution defined by `obj`. `obj` is an object created by `gmdistribution` or `fit`. `idx` is an  $n$ -by-1 vector, where `idx(I)` is the cluster index of observation  $I$ . The cluster index gives the component with the largest posterior probability for the observation, weighted by the component probability.

---

**Note** The data in  $X$  is typically the same as the data used to create the Gaussian mixture distribution defined by `obj`. Clustering with `cluster` is treated as a separate step, apart from density estimation. For `cluster` to provide meaningful clustering with new data,  $X$  should come from the same population as the data used to create `obj`.

---

`cluster` treats NaN values as missing data. Rows of  $X$  with NaN values are excluded from the partition.

`[idx,nlogl] = cluster(obj,X)` also returns `nlogl`, the negative log-likelihood of the data.

`[idx,nlogl,P] = cluster(obj,X)` also returns the posterior probabilities of each component for each observation in the  $n$ -by- $k$  matrix  $P$ .  $P(I,J)$  is the probability of component  $J$  given observation  $I$ .

`[idx,nlogl,P,logpdf] = cluster(obj,X)` also returns the  $n$ -by-1 vector `logpdf` containing the logarithm of the estimated probability density function for each observation. The density estimate for

## gmdistribution.cluster

---

observation  $I$  is a sum over all components of the component density at  $I$  times the component probability.

`[idx,nlogl,P,logpdf,M] = cluster(obj,X)` also returns an  $n$ -by- $k$  matrix  $M$  containing Mahalanobis distances in squared units.  $M(I,J)$  is the Mahalanobis distance of observation  $I$  from the mean of component  $J$ .

### Examples

Generate data from a mixture of two bivariate Gaussian distributions using the `mvnrnd` function:

```
MU1 = [1 2];  
SIGMA1 = [2 0; 0 .5];  
MU2 = [-3 -5];  
SIGMA2 = [1 0; 0 1];  
X = [mvnrnd(MU1,SIGMA1,1000);mvnrnd(MU2,SIGMA2,1000)];
```

```
scatter(X(:,1),X(:,2),10,'.')  
hold on
```

Fit a two-component Gaussian mixture model:

```
obj = gmdistribution.fit(X,2);  
h = ezcontour(@(x,y)pdf(obj,[x y]),[-8 6],[-8 6]);
```

# gmdistribution.cluster

Use the fit to cluster the data:

```
idx = cluster(obj,X);
cluster1 = X(idx == 1,:);
cluster2 = X(idx == 2,:);

delete(h)
h1 = scatter(cluster1(:,1),cluster1(:,2),10,'r. ');
h2 = scatter(cluster2(:,1),cluster2(:,2),10,'g. ');
legend([h1 h2],'Cluster 1','Cluster 2','Location','NW')
```

# clustering.evaluation.ClusterCriterion

---

**Purpose** Clustering evaluation object

**Description** Create a clustering evaluation object using `evalclusters`.

**Properties** **ClusteringFunction**

Clustering algorithm used to cluster the input data, stored as a valid clustering algorithm name string or function handle. If the clustering solutions are provided in the input, `ClusteringFunction` is empty.

**CriterionName**

Name of the criterion used for clustering evaluation, stored as a valid criterion name string.

**CriterionValues**

Criterion values corresponding to each proposed number of clusters in `InspectedK`, stored as a vector of numerical values.

**InspectedK**

List of the number of proposed clusters for which to compute criterion values, stored as a vector of positive integer values.

**Missing**

Logical flag for excluded data, stored as a column vector of logical values. If `Missing` equals `true`, then the corresponding value in the data matrix `x` is not used in the clustering solution.

**NumObservations**

Number of observations in the data matrix `X`, minus the number of missing (NaN) values in `X`, stored as a positive integer value.

**OptimalK**

Optimal number of clusters, stored as a positive integer value.

**OptimalY**

Optimal clustering solution corresponding to `OptimalK`, stored as a column vector of positive integer values. If the clustering solutions are provided in the input, `OptimalY` is empty.

## **x**

Data used for clustering, stored as a matrix of numerical values.

## **Methods**

<code>compact</code>	Compact clustering evaluation object
<code>plot</code>	Plot clustering evaluation object criterion values

- Property Attributes

# clusterdata

---

**Purpose** Agglomerative clusters from data

**Syntax**  
`T = clusterdata(X,cutoff)`  
`T = clusterdata(X,Name,Value)`

**Description** `T = clusterdata(X,cutoff)`  
`T = clusterdata(X,Name,Value)` clusters with additional options specified by one or more `Name,Value` pair arguments.

**Tips**

- The centroid and median methods can produce a cluster tree that is not monotonic. This occurs when the distance from the union of two clusters,  $r$  and  $s$ , to a third cluster is less than the distance between  $r$  and  $s$ . In this case, in a dendrogram drawn with the default orientation, the path from a leaf to the root node takes some downward steps. To avoid this, use another method. The following image shows a nonmonotonic cluster tree.

In this case, cluster 1 and cluster 3 are joined into a new cluster, while the distance between this new cluster and cluster 2 is less than the distance between cluster 1 and cluster 3. This leads to a nonmonotonic tree.

- You can provide the output  $T$  to other functions including `dendrogram` to display the tree, `cluster` to assign points to clusters, `inconsistent` to compute inconsistent measures, and `cophenet` to compute the cophenetic correlation coefficient.

## Input Arguments

### **X**

Matrix with two or more rows. The rows represent observations, the columns represent categories or dimensions.

### **cutoff**

When  $0 < \text{cutoff} < 2$ , `clusterdata` forms clusters when inconsistent values are greater than `cutoff` (see `inconsistent`). When `cutoff` is an integer  $\geq 2$ , `clusterdata` interprets `cutoff` as the maximum number of clusters to keep in the hierarchical tree generated by `linkage`.

### **Name-Value Pair Arguments**

Specify optional comma-separated pairs of `Name`, `Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( ' '). You can specify several name and value pair arguments in any order as `Name1, Value1, ..., NameN, ValueN`.

### **'criterion'**

Either 'inconsistent' or 'distance'.

### **'cutoff'**

Cutoff for inconsistent or distance measure, a positive scalar. When  $0 < \text{cutoff} < 2$ , `clusterdata` forms clusters when inconsistent values are greater than `cutoff` (see `inconsistent`). When `cutoff` is an integer  $\geq 2$ , `clusterdata` interprets `cutoff` as the maximum number of clusters to keep in the hierarchical tree generated by `linkage`.

### **'depth'**

Depth for computing inconsistent values, a positive integer.

## 'distance'

Any of the distance metric names allowed by `pdist` (follow the 'minkowski' option by the value of the exponent `p`):

Metric	Description
'euclidean'	Euclidean distance (default).
'seuclidean'	Standardized Euclidean distance. Each coordinate difference between rows in <code>X</code> is scaled by dividing by the corresponding element of the standard deviation <code>S=nansd(X)</code> . To specify another value for <code>S</code> , use <code>D=pdist(X, 'seuclidean', S)</code> .
'cityblock'	City block metric.
'minkowski'	Minkowski distance. The default exponent is 2. To specify a different exponent, use <code>D = pdist(X, 'minkowski', P)</code> , where <code>P</code> is a scalar
'chebychev'	Chebychev distance (maximum coordinate difference).
'mahalanobis'	Mahalanobis distance, using the sample covariance of <code>X</code> as computed by <code>nancov</code> . To compute the distance with a different covariance, use <code>D = pdist(X, 'mahalanobis', C)</code> , where the matrix <code>C</code> is symmetric and positive definite.
'cosine'	One minus the cosine of the included angle between points (treated as vectors).
'correlation'	One minus the sample correlation between points (treated as sequences of values).
'spearman'	One minus the sample Spearman's rank correlation between observations (treated as sequences of values).

Metric	Description
'hamming'	Hamming distance, which is the percentage of coordinates that differ.
'jaccard'	One minus the Jaccard coefficient, which is the percentage of nonzero coordinates that differ.
custom distance function	<p>A distance function specified using @:  <math>D = \text{pdist}(X, @\text{distfun})</math></p> <p>A distance function must be of form</p> $d2 = \text{distfun}(XI, XJ)$ <p>taking as arguments a 1-by-<math>n</math> vector <math>XI</math>, corresponding to a single row of <math>X</math>, and an <math>m2</math>-by-<math>n</math> matrix <math>XJ</math>, corresponding to multiple rows of <math>X</math>. <math>\text{distfun}</math> must accept a matrix <math>XJ</math> with an arbitrary number of rows. <math>\text{distfun}</math> must return an <math>m2</math>-by-1 vector of distances <math>d2</math>, whose <math>k</math>th element is the distance between <math>XI</math> and <math>XJ(k, :)</math>.</p>

### 'linkage'

Any of the linkage methods allowed by the `linkage` function:

- 'average'
- 'centroid'
- 'complete'
- 'median'
- 'single'
- 'ward'
- 'weighted'

For details, see the definitions in the `linkage` function reference page.

## 'maxclust'

Maximum number of clusters to form, a positive integer.

## 'savememory'

A string, either 'on' or 'off'. When applicable, the 'on' setting causes clusterdata to construct clusters without computing the distance matrix. savememory is applicable when:

- linkage is 'centroid', 'median', or 'ward'
- distance is 'euclidean' (default)

When savememory is 'on', linkage run time is proportional to the number of dimensions (number of columns of X). When savememory is 'off', linkage memory requirement is proportional to  $N^2$ , where N is the number of observations. So choosing the best (least-time) setting for savememory depends on the problem dimensions, number of observations, and available memory. The default savememory setting is a rough approximation of an optimal setting.

**Default:** 'on' when X has 20 columns or fewer, or the computer does not have enough memory to store the distance matrix; otherwise 'off'

## Output Arguments

### T

T is a vector of size m containing a cluster number for each observation.

- When  $0 < \text{cutoff} < 2$ ,  $T = \text{clusterdata}(X, \text{cutoff})$  is equivalent to:

```
Y = pdist(X, 'euclid');  
Z = linkage(Y, 'single');  
T = cluster(Z, 'cutoff', cutoff);
```

- When cutoff is an integer  $\geq 2$ ,  $T = \text{clusterdata}(X, \text{cutoff})$  is equivalent to:

```
Y = pdist(X, 'euclid');  
Z = linkage(Y, 'single');
```

```
T = cluster(Z, 'maxclust', cutoff);
```

## Examples

### Create Hierarchical Cluster Tree From Sample Data

This example shows how to create a hierarchical cluster tree from sample data, and visualize the clusters using a 3-dimensional scatter plot.

Generate sample data matrices containing random numbers from the standard uniform distribution.

```
rng('default'); % For reproducibility
X = [gallery('uniformdata', [10 3], 12);...
     gallery('uniformdata', [10 3], 13)+1.2;...
     gallery('uniformdata', [10 3], 14)+2.5];
```

Compute the distances between items and create a hierarchical cluster tree from the sample data. List all of the items in cluster 2.

```
T = clusterdata(X, 'maxclust', 3);
find(T==2)
```

```
ans =
```

```
11
12
13
14
15
16
17
18
19
20
```

Plot the data with each cluster shown in a different color.

```
scatter3(X(:,1),X(:,2),X(:,3),100,T,'filled')
```

## Create Hierarchical Cluster Tree Using Ward's Linkage

This example shows how to create a hierarchical cluster tree using Ward's linkage, and visualize the clusters using a 3-dimensional scatter plot.

Create a 20,000-by-3 matrix of sample data generated from the standard uniform distribution.

```
rng('default'); % For reproducibility  
X = rand(20000,3);
```

Create a hierarchical cluster tree from the sample data using Ward's linkage. Set 'savememory' to 'on' to construct clusters without computing the distance matrix.

```
c = clusterdata(X,'linkage','ward','savememory','on','maxclust',4);
```

Plot the data with each cluster shown in a different color.

```
scatter3(X(:,1),X(:,2),X(:,3),10,c)
```

# clusterdata

---

<b>Purpose</b>	Classical multidimensional scaling
<b>Syntax</b>	$Y = \text{cmdscale}(D)$ $[Y, e] = \text{cmdscale}(D)$
<b>Description</b>	<p><math>Y = \text{cmdscale}(D)</math> takes an <math>n</math>-by-<math>n</math> distance matrix <math>D</math>, and returns an <math>n</math>-by-<math>p</math> configuration matrix <math>Y</math>. Rows of <math>Y</math> are the coordinates of <math>n</math> points in <math>p</math>-dimensional space for some <math>p &lt; n</math>. When <math>D</math> is a Euclidean distance matrix, the distances between those points are given by <math>D</math>. <math>p</math> is the dimension of the smallest space in which the <math>n</math> points whose inter-point distances are given by <math>D</math> can be embedded.</p> <p><math>[Y, e] = \text{cmdscale}(D)</math> also returns the eigenvalues of <math>Y*Y'</math>. When <math>D</math> is Euclidean, the first <math>p</math> elements of <math>e</math> are positive, the rest zero. If the first <math>k</math> elements of <math>e</math> are much larger than the remaining <math>(n-k)</math>, then you can use the first <math>k</math> columns of <math>Y</math> as <math>k</math>-dimensional points whose inter-point distances approximate <math>D</math>. This can provide a useful dimension reduction for visualization, e.g., for <math>k = 2</math>.</p> <p><math>D</math> need not be a Euclidean distance matrix. If it is non-Euclidean or a more general dissimilarity matrix, then some elements of <math>e</math> are negative, and <math>\text{cmdscale}</math> chooses <math>p</math> as the number of positive eigenvalues. In this case, the reduction to <math>p</math> or fewer dimensions provides a reasonable approximation to <math>D</math> only if the negative elements of <math>e</math> are small in magnitude.</p> <p>You can specify <math>D</math> as either a full dissimilarity matrix, or in upper triangle vector form such as is output by <code>pdist</code>. A full dissimilarity matrix must be real and symmetric, and have zeros along the diagonal and positive elements everywhere else. A dissimilarity matrix in upper triangle form must have real, positive entries. You can also specify <math>D</math> as a full similarity matrix, with ones along the diagonal and all other elements less than one. <math>\text{cmdscale}</math> transforms a similarity matrix to a dissimilarity matrix in such a way that distances between the points returned in <math>Y</math> equal or approximate <math>\sqrt{1-D}</math>. To use a different transformation, you must transform the similarities prior to calling <math>\text{cmdscale}</math>.</p>

## Examples

Generate some points in 4-D space, but close to 3-D space, then reduce them to distances only.

```
X = [normrnd(0,1,10,3) normrnd(0,.1,10,1)];  
D = pdist(X,'euclidean');
```

Find a configuration with those inter-point distances.

```
[Y,e] = cmdscale(D);  
  
% Four, but fourth one small  
dim = sum(e > eps^(3/4))  
  
% Poor reconstruction  
maxerr2 = max(abs(pdist(X)-pdist(Y(:,1:2))))  
  
% Good reconstruction  
maxerr3 = max(abs(pdist(X)-pdist(Y(:,1:3))))  
  
% Exact reconstruction  
maxerr4 = max(abs(pdist(X)-pdist(Y)))  
  
% D is now non-Euclidean  
D = pdist(X,'cityblock');  
[Y,e] = cmdscale(D);  
  
% One is large negative  
min(e)  
  
% Poor reconstruction  
maxerr = max(abs(pdist(X)-pdist(Y)))
```

**Purpose** Confidence intervals of coefficient estimates of generalized linear model

**Syntax**  
`ci = coefCI mdl`  
`ci = coefCI mdl, alpha`

**Description**  
`ci = coefCI mdl` returns confidence intervals for the coefficients in `mdl`.  
`ci = coefCI mdl, alpha` returns confidence intervals with confidence level  $1 - \alpha$ .

**Input Arguments**  
**mdl**  
Generalized linear model, as constructed by `fitglm` or `stepwiseglm`.

**alpha**  
Scalar from 0 to 1, the probability that the confidence interval does not contain the true value.

**Default:** 0.05

**Output Arguments**  
**ci**  
k-by-2 matrix of confidence intervals. The *j*th row of `ci` is the confidence interval of coefficient *j* of `mdl`. The name of coefficient *j* of `mdl` is in `mdl.CoefficientNames`.

**Definitions**  
**Confidence Interval**  
Assume that model assumptions hold (data comes from a generalized linear model represented by the formula `mdl`. Formula and the specified link function, and with observations that are independent conditional on the predictor values). Then row *j* of the confidence interval matrix `ci` gives a *confidence interval*  $[ci(j, 1), ci(j, 2)]$  computed such that, with repeated experimentation, a proportion  $1 - \alpha$  of the intervals will contain the true value of the coefficient.

# GeneralizedLinearModel.coefCI

## Examples

### Confidence Interval for Coefficients of a Generalized Linear Model

Find confidence intervals for the coefficients of a fitted generalized nonlinear model.

Generate artificial data for the model using Poisson random numbers with two underlying predictors  $X(1)$  and  $X(2)$ .

```
rng('default') % for reproducibility
rndvars = randn(100,2);
X = [2+rndvars(:,1),rndvars(:,2)];
mu = exp(1 + X*[1;2]);
y = poissrnd(mu);
```

Create a generalized linear regression model of Poisson data.

```
mdl = fitglm(X,y,...
    'y ~ x1 + x2','distr','poisson')
```

```
mdl =
```

Generalized Linear regression model:

```
log(y) ~ 1 + x1 + x2
Distribution = Poisson
```

Estimated Coefficients:

	Estimate	SE	tStat	pValue
(Intercept)	1.0405	0.022122	47.034	0
x1	0.9968	0.003362	296.49	0
x2	1.987	0.0063433	313.24	0

100 observations, 97 error degrees of freedom

Dispersion: 1

Chi<sup>2</sup>-statistic vs. constant model: 2.95e+05, p-value = 0

Find 95% (default) confidence intervals on the coefficients of the model.

```
ci = coefCI mdl
```

```
ci =
```

```
    0.9966    1.0844  
    0.9901    1.0035  
    1.9744    1.9996
```

Find 99% confidence intervals on the coefficients.

```
alpha = .01;  
ci = coefCI(mdl,alpha)
```

```
ci =
```

```
    0.9824    1.0986  
    0.9880    1.0056  
    1.9703    2.0036
```

# LinearModel.coefCI

---

<b>Purpose</b>	Confidence intervals of coefficient estimates of linear model
<b>Syntax</b>	<code>ci = coefCI mdl</code> <code>ci = coefCI mdl, alpha</code>
<b>Description</b>	<code>ci = coefCI mdl</code> returns confidence intervals for the coefficients in <code>mdl</code> . <code>ci = coefCI mdl, alpha</code> returns confidence intervals with confidence level $1 - \alpha$ .
<b>Input Arguments</b>	<b>mdl</b> Linear model, as constructed by <code>fitlm</code> or <code>stepwiselm</code> . <b>alpha</b> Scalar from 0 to 1, the probability that the confidence interval does not contain the true value. <b>Default:</b> 0.05
<b>Output Arguments</b>	<b>ci</b> k-by-2 matrix of confidence intervals. The <i>j</i> th row of <code>ci</code> is the confidence interval of coefficient <i>j</i> of <code>mdl</code> . The name of coefficient <i>j</i> of <code>mdl</code> is in <code>mdl.CoefficientNames</code> .
<b>Definitions</b>	<b>Confidence Interval</b> Assume that model assumptions hold (data comes from a generalized linear model represented by the formula <code>mdl.Formula</code> , and with observations that are independent conditional on the predictor values). Then row <i>j</i> of the confidence interval matrix <code>ci</code> gives a <i>confidence interval</i> [ <code>ci(j,1)</code> , <code>ci(j,2)</code> ] computed such that, with repeated experimentation, a proportion $1 - \alpha$ of the intervals will contain the true value of the coefficient.

## Examples

### Default Confidence Intervals

Create a linear model for auto mileage based on the carbig data. Then obtain confidence intervals for the resulting model coefficients.

Load the data and create a model.

```
load carbig
Origin = nominal(Origin);
ds = dataset(Horsepower,Weight,MPG,Origin);
modelspec = 'MPG ~ 1 + Horsepower + Weight + Origin';
mdl = fitlm(ds,modelspec);
```

View the names of the coefficients.

```
mdl.CoeffNames
```

```
ans =
Columns 1 through 4
'(Intercept)' 'Horsepower' 'Weight' 'Origin_France'

Columns 5 through 8
'Origin_Germany' 'Origin_Italy' 'Origin_Japan' 'Origin_Sweden'

Column 9
'Origin_USA'
```

Find confidence intervals for the coefficients of the model.

```
ci = coefCI(mdl)
```

```
ci =
    43.361    59.939
   -0.074778   -0.031499
  -0.0058669  -0.0037122
   -17.362   -0.34772
   -15.75    0.74338
   -17.209    0.0613
   -14.511    1.8738
```

```
-18.582    -1.5036
-17.311    -0.96419
```

## Custom Confidence Intervals

Create a linear model for auto mileage based on the `carbig` data. Then obtain confidence intervals for the resulting model coefficients at the 99% level.

Load the data and create a model.

```
load carbig
Origin = nominal(Origin);
ds = dataset(Horsepower,Weight,MPG,Origin);
modelspec = 'MPG ~ 1 + Horsepower + Weight + Origin';
mdl fitlm(ds,modelspec);
```

Find 99% confidence intervals for the coefficients.

```
ci = coefCI(mdl,.01)

ci =
    40.737    62.564
   -0.081629   -0.024647
   -0.006208   -0.0033711
   -20.056     2.3459
   -18.361     3.3546
   -19.943     2.7955
   -17.104     4.4676
   -21.286     1.2002
   -19.899     1.6238
```

The confidence intervals are wider than the default 5% confidence intervals of “Default Confidence Intervals” on page 21-373.

## Alternatives

You can create the intervals from the model coefficients in `mdl.Coefficients.Estimate` and an appropriate multiplier of the standard errors `sqrt(diag(mdl.CoefficientCovariance))`. The multiplier is `tinvs(1-alpha/2,dof)`, where `level` is the confidence

level, and dof is the degrees of freedom (number of data points minus the number of coefficients).

LinearModel

**How To**

- “Linear Regression” on page 9-12

# LinearMixedModel.coefCI

---

**Purpose** Confidence intervals for coefficients of linear mixed-effects model

**Syntax**

```
feCI = coefCI(lme)
feCI = coefCI(lme,Name,Value)
[feCI,reCI] = coefCI( ___ )
```

**Description** `feCI = coefCI(lme)` returns the 95% confidence intervals for the fixed-effects coefficients in the linear mixed-effects model `lme`.

`feCI = coefCI(lme,Name,Value)` returns the 95% confidence intervals for the fixed-effects coefficients in the linear mixed-effects model `lme` with additional options specified by one or more `Name,Value` pair arguments.

For example, you can specify the confidence level or method to compute the degrees of freedom.

`[feCI,reCI] = coefCI( ___ )` also returns the 95% confidence intervals for the random-effects coefficients in the linear mixed-effects model `lme`.

## Input Arguments

### **lme - Linear mixed-effects model**

`LinearMixedModel` object

Linear mixed-effects model, returned as a `LinearMixedModel` object.

For properties and methods of this object, see `LinearMixedModel`.

### **Name-Value Pair Arguments**

Specify optional comma-separated pairs of `Name,Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( ' '). You can specify several name and value pair arguments in any order as `Name1,Value1,...,NameN,ValueN`.

### **'Alpha' - Confidence level**

0.05 (default) | scalar value in the range 0 to 1

Confidence level, specified as the comma-separated pair consisting of 'Alpha' and a scalar value in the range 0 to 1. For a value  $\alpha$ , the confidence level is  $100*(1-\alpha)\%$ .

For example, for 99% confidence intervals, you can specify the confidence level as follows.

**Example:** 'Alpha',0.01

## Data Types

single | double

## 'DFMethod' - Method for computing approximate degrees of freedom

'Residual' (default) | 'Satterthwaite' | 'None'

Method for computing approximate degrees of freedom for confidence interval computation, specified as the comma-separated pair consisting of 'DFMethod' and one of the following.

'Residual'	Default. The degrees of freedom are assumed to be constant and equal to $n - p$ , where $n$ is the number of observations and $p$ is the number of fixed effects.
'Satterthwaite'	Satterthwaite approximation.
'None'	All degrees of freedom are set to infinity.

For example, you can specify the Satterthwaite approximation as follows.

**Example:** 'DFMethod','Satterthwaite'

## Output Arguments

### **feCI - Fixed-effects confidence intervals**

*p*-by-2 matrix

Fixed-effects confidence intervals, returned as a *p*-by-2 matrix. **feCI** contains the confidence limits that correspond to the *p* fixed-effects estimates in the vector **beta** returned by the **fixedEffects** method. The first column of **feCI** has the lower confidence limits and the second column has the upper confidence limits.

### **reCI - Random-effects confidence intervals**

*q*-by-2 matrix

Random-effects confidence intervals, returned as a *q*-by-2 matrix. **reCI** contains the confidence limits corresponding to the *q* random-effects estimates in the vector **B** returned by the **randomEffects** method. The first column of **reCI** has the lower confidence limits and the second column has the upper confidence limits.

## Examples

### **95% Confidence Intervals for Fixed-Effects Coefficients**

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load weight
```

**weight** contains data from a longitudinal study, where 20 subjects are randomly assigned to 4 exercise programs, and their weight loss is recorded over six 2-week time periods. This is simulated data.

Store the data in a dataset array. Define **Subject** and **Program** as categorical variables.

```
ds = dataset(InitialWeight, Program, Subject, Week, y);
ds.Subject = nominal(ds.Subject);
```

```
ds.Program = nominal(ds.Program);
```

Fit a linear mixed-effects model where the initial weight, type of program, week, and the interaction between the week and type of program are the fixed effects. The intercept and week vary by subject.

```
lme = fitlme(ds, 'y ~ InitialWeight + Program*Week + (Week|Subject)');
```

Compute the fixed-effects coefficient estimates.

```
fe = fixedEffects(lme)
```

```
fe =
```

```
    0.6610  
    0.0032  
    0.3608  
   -0.0333  
    0.1132  
    0.1732  
    0.0388  
    0.0305  
    0.0331
```

The first estimate, 0.6610, corresponds to the constant term. The second row, 0.0032, and the third row, 0.3608, are estimates for the coefficient of initial weight and week, respectively. Rows four to six correspond to the indicator variables for programs B-D, and the last three rows correspond to the interaction of programs B-D and week.

Compute the 95% confidence intervals for the fixed-effects coefficients.

```
fecI = coefCI(lme)
```

```
fecI =
```

```
    0.1480    1.1741  
    0.0005    0.0059
```

# LinearMixedModel.coefCI

---

```
0.1004    0.6211
-0.2932   0.2267
-0.1471   0.3734
0.0395    0.3069
-0.1503   0.2278
-0.1585   0.2196
-0.1559   0.2221
```

Some confidence intervals include 0. To obtain specific  $p$ -values for each fixed-effects term, use the `fixedEffects` method. To test for entire terms use the `anova` method.

## Confidence Intervals with Specified Options

Load the sample data.

```
load carbig
```

Fit a linear mixed-effects model for miles per gallon (MPG), with fixed effects for acceleration and horsepower, and a potentially correlated random effect for intercept and acceleration grouped by model year. First, store the data in a dataset array.

```
ds = dataset(Acceleration,Horsepower,Model_Year,MPG);
```

Fit the model.

```
lme = fitlme(ds, 'MPG ~ Acceleration + Horsepower + (Acceleration|Model_Y
```

Compute the fixed-effects coefficient estimates.

```
fe = fixedEffects(lme)
```

```
fe =
```

```
50.1325
-0.5833
-0.1695
```

Compute the 99% confidence intervals for fixed-effects coefficients using the residuals method to determine the degrees of freedom. This is the default method.

```
feCI = coefCI(lme, 'Alpha', 0.01)
```

```
feCI =
```

```
    44.2690    55.9961  
   -0.9300   -0.2365  
   -0.1883   -0.1507
```

Compute the 99% confidence intervals for fixed-effects coefficients using the Satterthwaite approximation to compute the degrees of freedom.

```
feCI = coefCI(lme, 'Alpha', 0.01, 'DFMethod', 'Satterthwaite')
```

```
feCI =
```

```
    44.0949    56.1701  
   -0.9640   -0.2025  
   -0.1884   -0.1507
```

The Satterthwaite approximation produces similar confidence intervals to the residual method.

## Compute Confidence Intervals for Random Effects

Navigate to a folder containing sample data.

```
cd(matlabroot)  
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load shift
```

The data shows the deviations from the target quality characteristic measured from the products that five operators manufacture during

# LinearMixedModel.coefCI

---

three shifts: morning, evening, and night. This is a randomized block design, where the operators are the blocks. The experiment is designed to study the impact of the time of shift on the performance. The performance measure is the deviation of the quality characteristics from the target value. This is simulated data.

Shift and Operator are nominal variables.

```
shift.Shift = nominal(shift.Shift);  
shift.Operator = nominal(shift.Operator);
```

Fit a linear mixed-effects model with a random intercept grouped by operator to assess if there is significant difference in the performance according to the time of the shift.

```
lme = fitlme(shift, 'QCDev ~ Shift + (1|Operator)');
```

Compute the estimate of the BLUPs for random effects.

```
randomEffects(lme)
```

```
ans =
```

```
    0.5775  
    1.1757  
   -2.1715  
    2.3655  
   -1.9472
```

Compute the 95% confidence intervals for random effects.

```
[~,reCI] = coefCI(lme)
```

```
reCI =
```

```
   -1.3916    2.5467  
   -0.7934    3.1449  
   -4.1407   -0.2024  
    0.3964    4.3347
```

```
-3.9164    0.0219
```

Compute the 99% confidence intervals for random effects using the residuals method to determine the degrees of freedom. This is the default method.

```
[~,reCI] = coefCI(lme, 'Alpha', 0.01)
```

```
reCI =
```

```
-2.1831    3.3382  
-1.5849    3.9364  
-4.9322    0.5891  
-0.3951    5.1261  
-4.7079    0.8134
```

Compute the 99% confidence intervals for random effects using the Satterthwaite approximation to determine the degrees of freedom.

```
[~,reCI] = coefCI(lme, 'Alpha', 0.01, 'DFMethod', 'Satterthwaite')
```

```
reCI =
```

```
-2.6840    3.8390  
-2.0858    4.4372  
-5.4330    1.0900  
-0.8960    5.6270  
-5.2087    1.3142
```

The Satterthwaite approximation might produce smaller DF values than the residual method. That is why these confidence intervals are larger than the previous ones computed using the residual method.

# NonLinearModel.coefCI

---

<b>Purpose</b>	Confidence intervals of coefficient estimates of nonlinear regression model
<b>Syntax</b>	<code>ci = coefCI mdl</code> <code>ci = coefCI mdl, alpha</code>
<b>Description</b>	<code>ci = coefCI mdl</code> returns confidence intervals for the coefficients in <code>mdl</code> . <code>ci = coefCI mdl, alpha</code> returns confidence intervals with confidence level $1 - \alpha$ .
<b>Input Arguments</b>	<b>mdl</b> Nonlinear regression model, constructed by <code>fitnlm</code> . <b>alpha</b> Scalar from 0 to 1, the probability that the confidence interval does not contain the true value. <b>Default:</b> 0.05
<b>Output Arguments</b>	<b>ci</b> k-by-2 matrix of confidence intervals. The <i>j</i> th row of <code>ci</code> is the confidence interval of coefficient <i>j</i> of <code>mdl</code> . The name of coefficient <i>j</i> of <code>mdl</code> is in <code>mdl.CoeffNames</code> .
<b>Definitions</b>	<b>Confidence Interval</b> Assume that model assumptions hold (the data comes from a model represented by the formula <code>mdl.Formula</code> , with independent normally distributed errors). Then row <i>j</i> of the confidence interval matrix <code>ci</code> gives a <i>confidence interval</i> [ <code>ci(j,1)</code> , <code>ci(j,2)</code> ] that contains coefficient <i>j</i> with probability $1 - \alpha$ .

## Examples

### Default Confidence Intervals

Create a nonlinear model for auto mileage based on the `carbig` data. Then obtain confidence intervals for the resulting model coefficients.

Load the data and create a nonlinear model.

```
load carbig
ds = dataset(Horsepower,Weight,MPG);
modelfun = @(b,x)b(1) + b(2)*x(:,1) + ...
    b(3)*x(:,2) + b(4)*x(:,1).*x(:,2);
beta0 = [1 1 1 1];
mdl = fitnlm(ds,modelfun,beta0)
```

```
mdl =
```

```
Nonlinear regression model:
```

```
MPG ~ b1 + b2*Horsepower + b3*Weight + b4*Horsepower*Weight
```

```
Estimated Coefficients:
```

	Estimate	SE	tStat	pValue
b1	63.558	2.3429	27.127	1.2343e-91
b2	-0.25084	0.027279	-9.1952	2.3226e-18
b3	-0.010772	0.00077381	-13.921	5.1372e-36
b4	5.3554e-05	6.6491e-06	8.0542	9.9336e-15

```
Number of observations: 392, Error degrees of freedom: 388
```

```
Root Mean Squared Error: 3.93
```

```
R-Squared: 0.748, Adjusted R-Squared 0.746
```

```
F-statistic vs. constant model: 385, p-value = 7.26e-116
```

All the coefficients have extremely small  $p$ -values. This means a confidence interval around the coefficients will not contain the point 0, unless the confidence level is very high.

Find 95% confidence intervals for the coefficients of the model.

```
ci = coefCI(mdl)
```

```
ci =  
  
    58.9515    68.1644  
   -0.3045   -0.1972  
   -0.0123   -0.0093  
    0.0000    0.0001
```

The confidence interval for `b4` seems to contain 0. Examine it in more detail.

```
ci(4,:)

ans =  
    1.0e-04 *  
    0.4048    0.6663
```

As expected, the confidence interval does not contain the point 0.

## Alternatives

You can create the intervals from the model coefficients in `mdl.Coefficients.Estimate` and an appropriate multiplier of the standard errors `sqrt(diag(mdl.CoefficientCovariance))`. The multiplier is `tinvs(1-alpha/2,dof)`, where `level` is the confidence level, and `dof` is the degrees of freedom (number of data points minus the number of coefficients).

## Purpose

Linear hypothesis test on generalized linear regression model coefficients

## Syntax

```
p = coefTest mdl
p = coefTest mdl,H
p = coefTest mdl,H,C
[p,F] = coefTest mdl,...
[p,F,r] = coefTest mdl,...
```

## Description

`p = coefTest(mdl)` computes the  $p$ -value for an  $F$  test that all coefficient estimates in `mdl` are zero, except for the intercept term.

`p = coefTest(mdl,H)` performs an  $F$  test that  $H*B = 0$ , where  $B$  represents the coefficient vector.

`p = coefTest(mdl,H,C)` performs an  $F$  test that  $H*B = C$ .

`[p,F] = coefTest(mdl,...)` returns the  $F$  test statistic.

`[p,F,r] = coefTest(mdl,...)` returns the numerator degrees of freedom for the test.

## Input Arguments

### mdl

Generalized linear model, as constructed by `fitglm` or `stepwiseglm`.

### H

Numeric matrix having one column for each coefficient in the model. When  $H$  is an input, the output  $p$  is the  $p$ -value for an  $F$  test that  $H*B = 0$ , where  $B$  represents the coefficient vector.

### C

Numeric vector with the same number of rows as  $H$ . When  $C$  is an input, the output  $p$  is the  $p$ -value for an  $F$  test that  $H*B = C$ , where  $B$  represents the coefficient vector.

# GeneralizedLinearModel.coefTest

---

## Output Arguments

**p**

$p$ -value of the  $F$  test (see “Definitions” on page 21-388).

**F**

Value of the test statistic for the  $F$  test (see “Definitions” on page 21-388).

**r**

Numerator degrees of freedom for the  $F$  test (see “Definitions” on page 21-388). The  $F$  statistic has  $r$  degrees of freedom in the numerator and `mdl.DFE` degrees of freedom in the denominator.

## Definitions

### Test Statistics

The  $p$ -value,  $F$  statistic, and numerator degrees of freedom are valid under these assumptions:

- The data comes from a model represented by the formula `mdl.Formula`.
- The observations are independent conditional on the predictor values.

Suppose these assumptions hold. Let  $\beta$  represent the (unknown) coefficient vector of the linear regression. Suppose  $H$  is a full-rank matrix of size  $r$ -by- $s$ , where  $s$  is the number of terms in  $\beta$ . Let  $v$  be a vector the same size as  $\beta$ . The following is a test statistic for the hypothesis that  $H\beta = v$ :

$$F = (H\hat{\beta} - v)'(HCH')^{-1}(H\hat{\beta} - v).$$

Here  $\hat{\beta}$  is the estimate of the coefficient vector  $\beta$  in `mdl.Coeffs`, and  $C$  is the estimated covariance of the coefficient estimates in `mdl.CoeffCov`. When the hypothesis is true, the test statistic  $F$  has an “F Distribution” on page B-41 with  $r$  and  $u$  degrees of freedom.

## Examples

### Test Generalized Linear Model Coefficients

Test a generalized linear model to see if its coefficients differ from zero.

Create a generalized linear regression model of Poisson data.

```
X = 2 + randn(100,1);  
mu = exp(1 + X/2);  
y = poissrnd(mu);  
mdl = fitglm(X,y,'y ~ x1','distr','poisson');
```

Test whether the fitted model has coefficients that differ significantly from zero.

```
p = coefTest(mdl)
```

```
p =
```

```
1.2461e-30
```

There is no doubt that the coefficient of  $x_1$  is nonzero.

## Alternatives

The values of commonly used test statistics are available in the `mdl.Coefficients` dataset array.

## Examples

### Test Linear Regression Model

Make a linear model of mileage as a function of the weight, weight squared, and model year from the `carsmall` data set. Test the coefficients to see if all should be zero.

# LinearModel.coefTest

---

Load the data and make a dataset array, where the model year is an ordinal variable.

```
load carsmall
ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);
mdl = fitlm(ds,'MPG ~ Year + Weight + Weight^2');
```

Test the model for significant differences from a constant model.

```
p = coefTest(mdl)
```

```
p =
```

```
5.5208e-41
```

There is no doubt that the model contains more than the intercept term.

## Test a Particular Coefficient

Test the  $\text{Weight}^2$  coefficient in a linear model of mileage as a function of the weight, weight squared, and model year.

Load the data and make a dataset array, where the model year is an ordinal variable.

```
load carsmall
ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);
mdl = fitlm(ds,'MPG ~ Year + Weight + Weight^2');
```

Test the significance of the  $\text{Weight}^2$  coefficient. To do so, find the coefficient corresponding to  $\text{Weight}^2$ .

```
mdl.CoefficientNames
```

```
ans =
```

```
'(Intercept)' 'Weight' 'Year_76' 'Year_82' 'Weight^2'
```

Weight<sup>2</sup> is the fifth (final) coefficient.

Test the significance of the Weight<sup>2</sup> coefficient.

```
p = coefTest mdl, [0 0 0 0 1])
```

```
p =
```

```
0.0022
```

## Alternatives

The values of commonly used test statistics are available in the `mdl.Coefficients` dataset array.

`anova` provides a test for each model term.

## How To

- “Linear Regression” on page 9-12

# LinearMixedModel.coefTest

---

**Purpose** Hypothesis test on fixed and random effects of linear mixed-effects model

**Syntax**

```
pVal = coefTest(lme)
pVal = coefTest(lme,H)
pVal = coefTest(lme,H,C)
pVal = coefTest(lme,H,C,'REContrast',K)
pVal = coefTest( __ ,Name,Value)
[pVal,F,DF1,DF2] = coefTest( __ )
```

**Description** `pVal = coefTest(lme)` returns the  $p$ -value for an  $F$ -test that all fixed-effects coefficients except for the intercept are 0.

`pVal = coefTest(lme,H)` returns the  $p$ -value for an  $F$ -test on fixed-effects coefficients of linear mixed-effects model `lme`, using the contrast matrix `H`. It tests the null hypothesis that  $H_0: H\beta = 0$ , where  $\beta$  is the fixed-effects vector.

`pVal = coefTest(lme,H,C)` returns the  $p$ -value for an  $F$ -test on fixed-effects coefficients of the linear mixed-effects model `lme`, using the contrast matrix `H`. It tests the null hypothesis that  $H_0: H\beta = C$ , where  $\beta$  is the fixed-effects vector.

`pVal = coefTest(lme,H,C,'REContrast',K)` returns the  $p$ -value for an  $F$ -test on the fixed- and random-effects coefficients of the linear mixed-effects model `lme`, using the contrast matrices `H` and `K`. It tests the null hypothesis that  $H_0: H\beta + KB = C$ , where  $\beta$  is the fixed-effects vector and  $B$  is the random-effects vector.

`pVal = coefTest( __ ,Name,Value)` returns the  $p$ -value for an  $F$ -test on the fixed- and/or random-effects coefficients of the linear mixed-effects model `lme`, with additional options specified by one or more `Name,Value` pair arguments. It can accept any of the input arguments in the previous syntaxes.

For example, you can specify the method to compute the degrees of freedom.

[pVal,F,DF1,DF2] = coefTest( \_\_\_ ) also returns the  $F$ -statistic  $F$ , and the numerator and denominator degrees of freedom for  $F$ , respectively  $DF1$  and  $DF2$ .

## Input Arguments

### lme - Linear mixed-effects model

LinearMixedModel object

Linear mixed-effects model, returned as a LinearMixedModel object.

For properties and methods of this object, see LinearMixedModel.

### H - Fixed-effects contrasts

$m$ -by- $p$  matrix

Fixed-effects contrasts, specified as an  $m$ -by- $p$  matrix, where  $p$  is the number of fixed-effects coefficients in `lme`. Each row of `H` represents one contrast. The columns of `H` (left to right) correspond to the rows of the  $p$ -by-1 fixed-effects vector `beta` (top to bottom), returned by the `fixedEffects` method.

### Data Types

single | double

### C - Hypothesized value

$m$ -by-1 vector

Hypothesized value for testing the null hypothesis  $H*beta = C$ , specified as an  $m$ -by-1 matrix. Here, `beta` is the vector of fixed-effects estimates returned by the `fixedEffects` method.

### Data Types

single | double

### K - Random-effects contrasts

$m$ -by- $q$  matrix

Random-effects contrasts, specified as an  $m$ -by- $q$  matrix, where  $q$  is the number of random effects parameters in `lme`. The columns of  $K$  (left to right) correspond to the rows of the random-effects best linear unbiased predictor vector  $B$  (top to bottom), returned by the `randomEffects` method.

## Data Types

single | double

## Name-Value Pair Arguments

Specify optional comma-separated pairs of `Name`, `Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( ' '). You can specify several name and value pair arguments in any order as `Name1, Value1, ..., NameN, ValueN`.

## 'DFMethod' - Method for computing approximate denominator degrees of freedom

'Residual' (default) | 'Satterthwaite' | 'None'

Method for computing the approximate denominator degrees of freedom for the  $F$ -test, specified as the comma-separated pair consisting of 'DFMethod' and one of the following.

'Residual'	Default. The degrees of freedom are assumed to be constant and equal to $n - p$ , where $n$ is the number of observations and $p$ is the number of fixed effects.
'Satterthwaite'	Satterthwaite approximation.
'None'	All degrees of freedom are set to infinity.

For example, you can specify the Satterthwaite approximation as follows.

**Example:** 'DFMethod', 'Satterthwaite'

## Output Arguments

### **pVal - p-value**

scalar value

$p$ -value for the  $F$ -test on the fixed and/or random-effects coefficients of the linear mixed-effects model `lme`, returned as a scalar value.

### **F - F-statistic**

scalar value

$F$ -statistic, returned as a scalar value.

### **DF1 - Numerator degrees of freedom for F**

scalar value

Numerator degrees of freedom for  $F$ , returned as a scalar value.

- If you test the null hypothesis  $H_0: H\beta = 0$ , or  $H_0: H\beta = C$ , then DF1 is equal to the number of linearly independent rows in  $H$ .
- If you test the null hypothesis  $H_0: H\beta + KB = C$ , then DF1 is equal to the number of linearly independent rows in  $[H, K]$ .

### **DF2 - Denominator degrees of freedom for F**

scalar value

Denominator degrees of freedom for  $F$ , returned as a scalar value. The value of DF2 depends on the option you select for `DFMethod`.

## Examples

### **Randomized Block Design**

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load shift
```

# LinearMixedModel.coefTest

---

The data shows the absolute deviations from the target quality characteristic measured from the products that five operators manufacture during three different shifts: morning, evening, and night. This is a randomized block design, where the operators are the blocks. The experiment is designed to study the impact of the time of shift on the performance. The performance measure is the absolute deviation of the quality characteristics from the target value. This is simulated data.

Shift and Operator are nominal variables.

```
shift.Shift = nominal(shift.Shift);
shift.Operator = nominal(shift.Operator);
```

Fit a linear mixed-effects model with a random intercept grouped by operator to assess if there is significant difference in the performance according to the time of the shift.

```
lme = fitlme(shift, 'QCDev ~ Shift + (1|Operator)')
```

```
lme =
```

```
Linear mixed-effects model fit by ML
```

```
Model information:
```

Number of observations	15
Fixed effects coefficients	3
Random effects coefficients	5
Covariance parameters	2

```
Formula:
```

```
QCDev ~ 1 + Shift + (1 | Operator)
```

```
Model fit statistics:
```

AIC	BIC	LogLikelihood	Deviance
59.012	62.552	-24.506	49.012

```
Fixed effects coefficients (95% CIs):
```

Name	Estimate	SE	tStat	DF	pVal
'(Intercept)'	3.1196	0.88681	3.5178	12	0
'Shift_Morning'	-0.3868	0.48344	-0.80009	12	0
'Shift_Night'	1.9856	0.48344	4.1072	12	0

Random effects covariance parameters (95% CIs):

Group: Operator (5 Levels)

Name1	Name2	Type	Estimate
'(Intercept)'	'(Intercept)'	'std'	1.8297

Group: Error

Name	Estimate	Lower	Upper
'Res Std'	0.76439	0.49315	1.1848

Test if all fixed-effects coefficients except for the intercept are 0.

```
pVal = coefTest(lme)
```

```
pVal =
```

```
7.5956e-04
```

The small  $p$ -value indicates that not all fixed-effects coefficients are 0.

Test the significance of the Shift term using a contrast matrix.

```
H = [0 1 0; 0 0 1];
```

```
pVal = coefTest(lme,H)
```

```
pVal =
```

```
7.5956e-04
```

Test the significance of the Shift term using the anova method.

```
anova(lme)
```

```
ans =
```

# LinearMixedModel.coefTest

---

```
ANOVA marginal tests: DFMethod = 'Residual'
```

Term	FStat	DF1	DF2	pValue
'(Intercept)'	12.375	1	12	0.0042407
'Shift'	13.864	2	12	0.00075956

The  $p$ -value for Shift, 0.00075956, is the same as the  $p$ -value of the previous hypothesis test.

Test if there is any difference between the evening and morning shifts.

```
pVal = coefTest(lme,[0 1 -1])
```

```
pVal =
```

```
3.6147e-04
```

This small  $p$ -value indicates that the performance of the operators are not the same in the morning and the evening shifts.

## Hypothesis Test for Fixed Effects

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load weight
```

`weight` contains data from a longitudinal study, where 20 subjects are randomly assigned to 4 exercise programs, and their weight loss is recorded over six 2-week time periods. This is simulated data.

Store the data in a dataset array. Define `Subject` and `Program` as categorical variables.

```
ds = dataset(InitialWeight,Program,Subject,Week,y);
```

```
ds.Subject = nominal(ds.Subject);  
ds.Program = nominal(ds.Program);
```

Fit a linear mixed-effects model where the initial weight, type of program, week, and the interaction between the week and type of program are the fixed effects. The intercept and week vary by subject.

```
lme = fitlme(ds, 'y ~ InitialWeight + Program*Week + (Week|Subject)')
```

```
lme =
```

```
Linear mixed-effects model fit by ML
```

```
Model information:
```

Number of observations	120
Fixed effects coefficients	9
Random effects coefficients	40
Covariance parameters	4

```
Formula:
```

```
y ~ 1 + InitialWeight + Program*Week + (1 + Week | Subject)
```

```
Model fit statistics:
```

AIC	BIC	LogLikelihood	Deviance
-22.981	13.257	24.49	-48.981

```
Fixed effects coefficients (95% CIs):
```

Name	Estimate	SE	tStat	DF
'(Intercept)'	0.66105	0.25892	2.5531	111
'InitialWeight'	0.0031879	0.0013814	2.3078	111
'Program_B'	0.36079	0.13139	2.746	111
'Program_C'	-0.033263	0.13117	-0.25358	111
'Program_D'	0.11317	0.13132	0.86175	111
'Week'	0.1732	0.067454	2.5677	111
'Program_B:Week'	0.038771	0.095394	0.40644	111
'Program_C:Week'	0.030543	0.095394	0.32018	111

# LinearMixedModel.coefTest

---

```
'Program_D:Week'          0.033114      0.095394      0.34713      111
```

Random effects covariance parameters (95% CIs):

Group: Subject (20 Levels)

Name1	Name2	Type	Estimate
'(Intercept)'	'(Intercept)'	'std'	0.18407
'Week'	'(Intercept)'	'corr'	0.66841
'Week'	'Week'	'std'	0.15033

Group: Error

Name	Estimate	Lower	Upper
'Res Std'	0.10261	0.087882	0.11981

Test for the significance of the interaction between Program and Week.

```
H = [0 0 0 0 0 0 1 0 0;  
      0 0 0 0 0 0 0 1 0;  
      0 0 0 0 0 0 0 0 1];  
pVal = coefTest(lme,H)
```

```
pVal =  
  
0.9775
```

The high  $p$ -value indicates that the interaction between Program and Week is not statistically significant.

Now, test whether all coefficients involving Program are 0.

```
H = [0 0 1 0 0 0 0 0 0;  
      0 0 0 1 0 0 0 0 0;  
      0 0 0 0 1 0 0 0 0;  
      0 0 0 0 0 0 1 0 0;  
      0 0 0 0 0 0 0 1 0;  
      0 0 0 0 0 0 0 0 1];  
C = [0;0;0;0;0;0];  
pVal = coefTest(lme,H,C)
```

```
pVal =  
  
    0.0274
```

The  $p$ -value of 0.0274 indicates that not all coefficients involving Program are zero.

## Test for Fixed and Random Effects

Load the sample data.

```
load flu
```

The flu dataset array has a Date variable, and 10 variables containing estimated influenza rates (in 9 different regions, estimated from Google® searches, plus a nationwide estimate from the CDC).

To fit a linear-mixed effects model, your data must be in a properly formatted dataset array. To fit a linear mixed-effects model with the influenza rates as the responses and region as the predictor variable, combine the nine columns corresponding to the regions into a tall array. The new dataset array, flu2, must have the response variable, FluRate, the nominal variable, Region, that shows which region each estimate is from, and the grouping variable Date.

```
flu2 = stack(flu,2:10,'NewDataVarName','FluRate',...  
    'IndVarName','Region');  
flu2.Date = nominal(flu2.Date);
```

Fit a linear mixed-effects model with fixed effects for the region and a random intercept that varies by Date.

```
lme = fitlme(flu2,'FluRate ~ 1 + Region + (1|Date)')
```

Linear mixed-effects model fit by ML

## See Also

[LinearMixedModel](#) | [anova](#) | [coefCI](#) |

**Purpose** Linear hypothesis test on nonlinear regression model coefficients

**Syntax**

```
p = coefTest mdl
p = coefTest mdl,H
p = coefTest mdl,H,C
[p,F] = coefTest mdl,...
[p,F,r] = coefTest mdl,...
```

**Description**

`p = coefTest(mdl)` computes the  $p$ -value for an  $F$  test that all coefficient estimates in `mdl` are zero.

`p = coefTest(mdl,H)` performs an  $F$  test that  $H*B = 0$ , where  $B$  represents the coefficient vector.

`p = coefTest(mdl,H,C)` performs an  $F$  test that  $H*B = C$ .

`[p,F] = coefTest(mdl,...)` returns the  $F$  test statistic.

`[p,F,r] = coefTest(mdl,...)` returns the numerator degrees of freedom for the test.

## Input Arguments

### **mdl**

Nonlinear regression model, constructed by `fitnlm`.

### **H**

Numeric matrix having one column for each coefficient in the model. When  $H$  is an input, the output  $p$  is the  $p$ -value for an  $F$  test that  $H*B = 0$ , where  $B$  represents the coefficient vector.

### **C**

Numeric vector with the same number of rows as  $H$ . When  $C$  is an input, the output  $p$  is the  $p$ -value for an  $F$  test that  $H*B = C$ , where  $B$  represents the coefficient vector.

## Output Arguments

### **p**

$p$ -value of the  $F$  test (see “Definitions” on page 21-408).

### **F**

Value of the test statistic for the  $F$  test (see “Definitions” on page 21-408).

$r$

Numerator degrees of freedom for the  $F$  test (see “Definitions” on page 21-408). The  $F$  statistic has  $r$  degrees of freedom in the numerator and  $mdl.DFE$  degrees of freedom in the denominator.

## Definitions **Test Statistics**

The  $p$ -value,  $F$  statistic, and numerator degrees of freedom are valid under these assumptions:

- The data comes from a normal distribution.
- The entries are independent.

Suppose these assumptions hold. Let  $\beta$  represent the unknown coefficient vector of the linear regression. Suppose  $H$  is a full-rank matrix of size  $r$ -by- $s$ , where  $s$  is the number of terms in  $\beta$ . Let  $v$  be a vector the same size as  $\beta$ . The following is a test statistic for the hypothesis that  $H\beta = v$ :

$$F = (H\hat{\beta} - v)'(HCH')^{-1}(H\hat{\beta} - v).$$

Here  $\hat{\beta}$  is the estimate of the coefficient vector  $\beta$  in `mdl.Coeffs`, and  $C$  is the estimated covariance of the coefficient estimates in `mdl.CoeffCov`. When the hypothesis is true, the test statistic  $F$  has an “F Distribution” on page B-41 with  $r$  and  $u$  degrees of freedom.

## Examples **Test Nonlinear Regression Model Coefficients**

Make a nonlinear model of mileage as a function of the weight from the `carsmall` data set. Test the coefficients to see if all should be zero.

Create an exponential model of car mileage as a function of weight from the `carsmall` data. Scale the weight by a factor of 1000 so all the variables are roughly equal in size.

```
load carsmall
X = Weight;
y = MPG;
modelfun = 'y ~ b1 + b2*exp(-b3*x/1000)';
beta0 = [1 1 1];
mdl = fitnlm(X,y,modelfun,beta0);
```

Test the model for significant differences from a constant model.

```
p = coefTest(mdl)
```

```
p =
```

```
1.3708e-36
```

There is no doubt that the model contains nonzero terms.

## Alternatives

The values of commonly used test statistics are available in the `mdl.Coefficients` dataset array.

## Concepts

- “Nonlinear Regression” on page 11-2

# CompactTreeBagger.combine

---

**Purpose**            Combine two ensembles

**Syntax**            `B1 = combine(B1,B2)`

**Description**        `B1 = combine(B1,B2)` appends decision trees from ensemble B2 to those stored in B1 and returns ensemble B1. This method requires that the class and variable names be identical in both ensembles.

**See Also**            `TreeBagger.append`

**Purpose** Enumeration of combinations

**Syntax** `C = combnk(v,k)`

**Description** `C = combnk(v,k)` returns all combinations of the  $n$  elements in  $v$  taken  $k$  at a time.

`C = combnk(v,k)` produces a matrix  $C$  with  $k$  columns and  $n!/k!(n-k)!$  rows, where each row contains  $k$  of the elements in the vector  $v$ .

It is not practical to use this function if  $v$  has more than about 15 elements.

**Examples** Combinations of characters from a string.

```
C = combnk('tendrill',4);
last5 = C(31:35,:);
last5 =
tedr
tenl
teni
tenr
tend
```

Combinations of elements from a numeric vector.

```
c = combnk(1:4,2)
c =
 3  4
 2  4
 2  3
 1  4
 1  3
 1  2
```

**See Also** `perms`

# ClassificationDiscriminant.compact

---

<b>Purpose</b>	Compact discriminant analysis classifier
<b>Syntax</b>	<code>cobj = compact(obj)</code>
<b>Description</b>	<code>cobj = compact(obj)</code> creates a compact version of <code>obj</code> .
<b>Input Arguments</b>	<b>obj</b> Discriminant analysis classifier created using <code>ClassificationDiscriminant.fit</code> .
<b>Output Arguments</b>	<b>cobj</b> Compact classifier. <code>cobj</code> has class <code>CompactClassificationDiscriminant</code> . You can predict classifications using <code>cobj</code> exactly as you can using <code>obj</code> . However, since <code>cobj</code> does not contain training data, you cannot perform some actions, such as cross validation.
<b>Examples</b>	Compare the size of the discriminant analysis classifier for Fisher's iris data to the compact version of the classifier:  <pre>load fisheriris fullobj = ClassificationDiscriminant.fit(meas,species); cobj = compact(fullobj); b = whos('fullobj'); % b.bytes = size of fullobj c = whos('cobj'); % c.bytes = size of cobj [b.bytes c.bytes] % shows cobj uses 60% of the memory</pre> <pre>ans =     18578    11498</pre>

**Purpose**

Compact ensemble of decision trees

**Description**

Return an object of class `CompactTreeBagger` holding the structure of the trained ensemble. The class is more compact than the full `TreeBagger` class because it does not contain information for growing more trees for the ensemble. In particular, it does not contain `X` and `Y` used for training.

**See Also**

`CompactTreeBagger`

# CompactClassificationDiscriminant

---

**Purpose** Compact discriminant analysis class

**Description** A `CompactClassificationDiscriminant` object is a compact version of a discriminant analysis classifier. The compact version does not include the data for training the classifier. Therefore, you cannot perform some tasks with a compact classifier, such as cross validation. Use a compact classifier for making predictions (classifications) of new data.

**Construction** `cobj = compact(obj)` constructs a compact classifier from a full classifier.

`cobj = ClassificationDiscriminant.make(Mu, Sigma)` constructs a compact discriminant analysis classifier from the class means `Mu` and covariance matrix `Sigma`. For syntax details, see `ClassificationDiscriminant.make`.

## Input Arguments

### **obj**

Discriminant analysis classifier, created with `ClassificationDiscriminant.fit`.

## Properties

### **BetweenSigma**

p-by-p matrix, the between-class covariance, where p is the number of predictors.

### **CategoricalPredictors**

List of categorical predictors, always empty (`[]`) for discriminant analysis.

### **ClassNames**

List of the elements in the training data `Y` with duplicates removed. `ClassNames` can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. `ClassNames` has the same data type as the data in the argument `Y`.

## Coeffs

k-by-k structure of coefficient matrices, where k is the number of classes. `Coeffs(i, j)` contains coefficients of the linear or quadratic boundaries between classes i and j. Fields in `Coeffs(i, j)`:

- `DiscrimType`
- `Class1` — `ClassNames(i)`
- `Class2` — `ClassNames(j)`
- `Const` — A scalar
- `Linear` — A vector with p components, where p is the number of columns in X
- `Quadratic` — p-by-p matrix, exists for quadratic `DiscrimType`

The equation of the boundary between class i and class j is

$$\text{Const} + \text{Linear} * x + x' * \text{Quadratic} * x = 0,$$

where x is a column vector of length p.

If `ClassificationDiscriminant.fit` had the `FillCoeffs` name-value pair set to 'off' when constructing the classifier, `Coeffs` is empty (`[]`).

## Cost

Square matrix, where `Cost(i, j)` is the cost of classifying a point into class j if its true class is i. `Cost` is K-by-K, where K is the number of classes.

Change a `Cost` matrix using dot addressing:

```
obj.Cost = costMatrix
```

## Delta

# CompactClassificationDiscriminant

---

Value of the Delta threshold for a linear discriminant model, a nonnegative scalar. If a coefficient of `obj` has magnitude smaller than `Delta`, `obj` sets this coefficient to 0, and so you can eliminate the corresponding predictor from the model. Set `Delta` to a higher value to eliminate more predictors.

`Delta` must be 0 for quadratic discriminant models.

Change `Delta` by dot addressing:

```
obj.Delta = newDelta
```

## DeltaPredictor

Row vector of length equal to the number of predictors in `obj`. If `DeltaPredictor(i) < Delta` then coefficient `i` of the model is 0.

If `obj` is a quadratic discriminant model, all elements of `DeltaPredictor` are 0.

## DiscrimType

String specifying the discriminant type. One of:

- 'linear'
- 'quadratic'
- 'diagLinear'
- 'diagQuadratic'
- 'pseudoLinear'
- 'pseudoQuadratic'

Change `DiscrimType` using dot addressing:

```
obj.DiscrimType = newDiscrimType
```

You can change between linear types, or between quadratic types, but cannot change between linear and quadratic types.

## Gamma

# CompactClassificationDiscriminant

---

Value of the Gamma regularization parameter, a scalar from 0 to 1. Change Gamma using dot addressing:

```
obj.Gamma = newGamma
```

- If you set 1 for linear discriminant, the discriminant sets its type to 'diagLinear'.
- If you set a value between MinGamma and 1 for linear discriminant, the discriminant sets its type to 'linear'.
- You cannot set values below the value of the MinGamma property.
- For quadratic discriminant, you can set either 0 (for DiscrimType 'quadratic') or 1 (for DiscrimType 'diagQuadratic').

## LogDetSigma

Logarithm of the determinant of the within-class covariance matrix. The type of LogDetSigma depends on the discriminant type:

- Scalar for linear discriminant analysis
- Vector of length K for quadratic discriminant analysis, where K is the number of classes

## MinGamma

Nonnegative scalar, the minimal value of the Gamma parameter so that the correlation matrix is invertible. If the correlation matrix is not singular, MinGamma is 0.

## Mu

Matrix of class means of size K-by-p, where K is the number of classes, and p is the number of predictors. Each row of Mu represents the mean of the multivariate normal distribution of the corresponding class. The class indices are in the ClassNames attribute.

# CompactClassificationDiscriminant

---

## PredictorNames

Cell array of names for the predictor variables, in the order in which they appear in the training data X.

## Prior

Prior probabilities for each class. `Prior` is a numeric vector whose entries relate to the corresponding `ClassNames` property.

Add or change a `Prior` vector using dot addressing:

```
obj.Prior = priorVector
```

## ResponseName

String describing the response variable Y.

## ScoreTransform

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means  $@(x)x$ . For a list of built-in transformation functions and the syntax of custom transformation functions, see `ClassificationDiscriminant.fit`.

Add or change a `ScoreTransform` function by dot addressing:

```
obj.ScoreTransform = 'function'
```

or

```
obj.ScoreTransform = @function
```

## Sigma

Within-class covariance matrix or matrices. The dimensions depend on `DiscrimType`:

- 'linear' (default) — Matrix of size p-by-p, where p is the number of predictors

- 'quadratic' — Array of size  $p$ -by- $p$ -by- $K$ , where  $K$  is the number of classes
- 'diagLinear' — Row vector of length  $p$
- 'diagQuadratic' — Array of size  $1$ -by- $p$ -by- $K$
- 'pseudoLinear' — Matrix of size  $p$ -by- $p$
- 'pseudoQuadratic' — Array of size  $p$ -by- $p$ -by- $K$

## Methods

edge	Classification edge
logP	Log of the unconditional probability density
loss	Classification error

margin	Classification margins
nLinearCoeffs	Number of nonzero linear coefficients
predict	Predict classification

## Definitions

### Discriminant Classification

The model for discriminant analysis is:

- Each class ( $Y$ ) generates data ( $X$ ) using a multivariate normal distribution. That is, the model assumes  $X$  has a Gaussian mixture distribution (`gmdistribution`).
  - For linear discriminant analysis, the model has the same covariance matrix for each class, only the means vary.
  - For quadratic discriminant analysis, both means and covariances of each class vary.

# Compact Classification Discriminant

---

predict classifies so as to minimize the expected classification cost:

$$\hat{y} = \arg \min_{y=1, \dots, K} \sum_{k=1}^K \hat{P}(k | x) C(y | k),$$

where

- $\hat{y}$  is the predicted classification.
- $K$  is the number of classes.
- $\hat{P}(k | x)$  is the posterior probability of class  $k$  for observation  $x$ .
- $C(y | k)$  is the cost of classifying an observation as  $y$  when its true class is  $k$ .

For details, see “How the predict Method Classifies” on page 15-6.

## Regularization

Regularization is the process of finding a small set of predictors that yield an effective predictive model. For linear discriminant analysis, there are two parameters,  $\gamma$  and  $\delta$ , that control regularization as follows. `cvshrink` helps you select appropriate values of the parameters.

Let  $\Sigma$  represent the covariance matrix of the data  $X$ , and let  $\hat{X}$  be the centered data (the data  $X$  minus the mean by class). Define

$$D = \text{diag}(\hat{X}^T * \hat{X}).$$

The regularized covariance matrix  $\tilde{\Sigma}$  is

$$\tilde{\Sigma} = (1 - \gamma)\Sigma + \gamma D.$$

Whenever  $\gamma \geq \text{MinGamma}$ ,  $\tilde{\Sigma}$  is nonsingular.

Let  $\mu_k$  be the mean vector for those elements of  $X$  in class  $k$ , and let  $\mu_0$  be the global mean vector (the mean of the rows of  $X$ ). Let  $C$  be

the correlation matrix of the data  $X$ , and let  $\tilde{C}$  be the regularized correlation matrix:

$$\tilde{C} = (1 - \gamma)C + \gamma I,$$

where  $I$  is the identity matrix.

The linear term in the regularized discriminant analysis classifier for a data point  $x$  is

$$(x - \mu_0)^T \tilde{\Sigma}^{-1} (\mu_k - \mu_0) = \left[ (x - \mu_0)^T D^{-1/2} \right] \left[ \tilde{C}^{-1} D^{-1/2} (\mu_k - \mu_0) \right].$$

The parameter  $\delta$  enters into this equation as a threshold on the final term in square brackets. Each component of the vector

$\left[ \tilde{C}^{-1} D^{-1/2} (\mu_k - \mu_0) \right]$  is set to zero if it is smaller in magnitude than the threshold  $\delta$ . Therefore, for class  $k$ , if component  $j$  is thresholded to zero, component  $j$  of  $x$  does not enter into the evaluation of the posterior probability.

The `DeltaPredictor` property is a vector related to this threshold. When  $\delta \geq \text{DeltaPredictor}(i)$ , all classes  $k$  have

$$\left| \tilde{C}^{-1} D^{-1/2} (\mu_k - \mu_0) \right| \leq \delta.$$

Therefore, when  $\delta \geq \text{DeltaPredictor}(i)$ , the regularized classifier does not use predictor  $i$ .

## Copy Semantics

Value. To learn how value classes affect copy operations, see `Copying Objects` in the MATLAB documentation.

## Examples

Construct a compact discriminant analysis classifier for the Fisher iris data, and compare its size to that of the full classifier:

```
load fisheriris
fullobj = ClassificationDiscriminant.fit(meas,species);
```

# CompactClassificationDiscriminant

---

```
cobj = compact(fullobj);
b = whos('fullobj'); % b.bytes = size of fullobj
c = whos('cobj'); % c.bytes = size of cobj
[b.bytes c.bytes] % shows cobj uses 60% of the memory

ans =
      18578      11498
```

---

Construct a compact discriminant analysis classifier from the means and covariances of the Fisher iris data:

```
load fisheriris
mu(1,:) = mean(meas(1:50,:));
mu(2,:) = mean(meas(51:100,:));
mu(3,:) = mean(meas(101:150,:));

mm1 = repmat(mu(1,:),50,1);
mm2 = repmat(mu(2,:),50,1);
mm3 = repmat(mu(3,:),50,1);
cc = meas;
cc(1:50,:) = cc(1:50,:) - mm1;
cc(51:100,:) = cc(51:100,:) - mm2;
cc(101:150,:) = cc(101:150,:) - mm3;
sigstar = cc' * cc / 147;
cpct = ClassificationDiscriminant.make(mu,sigstar,...
    'ClassNames',{'setosa','versicolor','virginica'});
```

## How To

- “Discriminant Analysis” on page 15-3

<b>Purpose</b>	Compact classification ensemble class
<b>Description</b>	Compact version of a classification ensemble (of class <code>ClassificationEnsemble</code> ). The compact version does not include the data for training the classification ensemble. Therefore, you cannot perform some tasks with a compact classification ensemble, such as cross validation. Use a compact classification ensemble for making predictions (classifications) of new data.
<b>Construction</b>	<code>ens = compact(ens)</code> constructs a compact decision ensemble from a full decision ensemble.
	<b>Input Arguments</b>
	<b>ens</b> A classification ensemble created by <code>fitensemble</code> .
<b>Properties</b>	<b>CategoricalPredictors</b> List of categorical predictors. <code>CategoricalPredictors</code> is a numeric vector with indices from 1 to $p$ , where $p$ is the number of columns of $X$ .
	<b>ClassNames</b> List of the elements in $Y$ with duplicates removed. <code>ClassNames</code> can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. <code>ClassNames</code> has the same data type as the data in the argument $Y$ .
	<b>CombineWeights</b> String describing how <code>ens</code> combines weak learner weights, either 'WeightedSum' or 'WeightedAverage'.
	<b>Cost</b> Square matrix where <code>Cost(i, j)</code> is the cost of classifying a point into class $j$ if its true class is $i$ .
	<b>NTrained</b>

# CompactClassificationEnsemble

---

Number of trained weak learners in `cens`, a scalar.

## **PredictorNames**

A cell array of names for the predictor variables, in the order in which they appear in `X`.

## **Prior**

Prior probabilities for each class. `Prior` is a numeric vector whose entries relate to the corresponding `ClassNames` property.

## **ResponseName**

String with the name of the response variable `Y`.

## **ScoreTransform**

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means `@(x)x`. For a list of built-in transformation functions and the syntax of custom transformation functions, see `ClassificationTree.fit`.

Add or change a `ScoreTransform` function by dot addressing:

```
cens.ScoreTransform = 'function'
```

or

```
cens.ScoreTransform = @function
```

## **Trained**

Trained learners, a cell array of compact classification models.

## **TrainedWeights**

Numeric vector of trained weights for the weak learners in `ens`. `TrainedWeights` has `T` elements, where `T` is the number of weak learners in `learners`.

## **UsePredForLearner**

Logical matrix of size P-by-NTrained, where P is the number of predictors (columns) in the training data X. UsePredForLearner(i, j) is true when learner j uses predictor i, and is false otherwise. For each learner, the predictors have the same order as the columns in the training data X.

If the ensemble is not of type Subspace, all entries in UsePredForLearner are true.

## Methods

edge	Classification edge
loss	Classification error
margin	Classification margins
predict	Predict classification
predictorImportance	Estimates of predictor importance
removeLearners	Remove members of compact classification ensemble

## Copy Semantics

Value. To learn how value classes affect copy operations, see Copying Objects in the MATLAB documentation.

## Examples

Create a compact classification ensemble for the ionosphere data:

```
load ionosphere
ens = fitensemble(X,Y,'AdaBoostM1',100,'Tree');
cens = compact(ens)

cens =
classreg.learning.classif.CompactClassificationEnsemble:
    PredictorNames: {1x34 cell}
    CategoricalPredictors: []
    ResponseName: 'Y'
    ClassNames: {'b' 'g'}
    ScoreTransform: 'none'
```

# CompactClassificationEnsemble

<b>Purpose</b>	Compact classification tree
<b>Description</b>	Compact version of a classification tree (of class <code>ClassificationTree</code> ). The compact version does not include the data for training the classification tree. Therefore, you cannot perform some tasks with a compact classification tree, such as cross validation. Use a compact classification tree for making predictions (classifications) of new data.
<b>Construction</b>	<code>ctree = compact(tree)</code> constructs a compact decision tree from a full decision tree.
	<b>Input Arguments</b>
	<b>tree</b> A decision tree constructed by <code>ClassificationTree.fit</code> .
<b>Properties</b>	<b>CategoricalPredictors</b> List of categorical predictors. <code>CategoricalPredictors</code> is a numeric vector with indices from 1 to $p$ , where $p$ is the number of columns of $X$ .
	<b>CatSplit</b> An $n$ -by-2 cell array, where $n$ is the number of categorical splits in <code>tree</code> . Each row in <code>CatSplit</code> gives left and right values for a categorical split. For each branch node with categorical split $j$ based on a categorical predictor variable $z$ , the left child is chosen if $z$ is in <code>CatSplit(j,1)</code> and the right child is chosen if $z$ is in <code>CatSplit(j,2)</code> . The splits are in the same order as nodes of the tree. Find the nodes for these splits by selecting 'categorical' cuts from top to bottom in the <code>CutType</code> property.
	<b>Children</b> An $n$ -by-2 array containing the numbers of the child nodes for each node in <code>tree</code> , where $n$ is the number of nodes. Leaf nodes have child node 0.
	<b>ClassCount</b>

# CompactClassificationTree

---

An  $n$ -by- $k$  array of class counts for the nodes in `tree`, where  $n$  is the number of nodes and  $k$  is the number of classes. For any node number  $i$ , the class counts `ClassCount(i, :)` are counts of observations (from the data used in fitting the tree) from each class satisfying the conditions for node  $i$ .

## **ClassNames**

List of the elements in `Y` with duplicates removed. `ClassNames` can be a numeric vector, vector of categorical variables (nominal or ordinal), logical vector, character array, or cell array of strings. `ClassNames` has the same data type as the data in the argument `Y`.

## **ClassProb**

An  $n$ -by- $k$  array of class probabilities for the nodes in `tree`, where  $n$  is the number of nodes and  $k$  is the number of classes. For any node number  $i$ , the class probabilities `ClassProb(i, :)` are the estimated probabilities for each class for a point satisfying the conditions for node  $i$ .

## **Cost**

Square matrix, where `Cost(i, j)` is the cost of classifying a point into class  $j$  if its true class is  $i$ .

## **CutCategories**

An  $n$ -by-2 cell array of the categories used at branches in `tree`, where  $n$  is the number of nodes. For each branch node  $i$  based on a categorical predictor variable  $x$ , the left child is chosen if  $x$  is among the categories listed in `CutCategories{i, 1}`, and the right child is chosen if  $x$  is among those listed in `CutCategories{i, 2}`. Both columns of `CutCategories` are empty for branch nodes based on continuous predictors and for leaf nodes.

`CutPoint` contains the cut points for 'continuous' cuts, and `CutCategories` contains the set of categories.

## **CutPoint**

An  $n$ -element vector of the values used as cut points in `tree`, where  $n$  is the number of nodes. For each branch node  $i$  based on a continuous predictor variable  $x$ , the left child is chosen if  $x < \text{CutPoint}(i)$  and the right child is chosen if  $x \geq \text{CutPoint}(i)$ . `CutPoint` is NaN for branch nodes based on categorical predictors and for leaf nodes.

`CutPoint` contains the cut points for 'continuous' cuts, and `CutCategories` contains the set of categories.

## CutType

An  $n$ -element cell array indicating the type of cut at each node in `tree`, where  $n$  is the number of nodes. For each node  $i$ , `CutType{i}` is:

- 'continuous' — If the cut is defined in the form  $x < v$  for a variable  $x$  and cut point  $v$ .
- 'categorical' — If the cut is defined by whether a variable  $x$  takes a value in a set of categories.
- '' — If  $i$  is a leaf node.

`CutPoint` contains the cut points for 'continuous' cuts, and `CutCategories` contains the set of categories.

## CutVar

An  $n$ -element cell array of the names of the variables used for branching in each node in `tree`, where  $n$  is the number of nodes. These variables are sometimes known as *cut variables*. For leaf nodes, `CutVar` contains an empty string.

`CutPoint` contains the cut points for 'continuous' cuts, and `CutCategories` contains the set of categories.

## IsBranch

An  $n$ -element logical vector that is true for each branch node and false for each leaf node of `tree`.

# CompactClassificationTree

---

## **NodeClass**

An  $n$ -element cell array with the names of the most probable classes in each node of `tree`, where  $n$  is the number of nodes in the tree. Every element of this array is a string equal to one of the class names in `ClassNames`.

## **NodeErr**

An  $n$ -element vector of the errors of the nodes in `tree`, where  $n$  is the number of nodes. `NodeErr(i)` is the misclassification probability for node  $i$ .

## **NodeProb**

An  $n$ -element vector of the probabilities of the nodes in `tree`, where  $n$  is the number of nodes. The probability of a node is computed as the proportion of observations from the original data that satisfy the conditions for the node. This proportion is adjusted for any prior probabilities assigned to each class.

## **NodeRisk**

An  $n$ -element vector of the risk of the nodes in the tree, where  $n$  is the number of nodes. The risk for each node is the measure of impurity (Gini index or deviance) for this node weighted by the node probability. If the tree is grown by twining, the risk for each node is zero.

## **NodeSize**

An  $n$ -element vector of the sizes of the nodes in `tree`, where  $n$  is the number of nodes. The size of a node is defined as the number of observations from the data used to create the tree that satisfy the conditions for the node.

## **NumNodes**

The number of nodes in `tree`.

## **Parent**

An  $n$ -element vector containing the number of the parent node for each node in `tree`, where  $n$  is the number of nodes. The parent of the root node is 0.

## PredictorNames

A cell array of names for the predictor variables, in the order in which they appear in `X`.

## Prior

Prior probabilities for each class. `Prior` is a numeric vector whose entries relate to the corresponding `ClassNames` property.

## PruneAlpha

Numeric vector with one element per pruning level. If the pruning level ranges from 0 to  $M$ , then `PruneAlpha` has  $M + 1$  elements sorted in ascending order. `PruneAlpha(1)` is for pruning level 0 (no pruning), `PruneAlpha(2)` is for pruning level 1, and so on.

## PruneList

An  $n$ -element numeric vector with the pruning levels in each node of `tree`, where  $n$  is the number of nodes. The pruning levels range from 0 (no pruning) to  $M$ , where  $M$  is the distance between the deepest leaf and the root node.

## ResponseName

String describing the response variable `Y`.

## ScoreTransform

Function handle for transforming scores, or string representing a built-in transformation function. 'none' means no transformation; equivalently, 'none' means `@(x)x`. For a list of built-in transformation functions and the syntax of custom transformation functions, see `ClassificationTree.fit`.

Add or change a `ScoreTransform` function by dot addressing:

```
ctree.ScoreTransform = 'function'  
or
```

# CompactClassificationTree

---

```
ctree.ScoreTransform = @function
```

## SurrCutCategories

An  $n$ -element cell array of the categories used for surrogate splits in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrCutCategories{k}` is a cell array. The length of `SurrCutCategories{k}` is equal to the number of surrogate predictors found at this node. Every element of `SurrCutCategories{k}` is either an empty string for a continuous surrogate predictor, or is a two-element cell array with categories for a categorical surrogate predictor. The first element of this two-element cell array lists categories assigned to the left child by this surrogate split and the second element of this two-element cell array lists categories assigned to the right child by this surrogate split. The order of the surrogate split variables at each node is matched to the order of variables in `SurrCutVar`. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrCutCategories` contains an empty cell.

## SurrCutFlip

An  $n$ -element cell array of the numeric cut assignments used for surrogate splits in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrCutFlip{k}` is a numeric vector. The length of `SurrCutFlip{k}` is equal to the number of surrogate predictors found at this node. Every element of `SurrCutFlip{k}` is either zero for a categorical surrogate predictor, or a numeric cut assignment for a continuous surrogate predictor. The numeric cut assignment can be either  $-1$  or  $+1$ . For every surrogate split with a numeric cut  $C$  based on a continuous predictor variable  $Z$ , the left child is chosen if  $Z < C$  and the cut assignment for this surrogate split is  $+1$ , or if  $Z \geq C$  and the cut assignment for this surrogate split is  $-1$ . Similarly, the right child is chosen if  $Z \geq C$  and the cut assignment for this surrogate split is  $+1$ , or if  $Z < C$  and the cut assignment for this surrogate split is  $-1$ . The order of the surrogate split variables at each node is matched to the order of variables in `SurrCutVar`. The optimal-split variable at this

node does not appear. For nonbranch (leaf) nodes, `SurrCutFlip` contains an empty array.

## **SurrCutPoint**

An  $n$ -element cell array of the numeric values used for surrogate splits in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrCutPoint{k}` is a numeric vector. The length of `SurrCutPoint{k}` is equal to the number of surrogate predictors found at this node. Every element of `SurrCutPoint{k}` is either NaN for a categorical surrogate predictor, or a numeric cut for a continuous surrogate predictor. For every surrogate split with a numeric cut  $C$  based on a continuous predictor variable  $Z$ , the left child is chosen if  $Z < C$  and `SurrCutFlip` for this surrogate split is  $-1$ . Similarly, the right child is chosen if  $Z \geq C$  and `SurrCutFlip` for this surrogate split is  $+1$ , or if  $Z < C$  and `SurrCutFlip` for this surrogate split is  $-1$ . The order of the surrogate split variables at each node is matched to the order of variables returned by `SurrCutVar`. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrCutPoint` contains an empty cell.

## **SurrCutType**

An  $n$ -element cell array indicating types of surrogate splits at each node in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrCutType{k}` is a cell array with the types of the surrogate split variables at this node. The variables are sorted by the predictive measure of association with the optimal predictor in the descending order, and only variables with the positive predictive measure are included. The order of the surrogate split variables at each node is matched to the order of variables in `SurrCutVar`. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrCutType` contains an empty cell. A surrogate split type can be either 'continuous' if the cut is defined in the form  $Z < V$  for a variable  $Z$  and cut point  $V$  or 'categorical' if the cut is defined by whether  $Z$  takes a value in a set of categories.

# CompactClassificationTree

---

## SurrCutVar

An  $n$ -element cell array of the names of the variables used for surrogate splits in each node in `tree`, where  $n$  is the number of nodes in `tree`. Every element of `SurrCutVar` is a cell array with the names of the surrogate split variables at this node. The variables are sorted by the predictive measure of association with the optimal predictor in the descending order, and only variables with the positive predictive measure are included. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrCutVar` contains an empty cell.

## SurrVarAssoc

An  $n$ -element cell array of the predictive measures of association for surrogate splits in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrVarAssoc{k}` is a numeric vector. The length of `SurrVarAssoc{k}` is equal to the number of surrogate predictors found at this node. Every element of `SurrVarAssoc{k}` gives the predictive measure of association between the optimal split and this surrogate split. The order of the surrogate split variables at each node is the order of variables in `SurrCutVar`. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrVarAssoc` contains an empty cell.

## Methods

<code>edge</code>	Classification edge
<code>loss</code>	Classification error
<code>margin</code>	Classification margins
<code>meanSurrVarAssoc</code>	Mean predictive measure of association for surrogate splits in decision tree
<code>predict</code>	Predict classification
<code>predictorImportance</code>	Estimates of predictor importance
<code>view</code>	View tree

## Definitions

### Impurity and Node Error

ClassificationTree splits nodes based on either *impurity* or *node error*. Impurity means one of several things, depending on your choice of the SplitCriterion name-value pair:

- Gini's Diversity Index (gdi) — The Gini index of a node is

$$1 - \sum_i p^2(i),$$

where the sum is over the classes  $i$  at the node, and  $p(i)$  is the observed fraction of classes with class  $i$  that reach the node. A node with just one class (a *pure* node) has Gini index 0; otherwise the Gini index is positive. So the Gini index is a measure of node impurity.

- Deviance ('deviance') — With  $p(i)$  defined as for the Gini index, the deviance of a node is

$$-\sum_i p(i) \log p(i).$$

A pure node has deviance 0; otherwise, the deviance is positive.

- Twoing rule ('twoing') — Twoing is not a purity measure of a node, but is a different measure for deciding how to split a node. Let  $L(i)$  denote the fraction of members of class  $i$  in the left child node after a split, and  $R(i)$  denote the fraction of members of class  $i$  in the right child node after a split. Choose the split criterion to maximize

$$P(L)P(R) \left( \sum_i |L(i) - R(i)| \right)^2,$$

where  $P(L)$  and  $P(R)$  are the fractions of observations that split to the left and right respectively. If the expression is large, the split made each child node purer. Similarly, if the expression is small, the split made each child node similar to each other, and hence similar to the parent node, and so the split did not increase node purity.

# CompactClassificationTree

---

- Node error — The node error is the fraction of misclassified classes at a node. If  $j$  is the class with largest number of training samples at a node, the node error is

$$1 - p(j).$$

## Copy Semantics

Value. To learn how value classes affect copy operations, see Copying Objects in the MATLAB documentation.

## Examples

Construct a compact classification tree for the Fisher iris data, and compare the size of the resulting tree to that of the original tree:

```
load fisheriris
tree = ClassificationTree.fit(meas,species);
ctree = compact(tree);
t = whos('tree'); % t.bytes = size of tree in bytes
c = whos('ctree'); % c.bytes = size of ctree in bytes
[c.bytes t.bytes]
```

```
ans =
      6818      13913
```

# CompactRegressionTree

---

**Purpose** Compact regression tree

**Description** Compact version of a regression tree (of class `RegressionTree`). The compact version does not include the data for training the regression tree. Therefore, you cannot perform some tasks with a compact regression tree, such as cross validation. Use a compact regression tree for making predictions (regressions) of new data.

**Construction** `ctree = compact(tree)` constructs a compact decision tree from a full decision tree.

## Input Arguments

### **tree**

A decision tree constructed by `RegressionTree.fit`.

## Properties

### **CategoricalPredictors**

List of categorical predictors. `CategoricalPredictors` is a numeric vector with indices from 1 to  $p$ , where  $p$  is the number of columns of  $X$ .

### **CatSplit**

An  $n$ -by-2 cell array, where  $n$  is the number of categorical splits in `tree`. Each row in `CatSplit` gives left and right values for a categorical split. For each branch node with categorical split  $j$  based on a categorical predictor variable  $z$ , the left child is chosen if  $z$  is in `CatSplit(j,1)` and the right child is chosen if  $z$  is in `CatSplit(j,2)`. The splits are in the same order as nodes of the tree. Nodes for these splits can be found by running `cuttype` and selecting 'categorical' cuts from top to bottom.

### **Children**

An  $n$ -by-2 array containing the numbers of the child nodes for each node in `tree`, where  $n$  is the number of nodes. Leaf nodes have child node 0.

### **CutCategories**

An  $n$ -by-2 cell array of the categories used at branches in `tree`, where  $n$  is the number of nodes. For each branch node  $i$  based on a categorical predictor variable  $x$ , the left child is chosen if  $x$  is among the categories listed in `CutCategories{i,1}`, and the right child is chosen if  $x$  is among those listed in `CutCategories{i,2}`. Both columns of `CutCategories` are empty for branch nodes based on continuous predictors and for leaf nodes.

`CutPoint` contains the cut points for 'continuous' cuts, and `CutCategories` contains the set of categories.

## **CutPoint**

An  $n$ -element vector of the values used as cut points in `tree`, where  $n$  is the number of nodes. For each branch node  $i$  based on a continuous predictor variable  $x$ , the left child is chosen if `CutPoint < v(i)` and the right child is chosen if `x >= CutPoint(i)`. `CutPoint` is NaN for branch nodes based on categorical predictors and for leaf nodes.

## **CutType**

An  $n$ -element cell array indicating the type of cut at each node in `tree`, where  $n$  is the number of nodes. For each node  $i$ , `CutType{i}` is:

- 'continuous' — If the cut is defined in the form  $x < v$  for a variable  $x$  and cut point  $v$ .
- 'categorical' — If the cut is defined by whether a variable  $x$  takes a value in a set of categories.
- '' — If  $i$  is a leaf node.

`CutPoint` contains the cut points for 'continuous' cuts, and `CutCategories` contains the set of categories.

## **CutVar**

An  $n$ -element cell array of the names of the variables used for branching in each node in `tree`, where  $n$  is the number of nodes.

# CompactRegressionTree

---

These variables are sometimes known as *cut variables*. For leaf nodes, `CutVar` contains an empty string.

`CutPoint` contains the cut points for 'continuous' cuts, and `CutCategories` contains the set of categories.

## **IsBranch**

An  $n$ -element logical vector `ib` that is `true` for each branch node and `false` for each leaf node of `tree`.

## **NodeErr**

An  $n$ -element vector `e` of the errors of the nodes in `tree`, where  $n$  is the number of nodes. `e(i)` is the misclassification probability for node  $i$ .

## **NodeMean**

An  $n$ -element numeric array with mean values in each node of `tree`, where  $n$  is the number of nodes in the tree. Every element in `NodeMean` is the average of the true  $Y$  values over all observations in the node.

## **NodeProb**

An  $n$ -element vector `p` of the probabilities of the nodes in `tree`, where  $n$  is the number of nodes. The probability of a node is computed as the proportion of observations from the original data that satisfy the conditions for the node. This proportion is adjusted for any prior probabilities assigned to each class.

## **NodeRisk**

An  $n$ -element vector of the risk of the nodes in the tree, where  $n$  is the number of nodes. The risk for each node is the node error weighted by the node probability.

## **NodeSize**

An  $n$ -element vector `sizes` of the sizes of the nodes in `tree`, where  $n$  is the number of nodes. The size of a node is defined as

the number of observations from the data used to create the tree that satisfy the conditions for the node.

## **NumNodes**

The number of nodes  $n$  in `tree`.

## **Parent**

An  $n$ -element vector `p` containing the number of the parent node for each node in `tree`, where  $n$  is the number of nodes. The parent of the root node is 0.

## **PredictorNames**

A cell array of names for the predictor variables, in the order in which they appear in `X`.

## **PruneAlpha**

Numeric vector with one element per pruning level. If the pruning level ranges from 0 to  $M$ , then `PruneAlpha` has  $M + 1$  elements sorted in ascending order. `PruneAlpha(1)` is for pruning level 0 (no pruning), `PruneAlpha(2)` is for pruning level 1, and so on.

## **PruneList**

An  $n$ -element numeric vector with the pruning levels in each node of `tree`, where  $n$  is the number of nodes. The pruning levels range from 0 (no pruning) to  $M$ , where  $M$  is the distance between the deepest leaf and the root node.

## **ResponseName**

Name of the response variable `Y`, a string.

## **ResponseTransform**

Function handle for transforming the raw response values (mean squared error). The function handle should accept a matrix of response values and return a matrix of the same size. The default string 'none' means `@(x)x`, or no transformation.

Add or change a `ResponseTransform` function by dot addressing:

```
ctree.ResponseTransform = @function
```

## **SurrCutCategories**

An  $n$ -element cell array of the categories used for surrogate splits in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrCutCategories{k}` is a cell array. The length of `SurrCutCategories{k}` is equal to the number of surrogate predictors found at this node. Every element of `SurrCutCategories{k}` is either an empty string for a continuous surrogate predictor, or is a two-element cell array with categories for a categorical surrogate predictor. The first element of this two-element cell array lists categories assigned to the left child by this surrogate split, and the second element of this two-element cell array lists categories assigned to the right child by this surrogate split. The order of the surrogate split variables at each node is matched to the order of variables in `SurrCutVar`. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrCutCategories` contains an empty cell.

## **SurrCutFlip**

An  $n$ -element cell array of the numeric cut assignments used for surrogate splits in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrCutFlip{k}` is a numeric vector. The length of `SurrCutFlip{k}` is equal to the number of surrogate predictors found at this node. Every element of `SurrCutFlip{k}` is either zero for a categorical surrogate predictor, or a numeric cut assignment for a continuous surrogate predictor. The numeric cut assignment can be either  $-1$  or  $+1$ . For every surrogate split with a numeric cut  $C$  based on a continuous predictor variable  $Z$ , the left child is chosen if  $Z < C$  and the cut assignment for this surrogate split is  $+1$ , or if  $Z \geq C$  and the cut assignment for this surrogate split is  $-1$ . Similarly, the right child is chosen if  $Z \geq C$  and the cut assignment for this surrogate split is  $+1$ , or if  $Z < C$  and the cut assignment for this surrogate split is  $-1$ . The order of the surrogate split variables at each node is matched to the order of variables in `SurrCutVar`. The optimal-split variable at this

node does not appear. For nonbranch (leaf) nodes, `SurrCutFlip` contains an empty array.

## **SurrCutPoint**

An  $n$ -element cell array of the numeric values used for surrogate splits in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrCutPoint{k}` is a numeric vector. The length of `SurrCutPoint{k}` is equal to the number of surrogate predictors found at this node. Every element of `SurrCutPoint{k}` is either NaN for a categorical surrogate predictor, or a numeric cut for a continuous surrogate predictor. For every surrogate split with a numeric cut  $C$  based on a continuous predictor variable  $Z$ , the left child is chosen if  $Z < C$  and `SurrCutFlip` for this surrogate split is  $-1$ . Similarly, the right child is chosen if  $Z \geq C$  and `SurrCutFlip` for this surrogate split is  $+1$ , or if  $Z < C$  and `SurrCutFlip` for this surrogate split is  $-1$ . The order of the surrogate split variables at each node is matched to the order of variables returned by `SurrCutVar`. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrCutPoint` contains an empty cell.

## **SurrCutType**

An  $n$ -element cell array indicating types of surrogate splits at each node in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrCutType{k}` is a cell array with the types of the surrogate split variables at this node. The variables are sorted by the predictive measure of association with the optimal predictor in the descending order, and only variables with the positive predictive measure are included. The order of the surrogate split variables at each node is matched to the order of variables in `SurrCutVar`. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrCutType` contains an empty cell. A surrogate split type can be either 'continuous' if the cut is defined in the form  $Z < V$  for a variable  $Z$  and cut point  $V$  or 'categorical' if the cut is defined by whether  $Z$  takes a value in a set of categories.

# CompactRegressionTree

---

## SurrCutVar

An  $n$ -element cell array of the names of the variables used for surrogate splits in each node in `tree`, where  $n$  is the number of nodes in `tree`. Every element of `SurrCutVar` is a cell array with the names of the surrogate split variables at this node. The variables are sorted by the predictive measure of association with the optimal predictor in the descending order, and only variables with the positive predictive measure are included. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrCutVar` contains an empty cell.

## SurrVarAssoc

An  $n$ -element cell array of the predictive measures of association for surrogate splits in `tree`, where  $n$  is the number of nodes in `tree`. For each node  $k$ , `SurrVarAssoc{k}` is a numeric vector. The length of `SurrVarAssoc{k}` is equal to the number of surrogate predictors found at this node. Every element of `SurrVarAssoc{k}` gives the predictive measure of association between the optimal split and this surrogate split. The order of the surrogate split variables at each node is the order of variables in `SurrCutVar`. The optimal-split variable at this node does not appear. For nonbranch (leaf) nodes, `SurrVarAssoc` contains an empty cell.

## Methods

<code>loss</code>	Regression error
<code>meanSurrVarAssoc</code>	Mean predictive measure of association for surrogate splits in decision tree
<code>predict</code>	Predict response of regression tree
<code>predictorImportance</code>	Estimates of predictor importance
<code>view</code>	View tree

## Copy Semantics

Value. To learn how value classes affect copy operations, see Copying Objects in the MATLAB documentation.

## Examples

Construct a regression tree for the `carsmall` data. Make a compact version of the tree, and compare its size to that of the full tree:

```
load carsmall
tree = RegressionTree.fit([Weight, Cylinders],MPG,...
    'MinParent',20,...
    'PredictorNames',{'W','C'});
ctree = compact(tree);
t = whos('tree'); % t.bytes = size of tree in bytes
c = whos('ctree'); % c.bytes = size of ctree in bytes
[c.bytes t.bytes]
```

```
ans =
      4972      8173
```

## See Also

[RegressionTree.fit](#) | [RegressionTree](#) | [compact](#)

# CompactTreeBagger

---

**Purpose** Compact ensemble of decision trees grown by bootstrap aggregation

**Description** CompactTreeBagger class is a lightweight class that contains the trees grown using TreeBagger. CompactTreeBagger does not preserve any information about how TreeBagger grew the decision trees. It does not contain the input data used for growing trees, nor does it contain training parameters such as minimal leaf size or number of variables sampled for each decision split at random. You can only use CompactTreeBagger for predicting the response of the trained ensemble given new data X, and other related functions.

CompactTreeBagger lets you save the trained ensemble to disk, or use it in any other way, while discarding training data and various parameters of the training configuration irrelevant for predicting response of the fully grown ensemble. This reduces storage and memory requirements, especially for ensembles trained on large data sets.

**Construction** CompactTreeBagger Create CompactTreeBagger object

**Methods**

combine	Combine two ensembles
error	Error (misclassification probability or MSE)
margin	Classification margin
mdsProx	Multidimensional scaling of proximity matrix
meanMargin	Mean classification margin
outlierMeasure	Outlier measure for data
predict	Predict response

proximity	Proximity matrix for data
setDefaultYfit	Set default value for predict

## Properties

### ClassNames

The `ClassNames` property is a cell array containing the class names for the response variable `Y` supplied to `TreeBagger`. This property is empty for regression trees.

### DeltaCritDecisionSplit

The `DeltaCritDecisionSplit` property is a numeric array of size 1-by-`Nvars` of changes in the split criterion summed over splits on each variable, averaged across the entire ensemble of grown trees.

See also `TreeBagger.DeltaCritDecisionSplit`, `ClassificationTree.predictorImportance`, and `RegressionTree.predictorImportance`

### DefaultYfit

The `DefaultYfit` property controls what predicted value `CompactTreeBagger` returns when no prediction is possible, for example when the `predict` method needs to predict for an observation which has only false values in the matrix supplied through `'useifort'` argument.

For classification, you can set this property to either `''` or `'MostPopular'`. If you choose `'MostPopular'` (default), the property value becomes the name of the most probable class in the training data.

For regression, you can set this property to any numeric scalar. The default is the mean of the response for the training data.

See also `predict`, `setDefaultYfit`, `TreeBagger.DefaultYfit`.

### Method

The `Method` property is `'classification'` for classification ensembles and `'regression'` for regression ensembles.

# CompactTreeBagger

---

## **NTrees**

The `NTrees` property is a scalar equal to the number of decision trees in the ensemble.

## **NVarSplit**

The `NVarSplit` property is a numeric array of size 1-by-*Nvars*, where every element gives a number of splits on this predictor summed over all trees.

## **Trees**

The `Trees` property is a cell array of size `NTrees`-by-1 containing the trees in the ensemble.

## **VarAssoc**

The `VarAssoc` property is a matrix of size *Nvars*-by-*Nvars* with predictive measures of variable association, averaged across the entire ensemble of grown trees. If you grew the ensemble setting 'surrogate' to 'on', this matrix for each tree is filled with predictive measures of association averaged over the surrogate splits. If you grew the ensemble setting 'surrogate' to 'off' (default), `VarAssoc` is diagonal.

See also `ClassificationTree.meanSurrVarAssoc`, `RegressionTree.meanSurrVarAssoc`.

## **VarNames**

The `VarNames` property is a cell array containing the names of the predictor variables (features). These names are taken from the optional 'names' parameter that supplied to `TreeBagger`. The default names are 'x1', 'x2', etc.

## **Copy Semantics**

Value. To learn how this affects your use of the class, see [Comparing Handle and Value Classes in the MATLAB Object-Oriented Programming documentation](#).

# CompactTreeBagger

---

**Purpose** Create CompactTreeBagger object

**Description** When you use the TreeBagger constructor to grow trees, it creates a CompactTreeBagger object. You can obtain the compact object from the full TreeBagger object using the TreeBagger/compact method. You do not create an instance of CompactTreeBagger directly.

**See Also** TreeBagger

**How To**

- “Grouping Variables” on page 2-51
- “Ensemble Methods” on page 16-59

**Purpose** Compare linear mixed-effects models

## Syntax

```
results = compare(lme,altlme)
results = compare(__,Name,Value)

[results,siminfo] = compare(lme,altlme,'NSim',nsim)
[results,siminfo] = compare(__,Name,Value)
```

## Description

`results = compare(lme,altlme)` returns the results of a likelihood ratio test that compares the linear mixed-effects models `lme` and `altlme`. Both models must use the same response vector in the fit and `lme` must be nested in `altlme` for a valid theoretical likelihood ratio test. Always input the smaller model first, and the larger model second.

`compare` tests the following null and alternate hypotheses:

$H_0$ : Observed response vector is generated by `lme`.

$H_1$ : Observed response vector is generated by model `altlme`.

It is recommended that you fit `lme` and `altlme` using the maximum likelihood (ML) method prior to model comparison. If you use the restricted maximum likelihood (REML) method, then both models must have the same fixed-effects design matrix.

To test for fixed effects, use `compare` with the simulated likelihood ratio test when `lme` and `altlme` are fit using ML or use the `fixedEffects`, `anova`, or `coefTest` methods.

`results = compare(__,Name,Value)` also returns the results of a likelihood ratio test that compares linear mixed-effects models `lme` and `altlme` with additional options specified by one or more `Name,Value` pair arguments.

For example, you can check if the first input model is nested in the second input model.

# LinearMixedModel.compare

---

`[results,siminfo] = compare(lme,altlme,'NSim',nsim)` returns the results of a simulated likelihood ratio test that compares linear mixed-effects models `lme` and `altlme`.

You can fit `lme` and `altlme` using ML or REML. Also, `lme` does not have to be nested in `altlme`. If you use the restricted maximum likelihood (REML) method to fit the models, then both models must have the same fixed-effects design matrix.

`[results,siminfo] = compare(___,Name,Value)` also returns the results of a simulated likelihood ratio test that compares linear mixed-effects models `lme` and `altlme` with additional options specified by one or more `Name,Value` pair arguments.

For example, you can change the options for performing the simulated likelihood ratio test, or change the confidence level of the confidence interval for the  $p$ -value.

## Input Arguments

### **lme** - Linear mixed-effects model

`LinearMixedModel` object

Linear mixed-effects model, returned as a `LinearMixedModel` object.

For properties and methods of this object, see `LinearMixedModel`.

### **altlme** - Alternative linear mixed-effects model

`LinearMixedModel` object

Alternative linear mixed-effects model fit to the same response vector but with different model specifications, specified as a `LinearMixedModel` object. `lme` must be nested in `altlme`, that is, `lme` should be obtained from `altlme` by setting some parameters to fixed values, such as 0. You can create a linear mixed-effects object using `fitlme` or `fitlmematrix`.

### **nsim** - Number of replications for simulations

positive integer number

Number of replications for simulations in the simulated likelihood ratio test, specified as a positive integer number. You must specify `nsim` to do a simulated likelihood ratio test.

**Example:** `'NSim',1000`

## Data Types

double | single

## Name-Value Pair Arguments

Specify optional comma-separated pairs of `Name,Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( `' '` ). You can specify several name and value pair arguments in any order as `Name1,Value1,...,NameN,ValueN`.

## 'Alpha' - Confidence level

0.05 (default) | scalar value in the range 0 to 1

Confidence level, specified as the comma-separated pair consisting of `'Alpha'` and a scalar value in the range 0 to 1. For a value  $\alpha$ , the confidence level is  $100*(1-\alpha)\%$ .

For example, for 99% confidence intervals, you can specify the confidence level as follows.

**Example:** `'Alpha',0.01`

## Data Types

single | double

## 'Options' - Options for performing simulated likelihood ratio test

structure

Options for performing the simulated likelihood ratio test, specified as the comma-separated pair consisting of `'Options'`, and a structure created by `statset('LinearMixedModel')`.

`compare` uses the following fields.

# LinearMixedModel.compare

---

'UseParallel'

- False for serial computation. Default.
- True for parallel computation.

'UseSubstreams'

- False for not using a separate substream of the random number generator for each iteration. Default.
- True for using a separate substream of the random number generator for each iteration. You can only use this option with random stream types that support substreams.

'Streams'

- If 'UseSubstreams' is True, then 'Streams' must be a single random number stream, or a scalar cell array containing a single stream.
- If 'UseSubstreams' is False and
  - 'UseParallel' is False, then 'Streams' must be a single random number stream, or a scalar cell array containing a single stream.
  - 'UseParallel' is True, then 'Streams' must be equal to the number of processors used. If a parallel pool is open, then

the 'Streams' is the same length as the size of the parallel pool. If 'UseParallel' is True, a parallel pool might open up for you. But since 'Streams' must be equal to the number of processors used, it is best to open a pool explicitly using the `parpool` command, before calling `compare` with the 'UseParallel', 'True' option.

For information on parallel statistical computing at the command line, enter

```
help parallelstats
```

## Data Types

struct

### 'CheckNesting' - Indicator to check nesting between two models

false (default) | true

Indicator to check nesting between two models, specified as the comma-separated pair consisting of 'CheckNesting' and one of the following.

false

Default. No checks.

true

compare checks if the smaller model `lme` is nested in the bigger model `alllme`.

# LinearMixedModel.compare

---

`lme` must be nested in the alternate model `altlme` for a valid theoretical likelihood ratio test. `compare` returns an error message if the nesting requirements are not satisfied.

Although valid for both tests, the nesting requirements are weaker for the simulated likelihood ratio test.

**Example:** `'CheckNesting',true`

## Data Types

`single` | `double`

## Output Arguments

### **results** - Results of likelihood ratio test or simulated likelihood ratio test

`dataset array`

Results of the likelihood ratio test or simulated likelihood ratio test, returned as a dataset array with two rows. The first row is for `lme`, and the second row is for `altlme`. The columns of results depend on whether the test is a likelihood ratio or a simulated likelihood ratio test.

- If you use the likelihood ratio test, then `results` contains the following columns.

<code>Model</code>	Name of the model
<code>DF</code>	Degrees of freedom, that is, the number of free parameters in the model
<code>AIC</code>	Akaike information criterion for the model
<code>BIC</code>	Bayesian information criterion for the model
<code>LogLik</code>	Maximized log likelihood for the model

LRStat	Likelihood ratio test statistic for comparing altlme versus lme
deltaDF	DF for altlme minus DF for lme
pValue	<i>p</i> -value for the likelihood ratio test

- If you use the simulated likelihood ratio test, then results contains the following columns.

Model	Name of the model
DF	Degrees of freedom, that is, the number of free parameters in the model
LogLik	Maximized log likelihood for the model
LRStat	Likelihood ratio test statistic for comparing altlme versus lme
pValue	<i>p</i> -value for the likelihood ratio test
Lower	Lower limit of the confidence interval for pValue
Upper	Upper limit of the confidence interval for pValue

## **siminfo - Simulation output**

structure

Simulation output, returned as a structure with the following fields.

# LinearMixedModel.compare

---

<code>nsim</code>	Value set for <code>nsim</code> .
<code>alpha</code>	Value set for 'Alpha'.
<code>pValueSim</code>	Simulation-based $p$ -value.
<code>pValueSimCI</code>	Confidence interval for <code>pValueSim</code> . The first element of the vector is the lower limit and the second element of the vector contains the upper limit.
<code>deltaDF</code>	The number of free parameters in <code>altlme</code> minus the number of free parameters in <code>lme</code> . DF for <code>altlme</code> minus DF for <code>lme</code> .
<code>THO</code>	A vector of simulated likelihood ratio test statistics under the null hypothesis that the model <code>lme</code> generated the observed response vector <code>y</code> .

## Examples

### Test for Random Effects

Load the sample data.

```
load flu
```

The `flu` dataset array has a `Date` variable, and 10 variables containing estimated influenza rates (in 9 different regions, estimated from Google searches, plus a nationwide estimate from the CDC).

To fit a linear-mixed effects model, your data must be in a properly formatted dataset array. To fit a linear mixed-effects model with the influenza rates as the responses and region as the predictor variable, combine the nine columns corresponding to the regions into a tall array. The new dataset array, `flu2`, must have the response variable,

FluRate, the nominal variable, Region, that shows which region each estimate is from, and the grouping variable Date.

```
flu2 = stack(flu,2:10,'NewDataVarName','FluRate',...  
            'IndVarName','Region');  
flu2.Date = nominal(flu2.Date);
```

Fit a linear mixed-effects model, with a varying intercept and varying slope for each region, grouped by Date.

```
altlme = fitlme(flu2,'FluRate ~ 1 + Region + (1 + Region|Date)');
```

Fit a linear mixed-effects model with fixed effects for the region and a random intercept that varies by Date.

```
lme = fitlme(flu2,'FluRate ~ 1 + Region + (1|Date)');
```

Compare the two models. Also check if lme2 is nested in lme.

```
compare(lme,altlme,'CheckNesting',true)
```

```
ans =
```

## Theoretical Likelihood Ratio Test

Model	DF	AIC	BIC	LogLik	LRStat	deltaDF
lme	11	318.71	364.35	-148.36		
altlme	55	-305.51	-77.346	207.76	712.22	44

The small  $p$ -value of 0 indicates that model altlme is not significantly better than the simpler model lme.

## Test for Fixed and Random Effects

Navigate to a folder containing sample data.

```
cd(matlabroot)  
cd('help/toolbox/stats/examples')
```

# LinearMixedModel.compare

---

Load the sample data.

```
load fertilizer
```

The dataset array includes data from a split-plot experiment, where soil is divided into three blocks based on the soil type: sandy, silty, and loamy. Each block is divided into five plots, where five different types of tomato plants (cherry, heirloom, grape, vine, and plum) are randomly assigned to these plots. The tomato plants in the plots are then divided into subplots, where each subplot is treated by one of four fertilizers. This is simulated data.

Store the data in a dataset array called `ds`, for practical purposes, and define `Tomato`, `Soil`, and `Fertilizer` as categorical variables.

```
ds = fertilizer;  
ds.Tomato = nominal(ds.Tomato);  
ds.Soil = nominal(ds.Soil);  
ds.Fertilizer = nominal(ds.Fertilizer);
```

Fit a linear mixed-effects model, where `Fertilizer` and `Tomato` are the fixed-effects variables, and the mean yield varies by the block (soil type) and the plots within blocks (tomato types within soil types) independently.

```
lmeBig = fitlme(ds, 'Yield ~ Fertilizer * Tomato + (1|Soil) + (1|Soil:Tomato)');
```

Refit the model after removing the interaction term `Tomato:Fertilizer` and the random-effects term `(1 | Soil)`.

```
lmeSmall = fitlme(ds, 'Yield ~ Fertilizer + Tomato + (1|Soil:Tomato)');
```

Compare the two models using the simulated likelihood ratio test with 1000 replications. You must use this test to test for both fixed- and random-effect terms. Note that both models are fit using the default fitting method, ML. That's why, there is no restriction on the fixed-effects design matrices. If you use restricted maximum likelihood (REML) method, both models must have identical fixed-effects design matrices.

```
[table,siminfo] = compare(lmeSmall,lmeBig,'nsim',1000)
```

```
table =
```

```
Simulated Likelihood Ratio Test: Nsim = 1000, Alpha = 0.05
```

Model	DF	AIC	BIC	LogLik	LRStat	pValue
lme2	10	511.06	532	-245.53		
lme	23	522.57	570.74	-238.29	14.491	0.54845

```
siminfo =
```

```
    nsim: 1000  
    alpha: 0.0500  
    pvalueSim: 0.5485  
    pvalueSimCI: [0.5170 0.5796]  
    deltaDF: 13  
    TH0: [1000x1 double]
```

The high  $p$ -value 0.5485 suggests that the larger model, `lme` is not significantly better than the smaller model, `lme2`. The smaller values of AIC and BIC for `lme2` also support this.

## Models with Correlated and Uncorrelated Random Effects

Load the sample data.

```
load carbig
```

Fit a linear mixed-effects model for miles per gallon (MPG), with fixed effects for acceleration, horsepower, and the cylinders, and potentially correlated random effects for intercept and acceleration grouped by model year.

First, prepare the design matrices.

```
X = [ones(406,1) Acceleration Horsepower];
```

# LinearMixedModel.compare

---

```
Z = [ones(406,1) Acceleration];
Model_Year = nominal(Model_Year);
G = Model_Year;
```

Now, fit the model using `fitlmematrix` with the defined design matrices and grouping variables.

```
lme = fitlmematrix(X,MPG,Z,G,'FixedEffectPredictors',...
{'Intercept','Acceleration','Horsepower'},'RandomEffectPredictors',...
{'Intercept','Acceleration'}},'RandomEffectGroups',{'Model_Year'});
```

Refit the model with uncorrelated random effects for intercept and acceleration. First prepare the random effects design and the random effects grouping variables.

```
Z = {ones(406,1),Acceleration};
G = {Model_Year,Model_Year};
```

```
lme2 = fitlmematrix(X,MPG,Z,G,'FixedEffectPredictors',...
{'Intercept','Acceleration','Horsepower'},'RandomEffectPredictors',...
{'Intercept'},{'Acceleration'}},'RandomEffectGroups',...
{'Model_Year','Model_Year'});
```

Compare `lme` and `lme2` using the simulated likelihood ratio test.

```
compare(lme2,lme,'CheckNesting',true,'NSim',1000)
```

```
ans =
```

```
Simulated Likelihood Ratio Test: Nsim = 1000, Alpha = 0.05
```

Model	DF	AIC	BIC	LogLik	LRStat	pValue	
lme2	6	2194.5	2218.3	-1091.3			L
lme	7	2193.5	2221.3	-1089.7	3.0323	0.095904	C

The high  $p$ -value of 0.46807 indicates that `lme2` is not a significantly better fit than `lme`.

## Simulated Likelihood Ratio Test Using Parallel Computing

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load fertilizer
```

The dataset array includes data from a split-plot experiment, where soil is divided into three blocks based on the soil type: sandy, silty, and loamy. Each block is divided into five plots, where five different types of tomato plants (cherry, heirloom, grape, vine, and plum) are randomly assigned to these plots. The tomato plants in the plots are then divided into subplots, where each subplot is treated by one of four fertilizers. This is simulated data.

Store the data in a dataset array called `ds`, for practical purposes, and define `Tomato`, `Soil`, and `Fertilizer` as categorical variables.

```
ds = fertilizer;
ds.Tomato = nominal(ds.Tomato);
ds.Soil = nominal(ds.Soil);
ds.Fertilizer = nominal(ds.Fertilizer);
```

Fit a linear mixed-effects model, where `Fertilizer` and `Tomato` are the fixed-effects variables, and the mean yield varies by the block (soil type), and the plots within blocks (tomato types within soil types) independently.

```
lme = fitlme(ds, 'Yield ~ Fertilizer * Tomato + (1|Soil) + (1|Soil:Tomato)');
```

Refit the model after removing the interaction term `Tomato:Fertilizer` and the random-effects term `(1|Soil)`.

```
lme2 = fitlme(ds, 'Yield ~ Fertilizer + Tomato + (1|Soil:Tomato)');
```

```

```
ans =
```

```
Simulated Likelihood Ratio Test: Nsim = 1000, Alpha = 0.05
```

Model	DF	AIC	BIC	LogLik	LRStat	pValue
<code>lme2</code>	10	511.06	532	-245.53		
<code>lme</code>	23	522.57	570.74	-238.29	14.491	0.54845

The high  $p$ -value, 0.5485 suggests that the larger model, `lme` is not significantly better than the smaller model, `lme2`. The smaller values of AIC and BIC for `lme2` also support this.

## Definitions

### Likelihood Ratio Test

Under the null hypothesis  $H_0$ , the observed likelihood ratio test statistic has an approximate chi-squared reference distribution with degrees of freedom `deltaDF`. When comparing two models, `compare` computes the  $p$ -value for the likelihood ratio test by comparing the observed likelihood ratio test statistic with this chi-squared reference distribution.

The  $p$ -values obtained using the likelihood ratio test can be conservative when testing for the presence or absence of random-effects terms and anticonservative when testing for the presence or absence of fixed-effects

terms. Hence, use the `fixedEffects`, `anova`, or `coefTest` method or the simulated likelihood ratio test while testing for fixed effects.

## Simulated Likelihood Ratio Test

To perform the simulated likelihood ratio test, `compare` first generates the reference distribution of the likelihood ratio test statistic under the null hypothesis. Then, it assesses the statistical significance of the alternate model by comparing the observed likelihood ratio test statistic to this reference distribution.

`compare` produces the simulated reference distribution of the likelihood ratio test statistic under the null hypothesis as follows:

- Generate random data `ysim` from the fitted model `lme`.
- Fit the model specified in `lme` and alternate model `altlme` to the simulated data `ysim`.
- Calculate the likelihood ratio test statistic using results from step 2 and store the value.
- Repeat step 1 to 3 `nsim` times.

Then, `compare` computes the  $p$ -value for the simulated likelihood ratio test by comparing the observed likelihood ratio test statistic with the simulated reference distribution. The  $p$ -value estimate is the ratio of the number of times the simulated likelihood ratio test statistic is equal to or exceeds the observed value plus one, to the number of replications plus one.

Suppose the observed likelihood ratio statistic is  $T$ , and the simulated reference distribution is stored in vector  $T_{H_0}$ . Then,

$$p\text{-value} = \frac{\left[ \sum_{j=1}^{nsim} I(T_{H_0}(j) \geq T) \right] + 1}{nsim + 1}.$$

To account for the uncertainty in the simulated reference distribution, `compare` computes a  $100 \times (1 - \alpha)\%$  confidence interval for the true  $p$ -value.

You can use the simulated likelihood ratio test to compare arbitrary linear mixed-effects models. That is, when you are using the simulated likelihood ratio test, `lme` does not have to be nested within `altlme`, and you can fit `lme` and `altlme` using either maximum likelihood (ML) or restricted maximum likelihood (REML) methods. If you use the restricted maximum likelihood (REML) method to fit the models, then both models must have the same fixed-effects design matrix.

## Nesting Requirements

The `'CheckNesting', 'True'` name-value pair argument checks the following requirements.

For a simulated likelihood ratio test:

- You must use the same method to fit both models (`lme` and `altlme`). `compare` cannot compare a model fit using ML to a model fit using REML.
- You must fit both models to the same response vector.
- If you use REML to fit `lme` and `altlme`, then both models must have the same fixed-effects design matrix.
- The maximized log likelihood or restricted log likelihood of the bigger model (`altlme`) must be greater than or equal to that of the smaller model (`lme`).

For a theoretical test, `'CheckNesting', 'True'` checks all the requirements listed for a simulated likelihood ratio test and the following:

- Weight vectors you use to fit `lme` and `altlme` must be identical.
- If you use ML to fit `lme` and `altlme`, the fixed-effects design matrix of the bigger model (`altlme`) must contain that of the smaller model (`lme`).

- The random-effects design matrix of the bigger model (`alt1me`) must contain that of the smaller model (`1me`).

## Akaike and Bayesian Information Criteria

Akaike information criterion (AIC) is  $AIC = -2 * \log L_M + 2 * (nc + p + 1)$ , where  $\log L_M$  is the maximized log likelihood (or maximized restricted log likelihood) of the model, and  $nc + p + 1$  is the number of parameters estimated in the model.  $p$  is the number of fixed-effects coefficients, and  $nc$  is the total number of parameters in the random-effects covariance excluding the residual variance.

Bayesian information criterion (BIC) is  $BIC = -2 * \log L_M + \ln(n_{eff}) * (nc + p + 1)$ , where  $\log L_M$  is the maximized log likelihood (or maximized restricted log likelihood) of the model,  $n_{eff}$  is the effective number of observations, and  $(nc + p + 1)$  is the number of parameters estimated in the model.

- If the fitting method is maximum likelihood (ML), then  $n_{eff} = n$ , where  $n$  is the number of observations.
- If the fitting method is restricted maximum likelihood (REML), then  $n_{eff} = n - p$ .

A lower value of deviance indicates a better fit. As the value of deviance decreases, both AIC and BIC tend to decrease. Both AIC and BIC also include penalty terms based on the number of parameters estimated,  $p$ . So, when the number of parameters increase, the values of AIC and BIC tend to increase as well. When comparing different models, the model with the lowest AIC or BIC value is considered as the best fitting model.

## Deviance

`LinearMixedModel` computes the deviance of model  $M$  as minus two times the loglikelihood of that model. Let  $L_M$  denote the maximum value of the likelihood function for model  $M$ . Then, the deviance of model  $M$  is

$$-2 * \log L_M.$$

A lower value of deviance indicates a better fit. Suppose  $M_1$  and  $M_2$  are two different models, where  $M_1$  is nested in  $M_2$ . Then, the fit of the models can be assessed by comparing the deviances  $Dev_1$  and  $Dev_2$  of these models. The difference of the deviances is

$$Dev = Dev_1 - Dev_2 = 2(\log LM_2 - \log LM_1).$$

Usually, the asymptotic distribution of this difference has a chi-square distribution with degrees of freedom  $v$  equal to the number of parameters that are estimated in one model but fixed (typically at 0) in the other. That is, it is equal to the difference in the number of parameters estimated in  $M_1$  and  $M_2$ . You can get the  $p$ -value for this test using  $1 - \text{chi2cdf}(Dev, v)$ , where  $Dev = Dev_2 - Dev_1$ .

However, in mixed-effects models, when some variance components fall on the boundary of the parameter space, the asymptotic distribution of this difference is more complicated. For example, consider the hypotheses

$$H_0: D = \begin{pmatrix} D_{11} & 0 \\ 0 & 0 \end{pmatrix}, \text{ } D \text{ is a } q\text{-by-}q \text{ symmetric positive semidefinite matrix.}$$

$$H_1: D \text{ is a } (q+1)\text{-by-}(q+1) \text{ symmetric positive semidefinite matrix.}$$

That is,  $H_1$  states that the last row and column of  $D$  are different from zero. Here, the bigger model  $M_2$  has  $q + 1$  parameters and the smaller model  $M_1$  has  $q$  parameters. And  $Dev$  has a 50:50 mixture of  $\chi^2_q$  and  $\chi^2_{(q+1)}$  distributions (Stram and Lee, 1994).

# TreeBagger.ComputeOOBPrediction property

---

## Purpose

Flag to compute out-of-bag predictions

## Description

The ComputeOOBPrediction property is a logical flag specifying whether out-of-bag predictions for training observations should be computed. The default is `false`.

If this flag is true, the following properties are available:

- `OOBIndices`
- `OOBInstanceWeight`

If this flag is true, the following methods can be called:

- `oobError`
- `oobMargin`
- `oobMeanMargin`

## Purpose

Confusion matrix

## Syntax

```
C = confusionmat(group,grouphat)
C = confusionmat(group,grouphat,'order',groupporder)
[C,order] = confusionmat(...)
```

## Description

`C = confusionmat(group,grouphat)` returns the confusion matrix `C` determined by the known and predicted groups in `group` and `grouphat`, respectively. `group` and `grouphat` are grouping variables with the same number of observations, as described in “Grouping Variables” on page 2-51. Input vectors must be of the same type. `C` is a square matrix with size equal to the total number of distinct elements in `group` and `grouphat`. `C(i,j)` is a count of observations known to be in group `i` but predicted to be in group `j`. Group indices and their order are the same for the rows and columns of `C`, computed by `grp2idx` using `grp2idx(group;grouphat)`. NaN, empty, or 'undefined' groups are not counted.

`C = confusionmat(group,grouphat,'order',groupporder)` uses `groupporder` to order the rows and columns of `C`. `groupporder` is a grouping variable containing all of the distinct elements in `group` and `grouphat`. If `groupporder` contains elements that are not in `group` or `grouphat`, the corresponding entries in `C` will be 0.

`[C,order] = confusionmat(...)` also returns the order of the rows and columns of `C` in a variable `order` the same type as `group` and `grouphat`.

## Examples

### Example 1

Display the confusion matrix for data with two misclassifications and one missing classification:

```
g1 = [1 1 2 2 3 3]'; % Known groups
g2 = [1 1 2 3 4 NaN]'; % Predicted groups
```

```
[C,order] = confusionmat(g1,g2)
C =
```

```
    2    0    0    0
    0    1    1    0
    0    0    0    1
    0    0    0    0
order =
    1
    2
    3
    4
```

## Example 2

Randomize the measurements and groups in Fisher's iris data:

```
load fisheriris
numObs = length(species);
p = randperm(numObs);
meas = meas(p,:);
species = species(p);
```

Use `classify` to classify measurements in the second half of the data, using the first half of the data for training:

```
half = floor(numObs/2);
training = meas(1:half,:);
trainingSpecies = species(1:half);
sample = meas(half+1:end,:);
grouphat = classify(sample,training,trainingSpecies);
```

Display the confusion matrix for the resulting classification:

```
group = species(half+1:end);
[C,order] = confusionmat(group,grouphat)
C =
    22    0    0
     2   22    0
     0    0   29
order =
    'virginica'
```

```
'versicolor'  
'setosa'
```

## How To

- “Grouping Variables” on page 2-51

# controlchart

---

## Purpose

Shewhart control charts

## Syntax

```
controlchart(X)
controlchart(x,group)
controlchart(X,group)
[stats,plotdata] = controlchart(x,[group])
controlchart(x,group,'name',value)
```

## Description

`controlchart(X)` produces an xbar chart of the measurements in matrix *X*. Each row of *X* is considered to be a subgroup of measurements containing replicate observations taken at the same time. The rows should be in time order. If *X* is a time series object, the time samples should contain replicate observations.

The chart plots the means of the subgroups in time order, a center line (CL) at the average of the means, and upper and lower control limits (UCL, LCL) at three standard errors from the center line. The standard error is the estimated process standard deviation divided by the square root of the subgroup size. Process standard deviation is estimated from the average of the subgroup standard deviations. Out of control measurements are marked as violations and drawn with a red circle. Data cursor mode is enabled, so clicking any data point displays information about that point.

`controlchart(x,group)` accepts a grouping variable `group` for a vector of measurements `x`. `group` is a categorical variable, vector, string array, or cell array of strings the same length as `x`. Consecutive measurements `x(n)` sharing the same value of `group(n)` for  $1 \leq n \leq \text{length}(x)$  are defined to be a subgroup. Subgroups can have different numbers of observations.

`controlchart(X,group)` accepts a grouping variable `group` for a matrix of measurements in *X*. In this case, `group` is only used to label the time axis; it does not change the default grouping by rows.

`[stats,plotdata] = controlchart(x,[group])` returns a structure `stats` of subgroup statistics and parameter estimates, and a structure `plotdata` of plotted values. `plotdata` contains one record for each chart.

The fields in `stats` and `plotdata` depend on the chart type.

The fields in `stats` are selected from the following:

- `mean` — Subgroup means
- `std` — Subgroup standard deviations
- `range` — Subgroup ranges
- `n` — Subgroup size, or total inspection size or area
- `i` — Individual data values
- `ma` — Moving averages
- `mr` — Moving ranges
- `count` — Count of defects or defective items
- `mu` — Estimated process mean
- `sigma` — Estimated process standard deviation
- `p` — Estimated proportion defective
- `m` — Estimated mean defects per unit

The fields in `plotdata` are the following:

- `pts` — Plotted point values
- `cl` — Center line
- `lcl` — Lower control limit
- `ucl` — Upper control limit
- `se` — Standard error of plotted point
- `n` — Subgroup size
- `ooc` — Logical that is true for points that are out of control

`controlchart(x,group,'name',value)` specifies one or more of the following optional parameter name/value pairs, with *name* in single quotes:

# controlchart

---

- `charttype` — The name of a chart type chosen from among the following:
  - `'xbar'` — Xbar or mean
  - `'s'` — Standard deviation
  - `'r'` — Range
  - `'ewma'` — Exponentially weighted moving average
  - `'i'` — Individual observation
  - `'mr'` — Moving range of individual observations
  - `'ma'` — Moving average of individual observations
  - `'p'` — Proportion defective
  - `'np'` — Number of defectives
  - `'u'` — Defects per unit
  - `'c'` — Count of defects

Alternatively, a parameter can be a cell array listing multiple compatible chart types. There are four sets of compatible types:

- `'xbar', 's', 'r', and 'ewma'`
  - `'i', 'mr', and 'ma'`
  - `'p' and 'np'`
  - `'u' and 'c'`
- `display` — Either `'on'` (default) to display the control chart, or `'off'` to omit the display
  - `label` — A string array or cell array of strings, one per subgroup. This label is displayed as part of the data cursor for a point on the plot.
  - `lambda` — A parameter between 0 and 1 controlling how much the current prediction is influenced by past observations in an EWMA

plot. Higher values of 'lambda' give less weight to past observations and more weight to the current observation. The default is 0.4.

- **limits** — A three-element vector specifying the values of the lower control limit, center line, and upper control limits. Default is to estimate the center line and to compute control limits based on the estimated value of sigma. Not permitted if there are multiple chart types.
- **mean** — Value for the process mean, or an empty value (default) to estimate the mean from X. This is the p parameter for p and np charts, the mean defects per unit for u and c charts, and the normal mu parameter for other charts.
- **nsigma** — The number of sigma multiples from the center line to a control limit. Default is 3.
- **parent** — The handle of the axes to receive the control chart plot. Default is to create axes in a new figure. Not permitted if there are multiple chart types.
- **rules** — The name of a control rule, or a cell array containing multiple control rule names. These rules, together with the control limits, determine if a point is marked as out of control. The default is to apply no control rules, and to use only the control limits to decide if a point is out of control. See `controlrules` for more information. Control rules are applied to charts that measure the process level (xbar, i, c, u, p, and np) rather than the variability (r, s), and they are not applied to charts based on moving statistics (ma, mr, ewma).
- **sigma** — Either a value for sigma, or a method of estimating sigma chosen from among 'std' (the default) to use the average within-subgroup standard deviation, 'range' to use the average subgroup range, and 'variance' to use the square root of the pooled variance. When creating i, mr, or ma charts for data not in subgroups, the estimate is always based on a moving range.
- **specs** — A vector specifying specification limits. Typically this is a two-element vector of lower and upper specification limits. Since specification limits typically apply to individual measurements, this

# controlchart

---

parameter is primarily suitable for *i* charts. These limits are not plotted on *r*, *s*, or *mr* charts.

- `unit` — The total number of inspected items for *p* and *np* charts, and the size of the inspected unit for *u* and *c* charts. In both cases *X* must be the count of the number of defects or defectives found. Default is 1 for *u* and *c* charts. This argument is required (no default) for *p* and *np* charts.
- `width` — The width of the window used for computing the moving ranges and averages in *mr* and *ma* charts, and for computing the sigma estimate in *i*, *mr*, and *ma* charts. Default is 5.

## Examples

Create *xbar* and *r* control charts for the data in `parts.mat`:

```
load parts
st = controlchart(runout, 'chart', {'xbar' 'r'});
```

Display the process mean and standard deviation:

```
fprintf('Parameter estimates: mu = %g, sigma = %g\n',st.mu,st.sigma);
Parameter estimates: mu = -0.0863889, sigma = 0.130215
```

## See Also

controlrules

## How To

- “Grouping Variables” on page 2-51

# controlrules

---

**Purpose** Western Electric and Nelson control rules

**Syntax**  
`R = controlrules('rules',x,c1,se)`  
`[R,RULES] = controlrules('rules',x,c1,se)`

**Description** `R = controlrules('rules',x,c1,se)` determines which points in the vector `x` violate the control rules in `rules`. `c1` is a vector of center-line values. `se` is a vector of standard errors. (Typically, control limits on a control chart are at the values `c1 - 3*se` and `c1 + 3*se`.) `rules` is the name of a control rule, or a cell array containing multiple control rule names, from the list below. If `x` has  $n$  values and `rules` contains  $m$  rules, then `R` is an  $n$ -by- $m$  logical array, with `R(i, j)` assigned the value 1 if point  $i$  violates rule  $j$ , 0 if it does not.

The following are accepted values for `rules` (specified inside single quotes):

- `we1` — 1 point above `c1 + 3*se`
- `we2` — 2 of 3 above `c1 + 2*se`
- `we3` — 4 of 5 above `c1 + se`
- `we4` — 8 of 8 above `c1`
- `we5` — 1 below `c1 - 3*se`
- `we6` — 2 of 3 below `c1 - 2*se`
- `we7` — 4 of 5 below `c1 - se`
- `we8` — 8 of 8 below `c1`
- `we9` — 15 of 15 between `c1 - se` and `c1 + se`
- `we10` — 8 of 8 below `c1 - se` or above `c1 + se`
- `n1` — 1 point below `c1 - 3*se` or above `c1 + 3*se`
- `n2` — 9 of 9 on the same side of `c1`
- `n3` — 6 of 6 increasing or decreasing
- `n4` — 14 alternating up/down

- n5 — 2 of 3 below  $c1 - 2*se$  or above  $c1 + 2*se$ , same side
- n6 — 4 of 5 below  $c1 - se$  or above  $c1 + se$ , same side
- n7 — 15 of 15 between  $c1 - se$  and  $c1 + se$
- n8 — 8 of 8 below  $c1 - se$  or above  $c1 + se$ , either side
- we — All Western Electric rules
- n — All Nelson rules

For multi-point rules, a rule violation at point  $i$  indicates that the set of points ending at point  $i$  triggered the rule. Point  $i$  is considered to have violated the rule only if it is one of the points violating the rule's condition.

Any points with NaN as their  $x$ ,  $c1$ , or  $se$  values are not considered to have violated rules, and are not counted in the rules for other points.

Control rules can be specified in the `controlchart` function as values for the 'rules' parameter.

`[R,RULES] = controlrules('rules',x,c1,se)` returns a cell array of text strings RULES listing the rules applied.

## Examples

Create an xbar chart using the `we2` rule to mark out of control measurements:

```
load parts;
st = controlchart(runout, 'rules', 'we2');
x = st.mean;
c1 = st.mu;
se = st.sigma./sqrt(st.n);
hold on
plot(c1+2*se, 'm')
```

# controlrules

Use controlrules to identify the measurements that violate the control rule:

```
R = controlrules('we2',x,c1,se);  
I = find(R)  
I =  
    21  
    23
```

24  
25  
26  
27

# gmdistribution.Converged property

---

**Purpose** Determine if algorithm converged

**Description** Logical true if the algorithm has converged; logical false if the algorithm has not converged.

---

**Note** This property applies only to gmdistribution objects constructed with `fit`.

---

**Purpose** Cophenetic correlation coefficient

**Syntax**  
`c = cophenet(Z,Y)`  
`[c,d] = cophenet(Z,Y)`

**Description** `c = cophenet(Z,Y)` computes the cophenetic correlation coefficient for the hierarchical cluster tree represented by `Z`. `Z` is the output of the linkage function. `Y` contains the distances or dissimilarities used to construct `Z`, as output by the `pdist` function. `Z` is a matrix of size  $(m-1)$ -by-3, with distance information in the third column. `Y` is a vector of size  $m*(m-1)/2$ .

`[c,d] = cophenet(Z,Y)` returns the cophenetic distances `d` in the same lower triangular distance vector format as `Y`.

The cophenetic correlation for a cluster tree is defined as the linear correlation coefficient between the cophenetic distances obtained from the tree, and the original distances (or dissimilarities) used to construct the tree. Thus, it is a measure of how faithfully the tree represents the dissimilarities among observations.

The cophenetic distance between two observations is represented in a dendrogram by the height of the link at which those two observations are first joined. That height is the distance between the two subclusters that are merged by that link.

The output value, `c`, is the cophenetic correlation coefficient. The magnitude of this value should be very close to 1 for a high-quality solution. This measure can be used to compare alternative cluster solutions obtained using different algorithms.

The cophenetic correlation between `Z(:,3)` and `Y` is defined as

$$c = \frac{\sum_{i < j} (Y_{ij} - y)(Z_{ij} - z)}{\sqrt{\sum_{i < j} (Y_{ij} - y)^2 \sum_{i < j} (Z_{ij} - z)^2}}$$

where:

- $Y_{ij}$  is the distance between objects  $i$  and  $j$  in `Y`.

# cophenet

---

- $Z_{ij}$  is the cophenetic distance between objects  $i$  and  $j$ , from  $Z(:,3)$ .
- $y$  and  $z$  are the average of  $Y$  and  $Z(:,3)$ , respectively.

## Examples

```
X = [rand(10,3); rand(10,3)+1; rand(10,3)+2];
Y = pdist(X);
Z = linkage(Y, 'average');

% Compute Spearman's rank correlation between the
% dissimilarities and the cophenetic distances
[c,D] = cophenet(Z,Y);
r = corr(Y',D', 'type', 'spearman')
r =
    0.8279
```

```

**Description**

`Y = copulacdf('Gaussian',U,rho)` returns the cumulative probability of the Gaussian copula with linear correlation parameters `rho`, evaluated at the points in `U`. `U` is an `n`-by-`p` matrix of values in `[0,1]`, representing `n` points in the `p`-dimensional unit hypercube. `rho` is a `p`-by-`p` correlation matrix. If `U` is an `n`-by-2 matrix, `rho` may also be a scalar correlation coefficient.

`Y = copulacdf('t',U,rho,NU)` returns the cumulative probability of the `t` copula with linear correlation parameters `rho` and degrees of freedom parameter `NU`, evaluated at the points in `U`. `U` is an `n`-by-`p` matrix of values in `[0,1]`. `rho` is a `p`-by-`p` correlation matrix. If `U` is an `n`-by-2 matrix, `rho` may also be a scalar correlation coefficient.

`Y = copulacdf('family',U,alpha)` returns the cumulative probability of the bivariate Archimedean copula determined by `family`, with scalar parameter `alpha`, evaluated at the points in `U`. `family` is Clayton, Frank, or Gumbel. `U` is an `n`-by-2 matrix of values in `[0,1]`.

## Examples

```
u = linspace(0,1,10);
[U1,U2] = meshgrid(u,u);
F = copulacdf('Clayton',[U1(:) U2(:)],1);
surf(U1,U2,reshape(F,10,10))
xlabel('u1')
ylabel('u2')
```

# copulacdf

## See Also

[copulapdf](#) | [copularnd](#) | [copulastat](#) | [copulaparam](#)

## Purpose

Fit copula to data

## Syntax

```
RHOHAT = copulafit('Gaussian',U)
[RHOHAT,nuhat] = copulafit('t',U)
[RHOHAT,nuhat,nuci] = copulafit('t',U)
paramhat = copulafit('family',U)
[paramhat,paramci] = copulafit('family',U)
[...] = copulafit(...,'alpha',alpha)
[...] = copulafit('t',U,'Method','ApproximateML')
[...] = copulafit(...,'Options',options)
```

## Description

`RHOHAT = copulafit('Gaussian',U)` returns an estimate `RHOHAT` of the matrix of linear correlation parameters for a Gaussian copula, given data in `U`. `U` is an  $n$ -by- $p$  matrix of values in the open interval  $(0,1)$  representing  $n$  points in the  $p$ -dimensional unit hypercube.

`[RHOHAT,nuhat] = copulafit('t',U)` returns an estimate `RHOHAT` of the matrix of linear correlation parameters for a  $t$  copula and an estimate `nuhat` of the degrees of freedom parameter, given data in `U`. `U` is an  $n$ -by- $p$  matrix of values in the open interval  $(0,1)$  representing  $n$  points in the  $p$ -dimensional unit hypercube.

`[RHOHAT,nuhat,nuci] = copulafit('t',U)` also returns an approximate 95% confidence interval `nuci` for the degrees of freedom parameter estimated in `nuhat`.

`paramhat = copulafit('family',U)` returns an estimate `paramhat` of the copula parameter for an Archimedean copula specified by `family`, given data in `U`. `U` is an  $n$ -by-2 matrix of values in the open interval  $(0,1)$  representing  $n$  points in the unit square. `family` is one of Clayton, Frank, or Gumbel.

`[paramhat,paramci] = copulafit('family',U)` also returns an approximate 95% confidence interval `paramci` for the copula parameter estimated in `paramhat`.

`[...] = copulafit(...,'alpha',alpha)` returns approximate  $100 \cdot (1 - \alpha)\%$  confidence intervals in `nuci` or `paramci`.

---

**Note** By default, `copulafit` uses maximum likelihood to fit a copula to `U`. When `U` contains data transformed to the unit hypercube by parametric estimates of their marginal cumulative distribution functions, this is known as the *Inference Functions for Margins (IFM)* method. When `U` contains data transformed by the empirical cdf (see `ecdf`), this is known as *Canonical Maximum Likelihood (CML)*.

---

`[...] = copulafit('t',U,'Method','ApproximateML')` fits a  $t$  copula for large samples `U` by maximizing an objective function that approximates the profile log-likelihood for the degrees of freedom parameter (see [1]). This method can be significantly faster than maximum likelihood, but the estimates and confidence limits may not be accurate for small to moderate sample sizes.

`[...] = copulafit(...,'Options',options)` specifies control parameters for the iterative parameter estimation algorithm using an options structure `options` as created by `statset`. Type `statset('copulafit')` at the command prompt for fields and default values used by `copulafit`. This argument is not applicable to the 'Gaussian' family.

## Examples

Load and plot simulated stock return data:

```
load stockreturns
x = stocks(:,1);
y = stocks(:,2);

scatterhist(x,y)
```

Transform the data to the copula scale (unit square) using a kernel estimator of the cumulative distribution function:

```
u = ksdensity(x,x,'function','cdf');  
v = ksdensity(y,y,'function','cdf');  
  
scatterhist(u,v)  
xlabel('u')  
ylabel('v')
```

# copulafit

---

Fit a  $t$  copula:

```
[Rho,nu] = copulafit('t',[u v],'Method','ApproximateML')  
Rho =  
    1.0000    0.7220  
    0.7220    1.0000  
nu =  
    2.8934e+006
```

Generate a random sample from the  $t$  copula:

```
r = copularnd('t',Rho,nu,1000);
```

```
u1 = r(:,1);  
v1 = r(:,2);  
  
scatterhist(u1,v1)  
xlabel('u')  
ylabel('v')  
set(get(gca,'children'),'marker','.')
```

Transform the random sample back to the original scale of the data:

```
x1 = ksdensity(x,u1,'function','icdf');
```

# copulafit

---

```
y1 = ksdensity(y,v1,'function','icdf');  
  
scatterhist(x1,y1)  
set(get(gca,'children'),'marker','.')
```

**Purpose** Copula parameters as function of rank correlation

**Syntax**

```
rho = copulaparam('Gaussian',R)
rho = copulaparam('t',R,NU)
alpha = copulaparam(family,R)
[...] = copulaparam(...,'type',type)
```

**Description** `rho = copulaparam('Gaussian',R)` returns the linear correlation parameters `rho` corresponding to a Gaussian copula having Kendall's rank correlation `R`. If `R` is a scalar correlation coefficient, `rho` is a scalar correlation coefficient corresponding to a bivariate copula. If `R` is a `p`-by-`p` correlation matrix, `rho` is a `p`-by-`p` correlation matrix.

`rho = copulaparam('t',R,NU)` returns the linear correlation parameters `rho` corresponding to a `t` copula having Kendall's rank correlation `R` and degrees of freedom `NU`. If `R` is a scalar correlation coefficient, `rho` is a scalar correlation coefficient corresponding to a bivariate copula. If `R` is a `p`-by-`p` correlation matrix, `rho` is a `p`-by-`p` correlation matrix.

`alpha = copulaparam(family,R)` returns the copula parameter `alpha` corresponding to a bivariate Archimedean copula having Kendall's rank correlation `R`. `R` is a scalar. `family` is one of 'Clayton', 'Frank', or 'Gumbel'.

`[...] = copulaparam(...,'type',type)` assumes `R` is the specified type of rank correlation. `type` is 'Kendall' for Kendall's tau or 'Spearman' for Spearman's rho.

`copulaparam` uses an approximation to Spearman's rank correlation for copula families when no analytic formula exists. The approximation is based on a smooth fit to values computed at discrete values of the copula parameters. For a `t` copula, the approximation is accurate for degrees of freedom larger than 0.05.

**Examples** Get the linear correlation coefficient corresponding to a bivariate Gaussian copula having a rank correlation of -0.5.

```
tau = -0.5
```

# copulaparam

---

```
rho = copulaparam('gaussian',tau)
rho =
    -0.7071

% Generate dependent beta random values using that copula
u = copularnd('gaussian',rho,100);
b = betainv(u,2,2);

% Verify that the sample has a rank correlation
% approximately equal to tau
tau_sample = corr(b,'type','k')
tau_sample =
    1.0000    -0.4638
   -0.4638    1.0000
```

**Purpose**

Copula probability density function

**Syntax**

```
Y = copulapdf('Gaussian',U,rho)
Y = copulapdf('t',U,rho,NU)
Y = copulapdf('family',U,alpha)
```

**Description**

`Y = copulapdf('Gaussian',U,rho)` returns the probability density of the Gaussian copula with linear correlation parameters `rho`, evaluated at the points in `U`. `U` is an `n`-by-`p` matrix of values in `[0,1]`, representing `n` points in the `p`-dimensional unit hypercube. `rho` is a `p`-by-`p` correlation matrix. If `U` is an `n`-by-2 matrix, `rho` may also be a scalar correlation coefficient.

`Y = copulapdf('t',U,rho,NU)` returns the probability density of the `t` copula with linear correlation parameters `rho` and degrees of freedom parameter `NU`, evaluated at the points in `U`. `U` is an `n`-by-`p` matrix of values in `[0,1]`. `rho` is a `p`-by-`p` correlation matrix. If `U` is an `n`-by-2 matrix, `rho` may also be a scalar correlation coefficient.

`Y = copulapdf('family',U,alpha)` returns the probability density of the bivariate Archimedean copula determined by `family`, with scalar parameter `alpha`, evaluated at the points in `U`. `family` is Clayton, Frank, or Gumbel. `U` is an `n`-by-2 matrix of values in `[0,1]`.

**Examples**

```
u = linspace(0,1,10);
[U1,U2] = meshgrid(u,u);
F = copulapdf('Clayton',[U1(:) U2(:)],1);
surf(U1,U2,reshape(F,10,10))
xlabel('u1')
ylabel('u2')
```

## Purpose

Copula rank correlation

## Syntax

```
R = copulastat('Gaussian',rho)
R = copulastat('t',rho,NU)
R = copulastat(family,alpha)
R = copulastat(...,'type',type)
```

## Description

`R = copulastat('Gaussian',rho)` returns the Kendall's rank correlation  $R$  that corresponds to a Gaussian copula having linear correlation parameters  $\rho$ . If  $\rho$  is a scalar correlation coefficient,  $R$  is a scalar correlation coefficient corresponding to a bivariate copula. If  $\rho$  is a  $p$ -by- $p$  correlation matrix,  $R$  is a  $p$ -by- $p$  correlation matrix.

`R = copulastat('t',rho,NU)` returns the Kendall's rank correlation  $R$  that corresponds to a  $t$  copula having linear correlation parameters  $\rho$  and degrees of freedom  $NU$ . If  $\rho$  is a scalar correlation coefficient,  $R$  is a scalar correlation coefficient corresponding to a bivariate copula. If  $\rho$  is a  $p$ -by- $p$  correlation matrix,  $R$  is a  $p$ -by- $p$  correlation matrix.

`R = copulastat(family,alpha)` returns the Kendall's rank correlation  $R$  that corresponds to a bivariate Archimedean copula with scalar parameter  $\alpha$ . `family` is one of 'Clayton', 'Frank', or 'Gumbel'.

`R = copulastat(...,'type',type)` returns the specified type of rank correlation. `type` is 'Kendall' to compute Kendall's tau, or 'Spearman' to compute Spearman's rho.

`copulastat` uses an approximation to Spearman's rank correlation for copula families when no analytic formula exists. The approximation is based on a smooth fit to values computed at discrete values of the copula parameters. For a  $t$  copula, the approximation is accurate for degrees of freedom larger than 0.05.

## Examples

Get the theoretical rank correlation coefficient for a bivariate.

```
% Gaussian copula with linear correlation parameter rho
rho = -.7071;
tau = copulastat('gaussian',rho)
tau =
```

```
-0.5000
```

```
% Generate dependent beta random values using that copula  
u = copularnd('gaussian',rho,100);  
b = betainv(u,2,2);
```

```
% Verify that the sample has a rank correlation  
% approximately equal to tau  
tau_sample = corr(b,'type','k')  
tau_sample =  
    1.0000   -0.5265  
   -0.5265    1.0000
```

[copulacdf](#) | [copulaparam](#) | [copulapdf](#) | [copulastat](#)

**Purpose**

Coordinate exchange

**Syntax**

```
dCE = cordexch(nfactors,nruns)
[dCE,X] = cordexch(nfactors,nruns)
[dCE,X] = cordexch(nfactors,nruns,'model')
[dCE,X] = cordexch(...,'name',value)
```

**Description**

`dCE = cordexch(nfactors,nruns)` uses a coordinate-exchange algorithm to generate a  $D$ -optimal design `dCE` with `nruns` runs (the rows of `dCE`) for a linear additive model with `nfactors` factors (the columns of `dCE`). The model includes a constant term.

`[dCE,X] = cordexch(nfactors,nruns)` also returns the associated design matrix `X`, whose columns are the model terms evaluated at each treatment (row) of `dCE`.

`[dCE,X] = cordexch(nfactors,nruns,'model')` uses the linear regression model specified in `model`. `model` is one of the following strings, specified inside single quotes:

- `linear` — Constant and linear terms. This is the default.
- `interaction` — Constant, linear, and interaction terms
- `quadratic` — Constant, linear, interaction, and squared terms
- `purequadratic` — Constant, linear, and squared terms

The order of the columns of `X` for a full quadratic model with  $n$  terms is:

- 1** The constant term
- 2** The linear terms in order 1, 2, ...,  $n$
- 3** The interaction terms in order (1, 2), (1, 3), ..., (1,  $n$ ), (2, 3), ..., ( $n-1$ ,  $n$ )
- 4** The squared terms in order 1, 2, ...,  $n$

Other models use a subset of these terms, in the same order.

Alternatively, *model* can be a matrix specifying polynomial terms of arbitrary order. In this case, *model* should have one column for each factor and one row for each term in the model. The entries in any row of *model* are powers for the factors in the columns. For example, if a model has factors X1, X2, and X3, then a row [0 1 2] in *model* specifies the term  $(X1.^0) \cdot (X2.^1) \cdot (X3.^2)$ . A row of all zeros in *model* specifies a constant term, which can be omitted.

[dCE,X] = cordexch(..., 'name', value) specifies one or more optional name/value pairs for the design. Valid parameters and their values are listed in the following table. Specify *name* inside single quotes.

name	Value
bounds	Lower and upper bounds for each factor, specified as a 2-by-nfactors matrix. Alternatively, this value can be a cell array containing nfactors elements, each element specifying the vector of allowable values for the corresponding factor.
categorical	Indices of categorical predictors.
display	Either 'on' or 'off' to control display of the iteration counter. The default is 'on'.
excludefun	Handle to a function that excludes undesirable runs. If the function is <i>f</i> , it must support the syntax $b = f(S)$ , where <i>S</i> is a matrix of treatments with nfactors columns and <i>b</i> is a vector of Boolean values with the same number of rows as <i>S</i> . <i>b</i> ( <i>i</i> ) is true if the method should exclude <i>i</i> th row <i>S</i> .
init	Initial design as a nruns-by-nfactors matrix. The default is a randomly selected set of points.
levels	Vector of number of levels for each factor. Not used when bounds is specified as a cell array
maxiter	Maximum number of iterations. The default is 10.

name	Value
tries	Number of times to try to generate a design from a new starting point. The algorithm uses random points for each try, except possibly the first. The default is 1.
options	<p>A structure that specifies whether to run in parallel, and specifies the random stream or streams. Create the options structure with <code>statset</code>. Option fields:</p> <ul style="list-style-type: none"> <li>• <code>UseParallel</code> — Set to <code>true</code> to compute in parallel. Default is <code>false</code>.</li> <li>• <code>UseSubstreams</code> — Set to <code>true</code> to compute in parallel in a reproducible fashion. Default is <code>false</code>. To compute reproducibly, set <code>Streams</code> to a type allowing substreams: <code>'mlfg6331_64'</code> or <code>'mrg32k3a'</code>.</li> <li>• <code>Streams</code> — A <code>RandStream</code> object or cell array of such objects. If you do not specify <code>Streams</code>, <code>cordexch</code> uses the default stream or streams. If you choose to specify <code>Streams</code>, use a single object except in the case <ul style="list-style-type: none"> <li>▪ You have an open Parallel pool</li> <li>▪ <code>UseParallel</code> is <code>true</code></li> <li>▪ <code>UseSubstreams</code> is <code>false</code></li> </ul> <p>In that case, use a cell array the same size as the Parallel pool.</p> </li> </ul>

## Algorithms

Both `cordexch` and `rowexch` use iterative search algorithms. They operate by incrementally changing an initial design matrix  $X$  to increase  $D = |X^T X|$  at each step. In both algorithms, there is randomness built into the selection of the initial design and into the choice of the incremental changes. As a result, both algorithms may return locally, but not globally,  $D$ -optimal designs. Run each algorithm multiple times

and select the best result for your final design. Both functions have a 'tries' parameter that automates this repetition and comparison.

Unlike the row-exchange algorithm used by rowexch, cordexch does not use a candidate set. (Or rather, the candidate set is the entire design space.) At each step, the coordinate-exchange algorithm exchanges a single element of  $X$  with a new element evaluated at a neighboring point in design space. The absence of a candidate set reduces demands on memory, but the smaller scale of the search means that the coordinate-exchange algorithm is more likely to become trapped in a local minimum.

## Examples

Suppose you want a design to estimate the parameters in the following three-factor, seven-term interaction model:

$$y = \beta_0 + \beta_1x_1 + \beta_2x_2 + \beta_3x_3 + \beta_{12}x_1x_2 + \beta_{13}x_1x_3 + \beta_{23}x_2x_3 + \varepsilon$$

Use cordexch to generate a  $D$ -optimal design with seven runs:

```
nfactors = 3;
nruns = 7;
[dCE,X] = cordexch(nfactors,nruns,'interaction','tries',10)
dCE =
    -1     1     1
    -1    -1    -1
     1     1     1
    -1     1    -1
     1    -1     1
     1    -1    -1
    -1    -1     1
X =
     1    -1     1     1    -1    -1     1
     1    -1    -1    -1     1     1     1
     1     1     1     1     1     1     1
     1    -1     1    -1    -1     1    -1
     1     1    -1     1    -1     1    -1
     1     1    -1    -1    -1    -1     1
     1    -1    -1     1     1    -1    -1
```

Columns of the design matrix  $X$  are the model terms evaluated at each row of the design  $dCE$ . The terms appear in order from left to right: constant term, linear terms (1, 2, 3), interaction terms (12, 13, 23). Use  $X$  to fit the model, as described in “Linear Regression” on page 9-12, to response data measured at the design points in  $dCE$ .

rowexch | daugment | dcovary

**Purpose** Linear or rank correlation

**Syntax**

```
RHO = corr(X)
RHO = corr(X,Y)
[RHO,PVAL] = corr(X,Y)
[RHO,PVAL] = corr(X,Y, 'name', value)
```

**Description** RHO = corr(X) returns a  $p$ -by- $p$  matrix containing the pairwise linear correlation coefficient between each pair of columns in the  $n$ -by- $p$  matrix X.

RHO = corr(X,Y) returns a  $p1$ -by- $p2$  matrix containing the pairwise correlation coefficient between each pair of columns in the  $n$ -by- $p1$  and  $n$ -by- $p2$  matrices X and Y.

The difference between corr(X,Y) and the MATLAB function corrcoef(X,Y) is that corrcoef(X,Y) returns a matrix of correlation coefficients for the two column vectors X and Y. If X and Y are not column vectors, corrcoef(X,Y) converts them to column vectors.

[RHO,PVAL] = corr(X,Y) also returns PVAL, a matrix of  $p$ -values for testing the hypothesis of no correlation against the alternative that there is a nonzero correlation. Each element of PVAL is the  $p$  value for the corresponding element of RHO. If PVAL(i,j) is small, say less than 0.05, then the correlation RHO(i,j) is significantly different from zero.

[RHO,PVAL] = corr(X,Y, 'name', value) specifies one or more optional name/value pairs. Specify *name* inside single quotes. The following table lists valid parameters and their values.

Parameter	Values
type	<ul style="list-style-type: none"> <li>'Pearson' (the default) computes Pearson's linear correlation coefficient</li> <li>'Kendall' computes Kendall's tau</li> <li>'Spearman' computes Spearman's rho</li> </ul>
rows	<ul style="list-style-type: none"> <li>'all' (the default) uses all rows regardless of missing values (NaNs)</li> <li>'complete' uses only rows with no missing values</li> <li>'pairwise' computes <math>RHO(i, j)</math> using rows with no missing values in column <math>i</math> or <math>j</math></li> </ul>
tail — The alternative hypothesis against which to compute $p$ -values for testing the hypothesis of no correlation	<ul style="list-style-type: none"> <li>'both' — Correlation is not zero (the default)</li> <li>'right' — Correlation is greater than zero</li> <li>'left' — Correlation is less than zero</li> </ul>

Using the 'pairwise' option for the rows parameter may return a matrix that is not positive definite. The 'complete' option always returns a positive definite matrix, but in general the estimates are based on fewer observations.

corr computes  $p$ -values for Pearson's correlation using a Student's  $t$  distribution for a transformation of the correlation. This correlation is exact when  $X$  and  $Y$  are normal. corr computes  $p$ -values for Kendall's tau and Spearman's rho using either the exact permutation distributions (for small sample sizes), or large-sample approximations.

corr computes  $p$ -values for the two-tailed test by doubling the more significant of the two one-tailed  $p$ -values.

**Example****Find Correlation Between Two Matrices**

Find the correlation between two matrices and compare to the correlation between two column vectors.

Generate sample data.

```
rng('default')
x = randn(30,4);
y = randn(30,4);
y(:,4) = sum(x,2); % introduce correlation
```

Calculate the correlation between columns of X and Y.

```
[r,p] = corr(x,y)
```

r =

-0.3632    -0.0987    -0.0200     0.3504
-0.1365    -0.1804     0.0853     0.4908
```

p =

```
0.3731     0.8489     0.2260     0.0000
0.1045     0.8619     0.6491     0.1624
0.0485     0.6039     0.9166     0.0577
0.4721     0.3400     0.6539     0.0059
```

Calculate the correlation between X and Y using corrcoef.

```
[r,p] = corrcoef(x,y)
```

r =

```
1.0000     0.1252
0.1252     1.0000
```

p =

```
    1.0000    0.1729
    0.1729    1.0000
```

MATLAB function `corrcoef` converts X and Y into column vectors before computing the correlation between them.

# corrcoef

---

**Purpose** Convert covariance matrix to correlation matrix

**Syntax** `R = corrcoef(C)`  
`[R,sigma] = corrcoef(C)`

**Description** `R = corrcoef(C)` computes the correlation matrix `R` corresponding to the covariance matrix `C`. `C` must be square, symmetric, and positive semi-definite.

`[R,sigma] = corrcoef(C)` also computes the vector of standard deviations `sigma`.

**Examples** Use `cov` and `corrcoef` to compute covariances and correlations, respectively, for sample data on weight and blood pressure (systolic, diastolic) in `hospital.mat`:

```
load hospital
X = [hospital.Weight hospital.BloodPressure];
C = cov(X)
C =
    706.0404    27.7879    41.0202
    27.7879    45.0622    23.8194
    41.0202    23.8194    48.0590
R = corrcoef(X)
R =
    1.0000    0.1558    0.2227
    0.1558    1.0000    0.5118
    0.2227    0.5118    1.0000
```

Compare `R` with the correlation matrix computed from `C` by `corrcoef`:

```
corrcoef(C)
ans =
    1.0000    0.1558    0.2227
    0.1558    1.0000    0.5118
    0.2227    0.5118    1.0000
```

<b>Purpose</b>	Extract covariance parameters of linear mixed-effects model
<b>Syntax</b>	<pre>psi = covarianceParameters(lme) [psi,mse] = covarianceParameters(lme) [psi,mse,stats] = covarianceParameters(lme) [psi,mse,stats] = covarianceParameters(lme,Name,Value)</pre>
<b>Description</b>	<p><code>psi = covarianceParameters(lme)</code> returns the estimated covariance parameters that parameterize the prior covariance of random effects.</p> <p><code>[psi,mse] = covarianceParameters(lme)</code> also returns an estimate of the residual variance.</p> <p><code>[psi,mse,stats] = covarianceParameters(lme)</code> also returns a cell array, <code>stats</code>, containing the covariance parameters and related statistics.</p> <p><code>[psi,mse,stats] = covarianceParameters(lme,Name,Value)</code> returns the covariance parameters and related statistics in <code>stats</code> with additional options specified by one or more <code>Name,Value</code> pair arguments.</p> <p>For example, you can specify the confidence level for the confidence limits of covariance parameters.</p>
<b>Input Arguments</b>	<p><b>lme - Linear mixed-effects model</b> <code>LinearMixedModel</code> object</p> <p>Linear mixed-effects model, returned as a <code>LinearMixedModel</code> object.</p> <p>For properties and methods of this object, see <code>LinearMixedModel</code>.</p> <p><b>Name-Value Pair Arguments</b></p> <p>Specify optional comma-separated pairs of <code>Name,Value</code> arguments. <code>Name</code> is the argument name and <code>Value</code> is the corresponding</p>

value. Name must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as Name1, Value1, . . . , NameN, ValueN.

## 'Alpha' - Confidence level

0.05 (default) | scalar value in the range 0 to 1

Confidence level, specified as the comma-separated pair consisting of 'Alpha' and a scalar value in the range 0 to 1. For a value  $\alpha$ , the confidence level is  $100*(1-\alpha)\%$ .

For example, for 99% confidence intervals, you can specify the confidence level as follows.

**Example:** 'Alpha', 0.01

## Data Types

single | double

## Output Arguments

### psi - Estimate of covariance parameters

cell array

Estimate of covariance parameters that parameterize the prior covariance of the random effects, returned as a cell array of length  $R$ , such that  $\text{psi}\{r\}$  contains the covariance matrix of random effects associated with grouping variable  $g_r$ ,  $r = 1, 2, \dots, R$ . The order of grouping variables is the same order you enter when you fit the model.

### mse - Residual variance estimate

scalar value

Residual variance estimate, returned as a scalar value.

### stats - Covariance parameter estimates and related statistics

cell array

Covariance parameter estimates and related statistics, returned as a cell array of length  $(R + 1)$  containing dataset arrays with the following columns.

# LinearMixedModel.covarianceParameters

---

Group	Grouping variable name
Name1	Name of the first predictor variable
Name2	Name of the second predictor variable
Type	std (standard deviation), if Name1 and Name2 are the same corr (correlation), if Name1 and Name2 are different
Estimate	Standard deviation of the random effect associated with predictor Name1 or Name2, if Name1 and Name2 are the same Correlation between the random effects associated with predictors Name1 and Name2, if Name1 and Name2 are different
Lower	Lower limit of a 95% confidence interval for the covariance parameter
Upper	Upper limit of a 95% confidence interval for the covariance parameter

stats{r} is a dataset array containing statistics on covariance parameters for the  $r$ th grouping variable,  $r = 1, 2, \dots, R$ .  
stats{R+1} contains statistics on the residual standard deviation.  
The dataset array for the residual error has the fields Group, Name, Estimate, Lower, and Upper.

## Examples      **Two Random-Effects Terms for Intercept**

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load fertilizer
```

The dataset array includes data from a split-plot experiment, where soil is divided into three blocks based on the soil type: sandy, silty, and loamy. Each block is divided into five plots, where five different types of tomato plants (cherry, heirloom, grape, vine, and plum) are randomly assigned to these plots. The tomato plants in the plots are then divided into subplots, where each subplot is treated by one of four fertilizers. This is simulated data.

Store the data in a dataset array called `ds`, for practical purposes, and define `Tomato`, `Soil`, and `Fertilizer` as categorical variables.

```
ds = fertilizer;
ds.Tomato = nominal(ds.Tomato);
ds.Soil = nominal(ds.Soil);
ds.Fertilizer = nominal(ds.Fertilizer);
```

Fit a linear mixed-effects model, where `Fertilizer` is the fixed-effects variable, and the mean yield varies by the block (soil type), and the plots within blocks (tomato types within soil types) independently. This model corresponds to

$$y_{ijk} = \beta_0 + \sum_{j=2}^5 \beta_{2j} I[T]_{ij} + b_{0k} S_k + b_{0jk} (S^* T)_{jk} + \varepsilon_{ijk},$$

where  $i = 1, 2, \dots, 60$  corresponds to the observations,  $j = 2, \dots, 5$  corresponds to the tomato types, and  $k = 1, 2, 3$  corresponds to the blocks (soil).  $S_k$  represents the  $k$ th soil type, and  $(S^* T)_{jk}$  represents the  $j$ th tomato type nested in the  $k$ th soil type.  $I[T]_{ij}$  is the dummy variable representing the level  $j$  of the tomato type.

# LinearMixedModel.covarianceParameters

---

The random effects and observation error have the following prior distributions:  $b_{0k} \sim N(0, \sigma^2_S)$ ,  $b_{0jk} \sim N(0, \sigma^2_{S^*T})$ , and  $\varepsilon_{ijk} \sim N(0, \sigma^2)$ .

```
lme = fitlme(ds, 'Yield ~ Fertilizer + (1|Soil) + (1|Soil:Tomato)');
```

Compute the covariance parameter estimates (estimates of  $\sigma^2_S$  and  $\sigma^2_{S^*T}$ ) of the random-effects terms.

```
psi = covarianceParameters(lme)
```

```
psi =
```

```
    [ 4.4026e-17]
    [ 352.8481]
```

Compute the residual variance ( $\sigma^2$ ).

```
[~,mse] = covarianceParameters(lme)
```

```
mse =
```

```
    151.9007
```

## Potentially Correlated Random-Effects Terms

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load weight
```

`weight` contains data from a longitudinal study, where 20 subjects are randomly assigned to 4 exercise programs, and their weight loss is recorded over six 2-week time periods. This is simulated data.

Store the data in a dataset array. Define `Subject` and `Program` as categorical variables.

# LinearMixedModel.covarianceParameters

```
ds = dataset(InitialWeight,Program,Subject,Week,y);
ds.Subject = nominal(ds.Subject);
ds.Program = nominal(ds.Program);
```

Fit a linear mixed-effects model where the initial weight, type of program, week, and the interaction between the week and type of program are the fixed effects. The intercept and week vary by subject.

For 'reference' dummy variable coding, `fitlme` uses Program A as reference and creates the necessary dummy variables  $I[.]$ . This model corresponds to

$$y_{im} = \beta_0 + \beta_1 IW_i + \beta_2 Week_i + \beta_3 I[PB]_i + \beta_4 I[PC]_i + \beta_5 I[PD]_i \\ + b_{0m} + b_{1m} Week_{im} + \varepsilon_{im},$$

where  $i$  corresponds to the observation number,  $i = 1, 2, \dots, 120$ , and  $m$  corresponds to the subject number,  $m = 1, 2, \dots, 20$ .  $\beta_j$  are the fixed-effects coefficients,  $j = 0, 1, \dots, 8$ , and  $b_{0m}$  and  $b_{1m}$  are random effects.  $IW$  stands for initial weight and  $I[.]$  is a dummy variable representing a type of program. For example,  $I[PB]_i$  is the dummy variable representing Program B.

The random effects and observation error have the following prior

distributions: 
$$\begin{pmatrix} b_{0m} \\ b_{1m} \end{pmatrix} \sim N \left( 0, \begin{pmatrix} \sigma_0^2 & \sigma_{0,1} \\ \sigma_{0,1} & \sigma_1^2 \end{pmatrix} \right)$$
 and  $\varepsilon_{im} \sim N(0, \sigma^2)$ .

```
lme = fitlme(ds, 'y ~ InitialWeight + Program + (Week|Subject)');
```

Compute the estimates of covariance parameters for the random effects.

```
[psi,mse,stats] = covarianceParameters(lme)
```

```
psi =
```

```
[2x2 double]
```

# LinearMixedModel.covarianceParameters

---

```
mse =
```

```
0.0105
```

```
stats =
```

```
[3x7 classreg.regr.lmeutils.titledataset]  
[1x5 dataset]
```

mse is the estimated residual variance. It is the estimate for  $\sigma^2$ .

To see the covariance parameters estimates for the random-effects terms ( $\sigma^2_0$ ,  $\sigma^2_1$ , and  $\sigma^2_{0,1}$ ), index into `psi`.

```
psi{1}
```

```
ans =
```

```
0.0572    0.0490  
0.0490    0.0624
```

The estimate of the variance of the random effects term for the intercept,  $\sigma^2_0$ , is 0.0572. The estimate of the variance of the random effects term for week,  $\sigma^2_1$ , is 0.0624. The estimate for the covariance of the random effects terms for the intercept and week,  $\sigma_{0,1}$ , is 0.0490.

`stats` is a 2-by-1 cell array. The first cell of `stats` contains the confidence intervals for the standard deviation of the random effects and the correlation between the random effects for intercept and week. To display them, index into `stats`.

```
stats{1}
```

```
ans =
```

```
Covariance Type: FullCholesky
```

# LinearMixedModel.covarianceParameters

Group	Name1	Name2	Type
Subject	'(Intercept)'	'(Intercept)'	'std'
Subject	'Week'	'(Intercept)'	'corr'
Subject	'Week'	'Week'	'std'

The display shows the name of the grouping parameter (`Group`), the random-effects variables (`Name1`, `Name2`), the type of the covariance parameters (`Type`), the estimate (`Estimate`) for each parameter, and the 95% confidence intervals for the parameters (`Lower`, `Upper`). The estimates in this table are related to the estimates in `psi` as follows.

The standard deviation of the random-effects term for intercept is  $0.23927 = \sqrt{0.0527}$ . Likewise, the standard deviation of the random effects term for week is  $0.2497 = \sqrt{0.0624}$ . Finally, the correlation between the random-effects terms of intercept and week is  $0.81971 = 0.0490 / (0.23927 * 0.2497)$ .

Note that this display also shows which covariance pattern you use when fitting the model. In this case, the covariance pattern is `FullCholesky`. To change the covariance pattern for the random-effects terms, you must use the `'CovariancePattern'` name-value pair argument when fitting the model.

The second cell of `stats` includes similar statistics for the residual standard deviation. Display the contents of the second cell.

```
stats{2}
```

```
ans =
```

Group	Name	Estimate	Lower	Upper
Error	'Res Std'	0.10261	0.087882	0.11981

The estimate for residual standard deviation is the square root of `mse`,  $0.10261 = \sqrt{0.0105}$ .

## Two Grouping Variables

Load the sample data.

```
load carbig
```

Fit a linear mixed-effects model for miles per gallon (MPG), with fixed effects for acceleration and weight, a potentially correlated random effect for intercept and acceleration grouped by model year, and an independent random effect for weight, grouped by the origin of the car. This model corresponds to

$$MPG_{imk} = \beta_0 + \beta_1 Acc_i + \beta_2 Weight_i + b_{10m} + b_{11m} Acc_i + b_{21k} Weight_i + \varepsilon_{imk}, \\ m = 1, 2, \dots, 13, \quad k = 1, 2, \dots, 8,$$

where  $m$  represents the levels for the variable `Model_Year`, and  $k$  represents the levels for the variable `Origin`.  $MPG_{imk}$  is the miles per gallon for the  $i$ th observation,  $m$ th model year, and  $k$ th origin that correspond to the  $i$ th observation. The random-effects terms and the observation error have the following prior distributions:

$$b_{1m} = \begin{pmatrix} b_{10m} \\ b_{11m} \end{pmatrix} \sim N \left( 0, \begin{pmatrix} \sigma_{10}^2 & \sigma_{10,11} \\ \sigma_{10,11} & \sigma_{11}^2 \end{pmatrix} \right),$$

$$b_{2k} \sim N(0, \sigma_2^2),$$

$$\varepsilon_{imk} \sim N(0, \sigma^2).$$

Here, the random-effects term  $b_{1m}$  represents the first random effect at level  $m$  of the first grouping variable. The random-effects term  $b_{10m}$  corresponds to the first random effects term (1), for the intercept (0), at the  $m$ th level ( $m$ ) of the first grouping variable. Likewise  $b_{11m}$  is the level  $m$  for the first predictor (1) in the first random-effects term (1).

Similarly,  $b_{2k}$  stands for the second random effects-term at level  $k$  of the second grouping variable.

# LinearMixedModel.covarianceParameters

---

$\sigma_{10}^2$  is the variance of the random-effects term for the intercept,  $\sigma_{11}^2$  is the variance of the random effects term for the predictor acceleration, and  $\sigma_{10,11}$  is the covariance of the random-effects terms for the intercept and the predictor acceleration.  $\sigma_2^2$  is the variance of the second random-effects term, and  $\sigma^2$  is the residual variance.

First, prepare the design matrices for fitting the linear mixed-effects model.

```
X = [ones(406,1) Acceleration Weight];
Z = {[ones(406,1) Acceleration],[Weight]};
Model_Year = nominal(Model_Year);
Origin = nominal(Origin);
G = {Model_Year,Origin};
```

Fit the model using the design matrices.

```
lme = fitlmematrix(X,MPG,Z,G,'FixedEffectPredictors',...
{'Intercept','Acceleration','Weight'],'RandomEffectPredictors',...
{'Intercept','Acceleration'},{'Weight'}},'RandomEffectGroups',{'Model_Year','Origin'});
```

Compute the estimates of covariance parameters for the random effects.

```
[psi,mse,stats] = covarianceParameters(lme)
```

```
psi =
```

```
    [2x2 double]
    [6.7989e-08]
```

```
mse =
```

```
    9.0755
```

```
stats =
```

```
    [3x7 classreg.regr.lmeutils.titledataset]
```

# LinearMixedModel.covarianceParameters

---

```
[1x7 classreg.regr.lmeutils.titledataset]
[1x5 dataset                               ]
```

The residual variance `mse` is 9.0755. `psi` is a 2-by-1 cell array, and `stats` is a 3-by-1 cell array. To see the contents, you must index into these cell arrays.

First, index into the first cell of `psi`.

```
psi{1}
```

```
ans =
```

```
    8.5160   -0.8387
   -0.8387    0.1087
```

The first cell of `psi` contains the covariance parameters for the correlated random effects for intercept  $\sigma_{10}^2$  as 8.5160, and for acceleration  $\sigma_{11}^2$  as 0.1087. The estimate for the covariance of the random-effects terms for the intercept and acceleration  $\sigma_{10,11}$  is -0.8387.

Now, index into the second cell of `psi`.

```
psi{2}
```

```
ans =
```

```
6.7989e-08
```

The second cell of `psi` contains the estimate for the variance of the random-effects term for weight  $\sigma_2^2$ .

Index into the first cell of `stats`.

```
stats{1}
```

```
ans =
```

# LinearMixedModel.covarianceParameters

Covariance Type: FullCholesky

Group	Name1	Name2	Type
Model_Year	'Intercept'	'Intercept'	'std'
Model_Year	'Acceleration'	'Intercept'	'corr'
Model_Year	'Acceleration'	'Acceleration'	'std'

This table shows the standard deviation estimates for the random-effects terms for intercept and acceleration. Note that the standard deviations estimates are the square roots of the diagonal elements in the first cell of `psi`. Specifically,  $2.9182 = \sqrt{8.5160}$  and  $0.32968 = \sqrt{0.1087}$ . The correlation is a function of the covariance of intercept and acceleration, and the standard deviations of intercept and acceleration. The covariance of intercept and acceleration is the off-diagonal value in the first cell of `psi`,  $-0.8387$ . So, the correlation is  $-0.8387 / (0.32968 * 2.92182) = -0.87$ .

The grouping variable for intercept and acceleration is `Model_Year`.

Index into the second cell of `stats`.

```
stats{2}
```

```
ans =
```

Covariance Type: FullCholesky

Group	Name1	Name2	Type	Estimate
Origin	'Weight'	'Weight'	'std'	0.00026075

The second cell of `stats` has the standard deviation estimate and the 95% confidence limits for the standard deviation of the random-effects term for `Weight`. The grouping variable is `Origin`.

Index into the third cell of `stats`.

```
stats{3}
```

# LinearMixedModel.covarianceParameters

---

```
ans =
```

Group	Name	Estimate	Lower	Upper
Error	'Res Std'	3.0126	2.8028	3.238

The third cell of `stats` contains the estimate for residual standard deviation and the 95% confidence limits. The estimate for residual standard deviation is the square root of `mse`,  $\text{sqrt}(9.0755) = 3.0126$ .

Construct 99% confidence intervals for the covariance parameters.

```
[~,~,stats] = covarianceParameters(lme, 'Alpha', 0.01);  
stats{1}
```

```
ans =
```

```
Covariance Type: FullCholesky
```

Group	Name1	Name2	Type
Model_Year	'Intercept'	'Intercept'	'std'

# gmdistribution.CovType property

---

**Purpose** Type of covariance matrices

**Description** The string 'diagonal' if the covariance matrices are restricted to be diagonal; the string 'full' otherwise.

**Purpose**

Cox proportional hazards regression

**Syntax**

```
b = coxphfit(X,T)
b = coxphfit(X,T,Name,Value)
[b,logl,H,stats] = coxphfit( ___ )
```

**Description**

`b = coxphfit(X,T)` returns a  $p$ -by-1 vector, `b`, of coefficient estimates for a Cox proportional hazards regression of the observed responses in an  $n$ -by-1 vector, `T`, on the predictors in an  $n$ -by- $p$  matrix `X`.

The model does not include a constant term, and `X` cannot contain a column of 1s.

`b = coxphfit(X,T,Name,Value)` returns a vector of coefficient estimates, with additional options specified by one or more `Name,Value` pair arguments.

`[b,logl,H,stats] = coxphfit( ___ )` also returns the loglikelihood, `logl`, a structure, `stats`, that contains additional statistics, and a two-column matrix, `H`, that contains the `T` values in the first column and the estimated baseline cumulative hazard, in the second column. You can use any of the input arguments in the previous syntaxes.

**Input Arguments**

**X - Observations on predictor variables**

matrix

Observations on predictor variables, specified as an  $n$ -by- $p$  matrix of  $p$  predictors for each of  $n$  observations.

The model does not include a constant term, thus `X` cannot contain a column of 1s.

**Data Types**

single | double

**T - Time-to-event data**

vector

Time-to-event data, specified as an  $n$ -by-1 vector.

## Data Types

single | double

## Name-Value Pair Arguments

Specify optional comma-separated pairs of **Name**, **Value** arguments. **Name** is the argument name and **Value** is the corresponding value. **Name** must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as **Name1**, **Value1**, ..., **NameN**, **ValueN**.

### Example:

`'baseline',0,'censoring',censoreddata,'frequency',freq` specifies that `coxphfit` calculates the baseline hazard rate relative to 0, considering the censoring information in the vector `censoreddata`, and the frequency of observations on **T** and **X** given in the vector `freq`.

### 'baseline' - X values at which to compute the baseline hazard

`mean(X)` (default) | scalar value

**X** values at which to compute the baseline hazard, specified as the comma-separated pair consisting of 'baseline' and a scalar value.

The default is `mean(X)`, so the hazard rate at **X** is  $h(t) \cdot \exp((X - \text{mean}(X)) \cdot b)$ . Enter 0 to compute the baseline relative to 0, so the hazard rate at **X** is  $h(t) \cdot \exp(X \cdot b)$ . Changing the baseline does not affect the coefficient estimates, but the hazard ratio changes.

**Example:** `'baseline',0`

## Data Types

single | double

### 'censoring' - Indicator for censoring

array of 0s (default) | array of 0s and 1s

Indicator for censoring, specified as the comma-separated pair consisting of 'censoring' and a Boolean array of the same size as **T**.

Use 1 for observations that are right censored and 0 for observations that are fully observed. The default is all observations are fully observed.

**Example:** 'censoring',cens

### Data Types

logical

### 'frequency' - Frequency of observations

array of 1s (default) | vector of nonnegative integer counts

Frequency of observations, specified as the comma-separated pair consisting of 'frequency' and an array that is the same size as T containing nonnegative integer counts.

The  $j^{\text{th}}$  element of this vector gives the number of times the method observes the  $j^{\text{th}}$  element of T and the  $j^{\text{th}}$  row of X. The default is one observation per row of X and T.

**Example:** 'frequency',freq

### Data Types

single | double

### 'init' - Initial values for estimated coefficients

vector

Initial values for estimated coefficients, specified as the comma-separated pair consisting of 'init' and a vector containing the coefficient initial values.

**Example:** 'init',initcoef

### Data Types

single | double

### 'options' - Algorithm control parameters

structure

Algorithm control parameters for the iterative algorithm used to estimate b, specified as the comma-separated pair consisting of

'options' and a structure. A call to `statset` creates this argument. For parameter names and default values, type `statset('coxphfit')`. You can set the options under a new name and use that in the name-value pair argument.

**Example:** `'options',statset('coxphfit')`

## Data Types

char

## Output Arguments

### **b** - Coefficient estimates

vector

Coefficient estimates for a Cox proportional hazards regression, returned as a  $p$ -by-1 vector.

### **logl** - Loglikelihood

scalar

Loglikelihood of the fitted model, returned as a scalar.

You can use log likelihood values to compare different models and assess the significance of effects of terms in the model.

### **H** - Estimated baseline cumulative hazard

two-column matrix

Estimated baseline cumulative hazard rate evaluated at T values, returned as a two-column matrix. The first column of the matrix contains T values, and the second column contains cumulative hazard rate estimates.

### **stats** - Coefficient statistics

structure

Coefficient statistics, returned as a structure that contains the following fields.

beta	Coefficient estimates (same as <b>b</b> )
se	Standard errors of coefficient estimates, <b>b</b>
z	<i>z</i> -statistics for <b>b</b> (that is, <b>b</b> divided by standard error)
p	<i>p</i> -values for <b>b</b>
covb	Estimated covariance matrix for <b>b</b>

## Examples

### Lifetime of Light Bulbs

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load lightbulb
```

The first column of the light bulb data has the lifetime (in hours) of two different types of bulbs. The second column has the binary variable indicating whether the bulb is fluorescent or incandescent. 0 indicates that the bulb is incandescent, and 1 indicates that it is fluorescent. The third column contains the censorship information, where 0 indicates the bulb was observed until failure, and 1 indicates the bulb was censored.

Fit a Cox proportional hazards model for the lifetime of the light bulbs, also accounting for censoring. The predictor variable is the type of bulb.

```
b = coxphfit(lightbulb(:,2),lightbulb(:,1),...
'censoring',lightbulb(:,3))
```

```
b =
```

```
4.7262
```

The estimate of the hazard ratio is  $\exp(b) = 112.8646$ . This means that the hazard for the incandescent bulbs is 112.86 times the hazard for the fluorescent bulbs.

## Change the Algorithm Parameters

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load lightbulb
```

The first column of the data has the lifetime (in hours) of two types of bulbs. The second column has the binary variable indicating whether the bulb is fluorescent or incandescent. 0 indicates that the bulb is incandescent, and 1 indicates that it is fluorescent. The third column contains the censorship information, where 0 indicates the bulb is observed until failure, and 1 indicates the item (bulb) is censored.

Fit a Cox proportional hazards model, also accounting for censoring. The predictor variable is the type of bulb.

```
b = coxphfit(lightbulb(:,2),lightbulb(:,1),...
'censoring',lightbulb(:,3))
```

```
b =
```

```
4.7262
```

Display the default control parameters for the algorithm `coxphfit` uses to estimate the coefficients.

```
statset('coxphfit')
```

```
ans =
```

```
Display: 'off'
```

```

MaxFunEvals: 200
  MaxIter: 100
    TolBnd: 1.0000e-06
    TolFun: 1.0000e-08
  TolTypeFun: []
    TolX: 1.0000e-08
  TolTypeX: []
  GradObj: []
  Jacobian: []
  DerivStep: []
  FunValCheck: []
  Robust: []
  RobustWgtFun: []
  WgtFun: []
  Tune: []
  UseParallel: []
  UseSubstreams: []
  Streams: {}
  OutputFcn: []

```

Save the options under a different name and change how the results will be displayed and the maximum number of iterations, `Display` and `MaxIter`.

```

coxphopt = statset('coxphfit');
coxphopt.Display = 'final';
coxphopt.MaxIter = 50;

```

Run `coxphfit` with the new algorithm parameters.

```

b = coxphfit(lightbulb(:,2),lightbulb(:,1),...
'censoring',lightbulb(:,3),'options',coxphopt)

```

Successful convergence: Norm of gradient less than `OPTIONS.TolFun`

b =

```

4.7262

```

coxphfit displays a report on the final iteration. Changing the maximum number of iterations did not affect the coefficient estimate.

## Fit and Compare Cox and Weibull Survivor Functions

Generate Weibull data depending on predictor X.

```
rng('default') % for reproducibility
X = 4*rand(100,1);
A = 50*exp(-0.5*X);
B = 2;
y = wblrnd(A,B);
```

The response values are generated from a Weibull distribution with a shape parameter depending on the predictor variable X and a scale parameter of 2.

Fit a Cox proportional hazards model.

```
[b,logL,H,stats] = coxphfit(X,y);
[b logL]
```

```
ans =

    0.9409 -331.1479
```

The coefficient estimate is 0.9409 and the log likelihood value is -331.1479.

Request the model statistics.

```
stats

stats =

    covb: 0.0158
    beta: 0.9409
    se: 0.1256
    z: 7.4889
```

p: 6.9462e-14

The covariance matrix of the coefficient estimates, `covb`, contains only one value, which is equal to the variance of the coefficient estimate in this example. The coefficient estimate, `beta`, is the same as `b` and is equal to 0.9409. The standard error of the coefficient estimate, `se`, is 0.1256, which is the square root of the variance 0.0158. The z-statistic, `z`, is  $\text{beta}/\text{se} = 0.9409/0.1256 = 7.4880$ . The p-value, `p`, indicates that the effect of `X` is significant.

Plot the Cox estimate of the baseline survivor function together with the known Weibull function.

```
stairs(H(:,1),exp(-H(:,2)),'LineWidth',2)
xx = linspace(0,100);
line(xx,1-wblcdf(xx,50*exp(-0.5*mean(X)),B),'color','r','LineWidth',2)
xlim([0,50])
legend('Estimated Survivor Function','Weibull Survivor Function')
```

The fitted model gives a close estimate to the survivor function of the actual distribution.

## Definitions

### Cox Proportional Hazards Regression

Cox proportional hazards regression is a semiparametric method for adjusting survival rate estimates to remove the effect of confounding variables and to quantify the effect of predictor variables. The method represents the effects of explanatory and confounding variables as a multiplier of a common baseline hazard function,  $h_0(t)$ .

For a baseline relative to 0, this model corresponds to

$$h_X(t) = h_0(t)e^{\sum_i X_i b_i},$$

where  $h_X(t)$  is the hazard rate at X and  $h_0(t)$  is the baseline hazard rate function. The baseline hazard function is the nonparametric part of the Cox proportional hazards regression function, whereas the impact of the predictor variables is a loglinear regression. The assumption is that the baseline hazard function depends on time,  $t$ , but the predictor variables do not depend on time.

# NaiveBayes.Prior property

---

**Purpose**            Class priors

**Description**        The Prior property is a vector of length NClasses containing the class priors. The priors for empty classes are zero.

<b>Purpose</b>	Create object to use in <i>k</i> -nearest neighbors search
<b>Syntax</b>	<pre>NS = createns(X) NS = createns(X, 'Name', Value)</pre>
<b>Description</b>	<p>NS = createns(X) uses the data observations in an <i>m</i><i>x</i>-by-<i>n</i> matrix X to create an object NS. Rows of X correspond to observations and columns correspond to variables. NS is either an ExhaustiveSearcher or a KDTreeSearcher object which you can use to find nearest neighbors in X for desired query points. When NS is an ExhaustiveSearcher object, knnsearch uses the exhaustive search algorithm to find nearest neighbors. When NS is a KDTreeSearcher, createns creates and saves a <i>kd</i>-tree based on X in NS. knnsearch uses the <i>kd</i>-tree to find nearest neighbors. For information on these search methods, see “<i>k</i>-Nearest Neighbor Search and Radius Search” on page 16-12.</p> <p>NS = createns(X, 'Name', Value) accepts one or more optional name/value pairs. Specify <i>Name</i> inside single quotes. Specify NSMethod to determine which type of object to create. The object's properties save the information when you specify other arguments. For more information on the objects' properties, see ExhaustiveSearcher and KDTreeSearcher.</p>
<b>Input Arguments</b>	<b>Name-Value Pair Arguments</b>  <b>'NSMethod'</b>  Nearest neighbors search method, used to define the type of object created. Value is either: <ul style="list-style-type: none"><li>• 'kdtree' — Create a KDTreeSearcher object. If you do not specify NSMethod, this is the default value when the number of columns of X is less than 10, X is not sparse, and the distance measure is one of the following measures:<ul style="list-style-type: none"><li>▪ 'euclidean' (default)</li><li>▪ 'cityblock'</li></ul></li></ul>

- 'minkowski'
- 'chebychev'
- 'exhaustive' — Create an ExhaustiveSearcher object. If you do not specify NSMethod, this is the default value when the default criteria for 'kdtree' do not apply.

## 'Distance'

A string or a function handle specifying the default distance metric used when you call the `knnsearch` method to find nearest neighbors for future query points. If you specify a distance metric but not an NSMethod, this input determines the type of object `createns` creates, according to the default values described in NSMethod.

For both `KDTreeSearcher` and `ExhaustiveSearcher` objects, the following options apply:

- 'euclidean' (default) — Euclidean distance.
- 'cityblock' — City block distance.
- 'chebychev' — Chebychev distance (maximum coordinate difference).
- 'minkowski' — Minkowski distance.

The following options apply only to `ExhaustiveSearcher` objects:

- 'seuclidean' — Standardized Euclidean distance. Each coordinate difference between rows in  $X$  and the query matrix is scaled by dividing by the corresponding element of the standard deviation computed from  $X$ ,  $S = \text{nanstd}(X)$ . To specify another value for  $S$ , use the `Scale` argument.
- 'mahalanobis' — Mahalanobis distance, which is computed using a positive definite covariance matrix  $C$ . The default value of  $C$  is the sample covariance matrix of  $X$ , as computed by `nancov(X)`. To change the value of  $C$ , use the `Cov` parameter.
- 'cosine' — One minus the cosine of the included angle between observations (treated as vectors).

- 'correlation' — One minus the sample linear correlation between observations (treated as sequences of values).
- 'spearman' — One minus the sample Spearman's rank correlation between observations (treated as sequences of values).
- 'hamming' — Hamming distance, which is percentage of coordinates that differ.
- 'jaccard' — One minus the Jaccard coefficient, which is the percentage of nonzero coordinates that differ.
- custom distance function — A distance function specified using @ (for example, @distfun). A distance function must be of the form function D2 = distfun(ZI, ZJ), taking as arguments a 1-by- $n$  vector ZI containing a single row from X or from the query points Y, and an  $m$ -by- $n$  matrix ZJ containing multiple rows of X or Y, and returning an  $m$ -by-1 vector of distances  $d2$ , whose  $j$ th element is the distance between the observations ZI and ZJ( $j$ , :).

**'p'**

A positive scalar,  $p$ , indicating the exponent of the Minkowski distance. This parameter is only valid when Distance is 'minkowski'. Default is 2.

**'Cov'**

A positive definite matrix indicating the covariance matrix when computing the Mahalanobis distance. This parameter is only valid when Distance is 'mahalanobis'. Default is nancov(X).

**'Scale'**

A vector S with the length equal to the number of columns in X. Each coordinate of X and each query point is scaled by the corresponding element of S when computing the standardized Euclidean distance. This parameter is only valid when Distance is 'seuclidean'. Default is nanstd(X).

## 'BucketSize'

A positive integer, indicating the maximum number of data points in each leaf node of the *kd*-tree. This argument is only meaningful when using the *kd*-tree search method. Default is 50.

## Examples

Create a *kd*-tree with a Minkowski distance metric and a P value of 5:

```
load fisheriris
x = meas(:,3:4);
% Since x has only two columns and the Distance is Minkowski,
% createns creates a KDTreeSearcher object by default:
knnobj = createns(x, 'Distance', 'minkowski', 'P', 5)

knnobj =

KDTreeSearcher

Properties:
    BucketSize: 50
              X: [150x2 double]
              Distance: 'minkowski'
              DistParameter: 5
```

## How To

- “*k*-Nearest Neighbor Search and Radius Search” on page 16-12

**Purpose**

Cross-tabulation

**Syntax**

```
table = crosstab(x1,x2)
table = crosstab(x1,x2,...,xn)
[table,chi2,p] = crosstab(x1,...,xn)
[table,chi2,p,labels] = crosstab(x1,...,xn)
```

**Description**

`table = crosstab(x1,x2)` returns a cross-tabulation table of two vectors of the same length `x1` and `x2`. `table` is *m*-by-*n*, where *m* is the number of distinct values in `x1` and *n* is the number of distinct values in `x2`.

`x1` and `x2` are grouping variables, as described in “Grouping Variables” on page 2-51. `crosstab` uses `grp2idx` to assign a positive integer to each distinct value. `table(i,j)` is a count of indices where `grp2idx(x1)` is *i* and `grp2idx(x2)` is *j*. The numerical order of `grp2idx(x1)` and `grp2idx(x2)` order rows and columns of `table`, respectively.

`table = crosstab(x1,x2,...,xn)` returns a multi-dimensional table where `table(i,j,...,n)` is a count of indices where `grp2idx(x1)` is *i*, `grp2idx(x2)` is *j*, `grp2idx(x3)` is *k*, and so on.

`[table,chi2,p] = crosstab(x1,...,xn)` also returns the chi-square statistic `chi2` and its *p* value `p` for a test that `table` is independent in each dimension. The null hypothesis is that the proportion in any entry of `table` is the product of the proportions in each dimension.

`[table,chi2,p,labels] = crosstab(x1,...,xn)` also returns a cell array `labels` with one column for each input argument. The entries in the first column are labels for the rows of `table`, the entries in the second column are labels for the columns, and so on, for a multi-dimensional table.

**Examples****Cross-Tabulate Two Data Vectors**

This example shows how to cross-tabulate two data vectors.

Create two sample data vectors, containing three and four distinct values, respectively.

```
x = [1 1 2 3 1];  
y = [1 2 5 3 1];
```

Cross-tabulate x and y.

```
table = crosstab(x,y)
```

```
table =  
  
     2     1     0     0  
     0     0     0     1  
     0     0     1     0
```

## Cross-Tabulate Independent Data Vectors

This example shows how to cross-tabulate two independent data vectors.

Generate two independent vectors, each containing 50 discrete uniform random numbers in the range 1:3.

```
rng('default'); % For reproducibility  
x1 = unidrnd(3,50,1);  
x2 = unidrnd(3,50,1);
```

Cross-tabulate x1 and x2.

```
[table,chi2,p] = crosstab(x1,x2)
```

```
table =  
  
     1     6     7  
     5     5     2  
    11     7     6
```

```
chi2 =  
      7.5449
```

```
p =  
    0.1097
```

At the 95% confidence level, the  $p$  value fails to reject the null hypothesis that `table` is independent in each dimension.

### **Cross-Tabulate Grouped Data**

This example shows how to cross-tabulate grouped sample data.

Load the sample data, which contains measurements of large model cars during the years 1970-1982.

```
load carbig
```

Cross-tabulate the data of four-cylinder cars (`cy14`) based on model year (`when`) and country of origin (`org`).

```
[table,chi2,p,labels] = crosstab(cy14,when,org)
```

```
table(:, :, 1) =  
      82   75   25  
      12   22   38
```

```
table(:, :, 2) =  
      0    4    3  
      23  26  17
```

# crosstab

---

```
table(:, :, 3) =  
  
      3      3      4  
     12     25     32  
  
chi2 =  
  
     207.7689  
  
p =  
  
     8.0973e-38  
  
labels =  
  
      'Other'      'Early'      'USA'  
      'Four'      'Mid'      'Europe'  
      []      'Late'      'Japan'
```

The results in `table` and `labels` together show that the number of four-cylinder cars made in the USA during the late period of the data is located in `table(2,3,1)`, and equals 38 cars.

## How To

- “Grouping Variables” on page 2-51

**Purpose**

Loss estimate using cross validation

**Syntax**

```
vals = crossval(fun,X)
vals = crossval(fun,X,Y,...)
mse = crossval('mse',X,y,'Predfun',predfun)
mcr = crossval('mcr',X,y,'Predfun',predfun)
val = crossval(criterion,X1,X2,...,y,'Predfun',predfun)
vals = crossval(...,'name',value)
```

**Description**

`vals = crossval(fun,X)` performs 10-fold cross validation for the function `fun`, applied to the data in `X`.

`fun` is a function handle to a function with two inputs, the training subset of `X`, `XTRAIN`, and the test subset of `X`, `XTEST`, as follows:

```
testval = fun(XTRAIN,XTEST)
```

Each time it is called, `fun` should use `XTRAIN` to fit a model, then return some criterion `testval` computed on `XTEST` using that fitted model.

`X` can be a column vector or a matrix. Rows of `X` correspond to observations; columns correspond to variables or features. Each row of `vals` contains the result of applying `fun` to one test set. If `testval` is a non-scalar value, `crossval` converts it to a row vector using linear indexing and stored in one row of `vals`.

`vals = crossval(fun,X,Y,...)` is used when data are stored in separate variables `X`, `Y`, ... . All variables (column vectors, matrices, or arrays) must have the same number of rows. `fun` is called with the training subsets of `X`, `Y`, ... , followed by the test subsets of `X`, `Y`, ... , as follows:

```
testvals = fun(XTRAIN,YTRAIN,...,XTEST,YTEST,...)
```

`mse = crossval('mse',X,y,'Predfun',predfun)` returns `mse`, a scalar containing a 10-fold cross validation estimate of mean-squared error for the function `predfun`. `X` can be a column vector, matrix, or array of predictors. `y` is a column vector of response values. `X` and `y` must have the same number of rows.

`predfun` is a function handle called with the training subset of  $X$ , the training subset of  $y$ , and the test subset of  $X$  as follows:

```
yfit = predfun(XTRAIN,ytrain,XTEST)
```

Each time it is called, `predfun` should use `XTRAIN` and `ytrain` to fit a regression model and then return fitted values in a column vector `yfit`. Each row of `yfit` contains the predicted values for the corresponding row of `XTEST`. `crossval` computes the squared errors between `yfit` and the corresponding response test set, and returns the overall mean across all test sets.

`mcr = crossval('mcr',X,y,'Predfun',predfun)` returns `mcr`, a scalar containing a 10-fold cross validation estimate of misclassification rate (the proportion of misclassified samples) for the function `predfun`. The matrix  $X$  contains predictor values and the vector  $y$  contains class labels. `predfun` should use `XTRAIN` and `YTRAIN` to fit a classification model and return `yfit` as the predicted class labels for `XTEST`. `crossval` computes the number of misclassifications between `yfit` and the corresponding response test set, and returns the overall misclassification rate across all test sets.

`val = crossval(criterion,X1,X2,...,y,'Predfun',predfun)`, where *criterion* is 'mse' or 'mcr', returns a cross validation estimate of mean-squared error (for a regression model) or misclassification rate (for a classification model) with predictor values in  $X1$ ,  $X2$ , ... and, respectively, response values or class labels in  $y$ .  $X1$ ,  $X2$ , ... and  $y$  must have the same number of rows. `predfun` is a function handle called with the training subsets of  $X1$ ,  $X2$ , ..., the training subset of  $y$ , and the test subsets of  $X1$ ,  $X2$ , ..., as follows:

```
yfit=predfun(X1TRAIN,X2TRAIN,...,ytrain,X1TEST,X2TEST,...)
```

`yfit` should be a column vector containing the fitted values.

`vals = crossval(...,'name',value)` specifies one or more optional parameter name/value pairs from the following table. Specify *name* inside single quotes.

Name	Value
holdout	A scalar specifying the ratio or the number of observations $p$ for holdout cross validation. When $0 < p < 1$ , approximately $p \cdot n$ observations for the test set are randomly selected. When $p$ is an integer, $p$ observations for the test set are randomly selected.
kfold	A scalar specifying the number of folds $k$ for $k$ -fold cross validation.
leaveout	Specifies leave-one-out cross validation. The value must be 1.
mcreps	A positive integer specifying the number of Monte-Carlo repetitions for validation. If the first input of <code>crossval</code> is 'mse' or 'mcr', <code>crossval</code> returns the mean of mean-squared error or misclassification rate across all of the Monte-Carlo repetitions. Otherwise, <code>crossval</code> concatenates the values <code>vals</code> from all of the Monte-Carlo repetitions along the first dimension.
partition	An object <code>c</code> of the <code>cvpartition</code> class, specifying the cross validation type and partition.
stratify	A column vector <code>group</code> specifying groups for stratification. Both training and test sets have roughly the same class proportions as in <code>group</code> . NaNs or empty strings in <code>group</code> are treated as missing values, and the corresponding rows of the data are ignored.
options	A structure that specifies whether to run in parallel, and specifies the random stream or streams. Create the <code>options</code> structure with <code>statset</code> . Option fields:

Name	Value
	<ul style="list-style-type: none"><li>• <code>UseParallel</code> — Set to <code>true</code> to compute in parallel. Default is <code>false</code>.</li><li>• <code>UseSubstreams</code> — Set to <code>true</code> to compute in parallel in a reproducible fashion. Default is <code>false</code>. To compute reproducibly, set <code>Streams</code> to a type allowing substreams: <code>'mlfg6331_64'</code> or <code>'mrg32k3a'</code>.</li><li>• <code>Streams</code> — A <code>RandStream</code> object or cell array consisting of one such object. If you do not specify <code>Streams</code>, <code>crossval</code> uses the default stream.</li></ul>

Only one of `kfold`, `holdout`, `leaveout`, or `partition` can be specified, and `partition` cannot be specified with `stratify`. If both `partition` and `mcreps` are specified, the first Monte-Carlo repetition uses the partition information in the `cvpartition` object, and the `repartition` method is called to generate new partitions for each of the remaining repetitions. If no cross validation type is specified, the default is 10-fold cross validation.

---

**Note** When using cross validation with classification algorithms, stratification is preferred. Otherwise, some test sets may not include observations from all classes.

---

## Examples

### Example 1

Compute mean-squared error for regression using 10-fold cross validation:

```
load('fisheriris');  
y = meas(:,1);  
X = [ones(size(y,1),1),meas(:,2:4)];
```

```
regf=@(XTRAIN,ytrain,XTEST)(XTEST*regress(ytrain,XTRAIN));  
  
cvMse = crossval('mse',X,y,'predfun',regf)  
cvMse =  
    0.1015
```

### Example 2

Compute misclassification rate using stratified 10-fold cross validation:

```
load('fisheriris');  
y = species;  
X = meas;  
cp = cvpartition(y,'k',10); % Stratified cross-validation  
  
classf = @(XTRAIN, ytrain,XTEST)(classify(XTEST,XTRAIN,...  
ytrain));  
  
cvMCR = crossval('mcr',X,y,'predfun',classf,'partition',cp)  
cvMCR =  
    0.0200
```

### Example 3

Compute the confusion matrix using stratified 10-fold cross validation:

```
load('fisheriris');  
y = species;  
X = meas;  
order = unique(y); % Order of the group labels  
cp = cvpartition(y,'k',10); % Stratified cross-validation  
  
f = @(xtr,ytr,xte,yte)confusionmat(yte,...  
classify(xte,xtr,ytr),'order',order);  
  
cfMat = crossval(f,X,y,'partition',cp);  
cfMat = reshape(sum(cfMat),3,3)  
cfMat =
```

50	0	0
0	48	2
0	1	49

cfMat is the summation of 10 confusion matrices from 10 test sets.

## How To

• “Grouping Variables” on page 2-51

**Purpose** Cross-validated discriminant analysis classifier

**Syntax**  
`cvmodel = crossval(obj)`  
`cvmodel = crossval(obj,Name,Value)`

**Description**  
`cvmodel = crossval(obj)` creates a partitioned model from `obj`, a fitted discriminant analysis classifier. By default, `crossval` uses 10-fold cross validation on the training data to create `cvmodel`.  
`cvmodel = crossval(obj,Name,Value)` creates a partitioned model with additional options specified by one or more `Name,Value` pair arguments.

**Tips**

- Assess the predictive performance of `obj` on cross-validated data using the “kfold” methods and properties of `cvmodel`, such as `kfoldLoss`.

**Input Arguments**

**obj**  
Discriminant analysis classifier, produced using `ClassificationDiscriminant.fit`.

### Name-Value Pair Arguments

Specify optional comma-separated pairs of `Name,Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( ' '). You can specify several name and value pair arguments in any order as `Name1,Value1,...,NameN,ValueN`.

### 'cvpartition'

Object of class `cvpartition`, created by the `cvpartition` function. `crossval` splits the data into subsets with `cvpartition`.

Use only one of these options at a time: `'cvpartition'`, `'holdout'`, `'kfold'`, or `'leaveout'`.

**Default:** []

# ClassificationDiscriminant.crossval

---

## 'holdout'

Holdout validation tests the specified fraction of the data, and uses the rest of the data for training. Specify a numeric scalar from 0 to 1. Use only one of these options at a time: 'cvpartition', 'holdout', 'kfold', or 'leaveout'.

## 'kfold'

Number of folds to use in a cross-validated classifier, a positive integer.

Use only one of these options at a time: 'cvpartition', 'holdout', 'kfold', or 'leaveout'.

**Default:** 10

## 'leaveout'

Set to 'on' for leave-one-out cross validation.

Use only one of these options at a time: 'cvpartition', 'holdout', 'kfold', or 'leaveout'.

## Examples

Create a classification model for the Fisher iris data, and then create a cross-validation model. Evaluate the quality the model using `kfoldLoss`.

```
load fisheriris
obj = ClassificationDiscriminant.fit(meas,species);
cvmodel = crossval(obj);
L = kfoldLoss(cvmodel)

L =
    0.0200
```

## Alternatives

You can create a cross-validation classifier directly from the data, instead of creating a discriminant analysis classifier followed by a cross-validation classifier. To do so, include one of these options in

ClassificationDiscriminant.fit: 'crossval', 'cvpartition',  
'holdout', 'kfold', or 'leaveout'.

## How To

- “Discriminant Analysis” on page 15-3

# ClassificationEnsemble.crossval

---

**Purpose** Cross validate ensemble

**Syntax**  
`cvens = crossval(ens)`  
`cvens = crossval(ens,Name,Value)`

**Description**  
`cvens = crossval(ens)` creates a cross-validated ensemble from `ens`, a classification ensemble. Default is 10-fold cross validation.  
`cvens = crossval(ens,Name,Value)` creates a cross-validated ensemble with additional options specified by one or more `Name,Value` pair arguments. You can specify several name-value pair arguments in any order as `Name1,Value1, ,NameN,ValueN`.

## Input Arguments

**ens**  
A classification ensemble created with `fitensemble`.

### Name-Value Pair Arguments

Specify optional comma-separated pairs of `Name,Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as `Name1,Value1, . . . ,NameN,ValueN`.

#### 'cvpartition'

A partition of class `cvpartition`. Sets the partition for cross validation.

Use no more than one of the name-value pairs `cvpartition`, `holdout`, `kfold`, or `leaveout`.

#### 'holdout'

Holdout validation tests the specified fraction of the data, and uses the rest of the data for training. Specify a numeric scalar from 0 to 1. You can only use one of these four options at a time for creating a cross-validated tree: `'kfold'`, `'holdout'`, `'leaveout'`, or `'cvpartition'`.

## 'kfold'

Number of folds for cross validation, a numeric positive scalar.

Use no more than one of the name-value pairs 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

## 'leaveout'

If 'on', use leave-one-out cross validation.

Use no more than one of the name-value pairs 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

## 'nprint'

Printout frequency, a positive integer scalar. Use this parameter to observe the training of cross-validation folds.

**Default:** 'off', meaning no printout

## Output Arguments

### **cvens**

A cross-validated classification ensemble of class ClassificationPartitionedEnsemble.

## Alternatives

You can create a cross-validation ensemble directly from the data, instead of creating an ensemble followed by a cross-validation ensemble. To do so, include one of these five options in fitensemble: 'crossval', 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

## Examples

Create a cross-validated classification model for the Fisher iris data, and assess its quality using the kfoldLoss method.

```
load fisheriris
ens = fitensemble(meas,species,'AdaBoostM2',100,'Tree');
cvens = crossval(ens);
L = kfoldLoss(cvens)
```

```
L =
    0.0467
```

# ClassificationKNN.crossval

---

Holdout validation tests the specified fraction of the data, and uses the remaining data for training. Specify a numeric scalar from 0 to 1. Use only one of these four options at a time: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

## 'kfold'

Number of folds to use in a cross-validated tree, a positive integer.

Use only one of these four options at a time: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

**Default:** 10

## 'leaveout'

Set to 'on' for leave-one-out cross validation.

Use only one of these four options at a time: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

## Output Arguments

### cvmodel

Partitioned model of class ClassificationPartitionedModel.

## Examples

### Cross-Validated $K$ -Nearest Neighbor Model

Construct a cross-validated  $k$ -nearest neighbor model, and assess classification performance using the model.

Load the data.

```
load fisheriris
X = meas;
Y = species;
```

Construct a classifier for nearest neighbors.

```
mdl = ClassificationKNN.fit(X,Y);
```

Construct a cross-validated classifier.

```
cvmdl = crossval(md1)

cvmdl =

classreg.learning.partition.ClassificationPartitionedModel:
  CrossValidatedModel: 'KNN'
  PredictorNames: {'x1' 'x2' 'x3' 'x4'}
  CategoricalPredictors: []
  ResponseName: 'Y'
  NObservations: 150
  KFold: 10
  Partition: [1x1 cvpartition]
  ClassNames: {'setosa' 'versicolor' 'virginica'}
  ScoreTransform: 'none'
```

Find the cross-validated loss of the classifier.

```
cvmdlloss = kfoldLoss(cvmdl)

cvmdlloss =

    0.0400
```

The cross-validated loss is less than 5%. You can expect md1 to have a similar error rate.

## Alternatives

You can create a cross-validated model directly from the data, instead of creating a model followed by a cross-validated model. To do so, include one of these options in `ClassificationKNN.fit`: 'crossval', 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

## See Also

`RegressionTree.fit` | `crossval`

# categorical.ctranspose

---

**Purpose** Transpose categorical matrix

**Syntax** `B = ctranspose(A)`

**Description** `B = ctranspose(A)` returns the transpose of the 2-D categorical matrix A. Note that `ctranspose` is identical to `transpose` for categorical arrays.

**See Also** `transpose` | `permute`

**Purpose** Cut categories

**Syntax** `C = cutcategories(t)`  
`C = cutcategories(t,nodes)`

**Description** `C = cutcategories(t)` returns an  $n$ -by-2 cell array `C` of the categories used at branches in the decision tree `t`, where  $n$  is the number of nodes. For each branch node  $i$  based on a categorical predictor variable  $x$ , the left child is chosen if  $x$  is among the categories listed in `C{i,1}`, and the right child is chosen if  $x$  is among those listed in `C{i,2}`. Both columns of `C` are empty for branch nodes based on continuous predictors and for leaf nodes.

`C = cutcategories(t,nodes)` takes a vector `nodes` of node numbers and returns the categories for the specified nodes.

**Examples** Create a classification tree for car data:

```
load carsmall

t = classregtree([MPG Cylinders],Origin,...
                'names',{'MPG' 'Cyl'},'cat',2)
t =
Decision tree for classification
 1  if Cyl=4 then node 2 elseif Cyl in {6 8} then node 3 else USA

classregtree | cutpoint | cuttype | cutvar

# classregtree.cutpoint

---

**Purpose** Decision tree cut point values

**Syntax** `v = cutpoint(t)`  
`v = cutpoint(t,nodes)`

**Description** `v = cutpoint(t)` returns an  $n$ -element vector  $v$  of the values used as cut points in the decision tree  $t$ , where  $n$  is the number of nodes. For each branch node  $i$  based on a continuous predictor variable  $x$ , the left child is chosen if  $x < v(i)$  and the right child is chosen if  $x \geq v(i)$ .  $v$  is NaN for branch nodes based on categorical predictors and for leaf nodes.

`v = cutpoint(t,nodes)` takes a vector `nodes` of node numbers and returns the cut points for the specified nodes.

**Examples** Create a classification tree for car data:

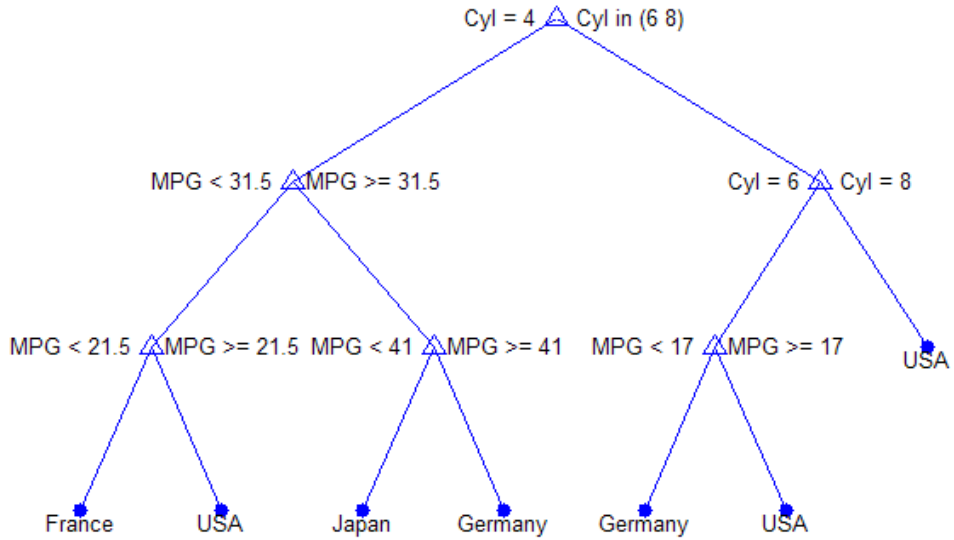

```
load carsmall

t = classregtree([MPG Cylinders],Origin,...

[classregtree](#) | [cutcategories](#) | [cuttype](#) | [cutvar](#)

**Purpose**

Cut types

**Syntax**

```
c = cuttype(t)
c = cuttype(t,nodes)
```

**Description**

`c = cuttype(t)` returns an  $n$ -element cell array `c` indicating the type of cut at each node in the tree `t`, where  $n$  is the number of nodes. For each node  $i$ , `c{i}` is:

- 'continuous' — If the cut is defined in the form  $x < v$  for a variable  $x$  and cut point  $v$ .
- 'categorical' — If the cut is defined by whether a variable  $x$  takes a value in a set of categories.
- '' — If  $i$  is a leaf node.

`cutvar` returns the cut points for 'continuous' cuts, and `cutcategories` returns the set of categories.

`c = cuttype(t,nodes)` takes a vector `nodes` of node numbers and returns the cut types for the specified nodes.

**Examples**

Create a classification tree for car data:

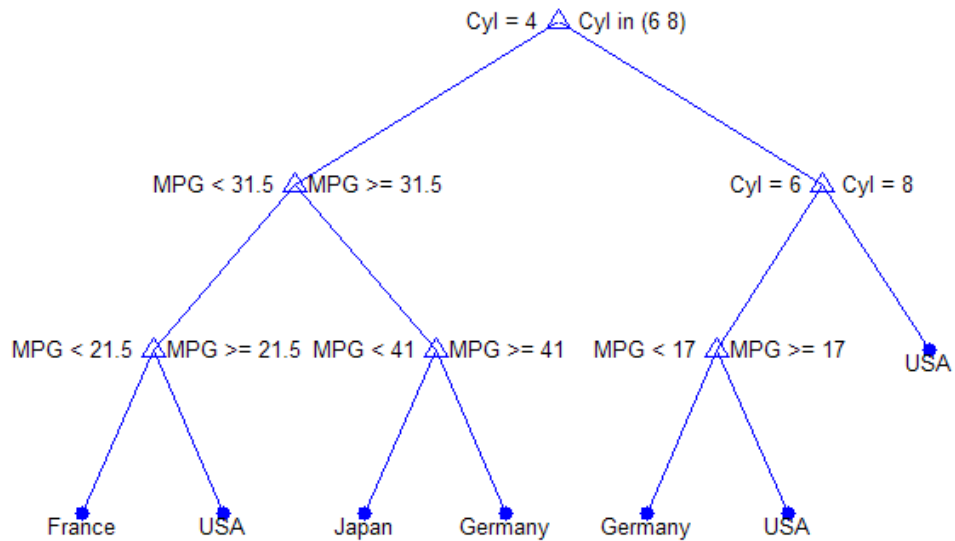

```
load carsmall

t = classregtree([MPG Cylinders],Origin,...
                'names',{'MPG' 'Cyl'},'cat',2)

`classregtree` | `numnodes` | `cutvar` | `cutcategories`

# classregtree.cutvar

---

**Purpose** Cut variable names

**Syntax**  
`v = cutvar(t)`  
`v = cutvar(t,nodes)`  
`[v,num] = cutvar(...)`

**Description** `v = cutvar(t)` returns an  $n$ -element cell array `v` of the names of the variables used for branching in each node of the tree `t`, where  $n$  is the number of nodes. These variables are sometimes known as *cut variables*. For leaf nodes, `v` contains an empty string.

`v = cutvar(t,nodes)` takes a vector `nodes` of node numbers and returns the cut variables for the specified nodes.

`[v,num] = cutvar(...)` also returns a vector `num` containing the number of each variable.

**Examples** Create a classification tree for car data:

```
load carsmall

t = classregtree([MPG Cylinders],Origin,...
                'names',{'MPG' 'Cyl'},'cat',2)

## Purpose

Classification error by cross validation

## Syntax

```
E = cvLoss(tree)
[E,SE] = cvLoss(tree)
[E,SE,Nleaf] = cvLoss(tree)
[E,SE,Nleaf,BestLevel] = cvLoss(tree)
[E,...] = cvLoss(tree,Name,Value)
```

## Description

`E = cvLoss(tree)` returns the cross-validated classification error (loss) for `tree`, a classification tree.

`[E,SE] = cvLoss(tree)` returns the standard error of `E`.

`[E,SE,Nleaf] = cvLoss(tree)` returns the number of leaves of `tree`.

`[E,SE,Nleaf,BestLevel] = cvLoss(tree)` returns the optimal pruning level for `tree`.

`[E,...] = cvLoss(tree,Name,Value)` cross validates with additional options specified by one or more `Name,Value` pair arguments. You can specify several name-value pair arguments in any order as `Name1,Value1, ...,NameN,ValueN`.

## Input Arguments

### `tree`

A classification tree produced by `ClassificationTree.fit`.

### Name-Value Pair Arguments

Specify optional comma-separated pairs of `Name,Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( ' '). You can specify several name and value pair arguments in any order as `Name1,Value1, ...,NameN,ValueN`.

### 'subtrees'

Vector of pruning levels, with 0 representing the full, unpruned tree. `tree` must include a pruning sequence as created either by `ClassificationTree.fit` with 'prune' set to 'on', or by the

# ClassificationTree.cvLoss

---

prune method. The returned `E`, `SE`, and `Nleaf` are vectors of the same length as `subtrees`; `BestLevel` is a scalar. If you set `subtrees` to `'all'`, `cvLoss` uses the entire pruning sequence.

**Default:** 0

## **'treesize'**

One of the following strings:

- `'se'` — `cvLoss` uses the smallest tree whose cost is within one standard error of the minimum cost.
- `'min'` — `cvLoss` uses the minimal cost tree.

**Default:** `'se'`

## **'kfold'**

Number of cross-validation samples, a positive integer.

**Default:** 10

## **Output Arguments**

### **E**

The cross-validation classification error (loss). A vector or scalar depending on the setting of the `subtrees` name-value pair.

### **SE**

The standard error of `E`. A vector or scalar depending on the setting of the `subtrees` name-value pair.

### **Nleaf**

Number of leaf nodes in `tree`. Leaf nodes are terminal nodes, which give classifications, not splits. A vector or scalar depending on the setting of the `subtrees` name-value pair.

### **BestLevel**

By default, a scalar representing the largest pruning level that achieves a value of  $E$  within  $SE$  of the minimum error. If you set `treeSize` to 'min', `BestLevel` is the smallest value in subtrees.

## Examples

Compute the cross-validation error for the default classification tree for the ionosphere data:

```
load ionosphere
tree = ClassificationTree.fit(X,Y);
[E,SE,Nleaf,BestLevel] = cvLoss(tree)
```

```
E =
    0.1282
```

```
SE =
    0.0178
```

```
Nleaf =
    19
```

```
BestLevel =
    0
```

Find the best level by using the subtrees name-value pair:

```
[~,~,~,BestLevel] = cvLoss(tree,'subtrees','all')
```

```
BestLevel =
    6
```

## Alternatives

You can construct a cross-validated tree model with `crossval`, and call `kfoldLoss` instead of `cvLoss`. The alternative can save time if you are going to examine the cross-validated tree more than once.

However, unlike `cvLoss`, `kfoldLoss` does not return `SE`, `Nleaf`, or `BestLevel`. `kfoldLoss` also does not allow you to examine any error other than classification error.

# ClassificationTree.cvLoss

---

## See Also

`ClassificationTree.fit` | `crossval` | `loss` | `kfoldLoss`

## Purpose

Regression error by cross validation

## Syntax

```
E = cvLoss(tree)
[E,SE] = cvLoss(tree)
[E,SE,Nleaf] = cvLoss(tree)
[E,SE,Nleaf,BestLevel] = cvLoss(tree)
[E,...] = cvLoss(tree,Name,Value)
```

## Description

`E = cvLoss(tree)` returns the cross-validated regression error (loss) for `tree`, a regression tree.

`[E,SE] = cvLoss(tree)` returns the standard error of `E`.

`[E,SE,Nleaf] = cvLoss(tree)` returns the number of leaves (terminal nodes) in `tree`.

`[E,SE,Nleaf,BestLevel] = cvLoss(tree)` returns the optimal pruning level for `tree`.

`[E,...] = cvLoss(tree,Name,Value)` cross validates with additional options specified by one or more `Name,Value` pair arguments. You can specify several name-value pair arguments in any order as `Name1,Value1, ...,NameN,ValueN`.

## Input Arguments

### `tree`

A regression tree produced by `RegressionTree.fit`.

### Name-Value Pair Arguments

Specify optional comma-separated pairs of `Name,Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as `Name1,Value1, ...,NameN,ValueN`.

### 'subtrees'

Vector of pruning levels, with 0 representing the full, unpruned tree. `tree` must include a pruning sequence as created either by

# RegressionTree.cvLoss

---

ClassificationTree.fit with 'prune' set to 'on', or by the prune method. The returned E, SE, and Nleaf are vectors of the same length as subtrees; BestLevel is a scalar. If you set subtrees to 'all', cvLoss uses the entire pruning sequence.

**Default:** 0

## 'treesize'

One of the following strings:

- 'se' — cvLoss uses the smallest tree whose cost is within one standard error of the minimum cost.
- 'min' — cvLoss uses the minimal cost tree.

**Default:** 'se'

## 'kfold'

Number of cross-validation samples, a positive integer.

**Default:** 10

## Output Arguments

### E

The cross-validation mean squared error (loss). A vector or scalar depending on the setting of the subtrees name-value pair.

### SE

The standard error of E. A vector or scalar depending on the setting of the subtrees name-value pair.

### Nleaf

Number of leaf nodes in tree. Leaf nodes are terminal nodes, which give responses, not splits. A vector or scalar depending on the setting of the subtrees name-value pair.

### BestLevel

By default, a scalar representing the largest pruning level that achieves a value of `E` within `SE` of the minimum error. If you set `treecsize` to `'min'`, `BestLevel` is the smallest value in subtrees.

## Examples

Compute the cross-validation error for the default classification tree for the `carsmall` data:

```
load carsmall
X = [Displacement Horsepower Weight];
tree = RegressionTree.fit(X,MPG);
[E,SE,Nleaf,BestLevel] = cvLoss(tree)
```

```
E =
    30.7558
```

```
SE =
    6.0651
```

```
Nleaf =
    19
```

```
BestLevel =
    0
```

Find the best level by using the subtrees name-value pair:

```
[~,~,~,BestLevel] = cvLoss(tree,'subtrees','all')
```

```
BestLevel =
    15
```

## Alternatives

You can construct a cross-validated tree model with `crossval`, and call `kfoldLoss` instead of `cvLoss`. The alternative can save time if you are going to examine the cross-validated tree more than once.

However, unlike `cvLoss`, `kfoldLoss` does not return `SE`, `Nleaf`, or `BestLevel`.

# cvpartition

---

## Examples

Use a 10-fold stratified cross validation to compute the misclassification error for `classify` on iris data.

```
load('fisheriris');
CVO = cvpartition(species,'k',10);
err = zeros(CVO.NumTestSets,1);
for i = 1:CVO.NumTestSets
    trIdx = CVO.training(i);
    teIdx = CVO.test(i);
    ytest = classify(meas(teIdx,:),meas(trIdx,:),...
        species(trIdx,:));
    err(i) = sum(~strcmp(ytest,species(teIdx)));
end
cvErr = sum(err)/sum(CVO.TestSize);
```

## See Also

`crossval`

## How To

- “Grouping Variables” on page 2-51

**Purpose**

Create cross validation partition for data

**Syntax**

```
c = cvpartition(n, 'kfold', k)
c = cvpartition(group, 'kfold', k)
c = cvpartition(n, 'holdout', p)
c = cvpartition(group, 'holdout', p)
c = cvpartition(n, 'leaveout')
c = cvpartition(n, 'resubstitution')
```

**Description**

`c = cvpartition(n, 'kfold', k)` constructs an object `c` of the `cvpartition` class defining a random partition for `k`-fold cross validation on `n` observations. The partition divides the observations into `k` disjoint subsamples (or *fold*s), chosen randomly but with roughly equal size. The default value of `k` is 10.

`c = cvpartition(group, 'kfold', k)` creates a random partition for a stratified `k`-fold cross validation. `group` is a numeric vector, categorical array, string array, or cell array of strings indicating the class of each observation. Each subsample has roughly equal size and roughly the same class proportions as in `group`. `cvpartition` treats NaNs or empty strings in `group` as missing values.

`c = cvpartition(n, 'holdout', p)` creates a random partition for holdout validation on `n` observations. This partition divides the observations into a training set and a test (or *holdout*) set. The parameter `p` must be a scalar. When  $0 < p < 1$ , `cvpartition` randomly selects approximately  $p*n$  observations for the test set. When `p` is an integer, `cvpartition` randomly selects `p` observations for the test set. The default value of `p` is 1/10.

`c = cvpartition(group, 'holdout', p)` randomly partitions observations into a training set and a test set with stratification, using the class information in `group`; that is, both training and test sets have roughly the same class proportions as in `group`.

`c = cvpartition(n, 'leaveout')` creates a random partition for leave-one-out cross validation on `n` observations. Leave-one-out is a special case of 'kfold', in which the number of folds equals the number of observations.

# cvpartition

---

`c = cvpartition(n, 'resubstitution')` creates an object `c` that does not partition the data. Both the training set and the test set contain all of the original `n` observations.

## Examples

Use stratified 10-fold cross validation to compute misclassification rate:

```
load fisheriris;
y = species;
c = cvpartition(y, 'k', 10);

fun = @(xT,yT,xt,yt)(sum(~strcmp(yt,classify(xt,xT,yT))));

rate = sum(crossval(fun,meas,y,'partition',c)...
           /sum(c.TestSize)
rate =
    0.0200
```

## See Also

`crossval` | `repartition`

## How To

- “Grouping Variables” on page 2-51

## Purpose

Cross-validate regularization of linear discriminant

## Syntax

```
err = cvshrink(obj)
[err,gamma] = cvshrink(obj)
[err,gamma,delta] = cvshrink(obj)
[err,gamma,delta,numpred] = cvshrink(obj)
[err,...] = cvshrink(obj,Name,Value)
```

## Description

`err = cvshrink(obj)` returns a vector of cross-validated classification error values for differing values of the regularization parameter Gamma.

`[err,gamma] = cvshrink(obj)` also returns the vector of Gamma values.

`[err,gamma,delta] = cvshrink(obj)` also returns the vector of Delta values.

`[err,gamma,delta,numpred] = cvshrink(obj)` returns the vector of number of nonzero predictors for each setting of the parameters Gamma and Delta.

`[err,...] = cvshrink(obj,Name,Value)` cross validates with additional options specified by one or more Name,Value pair arguments.

## Tips

- Examine the `err` and `numpred` outputs to see the tradeoff between cross-validated error and number of predictors. When you find a satisfactory point, set the corresponding `gamma` and `delta` properties in the model by dot addressing. For example, if  $(i, j)$  is the location of the satisfactory point, set

```
obj.Gamma = gamma(i);
obj.Delta = delta(i,j);
```

## Input Arguments

### **obj**

Discriminant analysis classifier, produced using `ClassificationDiscriminant.fit`.

# ClassificationDiscriminant.cvshrink

---

## Name-Value Pair Arguments

Specify optional comma-separated pairs of `Name`, `Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( ' '). You can specify several name and value pair arguments in any order as `Name1, Value1, . . . , NameN, ValueN`.

### 'delta'

- **Scalar delta** — `cvshrink` uses this value of `delta` with every value of `gamma` for regularization.
- **Row vector delta** — For each `i` and `j`, `cvshrink` uses `delta(j)` with `gamma(i)` for regularization.
- **Matrix delta** — The number of rows of `delta` must equal the number of elements in `gamma`. For each `i` and `j`, `cvshrink` uses `delta(i, j)` with `gamma(i)` for regularization.

**Default:** 0

### 'gamma'

Vector of Gamma values for cross-validation.

**Default:** 0:0.1:1

### 'NumDelta'

Number of Delta intervals for cross-validation. For every value of Gamma, `cvshrink` cross-validates the discriminant using `NumDelta + 1` values of Delta, uniformly spaced from zero to the maximal Delta at which all predictors are eliminated for this value of Gamma. If you set `delta`, `cvshrink` ignores `NumDelta`.

**Default:** 0

### 'NumGamma'

Number of Gamma intervals for cross-validation. `cvshrink` cross-validates the discriminant using `NumGamma + 1` values of Gamma, uniformly spaced from `MinGamma` to 1. If you set `gamma`, `cvshrink` ignores `NumGamma`.

**Default:** 10

## **'verbose'**

Verbosity level, an integer from 0 to 2. Higher values give more progress messages.

**Default:** 0

## **Output Arguments**

### **err**

Numeric vector or matrix of errors. `err` is the misclassification error rate, meaning the average fraction of misclassified data over all folds.

- If `delta` is a scalar (default), `err(i)` is the misclassification error rate for `obj` regularized with `gamma(i)`.
- If `delta` is a vector, `err(i,j)` is the misclassification error rate for `obj` regularized with `gamma(i)` and `delta(j)`.
- If `delta` is a matrix, `err(i,j)` is the misclassification error rate for `obj` regularized with `gamma(i)` and `delta(i,j)`.

### **gamma**

Vector of Gamma values used for regularization. See “Gamma and Delta” on page 21-610.

### **delta**

Vector or matrix of Delta values used for regularization. See “Gamma and Delta” on page 21-610.

# ClassificationDiscriminant.cvshrink

---

- If you give a scalar for the `delta` name-value pair, the output `delta` is a row vector the same size as `gamma`, with entries equal to the input scalar.
- If you give a row vector for the `delta` name-value pair, the output `delta` is a matrix with the same number of columns as the row vector, and with the number of rows equal to the number of elements of `gamma`. The output `delta(i, j)` is equal to the input `delta(j)`.
- If you give a matrix for the `delta` name-value pair, the output `delta` is the same as the input matrix. The number of rows of `delta` must equal the number of elements in `gamma`.

## **numpred**

Numeric vector or matrix containing the number of predictors in the model at various regularizations. `numpred` has the same size as `err`.

- If `delta` is a scalar (default), `numpred(i)` is the number of predictors for `obj` regularized with `gamma(i)` and `delta`.
- If `delta` is a vector, `numpred(i, j)` is the number of predictors for `obj` regularized with `gamma(i)` and `delta(j)`.
- If `delta` is a matrix, `numpred(i, j)` is the number of predictors for `obj` regularized with `gamma(i)` and `delta(i, j)`.

## **Definitions**

### **Gamma and Delta**

Regularization is the process of finding a small set of predictors that yield an effective predictive model. For linear discriminant analysis, there are two parameters,  $\gamma$  and  $\delta$ , that control regularization as follows. `cvshrink` helps you select appropriate values of the parameters.

Let  $\Sigma$  represent the covariance matrix of the data  $X$ , and let  $\hat{X}$  be the centered data (the data  $X$  minus the mean by class). Define

$$D = \text{diag}(\hat{X}^T * \hat{X}).$$

The regularized covariance matrix  $\tilde{\Sigma}$  is

$$\tilde{\Sigma} = (1 - \gamma)\Sigma + \gamma D.$$

Whenever  $\gamma \geq \text{MinGamma}$ ,  $\tilde{\Sigma}$  is nonsingular.

Let  $\mu_k$  be the mean vector for those elements of  $X$  in class  $k$ , and let  $\mu_0$  be the global mean vector (the mean of the rows of  $X$ ). Let  $C$  be the correlation matrix of the data  $X$ , and let  $\tilde{C}$  be the regularized correlation matrix:

$$\tilde{C} = (1 - \gamma)C + \gamma I,$$

where  $I$  is the identity matrix.

The linear term in the regularized discriminant analysis classifier for a data point  $x$  is

$$(x - \mu_0)^T \tilde{\Sigma}^{-1} (\mu_k - \mu_0) = \left[ (x - \mu_0)^T D^{-1/2} \right] \left[ \tilde{C}^{-1} D^{-1/2} (\mu_k - \mu_0) \right].$$

The parameter  $\delta$  enters into this equation as a threshold on the final term in square brackets. Each component of the vector

$\left[ \tilde{C}^{-1} D^{-1/2} (\mu_k - \mu_0) \right]$  is set to zero if it is smaller in magnitude than the threshold  $\delta$ . Therefore, for class  $k$ , if component  $j$  is thresholded to zero, component  $j$  of  $x$  does not enter into the evaluation of the posterior probability.

The `DeltaPredictor` property is a vector related to this threshold. When  $\delta \geq \text{DeltaPredictor}(i)$ , all classes  $k$  have

$$\left| \tilde{C}^{-1} D^{-1/2} (\mu_k - \mu_0) \right| \leq \delta.$$

Therefore, when  $\delta \geq \text{DeltaPredictor}(i)$ , the regularized classifier does not use predictor  $i$ .

# ClassificationDiscriminant.cvshrink

---

## Examples

### Regularize Data with Many Predictors

Regularize a discriminant analysis classifier, and view the tradeoff between the number of predictors in the model and the classification accuracy.

Create a linear discriminant analysis classifier for the ovariancancer data. Set the `SaveMemory` and `FillCoeffs` options to keep the resulting model reasonably small.

```
load ovariancancer
obj = ClassificationDiscriminant.fit(obs,grp,...
    'SaveMemory','on','FillCoeffs','off');
```

Use 10 levels of `Gamma` and 10 levels of `Delta` to search for good parameters. This search is time-consuming. Set `Verbose` to 1 to view the progress.

```
rng('default') % for reproducibility
[err,gamma,delta,numpred] = cvshrink(obj,...
    'NumGamma',9,'NumDelta',9,'Verbose',1);
```

```
Done building cross-validated model.
Processing Gamma step 1 out of 10.
Processing Gamma step 2 out of 10.
Processing Gamma step 3 out of 10.
Processing Gamma step 4 out of 10.
Processing Gamma step 5 out of 10.
Processing Gamma step 6 out of 10.
Processing Gamma step 7 out of 10.
Processing Gamma step 8 out of 10.
Processing Gamma step 9 out of 10.
Processing Gamma step 10 out of 10.
```

Plot the classification error rate against the number of predictors.

```
plot(err,numpred,'k.')
xlabel('Error rate');
ylabel('Number of predictors');
```

## Concepts

- “Discriminant Analysis” on page 15-3

# RegressionEnsemble.cvshrink

---

**Purpose** Cross validate shrinking (pruning) ensemble

**Syntax**

```
vals = cvshrink(ens)
[vals,nlearn] = cvshrink(ens)
[vals,nlearn] = cvshrink(ens,Name,Value)
```

**Description** `vals = cvshrink(ens)` returns an L-by-T matrix with cross-validated values of the mean squared error. L is the number of `lambda` values in the `ens.Regularization` structure. T is the number of `threshold` values on weak learner weights. If `ens` does not have a `Regularization` property filled in by the `regularize` method, pass a `lambda` name-value pair.

`[vals,nlearn] = cvshrink(ens)` returns an L-by-T matrix of the mean number of learners in the cross-validated ensemble.

`[vals,nlearn] = cvshrink(ens,Name,Value)` cross validates with additional options specified by one or more `Name,Value` pair arguments. You can specify several name-value pair arguments in any order as `Name1,Value1, ...,NameN,ValueN`.

## Input Arguments

**ens**

A regression ensemble, created with `fitensemble`.

### Name-Value Pair Arguments

Specify optional comma-separated pairs of `Name,Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( ' '). You can specify several name and value pair arguments in any order as `Name1,Value1, ...,NameN,ValueN`.

#### 'cvpartition'

A partition created with `cvpartition` to use in a cross-validated tree. You can only use one of these four options at a time: `'kfold'`, `'holdout'`, `'leaveout'`, or `'cvpartition'`.

#### 'holdout'

Holdout validation tests the specified fraction of the data, and uses the rest of the data for training. Specify a numeric scalar from 0 to 1. You can only use one of these four options at a time for creating a cross-validated tree: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

## **'kfold'**

Number of folds to use in a cross-validated tree, a positive integer. If you do not supply a cross-validation method, cvshrink uses 10-fold cross validation. You can only use one of these four options at a time: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

**Default:** 10

## **'lambda'**

Vector of nonnegative regularization parameter values for lasso. If empty, cvshrink does not perform cross validation.

**Default:** []

## **'leaveout'**

Use leave-one-out cross validation by setting to 'on'. You can only use one of these four options at a time: 'kfold', 'holdout', 'leaveout', or 'cvpartition'.

## **'threshold'**

Numeric vector with lower cutoffs on weights for weak learners. cvshrink discards learners with weights below threshold in its cross-validation calculation.

**Default:** 0

## **Output Arguments**

### **vals**

L-by-T matrix with cross-validated values of the mean squared error. L is the number of values of the regularization parameter

# RegressionEnsemble.cvshrink

---

'lambda', and T is the number of 'threshold' values on weak learner weights.

## nlearn

L-by-T matrix with cross-validated values of the mean number of learners in the cross-validated ensemble. L is the number of values of the regularization parameter 'lambda', and T is the number of 'threshold' values on weak learner weights.

## Examples

Create a regression ensemble for predicting mileage from the carsmall data. Cross validate the ensemble for three values each of lambda and threshold.

```
load carsmall
X = [Displacement Horsepower Weight];
ens = fitensemble(X,MPG,'bag',100,'Tree',...
    'type','regression');
[vals nlearn] = cvshrink(ens,'lambda',[.01 .1 1],...
    'threshold',[0 .01 .1])

vals =
    20.0949    19.9007    131.6316
    20.0924    19.8431    128.0989
    19.9759    19.7987    119.5574

nlearn =
    13.3000    11.6000     3.5000
    13.2000    11.5000     3.6000
    13.4000    11.4000     3.9000
```

Clearly, setting a threshold of 0.1 leads to unacceptable errors, while a threshold of 0.01 gives similar errors to a threshold of 0. The mean number of learners with a threshold of 0.1 is about 11.5, whereas the mean number is about 13.2 when the threshold is 0.

<b>Purpose</b>	Randomly sample from data, with or without replacement
<b>Syntax</b>	<pre> y = datasample(data,k) y = datasample(data,k,dim) [y,idx] = datasample(data,k,...) [y,...] = datasample(s,data,k,...) [y,...] = datasample(data,k,Name,Value) [y,...] = datasample(data,k,dim,Name,Value) </pre>
<b>Description</b>	<p><code>y = datasample(data,k)</code> returns <code>k</code> observations sampled uniformly at random, with replacement, from the data in <code>data</code>.</p> <p><code>y = datasample(data,k,dim)</code> returns a sample taken along dimension <code>dim</code> of data.</p> <p><code>[y,idx] = datasample(data,k,...)</code> returns an index vector indicating which values <code>datasample</code> sampled from <code>data</code>.</p> <p><code>[y,...] = datasample(s,data,k,...)</code> uses the random number stream <code>s</code> to generate random numbers.</p> <p><code>[y,...] = datasample(data,k,Name,Value)</code> or <code>[y,...] = datasample(data,k,dim,Name,Value)</code> samples with additional options specified by one or more <code>Name,Value</code> pair arguments.</p>
<b>Tips</b>	<ul style="list-style-type: none"> <li>• To sample random integers with replacement from a range, use <code>randi</code>.</li> <li>• To sample random integers without replacement, use <code>randperm</code> or <code>datasample</code>.</li> <li>• To randomly sample from data, with or without replacement, use <code>datasample</code>.</li> </ul>
<b>Input Arguments</b>	<p><b>data</b></p> <p>Vector, matrix, <math>N</math>-dimensional array, or dataset array representing the data from which to sample. By default, <code>datasample</code> regards the rows of a data matrix, or the first nonsingleton dimension of a data array, as data elements. Change this behavior with the <code>dim</code> argument.</p>

## **k**

Positive integer, the number of samples.

## **dim**

Integer specifying the dimension on which to take samples. For example, if `data` is a matrix and `dim` is 2, `y` contains a selection of columns in `data`. If `data` is a dataset array and `dim` is 2, `y` contains a selection of variables in `data`. Use `dim` to ensure sampling along a specific dimension regardless of whether `data` is a vector, matrix or  $N$ -dimensional array.

**Default:** 1

## **s**

Random number stream. Create `s` using `rng` or `RandStream`.

**Default:** The global random number stream

## **Name-Value Pair Arguments**

Specify optional comma-separated pairs of `Name`, `Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes (' '). You can specify several name and value pair arguments in any order as `Name1,Value1,...,NameN,ValueN`.

## **'Replace'**

Select the sample with replacement if `Replace` is true, or without replacement if `Replace` is false. If `Replace` is false, `k` must not be larger than the number of data elements in `data`.

**Default:** true

## **'Weights'**

Vector with the same number of elements as data elements in `data`, and with nonnegative elements. Sample with probability proportional to the elements of `Weights`.

**Default:** `ones(datasize,1)`, where `datasize` is the number of data elements in `data`

## Output Arguments

### `y`

- If `data` is a vector, `y` is a vector containing `k` elements selected from `data`.
- If `data` is a matrix, `y` is a matrix containing `k` rows selected from `data`. Or, if `dim = 2`, `y` is a matrix containing `k` columns selected from `data`
- If `data` is an  $N$ -dimensional array, `datasample` samples along its first non-singleton dimension. Or, if you give a `dim` name-value pair, `datasample` samples along the dimension `dim`.

When the sample is taken with replacement (default), `y` can contain repeated observations from `data`. Set the `Replace` name-value pair to `false` to sample without replacement.

### `idx`

Vector of indices indicating which elements `datasample` chose from `data` to create `y`. For example:

- If `data` is a vector, `y = data(idx)`.
- If `data` is a matrix, `y = data(idx,:)`.

## Examples

Draw five unique values from the integers `1:10`.

```
y = datasample(1:10,5,'Replace',false)
```

```
y =  
     6     3     7     8     5
```

---

# datasample

---

Generate a random sequence of the characters ACGT, with replacement, according to specified probabilities.

```
seq = datasample('ACGT',48,'Weights',[0.15 0.35 0.35 0.15])

seq =
CTTCGACTGTGAGTGGGCGCGACAAGGCTACCGGCCCGGGCGGCACTC
```

---

Select a random subset of columns from a data matrix.

```
X = randn(10,1000);
Y = datasample(X,5,2,'Replace',false)

Y =
    0.7007    0.3382    2.1298   -0.1891    0.5026
    0.6520   -0.6693   -0.1961   -0.9915    1.9107
    0.1785    0.6640    2.3247   -1.1735   -1.0020
    1.6760    2.6102   -0.8902   -0.7735    1.8676
   -0.3251   -0.6415   -0.2572   -0.1629   -1.0523
    0.1011    0.9323   -1.3088   -0.4477    0.8036
   -0.5767   -0.5778   -0.8556    0.8672   -0.0727
   -0.0615   -0.9084    0.9020   -0.4185   -1.9520
    0.7256   -1.1228    0.7558    1.2691    2.4997
   -1.2273    0.5754   -0.8755   -0.8224   -1.2066
```

---

Resample observations from a dataset array to create a bootstrap replicate dataset.

```
load hospital
y = datasample(hospital,size(hospital,1));
```

---

Use the second output to sample "in parallel" from two data vectors.

```
x1 = randn(100,1);
```

```
x2 = randn(100,1);  
[y1,idx] = datasample(x1,10);  
y2 = x2(idx);
```

## Algorithms

`datasample` uses `randperm`, `rand`, or `randi` to generate random values. Therefore, `datasample` changes the state of the MATLAB global random number generator. Control the random number generator using `rng`.

For selecting weighted samples without replacement, `datasample` uses the algorithm of Wong and Easton [1].

## References

[1] Wong, C. K. and M. C. Easton. *An Efficient Method for Weighted Sampling Without Replacement*. SIAM Journal of Computing 9(1), pp. 111–113, 1980.

## Alternatives

You can use `randi` or `randperm` to generate indices for random sampling with or without replacement, respectively. However, `datasample` can be more convenient because it samples directly from your data. `datasample` also allows weighted sampling.

# dataset

---

**Purpose** Arrays for statistical data

**Description** Dataset arrays are used to collect heterogeneous data and metadata including variable and observation names into a single container variable. Dataset arrays are suitable for storing column-oriented or tabular data that are often stored as columns in a text file or in a spreadsheet, and can accommodate variables of different types, sizes, units, etc.

Dataset arrays can contain different kinds of variables, including numeric, logical, character, categorical, and cell. However, a dataset array is a different class than the variables that it contains. For example, even a dataset array that contains only variables that are double arrays cannot be operated on as if it were itself a double array. However, using dot subscripting, you can operate on variable in a dataset array as if it were a workspace variable.

You can subscript dataset arrays using parentheses much like ordinary numeric arrays, but in addition to numeric and logical indices, you can use variable and observation names as indices.

**Construction** Use the dataset constructor to create a dataset array from variables in the MATLAB workspace. You can also create a dataset array by reading data from a text or spreadsheet file. You can access each variable in a dataset array much like fields in a structure, using dot subscripting. See the following section for a list of operations available for dataset arrays.

dataset Construct dataset array

**Methods** cat Concatenate dataset arrays

cellstr Create cell array of strings from dataset array

dataset2cell Convert dataset array to cell array

---

dataset2struct	Convert dataset array to structure
datasetfun	Apply function to dataset array variables
disp	Display dataset array
display	Display dataset array
double	Convert dataset variables to double array
end	Last index in indexing expression for dataset array
export	Write dataset array to file
get	Access dataset array properties
horzcat	Horizontal concatenation for dataset arrays
intersect	Set intersection for dataset array observations
isempty	True for empty dataset array
ismember	Dataset array elements that are members of set
ismissing	Find dataset array elements with missing values
join	Merge observations
length	Length of dataset array
ndims	Number of dimensions of dataset array
numel	Number of elements in dataset array
replacedata	Replace dataset variables

# dataset

---

<code>replaceWithMissing</code>	Insert missing data indicators into a dataset array
<code>set</code>	Set and display properties
<code>setdiff</code>	Set difference for dataset array observations
<code>setxor</code>	Set exclusive or for dataset array observations
<code>single</code>	Convert dataset variables to single array
<code>size</code>	Size of dataset array
<code>sortrows</code>	Sort rows of dataset array
<code>stack</code>	Stack data from multiple variables into single variable
<code>subsasgn</code>	Subscripted assignment to dataset array
<code>subsref</code>	Subscripted reference for dataset array
<code>summary</code>	Print summary of dataset array
<code>union</code>	Set union for dataset array observations
<code>unique</code>	Unique observations in dataset array
<code>unstack</code>	Unstack data from single variable into multiple variables
<code>vertcat</code>	Vertical concatenation for dataset arrays

## Properties

A dataset array `D` has properties that store metadata (information about your data). Access or assign to a property using `P =`

`D.Properties.PropName` or `D.Properties.PropName = P`, where `PropName` is one of the following:

<code>Description</code>	String describing data set
<code>DimNames</code>	Two-element cell array of strings giving names of dimensions of data set
<code>ObsNames</code>	Cell array of nonempty, distinct strings giving names of observations in data set
<code>Units</code>	Units of variables in data set
<code>UserData</code>	Variable containing additional information associated with data set
<code>VarDescription</code>	Cell array of strings giving descriptions of variables in data set
<code>VarNames</code>	Cell array giving names of variables in data set

## Copy Semantics

Value. To learn how this affects your use of the class, see [Comparing Handle and Value Classes in the MATLAB Object-Oriented Programming documentation](#).

## Examples

Load a dataset array from a `.mat` file and create some simple subsets:

```
load hospital
h1 = hospital(1:10,:)
h2 = hospital(:, {'LastName' 'Age' 'Sex' 'Smoker'})

% Access and modify metadata
hospital.Properties.Description
hospital.Properties.VarNames{4} = 'Wgt'
```

# dataset

---

```
% Create a new dataset variable from an existing one
hospital.AtRisk = hospital.Smoker | (hospital.Age > 40)

% Use individual variables to explore the data
boxplot(hospital.Age,hospital.Sex)
h3 = hospital(hospital.Age<30,...
    {'LastName' 'Age' 'Sex' 'Smoker'})

% Sort the observations based on two variables
h4 = sortrows(hospital,{'Sex','Age'})
```

## How To

- “Dataset Arrays” on page 2-135

**Purpose**

Construct dataset array

**Syntax**

```
A = dataset(varspec, 'ParamName', Value)  
A = dataset('File', filename, 'ParamName', Value)  
A = dataset('XLSFile', filename, 'ParamName', Value)  
A = dataset('XPTFile', xptfilename, 'ParamName', Value)
```

**Description**

`A = dataset(varspec, 'ParamName', Value)` creates dataset array `A` using the workspace variable input method `varspec` and one or more optional name/value pairs (see Parameter Name/Value Pairs).

The input method `varspec` can be one or more of the following:

- `VAR` — a workspace variable. `dataset` uses the workspace name for the variable name in `A`. To include multiple variables, specify `VAR_1,VAR_2,...,VAR_N`. Variables can be arrays of any size, but all variables must have the same number of rows. `VAR` can also be an expression. In this case, `dataset` creates a default name automatically.
- `{VAR,name}` — a workspace variable, `VAR` and a variable name, `name`. `dataset` uses `name` as the variable name. To include multiple variables and names, specify `{VAR_1,name_1}, {VAR_2,name_2},..., {VAR_N,name_N}`.
- `{VAR,name_1,...,name_m}` — an `m`-columned workspace variable, `VAR`. `dataset` uses the names `name_1, . . . , name_m` as variable names. You must include a name for every column in `VAR`. Each column becomes a separate variable in `A`.

You can combine these input methods to include as many variables and names as needed. Names must be valid, unique MATLAB identifier strings. For example input combinations, see Examples. For optional name/value pairs see Inputs.

To convert numeric arrays, cell arrays, or structure arrays to dataset arrays, you can also use (respectively):

- `mat2dataset`

- `cell2dataset`
- `struct2dataset`

---

**Note** Dataset arrays may contain built-in types or array objects as variables. Array objects must implement each of the following:

- Standard MATLAB parenthesis indexing of the form `var(i,...)`, where `i` is a numeric or logical vector corresponding to rows of the variable
  - A `size` method with a `dim` argument
  - A `vertcat` method
- 

`A = dataset('File', filename, 'ParamName', Value)` creates dataset array `A` from column-oriented data in the text file specified by the string `filename`. Variables in `A` are of type `double` if data in the corresponding column of the file, following the column header, are entirely numeric; otherwise the variables in `A` are cell arrays of strings. `dataset` converts empty fields to either `NaN` (for a numeric variable) or the empty string (for a string-valued variable). `dataset` ignores insignificant white space in the file. You cannot specify both a file and workspace variables as input. See Name/Value Pairs for more information.

`A = dataset('XLSFile', filename, 'ParamName', Value)` creates dataset array `A` from column-oriented data in the Excel spreadsheet specified by the string `filename`. Variables in `A` are of type `double` if data in the corresponding column of the spreadsheet, following the column header, are entirely numeric; otherwise the variables in `A` are cell arrays of strings. See Name/Value Pairs for more information.

`A = dataset('XPTFile', xptfilename, 'ParamName', Value)` creates a dataset array from a SAS® XPORT format file. Variable names from the XPORT format file are preserved. Numeric data types in the XPORT format file are preserved but all other data types are converted to cell

arrays of strings. The XPORT format allows for 28 missing data types. `dataset` represents these in the file by an upper case letter, '.' or '\_'. `dataset` converts all missing data to NaN values in A. However, if you need the specific missing types you can use the `xptread` function to recover the information. See Name/Value Pairs for more information.

## Parameter Name/Value Pairs

Specify one or more of the following name/value pairs when constructing a dataset:

### VarNames

A cell array `{name_1, ..., name_m}` naming the `m` variables in A with the specified variable names. Names must be valid, unique MATLAB identifier strings. The number of names must equal the number of variables in A. You cannot use the `VarNames` parameter if you provide names for individual variables using `{VAR, name}` pairs. To specify `VarNames` when using a file as input, set `ReadVarNames` to `false`.

### ObsNames

A cell array `{name_1, ..., name_n}` naming the `n` observations in A with the specified observation names. The names need not be valid MATLAB identifier strings, but must be unique. The number of names must equal the number of observations (rows) in A. To specify `ObsNames` when using a file as input, set `ReadObsNames` to `false`.

### Name/value pairs available when using text files as inputs:

#### Delimiter

A string indicating the character separating columns in the file. Values are

- '\t' (tab, the default when no format is specified)
- ' ' (space, the default when a format is specified)
- ',' (comma)

# dataset

---

- ';' (semicolon)
- '|' (bar)

## **Format**

A format string, as accepted by `textscan`. `dataset` reads the file using `textscan`, and creates variables in `A` according to the conversion specifiers in the format string. You may also provide any name/value pairs accepted by `textscan`. Using the `Format` parameter is much faster for large files. If `ReadObsNames` is `true`, the format string should include a format specifier for the first column of the file.

## **HeaderLines**

Numeric value indicating the number of lines to skip at the beginning of a file.

**Default:** 0

## **TreatAsEmpty**

Specifies strings to treat as the empty string in a numeric column. Values may be a character string or a cell array of strings. The parameter applies only to numeric columns in the file; `dataset` does not accept numeric literals such as `'-99'`.

## **Name/value pairs available when using text files or Excel spreadsheets as inputs:**

### **ReadVarNames**

A logical value indicating whether (`true`) or not (`false`) to read variable names from the first row of the file. The default is `true`. If `ReadVarNames` is `true`, variable names in the column headers of the file or range (if using an Excel spreadsheet) cannot be empty.

### **ReadObsNames**

A logical value indicating whether (`true`) or not (`false`) to read observation names from the first column of the file or range (if using an Excel spreadsheet). The default is `false`. If `ReadObsNames` and `ReadVarNames` are both `true`, `dataset` saves the header of the first column in the file or range as the name of the first dimension in `A.Properties.DimNames`.

When reading from an XPT format file, the `ReadObsNames` parameter name/value pair determines whether or not to try to use the first variable in the file as observation names. Specify as a logical value (default `false`). If the contents of the first variable are not valid observation names then `dataset` reads the variable into a variable of the dataset array and does not set the observation names.

### **Name/value pairs available when using Excel spreadsheets as input:**

#### **Sheet**

A positive scalar value of type `double` indicating the sheet number, or a quoted string indicating the sheet name.

#### **Range**

A string of the form `'C1:C2'` where `C1` and `C2` are the names of cells at opposing corners of a rectangular region to be read, as for `xlsread`. By default, the rectangular region extends to the right-most column containing data. If the spreadsheet contains empty columns between columns of data, or if the spreadsheet contains figures or other non-tabular information, specify a range that contains only data.

## **Examples**

Create a dataset array from workspace variables, including observation names:

```
load cereal
cereal = dataset(Calories,Protein,Fat,Sodium,Fiber,Carbo,...
    Sugars,'ObsNames',Name)
```

# dataset

---

```
cereal.Properties.VarDescription = Variables(4:10,2);
```

---

Create a dataset array from a single, multi-columned workspace variable, designating variable names for each column:

```
load cities
categories = cellstr(categories);
cities = dataset({ratings, categories{:}}, ...
    'ObsNames', cellstr(names))
```

---

Load data from a text or spreadsheet file

```
patients = dataset('File', 'hospital.dat', ...
    'Delimiter', ',', 'ReadObsNames', true)
patients2 = dataset('XLSFile', 'hospital.xls', ...
    'ReadObsNames', true)
```

---

- 1 Load patient data from the CSV file `hospital.dat` and store the information in a `dataset` array with observation names given by the first column in the data (patient identification):

```
patients = dataset('file', 'hospital.dat', ...
    'format', '%S%S%S%f%f%f%f%f%f%f', ...
    'Delimiter', ',', 'ReadObsNames', true);
```

You can also load the data without specifying a format string. `dataset` will automatically create dataset variables that are either double arrays or cell arrays of strings, depending on the contents of the file:

```
patients = dataset('file', 'hospital.dat', ...
    'delimiter', ',', ...
    'ReadObsNames', true);
```

- 2 Make the {0,1}-valued variable `smoke` nominal, and change the labels to 'No' and 'Yes':

```
patients.smoke = nominal(patients.smoke,{'No','Yes'});
```

- 3 Add new levels to `smoke` as placeholders for more detailed histories of smokers:

```
patients.smoke = addlevels(patients.smoke,...  
                           {'0-5 Years','5-10 Years','LongTerm'});
```

- 4 Assuming the nonsmokers have never smoked, relabel the 'No' level:

```
patients.smoke = setlabels(patients.smoke,'Never','No');
```

- 5 Drop the undifferentiated 'Yes' level from `smoke`:

```
patients.smoke = droplevels(patients.smoke,'Yes');
```

Warning: OLDLEVELS contains categorical levels that were present in A, caused some array elements to have undefined levels.

Note that smokers now have an undefined level.

- 6 Set each smoker to one of the new levels, by observation name:

```
patients.smoke('YPL-320') = '5-10 Years';
```

# dataset.dataset2struct

---

```
size(D)
```

```
ans =
```

```
      8      3
```

The dataset array `D` has 8 observations and 3 variables.

Convert `D` to a structure array.

```
S = dataset2struct(D)
```

```
S =
```

```
8x1 struct array with fields:
```

```
  ObsNames
```

```
  LastName
```

```
  Sex
```

```
  Age
```

The structure is `8x1`, corresponding to the 8 observations in the dataset array. `S` also has the field `ObsNames`, since `D` had observation names.

Display the field data for the first element of `S`.

```
S(1)
```

```
ans =
```

```
  ObsNames: 'YPL-320'
```

```
  LastName: 'SMITH'
```

```
    Sex: [1x1 nominal]
```

```
    Age: 38
```

This information corresponds to the first observation (row) of the dataset array.

## Convert Dataset Array to Scalar Structure

Load sample dataset array.

```
load('hospital')
```

Create a dataset array, D, that has only a subset of the observations and variables.

```
D = hospital(1:8, {'LastName', 'Sex', 'Age'});  
size(D)
```

```
ans =
```

```
      8      3
```

The dataset array D has 8 observations and 3 variables.

Convert D to a scalar structure array.

```
S = dataset2struct(D, 'AsScalar', true)
```

```
S =
```

```
    ObsNames: {8x1 cell}  
    LastName: {8x1 cell}  
           Sex: [8x1 nominal]  
           Age: [8x1 double]
```

The data in the fields of the scalar structure is 8x1, corresponding to the 8 observations in the dataset array. S also has the field `ObsNames`, since D had observation names.

Display the data for the field `LastName`.

```
S.LastName
```

```
ans =
```

# dataset.dataset2struct

---

```
'SMITH'  
'JOHNSON'  
'WILLIAMS'  
'JONES'  
'BROWN'  
'DAVIS'  
'MILLER'  
'WILSON'
```

The structure field `LastName` contains all of the data that was in the original dataset array variable, `LastName`.

## Concepts

- “Dataset Arrays” on page 2-135

**Purpose** Convert dataset array to table

**Syntax** `t = dataset2table(ds)`

**Description** `t = dataset2table(ds)` converts a dataset array to a table.

**Input Arguments** **ds - Input dataset array**  
dataset array

Input dataset array to convert to a table, specified as a dataset array. Each variable in `ds` becomes a variable in the output table `t`.

**Output Arguments** **t - Output table**  
table

Output table, returned as a table. The table can store metadata such as descriptions, variable units, variable names, and row names. For more information, see [Table Properties](#).

**Examples** **Convert a Dataset Array to a Table**

Load the sample data, which contains nutritional information for 77 cereals.

```
load cereal;
```

Create a dataset array containing the calorie, protein, fat, and name data for the first five cereals. Label the variables.

```
Calories = Calories(1:5);  
Protein = Protein(1:5);  
Fat = Fat(1:5);  
Name = Name(1:5);
```

```
cereal = dataset(Calories,Protein,Fat,'ObsNames',Name)  
cereal.Properties.VarDescription = Variables(4:6,2);
```

```
cereal =
```

# dataset2table

---

	Calories	Protein	Fat
100% Bran	70	4	1
100% Natural Bran	120	3	5
All-Bran	70	4	1
All-Bran with Extra Fiber	50	4	0
Almond Delight	110	2	2

Convert the dataset array to a table.

```
t = dataset2table(cereal)
```

```
t =
```

	Calories	Protein	Fat
	-----	-----	---
100% Bran	70	4	1
100% Natural Bran	120	3	5
All-Bran	70	4	1
All-Bran with Extra Fiber	50	4	0
Almond Delight	110	2	2

## Concepts

- “Array Dimensions”
- “Dataset Arrays” on page 2-135

## Purpose

Apply function to dataset array variables

## Syntax

```
b = datasetfun(fun,A)
[b,c,...] = datasetfun(fun,A)
[b,...] = datasetfun(fun,A,...,'UniformOutput',false)
[b,...] = datasetfun(fun,A,...,'DatasetOutput',true)
[b,...] = datasetfun(fun,A,...,'DataVars',vars)
[b,...] = datasetfun(fun,A,...,'ObsNames',obsnames)
[b,...] = datasetfun(fun,A,...,'ErrorHandler',efun)
```

## Description

`b = datasetfun(fun,A)` applies the function specified by `fun` to each variable of the dataset array `A`, and returns the results in the vector `b`. The  $i$ th element of `b` is equal to `fun` applied to the  $i$ th dataset variable of `A`. `fun` is a function handle to a function that takes one input argument and returns a scalar value. `fun` must return values of the same class each time it is called, and `datasetfun` concatenates them into the vector `b`. The outputs from `fun` must be one of the following types: numeric, logical, character, structure, or cell.

To apply functions that return results that are nonscalar or of different sizes and types, use the `'UniformOutput'` or `'DatasetOutput'` parameters described below.

Do not rely on the order in which `datasetfun` computes the elements of `b`, which is unspecified.

If `fun` is bound to more than one built-in function or file, (that is, if it represents a set of overloaded functions), `datasetfun` follows MATLAB dispatching rules in calling the function. (See “Function Precedence Order”.)

`[b,c,...] = datasetfun(fun,A)`, where `fun` is a function handle to a function that returns multiple outputs, returns vectors `b`, `c`, ..., each corresponding to one of the output arguments of `fun`. `datasetfun` calls `fun` each time with as many outputs as there are in the call to `datasetfun`. `fun` may return output arguments having different classes, but the class of each output must be the same each time `fun` is called.

# dataset.datasetfun

---

`[b,...] = datasetfun(fun,A,...,'UniformOutput',false)` allows you to specify a function `fun` that returns values of different sizes or types. `datasetfun` returns a cell array (or multiple cell arrays), where the  $i$ th cell contains the value of `fun` applied to the  $i$ th dataset variable of `A`. Setting `'UniformOutput'` to `true` is equivalent to the default behavior.

`[b,...] = datasetfun(fun,A,...,'DatasetOutput',true)` specifies that the output(s) of `fun` are returned as variables in a dataset array (or multiple dataset arrays). `fun` must return values with the same number of rows each time it is called, but it may return values of any type. The variables in the output dataset array(s) have the same names as the variables in the input. Setting `'DatasetOutput'` to `false` (the default) specifies that the type of the output(s) from `datasetfun` is determined by `'UniformOutput'`.

`[b,...] = datasetfun(fun,A,...,'DataVars',vars)` allows you to apply `fun` only to the dataset variables in `A` specified by `vars`. `vars` is a positive integer, a vector of positive integers, a variable name, a cell array containing one or more variable names, or a logical vector.

`[b,...] = datasetfun(fun,A,...,'ObsNames',obsnames)` specifies observation names for the dataset output when `'DatasetOutput'` is `true`.

`[b,...] = datasetfun(fun,A,...,'ErrorHandler',efun)`, where `efun` is a function handle, specifies the MATLAB function to call if the call to `fun` fails. The error-handling function is called with the following input arguments:

- A structure with the fields `identifier`, `message`, and `index`, respectively containing the identifier of the error that occurred, the text of the error message, and the linear index into the input array(s) at which the error occurred
- The set of input arguments at which the call to the function failed

The error-handling function should either re-throw an error, or return the same number of outputs as `fun`. These outputs are then returned as

the outputs of `datasetfun`. If `'UniformOutput'` is true, the outputs of the error handler must also be scalars of the same type as the outputs of `fun`. For example, the following code could be saved in a file as the error-handling function:

```
function [A,B] = errorFunc(S,varargin)

warning(S.identifier,S.message);
A = NaN;
B = NaN;
```

If an error-handling function is not specified, the error from the call to `fun` is rethrown.

## Examples

Compute statistics on selected variables in the `hospital` dataset array:

```
load hospital

stats = ...
    datasetfun(@mean,hospital,...
               'DataVars',{'Weight','BloodPressure'},...
               'UniformOutput',false)

stats =
    [154]    [1x2 double]
stats{2}
ans =
    122.7800    82.9600
```

Display the blood pressure variable:

```
datasetfun(@hist,hospital,...
           'DataVars','BloodPressure',...
           'UniformOutput',false);
title({'\bf Blood Pressure'})
legend('Systolic','Diastolic','Location','N')
```

## dataset.datasetfun

---

**See Also** `grpstats`

**Purpose**

*D*-optimal augmentation

**Syntax**

```
dCE2 = daugment(dCE,mruns)
[dCE2,X] = daugment(dCE,mruns)
[dCE2,X] = daugment(dCE,mruns,model)
[dCE2,X] = daugment(...,param1,val1,param2,val2,...)
```

**Description**

`dCE2 = daugment(dCE,mruns)` uses a coordinate-exchange algorithm to *D*-optimally add `mruns` runs to an existing experimental design `dCE` for a linear additive model.

`[dCE2,X] = daugment(dCE,mruns)` also returns the design matrix `X` associated with the augmented design.

`[dCE2,X] = daugment(dCE,mruns,model)` uses the linear regression model specified in `model`. `model` is one of the following strings:

- 'linear' — Constant and linear terms. This is the default.
- 'interaction' — Constant, linear, and interaction terms
- 'quadratic' — Constant, linear, interaction, and squared terms
- 'purequadratic' — Constant, linear, and squared terms

The order of the columns of `X` for a full quadratic model with  $n$  terms is:

- 1 The constant term
- 2 The linear terms in order 1, 2, ...,  $n$
- 3 The interaction terms in order (1, 2), (1, 3), ..., (1,  $n$ ), (2, 3), ..., ( $n-1$ ,  $n$ )
- 4 The squared terms in order 1, 2, ...,  $n$

Other models use a subset of these terms, in the same order.

Alternatively, `model` can be a matrix specifying polynomial terms of arbitrary order. In this case, `model` should have one column for each factor and one row for each term in the model. The entries in any row of `model` are powers for the factors in the columns. For example, if a

# daugment

model has factors X1, X2, and X3, then a row [0 1 2] in *model* specifies the term  $(X1.^0) \cdot (X2.^1) \cdot (X3.^2)$ . A row of all zeros in *model* specifies a constant term, which can be omitted.

[dCE2,X] = `daugment(...,param1,val1,param2,val2,...)` specifies additional parameter/value pairs for the design. Valid parameters and their values are listed in the following table.

Parameter	Value
'bounds'	Lower and upper bounds for each factor, specified as a 2-by-nfactors matrix, where nfactors is the number of factors. Alternatively, this value can be a cell array containing nfactors elements, each element specifying the vector of allowable values for the corresponding factor.
'categorical'	Indices of categorical predictors.
'display'	Either 'on' or 'off' to control display of the iteration counter. The default is 'on'.
'excldefun'	Handle to a function that excludes undesirable runs. If the function is <i>f</i> , it must support the syntax $b = f(S)$ , where <i>S</i> is a matrix of treatments with nfactors columns, where nfactors is the number of factors, and <i>b</i> is a vector of Boolean values with the same number of rows as <i>S</i> . <i>b</i> ( <i>i</i> ) is true if the <i>i</i> th row <i>S</i> should be excluded.
'init'	Initial design as an mruns-by-nfactors matrix, where nfactors is the number of factors. The default is a randomly selected set of points.
'levels'	Vector of number of levels for each factor.
'maxiter'	Maximum number of iterations. The default is 10.

Parameter	Value
'options'	<p>The value is a structure that contains options specifying whether to compute multiple tries in parallel, and specifying how to use random numbers when generating the starting points for the tries. Create the options structure with <code>statset</code>. Applicable <code>statset</code> parameters are:</p> <ul style="list-style-type: none"> <li>• 'UseParallel' — If true and if a parpool of the Parallel Computing Toolbox is open, compute in parallel. If the Parallel Computing Toolbox is not installed, or a parpool is not open, computation occurs in serial mode. Default is false, meaning serial computation.</li> <li>• UseSubstreams — Set to true to compute in parallel in a reproducible fashion. Default is false. To compute reproducibly, set Streams to a type allowing substreams: 'mlfg6331_64' or 'mrg32k3a'.</li> <li>• Streams — A RandStream object or cell array of such objects. If you do not specify Streams, daugment uses the default stream or streams. If you choose to specify Streams, use a single object except in the case             <ul style="list-style-type: none"> <li>▪ You have an open Parallel pool</li> <li>▪ UseParallel is true</li> <li>▪ UseSubstreams is false</li> </ul>             In that case, use a cell array the same size as the Parallel pool.           </li> </ul>
'tries'	<p>Number of times to try to generate a design from a new starting point. The algorithm uses random points for each try, except possibly the first. The default is 1.</p>

---

**Note** The `daugment` function augments an existing design using a coordinate-exchange algorithm; the `'start'` parameter of the `candexch` function provides the same functionality using a row-exchange algorithm.

---

## Examples

The following eight-run design is adequate for estimating main effects in a four-factor model:

```
dCEmain = cordexch(4,8)
dCEmain =
    1    -1    -1     1
   -1    -1     1     1
   -1     1    -1     1
    1     1     1    -1
    1     1     1     1
   -1     1    -1    -1
    1    -1    -1    -1
   -1    -1     1    -1
```

To estimate the six interaction terms in the model, augment the design with eight additional runs:

```
dCEinteraction = daugment(dCEmain,8,'interaction')
dCEinteraction =
    1    -1    -1     1
   -1    -1     1     1
   -1     1    -1     1
    1     1     1    -1
    1     1     1     1
   -1     1    -1    -1
    1    -1    -1    -1
   -1    -1     1    -1
   -1     1     1     1
   -1    -1    -1    -1
    1    -1     1    -1
```

1	1	-1	1
-1	1	1	-1
1	1	-1	-1
1	-1	1	1
1	1	1	-1

The augmented design is full factorial, with the original eight runs in the first eight rows.

## See Also

[dcovary](#) | [cordexch](#) | [candexch](#)

**Purpose** *D*-optimal design with fixed covariates

**Syntax**

```
dCV = dcovary(nfactors, fixed)
[dCV, X] = dcovary(nfactors, fixed)
[dCV, X] = dcovary(nfactors, fixed, model)
[dCV, X] = daugment(..., param1, val1, param2, val2, ...)
```

**Description** `dCV = dcovary(nfactors, fixed)` uses a coordinate-exchange algorithm to generate a *D*-optimal design for a linear additive model with `nfactors` factors, subject to the constraint that the model include the fixed covariate factors in `fixed`. The number of runs in the design is the number of rows in `fixed`. The design `dCV` augments `fixed` with initial columns for treatments of the model terms.

`[dCV, X] = dcovary(nfactors, fixed)` also returns the design matrix `X` associated with the design.

`[dCV, X] = dcovary(nfactors, fixed, model)` uses the linear regression model specified in `model`. `model` is one of the following strings:

- 'linear' — Constant and linear terms. This is the default.
- 'interaction' — Constant, linear, and interaction terms
- 'quadratic' — Constant, linear, interaction, and squared terms
- 'purequadratic' — Constant, linear, and squared terms

The order of the columns of `X` for a full quadratic model with  $n$  terms is:

- 1** The constant term
- 2** The linear terms in order 1, 2, ...,  $n$
- 3** The interaction terms in order (1, 2), (1, 3), ..., (1,  $n$ ), (2, 3), ..., ( $n-1$ ,  $n$ )
- 4** The squared terms in order 1, 2, ...,  $n$

Other models use a subset of these terms, in the same order.

Alternatively, *model* can be a matrix specifying polynomial terms of arbitrary order. In this case, *model* should have one column for each factor and one row for each term in the model. The entries in any row of *model* are powers for the factors in the columns. For example, if a model has factors *X1*, *X2*, and *X3*, then a row [0 1 2] in *model* specifies the term  $(X1.^0) \cdot (X2.^1) \cdot (X3.^2)$ . A row of all zeros in *model* specifies a constant term, which can be omitted.

[dCV,X] = daugment(...,param1,val1,param2,val2,...) specifies additional parameter/value pairs for the design. Valid parameters and their values are listed in the following table.

Parameter	Value
'bounds'	Lower and upper bounds for each factor, specified as a 2-by-nfactors matrix. Alternatively, this value can be a cell array containing nfactors elements, each element specifying the vector of allowable values for the corresponding factor.
'categorical'	Indices of categorical predictors.
'display'	Either 'on' or 'off' to control display of the iteration counter. The default is 'on'.
'excludefun'	Handle to a function that excludes undesirable runs. If the function is <i>f</i> , it must support the syntax $b = f(S)$ , where <i>S</i> is a matrix of treatments with nfactors columns and <i>b</i> is a vector of Boolean values with the same number of rows as <i>S</i> . <i>b</i> ( <i>i</i> ) is true if the <i>i</i> th row <i>S</i> should be excluded.
'init'	Initial design as an mruns-by-nfactors matrix. The default is a randomly selected set of points.
'levels'	Vector of number of levels for each factor.
'maxiter'	Maximum number of iterations. The default is 10.

Parameter	Value
'options'	<p>The value is a structure that contains options specifying whether to compute multiple tries in parallel, and specifying how to use random numbers when generating the starting points for the tries. Create the options structure with <code>statset</code>. Applicable <code>statset</code> parameters are:</p> <ul style="list-style-type: none"> <li>• <code>'UseParallel'</code> — If true and if a parpool of the Parallel Computing Toolbox is open, compute in parallel. If the Parallel Computing Toolbox is not installed, or a parpool is not open, computation occurs in serial mode. Default is false, meaning serial computation.</li> <li>• <code>UseSubstreams</code> — Set to true to compute in parallel in a reproducible fashion. Default is false. To compute reproducibly, set <code>Streams</code> to a type allowing substreams: <code>'mlfg6331_64'</code> or <code>'mrg32k3a'</code>.</li> <li>• <code>Streams</code> — A <code>RandStream</code> object or cell array of such objects. If you do not specify <code>Streams</code>, <code>dcovary</code> uses the default stream or streams. If you choose to specify <code>Streams</code>, use a single object except in the case <ul style="list-style-type: none"> <li>▪ You have an open Parallel pool</li> <li>▪ <code>UseParallel</code> is true</li> <li>▪ <code>UseSubstreams</code> is false</li> </ul> In that case, use a cell array the same size as the Parallel pool.</li> </ul>
'tries'	<p>Number of times to try to generate a design from a new starting point. The algorithm uses random points for each try, except possibly the first. The default is 1.</p>

## Examples

### Example 1

Suppose you want a design to estimate the parameters in a three-factor linear additive model, with eight runs that necessarily occur at different times. If the process experiences temporal linear drift, you may want to include the run time as a variable in the model. Produce the design as follows:

```
time = linspace(-1,1,8)';
[dCV1,X] = dcovary(3,time,'linear')
dCV1 =
-1.0000    1.0000    1.0000   -1.0000
 1.0000   -1.0000   -1.0000   -0.7143
-1.0000   -1.0000   -1.0000   -0.4286
 1.0000   -1.0000    1.0000   -0.1429
 1.0000    1.0000   -1.0000    0.1429
-1.0000    1.0000   -1.0000    0.4286
 1.0000    1.0000    1.0000    0.7143
-1.0000   -1.0000    1.0000    1.0000
X =
 1.0000   -1.0000    1.0000    1.0000   -1.0000
 1.0000    1.0000   -1.0000   -1.0000   -0.7143
 1.0000   -1.0000   -1.0000   -1.0000   -0.4286
 1.0000    1.0000   -1.0000    1.0000   -0.1429
 1.0000    1.0000    1.0000   -1.0000    0.1429
 1.0000   -1.0000    1.0000   -1.0000    0.4286
 1.0000    1.0000    1.0000    1.0000    0.7143
 1.0000   -1.0000   -1.0000    1.0000    1.0000
```

The column vector `time` is a fixed factor, normalized to values between  $\pm 1$ . The number of rows in the fixed factor specifies the number of runs in the design. The resulting design `dCV` gives factor settings for the three controlled model factors at each time.

### Example 2

The following example uses the `dummyvar` function to block an eight-run experiment into 4 blocks of size 2 for estimating a linear additive model with two factors:

# dcovary

---

```
fixed = dummyvar([1 1 2 2 3 3 4 4]);
dCV2 = dcovary(2, fixed(:, 1:3), 'linear')
dCV2 =
     1     1     1     0     0
    -1    -1     1     0     0
    -1     1     0     1     0
     1    -1     0     1     0
     1     1     0     0     1
    -1    -1     0     0     1
    -1     1     0     0     0
     1    -1     0     0     0
```

The first two columns of dCV2 contain the settings for the two factors; the last three columns are dummy variable codings for the four blocks.

## See Also

[daugment](#) | [cordexch](#) | [dummyvar](#)

# TreeBagger.DefaultYfit property

---

## Purpose

Default value returned by `predict` and `oobPredict`

## Description

The `DefaultYfit` property controls what predicted value `TreeBagger` returns when no prediction is possible, for example when the `oobPredict` method needs to predict for an observation that is in-bag for all trees in the ensemble.

For classification, you can set this property to either `' '` or `'MostPopular'`. If you choose `'MostPopular'` (default), the property value becomes the name of the most probable class in the training data.

For regression, you can set this property to any numeric scalar. The default is the mean of the response for the training data.

If you set this property to `' '` for classification or `NaN` for regression, `TreeBagger` excludes the in-bag observations from computation of the out-of-bag error and margin.

## See Also

`oobPredict` | `Predict` | `OOBIndices`

# grandstream.delete

---

**Purpose** Delete handle object

**Syntax** `delete(h)`

**Description** `delete(h)` deletes the handle object `h`, where `h` is a scalar handle. The `delete` method deletes a handle object but does not clear the handle from the workspace. A deleted handle is no longer valid.

**See Also** `clear` | `isvalid` | `grandstream`

# TreeBagger.DeltaCritDecisionSplit property

---

- Purpose** Split criterion contributions for each predictor
- Description** The DeltaCritDecisionSplit property is a numeric array of size 1-by-Nvars of changes in the split criterion summed over splits on each variable, averaged across the entire ensemble of grown trees.
- See Also** `classregtree.varimportance`

# dendrogram

---

## Purpose

Dendrogram plot

## Syntax

```
dendrogram(tree)
dendrogram(tree,Name,Value)
```

```
dendrogram(tree,P)
dendrogram(tree,P,Name,Value)
```

```
H = dendrogram( ___ )
[H,T,outperm] = dendrogram( ___ )
```

## Description

`dendrogram(tree)` generates a dendrogram plot of the hierarchical binary cluster tree. A dendrogram consists of many *U*-shaped lines that connect data points in a hierarchical tree. The height of each *U* represents the distance between the two data points being connected.

- If there are 30 or fewer data points in the original data set, then each leaf in the dendrogram corresponds to one data point.
- If there are more than 30 data points, then `dendrogram` collapses lower branches so that there are 30 leaf nodes. As a result, some leaves in the plot correspond to more than one data point.

`dendrogram(tree,Name,Value)` uses additional options specified by one or more name-value pair arguments.

`dendrogram(tree,P)` generates a dendrogram plot with no more than *P* leaf nodes. If there are more than *P* data points in the original data set, then `dendrogram` collapses the lower branches of the tree. As a result, some leaves in the plot correspond to more than one data point.

`dendrogram(tree,P,Name,Value)` uses additional options specified by one or more name-value pair arguments.

`H = dendrogram( ___ )` generates a dendrogram plot and returns a vector of line handles. You can use any of the input arguments from the previous syntaxes.

`[H,T,outperm] = dendrogram( ___ )` also returns a vector containing the leaf node number for each object in the original data set, `T`, and a vector giving the order of the node labels of the leaves as shown in the dendrogram, `outperm`.

- It is useful to return `T` when the number of leaf nodes, `P`, is less than the total number of data points, so that some leaf nodes in the display correspond to multiple data points.
- The order of the node labels given in `outperm` is from left to right for a horizontal dendrogram, and from bottom to top for a vertical dendrogram.

## Input Arguments

### **tree - Hierarchical binary cluster tree**

matrix returned by `linkage`

Hierarchical binary cluster tree, specified as an  $(M - 1)$ -by-3 matrix that you generate using `linkage`, where  $M$  is the number of data points in the original data set.

### **P - Maximum number of leaf nodes**

30 (default) | positive integer value

Maximum number of leaf nodes to include in the dendrogram plot, specified as a positive integer value.

- If there are `P` or fewer data points in the original data set, then each leaf in the dendrogram corresponds to one data point.
- If there are more than `P` data points, then `dendrogram` collapses lower branches so that there are `P` leaf nodes. As a result, some leaves in the plot correspond to more than one data point.

If you do not specify `P`, then `dendrogram` uses 30 as the maximum number of leaf nodes. To display the complete tree, set `P` equal to 0.

# dendrogram

---

## Data Types

single | double

## Name-Value Pair Arguments

Specify optional comma-separated pairs of `Name`, `Value` arguments. `Name` is the argument name and `Value` is the corresponding value. `Name` must appear inside single quotes ( ' '). You can specify several name and value pair arguments in any order as `Name1,Value1,...,NameN,ValueN`.

**Example:** `'Orientation','left','Reorder',myOrder`, specifies a vertical dendrogram with leaves in the order specified by `myOrder`.

## 'Reorder' - Order of leaf nodes

vector

Order of leaf nodes in the dendrogram plot, specified as the comma-separated pair consisting of `'Reorder'` and a vector giving the order of nodes in the complete tree. The order vector must be a permutation of the vector `1:M`, where  $M$  is the number of data points in the original data set. Specify the order from left to right for horizontal dendrograms, and from bottom to top for vertical dendrograms.

If  $M$  is greater than the number of leaf nodes in the dendrogram plot, `P` (by default, `P` is 30), then you can only specify a permutation vector that does not separate the groups of leaves that correspond to collapsed nodes.

**Example:**

## Data Types

single | double

## 'CheckCrossing' - Indicator for whether to check for crossing branches

true (default) | false

Indicator for whether to check for crossing branches in the dendrogram plot, specified as the comma-separated pair consisting of

'CheckCrossing' and either true or false. This option is only useful when you specify a value for Reorder.

When CheckCrossing has the value true, dendrogram issues a warning if the order of the leaf nodes causes crossing branches in the plot. If the dendrogram plot does not show a complete tree (because the number of data points in the original data set is greater than P), dendrogram only issues a warning when the order of the leaf nodes causes branch to cross in the dendrogram as shown in the plot. That is, there is no warning if the order causes crossing branches in the complete tree but not in the dendrogram as shown in the plot.

## Data Types

logical

## 'ColorThreshold' - Threshold for unique colors

'default' | scalar value in the range (0,max(tree(:,3)))

Threshold for unique colors in the dendrogram plot, specified as the comma-separated pair consisting of 'ColorThreshold' and either the string 'default' or a scalar value in the range (0,max(tree(:,3))). If ColorThreshold has the value  $T$ , then dendrogram assigns a unique color to each group of nodes in the dendrogram whose linkage is less than  $T$ .

- If ColorThreshold has the value 'default', then the threshold,  $T$ , is 70% of the maximum linkage,  $0.7*\max(\text{tree}(:,3))$ .
- If you do not specify a value for ColorThreshold, or if you specify a threshold outside the range (0,max(tree(:,3))), then dendrogram uses only one color for the dendrogram plot.

## 'Orientation' - Orientation of dendrogram

'top' (default) | 'bottom' | 'left' | 'right'

Orientation of the dendrogram in the figure window, specified as the comma-separated pair consisting of 'Orientation' and one of these strings:

# dendrogram

---

'top'	Top to bottom
'bottom'	Bottom to top
'left'	Left to right
'right'	Right to left

## Data Types

char

## 'Labels' - Label for each data point

character array | cell array of strings

Label for each data point in the original data set, specified as the comma-separated pair consisting of 'Labels' and a character array or cell array of strings. `dendrogram` labels any leaves in the dendrogram plot containing a single data point with that data point's label.

## Data Types

char | cell

## Output Arguments

### H - Handles to lines

vector

Handles to lines in the dendrogram plot, returned as a vector.

### T - Leaf node numbers

column vector

Leaf node numbers for each data point in the original data set, returned as a column vector of length  $M$ , where  $M$  is the number of data points in the original data set.

When there are fewer than  $P$  data points in the original data ( $P$  is 30, by default), all data points are displayed in the dendrogram, with each node containing a single data point. In this case,  $T$  is the identity map,  $T = (1:M)'$ .

$T$  is useful when  $P$  is less than the total number of data points. That is, when some leaf nodes in the dendrogram display correspond to multiple

data points. For example, to find out which data points are contained in leaf node  $k$  of the dendrogram plot, use `find(T==k)`.

## **outperm - Permutation of node labels**

vector

Permutation of the node labels of the leaves of the dendrogram as shown in the plot, returned as a row vector. `outperm` gives the order from left to right for a horizontal dendrogram, and from bottom to top for a vertical dendrogram. If there are  $P$  leaves in the dendrogram plot, `outperm` is a permutation of the vector `1:P`.

## **Examples**

### **Plot Dendrogram**

Generate sample data.

```
rng('default') % For reproducibility
X = rand(10,3);
```

Create a hierarchical binary cluster tree using `linkage`. Then, plot the dendrogram using the default options.

```
tree = linkage(X,'average');
```

```
figure()
dendrogram(tree)
```

# dendrogram

---

## Specify Dendrogram Leaf Node Order

Generate sample data.

```
rng('default') % For reproducibility  
X = rand(10,3);
```

Create a hierarchical binary cluster tree using linkage.

```
tree = linkage(X,'average');
```

```
D = pdist(X);  
leafOrder = optimalleaforder(tree,D)
```

```
leafOrder =
```

```
3 7 6 1 4 9 5 8 10 2
```

Plot the dendrogram using an optimal leaf order.

```
figure()  
dendrogram(tree, 'Reorder', leafOrder)
```

The order of the leaf nodes in the dendrogram plot corresponds—from left to right—to the permutation in `leafOrder`.

## Specify Number of Nodes in Dendrogram Plot

Generate sample data.

```
rng('default') % For reproducibility  
X = rand(100,2);
```

# dendrogram

---

There are 100 data points in the original data set, X.

Create a hierarchical binary cluster tree using `linkage`. Then, plot the dendrogram for the complete tree (100 leaf nodes) by setting the input argument `P` equal to 0.

```
tree = linkage(X, 'average');
```

```
figure()  
dendrogram(tree, 0)
```

Now, plot the dendrogram with only 25 leaf nodes. Return the mapping of the original data points to the leaf nodes shown in the plot.

```
figure()  
[~,T] = dendrogram(tree, 25);
```

List the original data points that are in leaf node 7 of the dendrogram plot.

```
find(T==7)
```

```
ans =
```

```
7  
33  
60  
70  
74  
76  
86
```

# dendrogram

---

## Change Dendrogram Orientation and Line Width

Generate sample data.

```
rng('default') % For reproducibility  
X = rand(10,3);
```

Create a hierarchical binary cluster tree using linkage. Then, plot the dendrogram with a vertical orientation, using the default color threshold. Return handles to the lines so you can change the dendrogram line widths.

```
tree = linkage(X,'average');  
  
figure()  
H = dendrogram(tree,'Orientation','left','ColorThreshold','default');  
set(H,'LineWidth',2)
```

# GeneralizedLinearModel.devianceTest

---

chi2Stat

number of parameters in the corresponding model.

F statistic or Chi-squared statistic, depending on whether the dispersion is estimated (F statistic) or not (Chi-squared statistic)

- *Chi-squared statistic* is the difference between the deviance of the constant model and the deviance of the full model.

- *F statistic* is the difference between the deviance of the constant model and the deviance of the full model, divided by the estimated dispersion.

pValue

*p*-value associated with the test. It is the Chi-squared statistic with (number of coefficients in the model minus one) degrees of freedom, or *F* statistic with (number of coefficients in the model minus one) numerator degrees of freedom, and DFE denominator degrees of freedom.

## Definitions

### Deviance

Deviance of a model  $M_1$  is twice the difference between the loglikelihood of that model and the saturated model,  $M_S$ . The saturated model is the model with the maximum number of parameters that can be estimated.

For example, if there are  $n$  observations  $y_i, i = 1, 2, \dots, n$ , with potentially different values for  $X_i^T\beta$ , then you can define a saturated model with  $n$  parameters. Let  $L(b,y)$  denote the maximum value of the likelihood function for a model. Then the deviance of model  $M_1$  is

$$-2(\log L(b_1, y) - \log L(b_S, y)),$$

where  $b_1$  are the estimated parameters for model  $M_1$  and  $b_S$  are the estimated parameters for the saturated model. The deviance has a chi-square distribution with  $n - p$  degrees of freedom, where  $n$  is the number of parameters in the saturated model and  $p$  is the number of parameters in model  $M_1$ .

If  $M_1$  and  $M_2$  are two different generalized linear models, then the fit of the models can be assessed by comparing the deviances  $D_1$  and  $D_2$  of these models. The difference of the deviances is

$$\begin{aligned} D = D_2 - D_1 &= -2(\log L(b_2, y) - \log L(b_S, y)) + 2(\log L(b_1, y) - \log L(b_S, y)) \\ &= -2(\log L(b_2, y) - \log L(b_1, y)). \end{aligned}$$

Asymptotically, this difference has a chi-square distribution with degrees of freedom  $v$  equal to the number of parameters that are estimated in one model but fixed (typically at 0) in the other. That is, it is equal to the difference in the number of parameters estimated in  $M_1$  and  $M_2$ . You can get the  $p$ -value for this test using `1 - chi2cdf(D, V)`, where  $D = D_2 - D_1$ .

## Examples

### Deviance Test

Perform a deviance test on a generalized linear model.

Construct a generalized linear model.

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:, [1 4 5]) * [.4; .2; .3]);
y = poissrnd(mu);
```

# GeneralizedLinearModel.devianceTest

---

```
mdl = fitglm(X,y,'linear','Distribution','poisson');
```

Test whether the model differs from a constant in a statistically significant way.

```
tbl = devianceTest(mdl)
```

```
tbl =
```

	Deviance	DFE	chi2Stat	pValue
log(y) ~ 1	128.58	99		
log(y) ~ 1 + x1 + x2 + x3 + x4 + x5	83.726	94	44.858	1.5502e-08

The  $p$ -value is very small, indicating that the model significantly differs from a constant.

## Purpose

Fixed- and random-effects design matrices

## Syntax

```
D = designMatrix(lme)
```

```
D = designMatrix(lme, 'Fixed')
```

```
D = designMatrix(lme, 'Random')
```

```
Dsub = designMatrix(lme, 'Random', gnumbers)
```

```
[Dsub, gnames] = designMatrix(lme, 'Random', gnumbers)
```

## Description

`D = designMatrix(lme)` or `D = designMatrix(lme, 'Fixed')` returns the fixed-effects design matrix for the linear mixed-effects model `lme`.

`D = designMatrix(lme, 'Random')` returns the random-effects design matrix for the linear mixed-effects model `lme`.

`Dsub = designMatrix(lme, 'Random', gnumbers)` returns a subset of the random-effects design matrix for the linear mixed-effects model `lme` corresponding to the grouping variables indicated by the integers in `gnumbers`.

`[Dsub, gnames] = designMatrix(lme, 'Random', gnumbers)` also returns the grouping variable names corresponding to the integers in `gnumbers`.

## Input Arguments

### **lme - Linear mixed-effects model**

LinearMixedModel object

Linear mixed-effects model, returned as a LinearMixedModel object.

For properties and methods of this object, see LinearMixedModel.

### **gnumbers - Grouping variable numbers**

integer array

# LinearMixedModel.designMatrix

---

Grouping variable numbers, specified as an integer array, where  $R$  is the length of the cell array that contains the grouping variables for the linear mixed-effects model `lme`.

For example, you can specify the grouping variables  $g_1$ ,  $g_3$ , and  $g_r$  as follows.

**Example:** `[1,3,r]`

## Data Types

`double` | `single`

## Output Arguments

### D - Design matrix

`matrix`

Design matrix of a linear mixed-effects model `lme` returned as one of the following:

- Fixed-effects design matrix —  $n$ -by- $p$  matrix consisting of the fixed-effects design of `lme`, where  $n$  is the number of observations and  $p$  is the number of fixed-effects terms.
- Random-effects design matrix —  $n$ -by- $k$  matrix, consisting of the random-effects design matrix of `lme`. Here,  $k$  is equal to `length(B)`, where **B** is the random-effects coefficients vector of linear mixed-effects model `lme`.

If `lme` has  $R$  grouping variables  $g_1, g_2, \dots, g_R$ , with levels  $m_1, m_2, \dots, m_R$ , respectively, and if  $q_1, q_2, \dots, q_R$  are the lengths of the random-effects vectors that are associated with  $g_1, g_2, \dots, g_R$ , respectively, then **B** is a column vector of length  $q_1 * m_1 + q_2 * m_2 + \dots + q_R * m_R$ .

**B** is made by concatenating the best linear unbiased predictors of random-effects vectors corresponding to each level of each grouping variable as `[g1_level1; g1_level2; ...; g1_level_m1; g2_level1; g2_level2; ...; g2_level_m2; ...; gR_level1; gR_level2; ...; gR_level_mR]`'.

## Data Types

single | double

## Dsub - Submatrix of random-effects design matrix

matrix

Submatrix of random-effects design matrix corresponding to the grouping variables indicated by the integers in `gnumbers`, returned as an  $n$ -by- $k$  matrix, where  $k$  is length of the column vector `Bsub`.

`Bsub` contains the concatenated best linear unbiased predictors (BLUPs) of random-effects vectors, corresponding to each level of the grouping variables, specified by `gnumbers`.

If, for example, `gnumbers` is `[1,3,r]`, this corresponds to the grouping variables  $g_1$ ,  $g_3$ , and  $g_r$ . Then, `Bsub` contains the concatenated BLUPs of random-effects vectors corresponding to each level of the grouping variables  $g_1$ ,  $g_3$ , and  $g_r$ , such as

$$[g_{1,level_1}; g_{1,level_2}; \dots; g_{1,level_{m_1}}; g_{3,level_1}; g_{3,level_2}; \dots; g_{3,level_{m_3}}; g_{r,level_1}; g_{r,level_2}; \dots; g_{r,level_{m_r}}]'$$

Thus, `Dsub*Bsub` represents the contribution of all random effects corresponding to grouping variables  $g_1$ ,  $g_3$ , and  $g_r$  to the response of `lme`.

If `gnumbers` is empty, then `Dsub` is the full random-effects design matrix.

## Data Types

single | double

## gnames - Names of grouping variables

$k$ -by-1 cell array

Names of grouping variables corresponding to the integers in `gnumbers` if the design type is 'Random', returned as a  $k$ -by-1 cell array. If the design type is 'Fixed', then `gnames` is an empty matrix `[]`.

# LinearMixedModel.designMatrix

## Data Types

cell

## Examples

### Display Fixed- and Random-Effects Design Matrices

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load shift
```

The data shows the deviations from the target quality characteristic measured from the products that 5 operators manufacture during three different shifts, morning, evening, and night. This is a randomized block design, where the operators are the blocks. The experiment is designed to study the impact of the time of shift on the performance. The performance measure is the deviation of the quality characteristics from the target value. This is simulated data.

Shift and Operator are nominal variables.

```
shift.Shift = nominal(shift.Shift);
shift.Operator = nominal(shift.Operator);
```

Fit a linear mixed-effects model with a random intercept grouped by operator to assess if performance significantly differs according to the time of the shift.

```
lme = fitlme(shift, 'QCDev ~ Shift + (1|Operator)');
```

Display the fixed-effects design matrix.

```
designMatrix(lme)
```

```
ans =
```

```
1      1      0
1      0      0
1      0      1
1      1      0
1      0      0
1      0      1
1      1      0
1      0      0
1      0      1
1      1      0
1      0      0
1      0      1
1      1      0
1      0      0
1      0      1
1      1      0
1      0      0
1      0      1
```

The column of 1s represents the constant term in the model. `fitlme` takes the evening shift as the reference group and creates two dummy variables to represent the morning and night shifts, respectively.

Display the random-effects design matrix.

```
designMatrix(lme, 'random')
```

```
ans =
```

```
(1,1)      1
(2,1)      1
(3,1)      1
(4,2)      1
(5,2)      1
(6,2)      1
(7,3)      1
(8,3)      1
(9,3)      1
(10,4)     1
(11,4)     1
(12,4)     1
```

# LinearMixedModel.designMatrix

---

```
(13,5)      1
(14,5)      1
(15,5)      1
```

The first number,  $i$ , in the  $(i,j)$  indices corresponds to the observation number, and  $j$  corresponds to the level of the grouping variable, Operator, i.e., the operator number.

Show the full display of the random-effects design matrix.

```
full(designMatrix(lme, 'random'))
```

```
ans =
```

```
1   0   0   0   0
1   0   0   0   0
1   0   0   0   0
0   1   0   0   0
0   1   0   0   0
0   1   0   0   0
0   0   1   0   0
0   0   1   0   0
0   0   1   0   0
0   0   0   1   0
0   0   0   1   0
0   0   0   1   0
0   0   0   0   1
0   0   0   0   1
0   0   0   0   1
```

Each column corresponds to a level of the grouping variable, Operator.

## Random-Effects Design Matrix of Multiple Grouping Variables

Navigate to a folder containing sample data.

```
cd(matlabroot)
cd('help/toolbox/stats/examples')
```

Load the sample data.

```
load fertilizer
