:=, _assign

Assign variables

Syntax

```
x := value
```

```
_assign(x, value)
```

```
 [x1, x2, …] := [value1, value2, …]
```

```
_assign([x1, x2, …], [value1, value2, …])
```

```
 f( X1, X2, … ) := value
```

```
_assign(f(X1, X2, …), value)
```

Description

`x := value` assigns the variable `x` a `value`.

`[x1, x2, ...] := [value1, value2, ...]` assigns the variables `x1`, `x2` etc. the corresponding values `value1`, `value2` etc.

`f(X1, X2, ...) := value` adds an entry to the remember table of the procedure `f`.

`_assign(x, value)` is equivalent to `x := value`.

`_assign([x1, x2, ...], [value1, value2, ...])` is equivalent to `[x1, x2, ...] := [value1, value2, ...]`. Both lists must have the same number of elements.

Note: If `x` is neither a list, nor a table, nor an array, nor an hfarray, nor a matrix, nor an element of a domain with a slot `"set_index"`, then an indexed assignment such as `x[i] := value` implicitly turns the identifier `x` into a table with a single entry `(i = value)`. See “Example 2” on page 1-15.

The assignment `f(X1, X2, ...) := value` adds an entry to the remember table of the procedure `f`.

Note: If `f` is neither procedure nor a function environment, then `f` is implicitly turned into a (trivial) procedure with a single entry `(X1, X2, ...) = value` in its remember table. See "Example 4" on page 1-17.

Identifiers on the left hand side of an assignment are not evaluated (use `evalassign` if this is not desired). I.e., in `x := value`, the previous value of `x`, if any, is deleted and replaced by the new value. Note, however, that the index of an indexed identifier is evaluated. I.e., in `x[i] := value`, the index `i` is replaced by its current value before the corresponding entry of `x` is assigned the value. See "Example 5" on page 1-18.

Examples

Example 1

The assignment operator `:=` can be applied to a single identifier as well as to a list of identifiers:

```
x := 42:
[x1, x2, x3] := [43, 44, 45]:
x, x1, x2, x3
```

```
42, 43, 44, 45
```

In case of lists, all variables of the left-hand side are assigned their values *simultaneously*:

```
[x1, x2] := [3, 4]:
[x1, x2] := [x2, x1]:
x1, x2
```

```
4, 3
```

The functional equivalent of the assign operator `:=` is the function `_assign`:

```
_assign(x, 13): _assign([x1, x2], [14, 15]): x, x1, x2
```

$$13,\ 14,\ 15$$

Assigned values are deleted via the keyword `delete`:

```
delete x, x1, x2:
x, x1, x2
```

$$x,\ x1,\ x2$$

Example 2

Assigning a value to an indexed identifier, a corresponding table (`table`, `DOM_TABLE`) is generated implicitly, if the identifier was not assigned a list, a table, an array, an hfarray, or a matrix before:

```
delete x:
x[1] := 7:
x
```

1	7

If `x` is a list, a table, an array, an hfarray, or a matrix, then an indexed assignment adds a further entry or changes an existing entry:

```
x[abc] := 8:
x
```

1	7
abc	8

```
x := [a, b, c, d]:
x[3] := new:
x
```

$$[a,\ b,\ \text{new},\ d]$$

```
x := array(1..2, 1..2):
```

```
x[2, 1] := value:
x
```

$$\begin{pmatrix} \text{NIL} & \text{NIL} \\ \text{value} & \text{NIL} \end{pmatrix}$$

```
delete x:
```

Example 3

For efficient use of indexed assignments (see “Example 2” on page 1-15 for an overview), programmers should note the following rules:

MuPAD® uses *reference counting* and thereby allows multiple references to identical data structures. Changing one of these logically distinct values means that the internal structure must be copied, which takes time:

```
n := 10^4:
L := [0$n]:
time((for i from 1 to n do
        L_old := L:
        L[i] := i:
      end_for))
```

```
19310
```

Compare this with the situation where only one variable or identifier refers to the internal structure:

```
n := 10^4:
L := [0$n]:
time((for i from 1 to n do
        L[i] := i:
      end_for))
```

```
60
```

For lists, there is another situation that requires copying the list structure: Changing the length of the list. The most frequently encountered example is appending to a list with `_concat` (`.`) or `append`:

```
n := 10^4:
L := []:
time((for i from 1 to n do
        L := L . [i]:
      end_for))
```

```
     13180
```

A loop written as above takes running time roughly proportional to the *square of the number of elements*. It is advisable to rewrite such loops. In the case where you know the length of the final list in advance, you can construct such a list and replace its entries inside the loop:

```
n := 10^4:
L := [NIL$n]:
time((for i from 1 to n do
        L[i] := i:
      end_for))
```

```
     60
```

If you don't know the final length, you can gain linear running time by first collecting the elements into a table:

```
n := 10^4:
T := table()
time((for i from 1 to n do
        T[nops(T)+1] := i;
      end_for;
      L := [T[i] $ i = 1..nops(T)]))
```

```
     190
```

Example 4

Consider a simple procedure:

```
f := x -> sin(x)/x:
f(0)
```

```
Error: Division by zero.
  Evaluating: f
```

The following assignment adds an entry to the remember table:

```
f(0) := 1:
f(0)
```

$$1$$

If `f` does not evaluate to a function, then a trivial procedure with a remember table is created implicitly:

```
delete f:
f(x) := x^2:
expose(f)
```

```
proc()
  name f;
  option remember;
begin
  procname(args())
end_proc
```

Note that the remember table only provides a result for the input `x`:

```
f(x), f(1.0*x), f(y)
```

$$x^2,\ f(1.0\,x),\ f(y)$$

```
delete f:
```

Example 5

The left hand side of an assignment is not evaluated. In the following, `x := 3` assigns a new value to `x`, not to `y`:

```
x := y:
x := 3:
x, y
```

$$3, y$$

Consequently, the following is not a multiple assignment to the identifiers in the list, but a single assignment to the list L:

```
L := [x1, x2]:
L := [21, 22]:
L, x1, x2
```

$$[21, 22], x1, x2$$

However, indices are evaluated in indexed assignments:

```
i := 2:
x[i] := value:
x
```

2	value

```
for i from 1 to 3 do
  x[i] := i^2;
end_for:
x
```

1	1
2	4
3	9

```
delete x, L, i:
```

Example 6

Since an assignment has a return value (the assigned value), the following command assigns values to several identifiers simultaneously:

```
a := b := c := 42:
a, b, c
```

$$42, 42, 42$$

For syntactical reasons, the inner assignment has to be enclosed by additional brackets in the following command:

```
a := sin((b := 3)):
a, b
```

$$\sin(3),\ 3$$

```
delete a, b, c:
```

Parameters

`x, x1, x2, …`

Identifiers or indexed identifiers

`value, value1, value2, …`

Arbitrary MuPAD objects

`f`

A procedure or a function environment

`X1, X2, …`

Arbitrary MuPAD objects

Return Values

`value` or `[value1, value2, ...]`, respectively.

See Also

MuPAD Functions

`anames` | `assign` | `assignElements` | `delete` | `evalassign`

., _concat

Concatenate objects

Syntax

`object`$_1$`. object`$_2$

`_concat(object`$_1$`, object`$_2$`, …)`

Description

`object_1.object_2` concatenates two objects.

`_concat( object`$_1$`, object`$_2$`, ...)` concatenates an arbitrary number of objects.

`_concat( object`$_1$`, object`$_2$`)` is equivalent to `object`$_1$`. object`$_2$. The function call `_concat( object`$_1$`, object`$_2$`, object`$_3$`, ...)` is equivalent to `(( object`$_1$`. object`$_2$`). object`$_3$`). ...`. `_concat()` returns the void object of type `DOM_NULL`.

The following combinations are possible:

object$_1$	**object$_2$**	**`object`$_1$`. object`$_2$**
string	string	string
string	identifier	string
string	integer	string
string	expression	string
identifier	string	identifier
identifier	identifier	identifier
identifier	integer	identifier
identifier	expression	identifier
list	list	list

E.g., `x.1` creates the identifier `x1`.

Note that the objects to be concatenated are evaluated before concatenation. Thus, if `x := y`, `i := 1`, the concatenation `x.i` produces the identifier `y1`. However, the resulting identifier `y1` is *not* fully evaluated. Cf. “Example 2” on page 1-22.

Examples

Example 1

We demonstrate all possible combinations of types that can be concatenated. Strings are produced if the first object is a string:

```
"x"."1", "x".y, "x".1, "x".f(a)
```

```
"x1", "xy", "x1", "xf(a)"
```

Identifiers are produced if the first object is an identifier:

```
x."1", x.y , x.1, x.f(a)
```

```
x1, xy, x1, xf(a)
```

The concatenation operator `.` also serves for concatenating lists:

```
[1, 2] . [3, 4]
```

```
[1, 2, 3, 4]
```

```
L := []: for i from 1 to 10 do L := L . [x.i] end_for: L
```

```
[x1, x2, x3, x4, x5, x6, x7, x8, x9, x10]
```

```
delete L:
```

Example 2

We demonstrate the evaluation strategy of concatenation. Before concatenation, the objects are evaluated:

```
x := "Val": i := ue: x.i
```

```
"Value"
```

```
ue := 1:  x.i
```

```
"Val1"
```

An identifier produced via concatenation is not fully evaluated:

```
delete x: x1 := 17: x.1, eval(x.1)
```

```
x1, 17
```

The `.` operator can be used to create variables dynamically. They can be assigned values immediately:

```
delete x: for i from 1 to 5 do x.i := i^2 end_for:
```

Again, the result of the concatenation is not fully evaluated:

```
x.i $ i= 1..5
```

```
x1, x2, x3, x4, x5
```

```
eval(%)
```

```
1, 4, 9, 16, 25
```

```
delete i, ue: (delete x.i) $ i = 1..5:
```

Example 3

The function `_concat` can be used to concatenate an arbitrary number of objects:

```
_concat("an", " ", "ex", "am", "ple")
```

```
"an example"
```

```
_concat("0", " ".i $ i = 1..15)
```

```
"0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15"
```

```
_concat([], [x.i] $ i = 1..10)
```

```
[x1, x2, x3, x4, x5, x6, x7, x8, x9, x10]
```

Parameters

$object_1$

A character string, an identifier, or a list

$object_2$, …

A character string, an identifier, an integer, a list, or an expression

Return Values

Object of the same type as $object_1$.

Overloaded By

object_1, object_2

See Also

MuPAD Functions
`@` | `append`

.., _range

Range operator

Syntax

```
l .. r
```

```
_range(l, r)
```

Description

`l..r` defines a "range" with the left bound `l` and the right bound `r`.

A range is a technical construct that is used to specify ranges of numbers when calling various system functions such as `int`, `array`, `op`, or the sequence operator `$`. Usually, `l..r` represents a real interval (e.g., `int(f(x), x = l..r)`), or the sequence of integers from `l` to `r`.

`_range(l, r)` is equivalent to `l..r`.

To create and operate on intervals in a mathematical sense, use the data type `Dom::Interval`.

Examples

Example 1

A range can be defined with the `..` operator as well as with a call to the function `_range`:

```
_range(1, 42), 1..42
```

```
1..42, 1..42
```

In the following call, the range represents an interval:

```
int(x, x = l..r)
```

$$\frac{r^2}{2} - \frac{l^2}{2}$$

Ranges can be used for accessing the operands of expressions or to define the size of arrays and hfarrays:

```
op(f(a, b, c, d, e), 2..4)
```

$$b, c, d$$

```
array(1..3, [a1, a2,a3])
```

$$(\,a1\;\;a2\;\;a3\,)$$

```
hfarray(1..3, 1..2)
```

$$\begin{pmatrix} 0.0 & 0.0 \\ 0.0 & 0.0 \\ 0.0 & 0.0 \end{pmatrix}$$

Ranges can also be used for creating expression sequences:

```
i^3 $ i = 1..5
```

$$1, 8, 27, 64, 125$$

Example 2

The range operator `..` is a technical device that does not check its parameters with respect to their semantics. It just creates a range which is interpreted in the context in which it is used later. Any bounds are accepted:

```
float(PI) .. -sqrt(2)/3
```

$$3.141592654.. - \frac{\sqrt{2}}{3}$$

Parameters

`l, r`

Arbitrary MuPAD objects

Return Values

Expression of type `"_range"`.

Overloaded By

See Also

MuPAD Domains
`Dom::Interval`

MuPAD Functions
`$`

=, _equal

Equations (equal)

Syntax

```
x = y

_equal(x, y)
```

Description

`x = y` defines an equation.

`x = y` is equivalent to the function call `_equal(x, y)`.

The operator = returns a symbolic expression representing an equation.

The resulting expression can be evaluated to `TRUE` or `FALSE` by the function `bool`. It also serves as control conditions in `if`, `repeat`, and `while` statements. In all these cases, testing for equality is a purely syntactical test. E.g., `bool(0.5 = 1/2)` returns `FALSE` although both numbers coincide numerically.

Further, Boolean expressions can be evaluated to `TRUE`, `FALSE`, or `UNKNOWN` by the function `is`. Tests using `is` are semantical comparing `x` and `y` subject to mathematical considerations.

Equations have two operands: the left hand side and the right hand side. One may use `lhs` and `rhs` to extract these operands.

The boolean expression `not x = y` is always converted to `x <> y`.

The expression `not x <> y` is always converted to `x = y`.

Examples

Example 1

In the following, note the difference between syntactical and numerical equality. The numbers 1.5 and $\frac{3}{2}$ coincide numerically. However, 1.5 is of domain type `DOM_FLOAT`, whereas $\frac{3}{2}$ is of domain type `DOM_RAT`. Consequently, they are not regarded as equal in the following syntactical test:

```
1.5 = 3/2; bool(%)
```

$$1.5 = \frac{3}{2}$$

$$\text{FALSE}$$

If floating-point numbers are involved, one should rather use the operator `~=` instead of `=`. The functions `bool` and `is` test whether the floating-point approximations coincide up to the relative precision given by `DIGITS`:

```
1.5 ~= 3/2;
bool(1.5 ~= 3/2);
is(1.5 ~= 3/2);
```

$$1.5 \approx \frac{3}{2}$$

$$\text{TRUE}$$

$$\text{TRUE}$$

The following expressions coincide syntactically:

```
_equal(1/x, diff(ln(x),x)); bool(%)
```

$$\frac{1}{x} = \frac{1}{x}$$

```
TRUE
```

The Boolean operator `not` converts equalities and inequalities:

```
not a = b, not a <> b
```

$$a \neq b,\ a = b$$

Example 2

The examples below demonstrate how = and <> deal with non-mathematical objects and data structures:

```
if "text" = "t"."e"."x"."t" then "yes" else "no" end
```

```
"yes"
```

```
bool(table(a = PI) <> table(a = sqrt(2)))
```

```
TRUE
```

Example 3

We demonstrate the difference between the syntactical test via `bool` and the semantical test via `testeq`:

```
bool(1 = x/(x + y) + y/(x + y)), testeq(1 = x/(x + y) + y/(x + y))
```

```
FALSE, TRUE
```

Example 4

Equations and inequalities are typical input objects for system functions such as `solve`:

```
solve(x^2 - 2*x = -1, x)
```

```
{1}
```

```
solve(x^2 - 2*x <> -1, x)
```

$$\mathbb{C} \setminus \{1\}$$

Parameters

x, y

Arbitrary MuPAD objects

Return Values

Expression of type `"_equal"`.

See Also

MuPAD Functions

`<` | `<=` | `<>` | `>` | `>=` | `and` | `bool` | `FALSE` | `if` | `lhs` | `not` | `or` | `repeat` | `rhs` | `solve` | `testeq` | `TRUE` | `UNKNOWN` | `while` | `~=`

<>, _unequal

Inequalities (unequal)

Syntax

```
x <> y

_unequal(x, y)
```

Description

`x <> y` defines an inequality.

`x <> y` is equivalent to the function call `_unequal(x, y)`.

The operator `<>` returns a symbolic expression representing an inequality.

The resulting expression can be evaluated to `TRUE` or `FALSE` by the function `bool`. It also serves as control conditions in `if`, `repeat`, and `while` statements. In all these cases, testing for equality or inequality is a purely syntactical test. E.g., `bool(0.5 <> 1/2)` returns `TRUE` although both numbers coincide numerically.

Further, Boolean expressions can be evaluated to `TRUE`, `FALSE`, or `UNKNOWN` by the function `is`. Tests using `is` are semantical comparing `x` and `y` subject to mathematical considerations.

Inequalities have two operands: the left hand side and the right hand side. One may use `lhs` and `rhs` to extract these operands.

The boolean expression `not x = y` is always converted to `x <> y`.

The expression `not x <> y` is always converted to `x = y`.

Examples

Example 1

In the following, note the difference between syntactical and numerical equality. The numbers 1.5 and $\frac{3}{2}$ coincide numerically. However, 1.5 is of domain type `DOM_FLOAT`, whereas $\frac{3}{2}$ is of domain type `DOM_RAT`. Consequently, they are not regarded as equal in the following syntactical test:

```
1.5 = 3/2; bool(%)
```

$$1.5 = \frac{3}{2}$$

$$\text{FALSE}$$

If floating-point numbers are involved, one should rather use the operator `~=` instead of `=`. The functions `bool` and `is` test whether the floating-point approximations coincide up to the relative precision given by `DIGITS`:

```
1.5 ~= 3/2;
bool(1.5 ~= 3/2);
is(1.5 ~= 3/2);
```

$$1.5 \approx \frac{3}{2}$$

$$\text{TRUE}$$

$$\text{TRUE}$$

The following expressions coincide syntactically:

```
_equal(1/x, diff(ln(x),x)); bool(%)
```

$$\frac{1}{x} = \frac{1}{x}$$

```
TRUE
```

The Boolean operator `not` converts equalities and inequalities:

```
not a = b, not a <> b
```

$$a \neq b,\ a = b$$

Example 2

The examples below demonstrate how = and <> deal with non-mathematical objects and data structures:

```
if "text" = "t"."e"."x"."t" then "yes" else "no" end
```

```
"yes"
```

```
bool(table(a = PI) <> table(a = sqrt(2)))
```

```
TRUE
```

Example 3

We demonstrate the difference between the syntactical test via `bool` and the semantical test via `testeq`:

```
bool(1 = x/(x + y) + y/(x + y)), testeq(1 = x/(x + y) + y/(x + y))
```

```
FALSE, TRUE
```

Example 4

Equations and inequalities are typical input objects for system functions such as `solve`:

```
solve(x^2 - 2*x = -1, x)
```

```
{1}
```

```
solve(x^2 - 2*x <> -1, x)
```

$$\mathbb{C} \setminus \{1\}$$

Parameters

x, y

Arbitrary MuPAD objects

Return Values

Expression of type `"_unequal"`.

See Also

MuPAD Functions

`<` | `<=` | `=` | `>` | `>=` | `and` | `bool` | `FALSE` | `if` | `lhs` | `not` | `or` | `repeat` | `rhs` | `solve` | `testeq` | `TRUE` | `UNKNOWN` | `while` | `~=`

~=, _approx

Approximate equality

Syntax

```
x ~= y
```

```
_approx(x, y)
```

Description

`x ~= y` symbolizes approximate equality.

`x ~= y` is equivalent to the function call `_approx(x, y)`.

The operator ~= returns a symbolic expression representing an approximate equality for numerical values `x` and `y`. The calls `bool(x ~= y)` and `is(x ~= y)` check whether `|float((x - y)/x)| < 10^(-DIGITS)` is satisfied, provided `x ≠ 0` and `y ≠ 0`. Thus, `TRUE` is returned if `x` and `y` coincide within the relative numerical precision set by `DIGITS`. For `x = 0`, the criterion is `|float(y)| < 10^(-DIGITS)`. For `y = 0`, the criterion is `|float(x)| < 10^(-DIGITS)`. If either `x` or `y` contains a symbolic object that cannot be converted to a real or complex floating point number, the functions `bool` and `is` return the value `UNKNOWN`.

Approximate equalities have two operands: the left hand side and the right hand side. One may use `lhs` and `rhs` to extract these operands.

Note: `a ~= b` is not equivalent to `a - b ~= 0`.

Examples

Example 1

In the following, note the difference between syntactical and numerical equality. The numbers 1.5 and $\frac{3}{2}$ coincide numerically. However, 1.5 is of domain type `DOM_FLOAT`,

whereas $\frac{3}{2}$ is of domain type DOM_RAT. Consequently, they are not regarded as equal in the following syntactical test:

```
1.5 = 3/2; bool(%)
```

$$1.5 = \frac{3}{2}$$

$$\text{FALSE}$$

If floating-point numbers are involved, one should rather use the operator ~= instead of =. The functions bool and is test whether the floating-point approximations coincide up to the relative precision given by DIGITS:

```
1.5 ~= 3/2;
bool(1.5 ~= 3/2);
is(1.5 ~= 3/2);
```

$$1.5 \approx \frac{3}{2}$$

$$\text{TRUE}$$

$$\text{TRUE}$$

The following expressions coincide syntactically:

```
_equal(1/x, diff(ln(x),x)); bool(%)
```

$$\frac{1}{x} = \frac{1}{x}$$

$$\text{TRUE}$$

The Boolean operator not converts equalities and inequalities:

```
not a = b, not a <> b
```

$$a \neq b,\ a = b$$

Example 2

The examples below demonstrate how = and <> deal with non-mathematical objects and data structures:

```
if "text" = "t"."e"."x"."t" then "yes" else "no" end
```

"yes"

```
bool(table(a = PI) <> table(a = sqrt(2)))
```

TRUE

Example 3

We demonstrate the difference between the syntactical test via `bool` and the semantical test via `testeq`:

```
bool(1 = x/(x + y) + y/(x + y)), testeq(1 = x/(x + y) + y/(x + y))
```

FALSE, TRUE

Example 4

Equations and inequalities are typical input objects for system functions such as `solve`:

```
solve(x^2 - 2*x = -1, x)
```

{1}

```
solve(x^2 - 2*x <> -1, x)
```

$\mathbb{C} \setminus \{1\}$

Parameters

x, y

Arbitrary MuPAD objects

Return Values

Expression of type `"_approx"`.

See Also

MuPAD Functions

`<` | `<=` | `<>` | `=` | `>` | `>=` | `and` | `bool` | `FALSE` | `if` | `lhs` | `not` | `or` | `repeat` | `rhs` | `solve` | `testeq` | `TRUE` | `UNKNOWN` | `while`

<, >, _less

Inequalities “less than” and “greater than”

Syntax

```
x < y

x > y

_less(x, y)
```

Description

`x < y` and `x > y` define inequalities.

`x < y` represents the Boolean statement “`x` is less than `y`”. It is equivalent to the function call `_less(x,y)`.

`x > y` represents the Boolean statement “`x` is greater than `y`”. It is always converted to `y < x`, which is equivalent to the function call `_less(y,x)`.

These operators return symbolic Boolean expressions. If only real numbers of `Type::Real` are involved, these expressions can be evaluated to `TRUE` or `FALSE` by the function `bool`. They also serve as control conditions in `if`, `repeat`, and `while` statements. For floating-point intervals, these operators are interpreted as “strictly smaller than” and so on, see “Example 2” on page 1-41.

Further, Boolean expressions can be evaluated to `TRUE`, `FALSE`, or `UNKNOWN` by the function `is`. Tests using `is` can also be applied to constant symbolic expressions. See “Example 4” on page 1-42.

`bool` also handles inequalities involving character strings. It compares them with respect to the lexicographical ordering.

Inequalities have two operands: the left hand side and the right hand side. One may use `lhs` and `rhs` to extract these operands.

Examples

Example 1

The operators <, <=, >, and >= produce symbolic inequalities. They can be evaluated to TRUE or FALSE by the function `bool` if only real numbers of type `Type::Real` (integers, rationals, and floats) are involved:

```
1.5 <= 3/2; bool(%)
```

$$1.5 \le \frac{3}{2}$$

TRUE

Note that `bool` may fail to handle Boolean expressions that involve exact expressions, even if they represent real numbers:

```
_less(PI,  sqrt(2) + 17/10); bool(%)
```

$$\pi < \sqrt{2} + \frac{17}{10}$$

FALSE

```
bool(sqrt(6) < sqrt(2)*sqrt(3))
```

```
Error: Cannot evaluate to Boolean. [_less]
```

Example 2

Comparison of intervals is interpreted as “strict”, that is, all combinations of numbers in the intervals must fulfill the relation:

```
bool(0...1 < 2...3), bool(0...2 < 1...3),
bool(0...1 < 1...2)
```

TRUE, FALSE, FALSE

```
bool(0...1 <= 2...3), bool(0...2 <= 1...3),
bool(0...1 <= 1...2)
```

```
TRUE, FALSE, TRUE
```

Example 3

This examples demonstrates how character strings can be compared:

```
if "text" < "t"."e"."x"."t"."book" then "yes" else "no" end
```

```
"yes"
```

```
bool("a" >= "b")
```

```
FALSE
```

Example 4

Note that `bool` does not perform symbolic simplification and therefore cannot handle some combinations of symbolic expressions; the function `is` does perform symbolic simplification:

```
bool(sqrt(6) < sqrt(2)*sqrt(3))
```

```
Error: Cannot evaluate to Boolean. [_less]
```

```
is(sqrt(6) < sqrt(2)*sqrt(3))
```

```
FALSE
```

Example 5

Inequalities are valid input objects for the system function `solve`:

```
solve(x^2 - 2*x < 3, x)
```

$$(-1, 3) \cup \{1 + y\,i \mid y \in \mathbb{R}\}$$

```
solve(x^2 - 2*x >= 3, x)
```

$$(-\infty, -1] \cup [3, \infty)$$

Example 6

The operators < and <= can be overloaded by user-defined domains:

```
myDom := newDomain("myDom"): myDom::print := x -> extop(x):
```

Without overloading `_less` or `_leequal`, elements of this domain cannot be compared:

```
x := new(myDom, PI): y := new(myDom, sqrt(10)): bool(x < y)
```

```
Error: Cannot evaluate to Boolean. [_less]
```

Now, a slot`"_less"` is defined. It is called, when an inequality of type `"_less"` is evaluated by `bool`. The slot compares floating-point approximations if the arguments are not of type `Type::Real`:

```
myDom::_less := proc(x, y)
begin
     x := extop(x, 1):
     y := extop(y, 1):
     if not testtype(x, Type::Real) then
        x := float(x):
        if not testtype(x, Type::Real) then
           error("cannot compare")
        end_if
     end_if:
     if not testtype(y, Type::Real) then
        y := float(y):
        if not testtype(y, Type::Real) then
           error("cannot compare")
        end_if
     end_if:
     bool(x < y)
end_proc:
```

```
x, y, bool(x < y), bool(x > y)
```

$$\pi,\ \sqrt{10},\ \text{TRUE},\ \text{FALSE}$$

```
bool(new(myDom, I) < new(myDom, PI))
```

```
Error: cannot compare [myDom::_less]
```

```
delete myDom, x, y:
```

Parameters

x, y

Arbitrary MuPAD objects

Return Values

Expression of type `"_less"`.

Overloaded By

x, y

See Also

MuPAD Functions

`<=` | `<>` | `=` | `>=` | `and` | `bool` | `FALSE` | `if` | `lhs` | `not` | `or` | `repeat` | `rhs` | `solve` | `TRUE` | `UNKNOWN` | `while`

<=, >=, _leequal

Inequalities “less than or equal to” and “greater than or equal to”

Syntax

```
x <= y

x >= y

_leequal(x, y)
```

Description

`x <= y` and `x >= y` define inequalities.

`x <= y` represents the Boolean statement “`x` is less than or equal to `y`”. It is equivalent to the function call `_leequal(x,y)`.

`x >= y` represents the Boolean statement “`x` is greater than or equal to `y`”. It is always converted to `y <= x`, which is equivalent to the function call `_leequal(y,x)`.

These operators return symbolic Boolean expressions. If only real numbers of `Type::Real` are involved, these expressions can be evaluated to `TRUE` or `FALSE` by the function `bool`. They also serve as control conditions in `if`, `repeat`, and `while` statements. For floating-point intervals, these operators are interpreted as “strictly smaller than” and so on, see “Example 2” on page 1-46.

Further, Boolean expressions can be evaluated to `TRUE`, `FALSE`, or `UNKNOWN` by the function `is`. Tests using `is` can also be applied to constant symbolic expressions. See “Example 4” on page 1-47.

`bool` also handles inequalities involving character strings. It compares them with respect to the lexicographical ordering.

Inequalities have two operands: the left hand side and the right hand side. One may use `lhs` and `rhs` to extract these operands.

Examples

Example 1

The operators <, <=, >, and >= produce symbolic inequalities. They can be evaluated to TRUE or FALSE by the function `bool` if only real numbers of type `Type::Real` (integers, rationals, and floats) are involved:

```
1.5 <= 3/2; bool(%)
```

$$1.5 \leq \frac{3}{2}$$

TRUE

Note that `bool` may fail to handle Boolean expressions that involve exact expressions, even if they represent real numbers:

```
_less(PI,  sqrt(2) + 17/10); bool(%)
```

$$\pi < \sqrt{2} + \frac{17}{10}$$

FALSE

```
bool(sqrt(6) < sqrt(2)*sqrt(3))
```

```
Error: Cannot evaluate to Boolean. [_less]
```

Example 2

Comparison of intervals is interpreted as “strict”, that is, all combinations of numbers in the intervals must fulfill the relation:

```
bool(0...1 < 2...3), bool(0...2 < 1...3),
bool(0...1 < 1...2)
```

TRUE, FALSE, FALSE

```
bool(0...1 <= 2...3), bool(0...2 <= 1...3),
bool(0...1 <= 1...2)
```

```
TRUE, FALSE, TRUE
```

Example 3

This examples demonstrates how character strings can be compared:

```
if "text" < "t"."e"."x"."t"."book" then "yes" else "no" end
```

```
"yes"
```

```
bool("a" >= "b")
```

```
FALSE
```

Example 4

Note that `bool` does not perform symbolic simplification and therefore cannot handle some combinations of symbolic expressions; the function `is` does perform symbolic simplification:

```
bool(sqrt(6) < sqrt(2)*sqrt(3))
```

```
Error: Cannot evaluate to Boolean. [_less]
```

```
is(sqrt(6) < sqrt(2)*sqrt(3))
```

```
FALSE
```

Example 5

Inequalities are valid input objects for the system function `solve`:

```
solve(x^2 - 2*x < 3, x)
```

$$(-1, 3) \cup \{1 + y\,i \mid y \in \mathbb{R}\}$$

```
solve(x^2 - 2*x >= 3, x)
```

$$(-\infty, -1] \cup [3, \infty)$$

Example 6

The operators < and <= can be overloaded by user-defined domains:

```
myDom := newDomain("myDom"): myDom::print := x -> extop(x):
```

Without overloading `_less` or `_leequal`, elements of this domain cannot be compared:

```
x := new(myDom, PI): y := new(myDom, sqrt(10)): bool(x < y)
```

```
Error: Cannot evaluate to Boolean. [_less]
```

Now, a slot`"_less"` is defined. It is called, when an inequality of type `"_less"` is evaluated by `bool`. The slot compares floating-point approximations if the arguments are not of type `Type::Real`:

```
myDom::_less := proc(x, y)
begin
     x := extop(x, 1):
     y := extop(y, 1):
     if not testtype(x, Type::Real) then
        x := float(x):
        if not testtype(x, Type::Real) then
           error("cannot compare")
        end_if
     end_if:
     if not testtype(y, Type::Real) then
        y := float(y):
        if not testtype(y, Type::Real) then
           error("cannot compare")
        end_if
     end_if:
     bool(x < y)
end_proc:
```

```
x, y, bool(x < y), bool(x > y)
```

$$\pi,\ \sqrt{10},\ \text{TRUE},\ \text{FALSE}$$

```
bool(new(myDom, I) < new(myDom, PI))
```

```
Error: cannot compare [myDom::_less]
```

```
delete myDom, x, y:
```

Parameters

x, y

Arbitrary MuPAD objects

Return Values

Expression of type `"_leequal"`.

Overloaded By

x, y

MuPAD Functions

`<` | `<>` | `=` | `>` | `and` | `bool` | `FALSE` | `if` | `lhs` | `not` | `or` | `repeat` | `rhs` | `solve` | `TRUE` | `UNKNOWN` | `while`

+, _plus

Add expressions

Syntax

```
x + y + ...
```

```
_plus(x, y, …)
```

Description

`x + y + ...` computes the sum of `x`, `y` etc.

`x + y + ...` is equivalent to the function call `_plus(x, y, ...)`.

All terms that are numbers of type `Type::Numeric` are automatically combined to a single number.

Terms of a symbolic sum may be rearranged internally. Cf. “Example 1” on page 1-51. The user can control the ordering by the preference `Pref::keepOrder`. See also the documentation for `print`.

`_plus` accepts an arbitrary number of arguments. In conjunction with the sequence operator `$`, this function is the recommended tool for computing finite sums. Cf. “Example 2” on page 1-52. The function `sum` may also serve for computing such sums. However, `sum` is designed for the computation of symbolic and infinite sums. It is slower than `_plus`.

`x - y` is internally represented as `x + y*(-1)` = `_plus(x, _mult(y, -1))`. See `_subtract` for details.

For adding equalities, inequalities, and comparisons, the following rules are implemented:

- Adding an arithmetical expression adds the expression to both sides.
- Adding an equality adds the left hand sides and the right hand sides separately.
- Adding a comparison does likewise, taking care of the correct operator. Adding a comparison to an inequality is not permitted.

Cf. “Example 4” on page 1-53.

Many library domains overload `_plus` by an appropriate slot`"_plus"`. Sums involving elements of library domains are processed as follows:

A sum `x + y + ...` is searched for elements of library domains from left to right. Let `z` be the first term that is not of one of the basic types provided by the kernel (numbers, expressions, etc.). If the domain `d` = `z::dom` = `domtype(z)` has a slot`"_plus"`, it is called in the form `d::_plus(x, y, ...)`. The result returned by `d::_plus` is the result of `x + y + ...`.

Users should implement the slot `d::_plus` of their domains `d` according to the following convention:

- If all terms are elements of `d`, an appropriate sum of type `d` should be returned.
- If at least one term cannot be converted to an element of `d`, the slot should return `FAIL`.
- Care must be taken if there are terms that are not of type `d`, but can be converted to type `d`. Such terms should be converted only if the mathematical semantics is obvious to any user who uses this domain as a 'black box' (e.g., integers may be regarded as rational numbers because of the natural mathematical embedding). If in doubt, the `"_plus"` method should return `FAIL` instead of using implicit conversions. If implicit conversions are used, they must be well-documented.

Cf. “Example 6” on page 1-55 and “Example 7” on page 1-56.

Most of the library domains in the MuPAD standard installation comply with this convention.

`_plus()` returns the number 0.

Polynomials of type `DOM_POLY` are added by `+`, if they have the same indeterminates and the same coefficient ring.

For finite sets `X`, `Y`, the sum `X + Y` is the set $\{x+y \mid x \in X, y \in Y\}$.

Examples

Example 1

Numerical terms are simplified automatically:

```
3 + x + y + 2*x + 5*x - 1/2 - sin(4) + 17/4
```

$$8\,x + y - \sin(4) + \frac{27}{4}$$

The ordering of the terms of a sum is not necessarily the same as on input:

```
x + y + z + a + b + c
```

$$a + b + c + x + y + z$$

```
1 + x + x^2 + x^10
```

$$x^{10} + x^2 + x + 1$$

Internally, this sum is a symbolic call of `_plus`:

```
op(%, 0), type(%)
```

$$\text{\_plus},\ \text{"\_plus"}$$

Example 2

The functional equivalent `_plus` of the operator + is a handy tool for computing finite sums. In the following, the terms are generated via the sequence operator $:

```
_plus(i^2 $ i = 1..100)
```

$$338350$$

E.g., it is easy to add up all elements in a set:

```
S := {a, b, 1, 2, 27}: _plus(op(S))
```

$$a + b + 30$$

The following command “zips” two lists by adding corresponding elements:

```
L1 := [a, b, c]: L2 := [1, 2, 3]: zip(L1, L2, _plus)
```

$$[a+1,\ b+2,\ c+3]$$

```
delete S, L1, L2:
```

Example 3

Polynomials of type `DOM_POLY` are added by `+`, if they have the same indeterminates and the same coefficient ring:

```
poly(x^2 + 1, [x]) + poly(x^2 + x - 1, [x])
```

$$\mathrm{poly}(2\,x^2+x,\ [x])$$

If the indeterminates or the coefficient rings do not match, `_plus` returns an error:

```
poly(x, [x]) + poly(x, [x, y])
```

```
Error: The argument is invalid. [_plus]
```

```
poly(x, [x]) + poly(x, [x], Dom::Integer)
```

```
Error: The argument is invalid. [_plus]
```

Example 4

Adding a constant to an equality, an inequality, or a comparison amounts to adding it to both sides:

```
(a = b) + c, (a <> b) + c, (a <= b) + c, (a < b) + c
```

$$a+c=b+c,\ a+c\neq b+c,\ a+c\leq b+c,\ a+c<b+c$$

Adding an equality is performed by adding the left hand sides and the right hand sides separately:

```
(a = b) + (c = d), (a <> b) + (c = d),
```

```
(a <= b) + (c = d), (a < b) + (c = d)
```

$$a+c=b+d,\ a+c\neq b+d,\ a+c\leq b+d,\ a+c<b+d$$

Inequalities can only be added to equalities:

```
(a = b) + (c <> d), (a <> b) + (c <> d),
(a <= b) + (c <> d), (a < b) + (c <> d)
```

$$a+c\neq b+d,\ \text{FAIL},\ \text{FAIL},\ \text{FAIL}$$

The addition of comparisons takes of the difference between < and <= into account. Note that MuPAD uses only these two comparison operators; $a > b$ and $a \geq b$ are automatically rewritten:

```
(a = b) + (c <= d), (a <> b) + (c <= d),
(a <= b) + (c <= d), (a < b) + (c <= d);
```

$$a+c\leq b+d,\ \text{FAIL},\ a+c\leq b+d,\ a+c<b+d$$

```
(a = b) + (c < d), (a <> b) + (c < d),
(a <= b) + (c < d), (a < b) + (c < d);
```

$$a+c<b+d,\ \text{FAIL},\ a+c<b+d,\ a+c<b+d$$

```
(a = b) + (c >= d), (a <> b) + (c >= d),
(a <= b) + (c >= d), (a < b) + (c >= d);
```

$$a+d\leq b+c,\ \text{FAIL},\ a+d\leq b+c,\ a+d<b+c$$

```
(a = b) + (c > d), (a <> b) + (c > d),
(a <= b) + (c > d), (a < b) + (c > d);
```

$$a+d<b+c,\ \text{FAIL},\ a+d<b+c,\ a+d<b+c$$

Example 5

For finite sets X, Y, the sum X + Y is the set $\{x+y \mid x \in X,\ y \in Y\}$:

```
{a, b, c} + {1, 2}
```

$$\{a+1, a+2, b+1, b+2, c+1, c+2\}$$

Example 6

Various library domains such as matrix domains overload `_plus`:

```
x := Dom::Matrix(Dom::Integer)([1, 2]):
y := Dom::Matrix(Dom::Rational)([2, 3]):
x + y, y + x
```

$$\begin{pmatrix} 3 \\ 5 \end{pmatrix}, \begin{pmatrix} 3 \\ 5 \end{pmatrix}$$

If the terms in a sum `x + y` are of different type, the first term `x` tries to convert `y` to the data type of `x`. If successful, the sum is of the same type as `x`. In the previous example, `x` and `y` have different types (both are matrices, but the component domains differ). Hence the sums `x + y` and `y + x` differ syntactically, because they inherit their type from the first term:

```
bool(x + y = y + x)
```

FALSE

```
domtype(x + y), domtype(y + x)
```

Dom::Matrix(Dom::Integer), Dom::Matrix(Dom::Rational)

If `x` does not succeed to convert `y`, then `FAIL` is returned. In the following call, the component `2/3` cannot be converted to an integer:

```
y := Dom::Matrix(Dom::Rational)([2/3, 3]): x + y
```

FAIL

```
delete x, y:
```

Example 7

This example demonstrates how to implement a slot `"_plus"` for a domain. The following domain `myString` is to represent character strings. The sum of such strings is to be the concatenation of the strings.

The `"new"` method uses `expr2text` to convert any MuPAD object to a string. This string is the internal representation of elements of `myString`. The `"print"` method turns this string into the screen output:

```
myString := newDomain("myString"):
myString::new := proc(x)
begin
  if args(0) = 0 then x := "": end_if;
  case domtype(x)
    of myString do return(x);
    of DOM_STRING do return(new(dom, x));
    otherwise return(new(dom, expr2text(x)));
  end_case
end_proc:
myString::print := x -> extop(x, 1):
```

Without a `"_plus"` method, the system function `_plus` handles elements of this domain like any symbolic object:

```
y := myString(y): z := myString(z): 1 + x + y + z + 3/2
```

$$x + y + z + \frac{5}{2}$$

Now, we implement the `"_plus"` method. It checks all arguments. Arguments are converted, if they are not of type `myString`. Generally, such an implicit conversion should be avoided. In this case, however, any object has a corresponding string representation via `expr2text` and an implicit conversion is implemented. Finally, the sum of `myString` objects is defined as the concatenation of the internal strings:

```
myString::_plus := proc()
local n, Arguments, i;
begin
  print(Unquoted, "Info: myString::_plus called with the arguments:",
           args()):
  n := args(0):
```

```
  Arguments := [args()];
  for i from 1 to n do
    if domtype(Arguments[i]) <> myString then
      // convert the i-th term to myString
      Arguments[i] := myString::new(Arguments[i]):
    end_if;
  end_for:
  myString::new(_concat(extop(Arguments[i], 1) $ i = 1..n))
end_proc:
```

Now, `myString` objects can be added:

```
myString("This ") + myString("is ") + myString("a string")
```

```
Info: myString::_plus called with the arguments:, This , is , a string
```

This is a string

In the following sum, `y` and `z` are elements of `myString`. The term `y` is the first term that is an element of a library domain. Its `"_plus"` method is called and concatenates all terms to a string of type `myString`:

```
1 + x + y + z + 3/2;
```

```
                                                                  3
Info: myString::_plus called with the arguments:, 1, x, y, z, -
                                                                  2
```

1xyz3/2

```
delete myString, y, z:
```

Parameters

`x, y, …`

arithmetical expressions, polynomials of type `DOM_POLY`, sets, equations, inequalities, or comparisons

Return Values

Arithmetical expression, a polynomial, a set, an equation, an inequality, or a comparison.

Overloaded By

x, y

See Also

MuPAD Functions

`*` | `-` | `/` | `^` | `_invert` | `_subtract` | `poly` | `Pref::keepOrder` | `sum`

-, _negate

Negative of an expression

Syntax

```
- x
```

```
_negate(x)
```

Description

`- x` computes the negative of `x`.

`-x` is equivalent to the function call `_negate(x)`. Both calls represent the inverse of the element `x` of an additive group.

The negative of a number of type `Type::Numeric` is also a number.

If `x` is an element of a domain that does not have the `_negate` method (slot), MuPAD internally represents `-x` as `x*(-1) = _mult(x, -1)`.

If `x` is an element of a domain that has the `_negate` method (slot), MuPAD uses this method to compute `-x`.

The difference `x - y` is equivalent to `x + (-y) = _plus (x, _negate(y))`.

The negative of a polynomial of type `DOM_POLY` produces a polynomial. The coefficients of the resulting polynomial are the negatives of the original coefficients.

For finite sets, `-X` is the set $\{-x \mid x \in X\}$.

Examples

Example 1

Compute the negatives of the following expressions. The negative of an expression is the inverse with respect to + (`_plus`):

```
x - x = x + _negate(x)
```

$$0 = 0$$

```
-1 + x - 2*x + 23
```

$$22 - x$$

Example 2

Internally, MuPAD represents `-x` as `_mult(x, -1)`:

```
type(-x), op(-x, 0), op(-x, 1), op(-x, 2)
```

$$\text{"\_mult"}, \_mult, x, -1$$

Example 3

Compute the negative of a polynomial. The result is a polynomial with the coefficients that are the negatives of the coefficients of the original polynomial:

```
-poly(x^2 + x - 1, [x])
```

$$\text{poly}(-x^2 - x + 1, [x])$$

```
-poly(x, [x], Dom::Integer)
```

$$\text{poly}(-x, [x], \text{Dom::Integer})$$

Example 4

Compute the negative of a finite set. For finite sets, `-X` is the set $\{-x \mid x \in X\}$:

```
-{a, b, c}
```

$$\{-a, -b, -c\}$$

Example 5

Various library domains such as matrix domains or residue class domains overload `_negate`:

```
x := Dom::Matrix(Dom::IntegerMod(7))([2, 10]): x, -x, x + (-x)
```

$$\begin{pmatrix} 2 \bmod 7 \\ 3 \bmod 7 \end{pmatrix}, \begin{pmatrix} 5 \bmod 7 \\ 4 \bmod 7 \end{pmatrix}, \begin{pmatrix} 0 \bmod 7 \\ 0 \bmod 7 \end{pmatrix}$$

```
delete x:
```

Parameters

x

An arithmetical expression, a polynomial of type `DOM_POLY`, or a set

Return Values

Arithmetical expression, a polynomial, or a set.

Overloaded By

x

See Also

MuPAD Functions

`* | + | / | ^ | _invert | _subtract | poly`

*, _mult

Multiply expressions

Syntax

```
x * y * ...
```

```
_mult(x, y, …)
```

Description

`x * y * ...` computes the product of `x`, `y` etc.

`x * y * ...` is equivalent to the function call `_mult(x, y, ...)`.

All terms that are numbers of type `Type::Numeric` are automatically combined to a single number.

The terms of a symbolic product may be rearranged internally if no term belongs to a library domain that overloads `_mult`: on terms composed of kernel domains (numbers, identifiers, expressions etc.), multiplication is assumed to be commutative. Cf. “Example 1” on page 1-63.

Via overloading, the user can implement a non-commutative product for special domains.

`_mult` accepts an arbitrary number of arguments. In conjunction with the sequence operator `$`, this function is the recommended tool for computing finite products. Cf. “Example 2” on page 1-64. The function `product` may also serve for computing such products. However, `product` is designed for the computation of symbolic and infinite products. It is slower than `_mult`.

The quotient `x/y` is internally represented as `x * (1/y)` = `_mult(x, _power(y, -1))`. See `_divide` for details.

Many library domains overload `_mult` by an appropriate slot`"_mult"`. Products involving elements of library domains are processed as follows:

A product `x * y * ...` is searched for elements of library domains from left to right. Let `z` be the first term that is not of one of the basic types provided by the

kernel (numbers, expressions, etc.). If the domain `d` = `z::dom` = `domtype(z)` has a slot`"_mult"`, it is called in the form `d::_mult(x, y, ...)`. The result returned by `d::_mult` is the result of `x * y * ...`.

Cf. “Example 6” on page 1-68 and “Example 7” on page 1-69.

`_mult()` returns the number 1.

Polynomials of type `DOM_POLY` are multiplied by `*`, if they have the same indeterminates and the same coefficient ring. Use `multcoeffs` to multiply polynomials with scalar factors.

For finite sets `X`, `Y`, the product `X * Y` is the set $\{x\,y \mid x \in X, y \in Y\}$.

Equalities, inequalities, and comparisons can be multiplied with one another or with arithmetical expressions. The results of such combinations are demonstrated in “Example 5” on page 1-66.

Examples

Example 1

Numerical terms are simplified automatically:

```
3 * x * y * (1/18) * sin(4) * 4
```

$$\frac{2\,x\,y\,\sin(4)}{3}$$

The ordering of the terms of a product is not necessarily the same as on input:

```
x * y * 3 * z * a * b * c
```

$$3\,a\,b\,c\,x\,y\,z$$

Internally, this product is a symbolic call of `_mult`:

```
op(%, 0), type(%)
```

```
_mult, "_mult"
```

Note that the screen output does not necessarily reflect the internal order of the terms in a product:

```
op(%2)
```

$$a, b, c, x, y, z, 3$$

In particular, a numerical factor is internally stored as the last operand. On the screen, a numerical factor is displayed in front of the remaining terms:

```
3 * x * y * 4
```

$$12\,x\,y$$

```
op(%)
```

$$x, y, 12$$

Example 2

The functional equivalent `_mult` of the operator `*` is a handy tool for computing finite products. In the following, the terms are generated via the sequence operator `$`:

```
_mult(i $ i = 1..20)
```

$$2432902008176640000$$

E.g., it is easy to multiply all elements in a set:

```
S := {a, b, 1, 2, 27}: _mult(op(S))
```

$$54\,a\,b$$

The following command “zips” two lists by multiplying corresponding elements:

```
L1 := [1, 2, 3]: L2 := [a, b, c]: zip(L1, L2, _mult)
```

$$[a, 2\,b, 3\,c]$$

```
delete S, L1, L2:
```

Example 3

Polynomials of type `DOM_POLY` are multiplied by `*`, if they have the same indeterminates and the same coefficient ring:

```
poly(x^2 + 1, [x]) * poly(x^2 + x - 1, [x])
```

$$\mathrm{poly}(x^4 + x^3 + x - 1, [x])$$

If the indeterminates or the coefficient rings do not match, `_mult` returns an error:

```
poly(x, [x]) * poly(x, [x, y])
```

```
Error: The argument is invalid. [_mult]
```

```
poly(x, [x]) * poly(x, [x], Dom::Integer)
```

```
Error: The argument is invalid. [_mult]
```

Using `*`, you can multiply polynomials by scalar factors:

```
2 * y * poly(x, [x])
```

$$\mathrm{poly}((2\,y)\,x, [x])$$

Use `multcoeffs` instead:

```
multcoeffs(poly(x^2 - 2, [x]), 2*y)
```

$$\mathrm{poly}((2\,y)\,x^2 - 4\,y, [x])$$

Example 4

For finite sets X, Y, the product X * Y is the set $\{x\,y \mid x \in X, y \in Y\}$:

```
{a, b, c} * {1, 2}
```

$$\{a, b, c, 2\,a, 2\,b, 2\,c\}$$

Note that complex numbers of type DOM_INT, DOM_RAT, DOM_COMPLEX, DOM_FLOAT, and identifiers are implicitly converted to one-element sets:

```
2 * {a, b, c}
```

$$\{2\,a, 2\,b, 2\,c\}$$

```
a * {b, c}, PI * {3, 4}
```

$$\{a\,b, a\,c\}, \{3\,\pi, 4\,\pi\}$$

Example 5

Multiplying by a constant expression is performed on both sides of an equation:

```
(a = b) * c
```

$$a\,c = b\,c$$

For inequalities, this step is only performed if the constant is known to be non-zero:

```
assume(d <> 0):
(a <> b) * c, (a <> b) * d;
delete d:
```

$$(a \neq b)\,c, a\,d \neq b\,d$$

The multiplication of a comparison with a constant is only defined for real numbers. Even for these, the result depends on the sign of the constant, since multiplication with a negative constant changes the direction of the comparison:

```
(a < b) * 2, (a < b) * (-3)
```

$$2\,a < 2\,b,\ -3\,b < -3\,a$$

```
(a < b) * I
```

```
Error: Inequalities must not be multiplied by complex numbers. [_less::_mult]
```

```
(a < b) * c, (a <= b) * c
```

$$\begin{cases} a\,c < b\,c & \text{if } 0 < c \\ b\,c < a\,c & \text{if } c < 0 \end{cases}, \begin{cases} a\,c \le b\,c & \text{if } 0 \le c \\ b\,c \le a\,c & \text{if } c \le 0 \end{cases}$$

Multiplication of two equalities is performed by multiplying the left hand sides and the right hand sides separately:

```
(a = b) * (c = d)
```

$$a\,c = b\,d$$

Inequalities cannot be multiplied with one another or with comparisons; multiplication with equalities is, however, defined, if at least one operand of the equation is known to be non-zero:

```
assume(d <> 0):
(a <> b) * (c = d);
delete d:
```

$$a\,c \neq b\,d$$

In other cases, the product is not expanded:

```
delete c, d:
(a <> b) * (c = d)
```

$$(a \neq b)\,(c = d)$$

Multiplication of comparisons with equalities and comparisons is performed similar to the cases above:

```
assume(c > 0):
(a < b) * (c = d);
delete c:
```

$$a\,c < b\,d$$

```
(a <= b) * (c <= d)
```

$$\begin{cases} a\,c \le b\,d & \text{if } 0 \le c \wedge 0 \le d \\ b\,d \le a\,c & \text{if } c \le 0 \wedge d \le 0 \end{cases}$$

Example 6

Various library domains such as matrix domains overload `_mult`. The multiplication is not commutative:

```
x := Dom::Matrix(Dom::Integer)([[1, 2], [3, 4]]):
y := Dom::Matrix(Dom::Rational)([[10, 11], [12, 13]]):
x * y, y * x
```

$$\begin{pmatrix} 34 & 37 \\ 78 & 85 \end{pmatrix}, \begin{pmatrix} 43 & 64 \\ 51 & 76 \end{pmatrix}$$

If the terms in `x * y` are of different type, the first term `x` tries to convert `y` to the data type of `x`. If successful, the product is of the same type as `x`. In the previous example, `x` and `y` have different types (both are matrices, but the component domains differ). Hence `x * y` and `y * x` have different types that is inherited from the first term:

```
domtype(x * y), domtype(y * x)
```

$$\text{Dom::Matrix(Dom::Integer)},\ \text{Dom::Matrix(Dom::Rational)}$$

If `x` does not succeed to convert `y`, then `y` tries to convert `x`. In the following call, the component `27/2` cannot be converted to an integer. Consequently, in `x * y`, the term `y` converts `x` and produces a result that coincides with the domain type of `y`:

```
y := Dom::Matrix(Dom::Rational)([[10, 11], [12, 27/2]]):
x * y, y * x
```

$$\begin{pmatrix} 34 & 38 \\ 78 & 87 \end{pmatrix}, \begin{pmatrix} 43 & 64 \\ \frac{105}{2} & 78 \end{pmatrix}$$

```
domtype(x * y), domtype(y * x)
```

$$\text{Dom::Matrix(Dom::Rational)}, \text{Dom::Matrix(Dom::Rational)}$$

```
delete x, y:
```

Example 7

This example demonstrates how to implement a slot `"_mult"` for a domain. The following domain `myString` is to represent character strings. Via overloading of `_mult`, integer multiples of such strings should produce the concatenation of an appropriate number of copies of the string.

The `"new"` method uses `expr2text` to convert any MuPAD object to a string. This string is the internal representation of elements of `myString`. The `"print"` method turns this string into the screen output:

```
myString := newDomain("myString"):
myString::new := proc(x)
begin
  if args(0) = 0 then x := "": end_if;
  case domtype(x)
    of myString do return(x);
    of DOM_STRING do return(new(dom, x));
    otherwise return(new(dom, expr2text(x)));
  end_case
end_proc:
myString::print := x -> extop(x, 1):
```

Without a `"_mult"` method, the system function `_mult` handles elements of this domain like any symbolic object:

```
y := myString(y):
z := myString(z):
4 * x * y * z * 3/2
```

$$6\,x\,y\,z$$

Now, we implement the "_mult" method. It uses split to pick out all integer terms in its argument list and multiplies them. The result is an integer n. If there is exactly one other term left (this must be a string of type myString), it is copied n times. The concatenation of the copies is returned:

```
myString::_mult:= proc()
local Arguments, intfactors, others, dummy, n;
begin
  print(Unquoted, "Info: myString::_mult called with the arguments:",
           args());
  Arguments := [args()];
  // split the argument list into integers and other factors:
  [intfactors, others, dummy] :=
      split(Arguments, testtype, DOM_INT);
  // multiply all integer factors:
  n := _mult(op(intfactors));
  if nops(others) <> 1 then
     return(FAIL)
  end_if;
  myString::new(_concat(extop(others[1], 1) $ n))
end_proc:
```

Now, integer multiples of myString objects can be constructed via the * operator:

```
2 * myString("string") * 3
```

```
Info: myString::_mult called with the arguments:, 2, string, 3
```

stringstringstringstringstringstring

Only products of integers and myString objects are allowed:

```
3/2 * myString("a ") * myString("string")
```

```
                                                    3
Info: myString::_mult called with the arguments:, -, a , string
                                                    2
```

FAIL

```
delete myString, y, z:
```

Parameters

`x, y, …`

arithmetical expressions, polynomials of type `DOM_POLY`, sets, equations, inequalities, or comparisons

Return Values

Arithmetical expression, a polynomial, a set, an equation, an inequality, or a comparison.

Overloaded By

x, y

See Also

MuPAD Functions

`+` | `-` | `/` | `^` | `_invert` | `_subtract` | `poly` | `product`

/, _divide

Divide expressions

Syntax

```
x / y
```

```
_divide(x, y)
```

Description

`x/y` computes the quotient of `x` and `y`.

`x/y` is equivalent to the function call `_divide(x, y)`.

For numbers of type `Type::Numeric`, the quotient is returned as a number.

If neither `x` nor `y` are elements of library domains with `"_divide"` methods, `x/y` is internally represented as `x * y^(-1)` = `_mult(x, _power(y, -1))`.

If `x` or `y` is an element of a domain with a slot`"_divide"`, then this method is used to compute `x/y`. Many library domains overload the `/` operator by an appropriate `"_divide"` slot. Quotients are processed as follows:

`x/y` is searched for elements of library domains from left to right. Let `z` (either `x` or `y`) be the first term that is not of one of the basic types provided by the kernel (numbers, expressions, etc.). If the domain `d` = `z::dom` = `domtype(z)` has a slot`"_divide"`, it is called in the form `d::_divide(x, y)`. The result returned by `d::_divide` is the result of `x/y`.

Cf. examples “Example 4” on page 1-74 and “Example 5” on page 1-75.

Polynomials of type `DOM_POLY` can be divided by `/`, if they have the same indeterminates and the same coefficient ring, and if exact division is possible. The function `divide` can be used to compute the quotient of polynomials with a remainder term.

For finite sets `X`, `Y`, the quotient `X/Y` is the set $\left\{ \frac{x}{y} \;\middle|\; x \in X, y \in Y \right\}$.

Examples

Example 1

The quotient of numbers is simplified to a number:

```
1234/234, 7.5/7, 6*I/2
```

$$\frac{617}{117},\ 1.071428571,\ 3\,i$$

Internally, a symbolic quotient `x/y` is represented as the product `x * y^(-1)`:

```
type(x/y), op(x/y, 0), op(x/y, 1), op(x/y, 2)
```

$$\text{"\_mult"},\ \_\text{mult},\ x,\ \frac{1}{y}$$

```
op(op(x/y, 2), 0), op(op(x/y, 2), 1), op(op(x/y, 2), 2)
```

$$\_\text{power},\ y,\ -1$$

Example 2

For finite sets `X`, `Y`, the quotient `X/Y` is the set $\left\{\frac{x}{y}\ \middle|\ x \in X,\ y \in Y\right\}$:

```
{a, b, c} / {2, 3}
```

$$\left\{\frac{a}{2},\ \frac{a}{3},\ \frac{b}{2},\ \frac{b}{3},\ \frac{c}{2},\ \frac{c}{3}\right\}$$

Example 3

Polynomials of type `DOM_POLY` can be divided by `/` if they have the same indeterminates, the same coefficient ring, and if exact division is possible:

```
poly(x^2 - 1, [x]) / poly(x - 1, [x])
```

$$\mathrm{poly}(x+1, [x])$$

```
poly(x^2 - 1, [x]) / poly(x - 2, [x])
```

$$\mathrm{FAIL}$$

The function `divide` provides division with a remainder:

```
divide(poly(x^2 - 1, [x]), poly(x - 2, [x]))
```

$$\mathrm{poly}(x+2, [x]), \mathrm{poly}(3, [x])$$

The polynomials must have the same indeterminates and the same coefficient ring:

```
poly(x^2 - 1, [x, y]) / poly(x - 1, [x])
```

```
Error: The argument is invalid. [divide]
```

Example 4

Various library domains such as matrix domains overload `_divide`. The matrix domain defines `x/y` as `x * (1/y)`, where `1/y` is the inverse of `y`:

```
x := Dom::Matrix(Dom::Integer)([[1, 2], [3, 4]]):
y := Dom::Matrix(Dom::Rational)([[10, 11], [12, 13]]):
x/y
```

$$\begin{pmatrix} \frac{11}{2} & -\frac{9}{2} \\ \frac{9}{2} & -\frac{7}{2} \end{pmatrix}$$

The inverse of `x` has rational entries. Therefore, `1/x` returns `FAIL`, because the component ring of `x` is `Dom::Integer`. Consequently, also `y/x` returns `FAIL`:

```
y/x
```

$$\mathrm{FAIL}$$

```
delete x, y:
```

Example 5

This example demonstrates the behavior of `_divide` on user-defined domains. In the first case below, the user-defined domain does not have a `"_divide"` slot. Thus `x/y` is transformed to `x * (1/y)`:

```
Do := newDomain("Do"): x := new(Do, 1): y := new(Do, 2):
x/y; op(x/y, 0..2)
```

$$\frac{\text{new(Do, 1)}}{\text{new(Do, 2)}}$$

$$\text{\_mult, new(Do, 1), } \frac{1}{\text{new(Do, 2)}}$$

After the slot `"_divide"` is defined in the domain `Do`, this method is used to divide elements:

```
Do::_divide := proc() begin "The Result" end: x/y
```

"The Result"

```
delete Do, x, y:
```

Parameters

`x, y, …`

arithmetical expressions, polynomials of type `DOM_POLY`, or sets

Return Values

Arithmetical expression, a polynomial, or a set.

Overloaded By

x, y

See Also

MuPAD Functions

`*` | `+` | `-` | `^` | `_invert` | `_subtract` | `div` | `divide` | `pdivide` | `poly`

^, _power

Raise an expression to a power

Syntax

```
x ^ y
```

```
_power(x, y)
```

Description

`x^y` computes the `y`-th power of `x`.

`x^y` is equivalent to the function call `_power(x, y)`.

The power operator `^` is left associative: `x^y^z` is parsed as `(x^y)^z`. Cf. “Example 2” on page 1-78.

If `x` is a polynomial of type `DOM_POLY`, then `y` must be a nonnegative integer smaller than 2^{31}.

`_power` is overloaded for matrix domains (`matrix`). In particular, `x^(-1)` returns the inverse of the matrix `x`.

Use `powermod` to compute modular powers. Cf. “Example 3” on page 1-79.

Mathematically, the call `sqrt(x)` is equivalent to `x^(1/2)`. Note, however, that `sqrt` tries to simplify the result. Cf. “Example 4” on page 1-79.

If `x` or `y` is an element of a domain with a slot`"_power"`, then this method is used to compute `x^y`. Many library domains overload the `^` operator by an appropriate `"_power"` slot. Powers are processed as follows:

`x^y` is searched for elements of library domains from left to right. Let `z` (either `x` or `y`) be the first term that is not of one of the basic types provided by the kernel (numbers, expressions, etc.). If the domain `d = z::dom = domtype(z)` has a slot`"_power"`, it is called in the form `d::_power(x, y)`. The result returned by `d::_power` is the result of `x^y`.

See “Example 6” on page 1-79 and “Example 7” on page 1-80.

For finite sets X, Y, the power X^Y is the set $\{x^y \mid x \in X, y \in Y\}$.

Examples

Example 1

Some powers are computed:

```
2^10, I^(-5), 0.3^(1/3), x^(1/2) + y^(-1/2), (x^(-10) + 1)^2
```

$$1024,\ -i,\ 0.6694329501,\ \sqrt{x} + \frac{1}{\sqrt{y}},\ \left(\frac{1}{x^{10}} + 1\right)^2$$

Use `expand` to “expand” powers of sums:

```
(x + y)^2 = expand((x + y)^2)
```

$$(x+y)^2 = x^2 + 2\,x\,y + y^2$$

Note that identities such as `(x*y)^z = x^z * y^z` only hold in certain areas of the complex plane:

```
((-1)*(-1))^(1/2) <> (-1)^(1/2) * (-1)^(1/2)
```

$$1 \neq -1$$

Consequently, the following `expand` command does not expand its argument:

```
expand((x*y)^(1/2))
```

$$\sqrt{x\,y}$$

Example 2

The power operator ^ is left associative:

```
2^3^4 = (2^3)^4, x^y^z
```

$$4096 = 4096,\ (x^y)^z$$

Example 3

Modular powers can be computed directly using `^` and `mod`. However, `powermod` is more efficient:

```
123^12345 mod 17 = powermod(123, 12345, 17)
```

$$4 = 4$$

Example 4

The function `sqrt` produces simpler results than `_power`:

```
sqrt(4*x*y), (4*x*y)^(1/2)
```

$$2\sqrt{x\,y},\ \sqrt{4\,x\,y}$$

Example 5

For finite sets, `X^Y` is the set $\{x^y \mid x \in X, y \in Y\}$:

```
{a, b, c}^2, {a, b, c}^{q, r, s}
```

$$\{a^2, b^2, c^2\},\ \{a^q, a^r, b^q, a^s, b^r, c^q, b^s, c^r, c^s\}$$

Example 6

Various library domains such as matrix domains or residue class domains overload `_power`:

```
x := Dom::Matrix(Dom::IntegerMod(7))([[2, 3], [3, 4]]):
x^2, x^(-1), x^3 * x^(-3)
```

$$\begin{pmatrix} 6 \bmod 7 & 4 \bmod 7 \\ 4 \bmod 7 & 4 \bmod 7 \end{pmatrix}, \begin{pmatrix} 3 \bmod 7 & 3 \bmod 7 \\ 3 \bmod 7 & 5 \bmod 7 \end{pmatrix}, \begin{pmatrix} 1 \bmod 7 & 0 \bmod 7 \\ 0 \bmod 7 & 1 \bmod 7 \end{pmatrix}$$

```
delete x:
```

Example 7

This example demonstrates the behavior of `_power` on user-defined domains. Without a `"power"` slot, powers of domain elements are handled like any other symbolic powers:

```
myDomain := newDomain("myDomain"): x := new(myDomain, 1): x^2
```

$$\text{new(myDomain, 1)}^2$$

```
type(x^2), op(x^2, 0), op(x^2, 1), op(x^2, 2)
```

"_power", _power, new(myDomain, 1), 2

After the `"_power"` slot is defined, this method is used to compute powers of `myDomain` objects:

```
myDomain::_power := proc() begin "The result" end: x^2
```

"The result"

```
delete myDomain, x:
```

Parameters

`x, y`

arithmetical expressions, polynomials of type `DOM_POLY`, floating-point intervals, or sets

Return Values

Arithmetical expression, a polynomial, a floating-point interval, or a set.

Overloaded By

x, y

MuPAD Functions

`*` | `+` | `-` | `/` | `_invert` | `_subtract` | `numlib::ispower` | `powermod` | `surd`

@, _fconcat

Compose functions

Syntax

```
f @ g @ ...
```

```
_fconcat(f, g, …)
```

Description

`f@g` represents the composition $x \to f(g(x))$ of the functions `f` and `g`.

In MuPAD, functions are usually represented by procedures of type `DOM_PROC`, functionenvironments, or functional expressions such as `f@g@exp + id^2`. In fact, practically any MuPAD object may serve as a function.

`f @ g` is equivalent to the function call `_fconcat(f, g)`.

`_fconcat()` returns the identity map `id`; `_fconcat(f)` returns `f`.

Examples

Example 1

The following function `h` is the composition of the system functions `abs` and `sin`:

```
h := abs@sin
```

$$\mathrm{abs} \circ \sin$$

```
h(x), h(y + 2), h(0.5)
```

$$|\sin(x)|,\ |\sin(y+2)|,\ 0.4794255386$$

The following functional expressions represent polynomials:

```
f := id^3 + 3*id - 1: f(x), (f@f)(x)
```

$$x^3 + 3\,x - 1,\ 9\,x + (x^3 + 3\,x - 1)^3 + 3\,x^3 - 4$$

The random generator `random` produces nonnegative integers with 12 digits. The following composition of `float` and `random` produces random floating-point numbers between 0.0 and 1.0:

```
rand := float@random/10^12: rand() $ k = 1..12
```

$$0.4274196691,\ 0.3211106933,\ 0.3436330737,\ 0.4742561436,\ 0.558458719,\ 0.7467538305,$$
$$0.03206222209,\ 0.7229741218,\ 0.6043056139,\ 0.7455800374,\ 0.2598119527,\ 0.3100754872$$

In conjunction with the function `map`, the composition operator `@` is a handy tool to apply composed functions to the operands of a data structure:

```
map([1, 2, 3, 4], (PI + id^2)@sin),
map({1, 2, 3, 4}, cos@float)
```

$$[\pi + \sin(1)^2,\ \pi + \sin(2)^2,\ \pi + \sin(3)^2,\ \pi + \sin(4)^2],$$

$$\{-0.9899924966,\ -0.6536436209,\ -0.4161468365,\ 0.5403023059\}$$

```
delete h, f, rand:
```

Example 2

Some simplifications of functional expressions are possible via `simplify`:

```
exp@ln + cos@arccos = simplify(cos@arccos + exp@ln)
```

$$\exp \circ \ln + \cos \circ \arccos = 2\ \mathrm{id}$$

Parameters

`f, g, …`

functions

Return Values

Expression of type `"_fconcat"`.

Overloaded By

f, g

See Also

MuPAD Functions
`@@`

@@, _fnest

Iterate a function

Syntax

```
f @@ n

_fnest(f, n)
```

Description

`f@@n` represents the `n`-fold iterate `x -> f(f(...(f(x))...))` of the function `f`.

The statement `f@@n` is equivalent to the call `_fnest(f, n)`.

For positive `n`, `f@@n` is also equivalent to `_fconcat(f $ n)`.

`f@@0` returns the identity map `id`.

If `f` is a function environment with the slot `"inverse"` set, `n` can also be negative. Cf. “Example 2” on page 1-86.

Iteration is only reasonable for functions that accept their own return values as input. Note that `fp::fixargs` is a handy tool for converting functions with parameters to univariate functions which may be suitable for iteration. Cf. “Example 3” on page 1-86.

Examples

Example 1

For a nonnegative integer `n`, `f@@n` is equivalent to an `_fconcat` call:

```
f@@4, (f@@4)(x)
```

$$f \circ f \circ f \circ f,\ f(f(f(f(x))))$$

`@@` simplifies the composition of symbolic iterates:

```
(f@@n)@@m
```

$$f@@(m\ n)$$

The iterate may be called like any other MuPAD function. If `f` evaluates to a procedure and `n` to an integer, a corresponding value is computed:

```
f := x -> x^2:  (f@@n)(x) $ n = 0..10
```

$$x,\ x^2,\ x^4,\ x^8,\ x^{16},\ x^{32},\ x^{64},\ x^{128},\ x^{256},\ x^{512},\ x^{1024}$$

```
delete f:
```

Example 2

For functions with a known inverse function, `n` may be negative. The function `f` must have been declared as a function environment with the `"inverse"` slot. Examples of such functions include the trigonometric functions which are implemented as function environments in MuPAD:

```
sin::"inverse", sin@@-3, (sin@@(-3))(x)
```

$$\text{"arcsin"},\ \arcsin \circ \arcsin \circ \arcsin,\ \arcsin(\arcsin(\arcsin(x)))$$

Example 3

`@@` can only be used for functions that accept their own output domain as an input, i.e., $f\colon M \to M$ for some set M. If you want to use `@@` with a function which needs additional parameters, `fp::fixargs` is a handy tool to generate a corresponding univariate function. In the following call, the function `f: x -> g(x, p)` is iterated:

```
g := (x, y) -> x^2 + y: f := fp::fixargs(g, 1, p): (f@@4)(x)
```

$$p + (p + (p + (x^2 + p)^2)^2)^2$$

```
delete g, f:
```

Parameters

f

A function

n

An integer or a symbolic name

Return Values

Function

See Also

MuPAD Functions
`@` | `fp::fixargs` | `fp::fold` | `fp::nest` | `fp::nestvals`

$, _seqgen, _seqin, _seqstep

Create an expression sequence

Syntax

```
$ a .. b
_seqgen(a .. b)
$ c .. d step e
_seqstep(c .. d, e)
f $ n
_seqgen(f, n)
f $ c step e
_seqstep(f, c, e)
f $ i = a .. b
_seqgen(f, i, a .. b)
f $ i = c .. d step e
_seqstep(f, i, c .. d, e)
f $ i in object
_seqin(f, i, object)
```

Description

`$ a..b` creates the sequence of integers from `a` through `b`.

`$c..d step e` creates the sequence of numbers from `c` through `d` with increment `e`.

`f $ n` creates the sequence `f,..., f` consisting of `n` copies of `f`.

`f $ c step e` creates the sequence `f,..., f` consisting of `trunc(c/e)` copies of `f`.

`f(i) $ i = a..b` creates the sequence `f(a), f(a+1),..., f(b)`.

`f(i) $ i = c..d step e` creates the sequence `f(c), f(c+e),..., f(c+j*e)`, with `j` such that `c+j*e <= d` and `c+(j+1)*e > d`.

`f(i) $ i in object` creates the sequence `f(i1), f(i2), ...`, where `i1`, `i2` etc. are the operands of the `object`.

The `$` operator is a most useful tool. It serves for generating sequences of objects. Sequences are used to define sets or lists, and may be passed as arguments to system functions. Cf. “Example 1” on page 1-90.

`$ a..b` and the equivalent function call `_seqgen(a..b)` produce the sequence of integers `a, a + 1, ... , b`. The void object of type `DOM_NULL` is produced if `a > b`.

`$ c..d step e` and the equivalent function call `_seqstep(c..d, e)` produce the sequence of numbers `c, c + e, ... , c + j*e`, with `j` such that `c + j*e <= d` and `c + (j + 1)*e > d`. The void object of type `DOM_NULL` is produced if `c > d`.

`f $ n` and the equivalent function call `_seqgen(f, n)` produce a sequence of `n` copies of the object `f`. Note that `f` is evaluated only once, before the sequence is created. The empty sequence of type `DOM_NULL` is produced if `n` is not positive.

`f $ c step e` and the equivalent function call `_seqstep(f, c, e)` produce a sequence of `trunc(c/e)` copies of the object `f`. Note that `f` is evaluated only once, before the sequence is created. The empty sequence of type `DOM_NULL` is produced if `trunc(c/e)` is not positive.

`f $ i = a..b` and the equivalent function call `_seqgen(f, i, a..b)` successively set `i := a` through `i := b` and evaluate `f` with these values. After this (or in case of an error, earlier), the previous value of `i` is restored.

Note that `f` is not evaluated before the first assignment. The void object of type `DOM_NULL` is produced if `a > b`.

`f $ i = c..d step e` and the equivalent function call `_seqstep(f, i, c..d, e)` successively set `i := c`, `i := c + e`, `...` until the value of `i` exceeds `d` and evaluate `f` with these values. After this (or in case of an error, earlier), the previous value of `i` is restored.

Note that `f` is not evaluated before the first assignment. The void object of type `DOM_NULL` is produced if `c > d`.

`f $ i in object` and the equivalent function call `_seqin(f, i, object)` successively assign the operands of the `object` to `i`: they set `i := op(object, 1)` through `i := op(object, n)` and evaluate `f` with these values, returning the result. (`n = nops(object)` is the number of operands.)

Note that `f` is not evaluated before the assignments. The empty sequence of type `DOM_NULL` is produced if the `object` has no operands.

The "loop variable" `i` in `f $ i = a..b` and `f $ i in object` may have a value. This value is restored after the `$` statement returns.

Examples

Example 1

The following sequence can be passed as arguments to the function `_plus`, which adds up its arguments:

```
i^2 $ i = 1..5
```

$$1, 4, 9, 16, 25$$

```
_plus(i^2 $ i = 1..5)
```

$$55$$

The 5-th derivative of the expression `exp(x^2)` is:

```
diff(exp(x^2), x $ 5)
```

$$120\,x\,e^{x^2} + 160\,x^3\,e^{x^2} + 32\,x^5\,e^{x^2}$$

We compute the first derivatives of `sin(x)`:

```
diff(sin(x), x $ i) $ i = 0..5
```

$$\sin(x),\ \cos(x),\ -\sin(x),\ -\cos(x),\ \sin(x),\ \cos(x)$$

We use `ithprime` to compute the first 10 prime numbers:

```
ithprime(i) $ i = 1..10
```

$$2, 3, 5, 7, 11, 13, 17, 19, 23, 29$$

We select all primes from the set of integers between 1990 and 2010:

```
select({$ 1990..2010}, isprime)
```

$$\{1993, 1997, 1999, 2003\}$$

The 3×3matrix with entries $A_{ij} = i\,j$ is generated:

```
n := 3: matrix([[i*j $ j = 1..n] $ i = 1..n])
```

$$\begin{pmatrix} 1 & 2 & 3 \\ 2 & 4 & 6 \\ 3 & 6 & 9 \end{pmatrix}$$

```
delete n:
```

Example 2

In `f $ n`, the object `f` is evaluated only once. The result is copied `n` times. Consequently, the following call produces copies of one single random number:

```
random() $ 3
```

$$427419669081, 427419669081, 427419669081$$

The following call evaluates `random` for each value of of `i`:

```
random() $ i = 1..3
```

$$321110693270, 343633073697, 474256143563$$

Example 3

In the following call, `i` runs through the list:

```
i^2 $ i in [3, 2, 1]
```

```
9, 4, 1
```

Note that the screen output of sets does not necessarily coincide with the internal ordering:

```
set := {i^2 $ i = 1..19}:
set;
[op(set)]
```

```
{1, 4, 9, 16, 25, 36, 49, 64, 81, 100, 121, 144, 169, 196, 225, 256, 289, 324, 361}
```

```
[1, 4, 361, 9, 16, 25, 36, 49, 64, 81, 100, 121, 144, 169, 196, 225, 256, 289, 324]
```

The $ operator respects the internal ordering:

```
i^2 $ i in set
```

```
1, 16, 130321, 81, 256, 625, 1296, 2401, 4096, 6561, 10000, 14641, 20736, 28561, 38416, 50625,
  65536, 83521, 104976
```

```
delete set:
```

Example 4

Arbitrary objects `f` are allowed in `f $ i = a..b`. In the following call, `f` is an assignment (it has to be enclosed in brackets). The sequence computes a table `f[i] = i!`:

```
f[0] := 1: (f[i] := i*f[i - 1]) $ i = 1..4: f
```

0	1
1	1
2	2
3	6
4	24

```
delete f:
```

Example 5

Apart from the usual sequence generator with the step size 1, `_seqstep` allows arbitrary integer, rational, or real numbers as step sizes:

```
1 $ 2 step 0.5
```

$$1, 1, 1, 1$$

```
$ 1..2 step .2
```

$$1, 1.2, 1.4, 1.6, 1.8, 2.0$$

```
f(i) $ i = 1..2 step 1/2
```

$$f(1), f\left(\frac{3}{2}\right), f(2)$$

Like in a `for`-loop, the step size can be negative:

```
f(i) $ i = 5..1 step -2
```

$$f(5), f(3), f(1)$$

In contrast to `_seqgen` the range bounds in `_seqstep` can be rational or floating-point numbers:

```
1 $ 5/2 step 0.5
```

$$1, 1, 1, 1, 1$$

```
$ 1.1..2.1 step .2
```

$$1.1, 1.3, 1.5, 1.7, 1.9, 2.1$$

```
f(i) $ i = 1/2..5/2 step 1/2
```

$$f\left(\frac{1}{2}\right), f(1), f\left(\frac{3}{2}\right), f(2), f\left(\frac{5}{2}\right)$$

Example 6

the $-expression returns symbolically, if the given range is symbolic:

```
x $ n, $ a..b, f(i) $ i = a..b
```

$$x\ \$\ n,\ \$\ a..b,\ f(i)\ \$\ i = a..b$$

Parameters

`f, object`

Arbitrary MuPAD objects

`n, a, b`

integers

`c, d, e`

integer, rational, or floating-point numbers

`i`

An identifier or a local variable (`DOM_VAR`) of a procedure

Return Values

Expression sequence of type "_exprseq" or the void object of type `DOM_NULL`.

Overloaded By

a..b, c..d, e, f, i, n, object

See Also

MuPAD Functions
`_exprseq` | `null`

,, _exprseq

Expression sequences

Syntax

```
object1, object2, ...

_exprseq(object1, object2, …)
```

Description

The function call `_exprseq(object1, object2, ...)` is the internal representation of the expression sequence `object1, object2, ...`.

In MuPAD, “sequences” are ordered collections of objects separated by commas. You may think of the comma as an operator that concatenates sequences. Internally, sequences are represented as function calls `_exprseq(object1, object2, ...)`. On the screen, sequences are printed as `object1, object2, ...`.

`_exprseq()` and the equivalent call `null()` yield the void object of type `DOM_NULL`.

When evaluating an expression sequence, all void objects of type `DOM_NULL` are removed from it, automatically.

The `$` operator is a useful tool for generating sequences.

When a MuPAD function or procedure is called with more than one argument, the parameters are passed as an expression sequence.

Examples

Example 1

A sequence is generated by “concatenating” objects with commas. The resulting object is of type `"_exprseq"`:

```
a, b, sin(x)
```

$$a, b, \sin(x)$$

```
op(%, 0), type(%)
```

$$\text{\_exprseq}, \text{"\_exprseq"}$$

On the screen, `_exprseq` just returns its argument sequence:

```
_exprseq(1, 2, x^2 + 5) = (1, 2, x^2 + 5)
```

$$(1, 2, x^2 + 5) = (1, 2, x^2 + 5)$$

Example 2

The object of domain `DOM_NULL` (the “empty sequence”) is automatically removed from expression sequences:

```
1, 2, null(), 3
```

$$1, 2, 3$$

Expression sequences are flattened. The following sequence does not have 2 operands, where the second operand is a sequence. Instead, it is flattened to a sequence with 3 operands:

```
x := 1: y := 2, 3: x, y
```

$$1, 2, 3$$

```
delete x, y:
```

Example 3

Sequences are used to build sets and lists. Sequences can also be passed to functions that accept several arguments:

```
s := 1, 2, 3: {s}, [s], f(s)
```

$$\{1, 2, 3\}, [1, 2, 3], f(1, 2, 3)$$

```
delete s:
```

Parameters

$\mathbf{object}_1$, $\mathbf{object}_2$, …

Arbitrary MuPAD objects

Return Values

Expression of type `"_exprseq"` or the void object of type `DOM_NULL`.

See Also

MuPAD Functions

`_stmtseq` | `null`

%if

Conditional creation of code by the parser

Syntax

```
%if condition1
then casetrue1
   elif condition2 then casetrue2
   elif condition3 then casetrue3
   ...
   else casefalse
 end_if
```

Description

`%if` controls the creation of code by the parser depending on a condition.

This statement is one of the more esoteric features of MuPAD. It is *not* executed at run time by the MuPAD interpreter. It controls the creation of code for the interpreter by the parser.

`%if` may be used to create different versions of a library which share a common code basis, or to insert debugging code which should not appear in the release version.

The first condition is executed by the parser in a Boolean context and must yield one of the Boolean values `TRUE` or `FALSE`:

- If the condition yields `TRUE`, the statement sequence `casetrue` is the code that is created by the parser for the `%if`-statement. The rest of the statement is ignored by the parser, no code is created for it.
- If the condition yields `FALSE`, then the condition of the next `elif`-part if evaluated and the parser continues as before.
- If all conditions evaluate to `FALSE` and no more `elif`-parts exist, the parser inserts the code of the statement sequence `casefalse` as the code for the `%if`-statement. If no `casefalse` exists, `NIL` is produced.

The whole statement sequence is read by the parser and must be syntactically correct. Also the parts that do not result in code must be syntactically correct.

Note that instead of `end_if`, one may also simply use the keyword `end`.

In case of an empty statement sequence, the parser creates `NIL` as code.

Note: The conditions are parsed in the lexical context where they occur, but are *evaluated by the parser in the context where the parser is executed*. This is the case because the environment where the conditions are exically bound simply does not exist during parsing. Thus, one must ensure that names in the conditions do not conflict with names of local variables or arguments in the surrounding lexical context. The parser does not check this!

No function exists in the interpreter which can execute the `%if`-statement. The reason is that the statement is implemented by the parser, not by the interpreter.

Examples

Example 1

In the following example, we create debugging code in a procedure depending on the value of the global identifier `DEBUG`.

Note that this example is somewhat academic, as the function `prog::trace` is a much more elegant way to trace a procedure during debugging.

```
DEBUG := TRUE:
p := proc(x) begin
     %if DEBUG = TRUE then
         print("entering p")
     end;
     x^2
end_proc:
p(2)
```

```
"entering p"
```

```
4
```

When we look at p, we see that only the print command was inserted by the parser:

```
expose(p)
```

```
proc(x)
  name p;
begin
  print("entering p");
  x^2
end_proc
```

Now we set DEBUG to FALSE and parse the procedure again to create the release version. No debug output is printed:

```
DEBUG := FALSE:
p := proc(x) begin
     %if DEBUG = TRUE then
         print("entering p")
     end;
     x^2
end_proc:
p(2)
```

```
     4
```

If we look at the procedure we see that NIL was inserted for the %if-statement:

```
expose(p)
```

```
proc(x)
  name p;
begin
  NIL;
  x^2
end_proc
```

Parameters

condition

A Boolean expression

`casetrue`

A statement sequence

`casefalse`

A statement sequence

Algorithms

This statement may remind C programmers of conditional compilation. In C, this is implemented by a pre-processor which is run before the parser. In MuPAD, such a pre-processor does not exist. The `%if`-statement is part of the parsing process.

See Also

MuPAD Functions
`if`

;, :, _stmtseq

Statement sequences

Syntax

```
object1; object2; ...

object1: object2: ...

_stmtseq(object1, object2, …)
```

Description

The function call `_stmtseq (object1, object2, ...)` is equivalent to the statement sequence `(object1; object2; ...)`.

The function call `_stmtseq (object1, object2, ...)` evaluates the statements `(object1; object2; ...)` from left to right.

`_stmtseq ()` returns the void object of type `DOM_NULL`.

Examples

Example 1

Usually, statements are entered imperatively:

```
x := 2; x := x^2 + 17; sin(x + 1)
```

```
2
```

```
21
```

```
sin(22)
```

This sequence of statements is turned into a single command (a “statement sequence”) by enclosing it in brackets. Now, only the result of the “statement sequence” is printed. It is the result of the last statement inside the sequence:

```
(x := 2; x := x^2 + 17; sin(x + 1))
```

$$\sin(22)$$

Alternatively, the statement sequence can be entered via `_stmtseq`. For syntactical reasons, the assignments have to be enclosed in brackets when using them as arguments for `_stmtseq`. Only the return value of the statement sequence (the return value of the last statement) is printed:

```
_stmtseq((x := 2), (x := x^2 + 17),  sin(x + 1))
```

$$\sin(22)$$

Statement sequences can be iterated:

```
x := 1: (x := x + 1; x := x^2; print(i, x)) $ i = 1..4
```

1, 4

2, 25

3, 676

4, 458329

```
delete x:
```

Parameters

$\mathtt{object}_1$, $\mathtt{object}_2$, …

Arbitrary MuPAD objects and statements

Return Values

Return value of the last statement in the sequence.

MuPAD Functions

`_exprseq`

abs

Absolute value of a real or complex number

Syntax

```
abs(z)
```

```
abs(L)
```

Description

`abs(z)` returns the absolute value of the number `z`.

For many constant expressions, `abs` returns the absolute value as an explicit number or expression. Cf. “Example 1” on page 1-107.

A symbolic call of `abs` is returned if the absolute value cannot be determined (e.g., because the argument involves identifiers). The result is subject to certain simplifications. In particular, `abs` extracts constant factors. Properties of identifiers are taken into account. See “Example 2” on page 1-107 and “Example 3” on page 1-108.

The `expand` function rewrites the absolute value of a product to a product of absolute values. E.g., `expand(abs(x*y))` yields `abs(x)*abs(y)`. Cf. “Example 4” on page 1-108.

The symbolic constants `CATALAN`, `E`, `EULER`, and `PI` are processed by `abs`. Cf. “Example 5” on page 1-108.

The absolute value of symbolic function calls can be defined via the slot `"abs"` of function environments. Cf. “Example 7” on page 1-109.

In the same way, the absolute value of domain elements can be defined via overloading. Cf. “Example 8” on page 1-109.

This function is automatically mapped to all entries of container objects such as arrays, lists, matrices, polynomials, sets, and tables.

Environment Interactions

`abs` respects properties of identifiers.

Examples

Example 1

For many constant expressions, the absolute value can be computed explicitly:

```
abs(1.2), abs(-8/3), abs(3 + I), abs(sqrt(-3))
```

$$1.2,\ \frac{8}{3},\ \sqrt{10},\ \sqrt{3}$$

```
abs(sin(42)), abs(PI^2 - 10), abs(exp(3) - tan(157/100))
```

$$-\sin(42),\ 10-\pi^2,\ \tan\left(\frac{157}{100}\right)-e^3$$

```
abs(exp(3 + I) - sqrt(2))
```

$$\sqrt{e^6\sin(1)^2+(\cos(1)\,e^3-\sqrt{2})^2}$$

Example 2

Symbolic calls are returned if the argument contains identifiers without properties:

```
abs(x), abs(x + 1), abs(sin(x + y))
```

$$|x|,\ |x+1|,\ |\sin(x+y)|$$

The result is subject to some simplifications. In particular, `abs` splits off constant factors in products:

```
abs(PI*x*y), abs((1 + I)*x), abs(sin(4)*(x + sqrt(3)))
```

$$\pi\,|x\,y|,\ \sqrt{2}\,|x|,\ -\sin(4)\,|x+\sqrt{3}|$$

Example 3

`abs` is sensitive to properties of identifiers:

```
assume(x < 0):  abs(3*x), abs(PI - x), abs(I*x)
```

$$-3\,x,\ \pi - x,\ -x$$

```
unassume(x):
```

Example 4

The `expand` function produces products of `abs` calls:

```
abs(x*(y + 1)), expand(abs(x*(y + 1)))
```

$$|x\,(y+1)|,\ |y+1|\,|x|$$

Example 5

The absolute value of the symbolic constants `PI`, `EULER`, etc. are known:

```
abs(PI), abs(EULER + CATALAN^2)
```

$$\pi,\ \mathrm{EULER} + \mathrm{CATALAN}^2$$

Example 6

Expressions containing `abs` can be differentiated:

```
diff(abs(x), x),  diff(abs(x), x, x)
```

$$\mathrm{sign}(x),\ 2\,\delta(x)$$

Example 7

The slot `"abs"` of a function environment `f` defines the absolute value of symbolic calls of `f`:

```
abs(f(x))
```

$$|f(x)|$$

```
f := funcenv(f):
f::abs := x -> f(x)/sign(f(x)):
abs(f(x))
```

$$\frac{f(x)}{\mathrm{sign}(f(x))}$$

```
delete f:
```

Example 8

The slot `"abs"` of a domain `d` defines the absolute value of its elements:

```
d := newDomain("d"):
e1 := new(d, 2):
e2 := new(d, x):
d::abs := x -> abs(extop(x, 1)):
abs(e1), abs(e2)
```

$$2,\ |x|$$

```
delete d, e1, e2:
```

Parameters

z

An arithmetical expression

L

A container object: an array, an hfarray, a list, a matrix, a polynomial, a set, or a table.

Return Values

arithmetical expression or a container object containing such expressions

Overloaded By

z

MuPAD Functions

`conjugate` | `Im` | `norm` | `Re` | `sign`

airyAi

Airy function of the first kind

Syntax

```
airyAi(z)

airyAi(z, n)
```

Description

`airyAi(z)` represents the Airy function of the first kind. The Airy functions `airyAi(z)` and `airyBi(z)` are linearly independent solutions of the differential equation $\frac{\partial^2}{\partial z^2} y - z\, y = 0$.

The call `airyAi(z)` is equivalent to `airyAi(z, 0)`.

`airyAi(z, n)` represents the n-th derivative of `airyAi(z)` with respect to z.

For $n \geq 2$, derivatives of the Airy functions are automatically expressed in terms of the Airy functions and their first derivative. See “Example 1” on page 1-112.

`airyAi` returns special values for $z = 0$ and $z = \pm\infty$. For all other symbolic values of z, unevaluated function calls are returned. See “Example 2” on page 1-112.

Environment Interactions

When called with floating-point arguments, this function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Second and higher derivatives of Airy functions are rewritten in terms of Airy functions and their first derivatives:

```
airyAi(x), airyAi(x, 1), airyBi(sin(x), 3)
```

$$\text{airyAi}(x, 0),\ \text{airyAi}(x, 1),\ \text{airyBi}(\sin(x), 0) + \sin(x)\ \text{airyBi}(\sin(x), 1)$$

Example 2

For $z = 0$, special values are returned:

```
airyAi(0), airyBi(0, 1), airyAi(0, 27)
```

$$\frac{3^{1/3}}{3\,\Gamma\left(\frac{2}{3}\right)},\ \frac{3^{2/3}\,\Gamma\left(\frac{2}{3}\right)}{2\,\pi},\ \frac{608608000\ 3^{1/3}}{3\,\Gamma\left(\frac{2}{3}\right)}$$

For $n = 0, 1$ and any symbolic $z \neq 0$, $z \neq \pm\infty$, a symbolic call is returned:

```
airyAi(-1), airyBi(x, 1)
```

$$\text{airyAi}(-1, 0),\ \text{airyBi}(x, 1)$$

floating-point values are returned for floating-point arguments:

```
airyBi(0.0), airyAi(-3.24819, 1), airyBi(-3.45 + 2.75*I);
```

$$0.6149266274,\ 0.00001031967672,\ -16.85910551 - 32.61659997\,i$$

Example 3

The functions `diff`, `float`, `limit`, and `series` handle expressions involving the Airy functions

```
diff(airyBi(x^2), x), float(airyAi(PI))
```

$$2\,x\,\mathrm{airyBi}(x^2,\,1),\,0.00508935348$$

```
limit(airyAi(-x), x = infinity),
series(airyBi(x, 1), x = infinity, 4)
```

$$0,\ \frac{x^{1/4}\,\sigma_1}{\sqrt{\pi}} - \frac{7\,\sigma_1}{48\,\sqrt{\pi}\,x^{5/4}} - \frac{455\,\sigma_1}{4608\,\sqrt{\pi}\,x^{11/4}} + O\left(\frac{\sigma_1}{x^{15/4}}\right)$$

where

$$\sigma_1 = \left(e^{x^{3/2}}\right)^{2/3}$$

Parameters

z

Arithmetical expression

n

Arithmetical expression representing a nonnegative integer

Return Values

Arithmetical expression.

Overloaded By

z

MuPAD Functions
`airyBi` | `besselI` | `besselJ` | `besselK`

airyBi

Airy function of the second kind

Syntax

```
airyBi(z)

airyBi(z, n)
```

Description

`airyBi(z)` represents the Airy function of the second kind. The Airy functions `airyAi(z)` and `airyBi(z)` are linearly independent solutions of the differential equation $\frac{\partial^2}{\partial z^2} y - z\, y = 0$.

The call `airyBi(z)` is equivalent to `airyBi(z, 0)`.

`airyBi(z, n)` represents the n-th derivative of `airyBi(z)` with respect to z.

For $n \geq 2$, derivatives of the Airy functions are automatically expressed in terms of the Airy functions and their first derivative. See “Example 1” on page 1-116.

`airyBi` returns special values for $z = 0$ and $z = \pm\infty$. For all other symbolic values of z, unevaluated function calls are returned. See “Example 2” on page 1-116.

Environment Interactions

When called with floating-point arguments, this functions is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Second and higher derivatives of Airy functions are rewritten in terms of Airy functions and their first derivatives:

```
airyAi(x), airyAi(x, 1), airyBi(sin(x), 3)
```

$$\text{airyAi}(x, 0),\ \text{airyAi}(x, 1),\ \text{airyBi}(\sin(x), 0) + \sin(x)\ \text{airyBi}(\sin(x), 1)$$

Example 2

For $z = 0$, special values are returned:

```
airyAi(0), airyBi(0, 1), airyAi(0, 27)
```

$$\frac{3^{1/3}}{3\,\Gamma\left(\frac{2}{3}\right)},\ \frac{3^{2/3}\,\Gamma\left(\frac{2}{3}\right)}{2\,\pi},\ \frac{608608000\ 3^{1/3}}{3\,\Gamma\left(\frac{2}{3}\right)}$$

For $n = 0, 1$ and any symbolic $z \neq 0$, $z \neq \pm\infty$, a symbolic call is returned:

```
airyAi(-1), airyBi(x, 1)
```

$$\text{airyAi}(-1, 0),\ \text{airyBi}(x, 1)$$

floating-point values are returned for floating-point arguments:

```
airyBi(0.0), airyAi(-3.24819, 1), airyBi(-3.45 + 2.75*I);
```

$$0.6149266274,\ 0.00001031967672,\ -16.85910551 - 32.61659997\,i$$

Example 3

The functions `diff`, `float`, `limit`, and `series` handle expressions involving the Airy functions

```
diff(airyBi(x^2), x), float(airyAi(PI))
```

$$2\,x\,\mathrm{airyBi}(x^2, 1),\ 0.00508935348$$

```
limit(airyAi(-x), x = infinity),
series(airyBi(x, 1), x = infinity, 4)
```

$$0,\ \frac{x^{1/4}\,\sigma_1}{\sqrt{\pi}} - \frac{7\,\sigma_1}{48\,\sqrt{\pi}\,x^{5/4}} - \frac{455\,\sigma_1}{4608\,\sqrt{\pi}\,x^{11/4}} + O\left(\frac{\sigma_1}{x^{15/4}}\right)$$

where

$$\sigma_1 = \left(e^{x^{3/2}}\right)^{2/3}$$

Parameters

z

Arithmetical expression

n

Arithmetical expression representing a nonnegative integer

Return Values

Arithmetical expression.

MuPAD Functions
`airyAi` | `besselI` | `besselJ` | `besselK`

alias

Defines an abbreviation or a macro

Syntax

```
alias(x1 = object1, x2 = object2, …, <Global>)
```

```
alias(<Global>)
```

Description

`alias(x = object)` defines `x` as an abbreviation for `object`.

`alias(x = object)` defines an abbreviation. It changes the configuration of the parser such that the identifier`x` is replaced by `object` whenever it occurs in the input, and such that `object` is in turn replaced by `x` in the output.

`alias(f(y1, y2, ...) = object)` defines `f` to be a macro. For arbitrary objects `a1, a2, ...`, `f(a1, a2, ...)` is equivalent to `object` with `a1` substituted for `y1`, `a2` substituted for `y2`, etc.

`alias(f(y1, y2, ...) = object)` defines a macro. It changes the configuration of the parser such that a function call of the form `f(a1, a2, ...)`, where `a1,a2,...` is a sequence of arbitrary objects of the same length as `y1,y2,...`, is replaced by `object` with `a1` substituted for `y1`, `a2` substituted for `y2`, etc.

No substitution takes place if the number of parameters `y1,y2,...` differs from the number of arguments `a1,a2,...`. No substitution takes place in the output.

It is valid to define a macro with no arguments via `alias(f()=object)`.

Multiple alias definitions may be given in a single call; abbreviations and macros may be mixed.

`alias()` displays a list of all currently defined aliases and macros.

`alias()` displays all currently defined aliases as a sequence of equations. For an abbreviation defined via `alias(x = object)`, the equation `x = object` is printed. For a macro defined via `alias(f(y1, y2, ...) = object)`, the equation `f(y1,`

`y2, ...) = object` is printed. If no aliases are defined, the message "No alias defined" is printed. See "Example 11" on page 1-127.

`alias` does not evaluate its arguments. Hence it has no effect if the aliased identifier has a value, and `alias` creates an alias for the right hand side of the alias definition and not for its evaluation. Cf. "Example 2" on page 1-122.

`alias` does not flatten its arguments. Thus an expression sequence is a valid right hand side of an alias definition. See "Example 5" on page 1-125.

An alias definition causes a substitution similar to the effect of `subs`, not just a textual replacement. Cf. "Example 3" on page 1-123.

Each identifier may be aliased to only one object. Each object may be abbreviated in only one way; otherwise `alias` aborts with an error.

An alias is in effect from the time when the call to `alias` has been evaluated. It affects exactly those inputs that are *parsed* after that moment. Cf. "Example 9" on page 1-126. In particular, an alias definition inside a procedure does not affect the rest of the procedure.

By default, back-substitution of aliases in the output happens only for abbreviations and not for macros. After a command of the form `alias(x = object)`, both the unevaluated object `object` and its evaluation are replaced by the unevaluated identifier `x` in the output. Cf. "Example 2" on page 1-122.

The user can control the behavior of the back-substitution in the output with the function `Pref::alias`; see the corresponding help page for details.

Substitutions in the output only happen for the results of computations at interactive level. The behavior of the functions `fprint`, `print`, `expr2text`, or `write` is not affected.

Alias substitutions are performed in parallel, both in the input and in the output. Thus it is not possible to define nested aliases. See "Example 10" on page 1-126.

If an identifier is used as an abbreviation, it is not possible to enter this identifier in its literal meaning any longer.

Note: In particular, it is necessary to use `unalias` before another abbreviation or macro for the same identifier can be defined. Cf. "Example 4" on page 1-124.

If a macro `f(y1,y2,...,yn)` with n arguments has been defined, it is not possible to enter a call to `f` with n arguments in its literal meaning any longer. However, entering a call to `f` with a different number of arguments is still possible. Cf. “Example 5” on page 1-125.

Macros with different numbers of arguments can be defined at the same time. See “Example 4” on page 1-124.

An alias definition affects all kinds of input: interactive input on the command line, input via the function `input`, input from a file using `finput`, `fread`, or `read` (for the latter two only if option `Plain` is not set), and input from a string using `text2expr`. Cf. “Example 8” on page 1-126.

An alias definition has no effect on the identifier used as an alias. In particular, that identifier retains its value and its properties. The alias and the aliased object are still distinguished by the evaluator. Cf. “Example 6” on page 1-125.

Assigning a value to one of the identifiers on the left hand side of an alias definition, or deleting its value has no effect on the alias substitution, neither in the input nor in the output. See “Example 7” on page 1-125.

Environment Interactions

`alias` with at least one argument and `unalias` change the parser configuration in the way described in the “Details” section.

Examples

Example 1

We define `d` as a shortcut for `diff`:

```
delete f, g, x, y: alias(d = diff):
d(sin(x), x) = diff(sin(x), x);
d(f(x, y), x) = diff(f(x, y), x)
```

$$\cos(x) = \cos(x)$$

$$d(f(x, y), x) = d(f(x, y), x)$$

We define a macro `Dx(f)` for `diff(f(x), x)`. Note that `hold` does not prevent alias substitution:

```
alias(Dx(f) = diff(f(x), x)):
Dx(sin); Dx(f + g); hold(Dx(f + g))
```

$$\cos(x)$$

$$d(f(x), x) + d(g(x), x)$$

$$d(f(x) + g(x), x)$$

After the call `unalias(d, Dx)`, no alias substitutions happen any longer:

```
unalias(d, Dx):
d(sin(x), x), diff(sin(x), x), d(f(x, y), x), diff(f(x, y), x);
Dx(sin), Dx(f + g)
```

$$d(\sin(x), x),\ \cos(x),\ d(f(x, y), x),\ \frac{\partial}{\partial x} f(x, y)$$

$$\mathrm{Dx}(\sin),\ \mathrm{Dx}(f + g)$$

Example 2

Suppose we want to avoid typing `longhardtotypeident` and therefore define an abbreviation `a` for it:

```
longhardtotypeident := 10;  alias(a = longhardtotypeident):
```

$$10$$

Since `alias` does not evaluate its arguments, `a` is now an abbreviation for `longhardtotypeident` and not for the number `10`:

```
type(a), type(hold(a))
```

DOM_INT, DOM_IDENT

```
a + 1, hold(a) + 1, eval(hold(a) + 1)
```

$11, a + 1, 11$

```
longhardtotypeident := 2:
a + 1, hold(a) + 1, eval(hold(a) + 1)
```

$3, a + 1, 3$

However, by default alias back-substitution in the output happens for both the identifier and its current value:

```
2, 10, longhardtotypeident, hold(longhardtotypeident)
```

$a, 10, a, a$

The command `Pref::alias(FALSE)` switches alias resubstitution off:

```
p := Pref::alias(FALSE):
a, hold(a), 2, longhardtotypeident, hold(longhardtotypeident);
Pref::alias(p): unalias(a):
```

2, longhardtotypeident, 2, 2, longhardtotypeident

Example 3

Aliases are substituted and not just replaced textually. In the following example, `3*succ(u)` is replaced by `3*(u+1)`, and not by `3*u+1`, which a search-and-replace function in a text editor would produce:

```
alias(succ(x) = x + 1): 3*succ(u);
unalias(succ):
```

$$3\,u+3$$

Example 4

We define a to be an abbreviation for b. Then the next alias definition is really an alias definition for b:

```
delete a, b:
alias(a = b): alias(a = 2): type(a), type(b); unalias(b):
```

DOM_IDENT, DOM_INT

Use `unalias` first before defining another alias for the identifier a:

```
unalias(a): alias(a = 2): type(a), type(b); unalias(a):
```

DOM_INT, DOM_IDENT

A macro definition, however, can be added if the newly defined macro has a different number of arguments. `unalias(a)` removes all macros defined for a:

```
alias(a(x)=sin(x^2)): a(y); alias(a(x)=cos(x^2)):
```

$$\sin(y^2)$$

```
Error: The operand is invalid. [_power]
  Evaluating: alias
```

```
alias(a(x, y) = sin(x + y)):
a(u, v);
alias():
unalias(a):
```

$$\sin(u+v)$$

```
a(x)   = sin(x^2)

a(x, y) = sin(x + y)
```

Example 5

A macro definition has no effect when called with the wrong number of arguments, and the sequence of arguments is not flattened:

```
alias(plus(x, y) = x + y):
plus(1), plus(3, 2), plus((3, 2));
unalias(plus):
```

$$\text{plus}(1),\ 5,\ \text{plus}(3,\ 2)$$

Expression sequences may appear on the right hand side of an alias definition, but they have to be enclosed in parenthesis:

```
alias(x = (1, 2)): f := 0, 1, 2, x;
nops(f); unalias(x):
```

$$0,\ 1,\ 2,\ 1,\ 2$$

$$5$$

Example 6

An identifier used as an abbreviation may still exist in its literal meaning inside expressions that were entered before the alias definition:

```
delete x: f := [x, 1]: alias(x = 1): f;
map(f, type); unalias(x):
```

$$[x,\ x]$$

$$[\text{DOM\_IDENT},\ \text{DOM\_INT}]$$

Example 7

It does not matter whether the identifier used as an alias has a value:

```
a := 5: alias(a = 7): 7, 5; print(a); unalias(a):
```

```
a, 5

7

delete a:
```

Example 8

Alias definitions also apply to input from files or strings:

```
alias(a = 3): type(text2expr("a")); unalias(a)

    DOM_INT
```

Example 9

An alias is valid for all input that is *parsed* after executing `alias`. A statement in a command line is not parsed before the previous commands in that command line have been executed. In the following example, the alias is already in effect for the second statement:

```
alias(a = 3): type(a); unalias(a)

    DOM_INT
```

This can be changed by entering additional parentheses:

```
(alias(a = 3): type(a)); unalias(a)

    DOM_IDENT
```

Example 10

We define `b` to be an alias for `c`, which in turn is defined to be an alias for `2`. It is recommended to avoid such chains of alias definitions beacuse of some probably unwanted effects.

```
alias(b=c): alias(c=2):
```

Now each `b` in the input is replaced by `c`, but no additional substitution step is taken to replace this again by `2`:

```
print(b)
```

$$c$$

On the other hand, the number `2` is replaced by `c` in every output and that `c` is then replaced by `b`:

```
2
```

$$b$$

```
unalias(c): unalias(b):
```

Example 11

When called without arguments, `alias` just displays all aliasses that are currently in effect:

```
alias(a = 5, F(x) = sin(x^2)):
alias(); unalias(F, a):
```

```
F(x) = sin(x^2)
```

```
a    = 5
```

Parameters

x_1, x_2, …

identifiers or symbolic expressions of the form `f(`y_1`, `y_2`, …)`, with identifiers `f`, y_1, y_2, `...`

$object_1$, $object_2$, …

Any MuPAD objects

Options

`Global`

Definition of an alias in the global parser context.

When an alias is defined in a library or package source file, it will be deleted automatically after reading the file. With option `Global` the alias is not active in the file being read, but in the interactive level after reading of the file is finished.

Return Values

Both `alias` and `unalias` return the void object of type `DOM_NULL`.

Algorithms

The aliases are stored in the parser configuration table displayed by `_parser_config()`. Note that by default, alias back-substitution happens for the right hand sides of the equations in this table, but not for the indices. Use `print(_parser_config())` to display this table without alias back-substitution.

Aliases are not in effect while a file is read using `read` or `fread` with option `Plain`. Conversely, if an alias is defined in a file which is read with option `Plain`, the alias is only in effect until the file has been read completely.

MuPAD Functions

`:=` | `finput` | `fprint` | `fread` | `input` | `Pref::alias` | `print` | `proc` | `read` | `subs` | `text2expr` | `unalias` | `write`

unalias

Deletes an alias-definition

Syntax

```
unalias(x1, x2, …, <Global>)
```

```
unalias(<Global>)
```

Description

`unalias(x)` deletes the abbreviation or macro `x`. To delete a macro defined by `alias(f(y1, y2, ...) = object)`, use `unalias(f)`. If no alias for `x` or `f`, respectively, is defined currently, the call is ignored.

`unalias()` deletes all abbreviations and macros.

Multiple alias definitions may be deleted by a single call of `unalias`. The call `unalias()` deletes all currently defined aliases.

`unalias` does not evaluate its arguments.

If an identifier is used as an abbreviation, it is not possible to enter this identifier in its literal meaning any longer.

Note: In particular, it is necessary to use `unalias` before another abbreviation or macro for the same identifier can be defined. Cf. “Example 4” on page 1-132.

Assigning a value to one of the identifiers on the left hand side of an alias definition, or deleting its value has no effect on the alias substitution, neither in the input nor in the output. See “Example 7” on page 1-134.

Environment Interactions

`alias` with at least one argument and `unalias` change the parser configuration in the way described in the “Details” section.

Examples

Example 1

We define `d` as a shortcut for `diff`:

```
delete f, g, x, y: alias(d = diff):
d(sin(x), x) = diff(sin(x), x);
d(f(x, y), x) = diff(f(x, y), x)
```

$$\cos(x) = \cos(x)$$

$$d(f(x, y), x) = d(f(x, y), x)$$

We define a macro `Dx(f)` for `diff(f(x), x)`. Note that `hold` does not prevent alias substitution:

```
alias(Dx(f) = diff(f(x), x)):
Dx(sin); Dx(f + g); hold(Dx(f + g))
```

$$\cos(x)$$

$$d(f(x), x) + d(g(x), x)$$

$$d(f(x) + g(x), x)$$

After the call `unalias(d, Dx)`, no alias substitutions happen any longer:

```
unalias(d, Dx):
d(sin(x), x), diff(sin(x), x), d(f(x, y), x), diff(f(x, y), x);
Dx(sin), Dx(f + g)
```

$$d(\sin(x), x),\ \cos(x),\ d(f(x, y), x),\ \frac{\partial}{\partial x} f(x, y)$$

$$\mathrm{Dx}(\sin),\ \mathrm{Dx}(f + g)$$

Example 2

Suppose we want to avoid typing `longhardtotypeident` and therefore define an abbreviation `a` for it:

```
longhardtotypeident := 10;  alias(a = longhardtotypeident):
```

$$10$$

Since `alias` does not evaluate its arguments, `a` is now an abbreviation for `longhardtotypeident` and not for the number `10`:

```
type(a), type(hold(a))
```

$$\text{DOM\_INT}, \text{DOM\_IDENT}$$

```
a + 1, hold(a) + 1, eval(hold(a) + 1)
```

$$11, a + 1, 11$$

```
longhardtotypeident := 2:
a + 1, hold(a) + 1, eval(hold(a) + 1)
```

$$3, a + 1, 3$$

However, by default alias back-substitution in the output happens for both the identifier and its current value:

```
2, 10, longhardtotypeident, hold(longhardtotypeident)
```

$$a, 10, a, a$$

The command `Pref::alias(FALSE)` switches alias resubstitution off:

```
p := Pref::alias(FALSE):
a, hold(a), 2, longhardtotypeident, hold(longhardtotypeident);
Pref::alias(p): unalias(a):
```

2, longhardtotypeident, 2, 2, longhardtotypeident

Example 3

Aliases are substituted and not just replaced textually. In the following example, `3*succ(u)` is replaced by `3*(u+1)`, and not by `3*u+1`, which a search-and-replace function in a text editor would produce:

```
alias(succ(x) = x + 1): 3*succ(u);
unalias(succ):
```

$$3\,u+3$$

Example 4

We define `a` to be an abbreviation for `b`. Then the next alias definition is really an alias definition for `b`:

```
delete a, b:
alias(a = b): alias(a = 2): type(a), type(b); unalias(b):
```

DOM_IDENT, DOM_INT

Use `unalias` first before defining another alias for the identifier `a`:

```
unalias(a): alias(a = 2): type(a), type(b); unalias(a):
```

DOM_INT, DOM_IDENT

A macro definition, however, can be added if the newly defined macro has a different number of arguments. `unalias(a)` removes all macros defined for `a`:

```
alias(a(x)=sin(x^2)): a(y); alias(a(x)=cos(x^2)):
```

$$\sin(y^2)$$

```
Error: The operand is invalid. [_power]
  Evaluating: alias
```

```
alias(a(x, y) = sin(x + y)):
a(u, v);
alias():
unalias(a):
```

$$\sin(u+v)$$

```
a(x)   = sin(x^2)

a(x, y) = sin(x + y)
```

Example 5

A macro definition has no effect when called with the wrong number of arguments, and the sequence of arguments is not flattened:

```
alias(plus(x, y) = x + y):
plus(1), plus(3, 2), plus((3, 2));
unalias(plus):
```

$$\text{plus}(1),\ 5,\ \text{plus}(3,\ 2)$$

Expression sequences may appear on the right hand side of an alias definition, but they have to be enclosed in parenthesis:

```
alias(x = (1, 2)): f := 0, 1, 2, x;
nops(f); unalias(x):
```

$$0,\ 1,\ 2,\ 1,\ 2$$

$$5$$

Example 6

An identifier used as an abbreviation may still exist in its literal meaning inside expressions that were entered before the alias definition:

```
delete x: f := [x, 1]: alias(x = 1): f;
map(f, type); unalias(x):
```

$[x, x]$

[DOM_IDENT, DOM_INT]

Example 7

It does not matter whether the identifier used as an alias has a value:

```
a := 5: alias(a = 7): 7, 5; print(a); unalias(a):
```

a, 5

7

```
delete a:
```

Example 8

Alias definitions also apply to input from files or strings:

```
alias(a = 3): type(text2expr("a")); unalias(a)
```

DOM_INT

Example 9

An alias is valid for all input that is *parsed* after executing `alias`. A statement in a command line is not parsed before the previous commands in that command line have been executed. In the following example, the alias is already in effect for the second statement:

```
alias(a = 3): type(a); unalias(a)
```

```
DOM_INT
```

This can be changed by entering additional parentheses:

```
(alias(a = 3): type(a)); unalias(a)
```

```
DOM_IDENT
```

Example 10

We define `b` to be an alias for `c`, which in turn is defined to be an alias for `2`. It is recommended to avoid such chains of alias definitions beacuse of some probably unwanted effects.

```
alias(b=c): alias(c=2):
```

Now each `b` in the input is replaced by `c`, but no additional substitution step is taken to replace this again by `2`:

```
print(b)
```

```
c
```

On the other hand, the number `2` is replaced by `c` in every output and that `c` is then replaced by `b`:

```
2
```

```
b
```

```
unalias(c): unalias(b):
```

Example 11

When called without arguments, `alias` just displays all aliasses that are currently in effect:

```
alias(a = 5, F(x) = sin(x^2)):
```

```
alias(); unalias(F, a):

F(x) = sin(x^2)

a    = 5
```

Parameters

x_1, x_2, …

identifiers or symbolic expressions of the form `f(`y_1`, `y_2`, …)`, with identifiers `f, `y_1`, `y_2`, ...`

$object_1$, $object_2$, …

Any MuPAD objects

Options

`Global`

Definition of an alias in the global parser context.

When an alias is defined in a library or package source file, it will be deleted automatically after reading the file. With option `Global` the alias is not active in the file being read, but in the interactive level after reading of the file is finished.

Return Values

Both `alias` and `unalias` return the void object of type `DOM_NULL`.

Algorithms

The aliases are stored in the parser configuration table displayed by `_parser_config()`. Note that by default, alias back-substitution happens for the right hand sides of the equations in this table, but not for the indices. Use `print(_parser_config())` to display this table without alias back-substitution.

Aliases are not in effect while a file is read using `read` or `fread` with option `Plain`. Conversely, if an alias is defined in a file which is read with option `Plain`, the alias is only in effect until the file has been read completely.

anames

Identifiers that have values or properties

Syntax

```
anames(<All>, <User>)
```

```
anames(<Properties>, <User>)
```

```
anames(<Protected>, <User>)
```

```
anames(d, <User>)
```

Description

`anames(All)` returns all identifiers that have values.

`anames(Properties)` returns all identifiers that have properties.

`anames(Protected)` returns all identifiers that are protected.

`anames(d)` returns all identifiers that have values from the given domain `d`.

The result returned by `anames` is a set of *unevaluated* identifiers.

`anames` does not take into account slots of function environments or domains. Moreover, functions of a MuPAD library are considered only if they are exported.

Examples

Example 1

`anames(All, User)` returns all user-defined identifiers:

```
a := b:  b := 2:  c := {2, 3}:
```

```
anames(All, User)
```

$$\{a, b, c\}$$

If the first argument is a domain, only identifiers with *values* from that domain are returned. These may differ from the identifiers whose *evaluation* belongs to the domain:

```
a, b;
anames(DOM_IDENT, User);
anames(DOM_INT, User)
```

$$2, 2$$

$$\{a\}$$

$$\{b\}$$

Example 2

`anames(Properties)` returns all identifiers that have been attached properties via `assume`:

```
assume(x > y): anames(Properties)
```

$$\{x, y\}$$

Example 3

`anames(Protected)` returns all identifiers that are protected via `protect`; since all system functions are protected, we use `anames(Protected, User)`:

```
protect(a): anames(Protected, User)
```

$$\{a\}$$

Parameters

`d`

A domain

Options

`All`

Get all identifiers that have values

`Properties`

Get all identifiers that have properties

`Protected`

Get all identifiers that are protected

`User`

Exclude all system variables

If the option `User` is given, only those identifiers are returned that have been assigned a value or a property, respectively, by the user.

Return Values

`set` of identifiers.

MuPAD Domains
`DOM_IDENT`

MuPAD Functions
`:=` | `_assign` | `assume`

and, _and

Logical “and”

Syntax

```
b1 and b2
```

```
_and(b1, b2, …)
```

Description

`b1 and b2` represents the logical ‘and’ of the Boolean expressions `b1`, `b2`.

MuPAD uses a three state logic with the Boolean constants `TRUE`, `FALSE`, and `UNKNOWN`. These are processed as follows:

and	TRUE	FALSE	UNKNOWN
TRUE	TRUE	FALSE	UNKNOWN
FALSE	FALSE	FALSE	FALSE
UNKNOWN	UNKNOWN	FALSE	UNKNOWN

Boolean expressions may be composed of these constants as well as of arbitrary arithmetical expressions. Typically, equations such as `x = y` and inequalities such as `x <> y`, `x < y`, `x <= y` etc. are used to construct Boolean expressions.

`_and(b1, b2, ...)` is equivalent to `b1 and b2 and ...`. This expression represents `TRUE` if each single expression evaluates to `TRUE`. It represents `FALSE` if at least one expression evaluates to `FALSE`. It represents `UNKNOWN` if at least one expression evaluates to `UNKNOWN` and all others evaluate to `TRUE`.

`_and()` returns `TRUE`.

Combinations of the constants `TRUE`, `FALSE`, `UNKNOWN` inside a Boolean expression are simplified automatically. However, symbolic Boolean subexpressions, equalities, and inequalities are not evaluated and simplified by logical operators. Use `bool` to evaluate such expressions to one of the Boolean constants. Note, however, that `bool` can

evaluate inequalities `x < y`, `x <= y` etc. only if they are composed of numbers of type `Type::Real`. Cf. “Example 2” on page 1-143.

Use `simplify` with the option `logic` to simplify expressions involving symbolic Boolean subexpressions. Cf. “Example 3” on page 1-144.

The precedences of the logical operators are as follows: The operator `not` is stronger binding than `and`, i.e, `not b1 and b2` = `(not b1) and b2`. The operator `and` is stronger binding than `xor`, i.e., `b1 and b2 or b3` = `(b1 and b2) xor b3`. The operator `xor` is stronger binding than `or`, i.e., `b1 xor b2 or b3` = `(b1 xor b2) or b3`. The operator `or` is stronger binding than `==>`, i.e., `b1 or b2 ==> b3` = `(b1 or b2) ==> b3`. The operator `==>` is stronger binding than `<=>`, i.e., `b1 ==> b2 <=> b3` = `(b1 ==> b2) <=> b3`.

If in doubt, use brackets to make sure that the expression is parsed as desired.

In the conditional context of `if`, `repeat`, and `while` statements, Boolean expressions are evaluated via “lazy evaluation” (see `_lazy_and`, `_lazy_or`). In any other context, all operands are evaluated.

Examples

Example 1

Combinations of the Boolean constants `TRUE`, `FALSE`, and `UNKNOWN` are simplified automatically to one of these constants:

```
TRUE and not (FALSE or TRUE)
```

```
    FALSE
```

```
FALSE and UNKNOWN, TRUE and UNKNOWN
```

```
    FALSE, UNKNOWN
```

```
FALSE or UNKNOWN, TRUE or UNKNOWN
```

```
    UNKNOWN, TRUE
```

```
not UNKNOWN
```

UNKNOWN

Example 2

Logical operators simplify subexpressions that evaluate to the constants TRUE, FALSE, UNKNOWN.

```
b1 or b2 and TRUE
```

$b1 \vee b2$

```
FALSE or ((not b1) and TRUE)
```

$\neg b1$

```
b1 and (b2 or FALSE) and UNKNOWN
```

$UNKNOWN \wedge b1 \wedge b2$

```
FALSE or (b1 and UNKNOWN) or x < 1
```

$(UNKNOWN \wedge b1) \vee x < 1$

```
TRUE and ((b1 and FALSE) or (b1 and TRUE))
```

$b1$

However, equalities and inequalities are not evaluated:

```
(x = x) and (1 < 2) and (2 < 3) and (3 < 4)
```

$x = x \wedge 1 < 2 \wedge 2 < 3 \wedge 3 < 4$

Boolean evaluation is enforced via `bool`:

```
bool(%)
```

```
TRUE
```

Example 3

Expressions involving symbolic Boolean subexpressions are not simplified by `and`, `or`, `not`. Simplification has to be requested explicitly via the function `simplify`:

```
(b1 and b2) or (b1 and (not b2)) and (1 < 2)
```

$$(b1 \wedge b2) \vee (b1 \wedge \neg b2 \wedge 1 < 2)$$

```
simplify(%, logic)
```

```
b1
```

Example 4

The Boolean functions `_and` and `_or` accept arbitrary sequences of Boolean expressions. The following call uses `isprime` to check whether *all* elements of the given set are prime:

```
set := {1987, 1993, 1997, 1999, 2001}:
_and(isprime(i) $ i in set)
```

```
FALSE
```

The following call checks whether *at least one* of the numbers is prime:

```
_or(isprime(i) $ i in set)
```

```
TRUE
```

```
delete set:
```

Parameters

b_1, b_2, …

Boolean expressions

Return Values

Boolean expression.

Overloaded By

b, b_1, b_2

See Also

MuPAD Functions

`<=>` | `==>` | `_lazy_and` | `_lazy_or` | `bool` | `FALSE` | `is` | `not` | `or` | `TRUE` | `UNKNOWN` | `xor`

or, _or

Logical “or”

Syntax

```
b1 or b2
```

```
_or(b1, b2, …)
```

Description

`b1 or b2` represents the non-exclusive logical ‘or’ of the Boolean expressions `b1`, `b2`.

MuPAD uses a three state logic with the Boolean constants `TRUE`, `FALSE`, and `UNKNOWN`. These are processed as follows:

or	TRUE	FALSE	UNKNOWN
TRUE	TRUE	TRUE	TRUE
FALSE	TRUE	FALSE	UNKNOWN
UNKNOWN	TRUE	UNKNOWN	UNKNOWN

Boolean expressions may be composed of these constants as well as of arbitrary arithmetical expressions. Typically, equations such as `x = y` and inequalities such as `x <> y`, `x < y`, `x <= y` etc. are used to construct Boolean expressions.

`_or(b1, b2, ...)` is equivalent to `b1 or b2 or ...`. This expression represents `FALSE` if each single expression evaluates to `FALSE`. It represents `TRUE` if at least one expression evaluates to `TRUE`. It represents `UNKNOWN` if at least one expression evaluates to `UNKNOWN` and all others evaluate to `FALSE`.

`_or()` returns `FALSE`.

Combinations of the constants `TRUE`, `FALSE`, `UNKNOWN` inside a Boolean expression are simplified automatically. However, symbolic Boolean subexpressions, equalities, and inequalities are not evaluated and simplified by logical operators. Use `bool` to evaluate such expressions to one of the Boolean constants. Note, however, that `bool` can

evaluate inequalities `x < y`, `x <= y` etc. only if they are composed of numbers of type `Type::Real`. Cf. “Example 2” on page 1-148.

Use `simplify` with the option `logic` to simplify expressions involving symbolic Boolean subexpressions. Cf. “Example 3” on page 1-149.

The precedences of the logical operators are as follows: The operator `not` is stronger binding than `and`, i.e, `not b1 and b2` = `(not b1) and b2`. The operator `and` is stronger binding than `xor`, i.e., `b1 and b2 or b3` = `(b1 and b2) xor b3`. The operator `xor` is stronger binding than `or`, i.e., `b1 xor b2 or b3` = `(b1 xor b2) or b3`. The operator `or` is stronger binding than `==>`, i.e., `b1 or b2 ==> b3` = `(b1 or b2) ==> b3`. The operator `==>` is stronger binding than `<=>`, i.e., `b1 ==> b2 <=> b3` = `(b1 ==> b2) <=> b3`.

If in doubt, use brackets to make sure that the expression is parsed as desired.

In the conditional context of `if`, `repeat`, and `while` statements, Boolean expressions are evaluated via “lazy evaluation” (see `_lazy_and`, `_lazy_or`). In any other context, all operands are evaluated.

Examples

Example 1

Combinations of the Boolean constants `TRUE`, `FALSE`, and `UNKNOWN` are simplified automatically to one of these constants:

```
TRUE and not (FALSE or TRUE)
```

```
     FALSE
```

```
FALSE and UNKNOWN, TRUE and UNKNOWN
```

```
     FALSE, UNKNOWN
```

```
FALSE or UNKNOWN, TRUE or UNKNOWN
```

```
     UNKNOWN, TRUE
```

```
not UNKNOWN
```

$$\text{UNKNOWN}$$

Example 2

Logical operators simplify subexpressions that evaluate to the constants TRUE, FALSE, UNKNOWN.

```
b1 or b2 and TRUE
```

$$b1 \vee b2$$

```
FALSE or ((not b1) and TRUE)
```

$$\neg b1$$

```
b1 and (b2 or FALSE) and UNKNOWN
```

$$\text{UNKNOWN} \wedge b1 \wedge b2$$

```
FALSE or (b1 and UNKNOWN) or x < 1
```

$$(\text{UNKNOWN} \wedge b1) \vee x < 1$$

```
TRUE and ((b1 and FALSE) or (b1 and TRUE))
```

$$b1$$

However, equalities and inequalities are not evaluated:

```
(x = x) and (1 < 2) and (2 < 3) and (3 < 4)
```

$$x = x \wedge 1 < 2 \wedge 2 < 3 \wedge 3 < 4$$

Boolean evaluation is enforced via `bool`:

```
bool(%)
```

```
TRUE
```

Example 3

Expressions involving symbolic Boolean subexpressions are not simplified by `and`, `or`, `not`. Simplification has to be requested explicitly via the function `simplify`:

```
(b1 and b2) or (b1 and (not b2)) and (1 < 2)
```

$$(b1 \wedge b2) \vee (b1 \wedge \neg b2 \wedge 1 < 2)$$

```
simplify(%, logic)
```

```
b1
```

Example 4

The Boolean functions `_and` and `_or` accept arbitrary sequences of Boolean expressions. The following call uses `isprime` to check whether *all* elements of the given set are prime:

```
set := {1987, 1993, 1997, 1999, 2001}:
_and(isprime(i) $ i in set)
```

```
FALSE
```

The following call checks whether *at least one* of the numbers is prime:

```
_or(isprime(i) $ i in set)
```

```
TRUE
```

```
delete set:
```

Parameters

b_1, b_2, …

Boolean expressions

Return Values

Boolean expression.

Overloaded By

MuPAD Functions

`<=>` | `==>` | `_lazy_and` | `_lazy_or` | `and` | `bool` | `FALSE` | `is` | `not` | `TRUE` | `UNKNOWN` | `xor`

not, _not

Logical negation

Syntax

```
not b
```

```
_not(b)
```

Description

`not b` represents the logical negation of the Boolean expression `b`.

MuPAD uses a three state logic with the Boolean constants `TRUE`, `FALSE`, and `UNKNOWN`. These are processed as follows:

`not TRUE = FALSE`, `not FALSE = TRUE`, `not UNKNOWN = UNKNOWN` .

Boolean expressions may be composed of these constants as well as of arbitrary arithmetical expressions. Typically, equations such as `x = y` and inequalities such as `x <> y`, `x < y`, `x <= y` etc. are used to construct Boolean expressions.

`_not(b)` is equivalent to `not b`.

Combinations of the constants `TRUE`, `FALSE`, `UNKNOWN` inside a Boolean expression are simplified automatically. However, symbolic Boolean subexpressions, equalities, and inequalities are not evaluated and simplified by logical operators. Use `bool` to evaluate such expressions to one of the Boolean constants. Note, however, that `bool` can evaluate inequalities `x < y`, `x <= y` etc. only if they are composed of numbers of type `Type::Real`. Cf. “Example 2” on page 1-152.

Use `simplify` with the option `logic` to simplify expressions involving symbolic Boolean subexpressions. Cf. “Example 3” on page 1-153.

The precedences of the logical operators are as follows: The operator `not` is stronger binding than `and`, i.e, `not b1 and b2` = `(not b1) and b2`. The operator `and` is stronger binding than `xor`, i.e., `b1 and b2 or b3` = `(b1 and b2) xor b3`. The operator `xor` is stronger binding than `or`, i.e., `b1 xor b2 or b3` = `(b1 xor b2) or`

b3. The operator or is stronger binding than ==>, i.e., b1 or b2 ==> b3 = (b1 or b2) ==> b3. The operator ==> is stronger binding than <=>, i.e., b1 ==> b2 <=> b3 = (b1 ==> b2) <=> b3.

If in doubt, use brackets to make sure that the expression is parsed as desired.

In the conditional context of if, repeat, and while statements, Boolean expressions are evaluated via "lazy evaluation" (see _lazy_and, _lazy_or). In any other context, all operands are evaluated.

Examples

Example 1

Combinations of the Boolean constants TRUE, FALSE, and UNKNOWN are simplified automatically to one of these constants:

```
TRUE and not (FALSE or TRUE)
```

```
    FALSE
```

```
FALSE and UNKNOWN, TRUE and UNKNOWN
```

```
    FALSE, UNKNOWN
```

```
FALSE or UNKNOWN, TRUE or UNKNOWN
```

```
    UNKNOWN, TRUE
```

```
not UNKNOWN
```

```
    UNKNOWN
```

Example 2

Logical operators simplify subexpressions that evaluate to the constants TRUE, FALSE, UNKNOWN.

```
b1 or b2 and TRUE
```

$$b1 \vee b2$$

```
FALSE or ((not b1) and TRUE)
```

$$\neg b1$$

```
b1 and (b2 or FALSE) and UNKNOWN
```

$$UNKNOWN \wedge b1 \wedge b2$$

```
FALSE or (b1 and UNKNOWN) or x < 1
```

$$(UNKNOWN \wedge b1) \vee x < 1$$

```
TRUE and ((b1 and FALSE) or (b1 and TRUE))
```

$$b1$$

However, equalities and inequalities are not evaluated:

```
(x = x) and (1 < 2) and (2 < 3) and (3 < 4)
```

$$x = x \wedge 1 < 2 \wedge 2 < 3 \wedge 3 < 4$$

Boolean evaluation is enforced via `bool`:

```
bool(%)
```

$$TRUE$$

Example 3

Expressions involving symbolic Boolean subexpressions are not simplified by `and`, `or`, `not`. Simplification has to be requested explicitly via the function `simplify`:

```
(b1 and b2) or (b1 and (not b2)) and (1 < 2)
```

$$(b1 \wedge b2) \vee (b1 \wedge \neg b2 \wedge 1 < 2)$$

```
simplify(%, logic)
```

$$b1$$

Example 4

The Boolean functions `_and` and `_or` accept arbitrary sequences of Boolean expressions. The following call uses `isprime` to check whether *all* elements of the given set are prime:

```
set := {1987, 1993, 1997, 1999, 2001}:
_and(isprime(i) $ i in set)
```

FALSE

The following call checks whether *at least one* of the numbers is prime:

```
_or(isprime(i) $ i in set)
```

TRUE

```
delete set:
```

Parameters

MuPAD Functions

<=> | ==> | _lazy_and | _lazy_or | and | bool | FALSE | is | or | TRUE | UNKNOWN | xor

xor, _xor

Logical exclusive-or

Syntax

```
b1 xor b2
```

```
_xor(b1, b2, …)
```

Description

`b1 xor b2` represents the exclusive logical 'or' of the Boolean expressions `b1`, `b2`.

MuPAD uses a three state logic with the Boolean constants `TRUE`, `FALSE`, and `UNKNOWN`. These are processed as follows:

The operator `xor` is defined as follows: `a xor b` is equivalent to `(a or b) and not (a and b)`.

Boolean expressions may be composed of these constants as well as of arbitrary arithmetical expressions. Typically, equations such as `x = y` and inequalities such as `x <> y`, `x < y`, `x <= y` etc. are used to construct Boolean expressions.

`_xor(b1, b2, ...)` is equivalent to `b1 xor b2 xor ...`. This expression represents `TRUE` if an odd number of operands evaluate to `TRUE` and the others evaluate to `FALSE`. It represents `FALSE` if an even number of operands evaluate to `TRUE` and the others evaluate to `FALSE`. It represents `UNKNOWN` if at least one operand evaluates to `UNKNOWN`.

Combinations of the constants `TRUE`, `FALSE`, `UNKNOWN` inside a Boolean expression are simplified automatically. However, symbolic Boolean subexpressions, equalities, and inequalities are not evaluated and simplified by logical operators. Use `bool` to evaluate such expressions to one of the Boolean constants. Note, however, that `bool` can evaluate inequalities `x < y`, `x <= y` etc. only if they are composed of numbers of type `Type::Real`. Cf. "Example 2" on page 1-158.

Use `simplify` with the option `logic` to simplify expressions involving symbolic Boolean subexpressions. Cf. "Example 3" on page 1-159.

The precedences of the logical operators are as follows: The operator `not` is stronger binding than `and`, i.e, `not b1 and b2` = `(not b1) and b2`. The operator `and` is stronger binding than `xor`, i.e., `b1 and b2 or b3` = `(b1 and b2) xor b3`. The operator `xor` is stronger binding than `or`, i.e., `b1 xor b2 or b3` = `(b1 xor b2) or b3`. The operator `or` is stronger binding than `==>`, i.e., `b1 or b2 ==> b3` = `(b1 or b2) ==> b3`. The operator `==>` is stronger binding than `<=>`, i.e., `b1 ==> b2 <=> b3` = `(b1 ==> b2) <=> b3`.

If in doubt, use brackets to make sure that the expression is parsed as desired.

In the conditional context of `if`, `repeat`, and `while` statements, Boolean expressions are evaluated via "lazy evaluation" (see `_lazy_and`, `_lazy_or`). In any other context, all operands are evaluated.

Examples

Example 1

Combinations of the Boolean constants `TRUE`, `FALSE`, and `UNKNOWN` are simplified automatically to one of these constants:

```
TRUE and not (FALSE or TRUE)
```

```
    FALSE
```

```
FALSE and UNKNOWN, TRUE and UNKNOWN
```

```
    FALSE, UNKNOWN
```

```
FALSE or UNKNOWN, TRUE or UNKNOWN
```

```
    UNKNOWN, TRUE
```

```
not UNKNOWN
```

```
    UNKNOWN
```

Example 2

Logical operators simplify subexpressions that evaluate to the constants TRUE, FALSE, UNKNOWN.

```
b1 or b2 and TRUE
```

$$b1 \vee b2$$

```
FALSE or ((not b1) and TRUE)
```

$$\neg b1$$

```
b1 and (b2 or FALSE) and UNKNOWN
```

$$UNKNOWN \wedge b1 \wedge b2$$

```
FALSE or (b1 and UNKNOWN) or x < 1
```

$$(UNKNOWN \wedge b1) \vee x < 1$$

```
TRUE and ((b1 and FALSE) or (b1 and TRUE))
```

$$b1$$

However, equalities and inequalities are not evaluated:

```
(x = x) and (1 < 2) and (2 < 3) and (3 < 4)
```

$$x = x \wedge 1 < 2 \wedge 2 < 3 \wedge 3 < 4$$

Boolean evaluation is enforced via `bool`:

```
bool(%)
```

$$TRUE$$

Example 3

Expressions involving symbolic Boolean subexpressions are not simplified by `and`, `or`, `not`. Simplification has to be requested explicitly via the function `simplify`:

```
(b1 and b2) or (b1 and (not b2)) and (1 < 2)
```

$$(b1 \wedge b2) \vee (b1 \wedge \neg b2 \wedge 1 < 2)$$

```
simplify(%, logic)
```

$$b1$$

Example 4

The Boolean functions `_and` and `_or` accept arbitrary sequences of Boolean expressions. The following call uses `isprime` to check whether *all* elements of the given set are prime:

```
set := {1987, 1993, 1997, 1999, 2001}:
_and(isprime(i) $ i in set)
```

FALSE

The following call checks whether *at least one* of the numbers is prime:

```
_or(isprime(i) $ i in set)
```

TRUE

```
delete set:
```

Parameters

b_1, b_2, …

Boolean expressions

Return Values

Boolean expression.

Overloaded By

b, b_1, b_2

MuPAD Functions

`<=>` | `==>` | `_lazy_and` | `_lazy_or` | `and` | `bool` | `FALSE` | `is` | `not` | `or` | `TRUE` | `UNKNOWN`

==>, _implies

Logical implication

Syntax

`b1 ==> b2`

`_implies(b1, b2)`

Description

`b1 ==> b2` represents the logical implication of the Boolean expressions `b1`, `b2`.

MuPAD uses a three state logic with the Boolean constants `TRUE`, `FALSE`, and `UNKNOWN`. These are processed as follows:

The operator `==>` is defined as follows: `a ==> b` is equivalent to `not a or b`.

Boolean expressions may be composed of these constants as well as of arbitrary arithmetical expressions. Typically, equations such as `x = y` and inequalities such as `x <> y`, `x < y`, `x <= y` etc. are used to construct Boolean expressions.

`_implies(a, b)` is equivalent to `a ==> b`.

Combinations of the constants `TRUE`, `FALSE`, `UNKNOWN` inside a Boolean expression are simplified automatically. However, symbolic Boolean subexpressions, equalities, and inequalities are not evaluated and simplified by logical operators. Use `bool` to evaluate such expressions to one of the Boolean constants. Note, however, that `bool` can evaluate inequalities `x < y`, `x <= y` etc. only if they are composed of numbers of type `Type::Real`. Cf. “Example 2” on page 1-162.

Use `simplify` with the option `logic` to simplify expressions involving symbolic Boolean subexpressions. Cf. “Example 3” on page 1-163.

The precedences of the logical operators are as follows: The operator `not` is stronger binding than `and`, i.e, `not b1 and b2` = `(not b1) and b2`. The operator `and` is stronger binding than `xor`, i.e., `b1 and b2 or b3` = `(b1 and b2) xor b3`. The operator `xor` is stronger binding than `or`, i.e., `b1 xor b2 or b3` = `(b1 xor b2) or`

b3. The operator or is stronger binding than ==>, i.e., b1 or b2 ==> b3 = (b1 or b2) ==> b3. The operator ==> is stronger binding than <=>, i.e., b1 ==> b2 <=> b3 = (b1 ==> b2) <=> b3.

If in doubt, use brackets to make sure that the expression is parsed as desired.

In the conditional context of if, repeat, and while statements, Boolean expressions are evaluated via "lazy evaluation" (see _lazy_and, _lazy_or). In any other context, all operands are evaluated.

Examples

Example 1

Combinations of the Boolean constants TRUE, FALSE, and UNKNOWN are simplified automatically to one of these constants:

```
TRUE and not (FALSE or TRUE)
```

```
    FALSE
```

```
FALSE and UNKNOWN, TRUE and UNKNOWN
```

```
    FALSE, UNKNOWN
```

```
FALSE or UNKNOWN, TRUE or UNKNOWN
```

```
    UNKNOWN, TRUE
```

```
not UNKNOWN
```

```
    UNKNOWN
```

Example 2

Logical operators simplify subexpressions that evaluate to the constants TRUE, FALSE, UNKNOWN.

```
b1 or b2 and TRUE
```

$$b1 \vee b2$$

```
FALSE or ((not b1) and TRUE)
```

$$\neg b1$$

```
b1 and (b2 or FALSE) and UNKNOWN
```

$$UNKNOWN \wedge b1 \wedge b2$$

```
FALSE or (b1 and UNKNOWN) or x < 1
```

$$(UNKNOWN \wedge b1) \vee x < 1$$

```
TRUE and ((b1 and FALSE) or (b1 and TRUE))
```

$$b1$$

However, equalities and inequalities are not evaluated:

```
(x = x) and (1 < 2) and (2 < 3) and (3 < 4)
```

$$x = x \wedge 1 < 2 \wedge 2 < 3 \wedge 3 < 4$$

Boolean evaluation is enforced via `bool`:

```
bool(%)
```

$$TRUE$$

Example 3

Expressions involving symbolic Boolean subexpressions are not simplified by `and`, `or`, `not`. Simplification has to be requested explicitly via the function `simplify`:

```
(b1 and b2) or (b1 and (not b2)) and (1 < 2)
```

$$(b1 \wedge b2) \vee (b1 \wedge \neg b2 \wedge 1 < 2)$$

```
simplify(%, logic)
```

$$b1$$

Example 4

The Boolean functions `_and` and `_or` accept arbitrary sequences of Boolean expressions. The following call uses `isprime` to check whether *all* elements of the given set are prime:

```
set := {1987, 1993, 1997, 1999, 2001}:
_and(isprime(i) $ i in set)
```

$$FALSE$$

The following call checks whether *at least one* of the numbers is prime:

```
_or(isprime(i) $ i in set)
```

$$TRUE$$

```
delete set:
```

Parameters

b_1, b_2, …

Boolean expressions

Return Values

Boolean expression.

MuPAD Functions

<=> | _lazy_and | _lazy_or | and | bool | FALSE | is | not | or | TRUE | UNKNOWN | xor

<=>, _equiv

Logical equivalence

Syntax

`b1 <=> b2`

`_equiv(b1, b2)`

Description

`b1 <=> b2` represents the logical equivalence of the Boolean expressions `b1`, `b2`.

MuPAD uses a three state logic with the Boolean constants `TRUE`, `FALSE`, and `UNKNOWN`. These are processed as follows:

The operator `<=>` is defined as follows: `a <=> b` is equivalent to `(a => b) and (b => a)`.

Boolean expressions may be composed of these constants as well as of arbitrary arithmetical expressions. Typically, equations such as `x = y` and inequalities such as `x <> y`, `x < y`, `x <= y` etc. are used to construct Boolean expressions.

`_equiv(a, b)` is equivalent to `a <=> b`.

Combinations of the constants `TRUE`, `FALSE`, `UNKNOWN` inside a Boolean expression are simplified automatically. However, symbolic Boolean subexpressions, equalities, and inequalities are not evaluated and simplified by logical operators. Use `bool` to evaluate such expressions to one of the Boolean constants. Note, however, that `bool` can evaluate inequalities `x < y`, `x <= y` etc. only if they are composed of numbers of type `Type::Real`. Cf. “Example 2” on page 1-167.

Use `simplify` with the option `logic` to simplify expressions involving symbolic Boolean subexpressions. Cf. “Example 3” on page 1-168.

The precedences of the logical operators are as follows: The operator `not` is stronger binding than `and`, i.e, `not b1 and b2` = `(not b1) and b2`. The operator `and` is stronger binding than `xor`, i.e., `b1 and b2 or b3` = `(b1 and b2) xor b3`. The

operator `xor` is stronger binding than `or`, i.e., `b1 xor b2 or b3` = `(b1 xor b2) or b3`. The operator `or` is stronger binding than `==>`, i.e., `b1 or b2 ==> b3` = `(b1 or b2) ==> b3`. The operator `==>` is stronger binding than `<=>`, i.e., `b1 ==> b2 <=> b3` = `(b1 ==> b2) <=> b3`.

If in doubt, use brackets to make sure that the expression is parsed as desired.

In the conditional context of `if`, `repeat`, and `while` statements, Boolean expressions are evaluated via "lazy evaluation" (see `_lazy_and`, `_lazy_or`). In any other context, all operands are evaluated.

Examples

Example 1

Combinations of the Boolean constants `TRUE`, `FALSE`, and `UNKNOWN` are simplified automatically to one of these constants:

```
TRUE and not (FALSE or TRUE)
```

```
    FALSE
```

```
FALSE and UNKNOWN, TRUE and UNKNOWN
```

```
    FALSE, UNKNOWN
```

```
FALSE or UNKNOWN, TRUE or UNKNOWN
```

```
    UNKNOWN, TRUE
```

```
not UNKNOWN
```

```
    UNKNOWN
```

Example 2

Logical operators simplify subexpressions that evaluate to the constants `TRUE`, `FALSE`, `UNKNOWN`.

```
b1 or b2 and TRUE
```

$$b1 \vee b2$$

```
FALSE or ((not b1) and TRUE)
```

$$\neg b1$$

```
b1 and (b2 or FALSE) and UNKNOWN
```

$$UNKNOWN \wedge b1 \wedge b2$$

```
FALSE or (b1 and UNKNOWN) or x < 1
```

$$(UNKNOWN \wedge b1) \vee x < 1$$

```
TRUE and ((b1 and FALSE) or (b1 and TRUE))
```

$$b1$$

However, equalities and inequalities are not evaluated:

```
(x = x) and (1 < 2) and (2 < 3) and (3 < 4)
```

$$x = x \wedge 1 < 2 \wedge 2 < 3 \wedge 3 < 4$$

Boolean evaluation is enforced via `bool`:

```
bool(%)
```

$$TRUE$$

Example 3

Expressions involving symbolic Boolean subexpressions are not simplified by `and`, `or`, `not`. Simplification has to be requested explicitly via the function `simplify`:

```
(b1 and b2) or (b1 and (not b2)) and (1 < 2)
```

$$(b1 \wedge b2) \vee (b1 \wedge \neg b2 \wedge 1 < 2)$$

```
simplify(%, logic)
```

$$b1$$

Example 4

The Boolean functions `_and` and `_or` accept arbitrary sequences of Boolean expressions. The following call uses `isprime` to check whether *all* elements of the given set are prime:

```
set := {1987, 1993, 1997, 1999, 2001}:
_and(isprime(i) $ i in set)
```

$$FALSE$$

The following call checks whether *at least one* of the numbers is prime:

```
_or(isprime(i) $ i in set)
```

$$TRUE$$

```
delete set:
```

Parameters

b_1, b_2, …

Boolean expressions

Return Values

Boolean expression.

Overloaded By

b, b_1, b_2

See Also

MuPAD Functions
`==>` | `_lazy_and` | `_lazy_or` | `and` | `bool` | `FALSE` | `is` | `not` | `or` | `TRUE` | `UNKNOWN` | `xor`

append

Add elements to a list

Syntax

```
append(l, object1, object2, …)
```

Description

`append(l, object)` adds `object` to the list `l`.

`append(l, object1, object2, ...)` appends `object1`, `object2`, etc. to the list `l` and returns the new list as the result.

`append(f(x), object1, object2, ...)` appends `object1`, `object2`, etc. to the expression `f(x)` and returns the new expression as the result.

The call `append(l)` is legal and returns `l`.

`append(l, object1, object2, ...)` is equivalent to both `[op(l), object1, object2, ...]` and `l.[object1, object2, ...]`. However, `append` is more efficient.

The function `append` always returns a new object. The first argument remains unchanged. See “Example 3” on page 1-172.

Examples

Example 1

The function `append` adds new elements to the end of a list:

```
append([a, b], c, d)
```

$$[a, b, c, d]$$

If no new elements are given, the first argument is returned unmodified:

```
l := [a, b]: append(l)
```

$$[a, b]$$

The first argument may be an empty list:

```
append([ ], c)
```

$$[c]$$

Example 2

The function append adds new elements to the end of an expression:

```
append(f(a, b), c, d)
```

$$f(a, b, c, d)$$

Expressions can be written in operator notation:

```
append(a + b, c)
```

$$a + b + c$$

Example 3

The function append always returns a new object. The first argument remains unchanged:

```
l := [a, b]: append(l, c, d), l
```

$$[a, b, c, d], [a, b]$$

Example 4

Users can overload append for their own domains. For illustration, we create a new domain T and supply it with an "append" slot, which simply adds the remaining arguments to the internal operands of its first argument:

```
T := newDomain("T"):
T::append := x -> new(T, extop(x), args(2..args(0))):
```

If we now call `append` with an object of domain type `T`, the slot routine `T::append` is invoked:

```
e := new(T, 1, 2): append(e, 3)
```

$$\mathrm{new}(T, 1, 2, 3)$$

Parameters

`1`

A list or an expression

`object1, object2, …`

Arbitrary MuPAD objects

Return Values

Extended list or expression.

Overloaded By

l

MuPAD Domains
`DOM_EXPR` | `DOM_LIST`

MuPAD Functions
`_concat` | `_index` | `op`

arcsin

Inverse sine function

Syntax

```
arcsin(x)
```

Description

`arcsin(x)` represents the inverse of the sine function.

The angle returned by this function is measured in radians, not in degrees. For example, the result π represents an angle of 180^o.

`arcsin` is defined for complex arguments.

Floating-point values are returned for floating-point arguments. Floating-point intervals are returned for interval arguments. Unevaluated function calls are returned for most exact arguments.

If the argument is a rational multiple of `I`, the result is expressed in terms of hyperbolic functions. See “Example 2” on page 1-176.

The inverse sine function is multivalued. The MuPAD `arcsin` function returns the value on the main branch. The branch cuts are the real intervals (- ∞, - 1) and (1, ∞). Thus, `arcsin` returns values, such that $y = arcsin(x)$ satisfies $-\frac{\pi}{2} \le \Re(y) \le \frac{\pi}{2}$ for any finite complex x

The `sin` function returns explicit values for arguments that are certain rational multiples of π. For these values, `arcsin` returns an appropriate rational multiple of π on the main branch. See “Example 3” on page 1-176.

The values jump when the arguments cross a branch cut. See “Example 4” on page 1-177.

The float attributes are kernel functions. Thus, floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, `arcsin` is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
arcsin(1), arccos(1/sqrt(2)), arctan(5 + I), arccsc(1/3),
arcsec(I), arccot(1)
```

$$\frac{\pi}{2},\ \frac{\pi}{4},\ \arctan(5+i),\ \arcsin(3),\ \frac{\pi}{2}+\operatorname{arcsinh}(1)\,i,\ \frac{\pi}{4}$$

```
arcsin(-x), arccos(x + 1), arctan(1/x)
```

$$-\arcsin(x),\ \arccos(x+1),\ \arctan\left(\frac{1}{x}\right)$$

Floating-point values are computed for floating-point arguments:

```
arcsin(0.1234), arccos(5.6 + 7.8*I), arccot(1.0/10^20)
```

$$0.1237153458,\ 0.950687977-2.956002937\,i,\ 1.570796327$$

On input of floating-point intervals, these functions compute floating-point intervals containing the image sets:

```
arcsin(0...1), arccos(0...1)
```

$$0.0\ldots 1.570796327,\ -3.469446952\,10^{-18}\ldots 1.570796327$$

```
arcsin(2...3)
```

$$1.570796326\ldots 1.570796327+-1.762747175\ldots -1.316957896\,i$$

Note that certain types of input lead to severe overestimation, sometimes returning the whole image set of the function in question:

```
arccsc(-2...2);
csc(arccsc(-2...2))
```

$$-3.141592654 \ldots 2.382564905\,10^{-323228497} + -0.6931471806 \ldots \mathrm{RD\_INF}\,i$$

$$\cup -2.382564905\,10^{-323228497} \ldots 3.141592654 + \mathrm{RD\_NINF} \ldots 0.6931471806\,i$$

$$\mathrm{RD\_NINF} \ldots \mathrm{RD\_INF} + \mathrm{RD\_NINF} \ldots \mathrm{RD\_INF}\,i$$

Example 2

Arguments that are rational multiples of `I` are rewritten in terms of hyperbolic functions:

```
arcsin(5*I), arccos(5/4*I), arctan(-3*I)
```

$$\operatorname{arcsinh}(5)\,i,\ \frac{\pi}{2} - \operatorname{arcsinh}\left(\frac{5}{4}\right) i,\ -\operatorname{arctanh}(3)\,i$$

For other complex arguments unevaluated function calls without simplifications are returned:

```
arcsin(1/2^(1/2) + I), arccos(1 -3*I)
```

$$\arcsin\left(\frac{\sqrt{2}}{2} + i\right),\ \arccos(1 - 3\,i)$$

Example 3

Some special values are implemented:

```
arcsin(1/sqrt(2)), arccos((5^(1/2) - 1)/4), arctan(3^(1/2) - 2)
```

$$\frac{\pi}{4},\ \frac{2\,\pi}{5},\ -\frac{\pi}{12}$$

Such simplifications occur for arguments that are trigonometric images of rational multiples of π:

```
sin(9/10*PI), arcsin(sin(9/10*PI))
```

$$\frac{\sqrt{5}}{4} - \frac{1}{4},\ \frac{\pi}{10}$$

```
cos(PI/8)/sin(PI/8), arctan(cos(PI/8)/sin(PI/8))
```

$$\frac{\sqrt{\sqrt{2}+2}}{\sqrt{2-\sqrt{2}}},\ \frac{3\,\pi}{8}$$

Example 4

The values jump when crossing a branch cut:

```
arcsin(2.0 + I/10^10), arcsin(2.0 - I/10^10)
```

$$1.570796327 + 1.316957897\,i,\ 1.570796327 - 1.316957897\,i$$

On the branch cut, the values of `arcsin` coincide with the limit "from below" for real arguments $x > 1$. The values coincide with the limit "from above" for real $x < -1$:

```
arcsin(1.2), arcsin(1.2 - I/10^10), arcsin(1.2 + I/10^10)
```

$$1.570796327 - 0.6223625037\,i,\ 1.570796327 - 0.6223625037\,i,\ 1.570796327 + 0.6223625037\,i$$

```
arcsin(-1.2), arcsin(-1.2 + I/10^10), arcsin(-1.2 - I/10^10)
```

$$-1.570796327 + 0.6223625037\,i,\ -1.570796327 + 0.6223625037\,i,\ -1.570796327 - 0.6223625037\,i$$

Example 5

The inverse trigonometric functions can be rewritten in terms of the logarithm function with complex arguments:

```
rewrite(arcsin(x), ln), rewrite(arctan(x), ln)
```

$$-\ln\left(\sqrt{1-x^2}+x\,\mathrm{i}\right)\mathrm{i},\ \frac{\ln(1-x\,\mathrm{i})\,\mathrm{i}}{2}-\frac{\ln(1+x\,\mathrm{i})\,\mathrm{i}}{2}$$

Example 6

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the inverse trigonometric functions:

```
diff(arcsin(x^2), x), float(arccos(3)*arctan(5 + I))
```

$$\frac{2x}{\sqrt{1-x^4}},\ -0.06540673615+2.433548516\,\mathrm{i}$$

```
limit(arcsin(x^2)/arctan(x^2), x = 0)
```

$$1$$

```
series(arctan(sin(x)) - arcsin(tan(x)), x = 0, 10)
```

$$-x^3-\frac{83\,x^7}{120}-\frac{4\,x^9}{189}-\frac{22831\,x^{11}}{28800}+O(x^{13})$$

```
series(arccos(2 + x), x, 3)
```

$$-\mathrm{signIm}(x+2)\,\arccos(2)-\frac{\sqrt{3}\,x\,\mathrm{signIm}(x+2)\,\mathrm{i}}{3}+\frac{\sqrt{3}\,x^2\,\mathrm{signIm}(x+2)\,\mathrm{i}}{9}+O(x^3)$$

Example 7

When you call `arctan` with two arguments, MuPAD calls the `arg` function and computes the polar angle of a complex number:

```
arctan(y, x)
```

$$\arg(x+y\,\mathrm{i})$$

Parameters

x

Arithmetical expression or floating-point interval

Return Values

Arithmetical expression or floating-point interval.

Overloaded By

x

`arccos` | `arccot` | `arccsc` | `arcsec` | `arctan` | `arg` | `cos` | `cot` | `csc` | `sec` | `sin` | `tan`

arccos

Inverse cosine function

Syntax

```
arccos(x)
```

Description

`arccos(x)` represents the inverse of the cosine function.

The angle returned by this function is measured in radians, not in degrees. For example, the result π represents an angle of 180^o.

`arccos` is defined for complex arguments.

Floating-point values are returned for floating-point arguments. Floating-point intervals are returned for interval arguments. Unevaluated function calls are returned for most exact arguments.

If the argument is a rational multiple of `I`, the result is expressed in terms of hyperbolic functions. See “Example 2” on page 1-182.

The inverse cosine function is multivalued. The MuPAD `arccos` function returns the value on the main branch. The branch cuts are the real intervals $(-\infty, -1)$ and $(1, \infty)$. Thus, `arccos` returns values, such that $y = arccos(x)$ satisfies $0 \le \Re(y) \le \pi$ for any finite complex x.

The `cos` function returns explicit values for arguments that are certain rational multiples of π. For these values, `arccos` returns an appropriate rational multiple of π on the main branch. See “Example 3” on page 1-182.

The values jump when the arguments cross a branch cut. See “Example 4” on page 1-183.

The float attributes are kernel functions. Thus, floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, `arccos` is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
arcsin(1), arccos(1/sqrt(2)), arctan(5 + I), arccsc(1/3),
arcsec(I), arccot(1)
```

$$\frac{\pi}{2},\ \frac{\pi}{4},\ \arctan(5+i),\ \arcsin(3),\ \frac{\pi}{2}+\operatorname{arcsinh}(1)\,i,\ \frac{\pi}{4}$$

```
arcsin(-x), arccos(x + 1), arctan(1/x)
```

$$-\arcsin(x),\ \arccos(x+1),\ \arctan\left(\frac{1}{x}\right)$$

Floating-point values are computed for floating-point arguments:

```
arcsin(0.1234), arccos(5.6 + 7.8*I), arccot(1.0/10^20)
```

$$0.1237153458,\ 0.950687977-2.956002937\,i,\ 1.570796327$$

On input of floating-point intervals, these functions compute floating-point intervals containing the image sets:

```
arcsin(0...1), arccos(0...1)
```

$$0.0\ldots 1.570796327,\ -3.469446952\,10^{-18}\ldots 1.570796327$$

```
arcsin(2...3)
```

$$1.570796326\ldots 1.570796327+-1.762747175\ldots -1.316957896\,i$$

Note that certain types of input lead to severe overestimation, sometimes returning the whole image set of the function in question:

```
arccsc(-2...2);
csc(arccsc(-2...2))
```

$$-3.141592654 \ldots 2.382564905\ 10^{-323228497} + -0.6931471806 \ldots \text{RD\_INF}\ i$$

$$\cup -2.382564905\ 10^{-323228497} \ldots 3.141592654 + \text{RD\_NINF} \ldots 0.6931471806\ i$$

$$\text{RD\_NINF} \ldots \text{RD\_INF} + \text{RD\_NINF} \ldots \text{RD\_INF}\ i$$

Example 2

Arguments that are rational multiples of `I` are rewritten in terms of hyperbolic functions:

```
arcsin(5*I), arccos(5/4*I), arctan(-3*I)
```

$$\operatorname{arcsinh}(5)\ i,\ \frac{\pi}{2} - \operatorname{arcsinh}\left(\frac{5}{4}\right) i,\ -\operatorname{arctanh}(3)\ i$$

For other complex arguments unevaluated function calls without simplifications are returned:

```
arcsin(1/2^(1/2) + I), arccos(1 -3*I)
```

$$\arcsin\left(\frac{\sqrt{2}}{2} + i\right),\ \arccos(1 - 3\ i)$$

Example 3

Some special values are implemented:

```
arcsin(1/sqrt(2)), arccos((5^(1/2) - 1)/4), arctan(3^(1/2) - 2)
```

$$\frac{\pi}{4},\ \frac{2\pi}{5},\ -\frac{\pi}{12}$$

Such simplifications occur for arguments that are trigonometric images of rational multiples of π:

```
sin(9/10*PI), arcsin(sin(9/10*PI))
```

$$\frac{\sqrt{5}}{4} - \frac{1}{4},\ \frac{\pi}{10}$$

```
cos(PI/8)/sin(PI/8), arctan(cos(PI/8)/sin(PI/8))
```

$$\frac{\sqrt{\sqrt{2}+2}}{\sqrt{2-\sqrt{2}}},\ \frac{3\,\pi}{8}$$

Example 4

The values jump when crossing a branch cut:

```
arcsin(2.0 + I/10^10), arcsin(2.0 - I/10^10)
```

$$1.570796327 + 1.316957897\,i,\ 1.570796327 - 1.316957897\,i$$

On the branch cut, the values of `arcsin` coincide with the limit "from below" for real arguments $x > 1$. The values coincide with the limit "from above" for real $x < -1$:

```
arcsin(1.2), arcsin(1.2 - I/10^10), arcsin(1.2 + I/10^10)
```

$$1.570796327 - 0.6223625037\,i,\ 1.570796327 - 0.6223625037\,i,\ 1.570796327 + 0.6223625037\,i$$

```
arcsin(-1.2), arcsin(-1.2 + I/10^10), arcsin(-1.2 - I/10^10)
```

$$-1.570796327 + 0.6223625037\,i,\ -1.570796327 + 0.6223625037\,i,\ -1.570796327 - 0.6223625037\,i$$

Example 5

The inverse trigonometric functions can be rewritten in terms of the logarithm function with complex arguments:

```
rewrite(arcsin(x), ln), rewrite(arctan(x), ln)
```

$$-\ln\left(\sqrt{1-x^2}+x\,\mathrm{i}\right)\mathrm{i},\ \frac{\ln(1-x\,\mathrm{i})\,\mathrm{i}}{2}-\frac{\ln(1+x\,\mathrm{i})\,\mathrm{i}}{2}$$

Example 6

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the inverse trigonometric functions:

```
diff(arcsin(x^2), x), float(arccos(3)*arctan(5 + I))
```

$$\frac{2x}{\sqrt{1-x^4}},\ -0.06540673615+2.433548516\,\mathrm{i}$$

```
limit(arcsin(x^2)/arctan(x^2), x = 0)
```

$$1$$

```
series(arctan(sin(x)) - arcsin(tan(x)), x = 0, 10)
```

$$-x^3-\frac{83\,x^7}{120}-\frac{4\,x^9}{189}-\frac{22831\,x^{11}}{28800}+O(x^{13})$$

```
series(arccos(2 + x), x, 3)
```

$$-\mathrm{signIm}(x+2)\,\arccos(2)-\frac{\sqrt{3}\,x\,\mathrm{signIm}(x+2)\,\mathrm{i}}{3}+\frac{\sqrt{3}\,x^2\,\mathrm{signIm}(x+2)\,\mathrm{i}}{9}+O(x^3)$$

Example 7

When you call `arctan` with two arguments, MuPAD calls the `arg` function and computes the polar angle of a complex number:

```
arctan(y, x)
```

$$\arg(x+y\,\mathrm{i})$$

Parameters

x

Arithmetical expression or floating-point interval

Return Values

Arithmetical expression or floating-point interval.

Overloaded By

x

MuPAD Functions

`arccot` | `arccsc` | `arcsec` | `arcsin` | `arctan` | `arg` | `cos` | `cot` | `csc` | `sec` | `sin` | `tan`

arctan

Inverse tangent function

Syntax

```
arctan(x)
```

```
arctan(y, x)
```

Description

`arctan(x)` represents the inverse of the tangent function.

`arctan(y, x)` is an alias for `arg(x, y)`.

The angle returned by this function is measured in radians, not in degrees. For example, the result π represents an angle of 180^o.

`arctan` is defined for complex arguments.

Floating-point values are returned for floating-point arguments. Floating-point intervals are returned for interval arguments. Unevaluated function calls are returned for most exact arguments.

If the argument is a rational multiple of `I`, the result is expressed in terms of hyperbolic functions. See “Example 2” on page 1-188.

The inverse tangent function is multivalued. The MuPAD `arctan` function returns the value on the main branch. The branch cuts are the intervals *interval*(- i ∞, [- i]) and *interval*([i], i ∞) on the imaginary axis. Thus, `arctan` returns values, such that y = *arctan*(x) satisfies $-\frac{\pi}{2} < \Re(y) < \frac{\pi}{2}$ for any finite complex x.

The `tan` function returns explicit values for arguments that are certain rational multiples of π. For these values, `arctan` returns an appropriate rational multiple of π on the main branch. See “Example 3” on page 1-189.

The values jump when the arguments cross a branch cut. See “Example 4” on page 1-189.

The float attributes are kernel functions. Thus, floating-point evaluation is fast.

If you call `arctan` with two arguments, `y` and `x`, MuPAD calls the `arg` function that computes the polar angle of a complex number `x + I*y`. See “Example 7” on page 1-191 and the `arg` help page.

Environment Interactions

When called with a floating-point argument, `arctan` is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
arcsin(1), arccos(1/sqrt(2)), arctan(5 + I), arccsc(1/3),
arcsec(I), arccot(1)
```

$$\frac{\pi}{2},\ \frac{\pi}{4},\ \arctan(5+i),\ \arcsin(3),\ \frac{\pi}{2}+\operatorname{arcsinh}(1)\,i,\ \frac{\pi}{4}$$

```
arcsin(-x), arccos(x + 1), arctan(1/x)
```

$$-\arcsin(x),\ \arccos(x+1),\ \arctan\left(\frac{1}{x}\right)$$

Floating-point values are computed for floating-point arguments:

```
arcsin(0.1234), arccos(5.6 + 7.8*I), arccot(1.0/10^20)
```

$$0.1237153458,\ 0.950687977-2.956002937\,i,\ 1.570796327$$

On input of floating-point intervals, these functions compute floating-point intervals containing the image sets:

```
arcsin(0...1), arccos(0...1)
```

$$0.0 \ldots 1.570796327,\ -3.469446952\ 10^{-18} \ldots 1.570796327$$

```
arcsin(2...3)
```

$$1.570796326 \ldots 1.570796327 + -1.762747175 \ldots -1.316957896\ i$$

Note that certain types of input lead to severe overestimation, sometimes returning the whole image set of the function in question:

```
arccsc(-2...2);
csc(arccsc(-2...2))
```

$$-3.141592654 \ldots 2.382564905\ 10^{-323228497} + -0.6931471806 \ldots \text{RD\_INF}\ i$$

$$\cup\ -2.382564905\ 10^{-323228497} \ldots 3.141592654 + \text{RD\_NINF} \ldots 0.6931471806\ i$$

$$\text{RD\_NINF} \ldots \text{RD\_INF} + \text{RD\_NINF} \ldots \text{RD\_INF}\ i$$

Example 2

Arguments that are rational multiples of `I` are rewritten in terms of hyperbolic functions:

```
arcsin(5*I), arccos(5/4*I), arctan(-3*I)
```

$$\operatorname{arcsinh}(5)\ i,\ \frac{\pi}{2} - \operatorname{arcsinh}\left(\frac{5}{4}\right) i,\ -\operatorname{arctanh}(3)\ i$$

For other complex arguments unevaluated function calls without simplifications are returned:

```
arcsin(1/2^(1/2) + I), arccos(1 -3*I)
```

$$\arcsin\left(\frac{\sqrt{2}}{2} + i\right),\ \arccos(1 - 3\ i)$$

Example 3

Some special values are implemented:

```
arcsin(1/sqrt(2)), arccos((5^(1/2) - 1)/4), arctan(3^(1/2) - 2)
```

$$\frac{\pi}{4}, \frac{2\,\pi}{5}, -\frac{\pi}{12}$$

Such simplifications occur for arguments that are trigonometric images of rational multiples of π:

```
sin(9/10*PI), arcsin(sin(9/10*PI))
```

$$\frac{\sqrt{5}}{4} - \frac{1}{4}, \frac{\pi}{10}$$

```
cos(PI/8)/sin(PI/8), arctan(cos(PI/8)/sin(PI/8))
```

$$\frac{\sqrt{\sqrt{2}+2}}{\sqrt{2-\sqrt{2}}}, \frac{3\,\pi}{8}$$

Example 4

The values jump when crossing a branch cut:

```
arcsin(2.0 + I/10^10), arcsin(2.0 - I/10^10)
```

$$1.570796327 + 1.316957897\,i,\ 1.570796327 - 1.316957897\,i$$

On the branch cut, the values of `arcsin` coincide with the limit "from below" for real arguments $x > 1$. The values coincide with the limit "from above" for real $x < -1$:

```
arcsin(1.2), arcsin(1.2 - I/10^10), arcsin(1.2 + I/10^10)
```

$$1.570796327 - 0.6223625037\,i,\ 1.570796327 - 0.6223625037\,i,\ 1.570796327 + 0.6223625037\,i$$

```
arcsin(-1.2), arcsin(-1.2 + I/10^10), arcsin(-1.2 - I/10^10)
```

$$-1.570796327 + 0.6223625037\,i,\ -1.570796327 + 0.6223625037\,i,\ -1.570796327 - 0.6223625037\,i$$

Example 5

The inverse trigonometric functions can be rewritten in terms of the logarithm function with complex arguments:

```
rewrite(arcsin(x), ln), rewrite(arctan(x), ln)
```

$$-\ln\left(\sqrt{1-x^2} + x\,i\right) i,\ \frac{\ln(1-x\,i)\,i}{2} - \frac{\ln(1+x\,i)\,i}{2}$$

Example 6

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the inverse trigonometric functions:

```
diff(arcsin(x^2), x), float(arccos(3)*arctan(5 + I))
```

$$\frac{2x}{\sqrt{1-x^4}},\ -0.06540673615 + 2.433548516\,i$$

```
limit(arcsin(x^2)/arctan(x^2), x = 0)
```

$$1$$

```
series(arctan(sin(x)) - arcsin(tan(x)), x = 0, 10)
```

$$-x^3 - \frac{83\,x^7}{120} - \frac{4\,x^9}{189} - \frac{22831\,x^{11}}{28800} + O(x^{13})$$

```
series(arccos(2 + x), x, 3)
```

$$-\operatorname{signIm}(x+2)\arccos(2) - \frac{\sqrt{3}\,x\,\operatorname{signIm}(x+2)\,i}{3} + \frac{\sqrt{3}\,x^2\,\operatorname{signIm}(x+2)\,i}{9} + O(x^3)$$

Example 7

When you call `arctan` with two arguments, MuPAD calls the `arg` function and computes the polar angle of a complex number:

```
arctan(y, x)
```

$$\arg(x + y\,\mathrm{i})$$

Parameters

x

Arithmetical expression or floating-point interval

y, x

Arithmetical expressions representing real numbers

Return Values

Arithmetical expression or floating-point interval.

Overloaded By

x

MuPAD Functions

`arccos` | `arccot` | `arccsc` | `arcsec` | `arcsin` | `arg` | `cos` | `cot` | `csc` | `sec` | `sin` | `tan`

arccsc

Inverse cosecant function

Syntax

```
arccsc(x)
```

Description

`arccsc(x)` represents the inverse of the cosecant function.

The angle returned by this function is measured in radians, not in degrees. For example, the result π represents an angle of 180^o.

`arccsc` is defined for complex arguments.

Floating-point values are returned for floating-point arguments. Floating-point intervals are returned for interval arguments. Unevaluated function calls are returned for most exact arguments.

If the argument is a rational multiple of `I`, the result is expressed in terms of hyperbolic functions. See “Example 2” on page 1-194.

MuPAD rewrites `arccsc` as `arccsc(x) = arcsin(1/x)`.

The inverse cosecant functions is multivalued. The MuPAD `arccsc` function returns values on the main branch defined as follows. The branch cut is the real interval (- 1, 1)

The `arccsc` function returns explicit values for arguments that are certain rational multiples of π. For these values, the inverse functions return an appropriate rational multiple of π on the main branch. See “Example 3” on page 1-194.

The values jump when the arguments cross a branch cut. See “Example 4” on page 1-195.

The float attributes are kernel functions. Thus, floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, `arccsc` is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
arcsin(1), arccos(1/sqrt(2)), arctan(5 + I), arccsc(1/3),
arcsec(I), arccot(1)
```

$$\frac{\pi}{2},\ \frac{\pi}{4},\ \arctan(5+i),\ \arcsin(3),\ \frac{\pi}{2}+\operatorname{arcsinh}(1)\,i,\ \frac{\pi}{4}$$

```
arcsin(-x), arccos(x + 1), arctan(1/x)
```

$$-\arcsin(x),\ \arccos(x+1),\ \arctan\left(\frac{1}{x}\right)$$

Floating-point values are computed for floating-point arguments:

```
arcsin(0.1234), arccos(5.6 + 7.8*I), arccot(1.0/10^20)
```

$$0.1237153458,\ 0.950687977-2.956002937\,i,\ 1.570796327$$

On input of floating-point intervals, these functions compute floating-point intervals containing the image sets:

```
arcsin(0...1), arccos(0...1)
```

$$0.0\ldots 1.570796327,\ -3.469446952\,10^{-18}\ldots 1.570796327$$

```
arcsin(2...3)
```

$$1.570796326\ldots 1.570796327+-1.762747175\ldots -1.316957896\,i$$

Note that certain types of input lead to severe overestimation, sometimes returning the whole image set of the function in question:

```
arccsc(-2...2);
csc(arccsc(-2...2))
```

$$-3.141592654 \ldots 2.382564905\ 10^{-323228497} + -0.6931471806 \ldots \text{RD\_INF}\ i$$

$$\cup -2.382564905\ 10^{-323228497} \ldots 3.141592654 + \text{RD\_NINF} \ldots 0.6931471806\ i$$

$$\text{RD\_NINF} \ldots \text{RD\_INF} + \text{RD\_NINF} \ldots \text{RD\_INF}\ i$$

Example 2

Arguments that are rational multiples of `I` are rewritten in terms of hyperbolic functions:

```
arcsin(5*I), arccos(5/4*I), arctan(-3*I)
```

$$\operatorname{arcsinh}(5)\ i,\ \frac{\pi}{2} - \operatorname{arcsinh}\left(\frac{5}{4}\right) i,\ -\operatorname{arctanh}(3)\ i$$

For other complex arguments unevaluated function calls without simplifications are returned:

```
arcsin(1/2^(1/2) + I), arccos(1 -3*I)
```

$$\arcsin\left(\frac{\sqrt{2}}{2} + i\right),\ \arccos(1 - 3\ i)$$

Example 3

Some special values are implemented:

```
arcsin(1/sqrt(2)), arccos((5^(1/2) - 1)/4), arctan(3^(1/2) - 2)
```

$$\frac{\pi}{4},\ \frac{2\pi}{5},\ -\frac{\pi}{12}$$

Such simplifications occur for arguments that are trigonometric images of rational multiples of π:

```
sin(9/10*PI), arcsin(sin(9/10*PI))
```

$$\frac{\sqrt{5}}{4} - \frac{1}{4},\ \frac{\pi}{10}$$

```
cos(PI/8)/sin(PI/8), arctan(cos(PI/8)/sin(PI/8))
```

$$\frac{\sqrt{\sqrt{2}+2}}{\sqrt{2-\sqrt{2}}},\ \frac{3\,\pi}{8}$$

Example 4

The values jump when crossing a branch cut:

```
arcsin(2.0 + I/10^10), arcsin(2.0 - I/10^10)
```

$$1.570796327 + 1.316957897\,i,\ 1.570796327 - 1.316957897\,i$$

On the branch cut, the values of `arcsin` coincide with the limit "from below" for real arguments $x > 1$. The values coincide with the limit "from above" for real $x < -1$:

```
arcsin(1.2), arcsin(1.2 - I/10^10), arcsin(1.2 + I/10^10)
```

$$1.570796327 - 0.6223625037\,i,\ 1.570796327 - 0.6223625037\,i,\ 1.570796327 + 0.6223625037\,i$$

```
arcsin(-1.2), arcsin(-1.2 + I/10^10), arcsin(-1.2 - I/10^10)
```

$$-1.570796327 + 0.6223625037\,i,\ -1.570796327 + 0.6223625037\,i,\ -1.570796327 - 0.6223625037\,i$$

Example 5

The inverse trigonometric functions can be rewritten in terms of the logarithm function with complex arguments:

```
rewrite(arcsin(x), ln), rewrite(arctan(x), ln)
```

$$-\ln\left(\sqrt{1-x^2}+x\,\mathrm{i}\right)\mathrm{i},\ \frac{\ln(1-x\,\mathrm{i})\,\mathrm{i}}{2}-\frac{\ln(1+x\,\mathrm{i})\,\mathrm{i}}{2}$$

Example 6

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the inverse trigonometric functions:

```
diff(arcsin(x^2), x), float(arccos(3)*arctan(5 + I))
```

$$\frac{2x}{\sqrt{1-x^4}},\ -0.06540673615+2.433548516\,\mathrm{i}$$

```
limit(arcsin(x^2)/arctan(x^2), x = 0)
```

$$1$$

```
series(arctan(sin(x)) - arcsin(tan(x)), x = 0, 10)

MuPAD Functions

`arccos` | `arccot` | `arcsec` | `arcsin` | `arctan` | `arg` | `cos` | `cot` | `csc` | `sec` | `sin` | `tan`

arcsec

Inverse secant function

Syntax

```
arcsec(x)
```

Description

`arcsec(x)` represents the inverse of the secant function.

The angle returned by this function is measured in radians, not in degrees. For example, the result π represents an angle of 180^o.

`arcsec` is defined for complex arguments.

Floating-point values are returned for floating-point arguments. Floating-point intervals are returned for interval arguments. Unevaluated function calls are returned for most exact arguments.

If the argument is a rational multiple of `I`, the result is expressed in terms of hyperbolic functions. See “Example 2” on page 1-200.

MuPAD rewrites `arcsec` as `arcsec(x) = arccos(1/x)`.

The inverse secant function is multivalued. The MuPAD `arccsc` function returns values on the main branch defined as follows. The branch cut is the real interval (- 1, 1).

The `arcsec` function returns explicit values for arguments that are certain rational multiples of π. For these values, the inverse functions return an appropriate rational multiple of π on the main branch. See “Example 3” on page 1-200.

The values jump when the arguments cross a branch cut. See “Example 4” on page 1-201.

The float attributes are kernel functions. Thus, floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, `arcsec` is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
arcsin(1), arccos(1/sqrt(2)), arctan(5 + I), arccsc(1/3),
arcsec(I), arccot(1)
```

$$\frac{\pi}{2},\ \frac{\pi}{4},\ \arctan(5+i),\ \arcsin(3),\ \frac{\pi}{2}+\operatorname{arcsinh}(1)\,i,\ \frac{\pi}{4}$$

```
arcsin(-x), arccos(x + 1), arctan(1/x)
```

$$-\arcsin(x),\ \arccos(x+1),\ \arctan\left(\frac{1}{x}\right)$$

Floating-point values are computed for floating-point arguments:

```
arcsin(0.1234), arccos(5.6 + 7.8*I), arccot(1.0/10^20)
```

$$0.1237153458,\ 0.950687977-2.956002937\,i,\ 1.570796327$$

On input of floating-point intervals, these functions compute floating-point intervals containing the image sets:

```
arcsin(0...1), arccos(0...1)
```

$$0.0\ldots 1.570796327,\ -3.469446952\,10^{-18}\ldots 1.570796327$$

```
arcsin(2...3)
```

$$1.570796326\ldots 1.570796327+-1.762747175\ldots -1.316957896\,i$$

Note that certain types of input lead to severe overestimation, sometimes returning the whole image set of the function in question:

```
arccsc(-2...2);
csc(arccsc(-2...2))
```

$$-3.141592654 \ldots 2.382564905\ 10^{-323228497} + -0.6931471806 \ldots \mathrm{RD\_INF}\ i$$

$$\cup -2.382564905\ 10^{-323228497} \ldots 3.141592654 + \mathrm{RD\_NINF} \ldots 0.6931471806\ i$$

$$\mathrm{RD\_NINF} \ldots \mathrm{RD\_INF} + \mathrm{RD\_NINF} \ldots \mathrm{RD\_INF}\ i$$

Example 2

Arguments that are rational multiples of `I` are rewritten in terms of hyperbolic functions:

```
arcsin(5*I), arccos(5/4*I), arctan(-3*I)
```

$$\operatorname{arcsinh}(5)\ i,\ \frac{\pi}{2} - \operatorname{arcsinh}\left(\frac{5}{4}\right) i,\ -\operatorname{arctanh}(3)\ i$$

For other complex arguments unevaluated function calls without simplifications are returned:

```
arcsin(1/2^(1/2) + I), arccos(1 -3*I)
```

$$\arcsin\left(\frac{\sqrt{2}}{2} + i\right),\ \arccos(1 - 3\ i)$$

Example 3

Some special values are implemented:

```
arcsin(1/sqrt(2)), arccos((5^(1/2) - 1)/4), arctan(3^(1/2) - 2)
```

$$\frac{\pi}{4},\ \frac{2\pi}{5},\ -\frac{\pi}{12}$$

Such simplifications occur for arguments that are trigonometric images of rational multiples of π:

```
sin(9/10*PI), arcsin(sin(9/10*PI))
```

$$\frac{\sqrt{5}}{4} - \frac{1}{4},\ \frac{\pi}{10}$$

```
cos(PI/8)/sin(PI/8), arctan(cos(PI/8)/sin(PI/8))
```

$$\frac{\sqrt{\sqrt{2}+2}}{\sqrt{2-\sqrt{2}}},\ \frac{3\,\pi}{8}$$

Example 4

The values jump when crossing a branch cut:

```
arcsin(2.0 + I/10^10), arcsin(2.0 - I/10^10)
```

$$1.570796327 + 1.316957897\,i,\ 1.570796327 - 1.316957897\,i$$

On the branch cut, the values of `arcsin` coincide with the limit "from below" for real arguments $x > 1$. The values coincide with the limit "from above" for real $x < -1$:

```
arcsin(1.2), arcsin(1.2 - I/10^10), arcsin(1.2 + I/10^10)
```

$$1.570796327 - 0.6223625037\,i,\ 1.570796327 - 0.6223625037\,i,\ 1.570796327 + 0.6223625037\,i$$

```
arcsin(-1.2), arcsin(-1.2 + I/10^10), arcsin(-1.2 - I/10^10)
```

$$-1.570796327 + 0.6223625037\,i,\ -1.570796327 + 0.6223625037\,i,\ -1.570796327 - 0.6223625037\,i$$

Example 5

The inverse trigonometric functions can be rewritten in terms of the logarithm function with complex arguments:

```
rewrite(arcsin(x), ln), rewrite(arctan(x), ln)
```

$$-\ln\left(\sqrt{1-x^2}+x\,\mathrm{i}\right)\mathrm{i},\ \frac{\ln(1-x\,\mathrm{i})\,\mathrm{i}}{2}-\frac{\ln(1+x\,\mathrm{i})\,\mathrm{i}}{2}$$

Example 6

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the inverse trigonometric functions:

```
diff(arcsin(x^2), x), float(arccos(3)*arctan(5 + I))
```

$$\frac{2x}{\sqrt{1-x^4}},\ -0.06540673615+2.433548516\,\mathrm{i}$$

```
limit(arcsin(x^2)/arctan(x^2), x = 0)
```

$$1$$

```
series(arctan(sin(x)) - arcsin(tan(x)), x = 0, 10)
```

$$-x^3-\frac{83\,x^7}{120}-\frac{4\,x^9}{189}-\frac{22831\,x^{11}}{28800}+O(x^{13})$$

```
series(arccos(2 + x), x, 3)
```

$$-\mathrm{signIm}(x+2)\,\arccos(2)-\frac{\sqrt{3}\,x\,\mathrm{signIm}(x+2)\,\mathrm{i}}{3}+\frac{\sqrt{3}\,x^2\,\mathrm{signIm}(x+2)\,\mathrm{i}}{9}+O(x^3)$$

Example 7

When you call `arctan` with two arguments, MuPAD calls the `arg` function and computes the polar angle of a complex number:

```
arctan(y, x)
```

$$\arg(x+y\,\mathrm{i})$$

Parameters

x

Arithmetical expression or floating-point interval

Return Values

Arithmetical expression or floating-point interval.

Overloaded By

x

MuPAD Functions

`arccos` | `arccot` | `arccsc` | `arcsin` | `arctan` | `arg` | `cos` | `cot` | `csc` | `sec` | `sin` | `tan`

arccot

Inverse cotangent function

Syntax

```
arccot(x)
```

Description

`arccot(x)` represents the inverse of the cotangent function.

The angle returned by this function is measured in radians, not in degrees. E.g., the result π represents an angle of 180^o.

`arccot` is defined for complex arguments.

Floating-point values are returned for floating-point arguments. Floating-point intervals are returned for interval arguments. Unevaluated function calls are returned for most exact arguments.

If the argument is a rational multiple of `I`, the result is expressed in terms of hyperbolic functions. See “Example 2” on page 1-206.

The inverse cotangent function is multivalued. The MuPAD `arccot` function returns the value on the main branch. The branch cut is the interval [- *i*, *i*] on the imaginary axis. Thus, `arcsin` returns values, such that $y = arccot(x)$ satisfies $-\frac{\pi}{2} < \Re(y) \le \frac{\pi}{2}$ for any finite complex x.

The `cot` function returns explicit values for arguments that are certain rational multiples of π. For these values, `arccot` returns an appropriate rational multiple of π on the main branch. See “Example 3” on page 1-207.

The values jump when the arguments cross a branch cut. See “Example 4” on page 1-207.

Note: MuPAD defines `arccot` as `arccot(x) = arctan(1/x)`, although `arccot` may return an unevaluated function call and does not rewrite itself in terms of `arctan`. As

a consequence of this definition, the real line crosses the branch cut and `arccot` has a jump discontinuity at the origin!

The float attributes are kernel functions. Thus, floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, `arccot` is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
arcsin(1), arccos(1/sqrt(2)), arctan(5 + I), arccsc(1/3),
arcsec(I), arccot(1)
```

$$\frac{\pi}{2},\ \frac{\pi}{4},\ \arctan(5+i),\ \arcsin(3),\ \frac{\pi}{2}+\operatorname{arcsinh}(1)\,i,\ \frac{\pi}{4}$$

```
arcsin(-x), arccos(x + 1), arctan(1/x)
```

$$-\arcsin(x),\ \arccos(x+1),\ \arctan\left(\frac{1}{x}\right)$$

Floating-point values are computed for floating-point arguments:

```
arcsin(0.1234), arccos(5.6 + 7.8*I), arccot(1.0/10^20)
```

$$0.1237153458,\ 0.950687977-2.956002937\,i,\ 1.570796327$$

On input of floating-point intervals, these functions compute floating-point intervals containing the image sets:

```
arcsin(0...1), arccos(0...1)
```

$$0.0 \ldots 1.570796327,\ -3.469446952\ 10^{-18} \ldots 1.570796327$$

```
arcsin(2...3)
```

$$1.570796326 \ldots 1.570796327 + -1.762747175 \ldots -1.316957896\ i$$

Note that certain types of input lead to severe overestimation, sometimes returning the whole image set of the function in question:

```
arccsc(-2...2);
csc(arccsc(-2...2))
```

$$-3.141592654 \ldots 2.382564905\ 10^{-323228497} + -0.6931471806 \ldots \text{RD\_INF}\ i$$

$$\cup\ -2.382564905\ 10^{-323228497} \ldots 3.141592654 + \text{RD\_NINF} \ldots 0.6931471806\ i$$

$$\text{RD\_NINF} \ldots \text{RD\_INF} + \text{RD\_NINF} \ldots \text{RD\_INF}\ i$$

Example 2

Arguments that are rational multiples of `I` are rewritten in terms of hyperbolic functions:

```
arcsin(5*I), arccos(5/4*I), arctan(-3*I)
```

$$\operatorname{arcsinh}(5)\ i,\ \frac{\pi}{2} - \operatorname{arcsinh}\left(\frac{5}{4}\right) i,\ -\operatorname{arctanh}(3)\ i$$

For other complex arguments unevaluated function calls without simplifications are returned:

```
arcsin(1/2^(1/2) + I), arccos(1 -3*I)
```

$$\arcsin\left(\frac{\sqrt{2}}{2} + i\right),\ \arccos(1 - 3\ i)$$

Example 3

Some special values are implemented:

```
arcsin(1/sqrt(2)), arccos((5^(1/2) - 1)/4), arctan(3^(1/2) - 2)
```

$$\frac{\pi}{4}, \frac{2\,\pi}{5}, -\frac{\pi}{12}$$

Such simplifications occur for arguments that are trigonometric images of rational multiples of π:

```
sin(9/10*PI), arcsin(sin(9/10*PI))
```

$$\frac{\sqrt{5}}{4} - \frac{1}{4}, \frac{\pi}{10}$$

```
cos(PI/8)/sin(PI/8), arctan(cos(PI/8)/sin(PI/8))
```

$$\frac{\sqrt{\sqrt{2}+2}}{\sqrt{2-\sqrt{2}}}, \frac{3\,\pi}{8}$$

Example 4

The values jump when crossing a branch cut:

```
arcsin(2.0 + I/10^10), arcsin(2.0 - I/10^10)
```

$$1.570796327 + 1.316957897\,i,\ 1.570796327 - 1.316957897\,i$$

On the branch cut, the values of `arcsin` coincide with the limit "from below" for real arguments $x > 1$. The values coincide with the limit "from above" for real $x < -1$:

```
arcsin(1.2), arcsin(1.2 - I/10^10), arcsin(1.2 + I/10^10)
```

$$1.570796327 - 0.6223625037\,i,\ 1.570796327 - 0.6223625037\,i,\ 1.570796327 + 0.6223625037\,i$$

```
arcsin(-1.2), arcsin(-1.2 + I/10^10), arcsin(-1.2 - I/10^10)
```

$$-1.570796327 + 0.6223625037\,i,\ -1.570796327 + 0.6223625037\,i,\ -1.570796327 - 0.6223625037\,i$$

Example 5

The inverse trigonometric functions can be rewritten in terms of the logarithm function with complex arguments:

```
rewrite(arcsin(x), ln), rewrite(arctan(x), ln)
```

$$-\ln\left(\sqrt{1-x^2} + x\,i\right) i,\ \frac{\ln(1-x\,i)\,i}{2} - \frac{\ln(1+x\,i)\,i}{2}$$

Example 6

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the inverse trigonometric functions:

```
diff(arcsin(x^2), x), float(arccos(3)*arctan(5 + I))
```

$$\frac{2x}{\sqrt{1-x^4}},\ -0.06540673615 + 2.433548516\,i$$

```
limit(arcsin(x^2)/arctan(x^2), x = 0)
```

$$1$$

```
series(arctan(sin(x)) - arcsin(tan(x)), x = 0, 10)
```

$$-x^3 - \frac{83\,x^7}{120} - \frac{4\,x^9}{189} - \frac{22831\,x^{11}}{28800} + O(x^{13})$$

```
series(arccos(2 + x), x, 3)
```

$$-\operatorname{signIm}(x+2)\arccos(2) - \frac{\sqrt{3}\,x\,\operatorname{signIm}(x+2)\,i}{3} + \frac{\sqrt{3}\,x^2\,\operatorname{signIm}(x+2)\,i}{9} + O(x^3)$$

Example 7

When you call `arctan` with two arguments, MuPAD calls the `arg` function and computes the polar angle of a complex number:

```
arctan(y, x)
```

$$\arg(x + y\,\mathrm{i})$$

Parameters

x

Arithmetical expression or floating-point interval

Return Values

Arithmetical expression or floating-point interval.

Overloaded By

x

MuPAD Functions

`arccos` | `arccsc` | `arcsec` | `arcsin` | `arctan` | `arg` | `cos` | `cot` | `csc` | `sec` | `sin` | `tan`

arcsinh

Inverse of the hyperbolic sine function

Syntax

```
arcsinh(x)
```

Description

`arcsinh(x)` represents the inverse of the hyperbolic sine function.

`arcsinh` is defined for complex arguments.

Floating-point values are returned for floating-point arguments. Floating-point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

The following special value is implemented:

`arcsinh`(0) = 0

The inverse hyperbolic sine function is multivalued. The MuPAD implementation returns values on the main branch defined by the following restriction of the imaginary part. For any finite complex x,

$$-\frac{\pi}{2} \le \Im(\operatorname{arcsinh}(x)) \le \frac{\pi}{2},$$

The inverse hyperbolic sine function is implemented according to the following relation to the logarithm function: `arcsinh(x) = ln(x + sqrt(x^2 + 1))`. See “Example 2” on page 1-212.

Consequently, the branch cuts are the intervals $(-i\infty, -i)$ and $(i, i\infty)$ on the imaginary axis. The values jump when the argument crosses a branch cut. See “Example 3” on page 1-212.

The float attributes are kernel functions, and floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, `arcsinh` is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
arcsinh(1), arccosh(1/sqrt(3)), arctanh(5 + I), arccsch(1/3),
arcsech(I), arccoth(2)
```

$$\operatorname{arcsinh}(1),\ \operatorname{arccosh}\left(\frac{\sqrt{3}}{3}\right),\ \operatorname{arctanh}(5+i),\ \operatorname{arcsinh}(3),\ \operatorname{arccosh}(-i),\ \operatorname{arccoth}(2)$$

```
arcsinh(-x), arccosh(x + 1), arctanh(1/x)
```

$$-\operatorname{arcsinh}(x),\ \operatorname{arccosh}(x+1),\ \operatorname{arctanh}\left(\frac{1}{x}\right)$$

Floating-point values are computed for floating-point arguments:

```
arcsinh(0.1234), arccosh(5.6 + 7.8*I), arccoth(1.0/10^20)
```

$$0.1230889466,\ 2.956002937 + 0.950687977\,i,\ -1.570796327\,i$$

Floating-point intervals are returned for arguments of this type:

```
arccoth(0.5 ... 1.5), arcsinh(0.1234...0.12345)
```

$$0.2554128118 \ldots \mathrm{RD\_INF} + -1.570796327 \ldots -1.570796326\,i \cup 0.8047189562 \ldots \mathrm{RD\_INF},\ 0.1230889466 \ldots 0.1231385701$$

The inverse of the hyperbolic tangent function has real values only in the interval (- 1, 1):

```
arctanh(-1/2...0), arctanh(2...3)
```

$$-0.5493061444 \ldots 0.0,\ 0.202732554 \ldots 0.6931471806 + -1.570796327 \ldots -1.570796326\,i$$

Example 2

The inverse hyperbolic functions can be rewritten in terms of the logarithm function:

```
rewrite(arcsinh(x), ln), rewrite(arctanh(x), ln)
```

$$\ln\left(x+\sqrt{x^2+1}\right),\ \frac{\ln(x+1)}{2}-\frac{\ln(1-x)}{2}$$

Example 3

The values jump when crossing a branch cut:

```
arctanh(2.0 + I/10^10), arctanh(2.0 - I/10^10)
```

$$0.5493061443 + 1.570796327\,i,\ 0.5493061443 - 1.570796327\,i$$

On the branch cut, the values of `arctanh` coincide with the limit "from below" for real arguments $x > 1$. The values coincide with the limit "from above" for real $x < -1$:

```
arctanh(1.2), arctanh(1.2 - I/10^10), arctanh(1.2 + I/10^10)
```

$$1.198947636 - 1.570796327\,i,\ 1.198947636 - 1.570796327\,i,\ 1.198947636 + 1.570796327\,i$$

```
arctanh(-1.2), arctanh(-1.2 + I/10^10), arctanh(-1.2 - I/10^10)
```

$$-1.198947636 + 1.570796327\,i,\ -1.198947636 + 1.570796327\,i,\ -1.198947636 - 1.570796327\,i$$

Example 4

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the inverse hyperbolic functions:

```
diff(arcsinh(x^2), x), float(arccosh(3)*arctanh(5 + I))
```

$$\frac{2\,x}{\sqrt{x^4+1}},\ 0.3427241326 + 2.698556745\,i$$

```
limit(arcsinh(x)/arctanh(x), x = 0)
```

$$1$$

```
series(arctanh(sinh(x)) - arcsinh(tanh(x)), x = 0, 10)
```

$$x^3 + \frac{83\,x^7}{120} - \frac{4\,x^9}{189} + \frac{22831\,x^{11}}{28800} + O(x^{13})$$

Parameters

arccosh

Inverse of the hyperbolic cosine function

Syntax

```
arccosh(x)
```

Description

`arccosh(x)` represents the inverse of the hyperbolic cosine function.

`arccosh` is defined for complex arguments.

Floating-point values are returned for floating-point arguments. Floating-point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

The following special values are implemented:

`arccosh`(1) = 0, `arccosh`$(0) = \frac{i\pi}{2}$, `arccosh`(- 1) = $i\,\pi$.

The inverse hyperbolic cosine function is multivalued. The MuPAD implementation returns values on the main branch defined by the following restriction of the imaginary part. For any finite complex x,

$$-\pi < \Im(\operatorname{arccosh}(x)) \le \pi$$

,

The inverse hyperbolic cosine function is implemented according to the following relation to the logarithm function: `arccosh(x) = ln(x + sqrt(x^2 - 1))`. See “Example 2” on page 1-216.

Consequently, the branch cuts are the real interval (-∞, 1) and the imaginary axis.

The values jump when the argument crosses a branch cut. See “Example 3” on page 1-216.

The float attributes are kernel functions, and floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, `arccosh` is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
arcsinh(1), arccosh(1/sqrt(3)), arctanh(5 + I), arccsch(1/3),
arcsech(I), arccoth(2)
```

$$\operatorname{arcsinh}(1),\ \operatorname{arccosh}\left(\frac{\sqrt{3}}{3}\right),\ \operatorname{arctanh}(5+i),\ \operatorname{arcsinh}(3),\ \operatorname{arccosh}(-i),\ \operatorname{arccoth}(2)$$

```
arcsinh(-x), arccosh(x + 1), arctanh(1/x)
```

$$-\operatorname{arcsinh}(x),\ \operatorname{arccosh}(x+1),\ \operatorname{arctanh}\left(\frac{1}{x}\right)$$

Floating-point values are computed for floating-point arguments:

```
arcsinh(0.1234), arccosh(5.6 + 7.8*I), arccoth(1.0/10^20)
```

$$0.1230889466,\ 2.956002937 + 0.950687977\,i,\ -1.570796327\,i$$

Floating-point intervals are returned for arguments of this type:

```
arccoth(0.5 ... 1.5), arcsinh(0.1234...0.12345)
```

$$0.2554128118 \ldots \mathrm{RD\_INF} + -1.570796327 \ldots -1.570796326\,i \cup 0.8047189562 \ldots \mathrm{RD\_INF},\ 0.1230889466 \ldots 0.1231385701$$

The inverse of the hyperbolic tangent function has real values only in the interval (- 1, 1):

```
arctanh(-1/2...0), arctanh(2...3)
```

$$-0.5493061444 \ldots 0.0,\ 0.202732554 \ldots 0.6931471806 + -1.570796327 \ldots -1.570796326\,i$$

Example 2

The inverse hyperbolic functions can be rewritten in terms of the logarithm function:

```
rewrite(arcsinh(x), ln), rewrite(arctanh(x), ln)
```

$$\ln\left(x+\sqrt{x^2+1}\right),\ \frac{\ln(x+1)}{2}-\frac{\ln(1-x)}{2}$$

Example 3

The values jump when crossing a branch cut:

```

arctanh

Inverse of the hyperbolic tangent function

Syntax

```
arctanh(x)
```

Description

`arctanh(x)` represents the inverse of the hyperbolic tangent function.

`arctanh` is defined for complex arguments.

Floating-point values are returned for floating-point arguments. Floating-point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

The following special value is implemented:

`arctanh`(0) = 0

The inverse hyperbolic tangent function is multivalued. The MuPAD implementation returns values on the main branch defined by the following restriction of the imaginary part. For any finite complex x,

$$-\frac{\pi}{2} < \Im(\operatorname{arctanh}(x)) < \frac{\pi}{2},$$

The inverse hyperbolic tangent function is implemented according to the following relation to the logarithm function: `arctanh(x) = (ln(1 + x) - ln(1 - x))/2`. See “Example 2” on page 1-220.

Consequently, the branch cuts are the real intervals (-∞, -1) and (1, ∞).

The values jump when the argument crosses a branch cut. See “Example 3” on page 1-220.

The float attributes are kernel functions, and floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, `arctanh` is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
arcsinh(1), arccosh(1/sqrt(3)), arctanh(5 + I), arccsch(1/3),
arcsech(I), arccoth(2)
```

$$\operatorname{arcsinh}(1),\ \operatorname{arccosh}\left(\frac{\sqrt{3}}{3}\right),\ \operatorname{arctanh}(5+i),\ \operatorname{arcsinh}(3),\ \operatorname{arccosh}(-i),\ \operatorname{arccoth}(2)$$

```
arcsinh(-x), arccosh(x + 1), arctanh(1/x)
```

$$-\operatorname{arcsinh}(x),\ \operatorname{arccosh}(x+1),\ \operatorname{arctanh}\left(\frac{1}{x}\right)$$

Floating-point values are computed for floating-point arguments:

```
arcsinh(0.1234), arccosh(5.6 + 7.8*I), arccoth(1.0/10^20)
```

$$0.1230889466,\ 2.956002937 + 0.950687977\,i,\ -1.570796327\,i$$

Floating-point intervals are returned for arguments of this type:

```
arccoth(0.5 ... 1.5), arcsinh(0.1234...0.12345)
```

$$0.2554128118 \ldots \mathrm{RD\_INF} + -1.570796327 \ldots -1.570796326\,i \cup 0.8047189562 \ldots \mathrm{RD\_INF},\ 0.1230889466 \ldots 0.1231385701$$

The inverse of the hyperbolic tangent function has real values only in the interval (- 1, 1):

```
arctanh(-1/2...0), arctanh(2...3)
```

$$-0.5493061444 \ldots 0.0,\ 0.202732554 \ldots 0.6931471806 + -1.570796327 \ldots -1.570796326\,i$$

Example 2

The inverse hyperbolic functions can be rewritten in terms of the logarithm function:

```
rewrite(arcsinh(x), ln), rewrite(arctanh(x), ln)
```

$$\ln\left(x+\sqrt{x^2+1}\right),\ \frac{\ln(x+1)}{2}-\frac{\ln(1-x)}{2}$$

Example 3

The values jump when crossing a branch cut:

```
arctanh(2.0 + I/10^10), arctanh(2.0 - I/10^10)
```

$$0.5493061443 + 1.570796327\,i,\ 0.5493061443 - 1.570796327\,i$$

On the branch cut, the values of `arctanh` coincide with the limit "from below" for real arguments $x > 1$. The values coincide with the limit "from above" for real $x < -1$:

```
arctanh(1.2), arctanh(1.2 - I/10^10), arctanh(1.2 + I/10^10)
```

$$1.198947636 - 1.570796327\,i,\ 1.198947636 - 1.570796327\,i,\ 1.198947636 + 1.570796327\,i$$

```
arctanh(-1.2), arctanh(-1.2 + I/10^10), arctanh(-1.2 - I/10^10)
```

$$-1.198947636 + 1.570796327\,i,\ -1.198947636 + 1.570796327\,i,\ -1.198947636 - 1.570796327\,i$$

Example 4

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the inverse hyperbolic functions:

```
diff(arcsinh(x^2), x), float(arccosh(3)*arctanh(5 + I))
```

$$\frac{2\,x}{\sqrt{x^4+1}},\ 0.3427241326 + 2.698556745\,i$$

```
limit(arcsinh(x)/arctanh(x), x = 0)
```

$$1$$

```
series(arctanh(sinh(x)) - arcsinh(tanh(x)), x = 0, 10)
```

$$x^3 + \frac{83\,x^7}{120} - \frac{4\,x^9}{189} + \frac{22831\,x^{11}}{28800} + O(x^{13})$$

Parameters

x

arccsch

Inverse of the hyperbolic cosecant function

Syntax

```
arccsch(x)
```

Description

`arccsch(x)` represents the inverse of the hyperbolic cosecant function.

`arccsch` is defined for complex arguments.

Floating-point values are returned for floating-point arguments. Floating-point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

The inverse hyperbolic cosecant function is multivalued. MuPAD rewrites `arccsch` as `arccsch(x) = arcsinh(1/x)`. The MuPAD implementation for `arcsinh` returns values on the main branch defined by the following restriction of the imaginary part. For any finite complex x,

$$-\frac{\pi}{2} \le \Im(\operatorname{arcsinh}(x)) \le \frac{\pi}{2},$$

The inverse hyperbolic cosecant function is implemented according to the following relation to the logarithm function: `arccsch(x) = arcsinh(1/x)`. See “Example 2” on page 1-224.

Consequently, the branch cut is the interval (-i, i) on the imaginary axis.

The values jump when the argument crosses a branch cut. See “Example 3” on page 1-224.

The float attributes are kernel functions, and floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, `arccsch` is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
arcsinh(1), arccosh(1/sqrt(3)), arctanh(5 + I), arccsch(1/3),
arcsech(I), arccoth(2)
```

$$\operatorname{arcsinh}(1),\ \operatorname{arccosh}\left(\frac{\sqrt{3}}{3}\right),\ \operatorname{arctanh}(5+i),\ \operatorname{arcsinh}(3),\ \operatorname{arccosh}(-i),\ \operatorname{arccoth}(2)$$

```
arcsinh(-x), arccosh(x + 1), arctanh(1/x)
```

$$-\operatorname{arcsinh}(x),\ \operatorname{arccosh}(x+1),\ \operatorname{arctanh}\left(\frac{1}{x}\right)$$

Floating-point values are computed for floating-point arguments:

```
arcsinh(0.1234), arccosh(5.6 + 7.8*I), arccoth(1.0/10^20)
```

$$0.1230889466,\ 2.956002937 + 0.950687977\,i,\ -1.570796327\,i$$

Floating-point intervals are returned for arguments of this type:

```
arccoth(0.5 ... 1.5), arcsinh(0.1234...0.12345)
```

$$0.2554128118 \ldots \mathrm{RD\_INF} + -1.570796327 \ldots -1.570796326\,i \cup 0.8047189562 \ldots \mathrm{RD\_INF},\ 0.1230889466 \ldots 0.1231385701$$

The inverse of the hyperbolic tangent function has real values only in the interval (- 1, 1):

```
arctanh(-1/2...0), arctanh(2...3)
```

$$-0.5493061444 \ldots 0.0,\ 0.202732554 \ldots 0.6931471806 + -1.570796327 \ldots -1.570796326\,i$$

Example 2

The inverse hyperbolic functions can be rewritten in terms of the logarithm function:

```
rewrite(arcsinh(x), ln), rewrite(arctanh(x), ln)
```

$$\ln\left(x+\sqrt{x^2+1}\right),\ \frac{\ln(x+1)}{2}-\frac{\ln(1-x)}{2}$$

Example 3

The values jump when crossing a branch cut:

```
arctanh(2.0 + I/10^10), arctanh(2.0 - I/10^10)
```

$$0.5493061443 + 1.570796327\,i,\ 0.5493061443 - 1.570796327\,i$$

On the branch cut, the values of `arctanh` coincide with the limit "from below" for real arguments $x > 1$. The values coincide with the limit "from above" for real $x < -1$:

```
arctanh(1.2), arctanh(1.2 - I/10^10), arctanh(1.2 + I/10^10)
```

$$1.198947636 - 1.570796327\,i,\ 1.198947636 - 1.570796327\,i,\ 1.198947636 + 1.570796327\,i$$

```
arctanh(-1.2), arctanh(-1.2 + I/10^10), arctanh(-1.2 - I/10^10)
```

$$-1.198947636 + 1.570796327\,i,\ -1.198947636 + 1.570796327\,i,\ -1.198947636 - 1.570796327\,i$$

Example 4

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the inverse hyperbolic functions:

```
diff(arcsinh(x^2), x), float(arccosh(3)*arctanh(5 + I))
```

$$\frac{2\,x}{\sqrt{x^4+1}},\ 0.3427241326 + 2.698556745\,i$$

```
limit(arcsinh(x)/arctanh(x), x = 0)
```

$$1$$

```
series(arctanh(sinh(x)) - arcsinh(tanh(x)), x = 0, 10)
```

$$x^3 + \frac{83\,x^7}{120} - \frac{4\,x^9}{189} + \frac{22831\,x^{11}}{28800} + O(x^{13})$$

arcsech

Inverse of the hyperbolic secant function

Syntax

```
arcsech(x)
```

Description

`arcsech(x)` represents the inverse of the hyperbolic secant function.

`arcsech` is defined for complex arguments.

Floating-point values are returned for floating-point arguments. Floating-point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

The inverse hyperbolic secant function is multivalued. MuPAD rewrites `arcsech` as `arcsech(x) = arccosh(1/x)`. The MuPAD implementation for `arccosh` returns values on the main branch defined by the following restriction of the imaginary part. For any finite complex x,

$$-\pi < \Im(\operatorname{arccosh}(x)) \le \pi$$,

The inverse hyperbolic secant function is implemented according to the following relation to the logarithm function: `arcsech(x) = arccosh(1/x)`. See “Example 2” on page 1-228.

Consequently, the branch cuts are the real intervals (-∞, 0) and (1, ∞) together with the imaginary axis.

The values jump when the argument crosses a branch cut. See “Example 3” on page 1-228.

The float attributes are kernel functions, and floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, `arcsech` is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
arcsinh(1), arccosh(1/sqrt(3)), arctanh(5 + I), arccsch(1/3),
arcsech(I), arccoth(2)
```

$$\operatorname{arcsinh}(1),\ \operatorname{arccosh}\left(\frac{\sqrt{3}}{3}\right),\ \operatorname{arctanh}(5+i),\ \operatorname{arcsinh}(3),\ \operatorname{arccosh}(-i),\ \operatorname{arccoth}(2)$$

```
arcsinh(-x), arccosh(x + 1), arctanh(1/x)
```

$$-\operatorname{arcsinh}(x),\ \operatorname{arccosh}(x+1),\ \operatorname{arctanh}\left(\frac{1}{x}\right)$$

Floating-point values are computed for floating-point arguments:

```
arcsinh(0.1234), arccosh(5.6 + 7.8*I), arccoth(1.0/10^20)
```

$$0.1230889466,\ 2.956002937 + 0.950687977\,i,\ -1.570796327\,i$$

Floating-point intervals are returned for arguments of this type:

```
arccoth(0.5 ... 1.5), arcsinh(0.1234...0.12345)
```

$$0.2554128118 \ldots \mathrm{RD\_INF} + -1.570796327 \ldots -1.570796326\,i \cup 0.8047189562 \ldots \mathrm{RD\_INF},\ 0.1230889466 \ldots 0.1231385701$$

The inverse of the hyperbolic tangent function has real values only in the interval (- 1, 1):

```
arctanh(-1/2...0), arctanh(2...3)
```

$$-0.5493061444 \ldots 0.0,\ 0.202732554 \ldots 0.6931471806 + -1.570796327 \ldots -1.570796326\,i$$

Example 2

The inverse hyperbolic functions can be rewritten in terms of the logarithm function:

```
rewrite(arcsinh(x), ln), rewrite(arctanh(x), ln)
```

$$\ln\left(x+\sqrt{x^2+1}\right),\ \frac{\ln(x+1)}{2}-\frac{\ln(1-x)}{2}$$

Example 3

The values jump when crossing a branch cut:

arccoth

Inverse of the hyperbolic cotangent function

Syntax

```
arccoth(x)
```

Description

`arccoth(x)` represents the inverse of the hyperbolic cotangent function.

`arccoth` is defined for complex arguments.

Floating-point values are returned for floating-point arguments. Floating-point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

The following special value is implemented:

$\texttt{arccoth}(0) = \frac{i\pi}{2}$

The inverse hyperbolic cotangent function is multivalued. The MuPAD implementation returns values on the main branch defined by the following restriction of the imaginary part. For any finite complex x,

$$-\frac{\pi}{2} < \Im(\operatorname{arccoth}(x)) \le \frac{\pi}{2}.$$

The inverse hyperbolic cotangent function is implemented according to the following relation to the logarithm function: `arccoth(x) = arctanh(1/x)`. See “Example 2” on page 1-232.

Consequently, the branch cut is the real interval [-1, 1].

The values jump when the argument crosses a branch cut. See “Example 3” on page 1-232.

`arccoth` is defined by `arccoth(x) = arctanh(1/x)`. However, MuPAD does not automatically rewrite it in terms of `arctanh`.

The float attributes are kernel functions, and floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, `arccoth` is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
arcsinh(1), arccosh(1/sqrt(3)), arctanh(5 + I), arccsch(1/3),
arcsech(I), arccoth(2)
```

$$\operatorname{arcsinh}(1),\ \operatorname{arccosh}\left(\frac{\sqrt{3}}{3}\right),\ \operatorname{arctanh}(5+i),\ \operatorname{arcsinh}(3),\ \operatorname{arccosh}(-i),\ \operatorname{arccoth}(2)$$

```
arcsinh(-x), arccosh(x + 1), arctanh(1/x)
```

$$-\operatorname{arcsinh}(x),\ \operatorname{arccosh}(x+1),\ \operatorname{arctanh}\left(\frac{1}{x}\right)$$

Floating-point values are computed for floating-point arguments:

```
arcsinh(0.1234), arccosh(5.6 + 7.8*I), arccoth(1.0/10^20)
```

$$0.1230889466,\ 2.956002937 + 0.950687977\,i,\ -1.570796327\,i$$

Floating-point intervals are returned for arguments of this type:

```
arccoth(0.5 ... 1.5), arcsinh(0.1234...0.12345)
```

$$0.2554128118 \ldots \mathrm{RD\_INF} + -1.570796327 \ldots - 1.570796326\,i \cup 0.8047189562 \ldots \mathrm{RD\_INF},\ 0.1230889466 \ldots 0.1231385701$$

The inverse of the hyperbolic tangent function has real values only in the interval (- 1, 1):

```
arctanh(-1/2...0), arctanh(2...3)
```

$$-0.5493061444 \ldots 0.0,\ 0.202732554 \ldots 0.6931471806 + -1.570796327 \ldots - 1.570796326\,i$$

Example 2

The inverse hyperbolic functions can be rewritten in terms of the logarithm function:

```
rewrite(arcsinh(x), ln), rewrite(arctanh(x), ln)
```

$$\ln\left(x + \sqrt{x^2+1}\right),\ \frac{\ln(x+1)}{2} - \frac{\ln(1-x)}{2}$$

Example 3

The values jump when crossing a branch cut:

```
arctanh(2.0 + I/10^10), arctanh(2.0 - I/10^10)
```

$$0.5493061443 + 1.570796327\,i,\ 0.5493061443 - 1.570796327\,i$$

On the branch cut, the values of `arctanh` coincide with the limit “from below” for real arguments $x > 1$. The values coincide with the limit “from above” for real $x < -1$:

```
arctanh(1.2), arctanh(1.2 - I/10^10), arctanh(1.2 + I/10^10)
```

$$1.198947636 - 1.570796327\,i,\ 1.198947636 - 1.570796327\,i,\ 1.198947636 + 1.570796327\,i$$

```
arctanh(-1.2), arctanh(-1.2 + I/10^10), arctanh(-1.2 - I/10^10)
```

$$-1.198947636 + 1.570796327\,i,\ -1.198947636 + 1.570796327\,i,\ -1.198947636 - 1.570796327\,i$$

Example 4

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the inverse hyperbolic functions:

```
diff(arcsinh(x^2), x), float(arccosh(3)*arctanh(5 + I))
```

$$\frac{2\,x}{\sqrt{x^4+1}},\ 0.3427241326 + 2.698556745\,i$$

```
limit(arcsinh(x)/arctanh(x), x = 0)
```

$$1$$

```
series(arctanh(sinh(x)) - arcsinh(tanh(x)), x = 0, 10)
```

$$x^3 + \frac{83\,x^7}{120} - \frac{4\,x^9}{189} + \frac{22831\,x^{11}}{28800} + O(x^{13})$$

MuPAD Functions

`arccosh` | `arccsch` | `arcsech` | `arcsinh` | `arctanh` | `cosh` | `coth` | `csch` | `sech` | `sinh` | `tanh`

arg

Argument (polar angle) of a complex number

Syntax

```
arg(z)
```

```
arg(x, y)
```

Description

`arg(z)` returns the argument of the complex number `z`.

`arg(x, y)` returns the argument of the complex number with real part `x` and imaginary part `y`.

This function is also known as `atan2` in other mathematical languages.

The argument of a non-zero complex number $z = x + i\,y = |z|\,e^{i\phi}$ is its real polar angle ϕ. `arg(x,y)` represents the principal value $\phi \in (-\pi, \pi]$. For $x \neq 0$, $y \neq 0$, it is given by

$$\arg(x, y) = \arctan\left(\frac{y}{x}\right) + \frac{\pi}{2}\,\mathrm{sign}(y)\,(1 - \mathrm{sign}(x))$$

An error occurs if `arg` is called with two arguments and either one of the arguments `x`, `y` is a non-real numerical value. Symbolic arguments are assumed to be real.

On the other hand, if `arg` is called with only one argument `x + I*y`, it is not assumed that `x` and `y` are real.

A floating-point number is returned if one argument is given which is a floating-point number; or if two arguments are given, both of them are numerical and at least one of them is a floating-point number.

If the sign of the arguments can be determined, then the result is expressed in terms of `arctan`. Cf. “Example 2” on page 1-237. Otherwise, a symbolic call of `arg` is returned.

Numerical factors are eliminated from the first argument. Cf. “Example 3” on page 1-237.

A symbolic call to `arg` returned has only one argument.

The call `arg(0,0)`, or equivalently `arg(0)`, returns `0`.

An alternative representation is $\arg(x, y) = -i \ln\left(\frac{z}{|z|}\right) = -i \ln(\operatorname{sign}(z))$. Cf. “Example 4” on page 1-238.

Environment Interactions

When called with floating-point arguments, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision. Properties of identifiers are taken into account.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
arg(2, 3), arg(x, 4), arg(4, y), arg(x, y), arg(10, y + PI)
```

$$\arctan\left(\frac{3}{2}\right),\ \arg(x+4\,i),\ \arctan\left(\frac{y}{4}\right),\ \arg(x+y\,i),\ \arctan\left(\frac{\pi}{10}+\frac{y}{10}\right)$$

If `arg` is called with two arguments, the arguments are implicitly assumed to be real, which allows some additional simplifications compared to a call with only one argument:

```
arg(1, y), arg(1 + I*y)
```

$$\arctan(y),\ \arg(1+y\,i)$$

```
arg(x, infinity), arg(-infinity, 3), arg(-infinity, -3)
```

$$\frac{\pi}{2},\ \pi,\ -\pi$$

Floating point values are computed for floating-point arguments:

```
arg(2.0, 3), arg(2, 3.0), arg(10.0^100, 10.0^(-100))
```

$$0.9827937232,\ 0.9827937232,\ 1.0\ 10^{-200}$$

Example 2

`arg` reacts to properties of identifiers set via `assume`:

```
assume(x > 0): assume(y < 0): arg(x, y)
```

$$\arctan\left(\frac{y}{x}\right)$$

```
assume(x < 0): assume(y > 0): arg(x, y)
```

$$\pi + \arctan\left(\frac{y}{x}\right)$$

```
assume(x <> 0): arg(x, 3)
```

$$\arctan\left(\frac{3}{x}\right) - \frac{\pi\ (\mathrm{sign}(x) - 1)}{2}$$

```
unassume(x), unassume(y):
```

Example 3

Certain simplifications may occur in unevaluated calls. In particular, numerical factors are eliminated from the first argument:

```
arg(3*x, 9*y), arg(-12*sqrt(2)*x, 12*y)
```

$$\mathrm{arg}(x + 3\ y\ \mathrm{i}),\ \mathrm{arg}(-\sqrt{2}\ x + y\ \mathrm{i})$$

Example 4

Use `rewrite` to convert symbolic calls of `arg` to the logarithmic representation:

```
rewrite(arg(x, y), ln)
```

$$-\ln\left(\frac{x+y\,\mathrm{i}}{|x+y\,\mathrm{i}|}\right)\mathrm{i}$$

Example 5

System functions such as `float`, `limit`, or `series` handle expressions involving `arg`:

```
limit(arg(x, x^2/(1+x)), x = infinity)
```

$$\frac{\pi}{4}$$

```
series(arg(x, x^2), x = 1, 4, Real)
```

$$\frac{\pi}{4}+\frac{x-1}{2}-\frac{(x-1)^2}{4}+\frac{(x-1)^3}{12}+O((x-1)^4)$$

Parameters

z

arithmetical expression

x, y

arithmetical expressions representing real numbers

Return Values

Arithmetical expression.

```

Description

`args(0)` returns the number of parameters of the current procedure.

`args(i)` returns the value of the `i`th parameter of the current procedure.

`args` accesses the actual parameters of a procedure and can only be used in procedures. It is mainly intended for procedures with a variable number of arguments, since otherwise parameters can simply be accessed by their names.

`args()` returns an expression sequence of all actual parameters.

`args(i..j)` returns an expression sequence containing the `i`th up to the `j`th parameter.

In procedures with option `hold`, `args` returns the parameters without further evaluation. Use `context` or `eval` to enforce a subsequent evaluation. See “Example 2” on page 1-242.

`procname ( args())` returns a symbolic function call of the current procedure with evaluated arguments.

Assigning values to formal parameters of a procedure changes the result of `args`. Cf. “Example 4” on page 1-242. `args(0)` remains unchanged.

Examples

Example 1

This example demonstrates the various ways of using `args`:

```
f := proc() begin
  print(Unquoted, "number of arguments" = args(0)):
  print(Unquoted, "sequence of all arguments" = args()):
  if args(0) > 0 then
    print(Unquoted, "first argument" = args(1)):
  end_if:
  if args(0) >= 3 then
    print(Unquoted, "second, third argument" = args(2..3)):
  end_if:
end_proc:

f():

number of arguments = 0

sequence of all arguments =

f(42):

number of arguments = 1

sequence of all arguments = 42

first argument = 42

f(a, b, c, d):

number of arguments = 4

sequence of all arguments = (a, b, c, d)
```

```
first argument = a

second, third argument = (b, c)
```

Example 2

`args` does not evaluate the returned parameters in procedures with the option `hold`. Use `context` to achieve this:

```
f := proc()
  option hold;
begin
  args(1), context(args(1))
end_proc:

delete x, y: x := y: y := 2: f(x)
```

$$x, 2$$

Example 3

We use `args` to access parameters of a procedure with an arbitrary number of arguments:

```
f := proc() begin
  args(1) * _plus(args(2..args(0)))
end_proc:
f(2, 3), f(2, 3, 4)
```

$$6, 14$$

Example 4

Assigning values to formal parameters affects the behavior of `args`. In the following example, `args` returns the value `4`, which is assigned inside the procedure, and not the value `1`, which is the argument of the procedure call:

```
f := proc(a) begin a := 4; args() end_proc:
f(1)
```

```
4
```

Parameters

`i, j`

Positive integers

Return Values

`args(0)` returns a nonnegative integer. All other calls return an arbitrary MuPAD object or a `sequence` of such objects.

array

Create an array

Syntax

```
array(m1 .. n1, <m2 .. n2, …>)

array(m1 .. n1, <m2 .. n2, …>, index1 = entry1, index2 = entry2, …)

array(m1 .. n1, <m2 .. n2, …>, List)

array(<m1 .. n1, m2 .. n2, …>, ListOfLists)
```

Description

`array(...)` creates an *array,* which is an n-dimensional rectangular structure holding arbitrary data.

`array( m_1..n_1, m_2..n_2 , ...)` creates an array with uninitialized entries, where the first index runs from m_1 to n_1, the second index runs from m_2 to n_2, etc.

`array( m_1..n_1, m_2..n_2 , ..., List)` creates an array with entries initialized from `List`.

`array(ListOfLists)` creates an array with entries initialized from `ListOfLists`. The dimension of the array is the same as of `ListOfLists`.

Arrays are container objects for storing data. In contrast to `tables`, the indices must be sequences of integers. While `tables` may grow in size dynamically, the number of entries in an array created by array is fixed.

Arrays created via `array` are of domain type `DOM_ARRAY`. They may contain arbitrary MuPAD objects as entries.

For an array `A`, say, of type `DOM_ARRAY` or `DOM_HFARRAY` and a sequence of integers `index` forming a valid array index, an indexed call `A[index]` returns the corresponding entry. If the entry of an array of type `DOM_ARRAY` is uninitialized, then the indexed

expression `A[index]` is returned. See“Example 1” on page 1-247 and “Example 5” on page 1-250.

An indexed assignment of the form `A[index]:=entry` initializes or overwrites the entry corresponding to `index`. See “Example 1” on page 1-247 and “Example 5” on page 1-250.

The index boundaries must satisfy $m_1 \le n_1$, $m_2 \le n_2$, etc. The dimension of the resulting array is the number of given range arguments; at least one range argument must be specified. The total number of entries of the resulting array is $(n_1 - m_1 + 1)\,(n_2 - m_2 + 1)\,\ldots$.

If only index range arguments are given to `array`, then an array with uninitialized entries is created. Hardware float arrays created via `hfarray` cannot have uninitialized entries. Entries are automatically set to 0.0 if no values are specified. Cf. “Example 1” on page 1-247.

If equations of the form `index=entry` are present, then the array entry corresponding to `index` is initialized with `entry`. This is useful for selectively initializing some particular array entries.

Each index must be a valid array index of the form i_1 for 1-dimensional arrays and $(i_1, i_2, \ldots)$ for higher-dimensional arrays, where $i_1, i_2, \ldots$ are integers within the valid boundaries, satisfying $m_1 \le i_1 \le n_1$, $m_2 \le i_2 \le n_2$, etc., and the number of integers in `index` matches the dimension of the array.

If the argument `List` is present, then the resulting array is initialized with the entries from `List`. This is useful for initializing all array entries at once. The list must have $(n_1 - m_1 + 1)\,(n_2 - m_2 + 1)\,\ldots$ elements, each becoming an operand of the array to be created. In case of 2-dimensional arrays, regarded as a matrix, the list contains the entries row after row.

The argument `ListOfLists` must be a nested list matching the structure of the array exactly. The nesting depth of the list must be greater or equal to the dimension of the array. The number of list entries at the k-th nesting level must be equal to the size of the k-th index range, i.e., $n_k - m_k + 1$. Cf. “Example 7” on page 1-253.

A call of the form `delete A[index]` deletes the entry corresponding to `index`, so that it becomes uninitialized. For arrays of domain type `DOM_HFARRAY` this means that the corresponding entry is set to 0.0. Cf. “Example 5” on page 1-250.

Note: Internally, uninitialized entries of an array of domain type DOM_ARRAY have the value NIL. Thus assigning NIL to an array entry has the same effect as deleting it via delete. Afterwards, an indexed call of the form A[index] returns the symbolic expression A[index], and not NIL, as one might expect. Cf. "Example 5" on page 1-250.

A 1-dimensional array is printed as a row vector. The index corresponds to the column number.

A 2-dimensional array is printed as a matrix. The first index corresponds to the row number and the second index corresponds to the column number.

A 1- or 2-dimensional array that is so big that it would exceed the maximal output width TEXTWIDTH is printed in the form `array( m_1..n_1, m_2..n_2, dots, index_1 = entry_1, index_2 = entry_2, dots )`. See "Example 10" on page 1-256. The same is true for arrays of dimension greater than two. See "Example 6" on page 1-252 and "Example 7" on page 1-253.

Arithmetic operations are not defined for arrays of domain type DOM_ARRAY. Use matrix to create 1-dimensional vectors or 2-dimensional matrices in the mathematical sense.

Arithmetic operations are defined for arrays of domain type DOM_HFARRAY!

E.g., linear combination of arrays A, B can be computed via a*A + b*B if A, B have the same format and if the scalar factors a, b are numbers (floats, integers or rationals).

2-dimensional hfarrays A, B are processed like matrices: Operations such as A*B (matrix multiplication), A^n (matrix powers), or 1/A (matrix inversion) are possible wherever this is meaningful mathematically.

Cf. "Example 8" on page 1-254.

Note the following special feature of arrays of domain type DOM_ARRAY:

Note: If an array is evaluated, it is only returned. The evaluation does not map recursively on the array entries! This is due to performance reasons. You have to map the function eval explicitly on the array in order to fully evaluate its entries.

Cf. "Example 9" on page 1-255.

Examples

Example 1

We create an uninitialized 1-dimensional array with indices ranging from 2 to 4:

```
A := array(2..4)
```

$$(\text{NIL}\ \text{NIL}\ \text{NIL})$$

The `NIL`s in the output indicate that the array entries are not initialized. We set the middle entry to 5 and last entry to `"MuPAD"`:

```
A[3] := 5: A[4] := "MuPAD": A
```

$$(\text{NIL}\ 5\ \text{"MuPAD"})$$

You can access array entries via indexed calls. Since the entry `A[2]` is not initialized, the symbolic expression `A[2]` is returned:

```
A[2], A[3], A[4]
```

$$A_2,\ 5,\ \text{"MuPAD"}$$

We can initialize an array already when creating it by passing initialization equations to `array`:

```
A := array(2..4, 3 = 5, 4 = "MuPAD")
```

$$(\text{NIL}\ 5\ \text{"MuPAD"})$$

We can initialize all entries of an array when creating it by passing a list of initial values to `array`:

```
array(2..4, [PI, 5, "MuPAD"])
```

$$(\pi\ 5\ \text{"MuPAD"})$$

Hardware float arrays do not have uninitialized entries. If no initialization value is given, the corrsponding entry is set to 0.0:

```
hfarray(-1..5)
```

(0.0 0.0 0.0 0.0 0.0 0.0 0.0)

```
hfarray(-1..5, 2 = PI, 4 = sqrt(2)*exp(2))
```

(0.0 0.0 0.0 3.141592654 0.0 10.44970335 0.0)

```
hfarray(-1..5, [frandom() $ i = -1..5])
```

[[0.2703581656, 0.8310371787, 0.153156516, 0.9948127808, 0.2662729021, 0.1801642277, 0.452083055]]

```
hfarray(1..2, 1..3, [[1, 2, 3], [4, 5, 6]])
```

$$\begin{pmatrix} 1.0 & 2.0 & 3.0 \\ 4.0 & 5.0 & 6.0 \end{pmatrix}$$

```
hfarray(1..2, 1..3, [1, 2, 3, 4, 5, 6])
```

$$\begin{pmatrix} 1.0 & 2.0 & 3.0 \\ 4.0 & 5.0 & 6.0 \end{pmatrix}$$

Example 2

Array boundaries may be negative integers as well:

```
A := array(-1..1, [2, sin(x), FAIL])
```

(2 $\sin(x)$ FAIL)

```
A[-1], A[0], A[1]
```

2, $\sin(x)$, FAIL

```
A := hfarray(-1..2, -3..-1, [[-1, -1, -1],
                             [ 0,  0,  0],
                             [ 1,  1,  1],
                             [ 2,  2,  2]])
```

$$\begin{pmatrix} -1.0 & -1.0 & -1.0 \\ 0.0 & 0.0 & 0.0 \\ 1.0 & 1.0 & 1.0 \\ 2.0 & 2.0 & 2.0 \end{pmatrix}$$

```
A[-1, -2], A[0, -3], A[2, -3]
```

$$-1.0,\ 0.0,\ 2.0$$

```
delete A:
```

Example 3

If the dimension and size of the `array` or `hfarray` are not specified explicitly then both values are taken from the given list:

```
hfarray([1.0,2.0,3.0,4.0,5.0]) = hfarray(1..5, [1.0,2.0,3.0,4.0,5.0]);
bool(%)
```

$$(\ 1.0\ \ 2.0\ \ 3.0\ \ 4.0\ \ 5.0\ ) = (\ 1.0\ \ 2.0\ \ 3.0\ \ 4.0\ \ 5.0\ )$$

TRUE

```
array([[1,2],[3,4],[5,6]]) = array(1..3, 1..2, [[1,2],[3,4],[5,6]]);
bool(%)
```

$$\begin{pmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{pmatrix} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{pmatrix}$$

TRUE

Note that all subfields of one dimension must have the same size and dimension. Therefore, the following input leads to an error:

```
array([[1],[3,4],[5,6]])
```

```
Error: The argument is invalid. [array]
```

Example 4

The $ operator may be used to create a sequence of initialization equations:

```
array(1..8, i = i^2 $ i = 1..8)
```

$$(1\ 4\ 9\ 16\ 25\ 36\ 49\ 64)$$

```
hfarray(1..4, 1..4, (i, i) = 1 $ i = 1..4)
```

$$\begin{pmatrix} 1.0 & 0.0 & 0.0 & 0.0 \\ 0.0 & 1.0 & 0.0 & 0.0 \\ 0.0 & 0.0 & 1.0 & 0.0 \\ 0.0 & 0.0 & 0.0 & 1.0 \end{pmatrix}$$

Equivalently, you can use the $ operator to create an initialization list:

```
array(1..8, [i^2 $ i = 1..8])
```

$$(1\ 4\ 9\ 16\ 25\ 36\ 49\ 64)$$

```
hfarray(1..8, [i*PI $ i = 1..8])
```

$$[[3.141592654, 6.283185307, 9.424777961, 12.56637061, 15.70796327, 18.84955592, 21.99114858, 25.13274123]]$$

Example 5

We create a 2×2 matrix as a 2-dimensional array:

```
A := array(1..2, 1..2, (1, 2) = 42, (2, 1) = 1 + I)
```

$$\begin{pmatrix} \text{NIL} & 42 \\ 1+i & \text{NIL} \end{pmatrix}$$

Internally, array entries are stored in a linearized form. They can be accessed in this form via `op`. Uninitialized entries internally have the value `NIL`:

```
op(A, 1), op(A, 2), op(A, 3), op(A, 4)
```

$$\text{NIL}, 42, 1+i, \text{NIL}$$

Note the difference to the indexed access:

```
A[1, 1], A[1, 2], A[2, 1], A[2, 2]
```

$$A_{1,1}, 42, 1+i, A_{2,2}$$

We can modify an array entry by an indexed assignment:

```
A[1, 1] := 0: A[1, 2] := 5:
A
```

$$\begin{pmatrix} 0 & 5 \\ 1+i & \text{NIL} \end{pmatrix}$$

You can delete the value of an array entry via `delete`. Afterwards, it is uninitialized again:

```
delete A[2, 1]: A[2, 1], op(A, 3)
```

$$A_{2,1}, \text{NIL}$$

Assigning `NIL` to an array entry has the same effect as deleting it:

```
A[1, 2] := NIL: A[1, 2], op(A, 2)
```

$$A_{1,2}, \text{NIL}$$

Apart from initialization and deleting entries via NIL assignments, hfarrays behave similarly:

```
A := hfarray(1..2, 1..2, (1, 1) = 1.0, (2, 2) = 1.0)
```

$$\begin{pmatrix} 1.0 & 0.0 \\ 0.0 & 1.0 \end{pmatrix}$$

```
op(A, 1), op(A, 2), op(A, 3), op(A, 4)
```

1.0, 0.0, 0.0, 1.0

```
A[1, 1], A[1, 2], A[2, 1], A[2, 2]
```

1.0, 0.0, 0.0, 1.0

```
A[2, 2] := PI:
A[2, 2]
```

3.141592654

```
delete A[2, 2]:
```

```
Error: The argument is invalid. [delete]
```

```
A
```

$$\begin{pmatrix} 1.0 & 0.0 \\ 0.0 & 3.141592654 \end{pmatrix}$$

```
delete A:
```

Example 6

We define a three-dimensional array with index values between 1 and 8 in each of the three dimensions and initialize two of the entries via initialization equations:

```
A := array(1..8, 1..8, 1..8, (1, 1, 1) = 111, (8, 8, 8) = 888)
```

```
array(1..8, 1..8, 1..8,
  (1, 1, 1) =  111
  (8, 8, 8) =  888
)
```

```
A[1, 1, 1], A[1, 1, 2]
```

$$111, A_{1,1,2}$$

We create a 3-dimensional hfarray:

```
A := hfarray(1..2, 2..3, 3..4, (1, 2, 3) = 123, (2, 3, 4) = 234)
```

```
hfarray(1..2, 2..3, 3..4, [123.0, 0.0, 0.0, 0.0, 0.0, 0.0, 0.0, 234.0])
```

```
delete A, B:
```

Example 7

A nested list may be used to initialize a 2-dimensional array. The inner lists are the rows of the created matrix:

```
array(1..2, 1..3, [[1, 2, 3], [4, 5, 6]])
```

$$\begin{pmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{pmatrix}$$

We create a three-dimensional array and initialize it from a nested list of depth three. The outer list has two entries for the first dimension. Each of these entries is a list with three entries for the second dimension. Finally, the innermost lists each have one entry for the third dimension:

```
array(2..3, 1..3, 1..1,
      [
        [ [1], [2], [3] ],
        [ [4], [5], [6] ]
      ])
```

```
array(2..3, 1..3, 1..1,
  (2, 1, 1) =  1
  (2, 2, 1) =  2
  (2, 3, 1) =  3
  (3, 1, 1) =  4
  (3, 2, 1) =  5
  (3, 3, 1) =  6
)
```

```
hfarray(2..3, 1..3, 1..1,
        [
          [ [1], [2], [3] ],
          [ [4], [5], [6] ]
        ])
```

```
hfarray(2..3, 1..3, 1..1, [1.0, 2.0, 3.0, 4.0, 5.0, 6.0])
```

Example 8

Basic arithmetic is available for arrays of domain type DOM_HFARRAY:

```
A := hfarray(1..5, [1, 2, 3, 4, 5]):
B := hfarray(1..5, [5, 4, 3, 2, 1]):
A + B
```

```
( 6.0 6.0 6.0 6.0 6.0 )
```

```
2*A
```

```
( 2.0 4.0 6.0 8.0 10.0 )
```

```
2*A - 3* B
```

```
( -13.0 -8.0 -3.0 2.0 7.0 )
```

2-dimensional arrays of type DOM_ARRAY are regarded as matrices. They can be multiplied accordingly:

```
A := hfarray(1..3, 1..3, [frandom() $ i = 1..9]):
B := hfarray(1..3, 1..2, [frandom() $ i = 1..6]):
A, B, A * B, A^10 * B
```

$$\begin{pmatrix} 0.6787819563 & 0.3549849261 & 0.6818588132 \\ 0.7219186551 & 0.4738297742 & 0.7889814922 \\ 0.2115258358 & 0.8556871754 & 0.04489739417 \end{pmatrix}, \begin{pmatrix} 0.8791601269 & 0.9193848479 \\ 0.7350574234 & 0.7875450269 \\ 0.9371484273 & 0.2953238727 \end{pmatrix},$$

$$\begin{pmatrix} 1.49669525 & 1.104997644 \\ 1.722366954 & 1.269888425 \\ 0.8570198134 & 0.8816251003 \end{pmatrix}, \begin{pmatrix} 104.6209923 & 83.25909538 \\ 121.6963323 & 96.84792749 \\ 80.3865413 & 63.97259571 \end{pmatrix}$$

The following command computes the matrix inverse of A:

```
1/A
```

$$\begin{pmatrix} 15.13041048 & -13.13273828 & 0.9952407788 \\ -3.111891486 & 2.632361162 & 1.001982382 \\ -11.97546309 & 11.70303455 & -1.512395388 \end{pmatrix}$$

Some functions such as `norm` act on hfarrays:

```
norm(A)
```

$$1.984729921$$

Example 9

If an array is evaluated, it is only returned. The evaluation does not map recursively on the array entries. Here, the entries a and b are not evaluated:

```
A := array(1..2, [a, b]):
a := 1:  b := 2:
A, eval(A)
```

$$(a\ b), (a\ b)$$

Due to the special evaluation of arrays the index operator evaluates array entries after extracting them from the array:

```
A[1], A[2]
```

$$1, 2$$

You have to `map` the function `eval` explicitly on the array in order to fully evaluate its entries:

```
map(A, eval)
```

$$(1\ 2)$$

Example 10

A 2-dimensional array is usually printed in matrix form:

```
A := array(1..4, 1..4, (1, 1) = 11, (4, 4) = 44)
```

$$\begin{pmatrix} 11 & \text{NIL} & \text{NIL} & \text{NIL} \\ \text{NIL} & \text{NIL} & \text{NIL} & \text{NIL} \\ \text{NIL} & \text{NIL} & \text{NIL} & \text{NIL} \\ \text{NIL} & \text{NIL} & \text{NIL} & 44 \end{pmatrix}$$

```
B := hfarray(1..2, 1..3, (1, 1) = 11, (2, 3) = 23)
```

$$\begin{pmatrix} 11.0 & 0.0 & 0.0 \\ 0.0 & 0.0 & 23.0 \end{pmatrix}$$

If the output does not fit into `TEXTWIDTH`, a more compact output is used in `print`:

```
PRETTYPRINT := FALSE:
TEXTWIDTH := 20:
print(Plain, A)
```

```
array(1..4, 1..4, (\
1, 1) = 11, (4, 4) \
= 44)
```

```
PRETTYPRINT := TRUE:
```

```
delete A, B, TEXTWIDTH:
```

Parameters

m_1, n_1, m_2, n_2, …

The index boundaries: integers

$index_1$, $index_2$, …

A sequence of integers defining a valid array index

$entry_1$, $entry_2$, …

Arbitrary objects

List

A plain list of entries for initializing the array

ListOfLists

A nested list (of lists of lists of …) of entries for initializing the array

Return Values

Object of type DOM_ARRAY or DOM_HFARRAY, respectively.

hfarray

Create an array of hardware floats

Syntax

```
hfarray(m1 .. n1, <m2 .. n2, …>)
hfarray(m1 .. n1, <m2 .. n2, …>, index1 = number1, index2 = number2, …)
hfarray(m1 .. n1, <m2 .. n2, …>, List)
hfarray(<m1 .. n1, m2 .. n2, …>, ListOfLists)
```

Description

`hfarray(...)` creates an array specialized to hold *hardware floating-point values.* These *do not* react to `DIGITS`, and no symbolic expressions can be placed into an `hfarray`. The values can be real or complex.

`hfarray( m_1..n_1, m_2..n_2 , ...)` creates an array of floating-point zeroes, where the first index runs from m_1 to n_1, the second index runs from m_2 to n_2, etc.

`hfarray( m_1..n_1, m_2..n_2 , ..., List)` creates an array of floating-point numbers with entries initialized from `List`.

`hfarray(ListOfLists)` creates an array of floating-point numbers with entries initialized from `ListOfLists`. The dimension of the `hfarray` is the same as of `ListOfLists`.

Arrays are container objects for storing data. In contrast to `tables`, the indices must be sequences of integers. While `tables` may grow in size dynamically, the number of entries in an array created by hfarray is fixed.

Arrays created via `hfarray` are of domain type `DOM_HFARRAY`. They can only contain floating-point numbers as entries. Internally, these floating-point numbers are stored as "hardware floats" with about 15 significant decimal digits ("double precision"). This data type serves for storing *large* amounts of numerical data. E.g., an array with 15 digits software floats created via `array` (using `DIGITS` = 15) takes nearly 10 times as much storage space as the corresponding hfarray.

On input, the entries passed to `hfarray` may be MuPAD floating-point numbers, integers or rational numbers, or exact numerical expressions such as `PI + sin(sqrt(2))` that can be converted to floating-point numbers. Exact input data are automatically converted to hardware floats of double precision. This conversion does not depend on the present value of `DIGITS`!

Note: Entries of absolute value smaller than about 10^{-308} are stored as 0.0 by `hfarray`!

An error is thrown if symbolic objects are passed to `hfarray`.

For an array `A`, say, of type `DOM_ARRAY` or `DOM_HFARRAY` and a sequence of integers `index` forming a valid array index, an indexed call `A[index]` returns the corresponding entry. If the entry of an array of type `DOM_ARRAY` is uninitialized, then the indexed expression `A[index]` is returned. See "Example 1" on page 1-261 and "Example 5" on page 1-265.

An indexed assignment of the form `A[index]:=entry` initializes or overwrites the entry corresponding to `index`. See "Example 1" on page 1-261 and "Example 5" on page 1-265.

The index boundaries must satisfy $m_1 \le n_1$, $m_2 \le n_2$, etc. The dimension of the resulting array is the number of given range arguments; at least one range argument must be specified. The total number of entries of the resulting array is $(n_1 - m_1 + 1)\,(n_2 - m_2 + 1)\,\ldots$.

If only index range arguments are given to `array`, then an array with uninitialized entries is created. Hardware float arrays created via `hfarray` cannot have uninitialized entries. Entries are automatically set to 0.0 if no values are specified. Cf. "Example 1" on page 1-261.

If equations of the form `index=entry` are present, then the array entry corresponding to `index` is initialized with `entry`. This is useful for selectively initializing some particular array entries.

Each index must be a valid array index of the form i_1 for 1-dimensional arrays and $(i_1, i_2, \ldots)$ for higher-dimensional arrays, where $i_1, i_2, \ldots$ are integers within the valid boundaries, satisfying $m_1 \le i_1 \le n_1$, $m_2 \le i_2 \le n_2$, etc., and the number of integers in `index` matches the dimension of the array.

If the argument `List` is present, then the resulting array is initialized with the entries from `List`. This is useful for initializing all array entries at once. The list must have (n_1 - m_1 + 1) (n_2 - m_2 + 1) … elements, each becoming an operand of the array to be created. In case of 2-dimensional arrays, regarded as a matrix, the list contains the entries row after row.

The argument `ListOfLists` must be a nested list matching the structure of the array exactly. The nesting depth of the list must be greater or equal to the dimension of the array. The number of list entries at the k-th nesting level must be equal to the size of the k-th index range, i.e., n_k - m_k + 1. Cf. “Example 7” on page 1-267.

A call of the form `delete A[index]` deletes the entry corresponding to `index`, so that it becomes uninitialized. For arrays of domain type `DOM_HFARRAY` this means that the corresponding entry is set to 0.0. Cf. “Example 5” on page 1-265.

Note: Internally, uninitialized entries of an array of domain type `DOM_ARRAY` have the value `NIL`. Thus assigning `NIL` to an array entry has the same effect as deleting it via `delete`. Afterwards, an indexed call of the form `A[index]` returns the symbolic expression `A[index]`, and not `NIL`, as one might expect. Cf. “Example 5” on page 1-265.

A 1-dimensional array is printed as a row vector. The index corresponds to the column number.

A 2-dimensional array is printed as a matrix. The first index corresponds to the row number and the second index corresponds to the column number.

Arrays of dimension greater than two are printed in the form `hfarray( m_1..n_1, m_2..n_2, dots, index_1 = entry_1, index_2 = entry_2, dots )`. See “Example 6” on page 1-267 and “Example 7” on page 1-267.

Arithmetic operations are not defined for arrays of domain type `DOM_ARRAY`. Use `matrix` to create 1-dimensional vectors or 2-dimensional matrices in the mathematical sense.

Arithmetic operations are defined for arrays of domain type `DOM_HFARRAY`!

E.g., linear combination of arrays `A, B` can be computed via `a*A + b*B` if `A, B` have the same format and if the scalar factors `a, b` are numbers (floats, integers or rationals).

2-dimensional hfarrays `A, B` are processed like matrices: Operations such as `A*B` (matrix multiplication), `A^n` (matrix powers), or `1/A` (matrix inversion) are possible wherever this is meaningful mathematically.

Cf. “Example 8” on page 1-268.

Note the following special feature of arrays of domain type `DOM_ARRAY`:

Note: If an array is evaluated, it is only returned. The evaluation does not map recursively on the array entries! This is due to performance reasons. You have to `map` the function `eval` explicitly on the array in order to fully evaluate its entries.

Cf. “Example 9” on page 1-270.

Examples

Example 1

We create an uninitialized 1-dimensional array with indices ranging from 2 to 4:

```
A := array(2..4)
```

$$(\text{NIL}\ \ \text{NIL}\ \ \text{NIL})$$

The `NIL`s in the output indicate that the array entries are not initialized. We set the middle entry to 5 and last entry to `"MuPAD"`:

```
A[3] := 5: A[4] := "MuPAD": A
```

$$(\text{NIL}\ \ 5\ \ \text{"MuPAD"})$$

You can access array entries via indexed calls. Since the entry `A[2]` is not initialized, the symbolic expression `A[2]` is returned:

```
A[2], A[3], A[4]
```

$$A_2,\ 5,\ \text{"MuPAD"}$$

We can initialize an array already when creating it by passing initialization equations to `array`:

```
A := array(2..4, 3 = 5, 4 = "MuPAD")
```

$$(\text{NIL}\ \ 5\ \ \text{"MuPAD"})$$

We can initialize all entries of an array when creating it by passing a list of initial values to `array`:

```
array(2..4, [PI, 5, "MuPAD"])
```

$$(\pi\ \ 5\ \ \text{"MuPAD"})$$

Hardware float arrays do not have uninitialized entries. If no initialization value is given, the corrsponding entry is set to 0.0:

```
hfarray(-1..5)
```

$$(0.0\ \ 0.0\ \ 0.0\ \ 0.0\ \ 0.0\ \ 0.0\ \ 0.0)$$

```
hfarray(-1..5, 2 = PI, 4 = sqrt(2)*exp(2))
```

$$(0.0\ \ 0.0\ \ 0.0\ \ 3.141592654\ \ 0.0\ \ 10.44970335\ \ 0.0)$$

```
hfarray(-1..5, [frandom() $ i = -1..5])
```

$$[[0.2703581656,\ 0.8310371787,\ 0.153156516,\ 0.9948127808,\ 0.2662729021,\ 0.1801642277,\ 0.452083055]]$$

```
hfarray(1..2, 1..3, [[1, 2, 3], [4, 5, 6]])
```

$$\begin{pmatrix} 1.0 & 2.0 & 3.0 \\ 4.0 & 5.0 & 6.0 \end{pmatrix}$$

```
hfarray(1..2, 1..3, [1, 2, 3, 4, 5, 6])
```

$$\begin{pmatrix} 1.0 & 2.0 & 3.0 \\ 4.0 & 5.0 & 6.0 \end{pmatrix}$$

Example 2

Array boundaries may be negative integers as well:

```
A := array(-1..1, [2, sin(x), FAIL])
```

$$\begin{pmatrix} 2 & \sin(x) & \text{FAIL} \end{pmatrix}$$

```
A[-1], A[0], A[1]
```

$$2,\ \sin(x),\ \text{FAIL}$$

```
A := hfarray(-1..2, -3..-1, [[-1, -1, -1],
                             [ 0,  0,  0],
                             [ 1,  1,  1],
                             [ 2,  2,  2]])
```

$$\begin{pmatrix} -1.0 & -1.0 & -1.0 \\ 0.0 & 0.0 & 0.0 \\ 1.0 & 1.0 & 1.0 \\ 2.0 & 2.0 & 2.0 \end{pmatrix}$$

```
A[-1, -2], A[0, -3], A[2, -3]
```

$$-1.0,\ 0.0,\ 2.0$$

```
delete A:
```

Example 3

If the dimension and size of the `array` or `hfarray` are not specified explicitly then both values are taken from the given list:

```
hfarray([1.0,2.0,3.0,4.0,5.0]) = hfarray(1..5, [1.0,2.0,3.0,4.0,5.0]);
bool(%)
```

$$(1.0\ 2.0\ 3.0\ 4.0\ 5.0) = (1.0\ 2.0\ 3.0\ 4.0\ 5.0)$$

TRUE

```
array([[1,2],[3,4],[5,6]]) = array(1..3, 1..2, [[1,2],[3,4],[5,6]]);
bool(%)
```

$$\begin{pmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{pmatrix} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{pmatrix}$$

TRUE

Note that all subfields of one dimension must have the same size and dimension. Therefore, the following input leads to an error:

```
array([[1],[3,4],[5,6]])
```

```
Error: The argument is invalid. [array]
```

Example 4

The $ operator may be used to create a sequence of initialization equations:

```
array(1..8, i = i^2 $ i = 1..8)
```

$$(1\ 4\ 9\ 16\ 25\ 36\ 49\ 64)$$

```
hfarray(1..4, 1..4, (i, i) = 1 $ i = 1..4)
```

$$\begin{pmatrix} 1.0 & 0.0 & 0.0 & 0.0 \\ 0.0 & 1.0 & 0.0 & 0.0 \\ 0.0 & 0.0 & 1.0 & 0.0 \\ 0.0 & 0.0 & 0.0 & 1.0 \end{pmatrix}$$

Equivalently, you can use the $ operator to create an initialization list:

```
array(1..8, [i^2 $ i = 1..8])
```

```
( 1  4  9  16  25  36  49  64 )
```

```
hfarray(1..8, [i*PI $ i = 1..8])
```

```
[[3.141592654, 6.283185307, 9.424777961, 12.56637061, 15.70796327, 18.84955592,
  21.99114858, 25.13274123]]
```

Example 5

We create a 2×2 matrix as a 2-dimensional array:

```
A := array(1..2, 1..2, (1, 2) = 42, (2, 1) = 1 + I)
```

$$\begin{pmatrix} \text{NIL} & 42 \\ 1+i & \text{NIL} \end{pmatrix}$$

Internally, array entries are stored in a linearized form. They can be accessed in this form via `op`. Uninitialized entries internally have the value `NIL`:

```
op(A, 1), op(A, 2), op(A, 3), op(A, 4)
```

$$\text{NIL},\ 42,\ 1+i,\ \text{NIL}$$

Note the difference to the indexed access:

```
A[1, 1], A[1, 2], A[2, 1], A[2, 2]
```

$$A_{1,1},\ 42,\ 1+i,\ A_{2,2}$$

We can modify an array entry by an indexed assignment:

```
A[1, 1] := 0: A[1, 2] := 5:
A
```

$$\begin{pmatrix} 0 & 5 \\ 1+i & \text{NIL} \end{pmatrix}$$

You can delete the value of an array entry via `delete`. Afterwards, it is uninitialized again:

```
delete A[2, 1]: A[2, 1], op(A, 3)
```

$$A_{2,1}, \text{NIL}$$

Assigning `NIL` to an array entry has the same effect as deleting it:

```
A[1, 2] := NIL: A[1, 2], op(A, 2)
```

$$A_{1,2}, \text{NIL}$$

Apart from initialization and deleting entries via `NIL` assignments, hfarrays behave similarly:

```
A := hfarray(1..2, 1..2, (1, 1) = 1.0, (2, 2) = 1.0)
```

$$\begin{pmatrix} 1.0 & 0.0 \\ 0.0 & 1.0 \end{pmatrix}$$

```
op(A, 1), op(A, 2), op(A, 3), op(A, 4)
```

1.0, 0.0, 0.0, 1.0

```
A[1, 1], A[1, 2], A[2, 1], A[2, 2]
```

1.0, 0.0, 0.0, 1.0

```
A[2, 2] := PI:
A[2, 2]
```

3.141592654

```
delete A[2, 2]:
```

```
Error: The argument is invalid. [delete]
```

```
A
```

$$\begin{pmatrix} 1.0 & 0.0 \\ 0.0 & 3.141592654 \end{pmatrix}$$

```
delete A:
```

Example 6

We define a three-dimensional array with index values between 1 and 8 in each of the three dimensions and initialize two of the entries via initialization equations:

```
A := array(1..8, 1..8, 1..8, (1, 1, 1) = 111, (8, 8, 8) = 888)
```

$$\begin{array}{l} \text{array}(1..8,\ 1..8,\ 1..8, \\ \quad (1,\ 1,\ 1) = \ 111 \\ \quad (8,\ 8,\ 8) = \ 888 \\ ) \end{array}$$

```
A[1, 1, 1], A[1, 1, 2]
```

$$111,\ A_{1,1,2}$$

We create a 3-dimensional hfarray:

```
A := hfarray(1..2, 2..3, 3..4, (1, 2, 3) = 123, (2, 3, 4) = 234)
```

```
hfarray(1..2, 2..3, 3..4, [123.0, 0.0, 0.0, 0.0, 0.0, 0.0, 0.0, 234.0])
```

```
delete A, B:
```

Example 7

A nested list may be used to initialize a 2-dimensional array. The inner lists are the rows of the created matrix:

```
array(1..2, 1..3, [[1, 2, 3], [4, 5, 6]])
```

$$\begin{pmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{pmatrix}$$

We create a three-dimensional array and initialize it from a nested list of depth three. The outer list has two entries for the first dimension. Each of these entries is a list with three entries for the second dimension. Finally, the innermost lists each have one entry for the third dimension:

```
array(2..3, 1..3, 1..1,
      [
        [ [1], [2], [3] ],
        [ [4], [5], [6] ]
      ])
```

```
array(2..3, 1..3, 1..1,
  (2, 1, 1) =  1
  (2, 2, 1) =  2
  (2, 3, 1) =  3
  (3, 1, 1) =  4
  (3, 2, 1) =  5
  (3, 3, 1) =  6
)
```

```
hfarray(2..3, 1..3, 1..1,
        [
          [ [1], [2], [3] ],
          [ [4], [5], [6] ]
        ])
```

```
hfarray(2..3, 1..3, 1..1, [1.0, 2.0, 3.0, 4.0, 5.0, 6.0])
```

Example 8

Basic arithmetic is available for arrays of domain type DOM_HFARRAY:

```
A := hfarray(1..5, [1, 2, 3, 4, 5]):
B := hfarray(1..5, [5, 4, 3, 2, 1]):
A + B
```

$$(\,6.0\ \ 6.0\ \ 6.0\ \ 6.0\ \ 6.0\,)$$

```
2*A
```

$$(\,2.0\ \ 4.0\ \ 6.0\ \ 8.0\ \ 10.0\,)$$

```
2*A - 3* B
```

$$(\,-13.0\ \ -8.0\ \ -3.0\ \ 2.0\ \ 7.0\,)$$

2-dimensional arrays of type `DOM_ARRAY` are regarded as matrices. They can be multiplied accordingly:

```
A := hfarray(1..3, 1..3, [frandom() $ i = 1..9]):
B := hfarray(1..3, 1..2, [frandom() $ i = 1..6]):
A, B, A * B, A^10 * B
```

$$\begin{pmatrix} 0.6787819563 & 0.3549849261 & 0.6818588132 \\ 0.7219186551 & 0.4738297742 & 0.7889814922 \\ 0.2115258358 & 0.8556871754 & 0.04489739417 \end{pmatrix}, \begin{pmatrix} 0.8791601269 & 0.9193848479 \\ 0.7350574234 & 0.7875450269 \\ 0.9371484273 & 0.2953238727 \end{pmatrix},$$

$$\begin{pmatrix} 1.49669525 & 1.104997644 \\ 1.722366954 & 1.269888425 \\ 0.8570198134 & 0.8816251003 \end{pmatrix}, \begin{pmatrix} 104.6209923 & 83.25909538 \\ 121.6963323 & 96.84792749 \\ 80.3865413 & 63.97259571 \end{pmatrix}$$

The following command computes the matrix inverse of `A`:

```
1/A
```

$$\begin{pmatrix} 15.13041048 & -13.13273828 & 0.9952407788 \\ -3.111891486 & 2.632361162 & 1.001982382 \\ -11.97546309 & 11.70303455 & -1.512395388 \end{pmatrix}$$

Some functions such as `norm` act on hfarrays:

```
norm(A)
```

$$1.984729921$$

Example 9

If an array is evaluated, it is only returned. The evaluation does not map recursively on the array entries. Here, the entries `a` and `b` are not evaluated:

```
A := array(1..2, [a, b]):
a := 1:  b := 2:
A, eval(A)
```

$$(a\ b), (a\ b)$$

Due to the special evaluation of arrays the index operator evaluates array entries after extracting them from the array:

```
A[1], A[2]
```

$$1, 2$$

You have to `map` the function `eval` explicitly on the array in order to fully evaluate its entries:

```
map(A, eval)
```

$$(1\ 2)$$

Parameters

m_1, n_1, m_2, n_2, …

The index boundaries: integers

$index_1$, $index_2$, …

A sequence of integers defining a valid array index

$number_1$, $number_2$, …

Real or complex floating-point numbers or numerical expressions that can be converted to real or complex floating-point numbers

`List`

A plain list of entries for initializing the array

`ListOfLists`

A nested list (of lists of lists of …) of entries for initializing the array

Return Values

Object of type DOM_ARRAY or DOM_HFARRAY, respectively.

assert

Assertions for debugging

Syntax

```
assert(cond)
```

Description

The statement `assert(cond)` declares that the condition `cond` holds true at the moment when the statement is evaluated. By default, MuPAD does not care about assertions. After setting `testargs(TRUE)`, however, MuPAD checks every assertion and stops with an error if boolean evaluation of `cond` does not give `TRUE`.

Assertions are a major debugging tool for programmers: by stating frequently what they think to have achieved, programmers make it easy for themselves to detect the first unintended intermediate result.

Examples

Example 1

Suppose we want to write a function `f` that takes an integer as its argument and returns 0 if that integer is a multiple of 3, and 1 otherwise. One idea how to code this could be the following: given an integer n, n modulo 3 must be equal to one of - 1, 1, or 0. In any case, `abs(n mod 3)` should do what we want:

```
f := proc(n: DOM_INT): DOM_INT
local k: DOM_INT;
begin
  k := n mod 3;
  assert(k = 1 or k = -1 or k = 0);
  abs(k)
end_proc
```

```
proc f(n) ... end
```

Checking assertions is switched on or off using `testargs`:

```
oldtestargs := testargs(): testargs(FALSE): f(5)
```

$$2$$

The result does not equal 1. For debugging purposes, we switch on assertion checking:

```
testargs(TRUE): f(5)
```

```
Error: Assertion 'k = 1 or k = -1 or k = 0' has failed. [f]
```

This shows that the local variable `k` must have gotten a wrong value. Indeed, when writing our program we overlooked the difference between `mod` and the symmetric remainder given by `mods`.

```
testargs(oldtestargs):
```

Parameters

cond

A boolean expression

Return Values

`assert` returns `TRUE` or raises an error.

See Also

MuPAD Functions

`testargs`

assign

Perform assignments given as equations

Syntax

```
assign(L)
```

```
assign(L, S)
```

Description

For each equation in a list, a set, or a table of equations `L`, `assign(L)` evaluates both sides of the equation and assigns the evaluated right hand side to the evaluated left hand side.

`assign(L, S)` does the same, but only for those equations whose left hand side is in the set `S`.

Since the arguments of `assign` are evaluated, the *evaluation* of the left hand side of each equation in `L` must be an admissible left hand side for an assignment. See the help page of the assignment operator `:=` for details.

Several assignments are performed from left to right. See “Example 4” on page 1-276.

`assign` can be conveniently used after a call to `solve` to assign a particular solution of a system of equations to the unknowns. See “Example 5” on page 1-276.

Examples

Example 1

We assign values to the three identifiers `B1,B2,B3`:

```
delete B1, B2, B3:
assign([B1 = 42, B2 = 13, B3 = 666]): B1, B2, B3
```

$$42,\ 13,\ 666$$

We specify a second argument to carry out only those assignments with left hand side `B1`:

```
delete B1, B2, B3:
assign([B1 = 42, B2 = 13, B3 = 666], {B1}): B1, B2, B3
```

$$42,\ B2,\ B3$$

The first argument may also be a table of equations:

```
delete B1, B2, B3:
assign(table(B1 = 42, B2 = 13, B3 = 666)): B1, B2, B3
```

$$42,\ 13,\ 666$$

Example 2

Unlike `_assign`, `assign` evaluates the left hand sides:

```
delete a, b: a := b: assign({a = 3}): a, b
```

$$3,\ 3$$

```
delete a, b: a := b: a := 3: a, b
```

$$3,\ b$$

Example 3

The object assigned may also be a sequence:

```
assign([X=(2,7)])
```

$$[X = (2,\ 7)]$$

```
X
```

$$2, 7$$

Example 4

The assignments are carried out one after another, from left to right. Since the right hand side is evaluated, the identifier `C` gets the value `3` in the following example:

```
assign([B=3, C=B])
```

$$[B = 3, C = B]$$

```
level(C,1)
```

$$3$$

Example 5

When called for an algebraic system, `solve` often returns a set of lists of assignments. `assign` can then be used to assign the solutions to the variables of the system:

```
sys:={x^2+y^2=2, x+y=5}:
S:= solve(sys)
```

$$\left\{\left[x = \frac{5}{2} - \frac{\sqrt{21}\,i}{2}, y = \frac{5}{2} + \frac{\sqrt{21}\,i}{2}\right], \left[x = \frac{5}{2} + \frac{\sqrt{21}\,i}{2}, y = \frac{5}{2} - \frac{\sqrt{21}\,i}{2}\right]\right\}$$

We want to check whether the first solution is really a solution:

```
assign(S[1]): sys
```

$$\left\{5 = 5, \left(-\frac{5}{2} + \frac{\sqrt{21}\,i}{2}\right)^2 + \left(\frac{5}{2} + \frac{\sqrt{21}\,i}{2}\right)^2 = 2\right\}$$

Things become clearer if we use floating-point evaluation:

```
float(sys)
```

$$\{2.0 = 2.0,\ 5.0 = 5.0\}$$

Parameters

L

A list, a set, or a table of equations

S

A set

Return Values

L.

See Also

MuPAD Functions

`:=` | `_assign` | `assignElements` | `delete` | `evalassign`

assignElements

Assign values to entries of an array, a list, or a table

Syntax

```
assignElements(L, [index1] = value1, [index2] = value2, …)

assignElements(L, [[index1], value1], [[index2], value2], …)
```

Description

`assignElements(L, [index1] = value1, [index2] = value2, ...)` returns a copy of `L` with `value1` stored at `index1`, `value2` stored at `index2`, etc.

`R:= assignElements(L,[index1]=value1,[index2]=value2,...)` has the same effect as the sequence of assignments `R:=L: R[index1]:=value1: R[index2]:=value2: ... R`, but is more efficient.

`assignElements` returns a modified copy of its first argument, which remains unchanged. See “Example 1” on page 1-279.

The second variant of the `assignElements` call, with lists instead of equations, is equivalent to the first variant. In fact, both equations and lists may be mixed in a single call. See “Example 1” on page 1-279.

All assignments are performed simultaneously, i.e., the order of the arguments is irrelevant. See “Example 3” on page 1-280.

All rules for indexed assignments apply, in particular with respect to the validity of indices. If `L` is a list, the indices must be positive integers not exceeding the length of `L`. If `L` is an array, the indices must be (sequences of) integers matching the dimension and lying within the valid ranges of the array. If `L` is a table, the indices may be arbitrary objects.

Examples

Example 1

Assignments may given as equations or lists, and both forms may be mixed in a single call:

```
L := array(1..3, [3, 4, 5]);
assignElements(L, [1] = one, [2] = two, [3] = three);
assignElements(L, [[1], one], [[2], two], [[3], three]);
assignElements(L, [1] = one, [[2], two], [3] = three);
```

$$(3\ 4\ 5)$$

$$(\text{one}\ \text{two}\ \text{three})$$

$$(\text{one}\ \text{two}\ \text{three})$$

$$(\text{one}\ \text{two}\ \text{three})$$

The array `L` itself is not modified by `assignElements`:

```
L
```

$$(3\ 4\ 5)$$

Example 2

Sequences, too, may be assigned as values to array elements, but they must be put in parentheses:

```
R := assignElements(array(1..2), [1] = (1, 7), [2] = PI);
[R[1]], [R[2]]
```

$$((1, 7)\ \pi)$$

$[1, 7], [\pi]$

Example 3

The sequence generator $ is useful to create sequences of assignments:

```
L := [i $ i = 1..10];
assignElements(L, [i] = L[i] + L[i + 1] $ i = 1..9)
```

$[1, 2, 3, 4, 5, 6, 7, 8, 9, 10]$

$[3, 5, 7, 9, 11, 13, 15, 17, 19, 10]$

The order of the arguments is irrelevant:

```
assignElements(L, [10 - i] = L[10 - i] + L[11 - i] $ i = 1..9)
```

$[3, 5, 7, 9, 11, 13, 15, 17, 19, 10]$

Example 4

The indices of a table may be arbitrary objects, for example, strings:

```
assignElements(table(), [expr2text(i)] = i^2 $ i = 1..4)
```

"1"	1
"2"	4
"3"	9
"4"	16

Example 5

For arrays of dimension greater than one, the indices are sequences of as many integers as determined by the dimension of the array:

```
assignElements(array(1..3, 1..3),
  ([i, j] = i + j $ i = 1..3) $ j = 1..3)
```

$$\begin{pmatrix} 2 & 3 & 4 \\ 3 & 4 & 5 \\ 4 & 5 & 6 \end{pmatrix}$$

Parameters

`L`

An array, an hfarray, a list, or a table

`index1, index2, …`

Valid indices for `L`

`value1, value2, …`

Any MuPAD objects

Return Values

Object of the same type as `L`.

assume

Set permanent assumption

Syntax

```
assume(condition)
```

```
assume(expr, set)
```

Description

`assume(condition)` sets the assumption that condition `condition` is true for all further calculations. This call removes all previous assumptions containing identifiers used in `condition`.

`assume(expr, set)` attaches the property `set` to the identifier or expression `expr`. This call overwrites all previous assumptions containing identifiers used in `expr`.

Assumptions are mathematical conditions that are assumed to hold true for all calculations. By default, all MuPAD identifiers are independent of each other and can take any value in the complex plane. For example, `sign(1 + x^2)` cannot be simplified any more because MuPAD assumes that `x` is a complex number. If you set an assumption that `x` is a real number, then MuPAD can simplify `sign(1 + x^2)` to `1`.

For this reason, many MuPAD functions return very general or piecewise-defined results that depend on further conditions. For example, `solve` or `int` can return `piecewise` results.

Many mathematical theorems hold only under certain conditions. For example, `x^b*y^b = (x*y)^b` holds if `b` is an integer. But this equation is not true for all combinations of `x`, `y`, and `b`. For example, it is not true if `x = y = -1, b = 1/2`. In such cases, you can use assumptions to get more specific results.

If you use `assume` inside a function or procedure, MuPAD uses the new assumption and ignores existing assumptions only inside the function or procedure. After the function or procedure call, MuPAD removes the new assumption and restores the assumptions that were set before the function or procedure call.

If `condition` is a relation (for example, `x < y`), then MuPAD implicitly assumes that both sides of the relation are real. See “Example 4” on page 1-285.

To delete assumptions previously set on `x`, use `unassume(x)` or `delete x`.

When you assign a value to an identifier with assumptions, the assigned value can be inconsistent with existing assumptions. Assignments overwrite all assumptions previously set on an identifier. See “Example 5” on page 1-286.

`assume` accepts any `condition` and Boolean combinations of `conditions`. See “Example 7” on page 1-288.

If `expr` is a list, vector, or matrix, use the syntax `assume(expr, set)`. Here `set` must be specified as one of `C_`, `R_`, `Q_`, `Z_`, `N_`, or an expression constructed with the set operations, such as `union`, `intersect`, or `minus`. `set` also can be a function of the `Type` library, for example, `Type::Real`, `Type::Integer`, `Type::PosInt`, and so on.

Do not use the syntaxes `assume(expr in set)` and `assume(condition)` for nonscalar `expr`.

Examples

Example 1

Set an assumption that identifier `n` is an integer. Here, `assume(n, Type::Integer)` is equivalent to `assume(n in Z_)` because `n` is a scalar.

```
assume(n, Type::Integer):
assume(n in Z_):
getprop(n);
```

$$\mathbb{Z}$$

Check if `n^2` is a nonnegative integer. MuPAD uses the assumption that you set on `n`.

```
is(n^2, Type::NonNegInt)
```

$$\text{TRUE}$$

Other system functions take this assumption into account:

```
abs(n^2 + 1);
simplify(sin(2*n*PI))
```

$$n^2 + 1$$

$$0$$

For further computations, delete the identifier `n`:

```
delete n
```

Example 2

To keep the existing assumptions and combine them with the new ones, use `assumeAlso`:

```
assume(n, Type::Integer):
getprop(n);
```

$$\mathbb{Z}$$

```
assumeAlso(n, Type::Positive):
getprop(n);
```

$$\mathbb{Z} \cap [1, \infty)$$

For further computations, delete the identifier `n`:

```
delete n
```

Alternatively, set multiple assumptions in one function call:

```
assume(n, Type::Integer and Type::Positive):
getprop(n);
```

$$\mathbb{Z} \cap [1, \infty)$$

For further computations, delete the identifier `n`:

```
delete n
```

Example 3

You can set separate assumptions on the real and imaginary parts of an identifier:

```
assume(Re(z) > 0);
assumeAlso(Im(z) < 0):

abs(Re(z));
sign(Im(z))
```

$$\Re(z)$$

$$-1$$

```
is(z, Type::Real), is(z > 0)
```

FALSE, FALSE

For further computations, delete the identifier `z`:

```
delete z
```

Example 4

Using `assume`, set the assumption `x > y`. Assumptions set as relations affect the properties of both identifiers.

```
assume(x > y)
```

To see the assumptions set on identifiers, use `getprop`:

```
getprop(x);
getprop(y);
```

$$(y, \infty)$$

$$(-\infty, x)$$

To keep an existing assumption on `y` and add a new one, use `assumeAlso`. For example, add the new assumption that `y` is greater than `0` while keeping the assumption that `y` is less than `x`:

```
assumeAlso(y > 0)
```

```
is(x^2 >= y^2)
```

$$\text{TRUE}$$

Relations, such as `x > y`, imply that the involved identifiers are real:

```
is(x, Type::Real), is(y, Type::Real)
```

$$\text{TRUE}, \text{TRUE}$$

You also can set a relational assumption where one side is not an identifier, but an expression:

```
assume(x > 1/y)
```

```
getprop(x);
getprop(y)
```

$$\left(\frac{1}{y}, \infty\right)$$

$$\mathbb{R}$$

For further computations, delete the identifiers `x` and `y`:

```
delete x, y
```

Example 5

`_assign` and `:=` do not check if an identifier has any assumptions. The assignment operation overwrites all assumptions:

```
assume(a > 0):
a := -2:
a, getprop(a)
```

$$-2,\ \{-2\}$$

For further computations, delete the identifier `a`:

```
delete a
```

Example 6

Set the assumption that x is positive and find the absolute value of `x`, the sign of `x`, and the real and imaginary parts of `x`. These system functions take assumptions set on identifiers into account:

```
assume(x > 0):
abs(x), sign(x), Re(x), Im(x)
```

$$x,\ 1,\ x,\ 0$$

Try expanding the expression `ln(z1*z2)` without additional assumptions. It does not expand because `ln(z1*z2) = ln(z1) + ln(z2)` is not true for arbitrary `z1`, `z2` in the complex plane:

```
expand(ln(z1*z2))
```

$$\ln(z1\ z2)$$

Now, set the assumption that one number is real and positive. Expand the same expression:

```
assume(z1 > 0): expand(ln(z1*z2))
```

$$\ln(z1) + \ln(z2)$$

For further computations, remove the assumptions on `x` and `z1`:

```
unassume(x); unassume(z1)
```

Example 7

Set these two assumptions on the identifier `a`. To combine the assumptions, use the Boolean operator `and`:

```
assume(a > 0 and a in Z_):
is(a = 0);
is(a = 1/2);
is(a = 2);
```

```
FALSE

FALSE

UNKNOWN
```

Parameters

`expr`

Identifier, mathematical expression, list, vector, or matrix containing identifiers.

If `expr` is a list, vector, or matrix, then only the syntax `assume(expr, set)` is valid.

`set`

Property representing a set of numbers or a set returned by `solve`.

For example, this set can be an element of `Dom::Interval`, `Dom::ImageSet`, `piecewise`, or one of `C_`, `R_`, `Q_`, `Z_`, `N_`. It also can be an expression constructed with the set operations, such as `union`,, `intersect` or `minus`. For more examples, see "Properties".

`condition`

Equality, inequality, element of relation, or Boolean combination (with the operators `and` or `or`).

Return Values

Void object `null()` of type `DOM_NULL`.

See Also

MuPAD Functions

`assumeAlso` | `assuming` | `assumingAlso` | `getprop` | `is` | `property::hasprop` | `property::showprops` | `unassume`

assumeAlso

Add permanent assumption

Syntax

```
assumeAlso(condition)
```

```
assumeAlso(expr, set)
```

Description

`assumeAlso(condition)` adds the assumption that `condition` is true for all further calculations. It does not remove previous assumptions containing identifiers used in `condition`.

`assumeAlso(expr, set)` attaches the property `set` to the identifier or expression `x`. It does not remove previous assumptions containing identifiers used in `expr`.

Assumptions are mathematical conditions that are assumed to hold true for all calculations. By default, all MuPAD identifiers are independent of each other and can take any value in the complex plane. For example, `sign(1 + x^2)` cannot be simplified any more because `x` MuPAD assumes that `x` is a complex number. If you set an assumption that `x` is a real number, then MuPAD can simplify `sign(1 + x^2)` to `1`.

For this reason, many MuPAD functions return very general or piecewise-defined results depending on further conditions. For example, `solve` or `int` can return `piecewise` results.

Many mathematical theorems hold only under certain conditions. For example, `x^b*y^b=(x*y)^b` holds if `b` is an integer. But this equation is not true for all combinations of `x`, `y`, and `b`. For example, it is not true if `x = y = -1, b = 1/2`. In such cases, you can use assumptions to get more specific results.

If you use `assumeAlso` inside a function or procedure, MuPAD uses that assumption only inside the function or procedure. After the function or procedure call, MuPAD removes that assumption and only keeps the assumptions that were set before the function or procedure call.

If `condition` is a relation (for example, `x < y`), then MuPAD implicitly assumes that both sides of the relation are real. See “Example 4” on page 1-293.

To delete assumptions previously set on `x`, use `unassume(x)` or `delete x`.

When assigning a value to an identifier with assumptions, the assigned value can be inconsistent with existing assumptions. Assignments overwrite all assumptions previously set on an identifier. See “Example 5” on page 1-295.

`assumeAlso` accepts any `condition` and Boolean combinations of `condition`s. See “Example 7” on page 1-295.

If `expr` is a list, vector, or matrix, use the syntax `assumeAlso(expr, set)`. Here, `set` must be specified as one of `C_`, `R_`, `Q_`, `Z_`, `N_`, or an expression constructed with the set operations, such as `union`, `intersect`, or `minus`. `set` also can be a function of the `Type` library, for example, `Type::Real`, `Type::Integer`, `Type::PosInt`, and so on.

Do not use the syntaxes `assumeAlso(expr in set)` and `assumeAlso(condition)` for nonscalar `expr`.

Examples

Example 1

Solve this equation without any assumptions on the variable `x`:

```
solve(x^5 - x, x)
```

$$\{-1, 0, 1, -i, i\}$$

Suppose, your computations deal with real numbers only. In this case, use the `assume` function to set the permanent assumption that `x` is real:

```
assume(x in R_)
```

If you solve the same equation now, you will get three real solutions:

```
solve(x^5 - x, x)
```

$$\{-1, 0, 1\}$$

If you also want to get only nonzero solutions, use `assumeAlso` to add the corresponding assumption:

```
assumeAlso(x <> 0);
solve(x^5 - x, x)
```

$$\{-1, 1\}$$

MuPAD keeps both assumptions for further computations:

```
getprop(x)
```

$$\mathbb{R} \setminus \{0\}$$

For further computations, delete the identifier `x`:

```
delete x
```

Example 2

When you use `assumeAlso`, MuPAD does not remove existing assumptions. Instead, it combines them with new assumptions. For example, assume that `n` is an integer:

```
assume(n, Type::Integer):
getprop(n);
```

$$\mathbb{Z}$$

Add the assumption that `n` is positive:

```
assumeAlso(n, Type::Positive):
getprop(n);
```

$$\mathbb{Z} \cap [1, \infty)$$

For further computations, delete the identifier `n`:

```
delete n
```

Alternatively, set multiple assumptions in one function call using the Boolean operator `and`:

```
assume(n, Type::Integer and Type::Positive):
getprop(n);
```

$$\mathbb{Z} \cap [1, \infty)$$

For further computations, delete the identifier `n`:

```
delete n
```

Example 3

You can set separate assumptions on the real and imaginary parts of an identifier:

```
assume(Re(z) > 0);
assumeAlso(Im(z) < 0):

abs(Re(z));
sign(Im(z))
```

$$\Re(z)$$

$$-1$$

For further computations, delete the identifier `z`:

```
delete z
```

Example 4

Using `assume`, set the assumption `x > y`. Assumptions set as relations affect the properties of both identifiers.

```
assume(x > y)
```

To see the assumptions set on identifiers, use `getprop`:

```
getprop(x);
```

```
getprop(y);
```

$$(y, \infty)$$

$$(-\infty, x)$$

To keep an existing assumption on `y` and add a new one, use `assumeAlso`. For example, add the new assumption that `y` is greater than `0` while keeping the assumption that `y` is less than `x`:

```
assumeAlso(y > 0)
```

```
is(x^2 >= y^2)
```

TRUE

Relations, such as `x > y`, imply that the involved identifiers are real:

```
is(x, Type::Real), is(y, Type::Real)
```

TRUE, TRUE

```
delete x, y:
```

You also can add a relational assumption where one side is not an identifier, but an expression:

```
assumeAlso(x > 1/y)
```

```
getprop(x);
getprop(y)
```

$$\left(\frac{1}{y}, \infty\right)$$

$$\mathbb{R}$$

For further computations, delete the identifiers `x` and `y`:

```
delete x, y
```

Example 5

_assign and := do not check if an identifier has any assumptions. The assignment operation overwrites all assumptions:

```
assume(a > 0):
a := -2:
a, getprop(a)
```

$$-2, \{-2\}$$

For further computations, delete the identifier a:

```
delete a
```

Example 7

Use assume to set the assumption that the identifier a is positive:

```
assume(a > 0)
```

Now, add two new assumptions using one call to assumeAlso. To combine the assumptions, use the Boolean operator and:

```
assumeAlso(a in Z_ and a < 5):
is(a = 0);
is(a = 1/2);
is(a = 2);
is(a = 6);
```

FALSE

FALSE

UNKNOWN

FALSE

Parameters

expr

Identifier, mathematical expression, list, vector, or matrix containing identifiers.

If `expr` is a list, vector, or matrix, then only the syntax `assumeAlso(expr, set)` is valid.

set

Property representing a set of numbers or a set returned by `solve`. This set can be an element of `Dom::Interval`, `Dom::ImageSet`, `piecewise`, or one of `C_`, `R_`, `Q_`, `Z_`, `N_`. It also can be an expression constructed with the set operations, such as `union`, `intersect` or `minus`. For more examples, see "Properties".

condition

Equality, inequality, element of relation, or Boolean combination (with the operators `and` or `or`).

Return Values

Void object `null()` of type `DOM_NULL`.

See Also

MuPAD Functions

`assume` | `assuming` | `assumingAlso` | `getprop` | `is` | `property::hasprop` | `property::showprops` | `unassume`

assuming, _assuming

Set temporary assumption

Syntax

```
calculation assuming condition
```

```
calculation assuming (expr, set)
```

```
_assuming(calculation, condition)
```

```
_assuming(calculation, (expr, set))
```

Description

`calculation assuming condition` evaluates `calculation` under the assumption that `condition` is true for that calculation.

`calculation assuming(expr, set)` temporarily attaches the property `set` to the identifier or expression `expr` and evaluates `calculation`. This call ignores all previous assumptions containing identifiers used in `expr`.

`calculation assuming condition` is equivalent to `_assuming(calculation, condition)`.

`calculation assuming (expr, set)` is equivalent to `_assuming(calculation, (expr, set))`.

`assuming` sets temporary assumptions. Temporary assumptions hold true only while the argument `calculation` is evaluated. After this evaluation, MuPAD removes these assumptions. Therefore, they do not affect further computations. MuPAD also removes temporary assumptions if the evaluation stops with an error.

`assuming` temporarily overwrites existing assumptions. If you have permanent assumptions, MuPAD ignores them while evaluating `calculation`. Instead, it uses temporary assumptions set by `assumimg`.

If assumptions contain linear equations with one variable, `assuming` solves these equations. Then the command inserts the solutions into `calculation` and evaluates the result. See “Example 6” on page 1-300.

If `expr` is a list, vector, or matrix, use the syntaxes `calculation assuming(expr, set)` and `_assuming(calculation, (expr, set))`. Here, `set` is specified as one of `C_`, `R_`, `Q_`, `Z_`, `N_`, or an expression constructed with the set operations, such as `union`, `intersect`, or `minus`. `set` also can be a function of the `Type` library, for example, `Type::Real`, `Type::Integer`, `Type::PosInt`, and so on.

Do not use the syntaxes `calculation assuming (expr in set)` (or its equivalent `_assuming(calculation, expr in set)`) and `calculation assuming condition` (or its equivalent `_assuming(calculation, condition)`) for nonscalar `expr`.

Examples

Example 1

Find the sign of the expression `x^2 + 1` assuming that the identifier `x` represents a real number:

```
sign(x^2+1) assuming (x, Type::Real)
```

```
    1
```

Example 2

Simplify this sine function assuming that `n` is an integer:

```
simplify(sin(n*PI)) assuming n in Z_
```

```
    0
```

Example 3

Additional assumptions let you simplify some expressions. For example, compute the right limit of x^p:

```
limit(x^p, x = 0, Right)
```

$$\begin{cases} 1 & \text{if } p = 0 \\ \infty & \text{if } p < 0 \\ 0 & \text{if } 0 < \Re(p) \\ \lim_{x \to 0^+} x^p & \text{if } \Re(p) < 0 \wedge \neg\, p \le 0 \end{cases}$$

Compute the right limit of the same expression for negative, positive, and zero values of p:

```
limit(x^p, x = 0, Right) assuming p < 0
```

$$\infty$$

```
limit(x^p, x = 0, Right) assuming p > 0
```

$$0$$

```
limit(x^p, x = 0, Right) assuming p = 0
```

$$1$$

Example 4

Assumptions set by `assuming` are temporary. They do not affect any previous or future computations:

```
getprop(a);
getprop(a) assuming a > 0;
getprop(a)
```

$$\mathbb{C}$$

$$(0, \infty)$$

$$\mathbb{C}$$

Example 5

If you already use a permanent assumption and want to add a temporary assumption on the same object, do not use `assuming`. It temporarily overwrites the permanent assumption:

```
assume(x in Z_):
solve(x^3 - (44*x^2)/3 + (148*x)/3 - 80/3 = 0, x) assuming x < 5
```

$$\left\{\frac{2}{3}, 4\right\}$$

Instead, use `assumingAlso`:

```
solve(x^3 - (44*x^2)/3 + (148*x)/3 - 80/3 = 0, x) assumingAlso x < 5
```

$$\{4\}$$

Example 6

If assumptions contain linear equations with one variable, `assuming` solves the equations, inserts the solutions into the expression, and then evaluates the expression:

```
a^2 + 1 assuming a - 2 = 1;
```

$$10$$

`assume` and `assumeAlso` do not solve equations:

```
assume(a - 2 = 1) ;
a^2 + 1
```

$$a^2 + 1$$

Parameters

`calculation`

Any MuPAD command or expression that you want to evaluate under the temporary assumption.

`condition`

Equality, inequality, element of relation, or Boolean combination (with the operators `and` or `or`).

`expr`

Identifier, mathematical expression, list, vector, or matrix containing identifiers.

If `expr` is a list, vector, or matrix, then only the syntaxes `calculation assuming(expr, set)` and `_assuming(calculation, (expr, set))` are valid.

`set`

Property representing a set of numbers or a set returned by `solve`.

For example, this set can be an element of `Dom::Interval`, `Dom::ImageSet`, `piecewise`, or one of `C_`, `R_`, `Q_`, `Z_`, `N_`. It also can be an expression constructed with the set operations, such as `union`, `intersect` or `minus`. For more examples, see "Properties".

Return Values

`assuming` returns the result of evaluating `calculation`.

See Also

MuPAD Functions

`assume` | `assumeAlso` | `assumingAlso` | `getprop` | `is` | `property::hasprop` | `property::showprops` | `unassume`

assumingAlso, _assumingAlso

Add temporary assumption

Syntax

```
calculation assumingAlso condition

calculation assumingAlso (expr, set)

_assumingAlso(calculation, condition)

_assumingAlso(calculation, (expr, set))
```

Description

`calculation assumingAlso condition` evaluates `calculation` under all existing assumptions along with the new assumption that `condition` is true for that calculation.

`calculation assumingAlso(expr, set)` temporarily attaches the property `set` to the identifier or expression `expr` and evaluates `calculation`. This call takes into account all previous assumptions containing identifiers used in `expr`.

`calculation assumingAlso condition` is equivalent to `_assumingAlso(calculation, condition)`.

`calculation assumingAlso (expr, set)` is equivalent to `_assumingAlso(calculation, (expr, set))`.

`assumingAlso` sets temporary assumptions in addition to existing permanent assumptions. Here, `condition` holds true only while the argument `calculation` is evaluated. After this evaluation, `condition` is removed. Therefore, it does not affect further computations. `condition` is also removed if the evaluation stops with an error.

If assumptions contain linear equations with one variable, `assumingAlso` solves these equations. Then the command inserts the solutions into `calculation` and evaluates the result. See “Example 3” on page 1-304.

If `expr` is a list, vector, or matrix, use the syntaxes `calculation assumingAlso(expr, set)` and `_assumingAlso(calculation, (expr, set))`.

Here, `set` is specified as one of `C_`, `R_`, `Q_`, `Z_`, `N_`, or an expression constructed with the set operations, such as `union`, `intersect`, or `minus`. `set` also can be a function of the `Type` library, for example, `Type::Real`, `Type::Integer`, `Type::PosInt`, and so on.

Do not use the syntaxes `calculation assumingAlso (expr in set)` (or its equivalent `_assumingAlso(calculation, expr in set)`) and `calculation assumingAlso condition` (or its equivalent `_assumingAlso(calculation, condition)`) for nonscalar `expr`.

Examples

Example 1

Solve this equation without any assumptions on the variable `x`:

```
solve(x^5 - x, x)
```

$$\{-1, 0, 1, -i, i\}$$

Suppose your computations deal with real numbers only. In this case, use the `assume` function to set the permanent assumption that `x` is real:

```
assume(x in R_)
```

If you solve the same equation now, you will get three real solutions:

```
solve(x^5 - x, x)
```

$$\{-1, 0, 1\}$$

To get only nonzero solutions for this particular equation, use `assumingAlso` to temporarily add the corresponding assumption:

```
solve(x^5 - x, x) assumingAlso x <> 0
```

$$\{-1, 1\}$$

After solving this equation, MuPAD discards the temporary assumption, but keeps the permanent one:

```
getprop(x)
```

$$\mathbb{R}$$

Example 2

If you already use a permanent assumption and want to add a temporary assumption on the same object, do not use `assuming`. It temporarily overwrites the permanent assumption:

```
assume(x in Z_):
solve(x^3 - (44*x^2)/3 + (148*x)/3 - 80/3 = 0, x) assuming x < 5
```

$$\left\{\frac{2}{3}, 4\right\}$$

Instead, use `assumingAlso`:

```
solve(x^3 - (44*x^2)/3 + (148*x)/3 - 80/3 = 0, x) assumingAlso x < 5
```

$$\{4\}$$

Example 3

If assumptions contain linear equations with one variable, `assumingAlso` solves the equations, inserts the solutions into the expression, and then evaluates the expression:

```
a^2 + 1 assumingAlso a - 2 = 1;
```

$$10$$

`assume` and `assumeAlso` do not solve equations:

```
assumeAlso(a - 2 = 1) ;
a^2 + 1
```

$$a^2 + 1$$

Parameters

`calculation`

Any MuPAD command or expression that you want to evaluate under the temporary assumption.

`condition`

Equality, inequality, element of relation, or Boolean combination (with the operators `and` or `or`).

`expr`

Identifier, mathematical expression, list, vector, or matrix containing identifiers.

If `expr` is a list, vector, or matrix, then only the syntaxes `calculation assumingAlso(expr, set)` and `_assumingAlso(calculation, (expr, set))` are valid.

`set`

Property representing a set of numbers or a set returned by `solve`. This set can be an element of `Dom::Interval`, `Dom::ImageSet`, `piecewise`, or one of `C_`, `R_`, `Q_`, `Z_`, `N_`. It also can be an expression constructed with the set operations, such as `union`, `intersect` or `minus`. For more examples, see "Properties".

Return Values

`assumingAlso` returns the result of evaluating `calculation`.

asympt

Compute an asymptotic series expansion

Syntax

```
asympt(f, x)

asympt(f, x, <order>, <dir>)

asympt(f, x = x0, <order>, <Left | Right>)
```

Description

`asympt(f, x)` computes the first terms of an asymptotic series expansion of `f` with respect to the variable `x` around the point `infinity`.

`asympt` is used to compute an asymptotic expansion of `f` when x tends to x_0. If such an expansion can be computed, a series object of domain type `Series::gseries` or `Series::Puiseux` is returned.

In contrast to the default behavior of `series`, `asympt` computes directed expansions that may be valid along the real line only.

`asympt` can compute more general types of asymptotic expansions than the related function `series`. Cf. “Example 5” on page 1-309.

If x_0 is a regular point of `f`, a pole, or an algebraic branch point, then `asympt` returns a Puiseux expansion. In this case it is recommended to use the faster function `series` instead.

If `asympt` cannot compute an asymptotic expansion, then a symbolic expression of type `"asympt"` is returned. Cf. “Example 4” on page 1-308.

The number of requested terms for the expansion is `order` if specified. Otherwise, the value of the environment variable `ORDER` is used. You can change the default value 6 by assigning a new value to `ORDER`.

The number of terms is counted from the lowest degree term on for finite expansion points, and from the highest degree term on for expansions around infinity, i.e., "`order`" has to be regarded as a "relative truncation order".

Note: The actual number of terms in the resulting series expansion may differ from the requested number of terms. See `series` for details.

The function `asympt` returns an object of domain type `Series::gseries` or `Series::Puiseux`. It can be manipulated via the standard arithmetic operations and various system functions. For example, `coeff` returns the coefficients; `expr` converts the series to an expression, removing the error term; `lmonomial` returns the leading monomial; `lterm` returns the leading term; `lcoeff` returns the leading coefficient; `map` applies a function to the coefficients; `nthcoeff` returns the n-th coefficient, `nthterm` the n-th term, and `nthmonomial` the n-th monomial.

Environment Interactions

The function is sensitive to the environment variable `ORDER`, which determines the default number of terms in series computations.

Examples

Example 1

We compute an asymptotic expansion for $x \to \infty$:

```
s := asympt(sin(1/x + exp(-x)) - sin(1/x), x)
```

$$e^{-x} - \frac{e^{-x}}{2\,x^2} + \frac{e^{-x}}{24\,x^4} - \frac{e^{-x}}{720\,x^6} + \frac{e^{-x}}{40320\,x^8} - \frac{e^{-x}}{3628800\,x^{10}} + O\left(\frac{e^{-x}}{x^{11}}\right)$$

The leading term and the third term are extracted:

```
lmonomial(s), nthterm(s, 3)
```

$$e^{-x}, \frac{e^{-x}}{x^4}$$

In the following call, only 2 terms of the expansion are requested:

```
asympt(
  exp(sin(1/x + exp(-exp(x)))) - exp(sin(1/x)), x, 2
)
```

$$e^{-e^x} + \frac{e^{-e^x}}{x} + O\left(\frac{e^{-e^x}}{x^2}\right)$$

```
delete s:
```

Example 2

We compute a expansion around a finite real point. By default, the expansion is valid "to the right" of the expansion point:

```
asympt(abs(x/(1+x)), x = 0)
```

$$x - x^2 + x^3 - x^4 + x^5 - x^6 + O(x^7)$$

A different expansion is valid "to the left" of the expansion point:

```
asympt(abs(x)/(1 + x), x = 0, Left)
```

$$-x + x^2 - x^3 + x^4 - x^5 + x^6 + O(-x^7)$$

Example 3

The following expansion is exact. Therefore, it has no "error term":

```
asympt(exp(x), x = infinity)
```

$$e^x$$

Example 4

Here is an example where `asympt` cannot compute an asymptotic series expansion:

```
asympt(cos(gamma(x*s))/s, x = infinity)
```

$$\text{asympt}\left(\frac{\cos(\Gamma(s\,x))}{s}, x = \infty\right)$$

Example 5

If we apply the function `series` to the following expression, it essentially returns the expression itself:

```
series((ln(ln(x)+ln(ln(x))) - ln(ln(x))) /
       ln(ln(x)+ln(ln(ln(x))))*ln(x), x = infinity)
```

$$\frac{\ln(x)\,(\ln(\ln(\ln(x))+\ln(x))-\ln(\ln(x)))}{\ln(\ln(\ln(\ln(x)))+\ln(x))}+O\left(\frac{1}{x^6}\right)$$

In this example, `asympt` computes a more detailed series expansion:

```
asympt((ln(ln(x)+ln(ln(x))) - ln(ln(x))) /
       ln(ln(x)+ln(ln(ln(x))))*ln(x), x = infinity)
```

$$1-\frac{\ln(\ln(x))}{2\ln(x)}-\frac{\sigma_1}{\ln(\ln(x))\ln(x)}+\frac{\sigma_2}{3\ln(x)^2}+\frac{\sigma_1}{2\ln(x)^2}+\frac{{\sigma_1}^2}{2\ln(\ln(x))\ln(x)^2}+O\left(\frac{1}{\sigma_2\ln(x)^2}\right)$$

where

$$\sigma_1 = \ln(\ln(\ln(x)))$$

$$\sigma_2 = \ln(\ln(x))^2$$

Parameters

`f`

An arithmetical expression representing a function in `x`

x

An identifier

x_0

The expansion point: an arithmetical expression; if not specified, the default expansion point `infinity` is used

order

The number of terms to be computed: a nonnegative integer; the default order is given by the environment variable `ORDER` (default value 6)

Options

Left, Right

With `Left`, the expansion is valid for real $x < x_0$; with `Right`, it is valid for $x > x_0$. For finite expansion points x_0, the default is `Right`.

Return Values

Object of domain type `Series::gseries` or `Series::Puiseux`, or an expression of type `"asympt"`.

Overloaded By

f

bernoulli

Bernoulli numbers and polynomials

Syntax

```
bernoulli(n)
```

```
bernoulli(n, x)
```

Description

`bernoulli(n)` returns the n-th Bernoulli number.

`bernoulli(n, x)` returns the n-th Bernoulli polynomial in x.

The Bernoulli polynomials are defined by the generating function

$$\frac{t\,e^{x\,t}}{e^t-1}=\sum_{n=0}^{\infty}\frac{\mathrm{bernoulli}(n,x)}{n!}\,t^n$$

.

The Bernoulli numbers are defined by `bernoulli(n)` = `bernoulli(n,0)`.

An error occurs if `n` is a numerical value not representing a nonnegative integer.

If `n` is an integer larger than the value returned by `Pref::autoExpansionLimit()`, then the call `bernoulli(n)` is returned symbolically. Use `expand(bernoulli(n))` to get an explicit numerical result for large integers `n`.

If `n` contains non-numerical symbolic identifiers, then the call `bernoulli(n)` is returned symbolically. In most cases, the same holds true for calls `bernoulli(n, x)`. Some simplifications are implemented for special numerical values such as `x = 0`, `x = 1/2`, `x = 1` etc. for symbolic `n` . Cf. “Example 3” on page 1-313.

Note: Note that floating-point evaluation for high degree polynomials may be numerically unstable. Cf. “Example 4” on page 1-314.

The floating-point evaluation on the standard interval $x \in [0, 1]$ is numerically stable for arbitrary n.

Environment Interactions

When called with a floating-point value x, the function is sensitive to the environment variable DIGITS which determines the numerical working precision.

Examples

Example 1

The first Bernoulli numbers are:

```
bernoulli(n) $ n = 0..11
```

$$1, -\frac{1}{2}, \frac{1}{6}, 0, -\frac{1}{30}, 0, \frac{1}{42}, 0, -\frac{1}{30}, 0, \frac{5}{66}, 0$$

The first Bernoulli polynomials:

```
bernoulli(n, x) $ n = 0..4
```

$$1, x - \frac{1}{2}, x^2 - x + \frac{1}{6}, x^3 - \frac{3\,x^2}{2} + \frac{x}{2}, x^4 - 2\,x^3 + x^2 - \frac{1}{30}$$

If n is symbolic, then a symbolic call is returned:

```
bernoulli(n, x), bernoulli(n + 3/2, x), bernoulli(n + 5*I, x)
```

$$\text{bernoulli}(n, x), \text{bernoulli}\left(n + \frac{3}{2}, x\right), \text{bernoulli}(n + 5\,\mathrm{i}, x)$$

Example 2

If x is not an indeterminate, then the evaluation of the Bernoulli polynomial at the point x is returned:

```
bernoulli(50, 1 + I)
```

$$\frac{1325499634525572673731793891 25}{66} + 25\,i$$

```
bernoulli(3, 1 - y), expand(bernoulli(3, 1 - y))
```

$$\frac{1}{2} - \frac{3\,(y-1)^2}{2} - (y-1)^3 - \frac{y}{2},\ -y^3 + \frac{3\,y^2}{2} - \frac{y}{2}$$

Example 3

Certain simplifications occur for some special numerical values of `x`, even if `n` is symbolic:

```
bernoulli(n, 0), bernoulli(n, 1/2), bernoulli(n, 1)
```

$$\text{bernoulli}(n),\ \text{bernoulli}(n)\left(2^{1-n} - 1\right),\ (-1)^n\,\text{bernoulli}(n)$$

Calls with numerical arguments between $\frac{1}{2}$ and 1 are automatically rewritten in terms of calls with arguments between 0 and $\frac{1}{2}$:

```
bernoulli(n, 2/3), bernoulli(n, 0.7)
```

$$(-1)^n\,\text{bernoulli}\left(n,\ \frac{1}{3}\right),\ (-1)^n\,\text{bernoulli}(n,\ 0.3)$$

Calls with negative numerical arguments are automatially rewritten in terms of calls with positive arguments:

```
bernoulli(n, -2)
```

$$(-1)^n\,\text{bernoulli}(n,\ 2) + (-1)^n\,2^{n-1}\,n$$

```
bernoulli(n, -12.345)
```

$$(-1)^n\,\text{bernoulli}(n,\ 12.345) + (-1)^n\,12.345^{n-1}\,n$$

Example 4

Float evaluation of high degree polynomials may be numerically unstable:

```
exact := bernoulli(50, 1 + I): float(exact);
```

$$2.00833278\ 10^{27} + 25.0\ i$$

```
bernoulli(50, float(1 + I))
```

$$2.00833278\ 10^{27} - 10835184500.0\ i$$

```
DIGITS := 40: bernoulli(50, float(1 + I))
```

$$2.0083327795842010208057483200757575758\ 10^{27}$$

$$+ 24.999999999999999999999167000202474718 52\ i$$

```
delete exact, DIGITS:
```

Example 5

Some system functions such as `diff` or `expand` handle symbolic calls of `bernoulli`:

Some system functions such as `diff` or `expand` handle symbolic calls of `bernoulli`:

```
diff(bernoulli(n, f(x)), x)
```

$$n\ \text{bernoulli}(n-1, f(x))\ \frac{\partial}{\partial x} f(x)$$

```
expand(bernoulli(n, x + 2))
```

$$\text{bernoulli}(n, x) + \frac{n\,(x+1)^n}{x+1} + \frac{n\,x^n}{x}$$

```
expand(bernoulli(n, -x))
```

$$(-1)^n \,\mathrm{bernoulli}(n, x) + \frac{n\,(-x)^n}{x}$$

```
expand(bernoulli(n, 3*x))
```

$$\frac{3^n \,\mathrm{bernoulli}(n, x)}{3} + \frac{3^n \,\mathrm{bernoulli}\left(n, x + \frac{1}{3}\right)}{3} + \frac{3^n \,\mathrm{bernoulli}\left(n, x + \frac{2}{3}\right)}{3}$$

Parameters

n

An arithmetical expression representing a nonnegative integer

x

An arithmetical expression

Return Values

Arithmetical expression.

MuPAD Functions

`euler`

bernstein

Bernstein polynomials

Syntax

```
bernstein(f, n, t)
```

```
bernstein(g, <var>, n, t)
```

Description

`bernstein(n, f, t)` with a univariate function f returns the `n`th-order Bernstein polynomial `sum(binomial(n,k)*t^k*(1-t)^(n-k)*f(k/n),k = 0..n)` evaluated at the point `t`. This polynomial is an approximation of f over the interval `[0,1]`. See "Example 1" on page 1-316.

`bernstein(g, <var>, n, t)` with a symbolic expression g returns the `n`th-order Bernstein polynomial approximation of `g`, evaluated at the point `t`. This syntax regards `g` as a univariate function of the variable `var`. You can omit specifying the variable `var` if the expression `g` is univariate. If it is multivariate, you must specify `var`. See "Example 2" on page 1-317 and "Example 3" on page 1-318.

The Bernstein representation of a polynomial is numerically stable when substituting numerical values between `0` and `1` for t. Nevertheless, if you simplify a Bernstein polynomial, the result can be unstable when substituting numerical values for t. See "Example 4" on page 1-319.

Examples

Example 1

Define the function representing a linear ramp as a MuPAD function:

```
f := t -> triangularPulse(1/4, 3/4, infinity, t):
```

Approximate `f` by the fifth-order Bernstein polynomials in the variable `t`:

```
b5 := bernstein(f, 5, t)
```

$$7\,t^3\,(t-1)^2 - 3\,t^2\,(t-1)^3 - 5\,t^4\,(t-1) + t^5$$

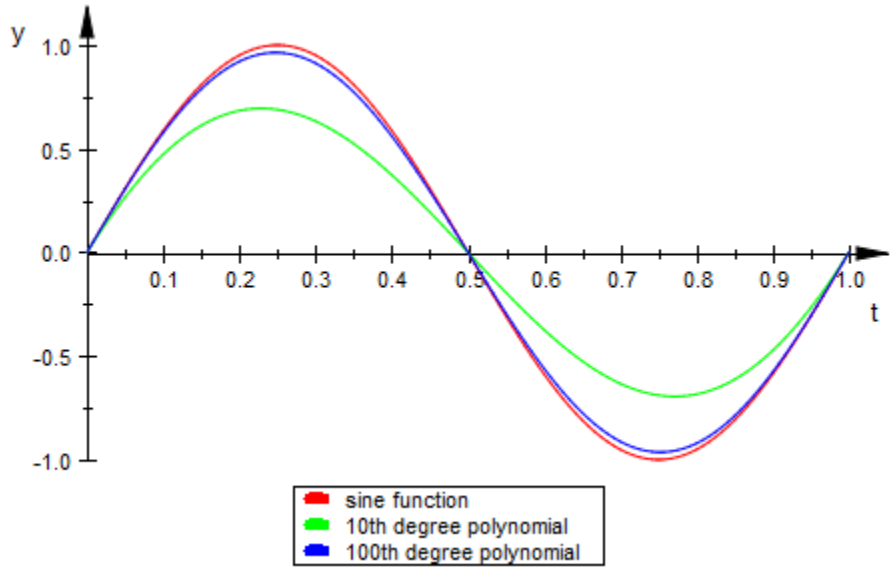
Example 2

Approximate the sine function `sin(2*PI*t)` by the 10th- and 100th-degree Bernstein polynomials:

```
b10 := bernstein(sin(2*PI*t), 10, t):
b100 := bernstein(sin(2*PI*t), 100, t):
```

Plot `sin(2*pi*t)` and its approximations:

```
p1 := plot::Function2d(sin(2*PI*t), t = 0..1,
                       LegendText = "sine function",
                       Color = RGB::Red):
p2 := plot::Function2d(b10, t = 0..1,
                       LegendText = "10th degree polynomial",
                       Color = RGB::Green):
p3 := plot::Function2d(b100, t = 0..1,
                       LegendText = "100th degree polynomial",
                       Color = RGB::Blue):
plot(p1, p2, p3, LegendVisible = TRUE)
```



Example 3

Approximate the exponential function by the second-order Bernstein polynomial in the variable `t`:

```
bernstein(exp(x), 2, t)
```

$$(t-1)^2 + t^2\,\mathrm{e} - 2\,t\,\sqrt{\mathrm{e}}\,(t-1)$$

Approximate the multivariate exponential function `y*exp(x*y)`. You must specify the variable because this expression contains more than one variable. `bernstein` regards the expression as a univariate function of that variable. For example, to treat this expression as a univariate function of `x`, enter:

```
bernstein(y*exp(x*y), x, 2, t)
```

$$y\,(t-1)^2 + t^2\,y\,\mathrm{e}^{y} - 2\,t\,y\,\mathrm{e}^{\frac{y}{2}}\,(t-1)$$

To treat this expression as a univariate function of `y`, enter:

```
bernstein(y*exp(x*y), y, 2, t)
```

$$t^2 e^x - t e^{\frac{x}{2}} (t-1)$$

Example 4

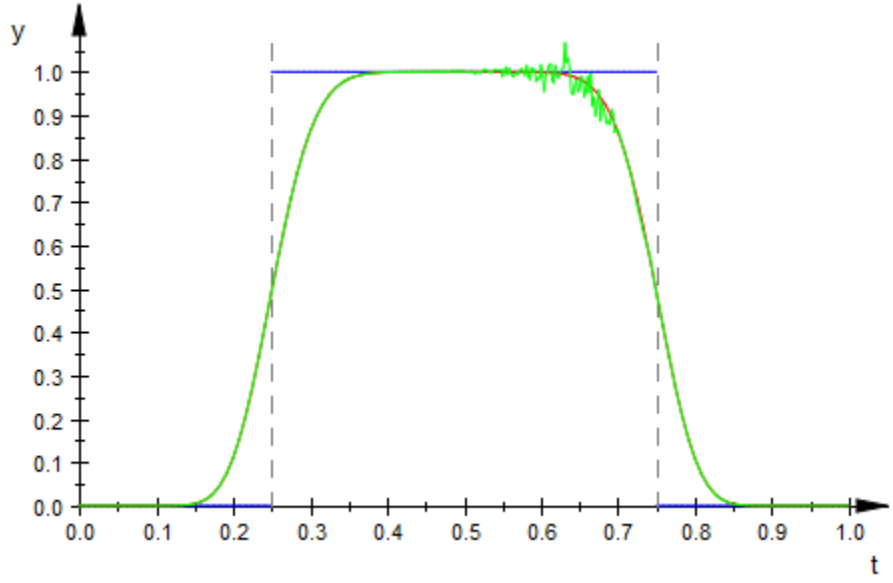
When you simplify a high-order symbolic Bernstein polynomial, the result often cannot be evaluated in a numerically stable way.

Approximate this rectangular pulse function by the 100th-degree Bernstein polynomial, and then simplify the result:

```
f := rectangularPulse(1/4,3/4,t):
f1 := bernstein(f, 100, t):
f2 := simplify(f1):
```

Compare the plot of the original rectangular pulse function `f`, its numerically stable Bernstein representation `f1`, and its simplified version `f2`. The simplified version shows a region of numerical instability.

```
plot(f, f1, f2, t = 0..1)
```



Parameters

`n`

Nonnegative integer.

`f`

Function accepting one input parameter and returning an arithmetical expression.

`g`

Arithmetical expression.

`t`

Arithmetical expression.

`var`

Indeterminate, specified as an identifier or indexed identifier.

Return Values

Arithmetical expression.

Algorithms

A Bernstein polynomial of degree `n` is defined as follows:

$$B(t) = \sum_{k=0}^{n} \beta_k \, b_{k,n}(t)$$

Here

$$b_{k,n}(t) = \binom{n}{k} t^k (1-t)^{n-k}$$

$k = 0,\ldots,n$

are the Bernstein basis polynomials, and

$$\binom{n}{k}$$

is a binomial coefficient.

The coefficients

$$\beta_k$$

are called Bernstein coefficients or Bezier coefficients.

If `f` is a continuous function on the interval `[0, 1]` and

$$B_n(f)(t) = \sum_{k=0}^{n} f\left(\frac{k}{n}\right) b_{k,n}(t)$$

is the approximating Bernstein polynomial, then

$$\lim_{n\to\infty} B_n(f)(t) = f(t)$$

uniformly in `t` on the interval `[0, 1]`.

See Also

MuPAD Functions

`bernsteinMatrix` | `binomial` | `fact` | `sum`

bernsteinMatrix

Bernstein matrix

Syntax

```
bernsteinMatrix(n, t)
```

Description

`bernsteinMatrix(n, t)`, where t is a vector of length `m`, returns the `m`-by-`(n+1)` Bernstein matrix M, such that `M(i,k+1) = binomial(n,k)*t[i]^k*(1-t[i])^(n-k)`. Here, the index `i` runs from 1 to `m`, and the index `k` runs from `0` to `n`. See "Example 2" on page 1-317 and "Example 3" on page 1-318.

The Bernstein matrix is also called the Bezier matrix.

Use Bernstein matrices to construct Bezier curves:

```
bezierCurve = bernsteinMatrix(n, t)*P
```
Here, the rows of matrix `P` specify the control points of the Bezier curve. For example, to construct the second-order 3-D Bezier curve, specify the control points as:

```
P = [p0x, p0y, p0z;  p1x, p1y, p1z;  p2x, p2y, p2z]
```

Examples

Example 1

Plot the fourth-order 2-D Bezier curve specified by the control points `p0 = [0, 1]`, `p1 = [4, 3]`, `p2 = [6, 2]`, `p3 = [3, 0]`, `p4 = [2, 4]`. Create a matrix with each row representing a control point:

```
P := matrix([[0, 1], [4, 3], [6, 2], [3, 0], [2, 4]]):
```

Construct the fourth-order Bernstein matrix `B`:

```
B := bernsteinMatrix(4, t)
```

$$\left((t-1)^4 \quad -4\,t\,(t-1)^3 \quad 6\,t^2\,(t-1)^2 \quad -4\,t^3\,(t-1) \quad t^4 \right)$$

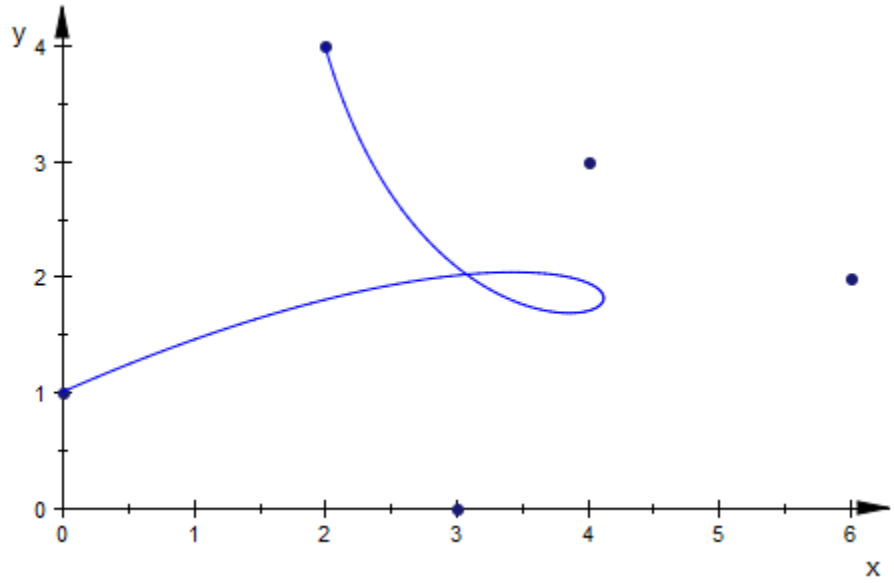
Construct the Bezier curve:

```
bezierCurve := simplify(B*P)
```

$$\left(-2\,t\,(-5\,t^3+6\,t^2+6\,t-8) \quad 5\,t^4+8\,t^3-18\,t^2+8\,t+1 \right)$$

Plot the curve and control points:

```
plot(plot::PointList2d(P),
       plot::Curve2d(bezierCurve, t = 0..a, a = 0..1))
```



Example 2

Construct the third-order 3-D Bezier curve specified by the 3-by-3 matrix `P` of control points. Each control point corresponds to a row of matrix `P`.

```
P := matrix([[0, 0, 0], [2, 2, 2], [2, -1, 1], [6, 1, 3]]):
```

Construct the Bernstein matrix:

```
B := bernsteinMatrix(3, t)
```

$$\left(-(t-1)^3 \;\; 3\,t\,(t-1)^2 \;\; -3\,t^2\,(t-1) \;\; t^3 \right)$$

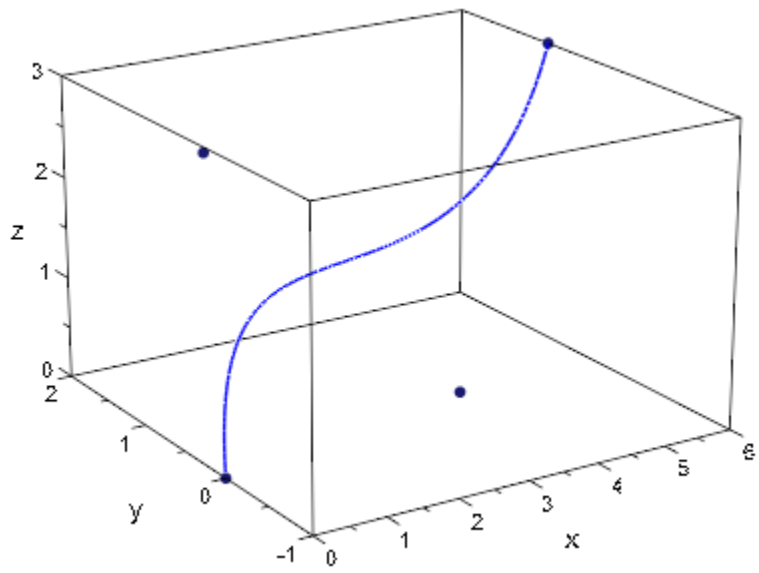
Construct the Bezier curve:

```
bezierCurve := simplify(B*P)
```

$$\left(6\,t\,(t^2-t+1) \;\; t\,(10\,t^2-15\,t+6) \;\; 3\,t\,(2\,t^2-3\,t+2) \right)$$

Plot the control points and Bezier curve:

```
plot(plot::PointList3d(P),
        plot::Curve3d(bezierCurve, t = 0..a, a = 0..1))
```



Parameters

`n`

Nonnegative integer.

`t`

Arithmetical expression, a list of expressions, or a vector of expressions. In MuPAD, a `1#m` or an `m#1` matrix represents a row or column vector, respectively.

Return Values

`nops(t)#(n+1)` matrix of the domain type `Dom::Matrix()`.

Algorithms

A Bernstein polynomial of degree `n` is defined as follows:

$$B(t) = \sum_{k=0}^{n} \beta_k \, b_{k,n}(t)$$

Here,

$$b_{k,n}(t) = \binom{n}{k} t^k (1-t)^{n-k}$$

$k = 0,\ldots,n$

are the Bernstein basis polynomials, and

$$\binom{n}{k}$$

is a binomial coefficient.

The coefficients

$$\beta_k$$

are called Bernstein coefficients or Bezier coefficients.

The Bernstein polynomial is given by the matrix multiplication of the Bernstein matrix and the vector of coefficients:

$$B(t) = b_{0n}(t)\ b_{1n}(t)\ \ldots\ b_{nn}(t) \begin{pmatrix} \beta_0 \\ \beta_1 \\ \vdots \\ \beta_n \end{pmatrix}$$

See Also

MuPAD Functions

`bernstein` | `binomial` | `fact` | `sum`

bessel

Modified Bessel functions of the first kind

Syntax

```
besselI(v, z)
```

Description

`besselI(v, z)` represents the modified Bessel functions of the first kind:

$$I_v(z) = \frac{\left(\frac{z}{2}\right)^v}{\sqrt{\pi}\,\Gamma\left(v+\frac{1}{2}\right)} \int_0^{\pi} e^{z\cos(t)} \sin(t)^{2v}\, dt$$

.

The Bessel functions are defined for complex arguments v and z.

A floating-point value is returned if either of the arguments is a floating-point number and the other argument is numerical. For most exact arguments the Bessel functions return an unevaluated function call. Special values at index $v = 0$ and/or argument $z = 0$ are implemented. Explicit symbolic expressions are returned, when the index v is a half integer. See “Example 2” on page 1-328.

For nonnegative integer indices v some of the Bessel functions have a branch cut along the negative real axis. A jump occurs when crossing this cut. See “Example 3” on page 1-328.

If floating-point approximations are desired for arguments that are exact numerical expressions, then we recommend to use `besselI(v, float(x))` rather than `float(besselI(v, x))`. In particular, for half integer indices the symbolic result `besselI(v,x)` is costly to compute. Further, floating-point evaluation of the resulting symbolic expression can be numerically unstable. See “Example 4” on page 1-329.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Unevaluated calls are returned for exact or symbolic arguments:

```
besselJ(2, 1 + I), besselK(0, x), besselY(v, x)
```

$$J_2(1+i),\ K_0(x),\ Y_v(x)$$

Floating point values are returned for floating-point arguments:

```
besselI(2, 5.0), besselK(3.2 + I, 10000.0)
```

$$17.50561497,\ 1.423757712\ 10^{-4345} + 4.555796986\ 10^{-4349}\ i$$

Example 2

Bessel functions can be expressed in terms of elementary functions if the index is an odd integer multiple of $\frac{1}{2}$:

```
besselJ(1/2, x), besselY(3/2, x)
```

$$\frac{\sqrt{2}\ \sin(x)}{\sqrt{\pi}\ \sqrt{x}},\ -\frac{\sqrt{2}\ \left(\sin(x)+\frac{\cos(x)}{x}\right)}{\sqrt{\pi}\ \sqrt{x}}$$

```
besselI(7/2, x), besselK(-7/2, x)
```

$$-\frac{\sqrt{2}\ \left(\sinh(x)\ \left(\frac{6}{x}+\frac{15}{x^3}\right)-\cosh(x)\ \left(\frac{15}{x^2}+1\right)\right)}{\sqrt{\pi}\ \sqrt{x}},\ \frac{\sqrt{2}\ \sqrt{\pi}\ e^{-x}\ \left(\frac{6}{x}+\frac{15}{x^2}+\frac{15}{x^3}+1\right)}{2\ \sqrt{x}}$$

Example 3

The negative real axis is a branch cut of the Bessel functions for non-integer indices v. A jump occurs when crossing this cut:

```
besselI(-3/4, -1.2), besselI(-3/4, -1.2 + I/10^10),
besselI(-3/4, -1.2 - I/10^10)
```

$$-0.76061492 - 0.76061492\,i,\ -0.76061492 - 0.7606149199\,i,\ -0.76061492 + 0.7606149199\,i$$

Example 4

The symbolic expressions returned by Bessel functions with half integer indices may be unsuitable for floating-point evaluation:

```
y := besselJ(51/2, PI)
```

$$\frac{\sqrt{2}\left(\frac{450675225}{\pi^4} - \frac{52650}{\pi^2} - \frac{1466947857375}{\pi^6} + \ldots + 1\right)}{\pi}$$

Floating point evaluation of this exact result is subject to numerical cancellation. The following result is dominated by round-off:

```
float(y)
```

$$-57.62024423$$

The numerical working precision has to be increased to obtain a more accurate result:

```
DIGITS:= 39: float(y)
```

$$1.1601295742121116493771032350748218236 1\,10^{-21}$$

Direct floating-point evaluation via the Bessel function yields a correct result within working precision:

```
DIGITS := 5: besselJ(51/2, float(PI))
```

$$1.1601\,10^{-21}$$

```
delete y, DIGITS:
```

Example 5

The functions `diff`, `float`, `limit`, and `series` handle expressions involving the Bessel functions:

```
diff(besselJ(0, x), x, x), float(ln(3 + besselI(17, sqrt(PI))))
```

$$\frac{J_1(x)}{x} - J_0(x),\ 1.098612289$$

```
limit(besselJ(2, x^2 + 1)*sqrt(x), x = infinity)
```

$$0$$

```
series(besselY(3, x)/x, x = infinity, 3)
```

$$\frac{\sqrt{2}\,\sigma_1}{\sqrt{\pi}\,x^{3/2}} + \frac{35\sqrt{2}\cos\left(x-\frac{7\pi}{4}\right)}{8\sqrt{\pi}\,x^{5/2}} - \frac{945\sqrt{2}\,\sigma_1}{128\sqrt{\pi}\,x^{7/2}} + O\left(\frac{1}{x^{9/2}}\right)$$

where

$$\sigma_1 = \sin\left(x - \frac{7\pi}{4}\right)$$

Parameters

v, z

arithmetical expressions

Return Values

Arithmetical expression.

Overloaded By

z

Algorithms

The modified Bessel functions $I_v(z)$ and $K_v(z)$ satisfy the modified Bessel equation:

$$z^2 \frac{\partial^2}{\partial z^2} w + z \frac{\partial}{\partial z} w - (z^2 + v^2)\, w = 0$$

.

When the index v is an integer, the modified Bessel functions of the first kind are governed by reflection formulas:

$$I_{-v}(z) = I_v(z)$$

.

See Also

MuPAD Functions

`besselJ` | `besselK` | `besselY`

besselJ

Bessel functions of the first kind

Syntax

```
besselJ(v, z)
```

Description

`besselJ(v, z)` represents the Bessel functions of the first kind:

$$J_v(z) = \frac{\left(\frac{z}{2}\right)^v}{\sqrt{\pi}\,\Gamma\left(v+\frac{1}{2}\right)} \int_0^{\pi} \cos(z\cos(t))\,\sin(t)^{2v}\,dt$$

.

The Bessel functions are defined for complex arguments v and z.

A floating-point value is returned if either of the arguments is a floating-point number and the other argument is numerical. For most exact arguments the Bessel functions return an unevaluated function call. Special values at index $v = 0$ and/or argument $z = 0$ are implemented. Explicit symbolic expressions are returned, when the index v is a half integer. See “Example 2” on page 1-333.

For nonnegative integer indices v some of the Bessel functions have a branch cut along the negative real axis. A jump occurs when crossing this cut. See “Example 3” on page 1-333.

If floating-point approximations are desired for arguments that are exact numerical expressions, then we recommend to use `besselJ(v, float(x))` rather than `float(besselJ(v, x))`. In particular, for half integer indices the symbolic result `besselJ(v,x)` is costly to compute. Further, floating-point evaluation of the resulting symbolic expression may be numerically unstable. Cf. “Example 4” on page 1-334.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Unevaluated calls are returned for exact or symbolic arguments:

```
besselJ(2, 1 + I), besselK(0, x), besselY(v, x)
```

$$J_2(1+i),\ K_0(x),\ Y_v(x)$$

Floating point values are returned for floating-point arguments:

```
besselI(2, 5.0), besselK(3.2 + I, 10000.0)
```

$$17.50561497,\ 1.423757712\ 10^{-4345} + 4.555796986\ 10^{-4349}\ i$$

Example 2

Bessel functions can be expressed in terms of elementary functions if the index is an odd integer multiple of $\frac{1}{2}$:

```
besselJ(1/2, x), besselY(3/2, x)
```

$$\frac{\sqrt{2}\,\sin(x)}{\sqrt{\pi}\,\sqrt{x}},\ -\frac{\sqrt{2}\left(\sin(x)+\frac{\cos(x)}{x}\right)}{\sqrt{\pi}\,\sqrt{x}}$$

```
besselI(7/2, x), besselK(-7/2, x)
```

$$-\frac{\sqrt{2}\left(\sinh(x)\left(\frac{6}{x}+\frac{15}{x^3}\right)-\cosh(x)\left(\frac{15}{x^2}+1\right)\right)}{\sqrt{\pi}\,\sqrt{x}},\ \frac{\sqrt{2}\,\sqrt{\pi}\,e^{-x}\left(\frac{6}{x}+\frac{15}{x^2}+\frac{15}{x^3}+1\right)}{2\,\sqrt{x}}$$

Example 3

The negative real axis is a branch cut of the Bessel functions for non-integer indices v. A jump occurs when crossing this cut:

```
besselI(-3/4, -1.2), besselI(-3/4, -1.2 + I/10^10),
besselI(-3/4, -1.2 - I/10^10)
```

$$-0.76061492 - 0.76061492\,i,\ -0.76061492 - 0.7606149199\,i,\ -0.76061492 + 0.7606149199\,i$$

Example 4

The symbolic expressions returned by Bessel functions with half integer indices may be unsuitable for floating-point evaluation:

```
y := besselJ(51/2, PI)
```

$$\frac{\sqrt{2}\left(\frac{450675225}{\pi^4} - \frac{52650}{\pi^2} - \frac{1466947857375}{\pi^6} + \ldots + 1\right)}{\pi}$$

Floating point evaluation of this exact result is subject to numerical cancellation. The following result is dominated by round-off:

```
float(y)
```

$$-57.62024423$$

The numerical working precision has to be increased to obtain a more accurate result:

```
DIGITS:= 39: float(y)
```

$$1.1601295742121116493771032350748218236 1\,10^{-21}$$

Direct floating-point evaluation via the Bessel function yields a correct result within working precision:

```
DIGITS := 5: besselJ(51/2, float(PI))
```

$$1.1601\,10^{-21}$$

```
delete y, DIGITS:
```

Example 5

The functions `diff`, `float`, `limit`, and `series` handle expressions involving the Bessel functions:

```
diff(besselJ(0, x), x, x), float(ln(3 + besselI(17, sqrt(PI))))
```

$$\frac{J_1(x)}{x} - J_0(x),\ 1.098612289$$

```
limit(besselJ(2, x^2 + 1)*sqrt(x), x = infinity)
```

$$0$$

```
series(besselY(3, x)/x, x = infinity, 3)
```

$$\frac{\sqrt{2}\,\sigma_1}{\sqrt{\pi}\,x^{3/2}} + \frac{35\sqrt{2}\cos\left(x-\frac{7\pi}{4}\right)}{8\sqrt{\pi}\,x^{5/2}} - \frac{945\sqrt{2}\,\sigma_1}{128\sqrt{\pi}\,x^{7/2}} + O\left(\frac{1}{x^{9/2}}\right)$$

where

$$\sigma_1 = \sin\left(x - \frac{7\pi}{4}\right)$$

Parameters

MuPAD Functions

`besselI` | `besselK` | `besselY`

besselK

Modified Bessel functions of the second kind

Syntax

```
besselK(v, z)
```

Description

`besselK(v, z)` represents the modified Bessel functions of the second kind:

$$K_v(z) = \frac{\frac{\pi}{2}\left(I_{-v}(z) - I_v(z)\right)}{\sin(v\,\pi)}$$

.

Here $I_v(z)$ are the modified Bessel functions of the first kind:

$$I_v(z) = \frac{\left(\frac{z}{2}\right)^v}{\sqrt{\pi}\,\Gamma\left(v + \frac{1}{2}\right)} \int_0^{\pi} e^{z\cos(t)} \sin(t)^{2v}\, dt$$

.

The Bessel functions are defined for complex arguments v and z.

A floating-point value is returned if either of the arguments is a floating-point number and the other argument is numerical. For most exact arguments the Bessel functions return an unevaluated function call. Special values at index $v = 0$ and/or argument $z = 0$ are implemented. Explicit symbolic expressions are returned, when the index v is a half integer. See “Example 2” on page 1-338.

For nonnegative integer indices v some of the Bessel functions have a branch cut along the negative real axis. A jump occurs when crossing this cut. See “Example 3” on page 1-339.

If floating-point approximations are desired for arguments that are exact numerical expressions, then we recommend to use `besselK(v, float(x))` rather than `float(besselK(v, x))`. In particular, for half integer indices the symbolic result

`besselK(v,x)` is costly to compute. Further, floating-point evaluation of the resulting symbolic expression may be numerically unstable. See “Example 4” on page 1-339.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Unevaluated calls are returned for exact or symbolic arguments:

MuPAD Functions

`besselI` | `besselJ` | `besselK`

beta

Beta function

Syntax

```
beta(x, y)
```

Description

`beta(x, y)` represents the beta function $\frac{\Gamma(x)\,\Gamma(y)}{\Gamma(x+y)}$.

The beta function is defined for complex arguments x and y.

The result is expressed by calls to the gamma function if both arguments are of type `Type::Numeric`. Note that the beta function may have a regular value, even if $\Gamma(x)$ or $\Gamma(y)$ and $\Gamma(x + y)$ are singular. In such cases `beta` returns the limit of the quotients of the singular terms.

A floating-point value is returned if both arguments are numerical and at least one of them is a floating-point value.

An unevaluated call of `beta` is returned, if none of the arguments vanishes and at least one of the arguments does not evaluate to a number of type `Type::Numeric`.

Environment Interactions

When called with floating-point arguments, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
beta(1, 5), beta(I, 3/2), beta(1, y + 1), beta(x, y)
```

$$\frac{1}{5},\ \frac{\sqrt{\pi}\,\Gamma(\mathrm{i})}{2\,\Gamma\left(\frac{3}{2}+\mathrm{i}\right)},\ \frac{1}{y+1},\ \beta(x,\ y)$$

Floating point values are computed for floating-point arguments:

```
beta(3.5, sqrt(2)), beta(sqrt(2), 2.0 + 10.0*I)
```

$$0.1395855454,\ -0.01112350756-0.03108193098\,\mathrm{i}$$

Example 2

The gamma function is singular if its argument is a nonpositive integer. Nevertheless, `beta` has a regular value for the following arguments:

```
beta(-3, 2)
```

$$\frac{1}{6}$$

Example 3

The functions `diff`, `expand` and `float` handle expressions involving `beta`:

```
diff(beta(x^2, x), x)
```

$$\beta(x,\ x^2)\,(\psi(x)+2\,x\,\psi(x^2)-\psi(x^2+x)\,(2\,x+1))$$

```
expand(beta(x - 1, y + 1))
```

$$-\frac{y\,\Gamma(x)\,\Gamma(y)}{\Gamma(x+y)-x\,\Gamma(x+y)}$$

```
float(beta(100, 1000))
```

$$7.730325902\ 10^{-147}$$

Example 4

The functions `diff` and `series` can handle `beta`:

```
diff(beta(x, y), x);
diff(beta(x, y), y);
```

$$-\beta(x, y)\,(\psi(x+y)-\psi(x))$$

$$-\beta(x, y)\,(\psi(x+y)-\psi(y))$$

```
normal(series(beta(x, y), y = 0, 3))
```

$$\frac{1}{y}-\mathrm{EULER}-\psi(x)+y\left(\frac{\psi(x)^2}{2}+\mathrm{EULER}\,\psi(x)+\frac{\mathrm{EULER}^2}{2}+\frac{\pi^2}{12}-\frac{\psi'(x)}{2}\right)+O(y^2)$$

```
series(beta(x, x), x = infinity, 4)
```

$$\frac{2\left(\frac{1}{4}\right)^x\sqrt{\pi}}{\sqrt{x}}+\frac{\left(\frac{1}{4}\right)^x\sqrt{\pi}}{4\,x^{3/2}}+\frac{\left(\frac{1}{4}\right)^x\sqrt{\pi}}{64\,x^{5/2}}+O\left(\frac{\left(\frac{1}{4}\right)^x}{x^{7/2}}\right)$$

Parameters

x, y

arithmetical expressions or floating-point intervals

Return Values

Arithmetical expression or a floating-point interval.

Overloaded By

x

MuPAD Functions
`binomial` | `fact` | `gamma` | `psi`

binomial

Binomial coefficients

Syntax

```
binomial(n, k)
```

Description

`binomial(n, k)` represents the binomial coefficient $\binom{n}{k} = \frac{n!}{(n-k)!\,k!}$.

Binomial coefficients are defined for complex arguments via the `gamma` function:

$$\binom{n}{k} = \frac{\Gamma(n+1)}{\Gamma(k+1)\,\Gamma(n-k+1)}.$$

With $\Gamma(n+1) = n!$, this coincides with the usual binomial coefficients for integer arguments satisfying $0 \le k \le n$.

A symbolic function call is returned if one of the arguments cannot be evaluated to a number of type `Type::Numeric`. However, for $k = 0$, $k = 1$, $k = n - 1$, and $k = n$, simplified results are returned for any n.

Let n be a number of type `Type::Numerical`. If k evaluates to a nonnegative integer, then $\frac{n\,(n-1)\,\ldots\,(n-k+1)}{k!}$ is returned. If $n - k$ evaluates to a nonnegative integer, then $\frac{n\,(n-1)\,\ldots\,(k+1)}{(n-k)!}$ is returned. If k or $n - k$ evaluates to a negative integer, then 0 is returned. If k evaluates to a floating-point number, then a floating-point value is returned. In all other cases, a symbolic call of `binomial` is returned.

A floating-point value is returned if both arguments are numerical and at least one of them is a floating-point value.

Environment Interactions

When called with floating-point arguments, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
binomial(10, k) $ k=-2..12
```

$$0, 0, 1, 10, 45, 120, 210, 252, 210, 120, 45, 10, 1, 0, 0$$

```
binomial(-23/12, 3), binomial(1 + I, 3)
```

$$-\frac{37835}{10368}, -\frac{i}{3}$$

```
binomial(n, k), binomial(n, 1), binomial(n, 4)
```

$$\binom{n}{k}, n, \binom{n}{4}$$

Floating point values are computed for floating-point arguments:

```
binomial(-235/123, 3.0), binomial(3.0, 1 + I)
```

$$-3.624343742, 4.411293492 + 2.205646746\,i$$

Example 2

The `expand` function handles expressions involving `binomial`:

```
binomial(n, 3) = expand(binomial(n, 3))
```

$$\binom{n}{3} = \frac{n^3}{6} - \frac{n^2}{2} + \frac{n}{3}$$

```
binomial(2, k) = expand(binomial(2, k))
```

$$\binom{2}{k} = \frac{2\sin(\pi k)}{\pi k (k-1)(k-2)}$$

The `float` attribute handles `binomial` if all arguments can be converted to floating-point numbers:

```
binomial(sin(3), 5/4), float(binomial(sin(3), 5/4))
```

$$\binom{\sin(3)}{\frac{5}{4}},\ -0.08360571366$$

Example 3

The functions `diff` and `series` can handle `binomial`:

```
diff(binomial(n, k), n);
diff(binomial(n, k), k);
```

$$-(\psi(n-k+1) - \psi(n+1))\binom{n}{k}$$

$$(\psi(n-k+1) - \psi(k+1))\binom{n}{k}$$

```
normal(series(binomial(n, k), k = 0, 3))
```

$$1 + k(\mathrm{EULER} + \psi(n+1)) + k^2\left(\frac{\psi(n+1)^2}{2} + \mathrm{EULER}\,\psi(n+1) - \frac{\psi'(n+1)}{2} + \frac{\mathrm{EULER}^2}{2} - \frac{\pi^2}{12}\right) + O(k^3)$$

```
series(binomial(2*n, n), n = infinity, 4)
```

$$\frac{4^n}{\sqrt{\pi}\,\sqrt{n}} - \frac{4^n}{8\,\sqrt{\pi}\,n^{3/2}} + \frac{4^n}{128\,\sqrt{\pi}\,n^{5/2}} + O\left(\frac{4^n}{n^{7/2}}\right)$$

Parameters

n, k

arithmetical expressions

Return Values

Arithmetical expression.

MuPAD Functions
`beta` | `fact` | `gamma` | `psi`

block

Create an object protected against evaluation

Syntax

```
block(a)
```

Description

`block(a)` creates a block, i.e., an object of special type that contains an unevaluated copy of `a`. It is treated as atomic and remains unchanged by evaluation.

`block` and domains derived thereof form a hierarchy of data types designed to provide control over the evaluation of certain subexpressions. Any object may be put as content into any type of block.

`block` is a domain If `d` is any block domain, `d(a)` creates a block belonging to that domain, with content `a`.

`block(a)` puts its argument into a block, without evaluating it. In order to evaluate `a` normally before putting it into a block, use `eval(hold(block)(a))`.

Blocks are invariant under evaluation.

Blocks of type `block` are atomic: the only operand of a block is the block itself.

Sequences may be put into blocks as well; in the case of `block`, they are not flattened. See “Example 4” on page 1-357.

You can create further block domains using inheritance. This particularly useful for creating own `evaluate` or `testtype` methods. See “Example 6” on page 1-357.

In case of nested blocks, only the outermost block is removed by both `expr` and `unblock`.

Examples

Example 1

A block is a sort of container that protects its content against evaluation:

```
y:= 1: bl:= block(1+y)
```

$$1+y$$

Blocks are atomic; thus y and 1 are not visible as operands:

```
op(bl), nops(bl)
```

$$1+y,\ 1$$

Although blocks are not arithmetical expressions, some basic arithmetical operations are defined for them:

```
collect(x+bl+x*bl, bl);
delete y, bl:
```

$$(x+1)\,(1+y)+x$$

Example 2

Transparent blocks protect against evaluation, too:

```
y:= 2:
bl:=blockTransparent(x+y+z)
```

$$x+y+z$$

However, a transparent block allows access to the operands of its content:

```
op(bl,1), subs(bl, hold(y) = y)
```

$$x,\ x+2+z$$

```
delete bl, y:
```

Example 3

With a third kind of block, suppressing evaluation may be limited to certain identifiers:

```
x:= 3: y:=1:
blockIdents({hold(x)})(x+y)
```

$$x+1$$

```
delete x, y:
```

Example 4

A block may also contain a sequence; flattening is suppressed:

```
block((x, y),z)
```

$$x, y, z$$

Example 5

The content of a block may be extracted and evaluated using `unblock`:

```
y:= 1: unblock(block(y)); delete y:
```

$$1$$

Example 6

We want to create blocks that represent arithmetical expressions. To do this, we need our own block domain that overloads `testtype`:

```
domain myblock
  inherits block;
  category  Cat::BaseCategory;
  testtype:= (bl, T) -> if T = Type::Arithmetical or T = dom then
                          TRUE
```

```
                        else
                          block::testtype(bl, T)
                        end_if;
end_domain:
```

This allows us to make the number zero invisible for the evaluator by enclosing it into a block, but to retain the option to plug it into special functions:

```
f := sin(x+myblock(0))
```

$$\sin(x+0)$$

We can now manipulate this expression, without being disturbed by automatic simplification:

```
expand(f)
```

$$\cos(0)\,\sin(x)+\cos(x)\,\sin(0)$$

```
 eval(unblock(%))
```

$$\sin(x)$$

Parameters

a

Any object or sequence of objects

Return Values

`block` creates objects of its own type.

See Also

MuPAD Functions

`blockIdents` | `blockTransparent` | `freeze` | `hold` | `unblock`

blockIdents

Create a transparent block with some identifiers protected against evaluation

Syntax

```
blockIdents(S)(a)
```

Description

`blockIdents(S)(a)` creates a transparent block which is evaluated like `a`, except that the identifiers in `S` are neither substituted by their values nor are their properties used.

`blockIdents` is a parametrized family of domains, depending on a parameter `S` which must be a set. If `d` is any block domain, `d(a)` creates a block belonging to that domain, with content `a`.

`blockIdents(S)(a)` replaces all identifiers in `a` that belong to `S` by newly created identifiers, evaluates the result and substitutes back; the final result is put into a block. In order to evaluate `a` normally before putting it into a block, use`eval(hold(blockIdents(S))(a))`.

Blocks of type `blockIdents(S)` are evaluated in the same way as their contents at the time of creation (see above).

Blocks of type `blockIndents(S)` have the same operands as their content.

Sequences can also be put into blocks.

You can create further block domains using inheritance. This particularly useful for creating own `evaluate` or `testtype` methods. See “Example 6” on page 1-361.

The call `expr(b)` replaces all transparent blocks in `b` by their content, without evaluating that content.

In case of nested blocks, only the outermost block is removed by both `expr` and `unblock`.

Examples

Example 1

A block is a sort of container that protects its content against evaluation:

```
y:= 1: bl:= block(1+y)
```

$$1+y$$

Blocks are atomic; thus y and 1 are not visible as operands:

```
op(bl), nops(bl)
```

$$1+y,\ 1$$

Although blocks are not arithmetical expressions, some basic arithmetical operations are defined for them:

```
collect(x+bl+x*bl, bl);
delete y, bl:
```

$$(x+1)\,(1+y)+x$$

Example 2

Transparent blocks protect against evaluation, too:

```
y:= 2:
bl:=blockTransparent(x+y+z)
```

$$x+y+z$$

However, a transparent block allows access to the operands of its content:

```
op(bl,1), subs(bl, hold(y) = y)
```

$$x,\ x+2+z$$

```
delete bl, y:
```

Example 3

With a third kind of block, suppressing evaluation may be limited to certain identifiers:

```
x:= 3: y:=1:
blockIdents({hold(x)})(x+y)
```

$$x + 1$$

```
delete x, y:
```

Example 4

A block may also contain a sequence; flattening is suppressed:

```
block((x, y),z)
```

$$x, y, z$$

Example 5

The content of a block may be extracted and evaluated using `unblock`:

```
y:= 1: unblock(block(y)); delete y:
```

$$1$$

Example 6

We want to create blocks that represent arithmetical expressions. To do this, we need our own block domain that overloads `testtype`:

```
domain myblock
  inherits block;
  category  Cat::BaseCategory;
  testtype:= (bl, T) -> if T = Type::Arithmetical or T = dom then
```

```
                          TRUE
                        else
                          block::testtype(bl, T)
                        end_if;
end_domain:
```

This allows us to make the number zero invisible for the evaluator by enclosing it into a block, but to retain the option to plug it into special functions:

```
f := sin(x+myblock(0))
```

$$\sin(x+0)$$

We can now manipulate this expression, without being disturbed by automatic simplification:

```
expand(f)
```

$$\cos(0)\sin(x)+\cos(x)\sin(0)$$

```
 eval(unblock(%))
```

$$\sin(x)$$

Parameters

a

Any object or sequence of objects

s

Set of identifiers

Return Values

`blockIdents` creates objects of its own type.

See Also

MuPAD Functions

`block` | `blockTransparent` | `freeze` | `hold` | `unblock`

blockTransparent

Create a transparent block protected against evaluation

Syntax

```
blockTransparent(a)
```

Description

`blockTransparent(a)` creates a transparent block, which is left unchanged by evaluation, too, but treated as expression with the same operands as `a`.

`blockTransparent` is a domain. If `d` is any block domain, `d(a)` creates a block belonging to that domain, with content `a`.

`blockTransparent(a)` puts its argument into a block, without evaluating it. In order to evaluate `a` normally before putting it into a block of some kind, use `eval(hold(blockTransparent)(a))`.

Transparent blocks are invariant under evaluation.

Transparent blocks, on the other hand, have the same operands as their content..

Sequences can also be put into block; in the case of `blockTransparent`, they are not flattened. See “Example 4” on page 1-366.

You can create further block domains using inheritance. This particularly useful for creating own `evaluate` or `testtype` methods. See “Example 6” on page 1-366.

The call `expr(b)` replaces all transparent blocks in `b` by their content, without evaluating that content. Thus, `expr(blockTransparent(a))` is similar to `hold(a)`.

In case of nested blocks, only the outermost block is removed by both `expr` and `unblock`.

Examples

Example 1

A block is a sort of container that protects its content against evaluation:

```
y:= 1: bl:= block(1+y)
```

$$1+y$$

Blocks are atomic; thus `y` and `1` are not visible as operands:

```
op(bl), nops(bl)
```

$$1+y,\ 1$$

Although blocks are not arithmetical expressions, some basic arithmetical operations are defined for them:

```
collect(x+bl+x*bl, bl);
delete y, bl:
```

$$(x+1)\,(1+y)+x$$

Example 2

Transparent blocks protect against evaluation, too:

```
y:= 2:
bl:=blockTransparent(x+y+z)
```

$$x+y+z$$

However, a transparent block allows access to the operands of its content:

```
op(bl,1), subs(bl, hold(y) = y)
```

$$x,\ x+2+z$$

```
delete bl, y:
```

Example 3

With a third kind of block, suppressing evaluation may be limited to certain identifiers:

```
x:= 3: y:=1:
blockIdents({hold(x)})(x+y)
```

$$x + 1$$

```
delete x, y:
```

Example 4

A block may also contain a sequence; flattening is suppressed:

```
block((x, y),z)
```

$$x, y, z$$

Example 5

The content of a block may be extracted and evaluated using `unblock`:

```
y:= 1: unblock(block(y)); delete y:
```

$$1$$

Example 6

We want to create blocks that represent arithmetical expressions. To do this, we need our own block domain that overloads `testtype`:

```
domain myblock
  inherits block;
  category  Cat::BaseCategory;
  testtype:= (bl, T) -> if T = Type::Arithmetical or T = dom then
                          TRUE
```

```
                        else
                          block::testtype(bl, T)
                        end_if;
end_domain:
```

This allows us to make the number zero invisible for the evaluator by enclosing it into a block, but to retain the option to plug it into special functions:

```
f := sin(x+myblock(0))
```

$$\sin(x + 0)$$

We can now manipulate this expression, without being disturbed by automatic simplification:

```
expand(f)
```

$$\cos(0)\,\sin(x) + \cos(x)\,\sin(0)$$

```
 eval(unblock(%))
```

$$\sin(x)$$

Parameters

a

Any object or sequence of objects

Return Values

`blockTransparent` creates objects of its own type.

See Also

MuPAD Functions

`block` | `blockIdents` | `freeze` | `hold` | `unblock`

unblock

Replace blocks by their contents

Syntax

```
unblock(b, <blockdomain, <Recurse>>)
```

Description

`unblock(b)` replaces all blocks that appear as subexpressions in `b` by their contents.

`unblock(b)` replaces all blocks in `b` by the result of evaluating their content. Thus, `unblock(block(a))` should in most cases be equivalent to `a`. The behavior of `unblock` may be controlled by additional arguments. If a second argument `blockdomain` is given, only blocks belonging to a domain that inherits from `blockdomain` are replaced by their content. If `FALSE` is provided as a third argument, only `b` is replaced by its content if it is a block of suitable type itself.

The call `expr(b)` replaces all transparent blocks in `b` by their content, without evaluating that content. Thus, `expr(blockTransparent(a))` is similar to `hold(a)`.

In case of nested blocks, only the outermost block is removed by both `expr` and `unblock`.

Examples

Example 1

A block is a sort of container that protects its content against evaluation:

```
y:= 1: bl:= block(1+y)
```

$$1+y$$

Blocks are atomic; thus `y` and `1` are not visible as operands:

```
op(bl), nops(bl)
```

$$1+y,\ 1$$

Although blocks are not arithmetical expressions, some basic arithmetical operations are defined for them:

```
collect(x+bl+x*bl, bl);
delete y, bl:
```

$$(x+1)\,(1+y)+x$$

Example 2

Transparent blocks protect against evaluation, too:

```
y:= 2:
bl:=blockTransparent(x+y+z)
```

$$x+y+z$$

However, a transparent block allows access to the operands of its content:

```
op(bl,1), subs(bl, hold(y) = y)
```

$$x,\ x+2+z$$

```
delete bl, y:
```

Example 3

With a third kind of block, suppressing evaluation may be limited to certain identifiers:

```
x:= 3: y:=1:
blockIdents({hold(x)})(x+y)
```

$$x+1$$

```
delete x, y:
```

Example 4

A block may also contain a sequence; flattening is suppressed:

```
block((x, y),z)
```

$$x, y, z$$

Example 5

The content of a block may be extracted and evaluated using `unblock`:

```
y:= 1: unblock(block(y)); delete y:
```

$$1$$

Example 6

We want to create blocks that represent arithmetical expressions. To do this, we need our own block domain that overloads `testtype`:

```
domain myblock
  inherits block;
  category  Cat::BaseCategory;
  testtype:= (bl, T) -> if T = Type::Arithmetical or T = dom then
                          TRUE
                        else
                          block::testtype(bl, T)
                        end_if;
end_domain:
```

This allows us to make the number zero invisible for the evaluator by enclosing it into a block, but to retain the option to plug it into special functions:

```
f := sin(x+myblock(0))
```

$$\sin(x+0)$$

We can now manipulate this expression, without being disturbed by automatic simplification:

```
expand(f)
```

$$\cos(0)\,\sin(x) + \cos(x)\,\sin(0)$$

```
 eval(unblock(%))
```

$$\sin(x)$$

Parameters

`b`

Any object

`blockdomain`

Any domain that inherits from `block`

`Recurse`

TRUE or FALSE

Return Values

In most cases, the object b.

See Also

MuPAD Functions

`block` | `blockIdents` | `blockTransparent` | `freeze` | `hold`

bool

Boolean evaluation

Syntax

```
bool(b)
```

Description

`bool(b)` evaluates the Boolean expression `b`.

The function `bool` serves for reducing Boolean expressions to one of the Boolean constants `TRUE`, `FALSE`, or `UNKNOWN`.

Boolean expressions are expressions that are composed of equalities, inequalities, elementhood relations, and these constants, combined via the logical operators `and`, `or`, `not`.

The function `bool` evaluates all equalities and inequalities inside a Boolean expression to either `TRUE` or `FALSE`. The resulting logical combination of the Boolean constants is reduced according to the rules of the MuPAD three state logic (see `and`, `or`, `not`).

Note: Equations `x = y` and inequalities `x <> y` are evaluated *syntactically* by `bool`. It does not test equality in any mathematical sense.

Note: Inequalities `x < y`, `x <= y` etc. can be evaluated by `bool` if and only if `x` and `y` are real numbers of type `Type::Real`. Otherwise, an error occurs.

`bool` evaluates *all* subexpressions of a Boolean expression before simplifying the result. The functions `_lazy_and`, `_lazy_or` provide an alternative: “lazy Boolean evaluation”.

There is no need to use `bool` in the conditional part of `if`, `repeat`, and `while` statements. Internally, these statements enforce Boolean evaluation by `_lazy_and` and `_lazy_or`. Cf. “Example 5” on page 1-375.

Use `simplify` with the option `logic` to simplify expressions involving symbolic Boolean subexpressions. Cf. “Example 7” on page 1-376.

`bool` is overloadable not only for domains, but also for function environments. This means that, if `f` evaluates to a function environment, then `bool(f(x1, …, xn))` returns `f::bool( x1, …, xn )`, or an error if no slot `f::bool` exists.

The call `bool(x ~= y)` serves for comparing numerical values `x` and `y`. If both `x` and `y` can be converted to non-zero real or complex floating-point numbers, it is checked whether `float((x - y)/x)| < 10^(-DIGITS)` is satisfied. Thus, `TRUE` is returned if `x` and `y` coincide within the relative numerical precision set by `DIGITS`. For `x = 0`, the criterion is `|float(y)| < 10^(-DIGITS)`. For `y = 0`, the criterion is `|float(x)| < 10^(-DIGITS)`. If either `x` or `y` contains a symbolic object that cannot be converted to a real or complex floating point number, the function `bool` returns the value `UNKNOWN`.

Examples

Example 1

MuPAD realizes that 1 is less than 2:

```
1 < 2 = bool(1 < 2)
```

$$1 < 2 = \text{TRUE}$$

Note that `bool` can fail to compare real numbers expressed symbolically:

```
bool(sqrt(14) <= sqrt(2)*sqrt(7))
```

```
Error: Cannot evaluate to Boolean. [_leequal]
```

You can compare floating-point approximations. Alternatively, you can use `is`:

```
bool(float(sqrt(14)) <= float(sqrt(2)*sqrt(7))),
is(sqrt(14) <= sqrt(2)*sqrt(7))
```

$$\text{TRUE}, \text{TRUE}$$

Example 2

The Boolean operators `and`, `or`, `not` do not evaluate equations and inequalities logically, and return a symbolic Boolean expression. Boolean evaluation and simplification is enforced by `bool`:

```
a = a and 3 < 4
```

$$a = a \wedge 3 < 4$$

```
bool(a = a and 3 < 4)
```

TRUE

Example 3

`bool` handles the special Boolean constant `UNKNOWN`:

```
bool(UNKNOWN and 1 < 2), bool(UNKNOWN or 1 < 2),
bool(UNKNOWN and 1 > 2), bool(UNKNOWN or 1 > 2)
```

UNKNOWN, TRUE, FALSE, UNKNOWN

Example 4

`bool` must be able to reduce all parts of a composite Boolean expression to one of the Boolean constants. No symbolic Boolean subexpressions may be involved:

```
b := b1 and b2 or b3: bool(b)
```

```
Error: Cannot evaluate to Boolean. [bool]
```

```
b1 := 1 < 2: b2 := x = x: b3 := FALSE: bool(b)
```

TRUE

```
delete b, b1, b2, b3:
```

Example 5

There is no need to use `bool` explicitly in the conditional parts of `if`, `repeat`, and `while` statements. Note, however, that these structures internally use "lazy evaluation" via `_lazy_and` and `_lazy_or` rather than "complete Boolean evaluation" via `bool`:

```
x := 0: if x <> 0 and sin(1/x) = 0 then 1 else 2 end
```

```
    2
```

In contrast to "lazy evaluation", `bool` evaluates *all* conditions. Consequently, a division by zero occurs in the evaluation of `sin(1/x) = 0`:

```
bool(x <> 0 and sin(1/x) = 0)
```

```
Error: Division by zero. [_invert]
```

```
delete x:
```

Example 6

Note that `bool` does not operate recursively. The following calls are completely different, the first one comparing the expression `TRUE = TRUE` and the constant `TRUE` (syntactically), the second one comparing the result of another `bool`-call with `TRUE`:

```
bool((TRUE = TRUE) = TRUE);
bool(bool(TRUE = TRUE) = TRUE)
```

```
    FALSE
```

```
    TRUE
```

Since `if`, `while` and similar constructs use the same Boolean evaluation internally, this also effects conditions in such clauses:

```
if (is(a < b) = TRUE) or (3 = 3) then YES else NO end;
if (is(a < b) or (3 = 3)) = TRUE then YES else NO end
```

```
    YES
```

NO

Example 7

Expressions involving symbolic Boolean subexpressions cannot be processed by `bool`. However, `simplify` with the option `logic` can be used for simplification:

```
(b1 and b2) or (b1 and (not b2)) and (1 < 2)
```

$$(b1 \wedge b2) \vee (b1 \wedge \neg b2 \wedge 1 < 2)$$

```
simplify(%, logic)
```

b1

Parameters

b

A Boolean expression

Return Values

`TRUE`, `FALSE`, or `UNKNOWN`.

Overloaded By

b

MuPAD Functions

`_lazy_and` | `_lazy_or` | `FALSE` | `if` | `is` | `repeat` | `TRUE` | `UNKNOWN` | `while`

break, _break

Terminate a loop or a Case switch prematurely

Syntax

```
break
```

```
_break()
```

Description

`break` terminates `for`, `repeat`, `while` loops, and `case` statements.

The `break` statement is equivalent to the function call `_break()`. The return value is the void object of type `DOM_NULL`.

Inside `for`, `repeat`, `while`, and `case` statements, the `break` statement exits from the loop/switch. Execution proceeds with the next statement after the `end` clause of the loop/switch.

In nested loops, only the innermost loop is terminated by `break`.

`break` also terminates a statement sequence `_stmtseq(..., break, ...)`.

Outside `for`, `repeat`, `while`, `case`, and `_stmtseq`, the `break` statement has no effect.

Examples

Example 1

Loops are exited prematurely by `break`:

```
for i from 1 to 10 do
  print(i);
  if i = 2 then break end_if
end_for
```

```
    1

    2

delete i:
```

Example 2

In a `case` statement, all commands starting with the first matching branch are executed:

```
x := 2:
case x
 of 1 do print(1); x^2;
 of 2 do print(2); x^2;
 of 3 do print(3); x^2;
 otherwise print(UNKNOWN)
end_case:
```

```
    2

    3

    UNKNOWN
```

In the next version, `break` ensures that only the statements in the matching branch are evaluated:

```
case x
 of 1 do print(1); x^2; break;
 of 2 do print(2); x^2; break;
 of 3 do print(3); x^2; break;
 otherwise print(UNKNOWN)
end_case:
```

```
    2

delete x:
```

MuPAD Functions
`case` | `for` | `next` | `repeat` | `return` | `while`

buildnumber

The Build number of

Syntax

```
buildnumber()
```

Description

`buildnumber()` returns the "build number" of the MuPAD library.

`buildnumber` is a natural number increasing over time which enables the MuPAD developers to exactly identify the version of the library used. Its primary use is for cooperating partners with access to development versions.

Examples

Example 1

At the time of this writing, the MuPAD build number was 42703:

```
buildnumber()
```

```
42703
```

Return Values

Integer.

See Also

MuPAD Functions

`Pref::kernel | version`

bytes

Memory used by the current session

Syntax

```
bytes()
```

Description

`bytes()` returns the current memory consumption.

`bytes` returns the following three numbers:

- The number of bytes used logically; this is the amount of memory which is actually used for storing MuPAD data.
- The number of bytes physically allocated by the memory management; this is the amount of memory MuPAD has allocated from the operating system. The difference between the physical and the logical bytes is the amount of memory which has already been reserved for future calculations.
- The maximum number of bytes ever allocated from the operating system during the current session. This value *never* decreases, not even on a call to `reset`.

Examples

Example 1

In a freshly started MuPAD session, `bytes` may return the following data on the memory consumption of the session:

```
bytes()
```

```
837168, 1572864, 1703936
```

Each computation increases the memory usage:

```
sin(PI): bytes()

     970204, 1638400, 1703936

solve(x-1=0, x): bytes()

     2361864, 3014656, 3014656
```

Return Values

Sequence of three integers.

MuPAD Functions
`rtime` | `time`

card

Cardinality of a set

Syntax

```
card(set)
```

```
card(d)
```

Description

`card(set)` returns the cardinality of `set`.

If `set` is a `DOM_SET`, the number of operands is returned; `card` does not attempt to investigate whether the members of `set` really represent pairwise different mathematical objects.

`card` does not distinguish different infinite cardinals; it just returns `infinity` if `set` is infinite.

`card` returns a symbolic call to itself if it cannot determine the cardinality.

If applied to a domain `d`, `card` returns the domain entry `d::size`. A domain that does not have this entry is not regarded as a set.

Examples

Example 1

The cardinality of a finite set equals the number of its operands:

```
card({1, 2, 3})
```

```
3
```

This holds true even if there exist two operands of the set that represent the same mathematical object:

```
card({1, 1.0})
```

$$2$$

Example 2

`card` does not distinguish different sizes of infinite sets:

```
card(R_), card(Z_)
```

$$\infty, \infty$$

Example 3

Set-theoretic expressions containing symbols are legal input, but usually `card` will not be able to determine their cardinality:

```
card(S union {3})
```

$$|\{3\} \cup S|$$

Example 4

Domains that have a `"size"` entry are regarded as sets:

```
card(Dom::IntegerMod(7))
```

$$7$$

Parameters

`set`

A set of type `DOM_SET`, or a set-theoretic expression

d

A domain representing a set

Return Values

Nonnegative integer, or `infinity`.

Overloaded By

d, set

MuPAD Functions
nops

case, of, otherwise, end_case, _case

Switch statement

Syntax

```
case x
  of match1 do
    statements1
  of match2 do
    statements2
  ...
  otherwise
    otherstatements
end_case
```

```
case x
  of match1 do
    statements1
  of match2 do
    statements2
  ...
end_case
```

```
_case(x, match1, statements1, match2, statements2, , …, <otherstatements>)
```

Description

A `case-end_case` statement allows to switch between various branches in a program.

The `case` statement is a control structure that extends the functionality of the `if` statement. In a `case` statement, an object is compared with a number of given values and one or more statement sequences are executed.

If the value of `x` equals one of the values `match1`, `match2` etc., the first matching branch *and all its following branches (including `otherwise`)* are executed, until the execution is terminated by a `break` or a `return` statement, or the `end_case`.

If the value of `x` does not equal any of the values `match1, match2, ...`, only the `otherwise` branch is executed. If no `otherwise` branch exists, the `case` statement terminates and returns the void object of type `DOM_NULL`.

The keyword `end_case` may be replaced by the keyword `end`.

Examples

Example 1

All statements after the first match are executed:

```
x := 2:
case x
  of 1 do print(1)
  of 2 do print(4)
  of 3 do print(9)
  otherwise print("otherwise")
end_case:
```

```
    4

    9

    "otherwise"
```

`break` may be used to ensure that only one matching branch is executed:

```
case x
  of 1 do print(1); 1; break
  of 2 do print(4); 4; break
  of 3 do print(9); 9; break
  otherwise print("otherwise")
end_case:
```

```
    4
```

```
delete x:
```

Example 2

The functionality of the `case` statement allows to share code that is to be used in several branches. The following function uses the statement `print(x, "is a real number")` for the three branches that correspond to real MuPAD numbers:

```
isReal := proc(x)
begin
   case domtype(x)
     of DOM_INT do
     of DOM_RAT do
     of DOM_FLOAT do print(x, "is a real number"); break
     of DOM_COMPLEX do print(x, "is not a real number"); break
     otherwise print(x, "cannot decide");
   end_case
end_proc:
isReal(3), isReal(3/7), isReal(1.23), isReal(3 + I), isReal(z)
```

3, "is a real number"

$\frac{3}{7}$, "is a real number"

1.23, "is a real number"

$3 + i$, "is not a real number"

z, "cannot decide"

```
delete isReal:
```

Example 3

The correspondence between the functional and the imperative form of the `case` statement is demonstrated:

```
hold(_case(x, match1, (1; break), match2, (4; break),
           print("otherwise")))
```

```
case x
  of match1 do
    1;
    break
  of match2 do
    4;
    break
  otherwise
    print("otherwise")
end_case
```

```
hold(_case(x, match1, (1; break), match2, (4; break)))
```

```
case x
  of match1 do
    1;
    break
  of match2 do
    4;
    break
end_case
```

Parameters

`x, match1, match2, …`

Arbitrary MuPAD objects

`statements1, otherstatements, …`

Arbitrary sequences of statements

Return Values

Result of the last command executed inside the `case` statement. The void object of type `DOM_NULL` is returned if no matching branch was found and no `otherwise` branch exists. `NIL` is returned if a matching branch was encountered, but no command was executed inside this branch.

Algorithms

The functionality of the `case` statement corresponds to the `switch` statement of the C programming language.

MuPAD Functions
`break` | `if` | `return`

ceil

Rounding up to the next integer

Syntax

```
ceil(x)
```

Description

`ceil` rounds a number to the next larger integer.

For complex arguments, rounding is applied separately to the real and the imaginary parts.

Integers are returned for real numbers and exact expressions representing real numbers.

Unevaluated function calls are returned for arguments that contain symbolic identifiers.

For floating-point intervals, the result will be a floating-point interval containing all the results of applying the rounding function to the real or complex numbers inside the interval.

If you think of `x` as a floating-point number, then `trunc(x)` truncates the digits after the decimal point. Thus, `trunc` coincides with `floor` for real positive arguments and with `ceil` for real negative arguments, respectively.

Note: If the argument is a floating-point number of absolute value larger than 10^{DIGITS}, the resulting integer is affected by internal non-significant digits! Cf. “Example 3” on page 1-393.

Note: Internally, exact numerical expressions that are neither integers nor rational numbers are approximated by floating-point numbers before rounding. Thus, the resulting integer may depend on the present value of `DIGITS`! Cf. “Example 4” on page 1-394.

Environment Interactions

The functions are sensitive to the environment variable DIGITS which determines the numerical working precision.

Examples

Example 1

We demonstrate the rounding of real and complex numbers:

```
ceil(3.5), floor(3.5), round(3.5), trunc(3.5)
```

$$4,\ 3,\ 4,\ 3$$

```
ceil(-7/2), floor(-7/2), round(-7/2), trunc(-7/2)
```

$$-3,\ -4,\ -3,\ -3$$

```
ceil(3 + 5/2*I), floor(4.3 + 7*I), round(I/2), trunc(I/2)
```

$$3+3\,i,\ 4+7\,i,\ i,\ 0$$

Also symbolic expressions representing numbers can be rounded:

```
x := PI*I + 7*sin(exp(2)): ceil(x), floor(x), round(x), trunc(x)
```

$$7+4\,i,\ 6+3\,i,\ 6+3\,i,\ 6+3\,i$$

Rounding of expressions with symbolic identifiers produces unevaluated function calls:

```
delete x: ceil(x), floor(x - 1), round(x + 1), trunc(x^2 + 3)
```

$$\lceil x \rceil,\ \lfloor x-1 \rfloor,\ \mathrm{round}(x+1),\ \mathrm{trunc}(x^2+3)$$

Example 2

The call `round(x, n)` serves for rounding the `n`-th decimal digit of the floating-point representation of `x`:

```
round(123.456, 1), round(123.456, 2), round(123.456, 3),
round(123.456, 4), round(123.456, 5)
```

```
123.5, 123.46, 123.456, 123.456, 123.456
```

```
float(exp(5)*PI), round(exp(5)*PI, 3)
```

```
466.2536903, 466.254
```

The second argument may also be negative, leading to rounding of the digits to the left of the decimal point:

```
round(123.45, 1), round(123.45, 0), round(123.45, -1),
round(123.45, -2), round(123.45, -3)
```

```
123.4, 123.0, 120.0, 100.0, 0.0
```

Example 3

Care should be taken when rounding floating-point numbers of large absolute value:

```
x := 10^30/3.0
```

$3.333333333\ 10^{29}$

Note that only the first 10 decimal digits are “significant”. Further digits are subject to round-off effects caused by the internal binary representation. These “insignificant” digits are part of the integer produced by rounding:

```
floor(x), ceil(x)
```

```
333333333333333332997967970304, 333333333333333332997967970304
```

```
delete x:
```

Example 4

Exact numerical expressions are internally converted to floating point numbers before rounding. Consequently, the present setting of `DIGITS` can affect the result:

```
x := 10^30 - exp(30)^ln(10)
```

$$10000000000000000000000000000 - (e^{30})^{\ln(10)}$$

Note that the exact value of this number is 0. Floating point evaluation is subject to severe cancellations:

```
DIGITS := 10: float(x), floor(x), ceil(x)
```

$$-6.157265116\ 10^{13},\ 671088640,\ 671088640$$

The floating-point result is more accurate when a higher precision is used. The rounded values change accordingly:

```
DIGITS := 20: float(x), floor(x), ceil(x)
```

$$5504.0,\ 5504,\ 5504$$

```
DIGITS := 30: float(x), floor(x), ceil(x)
```

$$0.000000312924385070800781 25,\ 0,\ 1$$

```
delete x, DIGITS:
```

Example 5

On floating-point intervals, `ceil` and `floor` behave as expected:

```
ceil(3.5...6.7); floor(3.5...6.7)
```

$$4.0 \ldots 7.0$$

$$3.0 \ldots 6.0$$

These intervals, as easily seen, contain the results of `ceil(x)` and `floor(x)` for all $x \in 3.5 \ldots 6.7$, respectively.

Because there are finite numbers represented as `RD_INF` and `RD_NINF`, respectively, `ceil` and `floor` return very small or large representable numbers in certain cases:

```
ceil(RD_NINF...RD_NINF)
```

$$\text{RD\_NINF} \ldots -2.098578716\ 10^{323228496}$$

Parameters

x

An arithmetical expression or a floating-point interval

Return Values

Arithmetical expression.

Overloaded By

x

MuPAD Functions

`floor` | `frac` | `round` | `trunc`

floor

Rounding down to the next integer

Syntax

```
floor(x)
```

Description

`floor` rounds a number to the next smaller integer.

For complex arguments, rounding is applied separately to the real and the imaginary parts.

Integers are returned for real numbers and exact expressions representing real numbers.

Unevaluated function calls are returned for arguments that contain symbolic identifiers.

For floating-point intervals, the result will be a floating-point interval containing all the results of applying the rounding function to the real or complex numbers inside the interval.

If you think of `x` as a floating-point number, then `trunc(x)` truncates the digits after the decimal point. Thus, `trunc` coincides with `floor` for real positive arguments and with `ceil` for real negative arguments, respectively.

Note: If the argument is a floating-point number of absolute value larger than 10^{DIGITS}, the resulting integer is affected by internal non-significant digits! Cf. “Example 3” on page 1-398.

Note: Internally, exact numerical expressions that are neither integers nor rational numbers are approximated by floating-point numbers before rounding. Thus, the resulting integer may depend on the present value of `DIGITS`! Cf. “Example 4” on page 1-399.

Environment Interactions

The functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate the rounding of real and complex numbers:

```
ceil(3.5), floor(3.5), round(3.5), trunc(3.5)
```

$$4,\ 3,\ 4,\ 3$$

```
ceil(-7/2), floor(-7/2), round(-7/2), trunc(-7/2)
```

$$-3,\ -4,\ -3,\ -3$$

```
ceil(3 + 5/2*I), floor(4.3 + 7*I), round(I/2), trunc(I/2)
```

$$3+3\,i,\ 4+7\,i,\ i,\ 0$$

Also symbolic expressions representing numbers can be rounded:

```
x := PI*I + 7*sin(exp(2)): ceil(x), floor(x), round(x), trunc(x)
```

$$7+4\,i,\ 6+3\,i,\ 6+3\,i,\ 6+3\,i$$

Rounding of expressions with symbolic identifiers produces unevaluated function calls:

```
delete x: ceil(x), floor(x - 1), round(x + 1), trunc(x^2 + 3)
```

$$\lceil x \rceil,\ \lfloor x-1 \rfloor,\ \mathrm{round}(x+1),\ \mathrm{trunc}(x^2+3)$$

Example 2

The call `round(x, n)` serves for rounding the `n`-th decimal digit of the floating-point representation of `x`:

```
round(123.456, 1), round(123.456, 2), round(123.456, 3),
round(123.456, 4), round(123.456, 5)
```

```
123.5, 123.46, 123.456, 123.456, 123.456
```

```
float(exp(5)*PI), round(exp(5)*PI, 3)
```

```
466.2536903, 466.254
```

The second argument may also be negative, leading to rounding of the digits to the left of the decimal point:

```
round(123.45, 1), round(123.45, 0), round(123.45, -1),
round(123.45, -2), round(123.45, -3)
```

```
123.4, 123.0, 120.0, 100.0, 0.0
```

Example 3

Care should be taken when rounding floating-point numbers of large absolute value:

```
x := 10^30/3.0
```

$3.333333333\ 10^{29}$

Note that only the first 10 decimal digits are “significant”. Further digits are subject to round-off effects caused by the internal binary representation. These “insignificant” digits are part of the integer produced by rounding:

```
floor(x), ceil(x)
```

```
333333333333333332997967970304, 333333333333333332997967970304
```

```
delete x:
```

Example 4

Exact numerical expressions are internally converted to floating point numbers before rounding. Consequently, the present setting of `DIGITS` can affect the result:

```
x := 10^30 - exp(30)^ln(10)
```

$$10000000000000000000000000000 - (e^{30})^{\ln(10)}$$

Note that the exact value of this number is 0. Floating point evaluation is subject to severe cancellations:

```
DIGITS := 10: float(x), floor(x), ceil(x)
```

$$-6.157265116\ 10^{13},\ 671088640,\ 671088640$$

The floating-point result is more accurate when a higher precision is used. The rounded values change accordingly:

```
DIGITS := 20: float(x), floor(x), ceil(x)
```

$$5504.0,\ 5504,\ 5504$$

```
DIGITS := 30: float(x), floor(x), ceil(x)
```

$$0.000000312924385070800781 25,\ 0,\ 1$$

```
delete x, DIGITS:
```

Example 5

On floating-point intervals, `ceil` and `floor` behave as expected:

```
ceil(3.5...6.7); floor(3.5...6.7)
```

$$4.0 \ldots 7.0$$

$$3.0 \ldots 6.0$$

These intervals, as easily seen, contain the results of `ceil(x)` and `floor(x)` for all $x \in 3.5 \ldots 6.7$, respectively.

Because there are finite numbers represented as `RD_INF` and `RD_NINF`, respectively, `ceil` and `floor` return very small or large representable numbers in certain cases:

```
ceil(RD_NINF...RD_NINF)
```

$$\text{RD\_NINF} \ldots -2.098578716\ 10^{323228496}$$

Parameters

x

An arithmetical expression or a floating-point interval

Return Values

Arithmetical expression.

Overloaded By

x

MuPAD Functions

`ceil` | `frac` | `round` | `trunc`

round

Rounding to the nearest integer

Syntax

```
round(x, <n>)
```

Description

`round` rounds a number to the nearest integer.

For complex arguments, rounding is applied separately to the real and the imaginary parts.

For the call `round(x, n)`, the result is a floating-point number with the `n`-th decimal digit after the decimal point being rounded. All further digits are set to zero. If the integer `n` is negative, the corresponding digit to the left of the decimal point is rounded. Cf. “Example 2” on page 1-403.

Unevaluated function calls are returned for arguments that contain symbolic identifiers.

For floating-point intervals, the result will be a floating-point interval containing all the results of applying the rounding function to the real or complex numbers inside the interval.

Note: If the argument is a floating-point number of absolute value larger than 10^{DIGITS}, the resulting integer is affected by internal non-significant digits! Cf. “Example 3” on page 1-403.

Note: Internally, exact numerical expressions that are neither integers nor rational numbers are approximated by floating-point numbers before rounding. Thus, the resulting integer may depend on the present value of `DIGITS`! Cf. “Example 4” on page 1-404.

Environment Interactions

The functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate the rounding of real and complex numbers:

```
ceil(3.5), floor(3.5), round(3.5), trunc(3.5)
```

$$4,\ 3,\ 4,\ 3$$

```
ceil(-7/2), floor(-7/2), round(-7/2), trunc(-7/2)
```

$$-3,\ -4,\ -3,\ -3$$

```
ceil(3 + 5/2*I), floor(4.3 + 7*I), round(I/2), trunc(I/2)
```

$$3+3\,i,\ 4+7\,i,\ i,\ 0$$

Also symbolic expressions representing numbers can be rounded:

```
x := PI*I + 7*sin(exp(2)): ceil(x), floor(x), round(x), trunc(x)
```

$$7+4\,i,\ 6+3\,i,\ 6+3\,i,\ 6+3\,i$$

Rounding of expressions with symbolic identifiers produces unevaluated function calls:

```
delete x: ceil(x), floor(x - 1), round(x + 1), trunc(x^2 + 3)
```

$$\lceil x \rceil,\ \lfloor x-1 \rfloor,\ \mathrm{round}(x+1),\ \mathrm{trunc}(x^2+3)$$

Example 2

The call `round(x, n)` serves for rounding the `n`-th decimal digit of the floating-point representation of `x`:

```
round(123.456, 1), round(123.456, 2), round(123.456, 3),
round(123.456, 4), round(123.456, 5)
```

123.5, 123.46, 123.456, 123.456, 123.456

```
float(exp(5)*PI), round(exp(5)*PI, 3)
```

466.2536903, 466.254

The second argument may also be negative, leading to rounding of the digits to the left of the decimal point:

```
round(123.45, 1), round(123.45, 0), round(123.45, -1),
round(123.45, -2), round(123.45, -3)
```

123.4, 123.0, 120.0, 100.0, 0.0

Example 3

Care should be taken when rounding floating-point numbers of large absolute value:

```
x := 10^30/3.0
```

$3.333333333\ 10^{29}$

Note that only the first 10 decimal digits are “significant”. Further digits are subject to round-off effects caused by the internal binary representation. These “insignificant” digits are part of the integer produced by rounding:

```
floor(x), ceil(x)
```

333333333333333332997967970304, 333333333333333332997967970304

```
delete x:
```

Example 4

Exact numerical expressions are internally converted to floating point numbers before rounding. Consequently, the present setting of `DIGITS` can affect the result:

```
x := 10^30 - exp(30)^ln(10)
```

$$10000000000000000000000000000 - (e^{30})^{\ln(10)}$$

Note that the exact value of this number is 0. Floating point evaluation is subject to severe cancellations:

```
DIGITS := 10: float(x), floor(x), ceil(x)
```

$$-6.157265116\ 10^{13},\ 671088640,\ 671088640$$

The floating-point result is more accurate when a higher precision is used. The rounded values change accordingly:

```
DIGITS := 20: float(x), floor(x), ceil(x)
```

$$5504.0,\ 5504,\ 5504$$

```
DIGITS := 30: float(x), floor(x), ceil(x)
```

$$0.000000312924385070800781 25,\ 0,\ 1$$

```
delete x, DIGITS:
```

Example 5

On floating-point intervals, `ceil` and `floor` behave as expected:

```
ceil(3.5...6.7); floor(3.5...6.7)
```

$$4.0 \ldots 7.0$$

$$3.0 \ldots 6.0$$

These intervals, as easily seen, contain the results of `ceil(x)` and `floor(x)` for all $x \in 3.5 \ldots 6.7$, respectively.

Because there are finite numbers represented as `RD_INF` and `RD_NINF`, respectively, `ceil` and `floor` return very small or large representable numbers in certain cases:

```
ceil(RD_NINF...RD_NINF)
```

$$\text{RD\_NINF} \ldots -2.098578716\ 10^{323228496}$$

Parameters

x

An arithmetical expression or a floating-point interval

n

An integer. If `n` is positive, the `n`-th digit after the decimal point is rounded. If `n` is negative, the `|n|`-th digit before the decimal point is rounded.

Return Values

Arithmetical expression.

Overloaded By

x

MuPAD Functions

`ceil` | `floor` | `frac` | `trunc`

trunc

Rounding towards zero

Syntax

```
trunc(x)
```

Description

`trunc` rounds a number to the next integer in the direction of 0.

For complex arguments, rounding is applied separately to the real and the imaginary parts.

Integers are returned for real numbers and exact expressions representing real numbers.

Unevaluated function calls are returned for arguments that contain symbolic identifiers.

For floating-point intervals, the result will be a floating-point interval containing all the results of applying the rounding function to the real or complex numbers inside the interval.

If you think of `x` as a floating-point number, then `trunc(x)` truncates the digits after the decimal point. Thus, `trunc` coincides with `floor` for real positive arguments and with `ceil` for real negative arguments, respectively.

Note: If the argument is a floating-point number of absolute value larger than 10^{DIGITS}, the resulting integer is affected by internal non-significant digits! Cf. “Example 3” on page 1-408.

Note: Internally, exact numerical expressions that are neither integers nor rational numbers are approximated by floating-point numbers before rounding. Thus, the resulting integer may depend on the present value of `DIGITS`! Cf. “Example 4” on page 1-409.

Environment Interactions

The functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate the rounding of real and complex numbers:

```
ceil(3.5), floor(3.5), round(3.5), trunc(3.5)
```

$$4,\ 3,\ 4,\ 3$$

```
ceil(-7/2), floor(-7/2), round(-7/2), trunc(-7/2)
```

$$-3,\ -4,\ -3,\ -3$$

```
ceil(3 + 5/2*I), floor(4.3 + 7*I), round(I/2), trunc(I/2)
```

$$3+3\,i,\ 4+7\,i,\ i,\ 0$$

Also symbolic expressions representing numbers can be rounded:

```
x := PI*I + 7*sin(exp(2)): ceil(x), floor(x), round(x), trunc(x)
```

$$7+4\,i,\ 6+3\,i,\ 6+3\,i,\ 6+3\,i$$

Rounding of expressions with symbolic identifiers produces unevaluated function calls:

```
delete x: ceil(x), floor(x - 1), round(x + 1), trunc(x^2 + 3)
```

$$\lceil x \rceil,\ \lfloor x-1 \rfloor,\ \mathrm{round}(x+1),\ \mathrm{trunc}(x^2+3)$$

Example 2

The call `round(x, n)` serves for rounding the `n`-th decimal digit of the floating-point representation of `x`:

```
round(123.456, 1), round(123.456, 2), round(123.456, 3),
round(123.456, 4), round(123.456, 5)
```

123.5, 123.46, 123.456, 123.456, 123.456

```
float(exp(5)*PI), round(exp(5)*PI, 3)
```

466.2536903, 466.254

The second argument may also be negative, leading to rounding of the digits to the left of the decimal point:

```
round(123.45, 1), round(123.45, 0), round(123.45, -1),
round(123.45, -2), round(123.45, -3)
```

123.4, 123.0, 120.0, 100.0, 0.0

Example 3

Care should be taken when rounding floating-point numbers of large absolute value:

```
x := 10^30/3.0
```

$3.333333333\ 10^{29}$

Note that only the first 10 decimal digits are “significant”. Further digits are subject to round-off effects caused by the internal binary representation. These “insignificant” digits are part of the integer produced by rounding:

```
floor(x), ceil(x)
```

333333333333333332997967970304, 333333333333333332997967970304

```
delete x:
```

Example 4

Exact numerical expressions are internally converted to floating point numbers before rounding. Consequently, the present setting of `DIGITS` can affect the result:

```
x := 10^30 - exp(30)^ln(10)
```

$$10000000000000000000000000000 - (e^{30})^{\ln(10)}$$

Note that the exact value of this number is 0. Floating point evaluation is subject to severe cancellations:

```
DIGITS := 10: float(x), floor(x), ceil(x)
```

$$-6.157265116\ 10^{13},\ 671088640,\ 671088640$$

The floating-point result is more accurate when a higher precision is used. The rounded values change accordingly:

```
DIGITS := 20: float(x), floor(x), ceil(x)
```

$$5504.0,\ 5504,\ 5504$$

```
DIGITS := 30: float(x), floor(x), ceil(x)
```

$$0.000000312924385070800781 25,\ 0,\ 1$$

```
delete x, DIGITS:
```

Example 5

On floating-point intervals, `ceil` and `floor` behave as expected:

```
ceil(3.5...6.7); floor(3.5...6.7)
```

$$4.0 \ldots 7.0$$

$$3.0 \ldots 6.0$$

These intervals, as easily seen, contain the results of `ceil(x)` and `floor(x)` for all $x \in 3.5 \ldots 6.7$, respectively.

Because there are finite numbers represented as `RD_INF` and `RD_NINF`, respectively, `ceil` and `floor` return very small or large representable numbers in certain cases:

```
ceil(RD_NINF...RD_NINF)
```

$$\text{RD\_NINF} \ldots -2.098578716\ 10^{323228496}$$

Parameters

x

An arithmetical expression or a floating-point interval

Return Values

Arithmetical expression.

MuPAD Functions

`ceil` | `floor` | `frac` | `round`

Ci

Cosine integral function

Syntax

```
Ci(x)
```

Description

`Ci(x)` represents the cosine integral $\mathrm{EULER} + \ln(x) + \int_0^x \frac{\cos(t)-1}{t}\,dt$.

If `x` is a floating-point number, then `Ci(x)` returns numerical values. The special values $Ci(\infty) = 0$ and $Ci(-\infty) = i\pi$ are implemented. For all other arguments, `Ci` returns symbolic function calls.

The float attribute of `Ci` is a kernel function, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
Ci(1), Ci(sqrt(2)), Ci(x + 1), Ci(infinity), Ci(-infinity)
```

$$\mathrm{Ci}(1),\ \mathrm{Ci}(\sqrt{2}),\ \mathrm{Ci}(x+1),\ 0,\ \pi\,i$$

```
Chi(1), Chi(sqrt(2)), Chi(x + 1), Chi(I*infinity), Chi(-I*infinity)
```

$$\mathrm{Chi}(1),\ \mathrm{Chi}(\sqrt{2}),\ \mathrm{Chi}(x+1),\ \frac{\pi\,i}{2},\ -\frac{\pi\,i}{2}$$

Floating point values are computed for floating-point arguments:

```
Ci(1.0), Ci(2.0 + 10.0*I)
```

$$0.3374039229,\ -242.5252694 - 1185.8387\,i$$

```
Chi(1.0), Chi(2.0 + 10.0*I)
```

$$0.837866941,\ -0.229320148 + 1.848954746\,i$$

Example 2

`Ci` and `Chi` are singular at the origin:

```
Ci(0)
```

```
Error: Singularity. [Ci]
```

```
Chi(0)
```

```
Error: Singularity. [Chi]
```

The negative real axis is a branch cut of `Ci` and `Chi`. A jump of height $2\,\pi\,i$ occurs when crossing this cut:

```
Ci(-1.0), Ci(-1.0 + 10^(-10)*I), Ci(-1.0 - 10^(-10)*I)
```

$$0.3374039229 + 3.141592654\,i,\ 0.3374039229 + 3.141592654\,i,\ 0.3374039229 - 3.141592654\,i$$

```
Chi(-1.0), Chi(-1.0 + 10^(-10)*I), Chi(-1.0 - 10^(-10)*I)
```

$$0.837866941 + 3.141592654\,i,\ 0.837866941 + 3.141592653\,i,\ 0.837866941 - 3.141592653\,i$$

Example 3

The functions `diff`, `float`, and `series` handle expressions involving `Ci` and `Chi`:

```
diff(Ci(x), x, x, x), float(ln(3 + Ci(sqrt(PI))))
```

$$\frac{2\cos(x)}{x^3} - \frac{\cos(x)}{x} + \frac{2\sin(x)}{x^2},\ 1.241299561$$

```
diff(Chi(x), x, x, x), float(ln(3 + Chi(sqrt(PI))))
```

$$\frac{\cosh(x)}{x} + \frac{2\cosh(x)}{x^3} - \frac{2\sinh(x)}{x^2},\ 1.618452185$$

```
series(Ci(x), x = 0)
```

$$\mathrm{EULER} + \ln(x) - \frac{x^2}{4} + \frac{x^4}{96} + O(x^6)$$

```
series(Chi(x), x = 0)
```

$$\mathrm{EULER} + \ln(x) + \frac{x^2}{4} + \frac{x^4}{96} + O(x^6)$$

```
series(Ci(x), x = infinity, 5)
```

$$\frac{\sin(x)}{x} - \frac{\cos(x)}{x^2} - \frac{2\sin(x)}{x^3} + \frac{6\cos(x)}{x^4} + \frac{24\sin(x)}{x^5} + O\left(\frac{1}{x^6}\right)$$

```
series(Chi(x), x = infinity, 3);
```

$$\frac{e^x}{2x} + \frac{e^x}{2x^2} + \frac{e^x}{x^3} + \frac{3e^x}{x^4} + O\left(\frac{e^x}{x^5}\right)$$

Parameters

x

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

x

Algorithms

The functions `Ci(x)-ln(x)` and `Chi(x)-ln(x)` are entire functions. Thus, `Ci` and `Chi` have a logarithmic singularity at the origin and a branch cut along the negative real axis. The values on the negative real axis coincide with the limit “from above”:

$$\mathrm{Ci}(x) = \lim_{\varepsilon \to 0^+} \mathrm{Ci}(x + \varepsilon\, \mathrm{i}),\ \mathrm{Chi}(x) = \lim_{\varepsilon \to 0^+} \mathrm{Chi}(x + \varepsilon\, \mathrm{i})$$

for real $x < 0$.

`Ci` and `Chi` are related by $Ci(x) - ln(x) = Chi(\mathrm{i}\, x) - ln(\mathrm{i}\, x)$ for all x in the complex plane.

Chi

Hyperbolic cosine integral function

Syntax

```
Chi(x)
```

Description

`Chi(x)` represents the hyperbolic cosine integral $\mathrm{EULER} + \ln(x) + \int_0^x \frac{\cosh(t)-1}{t}\,dt$.

If `x` is a floating-point number, then `Chi(x)` returns numerical values. The special values $Chi(\infty) = \infty$, $Chi(-\infty) = \infty + i\pi$, $\mathrm{Chi}(i\infty) = \frac{i\pi}{2}$, and $\mathrm{Chi}(-i\infty) = -\frac{i\pi}{2}$ are implemented. For all other arguments `Chi` returns symbolic function calls.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
Ci(1), Ci(sqrt(2)), Ci(x + 1), Ci(infinity), Ci(-infinity)

MuPAD Functions

`Ci` | `cos` | `Ei` | `int` | `Shi` | `Si` | `Ssi`

coeff

Coefficients of a polynomial

Syntax

```
coeff(p, <All>)

coeff(p, <x>, n, <All>)

coeff(p, <[x, …]>, [n, …], <All>)

coeff(f, <vars>, <All>)

coeff(f, <vars>, <x>, n, <All>)

coeff(f, <vars>, <[x, …]>, [n, …], <All>)
```

Description

`coeff(p)` returns a sequence of all nonzero coefficients of the polynomial `p`.

`coeff(p, x, n)` regards `p` as a univariate polynomial in `x` and returns the coefficient of the term `x^n`.

`coeff(p, [x,...], [n,...])` regards `p` as a multivariate polynomial in `x,...` and returns the coefficient of the term `x^n,...`.

If the first argument `f` is not element of a polynomial domain, then `coeff` converts the expression internally to a polynomial of type `DOM_POLY` via `poly(f)`. If a list of indeterminates is specified, the polynomial `poly(f, vars)` is considered.

Coefficients of polynomial expressions `f` are returned as arithmetical expressions.

There are various ways to call `coeff` with a polynomial `p` of type `DOM_POLY`:

- `coeff(p)` returns a sequence of all nonzero coefficients of `p`. They are ordered according to the lexicographical term ordering. The order in descending.

  The returned coefficients are elements of the coefficient ring of `p`.

- `coeff(p, x, n)` regards `p` as a univariate polynomial in the variable `x` and returns the coefficient of the term `x^n`.

  For univariate polynomials, the returned coefficients are elements of the coefficient ring of `p`.

  For multivariate polynomials, the coefficients are returned as polynomials of type `DOM_POLY` in the "remaining" variables.
- `coeff(p, n)` is equivalent to `coeff(p, x, n)`, where `x` is the "main variable" of `p`. This variable is the first element of the list of indeterminates `op(p, 2)`.
- `coeff(p, [x1,x2,...], [n1,n2,...])` regards `p` as a multivariate polynomial in the variables `x1,x2,...` and returns the coefficient of the term `x1^n1*x2^n2...`. Variable and exponent lists must have the same length.

  The returned coefficients are either elements of the coefficient ring of `p` or polynomials of type `DOM_POLY` in the "remaining" variables.
- `coeff(p, [n1,n2,...])` is equivalent to `coeff(p, [x1,x2,...], [n1,n2,...])`, where the variables `x1,x2,...` are the "main variables" of `p`, i.e., the leading elements of the list of indeterminates `op(p, 2)`.
- `coeff(p, All)` returns a sequence of coefficients of `p` including those equal to zero. The function returns the result in ascending lexicographical order. For univariate polynomial `p`, the call `coeff(p, All)` is equivalent to `coeff(p, i) $ i = 0 .. degree(p)`.

`coeff` returns 0 or a zero polynomial if the polynomial does not contain a term corresponding to the specified powers. In particular, this happens for a univariate polynomial if `n` is larger than the degree of the polynomial.

`coeff` returns `FAIL` if an expression cannot be regarded as a polynomial.

The result of `coeff` is not fully evaluated. Evaluation can be enforced by the function `eval`. See "Example 5" on page 1-423.

Examples

Example 1

`coeff(f)` returns a sequence of all non-zero coefficients:

```
f := 10*x^10 + 5*x^5 + 2*x^2: coeff(f)
```

$$10, 5, 2$$

`coeff(f, i)` returns a single coefficient:

```
coeff(f, i) $ i = 0..15
```

$$0, 0, 2, 0, 0, 5, 0, 0, 0, 0, 10, 0, 0, 0, 0, 0$$

```
delete f:
```

Example 2

We demonstrate how the indeterminates influence the result:

```
f := 3*x^3 + x^2*y^2 + 17*x + 23*y + 2
```

$$3\,x^3 + x^2\,y^2 + 17\,x + 23\,y + 2$$

```
coeff(f); coeff(f, [x, y]); coeff(f, [y, x])
```

$$3, 1, 17, 23, 2$$

$$3, 1, 17, 23, 2$$

$$1, 23, 3, 17, 2$$

```
delete f:
```

Example 3

The coefficients of `f` are selected with respect to the main variable `x` which is the first entry of the list of indeterminates:

```
f := 3*x^3 + x^2*y^2 + 2: coeff(f, [x, y], i) $ i = 0..3
```

$$2,\ 0,\ y^2,\ 3$$

The coefficients of `f` can be selected with respect to another main variable (in this case, `y`):

```
coeff(f, [y, x], i) $ i = 0..2
```

$$3\,x^3+2,\ 0,\ x^2$$

Alternatively:

```
coeff(f, y, i) $ i = 0..2
```

$$3\,x^3+2,\ 0,\ x^2$$

The coefficients of `f` can also be selected with respect to a multivariate term:

```
coeff(f, [x,y], [3,0]),
coeff(f, [x,y], [2,2]),
coeff(f, [x,y], [0,0])
```

$$3,\ 1,\ 2$$

```
delete f:
```

Example 4

In the same way, `coeff` can be applied to polynomials of type `DOM_POLY`:

```
p := poly(3*x^3 + x, [x], Dom::IntegerMod(7)):
coeff(p)
```

$$3 \bmod 7,\ 1 \bmod 7$$

```
coeff(p, i) $ i = 0..3
```

$$0 \bmod 7,\ 1 \bmod 7,\ 0 \bmod 7,\ 3 \bmod 7$$

For multivariate polynomials, the coefficients with respect to an indeterminate are polynomials in the other indeterminates:

```
p := poly(3*x^3 + x^2*y^2 + 2, [x, y]):
```

```
coeff(p, y, 0), coeff(p, y, 1), coeff(p, y, 2);
```

$$\mathrm{poly}(3x^3+2, [x]),\ \mathrm{poly}(0, [x]),\ \mathrm{poly}(x^2, [x])$$

```
coeff(p, x, 0), coeff(p, x, 1), coeff(p, x, 2)
```

$$\mathrm{poly}(2, [y]),\ \mathrm{poly}(0, [y]),\ \mathrm{poly}(y^2, [y])$$

Note that the indeterminates passed to `coeff` will be used, even if the polynomial provides different indeterminates :

```
coeff(p, z, 0), coeff(p, z, 1), coeff(p, z, 2)
```

$$\mathrm{poly}(3x^3+x^2y^2+2, [x, y]),\ \mathrm{poly}(0, [x, y]),\ \mathrm{poly}(0, [x, y])$$

```
delete p:
```

Example 5

The result of `coeff` is not fully evaluated:

```
p := poly(27*x^2 + a*x, [x]): a := 5:
coeff(p, x, 1), eval(coeff(p, x, 1))
```

$$a,\ 5$$

```
delete p, a:
```

Example 6

To return all coefficients of a polynomial, use the `All` option:

```
p := poly(a*x^3 + b*x^2 + c*x + d, [x, y]):
```

```
coefficients := coeff(p, All)
```

$$d, c, b, a$$

To revert the order of the resulting sequence, use the `revert` function. This function does not operate on sequences. To convert a sequence to a list, call `revert` for this list, and convert the result back to a sequence:

```
op(revert([coefficients]))
```

$$a, b, c, d$$

The `All` option also works for polynomial expressions:

```
p_expr := 2*x^5 + 5*x^2 + 10*x + 3:
coeff(p_expr, All)
```

$$3, 10, 5, 0, 0, 2$$

You can use the `coeff` function with the `All` option to compute scalar products of polynomials. For example, the following procedure computes a scalar product of two polynomials in an orthonormal basis. The `coeff` function extracts the coefficients of the polynomials and returns two lists of coefficients. The `zip` function multiplies the entries of these lists pairwise and returns a list. The `op` function accesses the entries of that list. Finally, the `_plus` function computes the sum of all products:

```
scalarProduct := proc(p, q)
  local lp, lq;
begin
  lp := [coeff(p, All)];
  lq := [coeff(conjugate(q), All)];
_plus(op(zip(lp, lq, _mult)));
end_proc:
```

The following polynomials are orthogonal:

```
scalarProduct(poly(x^2 + 2), poly(x^3 + 2*x^2 - 1))
```

$$0$$

Example 7

`coeff(p, All)` also works for multivariate polynomials and polynomial expressions:

```
p := poly(2*x^2*y + PI*x + y^2 - 2, [x, y]):
coeff(p, All)
```

$$-2,\ 0,\ 1,\ \pi,\ 0,\ 0,\ 0,\ 2,\ 0$$

For a multivariate polynomial or polynomial expression, the order in which `coeff` returns the coefficients is such that the coefficient of the exponent vector $[e_1, e_2, \ldots]$ appears at position $e_1 d_1 + e_2 d_2 + \ldots + 1$. For example, represent the coefficients returned for bivariate polynomial as a matrix:

```
A := matrix(degree(p, x) + 1, degree(p, y) + 1, [coeff(p, All)])
```

$$\begin{pmatrix} -2 & 0 & 1 \\ \pi & 0 & 0 \\ 0 & 2 & 0 \end{pmatrix}$$

Parameters

`p`

A polynomial of type `DOM_POLY`

`x`

An indeterminate

`n`

A power: a nonnegative integer

`f`

A polynomial expression

`vars`

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

Options

`All`

The `coeff` function with this option returns all the coefficients of a polynomial or a polynomial expression including those equal to zero. The function returns the result in ascending lexicographical order. See “Example 6” on page 1-423 and “Example 7” on page 1-425.

Return Values

One or more coefficients of the coefficient ring of the polynomial, or a polynomial, or `FAIL`.

Overloaded By

f, p

coerce

Type conversion

Syntax

```
coerce(object, T)
```

Description

`coerce(object, T)` tries to convert `object` into an element of the domain `T`.

If this is not possible or not implemented, then `FAIL` is returned.

Domains usually implement the two methods `"convert"` and `"convert_to"` for conversion tasks.

`coerce` uses these methods in the following way: It first calls `T::convert(object)` to perform the conversion. If this call yields `FAIL`, then the result of the call `object::dom::convert_to(object, T)` is returned, which again may be the value `FAIL`.

To find out the possible conversions for the `object` or which conversions are provided by the domain `T`, please read the description of the method `"coerce"` or `"convert"`, respectively, that can be found on the help page of the domain `T`, and the description of the method `"convert_to"` on the help page of the domain of `object`.

Only few basic domains currently implement the methods `"convert"` and `"convert_to"`.

Use the function `expr` to convert an object into an element of a basic domain.

Note that often a conversion can also be achieved by a call of the constructor of the domain `T`. See “Example 3” on page 1-430.

Examples

Example 1

We start with the conversion of an array into a list of domain type DOM_LIST:

```
a := array(1..2, 1..3, [[1, 2, 3], [4, 5, 6]])
```

$$\begin{pmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{pmatrix}$$

```
coerce(a, DOM_LIST)
```

[1, 2, 3, 4, 5, 6]

We convert the array into an hfarray of type DOM_HFARRAY:

```
coerce(a, DOM_HFARRAY)
```

$$\begin{pmatrix} 1.0 & 2.0 & 3.0 \\ 4.0 & 5.0 & 6.0 \end{pmatrix}$$

The conversion of an array into a polynomial is not implemented, and thus coerce returns FAIL:

```
coerce(a, DOM_POLY)
```

FAIL

One can convert a one- or two-dimensional array into a matrix, and vice versa. An example:

```
A := coerce(a, matrix); domtype(A)
```

$$\begin{pmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{pmatrix}$$

Dom::Matrix()

The conversion of a matrix into a list is also possible. The result is then a list of inner lists, where the inner lists represent the rows of the matrix:

```
coerce(A, DOM_LIST)
```

$$[[1, 2, 3], [4, 5, 6]]$$

```
coerce([1, 2, 3, 2], DOM_SET)
```

$$\{1, 2, 3\}$$

Any MuPAD object can be converted into a string, such as the arithmetical expression `2*x + sin(x^2)`:

```
coerce(2*x + sin(x^2), DOM_STRING)
```

"2*x + sin(x^2)"

Example 2

The function `factor` computes a factorization of a polynomial expression and returns an object of the library domain `Factored`:

```
f := factor(x^2 + 2*x + 1);
domtype(f)
```

$$(x+1)^2$$

Factored

This domain implements the conversion routine `"convert_to"`, which we can call directly to convert the factorization into a list (see `factor` for details):

```
Factored::convert_to(f, DOM_LIST)
```

$$[1, x+1, 2]$$

However, it is more convenient to use `coerce`, which internally calls the slot routine `Factored::convert_to`:

```
coerce(f, DOM_LIST)
```

$$[1, x+1, 2]$$

Example 3

Note that often a conversion can also be achieved by a call of the constructor of a domain `T`. For example, the following call converts an array into a matrix of the domain type `Dom::Matrix(Dom::Rational)`:

```
a := array(1..2, 1..2, [[1, 2], [3, 4]]):
MatQ := Dom::Matrix(Dom::Rational):

MatQ(a)
```

$$\begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$$

The call `MatQ(a)` implies the call of the method `"new"` of the domain `MatQ`, which in fact calls the method `"convert"` of the domain `MatQ` to convert the array into a matrix.

Here, the same can be achieved with the use of `coerce`:

```
A := coerce(a, MatQ);
domtype(A)
```

$$\begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$$

$$\text{Dom::Matrix(Dom::Rational)}$$

Note that the constructor of a domain `T` is supposed to *create* objects, not to convert objects of other domains into the domain type `T`. The constructor often allows more than one argument which allows to implement various user-friendly ways to create the objects (e.g., see the several possibilities for creating matrices offered by `matrix`).

Parameters

`object`

Any object

`T`

Any domain

Return Values

Object of the domain `T`, or the value `FAIL`.

Overloaded By

T

MuPAD Functions
`domtype` | `expr` | `testtype` | `type`

collect

Collect terms with the same powers

Syntax

```
collect(p, x, <f>)
```

```
collect(p, [x1, x2, …], <f>)
```

Description

`collect(p, x)` groups terms with the same powers of `x` in an expression `p`.

`collect(p, [x1, x2, ...])` groups terms with the same powers of x_1, x_2, … in a multivariate expression `p`.

If you pass a function name `f` as a third argument to `collect`, the procedure collects the powers of x (x_1, x_2, … for multivariate expression). Then it applies the function `f` to the coefficients.

`collect(p, x)` presents `p` as a sum $\sum_{i=0}^{n} a_i x^i$. The coefficients a_i are not polynomials in x. These coefficients can contain some terms with x, for example, $sin(x)$ or e^x.

`collect` returns a modified copy of a polynomial. The function does not change the polynomial itself. See “Example 1” on page 1-433.

If `p` is a rational expression in `x`, `collect` handles the numerator and denominator separately.

If `p` is a multivariate expression, *collect*(p, [x_1, x_2, …]) returns an expression in the following form:

$$\sum_{i_1\, i_2 \ldots} \left(a_{i_1, i_2, \ldots} {x_1}^{i_1} {x_2}^{i_2} \ldots \right).$$

The coefficients $a_{i_1, i_2, \ldots}$ are not polynomials in x. These coefficients can contain some terms with x_1, x_2, …, for example, $\sin(x_1)\, e^{x_2}$.

If `p` is a rational expression in x_1, x_2, …, the `collect` command handles the numerator and denominator separately.

For polynomial expressions, `collect` internally calls two functions: `poly` and then `expr`. The function `poly` converts an expression `p` into a polynomial in the given unknowns. This function returns a polynomial with the terms collected by the same powers. Then `expr` converts this polynomial into a polynomial expression. See `poly` for more information and examples. When applied to a rational expression, `collect` handles the numerator and denominator separately.

You can use arbitrary expressions as indeterminates. See “Example 2” on page 1-434.

You can specify a function name instead of a variable. In this case, `collect` treats all calls of the function with different arguments as different variables. See “Example 4” on page 1-435.

`collect` does not recursively collect the operands of nonpolynomial subexpressions of `p`. See “Example 2” on page 1-434.

If `p` is not a polynomial expression, `collect` can return the unchanged expression `p`. See “Example 5” on page 1-436.

Examples

Example 1

You can define a polynomial expression `p` and collect terms with the same powers of `x` and `y`:

```
p := x*y + z*x*y + y*x^2 - z*y*x^2 + x + z*x;
collect(p, [x, y])
```

$$x + x\,y + x\,z + x^2\,y - x^2\,y\,z + x\,y\,z$$

$$(1 - z)\,x^2\,y + (z + 1)\,x\,y + (z + 1)\,x$$

`collect` does not modify the original expression:

```
p
```

$$x + x\,y + x\,z + x^2\,y - x^2\,y\,z + x\,y\,z$$

You can collect terms with same powers of `x`:

```
collect(p, [x])
```

$$(y - y\,z)\,x^2 + (y + z + y\,z + 1)\,x$$

If an expression contains only one indeterminate, you can omit the square brackets in the second argument of the function call:

```
collect(p, x)
```

$$(y - y\,z)\,x^2 + (y + z + y\,z + 1)\,x$$

To factor coefficients in a resulting expression, pass `factor` as a third argument to `collect`:

```
collect(p, x, factor)
```

$$-(y\,(z - 1))\,x^2 + ((z + 1)\,(y + 1))\,x$$

Example 2

`collect` does not modify nonpolynomial subexpressions even if they contain a given indeterminate. In particular, `collect` does not recursively handle the operands of a nonpolynomial subexpression:

```
collect(sin((x + 1)^2)*(x + 1) + 5*sin((x + 1)^2) + x, x)
```

$$(\sin((x + 1)^2) + 1)\,x + 6\,\sin((x + 1)^2)$$

`collect` accepts nonpolynomial subexpressions as indeterminates:

```
collect(sin((x + 1)^2)*(x + 1) + 5*sin((x + 1)^2) + x,
        sin((x + 1)^2))
```

$$(x+6)\,\sin((x+1)^2)+x$$

Example 3

`collect` normalizes a rational expression, and then handles the numerator and denominator separately:

```
collect(z/(x+y) + 3*z/(x+z), z)
```

$$\frac{z^2+(4\,x+3\,y)\,z}{(x+y)\,z+x^2+y\,x}$$

Example 4

If you specify the name of a function as an indeterminate, `collect` handles functions calls with different arguments as different indeterminates:

```
collect(a*f(1) + c*f(1) + f(2) + d*f(2), f)
```

$$(a+c)\,f(1)+(d+1)\,f(2)$$

```
collect(a*sin(x) + b*sin(x) + c*sin(y) + d*sin(y), sin)
```

$$(a+b)\,\sin(x)+(c+d)\,\sin(y)$$

```
p:= diff(besselJ(0, x), x $ 4);
collect(p, besselJ);
collect(p, besselJ, expand);
```

$$\frac{2\,\mathrm{J}_1(x)}{x^3}-\frac{\mathrm{J}_1(x)}{x}+\frac{\frac{\mathrm{J}_1(x)}{x^2}-\mathrm{J}_1(x)+\frac{\frac{\mathrm{J}_1(x)}{x}-\mathrm{J}_0(x)}{x}}{x}+\mathrm{J}_0(x)+\frac{2\left(\frac{\mathrm{J}_1(x)}{x}-\mathrm{J}_0(x)\right)}{x^2}$$

$$\left(1-\frac{3}{x^2}\right)\mathrm{J}_0(x)+\left(\frac{\frac{2}{x^2}-1}{x}-\frac{1}{x}+\frac{4}{x^3}\right)\mathrm{J}_1(x)$$

$$\left(1-\frac{3}{x^2}\right)\mathrm{J}_0(x)+\left(\frac{6}{x^3}-\frac{2}{x}\right)\mathrm{J}_1(x)$$

Example 5

If `p` is not a polynomial expression, `collect` can return the unchanged expression `p`:

```
p :=  y^2*sin(x) + y*sin(x) + y^2*cos(x) + y*cos(x);
collect(p, x)
```

$$y^2\cos(x)+y^2\sin(x)+y\cos(x)+y\sin(x)$$

$$y^2\cos(x)+y^2\sin(x)+y\cos(x)+y\sin(x)$$

The expression `p` is a polynomial expression in `y`. You can group the terms with the same powers in this variable:

```
collect(p, y)
```

$$(\cos(x)+\sin(x))\,y^2+(\cos(x)+\sin(x))\,y$$

Parameters

`p`

An arithmetical expression.

`x, x1, x2, …`

The indeterminates: typically, identifiers or indexed identifiers.

`f`

A function.

Return Values

arithmetical expression.

Overloaded By

p

More About

- “Manipulate Expressions”
- “Choose Simplification Functions”

combine

Combine terms of same algebraic structure

Syntax

```
combine(f, <IgnoreAnalyticConstraints>)
```

```
combine(f, target, <IgnoreAnalyticConstraints>)
```

```
combine(f, [target1, target2, …], <IgnoreAnalyticConstraints>)
```

Description

`combine(f)` rewrites products of powers in the expression `f` as a single power.

`combine(f, target)` combines several calls to the target function(s) in the expression `f` to a single call.

`combine(f)` applies these rewriting rules to products of powers occurring as subexpressions in an arithmetical expression `f`:

- $x^a x^b = x^{a+b}$,
- $x^b y^b = (xy)^b$,
- $(x^a)^b = x^{ab}$.

The last two rules are only valid under certain additional restrictions, such as when b is an integer. Except for the third rule, this behavior of `combine` is the inverse functionality of `expand`. See “Example 1” on page 1-441.

Note: In certain cases, the MuPAD internal simplifier automatically applies these rules in the reverse direction, and `combine` sometimes has no effect. See “Example 2” on page 1-442.

`combine(f, target)` applies rewriting rules applicable to the target function(s) to an arithmetical expression `f`. Some of the rules are only valid under certain additional restrictions. For most of the rules, `combine` implements the inverse functionality of `expand`. This list shows the rewriting rules for the targets.

- `target = arctan`:

  $$\arctan(x) + \arctan(y) = \arctan\left(\frac{x+y}{1-xy}\right)$$

  for `x` and `y`, such that $|xy| < 1$.

- `target = exp` (see “Example 4” on page 1-442):

  - $e^a e^b = e^{a+b}$,
  - $(e^a)^b = e^{ab}$,

    where valid, reacting to properties.

- `target = int` (see “Example 5” on page 1-443):

  - $a\int f(x)dx = \int af(x)dx.$
  - $\int f(x)dx + \int g(x)dx = \int f(x) + g(x)dx.$
  - $\int_a^b f(x)dx + \int_a^b g(x)dx = \int_a^b f(x) + g(x)dx.$
  - $\int_a^b f(x)dx + \int_a^b g(y)dy = \int_a^b f(y) + g(y)dy.$
  - $\int_a^b yf(x)dx + \int_a^b xg(y)dy = \int_a^b yf(c) + xf(c)dc.$

- `target = gamma` (see “Example 6” on page 1-443):

  - $a\,\Gamma(a) = \Gamma(a+1)$,

- $\frac{\Gamma(a+1)}{\Gamma(a)} = a$,
- $\Gamma(1-a)\,\Gamma(a) = \frac{\pi}{\sin(\pi\,a)}$,
- $\Gamma(-a)\,\Gamma(a) = -\frac{\pi}{a\,\sin(\pi\,a)}$,
- $\Gamma(a+n)\,\Gamma(a) = \Gamma(a)^2\left(\prod_{i=0}^{n-1}(a+i)\right)$,

  for positive integers `n`.

- `target = ln` (see “Example 7” on page 1-444):
  - $\ln(a) + \ln(b) = \ln(ab)$,
  - $b\,\ln(a) = \ln(a^b)$,

    if b is less than `N`. By default, `N = 1000`. You can change the number `N` using the `Pref::autoExpansionLimit` command. See “Example 8” on page 1-444.

  The rules do not hold for arbitrary complex values of `a`, `b`. Specify appropriate properties for `a` or `b` to enable these rewriting rules. These rules are only applied to *natural* logarithms.
- `target = sincos` (see “Example 3” on page 1-442):
  - $\sin(x)\,\sin(y) = \frac{\cos(x-y)}{2} - \frac{\cos(x+y)}{2}$,

    where similar rules apply to *sin*(*x*) *cos*(*y*) and *cos*(*x*) *cos*(*y*):
  - $A\,\cos(x) + B\,\sin(x) = A\,\sqrt{1+\frac{B^2}{A^2}}\,\cos\left(x+\arctan\left(-\frac{B}{A}\right)\right)$.
- `target = sinhcosh`:

- $$\sinh(x)\,\sinh(y) = \frac{\cosh(x+y)}{2} - \frac{\cosh(x-y)}{2},$$

  where similar rules apply to $sinh(x)\,cosh(y)$ and $cosh(x)\,cosh(y)$.
- These rules apply recursively to powers of *sinh* and *cosh* with positive integral exponents.

`combine` works recursively on the subexpressions of `f`.

If the second argument is a list of targets, then `combine` is applied to `f` subsequently for each of the targets in the list. See "Example 10" on page 1-446.

If `f` is an array, a list, or a set, `combine` is applied to all entries of `f`. See "Example 11" on page 1-446. If `f` is a polynomial or a series expansion, of type `Series::Puiseux` or `Series::gseries`, `combine` is applied to each coefficient. See "Example 12" on page 1-446.

Environment Interactions

`combine` reacts to properties of identifiers appearing in the input.

Examples

Example 1

Combine powers of the same base using `combine`.

```
combine(sin(x) + x*y*x^(exp(1)))
```

$$\sin(x) + x^{e+1}\,y$$

`combine` also combines powers with the same exponent in certain cases:

```
combine(sqrt(2)*sqrt(3))
```

$$\sqrt{6}$$

Example 2

In most cases, however, `combine` does not combine powers with the same exponent:

```
combine(y^5*x^5)
```

$$x^5\,y^5$$

Example 3

Rewrite products of sines and cosines as a sum of sines and cosines by setting the second argument to `sincos`:

```
combine(sin(a)*cos(b) + sin(b)^2, sincos)
```

$$\frac{\sin(a+b)}{2} - \frac{\cos(2\,b)}{2} + \frac{\sin(a-b)}{2} + \frac{1}{2}$$

Rewrite sums of sines and cosines by setting the second argument to `sincos`:

```
combine(cos(a) + sin(a), sincos)
```

$$\sqrt{2}\,\cos\left(a - \frac{\pi}{4}\right)$$

Powers of sines or cosines with negative integer exponents are not rewritten:

```
combine(sin(b)^(-2), sincos)
```

$$\frac{1}{\sin(b)^2}$$

Example 4

Combine terms with the exponential function by specifying the second argument as `exp`.

```
combine(exp(3)*exp(2), exp)
```

$$e^5$$

```
combine(exp(a)^2, exp)
```

$$e^{2\,a}$$

Example 5

Rewrite integrals by setting the second argument to `int`.

```
combine(int(f(x),x)+int(g(x),x),int)
```

$$\int (f(x)+g(x))\,dx$$

`combine` combines a constant term with the integral.

```
combine(a*int(f(x),x),int)
```

$$\int a\,f(x)\,dx$$

`combine` combines integrals with the same limits.

```
combine(int(f(x),x=a..b)+int(g(y),y=a..b),int)
```

$$\int_a^b (f(x)+g(x))\,dx$$

Example 6

Combine calls to `gamma` by specifying the target as `gamma`. The `combine` function simplifies quotients of gammas to rational expressions.

```
combine(gamma(n+3)*gamma(n+4/3) / gamma(n+1) / gamma(n+10/3), gamma)
```

$$\frac{n^2+3\,n+2}{n^2+\frac{11\,n}{3}+\frac{28}{9}}$$

Example 7

This example shows the application of rules for the logarithm, and their dependence on properties of the identifiers appearing in the input. In the complex plane, the logarithm of a product does not always equal the sum of the logarithms of its factors. For real positive numbers, however, this rule can apply.

Try to combine terms with calls to `ln` by specifying the target as `ln`.

```
combine(ln(a) + ln(b), ln)
```

$$\ln(a)+\ln(b)$$

`combine` does not combine the terms. Set the appropriate assumptions to combine the terms.

```
assume(a > 0): assume(b > 0):
combine(ln(a) + ln(b), ln)
```

$$\ln(a\,b)$$

```
unassume(a): unassume(b):
```

Example 8

If a and b are integer or rational numbers and b is less than `1000`, `combine` returns logarithms.

```
combine(3*ln(2), ln)
```

$$\ln(8)$$

If b is greater than or equal to `1000`, `combine` returns results as $b\,\ln(a)$:

```
combine(1234*ln(5), ln)
```

$$1234 \ln(5)$$

You can change the limit on the number b by using the `Pref::autoExpansionLimit` function. For example, when you use the default value `N = 1000`, `combine` returns the following result for this logarithm:

```
combine(12*ln(12), ln)
```

$$\ln(8916100448256)$$

If you set the value of `Pref::autoExpansionLimit` to `10`, `combine` returns this logarithm in its original form:

```
Pref::autoExpansionLimit(10):
combine(12*ln(12), ln)
```

$$12 \ln(12)$$

For further computations, restore the default value of `Pref::autoExpansionLimit`:

```
Pref::autoExpansionLimit(NIL):
```

Example 9

The `IgnoreAnalyticConstraints` option applies a set of purely algebraic simplifications including the equality of sum of logarithms and a logarithm of a product. Using the `IgnoreAnalyticConstraints` option, you get a simpler result, but one that might be incorrect for some of the values of `a`.

Combine logarithms using the `IgnoreAnalyticConstraints` option.

```
combine(ln(a^5) - ln(a^4), ln, IgnoreAnalyticConstraints)
```

$$\ln(a)$$

Without using this option, you get a mathematically correct, but long result:

```
combine(ln(a^5) - ln(a^4), ln)
```

$$\ln(a^5) - \ln(a^4)$$

Example 10

The second argument also can be a list of targets. Then the rewriting rules for each of the targets in the list are applied.

Rewrite `ln` and `sincos` terms in the expression.

```
combine(ln(2) + ln(3) + sin(a)*cos(a), [ln, sincos])
```

$$\frac{\sin(2\,a)}{2} + \ln(6)$$

Example 11

`combine` maps to sets:

```
combine({sqrt(2)*sqrt(5), sqrt(2)*sqrt(11)})
```

$$\{\sqrt{10}, \sqrt{22}\}$$

Example 12

`combine` maps to the coefficients of polynomials:

```
combine(poly(sin(x)*cos(x)*y, [y]), sincos)
```

$$\mathrm{poly}\left(\frac{\sin(2\,x)}{2}\,y, [y]\right)$$

However, it does not touch the polynomial's indeterminates:

```
combine(poly(sin(x)*cos(x)), sincos)
```

$$\mathrm{poly}(\cos(x)\,\sin(x), [\cos(x), \sin(x)])$$

Parameters

`f`

An arithmetical expression, an array, a list, a polynomial, or a set

`target`

One of the identifiers: `arctan`, `exp`, `int`, `gamma`, `ln`, `sincos`, or `sinhcosh`

Options

`IgnoreAnalyticConstraints`

Apply purely algebraic simplifications to an expression. For more information see the options for the `Simplify` command.

Return Values

Object of the same type as the input object `f`.

Overloaded By

f

Algorithms

Advanced users can extend the functionality of `combine` by implementing additional rewriting rules for other target functions. To extend functionality, define a new slot `target` of `combine`. To define a new slot, you need to first unprotect the identifier `combine` using unprotect. Afterwards, the command `combine(f, target)` leads to the call `combine::target(f)` of the corresponding slot routine.

By default, `combine` handles a subexpression `g(x1,x2,...)` of `f` by calling itself recursively for the operands `x1`, `x2`, etc. Users can change this behavior for their own

mathematical function given by a function environment `g` by implementing a `combine` slot of `g`. To handle the subexpression `g(x1,x2,...)`, `combine` then calls the slot routine `g::combine` with the argument sequence `x1,x2,...` of `g`.

`denom` | `expand` | `factor` | `normal` | `numer` | `radsimp` | `rectform` | `rewrite` | `simplify`

Introduced in R2007b

complexInfinity

Complex infinity

Syntax

```
complexInfinity
```

Description

`complexInfinity` represents the only non-complex point of the one-point compactification of the complex numbers.

Mathematically, `complexInfinity` is the north pole of the Riemann sphere, with the unit circle as equator and the point 0 at the south pole.

With respect to arithmetic, `complexInfinity` behaves like "`1/0`". In particular, non-zero complex numbers may be multiplied or divided by `complexInfinity` or `1/ complexInfinity`. Adding `complexInfinity` to a finite number yields again `complexInfinity`.

With respect to arithmetical operations, `complexInfinity` is incompatible with the real `infinity`.

Examples

Example 1

`complexInfinity` can be used in arithmetical operations with complex numbers. The result in multiplications or divisions is either `complexInfinity`, `0`, or `undefined`:

```
3*complexInfinity, I*complexInfinity, 0*complexInfinity;
3/complexInfinity, I/complexInfinity, 0/complexInfinity;
complexInfinity/3, complexInfinity/I;
complexInfinity*complexInfinity, complexInfinity/complexInfinity;
```

```
complexInfinity, complexInfinity, undefined
```

```
0, 0, 0
```

```
complexInfinity, complexInfinity
```

```
complexInfinity, undefined
```

The result in additions is `undefined` if one of the operands is infinite, and `complexInfinity` otherwise:

```
complexInfinity + complexInfinity, infinity + complexInfinity;
3 + complexInfinity, I + complexInfinity, PI + complexInfinity
```

```
undefined, undefined
```

```
complexInfinity, complexInfinity, complexInfinity
```

Symbolic expressions in arithmetical operations involving `complexInfinity` are implicitly assumed to be different from both `0` and `complexInfinity`:

```
delete x:
x*complexInfinity, x/complexInfinity, complexInfinity/x,
x + complexInfinity
```

```
complexInfinity, 0, complexInfinity, complexInfinity
```

Algorithms

`complexInfinity` is the only element of the domain `stdlib::CInfinity`.

MuPAD Functions
`infinity`

conjugate

Complex conjugation

Syntax

```
conjugate(z)
```

```
conjugate(L)
```

Description

`conjugate(z)` computes the conjugate $\Re(z)$ - i $\Im(z)$ of a complex number $z = \Re(z) + i\,\Im(z)$.

For numbers of type `DOM_INT`, `DOM_RAT`, `DOM_FLOAT`, or `DOM_COMPLEX`, the conjugate is computed directly and very efficiently.

`conjugate` can handle symbolic expressions. Properties of identifiers are taken into account (see `assume`). An identifier `z` without any property is assumed to be complex, and the symbolic call `conjugate(z)` is returned. See “Example 2” on page 1-452.

`conjugate` knows how to handle special mathematical functions, such as:

```
_mult   _plus   _power  abs     cos     cosh    cot
coth    csc     csch    erf     erfc    exp     gamma
igamma  sec     sech    sin     sinh    tan     tanh
```

See “Example 1” on page 1-452.

If `conjugate` does not know how to handle a special mathematical function, then a symbolic `conjugate` call is returned. See “Example 3” on page 1-452.

This function is automatically mapped to all entries of container objects such as arrays, lists, matrices, polynomials, sets, and tables.

Environment Interactions

`conjugate` is sensitive to properties of identifiers set via `assume`.

Examples

Example 1

`conjugate` knows how to handle sums, products, the exponential function and the sine function:

```
conjugate((1 + I)*exp(2 - 3*I))
```

$$e^{2+3\,i}\,(1-i)$$

```
delete z: conjugate(z + 2*sin(3 - 5*I))
```

$$2\,\sin(3+5\,i)+\overline{z}$$

Example 2

`conjugate` reacts to properties of identifiers:

```
delete x, y: assume(x, Type::Real):
conjugate(x), conjugate(y)
```

$$x,\ \overline{y}$$

Example 3

If the input contains a function that the system does not know, then a symbolic `conjugate` call is returned:

```
delete f, z: conjugate(f(z) + I)
```

$$\overline{f(z)}-i$$

Now suppose that `f` is some user-defined mathematical function, and that $f(\overline{z}) = \overline{f(z)}$ holds for all complex numbers z. To extend the functionality of `conjugate` to `f`, we embed it into a function environment and suitably define its `"conjugate"` slot:

```
f := funcenv(f):
f::conjugate := u -> f(conjugate(u)):
```

Now, whenever `conjugate` is called with an argument of the form `f(u)`, it calls `f::conjugate(u)`, which in turn returns `f(conjugate(u))`:

```
conjugate(f(z) + I), conjugate(f(I))
```

$$f(\overline{z}) - i,\ f(-i)$$

Parameters

z

An arithmetical expression

L

A container object: an array, an hfarray, a list, a matrix, a polynomial, a set, or a table.

Return Values

arithmetical expression or a container object containing such expressions

Overloaded By

z

Algorithms

If a subexpression of the form `f(u,..)` occurs in `z` and `f` is a function environment, then `conjugate` attempts to call the slot `"conjugate"` of `f` to determine the conjugate of `f(u,..)`. In this way, you can extend the functionality of `conjugate` to your own special mathematical functions.

The slot `"conjugate"` is called with the arguments `u,..` of `f`.

If `f` has no slot `"conjugate"`, then the subexpression `f(u,..)` is replaced by the symbolic call `conjugate(f(u...))` in the returned expression.

See “Example 3” on page 1-452.

Similarly, if an element `d` of a library domain`T` occurs as a subexpression of `z`, then `conjugate` attempts to call the slot `"conjugate"` of that domain with `d` as argument to compute the conjugate of `d`.

If `T` does not have a slot `"conjugate"`, then `d` is replaced by the symbolic call `conjugate(d)` in the returned expression.

contains

Test if an entry exists in a container

Syntax

```
contains(s, object)
```

```
contains(l, object, <i>)
```

```
contains(t, object)
```

Description

`contains(s, object)` tests if `object` is an element of the set `s`.

`contains(l, object)` returns the index of `object` in the list `l`.

`contains(t, object)` tests if the array, table, or domain `t` has an entry corresponding to the index `object`.

`contains` is a fast membership test for the MuPAD basic container data types. For lists and sets, `contains` searches the elements for the given object. However, for arrays, tables, and domains, `contains` searches the indices.

`contains` works syntactically, i.e., mathematically equivalent objects are considered to be equal only if they are syntactically identical. `contains` does *not* represent elementhood in the mathematical sense. See “Example 2” on page 1-456.

`contains` does not descend recursively into subexpressions; use `has` to achieve this. See “Example 3” on page 1-457.

`contains(s, object)` returns `TRUE` if `object` is an element of the set `s`. Otherwise, it returns `FALSE`.

`contains(l, object)` returns the position of `object` in the list `l` as a positive integer if `object` is an entry of `l`. Otherwise, the return value is `0`. If more than one entry of `l` is equal to `object`, then the index of the first occurrence is returned.

By passing a third argument `i` to `contains`, you can specify a position in the list where the search is to start. Then, entries with index less than `i` are not taken into account. If `i` is out of range, then the return value is `0`.

See “Example 4” on page 1-457 and “Example 5” on page 1-457.

`contains(t, object)` returns `TRUE` if the array, table, or domain `t` has an entry corresponding to the index `object`. Otherwise, it returns `FALSE`. Cf. “Example 6” on page 1-458.

Examples

Example 1

`contains` may be used to test if a set contains a given element:

```
contains({a, b, c}, a), contains({a, b, c}, 2)
```

```
TRUE, FALSE
```

Example 2

`contains` works syntactically, i.e., mathematically equivalent objects are considered to be equal only if they are syntactically identical. In this example `contains` returns `FALSE` since `y*(x + 1)` and `y*x + y` are different representations of the same mathematical expression:

```
contains({y*(x + 1)}, y*x + y)
```

```
FALSE
```

Elementhood in the mathematical sense is represented by the operator `in`:

```
simplify(y*x + y in {y*(x+1)}, condition)
```

```
TRUE
```

Example 3

`contains` does not descend recursively into the operands of its first argument. In the following example, `c` is not an element of the set, and therefore `FALSE` is returned:

```
contains({a, b, c + d}, c)
```

```
    FALSE
```

If you want to test whether a given expression is contained *somewhere inside* a complex expression, please use `has`:

```
has({a, b, c + d}, c)
```

```
    TRUE
```

Example 4

`contains` applied to a `list` returns the position of the specified object in the list:

```
contains([a, b, c], b)
```

```
    2
```

If the list does not contain the object, `0` is returned:

```
contains([a, b, c], d)
```

```
    0
```

Example 5

`contains` returns the position of the first occurrence of the given object in the list if it occurs more than once:

```
l := [a, b, a, b]: contains(l, b)
```

```
    2
```

A starting position for the search may be given as optional third argument:

```
contains(l, b, 1), contains(l, b, 2),
contains(l, b, 3), contains(l, b, 4)
```

```
2, 2, 4, 4
```

If the third argument is out of range, then the return value is `0`:

```
contains(l, b, -1), contains(l, b, 0), contains(l, b, 5)
```

```
0, 0, 0
```

Example 6

For tables, `contains` returns `TRUE` if the second argument is a valid index in the table. The entries stored in the table are not considered:

```
t := table(13 = value): contains(t, 13), contains(t, value)
```

```
TRUE, FALSE
```

Similarly, `contains` tests if an `array` has a value for a given index. The array `a` has a value corresponding to the index `(1, 1)`, but none for the index `(1, 2)`:

```
a := array(1..3, 1..2, (1, 1) = x, (2, 1) = PI):
contains(a, (1, 1)), contains(a, (1, 2))
```

```
TRUE, FALSE
```

`contains` is not intended for testing if an array contains a given value:

```
contains(a, PI)
```

```
Error: Index dimension mismatch. [array]
```

Even if the dimensions match, the index must not be out of range:

```
contains(a, (4, 4))
```

```
Error: The argument is invalid. [array]
```

Example 7

`contains` may be used to test, whether a domain has the specified `slot`:

```
T := newDomain("T"):  T::index := value:
contains(T, index), contains(T, value)
```

```
    FALSE, FALSE
```

There is no entry corresponding to the slot `index` in `T`. Please keep in mind that the syntax `T::index` is equivalent to `slot(T, "index" )`:

```
contains(T, "index")
```

```
    TRUE
```

Example 8

Users can overload`contains` for their own domains. For illustration, we create a new domain `T` and supply it with an `"contains"` slot, which tests is the set of entries of an element contains the given value `idx`:

```
T := newDomain("T"):
T::contains := (e, idx) -> contains({extop(e)}, idx):
```

If we now call `contains` with an object of domain type `T`, the slot routine `T::contains` is invoked:

```
e := new(T, 1, 2): contains(e, 2), contains(e, 3)
```

```
    TRUE, FALSE
```

Parameters

s

A set

`l`

A list

`t`

An array of type `DOM_ARRAY`, a table, or a domain

`object`

An arbitrary MuPAD object

`i`

An integer

Return Values

For sets, arrays, tables, or domains, `contains` returns one of the Boolean values `TRUE` or `FALSE`. For lists, the return value is a nonnegative integer.

Overloaded By

l, s, t

MuPAD Functions
`_index` | `has` | `in` | `op` | `slot`

content

Content of a polynomial

Syntax

```
content(p)
```

```
content(f, <vars>)
```

Description

`content(p)` computes the content of the polynomial `p` or polynomial expression, i.e., the greatest common divisor of its coefficients.

If `p` is the zero polynomial, then `content` returns 0.

If `p` is a non-zero polynomial with coefficient ring `IntMod(n)` and `n` is a prime number, then `content` returns 1. If `n` is not a prime number, an error message is issued.

If `p` is a polynomial with a library domain `R` as coefficient ring, the `gcd` of its coefficients is computed using the slot `gcd` of `R`. If no such slot exists, then `content` returns `FAIL`.

If `p` is a polynomial with coefficient ring `Expr`, then `content` does the following.

If all coefficients of `p` are either integers or rational numbers, `content(p)` is equivalent to `gcd(coeff(p))`, and the return value is a positive integer or rational number. See “Example 1” on page 1-462.

If at least one coefficient is a floating point number or a complex number and all other coefficients are numbers, then `content` returns 1. See “Example 2” on page 1-463.

If at least one coefficient is not a number and all coefficients of `p` can be converted into polynomials via `poly`, then `content(p)` is equivalent to `gcd(coeff(p))`. See “Example 3” on page 1-463.

Otherwise, `content` returns 1.

A polynomial expression `f` is converted into a polynomial with coefficient ring `Expr` via `p :=poly(f, vars)`, and then `content` is applied to `p`. See “Example 1” on page 1-462.

Use `icontent` for polynomials that are known to have integer or rational coefficients, since it is much faster than `content`.

Dividing the coefficients of `p` by its content gives its primitive part. This one can also be obtained directly using `polylib::primpart`.

Examples

Example 1

If `p` is a polynomial with integer or rational coefficients, the result is the same as for `icontent`:

```
content(poly(6*x^3*y + 3*x*y + 9*y, [x, y]))
```

```
    3
```

The following call, where the first argument is a polynomial expression and not a polynomial, is equivalent to the one above:

```
content(6*x^3*y + 3*x*y + 9*y, [x, y])
```

```
    3
```

If no list of indeterminates is specified, then `poly` converts the expression into a polynomial with respect to all occurring indeterminates, and we obtain yet another equivalent call:

```
content(6*x^3*y + 3*x*y + 9*y)
```

```
    3
```

Above, we considered the polynomial as a bivariate polynomial with integer coefficients. We can also consider the same expression as a univariate polynomial in `x`, whose

coefficients contain a parameter `y`. Then the coefficients and their gcd—the content—are polynomial expressions in `y`:

```
content(poly(6*x^3*y + 3*x*y + 9*y, [x]))
```

$$3\,y$$

Here is another example where the coefficients and the content are again polynomial expressions:

```
content(poly(4*x*y + 6*x^3 + 6*x*y^2 + 9*x^3*y, [x]))
```

$$3\,y+2$$

The following call is equivalent to the previous one:

```
content(4*x*y + 6*x^3 + 6*x*y^2 + 9*x^3*y, [x])
```

$$3\,y+2$$

Example 2

If a polynomial or polynomial expression has numeric coefficients and at least one floating-point number is among them, its content is 1:

```
content(2.0*x+2.0)
```

$$1$$

Example 3

If not all of the coefficients are numbers, the gcd of the coefficients is returned:

```
content(poly(x^2*y+x, [y]))
```

$$x$$

Parameters

p

A polynomial of type DOM_POLY

f

A polynomial expression

vars

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

Return Values

an object of the same type as the coefficients of the polynomial or the value FAIL.

Overloaded By

p

MuPAD Functions

coeff | factor | gcd | icontent | ifactor | igcd | ilcm | lcm | poly | polylib::primpart

context

Evaluate an object in the enclosing context

Syntax

```
context(object)
```

Description

Within a procedure, `context(object)` evaluates `object` in the context of the calling procedure.

Most MuPAD procedures evaluate their arguments before executing the body of the procedure. However, if the procedure is declared with option `hold`, then the arguments are passed to the procedure unevaluated. `context` serves to evaluate such arguments a posteriori from within the procedure.

Like most MuPAD procedures, `context` first evaluates its argument `object` as usual in the context of the current procedure. Then the result is evaluated again in the dynamical context that was valid before the current procedure was called. The enclosing context is either the interactive level or the procedure that called the current procedure.

`"func_call"`-methods of domains never evaluate their arguments, whether the option `hold` is used or not. See “Example 2” on page 1-467.

`context` is sensitive to the value of the environment variable `LEVEL`, which determines the maximal depth of the recursive process that replaces an identifier by its value during evaluation. The evaluation of the argument takes place with the value of `LEVEL` that is valid in the current procedure, which is `1` by default. The second evaluation uses the value of `LEVEL` that is valid in the enclosing context, which is usually `1` if the enclosing context is also a procedure, while it is `100` by default if the enclosing context is the interactive level. See “Example 3” on page 1-467.

Note: The function `context` must not be called at interactive level, and `context` calls must not be nested. Thus it is not possible to evaluate an object in higher levels of the dynamical call stack. See “Example 4” on page 1-468.

Environment Interactions

`context` is sensitive to the value of the environment variable `LEVEL`, which determines the maximal substitution depth for identifiers.

Examples

Example 1

We define a procedure `f` with option `hold`. If this procedure is called with an identifier as argument, such as `a` below, the `identifier` itself is the actual argument inside of `f`. `context` may be used to get the value of `a` in the outer context:

```
a := 2:
f := proc(i)
       option hold;
     begin
       print(i, context(i), i^2 + 2, context(i^2 + 2));
     end_proc:
f(a):
```

$$a,\ 2,\ a^2+2,\ 6$$

If a procedure with option `hold` is called from another procedure you will see strange effects if the procedure with option `hold` does not evaluate its formal parameters with `context`. Here, the value of the formal parameter `j` in `g` is the `variable` `i` which is defined in the context of procedure `f` and not its value `4`. When you want to access the value of this variable you have to use `context`, otherwise you see the output `DOM_VAR(0,2)` which is the variable `i` of `f` which has lost its scope:

```
f := proc()
       local i;
     begin
       i := 4:
       g(i);
     end_proc:
g := proc(j)
       option hold;
     begin
```

```
      print(j, eval(j), context(j));
      print(j + 1)
    end_proc:
f()
```

$$\mathrm{DOM\_VAR}(0, 2), \mathrm{DOM\_VAR}(0, 2), 4$$

$$\mathrm{DOM\_VAR}(0, 2) + 1$$

Example 2

The `"func_call"` method of a domain is implicitly declared with `option hold`. We define a `"func_call"` method for the domain `DOM_STRING` of MuPAD strings. The slot routine converts its remaining arguments into strings and appends them to the first argument, which coincides with the string that is the 0th operand of the function call:

```
unprotect(DOM_STRING):
DOM_STRING::func_call :=
  string -> _concat(string, map(args(2..args(0)), expr2text)):
a := 1:  "abc"(1, a, x)
```

"abc1ax"

You see that the identifier `a` was added to the string, and not its value `1`. Use `context` to access the value that `a` has before the `"func_call"` method is invoked:

```
DOM_STRING::func_call :=
  string -> _concat(string, map(context(args(2..args(0))),
                                expr2text)):
"abc"(1, a, x);
delete DOM_STRING::func_call:  protect(DOM_STRING, Error):
```

"abc11x"

Example 3

This example shows the influence of the environment variable `LEVEL` on the evaluation of `context` and the differences to the functions `eval` and `level`. `p` is a function with

option `hold`. `x` is a formal parameter of this procedure. When evaluating their arguments `context`, `eval` and `level` all replace `x` first by its value `a`. Then `eval` evaluates `a` in the current context with `LEVEL = 1` and yields the value `b`. `context` evaluates `a` in the enclosing context (which is the interactive level) with `LEVEL = 100` and yields `c`. `level` always returns the result of the first evaluation step, which is `a`.

When the `LEVEL` of the interactive level is `1`, `context` returns `b` like `eval` since the second evaluation is performed with `LEVEL = 1` like in `eval`.

The local variable `b` of `p` does not influence the evaluation in `context`, `eval` and `level` since it is only a locally declared variable of type `DOM_VAR` which has nothing to do with the identifier `b`, which is the value of `a`:

```
delete a, b, c:  a := b:  b := c:
p := proc(x)
       option hold;
       local b;
     begin
       b := 2;
       eval(x), context(x), level(x), level(x,2);
     end:
p(a);
LEVEL := 1: p(a);
delete LEVEL:
```

$$b, c, a, a$$

$$b, b, a, a$$

Example 4

The function `context` must not be called at interactive level:

```
context(x)
```

```
Error: The function call is not allowed on the interactive level. [context]
```

```
 Error: Function call not
allowed on interactive level. [context]
```

Parameters

`object`

Any MuPAD object

Return Values

Evaluated object.

See Also

MuPAD Domains
`DOM_PROC`

MuPAD Functions
`eval` | `freeze` | `hold` | `LEVEL` | `level` | `MAXLEVEL` | `proc`

contfrac

Domain of continued fractions

Syntax

```
contfrac(r, <n>)

contfrac(f, x, <m>)

contfrac(f, x = x0, <m>)
```

Description

`contfrac(r)` creates a continued fraction approximation of the real number `r`.

`contfrac(f, x = x0)` creates a continued fraction approximation of the expression `f` as a function of `x` around `x = x0`.

The continued fraction expansion `contfrac(r n )` of a real number or numerical expression `r` is an expansion of the form

$$a_1 + \cfrac{1}{a_2 + \cfrac{1}{a_3 + \cfrac{1}{\ldots + a_{k-1} + \cfrac{1}{a_k + \ldots}}}}$$

where `a1` is the integer `floor(r)` and `a2`, `a3`, ... are positive integers.

The continued fraction is computed by `numlib::contfrac(r < n >)`; the expansion returned by `contfrac` is of domain type `numlib::contfrac`.

See the documentation of `numlib::contfrac` for further details.

A continued fraction expansion `contfrac(f, x = x0)` of a symbolic expression `f` in the indeterminate `x` is an expansion of the form

$$a_1 + \cfrac{(x-x_0)^{e_1}}{a_2 + \cfrac{(x-x_0)^{e_2}}{a_3 + \cfrac{(x-x_0)^{e_3}}{\ldots + a_{k-1} + \cfrac{(x-x_0)^{e_{k-1}}}{a_k + O\left((x-x_0)^{e_k}\right)}}}}$$

where

- $a_1, \ldots, a_k$ are arithmetical expressions not containing powers of $x - x_0$. The coefficients $a_2, \ldots, a_k$ are non-zero.
- e_1 is a rational number and $e_2, \ldots, e_k$ are positive rational numbers. If $a_1 \neq 0$, then e_1 is positive as well.

If $x_0 = \pm\infty$ or `x0 = complexInfinity`, the terms $(x - x_0)^{e_i}$ have to be replaced by $\frac{1}{x^{e_i}}$.

For symbolic expressions `f`, `contfrac(f, x = x0)` returns an expansion of domain type `contfrac`.

One may also call `contfrac(f)` without specifying an identifier `x`. In this case, `contfrac` extracts the indeterminates in `f` automatically via `indets`. `FAIL` is returned if more than one indeterminate is found.

If `m` is not specified, the default value `m = ORDER` is used.

`contfrac` uses the function `Series::Puiseux::contfrac` to compute the continued fraction in the symbolic case. If `f` is a rational function with respect to the expansion variable `x`, and the `truncation order' `m is not specified, then `contfrac` returns an exact continued fraction expansion of `f`. Cf. “Example 3” on page 1-473.

Environment Interactions

When called with an irrational numerical value `r`, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision. For symbolic expressions `f`, the function is sensitive to the environment variable `ORDER` which determines the number of terms in truncated series expansions.

Examples

Example 1

We compute some continued fraction expansions of real numbers:

```
contfrac(27/31), contfrac(PI, 5)
```

$$\frac{1}{1+\frac{1}{6+\frac{1}{1+\frac{1}{3+\ldots}}}},\ 3+\frac{1}{7+\frac{1}{15+\frac{1}{1+\ldots}}}$$

They can also be computed by direct calls to `numlib::contfrac`:

```
numlib::contfrac(27/31), numlib::contfrac(PI, 5)
```

$$\frac{1}{1+\frac{1}{6+\frac{1}{1+\frac{1}{3+\ldots}}}},\ 3+\frac{1}{7+\frac{1}{15+\frac{1}{1+\ldots}}}$$

Example 2

We compute symbolic continued fractions of functions:

```
contfrac(exp(x), x = 0), contfrac(exp(-3*x^2), x = 0)
```

$$1+\frac{x}{1+\frac{x}{-2+\frac{x}{-3+\frac{x}{2+\frac{x}{5+O(x)}}}}},\ 1+\frac{x^2}{-\frac{1}{3}+\frac{x^2}{-2+\frac{x^2}{1+O\left(x^2\right)}}}$$

If no expansion variable is specified, the symbolic expression to be expanded must be univariate:

```
contfrac(exp(x*y))
```

```
Error: The first argument must be a univariate expression. [contfrac::function]
```

Symbolic parameters are accepted if the expansion variable is specified:

```
contfrac(exp(x*y), x)
```

$$1+\cfrac{x}{y^{-1}+\cfrac{x}{-2+\cfrac{x}{-3\,y^{-1}+\cfrac{x}{2+\cfrac{x}{5\,y^{-1}+O(x)}}}}}$$

In the next call, we specify the expansion point `x = 1` and request a specific `number of terms' by the third argument:

```
contfrac(exp(x*y), x = 1, 3);
```

$$e^{y}+\cfrac{x-1}{y^{-1}\,e^{-y}+\cfrac{x-1}{-2\,e^{y}+O(x-1)}}$$

Example 3

For rational functions, exact representations are returned when no specific `number of terms' is requested. The method `"rational"` returns the rational expression equivalent to the continued fraction:

```
cf := contfrac((x - y)/(x^3 + y^3), x, 2):
cf, contfrac::rational(cf);
```

$$-y^{-2}+\cfrac{x}{y^{3}+O(x)},\ \frac{x-y}{y^{3}}$$

```
cf := contfrac((x - y)/(x^3 + y^3), x):
cf, contfrac::rational(cf);
```

$$-y^{-2}+\cfrac{x}{y^3+\cfrac{x^2}{-y^{-1}+\cfrac{x}{-y^2+\cfrac{x}{\frac{y^{-1}}{2}+\frac{x}{2\,y^2}}}}}, \quad \frac{x-y}{x^3+y^3}$$

Example 4

The coefficients and expansion terms of a continued fraction can be accessed by the functions `nthcoeff` and `nthterm`:

```
cf := contfrac(sin(1/x), x = infinity, 4)
```

$$\cfrac{x^{-1}}{1+\cfrac{x^{-2}}{6+O\left(x^{-2}\right)}}$$

```
nthcoeff(cf, 1), nthcoeff(cf, 2), nthcoeff(cf, 3), nthcoeff(cf, 4);
```

$$0,\ 1,\ 6,\ \text{FAIL}$$

```
nthterm(cf, 1), nthterm(cf, 2), nthterm(cf, 3)
```

$$\frac{1}{x},\ \frac{1}{x^2},\ \text{FAIL}$$

```
delete cf:
```

Example 5

We can compute a series expansion of a continued fraction via `series`:

```
cf := contfrac(sin(x)/(x - PI) - 1, x = PI)
```

$$-2+\cfrac{(\pi-x)^2}{6+\cfrac{(\pi-x)^2}{\frac{10}{3}+O\left((\pi-x)^2\right)}}$$

If no further arguments are given in `series`, the default expansion variable is `op`(cf, 3); the default expansion point is `op`(cf, 4):

```
op(cf, 3), op(cf, 4)
```

$$x,\ \pi$$

```
series(cf)
```

$$-2+\frac{(\pi-x)^2}{6}-\frac{(\pi-x)^4}{120}+O((\pi-x)^6)$$

Both the series variable as well as the expansion point may be passed explicitly to `series`.

```
series(cf, x = PI)
```

$$-2+\frac{(\pi-x)^2}{6}-\frac{(\pi-x)^4}{120}+O((\pi-x)^6)$$

However, the values must coincide with the values used to compute the continued fraction: In the following call, the default expansion point `x = 0` is used by `series`. This clashes with the expansion point `x = PI` of the continued fraction:

```
series(cf, x)
```

```
Error: The expansion point 'PI' of the continued fraction does not coincide with the re
```

```
delete cf:
```

Parameters

r

A real number or a numerical expression that can be converted to a real floating-point number

n

The number of significant decimal digits: a positive integer. The default value is `n` = `DIGITS`.

f

An arithmetical expression interpreted as a function of *x*

x

An identifier

x0

The expansion point: an arithmetical expression, $\pm\infty$ or `complexInfinity`. The default value is 0.

m

The `number of terms': a positive integer. The default value is `m` = `ORDER`.

Return Values

Call `contfrac(r n )` with a numerical value `r` returns an object of type `numlib::contfrac`. The call `contfrac(f, x = x0 m )` with a symbolic expression `f` returns an object of type `contfrac`. `FAIL` is returned if no series expansion of `f` around `x0` could be computed.

Methods

Mathematical Methods

`series` — Serie of a continued fraction

```
series(cf, <m>)
```

```
series(cf, <x>, <m>)
```

```
series(cf, <x = x0>, <m>)
```

If `x` is not specified, the default series variable is `op(cf, 3)`. If `x0` is not specified, the default expansion point is `op(cf, 4)`. If no `number of terms' `m` is specified, `m` = `ORDER` is used.

This method overloads the function `series`.

Access Methods

`op` — Operand of the continued fraction

```
op(cf, <n>)
```

See Also

MuPAD Functions

`numlib::contfrac` | `series`

copyClosure

Copies the lexical closure of a procedure

Syntax

```
copyClosure(f)
```

Description

`copyClosure(f)` copies the lexical closure of a procedure or procedure environment `f`.

Usually, when a procedure is copied, for example by assigning it to an identifier, the lexical closure of the procedure is not copied. Via the copied procedure one can change the lexical closure of the original procedure. Thus, the lexical closure of a procedure shows the so-called *reference effect*.

`copyClosure` may be used to copy the lexical closure of a procedure. Changes in the closure of the copy no longer affect the original procedure's closure.

Closures are implemented by procedure environments (kernel type `DOM_PROC_ENV`) in MuPAD. `copyClosure` works by copying all lexically enclosing procedure environments of a procedure.

`copyClosure` may also be used to copy a procedure environment and all its lexically enclosing environments only.

Examples

Example 1

Procedure closures show the reference effect: The procedure `f` generated by `gen` changes its closure via the variable `i`. A “normal” copy `g` of `f` changes the variable in the same closure, as is seen by repeatedly calling `f` versus `g`.

```
gen:= proc()
```

```
    option escape;
    local i;
begin
    i := 0;
    proc() begin i := i+1 end
end:

f := gen():
g := f:
f(), g(), f(), g()
```

$$1, 2, 3, 4$$

If one now generates `f` again by calling `gen`, but copies `g` by calling `copyClosure`, then `g` has its own closure and now longer changes the variable `i` in the closure of `f`.

```
f := gen():
g := copyClosure(f):
f(), g(), f(), g()
```

$$1, 1, 2, 2$$

Parameters

`f`

A procedure or procedure environment to be copied

Return Values

Copied procedure or procedure environment

MuPAD Functions

`_assign`

curl

Curl of a vector field

Syntax

```
curl(v, x)
curl(v, x, ogCoord, <c>)
```

Description

`curl(v, x)` computes the curl of the three-dimensional vector field $\vec{v}$ with respect to the three-dimensional vector $\vec{x}$ in Cartesian coordinates. This is the vector field

$$\mathrm{curl}(\vec{v}) = \begin{pmatrix} \frac{\partial}{\partial x_2} v_3 - \frac{\partial}{\partial x_3} v_2 \\ \frac{\partial}{\partial x_3} v_1 - \frac{\partial}{\partial x_1} v_3 \\ \frac{\partial}{\partial x_1} v_2 - \frac{\partial}{\partial x_2} v_1 \end{pmatrix}.$$

`curl(v, x, ogCoord)` computes the curl of `v` with respect to `x` in the orthogonally curvilinear coordinate system specified by `ogCoord`.

`ogCoord` can be the name of a three-dimensional orthogonal coordinate system predefined in the table `linalg::ogCoordTab`. See “Example 2” on page 1-481.

Alternatively, `ogCoord` can be a list of vector of algebraic expressions representing the scale factors of the coordinate system. See example “Example 3” on page 1-481. For details, see the description of the `Scales` option on the `linalg::ogCoordTab` page.

If `v` is a vector then the component ring of `v` must be a field (a domain of category `Cat::Field`) for which differentiation with respect to `x` is defined.

`curl` returns a vector of the domain `Dom::Matrix()`.

Examples

Example 1

Compute the curl of the vector field $\vec{v}(x, y, z) = (x\ y, 2\ y, z)$ in Cartesian coordinates:

```
delete x, y, z:
curl([x*y, 2*y, z], [x, y, z])
```

$$\begin{pmatrix} 0 \\ 0 \\ -x \end{pmatrix}$$

Example 2

Compute the curl of the vector field $\vec{v}(r, \phi, z) = (r, \cos(\phi), z)$, $(0 \le \phi < 2\,\pi)$ in cylindrical coordinates:

```
delete r, phi, z: V := matrix([r, cos(phi), z]):

curl(V, [r, phi, z], Cylindrical)
```

$$\begin{pmatrix} 0 \\ 0 \\ \frac{\cos(\mathrm{phi})}{r} \end{pmatrix}$$

The following relations between Cartesian and cylindrical coordinates hold:

$$x = r\cos(\phi),\ y = r\sin(\phi),\ z = z$$

.

Other predefined orthogonal coordinate systems can be found in the table `linalg::ogCoordTab`.

Example 3

Compute the curl of a vector field in spherical coordinates r, θ,ϕ given by

$$\vec{x} = \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} r \sin(\theta) \cos(\phi) \\ r \sin(\theta) \sin(\phi) \\ r \cos(\theta) \end{pmatrix}$$

with $0 \le \theta \le \pi$, $0 \le \phi < 2\,\pi$. The vectors

$$\vec{e}_r = \frac{\frac{\partial}{\partial r}\vec{x}}{\left|\frac{\partial}{\partial r}\vec{x}\right|} = \begin{pmatrix} \sin(\theta) \cos(\phi) \\ \sin(\theta) \sin(\phi) \\ \cos(\theta) \end{pmatrix}, \quad \vec{e}_\theta = \frac{\frac{\partial}{\partial \theta}\vec{x}}{\left|\frac{\partial}{\partial \theta}\vec{x}\right|} = \begin{pmatrix} \cos(\theta) \cos(\phi) \\ \cos(\theta) \sin(\phi) \\ -\sin(\theta) \end{pmatrix},$$

$$\vec{e}_\phi = \frac{\frac{\partial}{\partial \phi}\vec{x}}{\left|\frac{\partial}{\partial \phi}\vec{x}\right|} = \begin{pmatrix} -\sin(\phi) \\ \cos(\phi) \\ 0 \end{pmatrix}$$

form an orthogonal system of unit vectors corresponding to the spherical coordinates. The scaling factors of the coordinate transformation (see `linalg::ogCoordTab`) are $\left|\frac{\partial}{\partial r}\vec{x}\right| = 1$, $\left|\frac{\partial}{\partial \theta}\vec{x}\right| = r$, $\left|\frac{\partial}{\partial \phi}\vec{x}\right| = r \sin(\theta)$, which we use in the following example to compute the curl of the vector field $\vec{v}(r, \theta, \phi) = r^2\,\vec{e}_\phi$:

```
delete r, Theta, phi:
curl([0, 0, r^2], [r, Theta, phi], [1, r, r*sin(Theta)])
```

$$\begin{pmatrix} \frac{r \cos(\mathrm{Theta})}{\sin(\mathrm{Theta})} \\ -3\,r \\ 0 \end{pmatrix}$$

These are the coefficients of the curl of $\vec{v}$ in the bases given by the vectors $\vec{e}_r$, $\vec{e}_\theta$, $\vec{e}_\phi$, that is, the curl of $\vec{v}$ is given by the vector field $\frac{r \cos(\theta)}{\sin(\theta)}\,\vec{e}_r - 3\,r\,\vec{e}_\theta$.

The spherical coordinates are already defined in `linalg::ogCoordTab`. The last result can also be achieved with the input `curl([0, 0, r^2], [r, Theta, phi], Spherical[RightHanded])`.

```
curl([0, 0, r^2], [r, Theta, phi], Spherical[RightHanded])
```

$$\begin{pmatrix} \frac{r\cos(\mathrm{Theta})}{\sin(\mathrm{Theta})} \\ -3\,r \\ 0 \end{pmatrix}$$

Parameters

v

A list of three arithmetical expressions, or a three-dimensional vector (a 3×1 or 1 ×3 matrix of a domain of category `Cat::Matrix`)

x

A list of three (indexed) identifiers

ogCoord

The name of a three-dimensional orthogonal coordinate system predefined in the table `linalg::ogCoordTab`, or a list of algebraic expressions representing the scale factors of an orthogonal coordinate system.

c

The parameter of the coordinate systems EllipticCylindrical and Torus, respectively: an arithmetical expression. The default value is `c` = 1.

Return Values

Column vector.

MuPAD Functions

`divergence` | `gradient` | `laplacian` | `linalg::ogCoordTab` | `potential` | `vectorPotential`

', D

Differential operator for functions

Syntax

```
f '
```

```
D(f)
```

```
D([n1, n2, …], f)
```

Description

`D(f)` or, alternatively, `f'` computes the derivative of the univariate function `f`.

`D([n1, n2, ...], f)` computes the partial derivative $\frac{\partial}{\partial x_{n_2}} \frac{\partial}{\partial x_{n_1}} \cdots f$ of the multivariate function $f(x_1, x_2, \ldots)$.

MuPAD has two functions for differentiation: `diff` and `D`. `D` represents the differential operator that may be applied to functions; `diff` is used to differentiate arithmetical expressions. Mathematically, `D(f)(x)` coincides with `diff(f(x), x)`; `D([1, 2], f)(x, y)` coincides with `diff(f(x, y), x, y)`. Symbolic calls of `D` and `diff` can be converted to one another via `rewrite`. Cf. “Example 8” on page 1-490.

`D(f)` returns the derivative f' of the univariate function`f`. `f'` is shorthand for `D(f)`.

If `f` is a multivariate function and $D_n f$ denotes the partial derivative of `f` with respect to its n-th argument, then `D([n1, n2, ...], f)` computes the partial derivative $D_{n_1} D_{n_2} s f$. Cf. “Example 5” on page 1-488. In particular, `D([ ], f)` returns `f` itself.

Note: It is assumed that partial derivatives commute. Internally, `D([n1, n2, ...], f)` is converted to `D([m1, m2, ...], f)`, where `[m1, m2, ...] = sort([n1, n2, ...])`.

`f` may be any object which can represent a function. In particular, `f` may be a functional expression built from simple functions by means of arithmetic operators (`+`, `-`, `*`, `/`, `^`, `@`, `@@`). Any identifier different from CATALAN, EULER, and PI is regarded as an "unknown" function; the same holds for elements of kernel domains not explicitly mentioned on this page. Cf. "Example 1" on page 1-487. Any number and each of the three constant identifiers above is regarded as a constant function. Cf. "Example 2" on page 1-487.

If `f` is a list, a set, a table, or an array, then `D` is applied to each entry of `f`. Cf. "Example 3" on page 1-488.

A polynomial `f` of type `DOM_POLY` is regarded as polynomial function, the indeterminates being the arguments of the function. Cf. "Example 6" on page 1-489.

If `f` is a function environment, a procedure, then `D` can compute the derivative in some cases; see the "Background" section below. If this is not possible, a symbolic `D` call is returned.

Higher partial derivatives `D([n1], D([n2], f))` are simplified to `D([n1, n2], f)`. Cf. "Example 7" on page 1-490.

The derivative of a univariate function *f* —denoted by `D(f)`— is syntactically distinguished from the partial derivative `D([1], f)` with respect to the first variable, even if *f* represents a univariate function.

The usual rules of differentiation are implemented:

- `D(f + g) = D(f) + D(g)`,
- `D(f * g) = f * D(g) + g * D(f)`,
- `D(1/f) = -D(f) / f^2`,
- `D(f @ g) = D(f) @ g * D(g)`.

Note that the composition of functions is written as `f@g` and *not* as `f(g)`.

In order to express the *n*-th derivative of a univariate function for symbolic *n*, you can use the "repeated composition operator" `@@`. Cf. "Example 9" on page 1-491.

Environment Interactions

`D` uses `option remember`.

Examples

Example 1

`D(f)` computes the derivative of the function `f`:

```
D(sin), D(x -> x^2), D(id)
```

$$\cos,\ (x \to 2\,x),\ 1$$

`D` also works for more complex functional expressions:

```
D(sin @ exp + 2*(x -> x*ln(x)) + id^2)
```

$$(\cos \circ \exp)\ \exp + 2\ (x \to \ln(x) + 1) + 2\ \mathrm{id}$$

If `f` is an identifier without a value, a symbolic `D` call is returned:

```
delete f: D(f + sin)
```

$$f' + \cos$$

The same holds for objects of kernel type that cannot be regarded as functions:

```
D(NIL)
```

$$\mathrm{NIL}'$$

`f'` is shorthand for `D(f)`:

```
(f + sin)', (x -> x^2)', id'
```

$$f' + \cos,\ (x \to 2\,x),\ 1$$

Example 2

Constants are regarded as constant functions:

```
PI', 3', (1/2)'
```

0, 0, 0

Example 3

The usual rules of differentiation are implemented. Note that lists and sets may also be taken as input; in this case, `D` is applied to each element of the list or set:

```
delete f, g: D([f+g, f*g]); D({1/f, f@g})
```

$$[f' + g',\ f'\,g + f\,g']$$

$$\left\{g'\,(f' \circ g),\ -\frac{f'}{f^2}\right\}$$

Example 4

The derivatives of most special functions of the library can be computed. Again, `id` denotes the identity function:

```
D(tan); D(sin*cos); D(1/sin); D(sin@cos); D(2*sin + ln)
```

$$\tan^2 + 1$$

$$\cos^2 - \sin^2$$

$$-\frac{\cos}{\sin^2}$$

$$-(\cos \circ \cos)\,\sin$$

$$\frac{1}{\mathrm{id}} + 2\cos$$

Example 5

`D` can also compute derivatives of procedures:

```
f := x -> x^2:
g := proc(x) begin tan(ln(x)) end:
D(f), D(g)
```

$$(x \to 2\,x),\ \frac{(\tan \circ \ln)^2 + 1}{\mathrm{id}}$$

We differentiate a function of two arguments by passing a list of indices as first argument to `D`. In the example below, we first differentiate with respect to the second argument and then differentiate the result with respect to the first argument:

```
D([1, 2], (x, y) -> sin(x*y))
```

$$(x, y) \to \cos(x\,y) - x\,y\,\sin(x\,y)$$

The order of the partial derivatives is not relevant:

```
D([2, 1], (x, y) -> sin(x*y))
```

$$(x, y) \to \cos(x\,y) - x\,y\,\sin(x\,y)$$

```
delete f, g:
```

Example 6

A polynomial is regarded as a polynomial function:

```
D(poly(x^2 + 3*x + 2, [x]))
```

$$\mathrm{poly}(2\,x + 3, [x])$$

We differentiate the following bivariate polynomial `f` twice with respect to its second variable `y` and once with respect to its first variable `x`:

```
f := poly(x^3*y^3, [x, y]):
D([1, 2, 2], f) = diff(f, y, y, x)
```

$$\mathrm{poly}(18\,x^2\,y, [x, y]) = \mathrm{poly}(18\,x^2\,y, [x, y])$$

```
delete f:
```

Example 7

Nested calls to D are flattened:

```
D([1], D([2], f))
```

$$D_{1,2}(f)$$

However, this does not hold for calls with only one argument, since `D(f)` and `D([1], f)` are not considered to be the same:

```
D(D(f))
```

$$f''$$

Example 8

D may only be applied to functions whereas `diff` makes only sense for expressions:

```
D(sin), diff(sin(x), x)
```

$$\cos, \cos(x)$$

Applying D to expressions and `diff` to functions makes no sense:

```
D(sin(x)), diff(sin, x)
```

$$(\sin(x))', 0$$

`rewrite` allows to rewrite expressions with D into `diff`-expression:

```
rewrite(D(f)(y), diff), rewrite(D(D(f))(y), diff)
```

$$\frac{\partial}{\partial y} f(y), \frac{\partial^2}{\partial y^2} f(y)$$

The reverse conversion is possible as well:

```
map(%, rewrite, D)
```

$$f'(y),\ f''(y)$$

Example 9

Sometimes you may need the n-th derivative of a function, where n is unknown. This can be achieved using the repeated composition operator. For example, let us write a function that computes the k-th Taylor polynomial of a function f at a point x_0 and uses x as variable for that polynomial:

```
kthtaylorpoly:=
(f, k, x, x0) -> _plus(((D@@n)(f)(x0) * (x - x0)^n / n!) $ n = 0..k):
kthtaylorpoly(sin, 7, x, 0)
```

$$-\frac{x^7}{5040}+\frac{x^5}{120}-\frac{x^3}{6}+x$$

```
delete kthtaylorpoly:
```

Example 10

Advanced users can extend `D` to their own special mathematical functions (see "Background" section below). To this end, embed your mathematical function f, say, into a function environment`f` and implement the behavior of `D` for this function as the `"D"` slot of the function environment. The slot must handle two cases: it may be either called with only one argument which equals `f`, or with two arguments where the second one equals `f`. In the latter case, the first argument is a list of arbitrary many indices; that is, the slot must be able to handle higher partial derivatives also.

Suppose, for example, that we are given a function $f(t, x, y)$, and that we do not know anything about f except that it is differentiable infinitely often and satisfies the partial differential equation $\frac{\partial}{\partial t} f = \frac{\partial^2}{\partial x^2} f + \frac{\partial^2}{\partial y^2} f$. To make MuPAD eliminate derivatives with respect to `t`, we can do the following:

```
f := funcenv(f):
```

```
f::D :=
proc(indexlist, ff)
  local
    n        : DOM_INT,   // Number of t-derivatives.
    list_2_3 : DOM_LIST;  // List of indices of 2's and 3's.
                          // These remain unchanged.
begin
  if args(0) <> 2 then
    error("Wrong number of arguments")
  end_if;
  n        :=  nops(select(indexlist, _equal, 1));
  list_2_3 :=  select(indexlist, _unequal, 1);
  // rewrite (d/dt)^n = (d^2/dx^2 + d^2/dy^2)^n
  _plus(binomial(n, k) *
        hold(D)(sort([2 $ 2*(n-k), 3 $ 2*k].list_2_3), ff)
        $ k = 0..n)
end_proc:
```

Now, partial derivatives with respect to the first argument t are rewritten by derivatives with respect to the second and third argument:

```
D([1], f^2)(t, x, y)
```

$$2\left(\mathrm{D}_{2,2}(f)(t,x,y)+\mathrm{D}_{3,3}(f)(t,x,y)\right)f(t,x,y)$$

```
D([1, 2, 1], f)
```

$$\mathrm{D}_{2,2,2,2,2}(f)+2\,\mathrm{D}_{2,2,2,3,3}(f)+\mathrm{D}_{2,3,3,3,3}(f)$$

```
delete f:
```

Parameters

`f`

A function or a functional expression, an array, a list, a polynomial, a set, or a table

`n1, n2, …`

Indices: positive integers

Return Values

function or a functional expression. If `f` is an array or a list etc., a corresponding object containing the derivatives of the entries is returned.

Overloaded By

f

Algorithms

If `f` is a domain or a function environment with a slot`"D"`, this slot is called to compute the derivative. The slot procedure has the same calling syntax as `D`. In particular — and in contrast to the slot`"diff"`— the slot must be able to compute higher partial derivatives because the list of indices may have length greater than one. Cf. “Example 10” on page 1-491.

If `f` is a procedure, a function environment without a `"D"` slot, then `f` is called with auxiliary identifiers as arguments. The result of the call is then differentiated using the function `diff`. If the result of `diff` yields an expression which can be regarded as function in the auxiliary identifers, then this function is returned, otherwise an unevaluated call of `D` is returned.

Let us take the function environment`sin` as an example. It has no `"D"` slot, thus the procedure `op(sin, 1)`, which is responsible for evaluating the sine function, is used to compute `D(sin)`, as follows. This procedure is applied to an auxiliary identifier, say `x`, and differentiated with respect to this identifier via `diff`. The result is `diff(sin(x), x) = cos(x)`. Via `fp::expr_unapply` and `fp::unapply`, the function `cos` is computed as the derivative of `sin`.

See Also

MuPAD Functions
`diff` | `int` | `poly`

dawson

Dawson's integral

Syntax

```
dawson(x)
```

Description

`dawson(x)` represents Dawson's integral, which is defined as $e^{-x^2} \int_0^x e^{t^2} \, dt$.

`dawson(x)` returns special values for $x = 0$ and $x = \pm\infty$. For all other symbolic values of x, unevaluated function calls are returned. Cf. “Example 1” on page 1-494.

Environment Interactions

When called with floating-point arguments, this function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For the following arguments, special values are returned:

```
dawson(0), dawson(infinity), dawson(-infinity)
```

```
0, 0, 0
```

For other symbolic arguments, a symbolic call is returned:

```
dawson(1), dawson(5+I)
```

$$\text{dawson}(1),\ \text{dawson}(5+i)$$

Floating point values are returned for floating-point arguments:

```
dawson(0.0), dawson(1.0), dawson(-3.4 + 0.2*I)
```

$$0.0,\ 0.5380795069,\ -0.1538060524 - 0.0100961726\,i$$

Example 2

The functions `diff`, `float`, `limit`, and `series` handle expressions involving the dawson function:

```
diff(dawson(x^2), x), float(dawson(7))
```

$$-2\,x\,(2\,x^2\,\text{dawson}(x^2) - 1),\ 0.07218097466$$

```
limit(x*dawson(x), x = infinity)
```

$$\frac{1}{2}$$

```
series(dawson(x), x = infinity, 4)
```

$$\frac{1}{2\,x} + \frac{1}{4\,x^3} + O\left(\frac{1}{x^5}\right)$$

Parameters

x

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

x

See Also

MuPAD Functions
`erf` | `erfc`

debug

Execute a procedure in single-step mode

Syntax

```
debug()
```

```
debug(statement)
```

Description

`debug(statement)` starts the MuPAD debugger, allowing to execute `statement` step by step.

`debug` called with an argument switches the state of the MuPAD kernel to *debug mode* and, if `statement` contains procedure calls that can be debugged, enters the interactive MuPAD debugger for controlled single-step execution of `statement`.

If `debug` is called without arguments, the current state is returned *without* changing the state. If the debugger is on, the return value is `TRUE`, otherwise `FALSE`.

In a MuPAD version with a graphical user interface, a separate debugger window pops up. In the UNIX® terminal version, the text interface of the command line debugger is activated.

The debugger features single stepping, inspection of variables and stack frames, breakpoints, etc. Read the online help of the debugger window for a description.

Debugging is possible only for procedures written in the MuPAD language that do not have the option `noDebug`. In particular, debugging of kernel functions is not possible.

After calling `Pref::ignoreNoDebug(TRUE)`, the procedure option `noDebug` is ignored.

You can also debug a sequence of statements separated by semicolons if the sequence is enclosed in parentheses.

`debug(statement)` returns the same result as `statement`, if the execution is not aborted within the debugger by the user.

Examples

Example 1

`debug()` is called to check whether the kernel is in debug mode:

```
debug()
```

```
                              FALSE
```

To switch on the debugger mode, `debug(1)` is called:

```
debug(1)
```

```
Activating debugger...   For those library functions which are already
loaded, the format of the source code  displayed by the debugger
may differ from that of the original source code file. To avoid this,
restart the kernel in debug mode. Execution completed.
                     1
```

```
debug()
```

```
    TRUE
```

Example 2

We start the debugger for stepwise execution of the statement `int(cos(x),x)`, which integrates the cosine function:

```
debug(int(cos(x), x)):
```

Parameters

`statement`

Any MuPAD object; typically a function call

Return Values

Return value of `statement` or `TRUE` or `FALSE`.

Algorithms

In debug mode, the MuPAD parser is re-configured. When a procedure is read from a file, the parser inserts additional *debug nodes* containing file identifications and line numbers into procedures. These debug nodes allow the debugger to associate the currently executed piece of MuPAD code with the corresponding source text file.

If the debug mode is activated and MuPAD encounters a procedure without debug nodes, it will write the procedure to a temporary file and add debug nodes on the fly. This allows interactively entered procedures to be debugged in the same way as procedures read from files. The temporary debug file is deleted at the end of the session.

Since this also applies to procedures that were read before debug mode was switched on, it is recommended to start the kernel in debug mode (see below) when bigger applications are to be debugged.

If the MuPAD kernel was not started in debug mode, this mode is turned on at the first execution of `debug`. It remains activated until the end of the session.

It is possible to start the kernel in debug mode. In the MuPAD Notebook app, this can be configured by choosing “Configure …” in the “View” menu (“Preferences…” on the Apple Macintosh) and then clicking on “Kernel”. Enter “-g” in the text field “Arguments:”.

MuPAD Functions

`Pref::ignoreNoDebug` | `prog::check` | `prog::profile` | `prog::trace`

dedekindEta

The Dedekind eta function

Syntax

```
dedekindEta(z)
```

Description

`dedekindEta(z)` represents the Dedekind eta function $e^{\frac{\pi i z}{12}} \left(\prod_{n=1}^{\infty}\left(1-e^{2\pi i z n}\right)\right)$.

The Dedekind eta function is defined for all complex numbers `z` with positive imaginary part.

Floating-point results are computed for floating-point arguments. For all other arguments, the function returns symbolically.

Environment Interactions

When called with a floating-point argument, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

The Dedekind eta function takes on small values near the real axis:

```
dedekindEta(1 + 0.001*I)
```

$$6.122295553\ 10^{-113} + 1.640464149\ 10^{-113}\ i$$

Example 2

A symbolic call is returned if the argument is not a floating-point number:

```
dedekindEta(I), dedekindEta(x)
```

$$\text{dedekindEta}(i),\ \text{dedekindEta}(x)$$

Parameters

z

An arithmetical expression

Return Values

Arithmetical expression

See Also

MuPAD Functions
`theta`

degree

Degree of a polynomial

Syntax

```
degree(p)
degree(p, x)
degree(f, <vars>)
degree(f, <vars>, x)
```

Description

`degree(p)` returns the total degree of the polynomial `p`.

`degree(p, x)` returns the degree of `p` with respect to the variable `x`.

If the first argument `f` is not element of a polynomial domain, then `degree` converts the expression internally to a polynomial of type `DOM_POLY` via `poly(f)`. If a list of indeterminates is specified, the polynomial `poly(f, vars)` is considered.

`degree(f, vars, x)` returns 0 if `x` is not an element of the list `vars`.

The degree of the zero polynomial is defined as 0.

Examples

Example 1

The total degree of the terms in the following polynomial expression is computed:

```
degree(x^3 + x^2*y^2 + 2)
```

```
4
```

Example 2

`degree` may be applied to polynomials of type `DOM_POLY`:

```
degree(poly(x^2*z + x*z^3 + 1, [x, z]))
```

```
4
```

Example 3

The next expression is regarded as a bi-variate polynomial in `x` and `z`. The degree with respect to `z` is computed:

```
degree(x^2*z + x*z^3 + 1, [x, z], z)
```

```
3
```

Example 4

The degree of the zero polynomial is defined as 0:

```
degree(0, [x, y])
```

```
0
```

Parameters

`p`

A polynomial of type `DOM_POLY`

`f`

A polynomial expression

`vars`

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

x

An indeterminate

Return Values

Nonnegative number. `FAIL` is returned if the input cannot be converted to a polynomial.

Overloaded By

f, p

See Also

MuPAD Functions

`coeff` | `degreevec` | `ground` | `lcoeff` | `ldegree` | `lmonomial` | `lterm` | `monomials` | `nterms` | `nthcoeff` | `nthmonomial` | `nthterm` | `poly` | `poly2list` | `tcoeff`

degreevec

Exponents of the leading term of a polynomial

Syntax

```
degreevec(p, <order>)
```

```
degreevec(f, <vars>, <order>)
```

Description

`degreevec(p)` returns a list with the exponents of the leading term of the polynomial `p`.

For a polynomial in the variables x_1, x_2, …, x_n with the leading term $x_1^{e_1} x_2^{e_2} \ldots x_n^{e_n}$, the exponent vector $[e_1, e_2, \ldots, e_n]$ is returned.

`degreevec` returns a list of zeroes for the zero polynomial.

If the first argument `f` is not element of a polynomial domain, then `degreevec` converts the expression internally to a polynomial of type `DOM_POLY` via `poly(f)`. If a list of indeterminates is specified, the polynomial `poly(f, vars)` is considered. `FAIL` is returned if `f` cannot be converted to a polynomial.

Examples

Example 1

The leading term of the following polynomial expression (with respect to the main variable `x`) is x^4:

```
degreevec(x^4 + x^2*y^3 + 2, [x, y])
```

```
[4, 0]
```

With the main variable y, the leading term is $x^2 y^3$:

```
degreevec(x^4 + x^2*y^3 + 2, [y, x])
```

```
[3, 2]
```

For polynomials of type DOM_POLY, the indeterminates are an integral part of the data type:

```
degreevec(poly(x^4 + x^2*y^3 + 2, [x, y])),
degreevec(poly(x^4 + x^2*y^3 + 2, [y, x]))
```

```
[4, 0], [3, 2]
```

Example 2

For a univariate polynomial, the standard term orderings regard the same term as "leading":

```
degreevec(poly(x^2*z + x*z^3 + 1, [x]), LexOrder),
degreevec(poly(x^2*z + x*z^3 + 1, [x]), DegreeOrder),
degreevec(poly(x^2*z + x*z^3 + 1, [x]), DegInvLexOrder)
```

```
[2], [2], [2]
```

In the multivariate case, different polynomial orderings may yield different leading exponent vectors:

```
degreevec(poly(x^2*z + x*z^3 + 1, [x, z])),
degreevec(poly(x^2*z + x*z^3 + 1, [x, z]), DegreeOrder)
```

```
[2, 1], [1, 3]
```

```
degreevec(x^3 + x*y^2*z - 5*y^4, [x, y, z], LexOrder),
degreevec(x^3 + x*y^2*z - 5*y^4, [x, y, z], DegreeOrder),
degreevec(x^3 + x*y^2*z - 5*y^4, [x, y, z], DegInvLexOrder)
```

```
[3, 0, 0], [1, 2, 1], [0, 4, 0]
```

Example 3

The exponent vector of the zero polynomial is a list of zeroes:

```
degreevec(0, [x, y, z])
```

```
[0, 0, 0]
```

Parameters

`p`

A polynomial of type `DOM_POLY`

`f`

A polynomial expression

`vars`

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

`order`

The term ordering: either `LexOrder`, or `DegreeOrder`, or `DegInvLexOrder`, or a user-defined term ordering of type `Dom::MonomOrdering`. The default is the lexicographical ordering `LexOrder`.

Return Values

List of nonnegative integers. `FAIL` is returned if the input cannot be converted to a polynomial.

Overloaded By

f, p

delete, _delete

Delete the value of an identifier

Syntax

```
delete x1, x2, …
```

```
_delete(x1, x2, …)
```

Description

The statement `delete x` deletes the value of the identifier `x`.

For many computations, symbolic variables are needed. E.g., solving an equation for an unknown `x` requires an identifier `x` that does not have a value. If `x` has a value, the statement `delete x` deletes the value and `x` can be used as a symbolic variable.

The statement `delete x1, x2, ...` is equivalent to the function call `_delete(x1, x2, ...)`. The values of all specified identifiers are deleted.

The statement `delete x[j]` deletes the entry `j` of a list, an array, an hfarray, or a table named `x`. Deletion of elements or entries reduces the size of lists and tables, respectively.

If `x` is an identifier carrying properties set via `assume`, then `delete x` detaches all properties from `x`, i.e., `delete x` has the same effect as `unassume(x)`. Cf. “Example 3” on page 1-511.

Examples

Example 1

The identifiers `x`, `y` are assigned values. After deletion, the identifiers have no values any longer:

```
x := 42: y := 7: delete x: x, y
```

$x, 7$

```
delete y: x, y
```

x, y

More than one identifier can be deleted by one call:

```
a := b := c := 42: a, b, c
```

$42, 42, 42$

```
delete a, b, c: a, b, c
```

a, b, c

Example 2

`delete` can also be used to delete specific elements of lists, arrays, hfarrays, and tables:

```
L := [7, 13, 42]
```

$[7, 13, 42]$

```
delete L[2]: L
```

$[7, 42]$

```
A := array(1..3, [7, 13, 42])
```

$(7\ 13\ 42)$

```
delete A[2]: A, A[2]
```

$(7\ \text{NIL}\ 42), A_2$

```
T := table(1 = 7, 2 = 13, 3 = 42)
```

1	7
2	13
3	42

```
delete T[2]: T
```

1	7
3	42

Note that `delete` does not evaluate the objects that are to be deleted. In the following, an element of the list `U` is deleted. The original value of `U` (the list `L`) is not changed:

```
U := L: delete U[1]: U, L
```

$$[42], [7, 42]$$

Finally, all assigned values are deleted:

```
delete U, L, A, T: U, L, A, T
```

$$U, L, A, T$$

Example 3

`delete` can also be used to delete properties of identifiers set via `assume`. With the assumption "`x > 1`", the expression `ln(x)` has the property "`ln(x) > 0`", i.e., its sign is 1:

```
assume(x > 1): sign(ln(x))
```

$$1$$

Without a property of `x`, the function `sign` cannot determine the sign of `ln(x)`:

```
delete x: sign(ln(x))
```

$$\mathrm{sign}(\ln(x))$$

Parameters

x_1, x_2, …

identifiers or indexed identifiers

Return Values

Void object of type `DOM_NULL`.

See Also

MuPAD Functions

`:=` | `_assign` | `assign` | `assignElements` | `evalassign`

denom

Denominator of a rational expression

Syntax

```
denom(f)
```

Description

`denom(f)` returns the denominator of the expression `f`.

`denom` regards the input as a rational expression: non-rational subexpressions such as `sin(x)`, `x^(1/2)` etc. are internally replaced by "temporary variables". The denominator of this rationalized expression is computed, the temporary variables are finally replaced by the original subexpressions.

Note: Numerator and denominator are not necessarily cancelled: the denominator returned by `denom` may have a non-trivial `gcd` with the numerator returned by `numer`. Pre-process the expression by `normal` to enforce cancellation of common factors. Cf. "Example 2" on page 1-514.

Examples

Example 1

We compute the denominators of some expressions:

```
denom(-3/4)
```

```
     4
```

```
denom(x + 1/(2/3*x -2/x))
```

$$2x^2 - 6$$

```
denom((cos(x)^2 -1)/(cos(x) -1))
```

$$\cos(x) - 1$$

Example 2

`denom` performs no cancellations if the rational expression is of the form "numerator/denominator":

```
r := (x^2 - 1)/(x^3 - x^2 + x - 1): denom(r)
```

$$x^3 - x^2 + x - 1$$

This denominator has a common factor with the numerator of `r`; `normal` enforces cancellation of common factors:

```
denom(normal(r))
```

$$x^2 + 1$$

However, automatic normalization occurs if the input expression is a sum:

```
denom(r + x/(x + 1) + 1/(x + 1) - 1)
```

$$x^2 + 1$$

```
delete r:
```

Parameters

`f`

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

f

See Also

MuPAD Functions
`factor` | `gcd` | `normal` | `numer`

densematrix

Create a matrix or a vector

Syntax

```
densematrix(Array)
densematrix(List)
densematrix(ListOfRows)
densematrix(Matrix)
densematrix(m, n)
densematrix(m, n, Array)
densematrix(m, n, List)
densematrix(m, n, ListOfRows)
densematrix(m, n, f)
densematrix(m, n, List, Diagonal)
densematrix(m, n, g, Diagonal)
densematrix(m, n, List, Banded)
densematrix(1, n, Array)
densematrix(1, n, List)
densematrix(m, 1, Array)
densematrix(m, 1, List)
```

Description

`densematrix(m, n, [[a11, a12, ...], [a21, a22, ...], ...])` returns the $m \times n$ matrix

$$\begin{pmatrix} a_{11} & a_{12} & \cdots \\ a_{21} & a_{22} & \cdots \\ \vdots & \vdots & \vdots \end{pmatrix}.$$

`densematrix(n, 1, [a1, a2, ...])` returns the $n \times 1$ column vector

$$\begin{pmatrix} a_{11} \\ a_{21} \\ \vdots \end{pmatrix}.$$

`densematrix(1, n, [a1, a2, ...])` returns the $1 \times n$ row vector

$$\begin{pmatrix} a_{11} & a_{21} & \cdots \end{pmatrix}.$$

`densematrix` creates matrices and vectors. A vector with n entries is either an $n \times 1$ matrix (a column vector) or a $1 \times n$ matrix (a row vector).

Matrix and vector components must be arithmetical expressions. For specific component domains, refer to the help page of `Dom::DenseMatrix`.

Arithmetical operations with matrices can be performed by using the standard arithmetical operators of MuPAD.

E.g., if `A` and `B` are two matrices defined by `densematrix`, then `A + B` computes the sum and `A * B` computes the product of the two matrices, provided that the dimensions are correct.

Similarly, `A^(-1)` or `1/A` computes the inverse of a square matrix `A` if it exists. Otherwise, `FAIL` is returned.

See “Example 1” on page 1-520.

Many system functions accept matrices as input, such as `map`, `subs`, `has`, `zip`, `conjugate` to compute the complex conjugate of a matrix, `norm` to compute matrix norms, or even `exp` to compute the exponential of a matrix. See “Example 4” on page 1-523.

Most of the functions in the MuPAD linear algebra package linalg work with matrices. For example, the command `linalg::gaussJordan(A)` performs Gauss-Jordan elimination on `A` to transform `A` to its reduced row echelon form. See “Example 2” on page 1-521.

See the help page of linalg for a list of available functions of this package.

`dendematrix` is an abbreviation for the domain `Dom::DenseMatrix()`. You find more information about this data type for matrices on the corresponding help page.

Matrix components can be extracted by the usual index operator `[ ]`, which also works for lists, arrays, hfarrays, and tables. The call `A[i, j]` extracts the matrix component in the *i*th row and the *j*th column.

Assignments to matrix components are performed similarly. The call `A[i, j] := c` replaces the matrix component in the *i*th row and the *j*th column of *A* by `c`.

If one of the indices is not in its valid range, then an error message is issued.

The index operator also extracts submatrices. The call `A[r1..r2, c1..c2]` creates the submatrix of *A* comprising the rows with the indices r_1, $r_1 + 1$, …, r_2 and the columns with the indices c_1, $c_1 + 1$, …, c_2 of *A*.

See “Example 3” on page 1-522 and “Example 5” on page 1-525.

`dendematrix(Array)` or `dendematrix(Matrix)` create a new matrix with the same dimension and the components of `Array` or `Matrix`, respectively. The array must not contain any uninitialized entries. If `Array` is one-dimensional, then the result is a column vector. Cf. “Example 7” on page 1-527.

`dendematrix(List)` creates an $m \times 1$ column vector with components taken from the nonempty list, where m is the number of entries of `List`. See “Example 5” on page 1-525.

`dendematrix(ListOfRows)` creates an $m \times n$ matrix with components taken from the nested list`ListOfRows`, where m is the number of inner lists of `ListOfRows`, and n is the maximal number of elements of an inner list. Each inner list corresponds to a row of the matrix. Both m and n must be non-zero.

If an inner list has less than n entries, then the remaining components in the corresponding row of the matrix are set to zero. See “Example 6” on page 1-526.

It might be a good idea first to create a two-dimensional array from that list before calling `densematrix`. This is due to the fact that creating a matrix from an array is the fastest way one can achieve. However, in this case the sublists must have the same number of elements.

The call `densematrix(m, n)` returns the $m \times n$ zero matrix.

The call `densematrix(m, n, Array)` creates an $m \times n$ matrix with components taken from `Array`, which must be an array or an hfarray. `Array` must have $m\,n$ operands. The first m operands define the first row, the next m operands define the second row, etc. The formatting of the array is irrelevant. E.g., any array with 6 elements can be used to create matrices of dimension 1×6, or 2×3, or 3×2, or 6×1.

`densematrix(m, n, List)` creates an $m \times n$ matrix with components taken row after row from the non-empty list. The list must contain $m\,n$ entries. Cf. “Example 6” on page 1-526.

`densematrix(m, n, ListOfRows)` creates an $m \times n$ matrix with components taken from the list `ListOfRows`.

If $m \geq 2$ and $n \geq 2$, then `ListOfRows` must consist of at most `m` inner lists, each having at most `n` entries. The inner lists correspond to the rows of the returned matrix.

If an inner list has less than `n` entries, then the remaining components of the corresponding row of the matrix are set to zero. If there are less than `m` inner lists, then the remaining lower rows of the matrix are filled with zeroes. See “Example 6” on page 1-526.

`densematrix(m, n, f)` returns the matrix whose (i, j)th component is `f(i,j)`. The row index i runs from 1 to m and the column index j from 1 to n. See “Example 8” on page 1-529.

`densematrix(m, 1, Array)` returns the $m \times 1$ column vector with components taken from `Array`. The `array` or `hfarray` `Array` must have `m` entries.

`densematrix(m, 1, List)` returns the $m \times 1$ column vector with components taken from `List`. The list `List` must have at most `m` entries. If there are fewer entries, then the remaining vector components are set to zero. See “Example 5” on page 1-525.

`densematrix(1, n, Array)` returns the $1 \times n$ row vector with components taken from `Array`. The `array` or `hfarray` `Array` must have `n` entries.

`densematrix(1, n, List)` returns the $1 \times n$ row vector with components taken from `List`. The list `List` must have at most `n` entries. If there are fewer entries, then the remaining vector components are set to zero. See “Example 5” on page 1-525.

Note: The components of a matrix are no longer evaluated after the creation of the matrix, i.e., if they contain free identifiers they will not be replaced by their values.

Examples

Example 1

We create the 2×2 matrix

$$\begin{pmatrix} 1 & 5 \\ 2 & 3 \end{pmatrix}$$

by passing a list of two rows to `densematrix`, where each row is a list of two elements, as follows:

```
A := densematrix([[1, 5], [2, 3]])
```

$$\begin{pmatrix} 1 & 5 \\ 2 & 3 \end{pmatrix}$$

In the same way, we generate the following 2 ×3 matrix:

```
B := densematrix([[-1, 5/2, 3], [1/3, 0, 2/5]])
```

$$\begin{pmatrix} -1 & \frac{5}{2} & 3 \\ \frac{1}{3} & 0 & \frac{2}{5} \end{pmatrix}$$

We can do matrix arithmetic using the standard arithmetical operators of MuPAD. For example, the matrix product $A\,B$, the 4th power of A, and the scalar multiplication of A by $\frac{1}{3}$ are given by:

```
A * B, A^4, 1/3 * A
```

$$\begin{pmatrix} \frac{2}{3} & \frac{5}{2} & 5 \\ -1 & 5 & \frac{36}{5} \end{pmatrix}, \begin{pmatrix} 281 & 600 \\ 240 & 521 \end{pmatrix}, \begin{pmatrix} \frac{1}{3} & \frac{5}{3} \\ \frac{2}{3} & 1 \end{pmatrix}$$

Since the dimensions of the matrices *A* and *B* differ, the sum of *A* and *B* is not defined and MuPAD returns an error message:

```
A + B
```

```
Error: The dimensions do not match. [(Dom::DenseMatrix(Dom::ExpressionField()))::_plus]
```

To compute the inverse of *A*, enter:

```
1/A
```

$$\begin{pmatrix} -\frac{3}{7} & \frac{5}{7} \\ \frac{2}{7} & -\frac{1}{7} \end{pmatrix}$$

If a matrix is not invertible, then the result of this operation is `FAIL`:

```
C := densematrix([[2, 0], [0, 0]])
```

$$\begin{pmatrix} 2 & 0 \\ 0 & 0 \end{pmatrix}$$

```
C^(-1)
```

FAIL

Example 2

In addition to standard matrix arithmetic, the library linalg offers a lot of functions handling matrices. For example, the function `linalg::rank` determines the rank of a matrix:

```
A := densematrix([[1, 5], [2, 3]])
```

$$\begin{pmatrix} 1 & 5 \\ 2 & 3 \end{pmatrix}$$

```
linalg::rank(A)
```

$$2$$

The function `linalg::eigenvectors` computes the eigenvalues and the eigenvectors of A:

```
linalg::eigenvectors(A)
```

$$\left[\left[2-\sqrt{11},\ 1,\ \left[\begin{pmatrix} -\frac{\sqrt{11}}{2}-\frac{1}{2} \\ 1 \end{pmatrix}\right]\right],\ \left[\sqrt{11}+2,\ 1,\ \left[\begin{pmatrix} \frac{\sqrt{11}}{2}-\frac{1}{2} \\ 1 \end{pmatrix}\right]\right]\right]$$

To determine the dimension of a matrix use the function `linalg::matdim`:

```
linalg::matdim(A)
```

$$[2, 2]$$

The result is a list of two positive integers, the row and column number of the matrix.

Use `info(linalg)` to obtain a list of available functions, or enter `?linalg` for details about this library.

Example 3

Matrix entries can be accessed with the index operator `[ ]`:

```
A := densematrix([[1, 2, 3, 4], [2, 0, 4, 1], [-1, 0, 5, 2]])
```

$$\begin{pmatrix} 1 & 2 & 3 & 4 \\ 2 & 0 & 4 & 1 \\ -1 & 0 & 5 & 2 \end{pmatrix}$$

```
A[2, 1] * A[1, 2] - A[3, 1] * A[1, 3]
```

$$7$$

You can redefine a matrix entry by assigning a value to it:

```
A[1, 2] := a^2: A
```

$$\begin{pmatrix} 1 & a^2 & 3 & 4 \\ 2 & 0 & 4 & 1 \\ -1 & 0 & 5 & 2 \end{pmatrix}$$

The index operator can also be used to extract submatrices. The following call creates a copy of the submatrix of *A* comprising the second and the third row and the first three columns of *A*:

```
A[2..3, 1..3]
```

$$\begin{pmatrix} 2 & 0 & 4 \\ -1 & 0 & 5 \end{pmatrix}$$

The index operator does *not* allow to replace a submatrix of a given matrix by another matrix. Use `linalg::substitute` to achieve this.

Example 4

Some system functions can be applied to matrices. For example, if you have a matrix with symbolic entries and want to have all entries in expanded form, simply apply the function `expand`:

```
delete a, b:
A := densematrix([
  [(a - b)^2, a^2 + b^2],
  [a^2 + b^2, (a - b)*(a + b)]
])
```

$$\begin{pmatrix} (a-b)^2 & a^2+b^2 \\ a^2+b^2 & (a+b)\,(a-b) \end{pmatrix}$$

```
expand(A)
```

$$\begin{pmatrix} a^2 - 2ab + b^2 & a^2 + b^2 \\ a^2 + b^2 & a^2 - b^2 \end{pmatrix}$$

You can differentiate all matrix components with respect to some indeterminate:

```
diff(A, a)
```

$$\begin{pmatrix} 2a - 2b & 2a \\ 2a & 2a \end{pmatrix}$$

The following command evaluates all matrix components at a given point:

```
subs(A, a = 1, b = -1)
```

$$\begin{pmatrix} 4 & 2 \\ 2 & 0 \end{pmatrix}$$

Note that the function `subs` does not evaluate the result of the substitution. For example, we define the following matrix:

```
A := densematrix([[sin(x), x], [x, cos(x)]])
```

$$\begin{pmatrix} \sin(x) & x \\ x & \cos(x) \end{pmatrix}$$

Then we substitute $x = 0$ in each matrix component:

```
B := subs(A, x = 0)
```

$$\begin{pmatrix} \sin(0) & 0 \\ 0 & \cos(0) \end{pmatrix}$$

You see that the matrix components are not evaluated completely: for example, if you enter `sin(0)` directly, it evaluates to zero.

The function `eval` can be used to evaluate the result of the function `subs`. However, `eval` does not operate on matrices directly, and you must use the function `map` to apply the function `eval` to each matrix component:

```
map(B, eval)
```

$$\begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$$

The function `zip` can be applied to matrices. The following call combines two matrices A and B by dividing each component of A by the corresponding component of B:

```
A := densematrix([[4, 2], [9, 3]]):
B := densematrix([[2, 1], [3, -1]]):
zip(A, B, `/`)
```

$$\begin{pmatrix} 2 & 2 \\ 3 & -3 \end{pmatrix}$$

Example 5

A vector is either an $m \times 1$ matrix (a column vector) or a $1 \times n$ matrix (a row vector). To create a vector with `densematrix`, pass the dimension of the vector and a list of vector components as argument to `densematrix`:

```
row_vector    := densematrix(1, 3, [1, 2, 3]);
column_vector := densematrix(3, 1, [1, 2, 3])
```

$$\begin{pmatrix} 1 & 2 & 3 \end{pmatrix}$$

$$\begin{pmatrix} 1 \\ 2 \\ 3 \end{pmatrix}$$

If the only argument of `densematrix` is a non-nested list or a one-dimensional array, then the result is a column vector:

```
densematrix([1, 2, 3])
```

$$\begin{pmatrix} 1 \\ 2 \\ 3 \end{pmatrix}$$

For a row vector `r`, the calls `r[1, i]` and `r[i]` both return the *i*th vector component of `r`. Similarly, for a column vector `c`, the calls `c[i, 1]` and `c[i]` both return the *i*th vector component of `c`.

For example, to extract the second component of the vectors `row_vector` and `column_vector`, we enter:

```
row_vector[2], column_vector[2]
```

$$2, 2$$

Use the function `linalg::vecdim` to determine the number of components of a vector:

```
linalg::vecdim(row_vector), linalg::vecdim(column_vector)
```

$$3, 3$$

The number of components of a vector can also be determined directly by the call `nops(vector)`.

The dimension of a vector can be determined as described above in the case of matrices:

```
linalg::matdim(row_vector),
linalg::matdim(column_vector)
```

$$[1, 3], [3, 1]$$

See the linalg package for functions working with vectors, and the help page of `norm` for computing vector norms.

Example 6

In the following examples, we illustrate various calls of `densematrix` as described above. We start by passing a nested list to `densematrix`, where each inner list corresponds to a row of the matrix:

```
densematrix([[1, 2], [2]])
```

$$\begin{pmatrix} 1 & 2 \\ 2 & 0 \end{pmatrix}$$

The number of rows of the created matrix is the number of inner lists, namely $m = 2$. The number of columns is determined by the maximal number of entries of an inner list. In the example above, the first list is the longest one, and hence $n = 2$. The second list has only one element, and therefore the second entry in the second row of the returned matrix was set to zero.

In the following call, we use the same nested list, but in addition pass two dimension parameters to create a 4×4 matrix:

```
densematrix(4, 4, [[1, 2], [2]])
```

$$\begin{pmatrix} 1 & 2 & 0 & 0 \\ 2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

In this case, the dimension of the matrix is given by the dimension parameters. As before, missing entries in an inner list correspond to zero, and in addition missing rows are treated as zero rows.

If the dimension $m \times n$ of the matrix is stated explicitly, the entries may also be specified by a plain list with $m\ n$ elements. The matrix is filled with these elements row by row:

```
densematrix(2, 3, [1, 2, 3, 4, 5, 6])
```

$$\begin{pmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{pmatrix}$$

```
densematrix(3, 2, [1, 2, 3, 4, 5, 6])
```

$$\begin{pmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{pmatrix}$$

Example 7

A one- or two-dimensional array of arithmetical expressions, such as:

```
a := array(1..3, 2..4, [[ 1,  1/3 ,  0 ],
                        [-2,  3/5 , 1/2],
```

```
[-3/2, 0 ,  -1 ]])
```

$$\begin{pmatrix} 1 & \frac{1}{3} & 0 \\ -2 & \frac{3}{5} & \frac{1}{2} \\ -\frac{3}{2} & 0 & -1 \end{pmatrix}$$

can be converted into a matrix as follows:

```
A := densematrix(a)
```

$$\begin{pmatrix} 1 & \frac{1}{3} & 0 \\ -2 & \frac{3}{5} & \frac{1}{2} \\ -\frac{3}{2} & 0 & -1 \end{pmatrix}$$

Arrays serve, for example, as an efficient structured data type for programming. However, arrays do not have any algebraic meaning, and no mathematical operations are defined for them. If you convert an array into a matrix, you can use the full functionality defined for matrices as described above. For example, let us compute the matrix $2A - A^2$ and the Frobenius norm of A:

```
2*A - A^2, norm(A, Frobenius)
```

$$\begin{pmatrix} \frac{5}{3} & \frac{2}{15} & -\frac{1}{6} \\ -\frac{1}{20} & \frac{113}{75} & \frac{6}{5} \\ -3 & \frac{1}{2} & -3 \end{pmatrix}, \frac{\sqrt{450}\,\sqrt{4037}}{450}$$

Note that an array may contain uninitialized entries:

```
b := array(1..4): b[1] := 2: b[4] := 0: b
```

$$(2 \text{ NIL NIL } 0)$$

`densematrix` cannot handle arrays that have uninitialized entries, and responds with an error message:

```
densematrix(b)
```

```
Error: Cannot define a matrix over 'Dom::ExpressionField()'. [(Dom::DenseMatrix(Dom::Ex
```

We initialize the remaining entries of the array `b` and convert it into a matrix, or more precisely, into a column vector:

```
b[2] := 0: b[3] := -1: densematrix(b)
```

$$\begin{pmatrix} 2 \\ 0 \\ -1 \\ 0 \end{pmatrix}$$

Example 8

We show how to create a matrix whose components are defined by a function of the row and the column index. The entry in the *i*th row and the *j*th column of a Hilbert matrix (see also `linalg::hilbert`) is $\frac{1}{(i+j-1)}$. Thus the following command creates a 2×2 Hilbert matrix:

```
densematrix(2, 2, (i, j) -> 1/(i + j - 1))
```

$$\begin{pmatrix} 1 & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{3} \end{pmatrix}$$

The following two calls produce different results. In the first call, `x` is regarded as an unknown function, while it is a constant in the second call:

```
delete x:
densematrix(2, 2, x), densematrix(2, 2, (i, j) -> x)
```

$$\begin{pmatrix} x(1,1) & x(1,2) \\ x(2,1) & x(2,2) \end{pmatrix}, \begin{pmatrix} x & x \\ x & x \end{pmatrix}$$

Example 9

Diagonal matrices can be created by passing the option `Diagonal` and a list of diagonal entries:

```
densematrix(3, 4, [1, 2, 3], Diagonal)
```

$$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 \\ 0 & 0 & 3 & 0 \end{pmatrix}$$

Hence, you can generate the 3×3 identity matrix as follows:

```
densematrix(3, 3, [1 $ 3], Diagonal)
```

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

Equivalently, you can use a function of one argument:

```
densematrix(3, 3, i -> 1, Diagonal)
```

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

Since the integer `1` also represents a constant function, the following shorter call creates the same matrix:

```
densematrix(3, 3, 1, Diagonal)
```

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

Example 10

Banded Toeplitz matrices (see above) can be created with the option `Banded`. The following command creates a matrix of bandwidth 3 with all main diagonal entries equal to 2 and all entries on the first sub- and superdiagonal equal to - 1:

```
densematrix(4, 4, [-1, 2, -1], Banded)
```

$$\begin{pmatrix} 2 & -1 & 0 & 0 \\ -1 & 2 & -1 & 0 \\ 0 & -1 & 2 & -1 \\ 0 & 0 & -1 & 2 \end{pmatrix}$$

Parameters

`Array`

A one- or two-dimensional array of type `DOM_ARRAY` or `DOM_HFARRAY`

`List`

A list of arithmetical expressions

`ListOfRows`

A nested list of rows, each row being a list of arithmetical expressions

`Matrix`

A matrix, i.e., an object of a data type of category `Cat::Matrix`

`m`

The number of rows: a positive integer

`n`

The number of columns: a positive integer

`f`

A function or a functional expression of two arguments

`g`

A function or a functional expression of one argument

Options

`Diagonal`

Create a diagonal matrix

With the option `Diagonal`, diagonal matrices can be created with diagonal elements taken from a list, or computed by a function or a functional expression.

`densematrix(m, n, List, Diagonal)` creates the $m \times n$ diagonal matrix whose diagonal elements are the entries of `List`. See "Example 9" on page 1-530.

`List` must have at most $min(m, n)$ entries. If it has fewer elements, then the remaining diagonal elements are set to zero.

`densematrix(m, n, g, Diagonal)` returns the matrix whose ith diagonal element is `g(i, i)`, where the index i runs from 1 to $min(m, n)$. See "Example 9" on page 1-530.

`Banded`

Create a banded Toeplitz matrix

A *banded matrix* has all entries zero outside the main diagonal and some of the adjacent sub- and superdiagonals.

`densematrix(m, n, List, Banded)` creates an $m \times n$ banded Toeplitz matrix with the elements of `List` as entries. The number of entries of `List` must be odd, say $2h + 1$, and must not exceed `n`. The bandwidth of the resulting matrix is at most h.

All elements of the main diagonal of the created matrix are initialized with the middle element of `List`. All elements of the ith subdiagonal are initialized with the $(h + 1 - i)$th element of `List`. All elements of the ith superdiagonal are initialized with the $(h + 1 + i)$th element of `List`. All entries on the remaining sub- and superdiagonals are set to zero.

See "Example 10" on page 1-530.

Return Values

Matrix of the domain type`Dom::DenseMatrix()`.

`Dom::DenseMatrix` | `Dom::Matrix` | `DOM_ARRAY` | `DOM_HFARRAY`

MuPAD Functions
`array` | `hfarray` | `matrix`

det

Determinant of a matrix

Syntax

```
det(A, options)
```

Description

`det(A)` returns the determinant of the matrix *A*.

If the input matrix is an `array` of domain type `DOM_ARRAY`, then `numeric::det(A, Symbolic)` is called to compute the result.

The determinant of `hfarray`s of domain type `DOM_HFARRAY` is internally computed via `numeric::det(A)`.

If the argument does not evaluate to a matrix of one of the types mentioned above, a symbolic call `det(A)` is returned.

The `MinorExpansion` option is useful for small matrices (typically, matrices of dimension up to 10) containing many symbolic entries. By default, `det` tries to recognize matrices that can benefit from using `MinorExpansion`, and uses this option when computing their determinants. Nevertheless, `det` does not always recognize these matrices. Also, identifying that a matrix is small enough and contains many symbolic entries takes time. To improve performance, use the `MinorExpansion` option explicitly.

By default, `det` calls `normal` before returning results. This additional internal call ensures that the final result is normalized. This call can be computationally expensive. It also affects the result returned by `det` only if a matrix contains variables or exact expressions, such as `sqrt(5)` or `sin(PI/7)`.

To avoid this additional call, specify `Normal = FALSE`. In this case, `det` also can return normalized results, but does not guarantee such normalization. See “Example 3” on page 1-536 and “Example 4” on page 1-536.

Examples

Example 1

We compute the determinant of a matrix given by various data types:

```
A := array(1..2, 1..2, [[1, 2], [3, PI]]);
det(A)
```

$$\begin{pmatrix} 1 & 2 \\ 3 & \pi \end{pmatrix}$$

$$\pi - 6$$

```
B := hfarray(1..2, 1..2, [[1, 2], [3, PI]]);
det(B)
```

$$\begin{pmatrix} 1.0 & 2.0 \\ 3.0 & 3.141592654 \end{pmatrix}$$

$$-2.858407346$$

```
C := matrix(2, 2, [[1, 2], [3, PI]]);
det(C)
```

$$\begin{pmatrix} 1 & 2 \\ 3 & \pi \end{pmatrix}$$

$$\pi - 6$$

```
delete A, B, C:
```

Example 2

If the input does not evaluate to a matrix, then symbolic calls are returned:

```
delete A, B:
det(A + 2*B)
```

$$\det(A + 2B)$$

Example 3

If you use the `Normal` option, `det` calls the `normal` function for final results. This call ensures that `det` returns results in normalized form:

```
det(matrix([[x, x^2], [x/(x + 2), 1/x]]))
```

$$\frac{-x^3 + x + 2}{x + 2}$$

If you specify `Normal = FALSE`, `det` does not call `normal` for the final result:

```
det(matrix([[x, x^2], [x/(x + 2), 1/x]]), Normal = FALSE)
```

$$1 - \frac{x^3}{x + 2}$$

Example 4

Using `Normal` can significantly decrease performance of `det`. For example, computing the determinant of this matrix takes a long time:

```
n := 5:
det5 := det(matrix([[(x[i*j]^(i + j) + x[i+j]^j)/(i + j) $
                                                  j = 1..n] $
                                                  i = 1..n])):
```

For better performance, specify `Normal = FALSE`:

```
n := 5:
det5 := det(matrix([[(x[i*j]^(i + j) + x[i+j]^j)/(i + j) $
                                                  j = 1..n] $
                                                  i = 1..n]),
                                            Normal = FALSE):
```

Parameters

A

Square matrix: either a two-dimensional `array`, a two-dimensional `hfarray`, or an object of the category `Cat::Matrix`

Options

`MinorExpansion`

Compute the determinant by a recursive minor expansion along the first column.

`Normal`

Option, specified as `Normal = b`

Return normalized results. The value `b` must be `TRUE` or `FALSE`. By default, `Normal = TRUE`, meaning that `det` guarantees normalization of the returned results. Normalizing results can be computationally expensive.

Return Values

Arithmetical expression.

More About

- "Compute Determinants and Traces of Square Matrices"

diff

Differentiate an expression or a polynomial

Syntax

```
diff(f)
```

```
diff(f, x)
```

```
diff(f, x1, x2, …)
```

Description

`diff(f, x)` computes the derivative $\frac{\partial}{\partial x} f$ of the function `f` with respect to the variable `x`.

`diff(f, x)` computes the partial derivative of the arithmetical expression (or polynomial) `f` with respect to the indeterminate `x`.

`diff(f)` computes the 0th derivative of `f`. Since the 0th derivative of `f` is `f` itself, `diff(f)` returns its evaluated argument.

`diff(f, x1, x2, ...)` is equivalent to `diff(...diff(diff(f, x1), x2)...)`. In both cases, MuPAD first differentiates `f` with respect to `x1`, then differentiates the result with respect to `x2`, and so on. The result is the partial derivative $\cdots \frac{\partial}{\partial x_1} \frac{\partial}{\partial x_2} f$. See "Example 2" on page 1-540.

If you use nested `diff` calls, the system internally converts them into a single `diff` call with multiple arguments. See "Example 3" on page 1-540.

When computing the second and higher derivatives, use the sequence operator as a shortcut. If `n` is a nonnegative integer, `diff(f, x $ n)` returns the *n*th derivative of `f` with respect to `x`. See "Example 4" on page 1-540.

The indeterminates `x, x1, x2, ...` must be identifiers of domain type `DOM_IDENT` or indexed identifiers of the form `x[n]` where `x` is an identifier and `n` is an integer. If any

indeterminate comes in any other form, MuPAD returns an unresolved `diff` call. See “Example 5” on page 1-541.

If `f` is an arithmetical expression, `diff` returns an arithmetical expression. If `f` is a polynomial, `diff` returns a polynomial. See “Example 6” on page 1-541.

If the system cannot compute the derivative, it returns an unresolved `diff` call. See “Example 7” on page 1-541.

MuPAD assumes that partial derivatives with respect to different indeterminates commute. The function calls `diff(f, x1, x2)` and `diff(f, x2, x1)` produce the same result `diff(f, y1, y2)`. Here `[y1, y2] = sort([x1, x2])`. See “Example 8” on page 1-542.

MuPAD provides two functions, `diff` and `D`, for computing derivatives. Use the differential operator `D` to compute the derivatives of functions. Use the `diff` function to compute the derivatives of arithmetical expressions. Mathematically, `D(f)(x)` coincides with `diff(f(x), x)` and `D([1, 2], f)(x, y)` coincides with `diff(f(x, y), x, y)`. You can convert symbolic calls of `D` to the calls of `diff` and vice versa by using `rewrite`. See “Example 10” on page 1-542.

You can extend the functionality of `diff` for your own special mathematical functions via overloading. This approach works by turning the corresponding function into a function environment and implementing the differentiation rule for the function as the `"diff"` `slot` of the function environment.

If a subexpression of the form `g(..)` occurs in `f`, and `g` is a function environment, then `diff(f, x)` attempts to call the `"diff"` slot of `g` to determine the derivative of `g(..)`.

The system calls the `"diff"` slot with the arguments `g(..), x`.

If `g` does not have a `"diff"` slot, then the system function `diff` returns the symbolic expression `diff(g(..), x)` for the derivative of the subexpression.

The system always calls the `"diff"` slot with exactly two arguments. If you call the `diff` function with more indeterminates (for example, if you compute a higher derivative), then MuPAD calls the `"diff"` slot several times. Each call computes the derivative with respect to one indeterminate. The system caches the results of the calls of `"diff"` slots in `diff` in order to prevent redundant function calls. See “Example 11” on page 1-543.

Similarly, if an element `d` of a library domain `T` occurs as a subexpression of `f`, then `diff(f, x)` calls the slot `T::diff(d, x)` to compute the derivative of `d`.

If the domain `T` does not have a `"diff"` slot, then `diff` considers this object as a constant and returns 0 for the corresponding subexpression.

Examples

Example 1

Compute the derivative of x^2 with respect to `x`:

```
diff(x^2, x)
```

$$2\,x$$

Example 2

You can differentiate with respect to multiple variables within a single `diff` call. For example, differentiate this expression with respect to `x`, and then with differentiate the result with respect to `y`:

```
diff(x^2*sin(y), x, y) = diff(diff(x^2*sin(y), x), y)
```

$$2\,x\,\cos(y) = 2\,x\,\cos(y)$$

Example 3

MuPAD internally converts nested `diff` calls into a single `diff` call with multiple arguments:

```
diff(diff(f(x, y), x), y)
```

$$\frac{\partial}{\partial y}\,\frac{\partial}{\partial x}\,f(x, y)$$

Example 4

Use the sequence operator `$` as a shortcut to compute the third derivative of this expression with respect to `x`:

```
diff(sin(x)*cos(x), x $ 3)
```

$$4\sin(x)^2 - 4\cos(x)^2$$

Example 5

You can differentiate with respect to an indexed identifier. For example, differentiate this expression with respect to `x[1]`:

```
diff(x[1]*y + x[1]*x[r], x[1])
```

$$y + x_r + \delta_{r-1,0}\, x_1$$

Example 6

You can differentiate `polynomials` with respect to the polynomial indeterminates or the parameters in the coefficients. For example, differentiate this polynomial with respect to the indeterminate `x`:

```
diff(poly(sin(a)*x^3 + 2*x, [x]), x)
```

$$\mathrm{poly}((3\sin(a))\, x^2 + 2, [x])$$

Now differentiate the same polynomial with respect to its symbolic parameter `a`:

```
diff(poly(sin(a)*x^3 + 2*x, [x]), a)
```

$$\mathrm{poly}(\cos(a)\, x^3, [x])$$

Example 7

MuPAD returns the derivative of an unknown function as an unresolved `diff` call:

```
diff(f(x) + x, x)
```

$$\frac{\partial}{\partial x} f(x) + 1$$

Example 8

MuPAD assumes that all partial derivatives with respect to different indeterminates commute. Therefore, the system can change the order of indeterminates:

```
diff(f(x, y), x, y) = diff(f(x, y), y, x);
```

$$\frac{\partial}{\partial y}\frac{\partial}{\partial x} f(x, y) = \frac{\partial}{\partial y}\frac{\partial}{\partial x} f(x, y)$$

Example 9

You can use `diff` to differentiate symbolic integrals. For example, compute the second derivative of this indefinite integral:

```
F1 := int(f(x), x):
diff(F1, x, x)
```

$$\frac{\partial}{\partial x} f(x)$$

Now compute the derivative of the definite integral:

```
F2 := int(f(t, x), t = x..x^2):
diff(F2, x)
```

$$\int_x^{x^2} \frac{\partial}{\partial x} f(t, x)\, \mathrm{d}t - f(x, x) + 2\,x\, f(x^2, x)$$

Example 10

Use the operator `D` to compute the derivatives of functions. Use the `diff` function to compute the derivatives of expressions:

```
D(sin), diff(sin(x), x)
```

$$\cos, \cos(x)$$

Applying `D` to expressions and `diff` to functions makes no sense:

```
D(sin(x)), diff(sin, x)
```

$$(\sin(x))', 0$$

Use the `rewrite` function to rewrite an expression replacing the operator `D` with the `diff` function:

```
rewrite(D(f)(x), diff), rewrite(D(D(f))(x), diff)
```

$$\frac{\partial}{\partial x} f(x), \frac{\partial^2}{\partial x^2} f(x)$$

Also, use `rewrite` to rewrite an expression replacing `diff` with `D`:

```
diff(f(x, x), x) = rewrite(diff(f(x, x), x), D)
```

$$\frac{\partial}{\partial x} f(x, x) = \mathrm{D}_1(f)(x, x) + \mathrm{D}_2(f)(x, x)$$

Example 11

You can extend `diff` to your own special functions. To do so, embed your function, `f`, into a function environment, `g`, and implement the behavior of `diff` for this function as the `"diff"` slot of the function environment.

If a subexpression of the form `g(..)` occurs in an expression `f`, then `diff(f, x)` calls `g::diff(g(..), x)` to determine the derivative of the subexpression `g(..)`.

This example demonstrates extending `diff` to the exponential function. Since the function environment `exp` already has a `"diff"` slot, call the new function environment `Exp` to avoid overwriting the existing system function `exp`.

Here, the `"diff"` slot implements the chain rule for the exponential function. The derivative is the product of the original function call and the derivative of the argument:

```
Exp := funcenv(Exp):
Exp::diff := proc(f, x)
begin
```

```
   // f = Exp(something), i.e., something = op(f, 1)
   f*diff(op(f, 1), x):
end_proc:
diff(Exp(x^2), x)
```

$$2\,x\,\mathrm{Exp}(x^2)$$

The report created by `prog::trace` shows one call to `Exp::diff` with two arguments. Instead of calling `Exp::diff` twice, the system reads the required result of the second call from an internal cache for intermediate results in `diff`:

```
prog::trace(Exp::diff):
diff(Exp(x^2), x, x)
```

```
enter Exp::diff(Exp(x^2), x)
computed 2*x*Exp(x^2)
```

$$2\,\mathrm{Exp}(x^2) + 4\,x^2\,\mathrm{Exp}(x^2)$$

```
prog::untrace(Exp::diff):  delete f, Exp:
```

Parameters

`f`

An arithmetical expression or a polynomial of type `DOM_POLY`

`x, x1, x2, …`

Indeterminates: identifiers or indexed identifiers

Return Values

arithmetical expression or a polynomial

Overloaded By

f

DIGITS

Significant digits of floating-point numbers

Description

The environment variable `DIGITS` determines the number of significant decimal digits in floating-point numbers. The default value is `DIGITS = 10`.

Possible values: a positive integer larger than 1 and smaller than $2^{29} + 1$.

Floating point numbers are created by applying the function `float` to exact numbers or numerical expressions. Elementary objects are approximated by the resulting floats with a relative precision of `10^(-DIGITS)`, i.e., the first `DIGITS` decimal digits are correct. Cf. “Example 1” on page 1-547.

In arithmetical operations with floating-point numbers, only the first `DIGITS` decimal digits are taken into account. The numerical error propagates and may grow in the course of computations. Cf. “Example 2” on page 1-548.

If a real floating-point number is entered directly (e.g., by `x := 1.234`), a number with at least `DIGITS` internal decimal digits is created.

If a real float is entered with more than `DIGITS` digits, the internal representation stores the extra digits. However, they are not taken into account in arithmetical operations, unless `DIGITS` is increased accordingly. Cf. “Example 3” on page 1-548.

In particular, complex floating-point numbers are created by adding the real and imaginary part. This addition truncates extra decimal places in the real and imaginary part.

The value of `DIGITS` may be changed at any time during a computation. If `DIGITS` is decreased, only the leading digits of existing floating numbers are taken into account in the following arithmetical operations. If `DIGITS` is increased, existing floating-point numbers are internally padded with trailing binary zeroes. Cf. “Example 4” on page 1-549.

Depending on `DIGITS`, certain functions such as the trigonometric functions may give wrong results if floats as arguments are too inaccurate. Cf. “Example 5” on page 1-549.

Depending on DIGITS, only significant digits of floating-point numbers are displayed on the screen. The preferences Pref::floatFormat and Pref::trailingZeroes can be used to modify the screen output. Cf. “Example 4” on page 1-549.

At least one digit after the decimal point is displayed; if it is insignificant, it is replaced by zero. Cf. “Example 6” on page 1-550.

Internally, floating-point numbers are created and stored with some extra “guard digits.” These are also taken into account by the basic arithmetical operations.

For example, for DIGITS = 10, the function float converts exact numbers to floats with some more decimal digits. The number of guard digits depends on DIGITS.

At least 2 internal guard digits are available for any value of DIGITS.

See “Example 4” on page 1-549 and “Example 7” on page 1-550.

Environment variables such as DIGITS are global variables. Upon return from a procedure that changes DIGITS, the new value is valid outside the context of the procedure as well! Use save DIGITS to restrict the modified value of DIGITS to the procedure. See “Example 8” on page 1-551.

The default value of DIGITS is 10; DIGITS has this value after starting or resetting the system via reset. Also the command delete DIGITS; restores the default value.

See the helppage of float for further information.

Examples

Example 1

We convert some exact numbers and numerical expressions to floating point approximations:

```
DIGITS := 10:
float(PI), float(1/7), float(sqrt(2) + exp(3)), float(exp(-20))
```

```
3.141592654, 0.1428571429, 21.49975049, 0.000000002061153622
```

```
DIGITS := 20:
```

```
float(PI), float(1/7), float(sqrt(2) + exp(3)), float(exp(-20))
```

```
3.1415926535897932385, 0.14285714285714285714, 21.49975048556076279,
  0.000000002061153622438557828
```

```
delete DIGITS:
```

Example 2

We illustrate error propagation in numerical computations. The following rational number approximates `exp(2)` to 17 decimal digits:

```
r := 738905609893065023/100000000000000000:
```

The following `float` call converts `exp(2)` and `r` to floating point approximations. The approximation errors propagate and are amplified in the following numerical expression:

```
DIGITS := 6: float(10^20*(r - exp(2)))
```

```
16777200.0
```

None of the digits in this result is correct. A better result is obtained by increasing `DIGITS`:

```
DIGITS := 20: float(10^20*(r - exp(2)))
```

```
276.95725393295288086
```

```
delete r, DIGITS:
```

Example 3

In the following, only 10 of the entered 30 digits are regarded as significant. The extra digits are stored internally, anyway:

```
DIGITS := 10:
a := 1.23456789666666666666666666666;
b := 1.23456789444444444444444444444
```

```
1.234567897
```

```
1.234567894
```

We increase `DIGITS`. Because the internal representation of `a` and `b` is correct to 30 decimal place, the difference can be computed correctly to 20 decimal places:

```
DIGITS := 30: a - b
```

```
0.000000002222222222222222222222000000001
```

```
delete a, b, DIGITS:
```

Example 4

We compute a floating-point number with a precision of 10 digits. Internally, this number is stored with some guard digits. Increasing `DIGITS` to 30, the correct guard digits become visible. With the the call `Pref::trailingZeroes(TRUE)`, trailing zeroes of the decimal representation become visible:

```
DIGITS := 10: a := float(1/9)
```

```
0.1111111111
```

```
0.11111111111111111101473758466795516142155975103378295898437500000000000000000000000
```

```
Pref::trailingZeroes(TRUE): DIGITS := 100: a
```

```
0.11111111111111111101473758466795516142155975103378295898437500000000000000000000000
```

```
Pref::trailingZeroes(FALSE): delete a, DIGITS:
```

Example 5

For the float evaluation of the sine function, the argument is reduced to the standard interval [0, 2 π]. For this reduction, the argument must be known to some digits after the decimal point. For small `DIGITS`, the digits after the decimal point are pure round-off if the argument is a large floating-point number:

```
DIGITS := 10: sin(float(2*10^30))
```

$$-0.6054240282$$

Increasing `DIGITS` to 50, the argument of the the sine function has about 30 correct digits after the decimal point. The first 30 digits of the following result are reliable:

```
DIGITS := 50: sin(float(2*10^30))
```

$$0.17950046751493908795061771231643809505098047699633$$

```
delete DIGITS:
```

Example 6

At least one digit after the decimal point is always displayed. In the following example, the number `39.9` is displayed as `40.0` because "`40.`" would not be a valid MuPAD input:

```
DIGITS := 2: float(10*PI), 39.9, -30.2
```

$$31.0,\ 40.0,\ -30.0$$

```
delete DIGITS:
```

Example 7

We compute `float(10^40*8/9)` with various values of `DIGITS`. Rounding takes into account all guard digits, i.e., the resulting integer makes all guard digits visible:

```
for DIGITS in [7, 8, 9, 17, 18, 19, 26, 27, 28] do
    print("DIGITS" = DIGITS, round(float(10^40*8/9)))
end_for:
```

$$\text{"DIGITS"} = 7,\ 88888888888888880843201856109995486085 12$$

$$\text{"DIGITS"} = 8,\ 88888888888888892932460052256287233146 88$$

$$\text{"DIGITS"} = 9,\ 88888888888888888398988228701427827998 72$$

"DIGITS" = 17, 88888888888888888888888884187865840353 28

"DIGITS" = 18, 88888888888888888888888884099904910131 2

"DIGITS" = 19, 88888888888888888888888893775607234560

"DIGITS" = 26, 88888888888888888888888888888888655872

"DIGITS" = 27, 88888888888888888888888888888888918016

"DIGITS" = 28, 88888888888888888888888888888888885248

Example 8

The following procedure allows to compute numerical approximations with a specified precision without changing `DIGITS` as a global variable. Internally, `DIGITS` is set to the desired precision and the float approximation is computed. Because of `save DIGITS`, the value of `DIGITS` is not changed outside the procedure:

```
myfloat := proc(x, digits)
           save DIGITS;
           begin
             DIGITS := digits:
             float(x);
           end_proc:
```

The float approximation of the following value `x` suffers from numerical cancellation. The procedure `myloat` is used to approximate `x` with 30 digits. The result is displayed with only 7 digits because of the value `DIGITS` = 7 valid outside the procedure. However, all displayed digits are correct:

```
x := PI^7 - exp(8013109200945801/1000000000000000):
DIGITS := 7:
float(x), myfloat(x, 30)
```

$$5.09317\ 10^{-11},\ 6.614563\ 10^{-13}$$

```
delete myfloat, x, DIGITS:
```

Algorithms

If a floating-point number `x` has been created with high precision, and the computation is to continue at a lower precision, the easiest method to get rid of memory-consuming insignificant digits is `x := x + 0.0`.

MuPAD Functions

`float` | `Pref::floatFormat` | `Pref::outputDigits` | `Pref::trailingZeroes`

dilog

Dilogarithm function

Syntax

```
dilog(x)
```

Description

`dilog(x)` represents the dilogarithm function $\int_1^x \frac{\ln(t)}{1-t}\,dt$.

If `x` is a floating-point number, then `dilog(x)` returns the numerical value of the dilogarithm function. The special values:

`dilog(-1)` = $\frac{\pi^2}{4} - i\,\pi\,\ln(2)$,

`dilog(0)` = $\frac{\pi^2}{6}$,

`dilog(1/2)` = $\frac{\pi^2}{12} - \frac{\ln(2)^2}{2}$,

`dilog(1)` = 0,

`dilog(2)` = $-\frac{\pi^2}{12}$,

`dilog(I)` = $\frac{\pi^2}{16} - i\,\mathrm{CATALAN} - \frac{i\,\pi\,\ln(2)}{4}$,

`dilog(-I)`= $\frac{\pi^2}{16} + i\,\mathrm{CATALAN} + \frac{i\,\pi\,\ln(2)}{4}$,

`dilog(1+I)` = $-\frac{\pi^2}{48} - i\,\mathrm{CATALAN}$,

`dilog(1-I)` = $-\frac{\pi^2}{48} + i\,\mathrm{CATALAN}$,

`dilog(infinity) = -infinity`

are implemented. For all other arguments, `dilog` returns a symbolic function call.

Functional identities are used to rewrite the result for exact numerical arguments of `Type::Numeric` that have a negative real part or are of absolute value larger than 1. Cf. "Example 2" on page 1-554.

`dilog(x)` coincides with `polylog(2, 1-x)`.

Environment Interactions

When called with a floating-point argument, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
dilog(0), dilog(2/3), dilog(sqrt(2)), dilog(1 + I), dilog(x)
```

$$\frac{\pi^2}{6},\ \mathrm{Li}_2\left(\frac{2}{3}\right),\ \mathrm{Li}_2(\sqrt{2}),\ -\frac{\pi^2}{48}-\mathrm{CATALAN}\,i,\ \mathrm{Li}_2(x)$$

Floating point values are computed for floating-point arguments:

```
dilog(-1.2), dilog(3.4 - 5.6*I)
```

$$2.458586602-2.477011851\,i,\ -2.529187195+2.25273709\,i$$

Example 2

Arguments built from integers and rational numbers are rewritten, if they lie in the left half of the complex plane or are of absolute value larger than 1. The following arguments have a negative real part:

```
dilog(-400/3), dilog(-1/2 + I)
```

$$\mathrm{Li}_2\left(\frac{3}{403}\right) - \ln\left(\frac{403}{3}\right)\left(\ln\left(\frac{400}{3}\right) + \pi\,i\right) + \frac{\pi^2}{6} + \frac{\ln\left(\frac{403}{3}\right)^2}{2},\ \mathrm{Li}_2\left(\frac{6}{13} + \frac{4\,i}{13}\right) - \ln\left(-\frac{1}{2} + i\right)\sigma_1 + \frac{\pi^2}{6} + \frac{{\sigma_1}^2}{2}$$

where

$$\sigma_1 = \ln\left(\frac{3}{2} - i\right)$$

The following arguments have an absolute value larger than 1:

```
dilog(31/30), dilog(1 + 2/3*I)
```

$$-\mathrm{Li}_2\left(\frac{30}{31}\right) - \frac{\ln\left(\frac{31}{30}\right)^2}{2},\ -\mathrm{Li}_2\left(\frac{9}{13} - \frac{6\,i}{13}\right) - \frac{\ln\left(1 + \frac{2\,i}{3}\right)^2}{2}$$

Example 3

The negative real axis is a branch cut of `dilog`. A jump of height $2\,\pi\,i\,ln(1 - x)$ occurs when crossing this cut at the real point $x < 0$:

```
dilog(-1.2), dilog(-1.2 + I/10^100), dilog(-1.2 - I/10^100)
```

$$2.458586602 - 2.477011851\,i,\ 2.458586602 - 2.477011851\,i,\ 2.458586602 + 2.477011851\,i$$

Example 4

The functions `diff`, `float`, `limit`, and `series` handle expressions involving `dilog`:

```
diff(dilog(x), x, x, x), float(ln(3 + dilog(sqrt(PI))))
```

$$\frac{2}{x\,(x-1)^2} + \frac{1}{x^2\,(x-1)} - \frac{2\ln(x)}{(x-1)^3},\ 0.8503829845$$

```
limit(dilog(x^10 + 1)/x, x = infinity)
```

```
0
```

```
series(dilog(x + 1/x)/x, x = -infinity, 3)
```

$$-\frac{\frac{\pi^2}{6}+\frac{(\ln(-x)+\pi\,i)^2}{2}}{x}+\frac{\ln(-x)+1+\pi\,i}{x^2}-\frac{\frac{\ln(-x)}{2}-\frac{1}{4}+\frac{\pi\,i}{2}}{x^3}+O\left(\frac{1}{x^4}\right)$$

Parameters

x

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

x

Algorithms

`dilog(x)` coincides with $\sum_{k=1}^{\infty}\frac{(1-x)^k}{k^2}$ for $|x|<1$.

`dilog` has a branch cut along the negative real axis. The value at a point x on the cut coincides with the limit "from above":

$$\mathrm{Li}_2(x)=\lim_{\varepsilon\to 0+}x+\varepsilon\,i=\left(\lim_{\varepsilon\to 0-}x+\varepsilon\,i\right)-2\,\pi\,i\ln(1-x)$$

.

See Also

MuPAD Functions

`ln` | `polylog`

dirac

The Dirac delta distribution

Syntax

```
dirac(x)
```

```
dirac(x, n)
```

Description

`dirac(x)` represents the Dirac delta distribution.

`dirac(x, n)` represents the n-th derivative of the delta distribution.

The calls `dirac(x, 0)` and `dirac(x)` are equivalent.

If the argument `x` represents a non-zero number, then 0 is returned. If `x` is a non-real number of domain type `DOM_COMPLEX`, then `undefined` is returned. For all other arguments, a symbolic function call is returned.

`dirac` does not have a predefined value at the origin. Use

```
unprotect(dirac): dirac(0) := myValue:
```

and

```
dirac(float(0)) := myFloatValue: protect(dirac):
```

to assign a value (e.g., `infinity`).

For univariate linear expressions, the simplification rule

$$\delta^{(n)}(a\,x-b)=\frac{\operatorname{sign}(a)}{a^{n+1}}\,\delta^{(n)}\left(x-\frac{b}{a}\right)$$

is implemented for real numerical values `a`.

The integration function `int` treats `dirac` as the usual delta distribution. Cf. “Example 3” on page 1-560.

Environment Interactions

`dirac` reacts to properties of identifiers.

Examples

Example 1

`dirac` returns 0 for arguments representing non-zero real numbers:

```
dirac(-3), dirac(3/2), dirac(2.1, 1),
dirac(3*PI), dirac(sqrt(3), 3)
```

$$0,\ 0,\ 0.0,\ 0,\ 0$$

Arguments of domain type `DOM_COMPLEX` yield `undefined`:

```
dirac(1 + I), dirac(2/3 + 7*I), dirac(0.1*I, 1), dirac(ln(-5))
```

$$\text{undefined},\ \text{undefined},\ \text{undefined},\ \text{undefined}$$

A symbolic call is returned for other arguments:

```
dirac(0), dirac(x), dirac(x + I, 2), dirac(x, n)
```

$$\delta(0),\ \delta(x),\ \delta''(x+\mathrm{i}),\ \delta^{(n)}(x)$$

```
dirac(2*x - 1, n)
```

$$\frac{1}{2^{n+1}}\,\delta^{(n)}\left(x-\frac{1}{2}\right)$$

A natural value for `dirac(0)` is `infinity`:

```
unprotect(dirac): dirac(0) := infinity: dirac(0)
```

$$\infty$$

```
delete dirac(0): protect(dirac): dirac(0)
```

$$\delta(0)$$

Example 2

`dirac` reacts to assumptions set by `assume`:

```
assume(x < 0): dirac(x)
```

$$0$$

```
assume(x, Type::Real): assume(x <> 0, _and): dirac(x)
```

$$0$$

```
unassume(x):
```

Example 3

The symbolic integration function `int` treats `dirac` as the delta distribution:

```
int(f(x)*dirac(x - y^2), x = -infinity..infinity)
```

$$f(y^2)$$

```
int(int(f(x, y)*dirac(x - y^2), x = -infinity..infinity),
    y = -1..1)
```

$$\int_{-1}^{1} f(y^2, y)\,\mathrm{d}\,y$$

The indefinite integral of `dirac` involves the `sign` function:

```
int(f(x)*dirac(x), x), int(f(x)*dirac(x, 1), x)
```

$$\frac{f(0)\,\mathrm{sign}(x)}{2},\ f(0)\,\delta(x) - \frac{f'(0)\,\mathrm{sign}(x)}{2}$$

`int` can handle the distribution only if the argument of `dirac` is linear in the integration variable:

```
int(f(x)*dirac(2*x - 3), x = -10..10),
int(f(x)*dirac(x^2), x = -10..10)
```

$$\frac{f\left(\frac{3}{2}\right)}{2},\ \int_{-10}^{10} \delta(x^2)\,f(x)\,\mathrm{d}x$$

Also note that `dirac` should not be used for numerical integration, since the numerical algorithm will typically fail to detect the delta peak:

```
numeric::int(dirac(x - 3), x = -10..10)
```

$$0.0$$

Parameters

x

An arithmetical expression

n

An arithmetical expression representing a nonnegative integer

Return Values

Arithmetical expression.

Overloaded By

x

MuPAD Functions
`heaviside`

discont

Discontinuities of a function

Syntax

```
discont(f, x)

discont(f, x, <Undefined>)

discont(f, x, <Real>)

discont(f, x = a .. b)

discont(f, x = a .. b, <Undefined>)

discont(f, x = a .. b, <Real>)
```

Description

`discont(f, x)` computes the set of all discontinuities of the function $f(x)$.

`discont(f, x = a..b)` computes the set of all discontinuities of $f(x)$ lying in the interval $[a, b]$.

`discont(f, x)` returns a set of numbers containing all discontinuities of f when f is regarded as a function of x on the set of all complex numbers that may be attained by `x` as values, as specified by the assumptions on `x`. Please note that a real number that is a discontinuity of a complex function need not be a discontinuity of the restriction of that function to the set of real numbers: consider, for example, a function that has its branch cut on the real axis, as in "Example 2" on page 1-564 below.

Discontinuities include points where the function is not defined as well as points where the function is defined but not continuous. If the option `Undefined` is used, only points where the function is not defined are returned.

If the option `Real` is used, it is assumed that `f` and all of its subexpressions represent real numbers.

If a range `a..b` is given, it is assumed that `x` can take on values only in the interval $[a, b]$.

The set returned by `discont` may contain numbers that are not discontinuities of *f*. See “Example 7” on page 1-566.

If `discont` is unable to compute the discontinuities, then a symbolic `discont` call is returned; see “Example 8” on page 1-566.

`discont` can be extended to user-defined mathematical functions via overloading. To this end, embed the mathematical function in a function environment and assign the set of real discontinuities to its `"realDiscont"` slot, the set of its complex discontinuities to its `"complexDiscont"` slot, and the set of points where the function is not defined to its `"undefined"` slot. See `solve` for an overview of the various types of sets. See also “Example 8” on page 1-566 below.

Environment Interactions

`discont` reacts to properties of free parameters both in `f` as well as in `a` and `b`. `discont` sometimes reacts to properties of `x`.

Examples

Example 1

The `gamma` function has poles at all integers less or equal to zero. Hence `x -> gamma(x/2)` has poles at all even integers less or equal to zero:

```
discont(gamma(x/2), x)
```

$$(-\infty, 0] \cap \{2k \mid k \in \mathbb{Z}\}$$

Example 2

The logarithm has a branch cut on the negative real axis; hence, it is not continuous there. However, its restriction to the real numbers is continuous at every point except zero:

```
discont(ln(x), x), discont(ln(x), x, Real)
```

$$(-\infty, 0], \{0\}$$

Example 3

The function `sign` is defined everywhere; it is not continous at zero:

```
discont(sign(x), x), discont(sign(x), x, Undefined)
```

$$\{0\}, \varnothing$$

Example 4

If a range is given, only the discontinuities in that range are returned.

```
discont(1/x/(x - 1), x = 0..1/2)
```

$$\{0\}$$

Example 5

A range may have arbitrary arithmetical expressions as boundaries. `discont` implicitly assumes that the right boundary is greater or equal to the left boundary:

```
discont(1/x, x = a..b)
```

$$\begin{cases} \{0\} & \text{if } a \le 0 \wedge 0 \le b \\ \varnothing & \text{if } 0 < a \vee b < 0 \end{cases}$$

Example 6

As can be seen from the previous example, `discont` reacts to properties of free parameters (because `piecewise` does). The result also depends on the properties of `x`: it may omit values that `x` cannot take on anyway because of its properties.

```
assume(x > 0):
discont(1/x, x)
```

$$\varnothing$$

```
delete x:
```

Example 7

Sometimes, `discont` returns a proper superset of the set of discontinuities:

```
discont(piecewise([x<>0, x*sin(1/x)], [x=0, 0]), x)
```

$$\{0\}$$

Example 8

A symbolic `discont` call is returned if the system does not know how to determine the discontinuities of a given function:

```
delete f: discont(f(x), x)
```

$$\text{discont}(f(x), x)$$

You can provide the necessary information by adding slots to `f`. For example, assume that `f` is not continuous at `1` but everywhere else; and that also its restriction to the real numbers remains discontinuous at `1`. After adding the corresponding slots, `discont` takes care to handle `f` correctly also if it appears in a more complicated expression:

```
f:= funcenv(x->procname(x)):
f::realDiscont:= {1}:
f::complexDiscont:= {1}:
discont(f(sin(x)), x=-4..34)
```

$$\left\{\frac{\pi}{2}, \frac{5\,\pi}{2}, \frac{9\,\pi}{2}, \frac{13\,\pi}{2}, \frac{17\,\pi}{2}, \frac{21\,\pi}{2}\right\}$$

Example 9

We define a function that implements the logarithm to base 2. For simplicity, we let it always return the unevaluated function call. The logarithm has a branch cut on the negative real axis; its restriction to the reals is continuous everywhere except at zero:

```
binlog := funcenv(x -> procname(x)):
binlog::realDiscont := {0}:
binlog::undefined := {0}:
binlog::complexDiscont := Dom::Interval(-infinity, [0]):
discont(binlog(x), x);
discont(binlog(x), x=-2..2, Real);
discont(binlog(x), x=-2..2, Undefined)
```

$$(-\infty, 0]$$

$$\{0\}$$

$$\{0\}$$

Parameters

`f`

An arithmetical expression representing a function in `x`

`x`

An identifier

`a, b`

Interval boundaries: arithmetical expressions

Options

`Undefined`

Return only those points where `f` is not defined (and not just discontinous).

`Real`

Assume that all subexpressions of `f` are real.

Return Values

Set—see the help page for `solve` for an overview of all types of sets—or a symbolic `discont` call.

Overloaded By

f

See Also

MuPAD Functions
`limit` | `solve`

div, _div

Integer part of a quotient

Syntax

```
m div n
```

```
_div(x, m)
```

Description

`x div m` represents the integer q satisfying $x = q\,m + r$ with $0 \le r < |m|$.

For positive `x` and `m`, `q = x div m` is the integer part of the quotient `x/m`, i.e., `q = trunc(x/m)`.

`x div m` is equivalent to the function call `_div(x, m)`.

An integer is returned if both `x` and `m` evaluate to integers. A symbolic expression of type `"_div"` is returned if either `x` or `m` does not evaluate to a number. An error is raised if `x` or `m` evaluates to a number that is not an integer.

`div` does not operate on polynomials. Use `divide`.

Examples

Example 1

With the default setting for `mod`, the identity `(x div m) * m + (x mod m) = x` holds for integer numbers `x` and `m`:

```
43 div 13 = trunc(43/13), 43 mod 13 = frac(43/13) * 13
```

$$3 = 3,\ 4 = 4$$

```
(43 div 13) * 13 + (43 mod 13) = 43
```

$$43 = 43$$

Example 2

Symbolic expressions of type `"_div"` are returned, if either `x` or `m` does not evaluate to a number:

```
43 div m, x div 13, x div m
```

$$43 \operatorname{div} m,\ x \operatorname{div} 13,\ x \operatorname{div} m$$

```
type(x div m)
```

$$\text{"\_div"}$$

If `x` or `m` are numbers, they must be integer numbers:

```
1/2 div 2
```

```
Error: The argument is invalid. [div]
```

```
x div 2.0
```

```
Error: The argument is invalid. [div]
```

Parameters

`x, m`

Integers or symbolic arithmetical expressions; `m` must not be zero.

Return Values

Integer or an arithmetical expression of type `"_div"`.

Overloaded By

m, x

MuPAD Functions

`/` | `divide` | `mod` | `mod` | `modp` | `mods`

divergence

Divergence of a vector field

Syntax

```
divergence(v, x)
```

```
divergence(v, x, ogCoord, <c>)
```

Description

`divergence(v, x)` computes the divergence of the vector field $\vec{v}$ with respect to $\vec{x}$ in Cartesian coordinates. This is the sum $\mathrm{div}(\vec{v}) = \sum_{i=1}^{n} \frac{\partial}{\partial x_i} v_i$.

`ogCoord` can be the name of a three-dimensional orthogonal coordinate system predefined in the table `linalg::ogCoordTab`. See “Example 2” on page 1-573.

Alternatively, `ogCoord` can be a list of vector of algebraic expressions representing the scale factors of the coordinate system. See example “Example 3” on page 1-573. For details, see the description of the `Scales` option on the `linalg::ogCoordTab` page.

If `v` is a vector then the component ring of `v` must be a field (a domain of category `Cat::Field`) for which differentiation with respect to `x` is defined.

Examples

Example 1

Compute the divergence of the vector field $\vec{v}(x, y, z) = (x^2, 2\,y, z)$ in Cartesian coordinates:

```
delete x, y, z:
```

```
v := matrix([x^2, 2*y, z])
```

$$\begin{pmatrix} x^2 \\ 2\,y \\ z \end{pmatrix}$$

```
divergence(v, [x, y, z])
```

$$2\,x+3$$

Example 2

Compute the divergence of the vector field $\vec{v}(r, \phi, z) = (r, \cos(\phi), z)$ $(0 \le \phi < 2\,\pi)$ in cylindrical coordinates:

```
delete r, phi, z:
divergence([r, sin(phi), z], [r, phi, z], Cylindrical)
```

$$\frac{3\,r+\cos(\mathrm{phi})}{r}$$

The following relations between Cartesian and cylindrical coordinates hold:

$$x = r\,\cos(\phi),\ y = r\,\sin(\phi),\ z = z$$

.

Other predefined orthogonal coordinate systems can be found in the table `linalg::ogCoordTab`.

Example 3

Compute the divergence of a vector field in spherical coordinates r, θ, ϕ given by

$$\vec{x} = \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} r\,\sin(\theta)\,\cos(\phi) \\ r\,\sin(\theta)\,\sin(\phi) \\ r\,\cos(\theta) \end{pmatrix}$$

with $0 \le \theta \le \pi$, $0 \le \phi < 2\,\pi$. The vectors

$$\vec{e}_r = \frac{\frac{\partial}{\partial r}\vec{x}}{\left|\frac{\partial}{\partial r}\vec{x}\right|} = \begin{pmatrix} \sin(\theta)\cos(\phi) \\ \sin(\theta)\sin(\phi) \\ \cos(\theta) \end{pmatrix}, \quad \vec{e}_\theta = \frac{\frac{\partial}{\partial \theta}\vec{x}}{\left|\frac{\partial}{\partial \theta}\vec{x}\right|} = \begin{pmatrix} \cos(\theta)\cos(\phi) \\ \cos(\theta)\sin(\phi) \\ -\sin(\theta) \end{pmatrix},$$

$$\vec{e}_\phi = \frac{\frac{\partial}{\partial \phi}\vec{x}}{\left|\frac{\partial}{\partial \phi}\vec{x}\right|} = \begin{pmatrix} -\sin(\phi) \\ \cos(\phi) \\ 0 \end{pmatrix}$$

form an orthogonal system of unit vectors corresponding to the spherical coordinates. The scaling factors of the coordinate transformation (see `linalg::ogCoordTab`) are $\left|\frac{\partial}{\partial r}\vec{x}\right| = 1$, $\left|\frac{\partial}{\partial \theta}\vec{x}\right| = r$, $\left|\frac{\partial}{\partial \phi}\vec{x}\right| = r\sin(\theta)$, which we use in the following example to compute the divergence of the vector field $\vec{v}(r, \theta, \phi) = r^2\,\vec{e}_r$:

```
delete r, Theta, phi:
divergence([r^2, 0, 0], [r, Theta, phi], [1, r, r*sin(Theta)])
```

$$4\,r$$

Note that the spherical coordinates are already defined in `linalg::ogCoordTab`. The last result can also be achieved with the input `divergence([r^2, 0, 0], [r, Theta, phi], Spherical[RightHanded])`:

```
divergence([r^2, 0, 0], [r, Theta, phi], Spherical[RightHanded])
```

$$4\,r$$

Parameters

v

A list of arithmetical expressions, or a vector (i.e., an $n \times 1$ or $1 \times n$ matrix of a domain of category `Cat::Matrix`)

x

A list of identifiers or indexed identifiers

ogCoord

The name of a 3 dimensional orthogonal coordinate system predefined in the table `linalg::ogCoordTab`, or a list of algebraic expressions representing the scale factors of an orthogonal coordinate system.

c

The parameter of the coordinate systems EllipticCylindrical and Torus, respectively: an arithmetical expression. The default value is `c` = 1.

Return Values

Arithmetical expression, or an element of the component ring of `v`.

divide

Divide polynomials

Syntax

```
divide(p, q, <[x]>, <order>, options)
```

```
divide(p, q, <[x1, x2, …]>, <order>, options)
```

```
divide(p, q1, q2, …, <order>, options)
```

Description

`divide(p, q)` divides polynomials or polynomial expressions `p` and `q`. By default, the function returns the quotient s and the remainder r, such that $p = s\,q + r$. Here $degree(r) < degree(q)$.

`divide`(p, q_1, q_2, q_3, …, q_n) divides a polynomial or a polynomial expression `p` by polynomials or polynomial expressions q_1, q_2, q_3, …, q_n. The function returns the quotients s_1, s_2, s_3, …, s_n and the remainder `r`, such that $p = s_1\,q_1 + s_2\,q_2 + s_3\,q_3 + \ldots + s_4\,q_4 + r$. Here the leading coefficient of the remainder `r` cannot be divided by the leading coefficients of any of divisors q_1, q_2, q_3, …, q_n.

`divide(p, q)` divides the polynomial or polynomial expression `p` by the polynomial or polynomial expression `q`. Use the `Quo` option to return the quotient only. Use the `Rem` option to return the remainder only.

The `divide` function operates on polynomials or polynomial expressions.

Polynomials must be of the same type: their variables and coefficient rings must be identical.

When you call `divide` for polynomial expressions, MuPAD internally converts these expressions to polynomials. See the `poly` function. If you do not specify the list of indeterminates, `divide` treats all symbolic variables in the expressions as indeterminates. If the expressions cannot be converted to polynomials, the `divide` function returns `FAIL`. See “Example 1” on page 1-577.

If you call `divide` for polynomials, it returns polynomials. If you call `divide` for polynomial expressions, the function returns polynomial expressions. See “Example 2” on page 1-578.

If you divide polynomial expressions that contain more than one variable, you can specify particular variables to be treated as variables. The `divide` function treats all other variables as symbolic parameters. By default, `divide` assumes that all variables in polynomial expressions are variables, and none of them is a symbolic parameter. See “Example 3” on page 1-578.

`divide`(p, q_1, q_2, q_3, …, q_n) divides a polynomial or a polynomial expression `p` by polynomials or polynomial expressions q_1, q_2, q_3, …, q_n. The function returns quotients s_1, s_2, s_3, …, s_n and remainder `r`, such that $p = s_1 q_1 + s_2 q_2 + s_3 q_3 + \ldots + s_4 q_4 + r$. Here the leading coefficient of the remainder `r` cannot be divided by the leading coefficients of any of the divisors q_1, q_2, q_3, …, q_n. See “Example 6” on page 1-580.

When dividing a polynomial by one or more polynomials, you can select the term ordering. The ordering accepts the following values:

- `LexOrder` sets the lexicographical ordering.
- `DegreeOrder` sets the total degree ordering. When using this ordering, MuPAD sorts the terms of a polynomial according to the total degree of each term (the sum of the exponents of the variables).
- `DegInvLexOrder` sets the total degree inverse lexicographic ordering. When using this ordering, MuPAD sorts the terms of a polynomial according to the total degree of each term (the sum of the exponents of the variables). If the several terms have equal total degrees, MuPAD sorts them using the inverse lexicographic ordering.
- your custom term ordering of type `Dom::MonomOrdering`.

The coefficient ring of the polynomials must implement the `"_divide"` method. MuPAD uses this method internally to divide coefficients. If the coefficients cannot be divided, this method must return `FAIL`.

Examples

Example 1

For polynomial expressions, `divide` internally calls the `poly` function, which converts an expression to a polynomial. If you do not specify the indeterminate of an expression,

MuPAD assumes that all variables are indeterminates. For example, The `divide` function cannot divide the following polynomial expressions because it assumes that both `x` and `y` are indeterminates:

```
divide(x/y, x)
```

FAIL

If you specify that only `x` is an indeterminate, the result is:

```
divide(x/y, x, [x])
```

$$\frac{1}{y}, 0$$

Example 2

The `divide` divides polynomials or polynomial expressions. When you divide polynomials, the function returns polynomials:

```
divide(poly(x^3 + x + 1, [x]), poly(x^2 + x + 1, [x]))
```

$$\mathrm{poly}(x-1, [x]), \mathrm{poly}(x+2, [x])$$

When you divide polynomial expressions, MuPAD internally converts these expressions to polynomials, divides these polynomials, and then converts the result of division to polynomial expressions:

```
divide(x^3 + x + 1, x^2 + x + 1)
```

$$x-1, x+2$$

Example 3

When dividing multivariate polynomials, you can specify the list of variables. The `divide` function assumes all other variables are symbolic parameters. For example,

divide the following two polynomial expressions specifying that both `x` and `y` are variables:

```
divide(x^2 - 2*x - y, y*x - 1, [x, y])
```

$$0, x^2 - 2x - y$$

Divide the same polynomial expressions specifying that only `x` is a variable. MuPAD assumes that `y` is a symbolic parameter:

```
divide(x^2 - 2*x - y, y*x - 1, [x])
```

$$\frac{\frac{1}{y} - 2}{y} + \frac{x}{y}, \frac{\frac{1}{y} - 2}{y} - y$$

Now, divide these expressions specifying that only `y` is a variable. MuPAD assumes that `x` is a symbolic parameter:

```
divide(x^2 - 2*x - y, y*x - 1, [y])
```

$$-\frac{1}{x}, x^2 - \frac{1}{x} - 2x$$

By default, the `divide` function treats polynomial expressions with more than one variable as multivariate polynomial expressions. The function does not assume that any of the variables are symbolic parameters:

```
divide(x^2 - 2*x - y, y*x - 1)
```

$$0, x^2 - 2x - y$$

Example 4

By default, `divide` returns the quotient and the remainder of the division of polynomials:

```
divide(x^3 + x + 1, x^2 + x + 1)
```

$$x-1, x+2$$

To return the quotient only, use the `Quo` option:

```
divide(x^3 + x + 1, x^2 + x + 1, Quo)
```

$$x-1$$

To return the remainder only, use the `Rem` option:

```
divide(x^3 + x + 1, x^2 + x + 1, Rem)
```

$$x+2$$

Example 5

Suppose, you want to get the result of the division only when the exact division is possible. To return the quotient `s` of the exact division of polynomials or polynomial expressions, use the `Exact` option:

```
divide(x^4 + 12*x^3 + 28*x^2 + 204*x + 187, x + 11, Exact)
```

$$x^3+x^2+17x+17$$

When exact division without remainder is impossible, the `divide` function with the `Exact` option returns `FAIL`:

```
divide(x^4 + 12*x^3 + 28*x^2 + 204*x + 187, x + 12, Exact)
```

FAIL

Example 6

The `divide` function allows you to divide a polynomial (or polynomial expression) by multiple polynomials (or polynomial expressions):

```
divide(4*x^4 + 2*x^2 + 1, x^3 - x + 1, x - 1)
```

$$4\,x,\ 6\,x+2,\ 3$$

When dividing a polynomial by multiple polynomials, you can select the term ordering:

```
divide(x^2+y^3+1, x-y^2, y, LexOrder)
```

$$y^2+x,\ y^3+y^2,\ 1$$

```
divide(x^2+y^3+1, x-y^2, y, DegreeOrder)
```

$$-y,\ x,\ x^2+1$$

Parameters

`p, q`

Univariate or multivariate polynomials or polynomial expressions.

$p, q_1, q_2, \ldots$

Univariate or multivariate polynomials or polynomial expressions.

`x`

The indeterminate of the polynomial: typically, an identifier or an indexed identifier. `divide` treats the expressions as univariate polynomials in the indeterminate `x`.

$x_1, x_2, \ldots$

The indeterminates of the polynomial: typically, identifiers or indexed identifiers. `divide` treats multivariate expressions as multivariate polynomials in these indeterminates.

`order`

The term ordering when dividing one multivariate polynomial by one or more multivariate polynomials: `LexOrder`, `DegreeOrder`, `DegInvLexOrder`, or a custom term ordering of type `Dom::MonomOrdering`. The default is the lexicographical ordering `LexOrder`.

Options

`Exact`

Return the quotient `s` of the exact division of multivariate polynomials. If no exact division without remainder is possible, return `FAIL`.

`Quo, Rem`

Return the quotient `s` or the remainder `r`. By default, the `divide` function returns both the quotient and the remainder.

Return Values

Polynomial, a polynomial expression, a sequence of polynomials or polynomial expressions, or the value `FAIL`.

Overloaded By

p, q

See Also

MuPAD Functions

`/` | `content` | `degree` | `div` | `factor` | `gcd` | `gcdex` | `groebner::normalf` | `ground` | `lcoeff` | `mod` | `multcoeffs` | `pdivide` | `poly` | `powermod`

domtype

Data type of an object

Syntax

```
domtype(object)
```

Description

`domtype(object)` returns the domain type (the data type) of the object.

For most data types, the domain type as returned by `domtype` coincides with the type returned by the function `type`. Only for expressions of domain type `DOM_EXPR`, the function `type` yields a distinction according to the 0-th operand. Cf. “Example 2” on page 1-584.

In contrast to most other functions, `domtype` does not flatten arguments that are expression sequences.

Examples

Example 1

Real floating-point numbers are of domain type `DOM_FLOAT`:

```
domtype(12.345)
```

```
DOM_FLOAT
```

Complex numbers are of domain type `DOM_COMPLEX`. The operands may be integers (`DOM_INT`), rational numbers (`DOM_RAT`), or floating-point numbers (`DOM_FLOAT`). The operands can be accessed via `op`:

```
domtype(1 - 2*I), op(1 - 2*I);
domtype(1/2 - I), op(1/2 - I);
```

```
domtype(2.0 - 3.0*I), op(2.0 - 3.0*I)
```

DOM_COMPLEX, $1, -2$

DOM_COMPLEX, $\frac{1}{2}, -1$

DOM_COMPLEX, $2.0, -3.0$

Example 2

Expressions are objects of the domain type `DOM_EXPR`. The type of expressions can be queried further with the function `type`:

```
domtype(x + y), type(x + y);
domtype(x - 1.0*I), type(x - 1.0*I);
domtype(x*I), type(x*I);
domtype(x^y), type(x^y);
domtype(x[i]), type(x[i])
```

DOM_EXPR, "_plus"

DOM_EXPR, "_plus"

DOM_EXPR, "_mult"

DOM_EXPR, "_power"

DOM_EXPR, "_index"

Example 3

`domtype` evaluates its argument. In this example, the assignment is first evaluated and `domtype` is applied to the return value of the assignment. This is the right hand side of the assignment, i.e., `5`:

```
domtype((a := 5))
```

```
DOM_INT
```

```
delete a:
```

Example 4

Here the identifier `a` is first evaluated to the `expression sequence3, 4`. Its domain type is `DOM_EXPR`, its type is `"_exprseq"`:

```
a := 3, 4: domtype(a), type(a)
```

```
DOM_EXPR, "_exprseq"
```

```
delete a:
```

Example 5

`factor` creates objects of the domain type `Factored`:

```
domtype(factor(x^2 - x))
```

```
Factored
```

Example 6

`matrix` creates objects of the domain type `Dom::Matrix()`:

```
domtype(matrix([[1, 2], [3, 4]]))
```

```
Dom::Matrix()
```

Example 7

Domains are of the domain type `DOM_DOMAIN`:

```
domtype(DOM_INT), domtype(DOM_DOMAIN)
```

```
DOM_DOMAIN, DOM_DOMAIN
```

Example 8

`domtype` is overloadable, i.e., a domain can pretend to be of another domain type. The special `slot"dom"` always gives the actual domain:

```
d := newDomain("d"): d::domtype := x -> "domain type d":
e := new(d, 1): e::dom, type(e), domtype(e)
```

```
d, d, "domain type d"
```

```
delete d, e:
```

Parameters

`object`

Any MuPAD object

Return Values

Data type, i.e., an object of type `DOM_DOMAIN`.

Overloaded By

object

See Also

MuPAD Domains
`DOM_DOMAIN`

MuPAD Functions
`coerce | hastype | testtype | type`

doprint

Print large matrices

Syntax

```
doprint(object1, object2, …)
```

Description

`doprint` serves for displaying large matrices on the screen. In fact, `doprint(object)` displays any MuPAD object like `print(object)`. The only difference is that large matrices contained in the object are printed, too.

Matrices of type `matrix` or of the more general type `Dom::Matrix(R)` with some coefficient ring `R` are not willing to print themselves on the screen if they are large.

An $m \times n$ matrix `A` is printed like a formatted two-dimensional array only if $m\,n \le printMaxSize$, where the default value of `printMaxSize` is 500. (You can change the `printMaxSize` value to any other integer value `m` by calling `A::dom::setPrintMaxSize(m)`).

For larger matrices, a warning is issued and some symbolic dummy object without the matrix entries is printed.

This serves to avoid output problems when printing is invoked accidentally (the output for large formatted arrays is very expensive concerning time and memory).

If you do insist on printing large matrices on the screen, the function `doprint` can be used to create a sparse table like output of the matrix.

Note: With `doprint`, only non-zero entries of large matrices are printed!

`doprint` allows to print arbitrary MuPAD objects. It behaves like `print` for all objects apart from matrices contained in the object.

For small matrices, it switches off the formatted array like output and replaces it by a sparse table like output. For large matrices, it suppresses warnings such as `"This matrix is too large for display. ..."` and prints matrices using the sparse table like output.

See “Example 1” on page 1-588 and “Example 2” on page 1-589.

Environment Interactions

`doprint` is sensitive to the environment variables `DIGITS`, `PRETTYPRINT`, and `TEXTWIDTH`, and to the output preferences `Pref::floatFormat`, `Pref::keepOrder`, and `Pref::trailingZeroes`.

Examples

Example 1

Small matrices are printed like formatted arrays:

```
A := matrix(5, 5, [i $ i = 1..30], Diagonal)
```

$$\begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 & 0 \\ 0 & 0 & 3 & 0 & 0 \\ 0 & 0 & 0 & 4 & 0 \\ 0 & 0 & 0 & 0 & 5 \end{pmatrix}$$

Calling `doprint`, this matrix is printed in a different way:

```
doprint(A)
```

$$\text{Dom::Matrix}()(5, 5, [(1, 1) = 1, (2, 2) = 2, (3, 3) = 3, (4, 4) = 4, (5, 5) = 5])$$

We create a larger diagonal matrix of dimension 30 ×30:

```
A := matrix(30, 30, [i $ i = 1..30], Diagonal):
```

If we had not suppressed the output by the colon terminating the command above, the following warning would have been issued by the output system:

```
A
```

```
Warning: This matrix is too large for display. To see all nonzero entries of a matrix A
```

Dom::Matrix()(30, 30, ["..."])

```
 Warning: This matrix is too
large for display. If you want to see all nonzero entries of a matrix,
say A, then call 'A::dom::doprint(A)'. [(Dom::Matrix(Dom::ExpressionField()))::print]

 Warning: This matrix is too large for display.
If you want to see all nonzero entries of a matrix, say A, then call
'A::dom::doprint(A)'. [(Dom::Matrix(Dom::ExpressionField()))::print]
```

Dom::Matrix()(30, 30, ["..."])

Since the matrix is extremely sparse, it does make sense to print the matrix. Calling `doprint`, we obtain a print output of all non-zero elements:

```
doprint(A)
```

Dom::Matrix()(30, 30, [(1, 1) = 1, (2, 2) = 2, (3, 3) = 3, (4, 4) = 4, (5, 5) = 5, (6, 6) = 6,
(7, 7) = 7, (8, 8) = 8, (9, 9) = 9, (10, 10) = 10, (11, 11) = 11, (12, 12) = 12, (13, 13) = 13,
(14, 14) = 14, (15, 15) = 15, (16, 16) = 16, (17, 17) = 17, (18, 18) = 18, (19, 19) = 19,
(20, 20) = 20, (21, 21) = 21, (22, 22) = 22, (23, 23) = 23, (24, 24) = 24, (25, 25) = 25,
(26, 26) = 26, (27, 27) = 27, (28, 28) = 28, (29, 29) = 29, (30, 30) = 30])

```
delete A:
```

Example 2

We compute a numerical QR factorization of a zero matrix of dimension 30×30. Since the command is not terminated by a colon, the output system tries to print the list with the factors Q and R. Both matrices send a warning:

```
[Q, R] := numeric::factorQR(matrix(30, 30, [])):
```

```
Q, R
```

```
Warning: This matrix is too large for display. To see all nonzero entries of a matrix A

Warning: This matrix is too large for display. To see all nonzero entries of a matrix A
```

Dom::Matrix()(30, 30, ["..."]), Dom::Matrix()(30, 30, ["..."])

```
 Warning: This matrix is too
large for display. If you want to see all nonzero entries of a matrix,
say A, then call 'A::dom::doprint(A)'. [(Dom::Matrix(Dom::ExpressionField()))::print]

 Warning: This matrix is too large for display.
If you want to see all nonzero entries of a matrix, say A, then call
'A::dom::doprint(A)'. [(Dom::Matrix(Dom::ExpressionField()))::print]

 Warning: This matrix is too large for display.
If you want to see all nonzero entries of a matrix, say A, then call
'A::dom::doprint(A)'. [(Dom::Matrix(Dom::ExpressionField()))::print]

 Warning: This matrix is too large for display.
If you want to see all nonzero entries of a matrix, say A, then call
'A::dom::doprint(A)'. [(Dom::Matrix(Dom::ExpressionField()))::print]
```

Dom::Matrix()(30, 30, ["..."]), Dom::Matrix()(30, 30, ["..."])

We can enforce a sparse output via `doprint`. The matrix factor Q is the identity matrix, the matrix factor R is zero:

```
doprint([Q, R])
```

Ei

Exponential integral function

Syntax

```
Ei(x)
```

```
Ei(n, x)
```

Description

`Ei(x)` represents the exponential integral $\int_{-\infty}^{x} \frac{e^t}{t}\,dt$.

`Ei(n, x)` represents the exponential integral $\int_{1}^{\infty} \frac{e^{-x\,t}}{t^n}\,dt$.

If `x` is a floating-point number, then `Ei(x)` returns the numerical value of the exponential integral. The special values $Ei(\infty) = \infty$ and $Ei(-\infty) = 0$ are implemented. For all other arguments, `Ei(x)` returns a symbolic function call.

If both `n` and `x` are numerical values and if at least one of them is a floating-point number, then `Ei(n, x)` returns a floating-point value.

The special values $Ei(n, \infty) = 0$ and $Ei(n, -\infty) = -\infty$ are implemented for arbitrary `n`.

If `n` is a non-positive integer not larger than `Pref::autoExpansionLimit()`, then `Ei(n, x)` returns an explicit expression of the form `exp(-x)*p(1/x)`, where `p` is a polynomial of degree `1 - n`. E.g.:

$$\mathrm{Ei}(0, x) = \frac{e^{-x}}{x},\ \mathrm{Ei}(-1, x) = e^{-x}\left(\frac{1}{x} + \frac{1}{x^2}\right),\ \mathrm{Ei}(-2, x) = e^{-x}\left(\frac{1}{x} + \frac{2}{x^2} + \frac{2}{x^3}\right).$$

Use `expand` if such representations are also desired for `|n|` larger than `Pref::autoExpansionLimit()`.

If `x` is a positive constant, `Ei(1, x)` returns `- Ei(-x)`. For a negative constant `x`, `Ei(1, x)` returns `- Ei(-x) - π i`.

For all other arguments `Ei(n, x)` returns a symbolic function call.

Environment Interactions

When called with a floating-point argument, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
Ei(1), Ei(sqrt(2)), Ei(x + 1), Ei(infinity), Ei(-infinity)
```

$$\mathrm{Ei}(1),\ \mathrm{Ei}(\sqrt{2}),\ \mathrm{Ei}(x+1),\ \infty,\ 0$$

```
Ei(sqrt(2), PI), Ei(2, x + 1), Ei(3, infinity), Ei(I, -infinity)
```

$$\mathrm{Ei}(\sqrt{2},\ \pi),\ \mathrm{Ei}(2, x+1),\ 0,\ -\infty$$

If the first argument is a non-positive integer, an explicit expresssion is returned:

```
Ei(-5, x)
```

$$e^{-x}\left(\frac{1}{x}+\frac{5}{x^2}+\frac{20}{x^3}+\frac{60}{x^4}+\frac{120}{x^5}+\frac{120}{x^6}\right)$$

Floating point values are computed for floating-point arguments:

```
Ei(-1000.0), Ei(1.0), Ei(12.3), Ei(2.0 + 10.0*I)
```

$$-5.07089306\ 10^{-438},\ 1.895117816,\ 19643.40095,\ -0.4549646329 + 3.710255582\ i$$

```
Ei(3, -1000.0), Ei(1 + I, 1.0), Ei(-2, 12.3), Ei(1.0 + I, 2 + 10*I)
```

$$-1.976005087\,10^{431},\ 0.1866485916 - 0.08748205256\,i,$$

$$0.0000004351250372,\ 0.003718889079 + 0.01125612573\,i$$

For a positive constant `x`, `Ei(1, x)` returns `- Ei(-x)`. For a negative constant `x`, `Ei(1, x)` returns `- Ei(-x) - π i`:

```
Ei(1, 3), Ei(1, -3)
```

$$-\mathrm{Ei}(-3),\ -\mathrm{Ei}(3) - \pi\,i$$

Example 2

The 1-argument function `Ei(x)` is singular at the origin:

```
Ei(0)
```

```
Error: Singularity. [Ei]
```

The negative real axis is a branch cut. A jump of height $2\,\pi\,i$ occurs when crossing this cut:

```
Ei(-1.0), Ei(-1.0 + 10^(-10)*I), Ei(-1.0 - 10^(-10)*I)
```

$$-0.2193839344,\ -0.2193839344 + 3.141592654\,i,\ -0.2193839344 - 3.141592654\,i$$

Example 3

System functions such as `diff`, `float`, `limit`, `expand`, and `series` handle expressions involving `Ei`:

```
diff(Ei(x), x, x, x), float(ln(3 + Ei(sqrt(PI))))
```

$$\frac{e^x}{x} - \frac{2\,e^x}{x^2} + \frac{2\,e^x}{x^3},\ 1.968209389$$

```
diff(Ei(3, x), x, x, x), float(ln(3 + Ei(I, sqrt(PI))))
```

$$-\frac{e^{-x}}{x},\ 1.126485483 - 0.01132113135\,i$$

```
limit(Ei(2*x^2/(1+x)), x = infinity)
```

$$\infty$$

```
expand(Ei(3, x))
```

$$\frac{e^{-x}}{2} - \frac{x\,e^{-x}}{2} + \frac{x^2\,Ei(1, x)}{2}$$

```
series(Ei(3, x), x = 0, 3)
```

$$\frac{1}{2} - x - x^2\left(\frac{EULER}{2} + \frac{\ln(x)}{2} - \frac{3}{4}\right) + O(x^3)$$

```
series(Ei(7/2, x), x = infinity, 3)
```

$$\frac{e^{-x}}{x} - \frac{7\,e^{-x}}{2\,x^2} + \frac{63\,e^{-x}}{4\,x^3} + O\left(\frac{e^{-x}}{x^4}\right)$$

Parameters

n, x

arithmetical expressions

Return Values

Arithmetical expression.

Overloaded By

n, x

Algorithms

If `n` is a non-positive integer, then `Ei(n, x)` is an analytic function of `x` throughout the complex plane apart from a pole at the origin. For all other values of `n`, the function `Ei(n, x)` has a branch cut along the negative real semi axis, where the values coincide with the limit "from above":

$$\mathrm{Ei}(x) = \lim_{\varepsilon \to 0^+} \mathrm{Ei}(x + \varepsilon\, \mathrm{i})$$

for real $x < 0$.

The 1-argument function `Ei(x)` is related to the 2-argument function by

$$\mathrm{Ei}(x) = -\mathrm{Ei}(1, -x) + \frac{\ln(x) - \ln\left(\frac{1}{x}\right)}{2} - \ln(-x)$$

.

It has a logarithmic singularity at the origin and a branch cut along the negative real axis. Unlike the 2-argument function `Ei(n, x)` the 1-argument function $Ei(x)$ is not continuous from either above or below along the branch cut.

The functions `Ei(n, x)` are related to the incomplete gamma function `igamma` by $\mathrm{Ei}(n, x) = x^{n-1}\, \Gamma(1 - n, x)$.

The functions `Ei(x)` and `Ei(n, x)` correspond to the exponential integral functions $Ei(x)$ and $E_n(x)$ considered in M. Abramowitz and I. Stegun, "Handbook of Mathematical Functions", Dover Publications Inc., New York (1965).

ellipticK

Complete elliptic integral of the first kind

Syntax

```
ellipticK(m)
```

Description

`ellipticK(m)` represents the complete elliptic integral of the first kind $\mathrm{K}(m)$ which is defined as

$$\mathrm{K}(m) = \mathrm{F}\left(\frac{\pi}{2} \mid m\right) = \int_0^{\frac{\pi}{2}} \frac{1}{\sqrt{1 - m\,\sin(\theta)^2}}\,\mathrm{d}\,\theta$$

.

The complete elliptic integral of the first kind is defined for a complex argument m.

A floating-point value is computed if all arguments are numerical and at least one is a floating-point value. Unevaluated symbolic calls are returned for most exact arguments. For some special cases explicit symbolic representations are returned.

Environment Interactions

When called with floating-point arguments, this function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Most calls with exact arguments return themselves unevaluated:

```
ellipticK(1/2); ellipticF(PI/4, I);
```

$$K\left(\frac{1}{2}\right)$$

$$F\left(\frac{\pi}{4} \mid i\right)$$

Some special arguments return explicit symbolic representations:

```
ellipticF(PI/2, 1/2); ellipticF(1, 1);
```

$$K\left(\frac{1}{2}\right)$$

$$\ln\left(\tan\left(\frac{\pi}{4}+\frac{1}{2}\right)\right)$$

If one argument is a floating-point value and the others can be converted to a floating-point values, then a floating-point result will be returned:

```
ellipticPi(0.5, PI/3, 1);
```

$$1.625993807$$

Parameters

m

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

ellipticCK

Complementary complete elliptic integral of the first kind

Syntax

```
ellipticCK(m)
```

Description

`ellipticCK(m)` represents the complementary complete elliptic integral of the first kind $\mathrm{K}'(m) = \mathrm{K}(1-m)$.

The complementary complete elliptic integral of the first kind is defined for a complex argument m.

A floating-point value is computed if all arguments are numerical and at least one is a floating-point value. Unevaluated symbolic calls are returned for most exact arguments. For some special cases explicit symbolic representations are returned.

Environment Interactions

When called with floating-point arguments, this function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Most calls with exact arguments return themselves unevaluated:

```

ellipticF

Incomplete elliptic integral of the first kind

Syntax

```
ellipticF
 (φ, m)
```

Description

`ellipticF( φ ,m)` represents the incomplete elliptic integral of the first kind $F(\varphi \mid m)$ which is defined as

$$F(\varphi \mid m) = \int_0^{\varphi} \frac{1}{\sqrt{1 - m \sin(\theta)^2}} \, d\theta$$

.

The incomplete elliptic integral of the first kind is defined for complex arguments ϕ and m.

A floating-point value is computed if all arguments are numerical and at least one is a floating-point value. Unevaluated symbolic calls are returned for most exact arguments. For some special cases explicit symbolic representations are returned.

Environment Interactions

When called with floating-point arguments, this function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

ellipticE

Complete and incomplete elliptic integrals of the second kind

Syntax

```
ellipticE
 (<ϕ>, m)
```

Description

`ellipticE(m)` represents the complete elliptic integral of the second kind $E(m)$ which is defined as

$$E(m) = E\left(\frac{\pi}{2} \mid m\right) = \int_0^{\frac{\pi}{2}} \sqrt{1 - m \sin(\theta)^2}\, d\theta$$

.

`ellipticE( φ ,m)` represents the incomplete elliptic integral of the second kind $E(\varphi \mid m)$ which is defined as

$$E(\varphi \mid m) = \int_0^{\varphi} \sqrt{1 - m \sin(\theta)^2}\, d\theta$$

.

The elliptic integrals of the second kind are defined for complex arguments ϕ and m.

A floating-point value is computed if all arguments are numerical and at least one is a floating-point value. Unevaluated symbolic calls are returned for most exact arguments. For some special cases explicit symbolic representations are returned.

Environment Interactions

When called with floating-point arguments, this function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

ellipticCE

Complementary complete elliptic integral of the second kind

Syntax

```
ellipticCE(m)
```

Description

`ellipticCE(m)` represents the complementary complete elliptic integral of the second kind $\mathrm{E}'(m) = \mathrm{E}(1-m)$.

The complementary complete elliptic integral of the second kind is defined for a complex argument m.

A floating-point value is computed if all arguments are numerical and at least one is a floating-point value. Unevaluated symbolic calls are returned for most exact arguments. For some special cases explicit symbolic representations are returned.

Environment Interactions

When called with floating-point arguments, this function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

ellipticPi

Complete and incomplete elliptic integrals of the third kind

Syntax

```
ellipticPi(n, <φ>, m)
```

Description

`ellipticPi(n,m)` represents the complete elliptic integral of the third kind

$$\Pi(n \mid m) = \Pi\left(n; \frac{\pi}{2} \mid m\right) = \int_0^{\frac{\pi}{2}} \frac{1}{(1 - n \sin(\theta)^2)\sqrt{1 - m \sin(\theta)^2}}\, d\theta$$

`ellipticPi(n, φ ,m)` represents the incomplete elliptic integral of the third kind

$$\Pi(n; \varphi \mid m) = \int_0^{\varphi} \frac{1}{(1 - n \sin(\theta)^2)\sqrt{1 - m \sin(\theta)^2}}\, d\theta$$

The elliptic integrals of the third kind are defined for complex arguments m, ϕ, and n.

A floating-point value is computed if all arguments are numerical and at least one is a floating-point value. Unevaluated symbolic calls are returned for most exact arguments. For some special cases explicit symbolic representations are returned.

Environment Interactions

When called with floating-point arguments, this function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Most calls with exact arguments return themselves unevaluated:

```

```
ellipticF(PI/2, 1/2); ellipticF(1, 1);
```

$$K\left(\frac{1}{2}\right)$$

$$\ln\left(\tan\left(\frac{\pi}{4}+\frac{1}{2}\right)\right)$$

If one argument is a floating-point value and the others can be converted to a floating-point values, then a floating-point result will be returned:

```
ellipticPi(0.5, PI/3, 1);
```

$$1.625993807$$

Parameters

`m`

An arithmetical expression specifying the parameter.

φ

An arithmetical expression specifying the amplitude. In case of `ellipticE` and `ellipticPi`, the default is $\frac{\pi}{2}$.

n

An arithmetical expression specifying the characteristic.

Return Values

Arithmetical expression.

ellipticCPi

Complementary complete elliptic integral of the third kind

Syntax

```
ellipticCPi(n, m)
```

Description

`ellipticCPi(n,m)` represents the complementary complete elliptic integral of the third kind $\Pi'(n \mid m) = \Pi(n \mid 1 - m)$.

The complementary complete elliptic integral of the third kind is defined for complex arguments m and n.

A floating-point value is computed if all arguments are numerical and at least one is a floating-point value. Unevaluated symbolic calls are returned for most exact arguments. For some special cases explicit symbolic representations are returned.

Environment Interactions

When called with floating-point arguments, this function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Most calls with exact arguments return themselves unevaluated:

```
ellipticK(1/2); ellipticF(PI/4, I);
```

$$\mathrm{K}\left(\frac{1}{2}\right)$$

$$F\left(\frac{\pi}{4} \mid i\right)$$

Some special arguments return explicit symbolic representations:

```
ellipticF(PI/2, 1/2); ellipticF(1, 1);
```

$$K\left(\frac{1}{2}\right)$$

$$\ln\left(\tan\left(\frac{\pi}{4}+\frac{1}{2}\right)\right)$$

If one argument is a floating-point value and the others can be converted to a floating-point values, then a floating-point result will be returned:

```
ellipticPi(0.5, PI/3, 1);
```

$$1.625993807$$

Parameters

`m`

An arithmetical expression specifying the parameter.

`n`

An arithmetical expression specifying the characteristic.

Return Values

Arithmetical expression.

ellipticNome

Elliptic nome

Syntax

```
ellipticNome
 (m)
```

Description

`ellipticNome(m)` represents the elliptic nome q which is defined as

$$\mathrm{q}(m) = \mathrm{e}^{-\frac{\pi \mathrm{K}'(m)}{\mathrm{K}(m)}}.$$

The elliptic nome $\mathrm{q}(m)$ is defined for complex arguments m.

$|\mathrm{q}(m)| \le 1$ holds for all $m \in \mathbb{C}$.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For most exact arguments, `ellipticNome` will return unevaluated:

```
ellipticNome(1/3); ellipticNome(2); ellipticNome(I);
```

$$q\left(\frac{1}{3}\right)$$

$$q(2)$$

$$q(i)$$

For 0, $\frac{1}{2}$ and 1 an explicit result is returned:

```
ellipticNome(0); ellipticNome(1/2); ellipticNome(1);
```

$$0$$

$$e^{-\pi}$$

$$1$$

If the argument is a floating-point number, a floating-point result will be returned:

```
ellipticNome(0.5)
```

$$0.04321391826$$

Using `float`, floating-point evaluation can be enforced:

```
float(ellipticNome(3/4))
```

$$0.0857957337$$

Parameters

`m`

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

MuPAD Functions
`ellipticCK` | `ellipticK`

end

Close a block statement

Description

`end` is a keyword which, depending on the context, is parsed as one of the following keywords:

- `end_case`
- `end_for`
- `end_if`
- `end_proc`
- `end_repeat`
- `end_while`

Examples

Example 1

Each of the keywords `proc`, `case`, `if`, `for`, `repeat`, and `while` starts some block construct in the MuPAD language. Each block can be closed with `end` or with the corresponding special keyword `end_proc`, `end_case` etc.:

```
f :=
proc(a, b)
  local i;
begin
  for i from a to b do
    if isprime(i) then
       print(Unquoted, expr2text(i)." is a prime")
    end
  end
end:

f(20, 30):
```

```
23 is a prime

29 is a prime
```

The parser translates `end` to the appropriate keyword matching the type of the block:

```
expose(f)

proc(a, b)
  name f;
  local i;
begin
  for i from a to b do
    if isprime(i) then
      print(Unquoted, expr2text(i)." is a prime")
    end_if
  end_for
end_proc

delete f:
```

See Also

MuPAD Functions

`end_case` | `end_for` | `end_if` | `end_proc` | `end_repeat` | `end_while`

erf

Error function

Syntax

```
erf(x)
```

Description

`erf(x)` represents the error function $\frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2}\, dt$.

This function is defined for all complex arguments `x`.

For floating-point arguments the error functions `erf`, `erfc`, and `erfi` return floating-point values. The implemented exact values are:

$erf(0) = 0$, $erf(\infty) = 1$, $erf(-\infty) = -1$, $erf(i\infty) = i\infty$, $erf(-i\infty) = -i\infty$,

For all other arguments, the error function returns symbolic function calls.

For the function `erf` with floating-point arguments of large absolute value, internal numerical underflow or overflow can happen.

The error functions $erf(x) = 1 - erfc(x)$ and $erfi(x) = i\,(erfc(x\,i) - 1)$ return corresponding values for large arguments. See “Example 2” on page 1-623.

MuPAD can simplify expressions that contain error functions and their inverses. For real values `x`, the system applies the following simplification rules:

$inverf(erf(x)) = inverf(1 - erfc(x)) = inverfc(1 - erf(x)) = inverfc(erfc(x)) = x$,

$inverf(-erf(x)) = inverf(erfc(x) - 1) = inverfc(1 + erf(x)) = inverfc(2 - erfc(x)) = -x$

For any value `x`, the system applies the following simplification rules:

$inverf(-x) = -inverf(x)$,

$inverfc(2 - x) = - inverfc(x)$,

$erf(inverf(x)) = erfc(inverfc(x)) = x$.

$erf(inverfc(x)) = erfc(inverf(x)) = 1 - x$.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS`, which determines the numerical working precision.

Examples

Example 1

You can call error functions with exact and symbolic arguments:

```
erf(0), erf(3/2), erf(sqrt(2)), erf(infinity)
```

$$0,\ \mathrm{erf}\left(\frac{3}{2}\right),\ \mathrm{erf}(\sqrt{2}),\ 1$$

```
erfc(0), erfc(x + 1), erfc(-infinity)
```

$$1,\ \mathrm{erfc}(x+1),\ 2$$

```
erfc(0, n), erfc(x + 1, -1), erfc(-infinity, 5)
```

$$\frac{1}{2^n\,\Gamma\left(\frac{n}{2}+1\right)},\ \frac{2\,e^{-(x+1)^2}}{\sqrt{\pi}},\ \infty$$

```
erfi(0), erfi(x + 1), erfi(-infinity)
```

$$0,\ \mathrm{erfi}(x+1),\ -\infty$$

```
inverf(-1), inverf(0), inverf(1), inverf(x + 1), inverf(1/5)
```

$$-\infty,\ 0,\ \infty,\ \text{inverf}(x+1),\ \text{inverf}\left(\frac{1}{5}\right)$$

```
inverfc(0), inverfc(1), inverfc(2), inverfc(15), inverfc(x/5)
```

$$\infty,\ 0,\ -\infty,\ \text{inverfc}(15),\ \text{inverfc}\left(\frac{x}{5}\right)$$

For floating-point arguments, the error functions return floating-point values:

```
erf(-7.2), erfc(2.0 + 3.5*I), erfc(3.0, 4), erfi(5.5 + 1.0*I)
```

$$-1.0,\ -420.8123327 - 343.6612334\ i,$$

$$0.000000009433438115,\ -93412361266.0 - 5.089108513\ 10^{11}\ i$$

For floating-point arguments `x` from the interval `[-1, 1]`, `inverf` returns floating-point values:

```
inverf(-0.5), inverf(0.85)
```

$$-0.4769362762,\ 1.017902465$$

For floating-point arguments outside of this interval, `inverf` returns symbolic function calls:

```
inverf(-5.3), inverf(10.0)
```

$$-\text{inverf}(5.3),\ \text{inverf}(10.0)$$

For floating-point arguments `x` from the interval `[0, 2]`, `inverfc` returns floating-point values:

```
inverfc(0.5), inverfc(1.25)
```

$$0.4769362762,\ -0.225312055$$

For floating-point arguments outside of this interval, `inverfc` returns symbolic function calls:

```
inverfc(-1.25), inverfc(2.5)
```

$$-\text{inverfc}(3.25),\ \text{inverfc}(2.5)$$

Example 2

For large complex arguments, the error functions can return NaN:

```
erf(38000.0 + 3801.0*I),
erfi(38000.0 + 3801.0*I),
erfc(38000.0 + 3801.0*I)
```

$$\text{NaN},\ \text{NaN},\ \text{NaN}$$

For large floating-point arguments with positive real parts, `erfc` can return values truncated to `0.0`:

```
erfc(27281.1), erfc(27281.2)
```

$$4.085187475\ 10^{-323227329},\ 0.0$$

Example 3

The functions `diff`, `float`, `limit`, `expand`, `rewrite`, and `series` handle expressions involving the error functions:

```
diff(erf(x), x, x, x)
```

$$\frac{8\,x^2\,e^{-x^2}}{\sqrt{\pi}} - \frac{4\,e^{-x^2}}{\sqrt{\pi}}$$

```
diff(erfc(x, 3), x, x)
```

$$\text{erfc}(x,\ 1)$$

```
diff(inverf(x), x)
```

$$\frac{\sqrt{\pi}\, e^{\mathrm{inverf}(x)^2}}{2}$$

```
float(ln(3 + erfi(sqrt(PI)*I)))
```

$$1.150079617 + 0.3180894436\,i$$

```
limit(x/(1 + x)*erf(x), x = infinity)
```

$$1$$

```
expand(erfc(x, 3))
```

$$\frac{e^{-x^2}}{6\sqrt{\pi}} - \frac{x^3\,\mathrm{erfc}(x)}{6} - \frac{x\,\mathrm{erfc}(x)}{4} + \frac{x^2\, e^{-x^2}}{6\sqrt{\pi}}$$

```
rewrite(inverfc(x), inverf)
```

$$-\mathrm{inverf}(x-1)$$

```
series(erf(x), x = infinity, 3)
```

$$1 - \frac{e^{-x^2}}{\sqrt{\pi}\,x} + \frac{e^{-x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{-x^2}}{x^4}\right)$$

```
series(erfc(x), x = infinity, 3)
```

$$\frac{e^{-x^2}}{\sqrt{\pi}\,x} - \frac{e^{-x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{-x^2}}{x^4}\right)$$

```
series(erfi(x), x = I*infinity, 3)
```

$$i + \frac{e^{x^2}}{\sqrt{\pi}\,x} + \frac{e^{x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{x^2}}{x^4}\right)$$

Parameters

x

An arithmetical expression

Return Values

Arithmetical expression

Algorithms

`erf`, `erfc`, and `erfi` are entire functions.

More About

- "Error Functions and Fresnel Functions"

erfc

Complementary error function

Syntax

```
erfc(x)
erfc(x, n)
```

Description

$\mathrm{erfc}(x) = 1 - \mathrm{erf}(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-t^2}\, dt$ computes the complementary error function.

$\mathrm{erfc}(x, n) = \int_x^\infty \mathrm{erfc}(t, n-1)\, dt$ with $erfc(x, 0) = erfc(x)$ and $\mathrm{erfc}(x, -1) = \frac{2}{\sqrt{\pi}} e^{-x^2}$ returns the iterated integrals of the complementary error function.

This function is defined for all complex arguments `x`.

For floating-point arguments the error functions `erf`, `erfc`, and `erfi` return floating-point values. The implemented exact values are:

$erfc(0) = 1$, $erfc(\infty) = 0$, $erfc(-\infty) = 2$, $erfc(i\infty) = 1 - i\infty$, $erfc(-i\infty) = 1 + i\infty$,

$\mathrm{erfc}(0, n) = \frac{1}{2^n \Gamma\left(\frac{n}{2}+1\right)}$, $erfc(\infty, n) = 0$, $erfc(-\infty, n) = \infty$,

For all other arguments, the error function returns symbolic function calls.

The calls `erfc(x)` and `erfc(x, 0)` are equivalent.

If a numerical value of `n` is not an integer or if `n < -1`, the function call `erfc(x, n)` returns an error. The function also accepts symbolic values of `n`.

If `n` is a numerical value, you can use the `expand(erfc(x, n))` command to apply:

- The recurrence $\mathrm{erfc}(x, n) = -\frac{x\, \mathrm{erfc}(x, n-1)}{n} + \frac{\mathrm{erfc}(x, n-2)}{2n}$

- The reflection rule $\mathrm{erfc}(-x, n) = (-1)^{n+1}\,\mathrm{erfc}(x, n) + \frac{H(n, \mathrm{i}\,x)}{\mathrm{i}^n\, 2^{n-1}\, n!}$, where H = `orthpoly::hermite`

See “Example 3” on page 1-630.

For the function `erfc` with floating-point arguments of large absolute value, internal numerical underflow or overflow can happen. If a call to `erfc` causes underflow or overflow, this function returns:

- The result truncated to `0.0` if `x` is a large positive real number
- The result rounded to `2.0` if `x` is a large negative real number
- `RD_NAN` if `x` is a large complex number and MuPAD cannot approximate the function value

The error functions *erf*(*x*) = 1 - *erfc*(*x*) and *erfi*(*x*) = i (*erfc*(*x* i) - 1) return corresponding values for large arguments. See “Example 2” on page 1-629.

MuPAD can simplify expressions that contain error functions and their inverses. For real values `x`, the system applies the following simplification rules:

inverf(*erf*(*x*)) = *inverf*(1 - *erfc*(*x*)) = *inverfc*(1 - *erf*(*x*)) = *inverfc*(*erfc*(*x*)) = *x*,

inverf(- *erf*(*x*)) = *inverf*(*erfc*(*x*) - 1) = *inverfc*(1 + *erf*(*x*)) = *inverfc*(2 - *erfc*(*x*)) = - *x*

For any value `x`, the system applies the following simplification rules:

inverf(- *x*) = - *inverf*(*x*),

inverfc(2 - *x*) = - *inverfc*(*x*),

erf(*inverf*(*x*)) = *erfc*(*inverfc*(*x*)) = *x*.

erf(*inverfc*(*x*)) = *erfc*(*inverf*(*x*)) = 1 - *x*.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS`, which determines the numerical working precision.

Examples

Example 1

You can call error functions with exact and symbolic arguments:

```
erf(0), erf(3/2), erf(sqrt(2)), erf(infinity)
```

$$0,\ \operatorname{erf}\left(\frac{3}{2}\right),\ \operatorname{erf}(\sqrt{2}),\ 1$$

```
erfc(0), erfc(x + 1), erfc(-infinity)
```

$$1,\ \operatorname{erfc}(x+1),\ 2$$

```
erfc(0, n), erfc(x + 1, -1), erfc(-infinity, 5)
```

$$\frac{1}{2^n\,\Gamma\left(\frac{n}{2}+1\right)},\ \frac{2\,e^{-(x+1)^2}}{\sqrt{\pi}},\ \infty$$

```
erfi(0), erfi(x + 1), erfi(-infinity)
```

$$0,\ \operatorname{erfi}(x+1),\ -\infty$$

```
inverf(-1), inverf(0), inverf(1), inverf(x + 1), inverf(1/5)
```

$$-\infty,\ 0,\ \infty,\ \operatorname{inverf}(x+1),\ \operatorname{inverf}\left(\frac{1}{5}\right)$$

```
inverfc(0), inverfc(1), inverfc(2), inverfc(15), inverfc(x/5)
```

$$\infty,\ 0,\ -\infty,\ \operatorname{inverfc}(15),\ \operatorname{inverfc}\left(\frac{x}{5}\right)$$

For floating-point arguments, the error functions return floating-point values:

```
erf(-7.2), erfc(2.0 + 3.5*I), erfc(3.0, 4), erfi(5.5 + 1.0*I)
```

$$-1.0,\ -420.8123327 - 343.6612334\,i,$$

$$0.000000009433438115,\ -93412361266.0 - 5.089108513\,10^{11}\,i$$

For floating-point arguments `x` from the interval `[-1, 1]`, `inverf` returns floating-point values:

```
inverf(-0.5), inverf(0.85)
```

$$-0.4769362762,\ 1.017902465$$

For floating-point arguments outside of this interval, `inverf` returns symbolic function calls:

```
inverf(-5.3), inverf(10.0)
```

$$-\mathrm{inverf}(5.3),\ \mathrm{inverf}(10.0)$$

For floating-point arguments `x` from the interval `[0, 2]`, `inverfc` returns floating-point values:

```
inverfc(0.5), inverfc(1.25)
```

$$0.4769362762,\ -0.225312055$$

For floating-point arguments outside of this interval, `inverfc` returns symbolic function calls:

```
inverfc(-1.25), inverfc(2.5)
```

$$-\mathrm{inverfc}(3.25),\ \mathrm{inverfc}(2.5)$$

Example 2

For large complex arguments, the error functions can return NaN:

```
erf(38000.0 + 3801.0*I),
erfi(38000.0 + 3801.0*I),
```

```
erfc(38000.0 + 3801.0*I)
```

$$\mathrm{NaN},\ \mathrm{NaN},\ \mathrm{NaN}$$

For large floating-point arguments with positive real parts, `erfc` can return values truncated to `0.0`:

```
erfc(27281.1), erfc(27281.2)
```

$$4.085187475\ 10^{-323227329},\ 0.0$$

Example 3

The functions `diff`, `float`, `limit`, `expand`, `rewrite`, and `series` handle expressions involving the error functions:

```
diff(erf(x), x, x, x)
```

$$\frac{8\,x^2\,e^{-x^2}}{\sqrt{\pi}} - \frac{4\,e^{-x^2}}{\sqrt{\pi}}$$

```
diff(erfc(x, 3), x, x)
```

$$\mathrm{erfc}(x,\ 1)$$

```
diff(inverf(x), x)
```

$$\frac{\sqrt{\pi}\,e^{\mathrm{inverf}(x)^2}}{2}$$

```
float(ln(3 + erfi(sqrt(PI)*I)))
```

$$1.150079617 + 0.3180894436\,i$$

```
limit(x/(1 + x)*erf(x), x = infinity)
```

$$1$$

```
expand(erfc(x, 3))
```

$$\frac{e^{-x^2}}{6\sqrt{\pi}} - \frac{x^3\,\mathrm{erfc}(x)}{6} - \frac{x\,\mathrm{erfc}(x)}{4} + \frac{x^2\,e^{-x^2}}{6\sqrt{\pi}}$$

```
rewrite(inverfc(x), inverf)
```

$$-\mathrm{inverf}(x-1)$$

```
series(erf(x), x = infinity, 3)
```

$$1 - \frac{e^{-x^2}}{\sqrt{\pi}\,x} + \frac{e^{-x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{-x^2}}{x^4}\right)$$

```
series(erfc(x), x = infinity, 3)
```

$$\frac{e^{-x^2}}{\sqrt{\pi}\,x} - \frac{e^{-x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{-x^2}}{x^4}\right)$$

```
series(erfi(x), x = I*infinity, 3)
```

$$i + \frac{e^{x^2}}{\sqrt{\pi}\,x} + \frac{e^{x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{x^2}}{x^4}\right)$$

Parameters

x

An arithmetical expression

n

An arithmetical expression representing an integer larger than or equal to - 1

Return Values

Arithmetical expression

Algorithms

`erf`, `erfc`, and `erfi` are entire functions.

More About

- "Error Functions and Fresnel Functions"

erfi

Imaginary error function

Syntax

```
erfi(x)
```

Description

$\mathrm{erfi}(x) = -\mathrm{i}\,\mathrm{erf}(\mathrm{i}\,x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{t^2}\,dt$ computes the imaginary error function.

This function is defined for all complex arguments `x`.

For floating-point arguments the error functions `erf`, `erfc`, and `erfi` return floating-point values. The implemented exact values are:

erfi(0) = 0, *erfi*(∞) = ∞, *erfi*(- ∞) = - ∞, *erfi*(i ∞) = i, *erfi*(- i ∞) = - i

For all other arguments, the error function returns symbolic function calls.

For the function `erfi` with floating-point arguments of large absolute value, internal numerical underflow or overflow can happen.

The error functions *erf*(*x*) = 1 - *erfc*(*x*) and *erfi*(*x*) = i (*erfc*(*x* i) - 1) return corresponding values for large arguments. See “Example 2” on page 1-636.

MuPAD can simplify expressions that contain error functions and their inverses. For real values `x`, the system applies the following simplification rules:

inverf(*erf*(*x*)) = *inverf*(1 - *erfc*(*x*)) = *inverfc*(1 - *erf*(*x*)) = *inverfc*(*erfc*(*x*)) = *x*,

inverf(- *erf*(*x*)) = *inverf*(*erfc*(*x*) - 1) = *inverfc*(1 + *erf*(*x*)) = *inverfc*(2 - *erfc*(*x*)) = - *x*

For any value `x`, the system applies the following simplification rules:

inverf(- *x*) = - *inverf*(*x*),

$inverfc(2 - x) = - inverfc(x)$,

$erf(inverf(x)) = erfc(inverfc(x)) = x$.

$erf(inverfc(x)) = erfc(inverf(x)) = 1 - x$.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS`, which determines the numerical working precision.

Examples

Example 1

You can call error functions with exact and symbolic arguments:

```
erf(0), erf(3/2), erf(sqrt(2)), erf(infinity)
```

$$0,\ \mathrm{erf}\left(\frac{3}{2}\right),\ \mathrm{erf}(\sqrt{2}),\ 1$$

```
erfc(0), erfc(x + 1), erfc(-infinity)
```

$$1,\ \mathrm{erfc}(x+1),\ 2$$

```
erfc(0, n), erfc(x + 1, -1), erfc(-infinity, 5)
```

$$\frac{1}{2^n\,\Gamma\left(\frac{n}{2}+1\right)},\ \frac{2\,e^{-(x+1)^2}}{\sqrt{\pi}},\ \infty$$

```
erfi(0), erfi(x + 1), erfi(-infinity)
```

$$0,\ \mathrm{erfi}(x+1),\ -\infty$$

```
inverf(-1), inverf(0), inverf(1), inverf(x + 1), inverf(1/5)
```

$$-\infty,\ 0,\ \infty,\ \text{inverf}(x+1),\ \text{inverf}\left(\frac{1}{5}\right)$$

```
inverfc(0), inverfc(1), inverfc(2), inverfc(15), inverfc(x/5)
```

$$\infty,\ 0,\ -\infty,\ \text{inverfc}(15),\ \text{inverfc}\left(\frac{x}{5}\right)$$

For floating-point arguments, the error functions return floating-point values:

```
erf(-7.2), erfc(2.0 + 3.5*I), erfc(3.0, 4), erfi(5.5 + 1.0*I)
```

$$-1.0,\ -420.8123327 - 343.6612334\ i,$$

$$0.000000009433438115,\ -93412361266.0 - 5.089108513\ 10^{11}\ i$$

For floating-point arguments `x` from the interval `[-1, 1]`, `inverf` returns floating-point values:

```
inverf(-0.5), inverf(0.85)
```

$$-0.4769362762,\ 1.017902465$$

For floating-point arguments outside of this interval, `inverf` returns symbolic function calls:

```
inverf(-5.3), inverf(10.0)
```

$$-\text{inverf}(5.3),\ \text{inverf}(10.0)$$

For floating-point arguments `x` from the interval `[0, 2]`, `inverfc` returns floating-point values:

```
inverfc(0.5), inverfc(1.25)
```

$$0.4769362762,\ -0.225312055$$

For floating-point arguments outside of this interval, `inverfc` returns symbolic function calls:

```
inverfc(-1.25), inverfc(2.5)
```

$$-\text{inverfc}(3.25),\ \text{inverfc}(2.5)$$

Example 2

For large complex arguments, the error functions can return NaN:

```
erf(38000.0 + 3801.0*I),
erfi(38000.0 + 3801.0*I),
erfc(38000.0 + 3801.0*I)
```

$$\text{NaN},\ \text{NaN},\ \text{NaN}$$

For large floating-point arguments with positive real parts, `erfc` can return values truncated to `0.0`:

```
erfc(27281.1), erfc(27281.2)
```

$$4.085187475\ 10^{-323227329},\ 0.0$$

Example 3

The functions `diff`, `float`, `limit`, `expand`, `rewrite`, and `series` handle expressions involving the error functions:

```
diff(erf(x), x, x, x)
```

$$\frac{8\,x^2\,e^{-x^2}}{\sqrt{\pi}} - \frac{4\,e^{-x^2}}{\sqrt{\pi}}$$

```
diff(erfc(x, 3), x, x)
```

$$\text{erfc}(x,\ 1)$$

```
diff(inverf(x), x)
```

$$\frac{\sqrt{\pi}\, e^{\mathrm{inverf}(x)^2}}{2}$$

```
float(ln(3 + erfi(sqrt(PI)*I)))
```

$$1.150079617 + 0.3180894436\, i$$

```
limit(x/(1 + x)*erf(x), x = infinity)
```

$$1$$

```
expand(erfc(x, 3))
```

$$\frac{e^{-x^2}}{6\sqrt{\pi}} - \frac{x^3\,\mathrm{erfc}(x)}{6} - \frac{x\,\mathrm{erfc}(x)}{4} + \frac{x^2\, e^{-x^2}}{6\sqrt{\pi}}$$

```
rewrite(inverfc(x), inverf)
```

$$-\mathrm{inverf}(x-1)$$

```
series(erf(x), x = infinity, 3)
```

$$1 - \frac{e^{-x^2}}{\sqrt{\pi}\,x} + \frac{e^{-x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{-x^2}}{x^4}\right)$$

```
series(erfc(x), x = infinity, 3)
```

$$\frac{e^{-x^2}}{\sqrt{\pi}\,x} - \frac{e^{-x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{-x^2}}{x^4}\right)$$

```
series(erfi(x), x = I*infinity, 3)
```

$$i + \frac{e^{x^2}}{\sqrt{\pi}\,x} + \frac{e^{x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{x^2}}{x^4}\right)$$

Parameters

x

More About

- "Error Functions and Fresnel Functions"

inverf

Inverse of the error function

Syntax

```
inverf(x)
```

Description

inverf(*x*) computes the inverse of the error function.

This function is defined for all complex arguments `x`.

The inverse function `inverf` is singular at the points `x = -1` and `x = 1`.

The inverses of the error functions return floating-point values only for floating-point arguments that belong to a particular interval. Thus, the inverse of error function `inverf(x)` returns floating-point values for real values `x` from the interval `[-1, 1]`. The inverse of the complementary error function `inverfc(x)` returns floating-point values for real values `x` from the interval `[0, 2]`. The implemented exact values are:

inverf(- 1) = - ∞, *inverf*(0) = 0, *inverf*(1) = ∞,

inverfc(0) = ∞, *inverfc*(1) = 0, *inverfc*(2) = - ∞.

For all other arguments, the error functions return symbolic function calls.

MuPAD can simplify expressions that contain error functions and their inverses. For real values `x`, the system applies the following simplification rules:

inverf(*erf*(*x*)) = *inverf*(1 - *erfc*(*x*)) = *inverfc*(1 - *erf*(*x*)) = *inverfc*(*erfc*(*x*)) = *x*,

inverf(- *erf*(*x*)) = *inverf*(*erfc*(*x*) - 1) = *inverfc*(1 + *erf*(*x*)) = *inverfc*(2 - *erfc*(*x*)) = - *x*

For any value `x`, the system applies the following simplification rules:

inverf(- *x*) = - *inverf*(*x*),

inverfc(2 - *x*) = - *inverfc*(*x*),

$erf(inverf(x)) = erfc(inverfc(x)) = x$.

$erf(inverfc(x)) = erfc(inverf(x)) = 1 - x$.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS`, which determines the numerical working precision.

Examples

Example 1

You can call error functions with exact and symbolic arguments:

```
erf(0), erf(3/2), erf(sqrt(2)), erf(infinity)
```

$$0,\ \mathrm{erf}\left(\frac{3}{2}\right),\ \mathrm{erf}(\sqrt{2}),\ 1$$

```
erfc(0), erfc(x + 1), erfc(-infinity)
```

$$1,\ \mathrm{erfc}(x+1),\ 2$$

```
erfc(0, n), erfc(x + 1, -1), erfc(-infinity, 5)
```

$$\frac{1}{2^n\,\Gamma\left(\frac{n}{2}+1\right)},\ \frac{2\,e^{-(x+1)^2}}{\sqrt{\pi}},\ \infty$$

```
erfi(0), erfi(x + 1), erfi(-infinity)
```

$$0,\ \mathrm{erfi}(x+1),\ -\infty$$

```
inverf(-1), inverf(0), inverf(1), inverf(x + 1), inverf(1/5)
```

$$-\infty,\ 0,\ \infty,\ \mathrm{inverf}(x+1),\ \mathrm{inverf}\left(\frac{1}{5}\right)$$

```
inverfc(0), inverfc(1), inverfc(2), inverfc(15), inverfc(x/5)
```

$$\infty,\ 0,\ -\infty,\ \mathrm{inverfc}(15),\ \mathrm{inverfc}\left(\frac{x}{5}\right)$$

For floating-point arguments, the error functions return floating-point values:

```
erf(-7.2), erfc(2.0 + 3.5*I), erfc(3.0, 4), erfi(5.5 + 1.0*I)
```

$$-1.0,\ -420.8123327 - 343.6612334\ i,$$

$$0.000000009433438115,\ -93412361266.0 - 5.089108513\ 10^{11}\ i$$

For floating-point arguments `x` from the interval `[-1, 1]`, `inverf` returns floating-point values:

```
inverf(-0.5), inverf(0.85)
```

$$-0.4769362762,\ 1.017902465$$

For floating-point arguments outside of this interval, `inverf` returns symbolic function calls:

```
inverf(-5.3), inverf(10.0)
```

$$-\mathrm{inverf}(5.3),\ \mathrm{inverf}(10.0)$$

For floating-point arguments `x` from the interval `[0, 2]`, `inverfc` returns floating-point values:

```
inverfc(0.5), inverfc(1.25)
```

$$0.4769362762,\ -0.225312055$$

For floating-point arguments outside of this interval, `inverfc` returns symbolic function calls:

```
inverfc(-1.25), inverfc(2.5)
```

$$-\text{inverfc}(3.25),\ \text{inverfc}(2.5)$$

Example 2

For large complex arguments, the error functions can return NaN:

```
erf(38000.0 + 3801.0*I),
erfi(38000.0 + 3801.0*I),
erfc(38000.0 + 3801.0*I)
```

$$\text{NaN},\ \text{NaN},\ \text{NaN}$$

For large floating-point arguments with positive real parts, `erfc` can return values truncated to `0.0`:

```
erfc(27281.1), erfc(27281.2)
```

$$4.085187475\ 10^{-323227329},\ 0.0$$

Example 3

The functions `diff`, `float`, `limit`, `expand`, `rewrite`, and `series` handle expressions involving the error functions:

```
diff(erf(x), x, x, x)
```

$$\frac{8\,x^2\,e^{-x^2}}{\sqrt{\pi}} - \frac{4\,e^{-x^2}}{\sqrt{\pi}}$$

```
diff(erfc(x, 3), x, x)
```

$$\text{erfc}(x,\ 1)$$

```
diff(inverf(x), x)
```

$$\frac{\sqrt{\pi}\, e^{\mathrm{inverf}(x)^2}}{2}$$

```
float(ln(3 + erfi(sqrt(PI)*I)))
```

$$1.150079617 + 0.3180894436\, i$$

```
limit(x/(1 + x)*erf(x), x = infinity)
```

$$1$$

```
expand(erfc(x, 3))
```

$$\frac{e^{-x^2}}{6\sqrt{\pi}} - \frac{x^3\,\mathrm{erfc}(x)}{6} - \frac{x\,\mathrm{erfc}(x)}{4} + \frac{x^2\, e^{-x^2}}{6\sqrt{\pi}}$$

```
rewrite(inverfc(x), inverf)
```

$$-\mathrm{inverf}(x-1)$$

```
series(erf(x), x = infinity, 3)
```

$$1 - \frac{e^{-x^2}}{\sqrt{\pi}\,x} + \frac{e^{-x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{-x^2}}{x^4}\right)$$

```
series(erfc(x), x = infinity, 3)
```

$$\frac{e^{-x^2}}{\sqrt{\pi}\,x} - \frac{e^{-x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{-x^2}}{x^4}\right)$$

```
series(erfi(x), x = I*infinity, 3)
```

$$i + \frac{e^{x^2}}{\sqrt{\pi}\,x} + \frac{e^{x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{x^2}}{x^4}\right)$$

Parameters

More About

- "Error Functions and Fresnel Functions"

inverfc

Inverse of the complementary error function

Syntax

```
inverfc(x)
```

Description

inverfc(*x*) = *inverf*(1 - *x*) computes the inverse of the complementary error function.

This function is defined for all complex arguments `x`.

The inverse function `inverfc` is singular at the points `x = 0` and `x = 2`.

The inverses of the error functions return floating-point values only for floating-point arguments that belong to a particular interval. Thus, the inverse of error function `inverf(x)` returns floating-point values for real values `x` from the interval `[-1, 1]`. The inverse of the complementary error function `inverfc(x)` returns floating-point values for real values `x` from the interval `[0, 2]`. The implemented exact values are:

inverf(- 1) = - ∞, *inverf*(0) = 0, *inverf*(1) = ∞,

inverfc(0) = ∞, *inverfc*(1) = 0, *inverfc*(2) = - ∞.

For all other arguments, the error functions return symbolic function calls.

MuPAD can simplify expressions that contain error functions and their inverses. For real values `x`, the system applies the following simplification rules:

inverf(*erf*(*x*)) = *inverf*(1 - *erfc*(*x*)) = *inverfc*(1 - *erf*(*x*)) = *inverfc*(*erfc*(*x*)) = *x*,

inverf(- *erf*(*x*)) = *inverf*(*erfc*(*x*) - 1) = *inverfc*(1 + *erf*(*x*)) = *inverfc*(2 - *erfc*(*x*)) = - *x*

For any value `x`, the system applies the following simplification rules:

inverf(- *x*) = - *inverf*(*x*),

inverfc(2 - *x*) = - *inverfc*(*x*),

erf(*inverf*(*x*)) = *erfc*(*inverfc*(*x*)) = *x*.

erf(*inverfc*(*x*)) = *erfc*(*inverf*(*x*)) = 1 - *x*.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS`, which determines the numerical working precision.

Examples

Example 1

You can call error functions with exact and symbolic arguments:

```
erf(0), erf(3/2), erf(sqrt(2)), erf(infinity)
```

$$0,\ \mathrm{erf}\left(\frac{3}{2}\right),\ \mathrm{erf}(\sqrt{2}),\ 1$$

```
erfc(0), erfc(x + 1), erfc(-infinity)
```

$$1,\ \mathrm{erfc}(x+1),\ 2$$

```
erfc(0, n), erfc(x + 1, -1), erfc(-infinity, 5)
```

$$\frac{1}{2^n\,\Gamma\left(\frac{n}{2}+1\right)},\ \frac{2\,e^{-(x+1)^2}}{\sqrt{\pi}},\ \infty$$

```
erfi(0), erfi(x + 1), erfi(-infinity)
```

$$0,\ \mathrm{erfi}(x+1),\ -\infty$$

```
inverf(-1), inverf(0), inverf(1), inverf(x + 1), inverf(1/5)
```

$$-\infty,\ 0,\ \infty,\ \text{inverf}(x+1),\ \text{inverf}\left(\frac{1}{5}\right)$$

```
inverfc(0), inverfc(1), inverfc(2), inverfc(15), inverfc(x/5)
```

$$\infty,\ 0,\ -\infty,\ \text{inverfc}(15),\ \text{inverfc}\left(\frac{x}{5}\right)$$

For floating-point arguments, the error functions return floating-point values:

```
erf(-7.2), erfc(2.0 + 3.5*I), erfc(3.0, 4), erfi(5.5 + 1.0*I)
```

$$-1.0,\ -420.8123327 - 343.6612334\ i,$$

$$0.000000009433438115,\ -93412361266.0 - 5.089108513\ 10^{11}\ i$$

For floating-point arguments `x` from the interval `[-1, 1]`, `inverf` returns floating-point values:

```
inverf(-0.5), inverf(0.85)
```

$$-0.4769362762,\ 1.017902465$$

For floating-point arguments outside of this interval, `inverf` returns symbolic function calls:

```
inverf(-5.3), inverf(10.0)
```

$$-\text{inverf}(5.3),\ \text{inverf}(10.0)$$

For floating-point arguments `x` from the interval `[0, 2]`, `inverfc` returns floating-point values:

```
inverfc(0.5), inverfc(1.25)
```

$$0.4769362762,\ -0.225312055$$

For floating-point arguments outside of this interval, `inverfc` returns symbolic function calls:

```
inverfc(-1.25), inverfc(2.5)
```

$$-\text{inverfc}(3.25),\ \text{inverfc}(2.5)$$

Example 2

For large complex arguments, the error functions can return NaN:

```
erf(38000.0 + 3801.0*I),
erfi(38000.0 + 3801.0*I),
erfc(38000.0 + 3801.0*I)
```

$$\text{NaN},\ \text{NaN},\ \text{NaN}$$

For large floating-point arguments with positive real parts, `erfc` can return values truncated to `0.0`:

```
erfc(27281.1), erfc(27281.2)
```

$$4.085187475\ 10^{-323227329},\ 0.0$$

Example 3

The functions `diff`, `float`, `limit`, `expand`, `rewrite`, and `series` handle expressions involving the error functions:

```
diff(erf(x), x, x, x)
```

$$\frac{8\,x^2\,e^{-x^2}}{\sqrt{\pi}} - \frac{4\,e^{-x^2}}{\sqrt{\pi}}$$

```
diff(erfc(x, 3), x, x)
```

$$\text{erfc}(x,\ 1)$$

```
diff(inverf(x), x)
```

$$\frac{\sqrt{\pi}\, e^{\mathrm{inverf}(x)^2}}{2}$$

```
float(ln(3 + erfi(sqrt(PI)*I)))
```

$$1.150079617 + 0.3180894436\, i$$

```
limit(x/(1 + x)*erf(x), x = infinity)
```

$$1$$

```
expand(erfc(x, 3))
```

$$\frac{e^{-x^2}}{6\sqrt{\pi}} - \frac{x^3\,\mathrm{erfc}(x)}{6} - \frac{x\,\mathrm{erfc}(x)}{4} + \frac{x^2\, e^{-x^2}}{6\sqrt{\pi}}$$

```
rewrite(inverfc(x), inverf)
```

$$-\mathrm{inverf}(x-1)$$

```
series(erf(x), x = infinity, 3)
```

$$1 - \frac{e^{-x^2}}{\sqrt{\pi}\,x} + \frac{e^{-x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{-x^2}}{x^4}\right)$$

```
series(erfc(x), x = infinity, 3)
```

$$\frac{e^{-x^2}}{\sqrt{\pi}\,x} - \frac{e^{-x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{-x^2}}{x^4}\right)$$

```
series(erfi(x), x = I*infinity, 3)
```

$$i + \frac{e^{x^2}}{\sqrt{\pi}\,x} + \frac{e^{x^2}}{2\sqrt{\pi}\,x^3} + O\left(\frac{e^{x^2}}{x^4}\right)$$

Parameters

x

MuPAD Functions

`erf` | `erfc` | `erfi` | `inverf` | `stats::normalQuantile`

More About

- "Error Functions and Fresnel Functions"

error

Raise a user-specified exception

Syntax

```
error(message)
```

Description

`error(message)` aborts the current procedure, returns to the interactive level, and displays the error message `message`.

If the error is not caught via `traperror` by a procedure that has directly or indirectly called the current procedure, control is returned to the interactive level, and the string `message` is printed as an error message.

The printed error message has the form `Error: message [name]`, where `name` is the name of the procedure containing the call to `error`. See the examples.

Errors can be caught by the function `traperror`. If an error occurs while the arguments of `traperror` are evaluated, control is returned to the procedure containing the call to `traperror` and not to the interactive level. No error message is printed. The return value of `traperror` is `1028` when it catches an error raised by `error`; see “Example 2” on page 1-652.

The function `error` is useful to raise an error in the type checking part of a user-defined procedure, when this procedure is called with invalid arguments.

Examples

Example 1

If the divisor of the following simple division routine is `0`, then an error is raised:

```
mydivide := proc(n, d) begin
```

```
  if iszero(d) then
    error("Division by 0")
  end_if;
  n/d
end_proc:
mydivide(2, 0)
```

```
Error: Division by 0 [mydivide]
```

Example 2

When the error is raised in the following procedure p, control is returned to the interactive level immediately. The second call to `print` is never executed. Note that the procedure's name is printed in the error message:

```
p := proc() begin
  print("entering procedure p");
  error("oops");
  print("leaving procedure p")
end_proc:
p()
```

```
"entering procedure p"
```

```
Error: oops [p]
```

The following procedure q calls the procedure p and catches any error that is raised within p:

```
q := proc() begin
  print("entering procedure q");
  print("caught error: ", traperror(p()));
  print("leaving procedure q")
end_proc:
q()
```

```
"entering procedure q"
```

```
"entering procedure p"
```

"caught error: ", 1028

"leaving procedure q"

Parameters

`message`

The error message: a string

See Also

MuPAD Functions
`getlasterror` | `lasterror` | `traperror` | `warning`

euler

Euler numbers and polynomials

Syntax

```
euler(n)
```

```
euler(n, x)
```

Description

`euler(n)` returns the n-th Euler number.

`euler(n, x)` returns the n-th Euler polynomial in x.

The Euler polynomials are defined by the generating function

$$\frac{2\,e^{x\,t}}{e^{t}+1} = \sum_{n=0}^{\infty} \frac{\mathrm{euler}(n,x)}{n!}\,t^{n}$$

.

The Euler numbers are defined by `euler(n) = 2^n*euler(n,1/2)`.

An error occurs if `n` is a numerical value not representing a nonnegative integer.

If `n` is an integer larger than the value returned by `Pref::autoExpansionLimit()`, then the call `euler(n)` is returned symbolically. Use `expand(euler(n))` to get an explicit numerical result for large integers `n`.

If `n` contains non-numerical symbolic identifiers, then the call `euler(n)` is returned symbolically. In most cases, the same holds true for calls `euler(n, x)`. Some simplifications are implemented for special numerical values such as `x = 0`, `x = 1/2`, `x = 1` etc. for symbolic `n` . Cf. “Example 3” on page 1-656.

Note: Note that floating-point evaluation for high degree polynomials may be numerically unstable. See “Example 4” on page 1-657.

The floating-point evaluation on the standard interval $x \in [0, 1]$ is numerically stable for arbitrary `n`.

To use the Euler constant, call `E` or `exp(1)`. To use the Euler-Mascheroni constant, call `EULER`. See "Mathematical Constants Available in MuPAD". You can approximate these constants with floating-point numbers by using `float`.

Environment Interactions

When called with a floating-point value `x`, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

The first Euler numbers are:

```
euler(n) $ n = 0..11
```

$$1, 0, -1, 0, 5, 0, -61, 0, 1385, 0, -50521, 0$$

The first Euler polynomials:

```
euler(n, x) $ n = 0..4
```

$$1, x - \frac{1}{2}, x^2 - x, x^3 - \frac{3x^2}{2} + \frac{1}{4}, x^4 - 2x^3 + x$$

If `n` is symbolic, then a symbolic call is returned:

```
euler(n, x), euler(n + 3/2, x), euler(n + 5*I, x)
```

$$\text{euler}(n, x), \text{euler}\left(n + \frac{3}{2}, x\right), \text{euler}(n + 5\,i, x)$$

Example 2

If x is not an indeterminate, then the evaluation of the Euler polynomial at the point x is returned:

```
euler(50, 1 + I)
```

$$-1+620906113959162509876411268097228422281 71\,i$$

```
euler(3, 1 - y) = expand(euler(3, 1 - y))
```

$$\frac{1}{4}-(y-1)^3-\frac{3\,(y-1)^2}{2}=-y^3+\frac{3\,y^2}{2}-\frac{1}{4}$$

Example 3

Certain simplifications occur for some special numerical values of x, even if n is symbolic:

```
euler(n, 0), euler(n, 1/2), euler(n, 1)
```

$$-\frac{2\,\text{bernoulli}(n+1)\left(2^{n+1}-1\right)}{n+1},\ \frac{\text{euler}(n)}{2^n},\ \frac{2\,\text{bernoulli}(n+1)\left(2^{n+1}-1\right)}{n+1}$$

Calls with numerical arguments between $\frac{1}{2}$ and 1 are automatically rewritten in terms of calls with arguments between 0 and $\frac{1}{2}$:

```
euler(n, 2/3), euler(n, 0.7)
```

$$(-1)^n\,\text{euler}\left(n,\ \frac{1}{3}\right),\ (-1)^n\,\text{euler}(n,\ 0.3)$$

Calls with negative numerical arguments are automatially rewritten in terms of calls with positive arguments:

```
euler(n, -2)
```

$$(-1)^{n+1}\,\text{euler}(n,\ 2)+2\,(-2)^n$$

```
euler(n, -12.345)
```

$$2\,(-12.345)^{n} + (-1)^{n+1}\,\mathrm{euler}(n, 12.345)$$

Example 4

Float evaluation of high degree polynomials may be numerically unstable:

```
exact := euler(50, 1 + I): float(exact);
```

$$-1.0 + 6.20906114\ 10^{40}\,\mathrm{i}$$

```
euler(50, float(1 + I))
```

$$-1.774947368\ 10^{23} + 6.20906114\ 10^{40}\,\mathrm{i}$$

```
DIGITS := 40: euler(50, float(1 + I))
```

$$-0.9999999981373548507689370896315932124576$$
$$+\,6.2090611395916250987641126809722842228177\ 10^{40}\,\mathrm{i}$$

```
delete exact, DIGITS:
```

Example 5

Some system functions such as `diff` or `expand` handle symbolic calls of `euler`:

```
diff(euler(n, f(x)), x)
```

$$n\,\mathrm{euler}(n-1, f(x))\,\frac{\partial}{\partial x} f(x)$$

```
expand(euler(n, x + 2))
```

$$\mathrm{euler}(n, x) - 2\,x^{n} + 2\,(x+1)^{n}$$

```
expand(euler(n, -x))
```

$$2\,(-x)^n-(-1)^n\,\mathrm{euler}(n,x)$$

```
expand(euler(n, 3*x))
```

$$3^n\,\mathrm{euler}(n,x)-3^n\,\mathrm{euler}\left(n,x+\frac{1}{3}\right)+3^n\,\mathrm{euler}\left(n,x+\frac{2}{3}\right)$$

Parameters

n

An arithmetical expression representing a nonnegative integer

x

An arithmetical expression

Return Values

Arithmetical expression.

MuPAD Functions

`bernoulli`

eval

Evaluate an object

Syntax

```
eval(object)
```

Description

`eval(object)` evaluates its argument `object` by recursively replacing the identifiers occurring in it by their values and executing function calls, and then evaluates the result again.

`eval` serves to request the evaluation of unevaluated or partially evaluated objects. *Evaluation* means that identifiers are replaced by their values and function calls are executed.

Usually, every system function automatically evaluates its arguments and returns a fully evaluated object, and using `eval` is only necessary in exceptional cases. For example, the functions `map`, `op`, and `subs` may return objects that are not fully evaluated. See “Example 1” on page 1-661.

Like most other MuPAD functions, `eval` first evaluates its argument. Then it evaluates the result again. At interactive level, the second evaluation usually has no effect, but this is different within procedures. See “Example 3” on page 1-661 and “Example 4” on page 1-663.

`eval` is sensitive to the value of the environment variable `LEVEL`, which determines the maximal depth of the recursive process that replaces an identifier by its value during evaluation. The evaluation of the argument and the subsequent evaluation of the result both take place with substitution depth `LEVEL`. See “Example 3” on page 1-661.

If a local variable or a formal parameter, of type `DOM_VAR`, of a `procedure` occurs in `object`, then it is always replaced by its value when `eval` evaluates its argument, independent of the value of `LEVEL`. At the subsequent second evaluation, the value of the local variable is evaluated with substitution depth given by `LEVEL`, which usually is `1`. Cf. “Example 4” on page 1-663.

The behavior of `eval` within a procedure may sometimes not be what you expect, since the default substitution depth within procedures is `1` and `eval` evaluates with this substitution depth. Use `level` to request a complete evaluation within a procedure; see the corresponding help page for details.

`eval` enforces the evaluation of expressions of the form `hold(x)`: `eval(hold(x))` is equivalent to `x`. Cf. “Example 2” on page 1-661.

`eval` accepts expression sequences as arguments. See “Example 3” on page 1-661. In particular, the call `eval()` returns the empty sequence `null()`.

`eval` does not recursively descend into `arrays`. Use the call `map(object, eval)` to evaluate the entries of an array. Cf. “Example 5” on page 1-664.

`eval` does not recursively descend into `tables`. Use the call `map(object, eval)` to evaluate the entries of a table.

However, it is not possible to evaluate the indices of a given table. If you want to do this, create a new table with the evaluated operands of the old one. Cf. “Example 6” on page 1-664.

`Polynomials` are not further evaluated by `eval`. Use `evalp` to substitute values for the indeterminates of a polynomial, and use the call `mapcoeffs(object, eval)` to evaluate all coefficients. Cf. “Example 7” on page 1-665.

The evaluation of elements of a user-defined domain depends on the implementation of the domain. Usually, domain elements remain unevaluated. If the domain has a slot `"evaluate"`, the corresponding slot routine is called with the domain element as argument at each evaluation, and hence it is called twice when `eval` is invoked. Cf. “Example 8” on page 1-666.

Environment Interactions

`eval` is sensitive to the value of the environment variable `LEVEL`, which determines the maximal substitution depth for identifiers.

Examples

Example 1

`subs` performs a substitution, but does not evaluate the result:

```
subs(ln(x), x = 1)
```

$$\ln(1)$$

An explicit call of `eval` is necessary to evaluate the result:

```
eval(subs(ln(x), x = 1))
```

$$0$$

`text2expr` does not evaluate its result either:

```
a := c:
text2expr("a + a"), eval(text2expr("a + a"))
```

$$a + a,\ 2\,c$$

Example 2

The function `hold` prevents the evaluation of its argument. A later evaluation can be forced with `eval`:

```
hold(1 + 1);  eval(%)
```

$$1 + 1$$

$$2$$

Example 3

When an object is evaluated, identifiers are replaced by their values recursively. The maximal recursion depth of this process is given by the environment variable `LEVEL`:

```
delete a0, a1, a2, a3, a4:
a0 := a1:  a1 := a2 + 2:  a2 := a3 + a4:  a3 := a4^2:  a4 := 5:

LEVEL := 1:  a0, a0 + a2;
LEVEL := 2:  a0, a0 + a2;
LEVEL := 3:  a0, a0 + a2;
LEVEL := 4:  a0, a0 + a2;
LEVEL := 5:  a0, a0 + a2;
```

$$a1,\ a1 + a3 + a4$$

$$a2 + 2,\ a4^2 + a2 + 7$$

$$a3 + a4 + 2,\ a3 + a4 + 32$$

$$a4^2 + 7,\ a4^2 + 37$$

$$32,\ 62$$

`eval` first evaluates its argument and then evaluates the result again. Both evaluations happen with substitution depth given by `LEVEL`:

```
LEVEL := 1:  eval(a0, a0 + a2);
LEVEL := 2:  eval(a0, a0 + a2);
LEVEL := 3:  eval(a0, a0 + a2);
```

$$a2 + 2,\ a4^2 + a2 + 7$$

$$a4^2 + 7,\ a4^2 + 37$$

$$32,\ 62$$

Since the default value of `LEVEL` is `100`, `eval` usually has no effect at interactive level:

```
delete LEVEL:
```

```
a0, eval(a0), a0 + a2, eval(a0 + a2)
```

$$32,\ 32,\ 62,\ 62$$

Example 4

This example shows the difference between the evaluation of identifiers and local variables. By default, the value of LEVEL is 1 within a procedure, i.e., a global identifier is replaced by its value when evaluated, but there is no further recursive evaluation. This changes when LEVEL is assigned a bigger value inside the procedure:

```
delete a0, a1, a2, a3:
a0 := a1 + a2:  a1 := a2 + a3:  a2 := a3^2 - 1:  a3 := 5:
p := proc()
       save LEVEL;
     begin
       print(a0, eval(a0)):
       LEVEL := 2:
       print(a0, eval(a0)):
     end_proc:

p()
```

$$a1 + a2,\ a3^2 + a3 + a2 - 1$$

$$a3^2 + a3 + a2 - 1,\ 53$$

In contrast, evaluation of a local variable replaces it by its value, without further evaluation. When eval is applied to an object containing a local variable, then the effect is an evaluation of the value of the local variable with substitution depth LEVEL:

```
q := proc()
       save LEVEL;
       local x;
     begin
       x := a0:
       print(x, eval(x)):
       LEVEL := 2:
       print(x, eval(x)):
```

```
     end_proc:
q()
```

$$a1 + a2,\ a3^2 + a3 + a2 - 1$$

$$a1 + a2,\ a3^2 + 28$$

The command `x:=a0` assigns the value of the identifier `a0`, namely the unevaluated expression `a1+a2`, to the local variable `x`, and `x` is replaced by this value every time it is evaluated, independent of the value of `LEVEL`:

Example 5

In contrast to lists and sets, evaluation of an array does not evaluate its entries. Thus `eval` has no effect for arrays either. Use `map` to evaluate all entries of an array:

```
delete a, b:
L := [a, b]:  A := array(1..2, L):  a := 1:   b := 2:
L, A, eval(A), map(A, eval)
```

$$[1, 2],\ (a\ \ b),\ (a\ \ b),\ (1\ \ 2)$$

The call `map(A, gamma)` does not evaluate the entries of the array `A` before applying the function `gamma`. Map the function `gamma@eval` to enforce the evaluation:

```
map(A, gamma), map(A, gamma@eval)
```

$$(\Gamma(a)\ \ \Gamma(b)),\ (1\ \ 1)$$

Example 6

Similarly, evaluation of a table does not evaluate its entries, and you can use `map` to achieve this. However, this does not affect the indices:

```
delete a, b:
T := table(a = b):  a := 1:  b := 2:
T, eval(T), map(T, eval)
```

$$\overline{a\,|b},\ \overline{a\,|b},\ \overline{a\,|2}$$

If you want a table with evaluated indices as well, create a new table from the evaluated operands of the old table. Using `eval` is necessary here since the operand function `op` does not evaluate the returned operands:

```
op(T), table(eval(op(T)))
```

$$a = b,\ \overline{1\,|2}$$

Example 7

`Polynomials` are inert when evaluated, and also `eval` has no effect:

```
delete a, x:  p := poly(a*x, [x]):  a := 2:  x := 3:
p, eval(p), map(p, eval)
```

$$\mathrm{poly}(a\,x,\,[x]),\ \mathrm{poly}(a\,x,\,[x]),\ \mathrm{poly}(a\,x,\,[x])$$

Use `mapcoeffs` to evaluate all coefficients:

```
mapcoeffs(p, eval)
```

$$\mathrm{poly}(2\,x,\,[x])$$

If you want to substitute a value for the indeterminate `x`, use `evalp`:

```
delete x:  evalp(p, x = 3)
```

$$3\,a$$

As you can see, the result of an `evalp` call may contain unevaluated identifiers, and you can evaluate them by an application of `eval`:

```
eval(evalp(p, x = 3))
```

$$6$$

Example 8

The evaluation of an element of a user-defined domains depends on the implementation of the domain. Usually, it is not evaluated further:

```
delete a:  T := newDomain("T"):
e := new(T, a):  a := 1:
e, eval(e), map(e, eval), val(e)
```

$$\mathrm{new}(T, a), \mathrm{new}(T, a), \mathrm{new}(T, a), \mathrm{new}(T, a)$$

If the slot `"evaluate"` exists, the corresponding slot routine is called for a domain element each time it is evaluated. We implement the routine `T::evaluate`, which simply evaluates all internal operands of its argument, for our domain `T`. The unevaluated domain element can still be accessed via `val`:

```
T::evaluate := x -> new(T, eval(extop(x))):
e, eval(e), map(e, eval), val(e)
```

$$\mathrm{new}(T, 1), \mathrm{new}(T, 1), \mathrm{new}(T, 1), \mathrm{new}(T, a)$$

Parameters

`object`

Any MuPAD object

Return Values

Evaluated object.

More About

- “Evaluations in Symbolic Computations”
- “Level of Evaluation”
- “Actual and Displayed Results of Evaluations”

evalassign

Assignment with evaluation of the left hand side

Syntax

```
evalassign(x, value, i)

evalassign(x, value)
```

Description

`evalassign(x, value, i)` evaluates `x` with substitution depth `i` and assigns `value` to the result of the evaluation.

`evalassign(x, value, i)` evaluates `value`, as usual. Then it evaluates `x` with substitution depth `i`, and finally it assigns the evaluation of `value` to the evaluation of `x`.

The difference between `evalassign` and the assignment operator `:=` is that the latter does not evaluate its left hand side at all.

As usual, the evaluation of `value` takes place with substitution depth given by `LEVEL`. By default, it is `1` within a procedure.

See the help pages of `LEVEL` and `level` for the notion of substitution depth and for details about evaluation.

The third argument is optional. The calls `evalassign(x, value)`, `evalassign(x, value, 0)`, `x := value`, and `_assign(x, value)` are all equivalent.

The result of the evaluation of `x` must be a valid left hand side for an assignment. See the help page of `:=` for details.

The second argument is *not* flattened. Hence it may also be a sequence. Cf. “Example 2” on page 1-669.

Examples

Example 1

`evalassign` can be used in situations such as the following. Suppose that an identifier `a` has another identifier `b` as its value, and that we want to assign something to this *value* of `a`, not to `a` itself:

```
delete a, b: a := b:
evalassign(a, 100, 1): level(a, 1), a, b
```

```
b, 100, 100
```

This would not have worked with the assignment operator `:=`, which does not evaluate its left hand side:

```
delete a, b: a := b:
a := 100: level(a, 1), a, b
```

```
100, 100, b
```

Example 2

The second argument may also be a sequence:

```
a := b:
evalassign(a, (3,5), 1):
b
```

```
3, 5
```

Parameters

x

An object that evaluates to a valid left hand side of an assignment

value

Any MuPAD object

i

A nonnegative integer less than 2^{31}

Return Values

`value`.

Algorithms

The function `level` is used for the evaluation of `x`. Hence `i` may exceed the value of `LEVEL`.

All special rules for `_assign` apply: see there on further details on indexed assignments, assignments to slots, and the `protect` mechanism.

|, evalAt

Insert a value (evaluate at a point)

Syntax

```
 f | x = v

evalAt(f, x = v)

f | ( x1= v1, x2= v2, … )

evalAt(f, x1 = v1, x2 = v2, …)

evalAt(f, x1 = v1, x2 = v2, …)

f | [x1= v1, x2= v2, …]

evalAt(f, [x1 = v1, x2 = v2, …])

f | {x1= v1, x2= v2, …}

evalAt(f, {x1 = v1, x2 = v2, …})
```

Description

`evalAt(f, x = v)` substitutes `x = v` in the object `f` and evaluates.

The MuPAD statement `f | x = v` serves as a shortcut for calling `evalAt(f, x = v)`.

`evalAt(f, x = v)` evaluates the object `f` at the point `x = v`. Essentially, it is the same as `eval ( subs(f, x = v))`, but limited to free (as opposed to bound) variables.

Several substitutions of indeterminates by values can be done by `evalAt(f, x1 = v1, x2 = v2, ...)`. This is equivalent to `evalAt(... (evalAt(evalAt(f, x1 = v1), x2 = v2), ...), ...)`, i.e., `x1 = v1` is substituted in `f`, then `x2 = v2` is substituted in the result etc. E.g., `evalAt(x, x = y, y = 1)` yields 1.

Note that the three (equivalent) calls `evalAt(f, (x1 = v1, x2 = v2, ...))`, `evalAt(f, [x1 = v1, x2 = v2, ...])`, `evalAt(f, {x1 = v1, x2 =`

`v2, ...})` do parallel substitutions, i.e., the substitutions `x1 = v1`, `x2 = v2` are all performed on `f` simultaneously. Consequently, `evalAt(x, [x = y, y = 1])` yields `y`, not 1!

The operator `|` provides a shortcut for calling `evalAt`:

The command `f | x = v` is equivalent to calling `evalAt(f, x = v)`.

Similarly, `f | (x1=v1, x2=v2, ...)` is equivalent to `evalAt(f, (x1=v1, x2=v2, ...))`, `f | [x1=v1, x2=v2, ...]` is equivalent to `evalAt(f, [x1=v1, x2=v2, ...])`, `f | [x1=v1, x2=v2, ...}` is equivalent to `evalAt(f, {x1=v1, x2=v2, ...})`.

Note: The sequential substitution `evalAt(f, x1 = v1, x2 = v2, ...)` cannot be done via `f | x1 = v1, x2 = v2, ...`: this produces the sequence `evalAt(f, x1 = v1)`, x2 = v2, ... Use `f | x1 = v1 | x2 = v2 | ...` for sequential substitution. E.g., the statement `x | x = y | y = 1` yields 1.

Examples

Example 1

Calls to `evalAt` and corresponding statements using the operator `|` are equivalent:

```
evalAt(x^2 + sin(x), x = 1);
x^2 + sin(x) | x = 1
```

$$\sin(1) + 1$$

$$\sin(1) + 1$$

We use the operator `|` to evaluate an expression `f` representing a function of `x` at several points:

```
f := x + exp(x):
f | x = 3;
f | x = 5.0;
```

```
f | x = y;
```

$$e^3 + 3$$

$$153.4131591$$

$$y + e^y$$

We create a matrix with symbolic entries and evaluate the matrix with various values for the symbols:

```
A := matrix([[x, sin(PI*x)], [2, y]]);
A | x = a;
A | [x = a, y = b]
```

$$\begin{pmatrix} x & \sin(\pi x) \\ 2 & y \end{pmatrix}$$

$$\begin{pmatrix} a & \sin(\pi a) \\ 2 & y \end{pmatrix}$$

$$\begin{pmatrix} a & \sin(\pi a) \\ 2 & b \end{pmatrix}$$

```
delete f, A:
```

Example 2

We do several substitutions simultaneously:

```
f := cos(y) + sin(x) + x*y;
f | (x = 1, y = 2);
f | [x = 1, y = 2];
f | {x = 1, y = 2};
```

$$\cos(y) + \sin(x) + x\,y$$

$$\cos(2) + \sin(1) + 2$$

$$\cos(2) + \sin(1) + 2$$

$$\cos(2) + \sin(1) + 2$$

```
delete f:
```

Parameters

`f`

An arbitrary MuPAD object.

`x, x1, x2, …`

indeterminates or indexed indeterminates.

`v, v1, v2, …`

The values for `x, x1, x2, ….`

Return Values

Copy of the input object `f` with replaced operands.

Overloaded By

f

MuPAD Functions

`evalp | subs | subsex | subsop`

evalp

Evaluate a polynomial at a point

Syntax

```
evalp(p, x = v, …)

evalp(p, [x = v, …])

evalp(f, <vars>, x = v, …)

evalp(f, <vars>, [x = v, …])
```

Description

`evalp(p, x = v)` evaluates the polynomial `p` in the variable `x` at the point `v`.

An error occurs if `x` is not an indeterminate of `p`. The value `v` may be any object that could also be used as coefficient. The result is an element of the coefficient ring of `p` if `p` is univariate. If `p` is multivariate, the result is a polynomial in the remaining variables.

If several evaluation points are given, the evaluations take place in succession from left to right. Each evaluation follows the rules above.

For a polynomial `p` in the variables `x1,x2,...`, the syntax `p(v1,v2,...)` can be used instead of `evalp(p, x1 = v1, x2 = v2, ...)`.

`evalp(f, vars, x = v, ...)` first converts the polynomial expression `f` to a polynomial with the variables given by `vars`. If no variables are given, they are searched for in `f`. See `poly` about details of the conversion. `FAIL` is returned if `f` cannot be converted to a polynomial. A successfully converted polynomial is evaluated as above. The result is converted to an expression.

Horner's rule is used to evaluate the polynomial. The evaluation of variables at the point `0` is most efficient and should take place first. After that, the remaining main variable should be evaluated first.

The result of `evalp` is not evaluated further. One may use `eval` to fully evaluate the result.

Instead of `evalp(p, x1 = v1, x2 = v2, ...)` one may also use the equivalent form `evalp(p, [x1 = v1, x2 = v2, ...])`.

Examples

Example 1

`evalp` is used to evaluate the polynomial expression $x^2 + 2x + 3$ at the point $x = a + 2$. The form of the resulting expression reflects the fact that Horner's rule was used:

```
evalp(x^2 + 2*x + 3, x = a + 2)
```

$$(a+2)\,(a+4)+3$$

Example 2

`evalp` is used to evaluate a polynomial in the indeterminates x and y at the point $x = 3$. The result is a polynomial in the remaining indeterminate y:

```
p := poly(x^2 + x*y + 2, [x, y]): evalp(p, x = 3)
```

$$\mathrm{poly}(3\,y+11,\,[y])$$

```
delete p:
```

Example 3

Polynomials may be called like functions in order to evaluate all variables:

```
p := poly(x^2 + x*y, [x, y]): evalp(p, x = 3, y = 2) = p(3, 2)
```

$$15 = 15$$

```
delete p:
```

Example 4

If not all variables are replaced by values, the result is a polynomial in the remaining variables:

```
evalp(poly(x*y*z + x^2 + y^2 + z^2, [x, y, z]), x = 1, y = 1)
```

$$\mathrm{poly}(z^2 + z + 2, [z])$$

Example 5

The result of `evalp` is not evaluated further. We first define a polynomial `p` with coefficient `a` and then change the value of `a`. The change is not reflected by `p`, because polynomials do not evaluate their coefficients implicitly. One must map the function `eval` onto the coefficients in order to enforce evaluation:

```
p := poly(x^2 + a*y + 1, [x,y]): a := 2:
p, mapcoeffs(p, eval)
```

$$\mathrm{poly}(x^2 + a\,y + 1, [x, y]),\ \mathrm{poly}(x^2 + 2\,y + 1, [x, y])$$

If we use `evalp` to evaluate `p` at the point $x = 1$, the result is not fully evaluated. One must use `eval` to get fully evaluated coefficients:

```
r := evalp(p, x = 1):
r, mapcoeffs(r, eval)
```

$$\mathrm{poly}(a\,y + 2, [y]),\ \mathrm{poly}(2\,y + 2, [y])$$

```
delete p, a, r:
```

Parameters

p

A polynomial of type `DOM_POLY`

x

An indeterminate

v

The value for `x`: an element of the coefficient ring of the polynomial

f

A polynomial expression

vars

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

Return Values

Element of the coefficient ring, or a polynomial, or a polynomial expression, or `FAIL`

Overloaded By

f, p

See Also

MuPAD Functions
`eval` | `evalAt` | `poly`

exp

Exponential function

Syntax

```
exp(x)
```

Description

`exp(x)` represents the value of the exponential function at the point x.

The exponential function is defined for all complex arguments.

For most exact arguments, an unevaluated function call is returned subject to some simplifications:

- Calls of the form $e^{q\,\pi\,i}$ with integer or rational q are rewritten such that q lies in the interval $[0, 2)$. Explicit results are returned if the denominator of q is 1, 2, 3, 4, 5, 6, 8, 10, or 12.
- Further, the following special values are implemented: $e^0 = 1$, $e^{\infty} = \infty$, $e^{-\infty} = 0$.
- A call of the form $e^{c\,\ln(y)}$ with an unevaluated $ln(y)$ and a constant c (i.e., of type `Type::Constant`) yields the result y^c.
- The call $e^{f(y)}$ yields the result $\frac{y}{f(y)}$, if f is `lambertW`.

Floating point results are computed, when the argument is a floating-point number.

Note: Numerical exceptions may happen, when the absolute value of the real part of a floating-point argument x is large. If $\Re(x) < -7.4\,10^8$, then `exp(x)` may return the truncated result `0.0` (protection against underflow). If $\Re(x) > 7.4\,10^8$, then `exp(x)` may return the floating-point equivalent RD_INF of `infinity`. See “Example 2” on page 1-681.

For arguments of type DOM_INTERVAL, the return value is another interval containing the image set of the exponential function over the input interval. See “Example 4” on page 1-682.

The protected identifier E is an alias for exp(1).

Environment Interactions

When called with a floating-point argument, the function is sensitive to the environment variable DIGITS which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
exp(1), exp(2), exp(-3), exp(1/4), exp(1 + I), exp(x^2)
```

$$e,\ e^2,\ e^{-3},\ e^{\frac{1}{4}},\ e^{1+i},\ e^{x^2}$$

Floating point values are computed for floating-point arguments:

```
exp(1.23), exp(4.5 + 6.7*I), exp(1.0/10^20), exp(123456.7)
```

$$3.421229536,\ 82.31014791 + 36.44342846\,i,\ 1.0,\ 3.660698702\ 10^{53616}$$

Some special symbolic simplifications are implemented:

```
exp(I*PI), exp(x - 22*PI*I), exp(3 + I*PI)
```

$$-1,\ e^x,\ -e^3$$

```
exp(ln(-2)), exp(ln(x)*PI), exp(lambertW(5))
```

$$-2,\ x^{\pi},\ \frac{5}{W_0(5)}$$

Example 2

The truncated result `0.0` may be returned for floating-point arguments with negative real parts. This prevents numerical underflow:

```
exp(-742261118.6)
```

$$1.14996558\ 10^{-322359908}$$

```
exp(-744261118.7)
```

$$0.0$$

```
exp(-742261118.6 + 10.0^10*I), exp(-744261118.7 + 10.0^10*I)
```

$$1.004057513\ 10^{-322359908} - 5.606151488\ 10^{-322359909}\ i,\ 0.0$$

When internal numerical overflow occurs, the floating-point equivalent RD_INF of `infinity` is returned:

```
exp(744261117.2)
```

$$1.972919601\ 10^{323228496}$$

```
exp(744261117.3)
```

$$RD\_INF$$

Example 3

System functions such as `limit`, `series`, `expand`, `combine` etc. handle expressions involving `exp`:

```
limit(x*exp(-x), x = infinity), series(exp(x/(x + 1)), x = 0)
```

$$0,\ 1 + x - \frac{x^2}{2} + \frac{x^3}{6} + \frac{x^4}{24} - \frac{19\,x^5}{120} + O(x^6)$$

```
expand(exp(x + y + (sqrt(2) + 5)*PI*I))
```

$$-e^{\pi\sqrt{2}\,i}\,e^{x}\,e^{y}$$

```
combine(%, exp)
```

$$-e^{x+y+\pi\sqrt{2}\,i}$$

Example 4

`exp` transforms intervals (of type `DOM_INTERVAL`) to intervals:

```
exp(-1 ... 1)
```

$$0.3678794411 \ldots 2.718281829$$

Note that the MuPAD floating-point numbers cannot be arbitrarily large. In the context of floating-point intervals, all values larger than a machine-dependent constant are regarded as “infinite”:

```
exp(1 ... 1e1000)
```

$$2.718281828 \ldots \mathrm{RD\_INF}$$

Finally, we would like to mention that you can also use `exp` on disjunct unions of intervals:

```
exp((1 ... PI) union (10 ... 20))
```

$$2.718281828 \ldots 23.14069264 \cup 22026.46579 \ldots 485165195.5$$

Parameters

x

An arithmetical expression or a floating-point interval

Return Values

Arithmetical expression or a floating-point interval

Overloaded By

x

See Also

MuPAD Functions
`ln` | `log`

expand

Expand an expression

Syntax

```
expand(f, options)
```

```
expand(f, g1, g2, …, options)
```

Description

`expand(f)` expands the arithmetical expression `f`.

The most important use of `expand` is the application of the distributivity law to rewrite products of sums as sums of products. In this respect, `expand` is the inverse function of `factor`.

The numerator of a fraction is expanded, and then the fraction is rewritten as a sum of fractions with simpler numerators; see “Example 1” on page 1-685. In a certain sense, this is the inverse functionality of `normal`. Use `partfrac` for a more powerful way to rewrite a fraction as a sum of simpler fractions.

`expand(f)` applies the following rules when rewriting powers occurring as subexpressions in `f`:

- $x^{a+b} = x^a x^b$.
- If `b` is an integer, or $x \geq 0$ or $y \geq 0$, then $(x\,y)^b = x^b\,y^b$.
- If `b` is an integer, then $(x^a)^b = x^{a\,b}$.

Except for the third rule, this behavior of `expand` is the inverse functionality of `combine`. See “Example 2” on page 1-686.

`expand` works recursively on the subexpressions of an expression `f`. If `f` is of the container type `array` or `table`, `expand` only returns `f` and does not map on the entries. To expand all entries of one of the containers, use `map`. See “Example 3” on page 1-686.

If optional arguments `g1, g2, ...` are present, then any subexpression of `f` that is equal to one of these additional arguments is not expanded; see “Example 4” on page 1-687. See section “Background” for a description how this works.

Properties of identifiers are taken into account (see `assume`). Identifiers without any properties are assumed to be complex. See “Example 9” on page 1-690.

`expand` also handles various types of special mathematical functions. It rewrites a single call of a special function with a complicated argument as a sum or a product of several calls of the same function or related functions with simpler arguments. In this respect, `expand` is the inverse function of `combine`.

In particular, `expand` implements the functional equations of the exponential function and the logarithm, the gamma function and the polygamma function, and the addition theorems for the trigonometric functions and the hyperbolic functions. See “Example 10” on page 1-691.

Environment Interactions

`expand` is sensitive to properties of identifiers set via `assume`.

Examples

Example 1

`expand` expands products of sums by multiplying out:

```
expand((x + 1)*(y + z)^2)
```

$$2yz + xy^2 + xz^2 + y^2 + z^2 + 2xyz$$

After expansion of the numerator, a fraction is rewritten as a sum of fractions:

```
expand((x + 1)^2*y/(y + z)^2)
```

$$\frac{y}{y^2 + 2yz + z^2} + \frac{2xy}{y^2 + 2yz + z^2} + \frac{x^2 y}{y^2 + 2yz + z^2}$$

Example 2

A power with a sum in the exponent is rewritten as a product of powers:

```
expand(x^(y + z + 2))
```

$$x^y\, x^z\, x^2$$

Example 3

`expand` works in a recursive fashion. In the following example, the power $(x + y)^{z+2}$ is first expanded into a product of two powers. Then the power $(x + y)^2$ is expanded into a sum. Finally, the product of the latter sum and the remaining power $(x + y)^z$ is multiplied out:

```
expand((x + y)^(z + 2))
```

$$x^2\,(x+y)^z + y^2\,(x+y)^z + 2\,x\,y\,(x+y)^z$$

Here is another example:

```
expand(2^((x + y)^2))
```

$$2^{x^2}\, 2^{y^2}\, 2^{2\,x\,y}$$

`expand` maps on the entries of lists, sets, and matrices:

```
expand([(a + b)^2, (a - b)^2]);
expand({(a + b)^2, (a - b)^2});
expand(matrix([[(a + b)^2, 0],[0, (a - b)^2]]))
```

$$[a^2 + 2\,a\,b + b^2,\ a^2 - 2\,a\,b + b^2]$$

$$\{a^2 - 2\,a\,b + b^2,\ a^2 + 2\,a\,b + b^2\}$$

$$\begin{pmatrix} a^2 + 2\,a\,b + b^2 & 0 \\ 0 & a^2 - 2\,a\,b + b^2 \end{pmatrix}$$

`expand` does not map on the entries of tables or arrays:

```
expand(table((a + b)^2=(c + 1)^2)),
expand(array(1..1, [(a + b)^2]))
```

$$\begin{array}{|c|}\hline (a+b)^2 \\ \hline (c+1)^2 \\ \hline \end{array}, \left((a+b)^2 \right)$$

Use `map` in order to expand all entries of a container:

```
map(table((a + b)^2=(c + 1)^2), expand),
map(array(1..1, [(a + b)^2]), expand)
```

$$\begin{array}{|c|}\hline (a+b)^2 \\ \hline 2\,c+c^2+1 \\ \hline \end{array}, \left(a^2+2\,a\,b+b^2 \right)$$

Note that this call expands only the *entries* in a table, not the keys. In the (rare) case that you want the keys expanded as well, transform the table to a list or set of equations first:

```
T := table((a + b)^2=(c + 1)^2):
table(expand([op(T)]))
```

$$\begin{array}{|c|}\hline 2\,a\,b+a^2+b^2 \\ \hline 2\,c+c^2+1 \\ \hline \end{array}$$

Example 4

If additional arguments are provided, `expand` performs only a partial expansion. These additional expressions, such as `x + 1` in the following example, are not expanded:

```
expand((x + 1)*(y + z))
```

$$y+z+x\,y+x\,z$$

```
expand((x + 1)*(y + z), x + 1)
```

$$y\,(x+1)+z\,(x+1)$$

Example 5

By default, `expand` works on all subexpressions including trigonometric subexpressions:

```
e := (sin(2*x) + 1)*(1 - cos(2*x)):
expand(e)
```

$$-4\sin(x)\cos(x)^3 - 2\cos(x)^2 + 4\sin(x)\cos(x) + 2$$

To prevent expansion of subexpressions, use the `ArithmeticOnly` option:

```
expand(e, ArithmeticOnly)
```

$$\sin(2x) - \cos(2x) - \cos(2x)\sin(2x) + 1$$

The option does not prevent expansion of powers and roots:

```
expand((sin(2*x) + 1)^3, ArithmeticOnly)
```

$$\sin(2x)^3 + 3\sin(2x)^2 + 3\sin(2x) + 1$$

To keep subexpressions with integer powers unexpanded, use the `MaxExponent` option.

Example 6

The `IgnoreAnalyticConstraints` option applies a set of purely algebraic simplifications including the equality of sum of logarithms and a logarithm of a product. Using the `IgnoreAnalyticConstraints` option, you get a simpler result, but one that might be incorrect for some of the values of variables:

```
expand(ln(a*b*c*d), IgnoreAnalyticConstraints)
```

$$\ln(a) + \ln(b) + \ln(c) + \ln(d)$$

Without using this option, you get a mathematically correct result:

```
expand(ln(a*b*c*d))
```

$$\ln(a\,b\,c\,d)$$

Example 7

If the additional `MaxExponent` provided, `expand` performs only a partial expansion. Powers with an integer exponent larger than the given bound, are not expanded:

```
expand((a + b)^3, MaxExponent = 2)
```

$$(a+b)^3$$

If the exponent is smaller or equal the given bound, the power is expanded:

```
expand((a + b)^2, MaxExponent = 2)
```

$$a^2+2\,a\,b+b^2$$

Example 8

The `expand` function can accept several options simultaneously. Suppose you want to expand the following expression:

```
e := (sin(2*x) + 1)*(x + 1)^3
```

$$(\sin(2\,x)+1)\,(x+1)^3$$

`expand` without any options works recursively. The function expands all subexpressions including trigonometric functions and powers:

```
expand(e)
```

$$3\,x+2\,\cos(x)\,\sin(x)+3\,x^2+x^3+6\,x\,\cos(x)\,\sin(x)+6\,x^2\,\cos(x)\,\sin(x)+2\,x^3\,\cos(x)\,\sin(x)+1$$

The `ArithmeticOnly` option prevents the expansion of the term `sin(2x)`. The `MaxExponent` option prevents the expansion of $(x + 1)^3$:

```
expand(e, ArithmeticOnly);
expand(e, MaxExponent = 2)
```

$$3\,x+\sin(2\,x)+3\,x\,\sin(2\,x)+3\,x^2\,\sin(2\,x)+x^3\,\sin(2\,x)+3\,x^2+x^3+1$$

$$(x+1)^3 + 2\cos(x)\sin(x)(x+1)^3$$

Combining these options in one call of the `expand` function, you apply both restrictions for the expansion:

```
expand(e, MaxExponent = 2, ArithmeticOnly)
```

$$(x+1)^3 + \sin(2x)(x+1)^3$$

Example 9

The following expansions are not valid for all values `a`, `b` from the complex plane. Therefore, MuPAD does not expand these expressions:

```
expand(ln(a^2)), expand(ln(a*b)), expand((a*b)^n)
```

$$\ln(a^2),\ \ln(a\,b),\ (a\,b)^n$$

The expansions are valid under the assumption that `a` is a positive real number:

```
assume(a > 0):  expand(ln(a^2)), expand(ln(a*b)), expand((a*b)^n)
```

$$2\ln(a),\ \ln(a)+\ln(b),\ a^n\,b^n$$

Clear the assumption for further computations:

```
unassume(a):
```

Alternatively, to get the expanded result for the third expression, assume that `n` is an integer:

```
expand((a*b)^n) assuming n in Z_
```

$$a^n\,b^n$$

Use the `IgnoreAnalyticConstraints` option to expand these expressions without explicitly specified assumptions:

```
expand(ln(a^2), IgnoreAnalyticConstraints),
expand(ln(a*b), IgnoreAnalyticConstraints),
```

```
expand((a*b)^n, IgnoreAnalyticConstraints)
```

$$2\ln(a),\ \ln(a)+\ln(b),\ a^n\,b^n$$

Example 10

The addition theorems of trigonometry are implemented by `"expand"`-slots of the trigonometric functions `sin` and `cos`:

```
expand(sin(a + b)), expand(sin(2*a))
```

$$\cos(a)\sin(b)+\cos(b)\sin(a),\ 2\cos(a)\sin(a)$$

The same is true for the hyperbolic functions `sinh` and `cosh`:

```
expand(cosh(a + b)), expand(cosh(2*a))
```

$$\sinh(a)\sinh(b)+\cosh(a)\cosh(b),\ 2\cosh(a)^2-1$$

The exponential function with a sum as argument is expanded via `exp::expand`:

```
expand(exp(a + b))
```

$$e^a\,e^b$$

Here are some more expansion examples for the functions `sum`, `fact`, `abs`, `coth`, `sign`, `binomial`, `beta`, `gamma`, `cot`, `tan`, `exp` and `psi`:

```
sum(f(x) + g(x),x);  expand(%)
```

$$\sum_x (f(x)+g(x))$$

$$\left(\sum_x f(x)\right)+\left(\sum_x g(x)\right)$$

```
fact(x + 1);  expand(%)
```

$$(x+1)!$$

$$x!\,(x+1)$$

```
abs(a*b);  expand(%)
```

$$|a\,b|$$

$$|a|\,|b|$$

```
coth(a + b);  expand(%)
```

$$\coth(a+b)$$

$$\frac{\coth(a)\,\coth(b)+1}{\coth(a)+\coth(b)}$$

```
coth(a*b);  expand(%)
```

$$\coth(a\,b)$$

$$\coth(a\,b)$$

```
sign(a*b);  expand(%)
```

$$\operatorname{sign}(a\,b)$$

$$\operatorname{sign}(a)\,\operatorname{sign}(b)$$

```
binomial(n, m);  expand(%)
```

$$\binom{n}{m}$$

$$-\frac{n\,\Gamma(n)}{m^2\,\Gamma(n-m)\,\Gamma(m)-m\,n\,\Gamma(n-m)\,\Gamma(m)}$$

```
beta(n, m);  expand(%)
```

$$\beta(m, n)$$

$$\frac{\Gamma(m)\,\Gamma(n)}{\Gamma(m+n)}$$

```
gamma(x + 1);  expand(%)
```

$$\Gamma(x+1)$$

$$x\,\Gamma(x)$$

```
tan(a + b); expand(%)
```

$$\tan(a+b)$$

$$-\frac{\tan(a)+\tan(b)}{\tan(a)\,\tan(b)-1}$$

```
cot(a + b); expand(%)
```

$$\cot(a+b)$$

$$\frac{\cot(a)\,\cot(b)-1}{\cot(a)+\cot(b)}$$

```
exp(x + y);  expand(%)
```

$$e^{x+y}$$

$$e^{x}\,e^{y}$$

```
psi(x + 2);  expand(%)
```

$$\psi(x+2)$$

$$\psi(x)+\frac{1}{x+1}+\frac{1}{x}$$

In contrast to previous versions of MuPAD, `expand` does not rewrite `tan` in terms of `sin` and `cos`:

```
expand(tan(a))
```

$$\tan(a)$$

Example 11

This example illustrates how to extend the functionality of `expand` to user-defined mathematical functions. As an example, we consider the sine function. (Of course, the system function `sin` already has an `"expand"` slot; see “Example 10” on page 1-691.)

We first embed our function into a function environment, which we call `Sin`, in order not to overwrite the system function `sin`. Then we implement the addition theorem $sin(x + y) = sin(x)\,cos(y) + sin(y)\,cos(x)$ in the `"expand"` slot of the function environment, i.e., the slot routine `Sin::expand`:

```
Sin := funcenv(Sin):
Sin::expand := proc(u) // compute expand(Sin(u))
  local x, y;
begin
  // recursively expand the argument u
  u := expand(op(u));

   if type(u) = "_plus" then // u is a sum
    x := op(u, 1); // the first term
    y := u - x;    // the remaining terms

    // apply the addition theorem and
    // expand the result again
    expand(Sin(x)*cos(y) + cos(x)*Sin(y))
  else
    Sin(u)
  end_if
```

```
end_proc:
```

Now, if `expand` encounters a subexpression of the form `Sin(u)`, it calls `Sin::expand(u)` to expand `Sin(u)`. The following command first expands the argument `a*(b+c)` via the recursive call in `Sin::expand`, then applies the addition theorem, and finally `expand` itself expands the product of the result with `z`:

```
expand(z*Sin(a*(b + c)))
```

$$z\,\mathrm{Sin}(a\,b)\,\cos(a\,c) + z\,\mathrm{Sin}(a\,c)\,\cos(a\,b)$$

The expansion after the application of the addition theorem in `Sin::expand` is necessary to handle the case when `u` is a sum with more than two terms: then `y` is again a sum, and `cos(y)` and `Sin(y)` are expanded recursively:

```
expand(Sin(a + b + c))
```

$$\mathrm{Sin}(a)\,\cos(b)\,\cos(c) + \mathrm{Sin}(b)\,\cos(a)\,\cos(c) + \mathrm{Sin}(c)\,\cos(a)\,\cos(b) - \mathrm{Sin}(a)\,\sin(b)\,\sin(c)$$

Parameters

`f, g1, g2, …`

arithmetical expressions

Options

`ArithmeticOnly`

Expand arithmetic part of an expression without expanding trigonometric, hyperbolic, logarithmic and special functions.

This option does not prevent expansion of powers and roots. Technically, the option omits overloading the `expand` function for each term of the original expression. See “Example 5” on page 1-688.

`IgnoreAnalyticConstraints`

With this option `expand` applies the following rules when expanding expressions:

- $ln(a) + ln(b) = ln(a\,b)$ for all values of a and b. In particular:

  $(a\,b)^c = e^{c\,\ln(a\,b)} = e^{c\,(\ln(a)+\ln(b))} = a^c\,b^c$ for all values of a, b, and c
- $ln(a^b) = b\,ln(a)$ for all values of a and b. In particular:

  $(a^b)^c = e^{b\,c\,\ln(a)} = e^{\ln(a)^{b\,c}} = a^{b\,c}$ for all values of a, b, and c
- If f and g are standard mathematical functions and $f(g(x)) = x$ for all small positive numbers, $f(g(x)) = x$ is assumed to be valid for all complex x. In Particular:
  - $\ln(e^x) = x$
  - $arcsin(sin(x)) = x$, $arccos(cos(x)) = x$, $arctan(tan(x)) = x$
  - $arcsinh(sinh(x)) = x$, $arccosh(cosh(x)) = x$, $arctanh(tanh(x)) = x$
  - $W_k(x\,e^x) = x$ for all values of k

Using the option can give you simpler results for the expressions for which the default call to `expand` returns complicated results. With this option the function does not guarantee the equality of the initial expression and the result for all symbolic parameters. See “Example 6” on page 1-688.

`MaxExponent`

Option, specified as `MaxExponent = n`

Do not expand powers with integer exponents larger than `n`.

If you call `expand` with this option, the function expands does not expand powers with integer exponents larger than `n`. See “Example 7” on page 1-689.

Return Values

arithmetical expression.

Overloaded By

f

Algorithms

With optional arguments `g1, g2, ...`, the expansion of certain subexpressions of `f` can be prevented. This works as follows: every occurrence of `g1, g2, ...` in `f` is replaced by an auxiliary variable before the expansion, and afterwards the auxiliary variables are replaced by the original subexpressions.

Users can extend the functionality of `expand` to their own special mathematical functions via overloading. To this end, embed your function into a function environment `g` and implement the behavior of `expand` for this function in the `"expand"` slot of the function environment.

Whenever `expand` encounters a subexpression of the form `g(u,..)`, it issues the call `g::expand(g(u,..))` to the slot routine to expand the subexpression, passing the not yet expanded arguments `g(u,..)` as arguments. The result of this call is not expanded any further by `expand`. See “Example 11” on page 1-694 above.

Similarly, an `"expand"` slot can be defined for a user-defined library domain`T`. Whenever `expand` encounters a subexpression `d` of domain type`T`, it issues the call `T::expand(d)` to the slot routine to expand `d`. The result of this call is not expanded any further by `expand`. If `T` has no `"expand"` slot, then `d` remains unchanged.

MuPAD Functions

`collect` | `combine` | `denom` | `factor` | `normal` | `numer` | `partfrac` | `rationalize` | `rectform` | `rewrite` | `simplify`

expose

Display the source code of a procedure or the entries of a domain

Syntax

```
expose(f)
```

Description

`expose(f)` displays the source code of the MuPAD procedure `f` or the entries of the domain `f`.

Usually, procedures and domains are printed in abbreviated form. `expose` serves to display the complete source code of a procedure and all entries of a domain, respectively. However, you cannot use `expose` to look at the source code of kernel functions.

If `f` is a domain, then `expose` returns a symbolic `newDomain` call. The arguments of the call are equations of the form `index = value`, where `value` equals the value of `f::index`. `expose` is not recursively applied to `f::index`; hence, the source code of domain methods is not displayed.

Although `expose` returns a syntactically valid MuPAD object, this return value is intended for screen output only, and further processing of it is deprecated.

Examples

Example 1

Using `expose`, you can inspect the source code of procedures of the MuPAD library:

```
sin
```

```
sin
```

```
expose(%)

proc(x)   name sin;   local f, y;   option
noDebug; begin   if args(0) = 0 then     error("no arguments given")
  else   ... end_proc
```

Example 2

When applied to a domain, `expose` shows the entries of that domain:

```
expose(DOM_NULL)

domain DOM_NULL

  new := proc new() ... end;

  new_extelement := proc new_extelement(d) ... end;

  Content := proc DOM_NULL::Content(Out, x) ... end;
end_domain
```

Example 3

Applying `expose` to other objects is legal but generally useless:

```
expose(3)

     3
```

Parameters

`f`

Any object; typically, a procedure, a function environment, or a domain

Overloaded By

f

Algorithms

In addition to the usual overloading mechanism for domain elements, a domain method overloading `expose` must handle the following case: it will be called with zero arguments when the domain itself is to be exposed.

If `f` is a procedure, then `expose` returns an object of the domain `stdlib::Exposed`. The only purpose of this domain is its "print" method; manipulating its elements should never be necessary. Therefore it remains undocumented.

See Also

MuPAD Functions
`print`

expr

Convert into an element of a basic domain

Syntax

```
expr(object)
```

Description

`expr(object)` converts `object` into an element of a basic domain, such that all sub-objects are elements of basic domains as well.

`expr` is a type conversion function, for converting an element of a more complex library domain, such as a polynomial or a matrix, into an element of a basic kernel domain.

`expr` proceeds recursively, such that all sub-objects of the returned object are elements of basic domains, or infinities, or `undefined`. See “Example 1” on page 1-702 and “Example 2” on page 1-702.

The two special objects `infinity` and `complexInfinity` are translated into identifiers with the same name by `expr`. Evaluating these identifiers yields the original objects. See “Example 1” on page 1-702.

If `object` already belongs to a basic domain other than `DOM_POLY`, then `expr` is only applied recursively to the operands of `object`, if any.

If `object` is a polynomial of domain type`DOM_POLY`, then `expr` is applied recursively to the coefficients of `object`, and afterwards the result is converted into an identifier, a number, or an expression. See “Example 1” on page 1-702.

If `object` belongs to a library domain `T` with an `"expr"` slot, then the corresponding slot routine `T::expr` is called with `object` as argument, and the result is returned.

This can be used to extend the functionality of `expr` to elements of user-defined domains. If the slot routine is unable to perform the conversion, it must return `FAIL`. See “Example 6” on page 1-704.

If the domain `T` does not have an `"expr"` slot, then `expr` returns `FAIL`.

The result of `expr` is not evaluated further. Use `eval` to evaluate it. See "Example 4" on page 1-703.

Examples

Example 1

`expr` converts a polynomial into an expression, an identifier, or a number:

```
expr(poly(x^2 + y, [x])), expr(poly(x)), expr(poly(2, [x]));
map(%, domtype)
```

$$x^2 + y,\ x,\ 2$$

DOM_EXPR, DOM_IDENT, DOM_INT

`expr` also works with the objects `infinity`, `complexInfinity`, and `undefined`:

```
expr(infinity), expr(complexInfinity), expr(undefined);
map(%, domtype)
```

$$\infty,\ \text{complexInfinity},\ \text{undefined}$$

stdlib::Infinity, stdlib::CInfinity, stdlib::Undefined

Example 2

This example shows that `expr` works recursively on expressions. All subexpressions which are domain elements are converted into expressions. The construction with `hold(_plus)(..)` is necessary since `x + i(1)` would evaluate to `FAIL`:

```
i := Dom::IntegerMod(7):
hold(_plus)(x, i(1));  expr(%)
```

$$x + (1 \bmod 7)$$

$$x + 1$$

Example 3

The function `series` returns an element of the domain `Series::Puiseux`, which is not a basic domain:

```
s := series(sin(x), x);
domtype(s)
```

$$x - \frac{x^3}{6} + \frac{x^5}{120} + O(x^7)$$

Series::Puiseux

Use `expr` to convert the result into an element of domain type `DOM_EXPR`:

```
e := expr(s); domtype(e)
```

$$\frac{x^5}{120} - \frac{x^3}{6} + x$$

DOM_EXPR

Note that the information about the order term is lost after the conversion.

Example 4

`expr` does not evaluate its result. In this example the polynomial `p` has a parameter `a` and the global variable `a` has a value. `expr` applied on the polynomial `p` returns an expression containing `a`. If you want to insert the value of `a` use the function `eval`:

```
p := poly(a*x, [x]):  a := 2:  expr(p);  eval(%)
```

$$a\,x$$

$$2\,x$$

Example 5

A is an element of type `Dom::Matrix(Dom::Integer)`:

```
A := Dom::Matrix(Dom::Integer)([[1, 2], [3, 2]]);
domtype(A)
```

$$\begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix}$$

Dom::Matrix(Dom::Integer)

In this case, `expr` converts A into an element of type `DOM_ARRAY`:

```
a := expr(A); domtype(a)
```

$$\begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix}$$

DOM_ARRAY

However, it is not guaranteed that the result is of type `DOM_ARRAY` in future versions of MuPAD as well. For example, the internal representation of matrices might change in the future. Use `coerce` to request the conversion into a particular data type:

```
coerce(A, DOM_ARRAY)
```

$$\begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix}$$

A nested `list` is an alternative representation for a matrix:

```
coerce(A, DOM_LIST)
```

[[1, 2], [3, 2]]

Example 6

If a sub-object belongs to a domain without an `"expr"` slot, then `expr` returns `FAIL`:

```
T := newDomain("T"):
d := new(T, 1, 2);
expr(d)
```

$$\mathrm{new}(T, 1, 2)$$

FAIL

You can extend the functionality of `expr` to your own domains. We demonstrate this for the domain `T` by implementing an `"expr"` slot, which returns a list with the internal operands of its argument:

```
T::expr := x -> [extop(x)]:
```

If now `expr` encounters a sub-object of type `T` during the recursive process, it calls the slot routine `T::expr` with the sub-object as argument:

```
expr(d), expr([d, 3])
```

$$[1, 2], [[1, 2], 3]$$

Parameters

`object`

An arbitrary object

Return Values

Element of a basic domain.

Overloaded By

object

See Also

MuPAD Functions
`coerce` | `domtype` | `eval` | `testtype` | `type`

expr2text

Convert objects into character strings

Syntax

```
expr2text(object)
```

Description

`expr2text(object)` converts `object` into a character string. The result usually corresponds to the screen output of `object` when `PRETTYPRINT` is set to `FALSE`.

If the function is called without arguments, then an empty character string is created. If more than one argument is given, the arguments are interpreted as an expression sequence and are converted into a single character string.

Like most other MuPAD function, `expr2text` evaluates its arguments before the conversion.

If strings occur in `object`, they will be quoted in the result.

Examples

Example 1

Expressions are converted into character strings:

```
expr2text(a + b)
```

```
"a + b"
```

`expr2text` quotes strings. Note that the quotation marks are preceded by a backslash when they are printed on the screen:

```
expr2text(["text", 2])
```

```
"["text", 2]"
```

Example 2

If more than one argument is given, the arguments are treated as a single expression sequence:

```
expr2text(a, b, c)
```

```
"a, b, c"
```

If no argument is given, an empty string is generated:

```
expr2text()
```

```
""
```

Example 3

`expr2text` evaluates its arguments:

```
a := b: c := d: expr2text(a, c)
```

```
"b, d"
```

Use `hold` to prevent evaluation:

```
expr2text(hold(a, c));
delete a, c:
```

```
"a, c"
```

Here is another example:

```
expr2text((a := b; c := d));
delete a, c:
```

```
"d"
```

```
e := expr2text(hold((a := b; c := d)))
```

```
"(a := b;  c := d)"
```

The last string contains a newline character "\n". Use `print` with option `Unquoted` to expand this into a new line:

```
print(Unquoted, e):
```

```
(a := b;
c := d)
```

Example 4

`expr2text` is overloadable. It uses a default output for elements of a domain if the domain has neither a `"print"` slot nor an `"expr2text"` slot:

```
T := newDomain("T"): e := new(T, 1):
e;
print(e):
expr2text(e)
```

```
new(T, 1)
```

```
new(T, 1)
```

```
"new(T, 1)"
```

If a `"print"` slot exists, it will be called by `expr2text` to generate the output:

```
T::print := proc(x) begin
  _concat("foo: ", expr2text(extop(x)))
end_proc:
e;
print(e):
expr2text(e)
```

```
foo: 1
```

```
foo: 1
```

```
"foo: 1"
```

If you want `expr2text` to generate an output differing from the usual output generated by `print`, you can supply an `"expr2text"` method:

```
T::expr2text := proc(x) begin
  _concat("bar: ", expr2text(extop(x)))
end_proc:
e;
print(e):
expr2text(e)
```

```
foo: 1
```

```
foo: 1
```

```
"bar: 1"
```

Parameters

`object`

Any MuPAD object

Return Values

`string`.

Overloaded By

object

Algorithms

When processing a domain element `e`, `expr2text` first tries to call the `"expr2text"` method of the corresponding domain `T`. If it exists, `T::expr2text(e)` is called and the result is returned. If no `"expr2text"` method exists, `expr2text` tries to call the `"print"` method in the same way. If no `"print"` method exists either, `expr2text` will generate a default output. Cf. “Example 4” on page 1-709.

An `"expr2text"` method or a `"print"` method may return an arbitrary MuPAD object, which will be processed recursively by `expr2text`.

Note: The returned object must not contain the domain element `e` as a sub-object. Otherwise, the MuPAD kernel runs into infinite recursion and emits an error message.

For expressions, the result returned by `expr2text` always coincides with the output produced by `print`. If the 0th operand of the expression is a function environment, the result of `expr2text` is computed by the second operand of the function environment.

extnops

Number of operands of the internal representation a domain element

Syntax

```
extnops(object)
```

Description

`extnops(object)` returns the number of operands of the object's internal representation.

For objects of a basic data type such as expressions, sets, lists, tables, arrays, hfarrays etc., `extnops` yields the same result as the function `nops`. The only difference to the function `nops` is that `extnops` cannot be overloaded by domains implemented in the MuPAD language.

Internally, a domain element may consist of an arbitrary number of data objects; `extnops` returns the actual number of *internal* operands. Since every domain should provide interface methods, `extnops` should only be used from inside these methods. “From the outside”, the function `nops` should be used.

Examples

Example 1

`extnops` returns the number of entries of a domain element:

```
d := newDomain("demo"): e := new(d, 1, 2, 3, 4): extnops(e)
```

```
    4
```

```
delete d, e:
```

Example 2

For kernel domains, `extnops` is equivalent to `nops`:

```
extnops([1, 2, 3, 4]), nops([1, 2, 3, 4])
```

```
4, 4
```

Example 3

We define a domain of lists. Its internal representation is a single object (a list of kernel type `DOM_LIST`):

```
myList := newDomain("lists"):
myList::new := proc(l : DOM_LIST) begin new(myList, l) end_proc:
```

We want the functionality of `nops` for this domain to be the same as for the kernel type `DOM_LIST`. To achieve this, we overload the function `nops`. The internal list is accessed via `extop(l, 1)`:

```
myList::nops := l -> nops(extop(l, 1)):
```

We create an element of this domain:

```
mylist := myList([1, 2, 3])
```

```
new(lists, [1, 2, 3])
```

Since `nops` was overloaded, `extnops` provides the only way of determining the number of operands of the internal representation of `mylist`. In contrast to `nops`, `extnops` always returns 1, because the internal representation consists of exactly one list:

```
nops(mylist), extnops(mylist)
```

```
3, 1
```

```
delete myList, mylist:
```

Parameters

`object`

An arbitrary MuPAD object

Return Values

Nonnegative integer.

MuPAD Domains
`DOM_DOMAIN`

MuPAD Functions
`extop` | `extsubsop` | `new` | `nops` | `op` | `subsop`

extop

Internal operands of a domain element

Syntax

```
extop(object)

extop(object, i)

extop(object, i .. j)
```

Description

`extop(object)` returns all operands of the domain element `object`.

`extop(object, i)` returns the `i`-th operand.

`extop(object, i..j)` returns the `i`-th to `j`-th operand.

For objects of a basic data type such as expressions, sets, lists, tables, arrays, hfarrays etc., `extop` yields the same operands as the function `op`. See the corresponding documentation for details on operands. The main difference to the function `op` is that `extop` cannot be overloaded. Therefore, it guarantees direct access to the operands of the *internal representation* of elements of a library domain. Typically, `extop` is used in the implementation of the `"op"` method of a library domain that overloads the system's `op` function.

A domain element consists of a reference to the corresponding domain and a sequence of values representing its contents. The function `extop` allows access to the domain and the operands of this internal data sequence.

`extop(object)` returns a sequence of all internal operands except the 0-th one. This call is equivalent to `extop(object, 1..extnops(object))`.

`extop(object, i)` returns the `i`-th internal operand. In particular, the domain of the object is returned by `extop(object, 0)` if `object` is an element of a library domain. If `object` is an element of a kernel domain, the call `extop(object, 0)` is equivalent to `op(object, 0)`.

`extop(object, i..j)` returns the `i`-th to `j`-th internal operands of `object` as an expression sequence; `i` and `j` must be nonnegative integers with `i` smaller or equal to `j`. This sequence is equivalent to `extop(object, k) $k = i..j`.

`extop` returns `FAIL` if a specified operand does not exist. Cf. “Example 4” on page 1-718.

The operands of an expression sequence are its elements. Note that such sequences are not flattened by `extop`.

Examples

Example 1

We create a new domain `d` and use the function `new` to create an element of this type. Its internal data representation is the sequence of arguments passed to `new`:

```
d := newDomain("demo"): e := new(d, 1, 2, 3): extop(e)
```

```
1, 2, 3
```

Individual operands can be selected:

```
extop(e, 2)
```

```
2
```

Ranges of operands can be selected:

```
extop(e, 1..2)
```

```
1, 2
```

The 0-th operand of a domain element is its domain:

```
extop(e, 0)
```

```
demo
```

```
delete d, e:
```

Example 2

First, a new domain `d` is defined via `newDomain`. The `"new"` method serves for creating elements of this type. The internal representation of the domain is a sequence of all arguments of this `"new"` method:

```
d := newDomain("d"): d::new := () -> new(dom, args()):
```

The system's `op` function is overloaded by the following `"op"` method of this domain. It is to return the elements of a sorted copy of the internal data sequence. In the implementation of the `"op"` method, the function `extop` is used to access the internal data:

```
d::op := proc(x, i = null())
         local internalData;
         begin internalData := extop(x);
               op(sort([internalData]), i)
         end_proc:
```

Due to this overloading, `op` returns different operands than `extop`:

```
e := d(3, 7, 1): op(e); extop(e)
```

$$1, 3, 7$$

$$3, 7, 1$$

```
delete d, e:
```

Example 3

For kernel data types such as sets, lists etc., `extop` always returns the same operands as `op`:

```
extop([a, b, c]) = op([a, b, c])
```

$$(a, b, c) = (a, b, c)$$

Expressions are of kernel data type DOM_EXPR, thus extop(sin(x), 0) is equivalent to op(sin(x), 0):

```
domtype(sin(x)), extop(sin(x), 0) = op(sin(x), 0)
```

```
DOM_EXPR, sin = sin
```

Expression sequences are not flattened:

```
extop((1, 2, 3), 0), extop((1, 2, 3))
```

```
_exprseq, 1, 2, 3
```

Example 4

Non-existing operands are returned as FAIL:

```
extop([1, 2], 4),  extop([1, 2], 1..4)
```

```
FAIL, FAIL
```

Parameters

object

An arbitrary MuPAD object

i, j

Nonnegative integers

Return Values

sequence of operands or the specified operand. FAIL is returned if no corresponding operand exists.

DOM_DOMAIN

MuPAD Functions
extnops | extsubsop | new | nops | op | subsop

extsubsop

Substitute operands of a domain element

Syntax

```
extsubsop(d, i1 = new1, i2 = new2, …)
```

Description

`extsubsop(d, i = new)` returns a copy of the domain element `d` with the `i`-th operand of the internal representation replaced by `new`.

Internally, a domain element may consist of an arbitrary number of objects. `extsubsop` replaces one or more of these objects, without checking whether the substitution is meaningful.

Note: The operands of elements of domains of the MuPAD library must meet certain (undocumented) conditions; use `extsubsop` only for your own domains. It is good programming style to use `extsubsop` only inside low-level domain methods.

`extsubsop` returns a modified copy of the object, but does not change the object itself.

The numbering of operands is the same as the one used by `extop`.

If the 0-th operand is to be replaced, the corresponding new value must be a domain of type `DOM_DOMAIN`; `extsubsop` then replaces the domain of `d` by this new domain.

When trying to replace the `i`-th operand with `i` exceeding the actual number of operands, `extsubsop` first increases the number of operands by appending as many `NIL`'s as necessary and then performs the substitution. Cf. “Example 3” on page 1-722.

When the `i`-th operand is replaced by an expression sequence of `k` elements, each of these elements becomes an individual operand of the result, indexed from `i` to `i+k-1`. The remaining operands of `d` are shifted to the right accordingly. This new numbering is already in effect for the remaining substitutions in the same call to `extsubsop`. Cf. “Example 4” on page 1-722.

The void object `null()` becomes an operand of the result when it is substituted into an object.

After performing the substitution, `extsubsop` does not evaluate the result once more. Cf. “Example 5” on page 1-722.

In contrast to the function `subsop`, `extsubsop` cannot be overloaded.

Like `extop` and `extnops`, `extsubsop` can be applied to objects of a kernel domain. In this case `extsubsop` behaves like `subsop`.

Examples

Example 1

We create a domain element and then replace its first operand:

```
d := newDomain("1st"): e := new(d, 1, 2, 3): extsubsop(e, 1 = 5)
```

$$\text{new}(1\text{st}, 5, 2, 3)$$

This does not change the value of `e`:

```
e
```

$$\text{new}(1\text{st}, 1, 2, 3)$$

```
delete d, e:
```

Example 2

The domain type of an element can be changed by replacing its 0-th operand:

```
d := newDomain("some_domain"): e := new(d, 2):
extsubsop(e, 0 = Dom::IntegerMod(5))
```

$$2 \bmod 5$$

```
delete d, e:
```

Example 3

We substitute the sixth operand of a domain element that has less than six operands. In such cases, an appropriate number of `NIL`'s is inserted:

```
d := newDomain("example"): e := new(d, 1, 2, 3, 4):
extsubsop(e, 6 = 8)
```

$$\text{new}(\text{example}, 1, 2, 3, 4, \text{NIL}, 8)$$

```
delete d, e:
```

Example 4

We substitute the first operand of a domain element `e` by a sequence with three elements. These become the first three operands of the result; the second operand of `e` becomes the fourth operand of the result, and so on. This new numbering is already in effect when the second substitution is carried out:

```
d := newDomain("example"): e := new(d, 1, 2, 3, 4):
extsubsop(e, 1 = (11, 13, 17), 2 = (29, 99))
```

$$\text{new}(\text{example}, 11, 29, 99, 17, 2, 3, 4)$$

```
delete d, e:
```

Example 5

We define a domain with its own evaluation method. This method prints out its argument such that we can see whether it is called. Then we define an element of our domain.

```
d := newDomain("anotherExample"):
d::evaluate := x -> (print("Argument:", x); x):
e := new(d, 3)
```

$$\text{new}(\text{anotherExample}, 3)$$

We can now watch all evaluations that happen: `extsubsop` evaluates its arguments, performs the desired substitution, but does not evaluate the result of the substitution:

```
extsubsop(e, 1 = 0)
```

```
"Argument:", new(anotherExample, 3)

new(anotherExample, 0)
```

```
delete d, e:
```

Example 6

`extsubsop` applied to an object from a kernel type yields the same result as `subsop`:

```
extsubsop([1,2,3], 2=4), subsop([1,2,3], 2=4)
```

```
[1, 4, 3], [1, 4, 3]
```

Parameters

`d`

Arbitrary MuPAD object

`i1, i2, …`

Nonnegative integers

`new1, new2, …`

Arbitrary MuPAD objects

Return Values

Input object with replaced operands.

MuPAD Functions
extnops | extop | new | nops | op | subs | subsex | subsop

!, fact

Factorial function

Syntax

```
n !
```

```
fact(n)
```

Description

`fact(n)` represents the factorial $n! = 1\,2\,3\,\ldots$ of an integer.

The short hand call `n!` is equivalent to `fact(n)`.

If `n` is a nonnegative integer smaller than the value returned by `Pref::autoExpansionLimit()`, then an integer is returned. If `n` is a numerical value that is not an integer, then an error occurs. If `n` is a symbolic expression, then a symbolic call of `fact` is returned.

Use `expand(n!)` to compute an explicit result for large integers `n` equal to or larger than `Pref::autoExpansionLimit()`.

The `gamma` function generalizes the factorial function to arbitrary complex arguments. It satisfies `gamma(n+1) = n!` for nonnegative integers `n`. Expressions involving symbolic `fact` calls can be rewritten by `rewrite(expression, gamma)`. Cf. “Example 3” on page 1-726.

The operator `!` can also be used in prefix notation with an entirely different meaning: `! command` is equivalent to `system("command")`.

Examples

Example 1

Integer numbers are produced if the argument is a nonnegative integer:

```
fact(0), fact(5), fact(2^5)
```

$$1,\ 120,\ 263130836933693530167218012160000000$$

A symbolic call is returned if the argument is a symbolic expression:

```
fact(n), fact(n - sin(x)), fact(3.0*n + I)
```

$$n!,\ (n-\sin(x))!,\ (3.0\,n+\mathrm{i})!$$

The calls `fact(n)` and `n!` are equivalent:

```
5! = fact(5), fact(n^2 + 3)
```

$$120 = 120,\ (n^2+3)!$$

Example 2

Use `gamma(float(n+1))` rather than `float(fact(n))` for floating-point approximations of large factorials. This avoids the costs of computing large integer numbers:

```
float(fact(2^13)) = gamma(float(2^13 + 1))
```

$$1.275885799\ 10^{28503} = 1.275885799\ 10^{28503}$$

Example 3

The functions `expand`, `limit`, `rewrite` and `series` handle expressions involving `fact`:

```
expand(fact(n^2 + 4))
```

$$(n^2)!\,(n^2+1)\,(n^2+2)\,(n^2+3)\,(n^2+4)$$

```
limit(fact(n)/exp(n), n = infinity)
```

$$\infty$$

```
rewrite(fact(2*n^2 + 1)/fact(n - 1), gamma)
```

$$\frac{\Gamma(2\,n^2+2)}{\Gamma(n)}$$

The Stirling formula is obtained as an asymptotic series:

```
series(fact(n), n = infinity, 3)
```

$$\frac{\sqrt{2}\,\sqrt{\pi}\,\sqrt{n}\,e^{-n}}{\left(\frac{1}{n}\right)^n}+\frac{\sqrt{2}\,\sqrt{\pi}\,e^{-n}}{12\,\sqrt{n}\left(\frac{1}{n}\right)^n}+O\left(\frac{e^{-n}}{n^{3/2}\left(\frac{1}{n}\right)^n}\right)$$

Parameters

n

An arithmetical expression representing a nonnegative integer

Return Values

Arithmetical expression.

Overloaded By

n

See Also

MuPAD Functions

`beta` | `binomial` | `gamma` | `igamma` | `pochhammer` | `psi`

!!, fact2

Double factorial function

Syntax

```
n !!
```

```
fact2(n)
```

Description

`fact2(n)` represents the double factorial of an integer. The double factorial is defined as $n!! = 2\ 4\ \ldots\ n$ for even positive integers and $n!! = 1\ 3\ \ldots\ n$ for odd positive integers.

The short hand call `n!!` is equivalent to `fact2(n)`.

`0!!` and `(-1)!!` both return `1`.

If `n` is an integer greater or equal to `-1` and smaller than the value given by `Pref::autoExpansionLimit`(), then an integer is returned. If `n` is an integer smaller than `-1` or a non-integer numerical value then an error occurs. If `n` is a symbolic expression, then a symbolic call of `fact2` is returned.

Use `expand(n!!)` to compute an explicit result for large integers `n` equal to or larger than `Pref::autoExpansionLimit`().

Expressions involving symbolic calls of `fact2` can be rewritten in terms of the `gamma` function by `rewrite(expression, gamma)`. Cf. “Example 2” on page 1-729.

Note that the double factorial `n!!` does *not* equal the iterated factorial `(n!)!`.

Examples

Example 1

Integer numbers are produced if the argument is an integer greater than or equal to - 1:

```
fact2(-1), fact2(0), fact2(5), fact2(16)
```

$$1,\ 1,\ 15,\ 10321920$$

A symbolic call is returned if the argument is a symbolic expression:

```
fact2(n), fact2(4.7*I*n)
```

$$n!!,\ (4.7\,n\,\mathrm{i})!!$$

The calls `fact2(n)` and `n!!` are equivalent:

```
5!! = fact2(5), fact2(n^2 + 3)
```

$$15 = 15,\ (n^2+3)!!$$

Example 2

The function `rewrite` can be used to rewrite expressions involving `fact2` in terms of the `gamma` function. In most cases, `Simplify` has to be used to obtain a simple result:

```
rewrite(n!!, gamma)
```

$$2^{\frac{n}{2}-\frac{(-1)^n}{4}+\frac{1}{4}}\,\pi^{\frac{(-1)^n}{4}-\frac{1}{4}}\,\Gamma\left(\frac{n}{2}+1\right)$$

```
rewrite(fact2(2*n)/fact2(2*n - 1), gamma)
```

$$\frac{2^{\frac{(-1)^{2n-1}}{4}-n+\frac{1}{4}}\,2^{n-\frac{(-1)^{2n}}{4}+\frac{1}{4}}\,\pi^{\frac{(-1)^{2n}}{4}-\frac{1}{4}}\,\pi^{\frac{1}{4}-\frac{(-1)^{2n-1}}{4}}\,\Gamma(n+1)}{\Gamma\left(n+\frac{1}{2}\right)}$$

```
assume(n, Type::Integer): Simplify(%2)
```

$$\frac{2^{2n}\,n\,(n-1)!^2}{2\,\Gamma(2n)}$$

Example 3

For efficiency, the double factorial should be rewritten in terms of `gamma` if a floating-point evaluation for large arguments is desired. The following call produces a huge exact integer that is finally converted to a float:

```
float(fact2(2^17))
```

$$1.03441219\ 10^{306922}$$

The following call is much faster because no exact intermediate result is computed:

```
float(subs(rewrite(fact2(n), gamma), n = 2^17))
```

$$1.03441219\ 10^{306922}$$

Parameters

n

An arithmetical expression representing an integer greater than or equal to - 1.

Return Values

Arithmetical expression.

Overloaded By

n

See Also

MuPAD Functions

`beta` | `binomial` | `fact` | `gamma` | `igamma` | `psi`

factor

Factor a polynomial into irreducible polynomials

Syntax

```
factor(f, <Adjoin = adjoin>, <MaxDegree = n>)
```

```
factor(f, F | Domain = F | Full)
```

Description

`factor(f)` computes a factorization $f = u\, f_1^{e_1} \ldots f_r^{e_r}$ of the polynomial f, where u is the content of f, f_1, …, f_r are the distinct primitive irreducible factors of f, and e_1, …, e_r are positive integers.

`factor` rewrites its argument as a product of as many terms as possible. In a certain sense, it is the complementary function of `expand`, which rewrites its argument as a sum of as many terms as possible.

If `f` is a polynomial whose coefficient ring is not `Expr`, then `f` is factored over its coefficient ring. See “Example 10” on page 1-739.

If `f` is a polynomial with coefficient ring `Expr`, then `f` is factored over the smallest ring containing the coefficients. Mathematically, this *implied coefficient ring* always contains the ring $\mathbb{Z}$ of integers. See “Example 4” on page 1-736. If the coefficient ring `R` of `f` is not `Expr`, then we say that the implied coefficient ring is `R`. Elements of the implied coefficient ring are considered to be constants and are not factored any further. In particular, the content u is an element of the implied coefficient ring.

With the option `Adjoin`, the elements of `adjoin` are also adjoined to the coefficient ring.

If the second argument `F` or, alternatively, `Domain = F`is given, then f is factored over the real numbers $\mathbb{R}$ or the complex numbers $\mathbb{C}$. Factorization over $\mathbb{R}$ or $\mathbb{C}$ is performed using numerical calculations and the results will contain floating-point numbers. See “Example 5” on page 1-737.

If `f` is an arithmetical expression but not a number, it is considered as a rational expression. Non-rational subexpressions such as `sin(x)`, `exp(1)`, `x^(1/3)` etc., but

not constant algebraic subexpressions such as `I` and `(sqrt(2)+1)^3`, are replaced by auxiliary variables before factoring. Algebraic dependencies of the subexpressions, such as the equation $cos(x)^2 = 1 - sin(x)^2$, are not necessarily taken into account. See "Example 7" on page 1-738.

The resulting expression is then written as a quotient of two polynomial expressions in the original and the auxiliary indeterminates. The numerator and the denominator are converted into polynomials with coefficient ring `Expr` via `poly`, and the implied coefficient ring is the smallest ring containing the coefficients of the numerator polynomial and the denominator polynomial. Usually, this is the ring of integers. Then both polynomials are factored over the implied coefficient ring, and the multiplicities e_i corresponding to factors of the denominator are negative integers; see "Example 3" on page 1-736. After the factorization, the auxiliary variables are replaced by the original subexpressions. See "Example 6" on page 1-738.

If `f` is an integer, then it is decomposed into a product of primes, and the result is the same as for `ifactor`. If `f` is a rational number, then both the numerator and the denominator are decomposed into a product of primes. In this case, the multiplicities e_i corresponding to factors of the denominator are negative integers. See "Example 2" on page 1-735.

If `f` is a floating point number or a complex number, then `factor` returns a factorization with the single factor `f`.

The result of `factor` is an object of the domain type `Factored`. Let `g:=factor(f)` be such an object.

It is represented internally by the list `[u, f1, e1, ..., fr, er]` of odd length $2r + 1$. Here, `f1` through `fr` are of the same type as the input (either polynomials or expressions); `e1` through `er` are integers; and `u` is an arithmetical expression.

One may extract the content u and the terms $f_i^{e_i}$ by the ordinary index operator `[ ]`, i.e., `g[1] = f1^e1, g[2] = e1^e2, ...` if $u = 1$ and `g[1] = u, g[2] = f1^e1, g[3] = e1^e2, ...`, respectively, if $u \neq 1$.

The call `Factored::factors(g)` yields the list `[f1, f2, ...]` of factors, the call `Factored::exponents(g)` returns the list `[e1, e2, ...]` of exponents.

The call `coerce(g,DOM_LIST)` returns the internal representation of a factored object, i.e., the list `[u, f1, e1, f2, e2, ...]`.

Note that the result of `factor` is printed as an expression, and it is implicitly converted into an expression whenever it is processed further by other MuPAD functions. As an example, the result of `q:=factor(x^2+2*x+1)` is printed as `(x+1)^2`, which is an expression of type `"_power"`.

See “Example 1” on page 1-733 for illustrations, and the help page of `Factored` for details.

If `f` is not a number, then each of the polynomials $p_1, \ldots, p_r$ is primitive, i.e., the greatest common divisor of its coefficients (see `content` and `gcd`) over the implied coefficient ring (see above for a definition) is one.

Currently, factoring polynomials is possible over the following implied coefficient rings: integers, real numbers, complex numbers and rational numbers, finite fields—represented by `IntMod(n)` or `Dom::IntegerMod(n)` for a prime number `n`, or by a `Dom::GaloisField`—, and rings obtained from these basic rings by taking polynomial rings (see `Dom::DistributedPolynomial`, `Dom::MultivariatePolynomial`, `Dom::Polynomial`, and `Dom::UnivariatePolynomial`), fields of fractions (see `Dom::Fraction`), and algebraic extensions (see `Dom::AlgebraicExtension`).

If the input `f` is an arithmetical expression that is not a number, all occurring floating-point numbers are replaced by continued fraction approximations. The result is sensitive to the environment variable `DIGITS`, see `numeric::rationalize` for details.

Examples

Example 1

To factor the polynomial $x^3 + x$, enter:

```
g := factor(x^3+x)
```

$$x\,(x^2+1)$$

Usually, expressions are factored over the ring of integers, and factors with non-integral coefficients, such as `x - I` in the example above, are not considered.

One can access the internal representation of this factorization with the ordinary index operator:

```
g[1], g[2]
```

$$x,\ x^2+1$$

The internal representation of g, as described above, is given by the following command:

```
coerce(g, DOM_LIST)
```

$$[1,\ x,\ 1,\ x^2+1,\ 1]$$

The result of the factorization is an object of domain type `Factored`:

```
domtype(g)
```

Factored

Some of the functionality of this domain is described in what follows.

One may extract the factors and exponents of the factorization also in the following way:

```
Factored::factors(g), Factored::exponents(g)
```

$$[x,\ x^2+1],\ [1,\ 1]$$

One can ask for the type of factorization:

```
Factored::getType(g)
```

"irreducible"

This output means that all f_i are irreducible. Other possible types are `"squarefree"` (see `polylib::sqrfree`) or `"unknown"`.

One may multiply factored objects, which preserves the factored form:

```
g2 := factor(x^2 + 2*x + 1)
```

$$(x+1)^2$$

```
g * g2
```

$$x\,(x^2+1)\,(x+1)^2$$

It is important to note that one can apply (almost) any function working with arithmetical expressions to an object of type `Factored`. However, the result is then usually not of domain type `Factored`:

```
expand(g);
domtype(%)
```

$$x^3+x$$

DOM_EXPR

For a detailed description of these objects, please refer to the help page of the domain `Factored`.

Example 2

`factor` splits an integer into a product of prime factors:

```
factor(8)
```

$$2^3$$

For rational numbers, both the numerator and the denominator are factored:

```
factor(10/33)
```

$$2\,5\,3^{-1}\,11^{-1}$$

Note that, in contrast, constant polynomials are *not* factored:

```
factor(poly(8, [x]))
```

$$8$$

Example 3

Factors of the denominator are indicated by negative multiplicities:

```
factor((z^2 - 1)/z^2)
```

$$\frac{(z-1)\,(z+1)}{z^2}$$

```
Factored::factors(%), Factored::exponents(%)
```

$$[z-1,\ z+1,\ z],\ [1,\ 1,\ -2]$$

Example 4

If some coefficients are irrational but algebraic, the factorization takes place over the smallest field extension of the rationals that contains all of them. Hence, `x^2+1` is considered irreducible while its `I`-fold is considered reducible:

```
factor(x^2 + 1), factor(I*x^2 + I)
```

$$x^2+1,\ \mathrm{i}\,(x-\mathrm{i})\,(x+\mathrm{i})$$

MuPAD does not automatically factor over the field of algebraic numbers; only the coefficients of the input are adjoined to the rationals:

```
factor(sqrt(2)*x^4 - sqrt(2)*x^2 - sqrt(2)*2)
```

$$\sqrt{2}\,(x+\sqrt{2})\,(x-\sqrt{2})\,(x^2+1)$$

```
factor(I*x^4 - I*x^2 - I*2)
```

$$i\,(x-i)\,(x+i)\,(x^2-2)$$

```
factor(sqrt(2)*I*x^4 - sqrt(2)*I*x^2 - sqrt(2)*I*2)
```

$$(\sqrt{2}\,i)\,(x+\sqrt{2})\,(x+i)\,(x-i)\,(x-\sqrt{2})$$

Example 5

With the option *Adjoin*, additional elements can be adjoined to the implied coefficient ring:

```
factor(x^2 + 1, Adjoin = [I])
```

$$(x-i)\,(x+i)$$

```
factor( x^2-2, Adjoin = {sqrt(2)} )
```

$$(x-\sqrt{2})\,(x+\sqrt{2})$$

With the option `Full`, a complete factorization into linear factors can be computed.

```
factor( x^2-2, Full)
```

$$(x-\sqrt{2})\,(x+\sqrt{2})$$

If the argument R_ or C_ is given, factorization is done over the real or complex numbers using numeric calculations:

```
factor( x^2-2, R_ )
```

$$(x+1.414213562)\,(x-1.414213562)$$

```
factor(x^2 + 1, C_)
```

$$(x-1.0\,i)\,(x+1.0\,i)$$

Example 6

Transcendental objects are treated as indeterminates:

```
delete x:
factor(7*(cos(x)^2 - 1)*sin(1)^3)
```

$$7\sin(1)^3(\cos(x)-1)(\cos(x)+1)$$

```
Factored::factors(%), Factored::exponents(%)
```

$$[\sin(1), \cos(x)-1, \cos(x)+1], [3, 1, 1]$$

Example 7

`factor` regards transcendental subexpressions as algebraically independent of each other. Sometimes, the dependence is recognized:

```
factor(x + 2*sqrt(x) + 1)
```

$$(\sqrt{x}+1)^2$$

In many cases, however, the algebraic dependence is not recognized:

```
factor(x^2 + (2^y*3^y + 6^y)* x + (6^y)^2)
```

$$6^{2\,y} + 6^y x + x^2 + 2^y 3^y x$$

Example 8

`factor` replaces floating-point numbers by continued fraction approximations, factors the resulting polynomial, and finally applies `float` to the coefficients of the factors:

```
factor(x^2 + 2.0*x - 8.0)
```

$$1.0(x+4.0)(x-2.0)$$

Example 9

`factor` with the option `Full` can use `RootOf` to symbolically represent the roots of a polynomial:

```
factor(x^5 + x^2 + 1, Full)
```

$$\left(x-(\sigma_1)_1\right)\left(x-(\sigma_1)_2\right)\left(x-(\sigma_1)_3\right)\left(x-(\sigma_1)_4\right)\left(x-(\sigma_1)_5\right)$$

where

$$\sigma_1 = \mathrm{RootOf}(z^5+z^2+1,\ z)$$

Example 10

Polynomials with a coefficient ring other than `Expr` are factored over their coefficient ring. We factor the following polynomial modulo 17:

```
R := Dom::IntegerMod(17): f:= poly(x^3 + x + 1, R):
factor(f)
```

$$\mathrm{poly}(x+6,\ [x],\ \mathrm{Dom::IntegerMod}(17))\ \mathrm{poly}(x^2+11\,x+3,\ [x],\ \mathrm{Dom::IntegerMod}(17))$$

For every `p`, the expression `IntMod(p)` may be used instead of `Dom::IntegerMod(p)`:

```
R := IntMod(17): f:= poly(x^3 + x + 1, R):
factor(f)
```

$$\mathrm{poly}(x+6,\ [x],\ \mathrm{IntMod}(17))\ \mathrm{poly}(x^2-6\,x+3,\ [x],\ \mathrm{IntMod}(17))$$

Example 11

More complex domains are allowed as coefficient rings, provided they can be obtained from the rational numbers or from a finite field by iterated construction of algebraic extensions, polynomial rings, and fields of fractions. In the following example, we factor the univariate polynomial u^2 - x^3 in u over the coefficient field $F = \mathbb{Q}(x, \sqrt{x})$:

```
Q := Dom::Rational:
Qx := Dom::Fraction(Dom::DistributedPolynomial([x], Q)):
F := Dom::AlgebraicExtension(Qx, poly(z^2 - x, [z])):
f := poly(u^2 - x^3, [u], F)
```

$$\text{poly}(u^2 - x^3, [u], \text{Dom::AlgebraicExtension}(\text{Dom::Fraction}(\text{Dom::DistributedPolynomial}([x], \text{Dom::Rational}, \text{LexOrder})), -x + z^2 = 0, z))$$

```
factor(f)
```

$$\text{poly}(u + x\,z, [u], \text{Dom::AlgebraicExtension}(\text{Dom::Fraction}(\text{Dom::DistributedPolynomial}([x], \text{Dom::Rational}, \text{LexOrder})), -x + z^2 = 0, z))\ \text{poly}(u - x\,z, [u], \text{Dom::AlgebraicExtension}(\text{Dom::Fraction}(\text{Dom::DistributedPolynomial}([x], \text{Dom::Rational}, \text{LexOrder})), -x + z^2 = 0, z))$$

Parameters

f

A polynomial or an arithmetical expression

F

R_ or C_

Options

MaxDegree

Option, specified as `MaxDegree = n`

Only algebraic numbers of a maximum degree `n` will be adjoined to the rational numbers. If not specified, all coefficients up to degree 2 are adjoined. `n` must be a positive integer.

`Adjoin`

Option, specified as `Adjoin = adjoin`

In addition to the coefficients of `f`, the elements of `adjoin` are adjoined to the rational numbers. Elements of algebraic degree larger than the value of the option `MaxDegree` are not adjoined. `adjoin` must be a set or list.

`Domain`

Option, specified as `Domain = F`

Compute a numerical factorization over $\mathbb{R}$ or $\mathbb{C}$, respectively.

`Full`

Compute the full factorization of `f` into linear factors. This option has no effect on multivariate polynomials.

Return Values

Object of the domain type `Factored`.

Overloaded By

f

Algorithms

The factoring algorithms are collected in a separate library domain `faclib`; it should not be necessary to call these routines directly.

The implemented algorithms include Cantor-Zassenhaus (over finite fields) and Hensel lifting (over the rational numbers and in the multivariate case).

factorout

Factor out a given expression

Syntax

```
factorout(x, f, <list>)
```

Description

`factorout(x,f)` factors out a given expression `f` from the expression `x`.

The result is a product of the form $f\ \left(\frac{x}{f}\right)$.

If the optional parameter *list* is set to `TRUE`, a list of the factors is returned. See "Example 2" on page 1-744

Examples

Example 1

```
factorout(2*x+4, 2)
```

$$2\,(x+2)$$

```
factorout(a+a*2, a)
```

$$3\,a$$

```
factorout(a+a*3, 2)
```

$$2\,(2\,a)$$

```
factorout(a*b + b*c, b)
```

$$b\,(a+c)$$

```
factorout(a*sin(b) + c*sin(b), sin(b))
```

$$\sin(b)\,(a+c)$$

```
factorout(sqrt(50)*x^2+5*x-sqrt(10)*x-sqrt(10), sqrt(5))
```

$$\sqrt{5}\,(\sqrt{10}\,x^2+(\sqrt{5}-\sqrt{2})\,x-\sqrt{2})$$

```
factorout((a*b + b*c)/(d*c+c), b/c)
```

$$\frac{b}{c}\,\frac{a+c}{d+1}$$

Example 2

With the optional parameter 'list' set to true, a list of all factors is returned:

```
factorout(a*b + b*c, b, TRUE)
```

$$[b,\ a+c]$$

Parameters

x

An expression.

f

The expression to be factored out.

list

A boolean value. If list is TRUE, then a list is returned. By default, an expression is returned.

Return Values

Expression or a list.

FAIL

Indicate a failed computation

Syntax

```
FAIL
```

Description

FAIL is a keyword of the MuPAD language. Many functions of the library use the return value FAIL to indicate failed computations or non-existing elements.

FAIL is the only element of the domain DOM_FAIL.

FAIL is used as the return value for computations that failed. Also, requesting non-existing slots of domains or function environments yields FAIL. Due to this behavior, library functions can try computations without provoking errors.

A function should return FAIL or an error if at least one of its inputs is FAIL.

Examples

Example 1

The following attempt to convert sqrt(3) to an integer of a residue class ring must fail:

```
poly(sqrt(3)*x, [x], Dom::IntegerMod(3))
```

```
FAIL
```

The following matrix is not invertible. You can try to invert it without producing an error:

```
A := matrix([[1, 1], [1, 1]]): 1/A
```

```
FAIL
```

The `"inverse"` slot of a function environment yields the inverse of the function. The inverse of the sine function is implemented, but MuPAD does not know the inverse of the dilogarithm function:

```
sin::inverse, dilog::inverse
```

```
"arcsin", FAIL
```

```
delete A:
```

Example 2

Most functions return `FAIL` or an error on input of `FAIL`:

```
poly(FAIL)
```

```
FAIL
```

```
sin(FAIL)
```

```
Error: An arithmetical expression is expected. [sin]
```

Example 3

`FAIL` evaluates to itself:

```
FAIL, eval(FAIL), level(FAIL, 5)
```

```
FAIL, FAIL, FAIL
```

MuPAD Functions

`error` | `NIL` | `null`

fclose

Close a file

Syntax

```
fclose(n)
```

Description

`fclose(n)` closes the file specified by the file descriptor `n`.

The file must have been opened with `fopen`. The call to `fopen` yields the file descriptor `n` representing the file.

Only a limited number of file descriptors is available. The user should use `fclose` to close a file which is no longer needed because this releases the file descriptor. The exact number of file descriptors available depends on the used operating system.

Examples

Example 1

We open a file `test` for writing. This yields the file descriptor `n`:

```
fid := fopen(TempFile, Write, Text):
file := fname(fid):
n := fopen(file, Write):
```

We close the file:

```
fclose(n):
delete n:
```

Parameters

n

A file descriptor returned by `fopen`: a positive integer

Return Values

Void object of type `DOM_NULL`.

MuPAD Functions

`FILEPATH` | `finput` | `fname` | `fopen` | `fprint` | `fread` | `ftextinput` | `import::readbitmap` | `import::readdata` | `pathname` | `print` | `protocol` | `read` | `readbytes` | `READPATH` | `write` | `writebytes` | `WRITEPATH`

FILEPATH

Pathname of a file that is currently loaded

Description

FILEPATH is a variable containing the path of a currently read file.

Possible values: String

The variable FILEPATH represents the pathname of a file. It only has a value while reading a file via read or fread and corresponds to the path specified in read or fread. It can only be accessed from inside the file that is currently read. Using this variable, the read file can access its own pathname and read other files via absolute pathnames, even if it only knows their relative locations with respect to itself.

The value of FILEPATH is a string containing the operating system dependent path to the file that is currently read. The path string terminates with a path separator and, under Windows®, starts with the name of the current volume if this was specified in the read/fread command. Cf. “Example 1” on page 1-750.

Examples

Example 1

Assume that the file C:\TEMP\file.mu contains the following lines of code. It queries its own location via FILEPATH (= C:\TEMP) and reads two files installed relative to the location of file.mu via their absolute pathnames C:\TEMP\SubFolder\file1.mu and C:\TEMP\SubFolder\file2.mu, respectively:

```
print(Unquoted, "FILEPATH" = FILEPATH):
read(FILEPATH.pathname("SubFolder")."file1.mu"):
read(FILEPATH.pathname("SubFolder")."file2.mu"):
```

When reading the file file.mu, the part C:\TEMP\ of the specified path is accessed by file.mu via FILEPATH. It finds the files file1.mu and file2.mu if they were installed correctly relative to the path of file.mu:

```
read("C:".pathname(Root, "TEMP"), "file.mu")
```

```
 FILEPATH = C:\TEMP\
```

It is good programming style to use platform independent path strings. For this reason, we used the function `pathname` rather than a mere string concatenation to append appropriate path delimiters.

MuPAD Functions

`fclose` | `fopen` | `fread` | `pathname` | `read` | `READPATH`

finput

Read objects from file

Syntax

```
finput(filename | n, <Encoding = "encodingValue">)
```

```
finput(filename | n, <Encoding = "encodingValue">, x1, x2, …)
```

Description

`finput(filename, x)` reads a MuPAD object from a file and assigns it to the identifier `x`.

`finput(n, x)` reads from the file associated with the file descriptor `n`.

`finput` can read MuPAD binary files as well as ASCII text files. `finput` recognizes the format of the file automatically.

`finput(..., Encoding = "encodingValue", ...)` uses the specified encoding. For supported encodings, see “Options” on page 1-757. You can use this option with any of the previously specified syntaxes.

Binary files may be created via `fprint` or `write`. Text files can also be created in a MuPAD session via these functions (using the `Text` option; see the corresponding help pages for details). Alternatively, text files can be created and edited directly using your favorite text editor. The file must consist of syntactically correct MuPAD objects or statements, separated by semicolons or colons. An object may extend over more than one line.

`finput(filename)` reads the first object in the file and returns it to the MuPAD session.

`finput(filename, x1, x2, ...)` reads the contents of a file object by object. The i-th object is assigned to the identifier x_i. The identifiers are not evaluated while executing `finput`; previously assigned values are overwritten. The objects are not evaluated. Evaluation can be enforced with the function `eval`. Cf. “Example 2” on page 1-754.

Instead of a file name, also a file descriptor `n` of a file opened via `fopen` can be used. The functionality is as described above. However, there is one difference: With a file name, the file is closed automatically after the data were read. A subsequent call to `finput` starts at the beginning of the file. With a file descriptor, the file remains open (use `fclose` to close the file). The next time data are read from this file, the reading continues at the current position. Consequently, a file descriptor should be used if the individual objects in the file are to be read via several subsequent calls of `finput`. Cf. “Example 3” on page 1-755.

Files in `gzip` compressed format with a filename ending in “`.gz`” are automatically and transparently decompressed while reading.

If the number of identifiers specified in the `finput` call is larger than the number of objects in the file, the additional identifiers are assigned the value `null()`.

`finput` interprets the file name as a pathname relative to the “working folder.”

Note that the meaning of “working folder” depends on the operating system. On Windows systems and on Mac OS X systems, the “working folder” is the folder where MATLAB® is installed. On UNIX systems, it is the current working folder in which MATLAB was started. When started from a menu or desktop item, this is typically the user's home folder.

Also absolute path names are processed by `finput`.

Expression sequences are not flattened by `finput` and cannot be used to pass several identifiers to `finput`. Cf. “Example 4” on page 1-756.

Examples

Example 1

Create a new file in the system's temporary folder. The name of the temporary folder varies for different platforms. The `fopen` command with the `TempFile` option creates a file in any system's temporary folder (if such folder exists):

```
fid := fopen(TempFile, Write, Text):
```

Write the numbers 11, 22, 33 and 44 into a file:

```
fprint(fid, 11, 22, 33, 44):
```

Use `fname` to return the name of the temporary file you created:

```
file := fname(fid):
```

Read this file with `finput`:

```
finput(file, x1, x2, x3, x4)
```

```
    44
```

```
x1, x2, x3, x4
```

```
    11, 22, 33, 44
```

If you try to read more objects than stored in the file, `finput` returns the void object of type `DOM_NULL`:

```
finput(file, x1, x2, x3, x4, x5); domtype(%)
```

```
    DOM_NULL
```

```
delete x1, x2, x3, x4, x5:
```

Example 2

Objects read from a file are not evaluated:

```
fid := fopen(TempFile, Write, Text):
file := fname(fid):
fprint(file, x1):
x1 := 23:
finput(file)
```

```
    x1
```

```
eval(%)
```

```
    23
```

```
delete x1:
```

Example 3

Read some data from a file using several calls of `finput`. You have to use a file descriptor for reading from the file. The file is opened for reading with `fopen`:

```
fid := fopen(TempFile, Write, Text):
fprint(fid, 11, 22, 33, 44):
file := fname(fid):
n := fopen(file):
```

The file descriptor returned by `fopen` can be passed to `finput` for reading the data:

```
finput(n, x1, x2): x1, x2
```

```
     11, 22
```

```
finput(n, x3, x4):
x3, x4
```

```
     33, 44
```

Close the file and delete the identifiers:

```
fclose(n):
delete n, x1, x2, x3, x4:
```

Alternatively, the contents of a file can be read into a MuPAD session in the following way:

```
n := fopen(file):
for i from 1 to 4 do
   x.i := finput(n)
end_for:
x1, x2, x3, x4
```

```
     11, 22, 33, 44
```

```
fclose(n):
delete n, i, x1, x2, x3, x4:
```

Example 4

Expression sequences are not flattened by `finput` and cannot be used to pass identifiers to `finput`:

```
fid := fopen(TempFile, Write, Text):
fprint(fid, 11, 22, 33):
file := fname(fid):
finput(file, (x1, x2), x3)
```

```
Error: The argument is invalid. [finput]
```

The following call does not lead to an error because the identifier `x12` is not evaluated. Consequently, only one object is read from the file and assigned to `x12:`

```
x12 := x1, x2:
finput(file, x12):
x1, x2, x12
```

```
     x1, x2, 11
```

```
delete x1, x2, x12:
```

Example 5

To specify the encoding to write data, use Encoding. The Encoding option applies only to text files that are opened using a file name and not a file descriptor. Create a temporary file and store the values `"abcäöü"`, `11` and `22` in the encoding “`UTF-8`”:

```
fprint(Text, Encoding="UTF-8", "finput_test", "abcäöü", 11, 22):
```

Specify the encoding to read the stored values correctly:

```
finput("finput_test", Encoding="UTF-8", x1, x2, x3):
x1, x2, x3
```

```
     "abcäöü", 11, 22
```

If you do not specify an encoding, the default system encoding is used. Thus, your output might vary from that shown next. Characters unrecognized by the default system encoding are replaced by the default substitution character for that encoding:

```
finput("finput_test", x1, x2, x3):
x1, x2, x3

     "abc??????", 11, 22
```

Parameters

`filename`

The name of a file: a character string

`n`

A file descriptor provided by `fopen`: a positive integer

x_1, x_2, …

identifiers

Options

`Encoding`

This option lets you specify the character encoding to use. The allowed encodings are:

`"Big5"`	`"ISO-8859-1"`	`"windows-932"`
`"EUC-JP"`	`"ISO-8859-2"`	`"windows-936"`
`"GBK"`	`"ISO-8859-3"`	`"windows-949"`
`"KSC_5601"`	`"ISO-8859-4"`	`"windows-950"`
`"Macintosh"`	`"ISO-8859-9"`	`"windows-1250"`
`"Shift_JIS"`	`"ISO-8859-13"`	`"windows-1251"`
`"US-ASCII"`	`"ISO-8859-15"`	`"windows-1252"`
`"UTF-8"`		`"windows-1253"`
		`"windows-1254"`
		`"windows-1257"`

The default encoding is system dependent. If you specify the encoding incorrectly, characters might read incorrectly. Characters unrecognized by the encoding are replaced by the default substitution character for the specified encoding.

Encodings not listed here can be specified but might not produce correct results.

Return Values

Last object that was read from the file.

See Also

MuPAD Functions

`fclose` | `fname` | `fopen` | `fprint` | `fread` | `ftextinput` | `input` | `pathname` | `print` | `protocol` | `read` | `READPATH` | `textinput` | `write` | `WRITEPATH`

float

Convert to a floating-point number

Syntax

```
float(object)
```

```
float(object, n)
```

Description

`float(object)` converts the object or numerical subexpressions of the object to floating-point numbers.

`float` converts numbers and numerical expressions such as `sqrt(sin(2))` or `sqrt(3) + sin(PI/17)*I` to real or complex floating-point numbers of type `DOM_FLOAT` or `DOM_COMPLEX`, respectively. If symbolic objects other than the special constants CATALAN, E, EULER, and PI are present, only *numerical* subexpressions are converted to floats. In particular, identifiers and indexed identifiers are returned unchanged by `float`. Cf. “Example 1” on page 1-761.

A `float` call is mapped recursively to the operands of an expression. When numbers (or constants such as PI) are found, they are converted to floating-point approximations. The number of significant decimal digits is given by the environment variable `DIGITS`; the default value is 10. The converted operands are combined by arithmetical operations or function calls according to the structure of the expression. E.g., a call such as `float(PI - 314/100)` may be regarded as a sequence of numerical operations:

```
t1 := float(PI); t2 := float(314/100); result := t1 - t2
```

Consequently, float evaluation via `float` may be subject to error propagation. Cf. “Example 2” on page 1-761.

The second argument `n` in `float(object, n)` temporarily overwrites the current setting for `DIGITS`. See “Example 3” on page 1-762.

`float` is automatically mapped to the elements of sets and lists. However, it is not automatically mapped to the entries of arrays, hfarrays, tables, and operands of function

calls. Use `map(object, float)` for a fast floating-point conversion of all entries of an array or a table. Use `mapcoeffs(p, float)` to convert the coefficients of a polynomial `p` of type `DOM_POLY`. To control the behavior of `float` on a function call, use a function environment providing a `"float"` slot. Cf. “Example 4” on page 1-763 and “Example 5” on page 1-764.

The preferences `Pref::floatFormat` and `Pref::trailingZeroes` can be used to modify the screen output of floating-point numbers.

Rational approximations of floating-point numbers may be computed by the function `numeric::rationalize`.

MuPAD special functions such as `sin`, `exp`, `besselJ` etc. are implemented as function environments. Via overloading, the `"float"` attribute (slot) of a function environment `f`, say, is called for the float evaluation of symbolic calls `f(x1, x2, ...)` contained in an expression.

The user may extend the functionality of the system function `float` to his own functions. For this, the function `f` to be processed must be declared as a function environment via `funcenv`. A `"float"` attribute must be written, which is called by the system function `float` in the form `f::float(x1, x2, ...)` whenever a symbolic call `f(x1, x2, ...)` inside an expression is found. The arguments passed to `f::float` are not converted to floats, neither is the return value of the slot subject to any further float evaluation. Thus, the float conversion of symbolic functions calls of `f` is entirely determined by the slot routine. Cf. “Example 5” on page 1-764.

Also a domain `d`, say, written in the MuPAD language, can overload `float` to define the float evaluation of its elements. A slot `d::float` must be implemented. If an element `x`, say, of this domain is subject to a float evaluation, the slot is called in the form `d::float(x)`. As for function environments, neither `x` nor the return value of the slot are subject to any further float evaluation.

If a domain does not have a `"float"` slot, the system function `float` returns its elements unchanged.

Note that MuPAD floating-point numbers are restricted in size. On 32 bit architectures, an overflow/underflow occurs if numbers of absolute size larger/smaller than about $10.0^{\pm 2525222}$ are encountered. On 64 bit architectures, the limits are about $10.0^{\pm 42366205509363}$.

See the documentation for `DIGITS` for further information.

Environment Interactions

The function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We convert some numbers and numerical expressions to floats:

```
float(17), float(PI/7 + I/4), float(4^(1/3) + sin(7))
```

$$17.0,\ 0.4487989505 + 0.25\,i,\ 2.244387651$$

`float` is sensitive to `DIGITS`:

```
DIGITS := 20:
float(17), float(PI/7 + I/4), float(4^(1/3) + sin(7))
```

$$17.0,\ 0.44879895051282760549 + 0.25\,i,\ 2.2443876506869885651$$

Symbolic objects such as identifiers are returned unchanged:

```
DIGITS := 10: float(2*x + sin(3))
```

$$2.0\,x + 0.1411200081$$

Example 2

We illustrate error propagation in numerical computations. The following rational number approximates `exp(2)` to 17 decimal digits:

```
r := 738905609893065023/100000000000000000:
```

The following `float` call converts `exp(2)` and `r` to floating-point approximations. The approximation errors propagate and are amplified in the following numerical expression:

```
DIGITS := 10: float(10^20*(r - exp(2)))
```

```
0.0
```

None of the digits in this result is correct! To obtain a better result, use the second argument in `float` to increase the number of digits for this particular function call:

```
float(10^20*(r - exp(2)), 20)
```

```
276.9572539
```

For further calculations, free the variable `r`:

```
delete r:
```

Example 3

The second argument in `float` lets you temporarily overwrite the current setting for the number of significant decimal digits. For example, compute the following expression with 10 and 30 significant decimal digits. To display floating-point numbers with the number of digits that MuPAD used to compute them, set the value of `Pref::outputDigits` to `InternalPrecision`:

```
Pref::outputDigits(InternalPrecision):
```

Compute the following expression with the default value of `DIGITS = 10`:

```
x := 10^8:
float(sqrt(x^2 + 1) - x)
```

```
0.000000004889443517
```

Compute the same expression with 30 significant decimal digits:

```
float(sqrt(x^2 + 1) - x, 30)
```

```
0.000000004999999999999999875000638189 77
```

After evaluating `float`, MuPAD restores the value of `DIGITS`:

```
DIGITS
```

```
      10
```

For further calculations, restore the output precision and free the variable `x`:

```
Pref::outputDigits(UseDigits):
delete x
```

Example 4

`float` is mapped to the elements of sets and lists:

```
float([PI, 1/7, [1/4, 2], {sin(1), 7/2}])
```

```
      [3.141592654, 0.1428571429, [0.25, 2.0], {0.8414709848, 3.5}]
```

For tables and arrays, the function `map` must be used to forward `float` to the entries:

```
T := table("a" = 4/3, 3 = PI):
float(T), map(T, float)
```

```
      3  | π,          3  | 3.141592654
      "a"| 4/3         "a"| 1.333333333
```

```
A := array(1..2, [1/7, PI]):
float(A), map(A, float)
```

```
      ( 1/7 π ), ( 0.1428571429  3.141592654 )
```

Matrix domains overload the function `float`. In contrast to arrays, `float` works directly on a matrix:

```
float(matrix(A))
```

```
      ( 0.1428571429 )
      ( 3.141592654  )
```

Use `mapcoeffs` to apply `float` to the coefficients of a polynomial generated by `poly`:

```
p := poly(9/4*x^2 + PI, [x]): float(p), mapcoeffs(p, float)
```

$$\mathrm{poly}\left(\frac{9\,x^2}{4}+\pi,\,[x]\right),\ \mathrm{poly}(2.25\,x^2+3.141592654,\,[x])$$

```
delete A, T, p:
```

Example 5

We demonstrate overloading of `float` by a function environment. The following function `Sin` is to represent the sine function. In contrast to the `sin` function in MuPAD, `Sin` measures its argument in degrees rather than in radians (i.e., `Sin(x) = sin(PI/180*x)`). The only functionality of `Sin` is to produce floating point values if the argument is a real float. For all other kinds of arguments, a symbolic function call is to be returned:

```
Sin := proc(x)
begin
  if domtype(x) = DOM_FLOAT then
    return(Sin::float(x));
  else return(procname(args()))
  end_if;
end_proc:
```

The function is turned into a function environment via `funcenv`:

```
Sin := funcenv(Sin):
```

Finally, the `"float"` attribute is implemented. If the argument can be converted to a real floating-point number, a floating-point result is produced. In all other cases, a symbolic call of `Sin` is returned:

```
Sin::float := proc(x)
begin
  x := float(x):
  if domtype(x) = DOM_FLOAT then
    return(float(sin(PI/180*x)));
  else return(Sin(x))
  end_if;
end_proc:
```

Now, float evaluation of arbitrary expressions involving `Sin` is possible:

```
Sin(x), Sin(x + 0.3), Sin(120)
```

$$\mathrm{Sin}(x),\ \mathrm{Sin}(x+0.3),\ \mathrm{Sin}(120)$$

```
Sin(120.0), float(Sin(120)), float(Sin(x + 120))
```

$$0.8660254038,\ 0.8660254038,\ \mathrm{Sin}(x+120.0)$$

```
float(sqrt(2) + Sin(120 + sqrt(3)))
```

$$2.264730594$$

```
delete Sin:
```

Parameters

`object`

Any MuPAD object

`n`

An integer greater than 1

Return Values

Floating point number of type `DOM_FLOAT` or `DOM_COMPLEX`, or the input object with exact numbers replaced by floating-point numbers.

Overloaded By

object

See Also

MuPAD Functions

`DIGITS` | `isolate` | `Pref::floatFormat` | `Pref::outputDigits` | `Pref::trailingZeroes`

fname

Get a file's name

Syntax

```
fname(n)
```

Description

`fname(n)` returns the name of the file specified by the file descriptor `n`.

The file must have been opened with `fopen`. The call to `fopen` yields the file descriptor `n` representing the file.

The special file descriptor `0` represents no file but output to the user interface instead; `fname(0)` returns `NIL`.

Examples

Example 1

We open a temporary file for writing. This yields the file descriptor `n`:

```
n := fopen(TempFile);
```

```
    16
```

We get the file's name. Note that the name depends on the operating system:

```
fname(n);
```

```
    "/tmp/mtxM9fPT"
```

Parameters

n

A file descriptor returned by `fopen`: a positive integer

Return Values

the name of the file: a character string of type `DOM_STRING`, or `NIL`.

See Also

MuPAD Functions
`fclose` | `finput` | `fopen` | `fprint` | `fread` | `ftextinput`

fopen

Open file

Syntax

```
fopen(filename | TempFile, <Read | Write | Append>, <Bin | Text | Raw>, <Encoding = "er
```

Description

`fopen(filename, format)` opens an existing file for reading in the specified format. An error is raised if no file with the specified name is found or the format of the file does not coincide with the specified `format`. If the file is in `gzip`-compressed format and its name ends in "`.gz`", it will be transparently uncompressed upon reading.

`fopen(filename)` opens an existing file for reading. The file must hold data in text or MuPAD binary format (optionally compressed), `fopen` automatically identifies the file format in this case. The file must not be used as raw file.

`fopen(filename, mode, format)` opens the file for writing in the specified format if the mode is given as `Read` or `Append`. If no file with the specified name exists, a new file is created. If the filename ends in "`.gz`", all data written to the file will be transparently compressed in `gzip` compatible format.

`fopen(TempFile, format)` creates and opens a temporary file for writing in the specified format. The option `Read` and `Append` are not allowed in this case. If no format is given, `Bin` is used. Use `fname` to query the actual name and location of the temporary file. Cf. "Example 3" on page 1-772.

`fopen(..., Encoding = "encodingValue")` uses the specified encoding. For supported encodings, see "Options" on page 1-773. You can use this option with the previously specified syntaxes for text files.

In write mode (using one of the options `Write` or `Append`), the environment variable `WRITEPATH` is considered if no temporary file is created. If it has a value, a new file is created (or an existing file is searched for) in the corresponding folder. Otherwise, it is created/searched for in the "working folder."

Note that the meaning of “working folder” depends on the operating system. On Windows systems and on Mac OS X systems, the “working folder” is the folder where MATLAB is installed. On UNIX systems, it is the current working folder in which MATLAB was started. When started from a menu or desktop item, this is typically the user's home folder.

Note: In read mode, `fopen` does not search for files in the folders given by `READPATH` and the library path.

A temporary file is created in a special folder. This folder and the name of the file are system dependent.

Also absolute path names are processed by `fopen`.

The file descriptor returned by `fopen` can be used by various functions such as `fname`, `fclose`, `fread`, `fprint`, `read`, `write` etc.

A file opened by `fopen` should be closed by `fclose` after use. This holds also for temporary files.

`fopen` accepts its arguments in any order, not only in the order used above.

Environment Interactions

The function is sensitive to the environment variable `WRITEPATH` when creating files that are not temporary (temporary files are created via `TempFile`). If `WRITEPATH` has a value, in write mode (using the options `Write` or `Append`), the file is created in the corresponding folder. Otherwise, the file is created in the “working folder.” A temporary file is created in a special folder.

When using `Write` or `Append`, `fopen` creates a new file if no file under the given name exists.

Examples

Example 1

Open the file `test` for writing. With the option `Write`, it is not necessary that the file `test` exists. By default, the file is opened as a binary file:

```
fid := fopen("test", Write):
```

Write a string to the file and close it:

```
fprint(fid, "a string"):
fclose(fid):
```

Append another string to the file:

```
fid := fopen("test", Append):
fprint(fid, "another string"):
fclose(fid):
```

The binary file cannot be opened as a text file for appending data:

```
fid := fopen("test", Append, Text)
```

```
    FAIL
```

However, it may be opened as a text file with the option `Write`. The existing binary file is overwritten with a text file:

```
fid := fopen("test", Write, Text):
fclose(fid):
delete fid:
```

Example 2

`fopen` fails to open non-existing files for reading. Here, assume the file "`xyz`" does not exist:

```
n := fopen("xyz")
```

```
    FAIL
```

Assume the file "test" created in "Example 1" on page 1-771 exists. It can be opened for reading successfully:

```
n := fopen("test")
```

```
     119
```

```
fclose(n):
delete n:
```

Example 3

Open a temporary file, write 10 binary data bytes into it and close it. fname is used to query the name of the file:

```
fd := fopen(TempFile, Raw):
writebytes(fd, [i $ i=1..10]):
fn := fname(fd):
fclose(fd):
fn
```

```
     "/tmp/mupad.7aYAp4"
```

Re-open the file and read the data:

```
fd := fopen(fn, Read, Raw):
readbytes(fd);
```

```
     [1, 2, 3, 4, 5, 6, 7, 8, 9, 10]
```

```
fclose(fd):
delete fd, fn:
```

Example 4

To specify the encoding to read and write data, use Encoding. The Encoding option applies only to text files that are opened using a file name and not a file descriptor. Create a temporary file and write the string "abcäöü" in the encoding "UTF-8":

```
fid := fopen(TempFile, Text, Write, Encoding="UTF-8"):
file := fname(fid):
fprint(Unquoted, fid, "abcäöü"):
```

```
fclose(fid):
```

Use `ftextinput` to read the data with the specified encoding:

```
ftextinput(file, Encoding="UTF-8")
```

```
"abcäöü"
```

If you do not specify an encoding, the default system encoding is used. Thus, your output might vary from that shown next. Characters unrecognized by the default system encoding are replaced by the default substitution character for that encoding:

```
fid := fopen(TempFile, Text, Write):
file := fname(fid):
fprint(Unquoted, fid, "abcäöü"):
fclose(fid):
ftextinput(file)
```

```
"abc"
```

Parameters

`filename`

The name of a file: a character string or the flag `TempFile`

Options

`TempFile`

`fopen` creates a temporary file in the systems “temp” folder. The name of this file can be queried using `fname`.

`Append`, `Read`, `Write`

With `Read`, the file is opened for reading; with `Write` or `Append`, it is opened for writing. If a file opened for writing does not yet exist, it is created. With `Write`, existing files are overwritten. With `Append`, new data may be appended to an existing file. Note that in the `Append` mode, the specified format must coincide with the format of the existing file;

otherwise, the file cannot be opened and `fopen` returns `FAIL`. If the flag `TempFile` is given, the default mode is `Write`. Otherwise, the default mode is `Read`.

`Bin, Raw, Text`

With `Bin`, the data is stored in MuPAD internal binary format. With `Text`, the data may be strings or MuPAD objects stored as text. Newlines are handled according to the conventions of the operating system at hand. With `Raw`, the data is interpreted as binary machine numbers. See the functions `readbytes` and `writebytes`.

If the mode is `Read` or `Append`, the default is the format of the data in the existing file. If the mode is `Write`, the default is `Bin`.

`Encoding`

This option lets you specify the character encoding to use. The allowed encodings are:

`"Big5"`	`"ISO-8859-1"`	`"windows-932"`
`"EUC-JP"`	`"ISO-8859-2"`	`"windows-936"`
`"GBK"`	`"ISO-8859-3"`	`"windows-949"`
`"KSC_5601"`	`"ISO-8859-4"`	`"windows-950"`
`"Macintosh"`	`"ISO-8859-9"`	`"windows-1250"`
`"Shift_JIS"`	`"ISO-8859-13"`	`"windows-1251"`
`"US-ASCII"`	`"ISO-8859-15"`	`"windows-1252"`
`"UTF-8"`		`"windows-1253"`
		`"windows-1254"`
		`"windows-1257"`

The default encoding is system dependent. If you specify the encoding incorrectly, characters might read incorrectly. Characters unrecognized by the encoding are replaced by the default substitution character for the specified encoding.

Encodings not listed here can be specified but might not produce correct results.

Return Values

a positive integer: the file descriptor. `FAIL` is returned if the file cannot be opened.

for, from, to, step, end_for, _for_in, downto, _for_downto

For loop

Syntax

```
for i from start to stop do
  body
end_for

for i from start to stop step stepwidth do
  body
end_for

_for(i, start, stop, stepwidth, body)

for i from start downto stop do
  body
end_for

for i from start downto stop step stepwidth do
  body
end_for

_for_down(i, start, stop, stepwidth, body)

for x in object do
  body
end_for

_for_in(x, object, body)
```

Description

`for - end_for` is a repetition statement providing a loop for automatic iteration over a range of numbers or objects.

When entering an incrementing loop

`for i from start to stop step stepwidth do body end_for`,

the assignment `i := start` is made. The body is executed with this value of `i` (the body may reassign a new value to `i`). After all statements inside the body are executed, the loop returns to the beginning of the body, increments `i := i + stepwidth` and checks the stopping criterion `i > stop`. If `FALSE`, the body is executed again with the new value of `i`. If `TRUE`, the loop is terminated immediately without executing the body again.

The decrementing loop

```
for i from start downto stop step stepwidth do body end_for
```

implements a corresponding behavior. The only difference is that upon return to the beginning of the body, the loop variable is decremented by `i := i - stepwidth` before the stopping criterion `i < stop` is checked.

The loop `for x in object do body end_for` iterates `x` over all operands of the object. This loop is equivalent to

```
for i from 1 to nops(object) do
x := op(object, i);          body        end_for
```

Typically, `object` may be a list, an expression sequence, an array or an hfarray. Note that other container objects such as finite sets or tables do not have a natural internal ordering, i.e., care must be taken, if the loop expects a certain ordering of the iterative steps.

The body of a loop may consist of any number of statements which must be separated either by a colon `:` or a semicolon `;`. The last evaluated result inside the body is printed on the screen as the return value of the loop. Use `print` inside the loop to see intermediate results.

The loop variable `i`, respectively `x`, may have a value before the loop starts. After the loop is terminated, it has the value that was assigned in the last step of the loop. Typically, in an incrementing or decrementing loop with integer values of `start`, `stop`, and `stepwidth`, this is `i` = `stop` plus or minus `stepwidth`.

The arguments `start`, `stop`, `stepwidth`, and `object` are evaluated only once at the beginning of the loop and not after every iteration. E.g., if `object` is changed in a step of the loop, `x` still runs through all operands of the original object.

Loops can be exited prematurely using the `break` statement. Steps of a loop can be skipped using the `next` statement. Cf. “Example 2” on page 1-780.

The keyword `end_for` may be replaced by the keyword `end`. Cf. “Example 3” on page 1-780.

Instead of the the imperative loop statements, the equivalent calls of the functions `_for`, `_for_down`, or `_for_in` may be used. Cf. “Example 4” on page 1-781.

The `$`-operator is often a more elegant notation for `for`-loops.

`_for`, `_for_down` and `_for_in` are functions of the system kernel.

Examples

Example 1

The body of the following loop consists of several statements. The value of the loop variable `i` is overwritten when the loop is entered:

```
i := 20:
for i from 1 to 3 do
  a := i;
  b := i^2;
  print(a, b)
end_for:
```

```
    1, 1

    2, 4

    3, 9
```

The loop variable now has the value that satisfied the stopping criterion `i > 3`:

```
i
```

```
    4
```

The iteration range is not restricted to integers:

```
for i from 2.2 downto 1 step 0.5 do
  print(i)
end_for:
```

2.2

1.7

1.2

The following loop sums up all elements in a list. The return value of the loop is the final sum. It can be assigned to a variable:

```
s := 0: S := for x in [c, 1, d, 2] do s := s + x end_for
```

$c+d+3$

Note that for sets, the internal ordering is not necessarily the same as printed on the screen:

```
S := {c, d, 1}
```

$\{1, c, d\}$

```
for x in S do print(x) end_for:
```

c

d

1

```
delete a, b, i, s, S, x:
```

Example 2

Loops can be exited prematurely using the `break` statement:

```
for i from 1 to 3 do
  print(i);
  if i = 2 then break end_if
end_for:
```

```
    1
```

```
    2
```

With the `next` statement, the execution of commands in a step can be skipped. The evaluation continues at the beginning of the body with the incremented value of the loop variable:

```
a := 0:
for i from 1 to 3 do
  a := a + 1;
  if i = 2 then next end_if;
  print(i, a)
end_for:
```

```
    1, 1
```

```
    3, 3
```

```
delete i, a:
```

Example 3

Loops can be closed with the keyword `end` instead of `end_for`. The parser recognizes the scope of `end` statements automatically.

```
s:= 0:
for i from 1 to 3 do
  for j from 1 to 3 do
    s := i + j;
    if i + j > 4 then
```

```
      break;
    end
  end
end

    5

delete s, i, j:
```

Example 4

This example demonstrates the correspondence between the functional and the imperative form of `for` loops:

```
hold(
  _for(i, start, stop, stepwidth, (statement1; statement2))
)

for i from start to stop step stepwidth do
  statement1;
  statement2
end_for
```

The optional `step` clause is omitted by specifying the value `NIL` for the step width:

```
hold(
  _for_down(i, 10, 1, NIL, (x := i^2; x := x - 1))
)

for i from 10 downto 1 do
  x := i^2;
  x := x - 1
end_for

hold(
  _for_in(x, object, body)
)

for x in object do
  body
end_for
```

Parameters

i, x

The loop variable: an identifier or a local variable (DOM_VAR) of a procedure

start

The starting value for i: a real number. This may be an integer, a rational number, or a floating point number.

stop

The stopping value for i: a real number. This may be an integer, a rational number, or a floating point number.

stepwidth

The step width: a positive real number. This may be an integer, a rational number, or a floating-point number. The default value is 1.

object

An arbitrary MuPAD object

body

The body of the loop: an arbitrary sequence of statements

Return Values

Value of the last command executed in the body of the loop. If no command was executed, the value NIL is returned. If the iteration range is empty, the void object of type DOM_NULL is returned.

More About

- “Loops”

forceGarbageCollection

Force a garbage collection

Syntax

```
forceGarbageCollection()
```

Description

`forceGarbageCollection()` forces a garbage collection to be performed. This function serves a highly technical purpose. Usually, there should be no need for a user to call this function.

Each time the interactive level is reached, the garbage collection routine is called. A heuristic algorithmn decides whether a garbage collection is really performed. After a call to `forceGarbageCollection`, a garbage collection will be forced on the next call of the garbage collection routine.

Note: `forceGarbageCollection` does not cause an immediate garbage collection; it is only executed on returning to the interactive level. Therefore, it cannot be used in procedures to release memory during a longer computation.

Examples

Example 1

When the interactive level is reached, a garbage collection is performed:

```
forceGarbageCollection()
```

Return Values

Void object of type `DOM_NULL`.

See Also

MuPAD Functions
`bytes`

forget

Clear the remember table of a procedure

Syntax

```
forget(f)
```

Description

`forget(f)` clears the remember table of a procedure `f`. The `forget` function clears only remember tables created by the option remember.

The `forget` function clears only remember tables created by the option remember. The function does not affect the remember tables created by `prog::remember`.

Do not call the `forget` function for predefined MuPAD functions. Many predefined MuPAD functions have special values stored in their remember tables. The `forget` function does not throw an error when you call it for a predefined MuPAD function.

The `forget` function does not work recursively. If an inner procedure in a nested procedure uses the option remember, the `forget` function does not clear the remember table created for the inner procedure.

Examples

Example 1

If you use the option remember in a procedure, MuPAD stores all input arguments you used in the procedure calls as indices of the remember table, and the corresponding results as values of these entries. For example, create the following procedure `f` as a wrapper for the MuPAD `sign` function. Use the option remember to enable the remember mechanism for the procedure `f`:

```
f := proc(x)
option remember;
```

```
begin
  sign(x)
end:
```

Now compute the `sign` function for the values -1, 0, and 1:

```
f(-1), f(0), f(1)
```

$$-1, 0, 1$$

You can define a different value for `sign(0)`. First use the `unprotect` function to be able to overwrite the value of `sign`. Then assign the new value to `sign(0)`:

```
unprotect(sign):
sign(0):= 1/2:
```

Although you specified the new value for `sign(0)`, MuPAD does not recalculate the result of the function call `f(0)`. Instead, the system returns the result stored in the remember table:

```
f(0)
```

$$0$$

To clear a remember table created by the option `remember`, use the `forget` function:

```
forget(f):
f(0)
```

$$\frac{1}{2}$$

If you assign a value to a function call, calling the `forget` function also clears that value:

```
f(2) := 1/3:
f(2)
```

$$\frac{1}{3}$$

```
forget(f):
f(2)
```

```
    1
```

For further computations, restore the `sign` function to its default definition. Use the `protect` function with the `ProtectLevelError` option to prevent further changes to `sign`. Also, delete the procedure `f`:

```
sign(0):= 0:
protect(sign, ProtectLevelError):
delete f
```

Parameters

`f`

A procedure or function environment

Return Values

Void object of domain type `DOM_NULL`

See Also

MuPAD Functions

`proc` | `prog::remember`

More About

- “Clear Remember Tables”

fourier

Fourier transform

Syntax

```
fourier(f, t, w)
```

Description

`fourier(f, t, w)` computes the Fourier transform of the expression `f = f(t)` with respect to the variable `t` at the point `w` and is defined as follows:

$$F(w) = c \int_{-\infty}^{\infty} f(t)\, e^{i\, s\, w\, t}\, dt$$

.

`c` and `s` are parameters of the Fourier transform. By default, `c = 1` and `s = -1`.

To change the parameters `c` and `s` of the Fourier transform, use `Pref::fourierParameters`. See “Example 3” on page 1-791. Common choices for the parameter `c` are 1, $\frac{1}{2\pi}$, or $\frac{1}{\sqrt{2\pi}}$. Common choices for the parameter `s` are -1, 1, - 2 π, or 2 π.

If `fourier` cannot find an explicit representation of the transform, it returns an unevaluated function call. See “Example 4” on page 1-791.

If `f` is a matrix, `fourier` applies the Fourier transform to all components of the matrix.

To compute the inverse Fourier transform, use `ifourier`.

To compute the discrete Fourier transform, use `numeric::fft`.

Environment Interactions

Results returned by `fourier` depend on the current `Pref::fourierParameters` settings.

Examples

Example 1

Compute the Fourier transform of this expression with respect to the variable `t`:

```
fourier(exp(-t^2), t, w)
```

$$\sqrt{\pi}\, e^{-\frac{w^2}{4}}$$

Example 2

Compute the Fourier transform of this expression with respect to the variable `t` for positive values of the parameter w_0:

```
assume(w_0 > 0):
F := fourier(t*exp(-w_0^2*t^2), t, w)
```

$$-\frac{\sqrt{\pi}\, w\, e^{-\frac{w^2}{4 w_0^2}}\, i}{2 w_0^3}$$

Evaluate the Fourier transform of the expression at the points $w = 2\, w_0$ and $w = 5$. You can evaluate the resulting expression `F` using `|` (or its functional form `evalAt`):

```
F | w = 2*w_0
```

$$-\frac{\sqrt{\pi}\, e^{-1}\, i}{w_0^2}$$

Also, you can evaluate the Fourier transform at a particular point directly:

```
fourier(t*exp(-w_0^2*t^2), t, 5)
```

$$-\frac{5\sqrt{\pi}\,e^{-\frac{25}{4\,w_0^{\,2}}}\,i}{2\,w_0^{\,3}}$$

Example 3

The default parameters of the Fourier transform are `c = 1` and `s = -1`.

```
fourier(t*exp(-t^2), t, w)
```

$$-\frac{\sqrt{\pi}\,w\,e^{-\frac{w^2}{4}}\,i}{2}$$

To change these parameters, use `Pref::fourierParameters` before calling `fourier`:

```
Pref::fourierParameters(1, 1):
```

Evaluate the transform of the same expression with the new parameters:

```
fourier(t*exp(-t^2), t, w)
```

$$\frac{\sqrt{\pi}\,w\,e^{-\frac{w^2}{4}}\,i}{2}$$

For further computations, restore the default values of the Fourier transform parameters:

```
Pref::fourierParameters(NIL):
```

Example 4

If `fourier` cannot find an explicit representation of the transform, it returns an unevaluated call:

```
fourier(besselJ(1, 1/(1 + t^2)), t, w)
```

$$\text{fourier}\left(J_1\left(\frac{1}{t^2+1}\right), t, w\right)$$

`ifourier` returns the original expression:

```
ifourier(%, w, t)
```

$$J_1\left(\frac{1}{t^2+1}\right)$$

Example 5

Compute the following Fourier transforms that involve the Dirac and the Heaviside functions:

```
fourier(t^3, t, w)
```

$$-2\,\pi\,\delta'''(w)\,i$$

```
fourier(heaviside(t - t_0), t, w)
```

$$e^{-t_0\,w\,i}\left(\pi\,\delta(w) - \frac{i}{w}\right)$$

Example 6

The Fourier transform of a function is related to the Fourier transform of its derivative:

```
fourier(diff(f(t), t), t, w)
```

$$w\,\text{fourier}(f(t), t, w)\,i$$

Parameters

f

Arithmetical expression or unevaluated function call of type `fourier`. If the first argument is a matrix, the result is returned as a matrix.

t

Identifier or indexed identifier representing the transformation variable

w

Arithmetical expression representing the evaluation point

Return Values

Arithmetical expression or matrix of such expressions

Overloaded By

f

MuPAD Functions

`fourier::addpattern` | `ifourier` | `ifourier::addpattern` | `numeric::fft` | `numeric::invfft` | `Pref::fourierParameters`

fourier::addpattern

Add patterns for the Fourier transform

Syntax

```
fourier::addpattern(pat, t, w, res, <vars, <conds>>)
```

Description

`fourier::addpattern(pat, t, w, res)` teaches `fourier` to return `res` for the expression `pat`.

The `fourier` function uses a set of patterns for computing Fourier transforms. You can extend the set by adding your own patterns. To add a new pattern to the pattern matcher, use `fourier::addpattern`. MuPAD does not save custom patterns permanently. The new patterns are available in the *current* MuPAD session only.

After the call `fourier::addpattern(pat, t, w, res)`, the `fourier` function returns `res` for the expression `pat`. Note that the Fourier transform is defined as $c \int_{-\infty}^{\infty} \mathrm{pat}\, \mathrm{e}^{s\,i\,w\,t}\, \mathrm{d}\,t$, where `c` and `s` are the parameters specified by `Pref::fourierParameters`. If you add a new pattern, and then change the Fourier transform parameters, the result returned by `fourier(pat, t, w)` will also change. See “Example 2” on page 1-796.

Variable names that you use when calling `fourier::addpattern` can differ from the names that you use when calling `fourier`. See “Example 3” on page 1-796.

You can include a list of free parameters and a list of conditions on these parameters. These conditions and the result are protected from premature evaluation. This means that you can use `not iszero(a^2 - b)` instead of `hold( _not @ iszero )(a^2 - b)`.

The following conditions treat assumptions on identifiers differently:

- `a^2 - b <> 0` takes into account assumptions on identifiers.
- `not iszero(a^2 - b)` disregards assumptions on identifiers.

See “Example 4” on page 1-796 and “Example 5” on page 1-797.

Environment Interactions

The Fourier pair `(pat, res)` holds only for the current values of the Fourier transform parameters specified by `Pref::fourierParameters`.

Calling `fourier::addpattern` can change the expressions returned by future calls to `fourier` and `ifourier` in the current MuPAD session.

Examples

Example 1

Compute the Fourier transform of the function `foo`. By default, MuPAD does not have a pattern for this function:

```
fourier(foo(t), t, w)
```

$$\text{fourier}(\text{foo}(t), t, w)$$

Add a pattern for the Fourier transform of `foo` using `fourier::addpattern`:

```
fourier::addpattern(foo(t), t, w, bar(w)):
```

Now `fourier` returns the Fourier transform of `foo`:

```
fourier(foo(t), t, w)
```

$$\text{bar}(w)$$

After you add a new transform pattern, MuPAD can use that pattern indirectly:

```
fourier(t^3 + a*foo(2*t - 4), t, w)
```

$$-2\,\pi\,\delta'''(w)\,\mathrm{i} + \frac{a\,\text{bar}\left(\frac{w}{2}\right)\,\mathrm{e}^{-2\,w\,\mathrm{i}}}{2}$$

Example 2

Add this new Fourier transform pattern for the function `foo`:

```
fourier::addpattern(foo(t), t, w, bar(w)):
fourier(foo(t), t, w)
```

$$\mathrm{bar}(w)$$

Now change the Fourier transform parameters using `Pref::fourierParameters`:

```
Pref::fourierParameters(a, b):
```

Evaluate the transform with the new parameters:

```
fourier(foo(t), t, w)
```

$$a\,\mathrm{bar}(-b\,w)$$

For further computations, restore the default values of the Fourier transform parameters:

```
Pref::fourierParameters(NIL):
```

Example 3

Define the Fourier transform of `foo(x)` using the variables `x` and `y` as parameters:

```
fourier::addpattern(foo(x), x, y, bar(y)):
```

The `fourier` function recognizes the added pattern even if you use other variables as parameters:

```
fourier(foo(t), t, w)
```

$$\mathrm{bar}(w)$$

Example 4

Use assumptions when adding the following pattern for the Fourier transform:

```
fourier::addpattern(foo(x, t), t, w, bar(x, w), [x], [abs(x) < 1]):
fourier(foo(x, t), t, w) assuming -1 < x < 1
```

$$\mathrm{bar}(x, w)$$

If $|x| \geq 1$, you cannot apply this pattern:

```
fourier(foo(x, t), t, w) assuming x > 1
```

$$\mathrm{fourier}(\mathrm{foo}(x, t), t, w)$$

If MuPAD cannot determine whether the conditions are satisfied, it returns a `piecewise` object:

```
fourier(foo(x, t), t, w)
```

$$\begin{cases} \mathrm{bar}(x, w) & \text{if } |x| < 1 \end{cases}$$

Example 5

Add this pattern for the Fourier transform of `f`:

```
fourier::addpattern(f(a, t), t, w, g(a, w)/a):
fourier(f(a, T), T, W)
```

$$\frac{g(a, W)}{a}$$

This pattern holds only when the first argument of `f` is the symbolic parameter `a`. If you use any other value of this parameter, `fourier` ignores the pattern:

```
fourier(f(b, T), T, W);
fourier(f(2, T), T, W)
```

$$\mathrm{fourier}(f(b, T), T, W)$$

$$\mathrm{fourier}(f(2, T), T, W)$$

To use the pattern for arbitrary values of the parameter, declare the parameter `a` as an additional pattern variable:

```
fourier::addpattern(f(a, t), t, w, g(a, w)/a, [a]):
```

Now `fourier` applies the specified pattern for an arbitrary value of `a`:

```
fourier(f(2, T), T, W)
```

$$\frac{g(2, W)}{2}$$

```
fourier(f(a^2 + 1, T), T, W)
```

$$\frac{g(a^2 + 1, W)}{a^2 + 1}$$

Note that the resulting expression `g(a, w)/a` defining the Fourier transform of `f(a, t)` implicitly assumes that the value of `a` is not zero. A strict definition of the pattern is:

```
fourier::addpattern(f(a, t), t, w, g(a, w)/a, [a], [a <> 0]):
```

For this particular pattern, you can omit specifying the assumption `a <> 0` explicitly. If `a = 0`, MuPAD throws an internal "Division by zero." error and ignores the pattern:

```
fourier(f(0, T), T, W)
```

$$\text{fourier}(f(0, T), T, W)$$

Parameters

`pat`

Arithmetical expression in the variable `t` representing the pattern to match

`t`

Identifier or indexed identifier used as a variable in the pattern

`w`

Identifier or indexed identifier used as a variable in the result

`res`

Arithmetical expression in the variable `w` representing the pattern for the result of the transform

`vars`

List of identifiers or indexed identifiers used as "pattern variables" (placeholders in `pat` and `res`). You can use pattern variables as placeholders for almost any MuPAD expressions not containing `t` or `w`. You can restrict them by conditions given in the optional parameter `conds`.

`conds`

List of conditions on the pattern variables

Return Values

Object of type `DOM_NULL`

See Also

MuPAD Functions

`fourier` | `ifourier` | `ifourier::addpattern`

fprint

Write data to file

Syntax

```
fprint(<Unquoted | NoNL>, <Bin | Text>, <Encoding = "encodingValue">, filename, <object
```

```
fprint(<Unquoted | NoNL>, <Encoding = "encodingValue">, n, <object1, object2, …>)
```

Description

`fprint(f, objects)` writes MuPAD objects to the file `f`. The objects are evaluated, the results are stored in the file. These data can be read into another MuPAD session via the functions `finput` and `ftextinput`, respectively.

`fprint(Encoding = "encodingValue", f, objects)` uses the specified encoding. For supported encodings, see “Options” on page 1-805.

The file may be specified directly by its name. In this case, `fprint` creates a new file or overwrites an existing file. `fprint` opens and closes the file automatically.

If `WRITEPATH` does not have a value, `fprint` interprets the file name as a path name relative to the “working folder.”

Note that the meaning of “working folder” depends on the operating system. On Windows systems and on Mac OS X systems, the “working folder” is the folder where MATLAB is installed. On UNIX systems, it is the current working folder in which MATLAB was started; when started from a menu or desktop item, this is typically the user's home folder.

Also absolute path names are processed by `fprint`.

If the filename given ends in “`.gz`”, MuPAD automatically writes a compressed file in `gzip` format. These files are transparently uncompressed when read in again by MuPAD. The `gzip` format is supported by many other programs as well. See “Example 5” on page 1-804.

Instead of a file name, also a file descriptor of a file opened via `fopen` can be used. See “Example 2” on page 1-802. In this case, the data written by `fprint` are appended to the corresponding file. The file is not closed automatically by `fprint` and must be closed by a subsequent call to `fclose`.

Note that `fopen(filename)` opens the file in read-only mode. A subsequent `fprint` command to this file causes an error. Use the `Write` or `Append` option of `fopen` to open the file for writing.

Note: The file descriptor `0` represents the screen. See “Example 4” on page 1-803.

Text output occurs without the Pretty-Printer. A call to `fprint` writes all specified objects into a single line of the text file. A newline character is appended to this line, unless the option `NoNL` is used. By default, the written objects are separated by colons without any further white space. The resulting text data consists of syntactically correct MuPAD code and can be read again using `finput`. With the options `Unquoted` and `NoNL`, neither white space no colons are inserted to separate the objects. The resulting text data cannot be read again using `finput`. See “Example 3” on page 1-802.

Environment Interactions

The function is sensitive to the environment variable `WRITEPATH`. If this variable has a value, the file is created in the corresponding folder. Otherwise, the file is created in the “working folder”.

Examples

Example 1

Write some data to the file “`test`”. By default, this file is created as a binary file:

```
fid := fopen(TempFile, Write, Text):
d := 5:
fprint(fid, d, d*3):
file := fname(fid):
fclose(fid)
```

The file is read into the MuPAD session:

```
finput(file, e, f): d, e, f;
```

```
     5, 5, 15
```

```
delete d, e, f:
```

Example 2

Use a file descriptor to access the file `test`. Several calls to `fprint` append data to the file:

```
n := fopen(file, Write):
fprint(n, (d := 5), d*3):
fprint(n, "more data"):
```

Using a file descriptor, call `fclose` to close the file:

```
fclose(n):
```

The file is read into the MuPAD session, assigning the stored values to the identifiers `e`, `f`, and `g`:

```
finput(file, e, f, g ): e, f, g;
```

```
     5, 15, "more data"
```

```
delete n, d, e, f, g:
```

Example 3

With the option `Unquoted`, character strings are written without quotation marks:

```
fid1 := fopen(TempFile):
fid2 := fopen(TempFile):
file1 := fname(fid1):
file2 := fname(fid2):
fprint(Text, file1, "Hello World!", MuPAD + 1):
fprint(Unquoted, Text, file2, "Hello World!", MuPAD + 1):
```

Creates temporary files have the following content:

```
"Hello World!":MuPAD + 1:

Hello World!MuPAD + 1
```

Use `finput` or `ftextinput` to read the data from the file:

```
finput(file1, a, b):
a, b;

     "Hello World!", MuPAD + 1

ftextinput(file2, c): c

     "Hello World!MuPAD + 1"

delete a, b, c:
```

Example 4

Typically, the `print` function serves for displaying objects on screen. If the object produces a line that is longer than the `TEXTWIDTH` setting, `print` breaks that line into shorter lines and inserts the line continuation characters. To avoid inserting line continuation characters, display long objects on screen by using the `fprint` function with the file descriptor 0. For example, convert the following expression to a TeX formatted string. When you use the `print` function, the resulting string contains the line continuation character (\):

```
print(Unquoted, generate::TeX(diff(1/ln(1/x), x$4)))

\frac{22}{x^4\, {\ln\!\left(\frac{1}{x}\right)}^3} - \frac{6}{x^4\, {\ln\
\!\left(\frac{1}{x}\right)}^2} - \frac{36}{x^4\, {\ln\!\left(\frac{1}{x}\
\right)}^4} + \frac{24}{x^4\, {\ln\!\left(\frac{1}{x}\right)}^5}
```

If you want to use the generated string in TeX, you must remove these additional characters. Also, you can generate the string without these characters by using the `fprint` function:

```
fprint(Unquoted, 0, generate::TeX(diff(1/ln(1/x), x$4)))

\frac{22}{x^4\, {\ln\!\left(\frac{1}{x}\right)}^3} - \frac{6}{x^4\, {\ln\!\left(\frac{
```

Another way to avoid line continuation characters is to increase the TEXTWIDTH setting:

```
defaultWidth := TEXTWIDTH:
TEXTWIDTH := 250:
print(Unquoted, generate::TeX(diff(1/ln(1/x), x$4)));
TEXTWIDTH := defaultWidth:
```

```
\frac{22}{x^4\, {\ln\!\left(\frac{1}{x}\right)}^3} - \frac{6}{x^4\, {\ln\!\left(\frac{
```

Example 5

When writing to a file with a name ending in ".gz", MuPAD creates a compressed file automatically. On a UNIX system, the file command can be used to verify this:

```
fprint(Text, "test.gz", "test"):
system("file test.gz"):
```

```
test.gz: gzip compressed data, from Unix
```

Reading the file from MuPAD does not show a difference, because gzip-compressed files are automatically uncompressed in memory by MuPAD:

```
ftextinput("test.gz")
```

```
""test"."
```

Example 6

To specify the encoding to write data, use Encoding. The Encoding option applies only to text files that are opened using a file name and not a file descriptor. Create a file and write the string "abcäöü" in the encoding "UTF-8":

```
fprint(Unquoted, Text, Encoding="UTF-8", "fprint_test", "abcäöü"):
```

Use ftextinput to read the data with the specified encoding:

```
ftextinput("fprint_test", Encoding="UTF-8")
```

```
"abcäöü"
```

If you do not specify an encoding, the default system encoding is used. Thus, your output might vary from that shown next. Characters unrecognized by the default system encoding are replaced by the default substitution character for that encoding:

```
fprint(Unquoted, Text, "fprint_test", "abcäöü"):
ftextinput("fprint_test")
```

```
    "abc"
```

Parameters

`filename`

The name of a file: a character string

`object`$_1$`, object`$_2$`, …`

Arbitrary MuPAD objects

`n`

A file descriptor provided by `fopen`: a nonnegative integer

Options

`Unquoted`

With this option, character strings are written without quotation marks. Additionally, the control characters `'\n'`, `'\b'`, and `'\t'` in strings are expanded. Furthermore, no colons are inserted between the objects. A newline character is appended to the line written by `fprint`.

This option is relevant for text files only. It is useful for writing user-formated text files. Data written with this option cannot be read again via `finput`.

`NoNL`

This option has the same functionality as `Unquoted`, with the only difference that no newline character is appended to the line written by `fprint`.

Bin, Text

With Bin, the data is stored in MuPAD binary format. With Text, standard ASCII format is used. The default is Bin.

Encoding

This option lets you specify the character encoding to use. The allowed encodings are:

"Big5"	"ISO-8859-1"	"windows-932"
"EUC-JP"	"ISO-8859-2"	"windows-936"
"GBK"	"ISO-8859-3"	"windows-949"
"KSC_5601"	"ISO-8859-4"	"windows-950"
"Macintosh"	"ISO-8859-9"	"windows-1250"
"Shift_JIS"	"ISO-8859-13"	"windows-1251"
"US-ASCII"	"ISO-8859-15"	"windows-1252"
"UTF-8"		"windows-1253"
		"windows-1254"
		"windows-1257"

The default encoding is system dependent. If you specify the encoding incorrectly, characters might read incorrectly. Characters unrecognized by the encoding are replaced by the default substitution character for the specified encoding.

Encodings not listed here can be specified but might not produce correct results.

Return Values

Void object of type DOM_NULL.

frac

Fractional part of a number

Syntax

```
frac(x)
```

Description

`frac(x)` represents the "fractional part" `x-floor(x)` of the number `x`.

For complex arguments, `frac` is applied separately to the real and imaginary part.

For real numbers, the value `x-floor(x)` represented by `frac(x)` is a number from the interval $[0, 1)$. For positive arguments, you may think of `frac` as truncating all digits before the decimal point.

For integer arguments, `0` is returned. For rational arguments, a rational number is returned. For arguments that contain symbolic identifiers, symbolic function calls are returned. For floating-point arguments or non-rational exact expressions, floating-point values are returned.

Note: If the argument is a floating-point number of absolute value larger than 10^{DIGITS}, then the result is affected by internal non-significant digits! Cf. "Example 2" on page 1-808.

Note: Exact numerical data that are neither integers nor rational numbers are approximated by floating-point numbers. For such arguments, the result depends on the present value of `DIGITS`! Cf. "Example 3" on page 1-809.

Environment Interactions

The function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate the fractional part of real and complex numbers:

```
frac(1234), frac(123/4), frac(1.234)
```

$$0,\ \frac{3}{4},\ 0.234$$

```
frac(-1234), frac(-123/4), frac(-1.234)
```

$$0,\ \frac{1}{4},\ 0.766$$

```
frac(3/2 + 7/4*I), frac(4/3 + 1.234*I)
```

$$\frac{1}{2}+\frac{3\,i}{4},\ 0.3333333333+0.234\,i$$

The fractional part of a symbolic numerical expression is returned as a floating-point value:

```
frac(exp(123)), frac(3/4*sin(1) + I*tan(3))
```

$$0.7502040793,\ 0.6311032386+0.8574534569\,i$$

Expressions with symbolic identifiers produce symbolic function calls:

```
frac(x), frac(sin(1) + x^2), frac(exp(-x))
```

$$\mathrm{frac}(x),\ \mathrm{frac}(x^2+\sin(1)),\ \mathrm{frac}\left(e^{-x}\right)$$

Example 2

Care should be taken when computing the fractional part of floating-point numbers of large absolute value:

```
10^13/3.0
```

$$3.333333333\ 10^{12}$$

Note that only the first 10 decimal digits are “significant”. Further digits are subject to round-off effects caused by the internal binary representation. These “insignificant” digits can enter the fractional part:

```
frac(10^13/3.0)
```

$$0.3333282471$$

The mantissa of the next floating-point number does not have enough digits to store “digits after the decimal point”:

```
floor(10^25/9.0), ceil(10^25/9.0), frac(10^25/9.0)
```

$$1111111111111111109246976,\ 1111111111111111109246976,\ 0.0$$

Example 3

Exact numerical expressions are converted to floating-point numbers. Consequently, the present setting of `DIGITS` affects the result:

```
x := 10^30 - exp(30)^ln(10) + 1/3
```

$$\frac{3000000000000000000000000000001}{3} - (e^{30})^{\ln(10)}$$

Note that the exact value of this number is $\frac{1}{3}$. Floating-point evaluation can be subject to severe cancellation:

```
DIGITS := 24: frac(x)
```

$$0.765625$$

The floating-point result is more accurate when a higher precision used:

```
DIGITS := 30: frac(x)
```

```
      0.33333364129066467285156250
```

```
delete x, DIGITS:
```

Parameters

x

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

x

See Also

MuPAD Functions
`floor`

frandom

Generate random floating-point numbers

Syntax

```
frandom()
```

```
frandom(seed)
```

Description

`frandom()` returns a pseudo-random floating point number from the interval $[0.0, 1.0)$.

`frandom(seed)` returns a generator of pseudo-random floating-point numbers from the interval $[0.0, 1.0)$.

The calls `frandom()` produce uniformly distributed floating-point numbers from the interval $[0.0, 1.0)$.

`r := frandom(seed)` produces a random number generator `r`. Subsequent calls `r()` return uniformly distributed floating-point numbers from the interval $[0.0, 1.0)$.

Different generators created with the same integer seed generate the same sequences of numbers. See “Example 3” on page 1-813 and “Example 4” on page 1-813.

Generators created with `CurrentTime` use the time (in milliseconds) at their creation as their seed values. Generators created shortly after one another may thus return the same numbers.

Generators created in separate calls to `frandom` do not influence one another.

As for all functions returning floating point numbers, `frandom` reacts to `DIGITS` and returns numbers with the precision set by this variable.

Each time MuPAD is started or re-initialized with the `reset` function, random generators not using `CurrentTime` produce the same sequence of numbers.

`frandom` is the recommended function for generating uniform random floating-point numbers. It is much faster than the function `random` which produces uniform integer numbers.

Note: In contrast to `random`, `frandom` does not react to the environment variable `SEED`.

The function `stats::uniformRandom` allows to produce uniformly distributed floating-point numbers on arbitrary finite intervals. The stats library also provides random generators with various other distributions.

Environment Interactions

`frandom` and the procedures returned by `frandom` are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

`frandom` changes its internal state when generating a number and will thus produce a different number on the next call.

Examples

Example 1

The following call produces a sequence of pseudo-random numbers. Note that an index variable `i` must be used in the construction of the sequence. A call such as `frandom() $8` would produce 8 copies of the same random value:

```
frandom() $ i = 1..8
```

```
0.2703581656, 0.8310371787, 0.153156516, 0.9948127808, 0.2662729021, 0.1801642277,
  0.452083055, 0.6787819563
```

Example 2

`frandom` reacts to `DIGITS`, producing numbers which are equally random in the later digits as in the beginning ones:

```
DIGITS := 200: frandom(), frandom()
```

```
0.35498492614062364307860547970996890040547017454106048832367331188029835842270297\

```

```
delete DIGITS:
```

Example 3

`frandom(seed)`, for some integer value of `seed`, returns a generator of floating-point numbers. For different generators created with the same seed, the sequences of numbers will be identical (apart from the digits cut off when producing numbers at lower settings of `DIGITS`):

```
r1 := frandom(42):
r2 := frandom(42):
r3 := frandom(42):
r1() $ i=1..4;
r2() $ i=1..4;
DIGITS := 20:
r3() $ i=1..4;
```

```
0.9239565296, 0.7847883691, 0.1939738073, 0.8908726445

0.9239565296, 0.7847883691, 0.1939738073, 0.8908726445

0.92395652959956197579, 0.78478836910657330549, 0.19397380730447780085,
  0.89087264450316274217
```

```
delete r1, r2, r3, DIGITS:
```

Example 4

Usually, `frandom` is used to generate experimental input or “random” examples. In these cases, reproducibility is a good thing. However, on occasion a “more random” sequence is

desirable. The usual way to get a random seed in a program is to use the current system time, which can be done by using `CurrentTime` as the value of seed:

```
r := frandom(CurrentTime):

r(), r(), r(), r()
```

```
0.794272125, 0.9179931363, 0.2210726413, 0.7790319119
```

Parameters

`seed`

An initialization value for the generator: an integer or the option `CurrentTime`

Return Values

`frandom()` returns a floating point number; `frandom(seed)` returns a procedure (a pseudo-random number generator).

Algorithms

`frandom` uses a linear congruence generator to directly manipulate the internal representation of a `DOM_FLOAT`.

MuPAD Functions

`random` | `stats::uniformRandom`

fread

Read and execute file

Syntax

```
fread(filename | n, <Quiet>, <Plain>, <Encoding = "encodingValue">)
```

Description

`fread(file)` reads and executes a MuPAD file.

`fread(filename)` reads the file and evaluates each MuPAD statement in the file. If the filename ends in "`.gz`" and the file is in `gzip`-compressed format, it will be transparently uncompressed upon reading. `fread` automatically opens the file, performs the read operation, and closes the file.

`fread(..., Encoding = "encodingValue")` uses the specified encoding. For supported encodings, see "Options" on page 1-819. You can use this option with the previously specified syntaxes.

`fread` is similar to `read`. The only difference is that `fread` does not search for files in the folders given by `READPATH` and by the library path; `fread` only searches for the file relative to the "working folder."

Note that the meaning of "working folder" depends on the operating system. On Windows systems and on Mac OS X systems, the "working folder" is the folder where MATLAB is installed. On UNIX systems, it is the current working folder in which MATLAB was started. When started from a menu or desktop item, this is typically the user's home folder.

Also absolute path names are processed by `fread`.

`fread` can read MuPAD binary files (created via `fprint` or `write`) as well as ASCII text files. `fread` recognizes the format of the file automatically.

Instead of a file name, a file descriptor of a file opened via `fopen` can also be used. See "Example 3" on page 1-818. When a file descriptor is used, `fread` does not automatically open and close the file. `fclose` must be used to close the file.

When a file is read with `fread`, the variable `FILEPATH` contains the path of the file.

Examples

Example 1

Create a new file in the system's temporary folder. The name of the temporary folder varies for different platforms. The `fopen` command with the `TempFile` option creates a file in any system's temporary folder (if such folder exists):

```
fid := fopen(TempFile, Write, Text):
fprint(Unquoted, fid, "a := 3; b := 5; a + b;"):
```

Use `fname` to return the name of the temporary file you created. Use `fclose` to close the file:

```
file := fname(fid):
fclose(fid)
```

When reading the file, MuPAD executes the statements. Each produces a print output. The second `8` below is the return value of `fread`:

```
delete a, b:
fread(file);
```

```
    3

    5

    8

    8
```

Now, the variables `a` and `b` have the values assigned inside the file:

```
a, b
```

```
    3, 5
```

With the option `Quiet`, only the return value of `fread` is printed:

```
delete a, b:
fread(file, Quiet)
```

```
    8
```

```
delete a, b:
```

Example 2

The next example demonstrates the option `Plain`. First, an appropriate input file is created:

```
fid := fopen(TempFile, Write, Text):
fprint(Unquoted, fid,
       "f := proc(x) begin x^2 end_proc:",
       "a := f(3): b := f(4):"):
file := fname(fid):
fclose(fid)
```

Define an `alias` for `f`:

```
alias(f = "some text"):
```

An error occurs if you try to read the file without the option `Plain`. In the parser context of the MuPAD session, the alias replaces `f` by the corresponding string in the assignment `f := ...`. However, strings cannot be assigned a value:

```
fread(file)
```

```
Error: Invalid left-hand side. [_assign]
  Reading File: /tmp/mupad.351omQ
```

With the option `Plain`, no such error arises: the alias for `f` is ignored by `fread`:

```
fread(file, Plain):
a, b
```

$9, 16$

```
unalias(f):
delete f, a, b:
```

Example 3

You use `write` to save the value of the identifier `a` in a temporary file:

```
a := PI + 1:
fid := fopen(TempFile, Write, Text):
file := fname(fid):
write(file, a):
delete a:
```

This file is opened for reading with `fopen`:

```
n := fopen(file):
```

The file descriptor returned by `fopen` can be passed to `fread`. Reading the file restores the value of `a`:

```
fread(n):
a
```

$\pi + 1$

```
fclose(n):
delete a:
```

Example 4

To specify the encoding for reading data, use Encoding. The Encoding option applies only to text files that are opened using a file name and not a file descriptor. Open a temporary file and write the statement `str := "abcäöü"` in the encoding “`UTF-8`”:

```
fprint(Unquoted, Text, Encoding="UTF-8",
                       "fread_test",
                       "str := \"abcäöü\"")
```

Specify the encoding to read the file. `fread` executes the statement:

```
fread("fread_test", Encoding="UTF-8"):

    "abcäöü"
```

If you do not specify an encoding, the default system encoding is used. Thus, your output might vary from that shown next. Characters unrecognized by the default system encoding are replaced by the default substitution character for that encoding:

```
fread("fread_test"):

    "abc??????"
```

Parameters

`filename`

The name of a file: a character string

`n`

A file descriptor provided by `fopen`: a positive integer

Options

`Plain`

Makes `fread` use its own parser context

With this option, the file is read in a new parser context. This means that the history, as returned by the command `history`, is not modified by the statements in the file. Further, abbreviations set outside the file via `alias` or user-defined operators are ignored during the execution of the file. This option is useful for reading initialization files in a clean environment.

`Quiet`

Suppresses output during execution of `fread`

With this option, output is suppressed while reading and executing the file. However, warnings and error messages as well as the output of `print` commands are still visible.

`Encoding`

This option lets you specify the character encoding to use. The allowed encodings are:

`"Big5"`	`"ISO-8859-1"`	`"windows-932"`
`"EUC-JP"`	`"ISO-8859-2"`	`"windows-936"`
`"GBK"`	`"ISO-8859-3"`	`"windows-949"`
`"KSC_5601"`	`"ISO-8859-4"`	`"windows-950"`
`"Macintosh"`	`"ISO-8859-9"`	`"windows-1250"`
`"Shift_JIS"`	`"ISO-8859-13"`	`"windows-1251"`
`"US-ASCII"`	`"ISO-8859-15"`	`"windows-1252"`
`"UTF-8"`		`"windows-1253"`
		`"windows-1254"`
		`"windows-1257"`

The default encoding is system dependent. If you specify the encoding incorrectly, characters might read incorrectly. Characters unrecognized by the encoding are replaced by the default substitution character for the specified encoding.

Encodings not listed here can be specified but might not produce correct results.

Return Values

Return value of the last statement of the file.

freeIndets

Free indeterminates of an expression

Syntax

```
freeIndets(object, <All>)
```

Description

`freeIndets(object)` returns the free indeterminates of `object` as a set.

An identifier occurring in `object` is free if it cannot be replaced by another identifier without changing the mathematical meaning of `object`.

By default, `freeIndets` does not return free identifiers that occur only in the `0`th operand of subexpressions of `object`.

The special identifiers `PI`, `EULER`, `CATALAN` are not free indeterminates. See “Example 1” on page 1-821.

If `object` is a polynomial, a function environment, a procedure, or a built-in kernel function, then `freeIndets` returns the empty set. See “Example 3” on page 1-822.

Examples

Example 1

Find free identifiers in the following image set. In this set, `PI` is a mathematical constant; therefore, it is not a free identifier. The operand `f` is a `0`th operand. The variable `k` is not a free identifier because you can replace it by any other letter like `m` or `n` without changing the mathematical meaning. Therefore, only `u` is a free identifier:

```
e:= Dom::ImageSet(k*f(u)+PI, k, Z_)
```

$$\{\pi + k\, f(u) \mid k \in \mathbb{Z}\}$$

```
freeIndets(e)
```

$$\{u\}$$

To find all identifiers in the same image set, use `indets`:

```
indets(e)
```

$$\{\pi, k, u\}$$

Example 2

Use the `All` option to return free identifiers including the `0`th operands of subexpressions. For example, compare the sets of free identifiers returned by `freeIndets` with the `All` option and without this option:

```
e := Dom::ImageSet(k*f(u)+PI, k, Z_):
freeIndets(e, All);
freeIndets(e)
```

$$\{\_mult, \_plus, f, u\}$$

$$\{u\}$$

Example 3

`freeIndets` assumes that polynomials and functions do not have free indeterminates:

```
delete x, y:
freeIndets(poly(x*y, [x, y])),
freeIndets(sin),
freeIndets(x -> x^2+1)
```

$$\varnothing, \varnothing, \varnothing$$

Parameters

`object`

An arbitrary object

Options

`All`

Do not exclude free identifiers that occur in the `0`th operand of subexpressions of `object`.

With this option, `freeIndets` does not exclude the `0`th operand. If the `0`th operand of a subexpression is an indeterminate, such as `sin`, the `freeIndets` function includes this operand in the result. See “Example 2” on page 1-822.

Return Values

set of identifiers.

Overloaded By

object

Algorithms

If `object` is an element of a library domain `T` that has a slot `"freeIndets"`, then MuPAD calls the slot routine `T::freeIndets` with `object` as an argument. You can use this approach to extend the functionality of `freeIndets` to user-defined domains. If no such slot exists, then `freeIndets` regards all identifiers occurring in elements of that domain as free, with the exception of mathematical constants.

`domtype` | `indets` | `op` | `type` | `Type::Indeterminate`

freeze

Create an inactive copy of a function

Syntax

```
freeze(f)
```

Description

`freeze(f)` creates an inactive copy of the function `f`.

`ff := freeze(f)` returns a function that is an "inactive" copy of the argument `f`. This means:

1. `ff` only evaluates its arguments, but does not compute anything else,
2. `ff` is printed in the same way as `f`,
3. symbolic `ff` calls have the same type as symbolic `f` calls,
4. if `f` is a function environment, then `ff` has all the slots of `f`.

Note that `ff` evaluates its incoming parameters even if the function `f` has the procedure option `hold`.

`freeze` can be used when many operations with `f` are to be performed that require `f` only in its symbolic form, but `f` need not be executed.

Neither `eval` nor `level` can enforce the evaluation of an inactive function. See "Example 2" on page 1-825.

Examples

Example 1

We create an inactive form of the function environment `int`:

```
_int := freeze(int): F := _int(x*exp(x^2), x = 0..1)
```

$$\int_0^1 x\, e^{x^2}\, dx$$

The inactive form of `int` keeps every information that is known about the function `int`, e.g., the output, the type, and the `"float"` slot for floating-point evaluation:

```
F, type(F), float(F)
```

$$\int_0^1 x\, e^{x^2}\, dx,\ \text{"int"},\ 0.8591409142$$

The original function environment `int` is not modified by `freeze`:

```
int(x*exp(x^2), x = 0..1)
```

$$\frac{e}{2} - \frac{1}{2}$$

Use `unfreeze` to reactivate the inactive function `_int` and evaluate the result:

```
unfreeze(F), unfreeze(F + 1/2)
```

$$\frac{e}{2} - \frac{1}{2},\ \frac{e}{2}$$

Example 2

We demonstrate the difference between `hold` and `freeze`. The result of the command `S := hold(sum)(...)` does not contain an inactive version of `sum`, but the unevaluated identifier`sum`:

```
S := hold(sum)(1/n^2, n = 1..infinity)
```

$$\sum_{n=1}^{\infty} \frac{1}{n^2}$$

The next time S is evaluated, the identifier sum is replaced by its value, the function environmentsum, and the procedure computing the value of the infinite sum is invoked:

```
S
```

$$\frac{\pi^2}{6}$$

In contrast, evaluation of the result of freeze does not lead to an evaluation of the inactive function:

```
S := freeze(sum)(1/n^2, n = 1..infinity)
```

$$\sum_{n=1}^{\infty} \frac{1}{n^2}$$

```
S
```

$$\sum_{n=1}^{\infty} \frac{1}{n^2}$$

An inactive function does not even react to eval:

```
eval(S)
```

$$\sum_{n=1}^{\infty} \frac{1}{n^2}$$

The only way to undo a freeze is to use unfreeze, which reactivates the inactive function in S and then evaluates the result:

```
unfreeze(S)
```

$$\frac{\pi^2}{6}$$

Example 3

Note that `freeze(f)` does not change the object `f` but returns a copy of `f` in an inactive form. This means that computations with the inactive version of `f` may contain the original function `f`.

For example, if we create an inactive version of the sine function:

```
Sin := freeze(sin):
```

and expand the term `Sin(x+y)`, then the result is expressed in terms of the (original) sine function `sin`:

```
expand(Sin(x + y))
```

$$\cos(x)\,\sin(y) + \cos(y)\,\sin(x)$$

Example 4

The function `unfreeze` uses `misc::maprec` to operate recursively along the structure of `object`. For example, if `object` is an array containing inactive functions, such as:

```
a := array(1..2,
  [freeze(int)(sin(x), x = 0..2*PI), freeze(sum)(k^2, k = 1..n)]
)
```

$$\left(\int_0^{2\,\pi} \sin(x)\,\mathrm{d}\,x \quad \sum_{k=1}^{n} k^2 \right)$$

then `unfreeze(a)` operates on the operands of `a`:

```
unfreeze(a)
```

$$\left(0 \quad \frac{n\,(2\,n+1)\,(n+1)}{6} \right)$$

This means that for library domains, the effect of `unfreeze` is specified by the method `"maprec"`. If the domain does not implement this method, then `unfreeze` does not operate on the objects of this domain. For example, we create a dummy domain and an object containing an inactive function as its operand:

```
dummy := newDomain("dummy"):
o := new(dummy, freeze(int)(sin(x), x = 0..2*PI))
```

$$\mathrm{new}\left(\mathrm{dummy}, \int_0^{2\pi} \sin(x)\,\mathrm{d}x\right)$$

The function `unfreeze` applied to the object `o` has no effect:

```
unfreeze(o)
```

$$\mathrm{new}\left(\mathrm{dummy}, \int_0^{2\pi} \sin(x)\,\mathrm{d}x\right)$$

If we overload the function `misc::maprec` in order to operate on the first operand of objects of the domain `dummy`, then `unfreeze` operates on `o` as desired:

```
dummy::maprec :=
  x -> extsubsop(x,
    1 = misc::maprec(extop(x,1), args(2..args(0)))
  ):
unfreeze(o)
```

$$\mathrm{new}(\mathrm{dummy}, 0)$$

Parameters

`f`

A procedure or a function environment

Return Values

`freeze` returns an object of the same type as `f`. `unfreeze` returns the evaluation of `object` after reactivating all inactive functions in it.

See Also

MuPAD Functions
`eval` | `hold` | `MAXDEPTH` | `unfreeze`

unfreeze

Create an active copy of a frozen function

Syntax

```
unfreeze(object)
```

Description

`unfreeze(object)` reactivates all inactive functions occurring in `object`, proceeding recursively along the structure of `object`, and then evaluates the result.

`unfreeze` uses `misc::maprec` to proceed recursively along the structure of `object`. This means that for basic domains such as arrays, tables, lists, or polynomials, the function `unfreeze` is applied to each operand of `object`.

Note that if `object` is an element of a library domain, then the behavior of `unfreeze` is specified by the method `"maprec"` which overloads the function `misc::maprec`. If this method does not exist, then `unfreeze` has no effect on `object`. See “Example 4” on page 1-833.

`unfreeze` does not operate on the body of procedures, therefore it is recommended not to embed inactive functions inside procedures.

Examples

Example 1

We create an inactive form of the function environment `int`:

```
_int := freeze(int): F := _int(x*exp(x^2), x = 0..1)
```

$$\int_0^1 x\, e^{x^2}\, dx$$

The inactive form of `int` keeps every information that is known about the function `int`, e.g., the output, the type, and the `"float"` slot for floating-point evaluation:

```
F, type(F), float(F)
```

$$\int_0^1 x\, e^{x^2}\, dx,\ \text{"int"},\ 0.8591409142$$

The original function environment `int` is not modified by `freeze`:

```
int(x*exp(x^2), x = 0..1)
```

$$\frac{e}{2} - \frac{1}{2}$$

Use `unfreeze` to reactivate the inactive function `_int` and evaluate the result:

```
unfreeze(F), unfreeze(F + 1/2)
```

$$\frac{e}{2} - \frac{1}{2},\ \frac{e}{2}$$

Example 2

We demonstrate the difference between `hold` and `freeze`. The result of the command `S := hold(sum)(...)` does not contain an inactive version of `sum`, but the unevaluated identifier`sum`:

```
S := hold(sum)(1/n^2, n = 1..infinity)
```

$$\sum_{n=1}^{\infty} \frac{1}{n^2}$$

The next time `S` is evaluated, the identifier `sum` is replaced by its value, the function environment`sum`, and the procedure computing the value of the infinite sum is invoked:

```
S
```

$$\frac{\pi^2}{6}$$

In contrast, evaluation of the result of `freeze` does not lead to an evaluation of the inactive function:

```
S := freeze(sum)(1/n^2, n = 1..infinity)
```

$$\sum_{n=1}^{\infty} \frac{1}{n^2}$$

```
S
```

$$\sum_{n=1}^{\infty} \frac{1}{n^2}$$

An inactive function does not even react to `eval`:

```
eval(S)
```

$$\sum_{n=1}^{\infty} \frac{1}{n^2}$$

The only way to undo a `freeze` is to use `unfreeze`, which reactivates the inactive function in `S` and then evaluates the result:

```
unfreeze(S)
```

$$\frac{\pi^2}{6}$$

Example 3

Note that `freeze(f)` does not change the object `f` but returns a copy of `f` in an inactive form. This means that computations with the inactive version of `f` may contain the original function `f`.

For example, if we create an inactive version of the sine function:

```
Sin := freeze(sin):
```

and expand the term `Sin(x+y)`, then the result is expressed in terms of the (original) sine function `sin`:

```
expand(Sin(x + y))
```

$$\cos(x)\,\sin(y) + \cos(y)\,\sin(x)$$

Example 4

The function `unfreeze` uses `misc::maprec` to operate recursively along the structure of `object`. For example, if `object` is an array containing inactive functions, such as:

```
a := array(1..2,
  [freeze(int)(sin(x), x = 0..2*PI), freeze(sum)(k^2, k = 1..n)]
)
```

$$\left(\int_0^{2\,\pi} \sin(x)\,\mathrm{d}\,x \quad \sum_{k=1}^{n} k^2 \right)$$

then `unfreeze(a)` operates on the operands of `a`:

```
unfreeze(a)
```

$$\left(0 \quad \frac{n\,(2\,n+1)\,(n+1)}{6} \right)$$

This means that for library domains, the effect of `unfreeze` is specified by the method `"maprec"`. If the domain does not implement this method, then `unfreeze` does not operate on the objects of this domain. For example, we create a dummy domain and an object containing an inactive function as its operand:

```
dummy := newDomain("dummy"):
o := new(dummy, freeze(int)(sin(x), x = 0..2*PI))
```

$$\mathrm{new}\left(\mathrm{dummy},\ \int_0^{2\,\pi} \sin(x)\,\mathrm{d}\,x \right)$$

The function `unfreeze` applied to the object `o` has no effect:

```
unfreeze(o)
```

$$\text{new}\left(\text{dummy}, \int_0^{2\pi} \sin(x)\, \mathrm{d}x\right)$$

If we overload the function `misc::maprec` in order to operate on the first operand of objects of the domain `dummy`, then `unfreeze` operates on `o` as desired:

```
dummy::maprec :=
  x -> extsubsop(x,
    1 = misc::maprec(extop(x,1), args(2..args(0)))
  ):
unfreeze(o)
```

$$\text{new}(\text{dummy}, 0)$$

Parameters

`object`

Any MuPAD object

Return Values

`freeze` returns an object of the same type as `f`. `unfreeze` returns the evaluation of `object` after reactivating all inactive functions in it.

See Also

MuPAD Functions

`eval` | `freeze` | `hold` | `MAXDEPTH`

fresnelC

The Fresnel cosine integral function

Syntax

```
fresnelC(z)
```

Description

`fresnelC(z)` = $\int_0^z \cos\left(\frac{\pi t^2}{2}\right) \mathrm{d}\, t$.

The function C = `fresnelC` is analytic throughout the complex plane. It satisfies `fresnelC(-z) = -fresnelC(z)`, `fresnelC(conjugate(z)) = conjugate(fresnelC(z))`, `fresnelC(I*z) = I*fresnelC(z)` for all complex values of z.

`fresnelC(z)` returns special values for $z = 0$, $z = \pm\infty$, and $z = \pm i\,\infty$. Symbolic function calls are returned for all other symbolic values of z. In the graphical user interface of MuPAD symbolic function calls are typeset as `fresnelC(z)` = $C(z)$.

When called with floating-point arguments, the function returns floating-point values.

With `simplify` and `Simplify`, the reflection rule `fresnelC(-z) = -fresnelC(z)` is used to create a "normal form" of symbolic function calls. Cf. "Example 3" on page 1-837.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We call the Fresnel functions with various arguments: Symbolic calls are typeset as `fresnelC(z)` = $C(z)$ and `fresnelS(z)` = $S(z)$, respectively:

```
fresnelC(0),
fresnelC(1),
fresnelC(PI + I),
fresnelC(z),
fresnelC(infinity)
```

$$0,\ C(1),\ C(\pi + i),\ C(z),\ \frac{1}{2}$$

```
fresnelS(0),
fresnelS(1),
fresnelS(PI + I),
fresnelS(z),
fresnelS(infinity)
```

$$0,\ S(1),\ S(\pi + i),\ S(z),\ \frac{1}{2}$$

Floating point values are returned for floating-point arguments:

```
fresnelC(1.0),
fresnelC(float(PI)),
fresnelS(-3.45 + 0.75*I)
```

$$0.7798934004,\ 0.5236985437,\ 101.6764728 - 115.6164932\,i$$

Example 2

The functions `diff`, `float`, `limit`, and `series` handle expressions involving the Fresnel functions:

```
diff(fresnelC(x), x),
diff(fresnelS(x), x)
```

$$\cos\left(\frac{\pi x^2}{2}\right), \sin\left(\frac{\pi x^2}{2}\right)$$

```
float(fresnelC(PI)),
float(fresnelS(-100))
```

$$0.5236985437, -0.4968169011$$

```
limit(fresnelC(x), x = infinity),
limit(fresnelS(x), x = -infinity)
```

$$\frac{1}{2}, -\frac{1}{2}$$

```
series(fresnelC(x), x = 0),
series(fresnelS(x), x = infinity, 4)
```

$$x - \frac{\pi^2 x^5}{40} + O(x^7), \frac{1}{2} - \frac{\cos\left(\frac{\pi x^2}{2}\right)}{\pi x} - \frac{\sin\left(\frac{\pi x^2}{2}\right)}{\pi^2 x^3} + O\left(\frac{1}{x^4}\right)$$

Example 3

With `simplify` and `Simplify`, the reflection rules `fresnelC(-z) = -fresnelC(z)` and `fresnelS(-z) = -fresnelS(z)` are used to create a “normal form” of symbolic function calls:

```
Simplify(fresnelC(1 - x)),
Simplify(fresnelC(x - 1))
```

$$-C(x-1), C(x-1)$$

```
3*fresnelS(z) + 2*fresnelS(-z)
```

$$2\,S(-z) + 3\,S(z)$$

```
Simplify(%)
```

$S(z)$

Parameters

z

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

z

MuPAD Functions
`fresnelS`

fresnelS

The Fresnel sine integral function

Syntax

```
fresnelS(z)
```

Description

`fresnelS(z)` = $\int_0^z \sin\left(\frac{\pi t^2}{2}\right) dt$.

The function S = `fresnelS` is analytic throughout the complex plane. It satisfies `fresnelS(-z) = -fresnelS(z)`, `fresnelS(conjugate(z)) = conjugate(fresnelS(z))`, `fresnelS(I*z) =-I*fresnelS(z)` for all complex values of z.

`fresnelS(z)` returns special values for $z = 0$, $z = \pm\infty$, and $z = \pm i\,\infty$. Symbolic function calls are returned for all other symbolic values of z. In the graphical user interface of MuPAD symbolic function calls are typeset as `fresnelS(z)` = $S(z)$.

When called with floating-point arguments, the function returns floating-point values.

With `simplify` and `Simplify`, the reflection rule `fresnelS(-z) = -fresnelS(z)` is used to create a "normal form" of symbolic function calls. Cf. "Example 3" on page 1-841.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We call the Fresnel functions with various arguments: Symbolic calls are typeset as `fresnelC(z)` = $C(z)$ and `fresnelS(z)` = $S(z)$, respectively:

```
fresnelC(0),
fresnelC(1),
fresnelC(PI + I),
fresnelC(z),
fresnelC(infinity)
```

$$0,\ C(1),\ C(\pi + i),\ C(z),\ \frac{1}{2}$$

```
fresnelS(0),
fresnelS(1),
fresnelS(PI + I),
fresnelS(z),
fresnelS(infinity)
```

$$0,\ S(1),\ S(\pi + i),\ S(z),\ \frac{1}{2}$$

Floating point values are returned for floating-point arguments:

```
fresnelC(1.0),
fresnelC(float(PI)),
fresnelS(-3.45 + 0.75*I)
```

$$0.7798934004,\ 0.5236985437,\ 101.6764728 - 115.6164932\,i$$

Example 2

The functions `diff`, `float`, `limit`, and `series` handle expressions involving the Fresnel functions:

```
diff(fresnelC(x), x),
diff(fresnelS(x), x)
```

$$\cos\left(\frac{\pi x^2}{2}\right), \sin\left(\frac{\pi x^2}{2}\right)$$

```
float(fresnelC(PI)),
float(fresnelS(-100))
```

$$0.5236985437, -0.4968169011$$

```
limit(fresnelC(x), x = infinity),
limit(fresnelS(x), x = -infinity)
```

$$\frac{1}{2}, -\frac{1}{2}$$

```
series(fresnelC(x), x = 0),
series(fresnelS(x), x = infinity, 4)
```

$$x - \frac{\pi^2 x^5}{40} + O(x^7), \frac{1}{2} - \frac{\cos\left(\frac{\pi x^2}{2}\right)}{\pi x} - \frac{\sin\left(\frac{\pi x^2}{2}\right)}{\pi^2 x^3} + O\left(\frac{1}{x^4}\right)$$

Example 3

With `simplify` and `Simplify`, the reflection rules `fresnelC(-z) = -fresnelC(z)` and `fresnelS(-z) = -fresnelS(z)` are used to create a “normal form” of symbolic function calls:

```
Simplify(fresnelC(1 - x)),
Simplify(fresnelC(x - 1))
```

$$-C(x-1), C(x-1)$$

```
3*fresnelS(z) + 2*fresnelS(-z)
```

$$2\,S(-z) + 3\,S(z)$$

```
Simplify(%)
```

$S(z)$

Parameters

z

An arithmetical expression

Return Values

Arithmetical expression.

MuPAD Functions
`fresnelC`

ftextinput

Read text file

Syntax

```
ftextinput(filename | n, <Encoding = "encodingValue">)
```

```
ftextinput(filename | n, x1, x2, …, <Encoding = "encodingValue">)
```

Description

`ftextinput(file, x)` reads a line from a text file, interprets the line as a string and assigns this string to the identifier `x`.

`ftextinput(filename)` reads the first line of the text file and returns it as a string to the MuPAD session. If the file is in `gzip`-compressed format and its name ends in "`.gz`", it will be transparently uncompressed upon reading.

`ftextinput(filename, x1, x2, ...)` reads the file line by line. The *i*-th line is converted to a character string and assigned to the identifier x_i. The identifiers are not evaluated while executing `ftextinput`; previously assigned values are overwritten.

`fread(..., Encoding = "encodingValue")` uses the specified encoding. For the supported encodings, see "Options" on page 1-847. You can use this option with any of the previously specified syntaxes.

Instead of a file name, also a file descriptor `n` of a file opened via `fopen` can be used. The functionality is as described above. However, there is one difference: With a file name, `ftextinput` automatically opens the file, performs the operation, and closes the file. A subsequent call to `ftextinput` starts at the beginning of the file. With a file descriptor, the file remains open (use `fclose` to close the file). The next time data are read from this file, the reading continues at the current position. Consequently, a file descriptor should be used, if the individual lines in the file are to be read via several subsequent calls of `ftextinput`. Cf. "Example 2" on page 1-845.

If the number of identifiers specified in the `ftextinput` call is larger than the number of lines in the file, the exceeding identifiers are not assigned any values. In such a case, `ftextinput` returns the void object of type `DOM_NULL`.

`ftextinput` interprets the file name as a pathname relative to the "working directory."

Note that the meaning of "working directory" depends on the operating system. On Windows systems and on Mac OS X systems, the "working directory" is the folder where MATLAB is installed. On UNIX systems, it is the current working directory in which MATLAB was started. When started from a menu or desktop item, this is typically the user's home directory.

Also absolute path names are processed by `ftextinput`.

Expression sequences are not flattened by `ftextinput` and cannot be used to pass several identifiers to `ftextinput`. Cf. "Example 3" on page 1-846.

Examples

Example 1

Use `fprint` to create a text file with three lines:

```
fid := fopen(TempFile, Write, Text):
fprint(Unquoted, fid, "x + 1\n2nd line\n3rd line"):
file := fname(fid):
```

Read the first two lines of the file and assign the corresponding strings to the identifiers `x1` and `x2`:

```
ftextinput(file, x1, x2):
x1, x2
```

```
"x + 1", "2nd line"
```

If you try to read beyond the last line of the file, `ftextinput` returns the void object of type `DOM_NULL`:

```
ftextinput(file, x1, x2, x3, x4); domtype(%)
```

```
DOM_NULL
```

```
x1, x2, x3, x4
```

```
     "x + 1", "2nd line", "3rd line", x4
```

```
delete x1, x2, x3:
```

Example 2

Read some lines from a file using several calls of `ftextinput`. You have to use a file descriptor for reading from the file. The file is opened for reading with `fopen`:

```
fid := fopen(TempFile, Write, Text):
fprint(Unquoted, fid,
       "x + 1\nx + 2\n3rd line\n4th line"):
file := fname(fid):

n := fopen(file):
```

The file descriptor returned by `fopen` can be passed to `ftextinput` for reading the data:

```
ftextinput(n, x1, x2):
x1, x2
```

```
     "x + 1", "x + 2"
```

```
ftextinput(n, x3, x4):
x3, x4
```

```
     "3rd line", "4th line"
```

Finally, close the file and delete the identifiers:

```
fclose(n):
delete n, x1, x2, x3, x4:
```

Alternatively, the contents of a file can be read into a MuPAD session in the following way:

```
n := fopen(file):
for i from 1 to 4 do
   x.i := ftextinput(n)
end_for:
x1, x2, x3, x4
```

```
     "x + 1", "x + 2", "3rd line", "4th line"

fclose(n):
delete n, i, x1, x2, x3, x4:
```

Example 3

Expression sequences are not flattened by `ftextinput` and cannot be used to pass identifiers to `ftextinput`:

```
fid := fopen(TempFile, Write, Text):
fprint(Unquoted, fid, "1st line\n2nd line\n3rd line"):
file := fname(fid):
ftextinput(file, (x1, x2), x3)

Error: The argument is invalid. [ftextinput]
```

The following call does not lead to an error because the identifier `x12` is not evaluated. Consequently, only one line is read from the file and assigned to `x12:`

```
x12 := x1, x2:
ftextinput(file, x12):
x1, x2, x12

     x1, x2, "1st line"

delete x12:
```

Example 4

To specify the encoding for reading data, use Encoding. The Encoding option applies only to text files that are opened using a file name and not a file descriptor. Open a temporary file and write the string `"abcäöü"` in the encoding “`UTF-8`”:

```
fprint(Unquoted, Text, Encoding = "UTF-8",
                       "ftextinput_test",
                       "abcäöü"):
```

Specify the encoding to read the file correctly:

```
ftextinput("ftextinput_test", Encoding="UTF-8")
```

```
"abcäöü"
```

If you do not specify an encoding, the default system encoding is used. Thus, your output might vary from that shown next. Characters unrecognized by the default system encoding are replaced by the default substitution character for that encoding:

```
ftextinput("ftextinput_test")
```

```
"abc??????"
```

Parameters

`filename`

The name of a file: a character string

`n`

A file descriptor provided by `fopen`: a positive integer

$x_1, x_2, \ldots$

identifiers

Options

`Encoding`

This option lets you specify the character encoding to use. The allowed encodings are:

`"Big5"`	`"ISO-8859-1"`	`"windows-932"`
`"EUC-JP"`	`"ISO-8859-2"`	`"windows-936"`
`"GBK"`	`"ISO-8859-3"`	`"windows-949"`
`"KSC_5601"`	`"ISO-8859-4"`	`"windows-950"`

"Macintosh"	"ISO-8859-9"	"windows-1250"
"Shift_JIS"	"ISO-8859-13"	"windows-1251"
"US-ASCII"	"ISO-8859-15"	"windows-1252"
"UTF-8"		"windows-1253"
		"windows-1254"
		"windows-1257"

The default encoding is system dependent. If you specify the encoding incorrectly, characters might read incorrectly. Characters unrecognized by the encoding are replaced by the default substitution character for the specified encoding.

Encodings not listed here can be specified but might not produce correct results.

Return Values

Last line that was read from the file: a character string or null().

funcenv

Create a function environment

Syntax

```
funcenv(f1, <f2>, <slotTable>)
```

Description

`funcenv(f)` creates a function environment from `f`.

`funcenv` serves for generating a function environment of domain type `DOM_FUNC_ENV`.

From a user's point of view, function environments are similar to procedures and can be called like any MuPAD function.

However, in contrast to simple procedures, a function environment allows a tight integration into the MuPAD system. In particular, standard system functions such as `diff`, `expand`, `float` etc. can be told how to act on symbolic function calls to a function environment.

For this, a function environment stores special function attributes (slots) in an internal table. Whenever an overloadable system function such as `diff`, `expand`, `float` encounters an object of type `DOM_FUNC_ENV`, its searches the function environment for a corresponding slot. If found, it calls the corresponding slot and returns the value produced by the slot.

Slots can be incorporated into the function environment by creating a table `slotTable` and passing this to `funcenv`, when the function environment is created. Alternatively, the function `slot` can be used to add further slots to an existing function environment.

See “Example 1” on page 1-850 below for further information.

The first argument `f1` of `funcenv` determines the evaluation of function calls. With `f:= funcenv(f1)`, the call `f(x)` returns the result `f1(x)`. Note that calls of the form `f:= funcenv(f)` are possible (and, in fact, typical). This call embeds the procedure `f` into a function environment of the same name. The original procedure `f` is stored internally in

the function environment `f`. After this call, further function attributes can be attached to `f` via the `slot` function.

The second argument `f2` of `funcenv` determines the screen output of symbolic function calls. Consider `f:= funcenv(f1, f2)`. If the call `f(x)` returns a symbolic function call `f(x)` with 0-th operand `f`, then `f2` is called: the return value of `f2(f(x))` is used as the screen output of `f(x)`.

Note: Beware: `f2(f(x))` should not produce a result containing a further symbolic call of `f`, because this will lead to an infinite recursion, causing an error message.

The third argument `slotTable` of `funcenv` is a table containing function attributes (slots). The table has to use strings as indices to address system functions. E.g.,

```
   slotTable := table("diff" = mydiff, "float" = myfloat):      f
:= funcenv(f1, f2, slotTable):
```

attaches the slot functions `mydiff` and `myfloat` to `f`. They are called by the system functions `diff` and `float`, respectively, whenever they encounter a symbolic expression `f(x)` with 0-th operand `f`. The internal slot table can be changed or filled with additional function attributes via the function `slot`.

If the first argument `f1` of `funcenv` is itself a function environment, then the return value is a physical copy of `f1`.

The documentation of `float`, `print`, and `slot` provides further examples involving function environments.

Examples

Example 1

We want to introduce a function `f` that represents a solution of the differential equation $f'(x) = x + \sin(x)\, f(x)$. First, we define a function `f`, which returns any call `f(x)` symbolically:

```
f := proc(x) begin procname(args()) end_proc: f(x), f(3 + y)
```

$$f(x),\ f(y+3)$$

Because of the differential equation $f'(x) = x + \sin(x)\, f(x)$, derivatives of `f` can be rewritten in terms of `f`. How can we tell the MuPAD system to differentiate symbolic functions calls such as `f(x)` accordingly? For this, we first have to embed the procedure `f` into a function environment:

```
f := funcenv(f):
```

The function environment behaves like the original procedure:

```
f(x), f(3 + y)
```

$$f(x),\ f(y+3)$$

System functions such as `diff` still treat symbolic calls of `f` as calls to unknown functions:

```
diff(f(x + 3), x)
```

$$f'(x+3)$$

However, as a function environment, `f` can receive attributes that overload the system functions. The following `slot` call attaches a dummy `"diff"` attribute to `f`:

```
f::diff := mydiff:  diff(2*f(x^2) + x, x)
```

$$2\ \mathrm{mydiff}(f(x^2),\ x) + 1$$

We attach a more meaningful `"diff"` attribute to `f` that is based on $f'(x) = x + \sin(x)\, f(x)$. Note that arbitrary calls `diff(f(y), x1, x2, ..)` have to be handled by this slot:

```
fdiff := proc(fcall) local y; begin
    y:= op(fcall, 1);
    (y + sin(y)*f(y))*diff(y, args(2..args(0)))
end_proc:
f := slot(f, "diff", fdiff):
```

Now, as far as differentiation is concerned, the function `f` is fully integrated into MuPAD:

```
diff(f(x), x), diff(f(x), x, x)
```

$$x + f(x)\,\sin(x),\ \cos(x)\,f(x) + \sin(x)\,(x + f(x)\,\sin(x)) + 1$$

```
diff(sin(x)*f(x^2), x)
```

$$f(x^2)\,\cos(x) + 2\,x\,\sin(x)\,(x^2 + f(x^2)\,\sin(x^2))$$

Since Taylor expansion around finite points only needs to evaluate derivatives, also Taylor expansions of `f` can be computed:

```
taylor(f(x^2), x = 0, 9)
```

$$f(0) + x^4\left(\frac{f(0)}{2} + \frac{1}{2}\right) + x^8\left(\frac{f(0)}{12} + \frac{1}{8}\right) + O(x^9)$$

```
delete f, fdiff:
```

Example 2

Suppose that you have defined a function `f` that may return itself symbolically, and you want such symbolic expressions of the form `f(x,...)` to be printed in a special way. To this end, embed your procedure`f` in a function environment and supply an output procedure as second argument to the corresponding `funcenv` call. Whenever an expression of the form `f(x,...)` is to be printed, the output procedure will be called with the arguments `x,...` of the expression:

```
f := funcenv(f,
         proc(x) begin
            if nops(x) = 2 then
              "f does strange things with its arguments ".
              expr2text(op(x, 1))." and ".expr2text(op(x,2))
            else
              FAIL
            end
         end):

delete a, b:
print(f(a, b)/2):
print(f(a, b, c)/2):
```

$$\frac{\text{f does strange things with its arguments a and b}}{2}$$

$$\frac{f(a, b, c)}{2}$$

```
delete f:
```

Parameters

`f1`

An arbitrary MuPAD object. Typically, a procedure. It handles the evaluation of a function call to the function environment.

`f2`

A procedure handling the screen output of symbolic function calls

`slotTable`

A table of function attributes (slots)

Return Values

Function environment of type `DOM_FUNC_ENV`.

Algorithms

Mathematical functions such as `exp`, `ln` etc. or `abs`, `Re`, `Im` etc. are implemented as function environments.

More About

- “Integrate Custom Functions into MuPAD”

funm

General matrix function

Syntax

```
funm(A,f)
```

Description

`funm(A,f)` computes the function `f(A)` for the square matrix `A`. For details, see "Algorithms" on page 1-858.

Examples

Example 1

Find a matrix `B`, such that $B^3 = A$, where `A` is the 3-by-3 identity matrix.

To solve $B^3 = A$, compute the cube root of the matrix `A` using the `funm` function. Create the function that computes the cube root of its argument, and use it as the second argument for `funm`. The cube root of an identity matrix is the identity matrix itself.

```
A := matrix::identity(3):
f := x -> surd(x, 3)
```

$$x \to \sqrt[3]{x}$$

```
funm(A, f)
```

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

Replace one of the `0` elements of matrix `A` with `1` and compute the matrix cube root again.

```
A[1, 2] := 1:
```

```
A
```

$$\begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

```
funm(A, f)
```

$$\begin{pmatrix} 1 & \frac{1}{3} & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

Now, compute the cube root of the upper triangular matrix.

```
A[1..2, 3] := [1, 1]:
A
```

$$\begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix}$$

```
B := funm(A, f)
```

$$\begin{pmatrix} 1 & \frac{1}{3} & \frac{2}{9} \\ 0 & 1 & \frac{1}{3} \\ 0 & 0 & 1 \end{pmatrix}$$

Verify that $B^3 = A$.

```
B^3 = A
```

$$\begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix}$$

Example 2

Find the matrix Lambert W function.

Create the 3-by-3 Pascal matrix `A`.

```
A := linalg::pascal(3)
```

$$\begin{pmatrix} 1 & 1 & 1 \\ 1 & 2 & 3 \\ 1 & 3 & 6 \end{pmatrix}$$

To find the Lambert W function (W_0 branch) in a matrix sense, call `funm` using `lambertW` as its second argument. Approximate the result with floating-point numbers by using `float`.

```
W0 := funm(float(A), lambertW)
```

$$\begin{pmatrix} 0.4715911292 & 0.2869500057 & 0.09584568317 \\ 0.2869500057 & 0.5196607317 & 0.5264174526 \\ 0.09584568317 & 0.5264174526 & 1.285252109 \end{pmatrix}$$

Verify that this result is a solution of the matrix equation $A = W0 \cdot e^{W0}$ within the current floating-point accuracy.

```
A = W0*exp(W0)
```

$$\begin{pmatrix} 1 & 1 & 1 \\ 1 & 2 & 3 \\ 1 & 3 & 6 \end{pmatrix} = \begin{pmatrix} 1.0 & 1.0 & 1.0 \\ 1.0 & 2.0 & 3.0 \\ 1.0 & 3.0 & 6.0 \end{pmatrix}$$

Now, find the W_{-1} branch of the Lambert W function for the matrix `A`. Create the function `f` representing the branch W_{-1} of the Lambert W function.

```
f := x -> lambertW(-1, x)
```

$$x \to W_{-1}(x)$$

Call `funm` using `f` as its second argument. Approximate the result with floating-point numbers by using `float`.

```
Wm1 := funm(float(A), f)
```

```
[[-2.116372833 - 4.266440523 i, 1.130732372 - 0.2199437576 i,
  -0.03418665371 - 0.002454497511 i],
 [1.130732372 - 0.2199437576 i, -2.441789243 - 4.214522706 i,
  1.353588821 - 0.2792250676 i],
 [-0.03418665371 - 0.002454497511 i, 1.353588821 - 0.2792250676 i,
  -0.248697806 - 4.659319216 i]]
```

Verify that this result is a solution of the matrix equation `A = Wm1·e^Wm1` within the current floating-point accuracy.

```
A = Wm1*exp(Wm1)
```

$$\begin{pmatrix} 1 & 1 & 1 \\ 1 & 2 & 3 \\ 1 & 3 & 6 \end{pmatrix} = \begin{pmatrix} 1.0 + 7.047165043\ 10^{-15}\,i & 1.0 + 1.498020458\ 10^{-14}\,i & 1.0 + 8.012687736\ 10^{-15}\,i \\ 1.0 - 1.297139479\ 10^{-14}\,i & 2.0 - 1.910971381\ 10^{-14}\,i & 3.0 - 6.004224895\ 10^{-14}\,i \\ 1.0 + 1.15792792\ 10^{-14}\,i & 3.0 + 3.354608258\ 10^{-14}\,i & 6.0 + 1.192795862\ 10^{-14}\,i \end{pmatrix}$$

Parameters

A

A square array, hfarray, or matrix.

f

A function.

Return Values

An array, hfarray, or matrix.

Algorithms

Suppose `f(x)`, where `x` is a scalar, has a Taylor series expansion. Then the matrix function `f(A)`, where `A` is a matrix, is defined by the Taylor series of `f(A)`, with addition and multiplication performed in the matrix sense.

If `A` can be represented as `A = P·D·P^-1`, where `D` is a diagonal matrix, such that

$$D = \begin{pmatrix} d_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & d_n \end{pmatrix}$$

then the matrix function `f(A)` can be computed as follows:

$$f(A) = P \begin{pmatrix} f(d_1) & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & f(d_n) \end{pmatrix} P^{-1}$$

Nondiagonalizable matrices can be represented as `A = P·J·P^-1`, where `J` is a Jordan form of the matrix `A`. (For details, see `linalg::jordanForm`.) Then, the matrix function `f(A)` can be computed by using the following definition on each Jordan block:

$$f\left(\begin{pmatrix} \lambda & 1 & 0 & \cdots & 0 \\ 0 & \lambda & 1 & & \vdots \\ 0 & 0 & \lambda & \ddots & 0 \\ \vdots & & \ddots & \ddots & 1 \\ 0 & \cdots & 0 & 0 & \lambda \end{pmatrix}\right) = \begin{pmatrix} \frac{f(\lambda)}{0!} & \frac{f'(\lambda)}{1!} & \frac{f''(\lambda)}{2!} & \cdots & \frac{f^{(n)}(\lambda)}{n!} \\ 0 & \frac{f(\lambda)}{0!} & \frac{f'(\lambda)}{1!} & \cdots & \frac{f^{(n-1)}(\lambda)}{(n-1)!} \\ 0 & 0 & \frac{f(\lambda)}{0!} & & \vdots \\ \vdots & & & \ddots & \vdots \\ 0 & \cdots & 0 & \frac{f(\lambda)}{0!} & \frac{f'(\lambda)}{1!} \\ 0 & \cdots & 0 & 0 & \frac{f(\lambda)}{0!} \end{pmatrix}$$

gamma

Gamma function

Syntax

```
gamma(x)
```

```
gamma(iv)
```

Description

`gamma(x)` represents the gamma function $\Gamma(x) = \int_0^\infty e^{-t}\, t^{x-1}\, dt$.

The gamma function is defined for all complex arguments apart from the singular points 0, - 1, - 2, ….

The gamma function is related to the factorial function: `gamma(x)=fact(x-1)=(x-1)!` for all positive integers x.

If `x` is a floating-point value, then `gamma` returns a floating-point value. If `x` is a floating-point interval, a floating-point interval is returned. If `x` is a positive integer not larger than the value given by `Pref::autoExpansionLimit()`, then an integer is returned. (Use `expand(gamma(x))` to get an integer value for larger integers `x`.) If `x` is a rational number of domain type `DOM_RAT` not larger than the value given by `Pref::autoExpansionLimit()`, then the functional relation $\Gamma(x+1) = x\,\Gamma(x)$ is applied to "normalize" the result. (Again, use `expand(gamma(x))` to enforce this normalization for larger rational numbers `x`.) The functional relation

$$\Gamma(x)\,\Gamma(1-x) = \frac{\pi}{\sin(\pi\, x)}$$

is applied if $x < \frac{1}{2}$ is a rational number of domain type `DOM_RAT` that is an integer multiple of $\frac{1}{4}$ or $\frac{1}{6}$. The call `gamma(1/2)` yields `sqrt(PI)`; `gamma(infinity)` yields `infinity`.

For all other arguments, a symbolic function call is returned.

The float attribute of `gamma` is a kernel function, i.e., floating-point evaluation is fast.

The `expand` attribute uses the functional equation $\Gamma(x+1) = x\,\Gamma(x)$, the reflection formula

$$\Gamma(-x) = -\frac{\pi}{x \sin(\pi\, x\, \Gamma(x))},$$

and the Gauß multiplication formula for $\Gamma(k\,x)$ when k is a positive integer, to rewrite `gamma(x)`. Cf. “Example 3” on page 1-863. For numerical `x`, the functional equation is used to shift the argument to the range `0 < x < 1`.

The functional equations for *gamma* lead to various identities for *lngamma* which can be applied via `expand`. Cf. “Example 3” on page 1-863.

The logarithmic derivative of `gamma` is implemented by the digamma function `psi`.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
gamma(15),
gamma(3/2),
gamma(-3/2),
gamma(sqrt(2)),
gamma(x + 1)
```

$$87178291200,\ \frac{\sqrt{\pi}}{2},\ \frac{4\sqrt{\pi}}{3},\ \Gamma(\sqrt{2}),\ \Gamma(x+1)$$

```
lngamma(15),
lngamma(3/2),
lngamma(-3/2),
lngamma(sqrt(2)),
lngamma(x + 1)
```

$$\ln(87178291200),\ \ln\left(\frac{\sqrt{\pi}}{2}\right),\ \ln\Gamma\left(-\frac{3}{2}\right),\ \ln\Gamma(\sqrt{2}),\ \ln\Gamma(x+1)$$

Floating point values are computed for floating-point arguments:

```
gamma(11.5),
gamma(2.0 + 10.0*I)
```

$$11899423.08,\ -0.00001089258677 + 0.00000504737724\,i$$

```
lngamma(11.5),
lngamma(2.0 + 10.0*I)
```

$$16.29200048,\ -11.33017193 + 15.27404065\,i$$

Example 2

`gamma` and `lngamma` are singular for nonpositive integers:

```
gamma(0)
```

```
Error: Singularity. [gamma]
```

```
lngamma(-2)
```

```
Error: Singularity. [lngamma]
```

Example 3

The functions `diff`, `expand`, `float`, `limit`, and `series` handle expressions involving `gamma` and `lngamma`:

```
diff(gamma(x^2 + 1), x),
diff(lngamma(x^2 + 1), x)
```

$$2\,x\,\Gamma(x^2+1)\,\psi(x^2+1),\ 2\,x\,\psi(x^2+1)$$

```
float(ln(3 + gamma(sqrt(PI)))),
float(ln(3 + lngamma(sqrt(PI))))
```

$$1.367203476,\ 1.072044865$$

```
expand(gamma(x + 2)),
expand(lngamma(x + 2))
```

$$x\,\Gamma(x)\,(x+1),\ \ln(x+1)+\ln(x)+\ln\Gamma(x)$$

```
expand(gamma(2*x)),
expand(lngamma(2*x))
```

$$\frac{2^{2\,x}\,\Gamma\left(x+\frac{1}{2}\right)\Gamma(x)}{2\,\sqrt{\pi}},\ \ln\Gamma\left(x+\frac{1}{2}\right)-\ln(2)-\frac{\ln(\pi)}{2}+\ln\Gamma(x)+2\,x\,\ln(2)$$

```
expand(gamma(2*x - 1)),
expand(lngamma(2*x - 1))
```

$$\frac{2^{2\,x}\,\Gamma\left(x+\frac{1}{2}\right)\Gamma(x)}{2\,\sqrt{\pi}\,(2\,x-1)},\ \ln\Gamma\left(x+\frac{1}{2}\right)-\ln(2)-\ln(2\,x-1)-\frac{\ln(\pi)}{2}+\ln\Gamma(x)+2\,x\,\ln(2)$$

```
limit(1/gamma(x), x = infinity),
limit(1/lngamma(x), x = infinity)
```

$$0,\ 0$$

```
limit(gamma(x - 4)/gamma(x - 10), x = 0),
limit(lngamma(x - 4) - lngamma(x - 10), x = 0)
```

$$151200,\ \ln(151200) + 6\,\pi\,i$$

```
series(gamma(x), x = 0, 3),
series(lngamma(x), x = 0, 3)
```

$$\frac{1}{x} - \mathrm{EULER} + x\left(\frac{\mathrm{EULER}^2}{2} + \frac{\pi^2}{12}\right) + O(x^2),\ -\ln(x) - \mathrm{EULER}\,x + \frac{\pi^2\,x^2}{12} + O(x^3)$$

The Stirling formula is obtained as an asymptotic series:

```
series(gamma(x), x = infinity, 4),
series(lngamma(x), x = infinity, 4)
```

$$\frac{\sigma_1}{\sqrt{x}\left(\frac{1}{x}\right)^x} + \frac{\sigma_1}{12\,x^{3/2}\left(\frac{1}{x}\right)^x} + \frac{\sigma_1}{288\,x^{5/2}\left(\frac{1}{x}\right)^x} + O\left(\frac{e^{-x}}{x^{7/2}\left(\frac{1}{x}\right)^x}\right),\ x\,(\ln(x) - 1) + \frac{\ln(2)}{2} + \frac{\ln(\pi)}{2} - \frac{\ln(x)}{2}$$

$$+ \frac{1}{12\,x} + O\left(\frac{1}{x^3}\right)$$

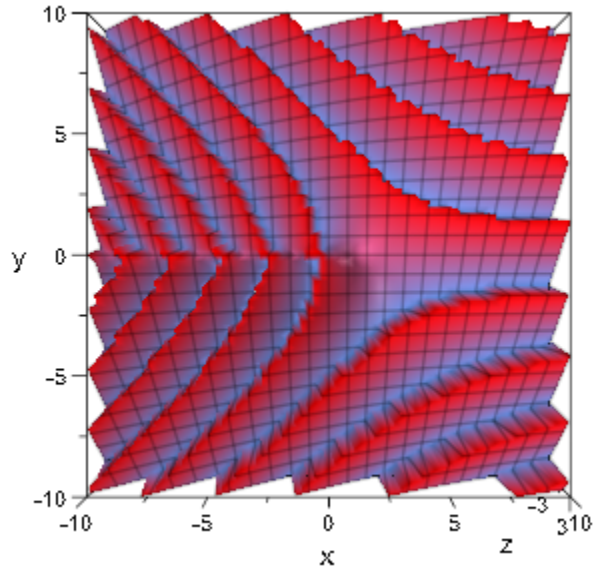
where

$$\sigma_1 = \sqrt{2}\,\sqrt{\pi}\,e^{-x}$$

Example 4

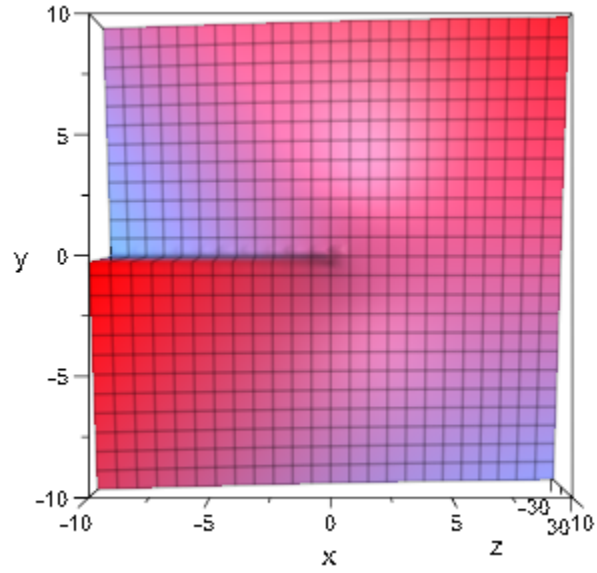
The logarithm function `ln` has a branch cut along the negative real semi axis, where the values jump by $2\,\pi\,i$ when crossing the cut. In the following plot of the imaginary part of the logarithm of the gamma function the lines in the complex z plane with $\Im(\Gamma(z)) = 0$ and $\Re(\Gamma(z)) \le 0$ are clearly visible as discontinuities:

```
plotfunc3d(Im(ln(gamma(x + I*y))), x = -10 .. 10, y = -10 .. 10,
           Submesh = [2, 2], CameraDirection = [0, -1, 1000]):
```



The function `lngamma(z)`, however, adds suitable integer multiples of $2\,\pi\,i$ to `ln(gamma(z))` making the function analytic throughout the complex plane with a branch cut along the negative real semi axis:

```
plotfunc3d(Im(lngamma(x + I*y)), x = -10 .. 10, y = -10 .. 10,
           Submesh = [2, 2], CameraDirection = [0, -1, 1000]):
```



Parameters

x

An arithmetical expression

iv

A floating-point interval

Return Values

Arithmetical expression or a floating-point interval.

Overloaded By

x

MuPAD Functions

`beta` | `binomial` | `fact` | `harmonic` | `igamma` | `lngamma` | `pochhammer` | `psi`

lngamma

Log-gamma function

Syntax

```
lngamma(x)
```

Description

`lngamma(x)` represents the logarithmic gamma function $\ln\Gamma(x) = \ln(\Gamma(x))$ for positive real `x`.

The logarithmic gamma function is defined for all complex arguments apart from the singular points 0, - 1, - 2, ….

Along the positive real semi axis, the logarithmic gamma function $\ln\Gamma(x)$ coincides with the logarithm $\ln(\Gamma(x))$ of the gamma function. For negative or general complex arguments *x*, however, one has $\ln\Gamma(x) = \ln(\Gamma(x)) + f(x)\ 2\ \pi\ i$ with some integer valued function *f*(*x*). The integer multiples of 2 π i are chosen such that *lngamma* is analytic throughout the complex plane with a branch cut along the negative real semi axes. Cf. “Example 4” on page 1-873. For negative real `x`, the value $\ln\Gamma(x)$ coincides with the limit “from above”.

If the argument `x` is a floating-point value, then `lngamma(x)` returns a floating-point value. For other values of `x` the call `lngamma(x)` returns `ln(gamma(x))` whenever `x` is a positive real number and `gamma(x)` is not returned as a symbolic call. For negative or non-real complex values `x` a symbolic call `lngamma(x)` is returned.

The functional equations for *gamma* lead to various identities for *lngamma* which can be applied via `expand`. Cf. “Example 3” on page 1-871.

The logarithmic derivative of `gamma` is implemented by the digamma function `psi`.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
gamma(15),
gamma(3/2),
gamma(-3/2),
gamma(sqrt(2)),
gamma(x + 1)
```

$$87178291200,\ \frac{\sqrt{\pi}}{2},\ \frac{4\sqrt{\pi}}{3},\ \Gamma(\sqrt{2}),\ \Gamma(x+1)$$

```
lngamma(15),
lngamma(3/2),
lngamma(-3/2),
lngamma(sqrt(2)),
lngamma(x + 1)
```

$$\ln(87178291200),\ \ln\left(\frac{\sqrt{\pi}}{2}\right),\ \ln\Gamma\left(-\frac{3}{2}\right),\ \ln\Gamma(\sqrt{2}),\ \ln\Gamma(x+1)$$

Floating point values are computed for floating-point arguments:

```
gamma(11.5),
gamma(2.0 + 10.0*I)
```

$$11899423.08,\ -0.00001089258677 + 0.00000504737724\,i$$

```
lngamma(11.5),
lngamma(2.0 + 10.0*I)
```

$$16.29200048,\ -11.33017193 + 15.27404065\,i$$

Example 2

`gamma` and `lngamma` are singular for nonpositive integers:

```
gamma(0)
```

```
Error: Singularity. [gamma]
```

```
lngamma(-2)
```

```
Error: Singularity. [lngamma]
```

Example 3

The functions `diff`, `expand`, `float`, `limit`, and `series` handle expressions involving `gamma` and `lngamma`:

```
diff(gamma(x^2 + 1), x),
diff(lngamma(x^2 + 1), x)
```

$$2\,x\,\Gamma(x^2+1)\,\psi(x^2+1),\ 2\,x\,\psi(x^2+1)$$

```
float(ln(3 + gamma(sqrt(PI)))),
float(ln(3 + lngamma(sqrt(PI))))
```

$$1.367203476,\ 1.072044865$$

```
expand(gamma(x + 2)),
expand(lngamma(x + 2))
```

$$x\,\Gamma(x)\,(x+1),\ \ln(x+1)+\ln(x)+\ln\Gamma(x)$$

```
expand(gamma(2*x)),
expand(lngamma(2*x))
```

$$\frac{2^{2\,x}\,\Gamma\left(x+\frac{1}{2}\right)\,\Gamma(x)}{2\,\sqrt{\pi}},\ \ln\Gamma\left(x+\frac{1}{2}\right)-\ln(2)-\frac{\ln(\pi)}{2}+\ln\Gamma(x)+2\,x\,\ln(2)$$

```
expand(gamma(2*x - 1)),
expand(lngamma(2*x - 1))
```

$$\frac{2^{2x}\,\Gamma\left(x+\frac{1}{2}\right)\Gamma(x)}{2\sqrt{\pi}\,(2x-1)},\ \ln\Gamma\left(x+\frac{1}{2}\right)-\ln(2)-\ln(2x-1)-\frac{\ln(\pi)}{2}+\ln\Gamma(x)+2x\ln(2)$$

```
limit(1/gamma(x), x = infinity),
limit(1/lngamma(x), x = infinity)
```

$$0,\ 0$$

```
limit(gamma(x - 4)/gamma(x - 10), x = 0),
limit(lngamma(x - 4) - lngamma(x - 10), x = 0)
```

$$151200,\ \ln(151200)+6\,\pi\,i$$

```
series(gamma(x), x = 0, 3),
series(lngamma(x), x = 0, 3)
```

$$\frac{1}{x}-\mathrm{EULER}+x\left(\frac{\mathrm{EULER}^2}{2}+\frac{\pi^2}{12}\right)+O(x^2),\ -\ln(x)-\mathrm{EULER}\,x+\frac{\pi^2\,x^2}{12}+O(x^3)$$

The Stirling formula is obtained as an asymptotic series:

```
series(gamma(x), x = infinity, 4),
series(lngamma(x), x = infinity, 4)
```

$$\frac{\sigma_1}{\sqrt{x}\left(\frac{1}{x}\right)^x}+\frac{\sigma_1}{12\,x^{3/2}\left(\frac{1}{x}\right)^x}+\frac{\sigma_1}{288\,x^{5/2}\left(\frac{1}{x}\right)^x}+O\left(\frac{e^{-x}}{x^{7/2}\left(\frac{1}{x}\right)^x}\right),\ x\,(\ln(x)-1)+\frac{\ln(2)}{2}+\frac{\ln(\pi)}{2}-\frac{\ln(x)}{2}$$

$$+\frac{1}{12\,x}+O\left(\frac{1}{x^3}\right)$$

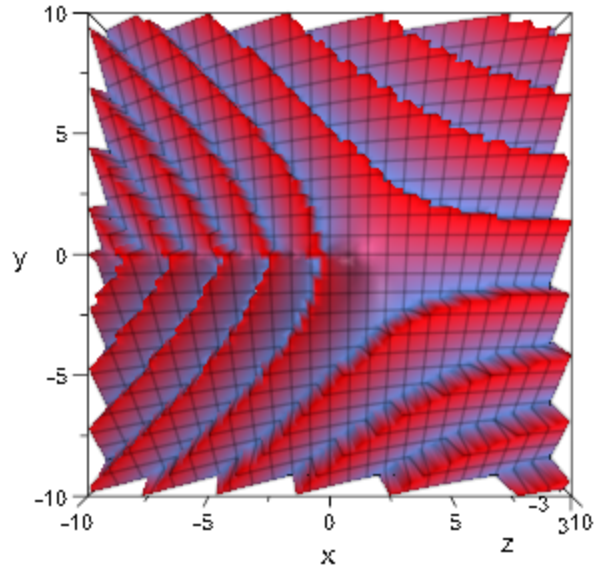
where

$$\sigma_1=\sqrt{2}\,\sqrt{\pi}\,e^{-x}$$

Example 4

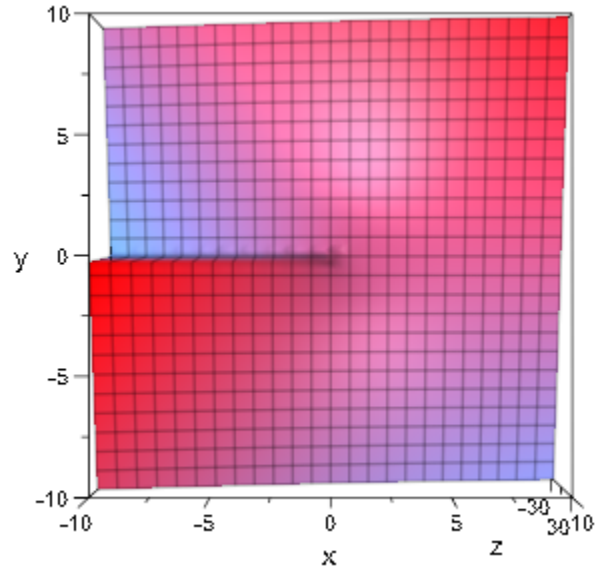
The logarithm function `ln` has a branch cut along the negative real semi axis, where the values jump by $2\,\pi\,i$ when crossing the cut. In the following plot of the imaginary part of the logarithm of the gamma function the lines in the complex z plane with $\Im(\Gamma(z)) = 0$ and $\Re(\Gamma(z)) \le 0$ are clearly visible as discontinuities:

```
plotfunc3d(Im(ln(gamma(x + I*y))), x = -10 .. 10, y = -10 .. 10,
           Submesh = [2, 2], CameraDirection = [0, -1, 1000]):
```



The function `lngamma(z)`, however, adds suitable integer multiples of $2\,\pi\,i$ to `ln(gamma(z))` making the function analytic throughout the complex plane with a branch cut along the negative real semi axis:

```
plotfunc3d(Im(lngamma(x + I*y)), x = -10 .. 10, y = -10 .. 10,
           Submesh = [2, 2], CameraDirection = [0, -1, 1000]):
```



Parameters

x

MuPAD Functions

`beta` | `binomial` | `fact` | `gamma` | `harmonic` | `igamma` | `pochhammer` | `psi`

gcd

Greatest common divisor of polynomials

Syntax

```
gcd(p, q, …)
```

```
gcd(f, g, …)
```

Description

`gcd(p, q, ...)` returns the greatest common divisor of the polynomials *p*, *q*, … The coefficient ring of the polynomials may either be the integers or the rational numbers, `Expr`, a residue class ring `IntMod(n)` with a prime number `n`, or a domain.

All polynomials must have the same indeterminates and the same coefficient ring.

Polynomial expressions are converted to polynomials. See `poly` for details.

The return value is of the same type as the input polynomials, i.e., either a polynomial of type `DOM_POLY` or a polynomial expression.

`gcd` returns 0 if all arguments are 0, or if no argument is given. If at least one of the arguments is - 1 or 1, then `gcd` returns 1.

Use `igcd` if all arguments are known to be integers, since it is much faster than `gcd`.

Examples

Example 1

The greatest common divisor of two polynomial expressions can be computed as follows:

```
gcd(6*x^3 + 9*x^2*y^2, 2*x + 2*x*y + 3*y^2 + 3*y^3)
```

$$3\,y^2 + 2\,x$$

```
f := (x - sqrt(2))*(x^2 + sqrt(3)*x-1):
g := (x - sqrt(2))*(x - sqrt(3)):
gcd(f, g)
```

$$x - \sqrt{2}$$

One may also choose polynomials as arguments:

```
p := poly(2*x^2 - 4*x*y - 2*x + 4*y, [x, y], IntMod(17)):
q := poly(x^2*y - 2*x*y^2, [x, y], IntMod(17)):
gcd(p, q)
```

$$\mathrm{poly}(x - 2\,y, [x, y], \mathrm{IntMod}(17))$$

```
delete f, g, p, q:
```

Parameters

`p, q, …`

polynomials of type `DOM_POLY`

`f, g, …`

polynomial expressions

Return Values

Polynomial or a polynomial expression.

Overloaded By

f, g, p, q

Algorithms

If the arguments are polynomials with coefficients from a domain, then the domain must have the methods `"gcd"` and `"_divide"`. The method `"gcd"` must return the greatest common divisor of any number of domain elements. The method `"_divide"` must divide two domain elements. If domain elements cannot be divided, this method must return `FAIL`.

gcdex

Extended Euclidean algorithm for polynomials

Syntax

```
gcdex(p, q, <x>)
```

```
gcdex(f, g, x)
```

Description

`gcdex(p, q, x)` regards `p` and `q` as univariate polynomials in `x` and returns their greatest common divisor as a linear combination of `p` and `q`.

`gcdex(p, q, x)` returns a sequence g, s, t with three elements, where the polynomial g is the greatest common divisor of p and q. The polynomials s and t satisfy $g = s\,p + t\,q$ and $deg(s) < deg(q)$, $deg(t) < deg(p)$. These data are computed by the extended Euclidean algorithm.

`gcdex` only processes univariate polynomials:

- If the indeterminate `x` is specified, the input polynomials are regarded as univariate polynomials in `x`.
- If no indeterminate is specified, the indeterminate of the polynomials is searched for internally. An error occurs if more than one indeterminate is found.

Note that `x` must be specified if polynomial expressions are used on input.

Polynomial expressions are converted to polynomials. See `poly` for details. `FAIL` is returned if an argument cannot be converted to a polynomial.

The returned polynomials are polynomial expressions if the input consists of polynomial expressions. Otherwise, polynomials of type `DOM_POLY` are returned.

The coefficient ring of the polynomials must provide the method `"_divide"`. This method must return `FAIL` if domain elements cannot be divided.

Note: If the coefficient domain of the polynomial is not a field, then it may not be possible to represent a greatest common divisor as a linear combination of the input polynomials. In such a case, an error is raised.

Examples

Example 1

The greatest common divisor of two univariate polynomials in extended form can be computed as follows:

```
gcdex(poly(x^3 + 1), poly(x^2 + 2*x + 1))
```

$$\mathrm{poly}(x+1,[x]),\ \mathrm{poly}\left(\frac{1}{3},[x]\right),\ \mathrm{poly}\left(-\frac{x}{3}+\frac{2}{3},[x]\right)$$

For multivariate polynomials, an indeterminate must be specified:

```
gcdex(poly(x^2*y), poly(x + y), x)
```

$$\mathrm{poly}(1,[x]),\ \mathrm{poly}\left(\frac{1}{y^3},[x]\right),\ \mathrm{poly}\left(\left(-\frac{1}{y^2}\right)x+\frac{1}{y},[x]\right)$$

```
gcdex(poly(x^2*y), poly(x + y), y)
```

$$\mathrm{poly}(1,[y]),\ \mathrm{poly}\left(-\frac{1}{x^3},[y]\right),\ \mathrm{poly}\left(\frac{1}{x},[y]\right)$$

```
gcdex(x^3 + a, x^2 + 1, x)
```

$$1,\ \frac{a}{a^2+1}+\frac{x}{a^2+1},\ \frac{1}{a^2+1}-\frac{x^2}{a^2+1}-\frac{a\,x}{a^2+1}$$

Parameters

p, q

polynomials of type DOM_POLY

f, g

polynomial expressions

x

An indeterminate: an identifier or an indexed identifier

Return Values

Sequence of three polynomials, or a sequence of three polynomial expressions, or FAIL.

Overloaded By

p, q

See Also

MuPAD Functions
div | divide | factor | gcd | ifactor | igcd | igcdex | ilcm | lcm | mod | poly

genident

Create an unused identifier

Syntax

```
genident()
```

```
genident(S)
```

Description

`genident()` creates an identifier not used before in the current session.

`genident()` creates an identifier with a name of the form `Xi`, where `i` is a positive integer. It is guaranteed that the returned identifier has not been used before in the current MuPAD session.

If a string`S` is given as argument, then `genident` returns an identifier with a name of the form `Si`, where `i` is a positive integer.

The returned identifier does not have a value.

Examples

Example 1

We create three new identifiers. The second identifier has a different prefix:

```
genident(), genident("Y"), genident()
```

```
X1, Y1, X2
```

In the next example, we assign a value to the identifier `X4`. Then the next two calls to `genident` skip the name `X4`:

```
X4 := 5:
genident(), genident()
```

```
X3, X5
```

Parameters

s

A character string

Return Values

identifier.

See Also

MuPAD Functions

`delete` | `hold`

genpoly

Create a polynomial using b-adic expansion

Syntax

```
genpoly(n, b, x)
```

Description

`genpoly(n, b, x)` creates a polynomial `p` in the variable `x` from the `b`-adic expansion of `n`, such that $p(b) = n$. The integer coefficients of the resulting polynomial are greater than $-\frac{b}{2}$ and less than or equal to $\frac{b}{2}$.

The b-adic expansion of an integer n is defined by $n = \sum_{i=0}^{m} c_i\, b^i$, such that the c_i are symmetric remainders modulo b, i.e., $-\frac{b}{2} < c_i \le \frac{b}{2}$ for all i (see `mods`). From this expansion the polynomial $p = \sum_{i=0}^{m} c_i\, x^i$ is created. The polynomial is defined over the coefficient ring `Expr`.

If the first argument of `genpoly` is a (multivariate) polynomial, then it must be defined over the coefficient ring `Expr` and must have only integer coefficients. The third argument `x` must not be a variable of the polynomial. In this case each integer coefficient is converted into a polynomial in `x` as described above. The result is a polynomial in the variable `x`, followed by the variables of the given polynomial. (`x` is the main variable of the returned polynomial.)

The first argument `n` may also be a polynomial expression. In this case, it is converted into a polynomial using `poly`, then `genpoly` is applied as described above, and the result is again converted into a polynomial expression.

If the first argument is an integer or a polynomial, then the result is a polynomial of domain type `DOM_POLY`; otherwise it is a polynomial expression.

Examples

Example 1

We create a polynomial `p` in the indeterminate `x` such that `p(7) = 15`. The coefficients of `p` are between `-3` and `3`:

```
p := genpoly(15, 7, x)
```

$$\mathrm{poly}(2x+1, [x])$$

```
p(7)
```

$$15$$

Here is an example with a polynomial expression as input:

```
p := genpoly(15*y^2 - 6*y + 3*z, 7, x)
```

$$y+3z-xy+2xy^2+y^2$$

The return value has the same type as the first argument:

```
p := genpoly(poly(15*y^2 + 8*z, [y, z]), 7, x)
```

$$\mathrm{poly}(2xy^2+xz+y^2+z, [x, y, z])$$

We check the result:

```
p(7, y, z)
```

$$15y^2+8z$$

Parameters

n

An integer, a polynomial of type `DOM_POLY`, or a polynomial expression

b

An integer greater than 1

x

The indeterminate: an identifier

Return Values

polynomial if the first argument is a polynomial or an integer. Otherwise, a polynomial expression.

`genident` | `indets` | `int2text` | `interpolate` | `mods` | `numlib::g_adic` | `poly` | `text2int`

getlasterror

Retrieve the last error number and text

Syntax

```
getlasterror()
```

Description

`getlasterror()` returns the last error that occurred in the current MuPAD session, as a list of the error number and the error string.

After an error has occurred (whether visible or caught by `traperror`), `getlasterror` will return both the error number (as returned by `traperror`) and the error string.

In a MuPAD session where no errors occurred, `getlasterror` returns the list `[0, ""]`. This is also true after a call to `reset()`.

Note: Note that the MuPAD library uses `traperror` itself and that `getlasterror()` may return errors that have been caught and properly handled by the library already. You should not use `getlasterror` to detect errors, use the return value of `traperror` instead!

Examples

Example 1

In a fresh session, `getlasterror` returns a list indicating “no errors yet”:

```
getlasterror()
```

```
[0, ""]
```

After an error has been thrown, `getlasterror` returns the corresponding number and string:

```
ln(0)
```

```
Error: Singularity. [ln]
```

```
getlasterror()
```

```
[1028, "Error: Singularity. [ln]"]
```

This includes errors not displayed because of `traperror`:

```
traperror(solve(a, b, c))
```

```
1126
```

```
getlasterror()
```

```
[1126, "Error: The argument number 3 is invalid.  Evaluating: solvelib::getOptions"]
```

Return Values

List of an integer and a string

See Also

MuPAD Functions

`error` | `lasterror` | `traperror`

getpid

Process ID of the running kernel

Syntax

```
getpid()
```

Description

`getpid()` returns the process ID of the running MuPAD kernel.

The process ID may be useful for generating names for temporary files by appending it to a file basename.

Examples

Example 1

Querying the process ID of the running kernel may produce a result like this:

```
getpid()
```

```
      16184
```

Return Values

Nonnegative integer.

See Also

MuPAD Functions

`sysname | system`

getprop

Query properties of expressions

Syntax

```
getprop(f)
```

```
getprop()
```

Description

`getprop(f)` returns a set containing all possible values of the expression `f`.

The property mechanism helps to simplify expressions involving identifiers that carry "mathematical assumptions". The function `assume` allows to set basic assumptions such as 'x is a real number' or 'x is an odd integer', say. Arithmetical expressions involving `x` may inherit such properties. E.g., '`1 + x^2` is positive' if 'x is a real number'.

`getprop(f)` examines the assumptions of all identifiers in the expression `f` and derives a superset of all values of `f`.

Only basic mathematical properties can be represented with the available properties. Therefore, `getprop` performs certain simplifications during the derivation of a property for an expression. Thus it may happen that `getprop` derives a too large set.

`getprop` only shows a mathematical (super-)set of all possible values in respect to the assumptions. The command `property::showprops` displays a list of all valid assumptions for a special identifier.

Examples

Example 1

If `x` is a real number, then `x^2 + 1` must be positive:

```
assume(x, Type::Real):
```

```
getprop(x^2 + 1)
```

$$[1, \infty)$$

If `x` represents a number in the interval `[1, infinity[`, the expression `1 - x` has the following property:

```
assume(x, Type::Interval([1], infinity)):
getprop(1 - x)
```

$$(-\infty, 0]$$

```
unassume(x):
```

Example 2

An expression returns the superset `C_` or a set if it is constant, or if no properties are attached to the identifiers involved:

```
getprop(x), getprop(x + 2*y), getprop(sin(3))
```

$$\mathbb{C},\ \mathbb{C},\ \{\sin(3)\}$$

Example 3

The functions `abs`, `Re`, and `Im` have a “minimal property”: they produce real values. In fact, `abs` produces nonnegative real values:

```
delete x:
getprop(abs(x)), getprop(Re(x)), getprop(Im(x))
```

$$[0, \infty),\ \mathbb{R},\ \mathbb{R}$$

Parameters

`f`

An arithmetical expression

Return Values

`getprop(f)` returns a (super-)set containig all possible values of the expression `f`.

gradient

Vector gradient

Syntax

```
gradient(f, x)
```

```
gradient(f, x, ogCoord, <c>)
```

Description

`gradient(f, x)` computes the vector gradient of the scalar function $f(\vec{x})$ with respect to $\vec{x}$ in Cartesian coordinates. This is the vector $\mathrm{grad}(f) = \left(\frac{\partial}{\partial x_1} f, \ldots, \frac{\partial}{\partial x_n} f\right)$.

`ogCoord` can be the name of a three-dimensional orthogonal coordinate system predefined in the table `linalg::ogCoordTab`. See “Example 2” on page 1-894.

Alternatively, `ogCoord` can be a list of vector of algebraic expressions representing the scale factors of the coordinate system. See example “Example 3” on page 1-894. For details, see the description of the `Scales` option on the `linalg::ogCoordTab` page.

Examples

Example 1

Compute the vector gradient of the scalar function $f(x, y) = x^2 + y$ in Cartesian coordinates:

```
delete x, y:
gradient(x^2 + y, [x, y])
```

$$\begin{pmatrix} 2x \\ 1 \end{pmatrix}$$

Example 2

Compute the gradient of the function $f(r, \phi, z) = r\,cos(\phi)\,z$ $(0 \le \phi < 2\pi)$ in cylindrical coordinates:

```
delete r, z, phi:
gradient(r*cos(phi)*z, [r, phi, z], Cylindrical)
```

$$\begin{pmatrix} z\cos(\mathrm{phi}) \\ -z\sin(\mathrm{phi}) \\ r\cos(\mathrm{phi}) \end{pmatrix}$$

Example 3

Compute the gradient of the function $f(r, \phi, \theta) = r\,sin(\phi)\,cos(\theta)$ in spherical coordinates given by

$$\vec{x} = \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} r\sin(\theta)\cos(\phi) \\ r\sin(\theta)\sin(\phi) \\ r\cos(\theta) \end{pmatrix}$$

with $0 \le \theta \le \pi$, $0 \le \phi < 2\,\pi$.

The vectors

$$\vec{e}_r = \frac{\frac{\partial}{\partial r}\vec{x}}{\left|\frac{\partial}{\partial r}\vec{x}\right|} = \begin{pmatrix} \sin(\theta)\cos(\phi) \\ \sin(\theta)\sin(\phi) \\ \cos(\theta) \end{pmatrix}, \quad \vec{e}_\theta = \frac{\frac{\partial}{\partial \theta}\vec{x}}{\left|\frac{\partial}{\partial \theta}\vec{x}\right|} = \begin{pmatrix} \cos(\theta)\cos(\phi) \\ \cos(\theta)\sin(\phi) \\ -\sin(\theta) \end{pmatrix},$$

$$\vec{e}_\phi = \frac{\frac{\partial}{\partial \phi}\vec{x}}{\left|\frac{\partial}{\partial \phi}\vec{x}\right|} = \begin{pmatrix} -\sin(\phi) \\ \cos(\phi) \\ 0 \end{pmatrix}$$

form an orthogonal system in spherical coordinates.

The scaling factors of the corresponding coordinate transformation (see `linalg::ogCoordTab`) are: $g_1 = \left|\vec{e}_r\right| = 1,\ g_2 = \left|\vec{e}_\theta\right| = r,\ g_3 = \left|\vec{e}_\phi\right| = r\sin(\theta)$, which we use in the following example to compute the gradient of the function *f* in spherical coordinates:

```
delete r, Theta, phi:
gradient(r*sin(phi)*cos(Theta), [r, Theta, phi],
                            [1, r, r*sin(Theta)])
```

$$\begin{pmatrix} \cos(\text{Theta})\ \sin(\text{phi}) \\ -\sin(\text{Theta})\ \sin(\text{phi}) \\ \frac{\cos(\text{Theta})\ \cos(\text{phi})}{\sin(\text{Theta})} \end{pmatrix}$$

The spherical coordinates are already defined in `linalg::ogCoordTab`. The last result can also be achieved with the input `gradient(r*sin(phi)*cos(Theta), [r, Theta, phi], Spherical[RightHanded])`:

```
gradient(r*sin(phi)*cos(Theta), [r, Theta, phi],
                          Spherical[RightHanded])
```

$$\begin{pmatrix} \cos(\text{Theta})\ \sin(\text{phi}) \\ -\sin(\text{Theta})\ \sin(\text{phi}) \\ \frac{\cos(\text{Theta})\ \cos(\text{phi})}{\sin(\text{Theta})} \end{pmatrix}$$

Parameters

`f`

An arithmetical expression in the variables given in `x`

`x`

A list of (indexed) identifiers

ogCoord

The name of a 3 dimensional orthogonal coordinate system predefined in the table `linalg::ogCoordTab`, or a list of algebraic expressions representing the scale factors of an orthogonal coordinate system.

c

The parameter of the coordinate systems EllipticCylindrical and Torus, respectively: an arithmetical expression. The default value is `c` = 1.

Return Values

Column vector of the domain `Dom::Matrix()`.

ground

Ground term (constant coefficient) of a polynomial

Syntax

```
ground(p)
```

```
ground(f)
```

```
ground(f, vars)
```

Description

`ground(p)` returns the constant coefficient $p(0, 0, \ldots)$ of the polynomial p.

The first argument can either be a polynomial expression, or a polynomial generated by `poly`, or an element of some polynomial domain overloading `ground`.

If the first argument `f` is not element of a polynomial domain, then `ground` converts the expression to a polynomial via `poly(f)`. If a list of indeterminates is specified, then the polynomial `poly(f, vars)` is considered.

The constant coefficient is returned as an arithmetical expression.

The result of `ground` is not fully evaluated. Evaluation can be enforced by the function `eval`. Cf. “Example 2” on page 1-898.

`ground` returns `FAIL` if `f` cannot be converted to a polynomial in the specified indeterminates. Cf. “Example 3” on page 1-898.

Examples

Example 1

We demonstrate how the indeterminates influence the result:

```
f := 2*x^2 + 3*y + 1:
```

```
ground(f), ground(f, [x]), ground(f, [y]),
ground(poly(f)), ground(poly(f, [x])), ground(poly(f, [y]))
```

$$1,\ 3\,y+1,\ 2\,x^2+1,\ 1,\ 3\,y+1,\ 2\,x^2+1$$

The result is the evaluation at the origin:

```
subs(f, x = 0, y = 0), subs(f, x = 0), subs(f, y = 0)
```

$$1,\ 3\,y+1,\ 2\,x^2+1$$

Note the difference between `ground` and `tcoeff`:

```
g := 2*x^2 + 3*y:
ground(g), ground(g, [x]);
tcoeff(g), tcoeff(g, [x]);
```

$$0,\ 3\,y$$

$$3,\ 3\,y$$

```
delete f, g:
```

Example 2

The result of `ground` is not fully evaluated:

```
p := poly(27*x^2 + a, [x]): a := 5:
ground(p), eval(ground(p))
```

$$a,\ 5$$

```
delete p, a:
```

Example 3

The following expression is syntactically not a polynomial expression, and `ground` returns `FAIL`:

```
f := (x^2 - 1)/(x - 1): ground(f)
```

```
FAIL
```

After cancellation via `normal`, `ground` can compute the constant coefficient:

```
ground(normal(f))
```

```
1
```

```
delete f:
```

Parameters

`p`

A polynomial of type `DOM_POLY`

`f`

A polynomial expression

`vars`

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

Return Values

Element of the coefficient ring of `p`, an arithmetical expression, or `FAIL`.

Overloaded By

f, p

harmonic

Harmonic function

Syntax

```
harmonic(x)
```

Description

`harmonic(x)` = $\psi(x+1) + \mathrm{EULER}$ represents the harmonic function.

The harmonic function is defined for all complex arguments `x` apart from the singular points - 1, - 2, … (first order poles).

For positive integers `x` not larger than the value `Pref::autoExpansionLimit`(), the harmonic function procudes the harmonic number $\mathrm{harmonic}(x) = \sum_{k=1}^{x} \frac{1}{k}$. Use `expand(harmonic(x))` to compute an explicit result for integers `x` larger than `Pref::autoExpansionLimit`().

If `x` is a floating-point value, then a floating point value is returned.

Simplifcations are implemented for rational numbers x with $|x| \le$ *Pref*::*autoExpansionLimit*(). In particular, if x = `numer(x)/k` with denominators k = 1, 2, 3, 4, or 6, then an explicit result is computed and returned. For other rational numbers the functional equation $\mathrm{harmonic}(x+1) = \mathrm{harmonic}(x) + \frac{1}{x}$ is used to obtain a result with an argument `x` from the interval $(0, 1]$.

For rational numbers x with $|x| >$ *Pref*::*autoExpansionLimit*(), these simplifications can be enforced via `expand`.

Some explicit formulas are implemented including

$$\mathrm{harmonic}(0) = 0,\ \mathrm{harmonic}\left(\frac{1}{2}\right) = 2 - 2\ln(2),$$

$$\mathrm{harmonic}\left(\frac{1}{3}\right) = 3 - \frac{3\ln(3)}{2} - \frac{\sqrt{3}}{6}\pi,\ \mathrm{harmonic}\left(\frac{2}{3}\right) = \frac{3}{2} - \frac{3\ln(3)}{2} + \frac{\sqrt{3}}{6}\pi,$$

$$\text{harmonic}\left(\frac{1}{4}\right) = 4 - 3\ln(2) - \frac{\pi}{2},\ \text{harmonic}\left(\frac{3}{4}\right) = \frac{4}{3} - 3\ln(2) + \frac{\pi}{2},$$

$$\text{harmonic}\left(\frac{1}{6}\right) = 6 - 2\ln(2) - \frac{3\ln(3)}{2} - \frac{\sqrt{3}}{2}\pi,\ \text{harmonic}\left(\frac{5}{6}\right) = \frac{6}{5} - 2\ln(2) - \frac{3\ln(3)}{2} + \frac{\sqrt{3}}{2}\pi,$$

$$\text{harmonic}(1) = 1.$$

The special value $harmonic(\infty) = \infty$ is implemented.

For all other arguments, a symbolic function call of `harmonic` is returned.

The `expand` attribute uses the functional equation $\text{harmonic}(x+1) = \text{harmonic}(x) + \frac{1}{x}$, the reflection rule $\text{harmonic}(-x) = \text{harmonic}(x) - \frac{1}{x} + \pi\cot(\pi x)$ and the Gauß multiplication formula for $harmonic(k\,x)$ with some integer k to rewrite `harmonic(x)`. See "Example 3" on page 1-902 and "Example 4" on page 1-903.

Environment Interactions

When called with a floating-point value `x`, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
harmonic(3), harmonic(10), harmonic(3/2), harmonic(25/7)
```

$$\frac{11}{6},\ \frac{7381}{2520},\ \frac{8}{3} - 2\ln(2),\ \text{harmonic}\left(\frac{4}{7}\right) + \frac{6461}{4950}$$

```
harmonic(x + sqrt(2)), harmonic(infinity)
```

$$\text{harmonic}(x + \sqrt{2}),\ \infty$$

Floating point values are computed for floating-point arguments:

```
harmonic(-5.2), harmonic(27.0), harmonic(2.0 + 3.0*I)
```

$$6.450681124,\ 3.891456753,\ 1.939042529 + 0.8733604498\ i$$

Example 2

`harmonic` is singular for negative integers:

```
harmonic(-2)
```

```
Error: Singularity. [harmonic]
```

Example 3

For positive integers and rational numbers x with denominators 2, 3, 4 and 6, respectively, the result is expressed in terms of PI and `ln`, if $|x| < 500$:

```
harmonic(-5/2)
```

$$\frac{8}{3} - 2\ln(2)$$

```
harmonic(13/3)
```

$$\frac{8571}{1820} - \frac{\pi\sqrt{3}}{6} - \frac{3\ln(3)}{2}$$

```
harmonic(101/6)
```

$$\frac{\pi\sqrt{3}}{2} - \frac{3\ln(3)}{2} - 2\ln(2) + \frac{257690034865853321191998}{68836669705906834284553}$$

For larger arguments, the `expand` attribute can be used to obtain such expressions:

```
harmonic(1001)
```

```
harmonic(1001)
```

$$\text{harmonic}(1001)$$

```
expand(%)
```

```
5337003...5042517 / 7128865...3520000
```

Example 4

The functions `diff`, `expand`, `float`, `limit`, and `series` handle expressions involving `harmonic`:

```
diff(harmonic(x^2 + 1), x), float(ln(3 + harmonic(sqrt(PI))))
```

$$2\,x\,\psi'(x^2+2),\ 1.482943321$$

```
expand(harmonic(2*x + 3))
```

$$\frac{\text{harmonic}\left(x+\frac{1}{2}\right)}{2}+\ln(2)+\frac{\text{harmonic}(x)}{2}-\frac{1}{2\left(x+\frac{1}{2}\right)}+\frac{1}{2x+1}+\frac{1}{2x+2}+\frac{1}{2x+3}$$

```
limit((x + 1)*harmonic(x), x = -1), limit(harmonic(x), x = infinity)
```

$$-1,\ \infty$$

```
series(harmonic(x), x = 0)
```

$$\frac{\pi^2 x}{6}-x^2\,\zeta(3)+\frac{\pi^4 x^3}{90}-x^4\,\zeta(5)+\frac{\pi^6 x^5}{945}-x^6\,\zeta(7)+O(x^7)$$

```
series(harmonic(x), x = infinity, 3)
```

$$\text{EULER}+\ln(x)+\frac{1}{2x}-\frac{1}{12x^2}+O\left(\frac{1}{x^3}\right)$$

Parameters

x

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

x

See Also

MuPAD Functions
`beta` | `binomial` | `fact` | `gamma` | `lngamma` | `zeta`

has

Check if an object occurs in another object

Syntax

```
has(object1, object2)
```

```
has(object1, l)
```

Description

`has(object1, object2)` checks, whether `object2` occurs syntactically in `object1`.

`has` is a fast test for the existence of sub-objects or subexpressions. It works syntactically, i.e., mathematically equivalent objects are considered to be equal only if they are syntactically identical. See “Example 2” on page 1-906.

If `object1` is an expression, then `has(object1, object2)` tests whether `object1` contains `object2` as a subexpression. Only complete subexpressions and objects occurring in the 0th operand of a subexpression are found (see “Example 1” on page 1-906).

If `object1` is a container, then `has` checks whether `object2` occurs in an entry of `object1`. See “Example 5” on page 1-908.

In this context, a floating-point interval is considered a container for (an infinite number of) complex numbers and `has` checks whether a given number is *inside* the interval. See “Example 4” on page 1-907.

If the second argument is a list or a set `l`, then `has` returns `TRUE` if at least one of the elements in `l` occurs in `object1` (see “Example 3” on page 1-907). In particular, if `l` is the empty list or the empty set, then the return value is `FALSE`.

If `object1` is an element of a domain with a `"has"` slot, then the slot routine is called with the same arguments, and its result is returned. If the domain does not have such a slot, then `FALSE` will be returned. See “Example 7” on page 1-909.

If has is called with a list or set as second argument, then the "has" slot of the domain of object1 is called for each object of the list or the set. When the first object is found that occurs in object1, the evaluation is terminated and TRUE is returned. If none of the objects occurs in object1, FALSE will be returned.

Examples

Example 1

The given expression has x as an operand:

```
has(x + y + z, x)
```

```
    TRUE
```

Note that x + y is not a complete subexpression. Only x, y, z and x + y + z are complete subexpressions:

```
has(x + y + z, x + y)
```

```
    FALSE
```

However, has also finds objects in the 0th operand of a subexpression:

```
has(x + sin(x), sin)
```

```
    TRUE
```

Every object occurs in itself:

```
has(x, x)
```

```
    TRUE
```

Example 2

has works in a purely syntactical fashion. Although the two expressions y*(x + 1) and y*x + y are mathematically equivalent, they differ syntactically:

```
has(sin(y*(x + 1)), y*x + y),
has(sin(y*(x + 1)), y*(x + 1))
```

```
FALSE, TRUE
```

Complex numbers are not regarded as atomic objects:

```
has(2 + 5*I, 2), has(2 + 5*I, 5), has(2 + 5*I, I)
```

```
TRUE, TRUE, TRUE
```

In contrast, rational numbers are considered to be atomic:

```
has(2/3*x, 2), has(2/3*x, 3), has(2/3*x, 2/3)
```

```
FALSE, FALSE, TRUE
```

Example 3

If the second argument is a list or a set, has checks whether one of the entries occurs in the first argument:

```
has((x + y)*z, [x, t])
```

```
TRUE
```

0th operands of subexpressions are checked as well:

```
has((a + b)*c, {_plus, _mult})
```

```
TRUE
```

Example 4

On floating-point intervals, has performs a containment check, not just testing the borders:

```
has(1...3, 1)
```

```
    TRUE
```

```
has(1...3, 2.7182), has(1...3, exp(1)), has(1...3, PI)
```

```
    TRUE, TRUE, FALSE
```

```
has(1...(3+I), [2, ln(3)])
```

```
    TRUE
```

Example 5

`has` works for lists, sets, tables, arrays, and hfarrays:

```
has([sin(f(a) + 2), cos(x), 3], {f, g})
```

```
    TRUE
```

```
has({a, b, c, d, e}, {a, z})
```

```
    TRUE
```

```
has(array(1..2, 1..2, [[1, 2], [3, 4]]), 2)
```

```
    TRUE
```

For an array `A`, the command `has(A,NIL)` checks whether the array has any uninitialized entries:

```
has(array(1..2, 1 = x), NIL),
has(array(1..2, [2, 3]), NIL)
```

```
    TRUE, FALSE
```

For tables, `has` checks indices, entries, as well as the internal operands of a table, given by equations of the form `index=entry`:

```
T := table(a = 1, b = 2, c = 3):
```

```
has(T, a), has(T, 2), has(T, b = 2)
```

TRUE, TRUE, TRUE

Example 6

has works syntactically. Although the variable x does not occur mathematically in the constant polynomial p in the following example, the identifier x occurs syntactically in p, namely, in the second operand:

```
delete x: p := poly(1, [x]):
has(p, x)
```

TRUE

Example 7

The second argument may be an arbitrary MuPAD object, even from a user-defined domain:

```
T := newDomain("T"):
e := new(T, 1, 2);
f := [e, 3];
```

new(*T*, 1, 2)

[new(*T*, 1, 2), 3]

```
has(f, e), has(f, new(T, 1))
```

TRUE, FALSE

If the first argument of has belongs to a domain without a "has" slot, then has always returns FALSE:

```
has(e, 1)
```

FALSE

Users can overload`has` for their own domains. For illustration, we supply the domain `T` with a `"has"` slot, which puts the internal operands of its first argument in a list and calls `has` for the list:

```
T::has := (object1, object2) -> has([extop(object1)], object2):
```

If we now call `has` with the object `e` of domain type `T`, the slot routine `T::has` is invoked:

```
has(e, 1), has(e, 3)
```

```
TRUE, FALSE
```

The slot routine is also called if an object of domain type `T` occurs syntactically in the first argument:

```
has(f, 1), has(f, 3)
```

```
TRUE, TRUE
```

Parameters

`object1, object2`

Arbitrary MuPAD objects

`l`

A list or a set

Return Values

Either `TRUE` or `FALSE`

Overloaded By

object1

See Also

MuPAD Functions

`_in` | `_index` | `contains` | `hastype` | `op` | `subs` | `subsex`

hastype

Test if an object of a specified type occurs in another object

Syntax

```
hastype(object, T, <inspect>)
```

Description

`hastype(object, T)` tests if an object of type `T` occurs syntactically in `object`.

`hastype(object, T)` tests if a sub-object `s` of type `T` occurs in `object`, i.e., such that `testtype(s, T)` returns `TRUE`.

The type specifier `T` may be either a domain type such as `DOM_INT`, `DOM_EXPR` etc., a string as returned by the function `type`, or a Type object. The latter are probably the most useful predefined values for the argument `T`.

If `T` is not a valid type specifier, then `hastype` returns `FALSE`.

See “Example 1” on page 1-913.

If `object` is an expression, then `hastype(object, T)` tests whether `object` contains a subexpression of type `T`; see “Example 1” on page 1-913.

If `object` is a container, then `hastype` checks whether a sub-object of type `T` occurs in an entry of `object`; see “Example 4” on page 1-915.

If the second argument is a list or a set, `hastype` checks whether a sub-object of one of the types in `T` occurs in `object`. See “Example 1” on page 1-913.

`hastype` works in a recursive fashion and descends into the following objects: expressions, arrays, hfarrays, lists, sets, and tables. See “Example 4” on page 1-915. `hastype` does not step into the other basic domains, such as rational numbers, complex numbers, polynomials, or procedures. See “Example 2” on page 1-914.

If the third argument `inspect` is present, then `hastype` also steps recursively into sub-objects of the domain types given in `inspect`. See “Example 2” on page 1-914.

Note: `hastype` looks only for sub-objects that are syntactically of type `T`. Properties of identifiers set via `assume` are not taken into account; see “Example 4” on page 1-915.

Examples

Example 1

In this example, we first test if a given expression has a subexpression of type `DOM_FLOAT`:

```
hastype(1.0 + x, DOM_FLOAT)
```

```
TRUE
```

```
hastype(1 + x, DOM_FLOAT)
```

```
FALSE
```

We may also test if an expressions contains a subexpression of one of the two types `DOM_FLOAT` or `DOM_INT`:

```
hastype(1.0 + x, {DOM_FLOAT, DOM_INT})
```

```
TRUE
```

While the first of following two tests returns `FALSE`, since `tan` is not a valid type specifier, the second test yields `TRUE`, since the given expression contains a subexpression of type `"tan"`:

```
hastype(sin(tan(x) + 1/exp(1 - x)), tan),
hastype(sin(tan(x) + 1/exp(1 - x)), "tan")
```

```
FALSE, TRUE
```

You can also use type specifiers from the Type library:

```
hastype([-1, 10, -5, 2*I], Type::PosInt)
```

```
TRUE
```

Example 2

We demonstrate the use of the optional third argument. We want to check if a procedure contains a subexpression of type `"float"`. By default, `hastype` does not descend recursively into a procedure:

```
f := x -> float(x) + 3.0:
hastype(f, "float")
```

```
FALSE
```

You can use the third argument to request the inspection of procedures explicitly:

```
hastype(f, "float", {DOM_PROC})
```

```
TRUE
```

Also, by default, `hastype` does not descend recursively into the basic domains `DOM_COMPLEX` and `DOM_RAT`:

```
hastype(1 + I, DOM_INT), hastype(2/3,  DOM_INT)
```

```
FALSE, FALSE
```

In order to inspect these data types, one has to use the third argument:

```
hastype(1 + I, DOM_INT, {DOM_COMPLEX}),
hastype(2/3,  DOM_INT, {DOM_RAT})
```

```
TRUE, TRUE
```

Example 3

Since matrices possess a slot `enableMaprec`, `hastype` automatically inspects their entries.

```
A := matrix([[1, 1], [1, 0]]):
```

```
hastype(A, DOM_INT)
```

```
TRUE
```

It is also possible to inspect elements of other domains using the third argument. As an example let us define a permutation and ask for a subexpression of type integer:

```
G:= Dom::SymmetricGroup(4):
perm:= G([2,4, 3, 1]):
hastype(perm, DOM_INT), hastype(perm, DOM_INT, {G})
```

```
FALSE, TRUE
```

Example 4

We demonstrate how `hastype` effects on container objects. Let us first stress tables:

```
hastype(table(1 = a), DOM_INT), hastype(table(a = 1), DOM_INT)
```

```
FALSE, TRUE
```

As shown, `hastype` does not inspect the indices of a table, but checks recursively whether a sub-object of a given type occurs in an entry. This is also true for arrays, hfarrays, lists and sets:

```
hastype(array(1..4, [1, 2, 3, 4]), DOM_INT),
hastype(hfarray(1..3, [1.0, 2.0, 3.0*I]), DOM_COMPLEX),
hastype([1, 2, 3, 4], DOM_INT),
hastype({1, 2, 3, 4}, DOM_INT),
hastype([[a, [1]], b, c], DOM_INT)
```

```
TRUE, TRUE, TRUE, TRUE, TRUE
```

`hastype` can only work syntactically, i.e. properties are not taken into account:

```
assume(a,Type::Integer):
hastype([a, b], Type::Integer), hastype([a, b], DOM_INT)
```

```
FALSE, FALSE
```

```
delete a:
```

Parameters

`object`

An arbitrary MuPAD object

`T`

A type specifier, or a set or a list of type specifiers

`inspect`

A set of domain types

Return Values

Either TRUE or FALSE.

Overloaded By

object

MuPAD Functions
`domtype` | `has` | `misc::maprec` | `testtype` | `type`

heaviside

The Heaviside step function

Syntax

```
heaviside(x)
```

Description

`heaviside(x)` represents the Heaviside step function.

If the argument represents a positive real number, then 1 is returned. If the argument represents a negative real number, then 0 is returned. If the argument is zero, $\frac{1}{2}$ is returned. If the argument is a complex number of domain type `DOM_COMPLEX`, then `undefined` is returned. For all other arguments, an unevaluated function call is returned.

The derivative of `heaviside` is the delta distribution `dirac`.

To change the value of `heaviside` at the origin, use `Pref::heavisideAtOrigin`. See “Example 4” on page 1-919. Common choices for this value are `0`, `1`, and `1/2`.

Examples

Example 1

`heaviside` returns 1 or 0 for arguments representing positive or negative real numbers, respectively:

```
heaviside(-3), heaviside(-sqrt(3)), heaviside(-2.1),
heaviside(PI - exp(1)), heaviside(sqrt(3))
```

```
0, 0, 0.0, 1, 1
```

`heaviside` returns $\frac{1}{2}$ if the argument is zero:

```
heaviside(0), heaviside(0.0)
```

$$\frac{1}{2}, 0.5$$

Arguments of domain type `DOM_COMPLEX` yield `undefined`:

```
heaviside(1 + I), heaviside(2/3 + 7*I), heaviside(0.1*I)
```

$$\text{undefined}, \text{undefined}, \text{undefined}$$

An unevaluated call is returned for other arguments:

```
heaviside(x), heaviside(ln(-5)), heaviside(x + I)
```

$$\text{heaviside}(x), \text{heaviside}(\ln(5) + \pi\, i), \text{heaviside}(x + i)$$

Example 2

`heaviside` reacts to assumptions set by `assume`:

```
assume(x > 0): heaviside(x)
```

$$1$$

```
unassume(x):
```

Example 3

The derivative of `heaviside` is the delta distribution `dirac`:

```
diff(heaviside(x - 4), x)
```

$$\delta(x-4)$$

The integrator `int` handles `heaviside`:

```
int(exp(-x)*heaviside(x), x = -infinity..infinity)
```

$$1$$

We do not recommend to use `heaviside` in numerical integration. It is much more efficient to split the quadrature into pieces, each of which having a smooth integrand:

```
DIGITS := 3: numeric::int(exp(-x)*heaviside(x^2 - 2), x=-3..10)
```

$$16.2$$

```
numeric::int(exp(-x), x = -3..-2^(1/2)) +
numeric::int(exp(-x), x = 2^(1/2)..10)
```

$$16.2$$

```
delete DIGITS:
```

Example 4

`heaviside` assumes that the value of the Heaviside function at the origin is `1/2`.

```
heaviside(0)
```

$$\frac{1}{2}$$

Other common values for the Heaviside function at the origin are `0` and `1`. To change the value of `heaviside` at the origin, use `Pref::heavisideAtOrigin`. Store the previous value, so that you can restore it later.

```
oldval := Pref::heavisideAtOrigin(1):
```

Check the new value of `heaviside` at `0`.

```
heaviside(0)
```

$$1$$

Restore the previous value of `heavisideAtOrigin` using `oldval`.

```
Pref::heavisideAtOrigin(oldval):
```

Also, you can restore the default value of `heavisideAtOrigin` by specifying the input as `NIL`.

```
Pref::heavisideAtOrigin(NIL):
```

Parameters

x

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

x

See Also

MuPAD Functions

`dirac` | `Pref::heavisideAtOrigin`

?, help

Display a help page

Syntax

```
?word
```

```
help("word")
```

Description

`help("word")` or `?word` displays a help page with information about the keyword `word`.

When you use `help("word")` interactively, you can use `?word` as a shortcut. The `?` command is not a MuPAD function. You cannot use `?` in expressions or in files. Do not enclose `word` in quotation marks, and do not terminate it with a semicolon.

Parameters

`word`

Any keyword

Return Values

Void object `null()` of type `DOM_NULL`.

See Also

MuPAD Functions
`info`

hessian

Hessian matrix of a scalar function

Syntax

```
hessian(f, x)
```

Description

`hessian(f, x)` computes the Hesse matrix (the Hessian) of the scalar function $f(\vec{x})$ in Cartesian coordinates, i.e., the square matrix of second partial derivatives of $f(\vec{x})$.

Examples

Example 1

The Hessian of the function $f(x, y, z) = x\,y + 2\,x\,z$ is the following matrix:

```
delete x, y, z:
hessian(x*y + 2*z*x, [x, y, z])
```

$$\begin{pmatrix} 0 & 1 & 2 \\ 1 & 0 & 0 \\ 2 & 0 & 0 \end{pmatrix}$$

Parameters

f

An arithmetical expression (the scalar function)

x

A list of (indexed) identifiers

Return Values

Matrix of the domain `Dom::Matrix()`.

Algorithms

For a function $f: X \to \mathbb{R}$, X a subset of $\mathbb{R}^p$, the $p \times p$ matrix

$$H_f(\vec{x}) = \begin{pmatrix} \frac{\partial^2}{\partial x_1^2} f & \frac{\partial}{\partial x_1}\frac{\partial}{\partial x_2} f & \cdots & \frac{\partial}{\partial x_1}\frac{\partial}{\partial x_p} f \\ \frac{\partial}{\partial x_2}\frac{\partial}{\partial x_1} f & \frac{\partial^2}{\partial x_2^2} f & \cdots & \frac{\partial}{\partial x_2}\frac{\partial}{\partial x_p} f \\ \vdots & \vdots & & \vdots \\ \frac{\partial}{\partial x_p}\frac{\partial}{\partial x_1} f & \frac{\partial}{\partial x_p}\frac{\partial}{\partial x_2} f & \cdots & \frac{\partial^2}{\partial x_p^2} f \end{pmatrix}$$

is called the *Hesse matrix* of f.

HISTORY

Maximal number of elements in the history table

Description

The environment variable HISTORY determines the maximal number of entries of the history table at interactive level.

Possible values: Nonnegative integer smaller than 2^{31}.

The commands that are entered interactively in a MuPAD session, executed in a procedure, or read from a file, as well as the resulting MuPAD outputs are stored in an internal data structure, the history table. Only the most recent entries are kept in memory.

Entries of the history table can be accessed via `history` or `last`.

The default value of HISTORY is 20; HISTORY has this value after starting or resetting the system via `reset`. Also the command `delete HISTORY` restores the default value.

Within a procedure, the maximal number of entries in the local history table of the procedure is always 3, independent of the value of HISTORY.

Examples

Example 1

In the following example, we set the value of HISTORY to 2. Afterwards, only the two most recent inputs and outputs are stored in the history table at interactive level:

```
HISTORY := 2:
a := 1: b := 2: max(a, b):
history(history() - 1), history(history())
```

$$[b := 2,\ 2],\ [\max(a,\ b),\ 2]$$

The attempt to access the third last entry in the history table leads to an error:

```
history(history() - 2)
```

```
Error: The argument is invalid. [history]
```

We use `delete` to restore the default value of `HISTORY`:

```
delete HISTORY: HISTORY
```

```
20
```

See Also

MuPAD Functions

`history` | `last`

history

Access an entry of the history table

Syntax

```
history(n)
```

```
history()
```

Description

`history(n)` returns the `n`th entry of the history table.

`history()` returns the index of the most recent entry in the history table.

The commands that are entered interactively in a MuPAD session, executed in a procedure, or read from a file, as well as the resulting MuPAD outputs are stored in an internal data structure, the history table. `history()` returns the index of the most recent entry in the history table. At interactive level, this is the number of commands that have been entered since the start of the session or the last restart.

`history(n)` returns the `n`th entry in the history table in form of a list with two elements. The first element of this list is a MuPAD command, and the second element is the result of this command returned by MuPAD. The order of the entries in the history table is such that larger indices correspond to more recent entries.

The command `last` accesses the result entries from the history table. The call `last(n)` is equivalent to `history ( history() - n + 1) [2]` at interactive level.

The environment variable `HISTORY` determines the maximal number of history entries that are stored at interactive level. The default value is `20`. Only the most recent entries are kept in memory. Thus valid arguments for `history` are all integers between `history() - HISTORY + 1` and `history()`. All other integers lead to an error message.

The result returned by `history` is not evaluated again (see example history-eval). Use the function `eval` to force a subsequent evaluation.

Commands and their results are stored in the history table even if the output is suppressed by a colon. See “Example 1” on page 1-927.

Compound statements, such as `for`, `repeat`, and `while` loops, `if` and `case` branching instructions, and procedure definitions via `proc` are stored in the history table as a whole at interactive level. See the help page of `last` for examples.

Commands appearing on the same input line lead to separate entries in the history table if they are separated by a colon or a semicolon. In contrast, a statement sequence is regarded as a single command (see “Example 3” on page 1-929).

Commands that are read from a file via `fread` or `read` are stored in the history table, and at last the `fread` or `read` command is stored in the history table (because the `fread` or `read` command is finished foremost after reading the file). However, if the option `Plain` is used, then a separate history table is in effect within the file, and the commands from the file do not appear in the history table of the enclosing context.

Note that every call of `history` modifies the history table and possibly erases the earliest history entry.

Every procedure has its own local history table. However, the entries of this table cannot be accessed via `history` (see `last`). The command `history` always refers to the history table at interactive level.

Examples

Example 1

The index of the most recent entry in the history table increases by one for each entered command, also by `history()`. Note that every command is stored in the history table, whether its output is suppressed by a colon or not:

```
history(); sqrt(1764); history(): history()
```

```
 3 42 6
```

`history ( history() )` returns a list with two elements. The first element is the last command, and the second element is the result returned by MuPAD, which is equal to `last(1)` or `%`:

```
int(2*x*exp(x^2), x);
```

```
history(history()), last(1)
```

$$e^{x^2}$$

$$\left[\int 2\,x\,e^{x^2}\,dx,\ e^{x^2}\right],\ e^{x^2}$$

The following command returns the next to last command and its result:

```
history(history() - 1)
```

$$\left[\int 2\,x\,e^{x^2}\,dx,\ e^{x^2}\right]$$

A restart cleans up the history table:

```
reset():
history()
```

```
4
```

The output of the command `history()` above depends on the number of commands in your MuPAD startup file `userinit.mu`.

Example 2

First `a` should be `0`:

```
a := 0:
a
```

$$0$$

Now `1` is assigned to `a`:

```
a := 1:
a
```

$$1$$

The command `history ( history() -2)` refers to the command `a` after assigning `0` to `a`, the return value of `history` is not the new value of `a`, because the result returned by `history` is not evaluated again:

```
history(history() - 2)
```

$$[a, 0]$$

Example 3

The following commands create two entries in the history table. The command `history ( history() -1)` returns only the last command `b:=a`, not both commands:

```
a := 0: b := a:
history(history() - 1)
```

$$[a := 0, 0]$$

If the commands are entered as a statement sequence (enclosed in `( )`), they create one entry. `history ( history() )` picks out the last command, that is, the statement sequence:

```
(a := 0; b := a;):
history(history())
```

```
[(a := 0;
b := a), 0]
```

The last input

```
type(op(%, 1))
```

"_stmtseq"

Parameters

n

A positive integer

Return Values

`history(n)` returns a list with two elements, and `history()` returns a nonnegative integer.

See Also

MuPAD Functions
`fread` | `HISTORY` | `last` | `read`

hold

Delay evaluation

Syntax

```
hold(object)
```

Description

`hold(object)` prevents the evaluation of `object`.

When a MuPAD object is entered interactively, then the system evaluates it and returns the evaluated result. When a MuPAD object is passed as an argument to a procedure, then the procedure usually evaluates the argument before processing it. *Evaluation* means that identifiers are replaced by their values and function calls are executed. `hold` is intended to prevent such an evaluation when it is undesirable.

A typical application of `hold` is when a function that can only process numerical arguments, but not symbolical ones, is to be used as an expression. See “Example 6” on page 1-936.

Another possible reason for using `hold` is efficiency. For example, if a function call `f(x, y)` with symbolic arguments is passed as argument to another function, but is known to return itself symbolically, then the possibly costly evaluation of the “inner” function call can be avoided by passing the expression `hold(f) (x, y)` as argument to the “outer” function instead. Then the arguments `x, y` are evaluated, but the call to `f` is not executed. See examples “Example 1” on page 1-932 and “Example 7” on page 1-936.

Since using `hold` may lead to strange effects, it is recommended to use it only when absolutely necessary.

`hold` only delays the evaluation of an object, but cannot completely prevent it on the long run; see “Example 5” on page 1-935.

You can use `freeze` to completely prevent the evaluation of a procedure or a function environment.

A MuPAD procedure can be declared with the option hold. This has the effect that arguments are passed to the procedure unevaluatedly. See the help page of `proc` for details.

The functions `eval` or `level` can be used to force a subsequent evaluation of an unevaluated object (see example “Example 2” on page 1-933). In procedures with `option hold`, use `context` instead.

Examples

Example 1

In the following two examples, the evaluation of a MuPAD expression is prevented using `hold`:

```
x := 2:
hold(3*0 - 1 + 2^2 + x)
```

$$3\,0 - 1 + 2^2 + x$$

```
hold(error("not really an error"))
```

error("not really an error")

Without `hold`, the results would be as follows:

```
x := 2:
3*0 - 1 + 2^2 + x
```

$$5$$

```
error("not really an error")
```

```
Error: not really an error
```

The following command prevents the evaluation of the operation `_plus`, but not the evaluation of the operands:

```
hold(_plus)(3*0, -1, 2^2, x)
```

$$0 - 1 + 4 + 2$$

Note that in the preceding example, the arguments of the function call are evaluated, because `hold` is applied only to the function `_plus`. In the following example, the argument of the function call is evaluated, despite that fact that `f` has the option hold:

```
f := proc(a)
       option hold;
     begin
       return(a + 1)
     end_proc:
x := 2:
hold(f)(x)
```

$$f(2)$$

This happens for the following reason. When `f` is evaluated, the option `hold` prevents the evaluation of the argument `x` of `f` (see the next example). However, if the evaluation of `f` is prevented by `hold`, then the option `hold` has no effect, and MuPAD evaluates the operands, but not the function call.

The following example shows the expected behavior:

```
f(x), hold(f(x))
```

$$x + 1,\ f(x)$$

The function `eval` undoes the effect of `hold`. Note that it yields quite different results, depending on how it is applied:

```
eval(f(x)), eval(hold(f)(x)), eval(hold(f(x))), eval(hold(f))(x)
```

$$3,\ 3,\ x + 1,\ x + 1$$

Example 2

Several `hold` calls can be nested to prevent subsequent evaluations:

```
x := 2:
hold(x), hold(hold(x))
```

$$x, \text{hold}(x)$$

The result of `hold ( hold(x) )` is the unevaluated operand of the outer call of `hold`, that is, `hold(x)`. Applying `eval` evaluates the result `hold(x)` and yields the unevaluated identifier `x`:

```
eval(%)
```

$$2, x$$

Another application of `eval` yields the value of `x`:

```
eval(%)
```

$$2, 2$$

```
delete x, f:
```

Example 3

The following command prevents the evaluation of the operation `_plus`, replaces it by the operation `_mult`, and then evaluates the result:

```
eval(subsop(hold(_plus)(2, 3), 0 = _mult))
```

$$6$$

Example 4

The function `domtype` evaluates its arguments:

```
x := 0:
domtype(x), domtype(sin), domtype(x + 2)
```

$$\text{DOM\_INT}, \text{DOM\_FUNC\_ENV}, \text{DOM\_INT}$$

Using `hold`, the domain type of the unevaluated objects can be determined: `x` and `sin` are identifiers, and `x + 2` is an expression:

```
domtype(hold(x)), domtype(hold(sin)), domtype(hold(x + 2))
```

DOM_IDENT, DOM_IDENT, DOM_EXPR

Example 5

`hold` prevents only one evaluation of an object, but it does not prevent evaluation at a later time. Thus using `hold` to obtain a a symbol without a value is usually not a good idea:

```
x := 2:
y := hold(x);
y
```

x

2

In this example, deleting the value of the identifier `x` makes it a symbol, and using `hold` is not necessary:

```
delete x:
y := x;
y
```

x

x

However, the best way to obtain a new symbol without a value is to use `genident`:

```
y := genident("z");
y
```

z1

```
    z1
```

```
delete y:
```

Example 6

Consider the piecewise defined function $f(x)$ that is identically zero on the negative real axis and equal to e^{-x} on the positive real axis:

```
f := x -> if x < 0 then 0 else exp(-x) end_if:
```

This function cannot be called with a symbolic argument, because the condition $x < 0$ cannot be decided:

```
f(x)
```

```
Error: Cannot evaluate to Boolean. [_less]
  Evaluating: f
```

We wish to integrate `f` numerically. However, the numerical integrator expects the function as an expression:

```
numeric::int(f(x), x = -2..2)
```

```
Error: Cannot evaluate to Boolean. [_less]
  Evaluating: f
```

The solution is to suppress premature evaluation of `f` when passing the function with a symbolic argument. Inside the numerical integrator, numerical values are substituted for x before the function is called and evaluated:

```
numeric::int(hold(f)(x), x = -2..2)
```

```
    0.8646647168
```

Example 7

The function `int` is unable to compute a closed form of the following integral and returns a symbolic `int` call:

```
int(sqrt(x)*sqrt(sqrt(x) + 1), x)
```

$$\int \sqrt{x}\,\sqrt{\sqrt{x}+1}\,dx$$

After the change of variables `sqrt(x)=t`, a closed form can be computed:

```
t := time():
f := intlib::changevar(int(sqrt(x)*sqrt(sqrt(x) + 1), x), sqrt(x) = y);
time() - t;
eval(f)
```

$$\int \frac{y\sqrt{y+1}}{\sqrt{-y^2+1}}\,dy$$

9210

$$-\frac{2\,(y+2)\sqrt{-y^2+1}}{3\sqrt{y+1}}$$

$$\int 2y^2\sqrt{y+1}\,dy$$

$$-\frac{4\,(y+1)^{3/2}\,(42y-15\,(y+1)^2+7)}{105}$$

Measuring computing times with `time` shows: Most of the time in the call to `intlib::changevar` is spent in re-evaluating the argument. This can be prevented by using `hold`:

```
t := time():
f := intlib::changevar(hold(int)(sqrt(x)*sqrt(sqrt(x) + 1), x),
                       sqrt(x) = y);
time() - t;
```

$$\int \frac{y\sqrt{y+1}}{\sqrt{-y^2+1}}\,dy$$

$$20$$

Parameters

`object`

Any MuPAD object

Return Values

Unevaluated object.

- "Prevent Evaluation"

..., hull

Convert to a floating-point interval

Syntax

```
l ... r
```

```
hull(object)
```

Description

`hull`(object) returns a floating-point interval enclosing object.

`l ... r` is equivalent to `hull(l, r)`.

`hull` converts numerical and interval expressions to numerical intervals of type `DOM_INTERVAL`. It accepts lists and sets of numerical expressions or intervals as well as numerical expressions, intervals, and set-theoretic functions of intervals and sets.

Infinities are displayed using `RD_INF` for `infinity` and `RD_NINF` for `-infinity`.

`hull` is mapped recursively to the operands of any expression given—but for subexpressions, lists and sets are not accepted. Identifiers are replaced by intervals, respecting a certain subset of properties. Cf. “Example 3” on page 1-941. Likewise, function calls and domain elements not overloading `hull` are converted to the interval representing the complex plane.

The output of floating-point intervals is influenced by the same parameters as the output of floating-point numbers:

`DIGITS`, `Pref::floatFormat`, and `Pref::trailingZeroes`.

Environment Interactions

The function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Each sub-object of object can be evaluated multiple times and must not have any side-effects.

Examples

Example 1

`hull` returns an interval enclosing its arguments. You can also use the operator `...` instead of the function call:

```
hull(0, PI) = 0 ... PI
```

$$0.0 \ldots 3.141592654 = 0.0 \ldots 3.141592654$$

Infinities are displayed using `RD_NINF` for $-\infty$ and `RD_INF` for *infinity*:

```
hull(-infinity, 9/7), hull({1/4, 9/7, infinity})
```

$$\mathrm{RD\_NINF} \ldots 1.285714286,\ 0.25 \ldots \mathrm{RD\_INF}$$

Please note that any number whose absolute value is larger than MuPAD can store in a float is considered infinite:

```
hull(0, 1e100000000)^4
```

$$0.0 \ldots \mathrm{RD\_INF}$$

Example 2

Inversion of intervals may lead to unions of intervals. If these are not required, you may use `hull` to unify them:

```
1/(-1 ... 1); hull(%)
```

$$\mathrm{RD\_NINF} \ldots -1.0 \cup 1.0 \ldots \mathrm{RD\_INF}$$

$$\mathrm{RD\_NINF} \ldots \mathrm{RD\_INF}$$

Example 3

The application of `hull` to an identifier without a value returns an interval representing the complex plane:

```
delete x:  hull(x)
```

$$\text{RD\_NINF} \ldots \text{RD\_INF} + \text{RD\_NINF} \ldots \text{RD\_INF}\, i$$

Certain properties are respected during this conversion:

```
assume(x > 0): hull(x);
delete x:
```

$$0.0 \ldots \text{RD\_INF}$$

This way, you can enclose the values of an expression:

```
hull(sin(abs(x)))
```

$$-1.0 \ldots 1.0$$

Calls to “unknown” functions are regarded as potentially returning the complex plane:

```
hull(f(x))
```

$$\text{RD\_NINF} \ldots \text{RD\_INF} + \text{RD\_NINF} \ldots \text{RD\_INF}\, i$$

Parameters

`l`, `r`, `object`

Arbitrary MuPAD objects

Return Values

floating-point interval, the empty set, or `FAIL`.

MuPAD Functions
`DIGITS` | `float` | `interval` | `Pref::floatFormat` | `Pref::trailingZeroes`

hypergeom

Hypergeometric functions

Syntax

```
hypergeom([a1, a2, …], [b1, b2, …], z)
```

Description

`hypergeom([a1, a2, ...], [b1, b2, ...], z)` represents the hypergeometric function.

The hypergeometric function is defined for complex arguments a_i, b_j, and z.

With $a = [a_1, a_2, \ldots, a_p]$ and $b = [b_1, b_2, \ldots, b_q]$, the hypergeometric function of order p, q is defined as

$$ {}_pF_q(a; b; z) = \sum_{k=0}^{\infty} \frac{(a_1)_k (a_2)_k \cdots (a_p)_k}{(b_1)_k (b_2)_k \cdots (b_q)_k} \frac{z^k}{k!} , $$

where $(c)_k = c\,(c + 1) \ldots (c + k - 1)$, $(c)_0 = 1$ is the usual Pochhammer symbol. The quantities a and b are called 'the lists for the upper and lower parameters,' respectively.

A floating-point value is returned if at least one of the arguments is a floating-point number and all other arguments can be converted to floating-point numbers.

For most exact arguments, the hypergeometric function returns a symbolic function call. If an upper parameter coincides with a lower parameter, these values cancel and are removed from the parameter lists.

The following special values are implemented:

- ${}_pF_p(a; a; z) = {}_0F_0(; ; z) = e^z$
- ${}_pF_q(a; b; z) = 1$ if the list of upper parameters `a` contains more zeroes than the list of lower parameters `b`.

- ${}_pF_q(a; b; 0) = 1$.

If, after cancellation of identical parameters, the upper parameters contain a negative integer larger than the largest negative integer in the lower parameters, then ${}_pF_q(a; b; z)$ is a polynomial in `z`. If all upper and lower parameters as well as the argument `z` do not contain any symbolic identifiers, a corresponding explicit result is returned. If the parameters or `z` contain symbols, expansion to the polynomial representation is available via `simplify`. Cf. “Example 2” on page 1-945.

Also empty lists a = [] or b = [] may be passed to `hypergeom`. The corresponding functions are:

$${}_0F_q(; b; z) = \sum_{k=0}^{\infty} \frac{1}{(b_1)_k (b_2)_k \cdots (b_q)_k} \frac{z^k}{k!},$$

$${}_pF_0(a; ; z) = \sum_{k=0}^{\infty} (a_1)_k (a_2)_k \cdots (a_p)_k \frac{z^k}{k!},$$

$${}_0F_0(; ; z) = \sum_{k=0}^{\infty} \frac{z^k}{k!} = e^z.$$

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Symbolic calls are returned for exact or symbolic arguments:

```
hypergeom([], [2], x),
```

```
hypergeom([1], [2, 3], PI),
hypergeom([1, 1/2], [1/3], x + 3*I)
```

$$ {}_0F_1(\text{Null};\ 2;\ x),\ {}_1F_2(1;\ 2,\ 3;\ \pi),\ {}_2F_1\left(\frac{1}{2},\ 1;\ \frac{1}{3};\ x+3\,i\right) $$

Floating point values are returned for floating-point arguments:

```
hypergeom([], [2], 3.0),
hypergeom([1], [2.0], PI),
hypergeom([PI], [2, 3], 4.0),
hypergeom([1, 2], [3, 4, 5, 6], 1.0*I),
hypergeom([1 + I], [1/(2 + I)], 1.0*I)
```

$$ 3.468649619,\ 7.047601352,\ 5.152314068,\ 0.9999801588 + 0.005555508314\,i,\ -0.7438410785 - 0.5956994573\,i $$

Example 2

${}_0F_0(;\ ;\ z)$ is equal to e^z:

```
hypergeom([], [], z)
```

$$ e^z $$

Because identical values in a and b cancel, the same is true for ${}_pF_p(a;\ a;\ z)$:

```
hypergeom([a, b], [a, b], z)
```

$$ e^z $$

Any hypergeometric function, evaluated at 0, has the value 1:

```
hypergeom([a, b], [c, d, e], 0)
```

$$ 1 $$

If, after cancelling identical parameters, the list of upper parameters contains a zero, the resulting hypergeometric function is constant with the value 1:

```
hypergeom([0, 0, 2, 3], [a, 0, 4], z)
```

$$1$$

If, after cancelling identical parameters, the upper parameters contain a negative integer larger than the largest negative integer in the lower parameters, the hypergeometric function is a polynomial. If all parameters as well as the argument `z` are numerical, a corresponding explicit value is returned:

```
hypergeom([-4, -2 , 3], [-3, 1, 4], PI*sqrt(2))
```

$$\frac{6\,\pi^2}{5} - 2\,\pi\,\sqrt{2} + 1$$

For symbolic parameters or symbolic `z`, the polynomial representation may be obtained via `simplify` or `Simplify`:

```
hypergeom([-40, -5], [1, 4], z) =
simplify(hypergeom([-40, -5], [1, 4], z))
```

$${}_2F_2(-40, -5; 1, 4; z) = \frac{27417\,z^5}{280} + \frac{45695\,z^4}{84} + \frac{2470\,z^3}{3} + 390\,z^2 + 50\,z + 1$$

```
hypergeom([-3, a], [b], z) =
Simplify(hypergeom([-3, a], [b], z))
```

$${}_2F_1(-3, a; b; z) = \frac{3\,a\,z^2\,(2\,a+2)}{2\,b\,(b+1)} - \frac{3\,a\,z}{b} - \frac{a\,z^3\,(2\,a+2)\,(a+2)}{2\,b\,(b+1)\,(b+2)} + 1$$

If the largest negative integer in the list of lower parameters is larger than the largest negative integer in the list of upper parameters, the corresponding hypergeometric function is not defined (because its definition involves a division by zero):

```
hypergeom([-40, -5, 3], [-3, 1, 4], z)
```

```
Error: Invalid arguments. [hypergeom]
```

Example 3

The functions `float`, `diff`, and `series` handle expressions involving the hypergeometric functions:

```
float(ln(3 + hypergeom([17], [exp(1), ln(5)], sqrt(PI))))
```

$$3.488880173$$

```
diff(hypergeom([a, b], [c, d], x), x)
```

$$\frac{a\,b\,{}_2F_2(a+1, b+1; c+1, d+1; x)}{c\,d}$$

Note that differentiation of a hypergeometric function w.r.t. one of its uppper or lower parameters does not, in general, lead to hypergeometric functions. Certain peculiar cases are an exception:

```
diff(hypergeom([a + 1, b], [a + 2], x), a)
```

$$\frac{b\,x\,{}_3F_2(a+2, a+2, b+1; a+3, a+3; x)}{(a+2)^2}$$

```
series(hypergeom([1, 2], [3], x), x)
```

$$1+\frac{2\,x}{3}+\frac{x^2}{2}+\frac{2\,x^3}{5}+\frac{x^4}{3}+\frac{2\,x^5}{7}+O(x^6)$$

Expansions about *infinity* are possible:

```
series(hypergeom([1/2], [1/3], x), x = infinity, 3)
```

$$\frac{2\sqrt{3}\,\sqrt{\pi}\,x^{1/6}\,e^x}{3\,\Gamma\left(\frac{2}{3}\right)}-\frac{\sqrt{3}\,\sqrt{\pi}\,e^x}{18\,x^{5/6}\,\Gamma\left(\frac{2}{3}\right)}-\frac{5\sqrt{3}\,\sqrt{\pi}\,e^x}{144\,x^{11/6}\,\Gamma\left(\frac{2}{3}\right)}+O\left(\frac{e^x}{x^{17/6}}\right)$$

However, there are very few (if any) complete expansions for hypergeometric functions about any of its upper or lower parameters.

Example 4

Often, at particular choices of parameters, the hypergeometric function reduces to simpler special functions. For example, in the case of ${}_1F_1$, also known as the standard confluent hypergeometric function, the hypergeometric function can be reduced to a Bessel function if its (single) lower parameter is exactly twice its (single) upper parameter. This is verified numerically below:

```
v:= 1.0 + I: z:= float(PI):
hypergeom([v + 1/2], [2*v + 1], 2*I*z) =
(gamma(1 + v)*exp(I*z)*((z/2)^(-v))*besselJ(v, z))
```

$$-0.2766083174 - 0.2537119431\,i = -0.2766083174 - 0.2537119431\,i$$

```
delete v, z:
```

In the following example, ${}_2F_1$, which is known as the Gauss hypergeometric function, can be reduced into a simple elementary function involving logarithms when the parameters are `[1, 1], [2]`, as verified numerically below:

```
eq := hypergeom([1, 1], [2], z) = -ln(1 - z)/z:
float(subs(eq, z = 1/3)), float(subs(eq, z = 1/2))
```

$$1.216395324 = 1.216395324,\ 1.386294361 = 1.386294361$$

```
delete eq:
```

Example 5

The interval $[1, \infty)$ is a branch cut for the hypergeometric function; the sign of the imaginary part changes when crossing the cut. The branch cut belongs to the lower branch:

```
eq := hypergeom([1, 1], [2], z) = -ln(1 - z)/z:
float(subs(eq, z = 2 + I*10^(-DIGITS)))
```

$$7.853981634\,10^{-11} + 1.570796327\,i = 7.853981634\,10^{-11} + 1.570796327\,i$$

```
float(subs(eq, z = 2 - I*10^(-DIGITS)))
```

$$7.853981634\,10^{-11} - 1.570796327\,i = 7.853981634\,10^{-11} - 1.570796327\,i$$

```
float(subs(eq, z = 2))
```

$$-1.570796327\,i = -1.570796327\,i$$

Parameters

a_1, a_2, …

The 'upper parameters': arithmetical expressions

b_1, b_2, …

The 'lower parameters': arithmetical expressions

z

The 'argument': an arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

z

Algorithms

When no b_j in the list b lies in the set {0, - 1, - 2, …}, the series

$$ {}_pF_q(a;\, b;\, z) = \sum_{k=0}^{\infty} \frac{(a_1)_k\,(a_2)_k \cdots (a_p)_k}{(b_1)_k\,(b_2)_k \cdots (b_q)_k}\,\frac{z^k}{k!} $$

converges if one of the following conditions hold:

1. $p \le q,\ |z| < \infty$;
2. $p = q + 1,\ |z| < 1$;
3. $p = q + 1,\ |z| = 1,\ \Re(\psi_q) > 0$;
4. $p = q + 1,\ |z| = 1,\ z \neq 1,\ -1 < \Re\left(\psi_q\right) \le 0$;
5. a contains a zero or a negative integer;

where $\psi_q = \left(\sum_{k=1}^{q} b_k\right) - \left(\sum_{j=1}^{q+1} a_j\right)$. The series diverges in the remaining cases. If one of the parameters in a isequal to zero or a negative integer, then the series terminates, turning into what is called a hypergeometric polynomial.

The generalized hypergeometric function of order (p, q) is given by the series definition in the region of convergence, while for $p = q + 1,\ |z| \ge 1$, it is defined as an analytic continuation of this series.

The function ${}_pF_q(a;\, b;\, z)$ is symmetric w.r.t. the parameters, i.e., it does not depend on the order of the arrangement $a_1, a_2, \ldots$ in a or $b_1, b_2, \ldots$ in b.

As mentioned above, if some upper parameter is equal to $n = 0, -1, -2, \ldots$, the function turns into a polynomial of degree n. If we relax the condition stated above for the lower parameters b and there is some lower parameter equal to $m = 0, -1, -2, \ldots$, the function ${}_pF_q(a;\, b;\, z)$ also reduces to a polynomial in z provided $n > m$. It is undefined if $m > n$ or if no upper parameter is a nonpositive integer (resulting in division by zero in one of the series coefficients). The case $m = n$ is handled by the following rule.

If for r values of the upper parameters, there are r values of the lower parameters equal to them (i.e., $a = [a_1, \ldots, a_{p-r}, c_1, \ldots, c_r]$, $b = [b_1, \ldots, b_{q-r}, c_1, \ldots, c_r]$), then the order (p, q) of the function ${}_pF_q(a;\, b;\, z)$ is reduced to $(p - r, q - r)$:

$$ {}_pF_q\left(a_1, \ldots, a_{p-r}, c_1, \ldots, c_r;\, b_1, \ldots, b_{q-r}, c_1, \ldots, c_r;\, z\right) = {}_{p-r}F_{q-r}\left(a_1, \ldots, a_{p-r};\, b_1, \ldots, b_{q-r};\, z\right). $$

The above rule applies even if any of the c_i happens to be zero or a negative integer (for details, see Luke in the list of references, p. 42).

$U(z) = {}_pF_q(a; b; z)$ satisfies a differential equation in z:

$$[\delta\,(\delta + b - 1) - z\,(\delta + a)]\,U(z) = 0,\ \delta = z\,\frac{\partial}{\partial z}$$

,

where $(\delta + a)$ and $(\delta + b)$ stand for $\prod_{i=1}^{p}\left(\delta + a_i\right)$ and $\prod_{j=1}^{q}\left(\delta + b_j\right)$, respectively.

Thus, the order of this differential equation is $max(p, q + 1)$ and the hypergeometric function is only one of its solutions. If $p < q + 1$, this differential equation has a regular singularity at $z = 0$ and an irregular singularity at $z = \infty$. If $p = q + 1$, the points $z = 0$, $z = 1$, and $z = \infty$ are regular singularities, thus explaining the convergence properties of the hypergeometric series.

The analytic continuation for $p = q + 1$, $|z| \geq 1$, is defined by selecting the principal branch of this continuation (also denoted as ${}_pF_q(a; b; z)$) satisfying the condition $|arg(1 - z)| < \pi$, the cut along $[1, \infty)$ is drawn in the complex z-plane. In particular, the analytic continuation can be obtained by means of an integral representation (for details, see Prudnikov *et al.* in the references) or by the Meijer G function.

icontent

Content of a polynomial with rational coefficients

Syntax

```
icontent(p)
```

Description

`icontent(p)` calculates the content of a polynomial or polynomial expression with integer or rational coefficients, i.e., the greatest common divisor of the coefficients, such that `p/ icontent(p)` has integral coefficients whose greatest common divisor is `1`. In particular, if `p` is itself an integer or a rational number, then `icontent` returns `abs(p)` (see “Example 1” on page 1-952).

If `p` is a polynomial or polynomial expression with integer coefficients, then the content is the greatest common divisor of the coefficients. If `p` is a polynomial or polynomial expression with rational coefficients, then the content is the greatest common divisor of the numerators of the coefficients divided by the least common multiple of the denominators (see “Example 2” on page 1-953).

If `p` is a polynomial expression, then it is first converted into a polynomial of domain type `DOM_POLY` using `poly`. If this conversion is not possible, then `icontent` returns `FAIL`.

`icontent` returns an error message if not all coefficients of `p` are integers or rational numbers.

Examples

Example 1

The first argument can be a polynomial or a polynomial expression. The following two calls of `icontent` are equivalent:

```
p := 6*x*y - 9*y^2 + 21:
```

```
icontent(poly(p)), icontent(p)
```

$$3,\ 3$$

The result of `icontent` is always nonnegative:

```
icontent(2*x - 4), icontent(-2*x + 4)
```

$$2,\ 2$$

The content of a constant polynomial is its absolute value:

```
icontent(0), icontent(-2), icontent(poly(-2, [x]))
```

$$0,\ 2,\ 2$$

Example 2

The content of a polynomial with rational coefficients is a rational number in general:

```
q := 6/7*x*y - 9/4*y + 12:
icontent(poly(q)), icontent(q)
```

$$\frac{3}{28},\ \frac{3}{28}$$

The polynomial divided by its content has integral coefficients whose greatest common divisor is 1:

```
q/icontent(q)
```

$$8\,x\,y - 21\,y + 112$$

```
icontent(%)
```

$$1$$

Parameters

p

A polynomial or polynomial expression with integer or rational number coefficients

Return Values

Nonnegative integer or rational number, or `FAIL`

See Also

MuPAD Functions

`coeff` | `content` | `factor` | `gcd` | `ifactor` | `igcd` | `ilcm` | `lcm` | `poly` | `polylib::primpart`

id

Identity map

Syntax

```
id(x)
```

```
id(x1, x2, …)
```

Description

`id(x)` evaluates and returns `x`; `id(x1, x2, ...)` returns the evaluated arguments as an expression sequence; `id()` returns the void object `null()`.

Examples

Example 1

`id` returns the evaluated arguments:

```
a := 2: id(a + 2)
```

$$4$$

```
id(a, b, 4 + 2)
```

$$2, b, 6$$

`id()` returns `null()`:

```
domtype(id())
```

$$\text{DOM\_NULL}$$

```
delete a:
```

Example 2

`id` is useful when working with functional expressions:

```
f := 3*id + sin + 5*id^2 + exp@(-id^2):
f(x)
```

$$3\,x + e^{-x^2} + \sin(x) + 5\,x^2$$

```
f'(x)
```

$$10\,x + \cos(x) - 2\,x\,e^{-x^2} + 3$$

```
delete f:
```

Parameters

`x, x1, x2, …`

Arbitrary MuPAD objects

Return Values

Sequence of the input parameters.

if, then, elif, else, end_if, _if

If-statement (conditional branch in a program)

Syntax

```
if condition1
then casetrue1
   elif condition2 then casetrue2
   elif condition3 then casetrue3
   ...
   else casefalse
 end_if

_if(condition1, casetrue1, casefalse)
```

Description

`if-then-else-end_if` allows conditional branching in a program.

If the Boolean expression `condition1` can be evaluated to `TRUE`, the branch `casetrue1` is executed and its result is returned. Otherwise, if `condition2` evaluates to `TRUE`, the branch `casetrue2` is executed and its result is returned etc. If all of the conditions evaluate to `FALSE`, the branch `casefalse` is executed and its result is returned.

All conditions that are evaluated during the execution of the `if` statement must be reducible to either `TRUE` or `FALSE`. Conditions may be given by equations or inequalities, combined with the logical operators `and`, `or`, `not`. There is no need to enforce Boolean evaluation of equations and inequalities via `bool`. Implicitly, the `if` statement enforces "lazy" Boolean evaluation via the functions `_lazy_and` or `_lazy_or`, respectively. A condition leads to a runtime error if it cannot be evaluated to `TRUE` or `FALSE` by these functions. Cf. "Example 3" on page 1-959.

The keyword `end_if` may be replaced by the keyword `end`.

The statement `if condition then casetrue else casefalse end_if` is equivalent to the function call `_if(condition, casetrue, casefalse)`.

Examples

Example 1

The `if` statement operates as demonstrated below:

```
if TRUE then YES else NO end_if,
if FALSE then YES else NO end_if
```

```
YES, NO
```

The `else` branch is optional:

```
if FALSE then YES end_if
```

```
if FALSE
  then if TRUE
         then NO_YES
         else NO_NO
       end_if
  else if FALSE
         then YES_NO
         else YES_YES
       end_if
end_if
```

```
YES_YES
```

Typically, the Boolean conditions are given by equations, inequalities or Boolean constants produced by system functions such as `isprime`:

```
for i from 100 to 600 do
  if 105 < i and i^2 <= 17000 and isprime(i) then
     print(expr2text(i)." is a prime")
  end_if;
  if i < 128 then
     if isprime(2^i - 1) then
        print("2^".expr2text(i)." - 1 is a prime")
     end_if
  end_if
end_for:
```

"107 is a prime"

"2^107 - 1 is a prime"

"109 is a prime"

"113 is a prime"

"127 is a prime"

"2^127 - 1 is a prime"

Example 2

Instead of using nested `if-then-else` statements, the `elif` statement can make the source code more readable. However, internally the parser converts such statements into equivalent `if-then-else` statements:

```
hold(if FALSE then NO elif TRUE then YES_YES else YES_NO end_if)
```

```
if FALSE then
  NO
else
  if TRUE then
    YES_YES
  else
    YES_NO
  end_if
end_if
```

Example 3

If the condition cannot be evaluated to either TRUE or FALSE, then a runtime error is raised. In the following call, `is(x > 0)` produces UNKNOWN if no corresponding properties was attached to `x` via `assume`:

```
if is(x > 0) then
  1
else
  2
end_if
```

```
Error: Cannot evaluate to Boolean. [if]
```

Note that Boolean conditions using <, <=, >, >= may fail if they involve symbolic expressions:

```
if 1 < sqrt(2) then print("1 < sqrt(2)"); end_if
```

"1 < sqrt(2)"

```
if 10812186006/7645370045 < sqrt(2)
  then print("10812186006/7645370045 < sqrt(2)");
end_if
```

"10812186006/7645370045 < sqrt(2)"

```
if is(10812186006/7645370045 < sqrt(2)) = TRUE
  then print("10812186006/7645370045 < sqrt(2)");
end_if
```

"10812186006/7645370045 < sqrt(2)"

Example 4

This example demonstrates the correspondence between the functional and the imperative use of the `if` statement:

```
condition := 1 > 0: _if(condition, casetrue, casefalse)
```

casetrue

```
condition := 1 > 2: _if(condition, casetrue, casefalse)
```

casefalse

```
delete condition:
```

Parameters

$condition_1$, $condition_2$, …

Boolean expressions

$casetrue_1$, $casetrue_2$, casefalse, …

Arbitrary sequences of statements

Return Values

Result of the last command executed inside the `if` statement. The empty sequence, `null()` is returned if no command was executed.

More About

- "Conditional Control"

ifactor

Factor an integer into primes

Syntax

```
ifactor(n, <UsePrimeTab>)
```

```
ifactor(<PrimeLimit>)
```

Description

`ifactor(n)` computes the prime factorization $n = s\,p_1^{e_1} \ldots p_r^{e_r}$ of the integer n, where s is the sign of n, p_1, …, p_r are the distinct positive prime divisors of n, and e_1, …, e_r are positive integers.

The result of `ifactor` is an object of domain type `Factored`. Let `f:= ifactor(n)` be such an object. Internally, it is represented by the list `[s, p1, e1, ..., pr, er]` of odd length $2r + 1$, where r is the number of distinct prime divisors of n. The p_i are not necessarily sorted by magnitude.

You may extract the sign s and the terms $p_i^{e_i}$ by means of the index operator `[ ]`, i.e., `f[1] = p1^e1, f[2] = p2^e2, ...` for positive n and `f[1] = s, f[2] = p1^e1, f[3] = p2^e2, ...` for negative n.

The call `Factored::factors(f)` yields a list of the factors `[p1, p2, ...]`, while `Factored::exponents(f)` returns a list of the exponents `[e1, e2, ...]` with $1 \le i \le r$.

The factorization of 0, 1, and - 1 yields the single factor 0, 1, and - 1, respectively. In these cases, the internal representation is the list `[0]`, `[1]`, and `[-1]`, respectively.

The call `coerce(f,DOM_LIST)` returns the internal representation of a factored object, i.e., the list `[s, p1, e1, p2, e2, ...]`.

Note that the result of `ifactor` is printed as an expression, and it is implicitly converted into an expression whenever it is processed further by other MuPAD functions. For

example, the result of `ifactor(12)` is printed as `2^2*3`, which is an expression of type `"_mult"`.

See “Example 1” on page 1-963 for illustrations, and the help page of `Factored` for more details.

If you do not need the prime factorization of `n`, but only want to know whether it is composite or prime, use `isprime` instead, which is much faster.

`ifactor` returns an error when the argument is a number but not an integer. A symbolic `ifactor` call is returned if the argument is not a number.

Examples

Example 1

To get the prime factorization of 120, enter:

```
f := ifactor(120)
```

$$2^3\ 3\ 5$$

You can access the terms of this factorization using the index operator:

```
f[1], f[2], f[3]
```

$$2^3,\ 3,\ 5$$

The internal representation of `f`, namely the list as described above, is returned by the following command:

```
coerce(f, DOM_LIST)
```

$$[1,\ 2,\ 3,\ 3,\ 1,\ 5,\ 1]$$

The result of `ifactor` is an object of domain type `Factored`:

```
domtype(f)
```

Factored

This domain implements some features for handling such objects. Some of them are described below.

You may extract the factors and exponents of the factorization also in the following way:

```
Factored::factors(f), Factored::exponents(f)
```

[2, 3, 5], [3, 1, 1]

You can ask for the type of the factorization:

```
Factored::getType(f)
```

"irreducible"

This output means that all factors p_i are prime. Other possible types are `"squarefree"` (see `polylib::sqrfree`) or `"unknown"`.

Multiplying factored objects preserves the factored form:

```
f2 := ifactor(12)
```

$2^2\ 3$

```
f*f2
```

$2^5\ 3^2\ 5$

It is important to note that you can apply nearly any function operating on arithmetical expressions to an object of domain type `Factored`. The result is usually not of this domain type:

```
expand(f);
```

```
domtype(%)
```

$$120$$

$$\mathrm{DOM\_INT}$$

For a detailed description of these objects, please refer to the help page of the domain `Factored`.

Example 2

The factorizations of `0`, `1`, and `-1` each have exactly one factor:

```
ifactor(0), ifactor(1), ifactor(-1)
```

$$0,\ 1,\ -1$$

```
map(%, coerce, DOM_LIST)
```

$$[0],\ [1],\ [-1]$$

The internal representation of the factorization of a prime number `p` is the list `[1, p, 1]`:

```
coerce(ifactor(5), DOM_LIST)
```

$$[1,\ 5,\ 1]$$

Example 3

The bound on the prime number table is:

```
ifactor(PrimeLimit)
```

$$1000000$$

We assign a large prime number to p:

```
p := nextprime(10^10);
q := nextprime(10^12)
```

```
10000000019
```

```
1000000000039
```

Completely factoring the 36 digit number 6*p^3 takes some time; the second output line shows the time in seconds:

```
t := time():
f := ifactor(p^3*q^4);
(time() - t)/1000.0
```

```
10000000019^3*1000000000039^4
```

```
2.5
```

```
Factored::getType(f)
```

```
"irreducible"
```

```
delete f
```

Extracting only the prime factors in the prime table is much faster, but it does not yield the complete factorization; the factor p^3 remains undecomposed:

```
t := time():
f := ifactor(p^3*q^4, UsePrimeTab);
(time() - t)/1000.0
```

```
10000000058560000117283260086007354771701933667061781196953525306500458678918 19
```

```
0.015625
```

```
Factored::getType(f)
```

```
"unknown"
```

```
delete f
```

Parameters

`n`

An arithmetical expression representing an integer

Options

`UsePrimeTab`

Internally, MuPAD has stored a pre-computed table of all prime numbers up to a certain bound. `ifactor(n, UsePrimeTab)` looks only for prime factors that are stored in this internal prime number table, extracts them from `n`, and returns the undecomposed product of all other prime factors as a single factor. This is usually much faster than without the option `UsePrimeTab`, but it does not necessarily yield the complete prime factorization of `n`. See “Example 2” on page 1-965.

`PrimeLimit`

`ifactor(PrimeLimit)` returns an integer, namely a bound on the size of prime numbers in the internal prime number table. The table contains all primes below this bound. The default values are: 1000000 on UNIX systems and 300000 on Mac OS platforms and Windows platforms.

The size of this table can be changed via the MuPAD command line flag `-L`.

Return Values

Object of domain type `Factored`, or a symbolic `ifactor` call.

Algorithms

`ifactor` uses the elliptic curve method.

`ifactor` is an interface to the kernel function `stdlib::ifactor`. It calls `stdlib::ifactor` with the given arguments and convert its result, which is the list

`[s, p1, e1, ..., pr, er]` as described above, into an object of the domain type `Factored`.

You may directly call the kernel function `stdlib::ifactor` inside your routines, in order to avoid this conversion and to decrease the running time.

ifourier

Inverse Fourier transform

Syntax

```
ifourier(F, w, t)
```

Description

`ifourier(F, w, t)` computes the inverse Fourier transform of the expression `F = F(w)` with respect to the variable `w` at the point `t`.

The inverse Fourier transform of the expression `F = F(w)` with respect to the variable `w` at the point `t` is defined as follows:

$$f(t) = \frac{|s|}{2\,\pi\,c} \int_{-\infty}^{\infty} F(w)\, e^{-i\,s\,w\,t}\, dw$$

.

`c` and `s` are parameters of the Fourier transform. By default, `c = 1` and `s = -1`.

To change the parameters `c` and `s` of the Fourier transform, use `Pref::fourierParameters`. See “Example 3” on page 1-971. Common choices for the parameter `c` are 1, $\frac{1}{2\,\pi}$, or $\frac{1}{\sqrt{2\,\pi}}$. Common choices for the parameter `s` are -1, 1, - 2 π, or 2 π.

If `F` is a matrix, `ifourier` applies the inverse Fourier transform to all components of the matrix.

MuPAD computes `ifourier(F, w, t)` as

$$\frac{|s|}{2\,\pi\,c^2}\ \mathrm{fourier}(F(w),\, w,\, -t)$$

.

If `ifourier` cannot find an explicit representation of the inverse Fourier transform, it returns results in terms of the direct Fourier transform. See “Example 4” on page 1-972.

To compute the direct Fourier transform, use `fourier`.

To compute the inverse discrete Fourier transform, use `numeric::invfft`.

Environment Interactions

Results returned by `ifourier` depend on the current `Pref::fourierParameters` settings.

Examples

Example 1

Compute the inverse Fourier transform of this expression with respect to the variable `w`:

```
ifourier(sqrt(PI)*exp(-w^2/4), w, t)
```

$$e^{-t^2}$$

Example 2

Compute the inverse Fourier transform of this expression with respect to the variable `w` for positive values of the parameter t_0:

```
assume(t_0 > 0):
f := ifourier(-(PI^(1/2)*w*exp(-w^2*t_0^2/4)*I)*t_0^3/2, w, t)
```

$$t\,e^{-\frac{t^2}{t_0^2}}$$

Evaluate the inverse Fourier transform of the expression at the points $t = -2\,t_0$ and $t = 1$. You can evaluate the resulting expression `f` using `|` (or its functional form `evalAt`):

```
f | t = -2*t_0
```

$$-2\,t_0\,e^{-4}$$

Also, you can evaluate the inverse Fourier transform at a particular point directly:

```
ifourier(-(PI^(1/2)*w*exp(-w^2*t_0^2/4)*I)*t_0^3/2, w, 1)
```

$$e^{-\frac{1}{t_0^2}}$$

Example 3

The default parameters of the Fourier and inverse Fourier transforms are `c = 1` and `s = -1`:

```
ifourier(-(sqrt(PI)*w*exp(-w^2/4)*I)/2, w, t)
```

$$t\,e^{-t^2}$$

To change these parameters, use `Pref::fourierParameters` before calling `ifourier`:

```
Pref::fourierParameters(1, 1):
```

Evaluate the transform of the same expression with the new parameters:

```
ifourier(-(sqrt(PI)*w*exp(-w^2/4)*I)/2, w, t)
```

$$-t\,e^{-t^2}$$

For further computations, restore the default values of the Fourier transform parameters:

```
Pref::fourierParameters(NIL):
```

Example 4

If `ifourier` cannot find an explicit representation of the transform, it returns results in terms of the direct Fourier transform:

```
ifourier(exp(-w^4), w, t)
```

$$\frac{\text{fourier}\left(e^{-w^4}, w, -t\right)}{2\,\pi}$$

Example 5

Compute the following inverse Fourier transforms that involve the Dirac and the Heaviside functions:

```
ifourier(dirac(w), w, t)
```

$$\frac{1}{2\,\pi}$$

```
ifourier(heaviside(w + 5), w, t)
```

$$\frac{e^{-5\,t\,i}\left(\pi\,\delta(t) + \frac{i}{t}\right)}{2\,\pi}$$

Parameters

F

Arithmetical expression or matrix of such expressions

w

Identifier or indexed identifier representing the transformation variable

t

Arithmetical expression representing the evaluation point

Return Values

Arithmetical expression or an expression containing an unevaluated function call of type `fourier`. If the first argument is a matrix, then the result is returned as a matrix.

MuPAD Functions

`fourier` | `fourier::addpattern` | `ifourier::addpattern` | `numeric::fft` | `numeric::invfft` | `Pref::fourierParameters`

ifourier::addpattern

Add patterns for the inverse Fourier transform

Syntax

```
ifourier::addpattern(pat, w, t, res, <vars, <conds>>)
```

Description

`ifourier::addpattern(pat, w, t, res)` teaches `ifourier` to return `res` for the expression `pat`.

The `ifourier` function uses a set of patterns for computing inverse Fourier transforms. You can extend the set by adding your own patterns. To add a new pattern to the pattern matcher, use `ifourier::addpattern`. MuPAD does not save custom patterns permanently. The new patterns are available in the *current* MuPAD session only.

After the call `ifourier::addpattern(pat, w, t, res)`, the `ifourier` function returns `res` for the expression `pat`. Note that the inverse Fourier transform is defined as $\frac{|s|}{2\pi c}\int_{-\infty}^{\infty} F\, \mathrm{e}^{-\mathrm{i}\,s\,w\,t}\,\mathrm{d}w$, where `c` and `s` are the parameters specified by `Pref::fourierParameters`. If you add a new pattern, and then change the Fourier transform parameters, the result returned by `ifourier(pat, w, t)` will also change. See “Example 2” on page 1-976.

Variable names that you use when calling `ifourier::addpattern` can differ from the names that you use when calling `ifourier`. See “Example 3” on page 1-976.

You can include a list of free parameters and a list of conditions on these parameters. These conditions and the result are protected from premature evaluation. That means you can use `not iszero(a^2-b)` instead of `hold( _not @ iszero )(a^2-b)`.

The following conditions treat assumptions on identifiers differently:

- `a^2-b <> 0` takes into account assumptions on identifiers.
- `not iszero(a^2-b)` disregards assumptions on identifiers.

See “Example 4” on page 1-976 and “Example 5” on page 1-977.

Environment Interactions

The Fourier pair `(pat, res)` holds only for the current values of the Fourier transform parameters specified by `Pref::fourierParameters`.

Calling `ifourier::addpattern` can change the expressions returned by future calls to `fourier` and `ifourier` in the current MuPAD session.

Examples

Example 1

Compute the inverse Fourier transform of the function `bar`. By default, MuPAD does not have a pattern for this function:

```
ifourier(bar(w), w, t)
```

$$\frac{\mathrm{fourier}(\mathrm{bar}(w), w, -t)}{2\,\pi}$$

Add a pattern for the inverse Fourier transform of `bar` using `ifourier::addpattern`:

```
ifourier::addpattern(bar(w), w, t, foo(t)):
```

Now `ifourier` returns the Fourier transform of `bar`:

```
ifourier(bar(w), w, t)
```

$$\mathrm{foo}(t)$$

After you add a new transform pattern, MuPAD can use that pattern indirectly:

```
ifourier(exp(-a*I*s)*bar(2*s + 10), s, t)
```

$$\frac{\mathrm{foo}\left(\frac{t}{2}-\frac{a}{2}\right)\,\mathrm{e}^{5\,a\,i-5\,t\,i}}{2}$$

Example 2

Add this pattern for the inverse Fourier transform of the function `bar`:

```
ifourier::addpattern(bar(w), w, t, foo(t)):
ifourier(bar(w), w, t)
```

$$\mathrm{foo}(t)$$

Now change the Fourier transform parameters using `Pref::fourierParameters`:

```
Pref::fourierParameters(a, b):
```

Evaluate the transform with the new parameters:

```
ifourier(bar(w), w, t)
```

$$\frac{\mathrm{foo}(-b\,t)\,|b|}{a}$$

For further computations, restore the default values of the Fourier transform parameters:

```
Pref::fourierParameters(NIL):
```

Example 3

Define the inverse Fourier transform of `bar(y)` using variables `y` and `x` as parameters:

```
ifourier::addpattern(bar(y), y, x, foo(x)):
```

The `ifourier` function recognizes the added pattern even if you use other variables as parameters:

```
ifourier(bar(w), w, t)
```

$$\mathrm{foo}(t)$$

Example 4

Use assumptions when adding the following pattern for the inverse Fourier transform:

```
ifourier::addpattern(bar(x, w), w, t, foo(x, t), [x], [abs(x) < 1]):
ifourier(bar(x, w), w, t) assuming abs(x) < 1/2
```

$$\mathrm{foo}(x, t)$$

If $|x| \geq 1$, you cannot apply these patterns:

```
ifourier(bar(x, w), w, t) assuming x < -1
```

$$\frac{\mathrm{fourier}(\mathrm{bar}(x, w), w, -t)}{2\,\pi}$$

If MuPAD cannot determine whether the conditions are satisfied, it returns a `piecewise` object:

```
ifourier(bar(x, w), w, t)
```

$$\begin{cases} \mathrm{foo}(x, t) & \text{if } |x| < 1 \end{cases}$$

Example 5

Add this pattern for the inverse Fourier transform of `g`:

```
ifourier::addpattern(g(a, w), w, t, f(a, t)/a):
ifourier(g(a, W), W, T)
```

$$\frac{f(a, T)}{a}$$

This pattern holds only when the first argument of `g` is the symbolic parameter `a`. If you use any other value of this parameter, `ifourier` ignores the pattern:

```
ifourier(g(b, W), W, T);
ifourier(g(2, W), W, T)
```

$$\frac{\mathrm{fourier}(g(b, W), W, -T)}{2\,\pi}$$

$$\frac{\text{fourier}(g(2, W), W, -T)}{2\,\pi}$$

To use the pattern for arbitrary values of the parameter, declare the parameter `a` as an additional pattern variable:

```
ifourier::addpattern(g(a, w), w, t, f(a, t)/a, [a]):
```

Now `ifourier` applies the specified pattern for an arbitrary value of `a`:

```
ifourier(g(2, W), W, T)
```

$$\frac{f(2, T)}{2}$$

```
ifourier(g(a^2 + 1, W), W, T)
```

$$\frac{f(a^2+1, T)}{a^2+1}$$

Note that the resulting expression `f(a, t)/a` defining the Fourier transform of `g(a, w)` implicitly assumes that the value of `a` is not zero. A strict definition of the pattern is:

```
ifourier::addpattern(g(a, w), w, t, f(a, t)/a, [a], [a <> 0]):
```

For this particular pattern, you can omit specifying the assumption `a <> 0` explicitly. If `a = 0`, MuPAD throws an internal "Division by zero." error and ignores the pattern:

```
ifourier(f(0, W), W, T)
```

$$\frac{\text{fourier}(f(0, W), W, -T)}{2\,\pi}$$

Parameters

`pat`

Arithmetical expression in the variable `w` representing the pattern to match

`w`

Identifier or indexed identifier used as a variable in the pattern

`t`

Identifier or indexed identifier used as a variable in the result

`res`

Arithmetical expression in the variable `t` representing a pattern for the result

`vars`

List of identifiers or indexed identifiers used as "pattern variables" (placeholders in `pat` and `res`). You can use pattern variables as placeholders for almost arbitrary MuPAD expressions not containing `w` or `t`. You can restrict them by conditions given in the optional parameter `conds`.

`conds`

List of conditions on the pattern variables

Return Values

Object of type `DOM_NULL`

See Also

MuPAD Functions

`fourier` | `fourier::addpattern` | `ifourier`

igamma

Incomplete gamma function

Syntax

```
igamma(a, x)
```

Description

`igamma(a, x)` returns the upper incomplete gamma function $\int_x^\infty e^{-t}\, t^{a-1}\, dt$.

Note: The MATLAB `gammainc` function returns the regularized lower incomplete gamma function: `igamma(a, x) = gamma(a)(1 - gammainc(x, a))`. See the `gamma` and `gammainc` function reference pages in the MATLAB documentation.

To find the lower incomplete gamma function for arguments a and x, subtract `igamma(a, x)` from `gamma(a)`.

A floating-point value is returned if at least one of the arguments is a floating-point value and both values are numerical. Otherwise, symbolic calls of `igamma` and/or other special functions may be returned.

The following simplifications and rewriting rules are implemented: $\Gamma(a, 0) = \Gamma(a)$, $\Gamma(0, x) = \mathrm{Ei}(x)$, $\Gamma\left(\frac{1}{2}, x\right) = \sqrt{\pi}\, \mathrm{erfc}(\sqrt{x})$, $\Gamma(1, x) = e^{-x}$.

For real numerical values of a of `Type::Real` satisfying $|a| \le$ *Pref*::*autoExpansionLimit*(), the functional relation

$$\Gamma(a, x) = x^{(a-1)}\, e^{-x} + (a-1)\, \Gamma(a-1, x)$$

is used recursively to shift the first argument to the interval $0 \le a \le 1$. Thus rewriting in terms of `Ei`, `erfc`, and `exp` occurs if a is an integer multiple of $\frac{1}{2}$. Cf. "Example

1" on page 1-981. Use `expand` if these transformations are also desired for $|a| >$ *Pref*::*autoExpansionLimit*().

The special value `igamma(a, infinity) = 0` for $a \neq \infty$ is implemented.

Environment Interactions

When called with a floating-point argument, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
igamma(2, 3), igamma(1/7, x), igamma(sqrt(2), 3)
```

$$4\,e^{-3},\ \Gamma\left(\frac{1}{7}, x\right),\ \Gamma(\sqrt{2}, 3)$$

```
igamma(a, 4), igamma(1 + I, x^2 + 1), igamma(a, infinity)
```

$$\Gamma(a, 4),\ \Gamma(1+i, x^2+1),\ 0$$

If the first argument a is a real numerical value with $|a| \leq$ *Pref*::*autoExpansionLimit*(), the functional relations are used recursively until `igamma` is called with a first argument from the the interval $0 \leq a \leq 1$:

```
igamma(-1/10, 1), igamma(7/4, 1)
```

$$10\,e^{-1} - 10\,\Gamma\left(\frac{9}{10}, 1\right),\ e^{-1} + \frac{3\,\Gamma\left(\frac{3}{4}, 1\right)}{4}$$

If the first argument is an integer multiple of $\frac{1}{2}$, then complete rewriting in terms of `Ei`, `erfc`, and `exp` occurs:

```
igamma(-3, x), igamma(-5/2, x), igamma(8, x), igamma(13/2, 4)
```

$$e^{-x}\left(\frac{1}{6x}-\frac{1}{6x^2}+\frac{1}{3x^3}\right)-\frac{Ei(1,x)}{6},\ e^{-x}\left(\frac{8}{15\sqrt{x}}-\frac{4}{15x^{3/2}}+\frac{2}{5x^{5/2}}\right)-\frac{8\sqrt{\pi}\,\mathrm{erfc}(\sqrt{x})}{15},$$

$$e^{-x}(x^7+7x^6+42x^5+210x^4+840x^3+2520x^2+5040x+5040),$$

$$\frac{210979\,e^{-4}}{16}+\frac{10395\sqrt{\pi}\,\mathrm{erfc}(2)}{64}$$

Floating point values are computed for floating-point arguments:

```
igamma(0.1, 4.0), igamma(7, 0.5), igamma(100, 100.0)
```

$$0.004420083058,\ 719.9992783,\ 4.542198121\ 10^{155}$$

Example 2

The functional relation between `igamma` with different first arguments is used to "normalize" the returned expressions:

```
igamma(-8, x), igamma(7/3, x)
```

$$\frac{Ei(1,x)}{40320}-e^{-x}\left(\frac{1}{40320x}-\frac{1}{40320x^2}+\frac{1}{20160x^3}-\frac{1}{6720x^4}+\frac{1}{1680x^5}-\frac{1}{336x^6}+\frac{1}{56x^7}-\frac{1}{8x^8}\right),\ e^{-x}\left(\frac{4x^{1/3}}{3}+x^{4/3}\right)+\frac{4\,\Gamma\left(\frac{1}{3},x\right)}{9}$$

Parameters

a, x

arithmetical expressions

Return Values

Arithmetical expression.

Overloaded By

a, x

See Also

MuPAD Functions
`Ei` | `erfc` | `exp` | `fact` | `gamma` | `int`

igcd

Greatest common divisor of integers and complex numbers with integer real and imaginary parts

Syntax

```
igcd(i1, i2, …)
```

Description

`igcd(i1, i2, ...)` computes the greatest common divisor of the integers i_1, i_2, …

`igcd` computes the greatest common nonnegative divisor of a sequence of integers. If an argument of `igcd` is a single integer number, the function returns the absolute value of that argument.

`igcd` also computes the greatest common divisor of a sequence of complex numbers of the domain `DOM_COMPLEX`. Both the real and the imaginary parts of all complex numbers in a sequence must be integers. The greatest common divisor is a complex number with a positive real part and a nonnegative imaginary part.

If all arguments are `0`, `igcd` returns `0`.

If there are no arguments, `igcd` also returns `0`.

If one argument is a number, but is neither an integer nor a complex number with integer real and imaginary parts, then `igcd` returns an error message.

If at least one of the arguments is `1` or `-1`, `igcd` returns `1`. Otherwise, if one argument is not a number, the `igcd` function returns a symbolic `igcd` call.

Examples

Example 1

Compute the greatest common divisor of the following integers:

```
igcd(-10, 6), igcd(6, 10, 15)
```

$$2, 1$$

```
a := 4420, 128, 8984, 488:
igcd(a), igcd(a, 64)
```

$$4, 4$$

Example 2

Compute the greatest common divisor of the following complex numbers:

```
igcd(-10*I, 6), igcd(10 - 5*I, 20 - 10*I, 30 - 15*I)
```

$$2, 5 + 10\,i$$

Example 3

The following example shows some special cases:

```
igcd(), igcd(0), igcd(1), igcd(-1), igcd(2)
```

$$0, 0, 1, 1, 2$$

Example 4

If one argument is not a number, then the result is a symbolic `igcd` call. However, if at least one of the arguments is `1` or `-1`, the greatest common divisor is always `1`:

```
delete x:
igcd(a, x), igcd(1, x), igcd(-1, x)
```

$$\mathrm{igcd}(4420, 128, 8984, 488, x), 1, 1$$

```
type(igcd(a, x))
```

"igcd"

Parameters

i1, i2, …

arithmetical expressions representing integers or arithmetical expressions representing complex numbers of the domain `DOM_COMPLEX`, of which both the real part and the imaginary part are integers.

Return Values

Nonnegative integer, a complex number both the real and imaginary parts of which are integers, or a symbolic `igcd` call.

See Also

MuPAD Functions

`content` | `div` | `divide` | `factor` | `gcd` | `gcdex` | `icontent` | `ifactor` | `igcdex` | `ilcm` | `lcm` | `mod`

igcdex

Extended Euclidean algorithm for two integers

Syntax

```
igcdex(x, y)
```

Description

`igcdex(x, y)` computes the nonnegative greatest common divisor `g` of the integers `x` and `y` and integers `s` and `t` such that $g = sx + ty$.

`igcdex(x, y)` returns an expression sequence `g, s, t` with three elements, where `g` is the nonnegative greatest common divisor of `x` and `y` and `s`, `t` are integers such that $g = sx + ty$. These data are computed by the extended Euclidean algorithm for integers.

`igcdex(0, 0)` returns the sequence `0, 1, 0`. If `x` is non-zero, then `igcdex(0, x)` and `igcdex(x, 0)` return `abs(x), 0, sign(x)` and `abs(x), sign(x), 0`, respectively.

If both `x` and `y` are non-zero integers, then the numbers `s,t` satisfy the inequalities $|s| < \left|\frac{y}{g}\right|$ and $|t| < \left|\frac{x}{g}\right|$.

If one of the arguments is a number but not an integer, then `igcdex` returns an error message. If some argument is not a number, then `igcdex` returns a symbolic `igcdex` call.

The function `numlib::igcdmult` is an extension of `igcdex` for more than two arguments.

Examples

Example 1

We compute the greatest common divisor of some integers:

```
igcdex(-10, 6)
```

$$2, 1, 2$$

```
igcdex(3839882200, 654365735423132432848652680)
```

$$109710920, -681651885490791809, 4$$

The returned numbers satisfy the described equation:

```
[g, s, t] := [igcdex(9, 15)];
g = s*9 + t*15
```

$$[3, 2, -1]$$

$$3 = 3$$

If one argument is not a number, the result is the a symbolic `igcdex` call:

```
delete x:
igcdex(4, x)
```

$$\text{igcdex}(4, x)$$

Parameters

x, y

arithmetical expressions representing integers

Return Values

Sequence of three integers, or a symbolic `igcdex` call.

See Also

MuPAD Functions

ilaplace

Inverse Laplace transform

Syntax

```
ilaplace(F, s, t)
```

Description

`ilaplace(F, s, t)` computes the inverse Laplace transform of the expression `F = F(s)` with respect to the variable `s` at the point `t`.

The inverse Laplace transform can be defined by a contour integral in the complex plane:

$$f(t) = \frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty} F(s)\, e^{s t}\, ds$$

,

where c is a suitable complex number.

If `ilaplace` cannot find an explicit representation of the transform, it returns an unevaluated function call. See “Example 3” on page 1-992.

If `F` is a matrix, `ilaplace` applies the inverse Laplace transform to all components of the matrix.

To compute the direct Laplace transform, use `laplace`.

Examples

Example 1

Compute the inverse Laplace transforms of these expressions with respect to the variable `s`:

```
ilaplace(1/(a + s), s, t)
```

$$e^{-a\,t}$$

```
ilaplace(1/(s^3 + s^5), s, t)
```

$$\cos(t) + \frac{t^2}{2} - 1$$

```
ilaplace(exp(-2*s)/(s^2 + 1) + s/(s^3 + 1), s, t)
```

$$\text{heaviside}(t-2)\,\sin(t-2) - \frac{e^{-t}}{3} + \frac{e^{\frac{t}{2}}\left(\cos\left(\frac{\sqrt{3}\,t}{2}\right) + \sqrt{3}\,\sin\left(\frac{\sqrt{3}\,t}{2}\right)\right)}{3}$$

Example 2

Compute the inverse Laplace transform of this expression with respect to the variable `s`:

```
f := ilaplace(1/(1 + s)^2, s, t)
```

$$t\,e^{-t}$$

Evaluate the inverse Laplace transform of the expression at the points $t = -2\,t_0$ and $t = 1$. You can evaluate the resulting expression `f` using `|` (or its functional form `evalAt`):

```
f | t = -2*t_0
```

$$-2\,t_0\,e^{2\,t_0}$$

Also, you can evaluate the inverse Laplace transform at a particular point directly:

```
ilaplace(1/(1 + s)^2, s, 1)
```

$$e^{-1}$$

Example 3

If `laplace` cannot find an explicit representation of the transform, it returns an unevaluated call:

```
ilaplace(1/(1 + sqrt(t)), t, s)
```

$$\text{ilaplace}\left(\frac{1}{\sqrt{t}+1}, t, s\right)$$

`laplace` returns the original expression:

```
laplace(%, s, t)
```

$$\frac{1}{\sqrt{t}+1}$$

Example 4

Compute this inverse Laplace transform. The result is the Dirac function:

```
ilaplace(1, s, t)
```

$$\delta(t)$$

Parameters

F

Arithmetical expression or matrix of such expressions

s

Identifier or indexed identifier representing the transformation variable

t

Arithmetical expression representing the evaluation point

Return Values

Arithmetical expression or unevaluated function call of type `ilaplace`. If the first argument is a matrix, then the result is returned as a matrix.

MuPAD Functions

`ilaplace::addpattern` | `laplace` | `laplace::addpattern`

ilaplace::addpattern

Add patterns for the inverse Laplace transform

Syntax

```
ilaplace::addpattern(pat, s, t, res, <vars, <conds>>)
```

Description

`ilaplace::addpattern(pat, s, t, res)` teaches `ilaplace` to return *ilaplace*(*pat*, *s*, *t*) = *res*.

The `ilaplace` function uses a set of patterns for computing inverse Laplace transforms. You can extend the set by adding your own patterns. To add a new pattern to the pattern matcher, use `ilaplace::addpattern`. MuPAD does not save custom patterns permanently. The new patterns are available in the *current* MuPAD session only.

Variable names that you use when calling `ilaplace::addpattern` can differ from the names that you use when calling `ilaplace`. See “Example 2” on page 1-995.

You can include a list of free parameters and a list of conditions on these parameters. These conditions and the result are protected from premature evaluation. This means that you can use `not iszero(a^2 - b)` instead of `hold( _not @ iszero )(a^2 - b)`.

The following conditions treat assumptions on identifiers differently:

- `a^2 - b <> 0` takes into account assumptions on identifiers.
- `not iszero(a^2 - b)` disregards assumptions on identifiers.

See “Example 4” on page 1-997.

Environment Interactions

Calling `ilaplace::addpattern` changes the expressions returned by future calls to `ilaplace`.

Examples

Example 1

Compute the inverse Laplace transform of the function `bar`. By default, MuPAD does not have a pattern for this function:

```
ilaplace(bar(s), s, t)
```

$$\text{ilaplace}(\text{bar}(s), s, t)$$

Add a pattern for the inverse Laplace transform of `bar` using `ilaplace::addpattern`:

```
ilaplace::addpattern(bar(s), s, t, foo(t)):
```

Now `ilaplace` returns the inverse Laplace transform of `bar`:

```
ilaplace(bar(s), s, t)
```

$$\text{foo}(t)$$

After you add a new transform pattern, MuPAD can use that pattern indirectly:

```
ilaplace(exp(-s)*bar(s), s, t)
```

$$\text{foo}(t-1)\ \text{heaviside}(t-1)$$

Example 2

Define the inverse Laplace transform of `bar(y)` using the variables `x` and `y` as parameters:

```
ilaplace::addpattern(bar(y), y, x, foo(x)):
```

The `ilaplace` function recognizes the added pattern even if you use other variables as parameters:

```
ilaplace(bar(s), s, t)
```

$$\mathrm{foo}(t)$$

Example 3

Add this pattern for the inverse Laplace transform of F:

```
ilaplace::addpattern(F(c, S)*G(c, S), S, T, T/(T^4 + 4*c^4)):
ilaplace(F(c, s)*G(c, s), s, t)
```

$$\frac{t}{4\,c^4 + t^4}$$

This pattern holds only when the first argument of F is the symbolic parameter c. If you use any other value of this parameter, `ilaplace` ignores the pattern:

```
ilaplace(F(A, s)*G(A, s), s, t)
```

$$\mathrm{ilaplace}(F(A, s)\,G(A, s), s, t)$$

To use the pattern for arbitrary values of the parameter, declare the parameter c as an additional pattern variable:

```
ilaplace::addpattern(F(c, S)*G(c, S), S, T, T/(T^4 + 4*c^4), [c]):
```

Now `ilaplace` applies the specified pattern for an arbitrary value of c:

```
ilaplace(F(C, s)*G(C, s), s, t)
```

$$\frac{t}{4\,C^4 + t^4}$$

You also can declare several parameters as pattern variables. For example, this pattern has two pattern variables, a and b:

```
ilaplace::addpattern(f(a*y + b), y, x, g(x/a - b), [a, b]):
ilaplace(f(2*s + B), s, t)
```

$$g\left(\frac{t}{2} - B\right)$$

Example 4

Use assumptions when adding this pattern for the inverse Laplace transform:

```
ilaplace::addpattern(BAR(x*s), s, t, sin(1/(x - 1/2))*FOO(t),
                                        [x], [abs(x) < 1]):
ilaplace(BAR(x*s), s, t) assuming -1 < x < 1
```

$$\sin\left(\frac{1}{x-\frac{1}{2}}\right)\,\mathrm{FOO}(t)$$

If $|x| \geq 1$, you cannot apply this pattern:

```
ilaplace(BAR(x*s), s, t) assuming x >= 1
```

$$\mathrm{ilaplace}(\mathrm{BAR}(s\,x),\,s,\,t)$$

If MuPAD cannot determine whether the conditions are satisfied, it returns a `piecewise` object:

```
ilaplace(BAR(x*s), s, t)
```

$$\begin{cases} \sin\left(\frac{1}{x-\frac{1}{2}}\right)\,\mathrm{FOO}(t) & \text{if } |x| < 1 \end{cases}$$

Note that the resulting expression defining the inverse Laplace transform of `BAR(x*s)` implicitly assumes that the value of `x` is not 1/2. A strict definition of the pattern is:

```
ilaplace::addpattern(BAR(x*t), s, t, sin(1/(x - 1/2))*FOO(t),
                     [x], [abs(x) < 1, x <> 1/2]):
```

If either the conditions are not satisfied or substituting the values into the result gives an error, `ilaplace` ignores the pattern. For this particular pattern, you can omit specifying the assumption `x <> 1/2`. If `x = 1/2`, MuPAD throws an internal "Division by zero." error and ignores the pattern:

```
ilaplace(BAR(s/2), s, t)
```

$$\mathrm{ilaplace}\left(\mathrm{BAR}\left(\frac{s}{2}\right),\,s,\,t\right)$$

Parameters

pat

Arithmetical expression in the variable `s` representing the pattern to match.

s

Identifier or indexed identifier used as a variable in the pattern

t

Identifier or indexed identifier used as a variable in the result

res

Arithmetical expression in the variable `t` representing a pattern for the result

vars

List of identifiers or indexed identifiers used as "pattern variables" (placeholders in `pat` and `res`). You can use pattern variables as placeholders for almost arbitrary MuPAD expressions not containing `s` or `t`. You can restrict them by conditions given in the optional parameter `conds`.

conds

List of conditions on the pattern variables

Return Values

Object of type `DOM_NULL`

See Also

MuPAD Functions

`ilaplace` | `laplace` | `laplace::addpattern`

ilcm

Least common multiple of integers

Syntax

```
ilcm(i1, i2, …)
```

Description

`ilcm(i1, i2, ...)` computes the least common multiple of the integers i_1, i_2, …

`ilcm` computes the least common nonnegative multiple of a sequence of integers. `ilcm` with a single numeric argument returns its absolute value. `ilcm` returns `1` when all arguments are `1` or `-1` or no argument is given.

`ilcm` returns an error message when one of the arguments is a number but not an integer. If at least one of the arguments is `0`, then `ilcm` returns `0`. Otherwise, if one argument is not a number, then a symbolic `ilcm` call is returned.

Examples

Example 1

We compute the least common multiple of some integers:

```
ilcm(-10, 6), ilcm(6, 10, 15)
```

```
30, 30
```

```
a := 4420, 128, 8984, 488:
ilcm(a), ilcm(a, 64)
```

```
9689064320, 9689064320
```

The next example shows some special cases:

```
ilcm(), ilcm(0), ilcm(1), ilcm(-1), ilcm(2)
```

$$1, 0, 1, 1, 2$$

If one argument is not a number, then the result is a symbolic `ilcm` call, except in some special cases:

```
delete x:
ilcm(a, x), ilcm(0, x)
```

$$\mathrm{ilcm}(4420, 128, 8984, 488, x), 0$$

```
type(ilcm(a, x))
```

$$\text{"ilcm"}$$

Parameters

`i1i2, …`

arithmetical expressions representing integers

Return Values

Nonnegative integer, or a symbolic `ilcm` call.

See Also

MuPAD Functions

`content` | `factor` | `gcd` | `gcdex` | `icontent` | `ifactor` | `igcd` | `igcdex` | `lcm`

in, _in

Membership

Syntax

```
x in set
```

```
_in(x, set)
```

```
for y in object do body end_for
```

```
f(y) $ y in object
```

Description

`x in set` is the MuPAD notation for the statement "*x* is a member of `set`."

In conjunction with one of the keywords `for` or `$`, the meaning changes to "iterate over all operands of the object". See `for` and `$` for details. Cf. "Example 6" on page 1-1004.

Apart from the usage with `for` and `$`, the statement `x in object` is equivalent to the function call `_in(x, object)`.

`x in set` is just evaluated to itself. `expand(x in set)` tries to return an equivalent expression without using the operator `in`, as described in the following paragraphs.

For sets of type `DOM_SET`, set unions, differences and intersections, `x in set` is expanded to an equivalent Boolean expression of equations and expressions involving `in`. Cf. "Example 1" on page 1-1002.

If `set` is a solution set of a single equation in one unknown, given by a symbolic call to `solve`, expanding `in` returns a Boolean condition that is equivalent to `x` being a solution. Cf. "Example 2" on page 1-1002.

If `set` is a `RootOf` expression, expanding `in` returns a Boolean condition that is equivalent to `x` being a root of the corresponding equation. Cf. "Example 3" on page 1-1003.

The function `bool` and every function that uses boolean evaluation can also handle many logical expressions involving `in`. Cf. “Example 4” on page 1-1003.

The function `is` handles various logical statements involving `in`, including a variety of types for the parameter `set` which are not handled by `in` itself. Cf. “Example 5” on page 1-1004 for a few typical cases.

Apart from the usual overloading mechanism by the first argument of an `in` call, `in` can be overloaded by its second argument, too. This argument must define the slot`"set2expr"` for this purpose. The slot will be called with the arguments `set, x`.

Examples

Example 1

`x in {1, 2, 3}` is expanded into an equivalent statement involving = and `or`:

```
expand(x in {1, 2, 3})
```

$$x = 1 \vee x = 2 \vee x = 3$$

The same happens if you replace `x` by a number, because Boolean expressions are only evaluated inside certain functions such as `bool` or `is`:

```
expand(1 in {1, 2, 3}), bool(1 in {1, 2, 3}), is(1 in {1, 2, 3})
```

$$1 = 1 \vee 1 = 2 \vee 1 = 3,\ \text{TRUE},\ \text{TRUE}$$

If only some part of the expression can be simplified this way, the returned expression can contain unevaluated calls to `in`:

```
expand(x in {1, 2, 3} union A)
```

$$x \in A \vee x = 1 \vee x = 2 \vee x = 3$$

Example 2

For symbolic calls to `solve` representing the solution set of a single equation in one unknown, `in` can be used to check whether a particular value lies in the solution set:

```
solve(cos(x) + x = cos(2) + 2, x);
expand(2 in %), bool(2 in %)
```

$$\text{solve}(x + \cos(x) = \cos(2) + 2, x)$$

$$\cos(2) + 2 = \cos(2) + 2, \text{TRUE}$$

Example 3

`in` can be used to check whether a value is a member of the solution set represented by a `RootOf` expression:

```
r := RootOf(x^2 - 1, x);
expand(1 in r), bool(1 in r), expand(2 in r), bool(2 in r)
```

$$\text{RootOf}(x^2 - 1, x)$$

$$0 = 0, \text{TRUE}, 3 = 0, \text{FALSE}$$

```
expand((y - 1) in RootOf(x^2 - 1 - y^2 + 2*y, x))
```

$$2y + (y - 1)^2 - y^2 - 1 = 0$$

```
expand(%)
```

$$0 = 0$$

```
delete r:
```

Example 4

Expressions with operator `in` are boolean expressions: they can be used like equations or inequalities.

```
if 2 in {2, 3, 5} then "ok" end
```

"ok"

Example 5

The MuPAD function `is` can investigate membership of objects in infinite sets. It respects properties of identifiers:

```
is(123 in Q_), is(2/3 in Q_)
```

$$\text{TRUE, TRUE}$$

Example 6

In conjunction with `for` and `$`, `y in object` iterates y over all operands of the object:

```
for y in [1, 2] do
   print(y)
end_for:
```

$$1$$

$$2$$

```
y^2 + 1 $ y in a + b*c + d^2
```

$$a^2+1,\ b^2\,c^2+1,\ d^4+1$$

```
delete y:
```

Parameters

`x`

An arbitrary MuPAD object

`set`

A set or an object of set-like type

y

An identifier or a local variable (DOM_VAR) of a procedure

object, f(y)

Arbitrary MuPAD objects

Return Values

`x in set` just returns the input.

Overloaded By

set, x

MuPAD Functions

`_seqin` | `bool` | `contains` | `for` | `has` | `is`

indets

Indeterminates of an expression

Syntax

```
indets(object)
indets(object, <All>)
indets(object, <PolyExpr>)
indets(object, <RatExpr>)
```

Description

`indets(object)` returns the indeterminates contained in `object`.

`indets(object)` returns the indeterminates of `object` as a set, i.e., the identifiers without a value that occur in `object`, with the exception of those identifiers occurring in the `0`th operand of a subexpression of `object` (see “Example 1” on page 1-1006).

`indets` regards the special identifiers `PI`, `EULER`, `CATALAN` as indeterminates, although they represent constant real numbers. If you want to exclude these special identifiers, use `indets(object) minus Type::ConstantIdents` (see example “Example 1” on page 1-1006).

If `object` is a polynomial, a function environment, a procedure, or a built-in kernelfunction, then `indets` returns the empty set. See “Example 2” on page 1-1008.

Examples

Example 1

Consider the following expression:

```
delete g, h, u, v, x, y, z:
```

```
e := 1/(x[u] + g^h) - f(1/3) + (sin(y) + 1)^2*PI^3 + z^(-3)*v^(1/2)
```

$$\frac{\sqrt{v}}{z^3} - f\left(\frac{1}{3}\right) + \frac{1}{g^h + x_u} + \pi^3\,(\sin(y) + 1)^2$$

```
indets(e)
```

$$\{\pi, g, h, u, v, x, y, z\}$$

Note that the returned set contains `x` and `u` and not, as one might expect, `x[u]`, since internally `x[u]` is converted into the functional form `_index(x, u)`. Moreover, the identifier `f` is not considered an indeterminate, since it is the `0`th operand of the subexpression `f(1/3)`.

Although `PI` mathematically represents a constant, it is considered an indeterminate by `indets`. Use `Type::ConstantIdents` to circumvent this:

```
indets(e) minus Type::ConstantIdents
```

$$\{g, h, u, v, x, y, z\}$$

The result of `indets` is substantially different if one of the two options `RatExpr` or `PolyExpr` is specified:

```
indets(e, RatExpr)
```

$$\left\{\pi, z, \sin(y), g^h, x_u, \sqrt{v}\right\}$$

Indeed, `e` is a rational expression in the "indeterminates" `z, PI, sin(y), g^h, x[u], v^(1/2)`: `e` is built from these atoms and the constant expression `f(1/3)` by using only the rational operations `+`, `-`, `*`, `/`, and `^` with integer exponents. Similarly, `e` is built from `PI,sin(y),z^(-3),1/(g^h+x[u]),v^(1/2)` and the constant expression `f(1/3)` using only the polynomial operations `+`, `-`, `*`, and `^` with nonnegative integer exponents:

```
indets(e, PolyExpr)
```

$$\left\{\pi,\ \sin(y),\ \frac{1}{g^h + x_u},\ \sqrt{v},\ \frac{1}{z^3}\right\}$$

Example 2

`indets` also works for various other data types. Polynomials and functions are considered to have no indeterminates:

```
delete x, y:
indets(poly(x*y, [x, y])), indets(sin), indets(x -> x^2+1)
```

$$\varnothing,\ \varnothing,\ \varnothing$$

For container objects, `indets` returns the union of the indeterminates of all entries:

```
indets([x, exp(y)]), indets([x, exp(y)], PolyExpr)
```

$$\{x, y\},\ \{x, e^y\}$$

For tables, only the indeterminates of the entries are returned; indeterminates in the indices are ignored:

```
indets(table(x = 1 + sin(y), 2 = PI))
```

$$\{\pi, y\}$$

Example 3

In the previous examples we saw that the `0`th operand of a subexpression is not used for finding indeterminates. With the option `All` this is changed:

```
delete x: e := sin(x):
indets(e, All)
```

$$\{\sin, x\}$$

A more complex example:

```
delete g, h, u, v, y, z:
e := 1/(x[u] + g^h) - f(1/3) + (sin(y) + 1)^2*PI^3 + z^(-3)*v^(1/2)
```

$$\frac{\sqrt{v}}{z^3} - f\left(\frac{1}{3}\right) + \frac{1}{g^h + x_u} + \pi^3\,(\sin(y)+1)^2$$

```
indets(e,All)
```

$$\{\pi,\ \_index,\ \_mult,\ \_plus,\ \_power,\ f,\ g,\ h,\ \sin,\ u,\ v,\ x,\ y,\ z\}$$

```
delete e:
```

Parameters

`object`

An arbitrary object

Options

`All`

Identifiers occurring in the `0`th operand of a subexpression of `object` are also included in the result.

With this option, the `0`th operand of a subexpression is not excluded from the search for indeterminates of `object`. So if the `0`th operand of a subexpression is a indeterminate e.g. like `sin` it is included in the result, Cf. “Example 3” on page 1-1008.

`PolyExpr`

Return a set of arithmetical expressions such that `object` is a polynomial expression in the returned expressions

With this option, `object` is considered as a polynomial expression. Non-polynomial subexpressions, such as `sin(x)`, `x^(1/3)`, `1/(x+1)`, or `f(a, b)`, are considered as indeterminates and are included in the returned set. However, subexpressions such

as `f(2, 3)` are considered as constants even when the identifier `f` has no value. The philosophy behind this is that the expression is constant because the operands are constant (see “Example 1” on page 1-1006).

If `object` is an array, a list, a set, or a table, then `indets` returns a set of arithmetical expressions such that each entry of `object` is a polynomial expression in these expressions. See “Example 2” on page 1-1008.

`RatExpr`

Return a set of arithmetical expressions such that `object` is a rational expression in the returned expressions

With this option, `object` is considered as a rational expression. Similar to `PolyExpr`, non-rational subexpressions are considered as indeterminates (see “Example 1” on page 1-1006).

Return Values

set of arithmetical expressions.

Overloaded By

object

Algorithms

If `object` is an element of a library domain`T` that has a slot `"indets"`, then the slot routine `T::indets` is called with `object` as argument. This can be used to extend the functionality of `indets` to user-defined domains. If no such slot exists, then `indets` returns the empty set.

[], _index

Indexed access

Syntax

```
x[ i ]

x[ i1,i2,... ]

x[ i1..i2 ]

x[ [i1,i2,...] ]

x[ [i1,i2,...], [k1,k2,...] ]

_index( x, i )

_index( x, i1,i2,... )

_index( x, i1..i2 )

_index( x, [i1,i2,...] )

_index( x, [i1,i2,...], [k1,k2,...] )
```

Description

`_index` is a functional form of the `[]` operator. The calls `x[...]` and `_index(x,...)` are equivalent.

`x[i]` returns the entry of `x` corresponding to the index `i`. Any MuPAD object `x` allows an indexed call of the form `x[i]`. If `x` is not a container object (such as sets, lists, vectors, arrays, hfarrays, tables, matrices), then `x[i]` returns a symbolic indexed object. In particular, if `x` is an identifier, then `x[i]` returns an "indexed identifier". In this case, indices can be arbitrary MuPAD objects. See "Example 1" on page 1-1013.

`x[i1,i2,...]` returns the entries of `x` corresponding to the indices `i1,i2,...`, specified as a sequence. For example, if `x` is a matrix, then `x[2, 3]` returns the third element of the second row of `x`.

`x[i1..i2]` returns the entries of `x` corresponding to integer indices in the range `[i1..i2]`, including `x[i1]` and `x[i2]`. In particular, this applies to lists, sets, expression sequences, and strings. See "Example 7" on page 1-1016.

`x[[i1,i2,...]]` returns the entries of `x` corresponding to the specified indices, given as a list of integers. Here, `x` must be a list, matrix, or vector.

- If `x` is a list, then `x[[i1,i2,...]]` returns the list `[x[i] $ i in [i1,i2,...]]`. See "Example 8" on page 1-1018.
- If `x` is a row vector, then `x[[i1,i2,...]]` returns the row vector `matrix(1, nops([i1,i2,...]), [x[i] $ i in [i1,i2,...]])`.
- If `x` is a column vector, then `x[[i1,i2,...]]` returns the column vector `matrix(nops([i1,i2,...]), 1, [x[i] $ i in [i1,i2,...]])`.

`x[[i1,i2,...],[k1,k2,...]]` returns the matrix `matrix([[x[i,k] $ k in [k1,k2,...]] $ i in [i1,i2,...]])`. Here, `x` must be a matrix. See "Example 9" on page 1-1018.

Depending on the type of `x`, these restrictions apply to the indices:

- For lists, finite sets, or expression sequences, the index `i` can only be an integer from `1` to `nops(x)`, or `-nops(x)` to `-1`, or a range of these numbers.
- For arrays and hfarrays, use appropriate indices `i` or multiple indices `i1,i2,...` from the index range defined by `array` or `hfarray`. Integers outside this range cause an error. If any specified index is not an integer (for example, a symbol `i`), then `x[i]` or `x[i1,i2,...]` is returned symbolically.
- For matrices, use appropriate indices `i` or double indices `i1,i2` from the index range defined by `matrix`. Indices outside this range or symbolic indices cause an error.
- For tables, you can use any object as an index. If there is no corresponding entry in the table, then `x[i]` or `x[i1,i2,...]` is returned symbolically.
- For character strings, the index `i` must be an integer from `1` to `length(x)`.

`_index` uses the order in which the entries appear on the screen, and `op` uses the internal order of the entries. For some container objects, these orders differ. In particular:

- For lists and sequences, `x[i] = op(x,i)` for positive indices. For negative indices, `x[i] = op(x, nops(x) + 1 + i)`.

- For finite sets, `x[i]` returns the `i`th element as printed on the screen. Before screen output and indexed access, the elements of sets are sorted via the slot `DOM_SET::sort`. In general, `x[i] <> op(x, i)` for finite sets `x`.
- For one-dimensional arrays `x := array(1..n, [...])` or `x := hfarray(1..n, [...])`, the entries correspond to the operands, `x[i] = op(x,i)`.
- For a one-dimensional matrix representing a column vector, `x[i] = x[i, 1] = op(x, i)`. For a one-dimensional matrix representing a row vector, `x[i] = x[1, i] = op(x, i)`.

The entry returned by an indexed call is fully evaluated. For lists, matrices, arrays, and tables, you can suppress evaluation in indexed calls by using `indexval`. See "Example 10" on page 1-1018.

Indexed access to expressions and numbers is implemented via library callbacks. Do not use `_index` in program files to access the operands of expressions and numbers. Use `op` instead for more efficiency.

If `x` is not a container object (such as sets, lists, vectors, arrays, hfarrays, tables, matrices), then indexed assignments (such as `x[i] := value`) implicitly convert `x` into a table with a single entry.

Examples

Example 1

Solve these equations specifying variables as indexed identifiers:

```
n := 4:
equations := {x[i-1] - 2*x[i] + x[i+1] = 1 $ i = 1..n}:
unknowns := {x[i] $ i = 1..n}:
linsolve(equations, unknowns)
```

$$\left[x_1 = \frac{4\,x_0}{5} + \frac{x_5}{5} - 2,\ x_2 = \frac{3\,x_0}{5} + \frac{2\,x_5}{5} - 3,\ x_3 = \frac{2\,x_0}{5} + \frac{3\,x_5}{5} - 3,\ x_4 = \frac{x_0}{5} + \frac{4\,x_5}{5} - 2\right]$$

Symbolic indexed objects are of type `"_index"`:

```
type(x[i])
```

```
"_index"
```

```
delete n, equations, unknowns:
```

Example 2

Use indices to access the entries of typical container objects, such as lists, arrays, hardware floating-point arrays, and tables:

```
L := [1, 2, [3, 4]]:
A := array(1..2, 2..3, [[a12, a13], [a22, a23]]):
B := hfarray(1..2, 2..3, [[12.0, 13.0], [22.0, 23.0]]):
T := table(1 = T1, x = Tx, (1, 2) = T12):
```

```
L[1], L[3][2], A[2, 3], B[2, 3], T[1], T[x], T[1, 2]
```

$$1,\ 4,\ a23,\ 23.0,\ T1,\ Tx,\ T12$$

Use indexed assignments to change the entries:

```
L[2]:= 22: L[3][2]:= 32: A[2, 3]:= 23: B[2, 3]:= 0: T[x]:= T12:
L, A, B, T
```

$$[1,\ 22,\ [3,\ 32]],\ \begin{pmatrix} a12 & a13 \\ a22 & 23 \end{pmatrix},\ \begin{pmatrix} 12.0 & 13.0 \\ 22.0 & 0.0 \end{pmatrix},\ \begin{array}{r|l} 1 & T1 \\ x & T12 \\ 1,\ 2 & T12 \end{array}$$

```
delete L, A, B, T:
```

Example 3

For finite sets, an indexed call `x[i]` returns the `i`th element as printed on the screen. This element does not necessarily coincide with the `i`th (internal) operand returned by `op`:

```
S := {3, 2, 1}
```

$$\{1,\ 2,\ 3\}$$

```
S[i] $ i = 1..3
```

$$1, 2, 3$$

```
op(S, i) $ i = 1..3
```

$$3, 2, 1$$

```
delete S:
```

Example 4

The index operator also operates on character strings. The characters are enumerated starting from 1:

```
"ABCDEF"[1], "ABCDEF"[6]
```

$$\text{"A"}, \text{"F"}$$

Example 5

The index operator also operates on mathematical expressions containing operators, such as +, -, *, and so on:

```
X := a - b + c - 2;
X[2], X[3..-1];
delete X:
```

$$a - b + c - 2$$

$$-b, c - 2$$

For expressions with `_plus`- and `_mult` operators, the output of `_index` corresponds to the output order of the operands. If an expression with `_mult` is printed as a fraction, you can access the nominator and the denominator via indices 1 and 2:

```
X := ((a/2 + b) * c * 2)/(e-f)/x^2;
```

```
X[1], X[2], X[1][3];
delete X:
```

$$\frac{2\,c\left(\frac{a}{2}+b\right)}{x^2\,(e-f)}$$

$$2\,c\left(\frac{a}{2}+b\right),\ x^2\,(e-f),\ \frac{a}{2}+b$$

Example 6

The index operator also operates on rational and complex numbers. For rational numbers, index 1 refers to the numerator, and index 2 refers to the denominator:

```
(2/3)[1], (2/3)[2]
```

$$2,\ 3$$

For complex numbers, indices 1 and 2 refer to the real and imaginary parts, respectively:

```
(3*I)[1], (1-I)[2]
```

$$0,\ -1$$

Example 7

You can use a range as an index. For lists, sets, expression sequences, and strings, this operation returns a “subexpression” consisting of the entries within the range, according to `_index`:

```
L := [1, 2, 3, 4, 5]:
S := {1, 2, 3, 4, 5}:
Str := "abcde":

L[3..4];
S[3..4];
Str[3..4]
```

```
[3, 4]
```

```
{3, 4}
```

```
"cd"
```

This includes ranges with negative numbers. When you use negative indices `i` for container type objects `x`, such as lists and sets, the call `x[i]` returns `x[nops(x) + 1 + i]`. Thus, you access elements counting indices from the end of `x`: the index `-1` refers to the last element of `x`, the index `-2` refers to the second element from the end, and so on.

```
L[3..-1];
S[1..-2]
```

```
[3, 4, 5]
```

```
{1, 2, 3, 4}
```

When you use negative indices `i` for strings, `_index` internally replaces `Str[i]` with indices `op(Str, i + 1 + length(Str))`:

```
Str[3..-1]
```

```
"cde"
```

You also can use this form of indexing to assign values to elements of lists and strings:

```
L[2..4] := [234]: L;
Str[3..-1] := " ??": Str;
```

```
[1, 234, 5]
```

```
"ab ??"
```

As seen above, this operation can change the number of elements in a list or the length of a string. If necessary, new places are filled with `NIL` or spaces, respectively:

```
L[42..42] := [42]: L;
Str[10..11] := "the end.": Str
```

[1, 234, 5, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, NIL, 42]

"ab ?? the end."

Example 8

Use the following indexed call to return a permutation of the list `L`. Here, the index list `perm` specifies the permutation.

```
L := [a, b, c, d, e]:
perm := [5, 3, 1, 2, 4]:
L[perm]
```

$[e, c, a, b, d]$

Example 9

Use two lists of indices to pick and return a particular submatrix of a matrix:

```
A := matrix([[a11, a12, a13], [a21, a22, a23], [a31,a32, a33]]):
l1 := [1,2]: l2 := [2,3]:
A[l1, l2]
```

$$\begin{pmatrix} a12 & a13 \\ a22 & a23 \end{pmatrix}$$

Example 10

Indexed calls evaluate the returned entry. Use `indexval` to suppress full evaluation:

```
delete a:
x := [a, b]: a := c:
```

```
x[1] = eval(x[1]), x[1] <> indexval(x, 1)
```

$$c = c,\ c \neq a$$

```
delete a:
x := table(1 = a, 2 = b): a := c:
x[1] = eval(x[1]), x[1] <> indexval(x, 1)
```

$$c = c,\ c \neq a$$

```
delete a:
x := array(1..2, [a, b]): a := c:
x[1] = eval(x[1]), x[1] <> indexval(x, 1)
```

$$c = c,\ c \neq a$$

```
delete a: x := matrix([a, b]): a := c:
x[1] = eval(x[1]), x[1] <> indexval(x, 1)
```

$$c = c,\ c \neq a$$

```
delete x, a:
```

Example 11

Indexed access is not implemented for some kernel domains:

```
12343[3]
```

```
Error: The operand is invalid. [_index]
```

Define a method implementing the indexed access to integer numbers:

```
unprotect(DOM_INT):
DOM_INT::_index := (n, i) -> text2expr(expr2text(n)[i]):
12343[3];
delete DOM_INT::_index: protect(DOM_INT):
```

```
3
```

Parameters

x

An arbitrary MuPAD object. In particular, a container object: a list, a finite set, an array, an hfarray, a matrix, a table, an expression sequence, an expression in operator notation, a rational number, a complex number, or a character string.

i

An index. For most container objects x, indices must be integers. If x is a table, you can use arbitrary MuPAD objects as indices.

i1,i2,...

Multiple indices for matrices and multidimensional arrays. For these containers, the indices must be integers. For tables, you can also use multiple indices given by arbitrary MuPAD objects.

i1..i2

Indices, specified as a range.

[i1,i2,...]

Indices, specified as a list of integers. In this case, x must be a list, matrix, or vector. (In MuPAD, a vector is a 1#n or n×1 matrix.)

[i1,i2...], [k1,k2...]

Indices, specified as two lists of integers. In this case, x must be a matrix.

Return Values

Entry of x corresponding to the index. Calls with lists of indices can return a sequence, a list, a vector, or a matrix of entries corresponding to the indices. If x is not a list, a set,

an array, or any other container object, then the return value is an indexed object of type `"_index"`.

MuPAD Domains

DOM_ARRAY | DOM_HFARRAY | DOM_LIST | DOM_SET | DOM_STRING | DOM_TABLE

MuPAD Functions

:= | _assign | array | contains | hfarray | indexval | op | slot | table | Type::Indeterminate

indexval

Indexed access to arrays and tables without evaluation

Syntax

```
indexval(x, i)
```

```
indexval(x, i1, i2, …)
```

Description

`indexval(x, i)` and `indexval(x, i1, i2, ...)` yields the entry of `x` corresponding to the indices `i` and `i1, i2, ...`, respectively, without evaluation.

The three calls `indexval(x, i)`, `_index(x, i)`, and `x[i]` all return the element of index `i` in the array or hfarray or list or table `x`. In contrast to `_index` and the equivalent index operator `[ ]`, however, `indexval` returns the corresponding entry without evaluating it. This is sometimes desirable for efficiency reasons.

The arguments `i` or i1, i2, ... must be a valid indices of `x`, otherwise an error message is printed (see “Example 3” on page 1-1024). When several indices i1, i2, ... are given, they are interpreted as a higher-dimensional index (see “Example 4” on page 1-1025).

The first argument `x` may also be a set, a string, or an expression sequence. However, in these cases `indexval` behaves exactly like `_index` and the index operator `[ ]`: it returns the evaluation of the corresponding element. In particular, `indexval` does not flatten its first argument.

For all other basic domains, `indexval` behaves exactly like `_index`: either an error occurs, or a symbolic `indexval` call is returned (see “Example 3” on page 1-1024).

Examples

Example 1

`indexval` works with tables:

```
T := table("1" = a, Be = b, `+` = a + b):
a := 1: b := 2:
indexval(T, Be), indexval(T, "1"), indexval(T, `+`)
```

$$b,\ a,\ a+b$$

In contrast `_index` evaluates returned entries:

```
_index(T, Be), _index(T, "1"), _index(T, `+`)
```

$$2,\ 1,\ 3$$

The next input line has the same meaning as the last:

```
T[Be], T["1"], T[`+`]
```

$$2,\ 1,\ 3$$

`indexval` works with arrays, too. The behavior is the same, but the indices must be positive integers:

```
delete a, b:
A := array(1..2, 1..2, [[a, a + b], [a - b, b]]):
a := 1: b := 2:
indexval(A, 2, 2), indexval(A, 1, 1), indexval(A, 1, 2)
```

$$b,\ a,\ a+b$$

```
_index(A, 2, 2), _index(A, 1, 1), _index(A, 1, 2)
```

$$2,\ 1,\ 3$$

```
A[2, 2], A[1, 1], A[1, 2]
```

$$2,\ 1,\ 3$$

```
delete A, T, a, b:
```

`indexval` works lists, too:

```
delete a, b:
L := [a, b, 2]:
b := 5:
L[2], _index(L, 2), indexval(L, 2), op(L, 2)
```

$$5, 5, b, 5$$

Example 2

However, there is no difference between `indexval` and `_index` for all other valid objects, e.g., sets:

```
delete a, b:
S := {a, b, 2}:
b := 5:
S[2], _index(S, 2), indexval(S, 2), op(S, 2)
```

$$5, 5, 5, 5$$

Similarly, there is no difference when the first argument is an expression sequence (which is not flattened by `indexval`):

```
delete a, b: S := a, b, 2:
b := 5:
S[2], _index(S, 2), indexval(S, 2), op(S, 2)
```

$$5, 5, 5, 5$$

```
delete L, S, a, b:
```

Example 3

If the second argument is not a valid index, an error occurs:

```
A := array(1..2, 1..2, [[a, b], [a, b]]):
indexval(A, 3)
```

```
Error: Index dimension mismatch. [array]
```

```
indexval(A, 1, 0)
```

```
Error: The argument is invalid. [array]
```

```
indexval("12345", 6)
```

```
Error: The index is invalid. [string]
```

However, the result of `indexval` can also be a symbolic `indexval` call:

```
T := table(1 = a, 2 = b):
indexval(T, 3)
```

$$\text{indexval}(T, 3)$$

```
delete X, i:
indexval(X, i)
```

$$\text{indexval}(X, i)$$

```
delete A, T:
```

Example 4

For arrays the number of indices must be equal to the number of dimensions of the array:

```
A := array(1..2, 1..2, [[a, b], [a, b]]):
a := 1: b := 2:
indexval(A, 1, 2), indexval(A, 2, 1)
```

$$b, a$$

Otherwise an error occurs:

```
indexval(A, 1)
```

```
Error: Index dimension mismatch. [array]
```

Tables can have expression sequences as indices, too:

```
delete a, b:
```

```
T := table((1, 1) = a, (2, 2) = b):
a := 1: b := 2:
indexval(T, 1, 1), indexval(T, 2, 2)
```

$$a, b$$

```
delete A, T, a, b:
```

Parameters

x

Essentially a table, a list, or an array. Also allowed: a hfarray, a finite set, an expression sequence, or a character string

i, i1, i2, …

Indices. For most “containers” x, indices must be integers. If x is a table, arbitrary MuPAD objects can be used as indices.

Return Values

Entry of x corresponding to the index. When x is a table, a list or an array, the returned entry is not evaluated again.

MuPAD Functions
:= | _assign | _index | array | contains | op | table

infinity

Real positive infinity

Syntax

```
infinity
```

Description

`infinity` represents the infinite point on the positive real semi-axis.

`infinity` is an element of the domain `stdlib::Infinity`. It may be used in arithmetical operations. Some system functions accept `infinity` as a parameter or return it as a result.

Examples

Example 1

`infinity` can be used in arithmetical operations with real numbers:

```
7*infinity + 3, -3.0*infinity, 1/infinity,
infinity*infinity, infinity^2, sqrt(infinity)
```

$$\infty,\ -\infty,\ 0,\ \infty,\ \infty,\ \infty$$

Arithmetic with complex numbers or symbolic objects yields symbolic expressions:

```
I*infinity + b
```

$$i\,\infty + b$$

The arithmetic responds to properties:

```
assume(a > 0): a*infinity
```

∞

```
assume(a < 0): a*infinity
```

$-\infty$

```
unassume(a): a*infinity
```

$a\,\infty$

Cancellation of infinities yields `undefined`:

```
infinity - infinity, infinity/infinity
```

undefined, undefined

Some system functions accept `infinity` as a parameter or return it as result:

```
exp(infinity), sum(1/n, n = 1..infinity),
int(exp(-x^2), x = -infinity..infinity),
limit(x, x = infinity)
```

$\infty, \infty, \sqrt{\pi}, \infty$

MuPAD Functions

`complexInfinity` | `undefined`

info

Prints short information

Syntax

```
info(object)

info()
```

Description

`info(object)` prints short information about `object`.

`info` prints a short descriptive information about `object`.

If `object` is a domain, additional information is given about the methods of the domain.

A call to `info` without arguments prints a reference to a random help page.

Users can add information about their own functions and domains by overloading`info`. If `object` is a user-defined domain or function environment providing a slot`"info"`, whose value is a string, then the call `info(object)` prints this string. See “Example 2” on page 1-1030.

Examples

Example 1

With `info()`, you obtain a reference to a random help page:

```
info()

-- Help page of the day:
```

```
?input
```

The next example shows information about the library property:

```
info(property)
```

```
Library 'property': properties of identifiers

-- Interface:

property::depends, property::hasprop,
```

`info` prints information about preferences:

```
info(Pref::autoPlot)
```

```
Automatically plot graphical objects instead of typesetting
```

If no more information is available, a short type description is given:

```
info(a + b):
info([a, b]):
```

```
a + b -- an expression of type "_plus"

[a, b] -- of domain type 'DOM_LIST'
```

Example 2

`info` prints information about a function environment:

```
info(sqrt)
```

```
sqrt -- the square root
```

`sqrt` is a function environment and has a slot named `"info"`:

```
domtype(sqrt), sqrt::info
```

```
DOM_FUNC_ENV, "sqrt -- the square root"
```

User-defined procedures can contain short information. By default, `info` does only return some general information:

```
f := x -> x^2:  info(f):
```

```
f(x) -- a procedure of domain type 'DOM_PROC'
```

To improve this, we embed the function `f` into a function environment and store an information string in its `"info"` slot:

```
f := funcenv(f):
f::info := "f -- the squaring function":
info(f)
```

```
f -- the squaring function
```

```
delete f:
```

Parameters

`object`

Any MuPAD object

Return Values

Void object `null()` of type `DOM_NULL`.

Algorithms

If the argument `object` of `info` is a domain, then the call `info(object)` first prints the entry `"info"`, which must be a string. Then the entry `"interface"`, which must be a set of identifiers, is used to display all public methods, and the entry `"exported"`,

which is a set of identifiers created by `export::stl`, is used to display all exported methods.

MuPAD Functions

`help` | `print`

input

Interactive input of objects

Syntax

```
input(<prompt1>)
```

```
input(<prompt1>, x1, <prompt2>, x2, …)
```

Description

`input` allows interactive input of MuPAD objects.

`input()` displays the prompt "`Please enter expression:`" and waits for input by the user. The input, terminated by pressing the Return key, is parsed and returned *unevaluatedly*.

`input(prompt1)` uses the character string `prompt1` instead of the default prompt "`Please enter expression:`".

`input( prompt1 x1)` assigns the input to the identifier or local variable `x1`. The default prompt is used, if no prompt string is specified.

Several objects can be read with a single `input` command. Each identifier or variable in the sequence of arguments makes `input` return a prompt, waiting for input to be assigned to it. A character string preceding an identifier or variable in the argument sequence replaces the default prompt (see "Example 2" on page 1-1035). Arguments that are neither prompt strings nor identifiers or variables are ignored.

The identifiers or variables `x1` etc. may have values. These are overwritten by `input`.

`input` only parses the input objects for syntactical correctness. It does not evaluate them. Use `eval` to evaluate the results (see "Example 3" on page 1-1035).

Examples

Example 1

The default prompt is displayed. The input is returned without evaluation:

```
input()

Please enter expression: << 1 + 2 >>

     1 + 2
```

A character string is used as a prompt:

```
input("enter a number: ")

enter a number: << 5
>>

     5
```

The input may be assigned to an identifier:

```
input(x)

Please enter expression: << 5 >>

     5

x

     5
```

A user-defined prompt is used, the input is assigned to an identifier:

```
input("enter a number: ", x)

enter a number: << 6
>>
```

```
    6

x

    6

delete x:
```

Example 2

If several objects are to be read, for each object a separate prompt can be defined:

```
input("enter a matrix: ", A, "enter a vector: ", x)

enter a matrix: << matrix([[a11,
a12], [a21, a22]]) >>

enter
a vector: << matrix([x1, x2]) >>

matrix([x1, x2])

A, x
```

$$\begin{pmatrix} a11 & a12 \\ a21 & a22 \end{pmatrix}, \begin{pmatrix} x1 \\ x2 \end{pmatrix}$$

```
delete A, x:
```

Example 3

The following procedure asks for an expression and a variable. After interactive input, the derivative of the expression with respect to the variable is computed:

```
interactiveDiff :=
  proc()
    local f, x;
  begin
     f := input("enter an expression: ");
     x := input("enter an identifier: ");
     print(Unquoted, "The derivative of " . expr2text(f) .
```

```
           " with respect to ". expr2text(x) . " is:");
     diff(f, x)
  end_proc:

interactiveDiff()

enter an expression: <<
x^2 + x*y^3 >>

enter an identifier:
<< x >>

 The derivative
of x^2 + x*y^3 with respect to x is:
```

$$2x + y^3$$

The function `input` does not evaluate the input. This leads to the following unexpected result:

```
f := x^2 + x*y^3:
z := x:
interactiveDiff()

enter
an expression: << f >>

enter
an identifier: << z >>

 The
derivative of f with respect to z is:
```

$$0$$

The following modification enforces full evaluation via `eval`:

```
interactiveDiff :=
  proc()
    local f, x;
  begin
     f := eval(input("enter an expression: "));
     x := eval(input("enter an identifier: "));
     print(Unquoted, "The derivative of " . expr2text(f) .
```

```
          " with respect to ". expr2text(x) . " is:");
    diff(f, x)
  end_proc:

interactiveDiff()

enter an expression: <<
f >>

enter an identifier:
<< z >>

 The derivative
of x^2 + x*y^3 with respect to x is:

```

$$2x + y^3$$

```
delete interactiveDiff, f, z:
```

Parameters

prompt1, prompt2, …

Input prompts: character strings

x1, x2, …

identifiers or local variables

Return Values

Last input

int

Definite and indefinite integrals

Syntax

```
int(f, x)
```

```
int(f, x = a .. b, options)
```

Description

`int(f, x)` computes the indefinite integral $\int f(x)\,\mathrm{d}x$.

`int(f, x = a..b)` computes the definite integral $\int_a^b f(x)\,\mathrm{d}x$.

`int(f, x)` determines a function F such that $\frac{\partial}{\partial x}F(x) = f(x)$. The function $F(x)$ is called the antiderivative of $f(x)$. Results returned by `int` do not include integration constants.

For indefinite integrals, `int` implicitly assumes that the integration variable `x` is real. For definite integrals, `int` restricts the integration variable `x` to the specified integration interval `[a, b]` of the type `Type::Interval`. If one or both integration bounds `a` and `b` are not numeric, `int` assumes that `a <= b` unless you explicitly specify otherwise. By default, `int` does not issue warnings about these assumptions. To display the warnings about using implicit assumptions, set the value of `intlib::printWarnings` to `TRUE`.

In general, the result of `int` is not required to be valid for all complex values of `x`. For example, the identity $\ln(e^x) = x$ is only valid for real values of x. Therefore, $\int \ln(e^x)\,\mathrm{d}x = \frac{x^2}{2}$ is also valid only for real values of x.

You can specify your own assumptions of the integration variable. If these assumptions do not conflict with the default assumption that the variable is real or with the integration interval, then MuPAD uses your assumptions. Otherwise, the `int` function issues a warning and changes the assumptions. Use `intlib::printWarnings` to enable or disable the warnings.

If you compute an indefinite integral and specify properties of the integration variable that describe a subset of the real numbers, MuPAD assumes that the variable is real. Otherwise, the system uses temporary assumption that the integration variable is complex. This assumption holds only during this particular integration.

If you compute a definite integral and specify properties that conflict with the integration interval, `int` uses the integration interval.

`int` can return results with discontinuities even if the integrand is continuous.

Integration techniques, such as table lookup or Risch integration for an indefinite integral, can add new discontinuities during the integration process. These new discontinuities appear because the antiderivatives can require the introduction of complex logarithms. Complex logarithms have a jump discontinuity when the argument crosses the negative real axis, and the integration algorithms sometimes cannot find a representation where these jumps cancel.

If you compute a definite integral by first computing an indefinite integral and then substituting the integration boundaries into the result, remember that indefinite integration can produce discontinuities. If it does, you must investigate the discontinuities in the integration interval.

If MuPAD cannot find a closed-form solution for the integral and cannot prove that such form does not exist, it returns an unresolved integral. In this case, you can approximate the integral numerically or try computing a series expansion of the integral. See “Example 2” on page 1-1041 and “Example 3” on page 1-1042.

You can approximate a definite integral numerically using `numeric::int` or `float`. Numeric approximation of a definite integral only works when the `float` function can convert the boundaries `a` and `b` of the integration interval to floating-point numbers. See “Example 2” on page 1-1041.

`int` might not find a closed form of a definite integral because of singularities of the integrand in the interval of integration. If the integral does not exist in a strict mathematical sense, `int` returns the value `undefined`. In this case, try using assumptions. Alternatively, use the `PrincipalValue` option to compute a weaker form of a definite integral called the Cauchy principal value. This form of an integral can exist even though the standard integral value is undefined. See “Example 6” on page 1-1043.

In general, the derivative of the result coincides with *f* on a dense subset of the real numbers (or, if you use assumptions on the integration variable, the subset of real numbers specified by these assumptions).

It is not always possible to decide algorithmically if $\frac{\partial}{\partial x} F(x)$ and f are equivalent. The reason is the so-called zero equivalence problem, which in general is undecidable.

Environment Interactions

`int` is sensitive to properties of identifiers set by `assume`. See “Example 6” on page 1-1043.

Examples

Example 1

Compute the indefinite integrals $\int \frac{1}{x \ln(x)}\, dx$ and $\int \frac{1}{x^2 - 8}\, dx$:

```
int(1/x/ln(x), x)
```

$$\ln(\ln(x))$$

```
int(1/(x^2 - 8), x)
```

$$-\frac{\sqrt{2}\,\operatorname{arctanh}\left(\frac{\sqrt{2}\,x}{4}\right)}{4}$$

Compute the definite integral $\frac{1}{(x \ln(x))}$ over the interval $[e, e^2]$:

```
int(1/x/ln(x), x = exp(1)..exp(2))
```

$$\ln(2)$$

When computing definite integrals, you can use infinities as the boundaries of the integration interval:

```
int(exp(-x^2), x = 0..infinity)
```

$$\frac{\sqrt{\pi}}{2}$$

You can compute multiple integrals. For example, compute the following definite multiple integral:

```
int(int(int(1, z = 0..c*(1 - x/a - y/b)),
        y = 0..b*(1 - x/a)), x = 0..a)
```

$$\frac{a\,b\,c}{6}$$

Example 2

Use `int` to compute this definite integral. Since `int` cannot find a closed form of this integral, it returns an unresolved integral:

```
S := int(sin(cos(x)), x = 0..1)
```

$$\int_0^1 \sin(\cos(x))\,dx$$

Use the `float` function to approximate the integral numerically:

```
float(S)
```

$$0.738642998$$

Alternatively, use the `numeric::int` function, which is faster because it does not involve any symbolic preprocessing:

```
numeric::int(sin(cos(x)), x = 0..1)
```

$$0.738642998$$

Example 3

Use `int` to compute this indefinite integral. Since `int` cannot find a closed form of this integral, it returns an unresolved integral:

```
int((x^2 + 1)/sqrt(sqrt(x + 1) + 1), x)
```

$$\int \frac{x^2+1}{\sqrt{\sqrt{x+1}+1}}\,dx$$

Use the `series` function to compute a series expansion of the integral:

```
series(%, x = 0)
```

$$\frac{\sqrt{2}\,x}{2} - \frac{\sqrt{2}\,x^2}{32} + \frac{45\sqrt{2}\,x^3}{256} - \frac{161\sqrt{2}\,x^4}{8192} + \frac{2507\sqrt{2}\,x^5}{327680} - \frac{12647\sqrt{2}\,x^6}{3145728} + O(x^7)$$

Alternatively, compute a series expansion of the integrand, and then integrate the result. This approach is faster because it does not try to integrate the original expression. It integrates an approximation (the series expansion) of the original expression:

```
int(series((x^2 + 1)/sqrt(sqrt(x + 1) + 1), x = 0), x)
```

$$\frac{\sqrt{2}\,x}{2} - \frac{\sqrt{2}\,x^2}{32} + \frac{45\sqrt{2}\,x^3}{256} - \frac{161\sqrt{2}\,x^4}{8192} + \frac{2507\sqrt{2}\,x^5}{327680} - \frac{12647\sqrt{2}\,x^6}{3145728} + O(x^7)$$

Example 4

The `IgnoreAnalyticConstraints` option applies a set of purely algebraic simplifications including the equality of sum of logarithms and a logarithm of a product. Using this option, you get a simpler result, but one that might be incorrect for some of the values of the variables:

```
int(ln(x) + ln(y) - ln(x*y), x, IgnoreAnalyticConstraints)
```

$$0$$

Without using this option, you get the following result, which is valid for all values of the parameters:

```
int(ln(x) + ln(y) - ln(x*y), x)
```

$$x\,(\ln(x) - \ln(x\,y) + \ln(y))$$

The results obtained with `IgnoreAnalyticConstraints` might be not generally valid:

```
f := int(ln(x) + ln(y) - ln(x*y), x):
g := int(ln(x) + ln(y) - ln(x*y), x, IgnoreAnalyticConstraints):
simplify([f, g]) assuming x = -1 and y = -1
```

$$[-2\,\pi\,i,\ 0]$$

Example 5

By default, `int` returns this integral as a piecewise object where every branch corresponds to a particular value (or a range of values) of the symbolic parameter `t`:

```
int(x^t, x)
```

$$\begin{cases} \ln(x) & \text{if } t = -1 \\ \frac{x^{t+1}}{t+1} & \text{if } t \neq -1 \end{cases}$$

To ignore special cases of parameter values, use `IgnoreSpecialCases`:

```
int(x^t, x, IgnoreSpecialCases)
```

$$\frac{x^{t+1}}{t+1}$$

Example 6

Compute this definite integral, where the integrand has a pole in the interior of the interval of integration. Mathematically, this integral is not defined:

```
int(1/(x - 1), x = 0..2)
```

$$\text{undefined}$$

However, the Cauchy principal value of the integral exists. Use the `PrincipalValue` option to compute the Cauchy principal value of the integral:

```
hold(int)(1/(x - 1), x = 0..2, PrincipalValue) =
     int( 1/(x - 1), x = 0..2, PrincipalValue)
```

$$\int_0^2 \frac{1}{x-1}\,dx = 0$$

For integrands with parameters, `int` might be unable to decide if the integrand has poles in the interval of integration. In this case, `int` returns a piecewise-defined function or an unresolved integral:

```
int(1/(x - a), x = 0..2)
```

$$\begin{cases} \int_0^2 \frac{1}{x-a}\,dx & \text{if } a \in [0, 2] \\ \ln(2-a) - \ln(-a) & \text{if } a < 0 \vee 2 < a \vee a \notin \mathbb{R} \end{cases}$$

`int` does not call simplification functions for its results. To simplify results returned by `int`, use `eval`, `simplify`, or `Simplify`:

```
Simplify(eval(%))
```

$$\{ \ln(2-a) - \ln(-a) \quad \text{if } a < 0 \vee 2 < a \vee a \notin \mathbb{R}$$

The resulting piecewise expression has only one branch. If the parameter `a` does not satisfy this condition, the integral is `undefined`.

Parameters

`f`

The integrand: an arithmetical expression representing a function in `x`

`x`

The integration variable: an identifier

a, b

The boundaries: arithmetical expressions

Options

IgnoreAnalyticConstraints

When you use this option, `int` applies these simplifications rules to the integrand:

- $ln(a) + ln(b) = ln(a\,b)$ for all values of a and b. In particular:

  $(a\,b)^c = e^{c\,\ln(a\,b)} = e^{c\,(\ln(a)+\ln(b))} = a^c\,b^c$ for all values of a, b, and c
- $ln(a^b) = b\,ln(a)$ for all values of a and b. In particular:

  $(a^b)^c = e^{b\,c\,\ln(a)} = e^{\ln(a)^{b\,c}} = a^{b\,c}$ for all values of a, b, and c
- If f and g are standard mathematical functions and $f(g(x)) = x$ for all small positive numbers, $f(g(x)) = x$ is assumed to be valid for all complex x. In particular:
- - $\ln(e^x) = x$
  - $arcsin(sin(x)) = x$, $arccos(cos(x)) = x$, $arctan(tan(x)) = x$
  - $arcsinh(sinh(x)) = x$, $arccosh(cosh(x)) = x$, $arctanh(tanh(x)) = x$
  - $W_k(x\,e^x) = x$ for all values of k

Using this option, you can get simpler solutions for some integrals for which the direct call of the integrator returns complicated results. With this option the integrator does not verify the correctness and completeness of the result. See “Example 4” on page 1-1042.

IgnoreSpecialCases

If integration requires case analysis, ignore cases that require one or more parameters to be elements of a comparatively small set, such as a fixed finite set or a set of integers.

With this option, `int` tries to reduce the number of branches in piecewise objects. MuPAD finds equations and memberships in comparatively small sets. First, MuPAD tries to prove such equations and memberships by using the property mechanism. If the property mechanism proves an equation or a membership is true, MuPAD keeps that statement. Otherwise, MuPAD can replace that statement with the value FALSE.

For example, if the property mechanism cannot prove that a denominator is equal to zero, MuPAD regards this denominator as nonzero. This option can significantly reduce the number of piecewise objects in the result.

See “Example 5” on page 1-1043.

`PrincipalValue`

Compute the Cauchy principal value of the integral.

If the interior of the integration interval contains poles of the integrand or the boundaries are $a = -\infty$ and $b = \infty$, then the definite integral might not exist in a strict mathematical sense. However, if the integrand changes sign at all poles in the integration interval, you can compute a weaker form of a definite integral called the *Cauchy principal value*. In this form, the so-called infinite parts of the integral to the left and to the right of a pole cancel each other. When you use the `PrincipalValue` option, `int` computes the Cauchy principal value. If the definite integral exists in a strict mathematical sense, it coincides with the Cauchy principal value. See “Example 6” on page 1-1043.

Return Values

arithmetical expression

int::addpattern

Add patterns for integration

Syntax

```
int::addpattern(pat, x, res, <[var, …], <[cond, …]>>)
```

```
int::addpattern(pat, x = u .. v, res, <[var, …], <[cond, …]>>)
```

Description

`int::addpattern(pat, x, res)` teaches `int` to make use of $\frac{\partial}{\partial x}\,\mathrm{res} = \mathrm{pat}$.

`int::addpattern(pat, x=u..v, res)` teaches `int` that $\int_u^v \mathrm{pat}\,\mathrm{d}x = \mathrm{res}$.

A large part of a computer algebra system's integration abilities stems from mathematical pattern matching. The MuPAD pattern matcher can be extended at runtime with `int::addpattern`.

Unless further limited by conditions in the fifth argument, pattern variables listed in the fourth argument represent arbitrary MuPAD expressions not containing the variable of integration, `x`.

Any identifier can be used as the variable of integration in a call to `int::addpattern`, and any identifier can be used in calls to `int`. They need not be identical.

For definite integration, each integration bound is either an arithmetical expression which may contain pattern variables, or an identifier which can be used as a variable in the result and condition terms.

Users can include additional conditions by giving additional arguments. These conditions, as well as the result, are protected from premature evaluation, i.e., it is not necessary to write `hold( _not @ iszero )(a^2-b)`, a simple `not iszero(a^2-b)` suffices.

The difference between `not iszero(a^2-b)` and `a^2-b <> 0` when given as a condition is that the latter takes into account asuumptions on the identifiers encountered, while the first does not. Cf. “Example 4” on page 1-1051.

Patterns introduced by `int::addpattern` are also used in recursive calls of the integrator and are automatically extended to include simple applications of integration by change of variables. Cf. “Example 1” on page 1-1049.

Patterns added by `int::addpattern` are *not* replaced by later calls, they remain active. `int` selects the most simple result found. There is no way to remove patterns once added. Cf. “Example 5” on page 1-1052.

Environment Interactions

Calling `int::addpattern` changes the expressions returned by future calls to `int`. Additionally, the remembered values of previous calls to `int` are forgotten.

Examples

Example 1

Not surprisingly, MuPAD does not know how to integrate the function *foo*:

```
int(foo(x), x)
```

$$\int \mathrm{foo}(x)\,\mathrm{d}x$$

We add a pattern for this function:

```
int::addpattern(foo(x), x, foo(x)^x)
```

```
int(foo(x), x)
```

$$\mathrm{foo}(x)^x$$

Note that this pattern is also used indirectly:

```
int(x*foo(x^2), x)
```

$$\frac{\mathrm{foo}(x^2)^{x^2}}{2}$$

```
intlib::byparts(int(foo(x)*sin(x), x), foo(x))
```

$$\mathrm{foo}(x)^x \sin(x) - \int \cos(x)\, \mathrm{foo}(x)^x \, dx$$

Example 2

Definite integrals can be added similarly. Note that the result does not depend on the integration variable:

```
int::addpattern(wilma(x), x=0..1, fred)
```

```
int(wilma(x), x=0..1)
```

$$\mathrm{fred}$$

The above pattern will not match integrals with different integration bounds:

```
int(wilma(x), x=0..2)
```

$$\int_0^2 \mathrm{wilma}(x)\, dx$$

Integration bounds may also contain variables occurring in the pattern or result:

```
int::addpattern(wilma(x, a), x=0..a, fred(a), [a])
```

```
int(wilma(x,2), x=0..2)
```

$$\mathrm{fred}(2)$$

Example 3

The integration variable in the call to `int::addpattern` need not be the same as used in the integration call:

```
int::addpattern(1/(t^2*(ln(t)+1)), t, -E*Ei(ln(t)+1))
```

```
int(cos(y)/sin(y)^2/(ln(sin(y)) + 1), y)
```

$$-e\,\mathrm{Ei}(\ln(\sin(y))+1)$$

Example 4

Conditions are checked using `is` and therefore react to assumptions:

```
int::addpattern(1/(a+b*tan(x)^2), x,
                x/(a-b)
                - b/(2*(a-b)*sqrt(-a*b))
                 * ln((b*tan(x)-sqrt(-a*b))
                     /(b*tan(x)+sqrt(-a*b))),
                [a, b],
                [a*b < 0])

int::addpattern(1/(a+b*tan(x)^2), x,
                x/(a-b)
                - b/((a-b)*sqrt(a*b))
                 * arctan(b*tan(x)/
                          sqrt(a*b)),
                [a, b],
                [a*b > 0])

int(1/(3+a*tan(x)^2), x) assuming a > 0
```

$$-\frac{3\,x-\sqrt{3}\,\sqrt{a}\,\arctan\left(\frac{\sqrt{3}\,\sqrt{a}\,\tan(x)}{3}\right)}{3\,a-9}$$

```
int(1/(3+a*tan(x)^2), x) assuming a < 0
```

$$-\frac{x}{a-3}-\frac{\ln\left(\frac{\sqrt{-3\,a}-a\,\tan(x)}{\sqrt{-3\,a}+a\,\tan(x)}\right)\sqrt{-3\,a}}{6\,(a-3)}$$

If either the conditions are not satisfied or substituting the values into the result yields an error, the pattern is ignored. In the patterns above, the case $a = b$ causes a division by zero. There is no need to include a condition to guard against this case, though, MuPAD simply computes the integral as usual:

```
int(1/(3+3*tan(x)^2), x)
```

$$\frac{x}{6} + \frac{\sin(2\,x)}{12}$$

Example 5

Assume we have added the following pattern:

```
int::addpattern(f(x), x, f(x)^x):
```

Now, *f* is a pretty generic name, so we could later regard it as a different function and attempt to redefine its antiderivative:

```
int::addpattern(f(x), x, 1/sin(f(x))):

int(f(x), x)
```

$$f(x)^x$$

What happened?

As it turns out, `int::addpattern` has simply *added* the new pattern, and since $f(x)^x$ is considered "simpler" than $\frac{1}{\sin(f(x))}$, the result of the first pattern added is still returned.

This behavior is reasonable, since there may be multiple ways of representing an antiderivative and depending on parameter values, one or the other may be preferable:

```
int::addpattern(f(a, x), x, x*f1(a, x^a), [a]):
int::addpattern(f(a, x), x, x*f2(a, x^(1-a)), [a]):

int(f(0, x), x)
```

$$x\,\mathrm{f1}(0, 1)$$

```
int(f(1, x), x)
```

$$x\,\mathrm{f2}(1, 1)$$

```
int(f(a, x), x)
```

$x\ \mathrm{fl}(a, x^a)$

Parameters

`pat`

The pattern to match: an arithmetical expression in `x`.

`x`

The variable of integration: an `identifier`.

`u .. v`

The interval of integration for a definite integral: arithmetical expressions or identifiers.

`res`

The antiderivative pattern: an arithmetical expression

`[var, …]`

"pattern variables": placeholders in `pat` and `ret`, i.e., `identifiers` that do not represent themselves but almost arbitrary MuPAD expressions not containing `x` and restricted by the conditions in the fifth parameter.

`[cond, …]`

Conditions on the pattern variables

Return Values

Object of type `DOM_NULL`

See Also

MuPAD Functions

`int`

int2text

Convert an integer to a character string

Syntax

```
int2text(n, <b>)
```

Description

`int2text(n, b)` converts the integer `n` to a string that corresponds to the `b`-adic representation of `n`.

The string returned by `int2text` consists of the first `b` characters in 0, 1, …, 9, *A*, *B*, …, *Z*, *a*, *b*, …, *z*. For bases larger than 10, the letters represent the `b`-adic digits larger than 9: *A* = 10, *B* = 11, …, *Z* = 35, *a* = 36, *b* = 37, …, *z* = 61.

For the bases 2, 8, or 16, `int2text` provides the conversion from decimal representation to binary, octal, or hexadecimal representation, respectively.

`int2text` is the inverse of `text2int`.

Since the output of the numerical datatypes in MuPAD uses the decimal representation, strings are used by `int2text` to represent `b`-adic numbers. The function `numlib::g_adic` provides an alternative representation via lists.

Examples

Example 1

Relative to the default base 10, `int2text` provides a mere datatype conversion from `DOM_INT` to `DOM_STRING`:

```
int2text(123), int2text(-45678)
```

```
"123", "-45678"
```

Example 2

The decimal integer 32 has the following binary representation:

```
int2text(32, 2)
```

```
"100000"
```

The decimal integer 10^9 has the following hexadecimal representation:

```
int2text(10^9, 16)
```

```
"3B9ACA00"
```

... and with the base 62:

```
int2text(10^9, 62)
```

```
"15ftgG"
```

Example 3

Negative integers can be converted as well:

```
int2text(-15, 8)
```

```
"-17"
```

Parameters

n

An integer

b

The base: an integer between 2 and 62. The default base is 10.

Return Values

character string.

interpolate

Polynomial interpolation

Syntax

```
interpolate(xList, yList, X, <F>)
```

```
interpolate(nodes, values, ind, <F>)
```

Description

`interpolate` computes an interpolating polynomial through data over a rectangular grid.

The call `interpolate(xList, yList, X)` with `xList = [x1, …, xn]` and `yList = [y1, …, yn]` returns the polynomial of degree less than n in the variable `X` which interpolates the points (x_1, y_1), …, (x_n, y_n).

This call with a 1-dimensional grid `xList` is equivalent to the corresponding 'multi-dimensional' call `interpolate([xList], array(1..n, [yList]), [X])`.

For d-dimensional interpolation, assume that indeterminates $ind = [X_1, \ldots, X_d]$ are specified. The interpolating polynomial $P = poly(\ldots, [X_1, \ldots, X_d], F)$ satisfies

$$\mathrm{evalp}\left(P, X_1 = L_1[i_1], \ldots, X_d = L_d[i_d]\right) = \mathrm{value}[i_1, \ldots, i_d]$$

for all points $\left[(L_1)_{i_1}, \ldots, L_d[i_d]\right]$ in the grid. P is the polynomial of minimal degree satisfying the interpolation conditions, i.e., `degree`$(P, X_i) < n_i$.

If only interpolating values at concrete numerical points $X_1 = v_1$, …, $X_d = v_d$ are required, we recommend not to compute P with symbolic indeterminates `ind` $= [X_1, \ldots, X_d]$ and then evaluate $P(v_1, \ldots, v_d)$. It is faster to compute this value directly by `interpolate` with `ind` $= [v_1, \ldots, v_d]$. Cf. examples "Example 1" on page 1-1058 and "Example 3" on page 1-1059.

Examples

Example 1

We consider a 1-dimensional interpolation problem. To each node x_i, a value y_i is associated. The interpolation polynomial P with $P(x_i) = y_i$ is:

```
xList := [1, 2, 3]:
yList := [y1, y2, y3]:
P := interpolate(xList, yList, X)
```

$$\text{poly}\left(\left(\frac{\text{y1}}{2} - \text{y2} + \frac{\text{y3}}{2}\right) X^2 + \left(-\frac{5\,\text{y1}}{2} + 4\,\text{y2} - \frac{3\,\text{y3}}{2}\right) X + 3\,\text{y1} - 3\,\text{y2} + \text{y3}, [X]\right)$$

The evaluation of P at the point $X = \frac{5}{2}$ is given by:

```
evalp(P, X = 5/2)
```

$$\frac{3\,\text{y2}}{4} - \frac{\text{y1}}{8} + \frac{3\,\text{y3}}{8}$$

This value can also be computed directly without the symbolic polynomial:

```
interpolate(xList,  yList, 5/2)
```

$$\frac{3\,\text{y2}}{4} - \frac{\text{y1}}{8} + \frac{3\,\text{y3}}{8}$$

```
delete xList, yList, P:
```

Example 2

We demonstrate multi-dimensional interpolation. Consider data over the following 2-dimensional 2 ×3 grid:

```
XList := [1, 2]: YList := [1, 2, 3]:
values := array(1..2, 1..3, [[1, 2, 3], [3, 2, 1]]):
P := interpolate([XList, YList], values, [X, Y])
```

$$\text{poly}(-2\,X\,Y+4\,X+3\,Y-4,\,[X,\,Y])$$

Next, interpolation over a 3-dimensional 2 ×3×2 grid is demonstrated:

```
L1 := [1, 2]: L2 := [1, 2, 3]: L3 := [1, 2]:
values := array(1..2, 1..3, 1..2,
   [[[1, 4], [1, 2], [3, 3]], [[1, 4], [1, 3], [4, 0]]]):
interpolate([L1, L2, L3], values, [X, Y, Z])
```

$$\text{poly}\left(-3\,X\,Y^2\,Z+\frac{7\,X\,Y^2}{2}+10\,X\,Y\,Z-\frac{23\,X\,Y}{2}-7\,X\,Z+8\,X+\frac{7\,Y^2\,Z}{2}-3\,Y^2-\frac{27\,Y\,Z}{2}\right.$$

$$\left.+12\,Y+13\,Z-11,\,[X,\,Y,\,Z]\right)$$

```
delete XList, values, P, L1, L2, L3:
```

Example 3

We interpolate data over a 2-dimensional grid:

```
n1 := 4: L1 := [i $ i = 1..n1]:
n2 := 5: L2 := [i $ i = 1..n2]:
f := (X, Y) -> 1/(1 + X^2 + Y^2):
values := array(1..n1, 1..n2,
                [[f(L1[i], L2[j]) $ j=1..n2] $ i=1..n1]):
```

First, we compute the symbolic polynomial:

```
P := interpolate([L1, L2], values, [X, Y])
```

$$\text{poly}\left(-\frac{5563\,X^3\,Y^4}{23108085}+\frac{16376\,X^3\,Y^3}{4621617}-\ldots-\frac{4401895\,Y}{3081078}+\frac{4199983}{2567565},\,[X,\,Y]\right)$$

```
poly(- (5563*X^3*Y^4)/23108085 + (16376*X^3*Y^3)/4621617 -
(176747*X^3*Y^2)/9243234 + (29440*X^3*Y)/660231 - (40922*X^3)/1100385 +
(22397*X^2*Y^4)/10270260 - (16691*X^2*Y^3)/513513 + (367151*X^2*Y^2)/2054052
- (220525*X^2*Y)/513513 + (645283*X^2)/1711710 - (1009*X*Y^4)/161595 +
(439024*X*Y^3)/4621617 - (452873*X*Y^2)/840294 + (6293720*X*Y)/4621617
```

```
- (1438453*X)/1100385 + (15199*Y^4)/2800980 - (263969*Y^3)/3081078 +
(452975*Y^2)/880308 - (4401895*Y)/3081078 + 4199983/2567565, [X, Y])
```

Fixing the value $Y = 2.5$, this yields a polynomial in X.

```
evalp(P, Y = 2.5)
```

$$\text{poly}(0.0007372500794\ X^3 - 0.002155538175\ X^2 - 0.03076935248\ X + 0.1533997618, [X])$$

It can also be computed directly by using an evaluation point for the indeterminate Y:

```
interpolate([L1, L2], values, [X, 2.5])
```

$$\text{poly}(0.0007372500794\ X^3 - 0.002155538175\ X^2 - 0.03076935248\ X + 0.1533997618, [X])$$

If all indeterminates are replaced by evaluation points, the corresponding interpolation value is returned:

```
interpolate([L1, L2], values, [1.2, 2.5])
```

$$0.114646532$$

```
delete n1, n2, f, values, P:
```

Example 4

We demonstrate interpolation over a special coefficient field. Consider the following data over a 2-dimensional 2 ×3 grid:

```
XList := [3, 4]: YList := [1, 2, 3]:
values := array(1..2, 1..3, [[0, 1, 2], [3, 2, 1]]):
```

With the following call, these data are converted to integers modulo 7. Arithmetic over this field is used:

```
F := Dom::IntegerMod(7):
P := interpolate([XList, YList], values, [X, Y], F)
```

$$\text{poly}(5\ X\ Y + 5\ X + 5, [X, Y], \text{Dom::IntegerMod}(7))$$

Evaluation of P at grid points reproduces the associated values converted to the field:

```
evalp(P, X = XList[2], Y = YList[3]) = F(values[2, 3])
```

$$1 \bmod 7 = 1 \bmod 7$$

```
delete XList, YList, values, F, P:
```

Parameters

xList

The nodes: a list `[x1, x2, ...]` of distinct arithmetical expressions

yList

The values: a list `[y1, y2, ...]` of arithmetical expressions. This list must have the same length as `xList`.

X

An indeterminate or an arithmetical expression. An indeterminate is either an identifier (of domain type `DOM_IDENT`) or an indexed identifier (of type `"_index"`).

nodes

A list $[L_1, \ldots, L_d]$ of d lists L_i defining a d-dimensional rectangular grid

$$\{(x_1, \ldots, x_d) \mid x_1 \in L_1, \ldots, x_d \in L_d\}.$$

The lists L_i may have different lengths $n_i = |L_i|$. The elements of each L_i must be distinct.

values

A d-dimensional `array(1..n[1],...,1..n[d], [...])` or `hfarray(1..n[1],...,1..n[d], [...])` associating a value with each grid point:

$$\left[(L_1)_{i_1}, \ldots, (L_d)_{i_d}\right] \to \text{values}[i_1, \ldots, i_d],\ i_1 = 1 \ldots n_1, \ldots, i_d = 1 \ldots n_d,$$

ind

A list of *d* indeterminates or arithmetical expressions. Indeterminates are either identifiers (of domain type `DOM_IDENT`) or indexed identifiers (of type `"_index"`).

F

Either `Expr` or any field of category `Cat::Field`

The returned polynomial is of type `poly(..., F)`.

For the default field `Expr`, all input data may be arbitrary MuPAD expressions. Standard arithmetic over such expressions is used to compute the polynomial.

For `F` not being `Expr`, the grid nodes as well as the entries of `values` must be elements of `F` or must be convertible to such elements. Conversion of the input data to elements of `F` is done automatically.

Return Values

Interpolating polynomial *P* of domain type `DOM_POLY` in the indeterminates specified by `ind` over the coefficient field `F` is returned. The elements in `ind` that are not indeterminates but arithmetical expressions are not used as indeterminates in *P*, but enter its coefficients: the polynomial is "evaluated" at these points. If no element of `ind` is an indeterminate, the value of the polynomial at the point specified by `ind` is returned. This is an element of the field `F` or an arithmetical expression if `F = Expr`.

Algorithms

For a *d*-dimensional rectangular grid

$$L_j = \left[x_{j,1}, \ldots, x_{j,n_j}\right], j = 1, \ldots, d$$

specified by the lists

$$\left\{(x_1, \ldots, x_d) \mid x_1 \in L_1, \ldots, x_d \in L_d\right\}$$

with associated values

$$P\left(x_{i_1}, \ldots, x_{i_d}\right) = v_{i_1, \ldots, i_d},$$

the interpolating polynomial in the indeterminates $X_1, \ldots, X_d$ is given by

$$P(X_1, \ldots, X_d) = \sum_{i_1=1}^{n_1} \cdots \sum_{i_d=1}^{n_d} v_{i_1, \ldots, i_d} \times p_{1, i_1}(X_1) \times p_{d, i_d}(X_d)$$

with the Lagrange polynomials

$$p_{j,k}(X) = \prod_{l=1}^{n_j} \frac{X - x_{j,l}}{x_{j,k} - x_{j,l}}, \; l \neq k, \; j = 1, \ldots, d, \; k = 1, \ldots, d$$

associated with the k-th node of the j-th coordinate.

`genpoly` | `numeric::cubicSpline` | `numeric::cubicSpline2d` | `poly`

intersect, _intersect

Intersection of sets and/or intervals

Syntax

```
set1intersect set2

_intersect(set1, set2, …)
```

Description

`intersect` computes the intersection of sets and intervals.

`set1 intersect set2` is equivalent to `_intersect(set1, set2)`.

The precedences of `intersect`, `minus`, `union` are as follows: The operator `intersect` is stronger binding than `minus`, i.e, `set1 intersect set2 minus set3` = `(set 1 intersect set2) minus set3`. The operator `minus` is stronger binding than `union`, i.e., `set1 minus set2 union set3` = `(set1 minus set2) union set3`. Further, `set1 minus set2 minus set3` = `(set 1 minus set2) minus set3`. If in doubt, use brackets to make sure that the expression is parsed as desired.

If sets or intervals are specified by symbolic expressions involving identifiers or indexed identifiers, then symbolic calls of `_intersect`, `_minus`, `_union` are returned. On the screen, they are represented via the operator notation `set1 intersect set2` etc.

Note: On finite sets of type `DOM_SET`, these operators act in a purely *syntactical* way. E.g., `{1}minus {x}` simplifies to `{1}`. Mathematically, this result may not be correct in general, because `x` might represent the value 1.

On intervals of type `Dom::Interval`, these operators act in a *semantical* way. In particular, properties of identifiers are taken into account.

`_intersect()` returns `universe` (of type `stdlib::Universe`) which represents the set of all mathematical objects.

`_union()` returns the empty set `{}`.

Examples

Example 1

`intersect`, `minus`, and `union` operate on finite sets:

```
{x, 1, 5} intersect {x, 1, 3, 4},
{x, 1, 5} union {x, 1, 3, 4},
{x, 1, 5} minus {x, 1, 3, 4}
```

$$\{1, x\}, \{1, 3, 4, 5, x\}, \{5\}$$

For symbolic sets, specified as identifiers or indexed identifiers, symbolic calls are returned:

```
{1, 2} union A union {2, 3}
```

$$\{1, 2, 3\} \cup A$$

Note that the set operations act on finite sets in a purely syntactical way. In the following call, `x` does not match any of the numbers 1, 2, 3 syntactically:

```
{1, 2, 3} minus {1, x}
```

$$\{2, 3\}$$

Example 2

`intersect`, `minus`, and `union` are overloaded by the domain `Dom::Interval`:

```
Dom::Interval([0, 1]) union Dom::Interval(1, 4)
```

$$[0, 4)$$

```
Dom::Interval([0, 1]) union Dom::Interval(4, infinity)
```

$$[0, 1] \cup (4, \infty)$$

```
Dom::Interval(2, infinity) intersect Dom::Interval([1, 3])
```

$$(2, 3]$$

```
{PI/2, 2, 2.5, 3} intersect Dom::Interval(1,3)
```

$$\left\{2, 2.5, \frac{\pi}{2}\right\}$$

```
Dom::Interval(1, PI) minus {2, 3}
```

$$(1, 2) \cup (2, 3) \cup (3, \pi)$$

In contrast to finite sets of type `DOM_SET`, the interval domain works semantically. It takes `properties` into account:

```
Dom::Interval(-1, 1) minus {x}
```

$$(-1, 1) \setminus \{x\}$$

```
assume(x > 2): Dom::Interval(-1, 1) minus {x}
```

$$(-1, 1)$$

```
unassume(x):
```

Example 3

The following list provides a collection of sets:

```
L := [{a, b}, {1, 2, a, c}, {3, a, b}, {a, c}]:
```

The functional equivalent `_intersect` of the `intersect` operator accepts an arbitray number of arguments. Thus, the intersection of all sets in `L` can be computed as follows:

```
_intersect(op(L))
```

$$\{a\}$$

The union of all sets in `L` is:

```
_union(op(L))
```

$$\{1, 2, 3, a, b, c\}$$

```
delete L:
```

Example 4

`universe` represents the set of all mathematical objects:

```
_intersect()
```

$$\text{universe}$$

Parameters

$\mathtt{set}_1$, $\mathtt{set}_2$, …

Finite sets of type `DOM_SET`, or intervals of type `Dom::Interval`, or arithmetical expressions

Return Values

Set, an interval, a symbolic expression of type `"_intersect"`, `"_minus"`, `"_union"`, or `universe`.

Overloaded By

set1, set2

See Also

MuPAD Functions
`minus` | `subset` | `union` | `universe`

minus, _minus

Difference of sets and/or intervals

Syntax

```
set1minus set2
```

```
_minus(set1, set2)
```

Description

`minus` computes the difference between sets and intervals.

`set1 minus set2` is equivalent to `_minus(set1, set2)`.

The precedences of `intersect`, `minus`, `union` are as follows: The operator `intersect` is stronger binding than `minus`, i.e, `set1 intersect set2 minus set3` = `(set 1 intersect set2) minus set3`. The operator `minus` is stronger binding than `union`, i.e., `set1 minus set2 union set3` = `(set1 minus set2) union set3`. Further, `set1 minus set2 minus set3` = `(set 1 minus set2) minus set3`. If in doubt, use brackets to make sure that the expression is parsed as desired.

If sets or intervals are specified by symbolic expressions involving identifiers or indexed identifiers, then symbolic calls of `_intersect`, `_minus`, `_union` are returned. On the screen, they are represented via the operator notation `set1 intersect set2` etc.

Note: On finite sets of type `DOM_SET`, these operators act in a purely *syntactical* way. E.g., `{1}minus {x}` simplifies to `{1}`. Mathematically, this result may not be correct in general, because `x` might represent the value 1.

On intervals of type `Dom::Interval`, these operators act in a *semantical* way. In particular, properties of identifiers are taken into account.

`_intersect()` returns `universe` (of type `stdlib::Universe`) which represents the set of all mathematical objects.

`_union()` returns the empty set `{}`.

Examples

Example 1

`intersect`, `minus`, and `union` operate on finite sets:

```
{x, 1, 5} intersect {x, 1, 3, 4},
{x, 1, 5} union {x, 1, 3, 4},
{x, 1, 5} minus {x, 1, 3, 4}
```

$$\{1, x\}, \{1, 3, 4, 5, x\}, \{5\}$$

For symbolic sets, specified as identifiers or indexed identifiers, symbolic calls are returned:

```
{1, 2} union A union {2, 3}
```

$$\{1, 2, 3\} \cup A$$

Note that the set operations act on finite sets in a purely syntactical way. In the following call, `x` does not match any of the numbers 1, 2, 3 syntactically:

```
{1, 2, 3} minus {1, x}
```

$$\{2, 3\}$$

Example 2

`intersect`, `minus`, and `union` are overloaded by the domain `Dom::Interval`:

```
Dom::Interval([0, 1]) union Dom::Interval(1, 4)
```

$$[0, 4)$$

```
Dom::Interval([0, 1]) union Dom::Interval(4, infinity)
```

$$[0, 1] \cup (4, \infty)$$

```
Dom::Interval(2, infinity) intersect Dom::Interval([1, 3])
```

$$(2, 3]$$

```
{PI/2, 2, 2.5, 3} intersect Dom::Interval(1,3)
```

$$\left\{2, 2.5, \frac{\pi}{2}\right\}$$

```
Dom::Interval(1, PI) minus {2, 3}
```

$$(1, 2) \cup (2, 3) \cup (3, \pi)$$

In contrast to finite sets of type `DOM_SET`, the interval domain works semantically. It takes `properties` into account:

```
Dom::Interval(-1, 1) minus {x}
```

$$(-1, 1) \setminus \{x\}$$

```
assume(x > 2): Dom::Interval(-1, 1) minus {x}
```

$$(-1, 1)$$

```
unassume(x):
```

Example 3

The following list provides a collection of sets:

```
L := [{a, b}, {1, 2, a, c}, {3, a, b}, {a, c}]:
```

The functional equivalent `_intersect` of the `intersect` operator accepts an arbitray number of arguments. Thus, the intersection of all sets in `L` can be computed as follows:

```
_intersect(op(L))
```

$$\{a\}$$

The union of all sets in `L` is:

```
_union(op(L))
```

$$\{1, 2, 3, a, b, c\}$$

```
delete L:
```

Example 4

`universe` represents the set of all mathematical objects:

```
_intersect()
```

$$\text{universe}$$

Parameters

`set`$_1$`, set`$_2$`, …`

Finite sets of type `DOM_SET`, or intervals of type `Dom::Interval`, or arithmetical expressions

Return Values

Set, an interval, a symbolic expression of type `"_intersect"`, `"_minus"`, `"_union"`, or `universe`.

Overloaded By

set1, set2

union, _union

Union of sets and/or intervals

Syntax

```
set1union set2
```

```
_union(set1, set2, …)
```

Description

`union` computes the union of sets and intervals.

`set1 union set2` is equivalent to `_union(set1, set2)`.

The precedences of `intersect`, `minus`, `union` are as follows: The operator `intersect` is stronger binding than `minus`, i.e, `set1 intersect set2 minus set3` = `(set 1 intersect set2) minus set3`. The operator `minus` is stronger binding than `union`, i.e., `set1 minus set2 union set3` = `(set1 minus set2) union set3`. Further, `set1 minus set2 minus set3` = `(set 1 minus set2) minus set3`. If in doubt, use brackets to make sure that the expression is parsed as desired.

If sets or intervals are specified by symbolic expressions involving identifiers or indexed identifiers, then symbolic calls of `_intersect`, `_minus`, `_union` are returned. On the screen, they are represented via the operator notation `set1 intersect set2` etc.

Note: On finite sets of type `DOM_SET`, these operators act in a purely *syntactical* way. E.g., `{1}minus {x}` simplifies to `{1}`. Mathematically, this result may not be correct in general, because `x` might represent the value 1.

On intervals of type `Dom::Interval`, these operators act in a *semantical* way. In particular, properties of identifiers are taken into account.

`_intersect()` returns `universe` (of type `stdlib::Universe`) which represents the set of all mathematical objects.

`_union()` returns the empty set `{}`.

Examples

Example 1

`intersect`, `minus`, and `union` operate on finite sets:

```
{x, 1, 5} intersect {x, 1, 3, 4},
{x, 1, 5} union {x, 1, 3, 4},
{x, 1, 5} minus {x, 1, 3, 4}
```

$$\{1, x\}, \{1, 3, 4, 5, x\}, \{5\}$$

For symbolic sets, specified as identifiers or indexed identifiers, symbolic calls are returned:

```
{1, 2} union A union {2, 3}
```

$$\{1, 2, 3\} \cup A$$

Note that the set operations act on finite sets in a purely syntactical way. In the following call, `x` does not match any of the numbers 1, 2, 3 syntactically:

```
{1, 2, 3} minus {1, x}
```

$$\{2, 3\}$$

Example 2

`intersect`, `minus`, and `union` are overloaded by the domain `Dom::Interval`:

```
Dom::Interval([0, 1]) union Dom::Interval(1, 4)
```

$$[0, 4)$$

```
Dom::Interval([0, 1]) union Dom::Interval(4, infinity)
```

$$[0, 1] \cup (4, \infty)$$

```
Dom::Interval(2, infinity) intersect Dom::Interval([1, 3])
```

$$(2, 3]$$

```
{PI/2, 2, 2.5, 3} intersect Dom::Interval(1,3)
```

$$\left\{2, 2.5, \frac{\pi}{2}\right\}$$

```
Dom::Interval(1, PI) minus {2, 3}
```

$$(1, 2) \cup (2, 3) \cup (3, \pi)$$

In contrast to finite sets of type `DOM_SET`, the interval domain works semantically. It takes `properties` into account:

```
Dom::Interval(-1, 1) minus {x}
```

$$(-1, 1) \setminus \{x\}$$

```
assume(x > 2): Dom::Interval(-1, 1) minus {x}
```

$$(-1, 1)$$

```
unassume(x):
```

Example 3

The following list provides a collection of sets:

```
L := [{a, b}, {1, 2, a, c}, {3, a, b}, {a, c}]:
```

The functional equivalent `_intersect` of the `intersect` operator accepts an arbitray number of arguments. Thus, the intersection of all sets in `L` can be computed as follows:

```
_intersect(op(L))
```

$$\{a\}$$

The union of all sets in `L` is:

```
_union(op(L))
```

$$\{1, 2, 3, a, b, c\}$$

```
delete L:
```

Example 4

`universe` represents the set of all mathematical objects:

```
_intersect()
```

$$\text{universe}$$

Parameters

$\mathtt{set}_1$, $\mathtt{set}_2$, …

Finite sets of type `DOM_SET`, or intervals of type `Dom::Interval`, or arithmetical expressions

Return Values

Set, an interval, a symbolic expression of type `"_intersect"`, `"_minus"`, `"_union"`, or `universe`.

Overloaded By

set1, set2

See Also

MuPAD Functions
`intersect` | `minus` | `subset` | `universe`

interval

Convert constant subexpressions to intervals

Syntax

```
interval(object)
```

Description

`interval(object)` converts all constant subexpressions of `object` to floating point intervals.

`interval` is the analogue of `float`. While the latter converts exact numbers and numerical expressions to floating-point approximations, `interval` converts numbers and numerical expressions to enclosing floating-point intervals.

If `object` is an arithmetical expression, `interval(object)` recursively descends into the subexpressions of `object` and replaces all integers,rationals, and floating point numbers as well as the constants CATALAN, EULER and PI by floating-point intervals enclosing them. Afterwards, the resulting expression is evaluated via interval arithmetic.

If `object` is not an arithmetical expression, `interval` returns the object unchanged.

Examples

Example 1

Only constant expressions such as numbers 1, $\frac{2}{3}$, $0.123 + 4.5\,i$ etc. and numerical expressions `PI + sqrt(2)`, `sin(PI/24)` etc. are converted to floating-point intervals. Symbolic objects such as identifiers, indexed identifiers etc. are left untouched:

```
interval(4*x[1] + PI*x[2]^2/sin(1) + 1/4)
```

$$3.733453333 \ldots 3.733453334\, x_2^{\,2} + x_1\; 4.0 \ldots 4.0 + 0.25 \ldots 0.25$$

```
interval(f(g(2 + x) + sin(1)*sqrt(PI)))
```

$$f(g(x + 2.0 \ldots 2.0) + 1.491468487 \ldots 1.491468488)$$

Example 2

The special MuPAD constants CATALAN, EULER and PI can be converted to an enclosing floating-point interval:

```
interval(CATALAN), interval(EULER), interval(PI)
```

$$0.9159655941 \ldots 0.9159655942,\ 0.5772156649 \ldots 0.577215665,\ 3.141592653 \ldots 3.141592654$$

Parameters

`object`

An arbitrary MuPAD object

Return Values

MuPAD object

See Also

MuPAD Domains
`Dom::FloatIV`

MuPAD Functions
`float` | `hull` | `misc::maprec`

inverse

Inverse of a matrix

Syntax

```
inverse(A, <Normal>)
```

Description

`inverse(A)` returns the inverse of the matrix *A*.

If the input is a matrix *A* of category `Cat::Matrix`, then `A^(-1)` is called to compute the result. In contrast to the overloaded arithmetics, the function `inverse` also operates on `array`s and `hfarray`s.

If the input matrix is an `array` of domain type `DOM_ARRAY`, then `numeric::inverse(A, Symbolic)` is called to compute the result.

The inverse of `hfarray`s of domain type `DOM_HFARRAY` is internally computed via `numeric::inverse(A)`.

If the argument does not evaluate to a matrix of one of the types mentioned above, a symbolic call `inverse(A)` is returned.

By default, `inverse` calls `normal` before returning results. This additional internal call ensures that the final result is normalized. This call can be computationally expensive. It also affects the result returned by `inverse` only if a matrix contains variables or exact expressions, such as `sqrt(5)` or `sin(PI/7)`.

To avoid this additional call, specify `Normal = FALSE`. In this case, `inverse` also can return normalized results, but does not guarantee such normalization. See “Example 4” on page 1-1083.

Examples

Example 1

Compute the inverse of a matrix given by various data types:

```
A := array(1..2, 1..2, [[1, 2], [3, PI]]);
inverse(A)
```

$$\begin{pmatrix} 1 & 2 \\ 3 & \pi \end{pmatrix}$$

$$\begin{pmatrix} \frac{\pi}{\pi-6} & -\frac{2}{\pi-6} \\ -\frac{3}{\pi-6} & \frac{1}{\pi-6} \end{pmatrix}$$

```
B := hfarray(1..2, 1..2, [[1, 2], [3, PI]]);
inverse(B)
```

$$\begin{pmatrix} 1.0 & 2.0 \\ 3.0 & 3.141592654 \end{pmatrix}$$

$$\begin{pmatrix} -1.099071012 & 0.6996903372 \\ 1.049535506 & -0.3498451686 \end{pmatrix}$$

```
C := matrix(2, 2, [[1, 2], [3, PI]]);
inverse(C)
```

$$\begin{pmatrix} 1 & 2 \\ 3 & \pi \end{pmatrix}$$

$$\begin{pmatrix} \frac{\pi}{\pi-6} & -\frac{2}{\pi-6} \\ -\frac{3}{\pi-6} & \frac{1}{\pi-6} \end{pmatrix}$$

```
delete A, B, C:
```

Example 2

The following matrix is not invertible:

```
inverse(matrix([[1, 2], [3, 6]]))
```

FAIL

Example 3

If the input does not evaluate to a matrix, then symbolic calls are returned:

```
delete A, B:
inverse(A + 2*B)
```

$$(A+2\,B)^{-1}$$

Example 4

Using `Normal` can significantly decrease the performance of `inverse`. For example, computing the inverse of this matrix takes a long time:

```
n := 5:
inv5 := inverse(matrix(n, n, [[1/(x[i] + x[j]) $
                                    j = 1..n] $
                                    i = 1..n])):
```

For better performance, specify `Normal = FALSE`:

```
n := 5:
inv5 := inverse(matrix(n, n, [[1/(x[i] + x[j]) $
                                    j = 1..n] $
                                    i = 1..n]),
                               Normal = FALSE):
```

Parameters

A

Square matrix: either a two-dimensional `array`, a two-dimensional `hfarray`, or an object of the category `Cat::Matrix`

Options

`Normal`

Option, specified as `Normal = b`

Return normalized results. The value `b` must be `TRUE` or `FALSE`. By default, `Normal = TRUE`, meaning that `inverse` guarantees normalization of the returned results. Normalizing results can be computationally expensive.

Return Values

The inverse is returned as a matrix of the same type as the input matrix. If the matrix is not invertible, then `FAIL` is returned. If the input does not evaluate to a matrix, then a symbolic call of `inverse` is returned.

Overloaded By

A

MuPAD Functions
`numeric::inverse`

_invert

Reciprocal of an expression

Syntax

```
1/ x

_invert(x)
```

Description

`_invert(x)` computes the reciprocal `1/x` of `x`.

`1/x` is equivalent to the function call `_invert(x)`. It represents the inverse of the element `x` with respect to multiplication, i.e., `x * (1/x) = 1`.

The reciprocal of a number of type `Type::Numeric` is returned as a number.

`1/x` is overloaded for matrix domains (`matrix`) and returns the inverse of the matrix `x`.

If `x` is not an element of a library domain with an `"_invert"` method, `1/x` is internally represented as `x^(-1) = _power(x, -1)`.

If `x` is an element of a domain with a slot`"_invert"`, then this method is used to compute `1/x`. Many library domains overload the `/` operator by an appropriate `"_invert"` slot. Note that `a/x` calls the overloading slot `x::dom::_invert(x)` only for `a = 1`.

If neither `x` nor `y` overload the binary operator `/` by a `"_divide"` method, the quotient `x/y` is equivalent to `x * y^(-1) = _mult(x, _power(y, -1))`.

For finite sets, `1/X` is the set $\left\{\frac{1}{x} \middle| x \in X\right\}$.

Examples

Example 1

The reciprocal of an expression is the inverse with respect to `*`:

```
_invert(x), x * (1/x) = x * _invert(x)
```

$$\frac{1}{x}, 1 = 1$$

```
3 * y * x^2 / 27 / x
```

$$\frac{x\,y}{9}$$

Internally, a symbolic expression `1/x` is represented as `x^(-1) = _power(x, -1)`:

```
type(1/x), op(1/x, 0), op(1/x, 1), op(1/x, 2)
```

"_power", _power, x, -1

Example 2

For finite sets, `1/X` is the set $\left\{\frac{1}{x} \middle| x \in X\right\}$:

```
1/{a, b, c}
```

$$\left\{\frac{1}{a}, \frac{1}{b}, \frac{1}{c}\right\}$$

Example 3

Various library domains such as matrix domains or residue class domains overload `_invert`:

```
x := Dom::Matrix(Dom::IntegerMod(7))([[2, 3], [3, 4]]):
```

```
x, 1/x, x * (1/x)
```

$$\begin{pmatrix} 2 \bmod 7 & 3 \bmod 7 \\ 3 \bmod 7 & 4 \bmod 7 \end{pmatrix}, \begin{pmatrix} 3 \bmod 7 & 3 \bmod 7 \\ 3 \bmod 7 & 5 \bmod 7 \end{pmatrix}, \begin{pmatrix} 1 \bmod 7 & 0 \bmod 7 \\ 0 \bmod 7 & 1 \bmod 7 \end{pmatrix}$$

```
delete x:
```

Parameters

x

An arithmetical expression or a set

Return Values

Arithmetical expression or a set.

Overloaded By

x

MuPAD Functions

`*` | `+` | `-` | `/` | `^` | `_divide` | `_subtract`

irreducible

Test irreducibility of a polynomial

Syntax

```
irreducible(p)
```

Description

`irreducible(p)` tests if the polynomial `p` is irreducible.

A polynomial $p \in k[x_1, \ldots, x_n]$ is irreducible over the field k if p is nonconstant and is not a product of two nonconstant polynomials in $k[x_1, \ldots, x_n]$.

`irreducible` returns `TRUE` if the polynomial is irreducible over the field implied by its coefficients. Otherwise, `FALSE` is returned. See the function `factor` for details on the coefficient field that is assumed implicitly.

The polynomial may be either a (multivariate) polynomial over the rationals, a (multivariate) polynomial over a field (such as the residue class ring `IntMod(n)` with a prime number `n`) or a univariate polynomial over an algebraic extension (see `Dom::AlgebraicExtension`).

Internally, a polynomial expression is converted to a polynomial of type `DOM_POLY` before irreducibility is tested.

Examples

Example 1

With the following call, we test if the polynomial expression x^2 - 2 is irreducible. Implicitly, the coefficient field is assumed to consist of the rational numbers:

```
irreducible(x^2 - 2)
```

```
irreducible(x^2 - 2)
```

TRUE

```
factor(x^2 - 2)
```

$x^2 - 2$

Since x^2 - 2 factors over a field extension of the rationals containing the radical $\sqrt{2}$, the following irreducibility test is negative:

```
irreducible(sqrt(2)*(x^2 - 2))
```

FALSE

```
factor(sqrt(2)*(x^2 - 2))
```

$\sqrt{2}\,(x-\sqrt{2})\,(x+\sqrt{2})$

The following calls use polynomials of type `DOM_POLY`. The coefficient field is given explicitly by the polynomials:

```
irreducible(poly(6*x^3 + 4*x^2 + 2*x - 4, IntMod(13)))
```

TRUE

```
factor(poly(6*x^3 + 4*x^2 + 2*x - 4, IntMod(13)))
```

$6\,\mathrm{poly}(x^3+5\,x^2-4\,x-5,\,[x],\,\mathrm{IntMod}(13))$

```
irreducible(poly(3*x^2 + 5*x + 2, IntMod(13)))
```

FALSE

```
factor(poly(3*x^2 + 5*x + 2, IntMod(13)))
```

$3\,\mathrm{poly}(x+5,\,[x],\,\mathrm{IntMod}(13))\,\mathrm{poly}(x+1,\,[x],\,\mathrm{IntMod}(13))$

Parameters

p

A polynomial of type DOM_POLY or a polynomial expression

Return Values

TRUE or FALSE.

Overloaded By

p

is

Check a mathematical property of an expression

Syntax

```
is(cond)
```

```
is(ex, set)
```

Description

`is(cond)` checks whether the condition `cond` holds for all possible values.

`is(ex, set)` checks whether the expression `ex` lies in the set `set`.

The property mechanism helps to simplify expressions involving expressions that carry “mathematical properties”. The function `assume` allows to assume “assumptions” such as `` `x is a real number' `` or `` `x is an odd integer' `` to an identifier `x`, say. Arithmetical expressions involving `x` may inherit such properties. E.g., `` `1 + x^2 is positive' `` if `` `x is a real number' ``. The function `is` is the basic tool for querying mathematical properties.

`is` queries the assumptions of all involved identifiers and checks whether the condition `cond` holds for all possible values. If this is the case, then `is` returns `TRUE`. If `is` derives that cond is not satisfied by any possible value it returns `FALSE`. Otherwise, `is` returns `UNKNOWN`.

If a relation is given to `is`, and the operands are complex numbers or identifiers with this property, `is` returns `FALSE`, because a relations holds only with real objects. Cf. “Example 4” on page 1-1094.

It may happen that `is` returns `UNKNOWN`, although the queried property holds mathematically. Cf. “Example 5” on page 1-1094.

In MuPAD, there also exists the function `bool` to check a relation `y rel z`. However, there are two main differences between `bool` and `is`:

1. `bool` produces an error if it cannot decide whether the relation holds or not; `is(y rel z)` returns `UNKNOWN` in this case.

2 `bool` does not take properties into account.

Cf. “Example 3” on page 1-1093.

If `bool(y rel z)` returns `TRUE`, then so does `is(y rel z)`. However, `is` is more powerful than `bool`, even when no properties are involved. Cf. “Example 3” on page 1-1093. On the other hand, `is` is usually much slower than `bool`.

Note: Be careful when using `is` in a condition of an `if` statement or a `for`, `while`, or `repeat` loop: these constructs cannot handle the value `UNKNOWN`. Use either `is(...) = TRUE` or a `case` statement. Cf. “Example 6” on page 1-1095.

If `is` needs to check whether a constant symbolic expression is zero, then it may employ a heuristic numerical zero test based on floating-point evaluation. Despite internal numerical stabilization, this zero test may return the wrong answer in exceptional pathological cases; in such a case, `is` may return a wrong result as well.

Examples

Example 1

The identifier `x` is assumed to be an integer:

```
assume(x, Type::Integer):
is(x, Type::Integer), is(x > 0), is(x^2 >= 0)
```

```
TRUE, UNKNOWN, TRUE
```

The identifier `x` is assumed to be a positive real number:

```
assume(x > 0):
is(x > 1), is(x >= 0), is(x < 0)
```

```
UNKNOWN, TRUE, FALSE
```

```
unassume(x):
```

Example 2

`is` can derive certain facts even when no properties were assumed explicitly:

```
is(x > x + 1), is(abs(x) >= 0)
```

```
FALSE, TRUE
```

```
is(Re(exp(x)), Type::Real)
```

```
TRUE
```

Example 3

For relations between numbers, `is` yields the same answers as `bool`:

```
bool(1 > 0), is(1 > 0)
```

```
TRUE, TRUE
```

`is` resolves more constant symbolic expressions than `bool`:

```
is(sqrt(14) <= sqrt(2)*sqrt(7)),
is(sin(10^20) > 0),
is(sqrt(2) > 1.41)
```

```
TRUE, FALSE, TRUE
```

```
bool(sqrt(14) <= sqrt(2)*sqrt(7))
```

```
Error: Cannot evaluate to Boolean. [_leequal]
```

```
bool(sin(10^20) > 0)
```

```
Error: Cannot evaluate to Boolean. [_less]
```

```
is(exp(5), Type::Real), is(PI, Type::PosInt)
```

```
TRUE, FALSE
```

Example 4

In the next example a relation with complex objects is given, the returned value is FALSE:

```
is(0 < I), is(I + 1 > I), is(1 + 2*I <= 2 + 3*I)
```

```
FALSE, FALSE, FALSE
```

The identifier in the next example is assumed to be complex, but it could be real too:

```
assume(x, Type::Complex):
is(x > 0)
```

```
UNKNOWN
```

The next relation is false, either the identifier `x` is real, then the relation is false, or the identifiers is not real, then the comparison is illegal:

```
unassume(x):
is(x + 1 < x)
```

```
FALSE
```

```
unassume(x):
```

Example 5

Here are some examples where the queried property can be derived mathematically. However, the current implementation of `is` is not yet strong enough to derive the property:

```
assume(x in Z_ and y in Z_ and x^2 + y^2 = 2);
is(x > 1)
```

```
UNKNOWN
```

```
unassume(x):
```

Example 6

Care must be taken when using `is` in `if` statements or `for`, `repeat`, `while` loops:

```
myabs := proc(x)
         begin
           if is(x >= 0) then
             x
           elif is(x < 0) then
             -x
           else
             procname(x)
           end_if
         end_proc:

assume(x < 0): myabs(1), myabs(-2), myabs(x)
```

$$1, 2, -x$$

When the call of `is` returns `UNKNOWN`, an error occurs because `if` expects `TRUE` or `FALSE`:

```
unassume(x): myabs(x)

Error: Cannot evaluate to Boolean. [if]
  Evaluating: myabs
```

The easiest way to achieve the desired functionality is a comparison of the result of `is` with `TRUE`:

```
myabs := proc(x)
         begin
           if is(x >= 0) = TRUE then
             x
           elif is(x < 0) = TRUE then
             -x
           else
             procname(x)
           end_if
         end_proc:

myabs(x)
```

$$\text{myabs}(x)$$

```
delete myabs:
```

Example 7

`is` can handle sets returned by `solve`. These include intervals of type `Dom::Interval` and `R_` = `solvelib::BasicSet(Dom::Real)`:

```
assume(x >= 0 and x <= 1):
is(x in Dom::Interval([0, 1])), is(x in R_)
```

$$\text{TRUE, TRUE}$$

The following `solve` command returns the solution as an infinite parameterized set of type `Dom::ImageSet`:

```
unassume(x): solutionset := solve(sin(x) = 0, x)
```

$$\{\pi\, k \mid k \in \mathbb{Z}\}$$

```
domtype(solutionset)
```

$$\text{DomImageSet}$$

`is` can be used to check whether an expression is contained in this set:

```
is(20*PI in solutionset), is(PI/2 in solutionset)
```

$$\text{TRUE, FALSE}$$

```
delete solutionset:
```

Parameters

`cond`

A condition

ex

arithmetical expression

set

A property representing a set of numbers (e.g., `Type::PosInt`) or a set returned by `solve`; such a set can be an element of `Dom::Interval`, `Dom::ImageSet`, `piecewise`, or one of `C_`, `R_`, `Q_`, `Z_`.

Return Values

`TRUE`, `FALSE`, or `UNKNOWN`.

See Also

MuPAD Functions
`assume` | `bool` | `getprop` | `unassume`

isolate

Isolate variable or expression from equation

Syntax

```
isolate(eq, expr)
```

Description

`isolate(eq, expr)` rearranges the equation eq so that the expression expr appears on the left side. The result is similar to solving eq for expr. However, `isolate` returns only one solution even if multiple solutions exist. If `isolate` cannot isolate expr from eq, it moves all terms containing expr to the left side. You can use the output of `isolate` as input to `subs` to eliminate expr from eq.

If eq has no solution, `isolate` returns an error. The `isolate` function also ignores special cases. If the only solutions to eq are special cases, then `isolate` ignores those special cases and returns an error. Additionally, if the solution returned contains parameters, the parameters might not be valid for special cases.

You cannot specify expr as a mathematical constant such as PI, EULER, and so on.

By default, `isolate(eq, expr)` returns only solutions consistent with the properties of `expr`.

If the input contains floating-point numbers, the solver replaces them by approximate rational values. The accuracy of these approximate values depends on the environment variable `DIGITS`. If `isolate` finds a solution, MuPAD internally calls the `float` function for that solution, and then returns the result.

Environment Interactions

`isolate` reacts to properties of identifiers.

Examples

Example 1

Isolate `x` from the equation `a*x^2 + b*x + c = 0`.

```
eqn := a*x^2 + b*x + c = 0:
xSol := isolate(eqn, x)
```

$$x = -\frac{b + \sqrt{b^2 - 4\,a\,c}}{2\,a}$$

Even though the equation has multiple solutions, `isolate` returns only one solution.

Eliminate `x` from `eqn` by calling `subs` to substitute for `x` using `xSol`.

```
subs(eqn, xSol)
```

$$c + \frac{\left(b + \sqrt{b^2 - 4\,a\,c}\right)^2}{4\,a} - \frac{b\left(b + \sqrt{b^2 - 4\,a\,c}\right)}{2\,a} = 0$$

You can also isolate expressions. Isolate `x(t)` from the following equation.

```
isolate(a*x(t)^2 + b*c = 0, x(t))
```

$$x(t) = \frac{\sqrt{-b}\,\sqrt{c}}{\sqrt{a}}$$

Isolate `a*x(t)` from the same equation.

```
isolate(a*x(t)^2 + b*c = 0, a*x(t))
```

$$a\,x(t) = -\frac{b\,c}{x(t)}$$

If `isolate` cannot find a symbolic solution, it returns an error. Because `isolate` does not return special cases, it also returns an error if the only solutions are special cases.

Compare `isolate` with `solve` for an equation whose only solution is a special case.

```
solve(x = x+a, x);
isolate(x = x+a, x)
```

$$\begin{cases} \mathbb{C} & \text{if } a = 0 \\ \varnothing & \text{if } a \neq 0 \end{cases}$$

```
Error: The equation has no solution. [isolate]
```

`solve` returns the special case while `isolate` ignores the special case and returns an error.

Example 2

For equations with multiple solutions, `isolate` returns the 'simplest' solution.

Isolate `x` from equations with many solutions to demonstrate this behavior of `isolate`.

```
isolate(cos(x) = x, x)
```

$$\cos(x) - x = 0$$

```
isolate(x^2 = 1, x)
```

$$x = 1$$

```
isolate(sin(x) = 0, x)
```

$$x = 0$$

```
isolate(sqrt(x) = C, x)
```

$$x = C^2$$

Example 3

`isolate` only returns results compatible with assumptions on the variable to be isolated. For example, assume that `x` represents a real negative number. Then, isolate it from the following equation.

```
assume(x, Type::Negative):
isolate(x^4 = 1, x)
```

$$x = -1$$

Remove the assumption. `isolate` chooses a different solution to return.

```
unassume(x):
isolate(x^4 = 1, x)
```

$$x = 1$$

Example 4

If the input contains floating-point numbers, MuPAD calls the `float` function for the obtained solution.

Isolate `x` from an equation with floating-point numbers.

```
isolate(x^3 + 3.0*x + 1 = 0, x)
```

$$x = -0.3221853546$$

Example 5

You can isolate an expression in an equation with symbolic parameters. The `isolate` function returns a general solution where the parameter values are not guaranteed to hold for special cases.

Isolate `x` in the equation.

```
isolate(a*x^2/(x-a) = 1, x)
```

$$x = \frac{\sqrt{-(2a-1)(2a+1)+1}}{2a}$$

The returned value of `x` does not hold in the special case that parameter `a` has value `0`.

Parameters

`eq`

An equation.

`expr`

The variable or expression to be isolated.

Return Values

`isolate(eq, expr)` returns an equation where the right side does not contain the variable or expression to be isolated. `isolate` does not introduce newly generated parameters. The returned equation is always a valid input to `subs`..

`float` | `lhs` | `linsolve` | `numeric::linsolve` | `numeric::solve` | `rhs` | `RootOf` | `solve`

Introduced in R2015a

isprime

Primality test

Syntax

```
isprime(n)
```

Description

`isprime(n)` checks whether `n` is a prime number.

`isprime` is a fast probabilistic prime number test (Miller-Rabin test). The function returns `TRUE` when the positive integer`n` is either a prime number or a strong pseudo-prime for 10 independently and randomly chosen bases. Otherwise, `isprime` returns `FALSE`.

If `n` is positive and `isprime` returns `FALSE`, then `n` is guaranteed to be composite. If `n` is positive and `isprime` returns `TRUE`, then `n` is prime with a very high probability.

Use `numlib::proveprime` for a prime number test that always returns the correct answer. Note, however, that it is usually much slower than `isprime`.

`isprime()` and `isprime(1)` return `FALSE`. `isprime` returns always `FALSE` if `n` is a negative integer.

`isprime` returns an error message if its argument is a number but not an integer. `isprime` returns a symbolic `isprime` call if the argument is not a number.

Examples

Example 1

The number `989999` is prime:

```
isprime(989999)
```

```
TRUE
```

```
ifactor(989999)
```

```
989999
```

In contrast to `ifactor`, `isprime` can handle large numbers:

```
isprime(2^(2^11) + 1)
```

```
FALSE
```

`isprime()` and `isprime(1)` return FALSE:

```
isprime(0), isprime(1)
```

```
FALSE, FALSE
```

Negative numbers yield FALSE as well:

```
isprime(-13)
```

```
FALSE
```

For non-numeric arguments, a symbolic `isprime` call is returned:

```
delete n: isprime(n)
```

```
isprime(n)
```

Parameters

n

An arithmetical expression representing an integer

Return Values

Either `TRUE` or `FALSE`, or a symbolic `isprime` call.

isqrt

Integer square root

Syntax

```
isqrt(n)
```

Description

`isqrt(n)` computes an integer approximation to the square root of the integer `n`.

If `n` is a perfect square, then `isqrt` returns the unique nonnegative integer whose square is `n`. More generally, if `n` is a nonnegative integer, then `isqrt` computes `trunc(sqrt(n))`. Thus the approximation error is less than `1`.

If `n` is a negative integer, then `isqrt` computes `trunc(sqrt(-n)) *I`.

`isqrt` returns an error message if its argument is a number but not an integer. `isqrt` returns a symbolic `isqrt` call if the argument is not a number.

Examples

Example 1

We compute some integer square roots:

```
isqrt(4), isqrt(5)
```

```
2, 2
```

The approximation error is less than `1`:

```
isqrt(99), float(sqrt(99))
```

```
9, 9.949874371
```

The integer square root of a negative integer is an integral multiple of `I`:

```
isqrt(-4), isqrt(-5)
```

$$2\,i,\ 2\,i$$

If the argument is not a number, the result is a symbolic `isqrt` call:

```
delete n: isqrt(n)
```

$$\mathrm{isqrt}(n)$$

```
type(%)
```

"isqrt"

Parameters

n

An arithmetical expression representing an integer

Return Values

Nonnegative integer, an integral multiple of `I`, or a symbolic `isqrt` call.

Overloaded By

n

iszero

Generic zero test

Syntax

```
iszero(object)
```

Description

`iszero(object)` checks whether `object` is the zero element in the domain of `object`.

Use the condition `iszero(object)` instead of `object = 0` to decide whether `object` is the zero element, because `iszero(object)` is more general than `object = 0`. If the call `bool(object = 0)` returns `TRUE`, then `iszero(object)` returns `TRUE` as well, but in general not vice versa (see "Example 1" on page 1-1109).

If `object` is an element of a basic type, then `iszero` returns `TRUE` precisely if one of the following is true: `object` is the integer `0` (of domain type `DOM_INT`), the floating-point value `0.0` (of domain type `DOM_FLOAT`), the floating-point interval (of domain type `DOM_INTERVAL`) `0...0`, or the zero polynomial (of domain type `DOM_POLY`). In the case of a polynomial, the result `FALSE` is guaranteed to be correct only if the coefficients of the polynomial are in normal form (i.e., if zero has a unique representation in the coefficient ring). See also `Ax::normalRep`.

If `object` is an element of a library domain, then the method `"iszero"` of the domain is called and the result is returned. If this method does not exist, then the function `iszero` returns `FALSE`.

`iszero` performs a purely syntactical zero test. If `iszero` returns `TRUE`, then the answer is always correct. If `iszero` returns `FALSE`, however, then it may still be true that mathematically `object` represents zero (see "Example 3" on page 1-1110). In such cases, the MuPAD functions `normal` or `simplify` may be able to recognize this.

Note: `iszero` does *not* take into account properties of identifiers in `object` that have been set via `assume`. In particular, you should not use `iszero` in an argument passed to `assume` or `is`; use the form `object = 0` instead (see "Example 2" on page 1-1110).

Note: Do not use `iszero` in a condition passed to `piecewise`. In contrast to `object = 0`, the command `iszero(object)` is evaluated immediately, before it is passed to `piecewise`, while the evaluation of `object = 0` is handled by `piecewise` itself. Thus using `iszero` in a `piecewise` command usually leads to unwanted effects (see "Example 4" on page 1-1110).

Examples

Example 1

`iszero` handles the basic data types:

```
iszero(0), iszero(1/2), iszero(0.0), iszero(I), iszero(-1...1)
```

```
TRUE, FALSE, TRUE, FALSE, FALSE
```

`iszero` works for polynomials:

```
p:= poly(x^2 + y, [x]):
iszero(p)
```

```
FALSE
```

```
iszero(poly(0, [x, y]))
```

```
TRUE
```

`iszero` is more general than =:

```
bool(0 = 0), bool(0.0 = 0), bool(poly(0, [x]) = 0)
```

```
TRUE, FALSE, FALSE
```

```
iszero(0), iszero(0.0), iszero(poly(0, [x]))
```

```
TRUE, TRUE, TRUE
```

Example 2

`iszero` does not react to properties:

```
assume(a = b): is(a - b = 0)
```

```
    TRUE
```

```
iszero(a - b)
```

```
    FALSE
```

Example 3

Although `iszero` returns `FALSE` in the following example, the expression in question mathematically represents zero:

```
iszero(sin(x)^2 + cos(x)^2 - 1)
```

```
    FALSE
```

In this case `simplify` is able to decide this:

```
simplify(sin(x)^2 + cos(x)^2 - 1)
```

```
    0
```

Example 4

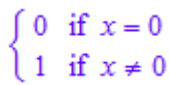
`iszero` should not be used in a condition passed to `piecewise`:

```
delete x:
piecewise([iszero(x), 0], [x <> 0, 1])
```

$$\begin{cases} 1 & \text{if } x \neq 0 \end{cases}$$

The first branch was discarded because `iszero(x)` immediately evaluates to `FALSE`. Instead, use the condition `x = 0`, which is passed unevaluated to `piecewise`:

```
piecewise([x = 0, 0], [x <> 0, 1])
```



Parameters

`object`

An arbitrary MuPAD object

Return Values

Either TRUE or FALSE

Overloaded By

object

See Also

MuPAD Axioms
`Ax::normalRep`

MuPAD Functions
`_equal` | `bool` | `is` | `normal` | `sign` | `simplify`

ithprime

I-th prime number

Syntax

```
ithprime(i)
```

```
ithprime(<PrimeLimit>)
```

Description

`ithprime(i)` returns the `i`-th prime number.

If the argument `i` is a positive integer, then `ithprime` returns the `i`-th prime number. An unevaluated call is returned, if the argument is not of type `Type::Numeric`. An error occurs if the argument is a number that is not a positive integer.

The first prime number `ithprime(1)` is 2.

If the `i`-th prime number is contained in the system's internal prime number table (see the help page for `ifactor`), then it is returned by a fast kernel function. Otherwise, MuPAD iteratively calls `nextprime`, using some suitable pre-computed value of `ithprime` as starting point. This is still reasonably fast for $i \leq 1000000$. If `i` exceeds this value, however, then the run time grows exponentially with the number of digits of `i`.

Examples

Example 1

The first 10 prime numbers:

```
ithprime(i) $ i = 1..10
```

$$2, 3, 5, 7, 11, 13, 17, 19, 23, 29$$

A larger prime:

```
ithprime(123456)
```

```
1632899
```

Symbolic arguments lead to an unevaluated call:

```
ithprime(i)
```

```
ithprime(i)
```

Parameters

`i`

An arithmetical expression

Options

`PrimeLimit`

Return the number of primes in the internal prime table

`ithprime(PrimeLimit)` returns an integer, namely the number of primes in the internal prime number table. The table contains all primes below some bound which can be obtained by calling `ifactor(PrimeLimit)`. On UNIX platforms, the size of this table can be changed via the MuPAD command line flag `-L`.

Return Values

Prime number or an unevaluated call to `ithprime`

See Also

MuPAD Functions

`ifactor` | `igcd` | `ilcm` | `isprime` | `nextprime` | `numlib::pi` | `prevprime`

iztrans

Inverse Z transform

Syntax

```
iztrans(F, z, k)
```

Description

`iztrans(F, z, k)` computes the inverse Z transform of the expression `F = F(z)` with respect to the variable `z` at the point `k`.

If `R` is a positive number, such that the function `F(Z)` is analytic on and outside the circle `|z| = R`, then the inverse Z-transform is defined as follows:

$$f(k) = \frac{1}{2\pi i} \oint_{|z|=R} F(z) z^{k-1} dz, \quad k = 0,1,2...$$

If `iztrans` cannot find an explicit representation of the transform, it returns an unevaluated function call. See “Example 3” on page 1-1115.

If `F` is a matrix, `iztrans` applies the inverse Z transform to all components of the matrix.

To compute the direct Z transform, use `ztrans`.

Examples

Example 1

Compute the inverse Z transform of these expressions:

```
iztrans(exp(1/z), z, k)
```

$$\frac{1}{k!}$$

```
iztrans((z*sin(1))/(z^2 - 2*cos(1)*z + 1), z, k)
```

$$\sin(k)$$

Example 2

Compute the inverse Z transform of this expression with respect to the variable `z`:

```
f := iztrans((3*z)/(z - 1) + (2*z)/(z - 1)^2, z, k)
```

$$2k+3$$

Evaluate the inverse Z transform of the expression at the points $k = 2a + 3$ and $k = 1 + i$. You can evaluate the resulting expression `f` using `|` (or its functional form `evalAt`):

```
f | k = 2*a + 3
```

$$4a+9$$

Also, you can evaluate the inverse Z transform at a particular point directly:

```
iztrans((3*z)/(z - 1) + (2*z)/(z - 1)^2, z, 1 + I)
```

$$5+2\,i$$

Example 3

If `iztrans` cannot find an explicit representation of the transform, it returns an unevaluated call:

```
iztrans(F(z), z, k)
```

$$\text{iztrans}(F(z), z, k)$$

`ztrans` returns the original expression:

```
ztrans(%, k, z)
```

$$F(z)$$

Example 4

Compute the inverse Z transforms of these expressions. The results involve the `kroneckerDelta` function:

```
iztrans(1/z, z, k)
```

$$\delta_{k-1,0}$$

```
iztrans((z^3 + 3*z^2 + 6*z + 5)/z^5, z, k)
```

$$\delta_{k-2,0} + 3\,\delta_{k-3,0} + 6\,\delta_{k-4,0} + 5\,\delta_{k-5,0}$$

Example 5

Compute the inverse Z tranform of this expression:

```
iztrans(z*diff(g(z), z), z, k)
```

$$-k\,\mathrm{iztrans}(g(z),\, z,\, k)$$

Parameters

F

Arithmetical expression or matrix of such expressions

z

Identifier or indexed identifier

k

Arithmetical expression representing the evaluation point

Return Values

Arithmetical expression or unevaluated function call of type `iztrans`. An explicit result can be a `piecewise` object. If the first argument is a matrix, then the result is returned as a matrix.

MuPAD Functions

`iztrans::addpattern` | `ztrans` | `ztrans::addpattern`

More About

- "Z-Transforms"

iztrans::addpattern

Add patterns for the inverse Z transform

Syntax

```
iztrans::addpattern(pat, z, k, res, <vars, <conds>>)
```

Description

`iztrans::addpattern(pat, z, k, res)` teaches `iztrans` to return *iztrans*(*pat*, *z*, *k*) = *res*.

The `iztrans` function uses a set of patterns for computing inverse Z transforms. You can extend the set by adding your own patterns. To add a new pattern to the pattern matcher, use `iztrans::addpattern`. MuPAD does not save custom patterns permanently. The new patterns are available in the *current* MuPAD session only.

Variable names that you use when calling `iztrans::addpattern` can differ from the names that you use when calling `iztrans`. See “Example 2” on page 1-1119.

You can include a list of free parameters and a list of conditions on these parameters. These conditions and the result are protected from premature evaluation. This means that you can use `not iszero(a^2 - b)` instead of `hold( _not @ iszero )(a^2 - b)`.

The following conditions treat assumptions on identifiers differently:

- `a^2 - b <> 0` takes into account assumptions on identifiers.
- `not iszero(a^2 - b)` disregards assumptions on identifiers.

See “Example 3” on page 1-1119.

Environment Interactions

Calling `iztrans::addpattern` changes the expressions returned by future calls to `iztrans`.

Examples

Example 1

Compute the inverse Z transform of the function `bar`. By default, MuPAD does not have a pattern for this function:

```
iztrans(bar(z), z, k)
```

$$\text{iztrans}(\text{bar}(z), z, k)$$

Add a pattern for the inverse Z transform of `bar` using `iztrans::addpattern`:

```
iztrans::addpattern(bar(z), z, k, foo(k)):
```

Now `iztrans` returns the inverse Z transform of `bar`:

```
iztrans(bar(z), z, k)
```

$$\text{foo}(k)$$

Example 2

Define the inverse Z transform of `bar(y)` using the variables `x` and `y` as parameters:

```
iztrans::addpattern(bar(y), y, x, foo(x))
```

The `iztrans` function recognizes the added pattern even if you use other variables as parameters:

```
iztrans(bar(z), z, k)
```

$$\text{foo}(k)$$

Example 3

Use assumptions when adding this pattern for the inverse Z transform:

```
iztrans::addpattern(BAR(x*z), z, k, FOO(k/(x - 1/2))*sin(x),
                                    [x], [abs(x) < 1]):
```

```
iztrans(BAR(x*z), z, k) assuming -1 < x < 1
```

$$\mathrm{FOO}\left(\frac{k}{x-\frac{1}{2}}\right)\sin(x)$$

If $|x| \geq 1$, you cannot apply this pattern:

```
iztrans(BAR(x*z), z, k) assuming x >= 1
```

$$\mathrm{iztrans}(\mathrm{BAR}(x\ z),\ z,\ k)$$

If MuPAD cannot determine whether the conditions are satisfied, it returns a `piecewise` object:

```
iztrans(BAR(x*z), z, k)
```

$$\begin{cases} \mathrm{FOO}\left(\frac{k}{x-\frac{1}{2}}\right)\sin(x) & \text{if } |x| < 1 \end{cases}$$

Note that the resulting expression defining the inverse Z transform of `BAR(x*z)` implicitly assumes that the value of `x` is not 1/2. A strict definition of the pattern is:

```
ztrans::addpattern(BAR(x*z), z, k, FOO(k/(x - 1/2))*sin(x),
                   [x], [abs(x) < 1, x <> 1/2]):
```

If either the conditions are not satisfied or substituting the values into the result gives an error, `iztrans` ignores the pattern. For this particular pattern, you can omit specifying the assumption `x <> 1/2`. If `x = 1/2`, MuPAD throws an internal "Division by zero." error and ignores the pattern:

```
iztrans(BAR(z/2), z, k)
```

$$\mathrm{iztrans}\left(\mathrm{BAR}\left(\frac{z}{2}\right),\ z,\ k\right)$$

Parameters

`pat`

Arithmetical expression in the variable `z` representing the pattern to match

`z`

Identifier used as a variable in the pattern

`k`

Identifier used as a variable in the result

`res`

Arithmetical expression in the variable `k` representing the pattern for the result of the transformation

`vars`

List of identifiers or indexed identifiers used as "pattern variables" (placeholders in `pat` and `res`). You can use pattern variables as placeholders for almost arbitrary MuPAD expressions not containing `z` or `k`. You can restrict them by conditions given in the optional parameter `conds`.

`conds`

List of conditions on the pattern variables

Return Values

Object of type `DOM_NULL`

See Also

MuPAD Functions

`iztrans` | `ztrans` | `ztrans::addpattern`

jacobiAM

Jacobi amplitude function am

Syntax

```
jacobiAM(u,m)
```

Description

`jacobiAM(u,m)` represents the Jacobi amplitude function which is defined as the solution $\mathrm{am}(u \mid m) := \varphi$ of $\mathrm{F}(\varphi \mid m) = u$.

The Jacobi amplitude $\mathrm{am}(u \mid m)$ is defined for complex arguments u and m.

Exact results are returned for $m = 0$, $m = 1$ or $u = 0$. In all other cases an unevaluated symbolic call is returned.

A floating-point value is computed if both arguments are numerical and at least one is a floating-point number.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Most calls with exact arguments are returned evaluated:

```
jacobiAM(PI/3, 1/2)
```

$$\mathrm{am}\left(\frac{\pi}{3} \mid \frac{1}{2}\right)$$

If $m = 0$, $m = 1$ or $u = 0$, an exact result is returned:

```
jacobiAM(PI/2, 0)
```

$$\frac{\pi}{2}$$

```
jacobiAM(2, 1)
```

$$2\arctan(e^2) - \frac{\pi}{2}$$

```
jacobiAM(0, 1/2)
```

$$0$$

Parameters

u

An arithmetical expression.

m

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

See Also

MuPAD Functions
`ellipticF`

jacobiSN

Jacobi elliptic function sn

Syntax

```
jacobiSN(u,m)
```

Description

`jacobiSN(u,m)` represents the Jacobi elliptic function sn.

Let $u = \mathrm{F}(\varphi \mid m)$. Then the Jacobi elliptic function SN is defined as follows:

$$\mathrm{sn}(u \mid m) = \sin(\varphi)$$

The Jacobi functions are defined for complex values of u and m.

The Jacobi functions are meromorphic and doubly periodic with periods $4\,\mathrm{K}(m)$ and $4\,\mathrm{i}\,\mathrm{K}'(m)$ with respect to u.

For $m = 0$ and $m = 1$, the Jacobi functions reduce to trigonometric or constant functions.

If one argument is a floating-point number, and the other one can be converted to a floating-point number, then a floating-point number is returned.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For most arguments, the Jacobi functions return themselves unevaluated:

```
jacobiSN(2,1/2)
```

$$\mathrm{sn}\left(2 \mid \frac{1}{2}\right)$$

Floating-point numbers are returned if at least one of the arguments is a floating-point number:

```
jacobiCN(1.5,1/2)
```

$$0.2502702593$$

Floating-point evaluation can be enforced by using `float`:

```
float(jacobiND(1,-1))
```

$$0.7404586624$$

Example 2

For $m = 0$ and $m = 1$, the result is expressed using a trigonometric function:

```
jacobiSC(u,0)
```

$$\tan(u)$$

```
jacobiND(u,1)
```

$$\cosh(u)$$

Parameters

`m`

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

jacobiCN

Jacobi elliptic function cn

Syntax

```
jacobiCN(u,m)
```

Description

`jacobiCN(u,m)` represents the Jacobi elliptic function cn.

Let $u = \mathrm{F}(\varphi \mid m)$. Then the Jacobi elliptic function cn is defined as follows:

$$\mathrm{cn}(u \mid m) = \cos(\varphi)$$

The Jacobi functions are defined for complex values of u and m.

The Jacobi functions are meromorphic and doubly periodic with periods $4\,\mathrm{K}(m)$ and $4\,\mathrm{i}\,\mathrm{K}'(m)$ with respect to u.

For $m = 0$ and $m = 1$, the Jacobi functions reduce to trigonometric or constant functions.

If one argument is a floating-point number, and the other one can be converted to a floating-point number, then a floating-point number is returned.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For most arguments, the Jacobi elliptic functions return themselves unevaluated:

```
jacobiSN(2,1/2)
```

$$\mathrm{sn}\left(2 \mid \frac{1}{2}\right)$$

Floating-point numbers are returned if at least one of the arguments is a floating-point number:

```
jacobiCN(1.5,1/2)
```

$$0.2502702593$$

Floating-point evaluation can be enforced by using `float`:

```
float(jacobiND(1,-1))
```

$$0.7404586624$$

Example 2

For $m = 0$ and $m = 1$, the result is expressed using a trigonometric function:

```
jacobiSC(u,0)
```

$$\tan(u)$$

```
jacobiND(u,1)
```

$$\cosh(u)$$

Parameters

`m`

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

jacobiDN

Jacobi elliptic function dn

Syntax

```
jacobiDN(u,m)
```

Description

`jacobiDN(u,m)` represents the Jacobi elliptic function dn.

Let $u = \mathrm{F}(\varphi \mid m)$. Then the Jacobi elliptic function dn is defined as follows:

$$\mathrm{dn}(u \mid m) = \sqrt{1 - m \sin(\varphi)^2}$$

The Jacobi functions are defined for complex values of u and m.

The Jacobi functions are meromorphic and doubly periodic with periods $4\,\mathrm{K}(m)$ and $4\,\mathrm{i}\,\mathrm{K}'(m)$ with respect to u.

For $m = 0$ and $m = 1$, the Jacobi functions reduce to trigonometric or constant functions.

If one argument is a floating-point number, and the other one can be converted to a floating-point number, then a floating-point number is returned.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For most arguments, the Jacobi functions return themselves unevaluated:

```
jacobiSN(2,1/2)
```

$$\mathrm{sn}\left(2 \mid \frac{1}{2}\right)$$

Floating-point numbers are returned if at least one of the arguments is a floating-point number:

```
jacobiCN(1.5,1/2)
```

$$0.2502702593$$

Floating-point evaluation can be enforced by using `float`:

```
float(jacobiND(1,-1))
```

$$0.7404586624$$

Example 2

For $m = 0$ and $m = 1$, the result is expressed using a trigonometric function:

```
jacobiSC(u,0)
```

$$\tan(u)$$

```
jacobiND(u,1)
```

$$\cosh(u)$$

Parameters

m

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

jacobiCD

Jacobi elliptic function cd

Syntax

```
jacobiCD(u,m)
```

Description

`jacobiCD(u,m)` represents the Jacobi elliptic function cd.

Let $u = \mathrm{F}(\varphi \mid m)$. Then the Jacobi elliptic function cd is defined as follows:

$$\mathrm{cd}(u \mid m) = \frac{\mathrm{cn}(u \mid m)}{\mathrm{dn}(u \mid m)}$$

The Jacobi functions are defined for complex values of u and m.

The Jacobi functions are meromorphic and doubly periodic with periods $4\,\mathrm{K}(m)$ and $4\,\mathrm{i}\,\mathrm{K}'(m)$ with respect to u.

For $m = 0$ and $m = 1$, the Jacobi functions reduce to trigonometric or constant functions.

If one argument is a floating-point number, and the other one can be converted to a floating-point number, then a floating-point number is returned.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For most arguments, the Jacobi functions return themselves unevaluated:

```
jacobiSN(2,1/2)
```

$$\mathrm{sn}\left(2 \mid \frac{1}{2}\right)$$

Floating-point numbers are returned if at least one of the arguments is a floating-point number:

```
jacobiCN(1.5,1/2)
```

$$0.2502702593$$

Floating-point evaluation can be enforced by using `float`:

```
float(jacobiND(1,-1))
```

$$0.7404586624$$

Example 2

For $m = 0$ and $m = 1$, the result is expressed using a trigonometric function:

```
jacobiSC(u,0)
```

$$\tan(u)$$

```
jacobiND(u,1)
```

$$\cosh(u)$$

Parameters

m

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

jacobiSD

Jacobi elliptic function sd

Syntax

```
jacobiSD(u,m)
```

Description

`jacobiSD(u,m)` represents the Jacobi elliptic function sd.

Let $u = \mathrm{F}(\varphi \mid m)$. Then the Jacobi function SD is defined as follows:

$$\mathrm{sd}(u \mid m) = \frac{\mathrm{sn}(u \mid m)}{\mathrm{dn}(u \mid m)}$$

The Jacobi functions are defined for complex values of u and m.

The Jacobi functions are meromorphic and doubly periodic with periods $4\,\mathrm{K}(m)$ and $4\,\mathrm{i}\,\mathrm{K}'(m)$ with respect to u.

For $m = 0$ and $m = 1$, the Jacobi functions reduce to trigonometric or constant functions.

If one argument is a floating-point number, and the other one can be converted to a floating-point number, then a floating-point number is returned.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For most arguments, the Jacobi functions return themselves unevaluated:

```
jacobiSN(2,1/2)
```

$$\mathrm{sn}\left(2 \mid \frac{1}{2}\right)$$

Floating-point numbers are returned if at least one of the arguments is a floating-point number:

```
jacobiCN(1.5,1/2)
```

$$0.2502702593$$

Floating-point evaluation can be enforced by using `float`:

```
float(jacobiND(1,-1))
```

$$0.7404586624$$

Example 2

For $m = 0$ and $m = 1$, the result is expressed using a trigonometric function:

```
jacobiSC(u,0)
```

$$\tan(u)$$

```
jacobiND(u,1)
```

$$\cosh(u)$$

Parameters

m

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

jacobiND

Jacobi elliptic function nd

Syntax

```
jacobiND(u,m)
```

Description

`jacobiND(u,m)` represents the Jacobi elliptic function nd.

Let $u = \mathrm{F}(\varphi \mid m)$. Then the Jacobi elliptic function nd is defined as follows:

$$\mathrm{nd}(u \mid m) = \frac{1}{\mathrm{dn}(u \mid m)}$$

The Jacobi functions are defined for complex values of u and m.

The Jacobi functions are meromorphic and doubly periodic with periods $4\,\mathrm{K}(m)$ and $4\,\mathrm{i}\,\mathrm{K}'(m)$ with respect to u.

For $m = 0$ and $m = 1$, the Jacobi functions reduce to trigonometric or constant functions.

If one argument is a floating-point number, and the other one can be converted to a floating-point number, then a floating-point number is returned.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For most arguments, the Jacobi functions return themselves unevaluated:

```
jacobiSN(2,1/2)
```

$$\mathrm{sn}\left(2 \mid \frac{1}{2}\right)$$

Floating-point numbers are returned if at least one of the arguments is a floating-point number:

```
jacobiCN(1.5,1/2)
```

$$0.2502702593$$

Floating-point evaluation can be enforced by using `float`:

```
float(jacobiND(1,-1))
```

$$0.7404586624$$

Example 2

For $m = 0$ and $m = 1$, the result is expressed using a trigonometric function:

```
jacobiSC(u,0)
```

$$\tan(u)$$

```
jacobiND(u,1)
```

$$\cosh(u)$$

Parameters

m

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

jacobiDC

Jacobi elliptic function dc

Syntax

```
jacobiDC(u,m)
```

Description

`jacobiDC(u,m)` represents the Jacobi elliptic function dc.

Let $u = \mathrm{F}(\varphi \mid m)$. Then the Jacobi elliptic function dc is defined as follows:

$$\mathrm{dc}(u \mid m) = \frac{\mathrm{dn}(u \mid m)}{\mathrm{cn}(u \mid m)}$$

The Jacobi functions are defined for complex values of u and m.

The Jacobi functions are meromorphic and doubly periodic with periods $4\,\mathrm{K}(m)$ and $4\,\mathrm{i}\,\mathrm{K}'(m)$ with respect to u.

For $m = 0$ and $m = 1$, the Jacobi functions reduce to trigonometric or constant functions.

If one argument is a floating-point number, and the other one can be converted to a floating-point number, then a floating-point number is returned.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For most arguments, the Jacobi functions return themselves unevaluated:

```
jacobiSN(2,1/2)
```

$$\mathrm{sn}\left(2 \mid \frac{1}{2}\right)$$

Floating-point numbers are returned if at least one of the arguments is a floating-point number:

```
jacobiCN(1.5,1/2)
```

$$0.2502702593$$

Floating-point evaluation can be enforced by using `float`:

```
float(jacobiND(1,-1))
```

$$0.7404586624$$

Example 2

For $m = 0$ and $m = 1$, the result is expressed using a trigonometric function:

```
jacobiSC(u,0)
```

$$\tan(u)$$

```
jacobiND(u,1)
```

$$\cosh(u)$$

Parameters

m

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

jacobiNC

Jacobi elliptic function nc

Syntax

```
jacobiNC(u,m)
```

Description

`jacobiNC(u,m)` represents the Jacobi elliptic function nc.

Let $u = \mathrm{F}(\varphi \mid m)$. Then the Jacobi elliptic function nc is defined as follows:

$$\mathrm{nc}(u \mid m) = \frac{1}{\mathrm{cn}(u \mid m)}$$

The Jacobi functions are defined for complex values of u and m.

The Jacobi functions are meromorphic and doubly periodic with periods $4\,\mathrm{K}(m)$ and $4\,\mathrm{i}\,\mathrm{K}'(m)$ with respect to u.

For $m = 0$ and $m = 1$, the Jacobi functions reduce to trigonometric or constant functions.

If one argument is a floating-point number, and the other one can be converted to a floating-point number, then a floating-point number is returned.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For most arguments, the Jacobi functions return themselves unevaluated:

```
jacobiSN(2,1/2)
```

$$\mathrm{sn}\left(2 \mid \frac{1}{2}\right)$$

Floating-point numbers are returned if at least one of the arguments is a floating-point number:

```
jacobiCN(1.5,1/2)
```

$$0.2502702593$$

Floating-point evaluation can be enforced by using `float`:

```
float(jacobiND(1,-1))
```

$$0.7404586624$$

Example 2

For $m = 0$ and $m = 1$, the result is expressed using a trigonometric function:

```
jacobiSC(u,0)
```

$$\tan(u)$$

```
jacobiND(u,1)
```

$$\cosh(u)$$

Parameters

m

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

jacobiSC

Jacobi elliptic function sc

Syntax

```
jacobiSC(u,m)
```

Description

`jacobiSC(u,m)` represents the Jacobi elliptic function sc.

Let $u = \mathrm{F}(\varphi \mid m)$. Then the Jacobi elliptic function sc is defined as follows:

$$\mathrm{sc}(u \mid m) = \frac{\mathrm{sn}(u \mid m)}{\mathrm{cn}(u \mid m)}$$

The Jacobi functions are defined for complex values of u and m.

The Jacobi functions are meromorphic and doubly periodic with periods $4\,\mathrm{K}(m)$ and $4\,\mathrm{i}\,\mathrm{K}'(m)$ with respect to u.

For $m = 0$ and $m = 1$, the Jacobi functions reduce to trigonometric or constant functions.

If one argument is a floating-point number, and the other one can be converted to a floating-point number, then a floating-point number is returned.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For most arguments, the Jacobi functions return themselves unevaluated:

```
jacobiSN(2,1/2)
```

$$\mathrm{sn}\left(2 \mid \frac{1}{2}\right)$$

Floating-point numbers are returned if at least one of the arguments is a floating-point number:

```
jacobiCN(1.5,1/2)
```

$$0.2502702593$$

Floating-point evaluation can be enforced by using `float`:

```
float(jacobiND(1,-1))
```

$$0.7404586624$$

Example 2

For $m = 0$ and $m = 1$, the result is expressed using a trigonometric function:

```
jacobiSC(u,0)
```

$$\tan(u)$$

```
jacobiND(u,1)
```

$$\cosh(u)$$

Parameters

m

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

jacobiNS

Jacobi elliptic function ns

Syntax

```
jacobiNS(u,m)
```

Description

`jacobiNS(u,m)` represents the Jacobi elliptic function ns.

Let $u = \mathrm{F}(\varphi \mid m)$. Then the Jacobi elliptic function ns is defined as follows:

$$\mathrm{ns}(u \mid m) = \frac{1}{\mathrm{sn}(u \mid m)}$$

The Jacobi functions are defined for complex values of u and m.

The Jacobi functions are meromorphic and doubly periodic with periods $4\,\mathrm{K}(m)$ and $4\,\mathrm{i}\,\mathrm{K}'(m)$ with respect to u.

For $m = 0$ and $m = 1$, the Jacobi functions reduce to trigonometric or constant functions.

If one argument is a floating-point number, and the other one can be converted to a floating-point number, then a floating-point number is returned.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For most arguments, the Jacobi functions return themselves unevaluated:

```
jacobiSN(2,1/2)
```

$$\mathrm{sn}\left(2 \mid \frac{1}{2}\right)$$

Floating-point numbers are returned if at least one of the arguments is a floating-point number:

```
jacobiCN(1.5,1/2)
```

$$0.2502702593$$

Floating-point evaluation can be enforced by using `float`:

```
float(jacobiND(1,-1))
```

$$0.7404586624$$

Example 2

For $m = 0$ and $m = 1$, the result is expressed using a trigonometric function:

```
jacobiSC(u,0)
```

$$\tan(u)$$

```
jacobiND(u,1)
```

$$\cosh(u)$$

Parameters

m

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

jacobiDS

Jacobi elliptic function ds

Syntax

```
jacobiDS(u,m)
```

Description

`jacobiDS(u,m)` represents the Jacobi elliptic function ds.

Let $u = \mathrm{F}(\varphi \mid m)$. Then the Jacobi elliptic function ds is defined as follows:

$$\mathrm{ds}(u \mid m) = \frac{\mathrm{dn}(u \mid m)}{\mathrm{sn}(u \mid m)}$$

The Jacobi functions are defined for complex values of u and m.

The Jacobi functions are meromorphic and doubly periodic with periods $4\,\mathrm{K}(m)$ and $4\,\mathrm{i}\,\mathrm{K}'(m)$ with respect to u.

For $m = 0$ and $m = 1$, the Jacobi functions reduce to trigonometric or constant functions.

If one argument is a floating-point number, and the other one can be converted to a floating-point number, then a floating-point number is returned.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For most arguments, the Jacobi functions return themselves unevaluated:

```
jacobiSN(2,1/2)
```

$$\mathrm{sn}\left(2 \mid \frac{1}{2}\right)$$

Floating-point numbers are returned if at least one of the arguments is a floating-point number:

```
jacobiCN(1.5,1/2)
```

$$0.2502702593$$

Floating-point evaluation can be enforced by using `float`:

```
float(jacobiND(1,-1))
```

$$0.7404586624$$

Example 2

For $m = 0$ and $m = 1$, the result is expressed using a trigonometric function:

```
jacobiSC(u,0)
```

$$\tan(u)$$

```
jacobiND(u,1)
```

$$\cosh(u)$$

Parameters

m

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

jacobiCS

Jacobi elliptic function cs

Syntax

```
jacobiCS(u,m)
```

Description

`jacobiCS(u,m)` represents the Jacobi elliptic function cs.

Let $u = \mathrm{F}(\varphi \mid m)$. Then the Jacobi elliptic function cs is defined as follows:

$$\mathrm{cs}(u \mid m) = \frac{\mathrm{cn}(u \mid m)}{\mathrm{sn}(u \mid m)}$$

The Jacobi functions are defined for complex values of u and m.

The Jacobi functions are meromorphic and doubly periodic with periods $4\,\mathrm{K}(m)$ and $4\,\mathrm{i}\,\mathrm{K}'(m)$ with respect to u.

For $m = 0$ and $m = 1$, the Jacobi functions reduce to trigonometric or constant functions.

If one argument is a floating-point number, and the other one can be converted to a floating-point number, then a floating-point number is returned.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For most arguments, the Jacobi functions return themselves unevaluated:

```
jacobiSN(2,1/2)
```

$$\mathrm{sn}\left(2 \mid \frac{1}{2}\right)$$

Floating-point numbers are returned if at least one of the arguments is a floating-point number:

jacobian

Jacobian matrix of a vector function

Syntax

```
jacobian(v, x)
```

Description

`jacobian(v, x)` computes the Jacobian matrix of the vector function $\vec{v}$ with respect to $\vec{x}$.

If `v` is a vector then the component ring of `v` must be a field (i.e., a domain of category `Cat::Field`) for which differentiation with respect to `x` is defined.

If `v` is given as a list of arithmetical expressions, then `jacobian` returns a matrix with the standard component ring `Dom::ExpressionField()`.

Examples

Example 1

The Jacobian matrix of the vector function $\vec{v} = \begin{pmatrix} x^3 \\ x\,z \\ y+z \end{pmatrix}$ is:

```
delete x, y, z:
jacobian([x^3, x*z, y+z], [x, y, z])
```

$$\begin{pmatrix} 3x^2 & 0 & 0 \\ z & 0 & x \\ 0 & 1 & 1 \end{pmatrix}$$

Parameters

v

A list of arithmetical expressions, or a vector (i.e., an $n \times 1$ or $1 \times n$ matrix of a domain of category `Cat::Matrix`)

x

A list of (indexed) identifiers

Return Values

Matrix of the domain `Dom::Matrix(R)`, where `R` is the component ring of `v` or the domain `Dom::ExpressionField()`.

Algorithms

For a vector function $\vec{v}: G \to R^m$, where G is a subset of $\mathbb{R}^n$ the matrix

$$H_f(\vec{x}) = \begin{pmatrix} \frac{\partial}{\partial x_1} v_1 & \frac{\partial}{\partial x_2} v_1 & \cdots & \frac{\partial}{\partial x_n} v_1 \\ \frac{\partial}{\partial x_1} v_2 & \frac{\partial}{\partial x_2} v_2 & \cdots & \frac{\partial}{\partial x_n} v_2 \\ \vdots & \vdots & & \vdots \\ \frac{\partial}{\partial x_1} v_m & \frac{\partial}{\partial x_2} v_m & \cdots & \frac{\partial}{\partial x_n} v_m \end{pmatrix}$$

is the *Jacobian matrix* of $\vec{v}$.

See Also

MuPAD Functions

`gradient` | `hessian`

jacobiZeta

Jacobi Zeta function

Syntax

```
jacobiZeta(u, m)
```

Description

`jacobiZeta(u,m)` represents the Jacobi Zeta function $Z(u \mid m)$ which is defined as

$$Z(u \mid m) = \frac{2\,\pi}{K(m)} \left(\sum_{s=1}^{\infty} \frac{q(m)^s}{1 - q(m)^{2\,s}} \sin\left(\frac{2\,\pi}{K(m)}\, s\, u \right) \right).$$

The Jacobi Zeta function $Z(u \mid m)$ is defined for complex arguments u and m.

Exact results are returned for $m = 0$, $m = 1$ or $u = 0$. In all other cases an unevaluated symbolic call is returned.

A floating-point value is computed if both arguments are numerical and at least one is a floating-point number.

Environment Interactions

When called with floating-point arguments, these functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Most calls with exact arguments are returned unevaluated:

```
jacobiZeta(2, -1)
```

$$Z(2 \mid -1)$$

If $m = 0$, $m = 1$ or $u = 0$, an exact result is returned:

```
jacobiZeta(0, 3)
```

$$0$$

```
jacobiZeta(1, 0)
```

$$0$$

```
jacobiZeta(2, 1)
```

$$\tanh(2)$$

Parameters

u

An arithmetical expression.

m

An arithmetical expression specifying the parameter.

Return Values

Arithmetical expression.

kroneckerDelta

Kronecker's delta symbol

Syntax

```
kroneckerDelta(m, <n>)
```

Description

`kroneckerDelta(m, n)` is Kronecker's delta symbol. It represents 1 if $m = n$ and 0 if $m \neq n$.

`kroneckerDelta(m)` represents 1 if $m = 0$ and 0 if $m \neq 0$.

The calls `kroneckerDelta(m, n)` and `kroneckerDelta(m - n)` are equivalent.

`kroneckerDelta(m, n)` yields `1` if the arguments `m`, `n` coincide.

It yields `0` if `m - n` yields a non-zero numerical value.

If either `m` or `n` contain symbolic objects and `m - n` does not yield a numerical value, then the symbolic call `kroneckerDelta(m, n)` or the equivalent call `kroneckerDelta(n, m)` is returned.

Floating point numbers such as 1.0, 2.0 etc. are treated like integers.

Note that `kroneckerDelta(m,n)` = `kroneckerDelta(n,m)` for arbitary arguments `m`, `n`. In symbolic return values, the ordering of the input arguments may be exchanged.

`kroneckerDelta` is used and processed by `sum` and `ztrans`, `iztrans`.

Examples

Example 1

`kroneckerDelta` returns 1 or 0, respectively, for arguments that definitely coincide or do not coincide:

```
kroneckerDelta(2, 2), kroneckerDelta(n, n),
kroneckerDelta(2, 3), kroneckerDelta(n - 1, n + 1)
```

$$1, 1, 0, 0$$

A symbolic call is returned if the system cannot decide whether the arguments coincide:

```
kroneckerDelta(m, n), kroneckerDelta(m, 3), kroneckerDelta(3, n)
```

$$\delta_{m-n,0}, \delta_{m-3,0}, \delta_{n-3,0}$$

Example 2

`kroneckerDelta` is processed by `sum`:

```
sum(a[n]*kroneckerDelta(n, 3), n = 0..infinity)
```

$$a_3$$

```
sum(a[n]*kroneckerDelta(n, m), n = 0..infinity)
```

$$\begin{cases} a_m & \text{if } 0 \le m \wedge m \in \mathbb{Z} \\ 0 & \text{if } m \le -1 \vee m \notin \mathbb{Z} \end{cases}$$

`iztrans` may produce terms involving `kroneckerDelta`:

```
iztrans(1/(z - 1), z, n)
```

$$1 - \delta_{n,0}$$

```
ztrans(%, n, z)
```

$$\frac{z}{z-1} - 1$$

Parameters

`m, n`

arithmetical expressions. The default value for n is 0.

Return Values

Arithmetical expression.

Overloaded By

m, n

See Also

MuPAD Functions
`iztrans` | `sum` | `ztrans`

kummerU

Confluent hypergeometric KummerU function

Syntax

```
kummerU(a, b, z)
```

Description

`kummerU(a, b, z)` represents the KummerU function $U(a, b, z)$, whose integral representation is given by

$$\frac{1}{\Gamma(a)} \int_0^\infty e^{-z\,t}\, t^{a-1}\, (1+t)^{b-a-1}\, dt$$

for $\Re(a) > 0$ and $\Re(z) > 0$.

`kummerU` is defined for complex arguments a, b, and z.

For most parameter values, an unevaluated function call is returned. Cf. “Example 1” on page 1-1168.

Explicit symbolic expressions are returned for some particular values of the parameters:

- If $b = 2\,a$, the `besselK` function may appear.
- If a is a negative integer, the result is a polynomial.
- If $a = 1$ or $b = a$, the `igamma` function may appear.

Cf. “Example 2” on page 1-1168.

Environment Interactions

When called with floating-point arguments, this function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Unevaluated calls are returned for exact or symbolic arguments:

```
kummerU(a, b, x), kummerU(1/2, -1, 0)
```

$$\text{kummerU}(a, b, x), \text{kummerU}\left(\frac{1}{2}, -1, 0\right)$$

Floating point values are returned for floating-point arguments:

```
kummerU(1/3, 2.0, -50), kummerU(1/2, -1, 0.0)
```

$$0.1351149381 - 0.2340259377\,i,\ 0.7522527781$$

Example 2

Explicit expressions are returned for some specific values of the parameters:

```
kummerU(1/2, 1, x), kummerU(-2, b, x),
kummerU(1, 1/3, x), kummerU(a, a, x)
```

$$\frac{e^{\frac{x}{2}}\,K_0\left(\frac{x}{2}\right)}{\sqrt{\pi}},\ b - 2x(b+1) + b^2 + x^2,\ x^{2/3}\,e^x\left(\frac{3\,e^{-x}}{2\,x^{2/3}} - \frac{3\,\Gamma\left(\frac{1}{3}, x\right)}{2}\right),\ e^x\,\Gamma(1-a, x)$$

Example 3

The functions `diff`, `float`, `limit`, and `series` handle expressions involving the `kummerU` function

```
diff(kummerU(a, b, z), z), float(kummerU(1/2, -1, 0))
```

$$\frac{a\,\text{kummerU}(a+1, b, z)\,(a-b+1)}{z} - \frac{a\,\text{kummerU}(a, b, z)}{z},\ 0.7522527781$$

```
limit(kummerU(1/2, -1, x), x),
series(kummerU(1/2, -1, x), x = infinity, 3)
```

$$\frac{4}{3\sqrt{\pi}},\ \frac{1}{\sqrt{x}} - \frac{5}{4x^{3/2}} + \frac{105}{32x^{5/2}} + O\left(\frac{1}{x^{7/2}}\right)$$

Parameters

a, b, z

arithmetical expressions

Return Values

Arithmetical expression.

Overloaded By

z

Algorithms

$U(a, b, z)$ satisfies Kummer's differential equation:

$$z\frac{\partial^2}{\partial z^2}y + (b-z)\frac{\partial}{\partial z}y - a\,y = 0$$

,

for which the hypergeometric function ${}_1F_1(a, b, z)$ is another solution.

$U(a, b, z)$ is related to the `whittakerW` function $W_{a,b}(z)$ by the formula:

$$W_{a,b}(z) = e^{-\frac{z}{2}} z^{\frac{1}{2}+b} U\left(\frac{1}{2}+b-a,\ 1+2b,\ z\right)$$

laguerreL

Laguerre polynomials and L function

Syntax

```
laguerreL(n, x)
```

```
laguerreL(n, a, x)
```

Description

`laguerreL(n, a, x)` represents Laguerre's L function. When `n` is a nonnegative integer, this is the classical Laguerre polynomial of degree n.

Laguerre's L function is defined in terms of hypergeometric functions by

$$\text{laguerreL}(n, a, x) = \binom{n+a}{a} {}_1F_1(-n; a+1; x)$$

.

For nonnegative integer values of n, the function returns the classical (generalized) polynomials that are orthogonal with respect to the scalar product $\langle \text{f1}, \text{f2} \rangle = \int_0^\infty e^{-x} x^a \, \text{f1}(x) \, \text{f2}(x) \, dx$. In particular:

$$\langle \text{laguerreL}(n, a, x), \text{laguerreL}(m, a, x) \rangle = \begin{cases} 0 & \text{if } n \neq m \\ \frac{\Gamma(a+n+1)}{n!} & \text{if } n = m \end{cases}$$

.

The Laguerre's L function is not well defined for all values of the parameters n and a, because certain restrictions on the parameters exist in the definition of the hypergeometric functions . If the Laguerre's L function is not defined for a particular pair n and a, the call `laguerreL(n, a, x)` returns 0 or issues an error message.

The calls `laguerre(n, x)` and `laguerre(n, 0, x)` are equivalent.

If n is a nonnegative integer, the function `laguerreL` returns the explicit form of the corresponding Laguerre polynomial. The special values $\text{laguerreL}(n, a, 0) = \binom{n+a}{a}$ are implemented for arbitrary values of n and a. If n is a negative integer and a is a numerical noninteger value satisfying $a \geq -n$, then the function `laguerreL` returns 0. If n is a negative integer and a is an integer satisfying $a < -n$, then the function returns an explicit expression defined by the reflection rule

$$\text{laguerreL}(n, a, x) = (-1)^a e^x \text{laguerreL}(-n-a-1, a, -x).$$

If all arguments are numerical and at least one of the arguments is a floating-point number, then `laguerreL(x)` returns a floating-point number. For all other arguments, `laguerreL(n, a, x)` returns a symbolic function call.

Environment Interactions

When called with floating-point arguments, the function is sensitive to the environment variable `DIGITS`, which determines the numerical working precision.

Examples

Example 1

You can call the `laguerreL` function with exact and symbolic arguments:

```
laguerreL(2, a, x), laguerreL(-2, -2, PI)
```

$$\frac{3a}{2} - x(a+2) + \frac{a^2}{2} + \frac{x^2}{2} + 1,\ e^{\pi}\left(\frac{\pi^2}{2} + \frac{\pi^3}{6}\right)$$

If the first argument is a nonnegative integer, the function returns a polynomial:

```
laguerreL(3, x)
```

$$-\frac{x^3}{6} + \frac{3x^2}{2} - 3x + 1$$

```
laguerreL(3, a, x)
```

$$\frac{11\,a}{6} - x\left(\frac{a^2}{2} + \frac{5\,a}{2} + 3\right) + x^2\left(\frac{a}{2} + \frac{3}{2}\right) + a^2 + \frac{a^3}{6} - \frac{x^3}{6} + 1$$

Floating-point values are computed for floating-point arguments:

```
laguerreL(2, 3, 4.0), laguerreL(5.0, sqrt(2), PI)
```

$$-2.0,\ 1.851157209$$

```
laguerreL(1 + I, 1.0), laguerreL(-2.0, exp(I))
```

$$-0.2457246594 - 0.6867435489\,i,\ 0.6848682701 + 2.933911244\,i$$

Example 2

The Laguerre function is not defined for all parameter values:

```
laguerreL(-5/2, -3/2, x)
```

```
Error: The function 'laguerreL' is not defined for parameter values '-5/2' and '-3/2'.
```

Example 3

System functions such as `diff`, `float`, `limit`, and `series` handle expressions involving `laguerreL`:

```
diff(laguerreL(n, a, x), x, x, x), float(laguerreL(2, 3, sqrt(PI)))
```

$$-\mathrm{laguerreL}(n-3,\ a+3,\ x),\ 2.708527072$$

```
limit(laguerreL(3, 4, x^2/(1+x)), x = infinity)
```

$$-\infty$$

```
limit(laguerreL(4, 3, x^2/(1+x)), x = infinity)
```

$$\infty$$

```
series(laguerreL(n, a, x), x = 0, 3)
```

$$\binom{a+n}{n} - \frac{n\,x\,\binom{a+n}{n}}{a+1} + \frac{n\,x^2\,(n-1)\,\binom{a+n}{n}}{2\,(a+1)\,(a+2)} + O(x^3)$$

```
series(laguerreL(3/2, x), x = infinity, 3)
```

$$\frac{3\,e^x}{4\,\sqrt{\pi}\,x^{5/2}} + \frac{75\,e^x}{16\,\sqrt{\pi}\,x^{7/2}} + \frac{3675\,e^x}{128\,\sqrt{\pi}\,x^{9/2}} + O\left(\frac{e^x}{x^{11/2}}\right)$$

Parameters

n, a, x

arithmetical expressions

Return Values

Arithmetical expression.

lambertW

The Lambert function

Syntax

```
lambertW(x)
```

```
lambertW(k, x)
```

Description

For integer k, the values $y = \mathrm{W}_k(x)$ represent the solutions of the equation $y\,e^y = x$.

`lambertW` is the inverse function of $y \to y\,e^y$.

In the complex plane, the equation $y\,e^y = x$ has a countably infinite number of solutions. They are represented by `lambertW(k, x)` with `k` ranging over the integers.

For all real $x \geq 0$, the equation $y\,\mathrm{e}^y = x$ has exactly one real solution. It is represented by `y=lambertW(x)` or, equivalently, `y=lambertW(0, x)`.

For all real x in the range $0 > x$, there are exactly two real solutions. The larger one is represented by `y=lambertW(x)`, the smaller one by `y=lambertW(-1, x)`.

Exactly one real solution `lambertW(0, -exp(-1))= lambertW(-1, -exp(-1))= -1` exists for $x = -\mathrm{e}^{-1}$.

For $k \notin \{0, -1\}$, `lambertW(k, x)` takes no real value.

The values `lambertW(-1, 0)=- infinity` and `lambertW(0, 0)=0` are implemented. Further, the result y is returned for some exact arguments of the form $x = y\,\mathrm{e}^y$. For floating-point arguments a floating-point value is returned. For all other arguments, unevaluated function calls are returned.

The `float` attributes are kernel functions, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
lambertW(-3), lambertW(-1, -5/2), lambertW(1/2),
lambertW(5, I), lambertW(3, 1 + I), lambertW(-1, x + 1)
```

$$W_0(-3),\ W_{-1}\left(-\frac{5}{2}\right),\ W_0\left(\frac{1}{2}\right),\ W_5(i),\ W_3(1+i),\ W_{-1}(x+1)$$

Some exact values are found:

```
lambertW(-1, -exp(-1)), lambertW(-1, -2*exp(-2)),
lambertW(-1, -3/2*exp(-3/2)), lambertW(exp(1)),
lambertW(2*exp(2)), lambertW(5/2*exp(5/2)),
lambertW(1, (3+4*I)*exp(3+4*I))
```

$$-1,\ -2,\ -\frac{3}{2},\ 1,\ 2,\ \frac{5}{2},\ 3+4\,i$$

Floating point values are computed for floating-point arguments:

```
lambertW(-1, -0.3), lambertW(2000.0)
```

$$-1.781337023,\ 5.836731495$$

```
lambertW(-3, -0.277), lambertW(1, 2345.6)
```

$$-3.951784369 - 13.85940405\,i,\ 5.690470601 + 5.513574431\,i$$

Example 2

The functions `diff`, `float`, and `series` handle expressions involving the Lambert function:

```
diff(lambertW(k, x), x)
```

$$\frac{W_k(x)}{x\,(W_k(x)+1)}$$

```
float(ln(3 + lambertW(sqrt(PI))))
```

$$1.334475971$$

```
series(lambertW(x), x = 0);
series(lambertW(x), x = -1/exp(1), 3);
series(lambertW(-1, x), x = -1/exp(1), 3);
```

$$x - x^2 + \frac{3\,x^3}{2} - \frac{8\,x^4}{3} + \frac{125\,x^5}{24} - \frac{54\,x^6}{5} + O(x^7)$$

$$-1 + \sqrt{2}\,\sqrt{e}\,\sqrt{x + e^{-1}} - \frac{2\,e\left(x + e^{-1}\right)}{3} + O\left(\left(x + e^{-1}\right)^{3/2}\right)$$

$$-1 - \sqrt{2}\,\sqrt{e}\,\sqrt{x + e^{-1}} - \frac{2\,e\left(x + e^{-1}\right)}{3} + O\left(\left(x + e^{-1}\right)^{3/2}\right)$$

Parameters

x

An arithmetical expression, the “argument”

k

An arithmetical expression representing an integer, the “branch”

Return Values

Arithmetical expression.

References

R.M. Corless, D.J. Jeffrey and D.E. Knuth: “A sequence of Series for the Lambert W Function”, in: Proceedings of ISSAC'97, Maui, Hawaii. W.W. Kuechlin (ed.). New York: ACM, pp. 197-204, 1997.

laplace

Laplace transform

Syntax

```
laplace(f, t, s)
```

Description

`laplace(f, t, s)` computes the Laplace transform of the expression `f = f(t)` with respect to the variable *t* at the point *s*.

The Laplace transform is defined as follows:

$$F(s) = \int_0^\infty f(t)\, e^{-s\,t}\, dt$$

.

If `laplace` cannot find an explicit representation of the transform, it returns an unevaluated function call. See "Example 3" on page 1-1180.

If `f` is a matrix, `laplace` applies the Laplace transform to all components of the matrix.

To compute the inverse Laplace transform, use `ilaplace`.

Examples

Example 1

Compute the Laplace transforms of these expressions with respect to the variable `t`:

```
laplace(exp(-a*t), t, s)
```

$$\frac{1}{a+s}$$

```
laplace(1 + exp(-a*t)*sin(b*t), t, s)
```

$$\frac{1}{s} + \frac{b}{(a+s)^2 + b^2}$$

Example 2

Compute the Laplace transform of this expression with respect to the variable `t`:

```
F := laplace(t^10*exp(-s_0*t), t, s)
```

$$\frac{3628800}{(s+s_0)^{11}}$$

Evaluate the Laplace transform of the expression at the points $s = -2\,s_0$ and $s = 1 + \pi$. You can evaluate the resulting expression `F` using `|` (or its functional form `evalAt`):

```
F | s = -2*s_0
```

$$-\frac{3628800}{s_0^{11}}$$

Also, you can evaluate the Laplace transform at a particular point directly:

```
laplace(t^10*exp(-s_0*t), t, 1 + PI)
```

$$\frac{3628800}{(\pi + s_0 + 1)^{11}}$$

Example 3

If `laplace` cannot find an explicit representation of the transform, it returns an unevaluated call:

```
laplace(exp(-t^3), t, s)
```

$$\text{laplace}\left(e^{-t^3}, t, s\right)$$

`ilaplace` returns the original expression:

```
ilaplace(%, s, t)
```

$$e^{-t^3}$$

Example 4

Compute the folllowing Laplace transforms that involve the Dirac and the Heaviside functions:

```
laplace(dirac(t - 3), t, s)
```

$$e^{-3s}$$

```
laplace(heaviside(t - PI), t, s)
```

$$\frac{e^{-\pi s}}{s}$$

Example 5

The Laplace transform of a function is related to the Laplace transform of its derivative:

```
laplace(diff(f(t), t), t, s)
```

$$s\,\mathrm{laplace}(f(t), t, s) - f(0)$$

Parameters

`f`

Arithmetical expression or matrix of such expressions

`t`

Identifier or indexed identifier representing the transformation variable

s

Arithmetical expression representing the evaluation point

Return Values

Arithmetical expression or unevaluated function call of type `laplace`. If the first argument is a matrix, then the result is returned as a matrix.

MuPAD Functions

`ilaplace` | `ilaplace::addpattern` | `laplace::addpattern`

More About

- "Integral Transforms"

laplace::addpattern

Add patterns for the Laplace transform

Syntax

```
laplace::addpattern(pat, t, s, res, <vars, <conds>>)
```

Description

`laplace::addpattern(pat, t, s, res)` teaches `laplace` to return

$\mathrm{laplace}(\mathrm{pat}, t, s) = \int_0^{\infty} \mathrm{pat}\, e^{-s\,t}\, dt = \mathrm{res}$.

The `laplace` function uses a set of patterns for computing Laplace transforms. You can extend the set by adding your own patterns. To add a new pattern to the pattern matcher, use `laplace::addpattern`. MuPAD does not save custom patterns permanently. The new patterns are available in the *current* MuPAD session only.

Variable names that you use when calling `laplace::addpattern` can differ from the names that you use when calling `laplace`. See “Example 2” on page 1-1184.

You can include a list of free parameters and a list of conditions on these parameters. These conditions and the result are protected from premature evaluation. This means that you can use `not iszero(a^2 - b)` instead of `hold( _not @ iszero )(a^2 - b)`.

The following conditions treat assumptions on identifiers differently:

- `a^2 - b <> 0` takes into account assumptions on identifiers.
- `not iszero(a^2 - b)` disregards assumptions on identifiers.

See “Example 4” on page 1-1185.

Environment Interactions

Calling `laplace::addpattern` changes the expressions returned by future calls to `laplace`.

Examples

Example 1

Compute the Laplace transform of the function `foo`. By default, MuPAD does not have a pattern for this function:

```
laplace(foo(t), t, s)
```

$$\text{laplace}(\text{foo}(t), t, s)$$

Add a pattern for the Laplace transform of `foo` using `laplace::addpattern`:

```
laplace::addpattern(foo(t), t, s, bar(s)):
```

Now `laplace` returns the Laplace transform of `foo`:

```
laplace(foo(t), t, s)
```

$$\text{bar}(s)$$

After you add a new transform pattern, MuPAD can use that pattern indirectly:

```
laplace(t^3 + exp(2*t)*foo(t), t, s)
```

$$\text{bar}(s-2)+\frac{6}{s^4}$$

Example 2

Define the Laplace transform of `foo(x)` using the variables `x` and `y` as parameters:

```
laplace::addpattern(foo(x), x, y, bar(y)):
```

The `laplace` function recognizes the added pattern even if you use other variables as parameters:

```
laplace(foo(t), t, s)
```

$$\text{bar}(s)$$

Example 3

Add this pattern for the Laplace transform of `f`:

```
laplace::addpattern(f(a*x)*g(a*x), x, y, y/(y^4 + 4*a^4)):
laplace(f(a*v)*g(a*v), v, w)
```

$$\frac{w}{4\,a^4 + w^4}$$

This pattern holds only when the first argument of `f` is the symbolic parameter `a`. If you use any other value of this parameter, `laplace` ignores the pattern:

```
laplace(f(A*v)*g(A*v), v, w)
```

$$\text{laplace}(f(A\,v)\,g(A\,v),\,v,\,w)$$

To use the pattern for arbitrary values of the parameter, declare the parameter `a` as an additional pattern variable:

```
laplace::addpattern(f(a*x)*g(a*x), x, y, y/(y^4 + 4*a^4), [a]):
```

Now `laplace` applies the specified pattern for an arbitrary value of `a`:

```
laplace(f(A*v)*g(A*v), v, w)
```

$$\frac{w}{4\,A^4 + w^4}$$

Example 4

Use assumptions when adding the following pattern for the Laplace transform:

```
laplace::addpattern(FOO(x*t), t, s, sin(1/(x-1/2))*BAR(s),
                                    [x], [abs(x) < 1]):
laplace(FOO(x*t),t,s) assuming -1 < x < 1
```

$$\sin\left(\frac{1}{x-\frac{1}{2}}\right)\,\text{BAR}(s)$$

If $|x| \geq 1$, you cannot apply this pattern:

```
laplace(FOO(x*t),t,s) assuming x >= 1
```

$$\text{laplace}(\text{FOO}(t\,x),\ t,\ s)$$

If MuPAD cannot determine whether the conditions are satisfied, it returns a `piecewise` object:

```
laplace(FOO(x*t), t, s)
```

$$\begin{cases} \sin\left(\frac{1}{x-\frac{1}{2}}\right)\ \text{BAR}(s) & \text{if } |x| < 1 \end{cases}$$

Note that the resulting expression defining the Laplace transform of `FOO(x*t)` implicitly assumes that the value of `x` is not 1/2. A strict definition of the pattern is:

```
laplace::addpattern(FOO(x*t), t, s, sin(1/(x-1/2))*BAR(s),
                    [x], [abs(x) < 1, x <> 1/2]):
```

If either the conditions are not satisfied or substituting the values into the result gives an error, `laplace` ignores the pattern. For this particular pattern, you can omit specifying the assumption `x <> 1/2`. If `x = 1/2`, MuPAD throws an internal "Division by zero." error and ignores the pattern:

```
laplace(FOO(1/2*t), t, s)
```

$$\text{laplace}\left(\text{FOO}\left(\frac{t}{2}\right),\ t,\ s\right)$$

Parameters

`pat`

Arithmetical expression in the variable `t` representing the pattern to match

`t`

Identifier or indexed identifier used as a variable in the pattern

`s`

Identifier or indexed identifier used as a variable in the result

`res`

Arithmetical expression in the variable `s` representing the pattern for the result of the transformation

`vars`

List of identifiers or indexed identifiers used as "pattern variables" (placeholders in `pat` and `res`). You can use pattern variables as placeholders for almost arbitrary MuPAD expressions not containing `t` or `s`. You can restrict them by conditions given in the optional parameter `conds`.

`conds`

List of conditions on the pattern variables

Return Values

Object of type `DOM_NULL`

See Also

MuPAD Functions

`ilaplace` | `ilaplace::addpattern` | `laplace`

laplacian

The Laplacian

Syntax

```
laplacian(f, [x1, x2, …])
```

```
laplacian(f, [x1, x2, …], ogCoord, <c>)
```

Description

`laplacian(f, [ x1, x2, ...])` computes the Laplacian $\Delta f = \sum_i \frac{\partial^2}{\partial x_i^2} f$, i.e. *div*(*grad*(*f*)), of the function $f = f(x_1, x_2, \ldots)$ in the Cartesian coordinates $x_1, x_2, \ldots$.

The table `linalg::ogCoordTab` provides some predefined three-dimensional orthogonal coordinate transformations. Presently, its entries are `Cartesian`, `Cylindrical`, `Spherical[RightHanded]` (or its equivalent `Spherical[RightHanded]`), `EllipticCylindrical`, `ParabolicCylindrical`, `RotationParabolic`, `Torus`. See `linalg::ogCoordTab` for details. For example, the command

```
laplacian(f(r, Theta, phi), [r, Theta, phi], Spherical[RightHanded])
```

produces the Laplacian of *f* in spherical coordinates r, θ, ϕ defined by the transformation

$$x = r \sin(\theta) \cos(\phi),\ y = r \sin(\theta) \sin(\phi),\ z = r \cos(\theta)$$

.

Arbitrary orthogonal systems $u = (u_1, \ldots, u_n)$ (in any dimension n) can be used by passing corresponding "scale parameters" as third argument to `laplacian`. These are defined as follows. Let $\vec{x} = (x_1, \ldots, x_n)$ be Cartesian coordinates, let $\vec{x}(\vec{u})$ be an orthognal transformation (i.e., the vectors $\frac{\partial}{\partial u_i} \vec{x}$ are orthogonal). The Euclidean lengths $s_i = \left| \frac{\partial}{\partial u_i} \vec{x} \right|$ of the vectors define the "scales". The list $s = [s_1, \ldots, s_n]$ can be passed as a

third argument to `laplacian`. For example, the usual two-dimensional polar coordinates $x = r\,cos(\phi)$, $y = r\,sin(\phi)$ lead to scale factors

$$s = \left[\left|\left(\frac{\partial}{\partial r}x, \frac{\partial}{\partial r}y\right)\right|, \left|\left(\frac{\partial}{\partial \phi}x, \frac{\partial}{\partial \phi}y\right)\right|\right] = [|(\cos(\phi), \sin(\phi))|, |(-r\sin(\phi), r\cos(\phi))|] =$$

$$[1, r]$$

.

Thus, `laplacian(f(r, phi), [r, phi], [1, r])` produces the Laplacian of $f(r, \phi)$ in polar coordinates r and ϕ.

Examples

Example 1

Compute the Laplacian in Cartesian coordinates:

```
laplacian(f(x[1], x[2]), [x[1], x[2]])
```

$$\frac{\partial^2}{\partial x_1^2} f(x_1, x_2) + \frac{\partial^2}{\partial x_2^2} f(x_1, x_2)$$

```
laplacian(x^2*y + c*exp(y) + u*v^2, [x, y, u, v])
```

$$2u + 2y + c\,e^y$$

Example 2

Compute the Laplacian in cylindrical coordinates (r, ϕ, z) given by

$$x = r\cos(\phi),\ y = r\sin(\phi),\ z = z$$

.

```
expand(laplacian(f(r, phi, z), [r, phi, z], Cylindrical))
```

$$\frac{\frac{\partial^2}{\partial \mathrm{phi}^2} f(r, \mathrm{phi}, z)}{r^2} + \frac{\frac{\partial}{\partial r} f(r, \mathrm{phi}, z)}{r} + \frac{\partial^2}{\partial r^2} f(r, \mathrm{phi}, z) + \frac{\partial^2}{\partial z^2} f(r, \mathrm{phi}, z)$$

```
laplacian(r*cos(phi)*z^3, [r, phi, z], Cylindrical)
```

$$6\,r\,z\,\cos(\mathrm{phi})$$

Passing the name `Cylindrical` of the orthogonal system predefined in `linalg::ogCoordTab` is the simplest way of using cylindrical coordinates. Alternatively, one may pass appropriate `scale parameters' explicitly. They are stored in `linalg::ogCoordTab` and can be called in the following way:

```
linalg::ogCoordTab[Cylindrical, Scales](r, phi, z)
```

$$[1,\ r,\ 1]$$

```
laplacian(r*cos(phi)*z^3, [r, phi, z], %)
```

$$6\,r\,z\,\cos(\mathrm{phi})$$

Example 3

Consider Torus coordinates (r, θ, ϕ) introduced by

$$x = (c - r\cos(\theta))\cos(\phi),\ y = (c - r\cos(\theta))\sin(\phi),\ z = r\sin(\theta)$$

Here, c is a real constant and $0 \le r < c$, $0 \le \theta \le 2\,\pi$, $0 \le \phi \le 2\,\pi$ is assumed. The “scale parameters” are stored in `linalg::ogCoordTab`:

```
linalg::ogCoordTab[Torus, Scales](r, thet, phi, c)
```

$$[1,\ r,\ c - r\cos(\mathrm{thet})]$$

The Laplacian of the function $f(r, \phi, z) = r$ in these coordinates is:

```
laplacian(r, [r, thet, phi], %)
```

$$\frac{c - 2\,r\cos(\mathrm{thet})}{r\,(c - r\cos(\mathrm{thet}))}$$

Example 4

You can introduce new orthogonal systems. For example, consider the orthogonal "6-sphere coordinates" (u, v, w) introduced by

$$x = \frac{u}{u^2+v^2+w^2},\ y = \frac{v}{u^2+v^2+w^2},\ z = \frac{w}{u^2+v^2+w^2}$$

.

This transformation $(u, v, w) \to \vec{x} = (x, y, z)$ is not stored in `linalg::ogCoordTab`, hence the corresponding "scale factors" of the metric have to be computed first:

$$\left|\frac{\partial}{\partial u}\vec{x}\right| = \left|\frac{\partial}{\partial v}\vec{x}\right| = \left|\frac{\partial}{\partial w}\vec{x}\right| = \frac{1}{u^2+v^2+w^2}$$

.

With these "scales", the Laplacian can be computed via `laplacian`:

```
s := 1/(u^2 + v^2 + w^2):
factor(laplacian(f(u, v, w), [u, v, w], [s, s, s]))
```

$$(u^2+v^2+w^2)\left(u^2\,\sigma_3+v^2\,\sigma_3+w^2\,\sigma_3-2\,u\,\frac{\partial}{\partial u}f(u, v, w)+u^2\,\sigma_2+v^2\,\sigma_2+w^2\,\sigma_2\right.$$

$$\left.-2\,v\,\frac{\partial}{\partial v}f(u, v, w)+u^2\,\sigma_1+v^2\,\sigma_1+w^2\,\sigma_1-2\,w\,\frac{\partial}{\partial w}f(u, v, w)\right)$$

where

$$\sigma_1 = \frac{\partial^2}{\partial w^2}f(u, v, w)$$

$$\sigma_2 = \frac{\partial^2}{\partial v^2}f(u, v, w)$$

$$\sigma_3 = \frac{\partial^2}{\partial u^2}f(u, v, w)$$

Since the Laplacian is the divergence of the gradient, you can compute it in the following way, too:

```
divergence(gradient(f(u, v, w), [u, v, w], [s, s, s]),
                    [u, v, w], [s, s, s])
```

$$\sigma_1^2 \frac{\partial^2}{\partial u^2} f(u, v, w) + \sigma_1^2 \frac{\partial^2}{\partial v^2} f(u, v, w) + \sigma_1^2 \frac{\partial^2}{\partial w^2} f(u, v, w) - 2\, u\, \sigma_1 \frac{\partial}{\partial u} f(u, v, w)$$

$$- 2\, v\, \sigma_1 \frac{\partial}{\partial v} f(u, v, w) - 2\, w\, \sigma_1 \frac{\partial}{\partial w} f(u, v, w)$$

where

$$\sigma_1 = u^2 + v^2 + w^2$$

```
expand(% - %2)
```

$$0$$

```
delete s:
```

Parameters

`f`

An arithmetical expression in the variables x_1, x_2 etc.

x_1, x_2, …

identifiers or indexed identifiers

`ogCoord`

The name of a three-dimensional orthogonal coordinate system predefined in the table `linalg::ogCoordTab`, or a list of algebraic expressions representing the scale factors of an orthogonal coordinate system.

`c`

The parameter of the coordinate systems EllipticCylindrical and Torus, respectively: an arithmetical expression. The default value is `c` = 1.

Return Values

Arithmetical expression.

Algorithms

Orthogonal coordinates $\vec{u}$ on $\mathbb{R}^n$ are defined by a transformation $\vec{x}(\vec{u})$ to Cartesian coordinates $\vec{x}$ on $\mathbb{R}^n$. The metric tensor associated with the coordinates $\vec{u}$ is given by

$$(g_{i,j}) = \left(\frac{\partial}{\partial u_i}\vec{x}, \frac{\partial}{\partial u_j}\vec{x}\right) = \mathrm{diag}\left({s_1}^2, \ldots, {s_n}^2\right), s_i = \left|\frac{\partial}{\partial u_i}\vec{x}\right|.$$

The Laplacian of a function *f* is given by the divergence

$$\Delta f = \mathrm{div}\left(\vec{F}\right) = \sum_{j=1}^{n}\left(\frac{\partial}{\partial u_j}\frac{F_j}{s_j} + \frac{F_j}{s_j}\left(\sum_{k=1}^{n}\frac{1}{s_k}\frac{\partial}{\partial u_j}s_k\right)\right),$$

where $F_j = \frac{1}{s_j}\frac{\partial}{\partial u_j}f$ are the components of the gradient $\vec{F} = \mathrm{grad}(f)$.

%, last

Access a previously computed object

Syntax

```
%
```

```
% n
```

```
last(n)
```

Description

`last()` or `%` returns the result of the last command.

`last(n)` or `%n` returns the result of the `n`th previous command.

By default, MuPAD stores the last 20 commands and their results in an internal history table. `last(n)` returns the result entry of the `n`th element in this table, counted from the end of the table. Thus `last(1)` returns the result of the last command, `last(2)` returns the result of the next to last one, etc. Instead of `last(n)` one can also write more briefly `%n`. Instead of `last(1)` or `%1`, one can use even more briefly `%`.

The environment variable `HISTORY` determines the number of previous results that can be accessed at interactive level, i.e., the number of entries in the history table. In procedures, the length of this table is always 3, independent of the value of `HISTORY`. Thus admissible values for `n` are the integers between `1` and `HISTORY` at interactive level, and the integers `1, 2, 3` inside a procedure.

Use `history` to access entries of the history table at interactive level directly, including the command that produced the corresponding result.

The result returned by `last` or `%` is not evaluated again. Use the function `eval` to force a subsequent evaluation. See “Example 4” on page 1-1197.

Note: `last` behaves differently at interactive level and in procedures. At interactive level, compound statements, such as `for`, `repeat`, and `while` loops and `if` and `case`

branching instructions, are stored in the history table as a whole. In procedures, the statements within a compound statement are stored in a separate history table of this procedure, but not the compound statement itself. See “Example 5” on page 1-1198.

Commands and their results are stored in the history table even if the output is suppressed by a colon. Thus the result of `last(n)` may differ from the `n`th previous output that is visible on the screen at interactive level. See “Example 1” on page 1-1195.

Commands appearing on the same input line lead to separate entries in the history table if they are separated by a colon or a semicolon. In contrast, an expression sequence is regarded as a single command. See “Example 2” on page 1-1196.

Commands that are read from a file via `fread` or `read` are stored in the history table *before* the `fread` or `read` command itself. If the option `Plain` is used, then a separate history table is valid within the file, and the commands from the file do not appear in the history table of the enclosing context. See the help page of `history` for examples.

Using `last` in procedures is generally considered bad programming style and is therefore deprecated. Future MuPAD releases may no longer support the use of `last` within procedures.

If the abbreviated syntax `%n` is used, then `n` must be a positive integer literally. If this is not the case, but `n` evaluates to a positive integer, use the equivalent functional notation `last(n)` (see “Example 3” on page 1-1197).

Examples

Example 1

Here are some examples for using `last` at interactive level. Note that `last(n)` refers to the `n`th previously computed result, whether it was displayed or not:

```
a := 42;
last(1), %, %1
```

$$42$$

$$42,\ 42,\ 42$$

```
a := 34: b := 56: last(2) = %2
```

```
34 = 34
```

Example 2

Commands appearing on one input line lead to separate entries in the history table:

```
"First command"; 11: 22; 33:
```

```
"First command"
```

```
22
```

```
last(1), last(2);
```

```
33, 22
```

If a sequence of commands is bracketed, it is regarded as a single command:

```
"First command"; (11: 22; 33:)
```

```
"First command"
```

```
33
```

```
last(1), last(2);
```

```
33, "First command"
```

An expression sequence is also regarded as a single command:

```
"First command"; 11, 22, 33;
```

```
"First command"
```

```
     11, 22, 33
```

```
last(1), last(2);
```

```
     11, 22, 33, "First command"
```

Example 3

Due to the fact that the MuPAD parser expects a number after the `%` sign, there is a difference between the use of `%` and `last`. `last` can be called with an expression that evaluates to a positive integer:

```
n := 2: a := 35: b := 56: last(n)
```

```
     35
```

If you try the same with `%`, an error occurs:

```
n := 2: a := 35: b := 56: %n
```

```
Error: Unexpected 'identifier'. [line 1, col 28]
```

Example 4

The result of `last` is not evaluated again:

```
delete a, b:
c := a + b + a: a:= b: %2
```

```
     2 a + b
```

Use `eval` to enforce the evaluation:

```
eval(%)
```

```
     3 b
```

Example 5

We demonstrate the difference between the use of `last` at interactive level and in procedures:

```
1: for i from 1 to 3 do i: print(%): end_for:
```

```
    1

    1

    1
```

Here `last(1)` refers to the most recent entry in the history table, which is the `1` executed before the `for` loop. We can also verify this by inspecting the history table after these commands. The command `history` returns a list with two elements. The first entry is a previously entered MuPAD command, and the second entry is the result of this command returned by MuPAD. You see that the history table contains the whole `for` loop as a single command:

```
history(history() - 1), history(history())
```

```
[1, 1], [(for i from 1 to 3 do
  i;
  print(%)
end_for), null()]
```

However, if the `for` loop defined above is executed inside a procedure, then we obtain a different result. In the following example, `last(1)` refers to the last evaluated expression, namely the `i` inside the loop:

```
f := proc()
begin
  1: for i from 1 to 3 do i: print(last(1)): end_for
end_proc:

f():
```

```
    1
```

$$2$$

$$3$$

The command `history` refers only to the interactive inputs and their results:

```
history(history())
```

$$[f(), \text{null}()]$$

Parameters

n

A positive integer

Return Values

MuPAD object.

See Also

MuPAD Functions

`HISTORY` | `history`

More About

- “History Mechanism”

lasterror

Reproduce the last error

Syntax

```
lasterror()
```

Description

`lasterror()` reproduces the last error that occurred in the current MuPAD session.

Typically, `lasterror` is used to reproduce errors that were caught by `traperror`. Cf. “Example 2” on page 1-1201.

Examples

Example 1

We produce an error:

```
x := 0: y := 1/x
```

```
Error: Division by zero. [_invert]
```

This error may be reproduced by `lasterror`:

```
lasterror()
```

```
Error: Division by zero. [_invert]
```

A further error is produced:

```
error("my error")
```

```
Error: my error
```

```
lasterror()
```

```
Error: my error
```

```
delete x, y:
```

Example 2

The following procedure `myln` computes the ln function of its argument. In case of an error produced by the system function `ln`, it prints information on the argument and reproduces the error:

```
myln := proc(x)
  local result;
begin
  if traperror((result := ln(x))) = 0 then
     return(result)
  else
     print(Unquoted, "the following error occurred " .
                     "when calling ln(".expr2text(x)."):");
     lasterror()
  end_if:
end:
```

Indeed, the ln has a singularity at 0 and produces:

```
myln(0)
```

```
the following error occurred when calling ln(0):
```

```
Error: Singularity. [ln]
  Evaluating: myln
```

```
delete myln:
```

See Also

MuPAD Functions

`error` | `getlasterror` | `traperror`

_lazy_and

"lazy and" of Boolean expressions

Syntax

```
_lazy_and(b1, b2, …)
```

Description

`_lazy_and(b1, b2, ...)` evaluates the Boolean expression `b1 and b2 and ...` by "lazy evaluation".

`_lazy_and(b1, b2, ...)` produces the same result as `bool(b1 and b2 and ...)`, provided the latter call does not produce an error. The difference between these calls is as follows:

`bool(b1 and b2 and ...)` evaluates *all* Boolean expressions before combining them logically via 'and'.

Note that the result is `FALSE` if one of `b1`, `b2` etc. evaluates to `FALSE`. "Lazy evaluation" is based on this fact: `_lazy_and(b1, b2, ...)` evaluates the arguments from left to right. The evaluation is stopped immediately if one argument evaluates to `FALSE`. In this case, `_lazy_and` returns `FALSE`*without* evaluating the remaining Boolean expressions. If none of the expressions `b1`, `b2` etc. evaluates to`FALSE`, then all arguments are evaluated and the corresponding result `TRUE` or `UNKNOWN` is returned.

`_lazy_and` is also called "conditional `and`".

If any of the considered Boolean expressions `b1`, `b2` etc. cannot be evaluated to `TRUE`, `FALSE`, or `UNKNOWN`, then `_lazy_and` produces errors.

`_lazy_and` is used internally by the `if`, `repeat`, and `while` statements. For example, the statement '`if b1 and b2 then ...`' is equivalent to '`if _lazy_and(b1, b2) then ...`'.

`_lazy_and()` returns `TRUE`.

Examples

Example 1

This example demonstrates the difference between lazy evaluation and complete evaluation of Boolean conditions. For $x = 0$, the evaluation of $\sin\left(\frac{1}{x}\right)$ leads to an error:

```
x := 0: bool(x <> 0 and sin(1/x) = 0)
```

```
Error: Division by zero. [_invert]
```

With “lazy evaluation”, the expression $\sin\left(\frac{1}{x}\right) = 0$ is not evaluated. This avoids the previous error:

```
_lazy_and(x <> 0, sin(1/x) = 0)
```

```
    FALSE
```

```
bool(x = 0 or sin(1/x) = 0)
```

```
Error: Division by zero. [_invert]
```

```
_lazy_or(x = 0, sin(1/x) = 0)
```

```
    TRUE
```

```
delete x:
```

Example 2

The following statements do no produce an error, because `if` uses lazy evaluation internally:

```
for x in [0, PI, 1/PI] do
  if x = 0 or sin(1/x) = 0 then
     print(x)
  end_if;
```

```
end_for:
```

$$0$$

$$\frac{1}{\pi}$$

```
delete x:
```

Example 3

Both functions can be called without parameters:

```
_lazy_and(), _lazy_or()
```

$$\text{TRUE, FALSE}$$

Parameters

`b1, b2, …`

Boolean expressions

Return Values

TRUE, FALSE, or UNKNOWN.

Overloaded By

b1, b2

See Also

MuPAD Functions

`_lazy_or` | `and` | `bool` | `FALSE` | `if` | `is` | `or` | `repeat` | `TRUE` | `UNKNOWN` | `while`

_lazy_or

"lazy or" of Boolean expressions

Syntax

```
_lazy_or(b1, b2, …)
```

Description

`_lazy_or(b1, b2, ...)` evaluates the Boolean expression `b1 or b2 or ...` by "lazy evaluation".

`_lazy_or(b1, b2, ...)` produces the same result as `bool(b1 or b2 or ...)`, provided the latter call does not produce an error. The difference between these calls is as follows:

`bool(b1 or b2 or ...)` evaluates *all* Boolean expressions before combining them logically via 'or'.

Note that the result is `TRUE` if one of `b1`, `b2` etc. evaluates to `TRUE`. "Lazy evaluation" is based on this fact: `_lazy_or(b1, b2, ...)` evaluates the arguments from left to right. The evaluation is stopped immediately if one argument evaluates to `TRUE`. In this case, `_lazy_or` returns `TRUE`*without* evaluating the remaining Boolean expressions. If none of the expressions `b1`, `b2` etc. evaluates to `TRUE`, then all arguments are evaluated and the corresponding result `FALSE` or `UNKNOWN` is returned.

`_lazy_or` is also called "conditional `or`".

If any of the considered Boolean expressions `b1`, `b2` etc. cannot be evaluated to `TRUE`, `FALSE`, or `UNKNOWN`, then `_lazy_or` produces errors.

`_lazy_or` is used internally by the `if`, `repeat`, and `while` statements.

`_lazy_or()` returns `FALSE`.

Examples

Example 1

This example demonstrates the difference between lazy evaluation and complete evaluation of Boolean conditions. For $x = 0$, the evaluation of $\sin\left(\frac{1}{x}\right)$ leads to an error:

```
x := 0: bool(x <> 0 and sin(1/x) = 0)
```

```
Error: Division by zero. [_invert]
```

With “lazy evaluation”, the expression $\sin\left(\frac{1}{x}\right) = 0$ is not evaluated. This avoids the previous error:

```
_lazy_and(x <> 0, sin(1/x) = 0)
```

```
    FALSE
```

```
bool(x = 0 or sin(1/x) = 0)
```

```
Error: Division by zero. [_invert]
```

```
_lazy_or(x = 0, sin(1/x) = 0)
```

```
    TRUE
```

```
delete x:
```

Example 2

The following statements do no produce an error, because `if` uses lazy evaluation internally:

```
for x in [0, PI, 1/PI] do
  if x = 0 or sin(1/x) = 0 then
     print(x)
  end_if;
```

```
end_for:
```

$$0$$

$$\frac{1}{\pi}$$

```
delete x:
```

Example 3

Both functions can be called without parameters:

```
_lazy_and(), _lazy_or()
```

$$\text{TRUE, FALSE}$$

Parameters

`b1, b2, …`

Boolean expressions

Return Values

TRUE, FALSE, or UNKNOWN.

Overloaded By

b1, b2

See Also

MuPAD Functions

lcm

Least common multiple of polynomials

Syntax

```
lcm(p, q, …)
```

```
lcm(f, g, …)
```

Description

`lcm(p, q, ...)` calculates the least common multiple of any number of polynomials. The coefficient ring of the polynomials may either be the integers or the rational numbers, `Expr`, a residue class ring `IntMod(n)` with a prime number `n`, or a domain.

All polynomials must have the same indeterminates and the same coefficient ring.

Polynomial expressions are converted to polynomials. See `poly` for details. `FAIL` is returned if an argument cannot be converted to a polynomial.

The return value is of the same type as the input polynomials, i.e., either a polynomial of type `DOM_POLY` or a polynomial expression.

`lcm` returns 1 if all arguments are 1 or - 1, or if no argument is given. If at least one of the arguments is 0, then `lcm` returns 0.

Use `ilcm` if all arguments are known to be integers, since it is much faster than `lcm`.

Examples

Example 1

The least common multiple of two polynomial expressions can be computed as follows:

```
lcm(x^3 - y^3, x^2 - y^2);
```

$$(x+y)\,(x^3-y^3)$$

One may also choose polynomials as arguments:

```
p := poly(x^2 - y^2, [x, y], IntMod(17)):
q := poly(x^2 - 2*x*y + y^2, [x, y], IntMod(17)):
lcm(p, q)
```

$$\mathrm{poly}(x^3-x^2\,y-x\,y^2+y^3,\,[x,\,y],\,\mathrm{IntMod}(17))$$

```
delete f, g, p, q:
```

Parameters

`pq, …`

polynomials of type `DOM_POLY`

`fg, …`

polynomial expressions

Return Values

Polynomial, a polynomial expression, or the value `FAIL`.

Overloaded By

f, g, p, q

See Also

MuPAD Functions

lcoeff

Leading coefficient of a polynomial

Syntax

```
lcoeff(p, <order>)
```

```
lcoeff(f, <vars>, <order>)
```

Description

`lcoeff(p)` returns the leading coefficient of the polynomial `p`.

The returned coefficient is "leading" with respect to the lexicographical ordering, unless a different ordering is specified via the argument `order`. Cf. "Example 1" on page 1-1210.

A polynomial expression `f` is first converted to a polynomial with the variables given by `vars`. If no variables are given, they are searched for in `f`. See `poly` about details of the conversion. The result is returned as polynomial expression. `FAIL` is returned if `f` cannot be converted to a polynomial. Cf. "Example 3" on page 1-1211.

The result of `lcoeff` is not fully evaluated. Evaluation can be enforced by the function `eval`. Cf. "Example 2" on page 1-1211.

Examples

Example 1

We demonstrate how various orderings influence the result:

```
p := poly(5*x^4 + 4*x^3*y*z^2 + 3*x^2*y^3*z + 2, [x, y, z]):
lcoeff(p), lcoeff(p, DegreeOrder), lcoeff(p, DegInvLexOrder)
```

```
5, 4, 3
```

The following call uses the reverse lexicographical order on 3 indeterminates:

```
lcoeff(p, Dom::MonomOrdering(RevLex(3)))
```

$$3$$

```
delete p:
```

Example 2

The result of `lcoeff` is not fully evaluated:

```
p := poly(a*x^2 + 27*x, [x]): a := 5:
lcoeff(p), eval(lcoeff(p))
```

$$a, 5$$

```
delete p, a:
```

Example 3

The expression `1/x` may not be regarded as polynomial:

```
lcoeff(1/x)
```

$$\text{FAIL}$$

Parameters

`p`

A polynomial of type `DOM_POLY`

`f`

A polynomial expression

vars

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

order

The term ordering: either `LexOrder`, or `DegreeOrder`, or `DegInvLexOrder`, or a user-defined term ordering of type `Dom::MonomOrdering`. The default is the lexicographical ordering `LexOrder`.

Return Values

Element of the coefficient domain of the polynomial or `FAIL`.

Overloaded By

p

See Also

MuPAD Functions

`coeff` | `collect` | `degree` | `degreevec` | `ground` | `ldegree` | `lmonomial` | `lterm` | `monomials` | `nterms` | `nthcoeff` | `nthmonomial` | `nthterm` | `poly` | `poly2list` | `tcoeff`

ldegree

Lowest degree of the terms in a polynomial

Syntax

```
ldegree(p)

ldegree(p, x)

ldegree(f, <vars>)

ldegree(f, <vars>, x)
```

Description

`ldegree(p)` returns the lowest total degree of the terms of the polynomial `p`.

`ldegree(p, x)` returns the lowest degree of the terms in `p` with respect to the variable `x`.

If the first argument `f` is not element of a polynomial domain, then `ldegree` converts the expression to a polynomial via `poly(f)`. If a list of indeterminates is specified, then the polynomial `poly(f, vars)` is considered.

`ldegree(f, vars, x)` returns 0 if `x` is not an element of `vars`.

The low degree of the zero polynomial is defined as 0.

Examples

Example 1

The lowest total degree of the terms in the following polynomial is computed:

```
ldegree(x^3 + x^2*y^2)
```

```
3
```

The next call regards the expression as a polynomial in `x` with a parameter `y`:

```
ldegree(x^3 + x^2*y^2, x)
```

```
2
```

The next expression is regarded as a bi-variate polynomial in `x` and `z` with coefficients containing the parameter `y`. The total degree with respect to `x` and `z` is computed:

```
ldegree(x^3*z^2 + x^2*y^2*z, [x, z])
```

```
3
```

We compute the low degree with respect to `x`:

```
ldegree(x^3*z^2 + x^2*y^2*z, [x, z], x)
```

```
2
```

A polynomial in `x` and `z` is regarded constant with respect to any other variable, i.e., its corresponding degree is 0:

```
ldegree(poly(x^3*z^2 + x^2*y^2*z, [x, z]), y)
```

```
0
```

Parameters

`p`

A polynomial of type `DOM_POLY`

`f`

A polynomial expression

vars

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

x

An indeterminate

Return Values

Nonnegative number. FAIL is returned if the input cannot be converted to a polynomial.

Overloaded By

f, p

See Also

coeff | degree | degreevec | ground | lcoeff | lmonomial | lterm | monomials | nterms | nthcoeff | nthmonomial | nthterm | poly | poly2list | tcoeff

length

The “length” of a object (heuristic complexity)

Syntax

```
length(object)
```

Description

`length(object)` returns an integer indicating the complexity of the object.

The (heuristic) complexity of an object may be useful in algorithms that need to predict the complexity and time for manipulating objects. E.g., a symbolic Gaussian algorithm for solving linear equations prefers Pivot elements of small complexity.

The length of an object is determined as follows:

- Objects of domain type `DOM_BOOL`, `DOM_DOMAIN`, `DOM_EXEC`, `DOM_FAIL`, `DOM_FLOAT`, `DOM_FUNC_ENV`, `DOM_IDENT`, `DOM_NIL`, `DOM_VAR`, and `DOM_PROC_ENV` are regarded as “atomic”. They have length 1. In particular, the length of identifiers and real floating-point numbers is 1.
- The length of an integer is (a close approximation of) the number of decimal digits, including the sign.
- The length of a string is the number of its characters.
- The length of composite objects such as complex numbers, rational numbers, arithmetical expressions, lists, sets, arrays, hfarrays, tables etc. is the sum of the lengths of the operands plus 1.

`length()` yields 0.

Note: `length` does *not* return the number of elements or entries in sets, lists or tables. Use `nops` instead!

Examples

Example 1

Intuitively, the length measures the complexity of an object:

```
length(1 + x) < length(x^3 + exp(a - b)/ln(45 - t) - 1234*I)
```

```
3 < 30
```

Example 2

We compute the lengths of some simple objects:

```
length(1.2), length(-1234.5), length(123456), length(-123456)
```

```
1, 1, 6, 7
```

```
length(17), length(123), length(17/123)
```

```
2, 3, 6
```

```
length(12), length(123), length(12 + 123*I)
```

```
2, 3, 6
```

```
length(x), length(x^2), length(x^12345)
```

```
1, 3, 7
```

```
length("123"), length("")
```

```
3, 0
```

```
length(x), length(a_long_name)
```

```
1, 1
```

Example 3

The length of an array is the sum of the lengths of all its elements plus 1:

```
A := array(1..2, [x, y]): length(A) = length(x) + length(y) + 1
```

```
3 = 3
```

```
A[1] := 12345: length(A) = length(12345) + length(y) + 1
```

```
7 = 7
```

```
A := hfarray(1..10, [1.0 $ 10]):
length(A) = 10*length(1.0) + 1
```

```
11 = 11
```

```
A := hfarray(1..10, [1.0 + 2.0*I $ 10]):
length(A) = 10*length(1.0 + 2.0*I) + 1
```

```
31 = 31
```

Beware: If only one complex number is contained in an hfarray, then *all* entries are regarded as complex numbers, even if they are real:

```
A := hfarray(1..10, [2.0 $ 9, 2.0 + 3.0*I]):
length(A) = 10*length(2.0 + 3.0*I) + 1
```

```
31 = 31
```

```
delete A:
```

Example 4

The operands of a table are the equations associating indices and entries. The length of each operand is the length of the index plus the length of the corresponding entry plus 1:

```
T[1] := 45: T
```

```
length(T) = length(1 = 45) + 1
```

```
delete T:
```

Parameters

`object`

An arbitrary MuPAD object

Return Values

Nonnegative integer.

MuPAD Functions
nops | op

LEVEL

Substitution depth of identifiers

Description

The environment variable LEVEL determines the maximal substitution depth of identifiers.

Possible values: a positive integer smaller than 2^{31}.

When a MuPAD object is evaluated, identifiers occurring in it are replaced by their values. This happens recursively, i.e., if the values themselves contain identifiers, then these are replaced as well. LEVEL determines the maximal recursion depth of this process.

Technically, evaluation of a MuPAD object works as follows. For a compound object, usually first the operands are evaluated recursively, and then the object itself is evaluated. E.g., if the object is a function call with arguments,the arguments are evaluated first, and then the function is executed with the evaluated arguments.

With respect to the evaluation of identifiers, the *current substitution depth* is recorded internally. Initially, this value is zero. If an identifier is encountered during the recursive evaluation process as described above and the current substitution depth is smaller than LEVEL, then the identifier is replaced by its value, the current substitution depth is increased by one, and evaluation proceeds recursively with the value of the identifier. After the identifier has been evaluated, the current substitution depth is reset to its previous value. If the current substitution depth equals LEVEL, however, then the recursion stops and the identifier remains unevaluated.

Note: The default value of LEVEL at interactive level is 100. However, the default value of LEVEL within a procedure is 1. Then an identifier is only replaced by its value, which is not evaluated recursively.

The value of LEVEL may be changed within a procedure, but it is reset to 1 each time a new procedure is entered. After the procedure returns, LEVEL is reset to its previous value. See “Example 3” on page 1-1223.

Note: The evaluation of local variables and formal parameters of procedures, of type DOM_VAR, is not affected by LEVEL: they are always evaluated with substitution depth 1. This means that a local variable or a formal parameter is replaced by its value when evaluated, but the value is not evaluated further.

See "Example 3" on page 1-1223.

Note: LEVEL does not affect the evaluation of arrays, tables and polynomials.

See "Example 4" on page 1-1224.

The function eval evaluates its argument with substitution depth given by LEVEL, and then evaluates the result again with the same substitution depth.

The call level(object, n) evaluates its argument with substitution depth n, independent of the value of LEVEL.

If, during evaluation, the substitution depth MAXLEVEL, is reached, then the evaluation is terminated with an error. This is a heuristic for recognizing recursive definitions, as in the example delete a; a := a + 1; a. Here, a would be replaced by a + 1 infinitely often. Note that this has no effect if MAXLEVEL is greater than LEVEL. The default value of MAXLEVEL is 100, i.e., it is equal to the default value of LEVEL at interactive level. However, unlike LEVEL, MAXLEVEL is not changed within a procedure, and hence recursive definitions are usually not recognized within procedures. See the help page of MAXLEVEL for examples.

The default value of LEVEL is 100 at interactive level; LEVEL has this value after starting or resetting the system via reset. Within a procedure, the default value is 1. The command delete LEVEL restores the default value.

Examples

Example 1

We demonstrate the effect of various values of LEVEL at interactive level:

```
delete a0, a1, a2, a3, a4, b: b := b + 1:
```

```
a0 := a1: a1 := a2 + 2: a2 := a3 + a4: a3 := a4^2: a4 := 5:

LEVEL := 1: a0, a0 + a2, b;
LEVEL := 2: a0, a0 + a2, b;
LEVEL := 3: a0, a0 + a2, b;
LEVEL := 4: a0, a0 + a2, b;
LEVEL := 5: a0, a0 + a2, b;
LEVEL := 6: a0, a0 + a2, b;
delete LEVEL:
```

$$a1,\ a1 + a3 + a4,\ b + 1$$

$$a2 + 2,\ a4^2 + a2 + 7,\ b + 2$$

$$a3 + a4 + 2,\ a3 + a4 + 32,\ b + 3$$

$$a4^2 + 7,\ a4^2 + 37,\ b + 4$$

$$32,\ 62,\ b + 5$$

$$32,\ 62,\ b + 6$$

Example 2

In the following calls, the identifier `a` is fully evaluated:

```
delete a, b, c:
a := b: b := c: c := 7: a
```

$$7$$

After assigning the value `2` to `LEVEL`, `a` is evaluated only with depth two:

```
LEVEL := 2: a;
delete LEVEL:
```

$$c$$

If we set MAXLEVEL to 2 as well, evaluation of a produces an error, although there is no recursive definition involved:

```
LEVEL := 2: MAXLEVEL := 2: a
```

```
Error: Recursive definition, the maximal evaluation level is reached.
```

```
delete LEVEL, MAXLEVEL:
```

Example 3

This example shows the difference between the evaluation of identifiers and local variables. By default, the value of LEVEL is 1 within a procedure, i.e., a global identifier is replaced by its value when evaluated, but there is no further recursive evaluation. This changes when LEVEL is assigned a bigger value inside the procedure:

```
delete a0, a1, a2, a3:
a0 := a1 + a2:  a1 := a2 + a3:  a2 := a3^2 - 1:  a3 := 5:
p := proc()
       save LEVEL;
     begin
       print(a0, eval(a0)):
       LEVEL := 2:
       print(a0, eval(a0)):
     end_proc:

p()
```

$$a1 + a2,\ a3^2 + a3 + a2 - 1$$

$$a3^2 + a3 + a2 - 1,\ 53$$

In contrast, evaluation of a local variable replaces it by its value, without further evaluation. When eval is applied to an object containing a local variable, then the effect is an evaluation of the value of the local variable with substitution depth LEVEL:

```
q := proc()
       save LEVEL;
       local x;
     begin
```

```
      x := a0:
      print(x, eval(x)):
      LEVEL := 2:
      print(x, eval(x)):
    end_proc:
q()
```

$$a1 + a2,\ a3^2 + a3 + a2 - 1$$

$$a1 + a2,\ a3^2 + 28$$

The command `x:=a0` assigns the value of the identifier `a0`, namely the unevaluated expression `a1+a2`, to the local variable `x`, and `x` is replaced by this value every time it is evaluated, independent of the value of `LEVEL`.

Example 4

`LEVEL` does not affect on evaluation of `polynomials`:

```
delete a, x:  p := poly(a*x, [x]):  a := 2:  x := 3:
p, eval(p);
LEVEL := 1: p, eval(p);
delete LEVEL:
```

$$\mathrm{poly}(a\,x, [x]),\ \mathrm{poly}(a\,x, [x])$$

$$\mathrm{poly}(a\,x, [x]),\ \mathrm{poly}(a\,x, [x])$$

The same is true for `arrays` and `tables`:

```
delete a, b:
A := array(1..2, [a, b]):  T := table(a = b):
a := 1:   b := 2:
A, eval(A), T, eval(T);
LEVEL := 1: A, eval(A), T, eval(T);
delete LEVEL:
```

$$(a\ b),\ (a\ b),\ \overline{a|b},\ \overline{a|b}$$

$$(a\ b), (a\ b), \overline{a|b}, \overline{a|b}$$

More About

- "Level of Evaluation"

level

Evaluate an object with a specified substitution depth

Syntax

```
level(object)
```

```
level(object, n)
```

Description

`level(object, n)` evaluates `object` with substitution depth `n`.

When a MuPAD object is evaluated, identifiers occurring in it are replaced by their values. This happens recursively, i.e., if the values themselves contain identifiers, then these are replaced as well. `level` serves to evaluate an object with a specified recursion depth for this substitution process.

With `level(object, 0)`, `object` is evaluated without replacing any identifier occurring in it by its value. In most cases, but not always, this equivalent to `hold(object)`, and `object` is returned unevaluated. See “Example 3” on page 1-1230.

With `level(object, 1)`, all identifiers occurring in `object` are replaced by their values, but not recursively, and then all function calls in the result of the substitution are executed. This is how objects are evaluated within a procedure by default.

The call `level(object)` is equivalent to `level(object, MAXLEVEL)`, i.e., identifiers occurring in `object` are recursively replaced by their values up to substitution depth `MAXLEVEL - 1`, and an error occurs if the substitution depth `MAXLEVEL` is reached. Usually, this leads to a complete evaluation of `object`. See “Example 1” on page 1-1228.

You can use `level` without a second argument to request the complete evaluation of an object not containing local variables or formal parameters within a procedure. This may be necessary since by default, objects are evaluated with substitution depth `1` within procedures. See “Example 2” on page 1-1229.

Otherwise, it should never be necessary to use `level`.

Note: `level` does not affect the evaluation of local variables and formal parameters, of type `DOM_VAR`, in procedures. When such a local variable occurs in `object`, then it is always replaced by its value, independent of the value of `n`, and the value is not further recursively evaluated. See "Example 2" on page 1-1229.

`level` works by temporarily setting the value of `LEVEL` to `n`, or to 2^{31} - 1 if `n` is not given. However, the value of `MAXLEVEL` remains unchanged. If the substitution depth `MAXLEVEL` is reached, then an error message is returned. See `LEVEL` and `MAXLEVEL` for more information on these environment variables.

In contrast to most other functions, `level` does not flatten its first argument if it is an expression sequence. See "Example 5" on page 1-1231.

`level` does not recursively descend into `arrays`, `tables`, `matrices` or `polynomials`. Use the call `map(object, eval)` to evaluate the entries of an array, a table, a matrix or `mapcoeffs(object, eval)` to evaluate the coefficients of a polynomial. See "Example 4" on page 1-1231 and "Example 6" on page 1-1231.

Further information concerning the evaluation of arrays, tables, matrices or polynomials can be found on the `eval` help page.

The maximal substitution depth of `level` depends on the environment variable `MAXLEVEL`, while the maximum evaluation depth of the function `eval` depends on the environment variable `LEVEL`. See "Example 7" on page 1-1232.

Because `eval` evaluates the result again there is a difference between evaluating an expression with depth *n* by `level` in comparison with `eval`. See "Example 7" on page 1-1232.

As mentioned `level` does not affect the evaluation of local variables and formal parameters, of type `DOM_VAR`, in procedures. Here `eval` behaves different. See "Example 7" on page 1-1232 and the `eval` help page for more information.

The result of `level(hold(x))` is always `x`, because a full evaluation of `hold(x)` leads to `x`. The same does not hold for `eval(hold(x))`, because `eval` first evaluates its argument and then evaluates the result again.

The evaluation of elements of a user-defined domain depends on the implementation of the domain. Usually domain elements remain unevaluated by `level`. If the domain has a slot `"evaluate"`, the corresponding slot routine is called with the domain element

as argument at each evaluation, and hence it is called once when `level` is invoked. Cf. “Example 8” on page 1-1233.

Examples

Example 1

We demonstrate the effect of `level` for various values of the second parameter:

```
delete a0, a1, a2, a3, a4, b: b := b + 1:
a0 := a1: a1 := a2 + 2: a2 := a3 + a4: a3 := a4^2: a4 := 5:

hold(a0), hold(a0 + a2), hold(b);
level(a0, 0), level(a0 + a2, 0), level(b, 0);
level(a0, 1), level(a0 + a2, 1), level(b, 1);
level(a0, 2), level(a0 + a2, 2), level(b, 2);
level(a0, 3), level(a0 + a2, 3), level(b, 3);
level(a0, 4), level(a0 + a2, 4), level(b, 4);
level(a0, 5), level(a0 + a2, 5), level(b, 5);
level(a0, 6), level(a0 + a2, 6), level(b, 6);
```

$$a0,\ a0 + a2,\ b$$

$$a0,\ a0 + a2,\ b$$

$$a1,\ a1 + a3 + a4,\ b + 1$$

$$a2 + 2,\ a4^2 + a2 + 7,\ b + 2$$

$$a3 + a4 + 2,\ a3 + a4 + 32,\ b + 3$$

$$a4^2 + 7,\ a4^2 + 37,\ b + 4$$

$$32,\ 62,\ b + 5$$

$$32, 62, b + 6$$

Evaluating `object` by just typing `object` at the command prompt is equivalent to `level(object, LEVEL)`:

```
LEVEL := 2: MAXLEVEL := 4: a0, a2, b;
level(a0, LEVEL), level(a2, LEVEL), level(b, LEVEL)
```

$$a2 + 2, a4^2 + 5, b + 2$$

$$a2 + 2, a4^2 + 5, b + 2$$

If the second argument is omitted, then this corresponds to a complete evaluation up to substitution depth `MAXLEVEL - 1`:

```
level(a0)
```

```
Error: Recursive definition, the maximal evaluation level is reached.
```

```
level(a2)
```

$$30$$

```
level(b)
```

```
Error: Recursive definition, the maximal evaluation level is reached.
```

```
delete LEVEL, MAXLEVEL:
```

Example 2

We demonstrate the behavior of `level` in procedures:

```
delete a, b, c: a := b: b := c: c := 42:
p := proc()
  local x;
begin
```

```
  x := a:
  print(level(x, 0), x, level(x, 2), level(x)):
  print(level(a, 0), a, level(a, 2), level(a)):
end_proc:
p()
```

b, b, b, b

$a, b, c, 42$

Since `a` is evaluated with the default substitution depth `1`, the assignment `x:=a` sets the value of the local variable `x` to the unevaluated identifier `b`. You can see that any evaluation of `x`, whether `level` is used or not, simply replaces `x` by its value `b`, but no further recursive evaluation happens. In contrast, evaluation of the identifier `a` takes place with the default substitution depth `1`, and `level(a, 2)` evaluates it with substitution depth `2`.

Thus `level` without a second argument can be used to request the complete evaluation of an object not containing any local variables or formal parameters.

Example 3

There are some rare cases where `level(object, 0)` and `hold(object)` behaves different. This is the case if `object` is not an identifier, e.g., a nameless function, because `level` influences only the evaluation of identifiers:

```
level((x -> x^2)(2),0), hold((x -> x^2)(2))
```

$4, (x \to x^2)(2)$

For the same reason `level(object, 0)` and `hold(object)` behave differently if `object` is a local variable of a procedure:

```
f:=proc() local x; begin
  x := 42;
  hold(x), level(x, 0);
end_proc:
f();
delete f:
```

DOM_VAR(0, 2), 42

Example 4

In contrast to lists and sets, evaluation of an array does not evaluate its entries. Thus `level` has no effect for arrays either. The same holds for tables and matrices. Use `map` to evaluate all entries of an array. On the `eval` help page further examples can be found:

```
delete a, b:
L := [a, b]:  A := array(1..2, L):  a := 1:   b := 2:
L, A, level(A), map(A, level), map(A, eval)
```

$[1, 2], (a\ b), (a\ b), (a\ b), (1\ 2)$

Example 5

The first argument of `level` may be an expression sequence, which is not flattened. However, it must be enclosed in parentheses:

```
delete a, b: a := b: b := 3:
level((a, b), 1);
level(a, b, 1)
```

$b, 3$

```
Error: The number of arguments is incorrect. [level]
```

Example 6

`Polynomials` are inert when evaluated, and so `level` has no effect:

```
delete a, x: p := poly(a*x, [x]): a := 2: x := 3:
p, level(p)
```

$\mathrm{poly}(a\,x, [x]), \mathrm{poly}(a\,x, [x])$

Use `mapcoeffs` and the function `eval` to evaluate all coefficients:

```
mapcoeffs(p, eval)
```

$$\mathrm{poly}(2\,x, [x])$$

If you want to substitute a value for the indeterminate `x`, use `evalp`:

```
delete x: evalp(p, x = 3)
```

$$3\,a$$

As you can see, the result of an `evalp` call may contain unevaluated identifiers, and you can evaluate them by an application of `eval`. It is necessary to use `eval` instead of `level` because `level` does not evaluate its result:

```
eval(evalp(p, x = 3))
```

$$6$$

Example 7

The subtle difference between `level` and `eval` is shown. The evaluation depth of `eval` is limited by the environment variable `LEVEL`. `level` pays no attention to `LEVEL`, but rather continues evaluating its argument either as many times as the second argument implies or until it has been evaluated completely:

```
delete a0, a1, a2, a3:
a0 := a1 + a2: a1 := a2 + a3: a2 := a3^2 - 1: a3 := 5:
LEVEL := 1:
eval(a0), level(a0);
```

$$a3^2 + a3 + a2 - 1,\ 53$$

If the evaluation depth exceeds the value of `MAXLEVEL`, an error is raised in both cases:

```
delete LEVEL:
MAXLEVEL := 3:
level(a0);
```

```
Error: Recursive definition, the maximal evaluation level is reached.
```

```
delete LEVEL:
MAXLEVEL := 3:
eval(a0);
delete MAXLEVEL:
```

```
Error: Recursive definition, the maximal evaluation level is reached.
```

It is not the same evaluating an expression `ex` with `eval` and an evaluation depth *n* and by `level((ex, n))`, because `eval` evaluates its result:

```
LEVEL := 2: eval(a0), level(a0, 2);
delete LEVEL:
```

$$53,\ a3^2 + a3 + a2 - 1$$

`level` does not affect the evaluation of local variables of type `DOM_VAR` while `eval` evaluates them with evaluation depth `LEVEL`, which is one in a procedure:

```
p := proc()
  local x;
begin
  x := a0:
  print(eval(x), level(x)):
end_proc:
p()
```

$$a3^2 + a3 + a2 - 1,\ a1 + a2$$

Example 8

The evaluation of an element of a user-defined domain depends on the implementation of the domain. Usually it is not further evaluated:

```
delete a: T := newDomain("T"):
e := new(T, a): a := 1:
e, level(e), map(e, level), val(e)
```

$$\mathrm{new}(T, a),\ \mathrm{new}(T, a),\ \mathrm{new}(T, a),\ \mathrm{new}(T, a)$$

If the slot `"evaluate"` exists, the corresponding slot routine is called for a domain element each time it is evaluated. We implement the routine `T::evaluate`, which simply evaluates all internal operands of its argument, for our domain `T`. The unevaluated domain element can still be accessed via `val`:

```
T::evaluate := x -> new(T, eval(extop(x))):
e, level(e), map(e, level), val(e);
```

$$\mathrm{new}(T, 1), \mathrm{new}(T, 1), \mathrm{new}(T, 1), \mathrm{new}(T, a)$$

```
delete e, T:
```

Parameters

`object`

Any MuPAD object

`n`

A nonnegative integer less than 2^{31}

Return Values

Evaluated object.

More About

- “Level of Evaluation”

lhs

Left hand side of equations, inequalities, relations, intervals, ranges and tables

Syntax

```
lhs(f)
```

Description

`lhs(f)` returns the left hand side of `f`.

The call `lhs(f)` is equivalent to the direct call `op(f, 2)`, of the operand function `op`, if `f` is not a table.

If `t` is a table, the call `lhs(t)` returns the list of keys of the table (left hand side). Note that the i-th value in `rhs(t)` corresponds to the i-th key in `lhs(t)`.

Examples

Example 1

We extract the left and right hand sides of various objects:

```
lhs(x = sin(2)), lhs(3.14 <> PI), lhs(x + 3 < 2*y),
rhs(a <= b), rhs(m-1..n+1)
```

$$x,\ 3.14,\ x+3,\ b,\ n+1$$

The operands of an expression depend on its internal representation. In particular, a "greater" relation is always converted to the corresponding "less" relation:

```
y > -infinity; lhs(y > -infinity)
```

$$-\infty < y$$

$$-\infty$$

```
y >= 4; rhs(y >= 4)
```

$$4 \le y$$

$$y$$

Example 2

We extract the left and right hand sides of the solution of the following system:

```
s := solve({x + y = 1, 2*x - 3*y = 2})
```

$$\{[x = 1, y = 0]\}$$

```
map(op(s), lhs) =  map(op(s), rhs)
```

$$[x, y] = [1, 0]$$

Calls to `lhs` and `rhs` may be easier to read than the equivalent calls to the operand function `op`:

```
map(op(s), op, 1) = map(op(s), op, 2)
```

$$[x, y] = [1, 0]$$

However, direct calls to `op` should be preferred inside procedures for higher efficiency.

```
delete s:
```

Example 3

We extract the keys (left hand side) and values (right hand side) from a table:

```
t := table(1=2, 4=PI, 5=5.6, 19=1/2):
l := lhs(t);
```

$$[1, 4, 5, 19]$$

```
r := rhs(t);
```

$$\left[2, \pi, 5.6, \frac{1}{2}\right]$$

Note that the i-th value corresponds to the i-th key:

```
bool(r = map(lhs(t), e->t[e]))
```

$$\text{TRUE}$$

```
delete t,l,r:
```

Parameters

`f`

An equation `x = y`, an inequality `x <> y`, a relation `x < y`, a relation `x <= y`, an "is element of"-relation `x in y`, an interval `x...y`, a range `x..y` or a table `table(x=y,...)`

Return Values

arithmetical expression.

Overloaded By

f

See Also

MuPAD Functions

`isolate` | `op` | `rhs`

rhs

Right hand side of equations, inequalities, relations, intervals, ranges and tables

Syntax

```
rhs(f)
```

Description

`rhs(f)` returns the right hand side of `f`.

The call `rhs(f)` is equivalent to the direct call `op(f, 2)`, of the operand function `op`, if `f` is not a table.

If `t` is a table, the call `rhs(t)` returns the list of values of the table (right hand side). Note that the i-th value in `rhs(t)` corresponds to the i-th key in `lhs(t)`.

Examples

Example 1

We extract the left and right hand sides of various objects:

```
lhs(x = sin(2)), lhs(3.14 <> PI), lhs(x + 3 < 2*y),
rhs(a <= b), rhs(m-1..n+1)
```

$$x,\ 3.14,\ x+3,\ b,\ n+1$$

The operands of an expression depend on its internal representation. In particular, a “greater” relation is always converted to the corresponding “less” relation:

```
y > -infinity; lhs(y > -infinity)
```

$$-\infty < y$$

$$-\infty$$

```
y >= 4; rhs(y >= 4)
```

$$4 \le y$$

$$y$$

Example 2

We extract the left and right hand sides of the solution of the following system:

```
s := solve({x + y = 1, 2*x - 3*y = 2})
```

$$\{[x = 1, y = 0]\}$$

```
map(op(s), lhs) =  map(op(s), rhs)
```

$$[x, y] = [1, 0]$$

Calls to `lhs` and `rhs` may be easier to read than the equivalent calls to the operand function `op`:

```
map(op(s), op, 1) = map(op(s), op, 2)
```

$$[x, y] = [1, 0]$$

However, direct calls to `op` should be preferred inside procedures for higher efficiency.

```
delete s:
```

Example 3

We extract the keys (left hand side) and values (right hand side) from a table:

```
t := table(1=2, 4=PI, 5=5.6, 19=1/2):
l := lhs(t);
```

$$[1, 4, 5, 19]$$

```
r := rhs(t);
```

$$\left[2, \pi, 5.6, \frac{1}{2}\right]$$

Note that the i-th value corresponds to the i-th key:

```
bool(r = map(lhs(t), e->t[e]))
```

$$\text{TRUE}$$

```
delete t,l,r:
```

Parameters

`f`

An equation `x = y`, an inequality `x <> y`, a relation `x < y`, a relation `x <= y`, an "is element of"-relation `x in y`, an interval `x...y`, a range `x..y` or a table `table(x=y,...)`

Return Values

arithmetical expression.

Li

Integral logarithm

Syntax

```
Li(x)
```

Description

`Li(x)` represents the integral logarithm $\int_0^x \frac{1}{\ln(t)}\,dt$.

Note that in some places in the literature, the notation `li` is used while `Li` is reserved for the offset logarithmic integral $\int_2^x \frac{1}{\ln(t)}\,dt$. The latter may be obtained by entering `Li(x) - Li(2)`.

Further, do not confuse the integral logarithm `Li` with the polylogarithms `polylog` which are displayed on the screen as Li_n (with an index).

If `x` is a floating-point number, then `Li(x)` returns the numerical value of the integral logarithm. The special values $Li(0) = 1$ and $Li(1) = -\infty$ are implemented. For all other arguments, `Li` returns a symbolic function call.

For all complex numbers `z`, the identity `Li(z) = Ei(ln(z))` holds.

The continuation of `Li` to the complex plane is chosen such that the resulting function is analytic with a singularity at 1 and a branch cut on the real axis left to that singularity; such that `conjugate(Li(z)) = Li(conjugate(z))` holds for non-real `z`; and such that `Li` is continuous from above on the negative real axis. Between 0 and 1, `Li` is real and thus neither continuous from above nor from below.

Environment Interactions

When called with a floating-point argument, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

For symbolic arguments, `Li` returns a symbolic function call in most cases:

```
Li(I), Li(0), Li(2), Li(x)
```

$$\mathrm{Li}(\mathrm{i}),\ 0,\ \mathrm{Li}(2),\ \mathrm{Li}(x)$$

Example 2

The integral logarithm of a large real number approximately equals the number of primes below that number:

```
numlib::pi(123456789), Li(123456789.0)
```

$$7027260,\ 7028122.595$$

Riemann suggested to use the approximation $\sum_{i=1}^{\infty} \mathrm{Li}\left(x^{1/i}\right)\ \mathrm{numlib::moebius}(i)$. This often gives a slightly better result, but it suffices to sum this series up to `i=2`:

```
R:= (x, n) -> _plus(float(Li(x^(1/i))) * numlib::moebius(i) $i=1..n):
for j from 1 to 9 do
  print(numlib::pi(10^j), float(Li(10^j)), R(10^j, 2), R(10^j, 50))
end_for:
delete j, R:
```

$$4,\ 6.165599505,\ 3.857761291,\ 5.065725444$$

$$25,\ 30.12614158,\ 23.96054208,\ 21.04138706$$

$$168,\ 177.609658,\ 164.1135957,\ 156.8772935$$

$$1229,\ 1246.137216,\ 1216.011074,\ 1202.985411$$

MuPAD Functions
`Ci` | `Ei` | `int` | `ln` | `Shi` | `Si` | `Ssi`

READPATH

Search path for the command ‘ Read ’

Description

READPATH determines the directories, where the function `read` searches for files.

Possible values: String or a sequence of strings.

The variable READPATH can represent more than one search directory. This variable can be assigned a sequence of strings: each element of the sequence represents a directory in which files are search for.

Note: When concatenated with a file name, the directories given by the path variables must produce valid path names.

Path names are slightly system dependent. You can separate subdirectories with a `/` on all systems. On Windows systems, you may alternatively use a backslash character (\).

Note that in MuPAD, a single backslash inside a character string is created by typing two backslashes. E.g., the MuPAD string representing the path “`C:\Programs\MuPAD`” must be defined by `"C:\\Programs\\MuPAD"`.

The function `pathname` allows to create path names independent of the current operating system.

Examples

Example 1

This example shows how to define a READPATH. More than one path may be given. `read` will look for files to be opened in the directories given by READPATH. The following produces a valid READPATH for UNIX and Linux® systems only, since the path separators are hard coded in the strings:

```
READPATH := "math/lib/", "math/local/"
```

```
"math/lib/", "math/local/"
```

It is good programming style to use platform independent path strings. This can be achieved with the function `pathname`:

```
READPATH := pathname("math", "lib"),
            pathname("math", "local")
```

```
"math/lib/", "math/local/"
```

All path variables can be set to their default values by deleting them:

```
delete READPATH:
```

Example 2

The path variable `WRITEPATH` only accepts one path string:

```
WRITEPATH := "math/lib/", "math/local/"
```

```
Error: The argument is invalid. [WRITEPATH]
```

See Also

MuPAD Functions

`fclose` | `FILEPATH` | `finput` | `fopen` | `fprint` | `fread` | `ftextinput` | `NOTEBOOKFILE` | `NOTEBOOKPATH` | `pathname` | `print` | `protocol` | `read` | `write` | `WRITEPATH`

WRITEPATH

Search path for the command ‘ Write ’ et al.

Description

Possible values: String or a sequence of strings.

`WRITEPATH` determines the directory, into which the functions `fopen`, `fprint`, `write`, and `protocol` write files which are not specified with a full (absolute) pathname. If `WRITEPATH` is not defined, then the files are written into the “working directory”.

Note that the “working directory” depends on the operating system. On Windows systems, it is the folder where MuPAD is installed. On UNIX or Linux systems, the “working directory” is the directory where MuPAD was started.

Note: When concatenated with a file name, the directories given by the path variables must produce valid path names.

Path names are slightly system dependent. You can separate subdirectories with a `/` on all systems. On Windows systems, you may alternatively use a backslash character (\).

Note that in MuPAD, a single backslash inside a character string is created by typing two backslashes. E.g., the MuPAD string representing the path `"math\lib\"` must be defined by `"math\\lib\\"`.

The function `pathname` allows to create path names independent of the current operating system.

Examples

Example 1

This example shows how to define a `READPATH`. More than one path may be given. `read` will look for files to be opened in the directories given by `READPATH`. The following

produces a valid READPATH for UNIX and Linux systems only, since the path separators are hard coded in the strings:

```
READPATH := "math/lib/", "math/local/"
```

```
"math/lib/", "math/local/"
```

It is good programming style to use platform independent path strings. This can be achieved with the function pathname:

```
READPATH := pathname("math", "lib"),
            pathname("math", "local")
```

```
"math/lib/", "math/local/"
```

All path variables can be set to their default values by deleting them:

```
delete READPATH:
```

Example 2

The path variable WRITEPATH only accepts one path string:

```
WRITEPATH := "math/lib/", "math/local/"
```

```
Error: The argument is invalid. [WRITEPATH]
```

MuPAD Functions

fclose | FILEPATH | finput | fopen | fprint | fread | ftextinput | NOTEBOOKFILE | NOTEBOOKPATH | pathname | print | protocol | read | READPATH | write

limit

Compute a limit

Syntax

```
limit(f, x, <Left | Right | Real>, <Intervals>, <NoWarning>)
limit(f, x = x0, <Left | Right | Real>, <Intervals>, <NoWarning>)
```

Description

`limit(f, x = x0, Real)` computes the bidirectional limit $\lim_{x \to x_0} f(x)$, $x - x_0 \in \mathbb{R} \setminus \{0\}$.

`limit(f, x = x0, Left | Right)` computes the one-sided limit $\lim_{x \to x_0^-} f(x)$, $\lim_{x \to x_0^+} f(x)$ respectively.

`limit(f, x = x0, Intervals)` computes a set containing all accumulation points of $\lim_{x \to x_0} f(x)$, $x - x_0 \in \mathbb{R} \setminus \{0\}$.

`limit(f, x = x0, <Real>)` computes the bidirectional limit of `f` when `x` tends to `x0` on the real axis. The limit point `x0` may be omitted, in which case `limit` assumes `x0 = 0`.

If the limit point `x0` is *infinity* or - ∞, then the limit is taken from the left to *infinity* or from the right to - ∞, respectively.

If provably no limit exists, then `undefined` is returned. See “Example 2” on page 1-1250.

`limit(f, x = x0, Left)` returns the limit when `x` tends to `x0` from the left.
`limit(f, x = x0, Right)` returns the limit when `x` tends to `x0` from the right. See “Example 2” on page 1-1250.

If it cannot be determined whether a limit exist, or cannot determine its value, then a symbolic to `limit` is returned. See "Example 3" on page 1-1250. The same holds, in case the option `Intervals` is given, if no information on the set of accumulation points could be obtained.

If `f` contains parameters, then `limit` reacts to properties of those parameters set by `assume`. See "Example 5" on page 1-1251. It may also return a case analysis (`piecewise`) depending on these parameters.

You can compute the limit of a piecewise function. The conditions you use to define a piecewise function can depend on the limit variable. See "Example 6" on page 1-1252.

Internally, `limit` tries to determine the limit from a series expansion of `f` around `x = x0` computed via `series`. It may be necessary to increase the value of the environment variable `ORDER` in order to find the limit.

Note: `limit` works on a symbolic level and should not be called with arguments containing floating point arguments.

Environment Interactions

The function is sensitive to the environment variable `ORDER`, which determines the default number of terms in series computations (see `series`).

Properties of identifiers set by `assume` are taken into account.

Examples

Example 1

The following command computes $\lim_{x \to 0} \frac{1-\cos(x)}{x^2}$:

```
limit((1 - cos(x))/x^2, x)
```

$$\frac{1}{2}$$

A possible definition of e is given by the limit of the sequence $\left(1+\frac{1}{n}\right)^n$ for $n \to \infty$:

```
limit((1 + 1/n)^n, n = infinity)
```

$$e$$

Here is a more complex example:

```
limit(
  (exp(x*exp(-x)/(exp(-x) + exp(-2*x^2/(x+1)))) - exp(x))/x,
  x = infinity
)
```

$$-e^2$$

Example 2

The bidirectional limit of $f(x) = \frac{1}{x}$ for $x \to 0$ does not exist:

```
limit(1/x, x = 0)
```

$$\text{undefined}$$

You can compute the one-sided limits from the left and from the right by passing the options `Left` and `Right`, respectively:

```
limit(1/x, x = 0, Left),
limit(1/x, x = 0, Right)
```

$$-\infty, \infty$$

Example 3

If `limit` is not able to compute the limit, then a symbolic `limit` call is returned:

```
delete f: limit(f(x), x = infinity)
```

$$\lim_{x \to \infty} f(x)$$

Example 4

The function *sin*(*x*) oscillates for $x \to \infty$ between - 1 and 1; no accumulation points outside that interval exist:

```
limit(sin(x), x = infinity, Intervals)
```

$$[-1, 1]$$

In fact, all elements of the interval returned are accumulation points. This need not be the case in general. In the following example, the limit inferior and the limit superior are in fact $-\sqrt{2}$ and $\sqrt{2}$, respectively:

```
limit(sin(1/x) + cos(1/x), x = 0, Intervals)
```

$$[-2, 2]$$

Example 5

`limit` is not able to compute the limit of x^n for $x \to \infty$ without additional information about the parameter n:

```
assume(n in R_):
limit(x^n, x = infinity)
```

$$\begin{cases} 1 & \text{if } n = 0 \\ \infty & \text{if } 0 < n \\ 0 & \text{if } n < 0 \end{cases}$$

We can also `assume` immediately that $n > 0$ and get no case analysis then:

```
assume(n > 0): limit(x^n, x = infinity)
```

$$\infty$$

Similarly, we can assume that $n < 0$:

```
assume(n < 0): limit(x^n, x = infinity)
```

```
    0
```

```
delete n:
```

Example 6

Compute limit of the piecewise function:

```
limit(piecewise([x^3 > 10000*x, 1/x],
                [x^3 <= 10000*x, 10]),
                            x = infinity)
```

```
    0
```

Example 7

Compute limits of the incomplete Gamma function:

```
limit(igamma(z, t), t = infinity);
limit(igamma(z, t), t = 0)
```

```
    0
```

```
    Γ(z)
```

Parameters

f

An arithmetical expression representing a function in x

x

An identifier

x_0

The limit point: an arithmetical expression, possibly `infinity` or `-infinity`

Options

`Left`, `Real`, `Right`

This controls the direction of the limit computation. The option `Real` is the default case and means the bidirectional limit (i.e., there is no need to specify this option).

`Intervals`

Either `TRUE` or `FALSE`, by default `FALSE`. If this option is set to `TRUE`, then a superset of the set of all accumulation points is returned. If the result contains only one element, that element is the limit; on the other hand, if it contains more elements, not all of them are necessarily accumulation points, such that the limit may nevertheless exist.

`NoWarning`

If this option is set to `TRUE`, no warning messages are printed on the screen. Default is `FALSE`.

Return Values

arithmetical expression. If the option `Intervals` was given, the result is a (finite or infinite) set.

Overloaded By

f

Algorithms

`limit` uses an algorithm based on the thesis of Dominik Gruntz: “On Computing Limits in a Symbolic Manipulation System”, Swiss Federal Institute of Technology, Zurich,

Switzerland, 1995. If this fails, it tries to proceed recursively; finally, it attempts a series expansion.

More About

- "If Limits Do Not Exist"

linsolve

Solve a system of linear equations

Syntax

```
linsolve(eqs, options)
```

```
linsolve(eqs, vars, options)
```

Description

`linsolve(eqs, vars)` solves a system of linear equations with respect to the unknowns `vars`.

`linsolve(eqs, < vars , < ShowAssumptions >>)` solves the linear system `eqs` with respect to the unknowns `vars`. If no unknowns are specified, then `linsolve` solves for all indeterminates in `eqs`; the unknowns are determined internally by `indets(eqs,PolyExpr)`.

`linsolve(eqs, vars, Domain = R)` solves the system over the domain `R`, which must be a field, i.e., a domain of category `Cat::Field`.

Note: Note that the return format does not allow to return kernel elements if elements of the domain `R` cannot be multiplied with the symbolic unknowns that span the kernel. In such a case, `linsolve` issues a warning and returns only a special solution. The kernel can be computed via `linalg::matlinsolve` for any field `R`.

Each element of `eqs` must be either an equation or an arithmetical expression `f`, which is considered to be equivalent to the equation `f = 0`.

The unknowns in `vars` need not be identifiers or indexed identifiers; expressions such as `sin(x)`, `f(x)`, or `y^(1/3)` are allowed as well. More generally, any expression accepted as indeterminate by `poly` is a valid unknown.

If the option `ShowAssumptions` is not given and the system is solvable, then the return value is a list of equations of the form `var = value`, where `var` is one of the

unknowns in `vars` and `value` is an arithmetical expression that does not involve any of the unknowns on the left side of a returned equation. Note that if the solution manifold has dimension greater than zero, then some of the unknowns in `vars` will occur on the right side of some returned equations, representing the degrees of freedom. See "Example 2" on page 1-1257.

If `vars` is a list, then the solved equations are returned in the the same order as the unknowns in `vars`.

The function `linsolve` can only solve systems of linear equations. Use `solve` for nonlinear equations.

`linsolve` is an interface function to the procedures `numeric::linsolve` and `linalg::matlinsolve`. For more details see the `numeric::linsolve`, `linalg::matlinsolve` help pages and the background section of this help page.

The system `eqs` is checked for linearity. Since such a test can be expensive, it is recommended to use `numeric::linsolve` or `linalg::matlinsolve` directly when you know that the system is linear.

Note: `linsolve` does *not* react to properties of identifiers set by `assume`.

Examples

Example 1

Equations and variables may be entered as sets or lists:

```
linsolve({x + y = 1, 2*x + y = 3}, {x, y}),
linsolve({x + y = 1, 2*x + y = 3}, [x, y]),
linsolve([x + y = 1, 2*x + y = 3], {x, y}),
linsolve([x + y = 1, 2*x + y = 3], [x, y])
```

$$[x = 2, y = -1], [x = 2, y = -1], [x = 2, y = -1], [x = 2, y = -1]$$

Also expressions may be used as variables:

```
linsolve({cos(x) + sin(x) = 1, cos(x) - sin(x) = 0},
```

```
          {cos(x), sin(x)})
```

$$\left[\cos(x) = \frac{1}{2}, \sin(x) = \frac{1}{2}\right]$$

Furthermore, indexed identifiers are valid, too:

```
linsolve({2*a[1] + 3*a[2] = 5, 7*a[2] + 11*a[3] = 13,
          17*a[3] + 19*a[1] = 23}, {a[1], a[2], a[3]})
```

$$\left[a_1 = \frac{691}{865}, a_2 = \frac{981}{865}, a_3 = \frac{398}{865}\right]$$

Next, we demonstrate the use of option `Domain` and solve a system over the field $\mathbb{Z}_{23}$ with it:

```
linsolve([2*x + y = 1, -x - y = 0],
         Domain = Dom::IntegerMod(23))
```

$$[x = 1 \bmod 23, y = 22 \bmod 23]$$

The following system does not have a solution:

```
linsolve({x + y = 1, 2*x + 2*y = 3}, {x, y})
```

FAIL

Example 2

If the solution of the linear system is not unique, then some of the unknowns are used as "free parameters" spanning the solution space. In the following example the unknown `z` is such a parameter. It does not appear on the left side of the solved equations:

```
eqs := [x + y = z, x + 2*y = 0, 2*x - z = -3*y, y + z = 0]:

vars := [w, x, y, z]:

linsolve(eqs, vars)
```

$$[x = 2\,z,\ y = -z]$$

Example 3

If you use the `Normal` option, `linsolve` calls the `normal` function for final results. This call ensures that `linsolve` returns results in normalized form:

```
linsolve([x + a*y = a + 1, b*x - y = b - 1], {x, y})
```

$$[x = 1,\ y = 1]$$

If you specify `Normal = FALSE`, `linsolve` does not call `normal` for the final result:

```
linsolve([x + a*y = a + 1, b*x - y = b - 1], {x, y}, Normal = FALSE)
```

$$\left[x = a - \frac{a\,(b\,(a+1) - b + 1)}{a\,b + 1} + 1,\ y = \frac{b\,(a+1) - b + 1}{a\,b + 1}\right]$$

Example 4

Solve this system:

```
eqs := [x + a*y = b, x + A*y = b]:
```

```
linsolve(eqs, [x, y])
```

$$[x = b,\ y = 0]$$

Note that more solutions exist for `a = A`. `linsolve` omits these solutions because it makes some additional assumptions on symbolic parameters of this system. To see the assumptions that `linsolve` made while solving this system, use the `ShowAssumptions` option:

```
linsolve(eqs, [x, y], ShowAssumptions)
```

$$[[x = b,\ y = 0],\ [],\ [A - a \neq 0]]$$

```
delete eqs:
```

Parameters

`eqs`

A list or a set of linear equations or arithmetical expressions

`vars`

A list or a set of unknowns to solve for: typically identifiers or indexed identifiers

Options

`Domain`

Option, specified as `Domain = R`

Solve the system over the field `R`, which must be a domain of category `Cat::Field`.

`Normal`

Option, specified as `Normal = b`

Return normalized results. The value `b` must be `TRUE` or `FALSE`. By default, `Normal = TRUE`, meaning that `linsolve` guarantees normalization of the returned results. Normalizing results can be computationally expensive.

By default, `linsolve` calls `normal` before returning results. This option affects the output only if the solution contains variables or exact expressions, such as `sqrt(5)` or `sin(PI/7)`.

To avoid this additional call, specify `Normal = FALSE`. In this case, `linsolve` also can return normalized results, but does not guarantee such normalization. See “Example 3” on page 1-1258.

`ShowAssumptions`

Return information about internal assumptions that `linsolve` made on symbolic parameters in `eqs`.

With this option, `linsolve` returns a list `[Solution, Constraints, Pivots]`. `Solution` is a list of solved equations representing the complete solution manifold of `eqs`, as described above. The lists `Constraints` and `Pivots` contain equations and

inequalities involving symbolic parameters in `eqs`. Internally, these were assumed to hold true when solving the system. See "Example 4" on page 1-1258.

When Gaussian elimination produces an equation `0 = c` with nonzero `c`, `linsolve` without `ShowAssumptions` returns `FAIL`. If `c` involves symbolic parameters, try using `linsolve` with `ShowAssumptions` to solve such systems. If the system is solvable, you will get the solution. In this case, an equation `0 = c` is returned in the `Constraints` list. If the system is not solvable, `linsolve` with `ShowAssumptions` returns `[FAIL, [], []]`.

Return Values

Without the `ShowAssumptions` option, a list of simplified equations is returned. It represents the general solution of the system `eqs`. `FAIL` is returned if the system is not solvable.

With `ShowAssumptions`, a list `[Solution, Constraints, Pivots]` is returned. `Solution` is a list of simplified equations representing the general solution of `eqs`. The lists `Constraints` and `Pivots` contain equations and inequalities involving symbolic parameters in `eqs`. Internally, these were assumed to hold true when solving the system.

Algorithms

If the option `Domain` is not present, the system is solved by calling `numeric::linsolve` with the option `Symbolic`.

If the option `Domain = R` is given and `R` is either `Dom::ExpressionField()` or `Dom::Float`, then `numeric::linsolve` is used to compute the solution of the system. This function uses a sparse representation of the equations.

Otherwise, `eqs` is first converted into a matrix and then solved by `linalg::matlinsolve`. A possibly sparse structure of the input system is not taken into account.

See Also

MuPAD Functions

`isolate` | `linalg::matlinsolve` | `numeric::linsolve` | `solve`

lllint

Compute an LLL-reduced basis of a lattice

Syntax

```
lllint(A)
```

Description

`lllint(A)` applies the LLL algorithm to the list of integer vectors `A`.

`lllint` applies the LLL algorithm to the entries of the list `A`. The entries of `A` must be lists of integers, all of the same length; the number of lists need not equal that length.

The return value of `lllint` has the same form.

The computations are done entirely with integers and are both accurate and quite fast.

Examples

Example 1

We apply the LLL algorithm to a list of two vectors of length three:

```
A := [[1, 2, 3], [4, 5, 6]]:
lllint(A)
```

$$[[2, 1, 0], [-1, 1, 3]]$$

The result is to be interpreted as follows: the two vectors in the output form an LLL-reduced basis of the lattice genberated by the two vectors in the input.

Example 2

If the input vectors are not linearly independent, `FAIL` is returned:

```
lllint([[1, 2], [2, 4]])
```

```
    FAIL
```

Parameters

A

A list of vectors, each being a list of integers

Return Values

list of lists is returned whose entries form an LLL-reduced basis of the lattice spanned by the entries of `A`. If the entries of `A` are not linearly independent, `FAIL` is returned.

lmonomial

Leading monomial of a polynomial

Syntax

```
lmonomial(p, <order>, <Rem>)

lmonomial(f, <vars>, <order>, <Rem>)
```

Description

`lmonomial(p)` returns the leading monomial of the polynomial `p`.

The returned monomial is "leading" with respect to the lexicographical ordering, unless a different ordering is specified via the argument `order`. Cf. "Example 1" on page 1-1263.

The leading monomial of the zero polynomial is the zero polynomial.

A polynomial expression `f` is first converted to a polynomial with the variables given by `vars`. If no variables are given, they are searched for in `f`. See `poly` about details of the conversion. The result is returned as polynomial expression. `FAIL` is returned if `f` cannot be converted to a polynomial. Cf. "Example 4" on page 1-1265.

The result of `lmonomial` is not fully evaluated. It can be evaluated by the functions `mapcoeffs` and `eval`. Cf. "Example 3" on page 1-1264.

Examples

Example 1

We demonstrate how various orderings influence the result:

```
p := poly(5*x^4 + 4*x^3*y*z^2 + 3*x^2*y^3*z + 2, [x, y, z]):
lmonomial(p), lmonomial(p, DegreeOrder),
lmonomial(p, DegInvLexOrder)
```

$$\text{poly}(5\,x^4, [x, y, z]),\ \text{poly}(4\,x^3\,y\,z^2, [x, y, z]),\ \text{poly}(3\,x^2\,y^3\,z, [x, y, z])$$

The following call uses the reverse lexicographical order on 3 indeterminates:

```
lmonomial(p, Dom::MonomOrdering(RevLex(3)))
```

$$\text{poly}(3\,x^2\,y^3\,z, [x, y, z])$$

```
delete p:
```

Example 2

We compute the reductum of a polynomial:

```
p := poly(2*x^2*y + 3*x*y^2 + 6, [x, y]):
q := lmonomial(p, Rem)
```

$$[\text{poly}(2\,x^2\,y, [x, y]),\ \text{poly}(3\,x\,y^2 + 6, [x, y])]$$

The leading monomial and the reductum add up to the polynomial `p`:

```
p = q[1] + q[2]
```

$$\text{poly}(2\,x^2\,y + 3\,x\,y^2 + 6, [x, y]) = \text{poly}(2\,x^2\,y + 3\,x\,y^2 + 6, [x, y])$$

```
delete p, q:
```

Example 3

We demonstrate the evaluation strategy of `lmonomial`:

```
p := poly(6*x^6*y^2 + x^2 + 2, [x]): y := 4: lmonomial(p)
```

$$\text{poly}((6\,y^2)\,x^6, [x])$$

Evaluation is enforced by `eval`:

```
mapcoeffs(%, eval)
```

$$\mathrm{poly}(96\,x^6, [x])$$

```
delete p, y:
```

Example 4

The expression `1/x` may not be regarded as polynomial:

```
lmonomial(1/x)
```

$$\mathrm{FAIL}$$

Parameters

`p`

A polynomial of type `DOM_POLY`

`f`

A polynomial expression

`vars`

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

`order`

The term ordering: either `LexOrder` or `DegreeOrder` or `DegInvLexOrder` or a user-defined term ordering of type `Dom::MonomOrdering`. The default is the lexicographical ordering `LexOrder`.

Options

`Rem`

Makes `lmonomial` return a list with two polynomials: the leading monomial and the reductum. The reductum of a polynomial `p` is `p - lmonomial(p)`.

Return Values

Polynomial of the same type as `p`. An expression is returned if an expression is given as input. `FAIL` is returned if the input cannot be converted to a polynomial. With `Rem`, a list of two polynomials is returned.

Overloaded By

p

ln

Natural logarithm

Syntax

```
ln(x)
```

Description

`ln(x)` represents the natural logarithm of `x`.

Natural logarithm is defined for all complex arguments $x \neq 0$.

`ln` applies the following simplification rules to its arguments:

- If `x` is of the type `Type::Numeric`, then $\ln(e^x) = x + k\,i\,2\,\pi$. Here `k` is an integer, such that the imaginary part of the result lies in the interval $(-\pi, \pi]$. Similar simplifications occur for $(e^y)^a$.
- If `x` is a negative integer or a negative rational, then $ln(x) = i\,\pi + ln(-x)$.
- If `x` is an integer, then $\ln\left(\frac{1}{x}\right) = -\ln(x)$.
- `ln` uses the following special values:

  $ln(1) = 0$, $ln(-1) = i\,\pi$, $\ln(i) = \frac{i\,\pi}{2}$, $\ln(-i) = -\frac{i\,\pi}{2}$, $ln(\infty) = \infty$, $ln(-\infty) = i\,\pi + \infty$.

For exact numeric and symbolic arguments, `ln` typically returns unresolved function calls.

If an argument is a floating-point value, `ln` returns a floating-point result. The imaginary part of the result takes values in the interval $(-\pi, \pi]$. The negative real axis is a branch cut; the imaginary part of the result jumps when crossing the cut. On the negative real axis, the imaginary part is π according to $ln(x) = i\,\pi + ln(-x)$, $x < 0$. See “Example 3” on page 1-1269.

If an argument is a floating-point interval of type DOM_INTERVAL, ln returns the results of type DOM_INTERVAL, properly rounded outwards. This implies that the result contains only real numbers. See “Example 4” on page 1-1269.

Arithmetical rules such as $ln(x\,y) = ln(x) + ln(y)$ are not valid throughout the complex plane. Use properties to mark identifiers as real and apply functions such as expand, combine or simplify to manipulate expressions involving ln. See “Example 5” on page 1-1270.

Environment Interactions

When called with a floating-point argument, the function is sensitive to the environment variable DIGITS which determines the numerical working precision.

Examples

Example 1

Compute the natural logarithms of these numeric and symbolic values:

```
ln(2), ln(-3), ln(1/4), ln(1 + I), ln(x^2)
```

$$\ln(2),\ \ln(3) + \pi\,i,\ -\ln(4),\ \ln(1+i),\ \ln(x^2)$$

For floating-point arguments, ln returns floating-point results:

```
ln(123.4), ln(5.6 + 7.8*I), ln(1.0/10^20)
```

$$4.815431111,\ 2.261980065 + 0.948125538\,i,\ -46.05170186$$

ln applies special simplification rules to its arguments:

```
ln(1), ln(-1), ln(exp(-5)), ln(exp(5 + 27/4*I))
```

$$0,\ \pi\,i,\ -5,\ 5 - 2\,\pi\,i + \frac{27\,i}{4}$$

Example 2

`diff`, `float`, `limit`, `series` and similar functions handle expressions involving `ln`:

```
diff(ln(x^2), x)
```

$$\frac{2}{x}$$

```
float(ln(PI + I))
```

$$1.192985153 + 0.3081690711\,i$$

```
limit(ln(x)/x, x = infinity)
```

$$0$$

```
series(x*ln(sin(x)), x = 0, 10)
```

$$x\ln(x) - \frac{x^3}{6} - \frac{x^5}{180} - \frac{x^7}{2835} - \frac{x^9}{37800} + O(x^{11})$$

Example 3

The negative real axis is a branch cut. The imaginary part of the values returned by `ln` jump when crossing this cut:

```
ln(-2.0), ln(-2.0 + I/10^1000), ln(-2.0 - I/10^1000)
```

$$0.6931471806 + 3.141592654\,i,\ 0.6931471806 + 3.141592654\,i,\ 0.6931471806 - 3.141592654\,i$$

Example 4

The natural logarithm of an interval is the image set of the logarithm function over the set represented by the interval:

```
ln(1 ... 2)
```

```
0.0 ... 0.6931471806
```

```
ln(-1 ... 1)
```

```
RD_NINF ... 0.0 ∪ RD_NINF ... 0.0 + 3.141592653 ... 3.141592654 i
```

This definition extends to unions of intervals:

```
ln(1 ... 2 union 3 ... 4)
```

```
0.0 ... 0.6931471806 ∪ 1.098612288 ... 1.386294362
```

Example 5

`expand`, `combine`, and `simplify` react to properties set via `assume`. The following call does not produce an expanded result, because the arithmetical rule $ln(x\,y) = ln(x) + ln(y)$ does not hold for arbitrary complex x, y:

```
expand(ln(x*y))
```

$$\ln(x\,y)$$

If one of the factors is real and positive, the rule is valid:

```
assume(x > 0): expand(ln(x*y))
```

$$\ln(x) + \ln(y)$$

```
combine(%, ln)
```

$$\ln(x\,y)$$

```
simplify(ln(x^3*y) - ln(x))
```

$$\ln(x^2\,y)$$

For further computations, clear the assumption:

```
unassume(x):
```

Parameters

x

An arithmetical expression

Return Values

Arithmetical expression

Overloaded By

x

MuPAD Functions

`dilog` | `log` | `log10` | `log2` | `polylog`

log

Logarithm to arbitrary base

Syntax

```
log(b, x)
```

```
log(x)
```

Description

Note: The output of syntax `log(b, x)` has been changed and is rewritten in terms of natural logarithms as `ln(x)/ln(b)`.

`log(b, x)` represents the logarithm of `x` to the base `b`.

`log(x)` is an alias for the natural logarithm `ln(x)`.

Mathematically, $\log_b(x)$ coincides with `ln(x)/ln(b)`. When you call `log`, the result is rewritten in terms of the natural logarithms.

The logarithm is defined for all complex arguments $x \neq 0$. The base b, however, is assumed to be real, positive and not equal to 1.

Note: For symbolic `b`, MuPAD applies simplifications based on these assumptions.

`log` applies the following simplification rules to its arguments:

- $\log_b(b^x) = x$ in the following cases:
  - `b` is a symbolic (indexed) identifier and `x` is of type `Type::Real`
  - `b` is numerical and `x` is integer or rational.

  Mathematically, this rule is valid for any real value `x`.

- If `x` is a negative integer or a negative rational, then $\log_b(x) = \frac{i\pi}{\ln(b)} + \frac{\ln(-x)}{\ln(b)}$.
- If x is an integer, then $\log_b\left(\frac{1}{x}\right) = -\frac{\ln(x)}{\ln(b)}$.
- `log` uses the following special values:

$$\log_b(1) = 0,\ \log_b(-1) = \frac{i\pi}{\ln(b)},\ \log_b(i) = \frac{i\pi}{2\ln(b)},\ \log_b(-i) = -\frac{i\pi}{2\ln(b)}.$$

For exact numeric and symbolic arguments, `log` rewrites the function call in terms of the natural logarithm.

If both arguments are numerical and at least one of them is a floating-point number, `log` returns a floating-point result. The imaginary part of the result takes values in the interval $\left(-\frac{\pi}{\ln(b)}, \frac{\pi}{\ln(b)}\right]$ if $b > 1$ and in the interval $\left[\frac{\pi}{\ln(b)}, -\frac{\pi}{\ln(b)}\right)$ if $b < 1$. The negative real axis is a branch cut, the imaginary part of the result jumps when crossing the cut. On the negative real axis, the imaginary part is $\frac{\pi}{\ln(b)}$ according to $\log_b(x) = \frac{i\pi}{\ln(b)} + \frac{\ln(-x)}{\ln(b)}$, $x < 0$. See “Example 3” on page 1-1275.

Arithmetical rules such as $\log_b(x\,y) = \frac{\ln(x)}{\ln(b)} + \frac{\ln(y)}{\ln(b)}$ are not valid throughout the complex plane. Use properties to mark identifiers as real and apply functions such as `expand` or `simplify` to manipulate expressions involving `log`. See “Example 4” on page 1-1275.

Environment Interactions

When called with a floating-point argument, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

When computing a logarithm to an arbitrary base, use identifiers, indexed identifiers, or numbers of type `Type::Positive` to specify the base of a logarithm:

```
log(b, 2), log(b[1], 3), log(2, 5), log(2/3, 4/9), log(0.3, x)
```

$$\frac{\ln(2)}{\ln(b)}, \frac{\ln(3)}{\ln(b_1)}, \frac{\ln(5)}{\ln(2)}, 2, -0.8305835451\,\ln(x)$$

Do not use general arithmetical expressions to specify the base:

```
log(-PI^2, 2)
```

```
Error: The base must be an identifier, an indexed identifier, or a positive real numbe
```

For floating-point arguments, `log` returns floating-point results:

```
log(2, 123.4), log(2.0, 5.6 + 7.8*I), log(10.0, 2/10^20)
```

$$6.947198584,\ 3.263347423 + 1.367856012\,i,\ -19.69897$$

`log` applies special simplification rules to its arguments:

```
log(b, 1), log(b, -1), log(2/3, (4/9)^10), log(b, b^(-5))
```

$$0, \frac{\pi\,i}{\ln(b)}, 20, -5$$

Example 2

`diff`, `float`, `limit`, `series` and similar functions handle expressions involving `log`:

```
diff(log(b, x^2), x)
```

$$\frac{2}{x\,\ln(b)}$$

```
float(log(10, PI + I))
```

$$0.5181068691 + 0.1338361271\,i$$

```
limit(log(10, x)/x, x = infinity)
```

$$0$$

```
series(x*log(x, sin(x)), x = 0)
```

$$x - \frac{x^3}{6\ln(x)} - \frac{x^5}{180\ln(x)} + O(x^7)$$

Example 3

The negative real axis is a branch cut. The imaginary part of the values returned by `log` jump when crossing this cut:

```
log(10, -2.0),
log(10, -2.0 + I/10^1000),
log(10, -2.0 - I/10^1000)
```

$$0.3010299957 + 1.364376354\,i,\ 0.3010299957 + 1.364376354\,i,\ 0.3010299957 - 1.364376354\,i$$

Example 4

`expand` and `simplify` react to properties set via `assume`. The following call does not produce an expanded result, because the arithmetical rule $\log_b(x\,y) = \log_b(x) + \log_b(y)$ does not hold for arbitrary complex x, y:

```
expand(log(10, x*y))
```

$$\frac{\ln(x\,y)}{\ln(10)}$$

If one of the factors is real and positive, the rule is valid:

```
assume(x > 0): expand(log(b, x*y))
```

$$\frac{\ln(x)}{\ln(b)} + \frac{\ln(y)}{\ln(b)}$$

```
simplify(log(b, x^3*y) - log(b, x))
```

$$\frac{\ln(x^2\,y)}{\ln(b)}$$

For further computations, clear the assumption:

```
unassume(x):
```

Parameters

b

An identifier of domain type `DOM_IDENT`, indexed identifier, real numerical value of type `Type::Positive`, or the expression `exp(1)` that leads to the natural logarithm: `log(exp(1), x)` = `ln(x)`.

x

An arithmetical expression

Return Values

Arithmetical expression

Overloaded By

x

MuPAD Functions

`dilog` | `ln` | `log10` | `log2` | `polylog`

log10

Logarithm to base 10

Syntax

```
log10(x)
```

Description

`log10(x)` represents the logarithm of `x` to the base 10.

Mathematically, `log10(x)` is equivalent to `log(10, x)`. See "Example 1" on page 1-1277.

The logarithm to the base 10 is defined for all complex arguments $x \neq 0$.

`log10(x)` rewrites logarithms to the base 10 in terms of the natural logarithm: `log10(x) = ln(x)/ln(10)`. See "Example 2" on page 1-1278.

See the `ln` help page for details.

Environment Interactions

When called with a floating-point argument, this function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Compute these logarithms using `log10`:

```
log10(10), log10(1000), log10(1)
```

```
    1, 3, 0
```

Compute the same logarithms using `log` with 10 as the first argument:

```
log(10, 10), log(10, 1000), log(10, 1)
```

$$1, 3, 0$$

Example 2

`log10` rewrites logarithms in terms of `ln`:

```
log10(x), log10(x^2 - 1)
```

$$\frac{\ln(x)}{\ln(10)}, \frac{\ln(x^2 - 1)}{\ln(10)}$$

Example 3

For floating-point values, `log10` returns floating-point results:

```
log10(123.4), log10(5.6 + 7.8*I), log10(-15.45)
```

$$2.09131516,\ 0.9823654605 + 0.4117656893\ i,\ 1.188928484 + 1.364376354\ i$$

Example 4

For floating-point intervals, `log10` returns results as floating-point intervals:

```
log10(2.0...10.15)
```

$$0.3010299956 \ldots 1.006466043$$

Parameters

x

An arithmetical expression

Return Values

Arithmetical expression

Overloaded By

x

See Also

MuPAD Functions
`dilog` | `ln` | `log` | `log2` | `polylog`

log2

Logarithm to base 2

Syntax

```
log2(x)
```

Description

`log2(x)` represents the logarithm of `x` to the base 2.

Mathematically, `log2(x)` is equivalent to `log(2, x)`. See "Example 1" on page 1-1280.

The logarithm to the base 2 is defined for all complex arguments $x \neq 0$.

`log2(x)` rewrites logarithms to the base 2 in terms of the natural logarithm: `log2(x) = ln(x)/ln(2)`. See "Example 2" on page 1-1281.

See the `ln` help page for details.

Environment Interactions

When called with a floating-point argument, this function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Compute these logarithms using `log2`:

```
log2(2), log2(8), log2(1)
```

```
     1, 3, 0
```

Compute the same logarithms using `log` with 2 as the first argument:

```
log(2, 2), log(2, 8), log(2, 1)
```

$$1,\ 3,\ 0$$

Example 2

`log2` rewrites logarithms in terms of `ln`:

```
log2(x), log2(x^2 - 1)
```

$$\frac{\ln(x)}{\ln(2)},\ \frac{\ln(x^2-1)}{\ln(2)}$$

Example 3

For floating-point values, `log2` returns floating-point results:

```
log2(123.4), log2(5.6 + 7.8*I), log2(-15.45)
```

$$6.947198584,\ 3.263347423 + 1.367856012\,i,\ 3.949534933 + 4.532360142\,i$$

Example 4

For floating-point intervals, `log2` returns results as floating-point intervals:

```
log2(2.0...10.15)
```

$$0.9999999999 \ldots 3.343407823$$

Parameters

x

MuPAD Functions
`dilog` | `ln` | `log` | `log10` | `polylog`

lterm

Leading term of a polynomial

Syntax

```
lterm(p, <order>)
```

```
lterm(f, <vars>, <order>)
```

Description

`lterm(p)` returns the leading term of the polynomial `p`.

The returned term is "leading" with respect to the lexicographical ordering, unless a different ordering is specified via the argument `order`. Cf. "Example 1" on page 1-1283.

The identity `lterm(p)*lcoeff(p) = lmonomial(p)` holds.

The leading term of the zero polynomial is the zero polynomial.

A polynomial expression `f` is first converted to a polynomial with the variables given by `vars`. If no variables are given, they are searched for in `f`. See `poly` about details of the conversion. The result is returned as polynomial expression. `FAIL` is returned if `f` cannot be converted to a polynomial. Cf. "Example 3" on page 1-1284.

Examples

Example 1

We demonstrate how various orderings influence the result:

```
p := poly(5*x^4 + 4*x^3*y*z^2 + 3*x^2*y^3*z + 2, [x, y, z]):
lterm(p), lterm(p, DegreeOrder), lterm(p, DegInvLexOrder)
```

$$\mathrm{poly}(x^4, [x, y, z]), \mathrm{poly}(x^3\, y\, z^2, [x, y, z]), \mathrm{poly}(x^2\, y^3\, z, [x, y, z])$$

The following call uses the reverse lexicographical order on 3 indeterminates:

```
lterm(p, Dom::MonomOrdering(RevLex(3)))
```

$$\mathrm{poly}(x^2\, y^3\, z, [x, y, z])$$

```
delete p:
```

Example 2

The leading monomial is the product of the leading coefficient and the leading term:

```
p := poly(2*x^2*y + 3*x*y^2 + 6, [x, y]):
mapcoeffs(lterm(p),lcoeff(p)) = lmonomial(p)
```

$$\mathrm{poly}(2\, x^2\, y, [x, y]) = \mathrm{poly}(2\, x^2\, y, [x, y])$$

```
delete p:
```

Example 3

The expression `1/x` may not be regarded as polynomial:

```
lterm(1/x)
```

$$\mathrm{FAIL}$$

Parameters

`p`

A polynomial of type `DOM_POLY`

`f`

A polynomial expression

vars

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

order

The term ordering: either `LexOrder` or `DegreeOrder` or `DegInvLexOrder` or a user-defined term ordering of type `Dom::MonomOrdering`. The default is the lexicographical ordering `LexOrder`.

Return Values

Polynomial of the same type as `p`. An expression is returned if an expression is given as input. `FAIL` is returned if the input cannot be converted to a polynomial.

Overloaded By

p

See Also

MuPAD Functions

match

Pattern matching

Syntax

```
match(expression, pattern, options)
```

Description

`match(expression, pattern)` checks whether the syntactical structure of `expression` matches `pattern`. If so, the call returns a set of replacement equations transforming `pattern` into `expression`.

`match` computes a set of replacement equations `S` for the identifiers occurring in `pattern`, such that `subs(pattern, S)` and `expression` coincide up to associativity, commutativity, and neutral elements.

Without additional options, a purely syntactical matching is performed; associativity, commutativity, or neutral elements are taken into account only for the builtin operators `+` and `*`, `and` and `or`, and `union` and `intersect`. In this case, `subs(pattern, S) = expression` holds for the set `S` of replacement equations returned by `match` if the matching was successful. Cf. “Example 1” on page 1-1287. You can declare these properties for operators via the options `Associative`, `Commutative`, and `Null` (see below). Then `subs(pattern, S)` and `expression` need no longer be equal in MuPAD, but they can be transformed into each other by application of the rules implied by the options.

Both `expression` and `pattern` may be arbitrary MuPAD expressions, i.e., both atomic expressions such as numbers, Boolean constants, and identifiers, and compositeexpressions.

Each identifier without a value that occurs in `pattern`, including the 0th operands, is regarded as a *pattern variable*, in the sense that it may be replaced by some expression in order to transform `pattern` into `expression`. Use the option `Const` (see below) to declare identifiers as non-replaceable.

With the exception of some automatic simplifications performed by the MuPAD kernel, distributivity is *not* taken into account. Cf. “Example 5” on page 1-1289.

Note: `match` evaluates its arguments, as usual. This evaluation usually encompasses a certain amount of simplification, which may change the syntactical structure of both `expression` and `pattern` in an unexpected way. Cf. “Example 6” on page 1-1289.

Even if there are several possible matches, `match` returns at most one of them. Cf. “Example 7” on page 1-1290.

If the structure of `expression` does not match `pattern`, `match` returns `FAIL`.

If `expression` and `pattern` are equal, the empty set is returned.

Otherwise, if a match is found and `expression` and `pattern` are different, then a set `S` of replacement equations is returned. For each pattern variable `x` occurring in `pattern` that is not declared constant via the option `Const`, `S` contains exactly one replacement equation of the form `x = y`, and `y` is the expression to be substituted for `x` in order to transform `pattern` into `expression`.

Examples

Example 1

All identifiers of the following pattern are pattern variables:

```
match(f(a, b), f(X, Y))
```

$$\{X = a, Y = b, f = f\}$$

The function `f` is declared non-replaceable:

```
match(f(a, b), f(X, Y), Const = {f})
```

$$\{X = a, Y = b\}$$

Example 2

The following call contains a condition for the pattern variable `X`:

```
match(f(a, b), f(X, Y), Const = {f}, Cond = {X -> not has(X, a)})
```

FAIL

If the function `f` is declared commutative, the expression matches the given pattern—in contrast to the preceding example:

```
match(f(a, b), f(X, Y), Const = {f}, Commutative = {f},
                        Cond = {X -> not has(X, a)})
```

$\{X = b, Y = a\}$

Example 3

The following expression cannot be matched since the number of arguments of the expression and the pattern are different:

```
match(f(a, b, c), f(X, Y), Const = {f})
```

FAIL

We declare the function `f` associative with the option `Associative`. In this case the pattern matches the given expression:

```
match(f(a, b, c), f(X, Y), Const = {f}, Associative = {f})
```

$\{X = a, Y = f(b, c)\}$

Example 4

If, however, the function call in the pattern has more arguments than the corresponding function call in the expression, no match is found:

```
match(f(a, b), f(X, Y, Z), Const = {f}, Associative = {f})
```

FAIL

If the neutral element with respect to the operator `f` is known, additional matches are possible by substituting it for some of the pattern variables:

```
match(f(a, b), f(X, Y, Z), Const = {f},
```

```
Associative = {f}, Null = {f = 0})
```

$$\{X = a, Y = b, Z = 0\}$$

Example 5

Distributivity is *not* taken into account in general:

```
match(a*x + a*y, a*(X + Y), Const = {a})
```

FAIL

The next call finds a match, but not the expected one:

```
match(a*(x + y), X + Y)
```

$$\{Y = 0, X = a\,(x + y)\}$$

The following declarations and conditions do not lead to the expected result, either:

```
match(a*(x + y), a*X + a*Y, Const = {a},
                            Cond = {X -> X <> 0, Y -> Y <> 0})
```

FAIL

Example 6

Automatic simplifications can “destroy” the structure of the given expression or pattern:

```
match(sin(-2), sin(X))
```

FAIL

The result is `FAIL`, because the first argument `sin(-2)` is evaluated and rewritten to `-sin(2)`:

```
sin(-2)
```

$$-\sin(2)$$

You can circumvent this problem by using `hold`:

```
match(hold(sin(-2)), sin(X))
```

$$\{X = -2\}$$

Example 7

`match` returns only one possible match:

```
match(a + b + c + 1, X + Y)
```

$$\{X = a,\ Y = b + c + 1\}$$

To obtain other solutions, use conditions to exclude the solutions that you already have:

```
match(a + b + c + 1, X + Y, Cond = {X <> a})
```

$$\{Y = a,\ X = b + c + 1\}$$

```
match(a + b + c + 1, X + Y, Cond = {X <> a and Y <> a})
```

$$\{X = b,\ Y = a + c + 1\}$$

```
match(a + b + c + 1, X + Y,
      Cond = {X <> a and X <> b and Y <> a})
```

$$\{X = c,\ Y = a + b + 1\}$$

Example 8

Every pattern variable can have at most one condition procedure. Simple conditions can be given by anonymous procedures (`->`):

```
match(a + b, X + Y, Cond = {X -> X <> a, Y -> Y <> b})
```

$$\{X = b,\ Y = a\}$$

Several conditions on a pattern variable can be combined in one procedure:

```
Xcond := proc(X) begin
  if domtype(X) = DOM_IDENT then
    X <> a and X <> b
  else
    X <> 0
  end_if
end_proc:

match(sin(a*b), sin(X*Y), Cond = {Xcond})
```

$$\{Y = 1, X = a\,b\}$$

```
match(sin(a*c), sin(X*Y), Cond = {Xcond})
```

$$\{Y = a, X = c\}$$

```
delete Xcond:
```

Parameters

`expression`

A MuPAD expression

`pattern`

The pattern: a MuPAD expression

`option1, option2, …`

Optional arguments as listed below

Options

`Associative`

Option, specified as `Associative = {f1, f2, …}`

It is assumed that identifiers `f1, f2, ...` represent associative operators and may take an arbitrary number of arguments, i.e., expressions such as `f1(f1(a, b), c)`, `f1(a, f1(b, c))`, and `f1(a, b, c)` are considered equal.

No special rules for associative operators with less than two arguments apply. In particular, `f1(a)` and `a` are *not* considered equal.

`Commutative`

Option, specified as `Commutative = {g1, g2, …}`

It is assumed that the identifiers `g1, g2, ...` represent commutative operators, i.e., expressions such as `g1(a, b)` and `g1(b, a)` are considered equal.

`Cond`

Option, specified as `Cond = {p1, p2, …}`

Only matches satisfying the conditions specified by the procedures `p1, p2, ...` are considered. Each procedure must take exactly one argument and represents a condition on exactly one pattern variable. The name of the procedure's formal argument must be equal to the name of a pattern variable occurring in `pattern` that is not declared constant via the option `Const`. Each condition procedure must return an expression that the function `bool` can evaluate to one of the Boolean values `TRUE` or `FALSE`.

Anonymous procedures created via `->` can be used to express simple conditions. Cf. “Example 8” on page 1-1290.

If a possible match is found, given by a set of replacement equations `S`, then `match` checks whether all specified conditions are satisfied by calling `bool(p1(y1) and p2(y2) and ...)`, where `y1` is the expression to be substituted for the pattern variable `x1` that agrees with the formal argument of the procedure `p1`, etc. If the return value of the call is `TRUE`, then `match` returns `S`. Otherwise, the next possible match is tried.

For example, if `p1` is a procedure with formal argument `x1`, where `x1` is a pattern variable occurring in `pattern`, then a match `S = {..., x1 = y1, ...}` is considered valid only if `bool(p1(y1))` returns `TRUE`.

There can be at most one condition procedure for each pattern variable. If necessary, use the logical operators `and` and `or` as well as the control structures `if` and `case` to combine several conditions for the same pattern variable in one condition procedure. Cf. “Example 8” on page 1-1290.

`Const`

Option, specified as `Const = {c1, c2, …}`

The identifiers `c1, c2, ...` are regarded as constants, i.e., they must match literally and must not be replaced in order to transform `pattern` into `expression`.

`Null`

Option, specified as `Null = {h1 = e1, h2 = e2, …}`

It is assumed that `e1, e2, ...` are the neutral elements with respect to the associative operations `h1, h2, ...` i.e., expressions such as `h1(a, e1)`, `h1(e1, a)`, and `h1(a)` are considered equal.

This declaration affects only operators that are declared associative via the option `Associative`. Moreover, the neutral elements are not implicitly assumed to be constants.

Return Values

Set of replacement equations, or `FAIL`.

See Also

MuPAD Functions

`simplify` | `subs` | `subsex` | `subsop`

map

Apply a function to all operands of an object

Syntax

```
map(object, f, <p1, p2, , …>)

map(object, f, <p1, p2, , …>, <Unsimplified>)
```

Description

`map(object, f)` returns a copy of `object` where each operand `x` has been replaced by `f(x)`. The object itself is not modified by `map` (see “Example 2” on page 1-1296).

The second argument `f` may be a procedure generated via `->` or `proc` (e.g., `x -> x^2 + 1`), a function environment (e.g., `sin`), or a functional expression (e.g., `sin@exp + 2*id`).

If optional arguments are present, then each operand `x` of `object` is replaced by `f(x, p1, p2, ...)` (see “Example 1” on page 1-1295).

It is possible to apply an operator, such as `+` or `*`, to all operands of `object`, by using its functional equivalent, such as `_plus` or `_mult`. See “Example 1” on page 1-1295.

In contrast to `op`, `map` does not decompose rational numbers and complex numbers further. Thus, if the argument is a rational number or a complex number, then `f` is applied to the number itself and not to the numerator and the denominator or the real part and the imaginary part, respectively (see “Example 3” on page 1-1296).

If `object` is a string, then `f` is applied to the string as a whole and not to the individual characters (see “Example 3” on page 1-1296).

If `object` is an expression, then `f` is applied to the operands of `f` as returned by `op` (see “Example 1” on page 1-1295).

If `object` is an expression sequence, then this sequence is not flattened by `map` (see “Example 4” on page 1-1297).

If `object` is a polynomial, then `f` is applied to the polynomial itself and not to all of its coefficients. Use `mapcoeffs` to achieve the latter (see “Example 3” on page 1-1296).

If `object` is a list, a set, an array, or an hfarray, then the function `f` is applied to all elements of the corresponding data structure.

Note: If `object` is a table, the function `f` is applied to all *entries* of the table, not to the indices (see “Example 9” on page 1-1300). The entries are the right sides of the operands of a table.

If `object` is an element of a library domain, then the slot `"map"` of the domain is called and the result is returned. This can be used to extend the functionality of `map` to user-defined domains. If no `"map"` slot exists, then `f` is applied to the object itself (see “Example 10” on page 1-1300).

`map` does not evaluate its result after the replacement; use `eval` to achieve this. Nevertheless, internal simplifications occur after the replacement, unless the option `Unsimplified` is given (see “Example 8” on page 1-1299).

`map` does not descend recursively into an object; the function `f` is only applied to the operands at first level. Use `misc::maprec` for a recursive version of `map` (see “Example 11” on page 1-1301).

The procedure `f` should be deterministic and should not have side effects (such as changing and using global variables). The user does not have any control over the ordering in which the function is applied to the operands of the object!

Examples

Example 1

`map` works for expressions:

```
map(a + b + 3, sin)
```

$$\sin(3) + \sin(a) + \sin(b)$$

The optional arguments of map are passed to the function being mapped:

```
map(a + b + 3, f, x, y)
```

$$f(3, x, y) + f(a, x, y) + f(b, x, y)$$

In the following example, we add 10 to each element of a list:

```
map([1, x, 2, y, 3, z], _plus, 10)
```

$$[11, x + 10, 12, y + 10, 13, z + 10]$$

Example 2

Like most other MuPAD functions, map does not modify its first argument, but returns a modified copy:

```
a := [0, PI/2, PI, 3*PI/2]:
map(a, sin)
```

$$[0, 1, 0, -1]$$

The list a still has its original value:

```
a
```

$$\left[0, \frac{\pi}{2}, \pi, \frac{3\,\pi}{2}\right]$$

Example 3

map does not decompose rational and complex numbers:

```
map(3/4, _plus, 1), map(3 + 4*I, _plus, 1)
```

$$\frac{7}{4}, 4 + 4\,i$$

map does not decompose strings:

```
map("MuPAD", text2expr)
```

MuPAD

`map` does not decompose polynomials:

```
map(poly(x^2 + x + 1), _plus, 1)
```

$$\mathrm{poly}(x^2 + x + 2, [x])$$

Use `mapcoeffs` to apply a function to all coefficients of a polynomial:

```
mapcoeffs(poly(x^2 + x + 1), _plus, 1)
```

$$\mathrm{poly}(2\,x^2 + 2\,x + 2, [x])$$

Example 4

The first argument is not flattened:

```
map((1, 2, 3), _plus, 2)
```

3, 4, 5

Example 5

Sometimes a MuPAD function returns a set or a list of big symbolic expressions containing mathematical constants etc. To get a better intuition about the result, you can map the function `float` to all elements, which often drastically reduces the size of the expressions:

```
solve(x^4 + x^2 + PI, x)
```

$$\left\{\sqrt{-\frac{\sqrt{1-4\,\pi}}{2}-\frac{1}{2}},\ \sqrt{\frac{\sqrt{1-4\,\pi}}{2}-\frac{1}{2}},\ -\sqrt{-\frac{\sqrt{1-4\,\pi}}{2}-\frac{1}{2}},\ -\sqrt{\frac{\sqrt{1-4\,\pi}}{2}-\frac{1}{2}}\right\}$$

```
map(%, float)
```

$$\{0.7976383425 - 1.065939457\,i,\ -0.7976383425 - 1.065939457\,i,\ 0.7976383425 + 1.065939457\,i,\ -0.7976383425 + 1.065939457\,i\}$$

Example 6

In the following example, we delete the values of all global identifiers in the current MuPAD session. The command `anames(All, User)` returns a set with the names of all user-defined global identifiers having a value. Mapping the function `_delete` to this set deletes the values of all these identifiers. Since the return value of `_delete` is the empty sequence `null()`, the result of the call is the empty set:

```
x := 3: y := 5: x + y
```

$$8$$

```
map(anames(All, User), _delete)
```

$$\varnothing$$

```
x + y
```

$$x + y$$

Example 7

It is possible to perform arbitrary actions with all elements of a data structure via a single `map` call. This works by passing an anonymous procedure as the second argument `f`. In the following example, we check that the fact "an integer $n \geq 2$ is prime if and only if $\varphi(n) = n - 1$", where φ denotes Euler's totient function, holds for all integer $2 \leq n < 10$. We do this by comparing the result of `isprime(n)` with the truth value of the equation $\varphi(n) = n - 1$ for all elements `n` of a list containing the integers between `2` and `9`:

```
map([2, 3, 4, 5, 6, 7, 8, 9],
    n -> bool(isprime(n) = bool(numlib::phi(n) = n - 1)))
```

$$[\mathrm{TRUE}, \mathrm{TRUE}, \mathrm{TRUE}, \mathrm{TRUE}, \mathrm{TRUE}, \mathrm{TRUE}, \mathrm{TRUE}, \mathrm{TRUE}]$$

Example 8

The result of `map` is not evaluated further. If desired, you must request evaluation explicitly by `eval`:

```
map(sin(5), float);
eval(%)
```

$$\sin(5.0)$$

$$-0.9589242747$$

```
delete a:
A := array(1..1, [a]);
a := 0:
map(A, sin);
map(A, eval@sin);
delete a:
```

$$(a)$$

$$(\sin(a))$$

$$(0)$$

Nevertheless, certain internal simplifications take place, such as the calculation of arithmetical operations with numerical arguments. The following call replaces `sqrt(2)` and `PI` by floating-point approximations, and the system automatically simplifies the resulting sum:

```
map(sin(5) + cos(5), float)
```

$$-0.6752620892$$

This internal simplification can be avoided by giving the option `Unsimplified`:

```
map(sin(5) + cos(5), float, Unsimplified)
```

$$0.2836621855 - 0.9589242747$$

Example 9

`map` applied to a table changes only the right sides (the entries) of each operand of the table. Assume the entries stand for net prices and the sales tax (16 percent in this case) must be added:

```
T := table(1 = 65, 2 = 28, 3 = 42):
map(T, _mult, 1.16)
```

1	75.4
2	32.48
3	48.72

Example 10

`map` can be overloaded for elements of library domains, if a slot`"map"` is defined. In this example `d` is a domain, its elements contains two integer numbers: an index and an entry (like a table). For nice input and printing elements of this domain the slots`"new"` and `"print"` are defined:

```
d := newDomain("d"):
d::new := () -> new(d, args()):
d::print := object -> _equal(extop(object)):
d(1, 65), d(2, 28), d(3, 42)
```

$$1 = 65,\ 2 = 28,\ 3 = 42$$

Without a slot `"map"` the function `f` will be applied to the domain element itself. Because the domain `d` has no slot `"_mult"`, the result is the symbolic `_mult` call:

```
map(d(1, 65), _mult, 1.16),
type(map(d(1, 65), _mult, 1.16))
```

$$1.16\ (1 = 65),\ \text{"\_mult"}$$

The slot `"map"` of this domain should map the given function only onto the second operand of a domain element. The domain `d` gets a slot `"map"` and `map` works properly (in the authors sense) with elements of this domain:

```
d::map := proc(obj, f)
```

```
          begin
            if args(0) > 2 then
              d(extop(obj, 1), f(extop(obj, 2), args(3..args(0))))
            else
              d(extop(obj, 1), f(extop(obj, 2)))
            end_if
          end_proc:
map(d(1, 65), _mult, 1.16),
map(d(2, 28), _mult, 1.16),
map(d(3, 42), _mult, 1.16)
```

$1 = 75.4,\ 2 = 32.48,\ 3 = 48.72$

Example 11

`map` does not work recursively. Suppose that we want to de-nest a nested list. We use `map` to apply the function `op`, which replaces a list by the sequence of its operands, to all entries of the list `l`. However, this only affects the entries at the first level:

```
l := [1, [2, [3]], [4, [5]]]:
map(l, op)
```

$[1, 2, [3], 4, [5]]$

Use `misc::maprec` to achieve the desired behavior:

```
[misc::maprec(l, {DOM_LIST} = op)]
```

$[1, 2, 3, 4, 5]$

Parameters

`object`

An arbitrary MuPAD object

`f`

A function

p_1, p_2, …

Any MuPAD objects accepted by `f` as additional parameters

Options

`Unsimplified`

The resulting expressions are not further simplified.

Return Values

Copy of `object` with `f` applied to all operands.

Overloaded By

object

mapcoeffs

Apply a function to the coefficients of a polynomial

Syntax

```
mapcoeffs(p, F, <a1, a2, …>)
```

```
mapcoeffs(f, <vars>, F, <a1, a2, …>)
```

Description

`mapcoeffs(p, F, a1, a2, ...)` applies the function `F` to the polynomial `p` by replacing each coefficient `c` in `p` by `F(c, a1, a2, ...)`.

For a polynomial `p` of type `DOM_POLY` generated by `poly`, the function `F` must accept arguments from the coefficient ring of `p` and must produce corresponding results.

A polynomial expression `f` is first converted to a polynomial with the variables given by `vars`. If no variables are given, they are searched for in `f`. See `poly` about details of the conversion. `FAIL` is returned if `f` cannot be converted to a polynomial. After applying the function `F`, the result is converted to an expression.

`mapcoeffs` evaluates its arguments. Note, however, that polynomials of type `DOM_POLY` do not evaluate their coefficients for efficiency reasons. Cf. “Example 4” on page 1-1305.

Examples

Example 1

The function `sin` is mapped to the coefficients of a polynomial expression in the indeterminates `x` and `y`:

```
mapcoeffs(3*x^3 + x^2*y^2 + 2, sin)
```

$$\sin(3)\,x^3 + \sin(1)\,x^2\,y^2 + \sin(2)$$

The following call makes `mapcoeffs` regard this expression as a polynomial in `x`. Consequently, `y` is regarded as a parameter that becomes part of the coefficients:

```
mapcoeffs(3*x^3 + x^2*y^2 + 2, [x], sin)
```

$$\sin(3)\,x^3 + \sin(y^2)\,x^2 + \sin(2)$$

The system function `_plus` adds its arguments. In the following call, it is used to add 2 to all coefficients by providing this shift as an additional argument:

```
mapcoeffs(c1*x^3 + c2*x^2*y^2 + c3, [x, y], _plus, 2)
```

$$(c1+2)\,x^3 + (c2+2)\,x^2\,y^2 + c3 + 2$$

Example 2

The function `sin` is mapped to the coefficients of a polynomial in the indeterminates `x` and `y`:

```
mapcoeffs(poly(3*x^3 + x^2*y^2 + 2, [x, y]), sin)
```

$$\mathrm{poly}(\sin(3)\,x^3 + \sin(1)\,x^2\,y^2 + \sin(2), [x, y])$$

In the following call, the polynomial has the indeterminate `x`. Consequently, `y` is regarded as a parameter that becomes part of the coefficients:

```
mapcoeffs(poly(3*x^3 + x^2*y^2 + 2, [x]), sin)
```

$$\mathrm{poly}(\sin(3)\,x^3 + \sin(y^2)\,x^2 + \sin(2), [x])$$

A user-defined function is mapped to a polynomial:

```
F := (c, a1, a2) -> exp(c + a1 + a2):
mapcoeffs(poly(x^3 + c*x, [x]), F, a1, a2)
```

$$\mathrm{poly}\left(e^{a1+a2+1}\,x^3 + e^{a1+a2+c}\,x, [x]\right)$$

```
delete F:
```

Example 3

We consider a polynomial over the integers modulo 7:

```
p := poly(x^3 + 2*x*y, [x, y], Dom::IntegerMod(7)):
```

A function to be applied to the coefficients must produce values in the coefficient ring of the polynomial:

```
mapcoeffs(p, c -> c^2)
```

$$\text{poly}(x^3 + 4\,x\,y, [x, y], \text{Dom::IntegerMod}(7))$$

The following call maps a function which converts its argument to an integer modulo 3. Such a return value is not a valid coefficient of `p`:

```
mapcoeffs(p, c -> Dom::IntegerMod(3)(expr(c)))
```

FAIL

```
delete p:
```

Example 4

Note that polynomials of type `DOM_POLY` do not evaluate their arguments:

```
delete a, x: p := poly(a*x, [x]): a := PI: p
```

$$\text{poly}(a\,x, [x])$$

Evaluation can be enforced by the function `eval`:

```
mapcoeffs(p, eval)
```

$$\text{poly}(\pi\,x, [x])$$

We map the sine function to the coefficients of `p`. The polynomial does not evaluate its coefficient `sin(a)` to `0`:

```
mapcoeffs(p, sin)
```

$$\mathrm{poly}(\sin(a)\, x, [x])$$

The composition of `sin` and `eval` is mapped to the coefficients of the polynomial:

```
mapcoeffs(p, eval@sin)
```

$$\mathrm{poly}(0, [x])$$

```
delete p, a:
```

Parameters

`p`

A polynomial of type `DOM_POLY`

`F`

A procedure

`a1, a2, …`

Additional parameters for the function `F`

`f`

A polynomial expression

`vars`

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

Return Values

Polynomial of type `DOM_POLY`, or a polynomial expression, or `FAIL`.

Overloaded By

f, p

See Also

MuPAD Functions

`coeff` | `degree` | `degreevec` | `lcoeff` | `ldegree` | `lterm` | `map` | `monomials` | `nterms` | `nthcoeff` | `nthmonomial` | `nthterm` | `poly` | `tcoeff`

maprat

Apply a function to a rationalized expression

Syntax

```
maprat(object, f, options)
```

Description

As a first step, `maprat(object, f, options)` calls `rationalize(object, options)`, which generates a rational expression. The `maprat` function uses the expression returned by `rationalize` as an input to the function `f`. As a second step, `maprat` replaces all variables generated by `rationalize` with the original subexpressions in `object`.

See the `rationalize` help page for details.

Examples

Example 1

Find the greatest common divisor (the `gcd` function) for the following two rationalized expressions. The first argument of `maprat` is a sequence of the two expressions `p`, `q`, which `gcd` takes as two parameters. Note the brackets around the sequence `p, q`:

```
p := (x - sqrt(2))*(x^2 + sqrt(3)*x - 1):
q := (x - sqrt(2))*(x - sqrt(3)):
maprat((p, q), gcd)
```

$$\sqrt{2} - x$$

Example 2

The `maprat` function accepts the same options as the `rationalize` function. For example, find the least common multiple (the `lcm` function) for the following two

rationalized expressions. Use the `FindRelations` option to detect trigonometric relations:

```
p := tan(x)^2 + 1/cos(x)^2:
q := 1/sin(x)^4 + cot(x)^4:
maprat((p, q), lcm, FindRelations = ["sin"])
```

$$\left(\tan\left(\frac{x}{2}\right)^4 + 6\tan\left(\frac{x}{2}\right)^2 + 1\right)\left(\tan\left(\frac{x}{2}\right)^8 + 6\tan\left(\frac{x}{2}\right)^4 + 1\right)$$

Without this option, the result is:

```
p := tan(x)^2 + 1/cos(x)^2:
q := 1/sin(x)^4 + cot(x)^4:
maprat((p, q), lcm)
```

$$(\cot(x)^4\sin(x)^4 + 1)(\cos(x)^2\tan(x)^2 + 1)$$

Free the variables for further calculations:

```
delete p, q:
```

Parameters

`object`

An arithmetical expression, or a sequence, or a set, or a list of such expressions

`f`

A procedure or a functional expression

Options

`ApproximateFloats`

Approximate floating-point numbers by rational numbers.

`FindRelations`

Detect algebraic dependencies for subexpressions of specified types.

`DescendInto`

If the original expression contains subexpressions, rationalize the specified types of subexpressions.

`ReplaceHardToEval`

Replace all subexpressions with limits, sums, and integrals by variables.

`ReplaceTypes`

Replace all subexpressions of the specified types by variables.

`StopOn`

Do not rationalize specified types of subexpressions.

`StopOnConstants`

Do not rationalize numbers, strings, Boolean constants, `NIL`, `FAIL`, PI, EULER, and CATALAN in the set `Type::ConstantIdents`.

Return Values

Object returned by the function `f`.

See Also

MuPAD Functions
`map` | `rationalize`

matrix

Create a matrix or a vector

Syntax

```
matrix(Array)
matrix(List)
matrix(ListOfRows)
matrix(Matrix)
matrix(m, n)
matrix(m, n, Array)
matrix(m, n, List)
matrix(m, n, ListOfRows)
matrix(m, n, Table)
matrix(m, n, [(i1, j1) = value1, (i2, j2) = value2, …])
matrix(m, n, f)
matrix(m, n, List, Diagonal)
matrix(m, n, g, Diagonal)
matrix(m, n, List, Banded)
matrix(1, n, [j1 = value1, j2 = value2, …])
matrix(m, 1, [i1 = value1, i2 = value2, …])
```

Description

`matrix(m, n, [[a11, a12, ...], [a21, a22, ...], ...])` returns an $m \times n$ matrix of the domain type `Dom::Matrix()`.

`matrix(m, n, [a11, a12, ..., a21, a22, ..., a.m.n])` returns an $m \times n$ matrix of the domain type `Dom::Matrix()`.

`matrix(m, 1, [a1, a2, ...])` returns an $m \times 1$ column vector of the domain type `Dom::Matrix()`.

`matrix(1, n, [a1, a2, ...])` returns an $1 \times n$ row vector of the domain type `Dom::Matrix()`.

`matrix` is equivalent to `Dom::Matrix()`.

`matrix` creates matrices and vectors. A column vector is represented as an $m \times 1$ matrix. A row vector is represented as a $1 \times n$ matrix.

Matrix and vector components must be arithmetical expressions (numbers and/or symbolic expressions). If matrices over special component rings are desired, use the domain constructor `Dom::Matrix` with a suitable component ring.

Arithmetical operations with matrices can be performed by using the standard arithmetical operators of MuPAD.

E.g., if `A` and `B` are two matrices defined by `matrix`, then `A + B` computes the sum and `A * B` computes the product of the two matrices, provided that the dimensions are appropriate.

Similarly, `A^(-1)` or `1/A` computes the inverse of a square matrix `A` if it can be inverted. Otherwise, `FAIL` is returned.

Cf. “Example 1” on page 1-1315.

Many system functions accept matrices as input, such as `map`, `subs`, `has`, `zip`, `conjugate`, `norm` or `exp`. Cf. “Example 4” on page 1-1318.

Most of the functions in the MuPAD linear algebra package linalg work with matrices. For example, the command `linalg::gaussJordan(A)` performs Gauss-Jordan elimination on `A` to transform `A` to its reduced row echelon form.

For numerical matrix computations, the corresponding functions of the `numeric` package accept matrices.

Matrix components can be extracted by the usual index operator `[ ]`, which also works for lists, arrays, and tables. The call `A[i, j]` extracts the matrix component in the i-th row and the j-th column.

Assignments to matrix components are performed similarly. The call `A[i, j] := c` replaces the matrix component in the *i*-th row and the *j*-th column of *A* by `c`.

If one of the indices is not in its valid range, an error message is issued.

The index operator also extracts submatrices. The call `A[r1..r2, c1..c2]` creates the submatrix of *A* comprising the rows with the indices r_1, $r_1 + 1$, …, r_2 and the columns with the indices c_1, $c_1 + 1$, …, c_2 of *A*.

See “Example 3” on page 1-1317 and “Example 5” on page 1-1320.

`matrix(Array)` or `matrix(Matrix)` create a new matrix with the same dimension and the components of `Array` or `Matrix`, respectively. The array must not contain any uninitialized entries. If `Array` is one-dimensional, the result is a column vector. Cf. “Example 8” on page 1-1324.

`matrix(List)` creates an $m \times 1$ column vector with components taken from the non-empty list, where *m* is the number of entries of `List`. Cf. “Example 5” on page 1-1320.

`matrix(ListOfRows)` creates an $m \times n$ matrix with components taken from the nested list `ListOfRows`, where *m* is the number of inner lists of `ListOfRows`, and *n* is the maximal number of elements of an inner list. Each inner list corresponds to a row of the matrix. Both *m* and *n* must be non-zero.

If a row has less than *n* entries, the remaining entries in the corresponding row of the matrix are regarded as zero. Cf. “Example 7” on page 1-1322.

The call `matrix(m, n)` returns the $m \times n$ zero matrix.

The call `matrix(m, n, Array)` creates an $m \times n$ matrix with components taken from `Array`, which must be an array or an hfarray. `Array` must have *m n* operands. The first *m* operands define the first row, the next *m* operands define the second row, etc. The formatting of the array is irrelevant. E.g., any array with 6 elements can be used to create matrices of dimension 1×6, or 2×3, or 3×2, or 6×1.

`matrix(m, n, List)` creates an $m \times n$ matrix with components taken row after row from the non-empty list. The list must contain *m n* entries. Cf. “Example 7” on page 1-1322.

`matrix(m, n, ListOfRows)` creates an $m \times n$ matrix with components taken from the list `ListOfRows`.

If $m \geq 2$ and $n \geq 2$, then `ListOfRows` must consist of at most `m` inner lists, each having at most `n` entries. The inner lists correspond to the rows of the returned matrix.

If a row has less than `n` entries, the remaining components of the corresponding row of the matrix are regarded as zero. If there are less than `m` rows, the remaining lower rows of the matrix are filled with zeroes. Cf. "Example 7" on page 1-1322.

`matrix(m,n,Table)` creates an $m \times n$ matrix with components taken from the table `Table`. The table entries `Table[i,j]` with positive integer values of `i` and `j` define the corresponding entries of the matrix. Zero entries need not be specified in the table. This way, sparse table input can be used to create the matrix.

For large sparse matrices, the fastest way of creation is the generation of an empty table that is filled by indexed assignments and then passed to `matrix`. Alternatively, one may first create an empty sparse matrix via `matrix(m, n)` and then fill in the non-zero entries via indexed assignments. Note that the indexed assignment to a matrix is somewhat slower than the indexed assignment to a table.

`matrix(m, n, [(i1, j1) = value1, (i2, j2) = value2, ...])` is a further way to create a matrix specifying only the non-zero entries `A[i1, j1] = value1`, `A[i2, j2] = value2` etc. The ordering of the entries in the input list is irrelevant.

`matrix(m, n, f)` returns the matrix whose (i, j)-th component is the return value of the function call `f(i,j)`. The row index i runs from 1 to m and the column index j from 1 to n. Cf. "Example 9" on page 1-1325.

`matrix(m, 1, Array)` returns the $m \times 1$ column vector with components taken from `Array`. The `array` or `hfarray` `Array` must have `m` entries.

`matrix(m, 1, List)` returns the $m \times 1$ column vector with components taken from `List`. The list `List` must have no more than `m` entries. If there are fewer entries, the remaining vector components are regarded as zero. Cf. "Example 5" on page 1-1320.

`matrix(m, 1, Table)` returns the $m \times 1$ column vector with components taken from `Table`. The table `Table` must have no more than `m` entries. If there are fewer entries, the remaining vector components are regarded as zero. Cf. "Example 6" on page 1-1322.

`matrix(m, 1, [i1 = value1, i2 = value2, ...])` provides a way to create a sparse column vector specifying only the non-zero entries `A[i1] = value1`, `A[i2] = value2` etc. The ordering of the entries in the input list is irrelevant.

`matrix(1, n, Array)` returns the $1 \times n$ row vector with components taken from `Array`. The `array` or `hfarray` `Array` must have `n` entries.

`matrix(1, n, List)` returns the $1 \times n$ row vector with components taken from `List`. The list `List` must not have more than `n` entries. If there are fewer entries, the remaining vector components are regarded as zero. Cf. “Example 5” on page 1-1320.

`matrix(1, n, Table)` returns the $1 \times n$ row vector with components taken from `Table`. The table `Table` must not have more than `n` entries. If there are fewer entries, the remaining vector components are regarded as zero. Cf. “Example 6” on page 1-1322.

`matrix(1, n, [j1 = value1, j2 = value2, ...])` provides a way to create a sparse row vector specifying only the non-zero entries `A[j1] = value1`, `A[j2] = value2` etc. The ordering of the entries in the input list is irrelevant.

Note: The number of rows and columns, respectively, of a matrix must be less than 2^{31}.

Note: The components of a matrix are no longer evaluated after the creation of the matrix, i.e., if they contain free identifiers they will not be replaced by their values.

Examples

Example 1

We create a 2×2 matrix by passing a list of two rows to `matrix`, where each row is a list of two elements:

```
A := matrix([[1, 5], [2, 3]])
```

$$\begin{pmatrix} 1 & 5 \\ 2 & 3 \end{pmatrix}$$

In the same way, we generate the following 2 ×3 matrix:

```
B := matrix([[-1, 5/2, 3], [1/3, 0, 2/5]])
```

$$\begin{pmatrix} -1 & \frac{5}{2} & 3 \\ \frac{1}{3} & 0 & \frac{2}{5} \end{pmatrix}$$

We can do matrix arithmetic using the standard arithmetical operators of MuPAD. For example, the matrix product $A\,B$, the fourth power of A, and the scalar multiplication of A by $\frac{1}{3}$ are given by:

```
A * B, A^4, 1/3 * A
```

$$\begin{pmatrix} \frac{2}{3} & \frac{5}{2} & 5 \\ -1 & 5 & \frac{36}{5} \end{pmatrix} \cdot \begin{pmatrix} 281 & 600 \\ 240 & 521 \end{pmatrix} \cdot \begin{pmatrix} \frac{1}{3} & \frac{5}{3} \\ \frac{2}{3} & 1 \end{pmatrix}$$

Since the dimensions of the matrices A and B differ, the sum of A and B is not defined and MuPAD returns an error message:

```
A + B
```

```
Error: The dimensions do not match. [(Dom::Matrix(Dom::ExpressionField()))::_plus]
```

To compute the inverse of A, enter:

```
1/A
```

$$\begin{pmatrix} -\frac{3}{7} & \frac{5}{7} \\ \frac{2}{7} & -\frac{1}{7} \end{pmatrix}$$

If a matrix is not invertible, the result of this operation is `FAIL`:

```
C := matrix([[2, 0], [0, 0]])
```

$$\begin{pmatrix} 2 & 0 \\ 0 & 0 \end{pmatrix}$$

```
C^(-1)
```

FAIL

```
delete A, B, C:
```

Example 2

In addition to standard matrix arithmetic, the library linalg offers numerous functions handling matrices. For example, the function `linalg::rank` determines the rank of a matrix:

```
A := matrix([[1, 5], [2, 3]])
```

$$\begin{pmatrix} 1 & 5 \\ 2 & 3 \end{pmatrix}$$

```
linalg::rank(A)
```

$$2$$

The function `linalg::eigenvectors` computes the eigenvalues and the eigenvectors of A:

```
linalg::eigenvectors(A)
```

$$\left[\left[2-\sqrt{11},\ 1,\ \left[\begin{pmatrix} -\frac{\sqrt{11}}{2}-\frac{1}{2} \\ 1 \end{pmatrix}\right]\right],\ \left[\sqrt{11}+2,\ 1,\ \left[\begin{pmatrix} \frac{\sqrt{11}}{2}-\frac{1}{2} \\ 1 \end{pmatrix}\right]\right]\right]$$

To determine the dimension of a matrix, use the function `linalg::matdim`:

```
linalg::matdim(A)
```

$$[2,\ 2]$$

The result is a list of two positive integers, the row and column number of the matrix.

Use `info(linalg)` to obtain a list of available functions, or enter `?linalg` for details about this library.

```
delete A:
```

Example 3

Matrix entries can be accessed with the index operator `[ ]`:

```
A := matrix([[1, 2, 3, 4], [2, 0, 4, 1], [-1, 0, 5, 2]])
```

$$\begin{pmatrix} 1 & 2 & 3 & 4 \\ 2 & 0 & 4 & 1 \\ -1 & 0 & 5 & 2 \end{pmatrix}$$

```
A[2, 1] * A[1, 2] - A[3, 1] * A[1, 3]
```

$$7$$

You can redefine a matrix entry by assigning a value to it:

```
A[1, 2] := a^2: A
```

$$\begin{pmatrix} 1 & a^2 & 3 & 4 \\ 2 & 0 & 4 & 1 \\ -1 & 0 & 5 & 2 \end{pmatrix}$$

The index operator can also be used to extract submatrices. The following call creates a copy of the submatrix of *A* comprising the second and the third row and the first three columns of *A*:

```
A[2..3, 1..3]
```

$$\begin{pmatrix} 2 & 0 & 4 \\ -1 & 0 & 5 \end{pmatrix}$$

The index operator does *not* allow to replace a submatrix of a given matrix by another matrix. Use `linalg::substitute` to achieve this.

```
delete A:
```

Example 4

Some system functions can be applied to matrices. For example, if you have a matrix with symbolic entries and want to have all entries in expanded form, simply apply the function `expand`:

```
delete a, b:
```

```
A := matrix([
  [(a - b)^2, a^2 + b^2],
  [a^2 + b^2, (a - b)*(a + b)]
])
```

$$\begin{pmatrix} (a-b)^2 & a^2+b^2 \\ a^2+b^2 & (a+b)\,(a-b) \end{pmatrix}$$

```
expand(A)
```

$$\begin{pmatrix} a^2-2\,a\,b+b^2 & a^2+b^2 \\ a^2+b^2 & a^2-b^2 \end{pmatrix}$$

You can differentiate all matrix components with respect to some indeterminate:

```
diff(A, a)
```

$$\begin{pmatrix} 2\,a-2\,b & 2\,a \\ 2\,a & 2\,a \end{pmatrix}$$

The following command evaluates all matrix components at a given point:

```
subs(A, a = 1, b = -1)
```

$$\begin{pmatrix} 4 & 2 \\ 2 & 0 \end{pmatrix}$$

Note that the function `subs` does not evaluate the result of the substitution. For example, we define the following matrix:

```
A := matrix([[sin(x), x], [x, cos(x)]])
```

$$\begin{pmatrix} \sin(x) & x \\ x & \cos(x) \end{pmatrix}$$

Then we substitute $x = 0$ in each matrix component:

```
B := subs(A, x = 0)
```

$$\begin{pmatrix} \sin(0) & 0 \\ 0 & \cos(0) \end{pmatrix}$$

You see that the matrix components are not evaluated completely. For example, if you enter `sin(0)` directly, it evaluates to zero.

The function `eval` can be used to evaluate the result of the function `subs`. However, `eval` does not operate on matrices directly, and you must use the function `map` to apply the function `eval` to each matrix component:

```
map(B, eval)
```

$$\begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$$

The function `zip` can be applied to matrices. The following call combines two matrices A and B by dividing each component of A by the corresponding component of B:

```
A := matrix([[4, 2], [9, 3]]):
B := matrix([[2, 1], [3, -1]]):
A, B, zip(A, B, `/`)
```

$$\begin{pmatrix} 4 & 2 \\ 9 & 3 \end{pmatrix}, \begin{pmatrix} 2 & 1 \\ 3 & -1 \end{pmatrix}, \begin{pmatrix} 2 & 2 \\ 3 & -3 \end{pmatrix}$$

```
delete A, B:
```

Example 5

A vector is either an $m \times 1$ matrix (a column vector) or a $1 \times n$ matrix (a row vector). To create a vector with `matrix`, pass the dimension of the vector and a list of vector components as argument to `matrix`:

```
row_vector := matrix(1, 3, [1, 2, 3]);
column_vector := matrix(3, 1, [1, 2, 3])
```

$$\begin{pmatrix} 1 & 2 & 3 \end{pmatrix}$$

$$\begin{pmatrix} 1 \\ 2 \\ 3 \end{pmatrix}$$

If the only argument of `matrix` is a non-nested list or a one-dimensional array, the result is a column vector:

```
matrix([1, 2, 3])
```

$$\begin{pmatrix} 1 \\ 2 \\ 3 \end{pmatrix}$$

For a row vector `r`, the calls `r[1, i]` and `r[i]` both return the *i*-th vector component of `r`. Similarly, for a column vector `c`, the calls `c[i, 1]` and `c[i]` both return the *i*-th vector component of `c`.

We extract the second component of the vectors defined above:

```
row_vector[2] = row_vector[1, 2],
column_vector[2] = column_vector[2, 1]
```

$$2 = 2,\ 2 = 2$$

Use the function `linalg::vecdim` to determine the number of components of a vector:

```
linalg::vecdim(row_vector), linalg::vecdim(column_vector)
```

$$3,\ 3$$

The number of components of a vector can also be determined directly by the call `nops(vector)`.

The dimension of a vector can be determined as described above in the case of matrices:

```
linalg::matdim(row_vector),
linalg::matdim(column_vector)
```

$$[1,\ 3],\ [3,\ 1]$$

See the linalg package for functions working with vectors, and the help page of `norm` for computing vector norms.

```
delete row_vector, column_vector:
```

Example 6

A vector is either an $m \times 1$ matrix (a column vector) or a $1 \times n$ matrix (a row vector). To create a vector with `matrix`, one may also pass the dimension of the vector and a table of vector components as argument to `matrix`:

```
delete v1, v2, t1, t2:
t1 := table():
t1[1,1] := 1:
t1[1,2] := 2:
t1[1,3] := 3:
v1 := matrix(1, 3, t1);
```

$$\begin{pmatrix} 1 & 2 & 3 \end{pmatrix}$$

```
t2 := table():
t2[1,1] := 1:
t2[2,1] := 2:
t2[3,1] := 3:
v2 := matrix(3, 1, t2);
```

$$\begin{pmatrix} 1 \\ 2 \\ 3 \end{pmatrix}$$

All functions applied to the vectors in the previous example (see above) can can also be used on these vectors.

```
delete t1, t2, v1, v2:
```

Example 7

In the following examples, we illustrate various calls of `matrix` as described above. We start by passing a nested list to `matrix`, where each inner list corresponds to a row of the matrix:

```
matrix([[1, 2], [2]])
```

$$\begin{pmatrix} 1 & 2 \\ 2 & 0 \end{pmatrix}$$

The number of rows of the created matrix is the number of inner lists, namely $m = 2$. The number of columns is determined by the maximal number of entries of an inner list. In the example above, the first list is the longest one, and hence $n = 2$. The second list has only one element and, therefore, the second entry in the second row of the returned matrix was set to zero.

In the following call, we use the same nested list, but in addition pass two dimension parameters to create a 4×4 matrix:

```
matrix(4, 4, [[1, 2], [2]])
```

$$\begin{pmatrix} 1 & 2 & 0 & 0 \\ 2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

In this case, the dimension of the matrix is given by the dimension parameters. As before, missing entries in an inner list correspond to zero, and in addition missing rows are treated as zero rows.

If the dimension $m \times n$ of the matrix is stated explicitly, the entries may also be specified by a plain list with $m\,n$ elements. The matrix is filled with these elements row by row:

```
matrix(2, 3, [1, 2, 3, 4, 5, 6])
```

$$\begin{pmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{pmatrix}$$

```
matrix(3, 2, [1, 2, 3, 4, 5, 6])
```

$$\begin{pmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{pmatrix}$$

Example 8

A one- or two-dimensional array of arithmetical expressions, such as:

```
a := array(1..3, 2..4,
  [[1, 1/3, 0], [-2, 3/5, 1/2], [-3/2, 0, -1]]
)
```

$$\begin{pmatrix} 1 & \frac{1}{3} & 0 \\ -2 & \frac{3}{5} & \frac{1}{2} \\ -\frac{3}{2} & 0 & -1 \end{pmatrix}$$

can be converted into a matrix as follows:

```
A := matrix(a)
```

$$\begin{pmatrix} 1 & \frac{1}{3} & 0 \\ -2 & \frac{3}{5} & \frac{1}{2} \\ -\frac{3}{2} & 0 & -1 \end{pmatrix}$$

Arrays serve, for example, as an efficient structured data type for programming. However, arrays do not have any algebraic meaning, and no mathematical operations are defined for them. If you convert an array into a matrix, you can use the full functionality defined for matrices as described above. For example, let us compute the matrix $2A - A^2$ and the Frobenius norm of A:

```
2*A - A^2, norm(A, Frobenius)
```

$$\begin{pmatrix} \frac{5}{3} & \frac{2}{15} & -\frac{1}{6} \\ -\frac{1}{20} & \frac{113}{75} & \frac{6}{5} \\ -3 & \frac{1}{2} & -3 \end{pmatrix}, \frac{\sqrt{2}\,\sqrt{4037}}{30}$$

Note that an array may contain uninitialized entries:

```
b := array(1..4): b[1] := 2: b[4] := 0: b
```

$$(2\ \text{NIL}\ \text{NIL}\ 0)$$

`matrix` cannot handle arrays that have uninitialized entries, and responds with an error message:

```
matrix(b)
```

```
Error: Cannot define a matrix over 'Dom::ExpressionField()'. [(Dom::Matrix(Dom::Express
```

We initialize the remaining entries of the array `b` and convert it into a matrix, or more precisely, into a column vector:

```
b[2] := 0: b[3] := -1: matrix(b)
```

$$\begin{pmatrix} 2 \\ 0 \\ -1 \\ 0 \end{pmatrix}$$

```
delete a, A, b:
```

Example 9

We show how to create a matrix whose components are defined by a function of the row and the column index. The entry in the i-th row and the j-th column of a Hilbert matrix (see also `linalg::hilbert`) is $\frac{1}{(i+j-1)}$. Thus the following command creates a 2×2 Hilbert matrix:

```
matrix(2, 2, (i, j) -> 1/(i + j - 1))
```

$$\begin{pmatrix} 1 & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{3} \end{pmatrix}$$

The following two calls produce different results. In the first call, `x` is regarded as an unknown function, while it is a constant in the second call:

```
delete x:
matrix(2, 2, x), matrix(2, 2, (i, j) -> x)
```

$$\begin{pmatrix} x(1,1) & x(1,2) \\ x(2,1) & x(2,2) \end{pmatrix}, \begin{pmatrix} x & x \\ x & x \end{pmatrix}$$

Example 10

Diagonal matrices can be created by passing the option `Diagonal` and a list of diagonal entries:

```
matrix(3, 4, [1, 2, 3], Diagonal)
```

$$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 \\ 0 & 0 & 3 & 0 \end{pmatrix}$$

One can generate the 3×3 identity matrix as follows:

```
matrix::identity(3)
```

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

Here are alternative ways to create this matrix:

```
matrix(3, 3, [1 $ 3], Diagonal)
```

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

Equivalently, you can use a function of one argument:

```
matrix(3, 3, i -> 1, Diagonal)
```

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

Since the integer 1 also represents a constant function, the following shorter call creates the same matrix:

```
matrix(3, 3, 1, Diagonal)
```

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

To demonstrate the use of tables for creating (sparse) matrices we can also create the identity matrix above by the lines:

```
t := table(): t[1, 1] := 1: t[2, 2] := 1: t[3, 3] := 1:
matrix(3, 3, t)
```

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

```
delete t:
```

Example 11

Banded Toeplitz matrices can be created with the option `Banded`. The following command creates a tri-diagonal matrix with constant bands:

```
matrix(4, 4, [-1, 2, -1], Banded)
```

$$\begin{pmatrix} 2 & -1 & 0 & 0 \\ -1 & 2 & -1 & 0 \\ 0 & -1 & 2 & -1 \\ 0 & 0 & -1 & 2 \end{pmatrix}$$

Example 12

Matrices can also be created by using a `table`:

```
t := table():
```

```
t[1, 2] := 12:
t[3, 1] := 31:
t[3, 2] := 32:
t
```

1, 2	12
3, 1	31
3, 2	32

The missing table entries correspond to empty matrix entries:

```
A := matrix(4, 6, t)
```

$$\begin{pmatrix} 0 & 12 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 31 & 32 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

By using tables, one can easily create large (sparse) matrices without being forced to define all zero entries of the matrix. Note that this is a great advantage over using arrays where every component has to be initialized before.

```
delete t, A:
```

Example 13

The method `"doprint"` of `Dom::Matrix()` prints only the non-zero components of a sparse matrix:

```
A := matrix(4, 6):
A[1, 2]:= 12: A[3, 1]:= 31: A[3, 2]:= 32:
print(A::dom::doprint(A)):
```

$$\begin{pmatrix} 0 & 12 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 31 & 32 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

```
delete A:
```

Parameters

`Array`

A one- or two-dimensional array or hfarray

`List`

A list of arithmetical expressions

`ListOfRows`

A nested list of rows, each row being a list of arithmetical expressions

`Matrix`

A matrix, i.e., an object of a data type of category `Cat::Matrix`

`Table`

A table of matrix components

`m`

The number of rows: a positive integer

`n`

The number of columns: a positive integer

`f`

A function or a functional expression of two arguments

`g`

A function or a functional expression of one argument

i_1, i_2, …

Row indices: integers between 1 and m

j_1, j_2, …

Column indices: integers between 1 and m

value$_1$, value$_2$, …

Matrix entries: arithmetical expressions

Options

Diagonal

Create a diagonal matrix

With this option, diagonal matrices can be created with diagonal elements taken from a list, or computed by a function or a functional expression.

`matrix(m, n, List, Diagonal)` creates the $m \times n$ diagonal matrix whose diagonal elements are the entries of `List`. Cf. "Example 10" on page 1-1326.

`List` must have no more than $min(m, n)$ entries. If it has fewer elements, the remaining diagonal elements are regarded as zero.

`matrix(m, n, g, Diagonal)` returns the sparse matrix whose i-th diagonal element is `g(i, i)`, where the index i runs from 1 to $min(m, n)$. Cf. "Example 10" on page 1-1326.

Banded

Create a banded Toeplitz matrix

A *banded matrix* has zero entries outside the main diagonal and some of the adjacent sub- and superdiagonals.

`matrix(m, n, List, Banded)` creates an $m \times n$ banded Toeplitz matrix with the elements of `List` as entries. The number of entries of `List` must be odd, say $2h + 1$, where h must not exceed `n`. The bandwidth of the resulting matrix is at most h.

All elements of the main diagonal of the created matrix are initialized with the middle element of `List`. All elements of the i-th subdiagonal are initialized with the $(h + 1 - i)$-th element of `List`. All elements of the i-th superdiagonal are initialized with the $(h + 1 + i)$-th element of `List`. All entries on the remaining sub- and superdiagonals are regarded as zero.

Cf. "Example 11" on page 1-1327.

Return Values

Matrix of the domain type `Dom::Matrix()`.

max

Maximum of numbers

Syntax

```
max(x1, x2, , …)
max({x1, x2, …})
max([x1, x2, …])
max(A)
```

Description

`max(x1, x2, ...)` returns the maximum of the numbers x_1, x_2, ….

If the arguments of `max` are either integers, rational numbers, or floating-point numbers, then `max` returns the numerical maximum of these arguments.

Exact numerical expressions such as `PI + sqrt(2)` etc. are internally converted to floating-point intervals using the current value of `DIGITS`. After comparison, the exact expression is restored in the return value. If the current value of `DIGITS` does not suffice to determine the maximum of several expressions, a symbolic call of `max` is returned. Cf. “Example 2” on page 1-1334.

The call `max()` is illegal and leads to an error message. If there is only one argument `x1`, then `max` evaluates `x1` and returns it. Cf. “Example 3” on page 1-1335.

If one of the arguments is `infinity`, then `max` returns `infinity`. If an argument is `-infinity`, then it is removed from the argument list. Cf. “Example 4” on page 1-1335.

`max` returns an error when one of its arguments is a complex number or a floating point interval with non-zero imaginary part. Cf. “Example 3” on page 1-1335.

If one of the arguments is not a number, then a symbolic `max` call with the maximum of the numerical arguments and the remaining evaluated arguments may be returned. Cf. “Example 1” on page 1-1333.

Nested `max` calls with symbolic arguments are rewritten as a single `max` call, i.e., they are flattened. Cf. “Example 5” on page 1-1335.

`max` reacts to a very limited set of properties of identifiers set via `assume`. Use `simplify` to handle more general assumptions. Cf. “Example 5” on page 1-1335.

Environment Interactions

When called with exact numerical expressions such as `PI`, `sqrt(2)` etc., the function is sensitive to the environment variable `DIGITS`, which determines the numerical working precision.

Examples

Example 1

`max` computes the maximum of integers, rational numbers, and floating-point values:

```
max(-3/2, 7, 1.4)
```

$$7$$

Floating point intervals are interpreted as “any number within this range” and may thus cause symbolic `max` calls to be returned:

```
max(2...3 union 6...7, 4)
```

$$\max(2.0 \ldots 3.0 \cup 6.0 \ldots 7.0, 4)$$

```
max(2...3, 6...7, 4)
```

$$6.0 \ldots 7.0$$

```
max(2...3, PI)
```

$$\pi$$

If the argument list contains symbolic expressions, then a symbolic `max` call may be returned:

```
delete b:
max(-4, b + 2, 1, 3)
```

$$\max(b+2, 3)$$

In the following two examples, `max` is able to determine the maximum despite getting symbolic arguments (contrast this with <):

```
max(sqrt(2), 1)
```

$$\sqrt{2}$$

```
assume(x > 0):
max(exp(x), exp(-x))
```

$$e^x$$

Example 2

The following rational number `pi` approximates π to about 20 decimal places:

```
pi := 314159265358979323846/10^20:
```

With the default value `DIGITS = 10`, the function `max` cannot distinguish between `PI` and `pi` via floating-point approximations:

```
max(pi, PI)
```

$$\max\left(\frac{15707963267948966192}{5000000000000000000}, \pi\right)$$

With an increased value of `DIGITS`, the floating-point interval approximation of `PI` considered by `max` allows to decide that `PI` is larger than `pi`:

```
DIGITS := 20:
max(pi, PI)
```

π

```
delete pi, DIGITS:
```

Example 3

`max` with one argument returns the evaluated argument:

```
delete a:
max(a), max(sin(2*PI)), max(2)
```

$a, 0, 2$

Complex numbers lead to an error message:

```
max(0, 1, I)
```

```
Error: The argument is invalid. [max]
```

Example 4

`infinity` is always the maximum of arbitrary arguments:

```
delete x:
max(100000000000, infinity, x)
```

∞

`-infinity` is removed from the argument list:

```
max(100000000000, -infinity, x)
```

$\max(100000000000, x)$

Example 5

`max` reacts only to very few properties of identifiers set via `assume`:

```
delete a, b, c:
assume(a > 0 and b > a and c > b):
max(a, max(b, c), 0)
```

$$\max(a, b, c)$$

An application of `simplify` yields the desired result:

```
simplify(%)
```

$$c$$

Parameters

`x1, x2, …`

Arbitrary MuPAD objects

`A`

An array of domain type `DOM_HFARRAY` with real entries

Return Values

One of the arguments, a floating-point number, or a symbolic `max` call.

Overloaded By

MuPAD Functions

`_leequal` | `_less` | `min` | `sort` | `sysorder`

MAXDEPTH

Prevent infinite recursion during procedure calls

Description

The environment variable MAXDEPTH determines the maximal recursion depth of nested procedure calls. When this recursion depth is reached, an error occurs.

Possible values: Positive integer; the maximum value depends on the operating system, see below.

The purpose of MAXDEPTH is to provide a heuristic for recognizing infinite recursion with respect to procedure calls, like in `p := x -> p(x): p(0)`. If, in this example, the recursion depth would not be limited, then the procedure p would call itself recursively infinitely often, and the system would "hang".

If during the evaluation of an object the recursion depth MAXDEPTH is reached, then the computation is aborted with an error.

Similarly, the environment variable MAXLEVEL provides a heuristic for recognizing infinite recursion with respect to the substitution of values for identifiers; see the corresponding help page for details and examples.

The default value of MAXDEPTH is 500; MAXDEPTH has this value after starting or resetting the system via `reset`. Also the command `delete MAXDEPTH` restores the default value.

MAXDEPTH is a global variable. Use the statement `save MAXDEPTH` in a procedure to confine any changes to MAXDEPTH to this procedure.

The maximum value of MAXDEPTH depends on the operating system. Under Windows it is $2^{11} = 2048$. Under UNIX operating systems the maximum value depends on the maximum size of the C-stack. With a default stack size of `8 MB` the value is 2048, too; with a bigger stack size it can be bigger (in a bash the stack size can be set with `ulimit -s`).

Examples

Example 1

Evaluation of objects defined by an infinite recursion produces an error:

```
p := proc() begin p() end_proc: p()
```

```
Error: Recursive definition: the maximal depth for nested procedure calls is reached.
  Evaluating: p
```

This also works for mutually recursive definitions:

```
p := proc(x) begin q(x + 1)^2 end_proc:
q := proc(y) begin p(x) + 2 end_proc:
p(0)
```

```
Error: Recursive definition: the maximal depth for nested procedure calls is reached.
  Evaluating: p
```

Example 2

If the maximal recursion depth is reached, then this does not necessarily mean that infinite recursion is involved. The following recursive procedure computes the factorial of a nonnegative integer. If we set the maximal recursion depth to a smaller value than necessary to compute $5!$, then an error occurs:

```
factorial := proc(n) begin
  if n = 0 then 1
  else n*factorial(n - 1)
  end_if
end_proc:
MAXDEPTH := 4: factorial(5)
```

```
Error: Recursive definition: the maximal depth for nested procedure calls is reached.
  Evaluating: factorial
```

If we set `MAXDEPTH` to 5, then the recursion depth is big enough for computing $5!$. The command `delete MAXDEPTH` resets `MAXDEPTH` to its default value `500`:

```
MAXDEPTH := 5: factorial(5); delete MAXDEPTH:
```

```
120
```

MuPAD Functions
`eval` | `freeze` | `LEVEL` | `level` | `MAXLEVEL` | `proc`

MAXEFFORT

Maximum amount of work to spend on the computation

Description

The environment variable MAXEFFORT determines the amount of effort allowed for heuristical parts of a computation, measured in "working units". The default value is MAXEFFORT = 1000000.

Possible values: Non-negative floating-point number; or `infinity`.

MAXEFFORT determines the maximum number of "working units" that may be spent on internal heuristics.

One working unit roughly corresponds to 1000 evaluation steps done by an average kernel function.

Whatever MAXEFFORT is set to, every MuPAD function returns a correct though possibly unsimplified result; in particular, some functions may return unevaluated. MAXEFFORT determines the amount of additional time spent on obtaining a better or more simplified result; a value of `infinity` means that all built-in heuristics are really tried, a value of `0` means that all heuristics that might take considerable effort are left out.

A function whose result is uniquely specified has no way to react to MAXEFFORT.

Other functions carry out, in any event, all computations necessary to obtain some correct result; MAXEFFORT only determines the time available for improving that result. In case of functions that may return unevaluated immediately (e.g., `solve` or `int`), or may return their input immediately (as, e.g., `simplify`), or may answer a question by UNKNOWN immediately (as, e.g., `is`), all of their time consumption is counted to be spent on heuristics (purely heuristic functions).

Purely heuristic functions will usually return immediately if their input is quite complicated in relation to the effort allowed. This is also true if the user has provided that input on the interactive level. In order to pose a difficult problem where a longer running time is acceptable, MAXEFFORT should be increased.

A simplification achieved by heuristic methods may speed up the deterministic parts, such that a small value of MAXEFFORT does not necessarily decrease the total computing time.

The user may employ MAXEFFORT in his own functions as follows: any function may use the amount of effort given by MAXEFFORT partly for own overhead, and distribute the rest on the functions it calls. To do this, the caller has to save the variable MAXEFFORT and set it to whatever it wants to make available to the called function. Depending on whether the call is necessary to obtain a correct result at all and whether the called function is a heuristic one, there are the following cases to handle. If the call is necessary and the called function is deterministic, MAXEFFORT has no influence. If the call is not absolutely necessary and as far as the called function is deterministic, the caller has to subtract the necessary amount as own overhead from MAXEFFORT if enough is available; otherwise, such call must not take place. As far as the called function works heuristically (for whatever reason it was called), it has to limit its efforts to the amount given by MAXEFFORT.

In no event may the value of MAXEFFORT on entering a procedure be different from the value on leaving it, even not in case of an error. save must be used to ensure this.

No function may distribute and/or use more than the amount it has been given by its caller. The own overhead should be estimated; if it is supposedly small, MAXEFFORT may be ignored.

In order to avoid casual, not reproducible effects, e.g., by other programs running on the same computer, MAXEFFORT should not be used in connection with time measurement using time or rtime. For example, the running time saved in one recursive call according to time measurement must not be supplied to another recursive call.

Examples

Example 1

The decomposition of an integer into prime factors is unique; hence the result of ifactor is uniquely determined, such that ifactor does not react to MAXEFFORT:

```
MAXEFFORT:= 0:
ifactor(2^10 + 1)
```

$$5^2\ 41$$

Example 2

The function solve may return unevaluated. Hence it will do so if there is no effort left to spend on the computation:

```
MAXEFFORT:= 0: solve(ln(x) + x = 3, x)
```

$$\text{solve}(x + \ln(x) - 3 = 0, x)$$

MuPAD Functions

`prog::ntime` | `time` | `traperror`

MAXLEVEL

Prevent infinite recursion during evaluation

Description

The environment variable MAXLEVEL determines the maximal substitution depth of identifiers. When this substitution depth is reached, an error occurs.

Possible values: integer greater 2; the maximum value depends on the operationg system, see below.

When a MuPAD object is evaluated, identifiers occurring in it are replaced by their values. This happens recursively, i.e., if the values themselves contain identifiers, then these are replaced as well. MAXLEVEL determines the maximal recursion depth of this process. If the substitution depth MAXLEVEL is reached, then an error occurs.

The purpose of MAXLEVEL is to provide a heuristic for recognizing infinite recursion with respect to the replacement of identifiers by their values, like in `delete a: a := a + 1; a`. If, in this example, the substitution depth would not be limited, then `a + 1` would be substituted for `a` infinitely often, and the system would "hang".

Similarly, the environment variable MAXDEPTH provides a heuristic for recognizing infinite recursion with respect to function calls; see the corresponding help page for details.

There is a close connection between LEVEL and MAXLEVEL. If the substitution depth LEVEL is reached during the evaluation process, then the recursion stops and any remaining identifiers remain unevaluated, but no error occurs.

Thus, if `MAXLEVEL > LEVEL`, then MAXLEVEL has no effect. By default, LEVEL and MAXLEVEL have the same value 100 at interactive level. However, the default value of LEVEL within a procedure is 1, and thus usually MAXLEVEL has no effect within procedures.

There are some notable differences between LEVEL and MAXLEVEL. The value of LEVEL depends on the context, namely whether the evaluation happens at interactive level or in a procedure. Moreover, some system functions, such as `context` and `level`, do not respect the current value of LEVEL. In contrast, MAXLEVEL is a global bound. It works as a last resort when the control of the evaluation via LEVEL fails.

The default value of MAXLEVEL is 100; MAXLEVEL has this value after starting or resetting the system via `reset`. Also the command `delete MAXLEVEL` restores the default value.

MAXLEVEL is a global variable. Use the statement `save MAXLEVEL` in a procedure to confine any changes to MAXLEVEL to this procedure.

The maximum value of MAXLEVEL depends on the operating system. Under Windows it is $2^{13} = 8192$. Under UNIX operating systems the maximum value depends on the maximum size of the C-stack. With a default stack size of `8 MB` the value is 8192, too; with a bigger stack size it can be bigger (in a bash the stack size can be set with `ulimit -s`).

Examples

Example 1

Evaluation of objects defined by an infinite recursion produces an error:

```
delete a: a := a + 1: a
```

```
Error: Recursive definition, the maximal evaluation level is reached.
```

This also works for mutually recursive definitions:

```
delete a, b: a := b^2: b := a + 1: b
```

```
Error: Recursive definition, the maximal evaluation level is reached.
```

Example 2

If MAXLEVEL is smaller or equal to LEVEL, as is the default at interactive level, then objects are evaluated completely up to depth MAXLEVEL-1, and an error occurs if the substitution depth MAXLEVEL is reached, whether a recursive definition is involved or not:

```
delete a, b, c, d:
a := b: b := c: c := 7: d := d + 1:
```

```
MAXLEVEL := 2: LEVEL := 2: c
```

$$7$$

```
a
```

```
Error: Recursive definition, the maximal evaluation level is reached.
```

```
d
```

```
Error: Recursive definition, the maximal evaluation level is reached.
```

On the other hand, MAXLEVEL has no effect if it exceeds LEVEL. Then any object is evaluated up to depth at most LEVEL, and the "recursive definition" error does not occur:

```
MAXLEVEL := 3: a, b, c, d
```

$$c, 7, 7, d + 2$$

In particular, MAXLEVEL normally has no effect within procedures, where by default LEVEL has the value 1:

```
MAXLEVEL := 2:
p := proc() begin a, d end_proc:
p();
delete MAXLEVEL, LEVEL:
```

$$b, d + 1$$

MuPAD Functions

context | eval | hold | LEVEL | level | MAXDEPTH | val

meijerG

The Meijer G function

Syntax

```
meijerG([[a1, …, an], [an + 1, …, ap]], [[b1, …, bm], [bm + 1, …, bq]], z)
```

```
meijerG([a1, …, an], [an + 1, …, ap], [b1, …, bm], [bm + 1, …, bq], z)
```

```
meijerG(m, n, [a1, …, ap], [b1, …, bq], z)
```

Description

`meijerG( [[ a1, …, an], [ an + 1, …, ap]], [[ b1, …, bm], [ bm + 1, …, bq]] , z)` represents the Meijer G function.

The following calls are equivalent:

`meijerG( [ a1, …, an], [ an + 1, …, ap], [ b1, …, bm], [ bm + 1, …, bq] , z)`, and

`meijerG(m, n, [ a1, …, an, an + 1, …, ap], [ b1, …, bm, bm + 1, …, bq] , z)`.

`meijerG( [[ a1, …, an], [ an + 1, …, ap]], [[ b1, …, bm], [ bm + 1, …, bq]] , z)` represents the Meijer G function $G^{m,n}_{p,q}\left(\begin{matrix}a_1,\ldots,a_n,a_{n+1},\ldots,a_p\\ b_1,\ldots,b_m,b_{m+1},\ldots,b_q\end{matrix}\middle|\, z\right)$. The function is defined as

$$G^{m,n}_{p,q}\left(\begin{matrix}a_1,\ldots,a_p\\ b_1,\ldots,b_q\end{matrix}\middle|\, z\right)=\frac{1}{2\pi i}\int\frac{\left(\prod_{j=1}^{m}\Gamma\left(b_j-s\right)\right)\left(\prod_{j=1}^{n}\Gamma\left(1-a_j+s\right)\right)}{\left(\prod_{j=m+1}^{q}\Gamma\left(1-b_j+s\right)\right)\left(\prod_{j=n+1}^{p}\Gamma\left(a_j-s\right)\right)}z^s\,ds,$$

where $0 \le m \le q$ and $0 \le n \le p$. The parameters a_i, b_j and the argument z can be complex numbers. The integral represents an inverse Laplace transform or, more specifically, a Mellin-Barnes type of integral. See the Algorithms section for more details.

If $m = 0$, $m = q$, $n = 0$, $n = p$, $p = 0$, or $q = 0$, you can pass empty parameter lists to `meijerG`: $[a_1, \ldots, a_n] = []$, $[a_{n+1}, \ldots, a_p] = []$, $[b_1, \ldots, b_m] = []$, or $[b_{m+1}, \ldots, b_q] = []$.

No pair of parameters a_i - b_j, $i = 1, \ldots, n$. $j = 1, \ldots, m$, should differ by a positive integer. Thus, no pole of $\Gamma\left(b_j - s\right)$ coincides with any pole of $\Gamma\left(1 - a_i + s\right)$. Otherwise, `meijerG` returns an error.

Meijer G functions with different parameters can represent the same function:

- The Meijer G function is symmetric with respect to the parameters. Changing the order inside each of the following lists of parameters does not change the resulting Meijer G function: $[a_1, \ldots, a_n]$, $[a_{n+1}, \ldots, a_p]$, $[b_1, \ldots, b_m]$, $[b_{m+1}, \ldots, b_q]$.
- If z is not a negative real number, the function satisfies the following identity:
$$G^{m,n}_{p,q}\left(\begin{matrix}a_1,\ldots,a_p\\ b_1,\ldots,b_q\end{matrix}\middle|\, z\right) = G^{n,m}_{q,p}\left(\begin{matrix}1-b_1,\ldots,1-b_q\\ 1-a_1,\ldots,1-a_p\end{matrix}\middle|\, \frac{1}{z}\right).$$
- If $0 < n < p$ and $r = a_1 - a_p$ is an integer, the function satisfies the following identity:
$$G^{m,n}_{p,q}\left(\begin{matrix}a_1,a_2,\ldots,a_{p-1},a_p\\ b_1,b_2,\ldots,b_{q-1},b_q\end{matrix}\middle|\, z\right) = (-1)^r\, G^{m,n}_{p,q}\left(\begin{matrix}a_p,a_2,\ldots,a_{p-1},a_1\\ b_1,b_2,\ldots,b_{q-1},b_q\end{matrix}\middle|\, z\right).$$
- If $0 < m < q$ and $r = b_1 - b_q$ is an integer, the function satisfies the following identity:
$$G^{m,n}_{p,q}\left(\begin{matrix}a_1,a_2,\ldots,a_{p-1},a_p\\ b_1,b_2,\ldots,b_{q-1},b_q\end{matrix}\middle|\, z\right) = (-1)^r\, G^{m,n}_{p,q}\left(\begin{matrix}a_1,a_2,\ldots,a_{p-1},a_p\\ b_q,b_2,\ldots,b_{q-1},b_1\end{matrix}\middle|\, z\right).$$

According to these rules, the `meijerG` function call can return `meijerG` with modified input parameters.

If at least one of the arguments is a floating-point number and all other arguments can be converted to floating-point numbers, the function returns a floating-point value.

Particular choices of parameters can reduce the Meijer G function to simpler special or elementary functions. Most special functions can be derived from the Meijer G function. In many cases, you can rewrite results involving `meijerG` in terms of more elementary functions using `simplify` or `Simplify`. See “Example 3” on page 1-1349.

The call `meijerG([[], []], [[], []], x)` returns 0.

Environment Interactions

When called with floating-point arguments, this function is sensitive to the environment variable `DIGITS`, which determines the numerical working precision.

Examples

Example 1

For exact or symbolic arguments, the `meijerG` function returns `meijerG`:

```
meijerG([[1],[]], [[],[2]],x)
```

$$G^{0,1}_{1,1}\left(\begin{matrix}1\\2\end{matrix}\middle|\, x\right)$$

```
meijerG([[1], [1/2]], [[], [1/2]], PI + I)
```

$$G^{1,0}_{1,2}\left(\begin{matrix}\frac{1}{2}\\0, \frac{1}{2}\end{matrix}\middle|\, \frac{1}{\pi + i}\right)$$

For floating-point arguments, `meijerG` returns floating-point values:

```
meijerG([[1], []], [[1], [1/2]], 3.0),
meijerG([[PI], [2]], [[], [3]], 4.0),
meijerG([[I+1,2], []], [[1/(I+1), 1/2],[]], 0.5*I)
```

$$0.7115950253,\ 0.3712122423,\ 0.3868927363 + 1.005593841\ i$$

Example 2

The functions `diff` and `float` handle expressions involving the Meijer G function:

```
diff(meijerG([[a], [b]], [[c], [d]], x), x)
```

$$\frac{G^{1,1}_{2,2}\left(\begin{matrix}a-1, b\\ c, d\end{matrix}\middle| x\right)}{x} + \frac{(a-1)\,G^{1,1}_{2,2}\left(\begin{matrix}a, b\\ c, d\end{matrix}\middle| x\right)}{x}$$

Differentiating a Meijer G function with respect to one of its parameters $a_1, \ldots, b_q$ does not generally result in Meijer G functions. Such derivatives are not implemented:

```
diff(meijerG([a], [b], [c], [d], z), a)
```

$$\frac{\partial}{\partial a}\, G^{1,1}_{2,2}\left(\begin{matrix}a, b\\ c, d\end{matrix}\middle| z\right)$$

You can evaluate the expressions involving `meierG` numerically using `float`:

```
meijerG([[1], []], [[2], [sqrt(PI)]], 3) ~=
  float(meijerG([[1], []], [[2], [sqrt(PI)]], 3))
```

$$G^{1,1}_{1,2}\left(\begin{matrix}1\\ 2, \sqrt{\pi}\end{matrix}\middle| 3\right) \approx -0.6659717596$$

```
delete z:
```

Example 3

Particular choices of parameters can reduce the Meijer G function to simpler special or elementary functions. Use `simplify` or `Simplify` to obtain such a representation:

```
simplify(meijerG([[], []], [[0], []], z))
```

$$e^{-z}$$

```
simplify(meijerG([[1], []], [[1/2], [0]], z))
```

$$\sqrt{\pi}\,\mathrm{erf}(\sqrt{z})$$

```
simplify(meijerG([[], []], [[1/2, -1/2], []], z))
```

$$2\,K_1(2\sqrt{z})$$

You can verify these relations numerically:

```
z:= float(PI+I):
meijerG([[], []], [[0], []], z) = exp(-z);
```

$$0.02334857968 - 0.03636325836\,i = 0.02334857968 - 0.03636325836\,i$$

```
meijerG([[1], []], [[1/2], [0]],z) = float(sqrt(PI)*erf(sqrt(z)))
```

$$1.76330129 + 0.01917545012\,i = 1.76330129 + 0.01917545012\,i$$

```
meijerG([[], []], [[1/2, -1/2], []], z) = 2*besselK(1, 2*sqrt(z))
```

$$0.03176922109 - 0.02400073308\,i = 0.03176922109 - 0.02400073308\,i$$

Parameters

a_1, …, a_p

The 'first list of parameters': arithmetical expressions

b_1, …, b_q

The 'second list of parameters': arithmetical expressions

z

The 'argument': an arithmetical expression

m, n

Integers satisfying $0 \le m \le q$, $0 \le n \le p$ or symbolic expressions.

Return Values

Arithmetical expression.

Algorithms

$$G^{m,n}_{p,q}\left(\begin{matrix}a_1,\ldots,a_p\\ b_1,\ldots,b_q\end{matrix}\middle|\, z\right)=\frac{1}{2\pi i}\int\frac{\left(\prod_{j=1}^{m}\Gamma\left(b_j-s\right)\right)\left(\prod_{j=1}^{n}\Gamma\left(1-a_j+s\right)\right)}{\left(\prod_{j=m+1}^{q}\Gamma\left(1-b_j+s\right)\right)\left(\prod_{j=n+1}^{p}\Gamma\left(a_j-s\right)\right)}z^s\,ds$$

involves a complex contour integral with one of the following types of integration paths:

- The contour goes from - i ∞ to i ∞ so that all poles of $\Gamma\left(b_j-s\right)$, j = 1, …, m, lie to the right of the path, and all poles of $\Gamma\left(1-a_k+s\right)$, k = 1, …, n, lie to the left of the path. The integral converges if $c=m+n-\frac{p+q}{2}>0$, $|arg(z)|<c\,\pi$. If $|arg(z)|=c\,\pi$, $c\geq 0$, the integral converges absolutely when $p=q$ and $\Re(\psi)<-1$, where $\psi=\left(\sum_{j=1}^{q}b_j\right)-\left(\sum_{i=1}^{p}a_i\right)$. When $p\neq q$, the integral converges if you choose the contour so that the contour points near i ∞ and - i ∞ have a real part σ satisfying $(q-p)\,\sigma>\Re(\psi)+1-\frac{q-p}{2}$.
- The contour is a loop beginning and ending at *infinity* and encircling all poles of $\Gamma\left(b_j-s\right)$, j = 1, …, m, moving in the negative direction, but none of the poles of $\Gamma\left(1-a_k+s\right)$, k = 1, …, n. The integral converges if $q\geq 1$ and either $p<q$ or $p=q$ and $|z|<1$.
- The contour is a loop beginning and ending at - ∞ and encircling all poles of $\Gamma\left(1-a_k+s\right)$, k = 1, …, n, moving in the positive direction, but none of the poles of $\Gamma\left(b_j+s\right)$, j = 1, …, m. The integral converges if $p\geq 1$ and either $p>q$ or $p=q$ and $|z|>1$.

For a given set of parameters, the contour chosen in the definition of the Meijer G function is the one for which the integral converges. To avoid confusion, if the integral converges for several contours, all contours lead to the same function.

The Meijer G function satisfies a differential equation of order $max(p, q)$ with respect to a variable z:

$$\left((-1)^{m+n-p}\, z \left(\prod_{i=1}^{p}\left(z\,\frac{d}{dz}-a_i-1\right)\right)-\prod_{j=1}^{q}\left(z\,\frac{d}{dz}-b_j\right)\right) G^{m,n}_{p,q}\left(\begin{matrix}a_1,\ldots,a_p\\ b_1,\ldots,b_q\end{matrix}\,\middle|\, z\right)=0 .$$

If $p < q$, this differential equation has a regular singularity at $z = 0$ and an irregular singularity at $z = \infty$. If $p = q$, the points $z = 0$ and $z = \infty$ are regular singularities, and there is an additional regular singularity at $z = (-1)^{m+n-p}$.

The Meijer G function represents an analytic continuation of the Hypergeometric Function (for details, see Luke in the references). For particular choices of parameters, you can express the Meijer G function through the hypergeometric function. For example, if no two of the b_h terms, $h = 1, \ldots, m$, differ by an integer or zero, all poles are simple, and

$$G^{m,n}_{p,q}\left(\begin{matrix}a_1,\ldots,a_p\\ b_1,\ldots,b_q\end{matrix}\,\middle|\, z\right)=\sum_{h=1}^{m}\frac{\left(\prod_{\substack{j=1..m\\ j\neq h}}\Gamma\left(b_j-b_h\right)\right)\left(\prod_{j=1}^{n}\Gamma\left(1+b_h-a_j\right)\right)}{\left(\prod_{j=m+1}^{q}\Gamma\left(1+b_h-b_j\right)\right)\left(\prod_{j=n+1}^{p}\Gamma\left(a_j-b_h\right)\right)}\, z^{b_h}\, {}_pF_{q-1}\left(A_h;\right.$$

$$\left. B_h;\,(-1)^{p-m-n}\, z\right),$$

where $p < q$ or $p = q$ and $|z| < 1$. The symbols A_h, B_h denote

$$A_h = 1+b_h-a_1,\ \ldots,\ 1+b_h-a_p$$

and

$$B_h = 1+b_h-b_1,\ \ldots,\ 1+b_h-b_{h-1},\ 1+b_h-b_{h+1},\ \ldots,\ 1+b_h-b_q .$$

`hypergeom`

min

Minimum of numbers

Syntax

```
min(x1, x2, , …)

min({x1, x2, …})

min([x1, x2, …])

min(A)
```

Description

`min(x1, x2, ...)` returns the minimum of the numbers x_1, x_2, ….

If the arguments of `min` are integers, rational numbers, or floating-point numbers, then `min` returns the numerical minimum of these arguments.

The call `min()` is illegal and leads to an error message. If there is only one argument x_1, then `min` evaluates x_1 and returns it. See “Example 2” on page 1-1356.

If one of the arguments is `-infinity`, then `min` returns `-infinity`. If an argument is `infinity`, then it is removed from the argument list (see “Example 3” on page 1-1356).

`min` returns an error when one of its arguments is a complex number or a floating point interval with on-zero imaginary part (see “Example 2” on page 1-1356).

If one of the arguments is not a number, then a symbolic `min` call with the minimum of the numerical arguments and the remaining evaluated arguments may be returned (see “Example 1” on page 1-1355).

Nested `min` calls with symbolic arguments are rewritten as a single `min` call, i.e., they are flattened; see “Example 4” on page 1-1356.

`min` reacts to a very limited set of properties of identifiers set via `assume`. Use `simplify` to handle more general assumptions (see “Example 4” on page 1-1356).

Examples

Example 1

`min` computes the minimum of integers, rational numbers, and floating-point values:

```
min(-3/2, 7, 1.4)
```

$$-\frac{3}{2}$$

If the argument list contains symbolic expressions, then a symbolic `min` call is returned:

```
delete b: min(-4, b + 2, 1, 3)
```

$$\min(-4, b+2)$$

In the following two examples, `min` is able to determine the minimum despite getting symbolic arguments:

```
min(sqrt(2), 1)
```

$$1$$

```
assume(x > 0): min(exp(x), exp(-x))
```

$$e^{-x}$$

Floating point intervals are interpreted as “any number within this range” and may thus cause symbolic `min` calls to be returned:

```
min(2...3 union 6...7, 4)
```

$$\min(2.0 \ldots 3.0 \cup 6.0 \ldots 7.0, 4)$$

```
min(2...3, 6...7, 4)
```

$$2.0 \ldots 3.0$$

```
min(6...7, 4)
```

$$4$$

Example 2

`min` with one argument returns the evaluated argument:

```
delete a:
min(a), min(sin(2*PI)), min(2)
```

$$a,\ 0,\ 2$$

Complex numbers lead to an error message:

```
min(0, 1, I)
```

```
Error: The argument is invalid. [min]
```

Example 3

`-infinity` is always the minimum of arbitrary arguments:

```
delete x:
min(-100000000000, -infinity, x)
```

$$-\infty$$

`infinity` is removed from the argument list:

```
min(-100000000000, infinity, x)
```

$$\min(-100000000000,\ x)$$

Example 4

`min` reacts only to very few properties of identifiers set via `assume`:

```
delete a, b, c:
assume(a > 0 and b > a and c > b):
min(a, min(b, c), 0)
```

$$\min(a, b, c, 0)$$

An application of `simplify` yields the desired result:

```
simplify(%)
```

$$0$$

Parameters

x_1, x_2, …

Arbitrary MuPAD objects

A

An array of domain type `DOM_HFARRAY` with real entries

Return Values

One of the arguments, a floating-point number, or a symbolic `min` call.

MuPAD Functions

`_leequal` | `_less` | `max` | `sort` | `sysorder`

mod, _mod

Modulo operator

Syntax

```
x mod m
```

```
_mod(x, m)
```

Description

If `m <> 0`, then `mod(x, m)` returns the value `x - n*m` where `n = floor(x/m)`. If `x` and `m` have different signs, then `mod(x, m)` has the same sign as `m`. If `m = 0`, then `mod(x, m)` returns `x`. See “Example 1” on page 1-1359.

`_mod(x, m)` is the functional equivalent of the operator notation `x mod m`. See “Example 2” on page 1-1359.

By default, `x mod m` and `_mod(x, m)` are both equivalent to `modp(x, m)`. You can redefine the modulo operator `mod` and its functional form `_mod` by using `modp` and `mods`. For example, after the assignment `_mod:=mods`, both the operator `mod` and the equivalent function `_mod` return remainders of least absolute value. See “Example 3” on page 1-1360.

All functions return an error when one of the arguments is a floating-point number, a complex number, or not an arithmetical expression.

If one of the arguments is not a number, then a symbolic function call is returned. See “Example 4” on page 1-1360.

`_mod` and `modp` are kernel functions.

Environment Interactions

By default the operator `mod` and the function `_mod` are equivalent to `modp`. This can be changed by assigning a new value to `_mod`. See “Example 3” on page 1-1360.

Examples

Example 1

Find the modulus after division of these integers.

```
27 mod 4, 27 mod -4, -27 mod 4, -27 mod -4
```

$$3, -1, 1, -3$$

Find the modulus after division by zero.

```
9 mod 0, -9 mod 0, 0 mod 0
```

$$9, -9, 0$$

Find the modulus after division of these rational numbers.

```
22/3 mod 5, 22 mod 5/3, 22/3 mod 5/4
```

$$\frac{7}{3}, \frac{1}{3}, \frac{13}{12}$$

Example 2

Find the modulus after division of 23 by 5 using the modulo operator and its functional form. `_mod` and the operator `mod` are equivalent.

```
hold(_mod(23, 5))
```

$$23 \bmod 5$$

```
23 mod 5 = _mod(23, 5)
```

$$3 = 3$$

Example 3

By default the binary operator `mod` and the equivalent function `_mod` are both equivalent to `modp`. You can redefine `_mod`.

```
modp(11, 7), mods(11,7);
11 mod 7
```

$$4,\ -3$$

$$4$$

```
_mod := mods:
11 mod 7
```

$$-3$$

For further computations, define `_mod` as `modp`.

```
_mod := modp:
```

Example 4

If one of the arguments is not a number, then the modulo operator returns a symbolic function call.

```
delete x, m:
x mod m, x mod 2, 2 mod m
```

$$x \bmod m,\ x \bmod 2,\ 2 \bmod m$$

When called with nonnumeric arguments, the function currently associated with `_mod` is printed in the operator notation.

```
_mod := mods:
modp(x, m), mods(x, m)
```

$$x \bmod m,\ x \bmod m$$

```
_mod := modp:
modp(x, m), mods(x, m)
```

$$x \bmod m,\ \mathrm{mods}(x,\ m)$$

Parameters

x

An integer, a rational number, or an arithmetical expression

m

An integer or an arithmetical expression

Return Values

arithmetical expression.

Overloaded By

m, x

modp

Positive modulo function

Syntax

```
modp(x, m)
```

Description

If `m <> 0`, then `modp(x, m)` returns the value `x - n*m` where `n = floor(x/m)`. If `x` and `m` have different signs, then `modp(x, m)` has the same sign as `m`. If `m = 0`, then `modp(x, m)` returns `x`. See "Example 1" on page 1-1362.

By default, `x mod m` and `_mod(x, m)` are both equivalent to `modp(x, m)`. You can redefine the modulo operator `mod` and its functional form `_mod` by using `modp` and `mods`. For example, after the assignment `_mod:=mods`, both the operator `mod` and the equivalent function `_mod` return remainders of least absolute value. See "Example 2" on page 1-1363.

All functions return an error when one of the arguments is a floating-point number, a complex number, or not an arithmetical expression.

If one of the arguments is not a number, then a symbolic function call is returned. See "Example 3" on page 1-1363.

`_mod` and `modp` are kernel functions.

Examples

Example 1

Find the modulus after division of these integers.

```
modp(27, 4), modp(27, -4), modp(-27, 4), modp(-27, -4)
```

```
3, -1, 1, -3
```

Find the modulus after division by zero.

```
modp(9, 0), modp(-9, 0), modp(0, 0)
```

```
9, -9, 0
```

Find the modulus after division of these rational numbers.

```
modp(22/3, 5), modp(22, 5/3), modp(22/3, 5/4)
```

$$\frac{7}{3}, \frac{1}{3}, \frac{13}{12}$$

Example 2

By default the binary operator `mod` and the equivalent function `_mod` are both equivalent to `modp`. You can redefine `_mod`.

```
modp(11, 7), mods(11,7);
11 mod 7
```

```
4, -3
```

```
4
```

```
_mod := mods:
11 mod 7
```

```
-3
```

For further computations, define `_mod` as `modp`.

```
_mod := modp:
```

Example 3

If one of the arguments is not a number, then `modp` returns a symbolic function call.

```
delete x, m:
modp(x, m), modp(x, 2), modp(2, m)
```

$$x \bmod m,\ x \bmod 2,\ 2 \bmod m$$

When called with nonnumeric arguments, the function currently associated with `_mod` is printed in the operator notation.

```
_mod := mods:
modp(x, m), mods(x, m)
```

$$x \bmod m,\ x \bmod m$$

```
_mod := modp:
modp(x, m), mods(x, m)
```

$$x \bmod m,\ \mathrm{mods}(x,\ m)$$

Parameters

x

An integer, a rational number, or an arithmetical expression

m

An integer or an arithmetical expression

Return Values

arithmetical expression.

mods

Symmetric modulo function

Syntax

```
mods(x, m)
```

Description

If `m <> 0`, then `mods(x, m)` returns the value `x + n*m` where `n = round(-x/m)`. If `m = 0`, then `mods(x, m)` returns `x`. See "Example 1" on page 1-1366.

By default, `x mod m` and `_mod(x, m)` are both equivalent to `modp(x, m)`. You can redefine the modulo operator `mod` and its functional form `_mod` by using `modp` and `mods`. For example, after the assignment `_mod:=mods`, both the operator `mod` and the equivalent function `_mod` return remainders of least absolute value. See "Example 2" on page 1-1367.

All functions return an error when one of the arguments is a floating-point number, a complex number, or not an arithmetical expression.

If one of the arguments is not a number, then a symbolic function call is returned. See "Example 3" on page 1-1367.

`mods` is a kernel function.

Examples

Example 1

Use the symmetric modulo function to find the modulus after division of these integers.

```
mods(27, 4), mods(27, -4), mods(-27, 4), mods(-27, -4)
```

$$-1, -1, 1, 1$$

Find the modulus after division by zero.

```
mods(9, 0), mods(-9, 0), mods(0, 0)
```

$$9, -9, 0$$

Use the symmetric modulo function to find the modulus after division of these rational numbers.

```
mods(22/3, 5), mods(22, 5/3), mods(22/3, 5/4)
```

$$\frac{7}{3}, \frac{1}{3}, -\frac{1}{6}$$

Example 2

By default the binary operator `mod` and the equivalent function `_mod` are both equivalent to `modp`. You can redefine `_mod`.

```
modp(11, 7), mods(11,7);
11 mod 7
```

$$4, -3$$

$$4$$

```
_mod := mods:
11 mod 7;
```

$$-3$$

For further computations, define `_mod` as `modp`.

```
_mod := modp:
```

Example 3

If one of the arguments is not a number, then the modulo operator returns a symbolic function call.

```
delete x, m:
x mod m, x mod 2, 2 mod m
```

$$x \bmod m,\ x \bmod 2,\ 2 \bmod m$$

When called with nonnumeric arguments, the function currently associated with `_mod` is printed in the operator notation.

```
_mod := mods: modp(x, m), mods(x, m)
```

$$x \bmod m,\ x \bmod m$$

```
_mod := modp: modp(x, m), mods(x, m)
```

$$x \bmod m,\ \mathrm{mods}(x,\ m)$$

Parameters

x

An integer, a rational number, or an arithmetical expression

m

An integer or an arithmetical expression

Return Values

arithmetical expression.

monomials

Sorted list of monomials of a polynomial

Syntax

```
monomials(p, <order>)
```

```
monomials(f, <vars>, <order>)
```

Description

`monomials(p, order)` returns the list of non-zero monomials of the polynomial `p`. The list is sorted with respect to the term ordering `order`.

`monomials` returns a list of all non-trivial monomials of the polynomial given. The monomials are sorted according to the term ordering given. The list is empty if the polynomial is zero.

A polynomial expression `f` is first converted to a polynomial with the variables given by `vars`. If no variables are given, they are searched for in `f`. See `poly` about details of the conversion. The result is returned as list of polynomial expressions. `FAIL` is returned if `f` cannot be converted to a polynomial.

The result of `monomials` is not fully evaluated. It can be evaluated by the functions `mapcoeffs` and `eval`. Cf. “Example 4” on page 1-1372.

Examples

Example 1

We give some self explaining examples:

```
p := poly(100*x^100 + 49*x^49 + 7*x^7, [x]):
monomials(p)
```

$$[\mathrm{poly}(100\,x^{100}, [x]), \mathrm{poly}(49\,x^{49}, [x]), \mathrm{poly}(7\,x^{7}, [x])]$$

```
monomials(poly(0, [x]))
```

$$[]$$

```
delete p:
```

Example 2

We demonstrate the effect of various term orders:

```
p := poly(5*x^4 + 4*x^3*y*z^2 + 3*x^2*y^3*z + 2, [x, y, z]):
monomials(p)
```

$$[\mathrm{poly}(5\,x^4, [x, y, z]), \mathrm{poly}(4\,x^3\,y\,z^2, [x, y, z]), \mathrm{poly}(3\,x^2\,y^3\,z, [x, y, z]), \mathrm{poly}(2, [x, y, z])]$$

```
monomials(p, DegreeOrder)
```

$$[\mathrm{poly}(4\,x^3\,y\,z^2, [x, y, z]), \mathrm{poly}(3\,x^2\,y^3\,z, [x, y, z]), \mathrm{poly}(5\,x^4, [x, y, z]), \mathrm{poly}(2, [x, y, z])]$$

```
monomials(p, DegInvLexOrder)
```

$$[\mathrm{poly}(3\,x^2\,y^3\,z, [x, y, z]), \mathrm{poly}(4\,x^3\,y\,z^2, [x, y, z]), \mathrm{poly}(5\,x^4, [x, y, z]), \mathrm{poly}(2, [x, y, z])]$$

```
delete p:
```

Example 3

This example features a user defined term ordering. Here we use the reverse lexicographical order on 3 indeterminates:

```
order := Dom::MonomOrdering(RevLex(3)):
p := poly(5*x^4 + 4*x^3*y*z^2 + 3*x^2*y^3*z + 2, [x, y, z]):
monomials(p, order)
```

$$[\mathrm{poly}(3\,x^2\,y^3\,z, [x, y, z]), \mathrm{poly}(4\,x^3\,y\,z^2, [x, y, z]), \mathrm{poly}(5\,x^4, [x, y, z]), \mathrm{poly}(2, [x, y, z])]$$

```
delete order, p:
```

Example 4

We demonstrate the evaluation strategy of `monomials`:

```
p := poly(3*x^3 + 6*x^2*y^2 + 2, [x]): y := 4:
monomials(p)
```

$$[\mathrm{poly}(3\,x^3, [x]),\ \mathrm{poly}((6\,y^2)\,x^2, [x]),\ \mathrm{poly}(2, [x])]$$

Evaluation is enforced by `eval`:

```
map(%, mapcoeffs, eval)
```

$$[\mathrm{poly}(3\,x^3, [x]),\ \mathrm{poly}(96\,x^2, [x]),\ \mathrm{poly}(2, [x])]$$

```
delete p, y:
```

Parameters

`p`

A polynomial of type `DOM_POLY`

`f`

A polynomial expression

`vars`

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

`order`

The term ordering: `LexOrder`, or `DegreeOrder`, or `DegInvLexOrder`, or a user-defined term ordering of type `Dom::MonomOrdering`. The default is the lexicographical ordering `LexOrder`.

Return Values

List of polynomials of the same type as `p`. A list of expressions is returned if an expression is given. The list is empty if the polynomial is zero.

Overloaded By

p

mtaylor

Compute a multivariate Taylor series expansion

Syntax

```
mtaylor(f, x = x0, <order>, <mode>, <weights>, <Mapcoeffs = mc>)
mtaylor(f, x, <order>, <mode>, <weights>, <Mapcoeffs = mc>)
mtaylor(f, x = x0, AbsoluteOrder = order, <weights>, <Mapcoeffs = mc>)
mtaylor(f, x = x0, RelativeOrder = order, <weights>, <Mapcoeffs = mc>)
mtaylor(f, [x = x0, y = y0, …], <order>, <mode>, <weights>, <Mapcoeffs = mc>)
mtaylor(f, [x, y, …], <order>, <mode>, <weights>, <Mapcoeffs = mc>)
mtaylor(f, [x = x0, y = y0, …], <AbsoluteOrder = order>, <weights>, <Mapcoeffs = mc>)
mtaylor(f, [x = x0, y = y0, …], RelativeOrder = order, <weights>, <Mapcoeffs = mc>)
```

Description

`mtaylor(f, [x = x0, y = y0, ...])` computes the first terms of the multivariate Taylor series of `f` with respect to the variables `x, y` etc. around the points `x = x0, y = y0` etc.

With the default mode `RelativeOrder`, the number of requested terms for the expansion is determined by `order` if specified. If no order is specified, the value of the environment variable `ORDER` is used. You can change the default value 6 by assigning a new value to `ORDER`.

The terms are counted from the lowest total degree on for finite expansion points, and from the highest total degree term on for expansions around infinity.

If `AbsoluteOrder` is specified, `order` represents the truncation order of the series, i.e., no terms of total degree `order` or higher are computed.

For infinite expansion points, the absolute values of the exponents of the corresponding variables are used to compute the total degree.

For finite expansion points `x0, y0, ...`, the computed series with respect to the variables `x, y, ...` of weight `w1, w2, ...` is

```
taylor(f(x0 + t^w1*(x - x0), y0 + t^w2*(y - y0), dots), t = 0),
```

evaluated at the point $t = 1$.

Environment Interactions

The function is sensitive to the environment variable `ORDER`, which determines the default number of terms in series computations.

Examples

Example 1

We compute a Taylor series around the origin (default). The expansion contains all terms through total degree 3:

```
mtaylor(exp(x^2 - y), [x, y], 4)
```

$$-x^2 y + x^2 - \frac{y^3}{6} + \frac{y^2}{2} - y + 1$$

We request additional terms of higher order:

```
mtaylor(exp(x^2 - y), [x, y], 5)
```

$$\frac{x^4}{2} + \frac{x^2 y^2}{2} - x^2 y + x^2 + \frac{y^4}{24} - \frac{y^3}{6} + \frac{y^2}{2} - y + 1$$

In the example above, the leading term is of total degree 0. In the following example, the leading term is of total degree 2. Thus, the default mode `RelativeOrder` produces terms of total degree smaller than4 + 2 = 6:

```
mtaylor(x*y*exp(x^2 - y), [x, y], 4)
```

$$-x^3 y^2 + x^3 y - \frac{x y^4}{6} + \frac{x y^3}{2} - x y^2 + x y$$

We request an absolute truncation order of 4, so that only terms of total degree smaller than 4 are computed:

```
mtaylor(x*y*exp(x^2 - y), [x, y], AbsoluteOrder = 4)
```

$$x y - x y^2$$

Example 2

For infinite expansions points a series in the reciprocal of the variable is returned:

```
mtaylor(exp(z)/(x - y), [x = infinity, y = 0, z])
```

$$\frac{y^2}{x^3} + \frac{z^2}{2 x} + \frac{z^3}{6 x} + \frac{z^4}{24 x} + \frac{z^5}{120 x} + \frac{y}{x^2} + \frac{z}{x} + \frac{1}{x} + \frac{y z}{x^2} + \frac{y z^2}{2 x^2} + \frac{y z^3}{6 x^2} + \frac{y^2 z}{x^3}$$

We reduce the order in `z` by giving `z` a higher weight:

```
mtaylor(exp(z)/(x - y), [x = infinity, y = 0, z], [1, 1, 2])
```

$$\frac{y^2}{x^3} + \frac{z^2}{2 x} + \frac{y}{x^2} + \frac{z}{x} + \frac{1}{x} + \frac{y z}{x^2}$$

Example 3

If a Taylor series expansion does not exist, or if `mtaylor` cannot find a Taylor series expansion, then `mtaylor` throws an error.

Try to find the Taylor series expansion of $f(x) = \frac{1}{x y - 1}$ around $x = 1$, $y = 1$. The Taylor series expansion does not exist, and `mtaylor` throws an error:

```
mtaylor(1/(x*y - 1), [x = 1, y = 1])
```

```
Error: Cannot compute a Taylor expansion of '1/(x*y - 1)'. [mtaylor]
```

Example 4

This is an example of a directed Taylor expansion along the real axis around `x = infinity`:

```
mtaylor(sqrt(y)*sin(sqrt(y)/x), [x = infinity, y = 0])
```

$$\frac{y}{x} - \frac{y^2}{6\,x^3}$$

In fact, this is even an undirected expansion:

```
mtaylor(sqrt(y)*sin(sqrt(y)/x), [x = complexInfinity, y = 0])
```

$$\frac{y}{x} - \frac{y^2}{6\,x^3}$$

Example 5

A common problem in symbolic calculations is "expression swell:" Intermediate expressions which are not or cannot be simplified lead to unnecessarily complicated results. The following is an example of such behavior:

```
mtaylor((a+x)^n, x, 4)
```

$$\sigma_1 - x^2\,\sigma_1\left(\frac{n}{2\,a^2} - \frac{n^2}{2\,a^2}\right) - x^3\,\sigma_1\left(\frac{n^2}{4\,a^3} - \frac{n}{3\,a^3} + \frac{n\left(\frac{n}{4\,a^2} - \frac{n^2}{6\,a^2}\right)}{a}\right) + \frac{n\,x\,\sigma_1}{a}$$

where

$$\sigma_1 = e^{n\ln(a)}$$

In general, applying `simplify` or `Simplify` to complicated results is a strategy that often helps. In this case, however, it would destroy the format of the series:

```
simplify(%)
```

$$\frac{a^{n-3}\,(6\,a^3+6\,a^2\,n\,x+3\,a\,n^2\,x^2-3\,a\,n\,x^2+n^3\,x^3-3\,n^2\,x^3+2\,n\,x^3)}{6}$$

What is required is a way to map a function like `simplify` to the coefficients of the series only. Since `mtaylor` returns an ordinary expression, this must be done in the `mtaylor` call itself, using the `Mapcoeffs` option:

```
mtaylor((a+x)^n, x, 4, Mapcoeffs=simplify)
```

$$a^n+a^{n-1}\,n\,x+\frac{a^{n-2}\,n\,x^2\,(n-1)}{2}+\frac{a^{n-3}\,n\,x^3\,(n^2-3\,n+2)}{6}$$

Parameters

`f`

An arithmetical expression representing a function in `x, y, ...`

`x, y, …`

identifiers or indexed identifiers

`x0, y0, …`

The expansion points: arithmetical expressions. Also expressions involving `infinity` or `complexInfinity` are accepted.

If not specified, the default expansion point 0 is used.

`order`

The truncation order (in conjunction with `AbsoluteOrder`) or, in conjunction with `RelativeOrder`, the number of terms to be computed, respectively. A nonnegative integer; the default order is given by the environment variable `ORDER` (default value 6).

The order concept refers to the total degree in the variables (the sum of all exponents).

`mode`

One of the flags `AbsoluteOrder` or `RelativeOrder`. The default is `RelativeOrder`.

`weights`

A list of positive integers determining the number of terms of the computed series. A variable `x` with weight `w` contributes as `x^w` to the total degree of the terms in the series. Thus, using weight 2 for *x*, halves the order in `x` to which the series is computed.

By default, all variables have the weight 1.

Options

`AbsoluteOrder`

With this flag, the integer value `order` is the truncation order of the computed series, i.e., only terms of total degree less than `order` are present.

`RelativeOrder`

With this flag, the terms in the computed series range from some leading total degree `v` to the highest total degree `v + order - 1` (i.e., the truncation order w.r.t. the total degree is `v + order`).

`Mapcoeffs`

Option, specified as `Mapcoeffs = mc`

When building the resulting expression, for each coefficient `c`, insert `mc(c)` instead.

Return Values

Arithmetical expression.

Overloaded By

f

See Also

MuPAD Functions

`asympt` | `diff` | `limit` | `O` | `series` | `Series::Puiseux` | `taylor` | `Type::Series`

multcoeffs

Multiply the coefficients of a polynomial with a factor

Syntax

```
multcoeffs(p, c)
```

```
multcoeffs(f, <vars>, c)
```

Description

`multcoeffs(p, c)` multiplies all coefficients of the polynomial `p` with the factor `c`.

A polynomial expression `f` is first converted to a polynomial with the variables given by `vars`. If no variables are given, they are searched for in `f`. See `poly` about details of the conversion. `FAIL` is returned if `f` cannot be converted to a polynomial. After multiplication with `c`, the result is converted to an expression.

For a polynomial expression `f`, the factor `c` may be any arithmetical expression. For a polynomial `p` of type `DOM_POLY`, the factor `c` must be convertible to an element of the coefficient ring of `p`.

Examples

Example 1

Some simple examples:

```
multcoeffs(3*x^3 + x^2*y^2 + 2, 5)
```

$$15\,x^3+5\,x^2\,y^2+10$$

```
multcoeffs(3*x^3 + x^2*y^2 + 2, c)
```

$$3\,c\,x^3+c\,x^2\,y^2+2\,c$$

```
multcoeffs(poly(x^3 + 2, [x]), sin(y))
```

$$\mathrm{poly}(\sin(y)\, x^3 + 2\, \sin(y), [x])$$

Example 2

Mathematically, `multcoeffs(f, c)` is the same as `f*c`. However, `multcoeffs` produces an expanded form of the product which depends on the indeterminates:

```
f := 3*x^3 + x^2*y^2 + 2:
multcoeffs(f, [x], c), multcoeffs(f, [y], c),
multcoeffs(f, [z], c)
```

$$3\, c\, x^3 + c\, x^2\, y^2 + 2\, c,\ c\, (3\, x^3 + 2) + c\, x^2\, y^2,\ c\, (3\, x^3 + x^2\, y^2 + 2)$$

```
delete f:
```

Parameters

`p`

A polynomial of type `DOM_POLY`

`c`

An arithmetical expression or an element of the coefficient ring of `p`

`f`

A polynomial expression

`vars`

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

Return Values

Polynomial of type `DOM_POLY`, or a polynomial expression, or `FAIL`.

Overloaded By

f, p

new

Create a domain element

Syntax

```
new(T, object1, object2, …)
```

Description

Within a method of the domain type `T`, `new(T, object1, object2, ...)` creates a new element of the domain `T` with the internal representation `object1, object2, ...`.

`new` is a low-level function for creating elements of library domains.

The internal representation of a domain element comprises a reference to the corresponding domain and an arbitrary number of MuPAD objects, the internal operands of the domain element.

`new(T, object1, object2, ...)` creates a new element of the domain `T`, whose internal representation is the sequence of operands `object1, object2, ...`, and returns this element.

`new(T)` creates a new element of the domain `T`, whose internal representation is an empty sequence of operands.

Note: `new` is intended only for programmers implementing their own domains in MuPAD. You should never use `new` directly to generate elements of a predefined domain `T`; use the corresponding constructor `T(...)` instead, for the following reasons. The internal representation of the predefined MuPAD domains may be subject to changes more often than the interface provided by the constructor. Moreover, in contrast to `new`, the constructors usually perform argument checking. Thus using `new` directly may lead to invalid internal representations of MuPAD objects.

New domains can be created via `newDomain`.

You can access the operands of the internal representation of a domain element via `extop`, which, in contrast to `op`, cannot be overloaded for the domain. The function `op` is sometimes overloaded for a domain in order to hide the internal, technical representation of an object and to provide a more user friendly and intuitive interface.

Similarly, the function `extnops` returns the number of operands of a domain element in the internal representation, and `extsubsop` modifies an operand in the internal representation. These functions, in contrast to the related functions `nops` and `subsop`, cannot be overloaded for a domain.

You can write a constructor for your own domain `T` by providing a `"new"` method. This method is invoked whenever the user calls `T(arg1, arg2, ...)`. This is recommended since it provides a more elegant and intuitive user interface than `new`. The `"new"` method usually performs some argument checking and converts the arguments `arg1, arg2, ...` into the internal representation of the domain, using `new` (see “Example 1” on page 1-1385).

Examples

Example 1

We create a new domain `Time` for representing clock times. The internal representation of an object of this domain has two operands: the hour and the minutes. Then we create a new domain element for the time `12:45`:

```
Time := newDomain("Time"):
a := new(Time, 12, 45)
```

```
new(Time, 12, 45)
```

The domain type of `a` is `Time`, the number of operands is `2`, and the operands are `12` and `45`:

```
domtype(a), extnops(a)
```

```
Time, 2
```

```
extop(a)
```

```
12, 45
```

We now implement a `"new"` method for our new domain `Time`, permitting several input formats. It expects either two integers, the hour and the minutes, or only one integer that represents the minutes, or a rational number or a floating-point number, implying that the integral part is the hour and the fractional part represents a fraction of an hour corresponding to the minutes, or no arguments, representing midnight. Additionally, the procedure checks that the arguments are of the correct type:

```
Time::new := proc(HR = 0, MN = 0)
  local m;
begin
  if args(0) = 2 and domtype(HR) = DOM_INT
     and domtype(MN) = DOM_INT then
    m := HR*60 + MN
  elif args(0) = 1 and domtype(HR) = DOM_INT then
    m := HR
  elif args(0) = 1 and domtype(HR) = DOM_RAT then
    m := trunc(float(HR))*60 + frac(float(HR))*60
  elif args(0) = 1 and domtype(HR) = DOM_FLOAT then
    m := trunc(HR)*60 + frac(HR)*60
  elif args(0) = 0 then
    m := 0
  else
    error("wrong number or type of arguments")
  end_if;
  new(Time, trunc(m/60), trunc(m) mod 60)
end_proc:
```

Now we can use this method to create new objects of the domain `Time`, either by calling `Time::new` directly, or, preferably, by using the equivalent but shorter call `Time(...)`:

```
Time::new(12, 45), Time(12, 45), Time(12 + 3/4)
```

```
new(Time, 12, 45), new(Time, 12, 45), new(Time, 12, 45)
```

```
Time(), Time(8.25), Time(1/2)
```

```
new(Time, 0, 0), new(Time, 8, 15), new(Time, 0, 30)
```

In order to have a nicer output for objects of the domain `Time`, we also define a `"print"` method (see the help page for `print`):

```
Time::print := proc(TM)
begin
  expr2text(extop(TM, 1)) . ":" .
  stringlib::format(expr2text(extop(TM, 2)), 2, Right, "0")
end_proc:
```

```
Time::new(12, 45), Time(12, 45), Time(12 + 3/4)
```

```
     12:45, 12:45, 12:45
```

```
Time(), Time(8.25), Time(1/2)
```

```
     0:00, 8:15, 0:30
```

Parameters

T

A MuPAD domain

object1, object2, …

Arbitrary MuPAD objects

Return Values

Element of the domain T.

DOM_DOMAIN

MuPAD Functions
extnops | extop | extsubsop | newDomain | op

newDomain

Create a new data type (domain)

Syntax

```
newDomain(k)
```

```
newDomain(k, T)
```

```
newDomain(k, t)
```

Description

`newDomain(k)` creates a new domain with key `k`.

`newDomain(k, T)` creates a copy of the domain `T` with new key `k`.

`newDomain(k, t)` creates a new domain with key `k` and slots from the table `t`.

Data types in MuPAD are called *domains*. `newDomain` is a low-level function for defining new data types. Cf. the corresponding entry in the Glossary for links to documentation about domains and more comfortable ways of defining new data types. The help page of `DOM_DOMAIN` contains a tutorial example for defining a new domain via `newDomain`.

Technically, a domain is something like a table. The entries of this table are called slots or *methods*. They serve for extending the functionality of standard MuPAD functions, such as the arithmetic operations `+` and `*`, the special mathematical functions `exp` and `sin`, or the symbolic manipulation functions `simplify` and `normal`, to objects of a domain in a modular, object-oriented way, without the need to modify the source code of the standard function. This is known as overloading.

The function `slot` and the equivalent operator `::` serve for defining and accessing a specific slot of a domain. The function `op` returns all slots of a domain.

Each domain has a distinguished slot `"key"`, which is its unique identification. There can be no two different domains with the same key. Typically, but not necessarily, the key is a string. However, the key serves mainly for internal and output purposes. Usually

a domain is assigned to an identifier immediately after its creation, and you access the domain via this identifier.

If a domain with the given key already exists, `newDomain(k)` returns that domain; both other forms of calling `newDomain` yield an error.

Examples

Example 1

We create new domain with key `"my-domain"`. This key is also used for output, but without quotes:

```
T := newDomain("my-domain")
```

```
my-domain
```

You can create elements of this domain with the function `new`:

```
e := new(T, 42);
domtype(e)
```

```
new(my-domain, 42)
```

```
my-domain
```

With the slot operator `::`, you can define a new slot or access an existing one:

```
op(T)
```

```
"key" = "my-domain"
```

```
T::key, T::myslot
```

```
"my-domain", FAIL
```

```
T::myslot := 42: op(T)
```

```
"key" = "my-domain", "myslot" = 42
```

```
T::myslot^2
```

```
1764
```

If a domain with key `k` already exists, then `newDomain(k)` does not create a new domain, but returns the existing domain instead:

```
T1 := newDomain("my-domain"):
op(T1)
```

```
"key" = "my-domain", "myslot" = 42
```

Note that you cannot delete a domain; the command `delete T` only deletes the value of the identifier `T`, but does not destroy the domain with the key `"my-domain"`:

```
delete T, T1:
T2 := newDomain("my-domain"):
op(T2);
delete T2:
```

```
"key" = "my-domain", "myslot" = 42
```

Example 2

There cannot exist different domains with the same key at the same time. Defining a slot for a domain implicitly changes all identifiers that have this domain as their value:

```
T := newDomain("1st"): T1 := T:
op(T);
op(T1);
```

```
"key" = "1st"
```

```
"key" = "1st"
```

```
T1::mySlot := 42:
op(T);
op(T1);
```

"key" = "1st", "mySlot" = 42

"key" = "1st", "mySlot" = 42

To avoid this, you can create a copy of a domain. You must reserve a new, unused key for that copy:

```
T2 := newDomain("2nd", T):
T2::anotherSlot := infinity:
op(T);
op(T2);
```

"key" = "1st", "mySlot" = 42

"key" = "2nd", "mySlot" = 42, "anotherSlot" = ∞

```
delete T, T1, T2:
```

Example 3

You can provide a domain with slots already when creating it:

```
T := newDomain("3rd",
  table("myslot" = 42, "anotherSlot" = infinity)):
op(T);
T::myslot, T::anotherSlot
```

"myslot" = 42, "anotherSlot" = ∞, "key" = "3rd"

42, ∞

```
delete T:
```

Parameters

k

An arbitrary object; typically a string

T

A domain

t

The slots of the domain: a table

Return Values

Object of type `DOM_DOMAIN`.

More About

- "Define Your Own Data Types"

next, _next

Skip a step in a loop

Syntax

```
next
```

```
_next()
```

Description

`next` interrupts the current step in `for`, `repeat`, and `while` loops. Execution proceeds with the next step of the loop.

The `next` statement is equivalent to the function call `_next()`. The return value is the void object of type `DOM_NULL`.

Inside `for`, `repeat`, and `while` loops, the `next` statement interrupts the current step of the loop. In `for` statements, the loop variable is incremented and execution continues at the beginning of the loop. Similarly, the control conditions at the beginning of a `while` loop and in the `until` clause of a `repeat` loop are verified, before execution continues at the beginning of the loop.

Outside `for`, `repeat`, and `while` loops, the `next` statement has no effect.

Examples

Example 1

In the following `for` loop, any step with even `i` is skipped:

```
for i from 1 to 5 do
  if testtype(i, Type::Even) then next end_if;
  print(i)
end_for:
```

```
    1

    3

    5
```

In the following `repeat` loop, all steps with odd `i` are skipped:

```
i := 0:
repeat
  i := i + 1;
  if testtype(i, Type::Odd) then next end_if;
  print(i)
until i >= 5 end_repeat:
```

```
    2

    4
```

```
delete i:
```

See Also

MuPAD Functions

`break` | `case` | `for` | `repeat` | `return` | `while`

nextprime

Next prime number

Syntax

```
nextprime(m)
```

Description

`nextprime(m)` returns the smallest prime number larger than or equal to `m`.

If the argument `m` is an integer, then `nextprime` returns the smallest prime number larger than or equal to `m`. A symbolic call of type `"nextprime"` is returned, if the argument is not of type `Type::Numeric`. An error occurs if the argument is a number that is not an integer.

The first prime number is 2.

Examples

Example 1

The first prime number is computed:

```
nextprime(-13)
```

```
    2
```

If the argument of `nextprime` is a prime number, this number is returned:

```
nextprime(11)
```

```
    11
```

We compute a large prime:

```
nextprime(56475767478567)
```

$$56475767478601$$

Symbolic arguments lead to a symbolic call:

```
nextprime(x)
```

$$\text{nextprime}(x)$$

Parameters

m

An arithmetical expression

Return Values

Prime number or a symbolic call to `nextprime`.

Algorithms

`nextprime` uses a fast probabilistic prime number test (Miller-Rabin test) to decide if the computed result is a prime number. The result returned by `nextprime` is either a prime number or a strong pseudo-prime for 10 randomly chosen bases.

MuPAD Functions

`ifactor` | `igcd` | `ilcm` | `isprime` | `ithprime` | `prevprime`

NIL

Singleton element of the domain DOM_NIL

Syntax

```
NIL
```

Description

`NIL` is a keyword of the MuPAD language which represents the singleton element of the domain `DOM_NIL`.

The kernel domain `DOM_NIL` has only one singleton element. `NIL` is a keyword of the MuPAD language which represents this element. `NIL` is not changed by evaluation, see `DOM_NIL`.

Most often, `NIL` is used to represent a “missing” or “void” operand in a data structure. The “void object” returned by `null` is not suitable for this, because it is removed from most containers (like lists, sets or expressions) during evaluation.

When a new array from the kernel domain `DOM_ARRAY` is created, its elements are initialized with the value `NIL`. The function `op` returns `NIL` for un-initialized array elements. Note, however, that an indexed access of an un-initialized array element returns the indexed expression instead of `NIL`.

Local variables of procedures defined by `proc` are initialized with `NIL`. Nevertheless, a warning is printed if one accesses a local variable without explicitly initializing its value.

In former versions of MuPAD, `NIL` was used to delete values of identifiers or entries of tables, by assigning `NIL` to the identifier or entry. This is no longer supported. One must use `delete` to delete values. `NIL` now is a valid value of an identifier and a valid entry of a table.

Examples

Example 1

Unlike the "void object" returned by `null`, `NIL` is not removed from lists and sets:

```
[1, NIL, 2, NIL], [1, null(), 2, null()],
{1, NIL, 2, NIL}, {1, null(), 2, null()}
```

$$[1, \mathrm{NIL}, 2, \mathrm{NIL}], [1, 2], \{1, 2, \mathrm{NIL}\}, \{1, 2\}$$

Example 2

`NIL` is used to represent "missing" entries of procedures. For example, the simplest procedure imaginable has the following operands:

```
op(proc() begin end)
```

$$\mathrm{NIL}, \mathrm{NIL}, \mathrm{NIL}, \mathrm{NIL}, \mathrm{NIL}, \mathrm{NIL}, \mathrm{NIL}, \mathrm{NIL}, \mathrm{NIL}, \mathrm{NIL}, \mathrm{NIL}, \mathrm{NIL}, \mathrm{NIL}, \mathrm{NIL}, \mathrm{NIL}, \mathrm{NIL}$$

The first `NIL`, for example, represents the empty argument list, the second the void list of local variables and the third the void set of procedure options.

Example 3

Array elements are initialized with `NIL` if not defined otherwise. Note, however, that the indexed access for such elements yields the indexed expression:

```
A := array(1..2): A[1], op(A,1)
```

$$A_1, \mathrm{NIL}$$

```
delete A:
```

Example 4

Local variables in procedures are implicitly initialized with `NIL`. Still, a warning is printed if one uses the variable without explicitly initializing it:

```
p := proc() local l; begin print(l) end:  p():
```

```
Warning: Uninitialized variable 'l' is used.
  Evaluating: p
```

```
    NIL
```

```
delete p:
```

Example 5

NIL may be assigned to an identifier or indexed identifier like any other value. Such an assignment no longer deletes the value of the identifier:

```
a := NIL:  b[1] := NIL:  a, b[1]
```

```
    NIL, NIL
```

```
delete a, b:
```

See Also

MuPAD Functions
delete | FAIL | null

nops

Number of operands

Syntax

```
nops(object)
```

Description

`nops(object)` returns the number of operands of the object.

See the help page of `op` for details on the MuPAD concept of “operands”.

For sets, lists, and tables, the function `nops` returns the number of elements or entries, respectively. Note that expressions of type `DOM_EXPR`, arrays and hfarrays have a 0-th operand which is *not counted* by `nops`. For arrays, also non-initialized elements are counted by `nops`.

The void object `null()` of type `DOM_NULL`, the empty list`[ ]`, the empty set`{ }`, and the empty table`table()` have no operands: `nops` returns `0`. Cf. “Example 1” on page 1-1400.

Integers of domain type `DOM_INT`, real floating-point numbers of domain type `DOM_FLOAT`, Boolean constants of domain type `DOM_BOOL`, identifiers of domain type `DOM_IDENT`, and strings of domain type `DOM_STRING` are `atomic' objects having only 1 operand: the object itself. Rational numbers of domain type `DOM_RAT` and complex numbers of domain type `DOM_COMPLEX` have 2 operands: the numerator and denominator and the real part and imaginary part, respectively. Cf. “Example 2” on page 1-1401.

In contrast to most other MuPAD functions, `nops` does not flattenexpression sequences. Cf. “Example 3” on page 1-1402.

Examples

Example 1

The following expression has the type "_plus" and the three operands `a*b`, `3*c`, and `d`:

```
nops(a*b + 3*c + d)
```

```
3
```

For sets and lists, `nops` returns the number of elements. Note that the sublist `[1, 2, 3]` and the subset `{1, 2}` each count as one operand in the following examples:

```
nops({a, 1, [1, 2, 3], {1, 2}})
```

```
4
```

```
nops([[1, 2, 3], 4, 5, {1, 2}])
```

```
4
```

Empty objects have no operands:

```
nops(null()), nops([ ]), nops({}), nops(table())
```

```
0, 0, 0, 0
```

The number of operands of a symbolic function call is the number of arguments:

```
nops(f(3*x, 4, y + 2)), nops(f())
```

```
3, 0
```

Example 2

Integers and real floating-point numbers only have one operand:

```
nops(12), nops(1.41)
```

```
1, 1
```

The same holds true for strings; use `length` to query the length of a string:

```
nops("MuPAD"), length("MuPAD")
```

```
1, 5
```

The number of operands of a rational number or a complex number is 2, even if the real part is zero:

```
nops(-3/2), nops(1 + I), nops(2*I)
```

```
2, 2, 2
```

A function environment has 3 and a procedure has 16 operands:

```
nops(sin), nops(op(sin, 1))
```

```
3, 16
```

Example 3

Expression sequences are not flattened by nops:

```
nops((1, 2, 3))
```

```
3
```

In contrast to the previous call, the following command calls nops with three arguments:

```
nops(1, 2, 3)
```

```
Error: The number of arguments is incorrect. [nops]
```

Parameters

object

An arbitrary MuPAD object

Return Values

Nonnegative integer.

Overloaded By

object

See Also

MuPAD Functions
`extnops` | `extop` | `extsubsop` | `length` | `op` | `subsop`

norm

Compute the norm of a matrix, a vector, or a polynomial

Syntax

```
norm(M, <1 | 2 | Frobenius | Infinity | Spectral>)
norm(v, <Frobenius | Infinity | kv>)
norm(p, <kp>)
norm(f, <vars>, <kp>)
```

Description

`norm(M, kM)` computes the norm of index `kM` of the matrix `M`.

`norm(v, kv)` computes the norm of index `kv` of the vector `v`.

`norm(p, kp)` computes the norm of index `kp` of the polynomial `p`.

In MuPAD, there is no difference between matrices and vectors: a vector is a matrix of dimension $1 \times n$ or $n \times 1$, respectively.

For an $m \times n$ matrix `M` = (M_{ij}) with $min(m, n) > 1$, only the 1-norm (maximum column sum)

$$\|M\|_1 = \max\left(\sum_{i=1}^{m} \left|M_{i,j}\right|\right),\ j = 1, \ldots, n$$

,

the Frobenius norm

$$\|M\| = \sqrt{\sum_{i=1}^{m}\left(\sum_{j=1}^{n} \left|M_{ij}\right|^2\right)}$$

,

the spectral norm

$$\|M\|_2 = \sqrt{\phi},$$

where ϕ is the largest eigenvalue of $A^H A$ and the *infinity*-norm (maximum row sum)

$$\|M\|_\infty = \max\left(\sum_{j=1}^{n} |M_{1,j}|, \sum_{j=1}^{n} |M_{2,j}|, \ldots, \sum_{j=1}^{n} |M_{m,j}|\right)$$

can be computed. The 1-norm and the `Infinity`-norm are operator norms with respect to the corresponding norms on the vector spaces the matrix is acting upon.

For vectors $\mathsf{v} = (v_i)$, represented by matrices of dimension $1 \times n$ or $n \times 1$, norms with arbitrary positive integer indices k as well as `Infinity` can be computed. For integers $k > 1$, the vector norms are given by

$$\|v\|_k = \left(\sum_{i=1}^{n} |v_i|^k\right)^{1/k}$$

for column vectors as well as for row vectors.

For indices 1, `Infinity`, and `Frobenius`, the vector norms are given by the corresponding matrix norms. For column vectors, the 1-norm is the sum norm

$$\|v\|_1 = \sum_{i=1}^{n} |v_i|,$$

the `Infinity`-norm is the maximum norm

$$\|v\|_\infty = \max\left(|v_1|, \ldots, |v_n|\right)$$

(this is the limit of the k-norms as k tends to infinity).

Note: For row vectors, the 1-norm is the maximum norm, whilst the `Infinity`-norm is the sum norm.

The Frobenius norm coincides with `norm(v, 2)` for both column and row vectors.

Cf. “Example 2” on page 1-1408.

Matrices and vectors may contain symbolic entries. No internal float conversion is applied.

For matrix and vector norms, also refer to the help page of `Dom::Matrix` (note that the function `matrix` generates matrices of type `Dom::Matrix()`).

For polynomials `p` with coefficients c_i, the norms are given by

$$\|p\|_\infty = \max\left(|c_i|\right),\ \|p\|_k = \left(\sum_{i=1}^{n} |c_i|^k\right)^{1/k}.$$

Also multivariate polynomials are accepted by `norm`. The coefficients with respect to all indeterminates are taken into account.

For polynomials, only numerical norms can be computed. The coefficients of the polynomial must not contain symbolic parameters that cannot be converted to floating-point numbers. Coefficients containing symbolic numerical expressions such as `PI+1`, `sqrt(2)` etc. are accepted. Internally, they are converted to floating-point numbers. Cf. “Example 3” on page 1-1408.

For indices `k> 1`, `norm(p, k)` always returns a floating-point number. The 1-norm produces an exact result if all coefficients are integers or rational numbers. The *infinity*-norm `norm(p)` produces an exact result, if the coefficient of largest magnitude is an integer or a rational number. In all other cases, also the 1-norm and the *infinity*-norm produce floating-point numbers. Cf. “Example 3” on page 1-1408.

For polynomials over the coefficient ring `IntMod(m)`, `norm` produces an error.

If the coefficient ring of the polynomial is a domain, it must implement the method `"norm"`. This method must return the norm of the coefficients as a number or as a numerical expression that can be converted to a floating-point number via `float`. With the coefficient norms $\|c_i\|$, `norm(p)` computes the maximum norm $\max\left(\|c_1\|, \ldots, \|c_n\|\right)$; `norm(p, k)` computes $\left(\sum_{i=1}^{n} \|c_i\|^k\right)^{1/k}$.

A polynomial expression `f` is internally converted to the polynomial `poly(f)`. If a list of indeterminates is specified, the norm of the polynomial `poly(f, vars)` is computed.

For polynomials and polynomial expressions, the norms are computed by a function of the system kernel.

Examples

Example 1

We compute various norms of a 2×3 matrix:

```
M := matrix([[2, 5, 8], [-2, 3, 5]]):
norm(M) = norm(M, Infinity),
norm(M, 1),
norm(M, Frobenius),
norm(M, Spectral)
```

$$15 = 15,\ 13,\ \sqrt{131},\ \sqrt{\frac{\sqrt{13429}}{2} + \frac{131}{2}}$$

For matrices, `norm` produces exact symbolic results:

```
M := matrix([[2/3, 63, PI],[x, y, z]]):
norm(M)
```

$$\max\left(\pi + \frac{191}{3},\ |x| + |y| + |z|\right)$$

```
norm(M, 1)
```

$$\max\left(|x| + \frac{2}{3},\ |y| + 63,\ \pi + |z|\right)$$

```
norm(M, Frobenius)
```

$$\sqrt{|x|^2 + |y|^2 + |z|^2 + \pi^2 + \frac{35725}{9}}$$

```
delete M:
```

Example 2

A column vector `col` and a row vector `row` are considered:

```
col := matrix([x1, PI]): row := matrix([[x1, PI]]): col, row
```

$$\begin{pmatrix} x1 \\ \pi \end{pmatrix}, \begin{pmatrix} x1 & \pi \end{pmatrix}$$

```
norm(col, 2) = norm(row, 2)
```

$$\sqrt{|x1|^2 + \pi^2} = \sqrt{|x1|^2 + \pi^2}$$

```
norm(col, 3) = norm(row, 3)
```

$$(|x1|^3 + \pi^3)^{1/3} = (|x1|^3 + \pi^3)^{1/3}$$

Note that the norms of index 1 and `Infinity` have exchanged meanings for column and row vectors:

```
norm(col, 1) = norm(row, Infinity)
```

$$\pi + |x1| = \pi + |x1|$$

```
norm(col, Infinity) = norm(row, 1)
```

$$\max(|x1|, \pi) = \max(|x1|, \pi)$$

```
delete col, row:
```

Example 3

The norms of some polynomials are computed:

```
p := poly(3*x^3 + 4*x, [x]): norm(p), norm(p, 1)
```

$$4, 7$$

If the coefficients are not integers or rational numbers, automatic conversion to floating-point numbers occurs:

```
p := poly(3*x^3 + sqrt(2)*x + PI, [x]): norm(p), norm(p, 1)
```

```
3.141592654, 7.555806216
```

Floating point numbers are always produced for indices greater than 1:

```
p := poly(3*x^3 + 4*x + 1, [x]):
norm(p, 1), norm(p, 2), norm(p, 5), norm(p, 10), norm(p)
```

```
8, 5.099019514, 4.174686339, 4.021974513, 4
```

```
delete p:
```

Example 4

The norms of some polynomial expressions are computed:

```
norm(x^3 + 1, 1), norm(x^3 + 1, 2), norm(x^3 + PI)
```

```
2, 1.414213562, 1
```

The following call yields an error, because the expression is regarded as a polynomial in `x`. Consequently, symbolic coefficients $6\,y$ and $9\,y^2$ are found which are not accepted:

```
f := 6*x*y + 9*y^2 + 2: norm(f, [x])
```

```
Error: The argument is invalid. [norm]
```

As a bivariate polynomial with the indeterminates `x` and `y`, the coefficients are 6, 9, and 2. Now, norms can be computed:

```
norm(f, [x, y], 1), norm(f, [x, y], 2), norm(f, [x, y])
```

```
17, 11.0, 9
```

```
delete f:
```

Parameters

`M`

A matrix of domain type `Dom::Matrix(...)`

`v`

A vector (a 1-dimensional matrix)

`kv`

A positive integer as index of the vector norm.

`p`

A polynomial generated by `poly`

`f`

A polynomial expression

`vars`

A list of identifiers or indexed identifiers, interpreted as the indeterminates of `f`

`kp`

The index of the norm of the polynomial: a real number greater or equal than 1. If no index is specified, the maximum norm (of index infinity) is computed.

Options

`Frobenius`

Computes the Frobenius norm for vectors and matrices.

`Infinity`

Computes the Infinity norm for vectors and matrices.

`Spectral`

Computes the Spectral norm for matrices.

Return Values

Arithmetical expression.

Overloaded By

f, p

See Also

MuPAD Functions
`coeff` | `float` | `matrix` | `poly`

normal

Normalize an expression

Syntax

```
normal(f, options)
```

```
normal(object)
```

Description

`normal(f)` returns a normal form of the rational expression `f`. MuPAD regards an expression as normalized when it is a fraction where both numerator and denominator are polynomials whose greatest common divisor is 1.

`normal(object)` replaces the operands of `object` with their normalized form.

`normal` and `simplifyFraction` are equivalent.

If argument `f` contains irrational subexpressions such as `sin(x)`, `x^(-1/3)` etc., then these are replaced by auxiliary variables before normalization. After normalization, these variables are replaced by the normalization of the original subexpressions. Algebraic dependencies of the subexpressions are not taken into account. The operands of the non-rational subexpressions are normalized recursively.

If argument `f` contains floating-point numbers, then these are replaced by rational approximants (see `numeric::rationalize`). In the end, `float` is applied to the result.

With the `Expand` option, the normal form is unique for rational expressions: it is the quotient of expanded polynomials whose greatest common divisor is 1. If `f` and `g` are rational expressions, the following statements are equivalent:

- `f` and `g` are mathematically equivalent.
- `normal(f, Expand) = normal(g, Expand)`
- `normal(f - g, Expand) = 0`

A normal form generated without the `Expand` option (which is equivalent to `Expand = FALSE`) is the quotient of products of powers of expanded polynomials, where all

factors of the numerator and the denominator are coprime. MuPAD regards factorized expressions, such as $x\,(x + 1)$, and equivalent expanded expressions, such as $x^2 + x$, as normalized. Therefore, if you do not use `Expand`, there is no unique normal form of a rational expression.

If `f` and `g` are rational expressions, these statements are equivalent:

- `f` and `g` are mathematically equivalent.
- `normal(f - g) = 0`

For special objects, `normal` is automatically mapped to its operands. In particular, if `object` is a polynomial of domain type `DOM_POLY`, then its coefficients are normalized. Further, if `object` is a set, list, table or array, respectively, then `normal` is applied to all entries. Further, the left and right sides of equations (type `"_equal"`), inequalities (type `"_unequal"`), and relations (type `"_less"` or `"_leequal"`) are normalized. Further, the operands of ranges (type `"_range"`) are normalized automatically.

Examples

Example 1

Compute the normal form of some rational expressions:

```
normal(x^2 - (x + 1)*(x - 1))
```

$$1$$

```
normal((x^2 - 1)/(x + 1))
```

$$x - 1$$

```
normal(1/(x + 1) + 1/(y - 1))
```

$$\frac{x + y}{(x + 1)\,(y - 1)}$$

The following expression must be regarded as a rational expression in the "indeterminates" `y` and `sin(x)`:

```
normal(1/sin(x)^2 + y/sin(x))
```

$$\frac{y \sin(x) + 1}{\sin(x)^2}$$

Example 2

Normalize the entries of this list:

```
[(x^2 - 1)/(x + 1), x^2 - (x + 1)*(x - 1)]
```

$$\left[\frac{x^2 - 1}{x + 1}, x^2 - (x - 1)\,(x + 1)\right]$$

```
normal(%)
```

$$[x - 1,\ 1]$$

Now, normalize the coefficients of polynomials:

```
poly((x^2-1)/(x+1)*Y^2 + (x^2-(x+1)*(x-1))*Y - 1, [Y])
```

$$\mathrm{poly}\left(\frac{x^2 - 1}{x + 1}\,Y^2 + (-(x - 1)\,(x + 1) + x^2)\,Y - 1, [Y]\right)$$

```
normal(%)
```

$$\mathrm{poly}((x - 1)\,Y^2 + Y - 1, [Y])$$

Example 3

If you use the `Expand` option, `normal` returns a fraction with the expanded numerator and denominator:

```
normal(x/(x^6 - 1) + x^2/(x^4 - 1), Expand)
```

$$-\frac{x^6+x^4+x^3+x^2+x}{-x^8-x^6+x^2+1}$$

Without `Expand`, a fraction returned by `normal` can contain factored expressions:

```
normal(x/(x^6 - 1) + x^2/(x^4 - 1))
```

$$\frac{x\,(x^5+x^3+x^2+x+1)}{(x^2-1)\,(x^2+1)\,(x^4+x^2+1)}$$

Example 4

If you use the `List` option, `normal` returns a list consisting of the numerator and denominator of the input:

```
normal((x^2-1)/(x^2+2*x+1), List)
```

$$[x-1,\ x+1]$$

Note that `normal(f, List)` is *not* the same as `[numer(f), denom(f)]`:

```
[numer, denom]((x^2-1)/(x^2+2*x+1))
```

$$[x^2-1,\ x^2+2\,x+1]$$

Example 5

To skip calculation of common divisors of the numerator and denominator of an expression, use the `NoGcd` option:

```
y := (x^4 - 1)/(x + 1) + 1:
normal(y);
normal(y, NoGcd)
```

$$x^3-x^2+x$$

$$\frac{x^4 + x}{x + 1}$$

Example 6

To specify common divisors that you want to cancel out, use the `ToCancel` option:

```
y := (x^4 - 1)/(x^2 - 1):
normal(y, ToCancel = {x - 1})
```

$$\frac{x^3 + x^2 + x + 1}{x + 1}$$

Example 7

By default, `normal` calls the `rationalize` function in attempt to rationalize the input expression. You might speed up computations by using `Rationalize = None` in conjunction with the `Expand` option. This combination of options lets you skip investigating algebraic dependencies and, therefore, saves some time:

```
n := exp(u):
a := (n^2 + n)/(n + 1) + 1:
normal(a, Expand, Rationalize = None)
```

$$\frac{e^{2u} + 2\,e^{u} + 1}{e^{u} + 1}$$

Without `Rationalize = None`, MuPAD analyzes algebraic dependencies and returns this result:

```
normal(a, Expand)
```

$$e^{u} + 1$$

Example 8

Disable recursive calls to `normal` for subexpressions by using `Recursive = FALSE`:

```
y := sqrt((x^2 + 2*x + 1)/(x + 1)):
normal(y, Recursive = FALSE)
```

$$\sqrt{\frac{x^2+2x+1}{x+1}}$$

Example 9

Solve this equation, and sum up the fifth powers of the solutions:

```
solutions := solve(x^3 + x^2 + 1, x, MaxDegree = 3):
f := _plus((solutions[i]^7) $i = 1..3)
```

$$-\left(\frac{1}{3}-\frac{\sigma_1}{2}-\frac{1}{18\,\sigma_1}+\frac{\sqrt{3}\left(\frac{1}{9\,\sigma_1}-\sigma_1\right)i}{2}\right)^7+\left(\frac{1}{18\,\sigma_1}+\frac{\sigma_1}{2}-\frac{1}{3}+\frac{\sqrt{3}\left(\frac{1}{9\,\sigma_1}-\sigma_1\right)i}{2}\right)^7$$

$$-\left(\frac{1}{9\,\sigma_1}+\sigma_1+\frac{1}{3}\right)^7$$

where

$$\sigma_1=\left(\frac{29}{54}-\frac{\sqrt{31}\,\sqrt{108}}{108}\right)^{1/3}$$

Normalizing the result returns:

```
normal(f)
```

$$-15$$

To limit the number of internally repeated calls to `normal` due to analysis of algebraic dependencies, use the `Iterations` option. The default number of iterations is 5. Use the `Iterations` option to increase or decrease the number of iterations. For example, normalize the result using just one iteration:

```
normal(f, Iterations = 1)
```

$$-\frac{\frac{181875\sqrt{31}\sqrt{108}}{4}+3168963\left(\frac{\sqrt{31}\sqrt{108}}{108}-\frac{29}{54}\right)^3-\frac{5261843}{2}}{531441\left(\frac{29\sqrt{31}\sqrt{108}}{2916}-\frac{839}{1458}\right)}$$

After two iterations, the result becomes shorter:

```
normal(f, Iterations = 2)
```

$$-\frac{5073840\sqrt{31}\sqrt{108}-293582880}{11664\,(29\sqrt{31}\sqrt{108}-1678)}$$

After three iterations, you get the simplest result:

```
normal(f, Iterations = 3)
```

$$-15$$

Parameters

`f`

An arithmetical expression

`object`

A polynomial of type `DOM_POLY`, list, set, table, array, equation, inequality, or range

Options

`Expand`

Return the numerator and denominator of the normalized expression in expanded form. See “Details” for more information. By default, `Expand = FALSE`.

`List`

Return a list consisting of the numerator and denominator of `f`. By default, `List = FALSE`.

`NoGcd`

Skip computing common divisors of the numerator and denominator of `f`. By default, `NoGcd = FALSE`.

`ToCancel`

Option, specified as `ToCancel = {expr1, expr2, …}`

Cancel out only the specified common divisors `{expr1, expr2,...}`.

`Rationalize`

Option, specified as `Rationalize = None`

Perform only basic rationalization of an irrational input expression. Skip investigating algebraic dependencies. This option works only in conjunction with the `Expand` option. Otherwise, `normal` ignores this option. See “Example 7” on page 1-1416.

`Recursive`

Recursively normalize subexpressions of an irrational expression. By default, `Recursive = TRUE`.

`Iterations`

Option, specified as `Iterations = n`

Specify the number of repeated calls to `normal`. Repeated calls appear when analysis of algebraic dependencies results in new irrational subexpressions. By default, `n = 5`.

Return Values

Object of the same type as the input object, or a list of two arithmetical expressions if the `List` option is used.

- "Choose Simplification Functions"

simplifyFraction

Normalize an expression

Syntax

```
simplifyFraction(f, options)
```

```
simplifyFraction(object)
```

Description

`simplifyFraction(f)` returns a normal form of the rational expression `f`. MuPAD regards an expression as normalized when it is a fraction where both numerator and denominator are polynomials whose greatest common divisor is 1.

`simplifyFraction(object)` replaces the operands of `object` with their normalized form.

`normal` and `simplifyFraction` are equivalent.

If argument `f` contains irrational subexpressions such as `sin(x)`, `x^(-1/3)` etc., then these are replaced by auxiliary variables before normalization. After normalization, these variables are replaced by the normalization of the original subexpressions. Algebraic dependencies of the subexpressions are not taken into account. The operands of the non-rational subexpressions are normalized recursively.

If argument `f` contains floating-point numbers, then these are replaced by rational approximants (see `numeric::rationalize`). In the end, `float` is applied to the result.

With the `Expand` option, the normal form is unique for rational expressions: it is the quotient of expanded polynomials whose greatest common divisor is 1. If `f` and `g` are rational expressions, the following statements are equivalent:

- `f` and `g` are mathematically equivalent.
- `normal(f, Expand) = normal(g, Expand)`
- `normal(f - g, Expand) = 0`

A normal form generated without the `Expand` option (which is equivalent to `Expand = FALSE`) is the quotient of products of powers of expanded polynomials, where all factors of the numerator and the denominator are coprime. MuPAD regards factorized expressions, such as $x\,(x + 1)$, and equivalent expanded expressions, such as $x^2 + x$, as normalized. Therefore, if you do not use `Expand`, there is no unique normal form of a rational expression.

If `f` and `g` are rational expressions, these statements are equivalent:

- `f` and `g` are mathematically equivalent.
- `normal(f - g) = 0`

For special objects, `normal` is automatically mapped to its operands. In particular, if `object` is a polynomial of domain type `DOM_POLY`, then its coefficients are normalized. Further, if `object` is a set, list, table or array, respectively, then `normal` is applied to all entries. Further, the left and right sides of equations (type `"_equal"`), inequalities (type `"_unequal"`), and relations (type `"_less"` or `"_leequal"`) are normalized. Further, the operands of ranges (type `"_range"`) are normalized automatically.

Examples

Example 1

Compute the normal form of some rational expressions:

```
normal(x^2 - (x + 1)*(x - 1))
```

$$1$$

```
normal((x^2 - 1)/(x + 1))
```

$$x - 1$$

```
normal(1/(x + 1) + 1/(y - 1))
```

$$\frac{x + y}{(x + 1)\,(y - 1)}$$

The following expression must be regarded as a rational expression in the "indeterminates" `y` and `sin(x)`:

```
normal(1/sin(x)^2 + y/sin(x))
```

$$\frac{y\,\sin(x)+1}{\sin(x)^2}$$

Example 2

Normalize the entries of this list:

```
[(x^2 - 1)/(x + 1), x^2 - (x + 1)*(x - 1)]
```

$$\left[\frac{x^2-1}{x+1},\ x^2-(x-1)\,(x+1)\right]$$

```
normal(%)
```

$$[x-1,\ 1]$$

Now, normalize the coefficients of polynomials:

```
poly((x^2-1)/(x+1)*Y^2 + (x^2-(x+1)*(x-1))*Y - 1, [Y])
```

$$\mathrm{poly}\left(\frac{x^2-1}{x+1}\,Y^2+(-(x-1)\,(x+1)+x^2)\,Y-1,\ [Y]\right)$$

```
normal(%)
```

$$\mathrm{poly}((x-1)\,Y^2+Y-1,\ [Y])$$

Example 3

If you use the `Expand` option, `normal` returns a fraction with the expanded numerator and denominator:

```
normal(x/(x^6 - 1) + x^2/(x^4 - 1), Expand)
```

$$-\frac{x^6+x^4+x^3+x^2+x}{-x^8-x^6+x^2+1}$$

Without `Expand`, a fraction returned by `normal` can contain factored expressions:

```
normal(x/(x^6 - 1) + x^2/(x^4 - 1))
```

$$\frac{x\,(x^5+x^3+x^2+x+1)}{(x^2-1)\,(x^2+1)\,(x^4+x^2+1)}$$

Example 4

If you use the `List` option, `normal` returns a list consisting of the numerator and denominator of the input:

```
normal((x^2-1)/(x^2+2*x+1), List)
```

$$[x-1,\ x+1]$$

Note that `normal(f, List)` is *not* the same as `[numer(f), denom(f)]`:

```
[numer, denom]((x^2-1)/(x^2+2*x+1))
```

$$[x^2-1,\ x^2+2\,x+1]$$

Example 5

To skip calculation of common divisors of the numerator and denominator of an expression, use the `NoGcd` option:

```
y := (x^4 - 1)/(x + 1) + 1:
normal(y);
normal(y, NoGcd)
```

$$x^3-x^2+x$$

$$\frac{x^4 + x}{x + 1}$$

Example 6

To specify common divisors that you want to cancel out, use the `ToCancel` option:

```
y := (x^4 - 1)/(x^2 - 1):
normal(y, ToCancel = {x - 1})
```

$$\frac{x^3 + x^2 + x + 1}{x + 1}$$

Example 7

By default, `normal` calls the `rationalize` function in attempt to rationalize the input expression. You might speed up computations by using `Rationalize = None` in conjunction with the `Expand` option. This combination of options lets you skip investigating algebraic dependencies and, therefore, saves some time:

```
n := exp(u):
a := (n^2 + n)/(n + 1) + 1:
normal(a, Expand, Rationalize = None)
```

$$\frac{e^{2u} + 2\,e^{u} + 1}{e^{u} + 1}$$

Without `Rationalize = None`, MuPAD analyzes algebraic dependencies and returns this result:

```
normal(a, Expand)
```

$$e^{u} + 1$$

Example 8

Disable recursive calls to `normal` for subexpressions by using `Recursive = FALSE`:

```
y := sqrt((x^2 + 2*x + 1)/(x + 1)):
normal(y, Recursive = FALSE)
```

$$\sqrt{\frac{x^2+2\,x+1}{x+1}}$$

Example 9

Solve this equation, and sum up the fifth powers of the solutions:

```
solutions := solve(x^3 + x^2 + 1, x, MaxDegree = 3):
f := _plus((solutions[i]^7) $i = 1..3)
```

$$-\left(\frac{1}{3}-\frac{\sigma_1}{2}-\frac{1}{18\,\sigma_1}+\frac{\sqrt{3}\left(\frac{1}{9\,\sigma_1}-\sigma_1\right)i}{2}\right)^7+\left(\frac{1}{18\,\sigma_1}+\frac{\sigma_1}{2}-\frac{1}{3}+\frac{\sqrt{3}\left(\frac{1}{9\,\sigma_1}-\sigma_1\right)i}{2}\right)^7$$

$$-\left(\frac{1}{9\,\sigma_1}+\sigma_1+\frac{1}{3}\right)^7$$

where

$$\sigma_1=\left(\frac{29}{54}-\frac{\sqrt{31}\,\sqrt{108}}{108}\right)^{1/3}$$

Normalizing the result returns:

```
normal(f)
```

$$-15$$

To limit the number of internally repeated calls to `normal` due to analysis of algebraic dependencies, use the `Iterations` option. The default number of iterations is 5. Use the `Iterations` option to increase or decrease the number of iterations. For example, normalize the result using just one iteration:

```
normal(f, Iterations = 1)
```

$$-\frac{\frac{181875\sqrt{31}\sqrt{108}}{4}+3168963\left(\frac{\sqrt{31}\sqrt{108}}{108}-\frac{29}{54}\right)^3-\frac{5261843}{2}}{531441\left(\frac{29\sqrt{31}\sqrt{108}}{2916}-\frac{839}{1458}\right)}$$

After two iterations, the result becomes shorter:

```
normal(f, Iterations = 2)
```

$$-\frac{5073840\sqrt{31}\sqrt{108}-293582880}{11664\,(29\sqrt{31}\sqrt{108}-1678)}$$

After three iterations, you get the simplest result:

```
normal(f, Iterations = 3)
```

$$-15$$

Parameters

`f`

An arithmetical expression

`object`

A polynomial of type `DOM_POLY`, list, set, table, array, equation, inequality, or range

Options

`Expand`

Return the numerator and denominator of the normalized expression in expanded form. See “Details” for more information. By default, `Expand = FALSE`.

`List`

Return a list consisting of the numerator and denominator of `f`. By default, `List = FALSE`.

NoGcd

Skip computing common divisors of the numerator and denominator of `f`. By default, `NoGcd = FALSE`.

ToCancel

Option, specified as `ToCancel = {expr1, expr2, …}`

Cancel out only the specified common divisors `{expr1, expr2,...}`.

Rationalize

Option, specified as `Rationalize = None`

Perform only basic rationalization of an irrational input expression. Skip investigating algebraic dependencies. This option works only in conjunction with the `Expand` option. Otherwise, `normal` ignores this option. See "Example 7" on page 1-1425.

Recursive

Recursively normalize subexpressions of an irrational expression. By default, `Recursive = TRUE`.

Iterations

Option, specified as `Iterations = n`

Specify the number of repeated calls to `normal`. Repeated calls appear when analysis of algebraic dependencies results in new irrational subexpressions. By default, `n = 5`.

Return Values

Object of the same type as the input object, or a list of two arithmetical expressions if the `List` option is used.

NOTEBOOKFILE

Notebook file name

Description

The environment variables NOTEBOOKFILE and NOTEBOOKPATH store the absolute file name and the directory name, respectively, of the current notebook in the MuPAD Notebook app as a string.

Possible values: String

The environment variable NOTEBOOKFILE stores the name of the current notebook that is connected to the MuPAD kernel.

The environment variable NOTEBOOKPATH stores the name of the directory where the current notebook is located.

These variables are useful, for example, when reading files that are located relative to the notebook.

Both variables only have a value if the notebook has a name, which is generally the case when an existing notebook has been opened or a new notebook has been saved.

The name given by NOTEBOOKFILE is an absolute file name.

Both variables are read-only and are write-protected. One cannot assign a new value to NOTEBOOKFILE in order to change the name of the notebook.

NOTEBOOKFILE and NOTEBOOKPATH are only defined in the MuPAD Notebook app. When using the MuPAD engine from MATLAB, the two variables are just normal identifiers.

Examples

Example 1

In the MuPAD Notebook app, you can specify startup commands for a notebook, which are executed when the notebook is connected to a kernel.

In the startup commands you can use NOTEBOOKPATH to read a source file "my_init.mu" which is stored in the directory of the notebook:

```
fread(NOTEBOOKPATH."my_init.mu")
```

nterms

Number of terms of a polynomial

Syntax

```
nterms(p)
```

```
nterms(f, <vars>)
```

Description

`nterms(p)` returns the number of terms of the polynomial `p`.

If the first argument `f` is not element of a polynomial domain, then `nterms` converts the expression to a polynomial via `poly(f)`. If a list of indeterminates is specified, then the polynomial `poly(f, vars)` is considered.

A zero polynomial has no terms: the return value is 0.

Examples

Example 1

We give some self explaining examples:

```
nterms(x^2*y^2 + x^2 + y + 2, [x, y])
```

```
    4
```

```
nterms(poly(x^2*y^2 + x^2 + y + 2))
```

```
    4
```

```
nterms(poly(0, [x]))
```

```
0
```

Example 2

The following polynomial expression may be regarded as a polynomial in different ways:

```
f := x^2*y^2 + x^2 + y + 2:
nterms(f, [x]), nterms(f, [y]), nterms(f, [x, y]),
nterms(f, [z])
```

```
2, 3, 4, 1
```

```
delete f:
```

Parameters

`p`

A polynomial of type `DOM_POLY`

`f`

A polynomial expression

`vars`

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

Return Values

Nonnegative number. `FAIL` is returned if the input cannot be converted to a polynomial.

Overloaded By

p

See Also

MuPAD Functions

`coeff` | `degree` | `degreevec` | `ground` | `lcoeff` | `ldegree` | `lmonomial` | `lterm` | `monomials` | `nthcoeff` | `nthmonomial` | `nthterm` | `poly` | `poly2list` | `tcoeff`

nthcoeff

N-th non-zero coefficient of a polynomial

Syntax

```
nthcoeff(p, n)
```

```
nthcoeff(f, <vars>, n)
```

Description

`nthcoeff(p, n)` returns the `n`-th non-zero coefficient of the polynomial `p`.

`nthcoeff` returns the `n`-th non-zero coefficient with respect to the lexicographical ordering.

The "first" coefficient is the leading coefficient as returned by `lcoeff`, the "last" coefficient is the trailing coefficient as returned by `tcoeff`.

A zero polynomial has no terms: `nthcoeff` returns `FAIL`.

A polynomial expression `f` is first converted to a polynomial with the variables given by `vars`. If no variables are given, they are searched for in `f`. See `poly` about details of the conversion. `FAIL` is returned if `f` cannot be converted to a polynomial.

The result of `nthcoeff` is not fully evaluated. Evaluation can be enforced by the function `eval`. Cf. "Example 2" on page 1-1438.

Examples

Example 1

We give some self explaining examples:

```
p := poly(100*x^100 + 49*x^49 + 7*x^7, [x]):
nthcoeff(p, 1), nthcoeff(p, 2), nthcoeff(p, 3)
```

```
     100, 49, 7

nthcoeff(p, 4)

     FAIL

nthcoeff(poly(0, [x]), 1)

     FAIL

delete p:
```

Example 2

We demonstrate the evaluation strategy of `nthcoeff`:

```
p := poly(3*x^3 + 6*x^2*y^2 + 2, [x]): y := 4:
nthcoeff(p, 2)
```

$$6\,y^2$$

Evaluation is enforced by `eval`:

```
eval(%)

     96

delete p, y:
```

Parameters

p

A polynomial of type `DOM_POLY`

f

A polynomial expression

`vars`

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

`n`

A positive integer

Return Values

Element of the coefficient domain of the polynomial. An expression is returned if a polynomial expression is given as input. `FAIL` is returned if `n` is larger than the actual number of terms.

Overloaded By

p

See Also

MuPAD Functions

`coeff` | `collect` | `degree` | `degreevec` | `ground` | `lcoeff` | `ldegree` | `lmonomial` | `lterm` | `monomials` | `nterms` | `nthmonomial` | `nthterm` | `poly` | `poly2list` | `tcoeff`

nthmonomial

N-th monomial of a polynomial

Syntax

```
nthmonomial(p, n)
```

```
nthmonomial(f, <vars>, n)
```

Description

`nthmonomial(p, n)` returns the `n`-th non-trivial monomial of the polynomial `p`.

`nthmonomial` returns the `n`-th non-trivial monomial with respect to the lexicographical ordering.

The "first" monomial is the leading monomial as returned by `lmonomial`.

A zero polynomial has no terms: `nthmonomial` returns `FAIL`.

A polynomial expression `f` is first converted to a polynomial with the variables given by `vars`. If no variables are given, they are searched for in `f`. See `poly` about details of the conversion. The result is returned as polynomial expression. `FAIL` is returned if `f` cannot be converted to a polynomial.

The result of `nthmonomial` is not fully evaluated. It can be evaluated by the functions `mapcoeffs` and `eval`. Cf. "Example 2" on page 1-1441.

Examples

Example 1

We give some self explaining examples:

```
p := poly(100*x^100 + 49*x^49 + 7*x^7, [x]):
nthmonomial(p, 1), nthmonomial(p, 2), nthmonomial(p, 3)
```

$$\text{poly}(100\,x^{100}, [x]),\ \text{poly}(49\,x^{49}, [x]),\ \text{poly}(7\,x^{7}, [x])$$

```
nthmonomial(p, 4)
```

$$\text{FAIL}$$

```
nthmonomial(poly(0, [x]), 1)
```

$$\text{FAIL}$$

```
delete p:
```

Example 2

We demonstrate the evaluation strategy of `nthmonomial`:

```
p := poly(3*x^3 + 6*x^2*y^2 + 2, [x]): y := 4:
nthmonomial(p, 2)
```

$$\text{poly}((6\,y^{2})\,x^{2}, [x])$$

Evaluation is enforced by `eval`:

```
mapcoeffs(%, eval)
```

$$\text{poly}(96\,x^{2}, [x])$$

```
delete p, y:
```

Parameters

p

A polynomial of type `DOM_POLY`

f

A polynomial expression

vars

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

n

A positive integer

Return Values

Polynomial of the same type as p. An expression is returned if a polynomial expression is given as input. FAIL is returned if n is larger than the actual number of terms of the polynomial.

Overloaded By

p

See Also

MuPAD Functions

coeff | degree | degreevec | ground | lcoeff | ldegree | lmonomial | lterm | monomials | nterms | nthcoeff | nthterm | poly | poly2list | tcoeff

nthterm

N-th term of a polynomial

Syntax

```
nthterm(p, n)
```

```
nthterm(f, <vars>, n)
```

Description

`nthterm(p, n)` returns the `n`-th non-zero term of the polynomial`p`.

`nthterm` returns the `n`-th non-zero term with respect to the lexicographical ordering.

The “first” term is the leading term as returned by `lterm`.

A zero polynomial has no terms: `nthterm` returns `FAIL`.

The identity *nthterm*(*p*, *n*) *nthcoeff*(*p*, *n*) = *nthmonomial*(*p*, *n*) holds.

A polynomial expression `f` is first converted to a polynomial with the variables given by `vars`. If no variables are given, they are searched for in `f`. See `poly` about details of the conversion. The result is returned as polynomial expression. `FAIL` is returned if `f` cannot be converted to a polynomial.

Examples

Example 1

We give some self explaining examples:

```
p := poly(100*x^100 + 49*x^49 + 7*x^7, [x]):
nthterm(p, 1), nthterm(p, 2), nthterm(p, 3)
```

$$\mathrm{poly}(x^{100}, [x]), \mathrm{poly}(x^{49}, [x]), \mathrm{poly}(x^{7}, [x])$$

```
nthterm(p, 4)
```

FAIL

```
nthterm(poly(0, [x]), 1)
```

FAIL

```
delete p:
```

Example 2

The n-th monomial is the product of the n-th coefficient and the n-th term:

```
p := poly(2*x^2*y + 3*x*y^2 + 6, [x, y]):
mapcoeffs(nthterm(p, 2), nthcoeff(p, 2)) =
nthmonomial(p, 2)
```

$$\mathrm{poly}(3\,x\,y^2, [x, y]) = \mathrm{poly}(3\,x\,y^2, [x, y])$$

```
delete p:
```

Parameters

p

A polynomial of type DOM_POLY

f

A polynomial expression

vars

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

n

A positive integer

Return Values

Polynomial of the same type as `p`. An expression is returned if a polynomial expression is given as input. `FAIL` is returned if `n` is larger than the actual number of terms of the polynomial.

Overloaded By

p

null

Generate the void object of type DOM_NULL

Syntax

```
null()
```

Description

`null()` returns the void object of domain type `DOM_NULL`. It represents an empty sequence of MuPAD expressions or statements.

The void object does not produce any output on the screen.

Various systems functions such as `print` or `reset` return the void object.

The void object is removed from sequences (“flattening”). It can be used to remove elements from lists or sets. Cf. “Example 2” on page 1-1447.

Examples

Example 1

`null()` returns the void object which does not produce any screen output:

```
null()
```

The resulting object is of domain type `DOM_NULL`:

```
domtype(null())
```

```
DOM_NULL
```

This object represents the empty expression sequence and the empty statement sequence:

```
domtype(_exprseq()), domtype(_stmtseq())
```

DOM_NULL, DOM_NULL

Some system functions such as `print` return the void object:

```
print("Hello world!"):
```

"Hello world!"

```
domtype(%)
```

DOM_NULL

Example 2

The void object is removed from lists, sets, and expression sequences:

```
[null(), a, b, null(), c], {null(), a, b, null(), c},
f(null(), a, b, null(), c)
```

$[a, b, c], \{a, b, c\}, f(a, b, c)$

```
a + null() + b = _plus(a, null(), b)
```

$a + b = a + b$

```
subsop([a, x, b], 2 = null()), subs({a, x, b}, x = null())
```

$[a, b], \{a, b\}$

However, `null()` is a valid entry in arrays and tables:

```
a := array(1..2): a[1] := 1: a[2] := null(): a
```

(1 null())

```
domtype(a[1]), domtype(a[2])
```

DOM_INT, DOM_NULL

```
t := table(null() = "void", 1 = 2.5, b = null())
```

1	2.5
b	null()
null()	"void"

```
domtype(t[b]), t[]
```

DOM_NULL, "void"

```
delete a, t:
```

Example 3

The void object remains if you delete all elements from an expression sequence:

```
a := (1, b): delete a[1]: delete a[1]: domtype(a)
```

DOM_NULL

The operand function `op` returns the void object when applied to an object with no operands:

```
domtype(op([])), domtype(op({})), domtype(op(f()))
```

DOM_NULL, DOM_NULL, DOM_NULL

```
delete a:
```

Return Values

Void object of domain type `DOM_NULL`.

See Also

MuPAD Functions
`_exprseq` | `_stmtseq` | `FAIL` | `NIL`

numer

Numerator of a rational expression

Syntax

```
numer(f)
```

Description

`numer(f)` returns the numerator of the expression `f`.

`numer` regards the input as a rational expression: non-rational subexpressions such as `sin(x)`, `x^(1/2)` etc. are internally replaced by "temporary variables". The numerator of this rationalized expression is computed, the temporary variables are finally replaced by the original subexpressions.

Note: Numerator and denominator are not necessarily cancelled: the numerator returned by `numer` may have a non-trivial `gcd` with the denominator returned by `denom`. Preprocess the expression by `normal` to enforce cancellation of common factors. Cf. "Example 2" on page 1-1451.

Examples

Example 1

We compute the numerators of some expressions:

```
numer(-3/4)
```

```
     -3
```

```
numer(x + 1/(2/3*x -2/x))
```

$$x\,(2\,x^2-3)$$

```
numer((cos(x)^2 -1)/(cos(x) -1))
```

$$\cos(x)^2-1$$

Example 2

`numer` performs no cancellations if the rational expression is of the form "numerator/denominator":

```
r := (x^2 - 1)/(x^3 - x^2 + x - 1): numer(r)
```

$$x^2-1$$

This numerator has a common factor with the denominator of `r`; `normal` enforces cancellation of common factors:

```
numer(normal(r))
```

$$x+1$$

However, automatic normalization occurs if the input expression is a sum:

```
numer(r + x/(x + 1) + 1/(x + 1) - 1)
```

$$x+1$$

```
delete r:
```

Parameters

`f`

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

f

See Also

MuPAD Functions
`denom` | `factor` | `gcd` | `normal`

O

Domain of order terms (Landau symbols)

Syntax

```
O(f, <x = x0, y = y0, …>)
```

Description

`O(f, x = x0)` represents the Landau symbol $O(f, x \to x_0)$.

Mathematically, for a function f in the variables $(x, y, \ldots)$, the Landau symbol

$$g := O(f, x \to x_0, y \to y_0, \ldots)$$

is a function in these variables with the following property: there exists a constant c and a neighborhood of the limit point $(x_0, y_0, \ldots)$ such that $|g| \le c\,|f|$ for all values $(x, y, \ldots)$ in that neighborhood.

Note: Typically, Landau symbols are used to denote the order terms ("error terms") of series expansions. Note, however, that the series expansions produced by `asympt`, `series`, and `taylor` represent order terms as a part of the data structures `Series::Puiseux` and `Series::gseries`; they do *not* use the domain `O`.

With the equations `x = x0`, `y = y0` etc., `f` is regarded as a function of the specified variables. All other identifiers contained in `f` are regarded as constant parameters.

If no variables and limit points are specified, then all identifiers in `f` are used as variables, each tending to the default limit point 0.

Variables tending to 0 are not printed on the screen.

The variables of an order term may be obtained with the function `indets`. The limit points may be queried with the function `O::points`.

The arithmetical operations +, -, *, /, and ^ are overloaded for order terms.

Automatic simplifications are currently restricted to polynomial expressions f. Univariate polynomial expressions are reduced to the leading monomial of the expansion around the limit point. In multivariate polynomial expressions, all terms are discarded that are divisible by lower order terms. For non-polynomial expressions, only integer factors are removed.

Examples

Example 1

For polynomial expressions, certain simplifications occur:

```
O(x^4 + 2*x^2), O(7*x^3), O(x, x = 1)
```

$$O(x^2),\ O(x^3),\ O(1, x = 1)$$

A zero limit point is not printed on the screen:

```
O(1), O(1, x = 1), O(x^2/(y + 1), x = 0, y = -1, z = PI)
```

$$O(1),\ O(1, x = 1),\ O\left(\frac{x^2}{y+1}, y = -1, z = \pi\right)$$

The arithmetical operations are overloaded for order terms:

```
7*O(x), O(x^2) + O(x^13), O(x^3) - O(x^3), O(x^2)^2 + O(x^4)
```

$$O(x),\ O(x^2),\ O(x^3),\ O(x^4)$$

Example 2

For multivariate polynomial expression, higher order terms are discarded if they are divisible by lower order terms:

```
O(15*x*y^2 + 3*x^2*y + x^2*y^2)
```

$$O(x^2\,y + 5\,x\,y^2)$$

```
O(x + x^2*y) = O(x)*O(1 + x*y)
```

$$O(x) = O(x)$$

Example 3

We demonstrate how to access the variables and the limit points of an order term:

```
a := O(x^2*y^2)
```

$$O(x^2\,y^2)$$

```
indets(a) = O::indets(a), O::points(a)
```

$$\{x, y\} = \{x, y\},\ \{x = 0, y = 0\}$$

```
delete a:
```

Parameters

`f`

An arithmetical expression representing a function in `x`, `y` etc.

`x, y, …`

The variables: identifiers

`x0, y0, …`

The limit points: arithmetical expressions

Return Values

Element of the domain `O`.

See Also

MuPAD Functions
`asympt` | `limit` | `series` | `taylor`

ode

Domain of ordinary differential equations

Syntax

```
ode(eq, y(x))

ode({eq, <inits>}, y(x))

ode({eq1, eq2, , …, <inits>}, {y1(x), y2(x), …})
```

Description

`ode(eq, y(x))` represents an ordinary differential equation (ODE) for the function `y(x)`.

`ode({eq1, eq2, ...}, {y1(x), y2(x), ...})` represents a system of ODEs for the functions `y1(x)`, `y2(x)` etc.

In the equations `eq`, `eq1` etc., the unknown functions must be represented by `y(x)`, `y1(x)` etc. Derivatives may be represented either by the `diff` function or by the differential operator `D`. Note that the token `'` provides a handy shortcut: `y'(x) = D(y)(x)` means the same as `diff(y(x), x)`.

The unknown functions must be univariate in the independent variable `x`. Multivariate expressions such as `y(x, t)` are not accepted.

The `ode` function does not accept `piecewise` input.

Initial and boundary conditions are defined by sequences of equations involving the unknown functions or their derivatives on the left hand side. The corresponding values must be specified on the right hand side of the equations. In particular, the differential operator `D` (or the token `'`) must be used to specify values of derivatives at some point. E.g.,

$$\{\{y(1) = 2,\ y'(0) = 0,\ y''(0) = 1\}\}$$

is a valid sequence of boundary conditions for `inits`.

Boundary conditions of the first and second kind are allowed. Mixed conditions are not accepted.

The initial/boundary points and the corresponding initial/boundary values may be symbolic expressions.

For scalar initial value or boundary value problems, use `ode({eq, inits}, y(x))` to specify the conditions.

For systems of ODEs, there must be as many equations as unknown functions.

The main purpose of the `ode` domain is to provide an environment for overloading the function `solve`.

In the case of one single equation (possibly together with initial or boundary conditions), `solve` returns a set of explicit solutions or an implicit solution. Each element of the set represents a solution branch.

In the case of a system of equations, `solve` returns a set of lists of equations for the unknown functions. Each list represents a solution branch.

An symbolic `solve` call is returned if no solution is found.

Examples

Example 1

In the following, we show how to create and solve a scalar ODE. First, we define the ODE $x^2\,y'(x) + 3\,x\,y(x) = \frac{\sin(x)}{x}$. We use the quote token `'` to represent derivatives:

```
eq := ode(x^2*y'(x) + 3*x*y(x) = sin(x)/x, y(x))
```

$$\mathrm{ode}\left(x^2\,y'(x) - \frac{\sin(x)}{x} + 3\,x\,y(x),\ y(x)\right)$$

We get an element of the domain `ode` which we can now solve:

```
solve(eq)
```

$$\left\{\frac{C2}{x^3} - \frac{\cos(x)}{x^3}\right\}$$

```
delete eq:
```

Example 2

An initial value problem is defined as a set consisting of the ODE and the initial conditions:

```
ivp := ode({f''(t) + 4*f(t) = sin(2*t),
            f(0) = a, f'(0) = b}, f(t))
```

$$\text{ode}(\{f(0) = a,\ f'(0) = b,\ f''(t) + 4\,f(t) - \sin(2\,t)\},\ f(t))$$

```
solve(ivp)
```

$$\left\{\frac{3\sin(2\,t)}{32} - \frac{\sin(6\,t)}{32} + \frac{b\sin(2\,t)}{2} - \cos(2\,t)\left(\frac{t}{4} - \frac{\sin(4\,t)}{16}\right) + a\cos(2\,t)\right\}$$

```
delete ivp:
```

Example 3

With some restrictions, it is also possible to solve systems of ODEs. First, define a system:

```
sys := {x'(t) - x(t) + y(t) = 0, y'(t) - x(t) - y(t) = 0}
```

$$\{x'(t) - x(t) + y(t) = 0,\ y'(t) - y(t) - x(t) = 0\}$$

A call to `solve` yields the general solution with arbitrary parameters:

```
solution := solve(ode(sys, {x(t), y(t)}))
```

$$\{[y(t) = C8\,e^t\cos(t) + C7\,e^t\sin(t),\ x(t) = C7\,e^t\cos(t) - C8\,e^t\sin(t)]\}$$

To verify the result, substitute it back into the system `sys`. However, for the substitution, you must rewrite the system into a notation using the `diff` function:

```
eval(subs(rewrite(sys, diff), op(solution)))
```

$$\{0 = 0\}$$

```
delete sys, solution:
```

If you have a system of differential equations in a matrix form, extract the components of the matrix to a set of differential equations:

```
Y:= matrix([x(t), y(t)]):
A:= matrix([[1, 2], [-1, 6]]):
s := ode({op(diff(Y, t) - A*Y)}, {x(t), y(t)})
```

$$\text{ode}(\{x'(t) - x(t) - 2\,y(t),\ y'(t) - 6\,y(t) + x(t)\},\ \{x(t),\ y(t)\})$$

Now, use the `solve` function to solve the system:

```
solve(s)
```

$$\left\{\left[y(t) = \text{C9}\,\sigma_2\left(\frac{\sqrt{17}}{4} + \frac{5}{4}\right) - \text{C10}\,\sigma_1\left(\frac{\sqrt{17}}{4} - \frac{5}{4}\right),\ x(t) = \text{C9}\,\sigma_2 + \text{C10}\,\sigma_1\right]\right\}$$

where

$$\sigma_1 = e^{-\frac{t\,(\sqrt{17}-7)}{2}}$$

$$\sigma_2 = e^{\frac{t\,(\sqrt{17}+7)}{2}}$$

Example 4

In this example, we point out the various return formats of `ode`'s solve facility. First, we solve an ODE with an initial condition. The solution involves a symbolic integral:

```
solve(ode({y'(x) + x*y(x) = cos(x), y(0) = 3}, y(x)))
```

$$\left\{3\,e^{-\frac{x^2}{2}} + e^{-\frac{x^2}{2}} \int_0^x e^{\frac{y^2}{2}} \cos(y)\,dy\right\}$$

For the next equation, we get an implicit solution:

```
solve(ode((x*y'(x) - y(x))^4*exp(x*y'(x) - y(x))
          - ln(x*y'(x) - y(x)), y(x)))
```

$$\text{solve}\left(e^{C13\,x - X1236}\,(X1236 - C13\,x)^4 - \ln(C13\,x - X1236) = 0,\ X1236\right)$$

This is an *algebraic* equation for `y`. Its solution defines `y` as a function of `x` and an arbitrary parameter `C` followed by a number automatically generated by MuPAD (constant of integration). However, the algebraic equation does not have a solution in closed form.

```
delete sys, solution:
```

Example 5

It may happen that MuPAD cannot solve a given equation. In such a case, a symbolic `solve` command is returned:

```
solve(ode(x*diff(y(x),x)-y(x)*(x*ln(x^3/y(x))+2), y(x)))
```

$$\text{solve}\left(\text{ode}\left(x\,y'(x) - y(x)\left(x\ln\left(\frac{x^3}{y(x)}\right) + 2\right),\ y(x)\right)\right)$$

Example 6

The MuPAD ODE solver contains algebraic algorithms for computing Liouvillian and non-Liouvillian solutions of linear ordinary differential equations. These algorithms are based on differential Galois theory and on additional methods for finding solutions of linear ordinary differential equations given in terms of special functions. For the famous Kovacic's example

$$y'' + \left(\frac{\frac{3}{16}}{x^2} + \frac{\frac{2}{9}}{(x-1)^2} - \frac{\frac{\frac{3}{16}}{x}}{x-1} \right) y = 0$$

,

the solution can be found as:

```
solve(ode(y''(x) + (3/(16*x^2) + 2/(9*(x - 1)^2)
                    - 3/(16*x*(x - 1)))*y(x), y(x)))
```

$$\left\{ C21\, x^{1/4} (x-1)^{2/3}\, {}_2F_1\left(\frac{1}{4}, \frac{7}{12}; \frac{1}{2}; x\right) + C22\, x^{3/4} (x-1)^{2/3}\, {}_2F_1\left(\frac{3}{4}, \frac{13}{12}; \frac{3}{2}; x\right) \right\}$$

MuPAD may find Liouvillian and non-Liouvillian solutions for higher order equations as well. However, in case of Liouvillian solutions, there is no guarantee that all of them are found.

MuPAD also finds non-Liouvillian solutions in terms of the Bessel, Airy, and Whittaker functions:

```
eq := y'(x) + y(x)^2 + b + a*x
```

$$y'(x) + y(x)^2 + b + a\,x$$

```
solve(ode(eq, y(x)))
```

$$\left\{ \frac{\sqrt{3}\ \text{airyBi}\left(\sigma_1, 1\right) i + \text{airyBi}\left(\sigma_1, 1\right) + C24\ \text{airyAi}\left(\sigma_1, 1\right) + \sqrt{3}\ C24\ \text{airyAi}\left(\sigma_1, 1\right) i}{2\ \text{airyBi}\left(\sigma_1, 0\right) \left(\frac{1}{a}\right)^{1/3} + 2\ C24\ \text{airyAi}\left(\sigma_1, 0\right) \left(\frac{1}{a}\right)^{1/3}} \right\}$$

where

$$\sigma_1 = \frac{b + \sqrt{3}\, b\, i + a\, x + \sqrt{3}\, a\, x\, i}{2\, a \left(\frac{1}{a}\right)^{1/3}}$$

We check this solution:

```
simplify(eval(subs(rewrite(eq, diff), y(x) = op(%))))
```

0

Example 7

It is also possible to compute the series solutions of an ordinary differential equation (cf. `ode::series` for further details):

```
series(ode(y''(x) + 4*y(x) = sin(w*x), y(x)), x = 0, 8)
```

$$\left\{y(0)+x\,y'(0)-2\,x^2\,y(0)+x^3\left(\frac{w}{6}-\frac{\sigma_1}{3}\right)+\frac{2\,x^4\,y(0)}{3}-x^5\left(-\frac{\sigma_1}{15}+\frac{w^3}{120}+\frac{w}{30}\right)-\frac{4\,x^6\,y(0)}{45}\right.$$
$$\left.+x^7\left(-\frac{4\,y'(0)}{315}+\frac{w^5}{5040}+\frac{w^3}{1260}+\frac{w}{315}\right)+O(x^8)\right\}$$

where

$$\sigma_1 = 2\,y'(0)$$

Parameters

`eq, eq1, eq2, …`

Equations or arithmetical expressions in the unknown functions and their derivatives with respect to `x`. An arithmetical expression is regarded as an equation with vanishing right hand side.

`y, y1, y2, …`

The unknown functions: identifiers

`x`

The independent variable: an identifier

`inits`

The initial or boundary conditions: a sequence of equations

Return Values

Object of type `ode`.

op

Operands of an object

Syntax

```
op(object)

op(object, i)

op(object, i .. j)

op(object, [i1, i2, …])
```

Description

`op(object)` returns all operands of the object.

`op(object, i)` returns the `i`-th operand.

`op(object, i..j)` returns the `i`-th to `j`-th operands.

MuPAD objects are composed of simpler parts: the “operands”. The function `op` is the tool to decompose objects and to extract individual parts. The actual definition of an operand depends on the type of the object. The 'Background' section below explains the meaning for some of the basic data types.

`op(object)` returns a sequence of all operands except the 0-th one. This call is equivalent to `op(object, 1..nops(object))`. Cf. “Example 1” on page 1-1466.

`op(object, i)` returns the `i`-th operand. Cf. “Example 2” on page 1-1467.

`op(object, i..j)` returns the `i`-th to `j`-th operands as an expression sequence; `i` and `j` must be nonnegative integers with `i` smaller or equal to `j`. This sequence is equivalent to `op(object, k) $k = i..j`. Cf. “Example 3” on page 1-1467.

`op(object, [i1, i2, ...])` is an abbreviation for the recursive call `op (... op ( op(object, i1) , i2) , ...)` if `i1, i2, ...` are integers.

A call such as `op(object, [i..j, i2])` with integers `i < j` corresponds to `map(op(object, i..j), op, i2)`. Cf. “Example 4” on page 1-1468.

`op` returns `FAIL` if the specified operand does not exist. Cf. “Example 5” on page 1-1469.

Expressions of domain type `DOM_EXPR`, arrays, hfarrays, and floating point intervals have a 0-th operand.

- For expressions, this is “the operator” connecting the other operands. In particular, for symbolic function calls, it is the name of the function.
- For array and hfarrays, the 0-th operand is a sequence consisting of an integer (the dimension of the array) and a range for each array index.
- For a floating-point interval, the value of the 0-th operand depends on the precise type of the interval: If the interval is a union of rectangles, the 0-th operand is `hold(_union)`. If the interval is not a union and consists only of real numbers, the 0-th operand is hold(hull). In the remaining case of a rectangle with non-vanishing imaginary part, the 0-th operand is `FAIL`.

Other basic data types such as lists or sets do not have a 0-th operand. Cf. “Example 6” on page 1-1469.

For library domains, `op` is overloadable. In the `"op"` method, the internal representation can be accessed with `extop`. It is sufficient to handle the cases `op(x)`, `op(x, i)`, and `op(x, i..j)` in the overloading method, the call `op(x, [i1, i2, ...])` needs not be considered. Cf. “Example 7” on page 1-1470.

`op` is not overloadable for kernel domains.

Examples

Example 1

The call `op(object)` returns all operands:

```
op([a, b, c, [d, e], x + y])
```

$$a,\ b,\ c,\ [d,\ e],\ x+y$$

```
op(a + b + c^d)
```

$$a,\ b,\ c^d$$

```
op(f(x1, x2, x3))
```

$$x1,\ x2,\ x3$$

Example 2

The call `op(object, i)` extracts a single operand:

```
op([a, b, c, [d, e], x + y], 4)
```

$$[d,\ e]$$

```
op(a + b + c^d, 3)
```

$$c^d$$

```
op(f(x1, x2, x3), 2)
```

$$x2$$

Example 3

The call `op(object, i..j)` extracts a range of operands:

```
op([a, b, c, [d, e], x + y], 3..5)
```

$$c,\ [d,\ e],\ x+y$$

```
op(a + b + c^d, 2..3)
```

$$b,\ c^d$$

```
op(f(x1, x2, x3), 2..3)
```

$$x2,\ x3$$

A range may include the 0-th operand if it exists:

```
op(a + b + c^d, 0..2)
```

$$\_plus, a, b$$

```
op(f(x1, x2, x3), 0..2)
```

$$f, x1, x2$$

Example 4

The call `op(object, [i1, i2, ...])` specifies suboperands:

```
op([a, b, c, [d, e], x + y], [4, 1])
```

$$d$$

```
op(a + b + c^d, [3, 2])
```

$$d$$

```
op(f(x1, x2, x3 + 17), [3, 2])
```

$$17$$

Also ranges of suboperands can be specified:

```
op([a, b, c, [d, e], x + y], [4..5, 2])
```

$$e, y$$

```
op(a + b + c^d, [2..3, 1])
```

$$b, c$$

```
op(f(x1, x2, x3 + 17), [2..3, 1])
```

```
x2, x3
```

Example 5

Nonexisting operands are returned as `FAIL`:

```
op([a, b, c, [d, e], x + y], 8), op(a + b + c^d, 4),
op(f(x1, x2, x3), 4)
```

```
FAIL, FAIL, FAIL
```

Example 6

For expressions of type `DOM_EXPR`, the 0-th operand is "the operator" connecting the other operands:

```
op(a + b + c, 0), op(a*b*c, 0), op(a^b, 0), op(a[1, 2], 0)
```

```
_plus, _mult, _power, _index
```

For symbolic function calls, it is the name of the function:

```
op(f(x1, x2, x3), 0), op(sin(x + y), 0), op(besselJ(0, x), 0)
```

```
f, sin, besselJ
```

The 0-th operand of an array is a sequence consisting of the dimension of the array and a range for each array index:

```
op(array(3..100), 0)
```

```
1, 3..100
```

```
op(array(1..2, 1..3, 2..4), 0)
```

```
3, 1..2, 1..3, 2..4
```

```
op(hfarray(3..100), 0)
```

```
1, 3..100
```

```
op(hfarray(1..2, 1..3, 2..4), 0)
```

```
3, 1..2, 1..3, 2..4
```

No 0-th operand exists for other kernel domains:

```
op([1, 2, 3], 0), op({1, 2, 3}, 0), op(table(1 = y), 0)
```

```
FAIL, FAIL, FAIL
```

Example 7

For library domains, `op` is overloadable. First, a new domain `d` is defined via `newDomain`. The `"new"` method serves for creating elements of this type. The internal representation of the domain is a list of all arguments of this `"new"` method:

```
d := newDomain("d"):  d::new := () -> new(dom, [args()]):
```

The `"op"` method of this domain is defined. It is to return the elements of a sorted copy of the internal list which is accessed via `extop`:

```
d::op := proc(x, i = null())
           local internalList;
         begin
           internalList := extop(x, 1);
           op(sort(internalList), i)
         end_proc:
```

By overloading, this method is called when the operands of an object of type `d` are requested via `op`:

```
e := d(3, 7, 1):
op(e);
op(e, 2);
op(e, 1..2)
```

```
1, 3, 7
```

```
3
```

```
1, 3
```

```
delete d, e:
```

Example 8

Identifiers, integers, real floating-point numbers, character strings, and the Boolean constants are “atomic” objects. The only operand is the object itself:

```
op(x), op(17), op(0.1234), op("Hello World!")
```

```
x, 17, 0.1234, "Hello World!"
```

For rational numbers, the operands are the numerator and the denominator:

```
op(17/3)
```

```
17, 3
```

For complex numbers, the operands are the real part and the imaginary part:

```
op(17 - 7/3*I)
```

$$17, -\frac{7}{3}$$

Example 9

For sets, op returns the elements according to the *internal* order. Note that this order may differ from the ordering with which sets are printed on the screen:

```
s := {i^2 $ i = 1..19}
```

```
{1, 4, 9, 16, 25, 36, 49, 64, 81, 100, 121, 144, 169, 196, 225, 256, 289, 324, 361}
```

```
op(s)
```

```
1, 4, 361, 9, 16, 25, 36, 49, 64, 81, 100, 121, 144, 169, 196, 225, 256, 289, 324
```

Indexed access to set elements uses the ordering visible on the screen:

```
s[1], s[2], s[3]
```

```
1, 4, 9
```

Note that access to set elements via `op` is *much faster* than indexed calls:

```
s := {sqrt(i) $ i = 1..500}:
time([op(s)])/time([s[i] $ i = 1..nops(s)]);
```

$$\frac{1}{364}$$

```
delete s:
```

Example 10

The operands of a list are its entries:

```
op([a, b, c, [d, e]])
```

$$a, b, c, [d, e]$$

```
op([[a11, a12], [a21, a22]], [2, 1])
```

```
a21
```

Example 11

Internally, the operands of arrays and hfarrays form a “linear” sequence containing all entries:

```
op(array(1..2, 1..2, [[11, 12], [21, 22]]))
```

```
11, 12, 21, 22
```

```
op(hfarray(1..2, 1..2, [[11, 12], [21, 22]]))
```

$$11.0,\ 12.0,\ 21.0,\ 22.0$$

Undefined entries are returned as `NIL`:

```
op(array(1..2, 1..2))
```

$$\mathrm{NIL},\ \mathrm{NIL},\ \mathrm{NIL},\ \mathrm{NIL}$$

Example 12

The operands of a table consist of equations relating the indices and the corresponding entries:

```
T := table((1, 2) = x + y, "diff(sin)" = cos, a = b)
```

	a	b
	$1, 2$	$x + y$
	"diff(sin)"	cos

```
op(T)
```

$$(1, 2) = x + y,\ \text{"diff(sin)"} = \cos,\ a = b$$

```
delete T:
```

Example 13

Expression sequences are not flattened:

```
op((a, b, c), 2)
```

$$b$$

Note, however, that the arguments passed to `op` are evaluated. In the following call, evaluation of `x` flattens this object:

```
x := hold((1, 2), (3, 4)):  op(x, 1)
```

```
    1
```

Use `val` to prevent simplification of `x`:

```
op(val(x), 1)
```

```
    1, 2
```

```
delete x:
```

Parameters

`object`

An arbitrary MuPAD object

`i, j`

Nonnegative integers

`i1, i2, …`

Nonnegative integers or ranges of such integers

Return Values

sequence of operands or the requested operand. `FAIL` is returned if no corresponding operand exists.

Overloaded By

object

Algorithms

We explain the meaning of “operands” for some basic data types:

- Identifiers, integers, real floating-point numbers, character strings, as well as the Boolean constants are “atomic” objects. They have only one operand: the object itself. Cf. “Example 8” on page 1-1471.
- A rational number of type `DOM_RAT` has two operands: the numerator and the denominator. Cf. “Example 8” on page 1-1471.
- A complex number of type `DOM_COMPLEX` has two operands: the real part and the imaginary part. Cf. “Example 8” on page 1-1471.
- The operands of a set are its elements.

Note: Note that the ordering of the elements as printed on the screen does not necessarily coincide with the internal ordering referred to by `op`. Cf. “Example 9” on page 1-1471.

- The operands of a list are its elements. Cf. “Example 10” on page 1-1472.
- The operands of arrays and hfarrays are its entries. Undefined entries are returned as `NIL`. Cf. “Example 11” on page 1-1472 and “Example 6” on page 1-1469.
- The operands of tables are the equations associating an index with the corresponding entry. Cf. “Example 12” on page 1-1473.
- The operands of an expression sequence are its elements. Note that such sequences are not flattened by `op`. Cf. “Example 13” on page 1-1473.
- The operands of a symbolic function call such as `f(x, y, ...)` are the arguments `x`, `y` etc. The function name `f` is the 0-the operand.
- In general, the operands of expressions of type `DOM_EXPR` are given by their internal representation. There is a 0-th operand (“the operator”) corresponding to the type of the expression. Internally, the operator is a system function, the expression corresponds to a function call. E.g., `a + b + c` has to be interpreted as `_plus(a, b, c)`, a symbolic indexed call such as `A[i, j]` corresponds to `_index(A, i, j)`. The name of the system function is the 0-th operand (i.e., `_plus` and `_index` in the previous examples), the arguments of the function call are the further operands.

operator

Define a new operator symbol

Syntax

```
operator(symb, f, <Prefix | Postfix | Binary | Nary, prio>, <Global>)
operator(symb, Delete, <Global>)
```

Description

`operator(symb, f, T, prio)` defines a new operator symbol `symb` of type `T` with priority `prio`. The function `f` evaluates expressions using the new operator.

`operator(symb, Delete)` removes the definition of the operator symbol `symb`.

`operator` is used to define new user-defined operator symbols or to delete them.

Given the operator symbol `"++"`, say, with evaluating function `f`, the following expressions are built by the parser, depending on the type of the operator:

- `Prefix`:

  The input `++x` results in `f(x)`.
- `Postfix`:

  The input `x++` results in `f(x)`.
- `Binary`:

  The input `x ++ y ++ z` results in `f(f(x, y), z)`.
- `Nary`:

  The input `x ++ y ++ z` results in `f(x, y, z)`.

There may exist operator symbols which are prefixes of other operator symbols. The scanner reads as many characters as possible and chooses the longest matching operator symbol. Cf. “Example 3” on page 1-1478.

It is not possible to define two operators with the same symbol. So one may not define a unary ++ and a binary ++ at the same time.

The following restrictions exist for the operator symbol string `symb`:

- It may not be longer than 32 characters.
- It may not start with a white-space.
- It may not start with a \ (backslash) character.

Thus, the strings `" @"` and `"/"` are not allowed. Please note that currently `operator` does not check these restrictions.

Builtin operators may be redefined.

It is not possible to define out-fix operators like $|x|$ or 3-nary or other types of operators.

The new operator symbol is also used if files are read, with one exception: if a file is read with the function `read` using the option `Plain`, the new operator is not taken into account. (This option is used if MuPAD library files are read, because otherwise user-defined operators could change the meaning of the source code in an uncontrolled way.)

If the operator is defined while reading a file with option `Plain`, the definition will be used for the remainder of the file and then be deleted automatically. If the operator is defined with the option `Global`, this behavior is changed and the operator will not be active while reading the file, but will exist at the interactive level instead.

Environment Interactions

The new operator symbol `symb` is known by the parser and may be used to enter expressions. The new operator symbol will *not* be used when reading files using the function `read` with the option `Plain`.

The function `f` corresponding to the new operator will always be converted into a `function environment` containing an additional output routine for the operator output, unless it contained an output routine already.

Examples

Example 1

This example shows how to define an operator symbol for the bit-shift operation (as in the language C):

```
bitshiftleft := (a, b) -> a * 2^b:
operator("<<", bitshiftleft, Binary, 950):
```

After this call, the symbol << can be used to enter expressions:

```
2 << 1, x << y
```

$$4, 2^{y} x$$

```
operator("<<", Delete):
```

Example 2

Identifiers can be used as operator symbols:

```
operator("x", _vector_product, Binary, 1000):

PRETTYPRINT := FALSE:
print(Plain, a x b x c)
```

```
(a x b) x c
```

```
PRETTYPRINT := TRUE:
operator("x", Delete):
```

Example 3

This example shows that the scanner tries to match the longest operator symbol:

```
operator("~", F, Prefix, 1000):
operator("~>", F1, Prefix, 1000):
operator("~~>", F2, Prefix, 1000):

print(Plain, ~~ x, ~~> x, ~ ~> x, ~~~> x)
```

```
~ ~ x, ~~> x, ~ ~> x, ~ ~~> x

operator("~", Delete):
operator("~>", Delete):
operator("~~>", Delete):
```

Parameters

`symb`

The operator symbol: a character string.

`f`

The function evaluating expressions using the operator.

`prio`

The priority of the operator: an integer between 1 and 1999. The default is 1300.

Options

`Prefix`

The operator is regarded as a unary operator with prefix notation. Given the operator symbol `"++"` and the evaluation function `f`, the input `++x` is parsed as the expression `f(x)`.

`Postfix`

The operator is regarded as a unary operator with postfix notation. Given the operator symbol `"++"` and the evaluation function `f`, the input `x++` is parsed as the expression `f(x)`.

`Binary`

The operator is regarded as a non-associative binary operator with infix notation. Given the operator symbol `"++"` and the evaluation function `f`, the input `x ++ y ++ z` is parsed as the expression `f(f(x, y), z)`, i.e. the operator binds left-to-right.

`Nary`

The operator is regarded as an associative n-ary operator with infix notation. Given the operator symbol `"++"` and the evaluation function `f`, the input `x ++ y ++ z` is parsed as the expression `f(x, y, z)`.

`Delete`

The operator with symbol `symb` is deleted

`Global`

When defining an operator inside library or package code (technically: inside a file which is read with the option `Plain`), the option `Global` changes the meaning of the operator definition: Instead of defining an operator for the remainder of the file, it defines an operator for the interactive level.

Return Values

Void object of type `DOM_NULL`.

Algorithms

When the scanner reads a new token, it first discards any whitespace and backslash characters. Then it tries to match user-defined operator symbols. The longest user-defined operator symbol matching the scanned characters is made the next token. If no user-defined operator symbol matches, it scans for the built-in tokens.

The parser uses both recursive-descend and a operator precedence parsing. Built-in and user-defined operators are parsed using operator precedence.

ORDER

Default number of terms in series expansions

Description

The environment variable `ORDER` controls the default number of terms that the system returns when you compute a series expansion.

Possible values: Positive integer less than 2^{31}. The default value is 6.

The functions `taylor`, `series`, and `asympt` have an optional third argument specifying the desired number of terms of the requested series expansion, counting from the dominant term on (relative order). If this optional argument is missing, then the value of `ORDER` is used instead.

`ORDER` may also affect the results returned by the function `limit`.

Deletion via the statement "`delete ORDER`" resets `ORDER` to its default value 6. Executing the function `reset` also restores the default value.

In some cases, the number of terms returned by `taylor`, `series`, or `asympt` may not agree with the value of `ORDER`. Cf. "Example 2" on page 1-1482.

Examples

Example 1

In the following example, we compute the first 6 terms of the series expansion of the function `exp(x)/x^2` around the origin:

```
series(exp(x)/x^2, x = 0)
```

$$\frac{1}{x^2} + \frac{1}{x} + \frac{1}{2} + \frac{x}{6} + \frac{x^2}{24} + \frac{x^3}{120} + O(x^4)$$

To obtain the first 10 terms, we specify the third argument of `series`:

```
series(exp(x)/x^2, x = 0, 10)
```

$$\frac{1}{x^2}+\frac{1}{x}+\frac{1}{2}+\frac{x}{6}+\frac{x^2}{24}+\frac{x^3}{120}+\frac{x^4}{720}+\frac{x^5}{5040}+\frac{x^6}{40320}+\frac{x^7}{362880}+O(x^8)$$

Alternatively, we increase the value of `ORDER`. This affects all subsequent calls to `series` or any other function returning a series expansion:

```
ORDER := 10: series(exp(x)/x^2, x = 0)
```

$$\frac{1}{x^2}+\frac{1}{x}+\frac{1}{2}+\frac{x}{6}+\frac{x^2}{24}+\frac{x^3}{120}+\frac{x^4}{720}+\frac{x^5}{5040}+\frac{x^6}{40320}+\frac{x^7}{362880}+O(x^8)$$

```
taylor(x^2/(1 - x), x = 0)
```

$$x^2+x^3+x^4+x^5+x^6+x^7+x^8+x^9+x^{10}+x^{11}+O(x^{12})$$

Finally, we reset `ORDER` to its default value 6:

```
delete ORDER: taylor(x^2/(1 - x), x = 0)
```

$$x^2+x^3+x^4+x^5+x^6+x^7+O(x^8)$$

Example 2

The number of terms returned by `series` may differ from the value of `ORDER` when cancellation or rational exponents occur:

```
ORDER := 3:
```

```
series(exp(x) - 1 - x - x^2/2 - x^3/6, x = 0)
```

$$\frac{x^4}{24}+\frac{x^5}{120}+O(x^6)$$

```
series(1/(1 - sqrt(x)), x = 0)
```

$$1+\sqrt{x}+x+x^{3/2}+x^2+x^{5/2}+O(x^3)$$

```
delete ORDER:
```

MuPAD Functions

asympt | limit | O | series | taylor

pade

Pade approximation

Syntax

```
pade(f, x, <[m, n]>)
pade(f, x = x0, <[m, n]>)
```

Description

`pade(f, ...)` computes a Pade approximant of the expression `f`.

The Pade approximant of order $[m, n]$ around $x = x_0$ is a rational expression

$$\frac{(x-x_0)^p\left(a_0+a_1\left(x-x_0\right)+\ldots+a_m\left(x-x_0\right)^m\right)}{1+b_1\left(x-x_0\right)+\ldots+b_n\left(x-x_0\right)^n}$$

approximating f. The parameters p and a_0 are given by the leading order term $f = a_0 (x - x_0)^p + O((x - x_0)^{p+1})$ of the series expansion of f around $x = x_0$. The parameters $a_1, \ldots, b_n$ are chosen such that the series expansion of the Pade approximant coincides with the series expansion of f to the maximal possible order.

The expansion points `infinity`, `-infinity`, and `complexInfinity` are not allowed.

If no series expansion of f can be computed, then `FAIL` is returned. Note that `series` must be able to produce a Taylor series or a Laurent series of f, i.e., an expansion in terms of integer powers of $x - x_0$ must exist.

Examples

Example 1

The Pade approximant is a rational approximation of a series expansion:

```
f := cos(x)/(1 + x): P := pade(f, x, [2, 2])
```

$$\frac{-7x^2+2x+12}{x^2+14x+12}$$

For most expressions of leading order 0, the series expansion of the Pade approximant coincides with the series expansion of the expression through order $m + n$:

```
S := series(f, x, 6)
```

$$1-x+\frac{x^2}{2}-\frac{x^3}{2}+\frac{13x^4}{24}-\frac{13x^5}{24}+O(x^6)$$

This differs from the expansion of the Pade approximant at order 5:

```
series(P, x, 6)
```

$$1-x+\frac{x^2}{2}-\frac{x^3}{2}+\frac{13x^4}{24}-\frac{85x^5}{144}+O(x^6)$$

The series expansion can be used directly as input to`pade`:

```
pade(S, x, [2, 3]), pade(S, x, [3, 2])
```

$$-\frac{5x^2-12}{x^3+x^2+12x+12}, \frac{-7x^3+7x^2+12x-12}{13x^2-12}$$

Both Pade approximants approximate `f` through order $m + n = 5$:

```
map([%], series, x)
```

$$\left[1-x+\frac{x^2}{2}-\frac{x^3}{2}+\frac{13x^4}{24}-\frac{13x^5}{24}+O(x^6), 1-x+\frac{x^2}{2}-\frac{x^3}{2}+\frac{13x^4}{24}-\frac{13x^5}{24}+O(x^6)\right]$$

```
delete f, P, S:
```

Example 2

The following expression does not have a Laurent expansion around $x = 0$:

```
series(x^(1/3)/(1 - x), x)
```

$$x^{1/3} + x^{4/3} + x^{7/3} + x^{10/3} + x^{13/3} + x^{16/3} + O\left(x^{19/3}\right)$$

Consequently, `pade` fails:

```
pade(x^(1/3)/(1 - x), x, [3, 2])
```

FAIL

Example 3

Note that the specified orders [m, n] do not necessarily coincide with the orders of the numerator and the denominator if the series expansion does not start with a constant term:

```
pade(x^10*exp(x), x, [2, 2]), pade(x^(-10)*exp(x), x, [2, 2])
```

$$\frac{x^{10}\,(x^2 + 6\,x + 12)}{x^2 - 6\,x + 12}, \frac{x^2 + 6\,x + 12}{x^{10}\,(x^2 - 6\,x + 12)}$$

Parameters

`f`

An arithmetical expression or a series of domain type `Series::Puiseux` generated by the function `series`

`x`

An identifier

`x0`

An arithmetical expression. If `x0` is not specified, then `x0` = 0 is assumed.

`[m, n]`

A list of nonnegative integers specifying the order of the approximation. The default values are `[3, 3]`.

Return Values

Arithmetical expression or `FAIL`.

MuPAD Functions

`series`

partfrac

Partial fraction decomposition

Syntax

```
partfrac(f, <x>)
```

```
partfrac(f, x, options)
```

Description

`partfrac(f, x)` returns the partial fraction decomposition of the rational expression `f` with respect to the variable `x`.

Consider the rational expression $f(x) = g(x) + \frac{p(x)}{q(x)}$ with polynomials g, p, q, such that `degree (p) < degree(q)`.

Factor of the denominator into non-constant and pair-wise coprime polynomials q_i with integer exponents e_i:

$$q(x) = q_1(x)^{e_1} q_2(x)^{e_2} \ldots$$

The partial fraction decomposition based on this factorization is a representation

$$f(x) = g(x) + \frac{p_{1,1}(x)}{q_1(x)} + \ldots + \frac{p_{1,e_1}(x)}{q_1(x)^{e_1}} + \frac{p_{2,1}(x)}{q_2(x)} + \ldots + \frac{p_{2,e_2}(x)}{q_2(x)^{e_2}} + \ldots$$

where $p_{i,j}$ are polynomials, such that `degree(p`$_{i,j}$`) < degree(q`$_i$`)`. In particular, $p_{i,j}$ are constants if q_i is a linear polynomial.

`partfrac` uses factors q_i found by the `factor` function. This function finds factorization over the field implied by the coefficients of the denominator. See “Example 2” on page 1-1490.

If `f` has only one indeterminate, and you do not use options, then you can omit the second argument `x` in a call to `partfrac`. Otherwise, specify the indeterminate as a second parameter.

`partfrac` can also find partial fraction decomposition with respect to expressions instead of variables. See "Example 3" on page 1-1490.

The option `Full` invokes a full factorization of the denominator into linear factors. The `MaxDegree` option determines whether partial fraction decomposition is a symbolic `sum` over `RootOf` or an expression in radicals. In general, roots belonging to an irreducible factor of the denominator of degree five or larger cannot be expressed in terms of radicals. See "Example 6" on page 1-1491.

Examples

Example 1

Find partial fraction decomposition of the following expressions. You can omit specifying a variable because these rational expressions are univariate.

```
partfrac(x^2/(x^3 - 3*x + 2))
```

$$\frac{5}{9\,(x-1)}+\frac{1}{3\,(x-1)^2}+\frac{4}{9\,(x+2)}$$

```
partfrac(23 + (x^4 + x^3)/(x^3 - 3*x + 2))
```

$$x+\frac{19}{9\,(x-1)}+\frac{2}{3\,(x-1)^2}+\frac{8}{9\,(x+2)}+24$$

```
partfrac(x^3/(x^2 + 3*I*x - 2))
```

$$x-\frac{7\,x+6\,\mathrm{i}}{x^2+3\,x\,\mathrm{i}-2}-3\,\mathrm{i}$$

Find partial fraction decomposition of the following expression containing two variables, `x` and `y`. For multivariate expressions, specify the variable with respect to which you compute the partial fraction decomposition.

```
f := x^2/(x^2 - y^2):
partfrac(f, x), partfrac(f, y)
```

$$\frac{y}{2\,(x-y)} - \frac{y}{2\,(x+y)} + 1,\ \frac{x}{2\,(x+y)} + \frac{x}{2\,(x-y)}$$

```
delete f:
```

Example 2

Find the partial fraction decomposition of this expression.

```
partfrac(1/(x^2 - 2), x)
```

$$\frac{1}{x^2-2}$$

The denominator x^2 - 2 does not factor over the rational numbers.

```
factor(x^2 - 2)
```

$$x^2-2$$

Extend the coefficient field used by `factor` and `partfrac` by using the `Adjoin` option.

```
partfrac(1/(x^2 - 2), x, Adjoin = [sqrt(2)])
```

$$\frac{\sqrt{2}}{4\,(x-\sqrt{2})} - \frac{\sqrt{2}}{4\,(x+\sqrt{2})}$$

Example 3

Find the partial fraction decomposition with respect to an expression, such as `sin(x)`.

```
partfrac(1/(sin(x)^4 - sin(x)^2 + sin(x) - 1), sin(x))
```

$$\frac{1}{3\,(\sin(x)-1)}-\frac{\frac{\sin(x)^2}{3}+\frac{2\sin(x)}{3}+\frac{2}{3}}{\sin(x)^3+\sin(x)^2+1}$$

Example 4

Return a list consisting of the numerators and denominators of the partial fraction decomposition by using the `List` option.

```
partfrac(x^2/(x^3 - 3*x + 2), x, List)
```

$$\left[\frac{4}{9},\ \frac{5}{9},\ \frac{1}{3}\right],\ [x+2,\ x-1,\ (x-1)^2]$$

Example 5

Find the partial fraction decomposition using numeric factorization over the field real numbers, `R_`.

```
partfrac(1/(x^3 - 2), x, Domain = R_)
```

$$\frac{0.2099868416}{x-1.25992105}-\frac{0.2099868417\,x+0.529133684}{x^2+1.25992105\,x+1.587401052}$$

Find the partial fraction decomposition of the same expression using numeric factorization over the field complex numbers, `C_`.

```
partfrac(1/(x^3 - 2), x, Domain = C_)
```

$$\frac{0.2099868416}{x-1.25992105}+\frac{-0.1049934208-0.1818539393\,i}{x+0.6299605249+1.091123636\,i}+\frac{-0.1049934208+0.1818539393\,i}{x+0.6299605249-1.091123636\,i}$$

Example 6

Find the partial fraction decomposition factoring the denominator into linear factors symbolically. For this, use the `Full` option.

```
partfrac(1/(x^3 + x - 2), x, Full)
```

$$\frac{1}{4\,(x-1)}+\frac{-\frac{1}{8}+\frac{3\sqrt{7}\,i}{56}}{x+\frac{1}{2}-\frac{\sqrt{7}\,i}{2}}-\frac{\frac{1}{8}+\frac{3\sqrt{7}\,i}{56}}{x+\frac{1}{2}+\frac{\sqrt{7}\,i}{2}}$$

For irreducible denominators of the third and higher degrees, the partial fraction decomposition is a symbolic sum over the roots.

```
S:= partfrac(1/(x^3 + x - 3), x, Full)
```

$$\sum_{\text{alpha3}\,\in\,\text{RootOf}\left(z^3+z-3,\,z\right)}\left(-\frac{\frac{6\,\text{alpha3}^2}{247}+\frac{27\,\text{alpha3}}{247}+\frac{4}{247}}{\text{alpha3}-x}\right)$$

MuPAD uses the `freeze` function to keep the result in the form of an unevaluated symbolic sum. To evaluate this symbolic sum, use `unfreeze`. Evaluating this symbolic sum simplifies it back to the original input.

```
unfreeze(S); delete S:
```

$$\frac{1}{x^3+x-3}$$

Parameters

`f`

Rational expression in `x`

`x`

Indeterminate: typically, an identifier or an indexed identifier

Options

`Full`

Factor the denominator completely into linear factors, and find the partial fraction decomposition with respect to that factorization.

`List`

Return a list consisting of the numerators and denominators of the partial fraction decomposition.

`MaxDegree`

Option, specified as `MaxDegree = n`

Adjoin only the coefficients of the denominator with the algebraic degree not exceeding `n` to the field over which the denominator is factored. If you also use `Full`, then `partfrac` does not use explicit formulas involving radicals to solve polynomial equations of a degree higher than `n`.

`Adjoin`

Option, specified as `Adjoin = g`

Factor the denominator over the smallest field containing the rational numbers, all coefficients of the denominator, and the elements of `g`.

`Domain`

Option, specified as `Domain = d`

Factor the denominator over the domain `d`, where `d` is one of the following: `Expr`, `R_`, or `C_`. By default, `d = Expr`. For more details, see `factor`.

`Mapcoeffs`

Option, specified as `Mapcoeffs = mp`

When building the resulting expression, insert `mp(c)` instead of each coefficient `c`.

Return Values

arithmetical expression.

pathname

Create a platform dependent path name

Syntax

```
pathname(dir, subdir, …)
```

```
pathname(<Root>, dir, subdir, …)
```

Description

`pathname(dir, subdir, ...)` returns a relative path name valid on the used operating system.

`pathname` is used to specify pathnames via MuPAD strings. Directories and subdirectories are concatenated in a suitable way creating a valid pathname for the currently used operating system. For example, this mechanism may be used to specify the location of library files independent of the platform.

In order to create valid path names for the operating systems supported by MuPAD, the conventions holding for the corresponding operating system must be complied with. In particular, the names must not contain the characters "/" , "\" or ":". Compliance with these conventions is tested by `pathname`.

Under Microsoft® Windows, `pathname` does not allow to specify a volume to become part of the path name. Names are always relative to the current volume.

Examples:

Call	Platform	Result
`pathname("lib", "linalg")`	UNIX (Linux/ Mac OS X)	`"lib/linalg/"`
	Microsoft Windows	`"lib\\linalg\\"`
`pathname(Root, "lib", "linalg")`	UNIX (Linux/Mac OS X)	`"/lib/linalg/"`

Call	Platform	Result
	Microsoft Windows	`"\\lib\\linalg\\"`

Examples

Example 1

The following examples are created on a UNIX/Linux system:

```
pathname("lib", "linalg")
```

```
"lib/linalg/"
```

```
pathname(Root, "lib", "linalg") . "det.mu"
```

```
"/lib/linalg/det.mu"
```

Parameters

`dir, subdir, …`

Names of directories: character strings

Options

`Root`

Makes `pathname` generate an absolute path name

Return Values

String.

pdivide

Pseudo-division of polynomials

Syntax

```
pdivide(p, q, <[x]>, <order>, options)
```

```
pdivide(p, q, <[x1, x2, …]>, <order>, options)
```

```
pdivide(p, q1, q2, …, <[x1, x2, …]>, <order>, options)
```

Description

`pdivide(p, q)` performs pseudo-division of polynomials or polynomial expressions `p` and `q`. The function returns the factor `b`, the pseudo-quotient `s`, and the pseudo-remainder `r`, such that `b*p = s*q + r`.

`pdivide(p, q1, q2, q3, ..., qN)` performs pseudo-division of a polynomial or a polynomial expression `p` by polynomials or polynomial expressions `q1, q2, q3, ..., qN`.

`pdivide(p, q)` returns the sequence `b, s, r`, where `b` is an element of the coefficient ring of the polynomials. The pseudo-quotient `s` and pseudo-remainder `r` satisfy these conditions: `b*p = s*q + r`, `degree(p) = degree(s) + degree(q)`, and `degree(r) < degree(q)`.

By default, `pdivide` determines the factor `b` as `b = lcoeff (q)^( degree (p) - degree(q) + 1)`. `AnyFactor` enables `pdivide` to use other values of `b`. See “Example 2” on page 1-1500.

`pdivide` operates on polynomials or polynomial expressions.

Polynomials must be of the same type, meaning that their variables and coefficient rings must be identical.

When you call `pdivide` for polynomial expressions, MuPAD internally converts these expressions to polynomials. See the `poly` function. If the expressions cannot be converted to polynomials, `pdivide` returns `FAIL`. See “Example 3” on page 1-1501.

If you call `pdivide` for polynomials, it returns polynomials. If you call `pdivide` for polynomial expressions, it returns polynomial expressions.

If you perform pseudo-division of polynomial expressions that contain multiple variables, you can specify particular variables to be treated as variables. The `pdivide` function treats all other variables as symbolic parameters. By default, `pdivide` assumes that all variables in polynomial expressions are variables, and none of them is a symbolic parameter. See "Example 4" on page 1-1501.

`pdivide(p, q1, q2, q3, ..., qN)` returns the factor `b`, pseudo-quotients `s1, s2, ..., sN` and the pseudo-remainder `r`, such that `b*p = s1*q1 + s2*q2 + ... + sN*qN + r`.

When performing pseudo-division of a polynomial by one or more polynomials, you can select the term ordering. The ordering accepts these values:

- `LexOrder` sets the lexicographical ordering.
- `DegreeOrder` sets the total degree ordering. When using this ordering, MuPAD sorts the terms of a polynomial according to the total degree of each term (the sum of the exponents of the variables).
- `DegInvLexOrder` sets the total degree inverse lexicographic ordering. When using this ordering, MuPAD sorts the terms of a polynomial according to the total degree of each term (the sum of the exponents of the variables). If several terms have equal total degrees, MuPAD sorts them using the inverse lexicographic ordering.
- Your custom term ordering of type `Dom::MonomOrdering`.

See "Example 5" on page 1-1502.

In contrast to `divide`, `pdivide` does not require that the coefficient ring of the polynomials implements a `"_divide"` slot because coefficients are not divided in this algorithm. See "Example 6" on page 1-1503.

Examples

Example 1

Perform pseudo-division of these two polynomials:

```
p:= poly(x^3 + x + 1):  q:= poly(3*x^2 + x + 1):
```

```
[b, s, r] := [pdivide(p, q)]
```

$$[9, \text{poly}(3x - 1, [x]), \text{poly}(7x + 10, [x])]$$

The result satisfies this equation:

```
p*b = s*q + r
```

$$\text{poly}(9x^3 + 9x + 9, [x]) = \text{poly}(9x^3 + 9x + 9, [x])$$

Now compute the pseudo-quotient and pseudo-remainder separately:

```
pdivide(p, q, Quo), pdivide(p, q, Rem)
```

$$\text{poly}(3x - 1, [x]), \text{poly}(7x + 10, [x])$$

```
delete p, q, b, s, r:
```

Example 2

By default, `pdivide` performs pseudo-division of `p` by `q` with the factor `b` determined by the formula `b = lcoeff (q)^( degree (p) - degree(q) + 1)`:

```
p := 4*x^2 + 3: q := 2*x + 2:
b = lcoeff(q)^(degree(p) - degree(q) + 1);
pdivide(p, q)
```

$$b = 4$$

$$4, 8x - 8, 28$$

To enable `pdivide` to alter the value of `b`, use `AnyFactor`:

```
pdivide(4*x^2 + 3, 2*x + 2, AnyFactor)
```

$$1, 2x - 2, 7$$

Example 3

If an expression cannot be converted to a polynomial, `pdivide` returns `FAIL`:

```
pdivide(1/x, x)
```

FAIL

Example 4

When performing pseudo-division of multivariate polynomials, you can specify the list of variables. The `pdivide` function assumes all other variables are symbolic parameters. For example, divide the following two polynomial expressions specifying that `x`, `y`, and `a` are variables. The resulting pseudo-quotient is 0, and the pseudo-remainder equals the dividend `p`:

```
p := x^3 + x + y:
q := a*x^2 + x + 1:
pdivide(p, q, [x, y, a])
```

$$1,\ 0,\ x^3 + x + y$$

Divide these expressions specifying that `x` and `y` are variables. MuPAD assumes that `a` is a symbolic parameter. Here, both the pseudo-quotient and pseudo-remainder are not equal to 0:

```
pdivide(p, q, [x, y])
```

$$a^2,\ a\,x - 1,\ a^2\,y + x\,(a^2 - a + 1) + 1$$

Now divide the same polynomial expressions specifying that only `y` is a variable. MuPAD assumes that `x` and `a` are symbolic parameters. Here the pseudo-remainder is 0:

```
pdivide(p, q, [y])
```

$$(a\,x^2 + x + 1)^2,\ y\,(a\,x^2 + x + 1) + (x^3 + x)\,(a\,x^2 + x + 1),\ 0$$

By default, the `pdivide` function treats polynomial expressions with multiple variables as multivariate polynomial expressions. The function does not assume that any of the variables are symbolic parameters:

```
pdivide(x^3 + x + y, a*x^2 + x + 1)
```

$$1, 0, x^3 + x + y$$

Example 5

`pdivide` lets you perform pseudo-division of a polynomial (or polynomial expression) by multiple polynomials (or polynomial expressions):

```
p := 4*x^4 + a*x^2*y^4:
q1 := x^3 - a:
q2 := x + y:
[b, s1, s2, r] := [pdivide(p, q1, q2)]
```

$$[-1, x^2 y^4, -x^4 y^4 + x^3 y^5 - 4 x^3 - x^2 y^6 + 4 x^2 y + x y^7 - 4 x y^2 - y^8 + 4 y^3, y^9 - 4 y^4]$$

The result satisfies the condition `b*p = s1*q1 + s2*q2 + r`:

```
testeq(b*p, s1*q1 + s2*q2 + r)
```

$$\text{TRUE}$$

When dividing a polynomial by multiple polynomials, you can select the term ordering:

```
pdivide(p, q1, q2, LexOrder)
```

$$-1, x^2 y^4, -x^4 y^4 + x^3 y^5 - 4 x^3 - x^2 y^6 + 4 x^2 y + x y^7 - 4 x y^2 - y^8 + 4 y^3, y^9 - 4 y^4$$

```
pdivide(p, q1, q2, DegreeOrder)
```

$$1, 4 x, -a y^5 + a x y^4 + 4 a, a y^6 - 4 a y$$

Example 6

The coefficient ring can be an arbitrary ring. For example, here the residue class ring of integers modulo 8 represents the coefficient ring:

```
pdivide(poly(x^3 + x + 1, IntMod(8)),
        poly(4*x^3 + x + 1, IntMod(8)))
```

$$4,\ \mathrm{poly}(1,\ [x],\ \mathrm{IntMod}(8)),\ \mathrm{poly}(3\,x+3,\ [x],\ \mathrm{IntMod}(8))$$

Note that `pdivide` does not require divisibility of the coefficients.

Parameters

`p, q`

Univariate or multivariate polynomials or polynomial expressions.

`p, q1, q2, …`

Univariate or multivariate polynomials or polynomial expressions.

`x`

The indeterminate of the polynomial, which is typically an identifier or an indexed identifier. `pdivide` treats the expressions as univariate polynomials in the indeterminate `x`.

`x1, x2, …`

The indeterminates of the polynomial, which are typically identifiers or indexed identifiers. `pdivide` treats multivariate expressions as multivariate polynomials in these indeterminates.

`order`

The term ordering when performing pseudo-division of one multivariate polynomial by one or more multivariate polynomials: `LexOrder`, `DegreeOrder`, `DegInvLexOrder`, or a custom term ordering of type `Dom::MonomOrdering`. The default is the lexicographical ordering `LexOrder`.

Options

`Quo, Rem`

Return only the pseudo-quotient or pseudo-remainder. By default, `pdivide` returns the sequence containing the factor `b`, pseudo-quotient `s` (or pseudo-quotients `s1, s2, ...`), and pseudo-remainder `r`. See “Example 1” on page 1-1499.

`AnyFactor`

Allow flexibility for the factor `b`. Without this option, `b = lcoeff (q)^( degree (p) - degree(q) + 1)`.

Return Values

Polynomial, or polynomial expression, or a sequence containing an element of the coefficient ring of the input polynomials and polynomials (or polynomial expressions), or the value `FAIL`.

Overloaded By

f, g, p, q

piecewise

Domain of conditionally defined objects

Syntax

```
piecewise([condition1, object1], [condition2, object2], …, <[Otherwise, objectN]>, <Ex
```

Description

`piecewise([condition1, object1], [condition2, object2], ...)` defines a conditional object that equals `object1` if `condition1` is provably true, `object2` if `condition2` is provably true, and so on. Typically, such objects define piecewise functions or express solutions based on a case analysis of the free parameters of the mathematical problem. See “Example 1” on page 1-1507.

A pair `[condition, object]` is called a *branch*. If `condition` is provably false, then `piecewise` discards the entire branch. If `condition` is provably true, then `piecewise` returns the corresponding `object`. If neither condition in a piecewise object is provably true, `piecewise` returns an object of type `piecewise` that contains all branches, except for branches with provably false conditions.

If all conditions are provably false, or if you call `piecewise` without any branches, then `piecewise` returns `undefined`. See “Example 1” on page 1-1507.

Conditions do not need to be exhaustive or exclusive. If conditions contain parameters, and you substitute values for the parameters, all conditions can become false. Also, several conditions can become true.

If several conditions are simultaneously true, `piecewise` returns the object from the first branch that contains the condition recognized as true. Ensure that all objects corresponding to the true conditions have the same mathematical meaning. Do not rely on the system to recognize the first mathematically true condition as true. Alternatively, you can use the `ExclusiveConditions` option to fix the order of the branches.

`piecewise([condition1, object1], [condition2, object2], ..., [Otherwise, objectN])` checks the conditions, and, if they are not satisfied, discards

them and returns `objectN`. The `Otherwise` condition occurs in the last branch. It can occur only once. It remains unchanged as long as there are other branches, but it is treated as true when all other branches are discarded because their conditions are false. See "Example 2" on page 1-1507.

The system checks the truth of the conditions for current values and properties of all involved identifiers each time it evaluates an object of type `piecewise`. Thus, it simplifies piecewise expressions under various different assumptions.

`piecewise` objects can be nested: both conditions and objects can be `piecewise` objects themselves. `piecewise` automatically "flattens" such objects. For example, `piecewise([conditionA, piecewise([conditionB, objectC])])` becomes `piecewise([conditionA and conditionB, objectC])`. See "Example 3" on page 1-1508.

Arithmetical and set-theoretic operations work for `piecewise` objects, provided these operations are defined for all objects contained in the branches. If `f` is such an operation and `p1, p2, ...` are `piecewise` objects, then `f(p1, p2, ...)` is the `piecewise` object consisting of all branches of the form `[condition1 and condition2 and ..., f(object1, object2, ...)]`, where `[condition1, object1]` is a branch of `p1`, `[condition2, object2]` is a branch of `p2`, and so on. In other words, applying `f` commutes with any assignment to free parameters in the conditions. See "Example 4" on page 1-1508.

`piecewise` objects can also be mixed with other objects in such operations. In such cases, if `p1` is not a `piecewise` object, the system treats it as a `piecewise` object with the only branch `[TRUE, p1]`. See "Example 5" on page 1-1509.

`diff`, `float`, `limit`, `int` and similar functions handle expressions involving `piecewise`. When you use a `piecewise` argument in unary operators and functions with one argument, the system maps the operator or function to the objects in each branch. See "Example 6" on page 1-1509, "Example 7" on page 1-1509, and "Example 8" on page 1-1510.

`piecewise` differs from the `if` and `case` branching statements. First, `piecewise` uses the property mechanism when deciding the truth of the conditions. Therefore, the result depends on the properties of the identifiers that appear in the conditions. Second, `piecewise` treats conditions mathematically, while `if` and `case` evaluate them syntactically. Third, `piecewise` internally sorts the branches. If conditions in several branches are true, `piecewise` can return any of these branches. See "Example 9" on page 1-1510.

The `ExclusiveConditions` option fixes the order of branches in a piecewise expression. If the condition in the first branch returns `TRUE`, then `piecewise` returns the expression from the first branch. If a true condition appears in any further branch, then `piecewise` returns the expression from that branch and removes all subsequent branches. Thus, `piecewise` with `ExclusiveConditions` is very similar to an `if-elif-end_if` statement. Nevertheless, `piecewise` with `ExclusiveConditions` still takes into account assumptions on identifiers and treats conditions mathematically while `if-elif-end_if` treats them syntactically. See “Example 10” on page 1-1511.

Environment Interactions

`piecewise` takes into account properties of identifiers.

Examples

Example 1

Define this rectangular function `f`. Without additional information about the variable x, the system cannot evaluate the conditions to `TRUE` or `FALSE`. Therefore, it returns the `piecewise` object.

```
f := x -> piecewise([x < 0 or x > 1, 0], [x >= 0 and x <= 1, 1])
```

$$x \to \begin{cases} 0 & \text{if } x < 0 \vee 1 < x \\ 1 & \text{if } 0 \le x \wedge x \le 1 \end{cases}$$

Call the function `f` with the following arguments. Every time you call this piecewise function, the system checks the conditions in its branches and evaluates the function.

```
f(0), f(2), f(I)
```

$$1,\ 0,\ \text{undefined}$$

Example 2

Create this piecewise function using the syntax that includes `Otherwise`:

```
pw:= piecewise([x > 0 and x < 1, 1], [Otherwise, 0])
```

$$\begin{cases} 1 & \text{if } x \in (0, 1) \\ 0 & \text{otherwise} \end{cases}$$

Evaluate pw for these three values:

```
pw | x = 1/2;
pw | x = 2;
pw | x = I;
```

$$1$$

$$0$$

$$0$$

For further computations, delete the identifier pw:

```
delete pw:
```

Example 3

Create this nested piecewise expression. MuPAD flattens nested `piecewise` objects.

```
p1 := piecewise([a > 0, a^2], [a <= 0, -a^2]):
piecewise([b > 0, a + b], [b = 0, p1 + b], [b < 0, a + b])
```

$$\begin{cases} a^2 & \text{if } 0 < a \wedge b = 0 \\ -a^2 & \text{if } a \le 0 \wedge b = 0 \\ a + b & \text{if } b \ne 0 \wedge b \in \mathbb{R} \end{cases}$$

Example 4

Find the sum of these piecewise functions. You can perform most operations on piecewise functions the same way as you would on ordinary arithmetical expressions. The result of an arithmetical operation is only defined at the points where all of the arguments are defined:

```
piecewise([x > 0, 1], [x < -3, x^2]) + piecewise([x < 2, x])
```

$$\begin{cases} x^2 + x & \text{if } x < -3 \\ x + 1 & \text{if } x \in (0, 2) \end{cases}$$

Example 5

Solve this equation. The solver returns the result as a piecewise set:

```
S := solve(a*x = 0, x)
```

$$\begin{cases} \mathbb{C} & \text{if } a = 0 \\ \{0\} & \text{if } a \neq 0 \end{cases}$$

You can use set-theoretic operations work for such sets. For example, find the intersection of this set and the interval `(3, 5)`:

```
S intersect Dom::Interval(3, 5)
```

$$\begin{cases} (3, 5) & \text{if } a = 0 \\ \varnothing & \text{if } a \neq 0 \end{cases}$$

Example 6

Many unary functions are overloaded for `piecewise` by mapping them to the objects in all branches of the input:

```
f := piecewise([x >= 0, arcsin(x)], [x < 0, arccos(x)]):
sin(f)
```

$$\begin{cases} \sqrt{1 - x^2} & \text{if } x < 0 \\ x & \text{if } 0 \le x \end{cases}$$

Example 7

Find the limit of this piecewise function:

```
limit(piecewise([a > 0, x],[a < 0 and x > 1, 1/x],
                [a < 0 and x <= 1, -x]), x = infinity)
```

$$\begin{cases} \infty & \text{if } 0 < a \\ 0 & \text{if } a < 0 \end{cases}$$

Example 8

Find the integral of this piecewise function:

```
int(piecewise([x < 0, x^2], [x > 0, x^3]), x = -1..1)
```

$$\frac{7}{12}$$

Example 9

Create this piecewise function. Here, `piecewise` cannot determine if any branch is true or false. To do that, `piecewise` needs additional information about the identifier `a`.

```
p1 := piecewise([a = 0, 0], [a <> 0, 1/a])
```

$$\begin{cases} 0 & \text{if } a = 0 \\ \frac{1}{a} & \text{if } a \neq 0 \end{cases}$$

Create a similar structure by using `if-then-else`. The `if-then-else` structure evaluates the conditions syntactically. Here, `a = 0` is technically false because the identifier `a` and the integer `0` are different objects.

```
p2 := (if a = 0 then 0 else 1/a end)
```

$$\frac{1}{a}$$

`piecewise` takes properties of identifiers into account:

```
p1 := piecewise([a + b = 0, 0], [Otherwise, 1/a]) assuming a + b = 0
```

```
0
```

`if-then-else` does not:

```
p2 := (if a + b = 0 then 0 else 1/a end) assuming a + b = 0
```

$$\frac{1}{a}$$

For further computations, delete identifiers `a`, `b`, `p1`, and `p2`:

```
delete a, b, p1, p2:
```

Example 10

Create this piecewise expression:

```
p := piecewise([x > 0, 1], [y > 0, 2])
```

$$\begin{cases} 1 & \text{if } 0 < x \\ 2 & \text{if } 0 < y \end{cases}$$

Evaluate the expression at `y = 1`:

```
p | y = 1
```

```
2
```

Now, create the piecewise expression with the same branches, but this time use `ExclusiveConditions` to fix the order of the branches. When you use this option, any branch can be true only if the previous branches are false.

```
pE := piecewise([x > 0, x], [y > 0, y], ExclusiveConditions)
```

$$\begin{cases} x & \text{if } 0 < x \\ y & \text{if } 0 < y \\ \text{ExclusiveConditions}_2 & \text{if } \text{ExclusiveConditions}_1 \end{cases}$$

Evaluate the expression at `y = 1`:

```
pE | y = 1
```

$$\begin{cases} x & \text{if } 0 < x \\ 1 & \text{if TRUE} \\ \text{ExclusiveConditions}_2 & \text{if ExclusiveConditions}_1 \end{cases}$$

When you use `ExclusiveConditions`, `piecewise` acts the same way as an `if-then-else` statement, but does not ignore properties of identifiers. For example, set the assumption that `x = 0`:

```
assume(x = 0)
```

The `piecewise` function call returns 0 because it uses the assumption on identifier `x`:

```
p := piecewise([x = 0, x], [Otherwise, 1/x^2])
```

$$x$$

The corresponding `if-then-else` statement ignores the assumption, and, therefore, returns `1/x^2`:

```
pIf := (if x = 0 then x else 1/x^2 end)
```

$$\frac{1}{x^2}$$

For further computations, delete identifiers `p`, `pE`, `x`, and `pIf`:

```
delete p, pE, x, pIf:
```

Example 11

Find a set of accumulation points of this piecewise function by calling `limit` with the `Intervals` option:

```
limit(piecewise([a > 0, sin(x)], [a < 0 and x > 1, 1/x],
         [a < 0 and x <= 1, -x]), x = infinity, Intervals)
```

$$\begin{cases} [-1, 1] & \text{if } 0 < a \\ \{0\} & \text{if } a < 0 \end{cases}$$

Example 12

Rewrite the `sign` function in terms of a `piecewise` object:

```
f := rewrite(sign(x), piecewise)
```

$$\begin{cases} 0 & \text{if } x = 0 \\ 1 & \text{if } 0 < x \\ -1 & \text{if } x < 0 \\ \frac{x}{\sqrt{\Im(x)^2 + \Re(x)^2}} & \text{if } x \notin \mathbb{R} \end{cases}$$

Example 13

Create this `piecewise` object:

```
f := piecewise([x > 0, 1], [x < -3, x^2])
```

$$\begin{cases} 1 & \text{if } 0 < x \\ x^2 & \text{if } x < -3 \end{cases}$$

Extract a particular condition or object:

```
piecewise::condition(f, 1), piecewise::expression(f, 2)
```

$$0 < x,\ x^2$$

The index operator has the same meaning as `piecewise::expression` and can be typed faster:

```
f[2]
```

$$x^2$$

The `piecewise::branch` function extracts whole branches:

```
piecewise::branch(f, 1)
```

$$[0 < x,\ 1]$$

You can form another `piecewise` object from the branches for which the condition satisfies a given selection criterion, or split the input into two `piecewise` objects, as the system functions `select` and `split` do it for lists:

```
piecewise::selectConditions(f, has, 0)
```

$$\{1 \text{ if } 0 < x$$

```
piecewise::splitConditions(f, has, 0)
```

$$[\{1 \text{ if } 0 < x,\ \{x^2 \text{ if } x < -3,\ \text{undefined}]$$

You can also create a copy of `f` with some branches added or removed:

```
piecewise::remove(f, 1)
```

$$\{x^2 \text{ if } x < -3$$

```
piecewise::insert(f, [x > -3 and x < 0, sin(x)])
```

$$\begin{cases} 1 & \text{if } 0 < x \\ x^2 & \text{if } x < -3 \\ \sin(x) & \text{if } x \in (-3, 0) \end{cases}$$

Parameters

`condition1, condition2, …`

Boolean constants, or expressions representing logical formulas

`object1, object2, …`

Arbitrary objects

`Otherwise`

Identifier that specifies the last condition. This condition is always treated as a true condition.

Options

`ExclusiveConditions`

The `ExclusiveConditions` option fixes the order of branches in a piecewise expression. This option causes `piecewise` to automatically remove branches with false conditions. Thus, `piecewise` with `ExclusiveConditions` is almost equivalent to an `if-elif-end_if` statement, except that `piecewise` takes into account assumptions on identifiers. For example, if the condition in the first branch returns `TRUE`, then `piecewise` returns the expression from the first branch. If a true condition appears in any further branch, then `piecewise` returns the expression from that branch and removes all subsequent branches.

Methods

Mathematical Methods

`_in` — Membership with `piecewise` on the left side

```
_in(p, S)
```

`contains` — Apply the function `contains` to the objects in all branches

```
contains(p, a)
```

This method overloads the function `contains`. The objects in all branches must be valid first arguments for `contains`.

`diff` — (partial) differentiation

```
diff(p, <x, …>)
```

If no variables are given, `p` is returned.

`discont` — Determine the discontinuities of a piecewise function

```
discont(p, x, <F>)
```

```
discont(p, x = a .. b, <F>)
```

The objects in all branches of `p` must be arithmetical expressions.

The optional third parameter has the same meaning as for the function `discont`.

As for the function `discont`, only discontinuities in the given interval `[a,b]` are returned when calling `piecewise(p, x = a..b)`.

`disregardPoints` — Heuristic for simplifying conditions

```
disregardPoints(p)
```

`expand` — Apply the function `expand` to the objects in all branches

```
expand(p)
```

`factor` — Apply the function `factor` to the objects in all branches

```
factor(p)
```

`getElement` — Get any element of a piecewise set

```
getElement(p)
```

The result is `FAIL` if no such common element is found.

This method overloads the function `solvelib::getElement`.

`has` — Test for the existence of a subobject

```
has(p, a)
```

`int` — Definite and indefinite integration of a piecewise function

```
int(p, x, <r>)
```

If a range `a..b` is given, this method computes the definite integral of `p` when `x` runs through that range.

`ilaplace` — Apply the function `ilaplace` to the objects in all branches

```
ilaplace(p, x, t)
```

`isFinite` — Test whether a piecewise set is finite

```
isFinite(p)
```

This method overloads `solvelib::isFinite`.

`laplace` — Apply the function `laplace` to the objects in all branches

```
laplace(p, x, t)
```

`limit` — Compute the limit of a piecewise function

```
limit(p, x, <Left | Right | Real>, <Intervals>, <NoWarning>)
```

```
limit(p, x = x0, <Left | Right | Real>, <Intervals>, <NoWarning>)
```

When called with the `Intervals` option, the method returns the set of accumulation points of a function.

If the method cannot find the function limit and cannot prove the limit does not exist, the function call returns an unevaluated `limit` function.

If the limit of a function does not exist, the method returns the special value `undefined`.

This method overloads the function `limit`.

`normal` — Apply the function `normal` to the objects in all branches

```
normal(p)
```

`partfrac` — Apply the function `partfrac` to the objects in all branches

```
partfrac(p)
```

`restrict` — Impose an additional condition

```
restrict(p, C)
```

`set2expr` — Membership with `piecewise` on the right side

```
set2expr(p, x)
```

The objects in all branches of `p` must represent sets.

This method overloads the system function `_in`.

`simplify` — Simplify a conditionally defined object

```
simplify(p)
```

`solve` — Solve a conditionally defined equation or inequality

```
solve(p, x, <option1, option2, …>)
```

For each branch `[condition, object]` of `p`, with `object` being an equation or inequality, the method determines the set of all values `x` such that both `condition` and `object` become true mathematically, and returns the union of all obtained sets. The return value can be a conditionally defined set.

This method overloads the function `solve`. See the corresponding help page for a description of the available options and an overview of the types of sets that can be returned.

`solveConditions` — Isolate a given identifier in all conditions

```
solveConditions(p, x)
```

`Union` — Union of a system of sets

```
Union(p, x, indexset)
```

The objects in all branches of `p` must represent sets.

For each branch `[condition, object]` of `p`, this method does the following. It substitutes for `x` in `object` all values from `indexset` satisfying `condition` and takes the union over all obtained sets. Then it returns the union over the resulting sets for all branches.

This method overloads the function `solvelib::Union`.

Access Methods

`_concat` — Merge piecewise objects

```
_concat(p, …)
```

`branch` — Nth branch

```
branch(p, n)
```

`op` — Branches

```
op(p)
```

```
op(p, n)
```

`op(p, n)` returns the `n`th branch of `p` as a list. If $n = 0$, then `piecewise` is returned.

`setBranch` — Replace the `i`th branch

```
setBranch(p, i, b)
```

`numberOfBranches` — Number of branches

```
numberOfBranches(p)
```

`condition` — Condition in a specific branch

```
condition(p, i)
```

`setCondition` — Replace the condition in a specific branch by another

```
setCondition(p, i, cond)
```

`expression` — Object in a specific branch

```
expression(p, i)
```

Instead of `piecewise::expression(p, i)`, the index operator `p[i]` can be used synonymously.

`_index` — Object in a specific branch

```
_index(p, i)
```

`piecewise::expression` can be used synonymously.

`setExpression` — Replace the object in a specific branch by another

```
setExpression(p, i, a)
```

`insert` — Insert a branch

```
insert(p, b)
```

`b` can either be a branch extracted from another conditionally defined object using `extop`, or a list `[condition, object]`.

See "Example 13" on page 1-1513.

`extmap` — Apply a function to the objects in all branches

```
extmap(p, f, <a, …>)
```

`mapConditions` — Apply a function to the conditions in all branches

```
mapConditions(p, f, <a, …>)
```

`map` — Apply the function `map` to the objects in all branches

```
map(p, f, <a, …>)
```

`map(p, f)` is equivalent to `piecewise::extmap(p, map, f)`.

`remove` — Remove a branch

```
remove(p, i)
```

`splitBranch` — Split a branch into two branches

```
splitBranch(p, i, newcondition)
```

`selectConditions` — Select branches depending on their condition

```
selectConditions(p, f, <a, …>)
```

For every condition in `p`, `f(condition a, …)` must return a Boolean constant.

If none of the conditions satisfies the selection criterion, `undefined` is returned.

`selectExpressions` — Select branches depending on their object

```
selectExpressions(p, f, <a, …>)
```

For every object in `p`, `f(object a, …)` must return a Boolean constant.

If none of the objects satisfies the selection criterion, `undefined` is returned.

`splitConditions` — Split branches depending on conditions

```
splitConditions(p, f, <a, …>)
```

For every condition in `p`, `f(condition a, …)` must return a Boolean constant.

See "Example 13" on page 1-1513.

`subs` — Substitution

```
subs(p, s, …)
```

This method overloads the function `subs`. The calling syntax is identical to that function. See the corresponding help page for a description of the various types that are allowed for `s`.

`zip` — Apply a binary operation pointwise

```
zip(p1, p2, f)
```

If we regard conditionally defined objects as functions from the set A of parameter values to a set B of objects, this method implements the canonical extension of the binary operation f on B to the binary operation g on the set B^A of all functions from A to B via $g(p1, p2)(a) = f(p1(a), p2(a))$ for all a in A.

If only one of the first two arguments—`p1`, say—is of type `piecewise`, then each branch `[condition, object]` of `p1` is replaced by `[condition, f(object, p2)]`.

If neither `p1` nor `p2` are of type `piecewise`, then `piecewise::zip(p1, p2, f)` returns `f(p1, p2)`.

Algorithms

The operands of a `piecewise` object (the branches) are pairs consisting of a condition and the object valid under that condition.

Methods overloading system functions always assume that they have been called via overloading, and that there is some conditionally defined object among their arguments. All other methods do not assume that one of their arguments is of type `piecewise`. This simplifies the use of `piecewise`: it is always allowed to enter `p:=piecewise(...)` and to call some method of `piecewise` with `p` as an argument. You do not need to care about the special case where `p` is not of type `piecewise` because some condition in its definition is true or all conditions are false.

MuPAD Functions

`assume` | `bool` | `case` | `if` | `is`

plot

Display graphical objects on the screen

Syntax

`plot(object`$_1$`, <object`$_2$`, …>, <attribute`$_1$`, attribute`$_2$`, …>)`

Description

`plot( object`$_1$`, object`$_2$`, ...)` displays the graphical objects object$_1$, object$_2$ etc. on the screen.

This function calls `plot::easy` for preprocessing its input.

The parameters object$_1$, object$_2$ etc. must be accepted by `plot::easy` or directly be graphical objects generated by routines of the plot library. This library provides many such objects including:

- function graphs (`plot::Function2d`, `plot::Function3d`),
- curves (`plot::Curve2d`, `plot::Curve3d`),
- points (`plot::Point2d`, `plot::Point3d`),
- lines (`plot::Line2d`, `plot::Line3d`),
- polygons (`plot::Polygon2d`, `plot::Polygon3d`),
- surfaces (of domain type `plot::Surface`)

and many more. Cf. “Example 1” on page 1-1524.

There are also many high level objects such as `plot::VectorField2d`, `plot::Ode2d`, `plot::Ode3d`, `plot::Implicit2d`, `plot::Implicit3d` etc. that can also be rendered by `plot`, `display`. Cf. “Example 2” on page 1-1526.

Graphical attributes `attribute1`, `attribute2` etc. are specified by equations of the form `AttributeName = AttributeValue`. There are several hundred such attributes that allow to modify almost any aspect of the graphics.

Note: The graphical objects `object1`, `object2` etc. must have the same dimension. A mix of 2D and 3D objects in one plot is not supported!

The command `plot()` creates an empty graphical 2D scene.

Examples

Example 1

The following calls return objects representing the graphs of the sine and the cosine function on the interval [0, 2 π]:

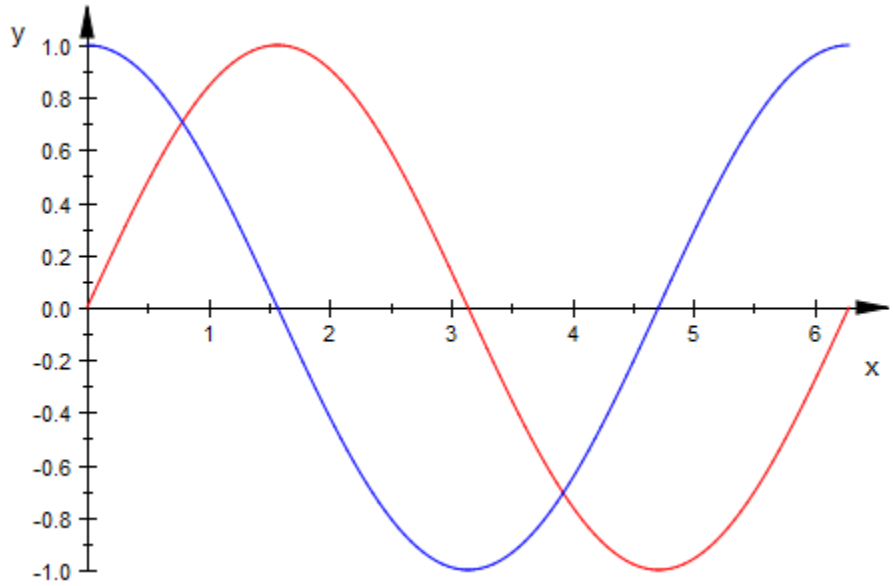
```
f1 := plot::Function2d(sin(x), x = 0..2*PI, Color = RGB::Red);
f2 := plot::Function2d(cos(x), x = 0..2*PI, Color = RGB::Blue)
```

$$\text{plot::Function2d}(\sin(x),\ x = 0..2\ \pi)$$

$$\text{plot::Function2d}(\cos(x),\ x = 0..2\ \pi)$$

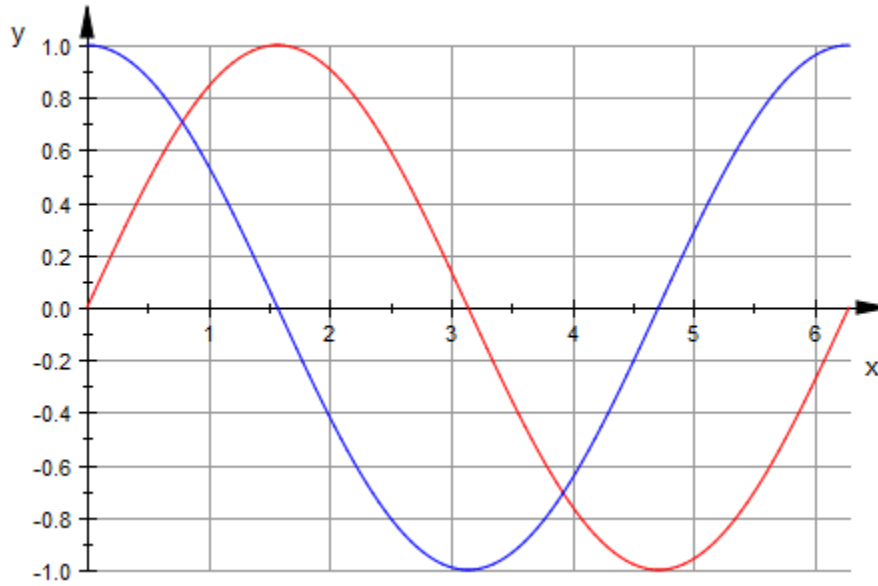
The following call renders these graphs:

```
plot(f1, f2)
```



Apart from the explicitly requested colors, this call uses the default values of all graphical attributes. If different values are desired, an arbitrary number of attributes may be passed as additional parameters to `plot`, `display`. For example, to draw grid lines in the background of the previous plot, we enter:

```
plot(f1, f2, GridVisible = TRUE)
```



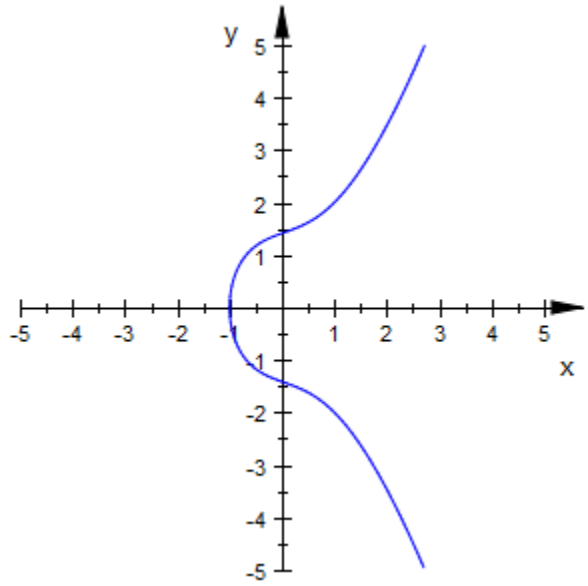
```
delete f1, f2:
```

Example 2

The plot library contains various routines for creating more complex graphical objects such as vectorfields, solution curves of ordinary differential equations, and implicitly defined curves.

For example, to plot the implicitly defined curve $x^2 + x + 2 = y^2$ with x, y from the interval [- 5, 5], we use the function `plot::Implicit2d`:

```
plot(plot::Implicit2d(x^3 + x + 2 = y^2,
                      x = -5..5, y = -5..5),
     Scaling = Constrained)
```



Here we used the `Scaling` attribute to guarantee an aspect ratio 1:1 between the x and y coordinates independent of the window size.

Parameters

`object`$_1$`, object`$_2$`, …`

2D or 3D graphical objects of the plot library or expressions accepted by `plot::easy`

`attribute`$_1$`, attribute`$_2$`, …`

Graphical attributes of the form `AttributeName = AttributeValue`

Overloaded By

object_1

Algorithms

Technically, `plot` is not a function but a domain representing the library plot library. Thus, when calling `plot(...)`, the method `plot` is called.

More About

- "Use Graphics"

display

Display graphical objects on the screen

Syntax

```
display(object1, <object2, …>, <attribute1, attribute2, …>)
```

Description

`display( object1, object2, ...)` displays the graphical objects object$_1$, object$_2$ etc. on the screen.

This function calls `plot::easy` for preprocessing its input.

The parameters object$_1$, object$_2$ etc. must be accepted by `plot::easy` or directly be graphical objects generated by routines of the plot library. This library provides many such objects including:

- function graphs (`plot::Function2d`, `plot::Function3d`),
- curves (`plot::Curve2d`, `plot::Curve3d`),
- points (`plot::Point2d`, `plot::Point3d`),
- lines (`plot::Line2d`, `plot::Line3d`),
- polygons (`plot::Polygon2d`, `plot::Polygon3d`),
- surfaces (of domain type `plot::Surface`)

and many more. Cf. “Example 1” on page 1-1530.

There are also many high level objects such as `plot::VectorField2d`, `plot::Ode2d`, `plot::Ode3d`, `plot::Implicit2d`, `plot::Implicit3d` etc. that can also be rendered by `plot`, `display`. Cf. “Example 2” on page 1-1532.

Graphical attributes `attribute1`, `attribute2` etc. are specified by equations of the form `AttributeName = AttributeValue`. There are several hundred such attributes that allow to modify almost any aspect of the graphics.

Note: The graphical objects `object1`, `object2` etc. must have the same dimension. A mix of 2D and 3D objects in one plot is not supported!

The command `display()` creates an empty graphical 2D scene.

Examples

Example 1

The following calls return objects representing the graphs of the sine and the cosine function on the interval [0, 2 π]:

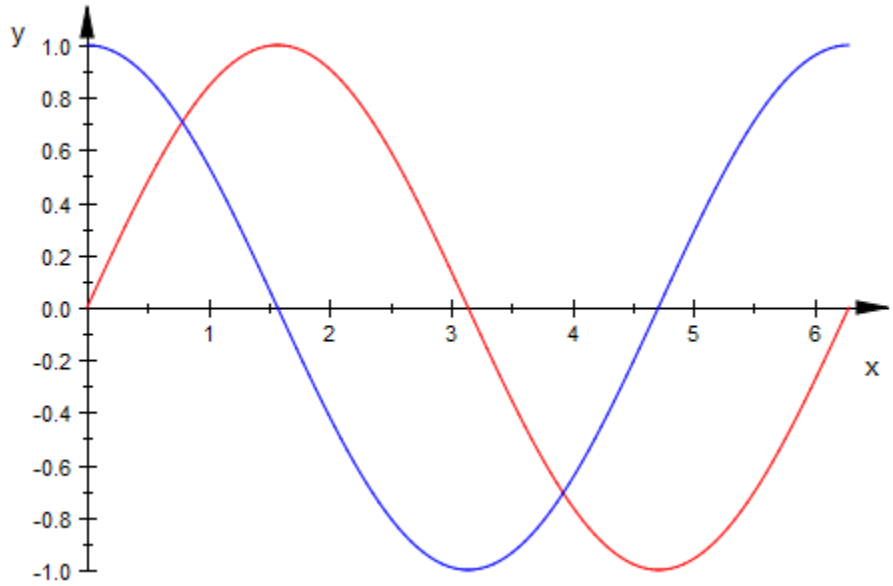
```
f1 := plot::Function2d(sin(x), x = 0..2*PI, Color = RGB::Red);
f2 := plot::Function2d(cos(x), x = 0..2*PI, Color = RGB::Blue)
```

$$\text{plot::Function2d}(\sin(x),\ x = 0..2\ \pi)$$

$$\text{plot::Function2d}(\cos(x),\ x = 0..2\ \pi)$$

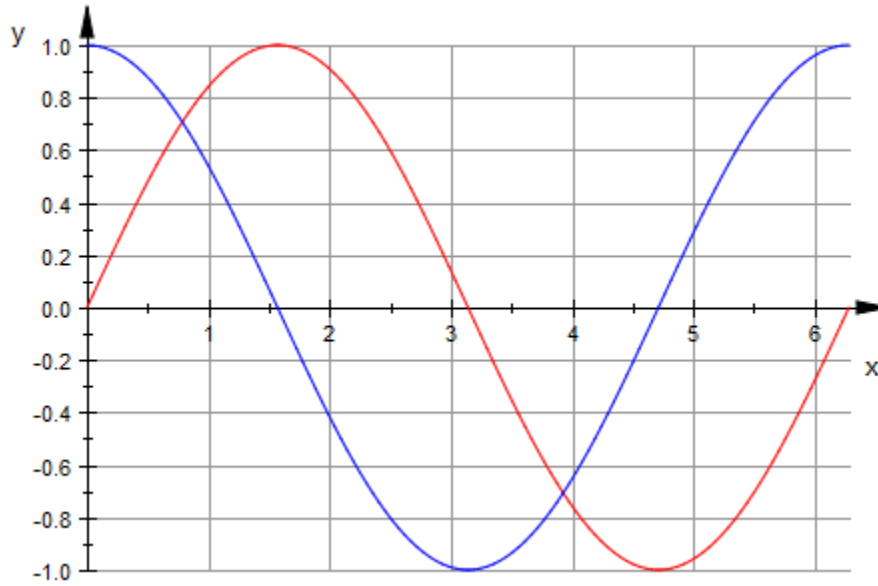
The following call renders these graphs:

```
plot(f1, f2)
```



Apart from the explicitly requested colors, this call uses the default values of all graphical attributes. If different values are desired, an arbitrary number of attributes may be passed as additional parameters to `plot`, `display`. For example, to draw grid lines in the background of the previous plot, we enter:

```
plot(f1, f2, GridVisible = TRUE)
```



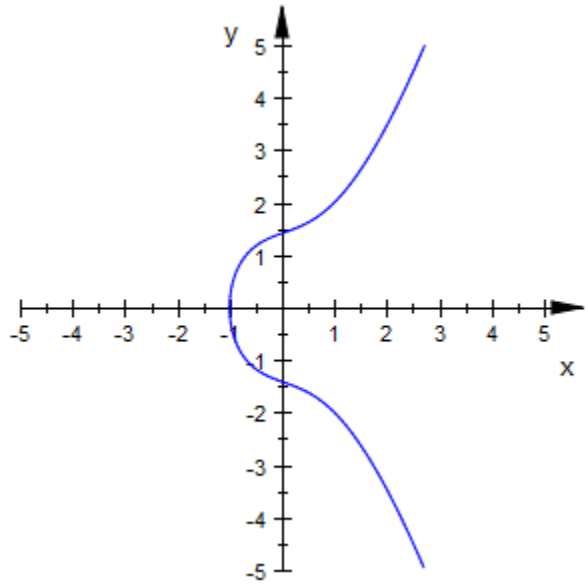
```
delete f1, f2:
```

Example 2

The plot library contains various routines for creating more complex graphical objects such as vectorfields, solution curves of ordinary differential equations, and implicitly defined curves.

For example, to plot the implicitly defined curve $x^2 + x + 2 = y^2$ with x, y from the interval [- 5, 5], we use the function `plot::Implicit2d`:

```
plot(plot::Implicit2d(x^3 + x + 2 = y^2,
                      x = -5..5, y = -5..5),
     Scaling = Constrained)
```



Here we used the `Scaling` attribute to guarantee an aspect ratio 1:1 between the x and y coordinates independent of the window size.

Parameters

`object`$_1$`, object`$_2$`, …`

plotfunc2d

Function plots in 2D

Syntax

```
plotfunc2d(f1, f2, …, <Colors = [c1, c2, …]>, <attributes>)

plotfunc2d(f1, f2, …, x = xmin .. xmax, <Colors = [c1, c2, …]>, <attributes>)

plotfunc2d(f1, f2, …, x = xmin .. xmax, a = amin .. amax, <Colors = [c1, c2, …]>, <attribut
```

Description

`plotfunc2d(f1, f2, ...)` generates a 2D plot of the univariate functions `f1`, `f2` etc.

We strongly recommend reading the introduction to `plotfunc2d` in Section 2.1 ("2D Function Graphs") of the plot document.

The functions to be plotted must not contain any symbolic parameters apart from the variable `x` and the animation parameter `a`. Exact numerical values such as `PI`, `sqrt(2)` etc. are accepted.

Animations are triggered by specifying a range $a = a_{min} .. a_{max}$ for a parameter `a` that is different from the indedependent variable `x`. Thus, in animations, both the *x*-range $x = x_{min} .. x_{max}$ as well as the animation range $a = a_{min} .. a_{max}$ must be specified. See "Example 2" on page 1-1539.

Non-real function values are ignored. See "Example 3" on page 1-1540.

Functions with singularities are handled. See "Example 4" on page 1-1541 and "Example 5" on page 1-1545. If unbounded functions are plotted, the vertical viewing range is clipped, automatically. An explicit vertical viewing range `ymin .. ymax` may be requested via `ViewingBoxYRange` = `` `y_{min}` .. `y_{max}` `` or `YRange` = `` `y_{min}` .. `y_{max}` ``.

Discontinuities and piecewise defined functions are handled. See "Example 6" on page 1-1546 and "Example 7" on page 1-1547.

The `plot` library provides the routine `plot::Function2d` which allows to create a function graph as a graphical primitive, and to combine it with other graphical objects.

A variety of graphical attributes can be specified for fine tuning the graphical output. Such attributes are passed as equations `AttributeName` = `AttributeValue` to the `plotfunc2d` command.

Section 2.3 (“Attributes for plotfunc2d and plotfunc3d”) provides an overview of the available attributes.

In particular, all attributes accepted by the graphical primitive `plot::Function2d` for function graphs are accepted by `plotfunc2d`. These attributes allow to specify the mesh for the numerical evaluation, the line width etc. The help page of plot::Function2d provides a concise list.

Further, all attributes accepted by `plot::CoordinateSystem2d` are accepted by `plotfunc2d`. These attributes include the specification of a viewing box, of the axes, their tick marks and tick labels, the coordinate type (such as linear versus logarithmic plots), grid lines etc. The help page of plot::CoordinateSystem2d provides a concise list.

Further, all attributes accepted by `plot::Scene2d` are accepted by `plotfunc2d`. These attributes include the specification of the layout of the graphical scene, the background color etc. The help page of plot::Scene2d provides a concise list.

Further, all attributes accepted by `plot::Canvas` are accepted by `plotfunc2d`. These attributes include the specification of the size of the graphics, of further layout parameters etc. The help page of plot::Canvas provides a concise list.

A graphical attribute such as `Mesh` = `500` (setting the number of mesh points for the numerical evaluation to 500) is applied to *all* functions in the call `plotfunc2d(`f_1`, `f_2`, …)`. If separate attributes are appropriate, use the equivalent call

`plot(plot::Function2d(`f_1`, `$attr_1$`), plot::Function2d(`f_2`, `$attr_2$`), …)`,

in which the attributes $attr_1$, $attr_2$ etc. can be set separately for each function.

Apart from few exceptions, `plotfunc2d` uses the standard default values for the graphical attributes (see the help page of `plot::Function2d`). The exceptions are:

- If more than one function is plotted, `plotfunc2d` automatically creates a legend. Use an explicit `LegendVisible` = `FALSE` to suppress the legend.

- `AdaptiveMesh` is set to 2, i.e., `plotfunc2d` uses adaptive function evaluation unless `AdaptiveMesh` = `0` is requested in `plotfunc2d`.
- If a parameter range such as `x = `x_{min}` .. `x_{max}`` is passed to `plotfunc2d`, the name `x` is used as the title for the horizontal axis. Pass the attribute `XAxisTitle` if a different label for the horizontal axis is desired.

Environment Interactions

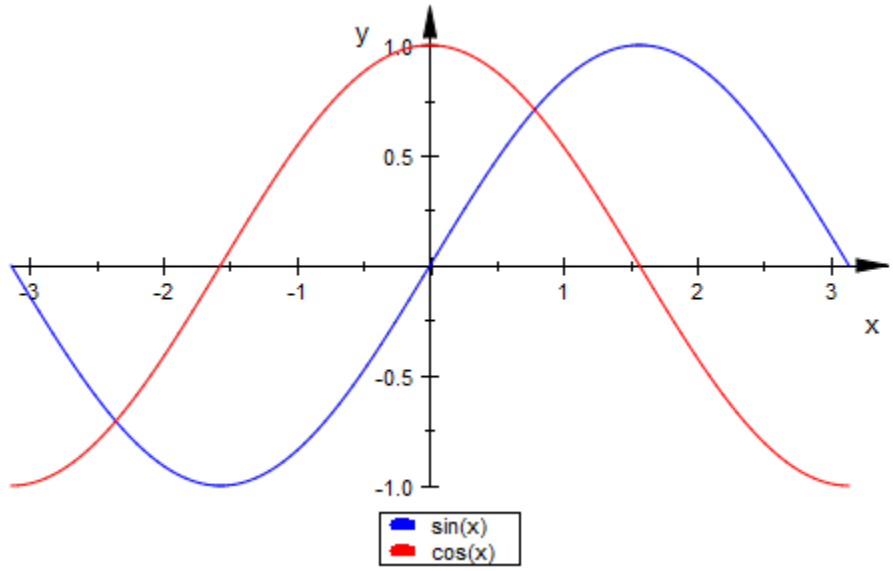
The function is sensitive to the environment variable `DIGITS` which determines the numerical working precision. Make sure that `DIGITS` is set to a sufficiently small value (such as the default value 10) to avoid the costs of computing unnecessarily precise plot data.

Examples

Example 1

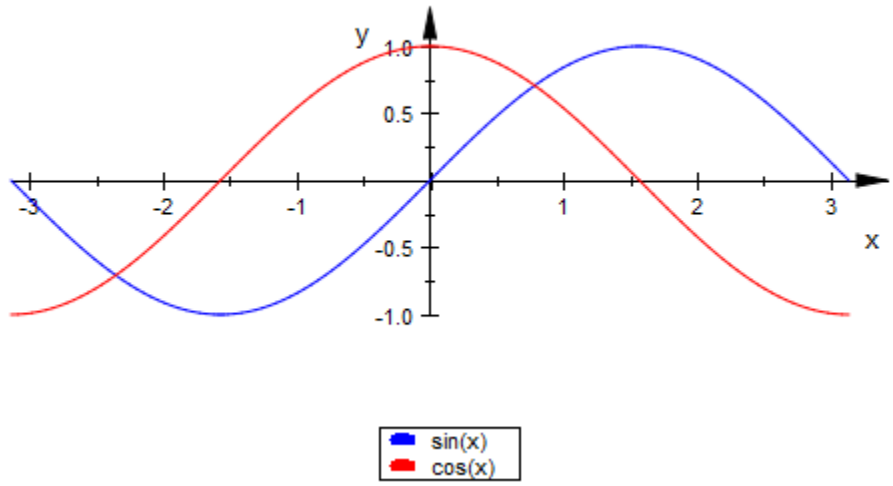
The following command draws the sine function and the cosine function on the interval [-π, π]:

```
plotfunc2d(sin(x), cos(x), x = -PI .. PI):
```



With the attribute `Scaling` = `Constrained`, the *y*-axis has the same scale as the *x*-axis:

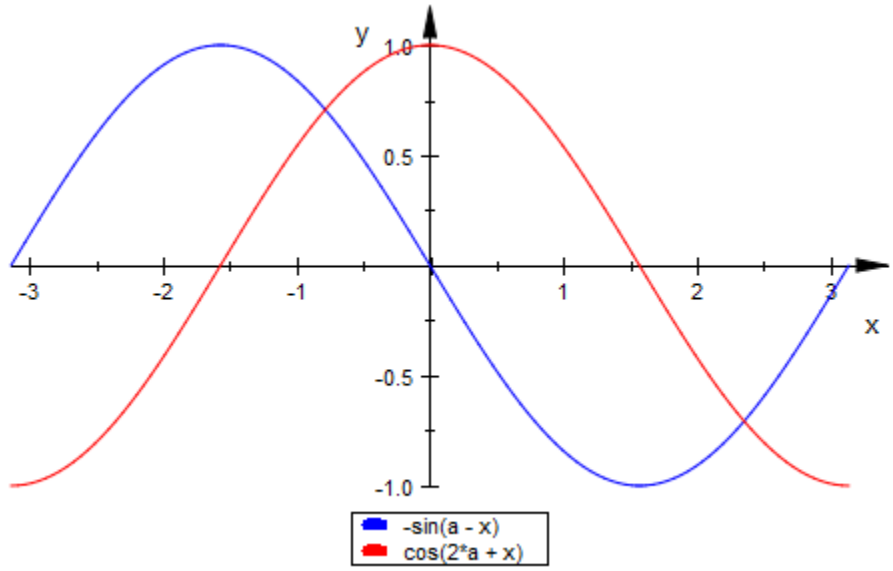
```
plotfunc2d(sin(x), cos(x), x = -PI .. PI, Scaling = Constrained):
```



Example 2

When creating an animation, a range for the independent variable *x* must be specified. An additional second range triggers the animation:

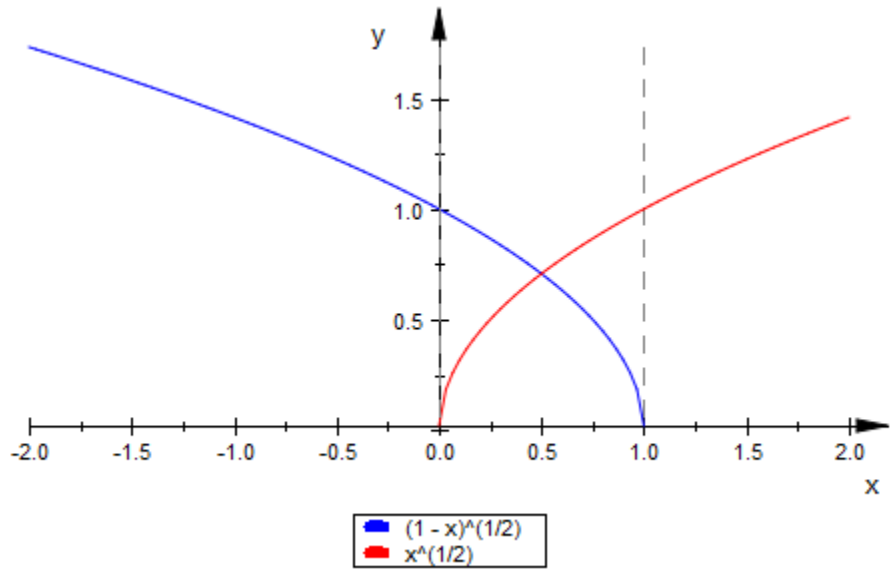
```
plotfunc2d(sin(x - a), cos(x + 2*a),
           x = -PI .. PI, a = -PI .. PI)
```



Example 3

Only real function values are plotted:

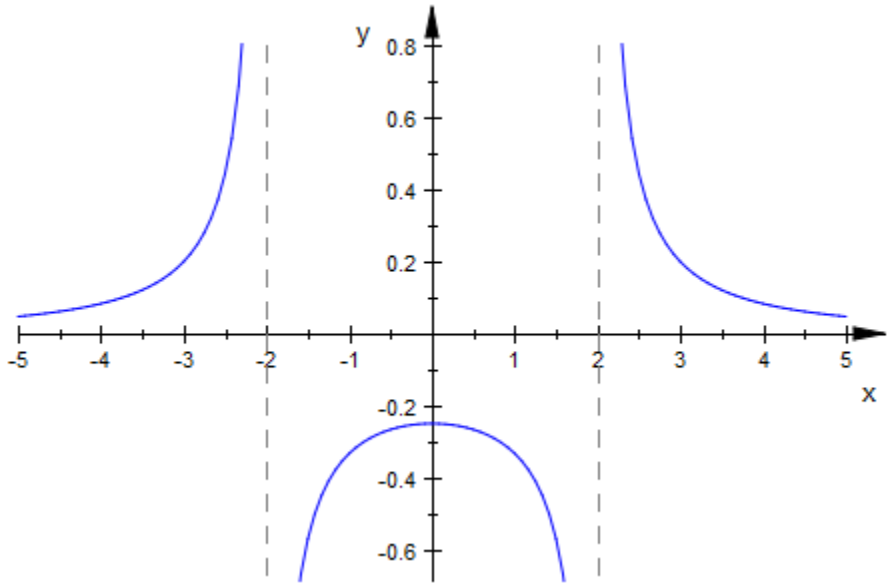
```
plotfunc2d(sqrt(1 - x), sqrt(x), x = -2 .. 2):
```



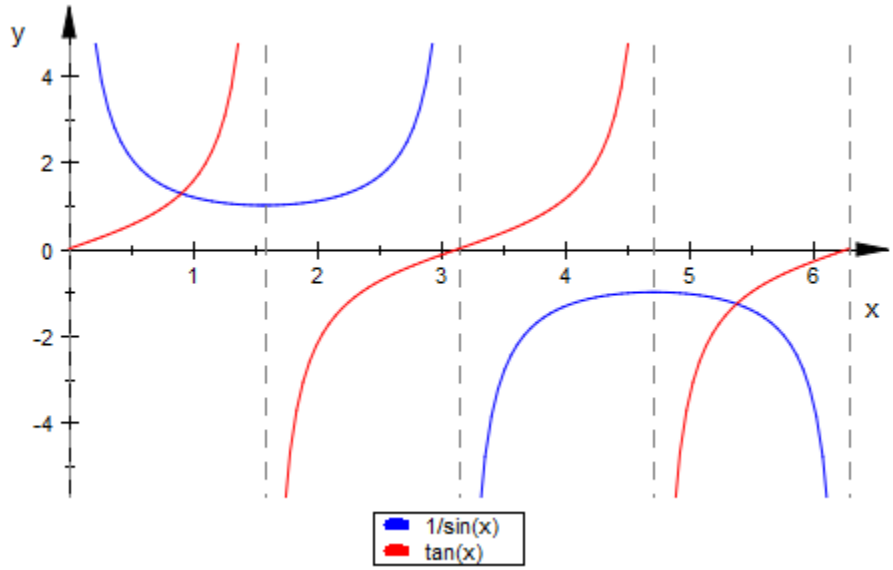
Example 4

The following functions have singularities in the specified interval:

```
plotfunc2d(x/(x^3 - 4*x), x = -5 .. 5):
```

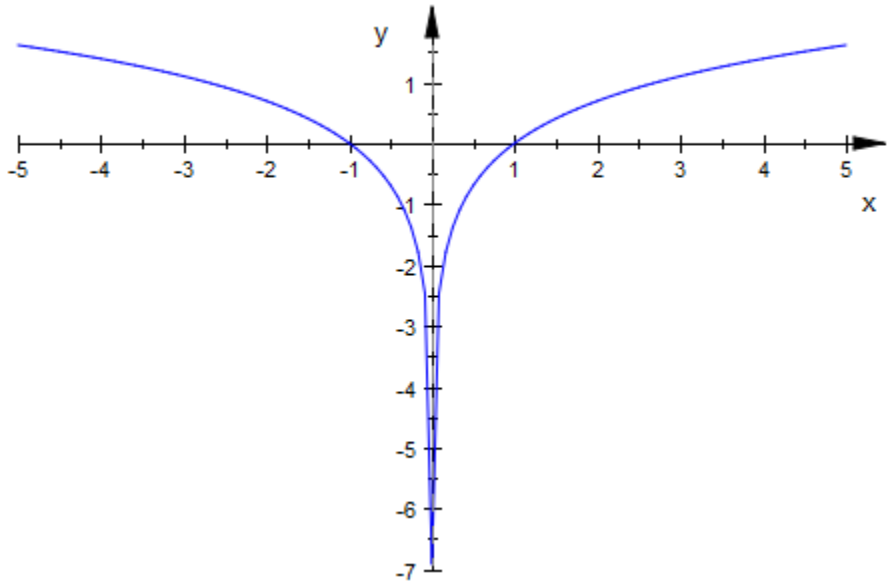


```
plotfunc2d(1/sin(x), tan(x), x = 0 .. 2*PI):
```



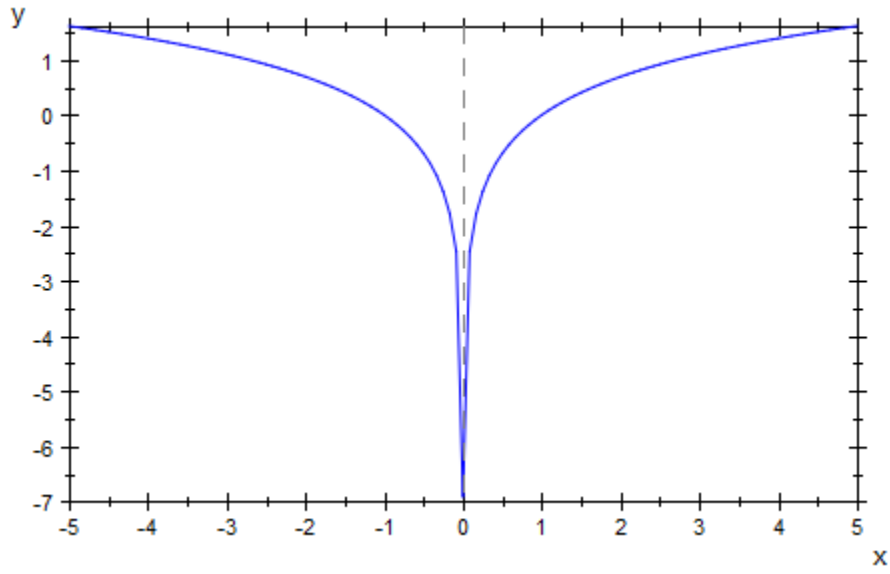
Note that the automatic clipping may in some cases lead to an incorrect impression, such as the following image where the function appears to converge to about - 4.6 (but actually goes to - ∞ for small absolute values of *x*:

```
plotfunc2d(ln(abs(x)))
```



In this case, the asymptote which points to the pole is not seen because of the axis:

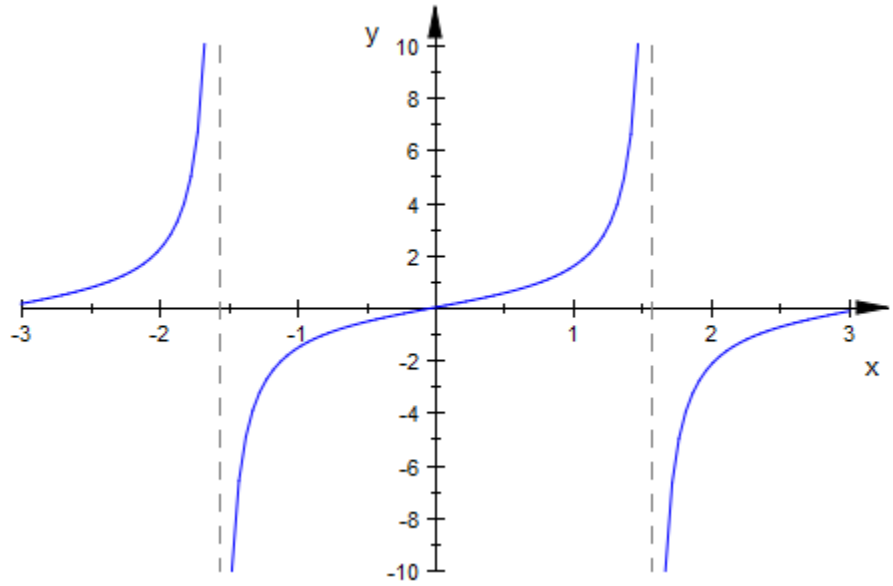
```
plotfunc2d(ln(abs(x)), Axes=Boxed)
```



Example 5

We specify a vertical range to which the function graph is restricted:

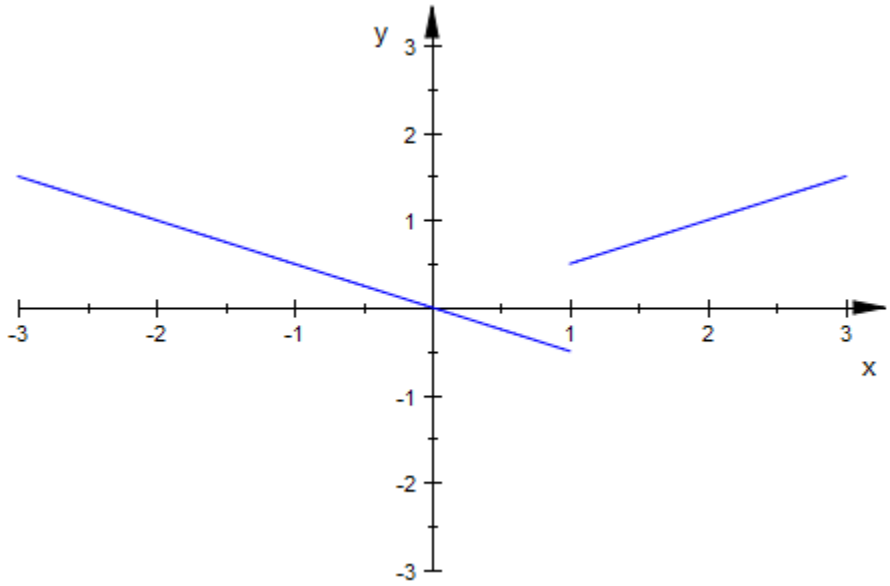
```
plotfunc2d(tan(x), x = -3 .. 3, YRange = -10 .. 10):
```



Example 6

The following function has a jump discontinuity:

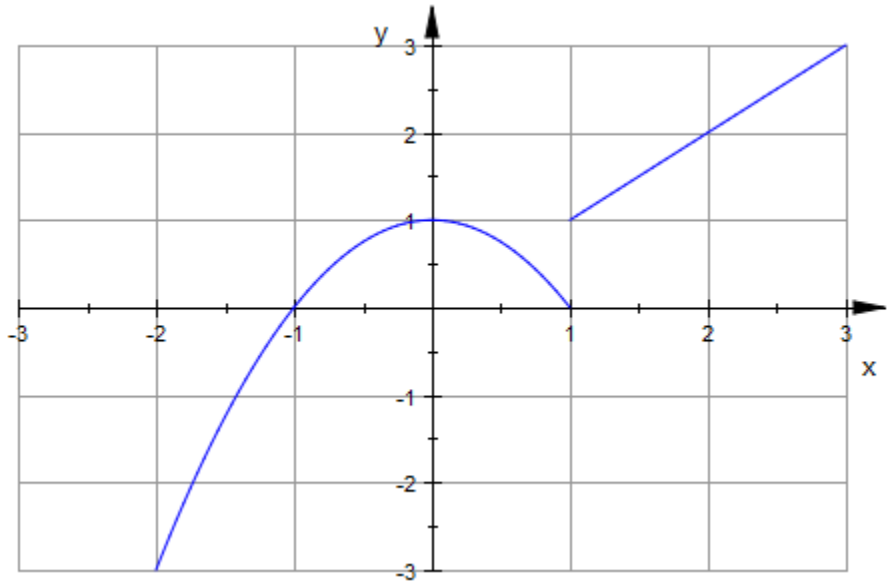
```
plotfunc2d((x^2 - x)/(2*abs(x - 1)), x = -3 .. 3,
           YRange = -3 .. 3)
```



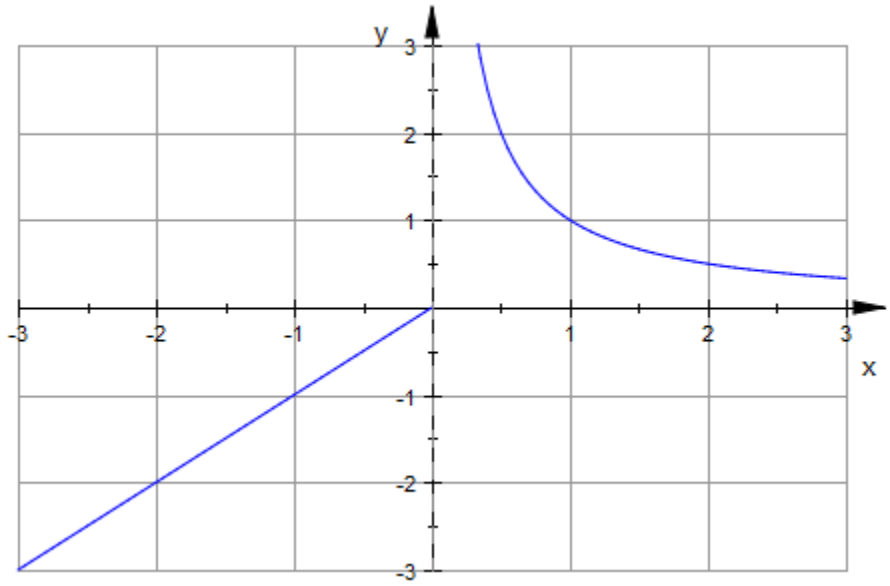
Example 7

Piecewise defined functions are handled:

```
f := piecewise([x < 1, -x^2 + 1], [x >= 1, x]):
plotfunc2d(f(x), x = -3 .. 3, YRange = -3 .. 3,
           GridVisible = TRUE, TicksDistance = 1)
```



```
f := piecewise([x <= 0, x], [x > 0, 1/x]):
plotfunc2d(f(x), x = -3 .. 3, YRange = -3 .. 3,
           GridVisible = TRUE, TicksDistance = 1)
```

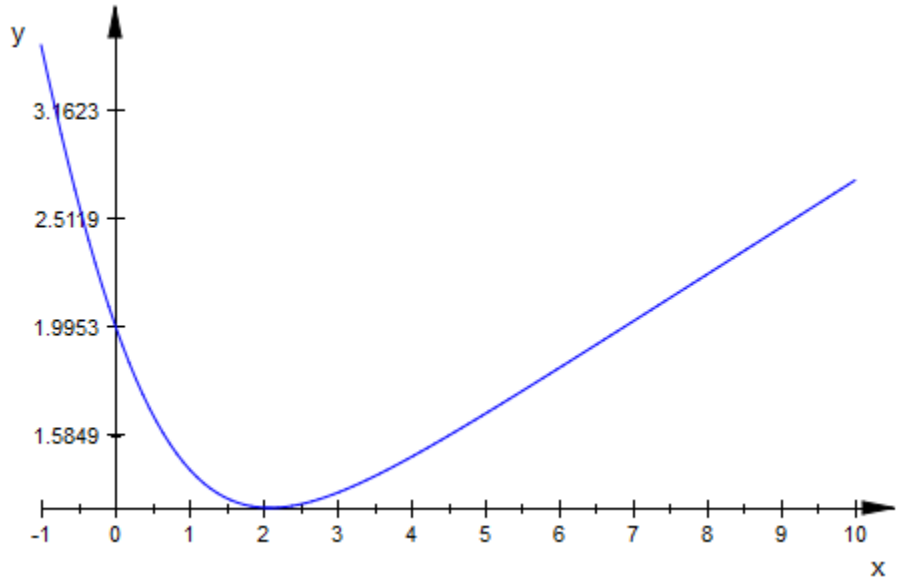


```
delete f:
```

Example 8

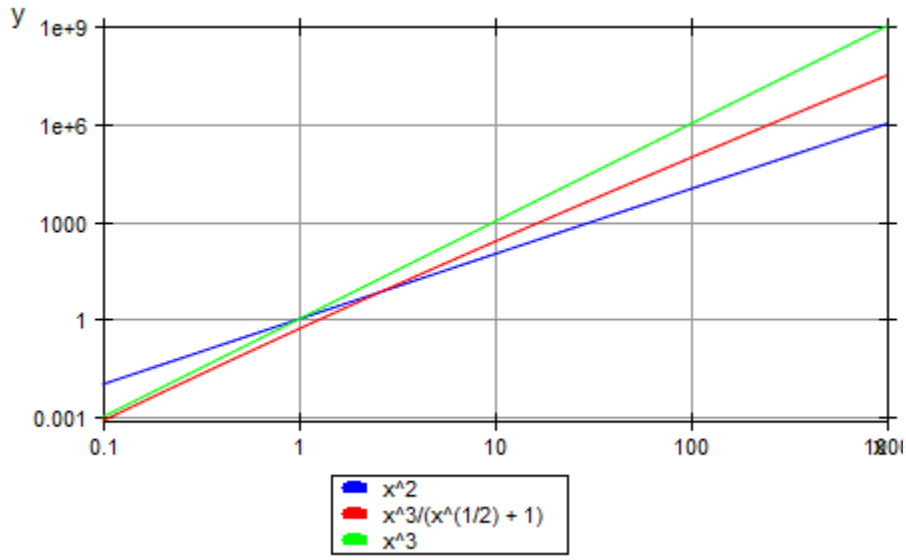
We use the attribute `CoordinateType` to create a logarithmic plot:

```
plotfunc2d(exp(x/10) + exp(-x), x = -1 .. 10,
           CoordinateType = LinLog)
```



We demonstrate various further graphical attributes in a doubly logarithmic plot:

```
plotfunc2d(x^2, x^3/(1 + x^(1/2)), x^3,
           x = 1/10 .. 10^3,
           CoordinateType = LogLog,
           Axes = Boxed,
           DiscontinuitySearch = FALSE,
           GridVisible = TRUE,
           TicksNumber = None,
           TicksAt = [[10^i $ i = -1 .. 3],
                      [10^i $ i in {-3, 0, 3, 6, 9}]
                     ]):
```



Parameters

`f1, f2, …`

The functions: arithmetical expressions or `piecewise` objects in the indeterminate `x` and the animation parameter `a`. Alternatively, procedures that accept 1 input parameter *x* or 2 input parameters *x*, *a* and return a real numerical value when the input parameters are numerical.

`x`

The independent variable: an identifier or an indexed identifier.

x_{min} `..` x_{max}

The plot range: x_{min}, x_{max} must be numerical real values or expressions of the animation parameter *a*. If not specified, the default range `x = -5 .. 5` is used.

`a`

The animation parameter: an identifier or an indexed identifier.

a_{min} .. a_{max}

The animation range: a_{min}, a_{max} must be numerical real values.

c_1, c_2, …

The colors for f_1, f_2 etc.: RGB or RGBa values. The length of the color list needs not coincide with the number of functions in the plot. The colors are used cyclically; surplus colors are ignored.

attributes

An arbitrary number of graphical attributes. Each attribute is given by an equation of the form `AttributeName` = `AttributeValue`.

Return Values

MuPAD graphics tool is called to render the graphical scene. The `null()` object is returned to the MuPAD session.

plotfunc3d

Function plots in 3D

Syntax

```
plotfunc3d(f1, f2, …, <Colors = [c1, c2, …]>, <attributes>)

plotfunc3d(f1, f2, …, x = xmin .. xmax, <Colors = [c1, c2, …]>, <attributes>)

plotfunc3d(f1, f2, …, x = xmin .. xmax, y = ymin .. ymax, <Colors = [c1, c2, …]>, <attribute

plotfunc3d(f1, f2, …, x = xmin .. xmax, y = ymin .. ymax, a = amin .. amax, <Colors = [c1, c2,
```

Description

`plotfunc3d(f1, f2, ...)` generates a 3D plot of the bivariate functions `f1`, `f2` etc.

The functions to be plotted must not contain any symbolic parameters apart from the variables `x`, `y` and the animation parameter `a`. Exact numerical values such as `PI`, `sqrt(2)` etc. are accepted.

Animations are triggered by specifying a range `a = `a_{min}` .. `a_{max}`` for a parameter `a` that is different from the indedependent variables `x`, `y`. Thus, in animations, the *x*-range `x = `x_{min}` .. `x_{max}``, the *y*-range `y = `y_{min}` .. `y_{max}`` as well as the animation range `a = `a_{min}` .. `a_{max}`` must be specified. See “Example 2” on page 1-1555.

If unbounded functions are plotted, the range of the *z* coordinate is clipped, automatically. An explicit *z* range `z = `z_{min}` .. `z_{max}`` may be requested via `ViewingBoxZRange = `z_{min}` .. `z_{max}`` or `ZRange = `z_{min}` .. `z_{max}``.

Discontinuities and piecewise defined functions are handled. See “Example 6” on page 1-1561 and “Example 7” on page 1-1562.

The `plot` library provides the routine `plot::Function3d` which allows to create a function graph as a graphical primitive, and to combine it with other graphical objects.

A variety of graphical attributes can be specified for fine tuning the graphical output. Such attributes are passed as equations `AttributeName = AttributeValue` to the `plotfunc3d` command.

Section 2.3 (“Attributes for plotfunc2d and plotfunc3d”) provides an overview of the available attributes.

In particular, all attributes accepted by the graphical primitive `plot::Function3d` for function graphs are accepted by `plotfunc3d`. These attributes allow to specify the mesh for the numerical evaluation, the line width etc. The help page of plot::Function3d provides a concise list.

Further, all attributes accepted by `plot::CoordinateSystem3d` are accepted by `plotfunc3d`. These attributes include the specification of a viewing box, of the axes, their tick marks and tick labels, the coordinate type (such as linear versus logarithmic plots), grid lines etc. The help page of plot::CoordinateSystem3d provides a concise list.

Further, all attributes accepted by `plot::Scene3d` are accepted by `plotfunc3d`. These attributes include the specification of the layout of the graphical scene, the background color etc. The help page of plot::Scene3d provides a concise list.

Further, all attributes accepted by `plot::Canvas` are accepted by `plotfunc3d`. These attributes include the specification of the size of the graphics, of further layout parameters etc. The help page of plot::Canvas provides a concise list.

A graphical attribute such as `Mesh = [20, 20]` (setting the number of mesh points for the numerical evaluation to 20 in each direction) is applied to *all* functions in the call `plotfunc3d(`f_1`, `f_2`, …)`. If separate attributes are appropriate, use the equivalent call

`plot(plot::Function3d(`f_1`, `$attr_1$`), plot::Function3d(`f_2`, `$attr_2$`), …)`,

in which the attributes $attr_1$, $attr_2$ etc. can be set separately for each function.

Apart from few exceptions, `plotfunc3d` uses the standard default values for the graphical attributes (see the help page of `plot::Function3d`). The exceptions are:

- If more than one function is plotted, `plotfunc3d` automatically creates a legend. Use an explicit `LegendVisible = FALSE` to suppress the legend.
- If parameter ranges such as `x = xmin .. xmax`, `y = ymin .. ymax` are passed to `plotfunc3d`, the names `x`, `y` are used as the titles for the corresponding axis. Pass the attributes `XAxisTitle`, `XAxisTitle` if different labels are desired.

Environment Interactions

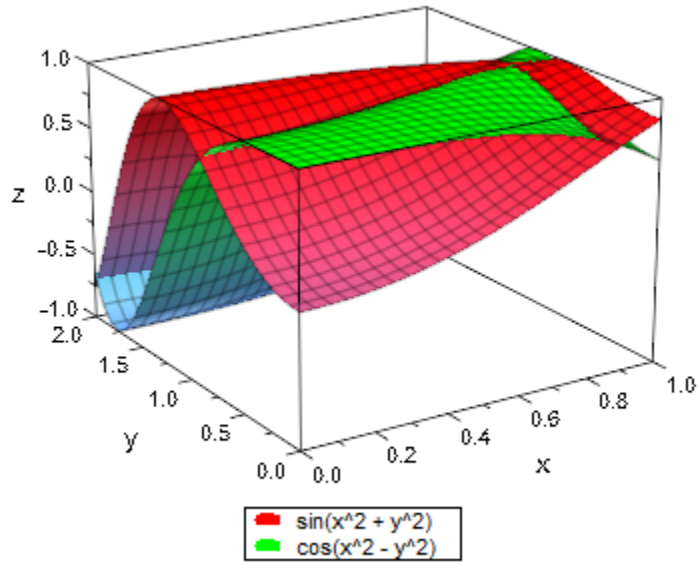
The function is sensitive to the environment variable `DIGITS` which determines the numerical working precision. Make sure that `DIGITS` is set to a sufficiently small value (such as the default value 10) to avoid the costs of computing unnecessarily precise plot data.

Examples

Example 1

The following command draws two functions over the unit square:

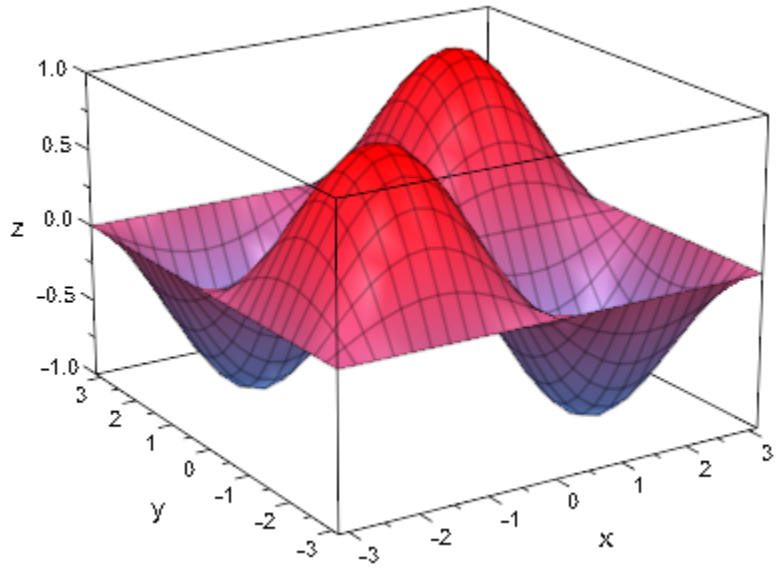
```
plotfunc3d(sin(x^2 + y^2), cos(x^2 - y^2), x = 0..1, y = 0..2)
```



Example 2

When creating an animation, ranges for the independent variables *x*, *y* must be specified. An additional third range triggers the animation:

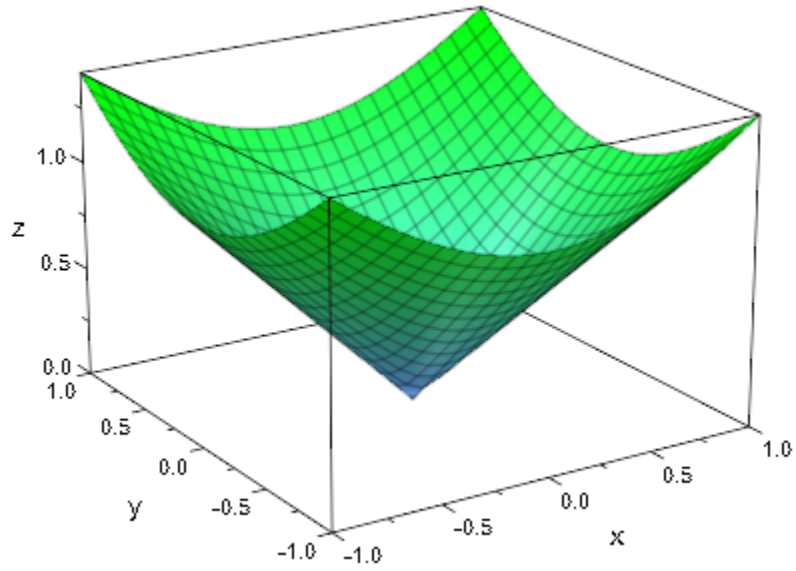
```
plotfunc3d(sin(x - a)*sin(y - a),
           x = -PI .. PI, y = -PI .. PI, a = -PI .. PI)
```



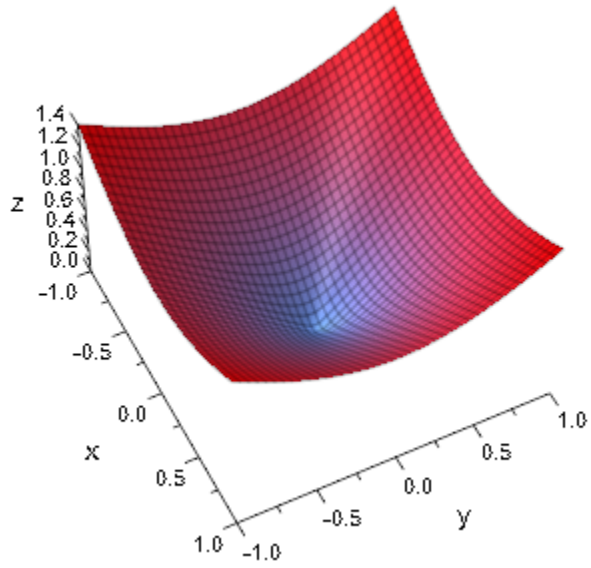
Example 3

We demonstrate the effect of various graphical attributes:

```
plotfunc3d(abs(x + I*y), x = -1..1, y = -1..1,
           FillColor = RGB::Green, TicksDistance = 0.5)
```



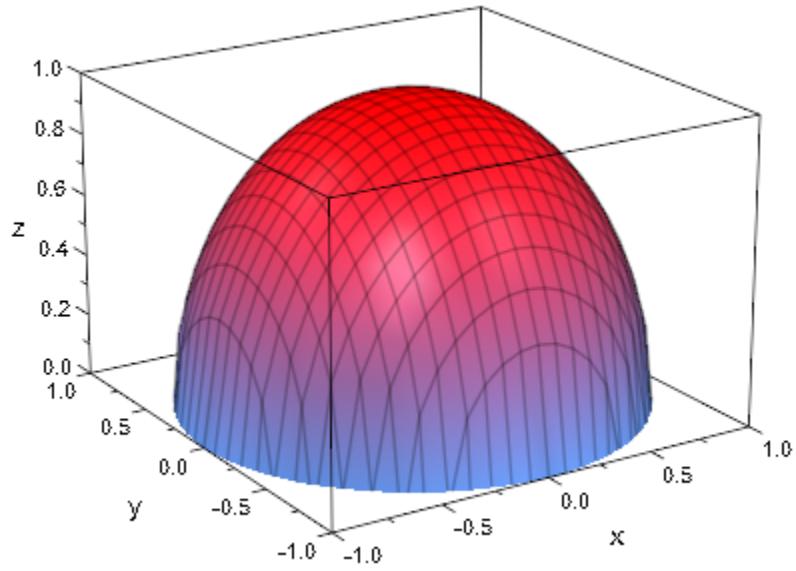
```
plotfunc3d(abs(x + I*y), x = -1..1, y = -1..1,
           Mesh = [40, 40], Axes = Frame,
           CameraDirection = [10, -5, 15])
```



Example 4

Points where the function to plot are not real-valued are left out from the plot:

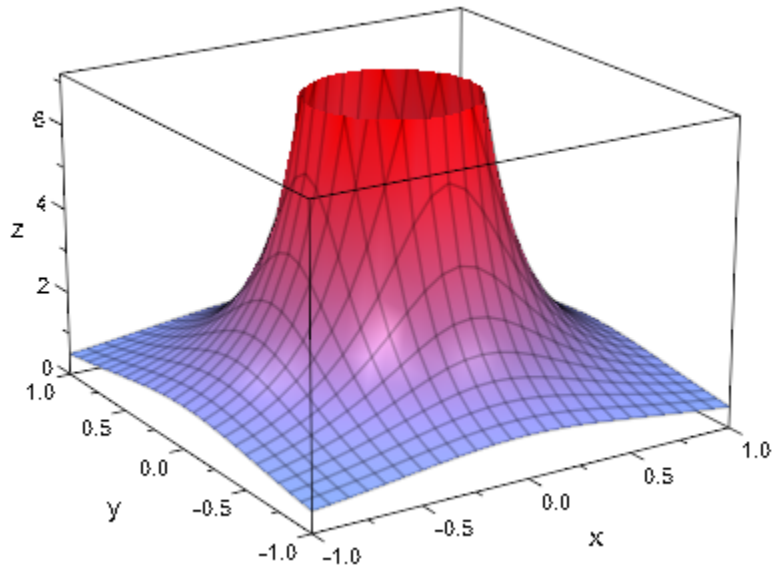
```
plotfunc3d(sqrt(1 - x^2 - y^2), x = -1..1, y = -1..1):
```



Example 5

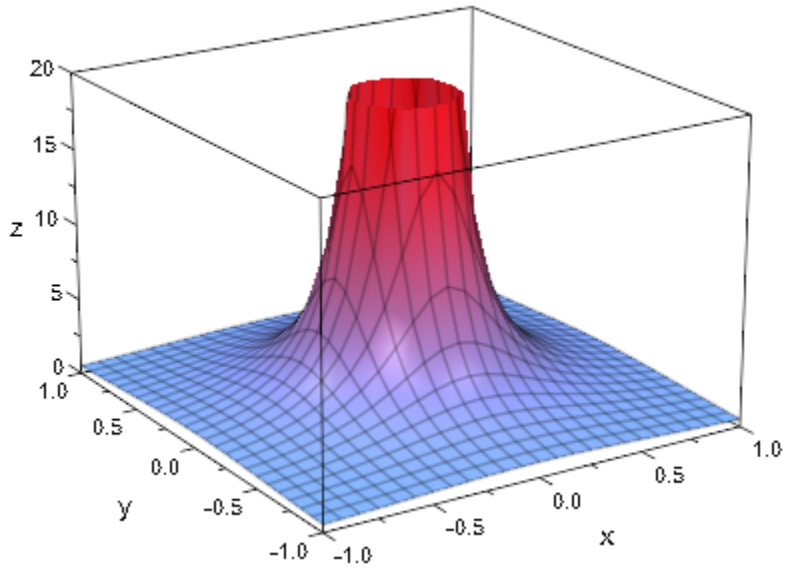
Singular functions are handled. The vertical coordinate range is automatically restricted by a heuristics:

```
plotfunc3d(1/(x^2 + y^2), x = -1..1, y = -1..1):
```



If the heuristics produces an inappropriate vertical range, you can request an appropriate range by the attribute `ViewingBoxZRange` or `ZRange`:

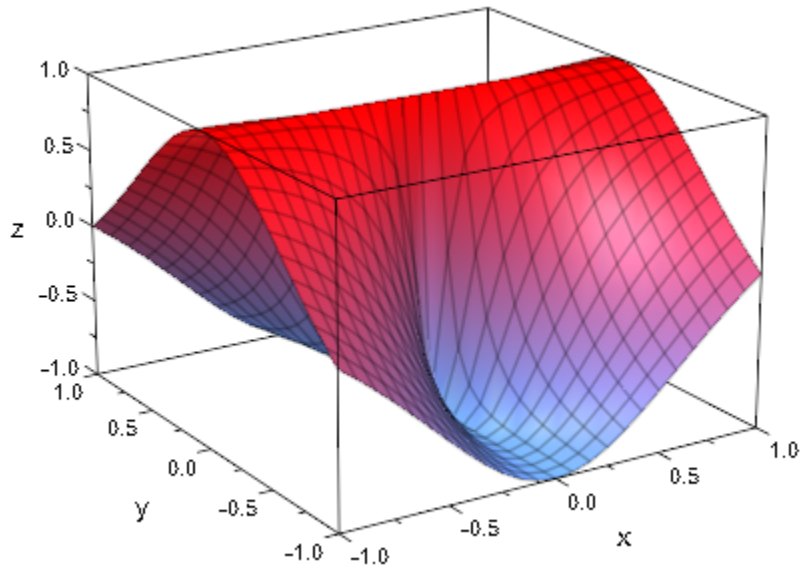
```
plotfunc3d(1/(x^2 + y^2), x = -1..1, y = -1..1,
           ZRange = 0 .. 20):
```



Example 6

The following function has a discontinuity at the origin:

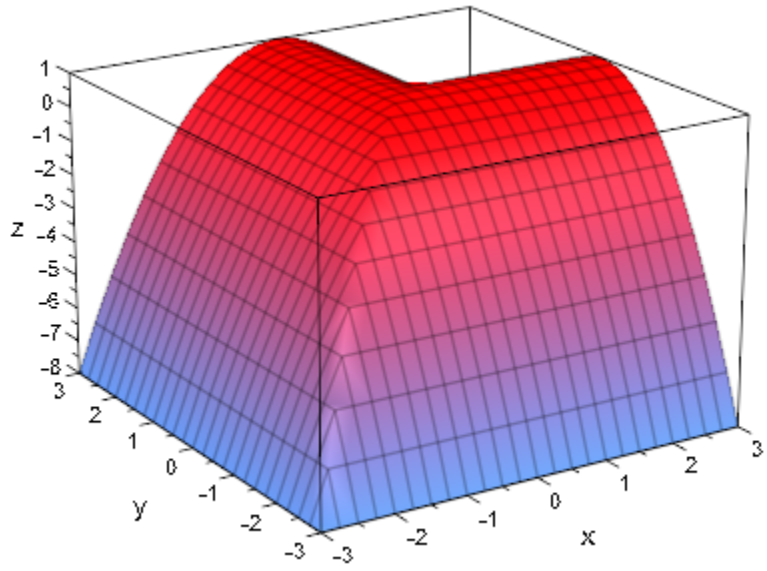
```
plotfunc3d((x^2 - y^2)/(x^2 + y^2),
           x = -1 .. 1, y = -1 .. 1)
```



Example 7

Piecewise defined functions are handled:

```
f := piecewise([x < y, 1 - x^2], [x >= y, 1 - y^2]):
plotfunc3d(f(x, y), x = -3..3, y = -3..3, TicksDistance = 1)
```



```
delete f:
```

Parameters

`f1, f2, …`

The functions: arithmetical expressions or `piecewise` objects in the indeterminates `x`, `y` and the animation parameter `a`. Alternatively, procedures that accept 2 input parameter *x*, *y* or 3 input parameters *x*, *y*, *a* and return a real numerical value when the input parameters are numerical.

`x`

The first independent variable: an identifier or an indexed identifier.

x_{min} `..` x_{max}

The range of `x`: x_{min}, x_{max} must be numerical real values or expressions of the animation parameter *a*. If not specified, the default range `x = -5 .. 5` is used.

y

The second independent variable: an identifier or an indexed identifier.

y_{min} .. y_{max}

The range of `y`: y_{min}, y_{max} must be numerical real values or expressions of the animation parameter a. If not specified, the default range `y = -5 .. 5` is used.

a

The animation parameter: an identifier or an indexed identifier.

a_{min} .. a_{max}

The animation range: a_{min}, a_{max} must be numerical real values.

c_1, c_2, …

The colors for f_1, f_2 etc.: RGB or RGBa values. The length of the color list needs not coincide with the number of functions in the plot. The colors are used cyclically; surplus colors are ignored.

attributes

An arbitrary number of graphical attributes. Each attribute is given by an equation of the form `AttributeName = AttributeValue`.

Return Values

MuPAD graphics tool is called to render the graphical scene. The `null()` object is returned to the MuPAD session.

More About

- "3D Function Graphs: plotfunc3d"

pochhammer

The Pochhammer symbol

Syntax

```
pochhammer(x, n)
```

Description

`pochhammer(x, n)` represents the Pochhammer symbol $(x)_n = \frac{\Gamma(x+n)}{\Gamma(x)}$.

If `n` is a positive integer, then $(x)_n = x\,(x+1)\,\ldots\,(x+n-1)$. This is extended analytically to arbitrary complex arguments via $(x)_n = \frac{\Gamma(x+n)}{\Gamma(x)}$, where *gamma* is the `gamma` function.

If both x and $x + n$ are non-positive integers, `pochhammer(x, n)` produces the limit $\lim_{t \to 0} \frac{\Gamma(x+n+t)}{\Gamma(x+t)}$.

If both `x` and `n` are numerical values, then an explicit numerical result is returned. Otherwise, a symbolic function call is returned.

If `n` is a negative integer, then the identity `pochhammer(x, n) = 1/pochhammer(x + n, -n)` is used to express the result.

The following special cases are implemented: `pochhammer(x, 0) = 1`, `pochhammer(x, 1) = x`, `pochhammer(x,-1) = 1/(x - 1)`, `pochhammer(1, n) = gamma(n + 1)`, `pochhammer(2, n) = gamma(n + 2)`.

If `n` is a positive integer, then `expand(pochhammer(x, n))` yields the expanded polynomial $x\,(x + 1)\,\ldots\,(x + n - 1)$.

If `n` is not an integer, then `expand(pochhammer(x, n))` yields a representation in terms of `gamma`.

Environment Interactions

When called with floating-point arguments, this function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

`pochhammer` returns explicit results if both arguments are numbers:

```
pochhammer(3, 5), pochhammer(3/2, 2), pochhammer(7/2, I - 1/2)
```

$$2520,\ \frac{15}{4},\ \frac{8\,\Gamma(3+i)}{15\,\sqrt{\pi}}$$

Some special cases are implemented:

```
pochhammer(x, -1), pochhammer(x, 0), pochhammer(x, 1)
```

$$\frac{1}{x-1},\ 1,\ x$$

```
pochhammer(1, n), pochhammer(2, n)
```

$$\Gamma(n+1),\ \Gamma(n+2)$$

A symbolic call is returned for other arguments:

```
pochhammer(x, 2), pochhammer(3, n), pochhammer(x + I, n)
```

$$(x)_2,\ (3)_n,\ (x+i)_n$$

Example 2

`expand` turns a symbolic `pochhammer` call into an explicit polynomial expression or rewrites it in terms of the `gamma` function if that function is known to be defined at its argument:

```
expand(pochhammer(x, 3))
```

$$x^3 + 3\,x^2 + 2\,x$$

```
expand(pochhammer(x, -3))
```

$$\frac{1}{x^3 - 6\,x^2 + 11\,x - 6}$$

```
expand(pochhammer(x, n)) assuming x>0 and n>0
```

$$\frac{\Gamma(n+x)}{\Gamma(x)}$$

```
expand(pochhammer(x + 1, n)) assuming x>0 and n>0
```

$$\frac{\Gamma(n+x)}{\Gamma(x)} + \frac{n\,\Gamma(n+x)}{x\,\Gamma(x)}$$

You can also use `rewrite` with the targets `gamma` or `fact` to rewrite `pochhammer`:

```
rewrite(pochhammer(x + 1, n), gamma)
```

$$\frac{\Gamma(n+x+1)}{\Gamma(x+1)}$$

```
rewrite(pochhammer(x + 1, n), fact)
```

$$\frac{(n+x)!}{x!}$$

Example 3

`diff` and `series` act on symbolic `pochhammer` calls:

```
diff(pochhammer(x, n), x)
```

$$(x)_n\,(\psi(n+x)-\psi(x))$$

```
diff(pochhammer(x, n), n)
```

$$\psi(n+x)\,(x)_n$$

```
series(pochhammer(x, -3), x = 2)
```

$$-\frac{1}{x-2}-(x-2)-(x-2)^3+O((x-2)^5)$$

Parameters

x

An arithmetical expression

n

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

n, x

MuPAD Functions
`fact` | `gamma`

poles

Poles of expression or function

Syntax

```
poles(f, x)
poles(f, x = a..b)
poles(f, x, options)
poles(f, x = a..b, options)
```

Description

`poles(f, x)` finds nonremovable singularities of f. These singularities are called the poles of f. Here, f is a function of the variable x. See "Example 1" on page 1-1570.

`poles(f, x = a..b)` finds the poles in the interval (a,b). See "Example 2" on page 1-1571.

If `poles` cannot find all nonremovable singularities and cannot prove that they do not exist, it returns an unevaluated call. See "Example 3" on page 1-1571.

If `poles` can prove that f has no poles (either in the specified interval (a,b) or in the complex plane), it returns an empty set. See "Example 4" on page 1-1571.

`a` and `b` must be real numbers or infinities. If you provide complex numbers, `poles` uses an empty interval and returns an empty set.

Examples

Example 1

Find the poles of these expressions:

```
poles(1/(x - I), x);
```

```
poles(sin(x)/(x - 1), x)
```

$$\{i\}$$

$$\{1\}$$

Example 2

Find the poles of the tangent function in the interval `(-PI, PI)`:

```
poles(tan(x), x = -PI..PI)
```

$$\left\{-\frac{\pi}{2}, \frac{\pi}{2}\right\}$$

Example 3

The tangent function has an infinite number of poles. If you do not specify the interval, `poles` cannot find all of them and, therefore, returns an unevaluated call:

```
poles(tan(x), x)
```

$$\text{poles}(\tan(x), x)$$

Example 4

If `poles` can prove that the expression or function does not have any poles in the specified interval, it returns an empty set:

```
poles(tan(x), x = -1..1)
```

$$\varnothing$$

Example 5

Use `Multiple` to find the poles of this expression and their orders. Restrict the search interval to `(-pi, 10*pi)`:

```
poles(tan(x)/(x - 1)^3, x = -PI..PI, Multiple)
```

$$\left\{[1, 3], \left[-\frac{\pi}{2}, 1\right], \left[\frac{\pi}{2}, 1\right]\right\}$$

Example 6

Use `Residues` to find the poles of this expression and their residues:

```
poles(a/x^2/(x - 1), x, Residues)
```

$$\{[0, -a], [1, a]\}$$

Example 7

Use `Multiple` and `Residues` to find the poles of this expression and their orders and residues:

```
poles(a/x^2/(x - 1), x, Multiple, Residues)
```

$$\{[0, 2, -a], [1, 1, a]\}$$

Parameters

`f`

Arithmetical expression representing a function in `x`.

`x`

Identifier.

`a, b`

Real numbers (including infinities) that specify the search interval for function poles. If you do not specify the interval `(a, b)`, then `poles` uses the entire complex plane.

Options

`Multiple`

When you use this option, `poles` finds the poles of f and their orders. It returns a set of lists. Each list contains two entries: the value of a pole and its order.

See “Example 5” on page 1-1571.

`Residues`

When you use this option, `poles` finds the poles of f and their residues. It returns a set of lists. Each list contains two entries: the value of a pole and its residue.

See “Example 6” on page 1-1572.

Return Values

Set or set of lists. Without the options, `poles` returns a set containing the values of poles. With `Multiple` or `Residues`, it returns a set of lists. Each list contains the value of a pole and its order or residue, respectively. With both options, `poles` returns a set of lists. Each list contains the value of a pole, its order, and residue.

MuPAD Functions

`discont` | `limit` | `solve`

poly, Expr, IntMod

Create a polynomial

Syntax

```
poly(f, <[x1, x2, …]>, <ring>)

poly(p, <[x1, x2, …]>, <ring>)

poly(list, [x1, x2, …], <ring>)

poly(coeffs, [x], <ring>)
```

Description

`poly(f)` converts a polynomial expression `f` to a polynomial of the kernel domain `DOM_POLY`.

The kernel domain `DOM_POLY` represents polynomials. The arithmetic for this data structure is more efficient than the arithmetic for polynomial expressions. Moreover, this domain allows you to use special coefficient rings that cannot be represented by expressions. The function `poly` is the tool for generating polynomials of this type.

`poly(f, [x1, x2, ...], ring)` converts the expression `f` to a polynomial in the indeterminates `x1, x2, ...` over the specified coefficient ring. The `poly` function does not require an expanded form of the expression `f`. The function internally expands expressions.

If you do not specify indeterminates, MuPAD searches for them internally. If MuPAD cannot identify indeterminates, it returns `FAIL`.

By default, the `poly` function uses the coefficient ring of arbitrary MuPAD expressions. In this case, you can use arbitrary MuPAD expressions as coefficients.

If the `poly` function cannot convert an expression to a polynomial, the function returns `FAIL`. See “Example 10” on page 1-1581.

If `f` is a domain element, the system calls `f::dom::poly` for the conversion into a polynomial. If `f` contains domain elements, the system recursively calls `f::dom::poly` for domain elements inside `f`. See "Example 11" on page 1-1582.

`poly(p, [x1, x2, ...], ring)` converts a polynomial `p` of the type `DOM_POLY` to a polynomial in the indeterminates `x1, x2, ...` over the specified coefficient ring. The indeterminates and the coefficient ring are part of the data structure `DOM_POLY`. Using this function call, you can change the indeterminates and the coefficient ring of a polynomial.

If you do not specify indeterminates, `poly` uses the indeterminates of the original polynomial `p`.

If you do not specify a coefficient ring, `poly` uses the ring of the original polynomial `p`.

See "Example 8" on page 1-1581 and "Example 9" on page 1-1581.

`poly(list, [x])` converts a list of coefficients $[a_0, a_1, a_2, \ldots]$ to a univariate polynomial $a_0 + a_1 x + a_2 x^2 + \ldots$. See "Example 3" on page 1-1578.

For a univariate polynomial `p`, the call `poly(list, [x])` converts the result of the call `coeff(p, All)` back to a polynomial.

`poly(list, [x1, x2, ...], ring)` converts a list of coefficients and exponents to a polynomial in the indeterminates `x1, x2, ...` over the specified coefficient ring. See "Example 4" on page 1-1579 and "Example 7" on page 1-1580.

This call is the fastest method to create polynomials of the type `DOM_POLY` because the input already has the form that MuPAD uses internally.

The list must contain an element for each nonzero monomial of the polynomial. Therefore, you must use sparse input involving only nonzero terms. In particular, an empty list results in the zero polynomial.

Each element of the list must be a list with two elements: the coefficient of the monomial and the exponent (or exponent vector). For a univariate polynomial in the variable x, the list

$$[[c_1, e_1], [c_2, e_2], \ldots]$$

corresponds to $c_1 x^{e_1} + c_2 x^{e_2} + \ldots$. For a multivariate polynomial, the exponent vectors are lists containing the exponents of all indeterminates of the polynomial. The order of

the exponents must be the same as the order given by the list of indeterminates. For a multivariate polynomial in the variables x_1, x_2, the term list

$$[[c_1, [e_{11}, e_{12}]], [c_2, [e_{21}, e_{22}]], \ldots]$$

corresponds to $c_1 x_1^{e_{11}} x_2^{e_{12}} + c_2 x_1^{e_{21}} x_2^{e_{22}} + \ldots$.

The order of the elements of the term list does not affect the resulting polynomial. If you provide multiple entries corresponding to the same term, `poly` adds the coefficients.

This call lets you restore polynomials from the term lists returned by `poly2list`.

The position of the indeterminates in the input list `[x1, x2, ...]` determines their order in the resulting polynomial. If you do not specify indeterminates, MuPAD searches the expression `f` for possible indeterminates and determines their order. See “Example 2” on page 1-1578.

You can perform arithmetical operations on polynomials that have the same indeterminates and the same coefficient ring. Also, you can perform arithmetical operations on polynomials and arithmetical expressions. When you operate on a polynomial and an arithmetical expression, MuPAD internally converts that arithmetical expression to a polynomial and performs the calculation. See “Example 1” on page 1-1577.

The `poly` function does not limit acceptable indeterminates to identifiers or indexed identifiers. You can use any expression (except for rational expressions) as an indeterminate. For example, `poly` accepts the expressions `sin(x)` and `f(x)` as indeterminates. See “Example 5” on page 1-1579.

After creating a polynomial, the `poly` function does not evaluate the coefficients of the polynomial. If the coefficients contain free identifiers, `poly` does not replace these identifiers with their values. See “Example 12” on page 1-1583.

If any domain of type `DOM_DOMAIN` provides arithmetical operations, you can use that domain as a coefficient ring. See the “Background” section for details.

If you specify a coefficient domain, MuPAD accepts only the elements of that domain as coefficients of the polynomial. On input, `poly` tries to convert a polynomial expression `f` to a polynomial over the coefficient ring. For some coefficient rings, you cannot use arithmetical expressions to represent a polynomial. The reason is that multiplication

with the indeterminates can be an invalid operation in the ring. In such cases, you can define the polynomial by using a term list. See “Example 7” on page 1-1580.

Examples

Example 1

The `poly` function creates a polynomial from a polynomial expression:

```
p := poly(2*x*(x + 3))
```

$$\mathrm{poly}(2x^2 + 6x, [x])$$

The operators `*`, `+`, `-` and `^` work on polynomials:

```
p^2 - p*(p + 1)
```

$$\mathrm{poly}(-2x^2 - 6x, [x])$$

You can multiply a polynomial by an arithmetical expression. MuPAD internally converts the expression to a polynomial of the appropriate type, and then multiplies polynomials. For example, multiply the polynomial `p` by the constant 5:

```
p*5
```

$$\mathrm{poly}(10x^2 + 30x, [x])$$

Now, multiply the polynomial `p` by `x - 1`:

```
p*(x - 1)
```

$$\mathrm{poly}(2x^3 + 4x^2 - 6x, [x])$$

If MuPAD cannot convert the expression to a polynomial of the appropriate type, the arithmetical operation between a polynomial and this expression fails:

```
p*(1/x - 1)
```

```
Error: The argument is invalid. [_mult]
```

```
delete p:
```

Example 2

You can create a polynomial with parameters. In the following call, `y` is a parameter (not an indeterminate):

```
poly((x*(y + 1))^2, [x])
```

$$\mathrm{poly}((y+1)^2\,x^2,\,[x])$$

If you do not specify indeterminates, MuPAD tries to find indeterminates automatically. The following call converts a multivariate expression to a multivariate polynomial:

```
poly((x*(y + 1))^2)
```

$$\mathrm{poly}(x^2\,y^2+2\,x^2\,y+x^2,\,[x,\,y])$$

Now, specify the order of the indeterminates explicitly:

```
poly((x*(y + 1))^2, [y, x])
```

$$\mathrm{poly}(y^2\,x^2+2\,y\,x^2+x^2,\,[y,\,x])$$

Example 3

Use the `poly` function to convert the following list of coefficients to a univariate polynomial in `x`. The first entry of the list produces the term with the zero exponent. The last entry produces the term with the highest exponent:

```
p := poly([1, 2, 3, 4, 5], [x])
```

$$\mathrm{poly}(5\,x^4+4\,x^3+3\,x^2+2\,x+1,\,[x])$$

To revert the ordering of the coefficients in a polynomial, use the `revert` function:

```
revert(p)
```

$$\text{poly}(x^4 + 2\,x^3 + 3\,x^2 + 4\,x + 5, [x])$$

Example 4

Create the following polynomials by term lists:

```
poly([[c2, 3], [c1, 7], [c3, 0]], [x])
```

$$\text{poly}(\text{c1}\,x^7 + \text{c2}\,x^3 + \text{c3}, [x])$$

If you provide multiple coefficients corresponding to the same exponent, `poly` adds those coefficients:

```
poly([[c2, 3], [c1, 7], [c3, 0], [a, 3]], [x])
```

$$\text{poly}(\text{c1}\,x^7 + (a + \text{c2})\,x^3 + \text{c3}, [x])$$

For multivariate polynomials, specify exponent vectors by lists:

```
poly([[c1, [2, 2]], [c2, [2, 1]], [c3, [2, 0]]], [x, y])
```

$$\text{poly}(\text{c1}\,x^2\,y^2 + \text{c2}\,x^2\,y + \text{c3}\,x^2, [x, y])$$

Example 5

You can use expressions as indeterminates:

```
poly(f(x)*(f(x) + x^2))
```

$$\text{poly}(x^2\,f(x) + f(x)^2, [x, f(x)])$$

Example 6

The residue class ring `IntMod(7)` is a valid coefficient ring:

```
p := poly(9*x^3 + 4*x - 7, [x], IntMod(7))
```

$$\text{poly}(2x^3 - 3x, [x], \text{IntMod}(7))$$

For computations that involve polynomials over this ring, MuPAD uses modular arithmetic:

```
p^3
```

$$\text{poly}(x^9 - x^7 - 2x^5 + x^3, [x], \text{IntMod}(7))$$

However, MuPAD does not return coefficients as elements of a special domain. Instead, it returns coefficients as plain integers of the type `DOM_INT`:

```
coeff(p)
```

$$2, -3$$

```
delete p:
```

Example 7

To create the following polynomial, combine the input syntax that uses term lists with a specified coefficient ring:

```
poly([[9, 3], [4, 1], [-2, 0]], [x], IntMod(7))
```

$$\text{poly}(2x^3 - 3x - 2, [x], \text{IntMod}(7))$$

MuPAD interprets the input coefficients as elements of the coefficient domain. For example, conversions such as `9 mod 7 = 2 mod 7` occur on input. You also can use the domain `Dom::IntegerMod(7)` to define an equivalent polynomial. If you use `IntMod(7)`, MuPAD uses the symmetric modulo function `mods` and represents the coefficients by the numbers - 3, …, 3. If you use `Dom::IntegerMod(7)`, MuPAD uses the positive modulo function `modp` and represents the coefficients by the numbers 0, …, 6:

```
poly([[9, 3], [4, 1], [-2, 0]], [x], Dom::IntegerMod(7))
```

$$\text{poly}(2x^3 + 4x + 5, [x], \text{Dom::IntegerMod}(7))$$

The domain `Dom::IntegerMod(7)` does not allow multiplication with identifiers:

```
c := Dom::IntegerMod(7)(3)
```

$$3 \bmod 7$$

```
poly(c*x^2, [x], Dom::IntegerMod(7))
```

FAIL

Instead, use the term list to specify the polynomial:

```
poly([[c, 2]], [x], Dom::IntegerMod(7))
```

$$\mathrm{poly}(3\,x^2, [x], \mathrm{Dom::IntegerMod}(7))$$

```
delete c:
```

Example 8

Change the indeterminates in a polynomial:

```
p:= poly(((a + b)*x - a^2)*x, [x]):
p, poly(p, [a, b])
```

$$\mathrm{poly}((a+b)\,x^2+(-a^2)\,x, [x]), \mathrm{poly}((-x)\,a^2+x^2\,a+x^2\,b, [a, b])$$

Example 9

Change the coefficient ring of a polynomial:

```
p := poly(-4*x + 5*y - 5, [x, y], IntMod(7)):
p, poly(p, IntMod(3))
```

$$\mathrm{poly}(3\,x-2\,y+2, [x, y], \mathrm{IntMod}(7)), \mathrm{poly}(y-1, [x, y], \mathrm{IntMod}(3))$$

Example 10

Create a polynomial over the coefficient ring `Dom::Float`:

```
poly(3*x - y, Dom::Float)
```

$$\text{poly}(3.0\,x - 1.0\,y, [x, y], \text{Dom::Float})$$

The identifier `y` cannot appear in coefficients from this ring because it cannot be converted to a floating-point number:

```
poly(3*x - y, [x], Dom::Float)
```

FAIL

Example 11

You can overload `poly` by its first operand. For example, create a domain `polyInX` that represents polynomials in `x`:

```
domain polyInX
  new   := () -> new(dom, poly(args(), [x]));
  print := p -> expr(extop(p, 1));
  poly  := p ->
           if args(0) = 1 then
             print(Unquoted, "polyInX::poly called with 1 argument");
             extop(p, 1);
           else
             print(Unquoted,
                   "polyInX::poly called with more than 1 argument");
             poly(extop(p, 1),
                  args(2..args(0)));
           end;
end_domain:
p := polyInX(3*x^2-2)
```

$$3\,x^2 - 2$$

You can convert the elements of `polyInX` into polynomials of the type `DOM_POLY`. The `poly` function calls the `poly` method of the domain:

```
poly(p)
```

```
polyInX::poly called with 1 argument
```

$$\mathrm{poly}(3\,x^2 - 2, [x])$$

By reacting to additional arguments, the overloading defined above also allows you to create polynomials over other coefficient rings:

```
poly(p, [x], IntMod(2))
```

```
polyInX::poly called with more than 1 argument
```

$$\mathrm{poly}(x^2, [x], \mathrm{IntMod}(2))$$

Example 12

Create a polynomial with coefficients containing the identifier `y`. Although you assign the value 1 to `y`, MuPAD does not substitute the new value into the polynomial:

```
f := poly(x^2 - y, [x]):
y := 1:
eval(f)
```

$$\mathrm{poly}(x^2 - y, [x])$$

You can evaluate the coefficients explicitly. Use the `mapcoeffs` function to apply `eval` to the coefficients of the polynomial:

```
f := mapcoeffs(f, eval)
```

$$\mathrm{poly}(x^2 - 1, [x])$$

Parameters

`f`

A polynomial expression

x_1, x_2, …

The indeterminates of the polynomial: typically, identifiers or indexed identifiers.

ring

The coefficient ring: either `Expr`, or `IntMod(n)` with some integer `n` greater than 1, or a domain of type `DOM_DOMAIN`. The default is the ring `Expr` of arbitrary MuPAD expressions.

p

A polynomial of type `DOM_POLY` generated by `poly`

list

A list containing coefficients and exponents

coeffs

A list containing coefficients of a univariate polynomial

x

The indeterminate of a univariate polynomial

Options

Expr

The default ring `Expr` represents arbitrary MuPAD expressions. Mathematically, this ring coincides with `Dom::ExpressionField()`. However, MuPAD operates differently on the polynomials created over `Expr` and the polynomials created over `Dom::ExpressionField()`. In particular, MuPAD performs arithmetic operations for polynomials over the ring `Expr` faster.

IntMod

The ring `IntMod(n)` represents the residue class ring $\mathbb{Z}_n$, using the symmetrical representation. Here, `n` is an integer greater than 1. Mathematically, this ring coincides with `Dom::IntegerMod(n)`. However, MuPAD operates differently on the polynomials

created over `IntMod(n)` and the polynomials created over `Dom::IntegerMod(n)`. In particular, MuPAD performs arithmetic operations for polynomials over the ring `IntMod` faster. Also, for polynomials over `IntMod`, `coeff` and similar functions return requested coefficients as integers of the type `DOM_INT`. See “Example 6” on page 1-1579, “Example 7” on page 1-1580, and “Example 9” on page 1-1581.

Return Values

Polynomial of the domain type `DOM_POLY`. If conversion to a polynomial is not possible, the return value is `FAIL`.

Overloaded By

f

Algorithms

To use a domain as a coefficient, the domain must contain the following:

- The entry `"zero"` that provides the neutral element with respect to addition.
- The entry `"one"` that provides the neutral element with respect to multiplication.
- The method `"_plus"` that adds domain elements.
- The method `"_negate"` that returns the inverse with respect to addition.
- The method `"_mult"` that multiplies domain elements.
- The method `"_power"` that computes integer powers of a domain element. Call this method with the domain element as the first argument and an integer as the second argument.

In addition, you must define the following methods. Functions (such as `gcd`, `diff`, `divide`, `norm` and so on) call these methods:

- The method `"gcd"` that returns the greatest common divisor of domain elements.
- The method `"diff"` that differentiates a domain element with respect to a variable.
- The method `"_divide"` that divides two domain elements. It must return `FAIL` if division is not possible.

- The method `"norm"` that computes the norm of a domain element and returns it as a number.
- The method `"convert"` that converts an expression to a domain element. The method must return `FAIL` if such conversion is not possible.

  The system calls this method to convert the coefficients of polynomial expressions to coefficients of the specified domain. If this method does not exist, you can specify the coefficients only by using domain elements.
- The method `"expr"` that converts a domain element to an expression.

  The system function `expr` calls this method to convert a polynomial over the coefficient domain to a polynomial expression. If this method does not exist, `expr` inserts domain elements into the expression.

You can convert a polynomial over a certain coefficient domain into a polynomial over the same domain, but a different set of indeterminates. This conversion is much more efficient when the domain has the axiom `Ax::indetElements`. MuPAD implicitly assumes that this axiom holds for the domain `IntMod(n)`, but not for `Expr`.

Internally, MuPAD stores polynomials of the type `DOM_POLY` in a sparse representation and uses machine integers for the exponents. This method implies that in a 32-bit environment, the exponent of each variable in each monomial cannot exceed $2^{31} - 1$.

poly2list

Convert a polynomial to a list of terms

Syntax

```
poly2list(p)
```

```
poly2list(f, <vars>)
```

Description

`poly2list(p)` returns a term list containing the coefficients and exponent vectors of the polynomial `p`.

The returned term list is a list where each element represents a monomial of the polynomial with non-zero coefficient. The monomials are also represented as lists, each containing two elements: The first element is the coefficient and the second the exponent or exponent vector of the monomial. If the polynomial is univariate, exponents are returned, otherwise exponent vectors are returned. Exponent vectors have the same form as returned by the function `degreevec`. A zero polynomial results in an empty list.

The elements of the term list are sorted lexicographically according to the exponent vectors. This is also the ordering used internally for the terms of polynomials.

`poly2list(f, vars)` is equivalent to `poly2list(poly(f, vars))`: First, the polynomial expression `f` is converted to a polynomial in the variables `vars` over the expressions. Then that polynomial is converted to a term list. If the variables `vars` are not given, the free identifiers contained in `f` are used as variables. See `poly` about details on how the expression is converted to a polynomial. `FAIL` is returned if the expression cannot be converted to a polynomial.

Examples

Example 1

The following expressions define univariate polynomials. Thus the term lists contain exponents and not exponent vectors:

```
poly2list(2*x^100 + 3*x^10 + 4)
```

$$[[2, 100], [3, 10], [4, 0]]$$

```
poly2list(2*x*(x + 1)^2)
```

$$[[2, 3], [4, 2], [2, 1]]$$

Specification of a list of indeterminates allows to distinguish symbolic parameters from the indeterminates:

```
poly2list(a*x^2 + b*x + c, [x])
```

$$[[a, 2], [b, 1], [c, 0]]$$

Example 2

In this example the polynomial is bivariate, thus exponent vectors are returned:

```
poly2list((x*(y + 1))^2, [x, y])
```

$$[[1, [2, 2]], [2, [2, 1]], [1, [2, 0]]]$$

Example 3

In this example a polynomial of domain type DOM_POLY is given. This form must be used if the polynomial has coefficients that does not consist of expressions:

```
poly2list(poly(-4*x + 5*y - 5, [x, y], IntMod(7)))
```

$$[[3, [1, 0]], [-2, [0, 1]], [2, [0, 0]]]$$

Parameters

p

A polynomial of type DOM_POLY

`f`

A polynomial expression

`vars`

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

Return Values

List containing the coefficients and exponent vectors of the polynomial. `FAIL` is returned if a given expression cannot be converted to a polynomial.

MuPAD Functions

`coeff` | `coerce` | `degree` | `degreevec` | `lcoeff` | `monomials` | `poly` | `tcoeff`

polylog

Polylogarithm function

Syntax

```
polylog(n, x)
```

Description

`polylog(n,x)` represents the polylogarithm function $Li_n(x)$ of index n at the point x.

For a complex number x of modulus $|x| < 1$, the polylogarithm function of index n is defined as

$$\mathrm{Li}_n(x) = \sum_{k=1}^{\infty} \frac{x^k}{k^n}$$

.

This function is extended to the whole complex plane by analytic continuation. Do not confuse the polylogarithms Li_n with the integral logarithm function `Li` which is displayed using the same symbol (without an index).

If `n` is an integer and `x` a floating-point number, then a floating-point result is computed.

If `n` is an integer less or equal to 1, then an explicit expression is returned for any input parameter `x`. If `n` is an integer larger than 1 or if `n` is a symbolic expression, then an unevaluated call of `polylog` is returned, unless `x` is a floating-point number. If `n` is a numerical value, but not an integer, then an error occurs.

Some special values for $n = 2$ are implemented (cf. `dilog`). The values $Li_n(0) = 0$ and $\mathrm{Li}_n(1) = \zeta(n)$ are implemented for any n. Furthermore, $\mathrm{Li}_n(-1) = \left(2^{1-n} - 1\right)\zeta(n)$ for any $n \neq 1$.

$Li_n(x)$ has a singularity at the point $x = 1$ for indices $n \leq 1$. For indices $n \geq 1$, the point $x = 1$ is a branch point. The branch cut is the real interval $[1, \infty)$. A jump occurs when crossing this cut. Cf. “Example 2” on page 1-1592.

Mathematically, `polylog(2,x)` coincides with `dilog(1-x)`.

Environment Interactions

When called with a floating-point argument `x`, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

Explicit results are returned for integer indices $n \le 1$:

```
polylog(-5, x), polylog(-1, x), polylog(0, x), polylog(1, x)
```

$$\frac{x^5 + 26\,x^4 + 66\,x^3 + 26\,x^2 + x}{(x-1)^6},\ \frac{x}{(x-1)^2},\ -\frac{x}{x-1},\ -\ln(1-x)$$

An unevaluated call is returned if the index is an integer $n > 1$ or a symbolic expression:

```
polylog(2, x), polylog(n^2 + 1, 2), polylog(n + 1, 2.0)
```

$$\text{polylog}(2, x),\ \text{polylog}(n^2 + 1, 2),\ \text{polylog}(n + 1, 2.0)$$

Floating point values are computed for integer indices n and floating-point arguments x:

```
polylog(-5, -1.2), polylog(10, 100.0 + 3.2*I)
```

$$-0.2326930882,\ 104.9131863 + 11.44600047\,i$$

Some special symbolic values are implemented:

```
polylog(4, 1), polylog(5, -1), polylog(2, I)
```

$$\frac{\pi^4}{90},\ -\frac{15\,\zeta(5)}{16},\ -\frac{\pi^2}{48} + \text{CATALAN}\,i$$

```
assume(n <> 1): polylog(n, -1)
```

$$\zeta(n)\left(2^{1-n}-1\right)$$

```
unassume(n): polylog(n, -1)
```

$$\mathrm{polylog}(n, -1)$$

Example 2

For indices $n \geq 1$, the real interval $[1, \infty)$ is a branch cut. The values returned by `polylog` jump when crossing this cut:

```
polylog(3, 1.2 + I/10^1000) - polylog(3, 1.2 - I/10^1000)
```

$$-1.379393155\ 10^{-18} + 0.1044301529\ \mathrm{i}$$

Example 3

The functions `diff`, `float`, `limit`, and `series` handle expressions involving `polylog`:

```
diff(polylog(n, x), x), float(polylog(4, 3 + I))
```

$$\frac{\mathrm{polylog}(n-1, x)}{x},\ 3.177636803 + 1.859135861\ \mathrm{i}$$

```
series(polylog(4, sin(x)), x = 0)
```

$$x + \frac{x^2}{16} - \frac{25\,x^3}{162} - \frac{13\,x^4}{768} + \frac{1523\,x^5}{405000} + \frac{49\,x^6}{51840} + O(x^7)$$

Parameters

n

An arithmetical expression representing an integer

x

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

x

Algorithms

The polylogarithms are characterized by $\frac{d}{dx}\,\mathrm{Li}_n(x) = \frac{1}{x}\mathrm{Li}_{n-1}(x)$ in conjunction with $Li_n(0) = 0$ and $Li_1(x) = -\ln(1 - x)$. $Li_n(x)$ is a rational function in x for $n \le 0$.

Li_n has a branch cut along the real interval $[1, \infty)$ for indices $n \ge 1$. The value at a point x on the cut coincides with the limit "from below":

$$\mathrm{Li}_n(x) = \lim_{\varepsilon \to 0^+} \mathrm{Li}_n(x - \varepsilon\, i) = \left(\lim_{\varepsilon \to 0^+} \mathrm{Li}_n(x + \varepsilon\, i)\right) - \frac{2\,\pi\, i}{(n-1)!}\ln(x)^{n-1}.$$

`dilog` | `ln`

potential

The (scalar) potential of a gradient field

Syntax

```
potential(f, [x1, x2, …], <[y1, y2, …]>, <Test>)
```

Description

`potential(f, x)` determines whether the vector field $\vec{f} = \vec{f}(\vec{x})$ is a gradient field $\vec{f}(\vec{x}) = \mathrm{grad}(p(\vec{x}))$ of some scalar potential p with respect to the variables $\vec{x}$, and computes that potential if it exists.

The potential of a vector field $\vec{f}(\vec{x})$ = [$f_1(x_1, x_2, \ldots)$, $f_2(x_1, x_2, \ldots)$, …] exists (locally) if and only if the Jacobian matrix $\left(\frac{\partial}{\partial x_j} f_i\right)$ is symmetric in i and j. In 3 space, this is the condition that $\mathrm{curl}\left(\vec{f}(\vec{x})\right)$ vanishes.

The potential $p(\vec{x})$ with $\vec{f}((\vec{x})) = \mathrm{grad}(p(\vec{x}))$ is uniquely determined up to an additive constant.

An integral representation of the potential is given by

$$p(\vec{x}) = \int_0^1 (\vec{x} - \vec{y})\, \vec{f}(\vec{y} + \lambda\,(\vec{x} - \vec{y}))\, \mathrm{d}\lambda$$

,

where $\vec{y}$ is an arbitrary “base point.” This is the contour integral of $\vec{f}(\vec{x})$ along the straight line from $\vec{y}$ to $\vec{x}$.

If the Jacobian matrix $\left(\frac{\partial}{\partial x_j} f_i\right)$ is not symmetric, the potential of $\vec{f}(\vec{x})$ does not exist.

In this case, `potential` returns `FALSE`.

Note: Note that the answer `FALSE` is not always conclusive. For arbitrary expressions f_i, f_j, there is no algorithm to decide whether $\left(\frac{\partial}{\partial x_j} f_i\right) = \left(\frac{\partial}{\partial x_i} f_j\right)$ holds mathematically:

`potential` may return `FALSE` due to insufficient simplification of the partial derivatives.

The representation of the potential depends on the strength of the symbolic integrator `int`. If `int` does not manage to find a closed form of the potential, symbolic calls of `int` may be returned. See “Example 3” on page 1-1596.

If no base point $\vec{y}$ is specified, the potential is only defined up to some additive constant.

`potential` does not consider irregular points of the vector field and its potential and investigates the potential only locally. The returned potential may be a valid potential only in a neighbourhood of the current point $\vec{x}$!

If `f` is a vector, the component ring of `f` must be a field (i.e., a domain of category `Cat::Field`) which allows integration.

Examples

Example 1

Using the option `Test`, we check whether a vector field is a gradient field:

```
f := [x, y, z*exp(z)]:
potential(f, [x, y, z], Test)
```

```
TRUE
```

Without the option `Test`, the potential is returned:

```
potential(f, [x, y, z])
```

$$\frac{x^2}{2}+\frac{y^2}{2}+e^z\,(z-1)$$

We check the result:

```
normal(gradient(%, [x, y, z]))
```

$$\begin{pmatrix} x \\ y \\ z\,e^z \end{pmatrix}$$

When a `base point' is specified, a suitable constant is added to the potential such that it vanishes at this point:

```
potential(f, [x, y, z], [0, 0, 0])
```

$$\frac{x^2}{2}+\frac{y^2}{2}+e^z\,(z-1)+1$$

```
potential(f, [x, y, z], [x0, y0, z0])
```

$$\frac{x^2}{2}-\frac{x0^2}{2}+\frac{y^2}{2}-\frac{y0^2}{2}+e^z\,(z-1)-e^{z0}\,(z0-1)$$

```
delete f:
```

Example 2

The vector field in this example is not a gradient field and has no potential:

```
potential([x[2], -x[1]], [x[1], x[2]])
```

FALSE

Example 3

The vector field in this example is a gradient field and has a potential. However, the symbolic integrator does not find a closed form of the integral representation for the potential and returns a symbolic definite integral:

```
potential([a + b*x, sin(y^2)*exp(y)], [x, y])
```

$$\frac{b\,x^2}{2} + a\,x + \int_0^y \sin(\mathrm{X42}^2)\,e^{\mathrm{X42}}\,d\,\mathrm{X42}$$

We check the result:

```
gradient(%, [x, y])
```

$$\begin{pmatrix} a + b\,x \\ \sin(y^2)\,e^y \end{pmatrix}$$

Parameters

`f`

The vector field: a list of arithmetical expressions, or a vector of such expressions. A vector is an $n \times 1$ or $1 \times n$ matrix of a domain of category `Cat::Matrix`.

x_1, x_2, …

The variables: identifiers or indexed identifiers

y_1, y_2, …

The components of the "base point:" arithmetical expressions. If a base point $\vec{y}$ is specified, the returned potential p satisfies $p(\vec{y}) = 0$.

Options

`Test`

Check whether the vector field has a potential and return `TRUE` or `FALSE`, respectively.

Return Values

Arithmetical expression or a Boolean value.

`curl` | `divergence` | `gradient` | `laplacian` | `vectorPotential`

powermod

Compute a modular power of a number or a polynomial

Syntax

```
powermod(b, e, m)
```

Description

`powermod(b, e, m)` computes b^e mod m.

If `b` and `m` are numbers, the modular power b^e mod m can also be computed by the direct call `b^e mod m`. However, `powermod(b, e, m)` avoids the overhead of computing the intermediate result b^e and computes the modular power much more efficiently.

If `b` is a rational number, then the modular inverse of the denominator is calculated and multiplied with the numerator.

If the modulus `m` is an integer, then the base `b` must either be a number, a polynomial expression or a polynomial that is convertible to an `IntMod(m)`-polynomial.

If the modulus `m` is a polynomial expression, then the base `b` must either be a number, a polynomial expression or a polynomial over the coefficient ring of MuPAD expressions.

If the modulus `m` is a polynomial of domain type `DOM_POLY`, then the base `b` must either be a number, or a polynomial of the same type as `m` or a polynomial expression that can be converted to a polynomial of the same type as `m`.

Note that the system function `mod` in charge of modular arithmetic may be changed by the user; see the help page of `mod`. The function `powermod` reacts accordingly. See “Example 5” on page 1-1601.

Internally, polynomials are divided by the function `divide`.

Examples

Example 1

We compute `3^(123456) mod 7`:

```
powermod(3, 123456, 7)
```

$$1$$

If the base is a rational number, the modular inverse of the denominator is computed and multiplied with the numerator:

```
powermod(3/5, 1234567, 7)
```

$$2$$

Example 2

The coefficients of the following polynomial expression are computed modulo 7:

```
powermod(x^2 + 7*x - 3, 10, 7)
```

$$x^{20} - 2\,x^{18} - x^{16} + x^{14} - 3\,x^6 - x^4 + 3\,x^2 - 3$$

Example 3

The power of the following polynomial expression is reduced modulo the polynomial $x^2 + 1$:

```
powermod(x^2 + 7*x - 3, 10, x^2 + 1)
```

$$1029668584\,x - 534842913$$

Example 4

The type of the return value coincides with the type of the base: a polynomial is returned if the base is a polynomial:

```
powermod(poly(x^2 + 7*x - 3), 2, x^2 + 1),
powermod(poly(x^2 + 7*x - 3), 2, poly(x^2 + 1))
```

$$\mathrm{poly}(-56\,x-33,\,[x]),\ \mathrm{poly}(-56\,x-33,\,[x])$$

If the base is a polynomial expression, `powermod` returns a polynomial expression:

```
powermod(x^2 + 7*x - 3, 2, x^2 + 1),
powermod(x^2 + 7*x - 3, 2, poly(x^2 + 1))
```

$$-56\,x-33,\ -56\,x-33$$

Example 5

The following re-definition of `_mod` switches to a symmetric representation of modular numbers:

```
R := Dom::IntegerMod(17):
_mod := mods: powermod(poly(2*x^2, R), 3, poly(3*x + 1, R))
```

$$\mathrm{poly}(-4,\,[x],\,\mathrm{Dom::IntegerMod}(17))$$

The following command restores the default representation:

```
_mod := modp: powermod(poly(2*x^2, R), 3, poly(3*x + 1, R))
```

$$\mathrm{poly}(13,\,[x],\,\mathrm{Dom::IntegerMod}(17))$$

```
unalias(R):
```

Parameters

b

The base: an integer, a rational number, or a polynomial of type `DOM_POLY`, or a polynomial expression

e

The power: a nonnegative integer

m

The modulus: an integer (at least 2), or a polynomial of type DOM_POLY, or a polynomial expression

Return Values

Depending on the type of b, the return value is an integer, a polynomial, or a polynomial expression. FAIL is returned if an expression cannot be converted to a polynomial.

Overloaded By

b

PRETTYPRINT

Control the formatting of output

Description

The environment variable PRETTYPRINT determines whether the MuPAD results are printed in the one-dimensional or the two-dimensional format.

Possible values: Either TRUE or FALSE

PRETTYPRINT controls the pretty printer, which is responsible for formatted output. If PRETTYPRINT has the value TRUE, then pretty printing is enabled for output.

The default value of PRETTYPRINT is TRUE; PRETTYPRINT has this value after starting or resetting the system via `reset`. Also the command `delete PRETTYPRINT` restores the default value.

In the MuPAD Notebook app, PRETTYPRINT normally has no effect when "typesetting" is activated. An exception occurs for MuPAD output without typesetting defined, where PRETTYPRINT determines the output style even if the typesetting is activated.

Typesetting is activated by default. You can switch it on or off by selecting **Notebook>Typeset Math** or via **View>Configure**.

Examples

Example 1

The following command disables pretty printing:

```
PRETTYPRINT := FALSE
```

```
FALSE
```

Now MuPAD results are printed in a one-dimensional, linearized form:

```
series(sin(x), x = 0, 14)
```

```
x - (1/6)*x^3 + (1/120)*x^5 - (1/5040)*x^7 + (1/362880)*x^9 - (1/39916800)\
*x^11 + (1/6227020800)*x^13 + O(x^15)
```

After setting PRETTYPRINT to TRUE again, the usual two-dimensional output format is used:

```
PRETTYPRINT := TRUE:
series(sin(x), x = 0, 14)
```

```
     3     5     7       9          11           13
    x     x     x       x          x            x           15
x - -- + --- - ---- + ------ - -------- + ---------- + O(x   )
     6   120   5040   362880   39916800   6227020800
```

print | TEXTWIDTH

prevprime

Next smaller prime

Syntax

```
prevprime(a)
```

Description

`prevprime(a)` returns the greatest prime number less or equal than a. If $a < 2$, then `prevprime(a)` returns `FAIL`.

`prevprime` returns the function call with evaluated argument if the argument is not an integer.

`prevprime` returns an error if the argument evaluates to zero or a negative integer.

Examples

Example 1

Computing the largest prime $p \leq 15485865$:

```
prevprime(15485865)
```

```
    15485863
```

Example 2

There are no primes smaller than 2:

```
prevprime(1)
```

```
    FAIL
```

Parameters

a

A positive integer

Return Values

`prevprime(a)` returns either a natural number or `FAIL`.

Algorithms

`prevprime` uses the probabilistic prime test `isprime` and may therefore return false results with small probability.

print

Print objects to the screen

Syntax

```
print(<Unquoted>, <NoNL>, <KeepOrder>, <Plain>, <Typeset>, object1, object2, …)
```

Description

`print(object)` displays `object` on the screen.

At interactive level, the result of a MuPAD command entered at the command prompt is usually displayed on the screen automatically. `print` serves to generate additional output from within loops or procedures.

Apart from some exceptions mentioned below, the output generated by `print` is identical to the usual output of MuPAD results at interactive level.

`print` evaluates its arguments sequentially from left to right (cf. “Example 3” on page 1-1609) and displays the results on the screen. The individual outputs are separated by commas. A new line is started at the end of the output if this is not suppressed by the option `NoNL`.

The output width for `print` with option `Plain` is limited by the environment variable `TEXTWIDTH`. Cf. “Example 4” on page 1-1610.

With option `Plain` the style of the output is determined by the value of the environment variable `PRETTYPRINT`. Cf. “Example 5” on page 1-1611.

`print` descends recursively into the operands of an object. For each subobject `s`, `print` first determines its domain type`T`. If the domain `T` has a `"print"` slot, then `print` issues the call `T::print(s)` to the slot routine. In contrast to the overloading mechanism for most other MuPAD functions, `print` processes the result of this call recursively, and the result of the recursive process is printed at the position of `s` (cf. “Example 6” on page 1-1611).

Note: The result returned by the `"print"` method must not contain the domain element `s` itself as a subobject, since this leads to infinite recursion (cf. “Example 7”

on page 1-1612). The same remark also applies to the output procedures of function environments (see below).

If T is a library domain without a "print" slot and the internal operands of s are op1, op2, ..., then s is printed as new(T, op1, op2, ...). (See "Example 6" on page 1-1611.)

"print" methods may return strings or expressions. Strings are always printed unquoted. Expressions are printed in normal mode. If they contain strings, they will be printed with quotation marks. Cf. "Example 8" on page 1-1612.

The output of an expression is determined by the 0th operand of the expression. If the 0th operand is a function environment, then its second operand handles the output of the expression. See "Example 9" on page 1-1613. Otherwise, the expression is printed in functional notation.

In contrast to the usual output of MuPAD objects at interactive level, print does not perform resubstitution of aliases (see Pref::alias for details). Moreover, the routines defined via Pref::output and Pref::postOutput are not called by print. Cf. "Example 14" on page 1-1615.

The output of floating-point numbers depends on the environment variable DIGITS and the settings of Pref::floatFormat (exponential or floating-point representation) and Pref::trailingZeroes (printing of trailing zeroes). Cf. "Example 16" on page 1-1617.

Environment Interactions

print is sensitive to the environment variables DIGITS, PRETTYPRINT, and TEXTWIDTH, and to the output preferences Pref::floatFormat, Pref::keepOrder, and Pref::trailingZeroes.

Examples

Example 1

This example shows a simple call of print with strings as arguments. They are printed with quotation marks:

```
print("Hello", "You"." !"):
```

"Hello", "You !"

Example 2

On platforms supporting typesetting, `print` can generate typeset output:

```
print(Typeset, int(f(x)/g(x), x = a..b)):
```

$$\int_a^b \frac{f(x)}{g(x)}\,dx$$

`print` uses the `Typeset` option by default:

```
print(int(f(x)/g(x), x = a..b)):
```

$$\int_a^b \frac{f(x)}{g(x)}\,dx$$

ASCII output is available with the option `Plain`:

```
print(Plain, int(f(x)/g(x), x = a..b)):
```

```
  b
  /
 |   f(x)
 |   ---- dx
/    g(x)
  a
```

Example 3

Like most other functions, `print` evaluates its arguments. In the following call, `x` evaluates to `0` and `cos(0)` evaluates to `1`:

```
a := 0: print(cos(a)^2):
```

$$1$$

Use `hold` if you want to print the expression `cos(a)^2` literally:

```
print(hold(cos(a)^2)):
```

$$\cos(a)^2$$

```
delete a:
```

Example 4

`print` with the option `Plain` is sensitive to the current value of `TEXTWIDTH`:

```
print(Plain, expand((a + b)^4)):
```

```
 4      3        2  2        3    4
a  + 4 a  b + 6 a  b  + 4 a b  + b
```

```
TEXTWIDTH := 25:
print(Plain, expand((a + b)^4)):
```

```
 4      3        2  2
a  + 4 a  b + 6 a  b

          3    4
   + 4 a b  + b
```

If you disable the pretty print mode, the `print` function inserts the line continuation character at the line breaks:

```
PRETTYPRINT:=FALSE:
print(Plain, expand((a + b)^4)):
```

```
a^4 + 4*a^3*b + 6*a^2*b^\
2 + 4*a*b^3 + b^4
```

The line continuation character can be invalid for some strings. For example, when you use the code generators, such as `generate::MATLAB` and `generate::Simscape`, the

displayed code containing the line continuation character is not valid. To avoid inserting this character, change the TEXTWIDTH setting or use the fprint function instead of print:

```
fprint(Unquoted, 0, expand((a + b)^4))
```

```
a^4 + 4*a^3*b + 6*a^2*b^2 + 4*a*b^3 + b^4
```

Also, see the Example 4 on the fprint help page.

```
PRETTYPRINT := TRUE:
delete TEXTWIDTH:
```

Example 5

print with option Plain is sensitive to the current value of PRETTYPRINT:

```
print(Plain, a/b):
old := PRETTYPRINT: PRETTYPRINT := FALSE:
print(Plain, a/b):
PRETTYPRINT := old:
```

```
a
-
b
```

```
a/b
```

```
delete old:
```

Example 6

We demonstrate how to achieve formatted output for elements of a user-defined domain. Suppose that we want to write a new domain Complex for complex numbers. Each element of this domain has two operands: the real part r and the imaginary part s:

```
Complex := newDomain("Complex"): z := new(Complex, 1, 3):
z + 1;
print(Plain, z + 1):
```

$$\mathrm{new}(\mathrm{Complex}, 1, 3) + 1$$

```
new(Complex, 1, 3) + 1
```

Now we want a nicer output for elements of this domain, namely in the form `r+s*I`, where `I` denotes the imaginary unit. We implement the slot routine `Complex::print` to handle this. This slot routine will be called by MuPAD with an element of the domain `Complex` as argument whenever such an element is to be printed on the screen:

```
Complex::print := (z -> extop(z, 1) + extop(z, 2)*I):
z + 1;
print(Plain, z + 1):
```

$$1 + 3\,i + 1$$

```
1 + 3 I + 1
```

```
delete Complex, z:
```

Example 7

The result of a `"print"` method must not contain the argument as a subobject; otherwise this leads to infinite recursion. In the following example, the slot routine `T::print` would be called infinitely often. MuPAD tries to trap such infinite recursions and prints `` `????` `` instead:

```
T := newDomain(T): T::print := id:
new(T, 1);
print(Plain, new(T, 1)):
```

```
`????`
```

```
`????`
```

```
delete T:
```

Example 8

If a `"print"` method returns a string, it will be printed unquoted:

```
Example := newDomain("Example"):  e := new(Example, 1):
```

```
Example::print := x -> "elementOfExample":
print(e):
```

elementOfExample

If a `"print"`-method returns an expression, it will be printed in normal mode. If the expression contains strings, they will be printed in the usual way with quotation marks:

```
Example::print := x -> ["elementOfExample", extop(x)]:
print(e):
```

["elementOfExample", 1]

```
delete Example, e:
```

Example 9

Suppose that you have defined a function `f` that may return itself symbolically, and you want such symbolic expressions of the form `f(x,...)` to be printed in a special way. To this end, embed your procedure`f` in a function environment and supply an output procedure as second argument to the corresponding `funcenv` call. Whenever an expression of the form `f(x,...)` is to be printed, the output procedure will be called with the arguments `x,...` of the expression:

```
f := funcenv(f,
         proc(x) begin
            if nops(x) = 2 then
              "f does strange things with its arguments ".
              expr2text(op(x, 1))." and ".expr2text(op(x,2))
            else
              FAIL
            end
         end):

delete a, b:
f(a, b)/2;
f(a, b, c)/2
```

$$\frac{\text{f does strange things with its arguments a and b}}{2}$$

$$\frac{f(a, b, c)}{2}$$

```
delete f:
```

Example 10

With the option `Unquoted`, quotation marks are omitted:

```
print(Unquoted, "Hello", "World"." !"):
```

```
Hello, World !
```

With `Unquoted` the special characters `\t` and `\n` are expanded:

```
print(Unquoted, "As you can see,\n".
                "'\\n' is the newline character\n".
                "\tand '\\t' a tabulator"):
```

```
As you can see,
'\n' is the newline character
  and '\t' a tabulator
```

Example 11

It is useful to construct output strings using `expr2text` and the concatenation operator `.`:

```
d := 5:  print(Unquoted, "d plus 3 = ".expr2text(d + 3)):
```

```
d plus 3 = 8
```

```
delete d:
```

Example 12

With the option `NoNL`, no new line is put at the end of the output and `PRETTYPRINT` is implicitly set to `FALSE`. Apart from that, the behavior is the same as with the option `Unquoted`:

```
print(NoNL, "Hello"):  print(NoNL, ",  You"." !\n"):
print(NoNL, "As you can see, PRETTYPRINT is FALSE: "):
print(NoNL, x^2-1):  print(NoNL, "\n"):
```

```
Hello
```

```
,  You !
```

```
As you can see, PRETTYPRINT is FALSE:
```

```
x^2 - 1
```

Example 13

If the option `KeepOrder` is given, sums are printed in their internal order:

```
print(b - a):  print(KeepOrder, b - a):
```

$$b - a$$

$$-a + b$$

Example 14

Alias resubstitution (see `Pref::alias`) takes place for normal result outputs in an interactive session, but not for outputs generated by `print`:

```
delete a, b: alias(a = b):
a; print(a):
unalias(a):
```

$$a$$

$$b$$

In contrast to the usual result output, `print` does not react to `Pref::output`:

```
old := Pref::output(generate::TeX):
sin(a)^b; print(sin(a)^b):
Pref::output(old):
```

```
"{\sin\!\left(a\right)}^b"
```

$$\sin(a)^b$$

The same is true for `Pref::postOutput`:

```
old := Pref::postOutput("postOutput was called"):
a*b; print(a*b):
Pref::postOutput(old):
```

$$a\,b$$

```
postOutput was called
```

$$a\,b$$

```
delete old:
```

Example 15

The output of summands of a sum depends on the form of these summands. If the summand is a `_mult` expression, only the first and last operand of the product are taken into account for determining the sign of that term in the output. If one of them is a negative number then the "+"-symbol in the sum is replaced by a "-"-symbol:

```
print(hold(a + b*c*(-2)),
      hold(a + b*(-2)*c),
      hold(a + (-2)*b*c)):
```

$$a-2\,b\,c,\ a-b\,2\,c,\ a-2\,b\,c$$

This has to be taken into account when writing "print"-methods for polynomial domains.

Example 16

Floating point numbers are usually printed in fixed-point notation. You can change this to floating-point form with mantissa and exponent via Pref::floatFormat:

```
print(0.000001, 1000.0): old := Pref::floatFormat("e"):
print(0.000001, 1000.0): Pref::floatFormat(old):
```

```
0.000001, 1000.0
```

```
0.000001, 1000.0
```

In the default output of floating-point numbers, trailing zeroes are cut off. This behavior can be changed via Pref::trailingZeroes:

```
0.000001, 1000.0
```

```
0.000001, 1000.0
```

```
print(0.000001, 1000.0): old := Pref::trailingZeroes(TRUE):
print(0.000001, 1000.0): Pref::trailingZeroes(old):
```

```
0.000001, 1000.0
```

```
0.000001000000000, 1000.000000
```

The number of digits of floating-point numbers in output depends on the environment variable DIGITS:

```
print(float(PI)):
DIGITS := 20:  print(float(PI)):
DIGITS := 30:  print(float(PI)):
```

```
3.141592654
```

```
3.14159265358979323850
```

$$3.14159265358979323846264338328$$

```
delete old, DIGITS:
```

Example 17

The output order of `sets` differs from the internal order of sets, which is returned by `op`:

```
s := {a, b, 1}:
s;
print(Plain, s):
op(s)
```

$$\{1, a, b\}$$

```
{1, a, b}
```

$$a, b, 1$$

The index operator `[]` can be used to access the elements of a set with respect to the output order:

```
s[1], s[2], s[3]
```

$$1, a, b$$

```
delete s:
```

Example 18

The output of a domain is determined by its `"Name"` slot if it exists, and otherwise by its *key*:

```
T := newDomain("T"):
T;
print(Plain, T):
```

$$T$$

```
T
```

```
T::Name := "domain T":
T;
print(Plain, T):
```

```
domain T
```

```
delete T:
```

Example 19

It is sometimes desirable to combine strings with “pretty” expressions in an output. This is not possible via `expr2text`. On the other hand, an output with commas as separators is usually regarded as ugly. The following dummy expression sequence may be used to achieve the desired result. It uses the MuPAD internal function for standard operator output `builtin(1100,...)`, with priority `20`—the priority of `_exprseq`—and with an empty operator symbol `""`:

```
myexprseq := funcenv(myexprseq,
                     builtin(1100, 20, "", "myexprseq")):
print(Unquoted,
      myexprseq("String and pretty expression ", a^b, ".")):
```

```
                                b
String and pretty expression a .
```

```
delete myexprseq:
```

Example 20

If the option `Typeset` is combined with `Unquoted` or `NoNL`, a warning is given and `Typeset` is ignored:

```
print(Typeset, Unquoted, "1"):
```

```
Warning: Conflicting options, ignoring 'Typeset' [print]
```

Example 21

For more elaborate constructions, you may want to combine multi-line strings with MuPAD expressions. A first attempt might look like the following:

```
myexprseq := funcenv(myexprseq,
                     builtin(1100, 20, "", "myexprseq")):
Example := newDomain("Example"):
Example::print :=
  x -> myexprseq("--- \n--\n-\n--\n---", op(x)):
e := new(Example, 1):
print(Plain, e):
```

```
"--- \n--\n-\n--\n---"1
```

Obviously, this approach doesn't work. The return value of the `"print"` method defined above is not a string, it's a (special) sequence, so the special rules for printing a string do not apply. We would need another domain that simply takes a string and returns exactly this string from its `"print"` slot. Fortunately, MuPAD already has such a domain, `stdlib::Exposed`:

```
Example::print :=
  x -> myexprseq(stdlib::Exposed("--- \n--\n-\n--\n---"),
                 op(x)):
print(e):
```

```
---
--
-   1
--
---
```

For expressions with a higher output, you see that the alignment of the string is constant:

```
new(Example,x^(1/n));
new(Example,x/y)
```

```
---
--   1/n
-   x
```

```
--
---

---
--  x
-   -
--  y
---
```

To change this alignment, replace a `\n` by `\b`, thereby making the line it terminates the "baseline" of the string:

```
Example::print :=
  x -> myexprseq(stdlib::Exposed("--- \b--\n-\n--\n---"),
                 op(x)):
print(e+2):

--- 1 + 2
--
-
--
---
```

When multiple `\b` appear in a string, the first one is taken as defining the base line:

```
Example::print :=
  x -> myexprseq(stdlib::Exposed("--- \n--\n-\b--\b---"),
                 op(x)):
print(e+2):

---
--
-   1 + 2
--
---
```

Parameters

`object1, object2, …`

Any MuPAD objects

Options

Unquoted

With this option, character strings are displayed without quotation marks. Moreover, the control characters `\n`, `\t`, and `\\` in strings are expanded into a new line, a tabulator skip, and a single backslash `\`, respectively. Cf. “Example 10” on page 1-1614.

The control character `\t` is expanded with tab-size 8. The following character is placed in the next column `i` with `i mod 8 = 0`.

`\b` is expanded into a newline, too, but when combining multiple strings, the last line with `\b` at its end is regarded as the “baseline”. Cf. “Example 21” on page 1-1620.

Note: The option `Unquoted` implicitly sets the option `Plain`. If the option `Typeset` is used together with `Unquoted`, a warning is given and `Typeset` is ignored. Cf. “Example 20” on page 1-1619.

NoNL

This option has the same functionality as `Unquoted`. In addition, the new line at the end of the output is suppressed. Cf. “Example 12” on page 1-1614.

Moreover, this option implicitly sets `PRETTYPRINT` to `FALSE`.

Note: The option `NoNL` implicitly sets the option `Plain`. If the option `Typeset` is used together with `NoNL`, a warning is given and `Typeset` is ignored. Cf. “Example 20” on page 1-1619.

KeepOrder

This option determines the order of terms in sums. Normally, the system sorts the terms of a `sum` such that a positive term is in the first position of the output. If `KeepOrder` is given, no such re-ordering takes place and sums are printed in the internal order. Cf. “Example 13” on page 1-1615.

This behavior can also be controlled via `Pref::keepOrder`. More precisely, the call `print(KeepOrder, ...)` generates the same output as the following command:

```
Pref::keepOrder(Always):
print(...):
Pref::keepOrder(%2):
```

`Plain`

The output is in plain text mode. This is the default behavior in the terminal version. In text mode the value of `PRETTYPRINT` determines if the output is linear or in a more readable 2D form.

`Typeset`

The output is in typesetting mode. This is the default print behavior in the notebook, if no other options are given. The option is only kept for backward compatibility.

In typesetting mode the value of `PRETTYPRINT` is ignored.

Return Values

`print` returns the void object `null()` of type `DOM_NULL`.

Overloaded By

object1, object2

Algorithms

The output order of `sets` differs from the internal order of sets, which can be obtained via `op`. For this reordering in the output, the kernel calls the method `DOM_SET::sort`, which takes the set as argument and returns a sorted list. The elements of the set are then printed in the order given by this list.

->, -->, proc, name, option, local, begin, end_proc, procname

Define a procedure

Syntax

```
( x1, x2, … ) -> body

proc(
     x1 <= default1> <: type1>,
     x2 <= default2> <: type2>,
     ...
    ) <: returntype>
  <name pname;>
  <option option1, option2, …>
  <local local1, local2, …>
  <save global1, global2, …>
begin
   body
end_proc

( x1, x2, … ) --> body

_procdef(, …)
```

Description

`proc - end_proc` defines a procedure.

Procedures `f := proc(x1, x2, ...) ... end_proc` may be called like a system function in the form `f(x1, x2, ...)`. The return value of this call is the value of the last command executed in the procedure body (or the value returned by the body via the function `return`).

The procedure declaration `(x1, x2, ...) -> body` is equivalent to `proc(x1, x2, ...) begin body end_proc`. It is useful for defining *simple* procedures that

do not need local variables. E.g., `f := x -> x^2` defines the mathematical function $f: x \to x^2$. If the procedure uses more than one parameter, use brackets as in `f := (x, y) -> x^2 + y^2`. Cf. “Example 1” on page 1-1629.

The procedure declaration `(x1, x2, ...) --> body` is equivalent to `fp::unapply(body, x1, x2, ...)`. The difference from the other definitions is that `body` is *evaluated* before defining the procedure. Cf. “Example 2” on page 1-1629.

Note: The evaluation of `body` must not contain references to parameters or local variables of an outer procedure.

A MuPAD procedure may have an arbitrary number of parameters. For each parameter, a default value may be specified. This value is used if no actual value is passed when the procedure is called. E.g.,

```
f := proc(x = 42) begin body end_proc
```

defines the default value of the parameter `x` to be `42`. The call `f()` is equivalent to `f(42)`. Cf. “Example 3” on page 1-1630.

For each parameter, a type may be specified. This invokes an automatic type checking when the procedure is called. E.g.,

```
f := proc(x : DOM_INT) begin body end_proc
```

restricts the argument `x` to integer values. If the procedure is called with an argument of a wrong data type, the evaluation is aborted with an error message. Cf. “Example 4” on page 1-1630. Checking the input parameters should be a standard feature of every procedure. See Testing Arguments.

Also an automatic type checking for the return value may be implemented specifying `returntype`. Cf. “Example 4” on page 1-1630.

With the keyword `name`, a name may be defined for the procedure, e.g.,

```
f := proc(...) name myName; begin body end_proc.
```

There is a special variable `procname` associated with a procedure which stores its name. When the body returns a symbolic call `procname(args())`, the actual name is

substituted. This is the name defined by the optional `name` entry. If no `name` entry is specified, the first identifier the procedure has been assigned to is used as the name, i.e., `f` in this case. Cf. “Example 5” on page 1-1631.

With the keyword `option`, special features may be specified for a procedure:

- `escape`

  Must be used if the procedure creates and returns a new procedure which accesses local values of the enclosing procedure. Cf. “Example 6” on page 1-1632. This option should only be used if necessary. Also refer to `Pref::warnDeadProcEnv`.

- `hold`

  Prevents the procedure from evaluating the actual parameters it is called with. See “Example 7” on page 1-1633.

- `noDebug`

  Prevents the MuPAD source code debugger from entering this procedure. Also refer to `Pref::ignoreNoDebug`. Cf. “Example 8” on page 1-1634.

- `noFlatten`

  Prevents flattening of sequences passed as arguments of the procedure. See “Example 9” on page 1-1634.

- `remember`

  Instructs the procedure to store each computed result in a so-called remember table. When this procedure is called later with the same input parameters, the result is read from this table and needs not be computed again.

  This may speed up, e.g., recursive procedures drastically. Cf. “Example 10” on page 1-1635. However, the remember table may grow large and use a lot of memory. Furthermore, the usefulness of this function is very limited in the light of properties—identification of “the same input parameters” does not depend on assumptions on identifiers or global variables such as `DIGITS` and `ORDER`, so the returned result may not be compatible with new assumptions. Use of `prog::remember` instead of this option is highly recommended for any function accepting symbolic input.

- `noExpose`

  Instructs MuPAD to hide the procedure body from the user. Note that this prevents debugging the procedure, too. Cf. “Example 15” on page 1-1640.

With the keyword `local`, the local variables of the procedure are specified, e.g.,

```
f := proc(...) local x, y; begin body end_proc.
```

Cf. “Example 11” on page 1-1637.

Local variables cannot be used as “symbolic variables” (identifiers). They must be assigned values before they can be used in computations.

Note that the names of global MuPAD variables such `DIGITS`, `READPATH` etc. should not be used as local variables. Also refer to the keyword `save`.

With the keyword `save`, a local context for global MuPAD variables is created, e.g.,

```
f := proc(...) save DIGITS; begin DIGITS := newValue; ... end_proc.
```

This means that the values these variables have on entering the procedure are restored on exiting the procedure. This is true even if the procedure is exited because of an error. Cf. “Example 12” on page 1-1637.

One can define procedures that accept a variable number of arguments. E.g., one may declare the procedure without any formal parameters. Inside the body, the actual parameters the procedure is called with may be accessed via the function `args`. Cf. “Example 13” on page 1-1639.

Calling a procedure name `f`, say, usually does not print the source code of the body to the screen. Use `expose(f)` to see the body. Cf. “Example 14” on page 1-1639.

The environment variable `MAXDEPTH` limits the “nesting depth” of recursive procedure calls. The default value is `MAXDEPTH` = 500. Cf. “Example 10” on page 1-1635.

If a procedure is a domain slot, the special variable `dom` contains the name of the domain the slot belongs to. If the procedure is not a domain slot, the value of `dom` is `NIL`.

Instead of `end_proc`, also the keyword `end` can be used.

The imperative declaration `proc - end_proc` internally results in a call of the kernel function `_procdef`. There is no need to call `_procdef` directly.

When evaluating a procedure, MuPAD parses the entire procedure first, and only then executes it. If you want to introduce a new syntax (for example, define a new `operator`), do it outside a procedure. See “Example 16” on page 1-1641.

Examples

Example 1

Simple procedures can be generated with the "arrow operator" `->`:

```
f := x -> x^2 + 2*x + 1:
f(x), f(y), f(a + b), f(1.5)
```

$$x^2+2\,x+1,\ y^2+2\,y+1,\ 2\,a+2\,b+(a+b)^2+1,\ 6.25$$

```
f := n -> isprime(n) and isprime(n + 2):
f(i) $ i = 11..18
```

TRUE, FALSE, FALSE, FALSE, FALSE, FALSE, TRUE, FALSE

The following command maps an "anonymous" procedure to the elements of a list:

```
map([1, 2, 3, 4, 5, 6], x -> x^2)
```

[1, 4, 9, 16, 25, 36]

```
delete f:
```

Example 2

The declaration of procedures with the "arrow operator" is a powerful tool. In some situations, however, it results in potentially unexpected results:

```
f := x -> sin(x^2)
```

$$x \to \sin(x^2)$$

```
g := x -> f'(x)
```

$$x \to f'(x)$$

The reason is simple: The body of a procedure definition is not evaluated at the time of definition. For those occasions where evaluation is desired, the long version of the arrow operator should be used:

```
g := x --> f'(x)
```

$$x \to 2\,x\,\cos(x^2)$$

Of course, in this example, there is an even shorter way:

```
g := f'
```

$$x \to 2\,x\,\cos(x^2)$$

Example 3

The declaration of default values is demonstrated. The following procedure uses the default values if the procedure call does not provide all parameter values:

```
f := proc(x, y = 1, z = 2) begin [x, y, z] end_proc:
f(x, y, z), f(x, y), f(x)
```

$$[x, y, z],\ [x, y, 2],\ [x, 1, 2]$$

No default value was declared for the first argument. A warning is issued if this argument is missing:

```
f()
```

```
Warning: Uninitialized variable 'x' is used.
  Evaluating: f
```

$$[\mathrm{NIL}, 1, 2]$$

```
delete f:
```

Example 4

The automatic type checking of procedure arguments and return values is demonstrated. The following procedure accepts only positive integers as argument:

```
f := proc(n : Type::PosInt) begin n! end_proc:
```

An error is raised if an unsuitable parameter is passed:

```
f(-1)
```

```
Error: The object '-1' is incorrect. The type of argument number 1 must be 'Type::PosIn
  Evaluating: f

Error: Wrong type of 1. argument (type 'Type::PosInt'
expected,        got argument '-1');   Evaluating: f
```

In the following procedure, automatic type checking of the return value is invoked:

```
f := proc(n : Type::PosInt) : Type::Integer
begin
  n/2
end_proc:
```

An error is raised if the return value is not an integer:

```
f(3)
```

```
Error: The return value '3/2' is incorrect. The type of the return value must be 'Type
  Evaluating: f

Error: Wrong type of return value (type 'Type::Integer'
expected,        value is '3/2');   Evaluating: f
```

```
delete f:
```

Example 5

The `name` entry of procedures is demonstrated. A procedure returns a symbolic call to itself by using the variable `procname` that contains the current procedure name:

```
f := proc(x)
begin
  if testtype(x,Type::Numeric)
    then return(float(1/x))
    else return(procname(args()))
  end_if
end_proc:
```

```
f(x), f(x + 1), f(3), f(2*I)
```

$$f(x),\ f(x+1),\ 0.3333333333,\ -0.5\,i$$

Also error messages use this name:

```
f(0)
```

```
Error: Division by zero. [_invert]
  Evaluating: f
```

If the procedure has a name entry, this entry is used:

```
f := proc(x)
name myName;
begin
  if testtype(x,Type::Numeric)
    then return(float(1/x))
    else return(procname(args()))
  end_if
end_proc:
f(x), f(x + 1), f(3), f(2*I)
```

$$\mathrm{myName}(x),\ \mathrm{myName}(x+1),\ 0.3333333333,\ -0.5\,i$$

```
f(0)
```

```
Error: Division by zero. [_invert]
  Evaluating: myName
```

```
delete f:
```

Example 6

The option `escape` is demonstrated. This option must be used if the procedure returns another procedure that references a formal parameter or a local variable of the generating procedure:

```
f := proc(n)
begin
```

```
  proc(x) begin x^n end_proc
end_proc:
```

Without the option `escape`, the formal parameter `n` of `f` leaves its scope: `g := f(3)` references `n` internally. When `g` is called, it cannot evaluate `n` to the value `3` that `n` had inside the scope of the function `f`:

```
g := f(3): g(x)
```

```
Warning: Uninitialized variable 'unknown' is used.
  Evaluating: g
```

```
Error: The operand is invalid. [_power]
  Evaluating: g
```

The option `escape` instructs the procedure `f` to deal with variables escaping the local scope. Now, the procedure `g := f(3)` references the value `3` rather than the formal parameter `n` of `f`, and `g` can be executed correctly:

```
f := proc(n)
option escape;
begin
  proc(x) begin x^n end_proc
end_proc:
g := f(3): g(x), g(y), g(10)
```

$$x^3,\ y^3,\ 1000$$

```
delete f, g:
```

Example 7

The option `hold` is demonstrated. With `hold`, the procedure sees the actual parameter in the form that was used in the procedure call. Without `hold`, the function only sees the value of the parameter:

```
f := proc(x) option hold; begin x end_proc:
g := proc(x) begin x end_proc:
x := PI/2:
f(sin(x) + 2) = g(sin(x) + 2), f(1/2 + 1/3) = g(1/2 + 1/3)
```

$$\sin(x) + 2 = 3,\ \frac{1}{2} + \frac{1}{3} = \frac{5}{6}$$

Procedures using `option hold` can evaluate the arguments with the function `context`:

```
f := proc(x) option hold; begin x = context(x) end_proc:
f(sin(x) + 2), f(1/2 + 1/3)
```

$$\sin(x) + 2 = 3,\ \frac{1}{2} + \frac{1}{3} = \frac{5}{6}$$

```
delete f, g, x:
```

Example 8

The option `noDebug` is demonstrated. The `debug` command starts the debugger which steps inside the procedure `f`. After entering the debugger command `c` (continue), the debugger continues the evaluation:

```
f := proc(x) begin x end_proc: debug(f(42))
```

```
Activating debugger...   #0 in f($1=42) at
/tmp/debug0.556:4 mdx> c Execution completed.
               42
```

With the option `noDebug`, the debugger does not step into the procedure:

```
f := proc(x) option noDebug; begin x end_proc: debug(f(42))
```

```
Execution completed.
          42
```

```
delete f:
```

Example 9

Create a procedure that accepts two arguments and returns a table containing the arguments:

```
f := proc(x, y) begin table(x = y) end_proc:
```

The parameters `x, y` of the procedure `f` form a sequence. If you call this procedure for the sequence `(a, b)` and a variable `c`, MuPAD flattens the nested sequence `((a, b),`

`c)` into `(a, b, c)`. The procedure `f` accepts only two arguments. Thus, it uses `a` and `b`, and ignores `c`:

```
f((a, b), c)
```

$$\overline{a \mid b}$$

When you use the `noFlatten` option, MuPAD does not flatten the arguments of the procedure:

```
g := proc(x, y) option noFlatten; begin table(x = y) end_proc:
g((a, b), c)
```

$$\overline{a, b \mid c}$$

For further computations, delete `f` and `g`:

```
delete f, g:
```

Example 10

The option `remember` is demonstrated. The `print` command inside the following procedure indicates if the procedure body is executed:

```
f:= proc(n : Type::PosInt)
option remember;
begin
   print("computing ".expr2text(n)."!");
   n!
end_proc:
f(5), f(10)
```

"computing 5!"

"computing 10!"

120, 3628800

When calling the procedure again, all values that were computed before are taken from the internal “remember table” without executing the procedure body again:

```
f(5)*f(10) + f(15)
```

```
"computing 15!"
```

```
1308109824000
```

`option remember` is used in the following procedure which computes the Fibonacci numbers $F(0) = 0$, $F(1) = 1$, $F(n) = F(n - 1) + F(n - 2)$ recursively:

```
f := proc(n : Type::NonNegInt)
option remember;
begin
   if n = 0 or n = 1 then return(n) end_if;
   f(n - 1) + f(n - 2)
end_proc:

f(123)
```

```
22698374052006863956975682
```

Due to the recursive nature of `f`, the arguments are restricted by the maximal recursive depth (see `MAXDEPTH`):

```
f(1000)
```

```
Error: Recursive definition: the maximal depth for nested procedure calls is reached.
  Evaluating: f
```

Without `optionremember`, the recursion is rather slow:

```
f := proc(n : Type::NonNegInt)
begin
   if n = 0 or n = 1 then return(n) end_if;
   f(n - 1) + f(n - 2)
end_proc:

f(28)
```

```
     317811

delete f:
```

Example 11

We demonstrate the use of local variables:

```
f := proc(a)
local x, y;
begin
  x := a^2;
  y := a^3;
  print("x, y" = (x, y));
  x + y
end_proc:
```

The local variables `x` and `y` do not coincide with the global variables `x`, `y` outside the procedure. The call to `f` does not change the global values:

```
x := 0: y := 0: f(123), x, y
```

```
     "x, y" = (15129, 1860867)

     1875996, 0, 0

delete f, x, y:
```

Example 12

The `save` declaration is demonstrated. The following procedure changes the environment variable `DIGITS` internally. Because of `save DIGITS`, the original value of `DIGITS` is restored after return from the procedure:

```
myfloat := proc(x, digits)
save DIGITS;
begin
  DIGITS := digits;
  float(x);
```

```
end_proc:
```

The current value of DIGITS is:

```
DIGITS
```

$$10$$

With the default setting DIGITS = 10, the following float conversion suffers from numerical cancellation. Due to the higher internal precision, myfloat produces a more accurate result:

```
x := 10^20*(PI - 21053343141/6701487259):
float(x), myfloat(x, 20)
```

$$0.0,\ 0.02616405487$$

The value of DIGITS was not changed by the call to myfloat:

```
DIGITS
```

$$10$$

The following procedure needs a global identifier, because local variables cannot be used as integration variables in the int function. Internally, the global identifier x is deleted to make sure that x does not have a value:

```
f := proc(n)
save x;
begin
  delete x;
  int(x^n*exp(-x), x = 0..1)
end_proc:
```

```
x := 3: f(1), f(2), f(3)
```

$$1 - 2\,e^{-1},\ 2 - 5\,e^{-1},\ 6 - 16\,e^{-1}$$

Because of save x, the previously assigned value of x is restored after the integration:

```
x
```

```
    3
```

```
delete myfloat, x, f:
```

Example 13

The following procedure accepts an arbitrary number of arguments. It accesses the actual parameters via `args`, puts them into a list, reverses the list via `revert`, and returns its arguments in reverse order:

```
f := proc()
local arguments;
begin
   arguments := [args()];
   op(revert(arguments))
end_proc:
```

```
f(a, b, c)
```

```
    c, b, a
```

```
f(1, 2, 3, 4, 5, 6, 7)
```

```
    7, 6, 5, 4, 3, 2, 1
```

```
delete f:
```

Example 14

Use `expose` to see the source code of a procedure:

```
f := proc(x = 0, n : DOM_INT)
begin
  sourceCode;
end_proc
```

```
    proc f(x, n) ... end
```

```
expose(f)
```

```
proc(x = 0, n : DOM_INT)
  name f;
begin
  sourceCode
end_proc

delete f:
```

Example 15

The option `noExpose` prevents users from reading the definition of a procedure:

```
f := proc(a)
  option noExpose;
begin
  print(sin(a));
  if is(a>1)=TRUE then
    cos(a)
  else
    cos(a + 2)
  end_if
end_proc
```

proc f(a) ... end

```
f(x), f(0), f(3)
```

$\sin(x)$

0

$\sin(3)$

$\cos(x+2), \cos(2), \cos(3)$

```
expose(f)
```

```
proc(a)
  name f;
  option noDebug, noExpose;
begin
  /* Hidden */
end_proc
```

As you can see, setting option `noExpose` implicitly sets the option `noDebug`, too.

For more information on the intended use of this option, refer to the documentation of `write`.

Example 16

When you evaluate a procedure, MuPAD parses the entire procedure, and only then executes it. Thus, you cannot define and use a new operator inside a procedure. For example, when MuPAD parses this procedure, it does not recognize the new operator <<. The reason is that the procedure is not executed yet, and therefore, the new operator is not defined:

```
f := proc(A, B)
begin
  bitshiftleft := (a, b) -> a * 2^b:
  operator("<<", bitshiftleft, Binary, 950):

  C := A<<B;

end_proc:

Error: Invalid input. 'expression' is expected. [line 6, col 10]
```

Define the operator << on the interactive level:

```
bitshiftleft := (a, b) -> a * 2^b:
operator("<<", bitshiftleft, Binary, 950):
```

Now you can use << inside procedures on the interactive level:

```
f := proc(A, B)
begin
  C := A<<B;
end_proc:
f(2, 1)
```

```
     4
```

```
m<<n
```

$$2^n\, m$$

Parameters

x_1, x_2, …

The formal parameters of the procedure: identifiers

$default_1$, $default_2$, …

Default values for the parameters: arbitrary MuPAD objects

$type_1$, $type_2$, …

Admissible types for the parameters: type objects as accepted by the function `testtype`

returntype

Admissible type for the return value: a type object as accepted by the function `testtype`

pname

The name of the procedure: an expression

$option_1$, $option_2$, …

Available options are: `escape`, `hold`, `noDebug`, `noExpose`, `noFlatten`, `remember`

$local_1$, $local_2$, …

The local variables: identifiers

global1, global2, …

Global variables: identifiers

`body`

The body of the procedure: an arbitrary sequence of statements

Return Values

Procedure of type `DOM_PROC`.

product

Definite and indefinite products

Syntax

```
product(f, i)
product(f, i = a .. b)
product(f, i = RootOf(p, <x>))
product(f, i in RootOf(p, <x>))
product(f, i in {x1, x2, …})
```

Description

`product(f, i)` computes the indefinite product of $f(i)$ with respect to i, i.e., a closed form g such that $\frac{g(i+1)}{g(i)} = f(i)$.

`product(f, i = a..b)` tries to find a closed form representation of the product $\prod_{i=a}^{b} f(i)$.

`product (f, i = RootOf(p, x))` computes the product of $f(i)$ over the roots of the polynomial p.

`product(f, i in { x1, x2, …})` computes the product $\prod_{i \in \{x_1, x_2, \ldots\}} f(i)$.

`product` serves for simplifying *symbolic* products. It should *not* be used for multiplying a finite number of terms: if `a` and `b` are integers of type `DOM_INT`, the call `_mult(f $ i = a..b)` is more efficient than `product(f, i = a..b)`.

`product(f, i)` computes the indefinite product of `f` with respect to `i`. This is an expression `g` such that $f(i) = \frac{g(i+1)}{g(i)}$.

It is implicitly assumed that `i` runs through integers only.

`product(f, i = a..b)` computes the definite product with `i` running from `a` to `b`. It is implicitly assumed that $a \le b$; it is an error if this is inconsistent.

`a` and `b` must not be numbers other than integers.

If `b-a` is an integer, the explicit product $f(a)\, f(a+1) \ldots f(b)$ is returned if it has no more than 1000 factors.

`product (f, i = RootOf(p, x))` computes the definite product with `i` running through the roots of the polynomial `p` in `x` according to their multiplicity, i.e., the number of factors is equal to the degree of `p`.

The calls `product (f, i = RootOf(p, x))` and `product (f, i in RootOf(p, x))` are equivalent.

The system returns a symbolic `product` call if it cannot compute a closed form representation of the product.

Examples

Example 1

Each of the following two calls computes the product 1 2 3 4 5:

```
product(i, i = 1..5) = _mult(i $ i = 1..5)
```

$$120 = 120$$

However, using `_mult` is usually more efficient when the boundaries are integers of type `DOM_INT`.

There is a closed form of this definite product from 1 to n:

```
product(i, i = 1..n)
```

$$n!$$

Since the upper boundary is a symbolic identifier, `_mult` cannot handle this product:

```
_mult(i $ i = 1..n)
```

$$\_\mathrm{mult}(i\ \$\ i = 1..n)$$

The corresponding indefinite product is:

```
product(i, i)
```

$$\begin{cases} \Gamma(i) & \text{if } 1 \le i \\ \frac{(-1)^i}{\Gamma(1-i)} & \text{if } i \le -1 \end{cases}$$

The indefinite and the definite product of $2\,i + 1$ are:

```
product(2*i + 1, i)
```

$$2^i\,\Gamma\left(i + \frac{1}{2}\right)$$

```
product(2*i + 1, i = 1..n)
```

$$\frac{\frac{1}{2^{n+1}}\,(2\,n+2)!}{(n+1)!}$$

The boundaries may be symbolic expressions or $\pm\infty$ as well:

```
product(i^2/(i^2 - 1), i = 2..infinity)
```

$$2$$

The system cannot find closed forms of the following two products and returns symbolic `product` calls:

```
delete f: product(f(i), i)
```

$$\prod_i f(i)$$

```
product((1 + 2^(-i)), i = 1..infinity)
```

$$\prod_{i=1}^{\infty} \frac{2^i+1}{2^i}$$

An approximation can be computed numerically via `float`:

```
float(%)
```

$$2.384231029$$

Alternatively, you can call `numeric::product` directly. This is usually more efficient, since it skips the symbolic computations performed by `product`:

```
numeric::product((1 + 2^(-i)), i = 1..infinity)
```

$$2.384231029$$

Example 2

Some products over the roots of a polynomial:

```
product(1 + 1/x, x = RootOf(x^2 - 5*x + 6))
```

$$2$$

```
product(r+c, r = RootOf(x^3 + a*x^2 + b*x + c, x))
```

$$b\,c - c - a\,c^2 + c^3$$

The multiplicity of roots is taken into account:

```
product(x+2, x in RootOf(x^5))
```

$$32$$

MuPAD finds closed forms for products of rational expressions. In other cases, a symbolic call to `product` is returned:

```
product(sin(r), r = RootOf(x^2 - PI^2/4, x))
```

$$\prod_{r=\mathrm{RootOf}\left(x^2-\frac{\pi^2}{4},x\right)} \sin(r)$$

An approximation can be computed numerically via `float`:

```
float(%)
```

$$-1.0$$

Example 3

Some products over elements of a set:

```
product(x+2, x in {2,4,8})
```

$$240$$

```
product(a*x, x in {3, b, 5})
```

$$15\,a^3\,b$$

Identical objects appear only once in a set. Therefore, the second `a` in the following example has no effect on the result:

```
product(-x, x in {a,a,7,b})
```

$$-7\,a\,b$$

Parameters

`f`

An arithmetical expression depending on `i`

`i`

The product index: an identifier or indexed indentifier

`a`, `b`

The boundaries: arithmetical expressions

`p`

A polynomial expression in `x`

`x`

Indeterminate

Return Values

arithmetical expression.

Algorithms

The product over the roots of a polynomial is computed via `polylib::resultant`.

MuPAD Functions

`*` | `_mult` | `numeric::product` | `sum`

protect

Protect an identifier

Syntax

```
protect(x, <ProtectLevelError | ProtectLevelWarning | ProtectLevelNone>)
```

Description

`protect(x)` protects the identifier `x`.

`protect(x, ProtectLevelError)` sets full write-protection for the identifier. Any subsequent attempt to assign a value to the identifier will lead to an error.

`protect(x, ProtectLevelWarning)` sets a "soft" protection. Any subsequent assignment to the identifier results in a warning message. However, the identifier will be assigned a value, anyway.

`protect(x)` is equivalent to `protect(x, ProtectLevelWarning)`.

`protect(x, ProtectLevelNone)` removes any protection from the identifier. This call is equivalent to `unprotect(x)`.

Note: Overwriting protected identifiers such as the names of MuPAD functions may damage your current session.

Examples

Example 1

The following call protects the identifier `important` with the protection level "`ProtectLevelWarning`":

```
protect(important, ProtectLevelWarning)
```

ProtectLevelNone

The identifier can still be overwritten:

```
important := 1
```

```
Warning: The protected variable 'important' is overwritten. [_assign]
```

1

We protect the identifier with the level "`ProtectLevelError`":

```
protect(important, ProtectLevelError)
```

ProtectLevelWarning

Now, it is no longer possible to overwrite `important`:

```
important := 2
```

```
Error: The identifier 'important' is protected. [_assign]
```

The identifier keeps its previous value:

```
important
```

1

In order to overwrite this value, we must unprotect `important`:

```
protect(important, ProtectLevelNone)
```

ProtectLevelError

```
important := 2
```

2

The identifier is protected again with the default level "`ProtectLevelWarning`":

```
protect(important)
```

```
     ProtectLevelNone
```

```
important := 1
```

```
Warning: The protected variable 'important' is overwritten. [_assign]
```

```
     1
```

```
unprotect(important): delete important:
```

Example 2

`protect` does not evaluate its first argument. Here the identifier `x` can still be overwritten, while its value – which is the identifier `y` – remains write protected:

```
protect(y, ProtectLevelError):  x := y:  protect(x):  x := 1
```

```
Warning: The protected variable 'x' is overwritten. [_assign]
```

```
     1
```

```
y := 2
```

```
Error: The identifier 'y' is protected. [_assign]
```

```
unprotect(x):  unprotect(y):  delete x, y:
```

Parameters

x

An identifier

Options

`ProtectLevelError`, `ProtectLevelNone`, `ProtectLevelWarning`

The level of protection to set. The default value is `ProtectLevelWarning`.

Return Values

Previous protection level of `x`: either `ProtectLevelError` or `ProtectLevelWarning` or `ProtectLevelNone`.

Algorithms

`protect` does not evaluate its first argument. This way identifiers can be protected that have been assigned a value.

Identifiers starting with a # are implicitly protected and cannot be assigned a value nor receive assumptions.

See Also

MuPAD Functions

`:=` | `unprotect`

protocol

Create a protocol of a session

Syntax

```
protocol(filename | n, <InputOnly | OutputOnly>)
```

```
protocol()
```

Description

`protocol(file)` starts a protocol of the current MuPAD terminal session.

`protocol()` stops the protocol.

`protocol` writes a protocol of input commands and corresponding MuPAD output of a terminal session to a text file.

When used from the MuPAD Notebook app, `protocol` is disabled and raises an error.

The file may be specified directly by its name. This either creates a new file or overwrites an existing file. `protocol` opens and closes the file automatically.

If the filename ends in "`.gz`", MuPAD will write a `gzip`-compressed text file.

If `WRITEPATH` does not have a value, `protocol` interprets the file name as a pathname relative to the "working directory."

Note that the meaning of "working directory" depends on the operating system. On Microsoft Windows systems and on Mac OS X systems, the "working directory" is the folder where MuPAD is installed. On UNIX systems, it is the current working directory in which MuPAD was started; when started from a menu or desktop item, this is typically the user's home directory.

Also absolute path names are processed by `protocol`.

Alternatively, the file may be specified by a file descriptor `n`. In this case, the file must have been opened via `fopen(Text, filename, Write)` or `fopen(Text, filename,`

`Append)`. This returns the file descriptor as an integer `n`. Note that `fopen(filename)` opens the file in read-only mode. A subsequent `protocol` command to this file causes an error.

The file is not closed automatically by `protocol()` and must be closed by a subsequent call to `fclose`.

A call of `protocol` without arguments terminates a running protocol and closes the corresponding file if it has been opened by `protocol`. Closing the protocol file with `fclose` also terminates the protocol.

If a new protocol is started while a protocol is running, then the old one is terminated and the corresponding file is closed.

Environment Interactions

The function is sensitive to the environment variable `WRITEPATH`. If this variable has a value, then the protocol file is created in the corresponding directory. Otherwise, the file is created in the "current working directory."

Examples

Example 1

We open a text file `test` in write mode with `fopen`:

```
n := fopen(Text, "test", Write):
```

A protocol is written into this file:

```
protocol(n):
1 + 1, a/b;
solve(x^2 = 2);
protocol():
fclose(n):
```

The file now has the following content:

```
1 + 1, a/b;

     a
  2, -
     b
solve(x^2 = 2);

          1/2            1/2
  {[x = 2   ], [x = - 2   ]}
protocol():
```

Example 2

The protocol file is opened directly by `protocol`. Only input is protocolled:

```
protocol("test", InputOnly):
1 + 1, a/b;
solve(x^2 = 2);
protocol():
```

The file now has the following content:

```
1 + 1, a/b;
solve(x^2 = 2);
protocol():
```

Example 3

The protocol file is opened directly by `protocol`. Only output is protocolled:

```
protocol("test", OutputOnly):
1 + 1, a/b;
solve(x^2 = 2);
protocol():
```

The file now has the following content:

```
     a
  2, -
     b
```

```
       1/2           1/2
{[x = 2   ], [x = - 2   ]}
```

Parameters

`filename`

The name of a file: a character string

`n`

A file descriptor provided by `fopen`: a positive integer

Options

`InputOnly`

Only input is protocolled

The protocol file only contains the input lines. All output is omitted.

`OutputOnly`

Only output is protocolled

The protocol file only contains the output lines. All input is omitted.

Return Values

Void object of type `DOM_NULL`.

psi

Digamma/polygamma function

Syntax

```
psi(x)
```

```
psi(x, n)
```

Description

`psi(x)` represents the digamma function, i.e., the logarithmic derivative $\psi(x) = \frac{\Gamma'(x)}{\Gamma(x)}$ of the `gamma` function.

`psi(x, n)` represents the n-th polygamma function, i.e., the n-th derivative $\psi^{(n)}(x)$.

`psi(x, 0)` is equivalent to `psi(x)`.

The digamma/polygamma function is defined for all complex arguments `x` apart from the singular points 0, - 1, - 2, ….

If `x` is a floating-point value, then a floating point value is returned.

Simplifications are implemented for rational numbers x. In particular, if x = `numer(x)/k` with denominators k = 1, 2, 3, 4 or 6, explicit results expressed in terms of EULER, PI, and `ln` are returned. In general, for any rational `x` with `|x| (n + 1) ≤ 6 Pref::autoExpansionLimit() = 6000` (see `Pref::autoExpansionLimit`), the functional equation

$$\psi^{(n)}(x+1) = \psi^{(n)}(x) + \frac{(-1)^n n!}{x^{n+1}},$$

is used to obtain a result with an argument `x` from the interval $(0, 1]$. Use `expand(psi(x, n))` to obtain such a shift of the argument for larger values of `x`.

Some explicit formulas are implemented including

$$\psi(1) = -\mathrm{EULER},$$

$$\psi^{(n)}(1) = (-1)^{n+1}\, n!\, \zeta(n+1),\ n > 1,$$

$$\psi\left(\frac{1}{2}\right) = -2\ln(2) - \mathrm{EULER},$$

$$\psi^{(n)}\left(\frac{1}{2}\right) = (-1)^{n+1}\, n!\, \left(2^{n+1}-1\right)\, \zeta(n+1),\ n > 1.$$

The special values $\psi(\infty) = \infty$ and $\psi^{(n)}(\infty) = 0$ for $n > 0$ are implemented.

For all other arguments, a symbolic function call of `psi` is returned.

The float attribute of the digamma function `psi(x)` is a kernel function, i.e., floating-point evaluation is fast. The float attribute of the polygamma function `psi(x, n)` with `n > 0` is a library function. Note that `psi(float(x))` and `psi(float(x), n)` rather than `float(psi(x))` and `float(psi(x, n))` should be used for float evaluation because, for rational values of `x`, the computation of the symbolic result `psi(x)`, `psi(x, n)` may be costly. Further, the float evaluation of the symbolic result may be numerically unstable.

The `expand` attribute uses the functional equation

$$\psi^{(n)}(x+1) = \psi^{(n)}(x) + \frac{(-1)^n\, n!}{x^{n+1}},$$

the nth derivative of the reflection formula

$$\psi(-x) = \psi(x) + \frac{1}{x} + \pi\, \cot(\pi\, x),$$

and the Gauß multiplication formula for $\psi^{(n)}(k\,x)$ when k is a positive integer, to rewrite `psi(x, n)`. For numerical `x`, the functional equation is used to shift the argument to the range `0 < x < 1`. Cf. examples “Example 3” on page 1-1661 and “Example 4” on page 1-1661.

Environment Interactions

When called with a floating-point value `x`, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
psi(-3/2), psi(4, 1), psi(3/2, 2)
```

$$\frac{8}{3} - 2\ln(2) - \text{EULER},\ \frac{\pi^2}{6} - \frac{49}{36},\ 16 - 14\,\zeta(3)$$

```
psi(x + sqrt(2), 4), psi(infinity, 5)
```

$$\psi^{(4)}(x + \sqrt{2}),\ 0$$

Floating point values are computed for floating-point arguments:

```
psi(-5.2), psi(1.0, 3), psi(2.0 + 3.0*I, 10)
```

$$6.065773152,\ 6.493939402,\ 0.7526409593 - 2.299472238\,i$$

Example 2

`psi` is singular for nonpositive integers:

```
psi(-2)
```

```
Error: Singularity. [psi]
```

Example 3

For positive integers and rational numbers x with denominators 2, 3, 4 and 6, respectively, the result is expressed in terms of EULER, PI, `ln`, and `zeta` if `|x| (n + 1) ≤ 6 Pref::autoExpansionLimit() = 6000`:

```
Pref::autoExpansionLimit()
```

$$1000$$

```
psi(-5/2), psi(-3/2, 1), psi(13/3, 2), psi(11/6, 4)
```

$$\frac{46}{15} - 2\ln(2) - \text{EULER},\ \frac{\pi^2}{2} + \frac{40}{9},\ \frac{75535713}{1372000} - \frac{4\sqrt{3}\,\pi^3}{9} - 26\,\zeta(3),$$
$$176\sqrt{3}\,\pi^5 - 90024\,\zeta(5) + \frac{186624}{3125}$$

For larger arguments, use `expand` to obtain such expressions:

```
psi(1001, 5)
```

$$\psi^{(5)}(1001)$$

```
expand(%)
```

```
     6 8 PI ----- -   63 13353338895557883398775 68.../109380825689800611313229 6...
```

Example 4

The functions `diff`, `expand`, `float`, `limit`, and `series` handle expressions involving `psi`:

```
diff(psi(x^2 + 1, 3), x), float(ln(3 + psi(sqrt(PI))))
```

$$2\,x\,\psi^{(4)}(x^2+1),\ 1.183103343$$

```
expand(psi(2*x + 3, 2))
```

$$\frac{\psi''\left(x+\frac{1}{2}\right)}{8}+\frac{2}{(2x+1)^3}+\frac{2}{(2x+2)^3}+\frac{1}{4x^3}+\frac{\psi''(x)}{8}$$

```
limit(x*psi(x), x = 0), limit(psi(x, 3), x = infinity)
```

$$-1,\ 0$$

```
series(psi(x), x = 0), series(psi(x, 3), x = infinity, 3)
```

$$-\frac{1}{x}-\mathrm{EULER}+\frac{\pi^2 x}{6}-x^2\,\zeta(3)+\frac{\pi^4 x^3}{90}-x^4\,\zeta(5)+O(x^5),\ \frac{2}{x^3}+\frac{3}{x^4}+\frac{2}{x^5}+O\left(\frac{1}{x^6}\right)$$

Parameters

x

An arithmetical expression

n

A nonnegative integer

Return Values

Arithmetical expression.

Overloaded By

x

MuPAD Functions

`beta` | `binomial` | `fact` | `gamma` | `harmonic` | `lngamma` | `zeta`

radsimp

Simplify radicals in arithmetical expressions

Syntax

```
radsimp(z)
```

Description

`radsimp(z)` tries to simplify the radicals in the expression `z`. The result is mathematically equivalent to `z`.

`radsimp` and `simplifyRadical` are equivalent.

Examples

Example 1

Simplify these constant expressions with square roots and higher order radicals:

```
radsimp(3*sqrt(7)/(sqrt(7) - 2)),
radsimp(sqrt(5 + 2*sqrt(6)));
radsimp(sqrt(5*sqrt(3) + 6*sqrt(2))),
radsimp(sqrt(3 + 2*sqrt(2)))
```

$$2\sqrt{7}+7,\ \sqrt{2}+\sqrt{3}$$

$$\sqrt{2}\,3^{1/4}+3^{3/4},\ \sqrt{2}+1$$

```
radsimp((1/2 + 1/4*3^(1/2))^(1/2))
```

$$\frac{\sqrt{2}}{4}+\frac{\sqrt{6}}{4}$$

```
radsimp((5^(1/3) - 4^(1/3))^(1/2))
```

$$\frac{2^{2/3}\,5^{1/3}}{3} + \frac{2^{1/3}}{3} - \frac{5^{2/3}}{3}$$

```
radsimp(sqrt(3*sqrt(3 + 2*sqrt(5 - 12*sqrt(3 - 2*sqrt(2))))
             + 14))
```

$$\sqrt{2} + 3$$

```
radsimp(2*2^(1/4) + 2^(3/4) - (6*2^(1/2) + 8)^(1/2))
```

$$0$$

```
radsimp(sqrt(1 + sqrt(3)) + sqrt(3 + 3*sqrt(3))
             - sqrt(10 + 6*sqrt(3)))
```

$$0$$

Example 2

Create the following expression and then simplify it using `radsimp`:

```
x := sqrt(3)*I/2 + 1/2: y := x^(1/3) + x^(-1/3): z := y^3 - 3*y
```

$$-\frac{3}{\left(\frac{1}{2}+\frac{\sqrt{3}\,i}{2}\right)^{1/3}} - 3\left(\frac{1}{2}+\frac{\sqrt{3}\,i}{2}\right)^{1/3} + \left(\frac{1}{\left(\frac{1}{2}+\frac{\sqrt{3}\,i}{2}\right)^{1/3}} + \left(\frac{1}{2}+\frac{\sqrt{3}\,i}{2}\right)^{1/3}\right)^3$$

```
radsimp(z)
```

$$1$$

```
delete x, y, z:
```

Example 3

Use `radsimp` to simplify these arithmetical expressions containing variables:

```
z := x/(sqrt(3) - 1) - x/2
```

$$\frac{x}{\sqrt{3}-1}-\frac{x}{2}$$

```
radsimp(z) = expand(radsimp(z))
```

$$x\left(\frac{\sqrt{3}}{2}+\frac{1}{2}\right)-\frac{x}{2}=\frac{\sqrt{3}\,x}{2}$$

```
delete z:
```

Example 4

Use `radsimp` to simplify nested radicals. When simplifying nested radicals, `radsimp` tries to reduce the nesting depth:

```
radsimp((6*2^(1/2) + 8)^(1/2));
radsimp(((32/5)^(1/5) - (27/5)^(1/5))^(1/3));
radsimp(sqrt((3+2^(1/3))^(1/2) * (4-2^(1/3))^(1/2)))
```

$$2\,2^{1/4}+2^{3/4}$$

$$\frac{5^{3/5}\left(3^{1/5}-3^{2/5}+1\right)}{5}$$

$$\left(2^{1/3}-2^{2/3}+12\right)^{1/4}$$

Parameters

z

An arithmetical expression

Return Values

Arithmetical expression.

simplifyRadical

Simplify radicals in arithmetical expressions

Syntax

```
simplifyRadical(z)
```

Description

`simplifyRadical(z)` tries to simplify the radicals in the expression `z`. The result is mathematically equivalent to `z`.

`radsimp` and `simplifyRadical` are equivalent.

Examples

Example 1

Simplify these constant expressions with square roots and higher order radicals:

```
simplifyRadical(3*sqrt(7)/(sqrt(7) - 2)),
simplifyRadical(sqrt(5 + 2*sqrt(6)));
simplifyRadical(sqrt(5*sqrt(3) + 6*sqrt(2))),
simplifyRadical(sqrt(3 + 2*sqrt(2)))
```

$$2\sqrt{7}+7,\ \sqrt{2}+\sqrt{3}$$

$$\sqrt{2}\,3^{1/4}+3^{3/4},\ \sqrt{2}+1$$

```
simplifyRadical((1/2 + 1/4*3^(1/2))^(1/2))
```

$$\frac{\sqrt{2}}{4}+\frac{\sqrt{6}}{4}$$

```
simplifyRadical((5^(1/3) - 4^(1/3))^(1/2))
```

$$\frac{2^{2/3}\,5^{1/3}}{3} + \frac{2^{1/3}}{3} - \frac{5^{2/3}}{3}$$

```
simplifyRadical(sqrt(3*sqrt(3 + 2*sqrt(5 - 12*sqrt(3 - 2*sqrt(2))))
            + 14))
```

$$\sqrt{2} + 3$$

```
simplifyRadical(2*2^(1/4) + 2^(3/4) - (6*2^(1/2) + 8)^(1/2))
```

$$0$$

```
simplifyRadical(sqrt(1 + sqrt(3)) + sqrt(3 + 3*sqrt(3))
            - sqrt(10 + 6*sqrt(3)))
```

$$0$$

Example 2

Create the following expression and then simplify it using `simplifyRadical`:

```
x := sqrt(3)*I/2 + 1/2: y := x^(1/3) + x^(-1/3): z := y^3 - 3*y
```

$$-\frac{3}{\left(\frac{1}{2}+\frac{\sqrt{3}\,i}{2}\right)^{1/3}} - 3\left(\frac{1}{2}+\frac{\sqrt{3}\,i}{2}\right)^{1/3} + \left(\frac{1}{\left(\frac{1}{2}+\frac{\sqrt{3}\,i}{2}\right)^{1/3}} + \left(\frac{1}{2}+\frac{\sqrt{3}\,i}{2}\right)^{1/3}\right)^3$$

```
simplifyRadical(z)
```

$$1$$

```
delete x, y, z:
```

Example 3

Use `simplifyRadical` to simplify these arithmetical expressions containing variables:

```
z := x/(sqrt(3) - 1) - x/2
```

$$\frac{x}{\sqrt{3}-1}-\frac{x}{2}$$

```
simplifyRadical(z) = expand(radsimp(z))
```

$$x\left(\frac{\sqrt{3}}{2}+\frac{1}{2}\right)-\frac{x}{2}=\frac{\sqrt{3}\,x}{2}$$

```
delete z:
```

Example 4

Use `simplifyRadical` to simplify nested radicals. When simplifying nested radicals, `simplifyRadical` tries to reduce the nesting depth:

```
simplifyRadical((6*2^(1/2) + 8)^(1/2));
simplifyRadical(((32/5)^(1/5) - (27/5)^(1/5))^(1/3));
simplifyRadical(sqrt((3+2^(1/3))^(1/2) * (4-2^(1/3))^(1/2)))
```

$$2\,2^{1/4}+2^{3/4}$$

$$\frac{5^{3/5}\left(3^{1/5}-3^{2/5}+1\right)}{5}$$

$$\left(2^{1/3}-2^{2/3}+12\right)^{1/4}$$

Parameters

z

An arithmetical expression

Return Values

Arithmetical expression.

Algorithms

For constant algebraic expressions, `simplifyRadical` constructs a tower of algebraic extensions of $\mathbb{Q}$ using the domain `Dom::AlgebraicExtension`. It tries to return the simplest possible form.

This function is based on an algorithm described in Borodin, Fagin, Hopcroft and Tompa, "Decreasing the Nesting Depth of Expressions Involving Square Roots", JSC 1, 1985, pp. 169-188.In some special cases, an algorithm based on Landau, "How to tangle with a nested radical", The Mathematical Intelligencer 16, 1994, no. 2, pp. 49-55, is used.

random

Generate random integer numbers

Syntax

```
random()
```

```
random(n1 .. n2)
```

```
random(n)
```

Description

`random()` returns a random integer number between 0 and 10^{12}.

`random(n1..n2)` returns a procedure that generates random integers between `n1` and `n2`.

The calls `random()` return uniformly distributed random integers between 0 and 999999999988 (approximately 10^{12}).

`r := random(n1..n2)` produces a random number generator `r`. Subsequent calls `r()` generate uniformly distributed random integers between `n1` and `n2`.

`random(n)` is equivalent to `random(0 .. n - 1)`.

The global variable `SEED` is used for initializing or changing the sequence of random numbers. It may be assigned any *non-zero* integer. The value of `SEED` fixes the sequence of random numbers. This may be used to reset random generators and reproduce random sequences.

`SEED` is set to a default value when MuPAD is initialized. Thus, each time MuPAD is started or re-initialized with the `reset` function, the random generators produce the same sequence of numbers.

To get a non-predictable initial value, make it dependent on the current time. See “Example 5” on page 1-1674.

Several random generators produced by `random` may run simultaneously. All generators make use of the same global variable `SEED`.

For producing uniformly distributed floating-points numbers, it is recommended to use the faster function `frandom` instead. The stats library provides random generators with various other distributions. Cf. “Example 4” on page 1-1673.

Environment Interactions

`random` as well as the random number generators created by it are sensitive to the environment variable `SEED`.

`random` and the random number generators created by it change the environment variable `SEED` on each call.

Examples

Example 1

The following call produces a sequence of random integers. Note that an index variable `i` must be used in the construction of the sequence. A call such as `random() $8` would produce 8 copies of the same random value:

```
random() $ i = 1..8
```

```
427419669081, 321110693270, 343633073697, 474256143563, 558458718976, 746753830538,
  32062222085, 722974121768
```

The following call produces a “die” that is rolled 20 times:

```
die := random(1..6): die() $ i = 1..20
```

```
     2, 2, 2, 4, 4, 3, 3, 2, 1, 4, 4, 6, 1, 1, 1, 2, 4, 2, 1, 3
```

The following call produces a “coin” that produces “head” or “tail”:

```
coin := random(2): coin() $ i = 1..10
```

```
     1, 0, 1, 1, 0, 1, 0, 1, 0, 0
```

```
subs(%, [0 = head, 1 = tail])
```

```
     tail, head, tail, tail, head, tail, head, tail, head, head
```

```
delete dice, coin:
```

Example 2

`random` is sensitive to the global variable `SEED` which is set and reset when MuPAD is (re-)initialized. The seed may also be set by the user. Random sequences can be reproduced by starting with a fixed `SEED`:

```
SEED := 1: random() $ i = 1..4
```

```
     427419669081, 321110693270, 343633073697, 474256143563
```

```
SEED := 1: random() $ i = 1..4
```

```
     427419669081, 321110693270, 343633073697, 474256143563
```

Example 3

`random` allows you to create several random number generators for different ranges of numbers, and to use them simultaneously:

```
r1 := random(0..4): r2 := random(2..9): [r1(), r2()] $ i = 1..6
```

```
     [1, 4], [0, 2], [1, 3], [0, 5], [2, 2], [4, 7]
```

```
delete r1, r2:
```

Example 4

`random` can be used to build a random generator for uniformly distributed floating-point numbers. The following generator produces such numbers between `-1.0` and `1.0`:

```
r := float@random(-10^DIGITS..10^DIGITS)/10^DIGITS:
r() $ i = 1..12;
```

0.2920457876, 0.3747019439, −0.5968604725, −0.9375052697, 0.1053530039, −0.3513692809,
0.5590763459, −0.0607326312, −0.4571489053, 0.2600608968, 0.9760099364, 0.5982933733

However, it is strongly recommended to use the much more efficient functions `frandom` or `stats::uniformRandom` instead:

```
r := stats::uniformRandom(-1, 1, Seed = 10^10):
r() $ i = 1..12
```

−0.5438091778, 0.1842867446, −0.9859463167, −0.6071964914, −0.8190627066,
−0.4262015812, 0.978028969, 0.4404626935, 0.05402948609,
0.3740704365, −0.2952265339, −0.06597080227

```
delete r:
```

Example 5

Usually, `random` is used to generate experimental input or "random" examples. In these cases, reproducibility is a good thing. However, on occasion a "more random" sequence is desirable. The usual way to get a random seed in a program is to use the current system time:

```
SEED := round(1e10*frandom(CurrentTime()))
```

```
1035804049
```

```
random(), random()
```

```
861209862222, 269921735546
```

Parameters

n_1, n_2

Integers with $n_1 < n_2$

n

A positive integer

Return Values

`random()` returns a nonnegative integer. The calls `random(n1..n2)` and `random(n)` return a procedure of type `DOM_PROC`.

Algorithms

`random` implements a linear congruence generator. The sequence of pseudo-random numbers generated by calling `random()` over and over again is $f(x)$, $f(f(x))$, …., where x is the initial value of `SEED` and f is the function mapping x to $a\,x \bmod m$ with suitable integer constants a and m.

See Also

MuPAD Functions

`frandom` | `stats::uniformRandom`

rationalize

Transform an expression into a rational expression

Syntax

```
rationalize(object, options)
```

Description

`rationalize(object)` transforms the expression `object` into an equivalent rational expression by replacing non-rational subexpressions by newly generated variables.

By default, a rational expression is an expression that contains only sums, products, powers with integer exponents, integers, rational numbers, and identifiers as subexpressions.

The `rationalize` function returns a sequence `(rat, subsSet)`. The rationalized expression `rat` contains new variables. The set of substitutions `subsSet` expresses the new variables by the old ones.

If the original expression contains subexpressions, the `rationalize` function can rationalize or replace subexpressions or keep them in their original form. Use the options `DescendInto`, `ReplaceType`, and `StopOn` to control the action `rationalize` takes for particular types of subexpressions.

If `FindRelations = ["exp", "_power", "sin"]`, the `rationalize` function detects maximal number of algebraic dependencies.

If you call `rationalize` with any combination of the following three contradicting options, the function chooses the option using the following priorities: `ReplaceType`, `StopOn`, `DescendInto`. For example, if you specify the same type of subexpression with `StopOn` and `DescendInto`, the `rationalize` function uses only the `StopOn` option for subexpressions of the specified type. If you combine any of these options with the `ReplaceType` option, `rationalize` uses only the `ReplaceType` option.

Examples

Example 1

`rationalize` operates on single arithmetical expressions, lists, and sets of expressions:

```
rationalize(2*sqrt(3) + 0.5*x^3)
```

$$X4\,x^3 + 2\,X3,\ \{X3 = \sqrt{3},\ X4 = 0.5\}$$

```
rationalize([(x - sqrt(2))*(x^2 + sqrt(3)),
             (x - sqrt(2))*(x - sqrt(3))])
```

$$[-(X5 - x)\,(x^2 + X6),\ (X5 - x)\,(X6 - x)],\ \{X5 = \sqrt{2},\ X6 = \sqrt{3}\}$$

Example 2

Use the `ApproximateFloats` option to replace all floating-point numbers with rational numbers:

```
rationalize([0.4, 0.333, 0.74], ApproximateFloats)
```

$$\left[\frac{2}{5},\ \frac{333}{1000},\ \frac{37}{50}\right],\ \varnothing$$

If you use both `ApproximateFloats` and `ReplaceTypes` options, `ApproximateFloats` does not apply to the types of subexpressions specified in `ReplaceTypes`:

```
rationalize(0.4*x^2 + sin(0.33/x),
                ApproximateFloats,
                ReplaceTypes={DOM_FLOAT})
```

$$X8\,x^2 + X9,\ \left\{X7 = 0.33,\ X8 = 0.4,\ X9 = \sin\left(\frac{0.33}{x}\right)\right\}$$

Instead of specifying the value of `ReplaceTypes` as a sequence of types, you can specify it as a function. The function must return `TRUE` or `FALSE` as a result. For example, rationalize the same expression $0.4\,x^2 + \sin\left(\frac{0.33}{x}\right)$. This time, use the function `F` to specify the type of subexpressions which you want to replace by variables:

```
F := X -> testtype(X, DOM_FLOAT):
rationalize(0.4*x^2 + sin(0.33/x),
                ApproximateFloats,
                ReplaceTypes = F)
```

$$X11\, x^2 + X12,\ \left\{X10 = 0.33,\ X11 = 0.4,\ X12 = \sin\left(\frac{0.33}{x}\right)\right\}$$

Example 3

By default, `rationalize` rationalizes sums, products, bases of integer powers, lists, and sets:

```
rationalize(ln(sin(x)^2 + cos(x)*exp(x)))
```

$$X13,\ \{X13 = \ln(\sin(x)^2 + e^x \cos(x))\}$$

The `DescendInto` option lets you specify the types of subexpressions that you want to rationalize. Each type can be a domain type, a string as returned by the function `type` or a Type object. Note that `DescendInto` overwrites the default types with the types that you specify:

```
rationalize(ln(sin(x)^2 + cos(x)*exp(x)), DescendInto = {"ln"})
```

$$\ln(X14),\ \{X14 = \sin(x)^2 + e^x \cos(x)\}$$

If you want to add new types of subexpressions to the default ones, define the value of `DescendInto` as a procedure that specifies all required types explicitly. The procedure must return `TRUE` or `FALSE`:

```
F := proc(X)
begin
  hastype(X, {"_plus", "_mult", DOM_SET, DOM_LIST, "ln"}) or
  (hastype(X, "_power") and hastype(op(X, 2), DOM_INT))
end:

rationalize(ln(sin(x)^2 + cos(x)*exp(x)), DescendInto = F)
```

$$\ln(X17^2 + X15\, X16),\ \{X16 = \cos(x),\ X15 = e^x,\ X17 = \sin(x)\}$$

Example 4

Use the `MinimalPolynomials` option to find minimal polynomials of irrational expressions:

```
rationalize(x^(7/6) + x^(3/2), MinimalPolynomials)
```

$$\mathrm{X18} + \mathrm{X19},\ \left\{\mathrm{X18} = x^{3/2},\ \mathrm{X19} = x^{7/6}\right\},\ \left\{\mathrm{X18}^2 - x^3,\ \mathrm{X19}^6 - x^7\right\}$$

Example 5

Use `Prefix = s`, where `s` is a string, to specify the prefix for generated variables (the default prefix is `X`):

```
rationalize(x^(7/6) + x^(3/2), Prefix = "ABC")
```

$$\mathrm{ABC1} + \mathrm{ABC2},\ \left\{\mathrm{ABC1} = x^{3/2},\ \mathrm{ABC2} = x^{7/6}\right\}$$

Example 6

Use the `ReplaceHardToEval` option to replace limits, sums, and integrals with generated variables. Expressions with limits, sums, and integrals tend to be the most computationally expensive:

```
rationalize(sum(exp(x)/(x^2 + 1), x) +
            limit(sin(cos(1/x))*cos(1/x), x),
                          ReplaceHardToEval)
```

$$\mathrm{X48} + \mathrm{X49},\ \left\{\mathrm{X48} = \lim_{x \to 0} \cos\left(\frac{1}{x}\right) \sin\left(\cos\left(\frac{1}{x}\right)\right),\ \mathrm{X49} = \sum_x \frac{e^x}{x^2 + 1}\right\}$$

Example 7

By default, `rationalize` avoids rationalization of integers, rational numbers, and identifiers:

```
rationalize(2*sqrt(3) + 0.5*x^3)
```

$$\mathrm{X51}\,x^3 + 2\,\mathrm{X50},\ \{\mathrm{X50} = \sqrt{3},\ \mathrm{X51} = 0.5\}$$

The `DescendInto` option lets you avoid rationalization of particular types of subexpressions. Each type can be specified as a domain type, a string as returned by the function `type`, or a Type object. For example, rationalize the same expression leaving the subexpression `x^3` (of the type `"_power"`) unchanged:

```
rationalize(2*sqrt(3) + 0.5*x^3, StopOn = {"_power"})
```

$$\mathrm{X53}\,x^3 + \sqrt{3}\,\mathrm{X52},\ \{\mathrm{X52} = 2,\ \mathrm{X53} = 0.5\}$$

Rationalize the same expression including all subexpressions. Keep floating-point numbers, integers, and identifiers (do not replace them with generated variables):

```
rationalize(2*sqrt(3) + 0.5*x^3,
            StopOn = {DOM_FLOAT, DOM_INT, DOM_IDENT})
```

$$0.5\,x^3 + 2\,\mathrm{X54},\ \{\mathrm{X54} = \sqrt{3}\}$$

Note that `StopOn` overwrites the default types with the types that you specify. If you want to add new types of subexpressions to the default ones, specify all the types explicitly:

```
rationalize(2*sqrt(3) + 0.5*x^3,
            StopOn = {DOM_INT, DOM_IDENT, DOM_RAT, DOM_FLOAT})
```

$$0.5\,x^3 + 2\,\mathrm{X55},\ \{\mathrm{X55} = \sqrt{3}\}$$

```
rationalize(2*sqrt(3) + 0.5*x^3,
            StopOn = {DOM_INT, DOM_IDENT,
                      DOM_RAT, DOM_FLOAT,
                               "_power"})
```

$$0.5\,x^3 + 2\sqrt{3},\ \varnothing$$

The `StopOn` option also can accept a function as its value. The function must return `TRUE` or `FALSE`. For example, use generated variables to replace only subexpressions that contain `sin`. Keep all other subexpressions intact:

```
F := X -> not hastype(X, "sin"):
rationalize(sin(x^2) + x^3 + exp(x) + 1/x, StopOn = F)
```

$$X56 + e^x + \frac{1}{x} + x^3, \{X56 = \sin(x^2)\}$$

Example 8

Use the `FindRelations` option to detect algebraic dependencies between exponentials:

```
rationalize(exp(x/2) + exp(x/3), FindRelations = ["exp"])
```

$$X63^3 + X63^2, \left\{X63 = e^{\frac{x}{6}}\right\}$$

Detect algebraic dependencies for different powers of the same base by specifying the type `"_power"`:

```
rationalize(x^(3/2) + x^(7/4), FindRelations = ["_power"])
```

$$X67^7 + X67^6, \left\{X67 = x^{1/4}\right\}$$

Detect algebraic dependencies for trigonometric functions by specifying the type `"sin"` or `"cos"`:

```
rationalize(sin(x) + cos(x), FindRelations = ["sin"]);
rationalize(sin(x)^3 + cos(x)^3, FindRelations = ["cos"])
```

$$\frac{2\,X70}{X70^2+1} - \frac{X70^2-1}{X70^2+1}, \left\{X70 = \tan\left(\frac{x}{2}\right)\right\}$$

$$\frac{8\,X73^3}{(X73^2+1)^3} - \frac{(X73^2-1)^3}{(X73^2+1)^3}, \left\{X73 = \tan\left(\frac{x}{2}\right)\right\}$$

Example 9

For nested exponentials, use the `Recursive` option to obtain a list of substitutions:

```
rationalize(exp(exp(x)), FindRelations = ["exp"], Recursive)
```

$$X74,\ [X74 = e^{X77},\ X77 = e^{x}]$$

The option also works for trigonometric functions:

```
rationalize(sin(sin(x)), FindRelations = ["sin"], Recursive)
```

$$X78,\ [X78 = \sin(X79),\ X79 = \sin(x)]$$

Example 10

The `ShowDependencies` option shows all original variables upon which each generated variable depends:

```
rationalize(sin(x)^3, ShowDependencies)
```

$$X80(x)^3,\ \{X80(x) = \sin(x)\}$$

Parameters

`object`

Any MuPAD object

Options

`ApproximateFloats`

When you use the `ApproximateFloats` option, the `rationalize` function replaces floating-point numbers with rational numbers. By default, `ApproximateFloats=FALSE`: the `rationalize` function replaces all floating-point numbers with the

new variables. If you rationalize an expression using both `ApproximateFloats` and `StopOn` options, `StopOn` does not prevent rationalization of floating-point numbers in the specified subexpressions. If you rationalize an expression using both `ApproximateFloats` and `ReplaceTypes` options, `ApproximateFloats` does not apply to the types of subexpressions specified in `ReplaceTypes`. See "Example 2" on page 1-1677.

`DescendInto`

When you use the `DescendInto` option, the `rationalize` function rationalizes all subexpressions of the specified types. You can specify the value of this option as a set (even if there is only one type) or a procedure that returns `TRUE` or `FALSE`. Each type can be

- A domain type (such as `DOM_INT`, `DOM_EXPR`, and so on)
- A string as returned by the function `type` (such as `"_plus"`, `"_mult"`, `"sin"`, and so on)
- A Type object (`Type::Boolean`, `Type::Equation`, and so on)

By default, the `rationalize` function rationalizes the following types of subexpresssions: sums, products, bases of integer powers, lists, and sets. When you specify other types of subexpressions, `rationalize` uses them instead of the default types. (`DescendInto` overwrites the default types with the types that you specify.) If you want to extend the set of types of subexpressions retaining the default types, define the value of `DescendInto` as a procedure that specifies all default and additional types explicitly. See "Example 3" on page 1-1678.

`FindRelations`

When you use the `FindRelations` option, the `rationalize` function detects algebraic dependencies for subexpressions of specified types. This option accepts the types of subexpressions in the form of a list. The following types are available: `"sin"`, `"cos"`, `"exp"`, and `"_power"`. By default, `rationalize` does not look for dependencies for irrational subexpressions: `FindRelations= []`.

`MinimalPolynomials`

When you use the `MinimalPolynomials` option, the `rationalize` function returns the minimal polynomials of irrational expressions. The function returns the rationalized expression, the set of substitution equations, and minimal polynomials. By default, `MinimalPolynomials= FALSE`. See "Example 4" on page 1-1679.

Prefix

Use the `Prefix` option to specify the prefix for new variables generated by the `rationalize` function. The value of this option must be a string. By default, `Prefix= "X"`. See “Example 5” on page 1-1679.

Recursive

When you use the `Recursive` option, the `rationalize` function recursively rationalizes nested subexpressions, and returns a list of substitution equations. Each generated variable in the returned list can depend on other variables in the list. By default, `Recursive= FALSE`. See “Example 9” on page 1-1682.

ReplaceHardToEval

When you use the `ReplaceHardToEval` option, the `rationalize` function replaces all limits, sums, and integrals by generated variables. Generally, this option allows you to avoid most expensive rationalizations of sums, limits, and integrals. By default, `ReplaceHardToEval= FALSE`. See “Example 6” on page 1-1679.

ReplaceTypes

When you use the `ReplaceTypes` option, the `rationalize` function replaces all subexpressions of the specified types with generated variables. You can specify the value of this option as a set (even if there is only one type) or a procedure that returns `TRUE` or `FALSE`. Each type can be

- A domain type (such as `DOM_INT`, `DOM_EXPR`, and so on)
- A string as returned by the function `type` (such as `"_plus"`, `"_mult"`, `"sin"`, and so on)
- A Type object (`Type::Boolean`, `Type::Equation`, and so on)

This option allows you to specify and avoid most expensive rationalizations for your particular expression. If you use this option in combination with `ReplaceHardToEval`, the `rationalize` function uses generated variables to replace all limits, sums, integrals, and the types that you specify. If `ReplaceTypes` specifies the same type of subexpression as `DescendInto`, the `ReplaceTypes` option prevails. By default, `ReplaceTypes= {}`.

Alternatively, specify the value of this option as a function that returns `TRUE` or `FALSE`. See “Example 2” on page 1-1677.

ShowDependencies

When you use the ShowDependencies option, the rationalize function replaces any irrational subexpression containing the identifiers vars with an expression of the form newvar(vars), showing the dependencies of the generated variables on the original variables. By default, ShowDependencies= FALSE.

StopOn

When you use the StopOn option, the rationalize function does not rationalize the specified types of subexpressions. You can specify the value of this option as a set (even if there is only one type) or a function that returns TRUE or FALSE. Each type can be

- A domain type (such as DOM_INT, DOM_EXPR, and so on)
- A string as returned by the function type (such as "_plus", "_mult", "sin", and so on)
- A Type object (Type::Boolean, Type::Equation, and so on)

By default, the rationalize function does not rationalize or replace integers, rational numbers, and identifiers. When you specify other types of subexpressions, rationalize uses them instead of the default types. (StopOn overwrites the default types with the types that you specify.) If you want to extend the set of types of subexpressions retaining the default types, specify StopOn = {DOM_INT, DOM_IDENT, DOM_RAT, extra types}, where extra types are the additional types of subexpressions that you do not want to rationalize. See “Example 7” on page 1-1679.

If StopOn specifies the same type of subexpression as DescendInto, the StopOn option prevails.

StopOnConstants

When you use the StopOnConstants option, the rationalize function does not rationalize the object of the type Type::Constant: numbers, strings, Boolean constants, NIL, FAIL, PI, EULER, and CATALAN in the set Type::ConstantIdents. By default, StopOnConstants= FALSE.

Return Values

Sequence consisting of the rationalized object and a set of substitution equations. If you use the Recursive option, the rationalize function returns a list of substitution

equations instead of a set. If you use the `MinimalPolynomials` option, the returned value has a third argument: the minimal polynomials.

Re

Real part of an arithmetical expression

Syntax

```
Re(z)
```

```
Re(L)
```

Description

`Re(z)` returns the real part of *z*.

The intended use of `Re` is for constant arithmetical expressions. Especially for numbers, of type `DOM_INT`, `DOM_RAT`, `DOM_FLOAT`, or `DOM_COMPLEX`, the real part is computed directly and very efficiently.

`Re` can handle symbolic expressions. Properties of identifiers are taken into account (see `assume`). An identifier without any property is assumed to be complex. See “Example 2” on page 1-1688.

However, for arbitrary symbolic expressions, `Re` may be unable to extract the real part of `z`. You may then use the function `rectform` (see “Example 3” on page 1-1688). Note, however, that using `rectform` is computationally expensive.

If `Re` cannot extract the whole real part of `z`, then the returned expression contains symbolic `Re` and `Im` calls. The same is true for `Im`. See “Example 2” on page 1-1688.

The `Re` function is automatically mapped to all entries of container objects such as arrays, lists, matrices, polynomials, sets, and tables.

Environment Interactions

These functions are sensitive to properties of identifiers set via `assume`. See “Example 2” on page 1-1688.

Examples

Example 1

The real and the imaginary part of $2\,e^{1+i}$ are:

```
Re(2*exp(1 + I)), Im(2*exp(1 + I))
```

$$2\cos(1)\,e,\ 2\,e\,\sin(1)$$

Example 2

`Re` and `Im` are not able to extract the whole real and imaginary part, respectively, of symbolic expressions containing identifiers without a value. However, in some cases they can still simplify the input expression, as in the following two examples:

```
delete u, v: Re(u + v*I), Im(u + v*I)
```

$$\Re(u) - \Im(v),\ \Im(u) + \Re(v)$$

```
delete z: Re(z + 2), Im(z + 2)
```

$$\Re(z) + 2,\ \Im(z)$$

By default, identifiers without a value are assumed to represent arbitrary complex numbers. You can use `assume` to change this. The following command tells the system that `z` represents only real numbers:

```
assume(z, Type::Real): Re(z + 2), Im(z + 2)
```

$$z + 2,\ 0$$

Example 3

Here is another example of a symbolic expression for which `Re` and `Im` fail to extract its real and imaginary part, respectively:

```
delete z: Re(exp(I*sin(z))), Im(exp(I*sin(z)))
```

$$\Re\left(e^{\sin(z)\,i}\right),\ \Im\left(e^{\sin(z)\,i}\right)$$

You may use the function `rectform`, which splits a complex expression *z* into its real and imaginary part and is more powerful than `Re` and `Im`:

```
r := rectform(exp(I*sin(z)))
```

$$\cos(\cosh(\Im(z))\,\sin(\Re(z)))\,e^{-\cos(\Re(z))\,\sinh(\Im(z))} + \left(\sin(\cosh(\Im(z))\,\sin(\Re(z)))\,e^{-\cos(\Re(z))\,\sinh(\Im(z))}\right) i$$

Then `Re(r)` and `Im(r)` give the real and the imaginary part of `r`, respectively:

```
Re(r)
```

$$\cos(\cosh(\Im(z))\,\sin(\Re(z)))\,e^{-\cos(\Re(z))\,\sinh(\Im(z))}$$

```
Im(r)
```

$$\sin(\cosh(\Im(z))\,\sin(\Re(z)))\,e^{-\cos(\Re(z))\,\sinh(\Im(z))}$$

Example 4

Symbolic expressions of type `"Re"` and `"Im"` always have the property `Type::Real`, even if no identifier of the symbolic expression has a property:

```
is(Re(sin(2*x)), Type::Real)
```

TRUE

Example 5

Advanced users can extend the functions `Re` and `Im` to their own special mathematical functions (see section “Backgrounds” below). To this end, embed your mathematical function into a function environment`f` and implement the behavior of the functions `Re` and `Im` for this function as the slots `"Re"` and `"Im"` of the function environment.

If a subexpression of the form `f(u,..)` occurs in `z`, then `Re` and `Im` issue the call `f::Re(u,..)` and `f::Im(u,..)`, respectively, to the slot routine to determine the real and the imaginary part of `f(u,..)`, respectively.

For illustration, we show how this works for the sine function and the slot `"Re"`. Of course, the function environment `sin` already has a `"Re"` slot. We call our function environment `Sin` in order not to overwrite the existing system function `sin`:

```
Sin := funcenv(Sin):
Sin::Re := proc(u) // compute Re(Sin(u))
  local r, s;
begin
  r := Re(u);
  if r = u then
    return(Sin(u))
  elif not has(r, {hold(Im), hold(Re)}) then
    s := Im(u);
    if not has(s, {hold(Im), hold(Re)}) then
      return(Sin(r)*cosh(s))
    end_if
  end_if;
  return(FAIL)
end:

Re(Sin(2)), Re(Sin(2 + 3*I))
```

$$\mathrm{Sin}(2),\ \mathrm{Sin}(2)\cosh(3)$$

The return value `FAIL` tells the function `Re` that `Sin::Re` was unable to determine the real part of the input expression. The result is then a symbolic `Re` call:

```
delete f, z: Re(2 + Sin(f(z)))
```

$$\Re(\mathrm{Sin}(f(z))) + 2$$

Parameters

z

An arithmetical expression

`L`

A container object: an array, an hfarray, a list, a matrix, a polynomial, a set, or a table.

Return Values

arithmetical expression or a container object containing such expressions

Overloaded By

z

Algorithms

If a subexpression of the form `f(u,..)` occurs in `z` and `f` is a function environment, then `Re` attempts to call the slot `"Re"` of `f` to determine the real part of `f(u,..)`. In this way, you can extend the functionality of `Re` to your own special mathematical functions.

The slot `"Re"` is called with the arguments `u,..` of `f`. If the slot routine `f::Re` is not able to determine the real part of `f(u,..)`, then it must return `FAIL`.

If `f` does not have a slot `"Re"`, or if the slot routine `f::Re` returns `FAIL`, then `f(u,..)` is replaced by the symbolic call `Re(f(u...))` in the returned expression.

The same holds for the function `Im`, which attempts to call the corresponding slot `"Im"` of `f`.

See “Example 5” on page 1-1689.

Similarly, if an element `d` of a library domain`T` occurs as a subexpression of `z`, then `Re` attempts to call the slot `"Re"` of that domain with `d` as argument to compute the real part of `d`.

If the slot routine `T::Re` is not able to determine the real part of `d`, then it must return `FAIL`.

If `T` does not have a slot `"Re"`, or if the slot routine `T::Re` returns `FAIL`, then `d` is replaced by the symbolic call `Re(d)` in the returned expression.

The same holds for the function `Im`, which attempts to call the corresponding slot `"Im"` of the `T`.

Im

Imaginary part of an arithmetical expression

Syntax

```
Im(z)
```

```
Im(L)
```

Description

`Im(z)` returns the imaginary part of *z*.

The intended use of `Im` is for constant arithmetical expressions. Especially for numbers, of type `DOM_INT`, `DOM_RAT`, `DOM_FLOAT`, or `DOM_COMPLEX`, the imaginary part is computed directly and very efficiently.

`Im` can handle symbolic expressions. Properties of identifiers are taken into account (see `assume`). An identifier without any property is assumed to be complex. See “Example 2” on page 1-1694.

However, for arbitrary symbolic expressions, `Im` may be unable to extract the imaginary part of `z`. You may then use the function `rectform` (see “Example 3” on page 1-1694). Note, however, that using `rectform` is computationally expensive.

If `Re` cannot extract the whole real part of `z`, then the returned expression contains symbolic `Re` and `Im` calls. The same is true for `Im`. See “Example 2” on page 1-1694.

The `Im` function is automatically mapped to all entries of container objects such as arrays, lists, matrices, polynomials, sets, and tables.

Environment Interactions

These functions are sensitive to properties of identifiers set via `assume`. See “Example 2” on page 1-1694.

Examples

Example 1

The real and the imaginary part of $2\,e^{1+i}$ are:

```
Re(2*exp(1 + I)), Im(2*exp(1 + I))
```

$$2\cos(1)\,e,\ 2\,e\,\sin(1)$$

Example 2

`Re` and `Im` are not able to extract the whole real and imaginary part, respectively, of symbolic expressions containing identifiers without a value. However, in some cases they can still simplify the input expression, as in the following two examples:

```
delete u, v: Re(u + v*I), Im(u + v*I)
```

$$\Re(u) - \Im(v),\ \Im(u) + \Re(v)$$

```
delete z: Re(z + 2), Im(z + 2)
```

$$\Re(z) + 2,\ \Im(z)$$

By default, identifiers without a value are assumed to represent arbitrary complex numbers. You can use `assume` to change this. The following command tells the system that `z` represents only real numbers:

```
assume(z, Type::Real): Re(z + 2), Im(z + 2)
```

$$z + 2,\ 0$$

Example 3

Here is another example of a symbolic expression for which `Re` and `Im` fail to extract its real and imaginary part, respectively:

```
delete z: Re(exp(I*sin(z))), Im(exp(I*sin(z)))
```

$$\Re\left(e^{\sin(z)\,i}\right),\ \Im\left(e^{\sin(z)\,i}\right)$$

You may use the function `rectform`, which splits a complex expression *z* into its real and imaginary part and is more powerful than `Re` and `Im`:

```
r := rectform(exp(I*sin(z)))
```

$$\cos(\cosh(\Im(z))\,\sin(\Re(z)))\,e^{-\cos(\Re(z))\,\sinh(\Im(z))} + \left(\sin(\cosh(\Im(z))\,\sin(\Re(z)))\,e^{-\cos(\Re(z))\,\sinh(\Im(z))}\right) i$$

Then `Re(r)` and `Im(r)` give the real and the imaginary part of `r`, respectively:

```
Re(r)
```

$$\cos(\cosh(\Im(z))\,\sin(\Re(z)))\,e^{-\cos(\Re(z))\,\sinh(\Im(z))}$$

```
Im(r)
```

$$\sin(\cosh(\Im(z))\,\sin(\Re(z)))\,e^{-\cos(\Re(z))\,\sinh(\Im(z))}$$

Example 4

Symbolic expressions of type `"Re"` and `"Im"` always have the property `Type::Real`, even if no identifier of the symbolic expression has a property:

```
is(Re(sin(2*x)), Type::Real)
```

$$\text{TRUE}$$

Example 5

Advanced users can extend the functions `Re` and `Im` to their own special mathematical functions (see section “Backgrounds” below). To this end, embed your mathematical function into a function environment`f` and implement the behavior of the functions `Re` and `Im` for this function as the slots `"Re"` and `"Im"` of the function environment.

If a subexpression of the form `f(u,..)` occurs in `z`, then `Re` and `Im` issue the call `f::Re(u,..)` and `f::Im(u,..)`, respectively, to the slot routine to determine the real and the imaginary part of `f(u,..)`, respectively.

For illustration, we show how this works for the sine function and the slot `"Re"`. Of course, the function environment `sin` already has a `"Re"` slot. We call our function environment `Sin` in order not to overwrite the existing system function `sin`:

```
Sin := funcenv(Sin):
Sin::Re := proc(u) // compute Re(Sin(u))
  local r, s;
begin
  r := Re(u);
  if r = u then
    return(Sin(u))
  elif not has(r, {hold(Im), hold(Re)}) then
    s := Im(u);
    if not has(s, {hold(Im), hold(Re)}) then
      return(Sin(r)*cosh(s))
    end_if
  end_if;
  return(FAIL)
end:

Re(Sin(2)), Re(Sin(2 + 3*I))
```

$$\mathrm{Sin}(2),\ \mathrm{Sin}(2)\cosh(3)$$

The return value `FAIL` tells the function `Re` that `Sin::Re` was unable to determine the real part of the input expression. The result is then a symbolic `Re` call:

```
delete f, z: Re(2 + Sin(f(z)))
```

$$\Re(\mathrm{Sin}(f(z))) + 2$$

Parameters

z

An arithmetical expression

`L`

A container object: an array, an hfarray, a list, a matrix, a polynomial, a set, or a table.

Return Values

arithmetical expression or a container object containing such expressions

Overloaded By

z

Algorithms

If a subexpression of the form `f(u,..)` occurs in `z` and `f` is a function environment, then `Re` attempts to call the slot `"Re"` of `f` to determine the real part of `f(u,..)`. In this way, you can extend the functionality of `Re` to your own special mathematical functions.

The slot `"Re"` is called with the arguments `u,..` of `f`. If the slot routine `f::Re` is not able to determine the real part of `f(u,..)`, then it must return `FAIL`.

If `f` does not have a slot `"Re"`, or if the slot routine `f::Re` returns `FAIL`, then `f(u,..)` is replaced by the symbolic call `Re(f(u...))` in the returned expression.

The same holds for the function `Im`, which attempts to call the corresponding slot `"Im"` of `f`.

See “Example 5” on page 1-1695.

Similarly, if an element `d` of a library domain`T` occurs as a subexpression of `z`, then `Re` attempts to call the slot `"Re"` of that domain with `d` as argument to compute the real part of `d`.

If the slot routine `T::Re` is not able to determine the real part of `d`, then it must return `FAIL`.

If `T` does not have a slot `"Re"`, or if the slot routine `T::Re` returns `FAIL`, then `d` is replaced by the symbolic call `Re(d)` in the returned expression.

The same holds for the function `Im`, which attempts to call the corresponding slot `"Im"` of the `T`.

MuPAD Functions

`abs` | `assume` | `conjugate` | `Re` | `rectform` | `sign`

read

Search, read, and execute file

Syntax

```
read(filename | n, <Quiet>, <Plain>, <Encoding = "encodingValue">)
```

Description

`read(filename)` searches for the file in various folders:

- First, `filename` is concatenated to each folder given by the environment variable `READPATH`.
- Then the file name is interpreted as an absolute path name.
- Then the file name is interpreted as a relative pathname, i.e., relative to the "working folder."
- Last, the file name is concatenated to the library path.

If a file can be opened with one of these names, then the file is read and executed with `fread`.

`read(filename, Encoding = "encodingValue")` uses the specified encoding for text files. For supported encodings, see "Options" on page 1-1703.

If the file is in `gzip`-compressed format and its name ends in "`.gz`", it will be transparently uncompressed upon reading.

Note that the meaning of "working folder" depends on the operating system. On Microsoft Windows systems and on Mac OS X systems, the "working folder" is the folder where MATLAB is installed. On UNIX systems, it is the current working folder in which MATLAB was started. When started from a menu or desktop item, this is typically the user's home folder.

A path separator ("/") is inserted as necessary when concatenating a given path and `filename`.

`read(n)` with a file descriptor `n` as returned by `fopen` is equivalent to the call `fread(n)`. When called with a file description, `read` does not automatically open and close the file. Use `fopen` and `fclose` to open and close the file. The Encoding option does not work with this syntax.

When you use the `read` command to read a file, the command evaluates all the statements in that file with the maximal substitution depth defined by `LEVEL`. The default value of `LEVEL` for interactive computations is 100. See “Example 3” on page 1-1701.

See the function `fread` for details about reading and executing the file's content and for a detailed description of the options `Plain` and `Quiet`.

When a file is read with `read`, the variable `FILEPATH` contains the path of the file.

Examples

Example 1

Create a new file in the system's temporary folder. The name of the temporary folder varies for different platforms. The `fopen` command with the `TempFile` option creates a file in any system's temporary folder (if such folder exists):

```
a := 3:
b := 5:
fid := fopen(TempFile, Write, Text):
```

Use the `write` command to store values `a` and `b` in the temporary file:

```
write(fid, a, b):
```

Use `fname` to return the name of the temporary file you created:

```
file := fname(fid):
```

After reading the file, the values of `a` and `b` are restored:

```
delete a, b:
read(file):
a, b
```

```
3, 5
```

Alternatively, use `fopen` to open the file and read its content:

```
delete a, b:
n := fopen(file):
read(n):
fclose(n):
a, b
```

```
3, 5
```

```
delete a, b, READPATH, n:
```

Example 2

You can explicitly specify the folder and file names. The following example only works on systems like UNIX. To make it work on other operating systems, change the path names accordingly. First, use `write` to store values in the file "`testfile.mb`" in the "`/tmp`" folder:

```
a := 3:
b := 5:
write("/tmp/testfile.mb", a, b):
```

Now, define "`/tmp`" as the search folder and provide a path name relative to it. Note that the path separator "`/`" is inserted by `read`:

```
delete a, b:
READPATH := "/tmp":
read("testfile.mb"):
a, b
```

```
3, 5
```

Example 3

The `read` command evaluates all the statements in a file it reads with the maximal substitution depth defined by `LEVEL`. For example, create and read a file that specifies

the value of the variable `a` by using another variable `b`. Use the `fopen` command with the `TempFile` option to create a new file in the system's temporary folder:

```
fid := fopen(TempFile, Write, Text):
```

Write the following statements to the file:

```
fprint(Unquoted, fid, "a := b^2:  b := 5: c := a/3: delete a, b:"):
```

Use `fname` to return the name of the temporary file you created. Use `fclose` to close the file:

```
file := fname(fid):
fclose(fid)
```

Read the file. The `read` command evaluates the statements in the file recursively:

```
read(file):
c
```

$$\frac{25}{3}$$

To supress recursive evaluations, change the maximal substitution depth to 1:

```
delete c:
LEVEL := 1:
read(file):
c
```

$$\frac{b^2}{3}$$

Restore the default value of `LEVEL` for further computations:

```
delete LEVEL
```

Example 4

To specify the encoding to read data, use Encoding. The Encoding option applies only to text files that are opened using a file name and not a file descriptor. Open a file and write the statement `"str = abcäöü"` in the encoding “`UTF-8`”:

```
fprint(Unquoted, Text, Encoding="UTF-8",
                       "read_test",
                       "str := \"abcäöü\"")
```

Specify the encoding to read the file. `read` returns the correct output:

```
read("read_test",Encoding="UTF-8"):

"abcäöü"
```

If you do not specify an encoding, the default system encoding is used. Thus, your output might vary from that shown next. Characters unrecognized by the default system encoding are replaced by the default substitution character for that encoding:

```
read("read_test"):

"abc??????"
```

Parameters

`filename`

The name of a file: a character string

`n`

A file descriptor provided by `fopen`: a positive integer

Options

`Plain`

Makes `read` use its own parser context

`Quiet`

Suppresses output during execution of `read`

`Encoding`

This option lets you specify the character encoding to use. The allowed encodings are:

"Big5"	"ISO-8859-1"	"windows-932"
"EUC-JP"	"ISO-8859-2"	"windows-936"
"GBK"	"ISO-8859-3"	"windows-949"
"KSC_5601"	"ISO-8859-4"	"windows-950"
"Macintosh"	"ISO-8859-9"	"windows-1250"
"Shift_JIS"	"ISO-8859-13"	"windows-1251"
"US-ASCII"	"ISO-8859-15"	"windows-1252"
"UTF-8"		"windows-1253"
		"windows-1254"
		"windows-1257"

The default encoding is system dependent. If you specify the encoding incorrectly, characters might read incorrectly. Characters unrecognized by the encoding are replaced by the default substitution character for the specified encoding.

Encodings not listed here can be specified but might not produce correct results.

Return Values

Return value of the last statement of the file.

readbytes

Read binary data from a file

Syntax

```
readbytes(filename | n, <m>, <format>, <BigEndian | LittleEndian>, <ReturnType = DOM_HF
```

Description

`readbytes(file)` reads binary data from a file.

`readbytes` enables the user to read arbitrary files and interpret their contents as a sequence of numbers.

This function is particularly useful to work on data provided by or destined for external programs. You can use it, for example, to implement encryption or compression algorithms in MuPAD. Cf. “Example 2” on page 1-1708.

The results of `readbytes` depend on the interpretation of the binary data set by the `format` option. When reading a file, you can interpret it as a stream of `Byte`, `SignedByte`, `Short`, `SignedShort`, `Word`, `SignedWord`, `Float` or `Double`. These are standard formats that are used by many program packages to read data. Cf. “Example 1” on page 1-1707.

Be sure to read the data in the appropriate way. You need to know the format used by the program which created the file.

If a hardware float array with complex numbers is written to a file, then first the real parts of the elements are written and then the complex parts are written to the file. Because `readbytes` can only read real values, first one have to create the real and then the complex part to reconstruct the complex array. Cf. “Example 9” on page 1-1712.

The file may be specified directly by its name.

If a file name is specified, `readbytes` opens and closes the file automatically.

If READPATH has no value, readbytes interprets the file name as a pathname relative to the "working directory."

Note that the meaning of "working directory" depends on the operating system. On Microsoft Windows systems and on Mac OS X systems, the "working directory" is the folder where MuPAD is installed. On UNIX systems, it is the current working directory in which MuPAD was started; when started from a menu or desktop item, this is typically the user's home directory.

Absolute path names are processed by readbytes, too.

If a file name is specified, each call to readbytes opens the file at the beginning. If the file was opened via fopen, subsequent calls of readbytes with the corresponding file descriptor start at the point in the file that was reached by the last readbytescommand.

Hence, if you want to read a file by portions, you must open it with fopen and use the returned file descriptor instead of the filename. Cf. "Example 3" on page 1-1708.

Note: If the file is to be opened via fopen, be sure to pass the flag Raw to fopen. Otherwise, readbytes raises an error.

Note: If the number of bytes in the file in a readbytes call is not a multiple of units of the specified format, the data are read up to the last complete number. The remaining bytes are ignored. Cf. "Example 5" on page 1-1709.

Environment Interactions

The function readbytes is sensitive to the environment variable READPATH. First, the file is searched in the "working directory." If it cannot be found there, all paths in READPATH are searched.

The function writebytes is sensitive to the environment variable WRITEPATH. If this variable has a value, the file is created in the corresponding directory. Otherwise, the file is created in the "working directory."

Examples

Example 1

In this example, we write a sequence of numbers to the file `test.tst` with the default settings. Then, we load them back in:

```
writebytes("test.tst", [42, 17, 1, 3, 5, 7, 127, 250]):
readbytes("test.tst")
```

```
[42, 17, 1, 3, 5, 7, 127, 250]
```

We now read the above data with some other option: `SignedByte` interprets all values from 0 to 127 exactly as `Byte` does. Higher values x, however, are interpreted as x - 256. For example, 250 - 256 = - 6:

```
readbytes("test.tst", SignedByte)
```

```
[42, 17, 1, 3, 5, 7, 127, −6]
```

`Short` interprets two bytes to be one number. Therefore, the eight written bytes are interpreted as four numbers. For example, the first 2 bytes yield $42\,2^8 + 17 = 10769$:

```
readbytes("test.tst", Short)
```

```
[10769, 259, 1287, 32762]
```

With the flag `LittleEndian`, the byte order is reversed. For example, the first 2 bytes now yield $17\,2^8 + 42 = 4394$:

```
readbytes("test.tst", Short, LittleEndian)
```

```
[4394, 769, 1797, 64127]
```

`Word` interprets four bytes to be one number. Therefore, the eight written bytes give two numbers. The first 4 bytes yield $10769\,2^{16} + 259 = 705757443$:

```
readbytes("test.tst", Word)
```

```
[705757443, 84377594]
```

`Double` interprets eight bytes to represent one floating-point number. The interpretation is machine dependent and may be different for you:

```
readbytes("test.tst", Double)
```

$$\left[4.633737352\ 10^{-106}\right]$$

Example 2

We use `readbytes` and `writebytes` to encrypt the file created in the previous example with a simple "Caesar type encoding": Any integer x (a byte) is replaced by $x + 13 \bmod 256$:

```
L := readbytes("test.tst"):
L := map(L, x -> (x + 13 mod 256)):
writebytes("test.tst", L):
```

Knowing the encryption and its key, we can successfully decrypt the file:

```
L := readbytes("test.tst")
```

```
[55, 30, 14, 16, 18, 20, 140, 7]
```

```
map(L, x -> (x - 13 mod 256))
```

```
[42, 17, 1, 3, 5, 7, 127, 250]
```

```
delete L:
```

Example 3

In this example, we use `fopen` to write and read a file in portions:

```
n := fopen("test.tst", Write, Raw):
for i from 1 to 10 do writebytes(n, [i]) end_for:
```

```
fclose(n):
```

Equivalently, we could have written all data in one go:

```
n := fopen("test.tst", Write, Raw):
writebytes(n, [i $ i = 1..10]):
fclose(n):
```

We read the data byte by byte:

```
n := fopen("test.tst", Read, Raw):
readbytes(n, 1), readbytes(n, 1), readbytes(n, 1);
fclose(n):
```

```
[1], [2], [3]
```

The next command reads in portions of 5 bytes each:

```
n := fopen("test.tst", Read, Raw):
readbytes(n, 5), readbytes(n, 5);
fclose(n):
```

```
[1, 2, 3, 4, 5], [6, 7, 8, 9, 10]
```

```
delete n, i:
```

Example 4

An error is raised if the data do not match the specified format. Here, `-5` does not match `Byte`. This format does not include negative numbers:

```
writebytes("test.tst", [42, 17, -5, 7], Byte)
```

```
Error: The argument is invalid. [writebytes]
```

Example 5

Here we demonstrate what happens if the number of bytes in the file does not match a multiple of units of the specified format. Since both `SignedShort` and `Float` consist of an even number of bytes, the trailing 5-th byte corresponding to `11` is ignored:

```
writebytes("test.tst", [42, 17, 7, 9, 11], Byte):
readbytes("test.tst", SignedShort),
readbytes("test.tst", Float)
```

$$[10769, 1801], \left[1.28810279\ 10^{-13}\right]$$

Example 6

Here we show the effects of `BigEndian` and `LittleEndian`:

```
writebytes("test.tst", [129, 255, 145, 171, 191, 253], Byte):
L1 := readbytes("test.tst", Short, BigEndian)
```

$$[33279, 37291, 49149]$$

```
L2 := readbytes("test.tst", Short, LittleEndian)
```

$$[65409, 43921, 64959]$$

We look at the data in a binary representation (see `numlib::g_adic` for details). The effect of using `LittleEndian` instead of `BigEndian` is to exchange the first 8 bits and the last 8 bits of each number:

```
map(L1, numlib::g_adic, 2)
```

$$[[1, 1, 1, 1, 1, 1, 1, 1, 1, 0, 0, 0, 0, 0, 0, 1], [1, 1, 0, 1, 0, 1, 0, 1, 1, 0, 0, 0, 1, 0, 0, 1], [1, 0, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 0, 1]]$$

```
map(L2, numlib::g_adic, 2)
```

$$[[1, 0, 0, 0, 0, 0, 0, 1, 1, 1, 1, 1, 1, 1, 1, 1], [1, 0, 0, 0, 1, 0, 0, 1, 1, 1, 0, 1, 0, 1, 0, 1], [1, 1, 1, 1, 1, 1, 0, 1, 1, 0, 1, 1, 1, 1, 1, 1]]$$

```
delete L1, L2:
```

Example 7

We are writing the elements of a DOM_HFARRAY to a file. All the elements are double values and `writebytes` does not allow to write the elements of the array in another format than `Double`.

```
A:=hfarray(1..2,1..6,
   [   0.2703,   12.8317, -33.1531, 9999.9948, 0.2662,  -14.3421,
    1000.1801,    0.4521, -34.6787,  -67.3549, 0.6818,   13]):
writebytes("test.tst", A):
```

But if we try to write the elements as bytes we will get an error.

```
writebytes("test.tst", A, Byte);
```

```
Error: The argument is invalid. [writebytes]
```

```
delete A:
```

Example 8

Now we are reading data from a file and we are creating a DOM_HFARRAY with the data using the option `ReturnType`.

```
writebytes("test.tst",
  [    0.2703,   12.8317, -33.1531, 9999.9948, 0.2662,  -14.3421,
    1000.1801,    0.4521, -34.6787,  -67.3549, 0.6818,   13], Double):
readbytes("test.tst", ReturnType=[DOM_HFARRAY,2,6]);
readbytes("test.tst", ReturnType=[DOM_HFARRAY,2,3,2]);
```

$$\begin{pmatrix} 0.2703 & 12.8317 & -33.1531 & 9999.9948 & 0.2662 & -14.3421 \\ 1000.1801 & 0.4521 & -34.6787 & -67.3549 & 0.6818 & 13.0 \end{pmatrix}$$

```
hfarray(1..2, 1..3, 1..2, [0.2703, 12.8317, -33.1531, 9999.9948, 0.2662, -\
14.3421, 1000.1801, 0.4521, -34.6787, -67.3549, 0.6818, 13.0])
```

If we try to read more elements, exactly the elements of the array are read.

```
readbytes("test.tst", ReturnType=[DOM_HFARRAY,2,4]);
readbytes("test.tst", 12, ReturnType=[DOM_HFARRAY,2,3]);
```

$$\begin{pmatrix} 0.2703 & 12.8317 & -33.1531 & 9999.9948 \\ 0.2662 & -14.3421 & 1000.1801 & 0.4521 \end{pmatrix}$$

$$\begin{pmatrix} 0.2703 & 12.8317 & -33.1531 \\ 9999.9948 & 0.2662 & -14.3421 \end{pmatrix}$$

If we read just a part of the array, the other elements are initialized with 0.0.

```
readbytes("test.tst", ReturnType=[DOM_HFARRAY,2,7]);
readbytes("test.tst", 4, ReturnType=[DOM_HFARRAY,2,6]);
```

$$\begin{pmatrix} 0.2703 & 12.8317 & -33.1531 & 9999.9948 & 0.2662 & -14.3421 & 1000.1801 \\ 0.4521 & -34.6787 & -67.3549 & 0.6818 & 13.0 & 0.0 & 0.0 \end{pmatrix}$$

$$\begin{pmatrix} 0.2703 & 12.8317 & -33.1531 & 9999.9948 & 0.0 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 \end{pmatrix}$$

If we just try to read all the data from the file using the option `ReturnType` without a dimension for the `DOM_HFARRAY` a one dimensional array of the right size is created.

```
readbytes("test.tst", ReturnType=DOM_HFARRAY)
```

$$[[0.2703, 12.8317, -33.1531, 9999.9948, 0.2662, -14.3421, 1000.1801, 0.4521, -34.6787, -67.3549, 0.6818, 13.0]]$$

Example 9

We write a `DOM_HFARRAY` with complex numbers to a file and try to reconstruct it by reading the data.

```
A := hfarray(1..2, 1..3,
             [[2342.133 + 56*I, -342.56, PI + I],
              [           -3*E, I^2 + I,     13]]);
writebytes("test.tst", A);
fd := fopen("test.tst", Read, Raw):
B := readbytes(fd, ReturnType = [DOM_HFARRAY, 2, 3]);
```

```
C := readbytes(fd, ReturnType = [DOM_HFARRAY, 2, 3]);
bool(A = B + C*I);
flose(fd):
```

$$\begin{pmatrix} 2342.133 + 56.0\,i & -342.56 & 3.141592654 + 1.0\,i \\ -8.154845485 & -1.0 + 1.0\,i & 13.0 \end{pmatrix}$$

$$\begin{pmatrix} 2342.133 & -342.56 & 3.141592654 \\ -8.154845485 & -1.0 & 13.0 \end{pmatrix}$$

$$\begin{pmatrix} 56.0 & 0.0 & 1.0 \\ 0.0 & 1.0 & 0.0 \end{pmatrix}$$

TRUE

```
delete A, B, C, fd:
```

Example 10

Lets assume we have a DOM_HFARRAY with entries which are integer numbers between -32768 and 32767 and we want to write this data as SignedShort to a file. If we try it without the option Force we will get an error, because a floating-point number of type DOM_FLOAT cannot be written as a SignedShort. With the option Force writebytes tries to convert the floating-point number to a signed word and writes it in any case to the file.

```
A:=hfarray( 1..2,1..3, [[234,-32768,1],[32767,-12111,-3]]);
writebytes("test.tst", SignedShort, A):
```

$$\begin{pmatrix} 234.0 & -32768.0 & 1.0 \\ 32767.0 & -12111.0 & -3.0 \end{pmatrix}$$

```
Error: The argument is invalid. [writebytes]
```

```
writebytes("test.tst", SignedShort, Force, A):
l:= readbytes("test.tst", SignedShort);
op(A,i)-l[i] $i=1..6;
```

```
[234, -32768, 1, 32767, -12111, -3]

0.0, 0.0, 0.0, 0.0, 0.0, 0.0

delete A, 1:
```

Parameters

`filename`

The name of a file: a character string

`n`

A file descriptor provided by `fopen`: a positive integer. The file must have been be opened using the `fopen`-flag `Raw`.

`m`

The number of values to be read or written: a positive integer.

`format`

The format of binary data. Permissible values are `Byte`, `SignedByte`, `Short`, `SignedShort`, `Word`, `SignedWord`, `Float`, and `Double`.

Options

`Byte`, `SignedByte`, `Short`, `SignedShort`, `SignedWord`, `Word`, `Double`, `Float`

The format of the binary data. The default format is `Byte`.

A byte is an 8-bit binary number. Therefore, a byte can have 2^8 different values. For `Byte`, these are the integers from 0 to 255. For `SignedByte`, they are the integers from -128 to 127.

With `Byte`, the data are read/written in 8-bit blocks, interpreted as unsigned bytes. When writing, the numbers are checked for being in the range from 0 to 255.

With `SignedByte`, the data are read or written using the 2-complement.

`Byte` is the default format.

A “short” is a 16-bit binary number (2 bytes). Therefore, a “short” can have 2^{16} different values. For `Short`, these are the integers from 0 to 65536. For `SignedShort`, they are the integers from - 32768 to 32767.

The semantics of `Short` or `SignedShort` is analogous to that of `Byte` or `SignedByte`, respectively.

A “word” is a 32-bit binary number (4 bytes). Therefore, a “word” can have 2^{32} different values. For `Word`, these are the integers from 0 to 4294967296. For `SignedWord`, they are the integers from - 2147483648 to 2147483647.

The semantics of `Word` or `SignedWord` is analogous to that of `Byte` or `SignedByte`, respectively.

A “float” is a 32-bit representation of a real number (4 bytes). A “double” is a 64-bit representation of a real number (8 bytes).

Note: Floats and doubles are read/written in the format of the machine/operating system MuPAD is currently running on. Therefore, the results may differ between different platforms.

Binary files containing floating-point numbers are, in general, not portable to other platforms.

See the flags `BigEndian` and `LittleEndian` for details on the byte ordering.

See “Example 1” on page 1-1707 for an overview over the different format options.

`BigEndian`, `LittleEndian`

The byte ordering: either `BigEndian` or `LittleEndian`. The default odering is `BigEndian`.

`BigEndian` and `LittleEndian` specify the order in which the bytes are arranged for `Short`, `SignedShort`, `Word`, `SignedWord`, `Float`, and `Double`.

For all formats, the data are written in 8-bit blocks (bytes). This also includes the formats where a unit is longer than one byte (all formats but `Byte` and `SignedByte`). With `BigEndian`, the bytes with the most significant bits ("high bits") are written first. With `LittleEndian`, the bytes with the least significant bits are written first.

If, for example, `Short` is selected, there are 16 bits that are to be written. If you pass `BigEndian`, first the byte with the bits for 2^{15} to 2^{8} and then the byte with the bits for 2^{7} to 2^{0} are written. If you specify `LittleEndian`, the order of the bytes is reversed.

`BigEndian` and `LittleEndian` have no effect if the formats `Byte` or `SignedByte` are specified.

`BigEndian` is the default byte order.

Cf. "Example 6" on page 1-1710 for the effects of `BigEndian` and `LittleEndian`.

`Force`

Write the binary data in any case even if the numbers does not match the given format.

If the option `Force` is set, data are written in the given format, e.g. `Byte` even if they does not have the right format. E.g. 100.00 is a `DOM_FLOAT` and normally `writebytes` only writes this data if the format is `Float` or `Double`. With the option `Force` the value is written as a `Byte`. Cf. "Example 10" on page 1-1713.

If the given value does not fit the given data format, the written value is not specified. E.g. 53425.00 written as a `Byte` can be 177 which is `53425.00 mod 256` or just 0. But for sure 100.00 is written as 100.

`ReturnType`

Option, specified as `ReturnType = DOM_HFARRAY | DOM_LIST | [DOM_HFARRAY] | [DOM_HFARRAY, dim1, dim2, …]`that sets the type of the return value.

If set to `DOM_LIST`, the return value is a list which contains the read data.

If set to `DOM_HFARRAY`, the return value is a one dimensional array which contains the read data.

If set to [`DOM_HFARRAY`, $\texttt{dim}_1$, $\texttt{dim}_2$, …], the return value is a (multidimensional) array and $\texttt{dim}_1$, $\texttt{dim}_2$, … are positive integers which specifies the size of the dimensions of the array.

Return Values

`readbytes` returns a list of MuPAD numbers (either integers or floating-point numbers) or an array of hardware floats of type `DOM_HFARRAY`. Its type depends on the setting of the option `ReturnType`; `writebytes` returns the void object `null()` of type `DOM_NULL`.

writebytes

Write binary data to a file

Syntax

```
writebytes(filename | n, list | hfarray, <format>, <BigEndian | LittleEndian>, <Force>)
```

Description

`writebytes(file, list)` writes binary data to a file.

`writebytes(file, hfarray)` writes binary data to a file.

`writebytes` enables the user to write arbitrary files and interpret their contents as a sequence of numbers.

This function is particularly useful to work on data provided by or destined for external programs. You can use it, for example, to implement encryption or compression algorithms in MuPAD. Cf. “Example 2” on page 1-1721.

The results of `writebytes` depend on the interpretation of the binary data set by the `format` option. When writing a file, you can interpret it as a stream of `Byte`, `SignedByte`, `Short`, `SignedShort`, `Word`, `SignedWord`, `Float` or `Double`. These are standard formats that are used by many program packages to write data. Cf. “Example 1” on page 1-1720.

Be sure to write the data in the appropriate way. You need to know the format used by the program which is supposed to read the file.

When writing data via `writebytes`, each entry in the list is checked for whether it can be converted to the specified format. If this is not the case, `writebytes` raises an error. Cf. “Example 4” on page 1-1722.

When writing an array of hardware floats of type `DOM_HFARRAY` only `Double` is allowed as the binary format. If no format option is given hardware floats arrays are written as doubles. Cf. “Example 7” on page 1-1724.

If a hardware float array with complex numbers is written to a file, then first the real parts of the elements are written and then the complex parts are written to the file. Because `readbytes` can only read real values, first one have to create the real and then the complex part to reconstruct the complex array. Cf. “Example 9” on page 1-1725.

The file may be specified directly by its name. In this case, `writebytes` creates a new file or overwrites an existing file.

If a file name is specified, `writebytes` opens and closes the file automatically.

If `WRITEPATH` has no value `writebytes` interprets the file name as a pathname relative to the “working directory.”

Note that the meaning of “working directory” depends on the operating system. On Microsoft Windows systems and on Mac OS X systems, the “working directory” is the folder where MuPAD is installed. On UNIX systems, it is the current working directory in which MuPAD was started; when started from a menu or desktop item, this is typically the user's home directory.

Absolute path names are processed by `writebytes`, too.

If a file name is specified, each call to `writebytes` opens the file at the beginning. If the file was opened via `fopen`, subsequent calls of `writebytes` with the corresponding file descriptor start at the point in the file that was reached by the last `writebytes` command.

Hence, if you want to write a file by portions, you must open it with `fopen` and use the returned file descriptor instead of the filename. Cf. “Example 3” on page 1-1722.

Note: If the file is to be opened via `fopen`, be sure to pass the flag `Raw` to `fopen`. Otherwise, `writebytes` raises an error.

If `writebytes` is used with the option `ReturnType` = [`DOM_HFARRAY`, $\texttt{dim}_1$, $\texttt{dim}_2$, …]the return value is a `DOM_HFARRAY` of the appropriate size. Here $\texttt{dim}_1$, $\texttt{dim}_2$, … and positive integers which specifies the size of the dimensions of the array. If the file contains lesser values or the number of values to be read is limited, the not read elements of the array are initialized to 0.0. In other cases exactly the elements of the array are read. Cf. “Example 8” on page 1-1724.

Environment Interactions

The function `readbytes` is sensitive to the environment variable `READPATH`. First, the file is searched in the "working directory." If it cannot be found there, all paths in `READPATH` are searched.

The function `writebytes` is sensitive to the environment variable `WRITEPATH`. If this variable has a value, the file is created in the corresponding directory. Otherwise, the file is created in the "working directory."

Examples

Example 1

In this example, we write a sequence of numbers to the file `test.tst` with the default settings. Then, we load them back in:

```
writebytes("test.tst", [42, 17, 1, 3, 5, 7, 127, 250]):

readbytes("test.tst")
```

```
[42, 17, 1, 3, 5, 7, 127, 250]
```

We now read the above data with some other option: `SignedByte` interprets all values from 0 to 127 exactly as `Byte` does. Higher values x, however, are interpreted as x - 256. For example, 250 - 256 = - 6:

```
readbytes("test.tst", SignedByte)
```

```
[42, 17, 1, 3, 5, 7, 127, −6]
```

`Short` interprets two bytes to be one number. Therefore, the eight written bytes are interpreted as four numbers. For example, the first 2 bytes yield $42\,2^8 + 17 = 10769$:

```
readbytes("test.tst", Short)
```

```
[10769, 259, 1287, 32762]
```

With the flag `LittleEndian`, the byte order is reversed. For example, the first 2 bytes now yield $17\,2^8 + 42 = 4394$:

```
readbytes("test.tst", Short, LittleEndian)
```

```
[4394, 769, 1797, 64127]
```

`Word` interprets four bytes to be one number. Therefore, the eight written bytes give two numbers. The first 4 bytes yield $10769\,2^{16} + 259 = 705757443$:

```
readbytes("test.tst", Word)
```

```
[705757443, 84377594]
```

`Double` interprets eight bytes to represent one floating-point number. The interpretation is machine dependent and may be different for you:

```
readbytes("test.tst", Double)
```

$$\left[4.633737352\ 10^{-106}\right]$$

Example 2

We use `readbytes` and `writebytes` to encrypt the file created in the previous example with a simple "Caesar type encoding": Any integer x (a byte) is replaced by $x + 13 \bmod 256$:

```
L := readbytes("test.tst"):
L := map(L, x -> (x + 13 mod 256)):
writebytes("test.tst", L):
```

Knowing the encryption and its key, we can successfully decrypt the file:

```
L := readbytes("test.tst")
```

```
[55, 30, 14, 16, 18, 20, 140, 7]
```

```
map(L, x -> (x - 13 mod 256))
```

```
[42, 17, 1, 3, 5, 7, 127, 250]
```

```
delete L:
```

Example 3

In this example, we use `fopen` to write and read a file in portions:

```
n := fopen("test.tst", Write, Raw):
for i from 1 to 10 do writebytes(n, [i]) end_for:
fclose(n):
```

Equivalently, we could have written all data in one go:

```
n := fopen("test.tst", Write, Raw):
writebytes(n, [i $ i = 1..10]):
fclose(n):
```

We read the data byte by byte:

```
n := fopen("test.tst", Read, Raw):
readbytes(n, 1), readbytes(n, 1), readbytes(n, 1);
fclose(n):
```

```
[1], [2], [3]
```

The next command reads in portions of 5 bytes each:

```
n := fopen("test.tst", Read, Raw):
readbytes(n, 5), readbytes(n, 5);
fclose(n):
```

```
[1, 2, 3, 4, 5], [6, 7, 8, 9, 10]
```

```
delete n, i:
```

Example 4

An error is raised if the data do not match the specified format. Here, `-5` does not match `Byte`. This format does not include negative numbers:

```
writebytes("test.tst", [42, 17, -5, 7], Byte)
```

```
Error: The argument is invalid. [writebytes]
```

Example 5

Here we demonstrate what happens if the number of bytes in the file does not match a multiple of units of the specified format. Since both `SignedShort` and `Float` consist of an even number of bytes, the trailing 5-th byte corresponding to `11` is ignored:

```
writebytes("test.tst", [42, 17, 7, 9, 11], Byte):
readbytes("test.tst", SignedShort),
readbytes("test.tst", Float)
```

$$[10769, 1801], \left[1.28810279\ 10^{-13}\right]$$

Example 6

Here we show the effects of `BigEndian` and `LittleEndian`:

```
writebytes("test.tst", [129, 255, 145, 171, 191, 253], Byte):
L1 := readbytes("test.tst", Short, BigEndian)
```

$$[33279, 37291, 49149]$$

```
L2 := readbytes("test.tst", Short, LittleEndian)
```

$$[65409, 43921, 64959]$$

We look at the data in a binary representation (see `numlib::g_adic` for details). The effect of using `LittleEndian` instead of `BigEndian` is to exchange the first 8 bits and the last 8 bits of each number:

```
map(L1, numlib::g_adic, 2)
```

$$[[1, 1, 1, 1, 1, 1, 1, 1, 1, 0, 0, 0, 0, 0, 0, 1], [1, 1, 0, 1, 0, 1, 0, 1, 1, 0, 0, 0, 1, 0, 0, 1], [1, 0, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 0, 1]]$$

```
map(L2, numlib::g_adic, 2)
```

```
[[1, 0, 0, 0, 0, 0, 0, 1, 1, 1, 1, 1, 1, 1, 1, 1], [1, 0, 0, 0, 1, 0, 0, 1, 1, 1, 0, 1, 0, 1, 0, 1],
  [1, 1, 1, 1, 1, 1, 0, 1, 1, 0, 1, 1, 1, 1, 1, 1]]
```

```
delete L1, L2:
```

Example 7

We are writing the elements of a DOM_HFARRAY to a file. All the elements are double values and writebytes does not allow to write the elements of the array in another format than Double.

```
A:=hfarray(1..2,1..6,
   [   0.2703,   12.8317, -33.1531, 9999.9948, 0.2662,  -14.3421,
    1000.1801,    0.4521, -34.6787,  -67.3549, 0.6818,   13]):
writebytes("test.tst", A):
```

But if we try to write the elements as bytes we will get an error.

```
writebytes("test.tst", A, Byte);
```

```
Error: The argument is invalid. [writebytes]
```

```
delete A:
```

Example 8

Now we are reading data from a file and we are creating a DOM_HFARRAY with the data using the option ReturnType.

```
writebytes("test.tst",
  [   0.2703,   12.8317, -33.1531, 9999.9948, 0.2662,  -14.3421,
    1000.1801,    0.4521, -34.6787,  -67.3549, 0.6818,   13], Double):
readbytes("test.tst", ReturnType=[DOM_HFARRAY,2,6]);
readbytes("test.tst", ReturnType=[DOM_HFARRAY,2,3,2]);
```

$$\begin{pmatrix} 0.2703 & 12.8317 & -33.1531 & 9999.9948 & 0.2662 & -14.3421 \\ 1000.1801 & 0.4521 & -34.6787 & -67.3549 & 0.6818 & 13.0 \end{pmatrix}$$

```
hfarray(1..2, 1..3, 1..2, [0.2703, 12.8317, -33.1531, 9999.9948, 0.2662, -\
14.3421, 1000.1801, 0.4521, -34.6787, -67.3549, 0.6818, 13.0])
```

If we try to read more elements, exactly the elements of the array are read.

```
readbytes("test.tst", ReturnType=[DOM_HFARRAY,2,4]);
readbytes("test.tst", 12, ReturnType=[DOM_HFARRAY,2,3]);
```

$$\begin{pmatrix} 0.2703 & 12.8317 & -33.1531 & 9999.9948 \\ 0.2662 & -14.3421 & 1000.1801 & 0.4521 \end{pmatrix}$$

$$\begin{pmatrix} 0.2703 & 12.8317 & -33.1531 \\ 9999.9948 & 0.2662 & -14.3421 \end{pmatrix}$$

If we read just a part of the array, the other elements are initialized with 0.0.

```
readbytes("test.tst", ReturnType=[DOM_HFARRAY,2,7]);
readbytes("test.tst", 4, ReturnType=[DOM_HFARRAY,2,6]);
```

$$\begin{pmatrix} 0.2703 & 12.8317 & -33.1531 & 9999.9948 & 0.2662 & -14.3421 & 1000.1801 \\ 0.4521 & -34.6787 & -67.3549 & 0.6818 & 13.0 & 0.0 & 0.0 \end{pmatrix}$$

$$\begin{pmatrix} 0.2703 & 12.8317 & -33.1531 & 9999.9948 & 0.0 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 \end{pmatrix}$$

If we just try to read all the data from the file using the option `ReturnType` without a dimension for the `DOM_HFARRAY` a one dimensional array of the right size is created.

```
readbytes("test.tst", ReturnType=DOM_HFARRAY)
```

$$[[0.2703, 12.8317, -33.1531, 9999.9948, 0.2662, -14.3421, 1000.1801, 0.4521, -34.6787, -67.3549, 0.6818, 13.0]]$$

Example 9

We write a `DOM_HFARRAY` with complex numbers to a file and try to reconstruct it by reading the data.

```
A := hfarray(1..2, 1..3,
             [[2342.133 + 56*I, -342.56, PI + I],
```

```
              [           -3*E, I^2 + I,     13]]);
writebytes("test.tst", A);
fd := fopen("test.tst", Read, Raw):
B := readbytes(fd, ReturnType = [DOM_HFARRAY, 2, 3]);
C := readbytes(fd, ReturnType = [DOM_HFARRAY, 2, 3]);
bool(A = B + C*I);
flose(fd):
```

$$\begin{pmatrix} 2342.133 + 56.0\,i & -342.56 & 3.141592654 + 1.0\,i \\ -8.154845485 & -1.0 + 1.0\,i & 13.0 \end{pmatrix}$$

$$\begin{pmatrix} 2342.133 & -342.56 & 3.141592654 \\ -8.154845485 & -1.0 & 13.0 \end{pmatrix}$$

$$\begin{pmatrix} 56.0 & 0.0 & 1.0 \\ 0.0 & 1.0 & 0.0 \end{pmatrix}$$

TRUE

```
delete A, B, C, fd:
```

Example 10

Lets assume we have a DOM_HFARRAY with entries which are integer numbers between -32768 and 32767 and we want to write this data as SignedShort to a file. If we try it without the option Force we will get an error, because a floating-point number of type DOM_FLOAT cannot be written as a SignedShort. With the option Force writebytes tries to convert the floating-point number to a signed word and writes it in any case to the file.

```
A:=hfarray( 1..2,1..3, [[234,-32768,1],[32767,-12111,-3]]);
writebytes("test.tst", SignedShort, A):
```

$$\begin{pmatrix} 234.0 & -32768.0 & 1.0 \\ 32767.0 & -12111.0 & -3.0 \end{pmatrix}$$

```
Error: The argument is invalid. [writebytes]
```

```
writebytes("test.tst", SignedShort, Force, A):
l:= readbytes("test.tst", SignedShort);
op(A,i)-l[i] $i=1..6;
```

$$[234, -32768, 1, 32767, -12111, -3]$$

$$0.0, 0.0, 0.0, 0.0, 0.0, 0.0$$

```
delete A, l:
```

Parameters

`filename`

The name of a file: a character string

`n`

A file descriptor provided by `fopen`: a positive integer. The file must have been be opened using the `fopen`-flag `Raw`.

`list`

A list of MuPAD numbers that are to be written to the file. The entries must match the specified `format`.

`hfarray`

An array of hardware floats of type `DOM_HFARRAY`.

`format`

The format of binary data. Permissible values are `Byte`, `SignedByte`, `Short`, `SignedShort`, `Word`, `SignedWord`, `Float`, and `Double`.

Options

`Byte`, `SignedByte`, `Short`, `SignedShort`, `SignedWord`, `Word`, `Double`, `Float`

The format of the binary data. The default format is `Byte`.

A byte is an 8-bit binary number. Therefore, a byte can have 2^8 different values. For `Byte`, these are the integers from 0 to 255. For `SignedByte`, they are the integers from -128 to 127.

With `Byte`, the data are read/written in 8-bit blocks, interpreted as unsigned bytes. When writing, the numbers are checked for being in the range from 0 to 255.

With `SignedByte`, the data are read or written using the 2-complement.

`Byte` is the default format.

A "short" is a 16-bit binary number (2 bytes). Therefore, a "short" can have 2^{16} different values. For `Short`, these are the integers from 0 to 65536. For `SignedShort`, they are the integers from - 32768 to 32767.

The semantics of `Short` or `SignedShort` is analogous to that of `Byte` or `SignedByte`, respectively.

A "word" is a 32-bit binary number (4 bytes). Therefore, a "word" can have 2^{32} different values. For `Word`, these are the integers from 0 to 4294967296. For `SignedWord`, they are the integers from - 2147483648 to 2147483647.

The semantics of `Word` or `SignedWord` is analogous to that of `Byte` or `SignedByte`, respectively.

The format of the binary data. The default format is `Byte`.

A "float" is a 32-bit representation of a real number (4 bytes). A "double" is a 64-bit representation of a real number (8 bytes).

Note: Floats and doubles are read/written in the format of the machine/operating system MuPAD is currently running on. Therefore, the results may differ between different platforms.

Binary files containing floating-point numbers are, in general, not portable to other platforms.

See the flags `BigEndian` and `LittleEndian` for details on the byte ordering.

See "Example 1" on page 1-1720 for an overview over the different format options.

BigEndian, LittleEndian

The byte ordering: either `BigEndian` or `LittleEndian`. The default odering is `BigEndian`.

`BigEndian` and `LittleEndian` specify the order in which the bytes are arranged for `Short`, `SignedShort`, `Word`, `SignedWord`, `Float`, and `Double`.

For all formats, the data are written in 8-bit blocks (bytes). This also includes the formats where a unit is longer than one byte (all formats but `Byte` and `SignedByte`). With `BigEndian`, the bytes with the most significant bits ("high bits") are written first. With `LittleEndian`, the bytes with the least significant bits are written first.

If, for example, `Short` is selected, there are 16 bits that are to be written. If you pass `BigEndian`, first the byte with the bits for 2^{15} to 2^{8} and then the byte with the bits for 2^{7} to 2^{0} are written. If you specify `LittleEndian`, the order of the bytes is reversed.

`BigEndian` and `LittleEndian` have no effect if the formats `Byte` or `SignedByte` are specified.

`BigEndian` is the default byte order.

See "Example 6" on page 1-1723 for the effects of `BigEndian` and `LittleEndian`.

Force

Write the binary data in any case even if the numbers does not match the given format.

If the option `Force` is set, data are written in the given format, e.g. `Byte` even if they does not have the right format. E.g. 100.00 is a `DOM_FLOAT` and normally `writebytes` only writes this data if the format is `Float` or `Double`. With the option `Force` the value is written as a `Byte`. Cf. "Example 10" on page 1-1726.

If the given value does not fit the given data format, the written value is not specified. E.g. 53425.00 written as a `Byte` can be 177 which is `53425.00 mod 256` or just 0. But for sure 100.00 is written as 100.

ReturnType

Option, specified as `ReturnType = DOM_HFARRAY | DOM_LIST | [DOM_HFARRAY] | [DOM_HFARRAY, dim1, dim2, …]` that sets the type of the return value.

If set to DOM_LIST, the return value is a list which contains the read data.

If set to DOM_HFARRAY, the return value is a one dimensional array which contains the read data.

If set to [DOM_HFARRAY, dim_1, dim_2, ...], the return value is a (multidimensional) array and dim_1, dim_2, ... are positive integers which specifies the size of the dimensions of the array.

Return Values

readbytes returns a list of MuPAD numbers (either integers or floating-point numbers) or an array of hardware floats of type DOM_HFARRAY. Its type depends on the setting of the option ReturnType; writebytes returns the void object null() of type DOM_NULL.

repeat, until, end_repeat, _repeat

"repeat" loop

Syntax

```
repeat
  body
until condition end_repeat

_repeat(body, condition)
```

Description

`repeat - end_repeat` is a loop that evaluates its body until a specified stopping criterion is satisfied.

In a `repeat` loop, first `body` and then `condition` are evaluated until `condition` evaluates to `TRUE`.

In contrast to the `while` loop, the body of a `repeat` loop is always evaluated at least once.

The body may consist of any number of statements which must be separated either by a colon `:` or a semicolon `;`. Only the last evaluated result inside the body (the return value of the loop) is printed on the screen. Use `print` to see intermediate results.

The Boolean expression `condition` must be reducible to either `TRUE` or `FALSE`. Internally, the condition is evaluated in the lazy evaluation context of the functions `_lazy_and` and `_lazy_or`.

The statements `next` and `break` can be used in `repeat` loops in the same way as in `for` loops.

The keyword `end_repeat` may be replaced by the keyword `end`.

The imperative form `repeat - end_repeat` is equivalent to corresponding call of the function `_repeat`. In most cases, the imperative form should be preferred because it leads to simpler code.

The $-operator is often a more elegant notation for loops.

`_repeat` is a function of the system kernel.

Examples

Example 1

Intermediate results of statements within a `repeat` and `while` loop are not printed to the screen:

```
i := 1:
s := 0:
while i < 3 do
  s := s + i;
  i := i + 1;
end_while
```

```
3
```

Above, only the return value of the loop is displayed. Use `print` to see intermediate results:

```
i := 1:
s := 0:
while i < 3 do
  print("intermediate sum" = s);
  s := s + i;
  i := i + 1;
  s
end_while
```

```
"intermediate sum" = 0

"intermediate sum" = 1

3
```

```
delete i, s:
```

Example 2

A simple example is given, how a `repeat` loop can be expressed via an equivalent `while` loop. For other examples, this may be more complicated and additional initializations of variables may be needed:

```
i := 1:
repeat
  print(i);
  i := i + 1;
until i = 3 end:
```

```
    1

    2
```

```
i := 1:
while i < 3 do
  print(i);
  i := i + 1;
end:
```

```
    1

    2
```

```
delete i:
```

Example 3

The Boolean expression `condition` must evaluate to `TRUE` or `FALSE`:

```
condition := UNKNOWN:
while not condition do
  print(Condition = condition);
  condition := TRUE;
end_while:
```

```
Error: The Boolean 'TRUE' or 'FALSE' is expected. [while]
```

To avoid this error, change the stopping criterion to `condition <> TRUE`:

```
condition := UNKNOWN:
while condition <> TRUE do
  print(Condition = condition);
  condition := TRUE;
end_while:
```

```
Condition = UNKNOWN
```

```
delete condition:
```

Example 4

We demonstrate the correspondence between the functional and the imperative form of the `repeat` and `while` loop, respectively:

```
hold(_repeat((statement1; statement2), condition))
```

```
repeat
  statement1;
  statement2
until condition end_repeat
```

```
hold(_while(condition, (statement1; statement2)))
```

```
while condition do
  statement1;
  statement2
end_while
```

Parameters

`body`

The body of the loop: an arbitrary sequence of statements

`condition`

A Boolean expression

Return Values

Value of the last command executed in the body of the loop. If no command was executed, the value `NIL` is returned. If the body of a `while` loop is not evaluated due to a false condition, the void object of type `DOM_NULL` is returned.

More About

- "Loops"

while, end_while, _while

"while" loop

Syntax

```
while condition do
  body
end_while
```

```
_while(condition, body)
```

Description

`while - end_while` represents a loop that evaluates its body while a specified condition holds true.

In a `while` loop, `condition` is evaluated before the body is executed for the first time. If `condition` evaluates to `TRUE`, the loop is entered and `body` and `condition` are evaluated until `condition` evaluates to `FALSE`.

In contrast to the `while` loop, the body of a `repeat` loop is always evaluated at least once.

The body may consist of any number of statements which must be separated either by a colon `:` or a semicolon `;`. Only the last evaluated result inside the body (the return value of the loop) is printed on the screen. Use `print` to see intermediate results.

The Boolean expression `condition` must be reducible to either `TRUE` or `FALSE`. Internally, the condition is evaluated in the lazy evaluation context of the functions `_lazy_and` and `_lazy_or`.

The statements `next` and `break` can be used in `while` loops in the same way as in `for` loops.

The keyword `end_while` may be replaced by the keyword `end`.

The imperative form `while - end_while` is equivalent to corresponding call of the function `_while`. In most cases, the imperative form should be preferred because it leads to simpler code.

The $-operator is often a more elegant notation for loops.

_while is a function of the system kernel.

Examples

Example 1

Intermediate results of statements within a repeat and while loop are not printed to the screen:

```
i := 1:
s := 0:
while i < 3 do
  s := s + i;
  i := i + 1;
end_while
```

```
     3
```

Above, only the return value of the loop is displayed. Use print to see intermediate results:

```
i := 1:
s := 0:
while i < 3 do
  print("intermediate sum" = s);
  s := s + i;
  i := i + 1;
  s
end_while
```

```
     "intermediate sum" = 0

     "intermediate sum" = 1

     3
```

```
delete i, s:
```

Example 2

A simple example is given, how a `repeat` loop can be expressed via an equivalent `while` loop. For other examples, this may be more complicated and additional initializations of variables may be needed:

```
i := 1:
repeat
  print(i);
  i := i + 1;
until i = 3 end:
```

```
    1
```

```
    2
```

```
i := 1:
while i < 3 do
  print(i);
  i := i + 1;
end:
```

```
    1
```

```
    2
```

```
delete i:
```

Example 3

The Boolean expression `condition` must evaluate to `TRUE` or `FALSE`:

```
condition := UNKNOWN:
while not condition do
  print(Condition = condition);
  condition := TRUE;
end_while:
```

```
Error: The Boolean 'TRUE' or 'FALSE' is expected. [while]
```

To avoid this error, change the stopping criterion to `condition <> TRUE`:

```
condition := UNKNOWN:
while condition <> TRUE do
  print(Condition = condition);
  condition := TRUE;
end_while:
```

```
Condition = UNKNOWN
```

```
delete condition:
```

Example 4

We demonstrate the correspondence between the functional and the imperative form of the `repeat` and `while` loop, respectively:

```
hold(_repeat((statement1; statement2), condition))
```

```
repeat
  statement1;
  statement2
until condition end_repeat
```

```
hold(_while(condition, (statement1; statement2)))
```

```
while condition do
  statement1;
  statement2
end_while
```

Parameters

`body`

The body of the loop: an arbitrary sequence of statements

condition

A Boolean expression

Return Values

Value of the last command executed in the body of the loop. If no command was executed, the value `NIL` is returned. If the body of a `while` loop is not evaluated due to a false condition, the void object of type `DOM_NULL` is returned.

- "Loops"

rec

Domain of recurrence equations

Syntax

```
rec(eq, y(n), <cond>)
```

Description

`rec(eq, y(n))` creates an object of type `rec` representing a recurrence equation for the sequence `y(n)`.

The equation `eq` must involve only shifts `y(n + i)` with integer values of `i`; at least one such expression must be present in `eq`. An arithmetical expression`eq` is equivalent to the equation `eq = 0`.

Initial or boundary conditions `cond` must be specified as sets of equations of the form `{y(n0) = y0, y(n1) = y1, ...}` with arithmetical expressions `n0, n1, ...` that must not contain the identifier `n`, and arithmetical expressions `y0, y1, ...` that must not contain the identifier `y`.

The main purpose of the `rec` domain is to provide an environment for overloading the function `solve`. For a recurrence `r` of type `rec`, the call `solve(r)` returns a set representing an affine subspace of the complete solution space. Its only entry is an expression in `n` that may contain free parameters such as `C1`, `C2`, etc. See“Example 1” on page 1-1742, “Example 4” on page 1-1743, and “Example 5” on page 1-1743.

Currently only linear recurrences with coefficients that are rational functions of `n` can be solved. `solve` handles recurrences with constant coefficients, it finds hypergeometric solutions of first order recurrences, and polynomial solutions of higher order recurrences with non-constant coefficients.

`solve` is not always able to find the complete solution space. Cf. “Example 5” on page 1-1743. If `solve` cannot find a solution, then the `solve` call is returned symbolically. For parametric recurrences, the output of `solve` may be a conditionally defined set of type `piecewise`. Cf. “Example 6” on page 1-1743.

Examples

Example 1

The first command defines the homogeneous first order recurrence equation $y(n+1) = \frac{2\,(n+1)\,y(n)}{n}$ for the sequence $y(n)$. It is solved by a call to the `solve` function:

```
rec(y(n + 1) = 2*y(n)*(n + 1)/n, y(n))
```

$$\mathrm{rec}\left(y(n+1) - \frac{2\,y(n)\,(n+1)}{n},\ y(n),\ \varnothing\right)$$

```
solve(%)
```

$$\{2^n\ C1\ n\}$$

Thus, the general solution of the recurrence equation is $y(n) = C_1\, n\, 2^n$, where C_1 is an arbitrary constant.

Example 2

In the next example, the homogeneous first order recurrence $y(n + 1) = 3\,(n + 1)\,y(n)$ with the initial condition $y(0) = 1$ is solved for the unknown sequence $y(n)$:

```
solve(rec(y(n + 1) = 3*(n + 1)*y(n), y(n), {y(0) = 1}))
```

$$\{3^n\,\Gamma(n+1)\}$$

Thus, the solution is $y(n) = 3^n\,\Gamma(n+1) = 3^n\,n!$ for all integers $n \geq 0$ (*gamma* is the gamma function).

Example 3

In the following example, the inhomogeneous second order recurrence $y(n + 2) - 2\,y(n + 1) + y(n) = 2$ is solved for the unknown sequence $y(n)$. The initial conditions $y(0) = -1$ and $y(1) = m$ with some parameter m are taken into account by `solve`:

```
solve(rec(y(n + 2) - 2*y(n + 1) + y(n) = 2, y(n),
          {y(0) = -1, y(1) = m}))
```

$$\{n^2 + m\,n - 1\}$$

Example 4

We compute the general solution of the homogeneous second order recurrence $y(n + 2) + 3\,y(n + 1) + 2\,y(n) = 0$:

```
solve(rec(y(n + 2) + 3*y(n + 1) + 2*y(n), y(n)))
```

$$\{(-1)^n\,C7 + (-2)^n\,C6\}$$

Here, `C6` and `C7` are arbitrary constants.

Example 5

For the following homogeneous third order recurrence with non-constant coefficients, the system only finds the polynomial solutions:

```
solve(rec(n*y(n + 3) = (n + 3)*y(n), y(n)))
```

$$\{C9\,n\}$$

Example 6

The following homogeneous second order recurrence with constant coefficients involves a parameter `a`. The solution set depends on the value of this parameter, and `solve` returns a `piecewise` object:

```
solve(rec(a*y(n + 2) = y(n), y(n)))
```

$$\begin{cases} \{0\} & \text{if } a = 0 \\ \left\{C11\left(\frac{1}{\sqrt{a}}\right)^n + C10\left(-\frac{1}{\sqrt{a}}\right)^n\right\} & \text{if } a \neq 0 \end{cases}$$

Example 7

The following homogeneous second order recurrence with non-constant coefficients involves a parameter `a`. Although it has a polynomial solution for $a = 2$, the system does not recognize this:

```
solve(rec(n*y(n + 2) = (n + a)*y(n), y(n)))
```

```
{0}
```

Parameters

`eq`

An equation or an arithmetical expression

`y`

The unknown function: an identifier

`n`

The index: an identifier

`cond`

A set of initial or boundary conditions

Return Values

Object of type `rec`.

Algorithms

For homogeneous recurrences with constant coefficients, `solve` computes the roots of the characteristic polynomial. If some of them cannot be given in explicit form, i.e., only

by means of `RootOf`, then `solve` does not return a solution. Otherwise, the complete solution space is returned.

For first order homogeneous recurrences with nonconstant coefficients, `solve` returns the complete solution space if the coefficients of the recurrence can be factored into at most quadratic polynomials. Otherwise, `solve` does not return a solution.

For homogeneous recurrences of order at least two with nonconstant coefficients, `solve` finds the complete space of all *polynomial* solutions.

Currently, inhomogeneous recurrences can only be solved if they have a polynomial solution. The previous remarks apply.

For parametric recurrences, the system may not find solutions that are valid only for special values of the parameters. Cf. “Example 7” on page 1-1744.

MuPAD Functions

`ode` | `solve` | `sum`

rectform

Rectangular form of a complex expression

Syntax

```
rectform(z)
```

Description

`rectform(z)` computes the rectangular form of the complex expression z, i.e., it splits z into $z = \Re(z) + i\,\Im(z)$.

`rectform(z)` tries to split `z` into its real and imaginary part and to return `z` in the form $z = \Re(z) + i\,\Im(z)$.

`rectform` works recursively, i.e., it first tries to split each subexpression of `z` into its real and imaginary part and then tackles `z` as a whole.

Use `Re` and `Im` to extract the real and imaginary parts, respectively, from the result of `rectform`. See “Example 1” on page 1-1747.

`rectform` is more powerful than a direct application of `Re` and `Im` to `z`. However, usually it is much slower. For constant arithmetical expressions, it is therefore recommended to use the functions `Re` and `Im` directly. See “Example 2” on page 1-1748.

The main use of `rectform` is for symbolic expressions, and properties of identifiers are taken into account (see `assume`). An identifier without any property is assumed to be complex valued. See “Example 3” on page 1-1749.

If `z` is an array, a list, or a set, then `rectform` is applied to each entry of `z`.

If `z` is an hfarray, then `rectform` returns `z` unchanged.

If `z` is a polynomial or a series expansion, of type `Series::Puiseux` or `Series::gseries`, then `rectform` is applied to each coefficient of `z`.

See “Example 5” on page 1-1751.

The result `r := rectform(z)` is an element of the domain `rectform`. Such a domain element consists of three operands, satisfying the following equality: `z = op(r, 1) + I*op(r, 2) + op(r, 3)`. The first two operands are real arithmetical expressions, and the third operand is an expression that cannot be split into its real and imaginary part.

Sometimes `rectform` is unable to compute the required decomposition. Then it still tries to return some partial information by extracting as much as possible from the real and imaginary part of `z`. The extracted parts are stored in the first two operands, and the third operand contains the remainder, where no further extraction is possible. In extreme cases, the first two operands may even be zero. “Example 6” on page 1-1752 illustrates some possible cases.

Arithmetical operations with elements of the domain type `rectform` are possible. The result of an arithmetical operation is again an element of this domain (see “Example 4” on page 1-1749).

Most MuPAD functions handling arithmetical expressions (e.g., `expand`, `normal`, `simplify` etc.) can be applied to elements of type `rectform`. They act on each of the three operands individually.

Use `expr` to convert the result of `rectform` into an element of a basic domain. See “Example 4” on page 1-1749.

Environment Interactions

The function is sensitive to properties of identifiers set via `assume`. See “Example 3” on page 1-1749.

Examples

Example 1

The rectangular form of *sin*(*z*) for complex values *z* is:

```
delete z: r := rectform(sin(z))
```

$$\cosh(\Im(z))\,\sin(\Re(z)) + (\cos(\Re(z))\,\sinh(\Im(z)))\,i$$

The real and the imaginary part can be extracted as follows:

```
Re(r), Im(r)
```

$$\cosh(\Im(z))\,\sin(\Re(z)),\ \cos(\Re(z))\,\sinh(\Im(z))$$

The complex conjugate of `r` can be obtained directly:

```
conjugate(r)
```

$$\cosh(\Im(z))\,\sin(\Re(z)) - (\cos(\Re(z))\,\sinh(\Im(z)))\,i$$

Example 2

The real and the imaginary part of a constant arithmetical expression can be determined by the functions `Re` and `Im`, as in the following example:

```
Re(ln(-4)) + I*Im(ln(-4))
```

$$\ln(4) + \pi\,i$$

In fact, they work much faster than `rectform`. However, they fail to compute the real and the imaginary part of arbitrary symbolic expressions, such as for the term $e^{i\,sin(z)}$:

```
delete z: f := exp(I*sin(z)):
Re(f), Im(f)
```

$$\Re\left(e^{\sin(z)\,i}\right),\ \Im\left(e^{\sin(z)\,i}\right)$$

The function `rectform` is more powerful. It is able to split the expression above into its real and imaginary part:

```
r := rectform(f)
```

$$\cos(\cosh(\Im(z))\,\sin(\Re(z)))\,e^{-\cos(\Re(z))\,\sinh(\Im(z))} + \left(\sin(\cosh(\Im(z))\,\sin(\Re(z)))\,e^{-\cos(\Re(z))\,\sinh(\Im(z))}\right)i$$

Now we can extract the real and the imaginary part of `f`:

```
Re(r)
```

$$\cos(\cosh(\Im(z))\,\sin(\Re(z)))\,e^{-\cos(\Re(z))\,\sinh(\Im(z))}$$

```
Im(r)
```

$$\sin(\cosh(\Im(z))\,\sin(\Re(z)))\,e^{-\cos(\Re(z))\,\sinh(\Im(z))}$$

Example 3

Identifiers without properties are considered to be complex variables:

```
delete z: rectform(ln(z))
```

$$\frac{\ln(\Im(z)^2+\Re(z)^2)}{2}+\arg(\Im(z)\,i+\Re(z))\,i$$

However, you can affect the behavior of `rectform` by attaching properties to the identifiers. For example, if z assumes only real negative values, the real and the imaginary part simplify considerably:

```
assume(z < 0): rectform(ln(z))
```

$$\ln(-z)+\pi\,i$$

Example 4

We compute the rectangular form of the complex variable x:

```
delete x: a := rectform(x)
```

$$\Re(x)+\Im(x)\,i$$

Then we do the same for the real variable y:

```
delete y: assume(y, Type::Real): b := rectform(y)
```

$$y$$

```
domtype(a), domtype(b)
```

$$\text{rectform, rectform}$$

We have stored the results, i.e., the elements of domain type `rectform`, in the two identifiers `a` and `b`. We compute the sum of `a` and `b`, which is again of domain type `rectform`, i.e., it is already splitted into its real and imaginary part:

```
c := a + b
```

$$y + \Re(x) + \Im(x)\,\mathrm{i}$$

```
domtype(c)
```

$$\text{rectform}$$

The result of an arithmetical operation between an element of domain type `rectform` and an arbitrary arithmetical expression is of domain type `rectform` as well:

```
delete z: d := a + 2*b + exp(z)
```

$$2\,y + \Re(x) + \cos(\Im(z))\,\mathrm{e}^{\Re(z)} + \left(\Im(x) + \sin(\Im(z))\,\mathrm{e}^{\Re(z)}\right)\mathrm{i}$$

```
domtype(d)
```

$$\text{rectform}$$

Use the function `expr` to convert an element of domain type `rectform` into an element of a basic domain:

```
expr(d)
```

$$2\,y + \Im(x)\,\mathrm{i} + \Re(x) + \cos(\Im(z))\,\mathrm{e}^{\Re(z)} + \sin(\Im(z))\,\mathrm{e}^{\Re(z)}\,\mathrm{i}$$

```
domtype(%)
```

DOM_EXPR

Example 5

`rectform` also works for polynomials and series expansions, namely individually on each coefficient:

```
delete x, y: p := poly(ln(-4) + y*x, [x]):
rectform(p)
```

$$\mathrm{poly}((\Re(y) + \Im(y)\,\mathrm{i})\,x + \ln(4) + \pi\,\mathrm{i},\ [x])$$

Similarly, `rectform` works for lists, sets, or arrays, where it is applied to each individual entry:

```
a := array(1..2, [x, y]):
rectform(a)
```

$$(\ \Re(x) + \Im(x)\,\mathrm{i}\ \ \Re(y) + \Im(y)\,\mathrm{i}\ )$$

hfarrays are returned unchanged:

```
a := hfarray(1..2, [1.0, 2.0]):
rectform(a)
```

$$(\ 1.0\ \ 2.0\ )$$

Note that `rectform` does not work directly for other basic data types. For example, if the input expression is a table of arithmetical expressions, then `rectform` responds with an error message:

```
a := table("1st" = x, "2nd" = y):
rectform(a)
```

```
Error: An arithmetical expression is expected. [rectform::new]
```

Use `map` to apply `rectform` to the operands of such an object:

```
map(a, rectform)
```

"1st"	$\Im(x)\,\mathrm{i} + \Re(x)$
"2nd"	$\Im(y)\,\mathrm{i} + \Re(y)$

Example 6

This example illustrates the meaning of the three operands of an object returned by `rectform`.

We start with the expression $x + sin(y)$, for which `rectform` is able to compute a complete decomposition into real and imaginary part:

```
delete x, y: r := rectform(x + sin(y))
```

$$\Re(x) + \cosh(\Im(y))\,\sin(\Re(y)) + (\Im(x) + \cos(\Re(y))\,\sinh(\Im(y)))\,\mathrm{i}$$

The first two operands of `r` are the real and imaginary part of the expression, and the third operand is 0:

```
op(r)
```

$$\Re(x) + \cosh(\Im(y))\,\sin(\Re(y)),\ \Im(x) + \cos(\Re(y))\,\sinh(\Im(y)),\ 0$$

Next we consider the expression $x + f(y)$, where $f(y)$ represents an unknown function in a complex variable. `rectform` can split x into its real and imaginary part, but fails to do this for the subexpression $f(y)$:

```
delete f: r := rectform(x + f(y))
```

$$\Re(x) + \Im(x)\,\mathrm{i} + f(y)$$

The first two operands of the returned object are the real and the imaginary part of x, and the third operand is the remainder $f(y)$, for which `rectform` was not able to extract any information about its real and imaginary part:

```
op(r)
```

$$\Re(x),\ \Im(x),\ f(y)$$

```
Re(r), Im(r)
```

$$\Re(f(y)) + \Re(x),\ \Im(f(y)) + \Im(x)$$

Sometimes `rectform` is not able to extract any information about the real and imaginary part of the input expression. Then the third operand contains the whole input expression, possibly in a rewritten form, due to the recursive mode of operation of `rectform`. The first two operands are 0. Here is an example:

```
r := rectform(sin(x + f(y)))
```

$$\sin(\Im(x)\,\mathrm{i} + \Re(x) + f(y))$$

```
op(r)
```

$$0,\ 0,\ \sin(\Re(x) + f(y) + \Im(x)\,\mathrm{i})$$

```
Re(r), Im(r)
```

$$\Re(\sin(\Re(x) + f(y) + \Im(x)\,\mathrm{i})),\ \Im(\sin(\Re(x) + f(y) + \Im(x)\,\mathrm{i}))$$

Example 7

Advanced users can extend `rectform` to their own special mathematical functions (see section “Backgrounds” below). To this end, embed your mathematical function into a function environment`f` and implement the behavior of `rectform` for this function as the `"rectform"` slot of the function environment.

If a subexpression of the form `f(u,..)` occurs in `z`, then `rectform` issues the call `f::rectform(u,..)` to the slot routine to determine the rectangular form of `f(u,..)`.

For illustration, we show how this works for the sine function. Of course, the function environment `sin` already has a `"rectform"` slot. We call our function environment `Sin` in order not to overwrite the existing system function `sin`:

```
Sin := funcenv(Sin):
```

```
Sin::rectform := proc(u) // compute rectform(Sin(u))
  local r, a, b;
begin
  // recursively compute rectform of u
  r := rectform(u);

   if op(r, 3) <> 0 then
    // we cannot split Sin(u)
    new(rectform, 0, 0, Sin(u))
  else
    a := op(r, 1); // real part of u
    b := op(r, 2); // imaginary part of u
    new(rectform, Sin(a)*cosh(b), cos(a)*sinh(b), 0)
  end_if
end:

delete z: rectform(Sin(z))
```

$$\mathrm{Sin}(\Re(z))\cosh(\Im(z)) + (\cos(\Re(z))\sinh(\Im(z)))\,i$$

If the `if` condition is true, then `rectform` is unable to split `u` completely into its real and imaginary part. In this case, `Sin::rectform` is unable to split `Sin(u)` into its real and imaginary part and indicates this by storing the whole expression `Sin(u)` in the third operand of the resulting `rectform` object:

```
delete f: rectform(Sin(f(z)))
```

$$\mathrm{Sin}(f(z))$$

```
op(%)
```

$$0,\ 0,\ \mathrm{Sin}(f(z))$$

Parameters

z

An arithmetical expression, a polynomial, a series expansion, an array, an hfarray, a list, or a set

Return Values

Element of the domain `rectform` if `z` is an arithmetical expression, and an object of the same type as `z` otherwise.

Function Calls

Calling an element of `rectform` as a function yields the object itself, regardless of the arguments. The arguments are *not* evaluated.

Operations

You can apply (almost) any function to elements of `rectform` which transforms a complex-valued expression into a complex-valued expression.

For example, you may add or multiply those elements, or apply functions such as `expand` and `diff` to them. The result of such an operation, which is not explicitely overloaded by a method of `rectform` (see below), is an element of `rectform`.

This "automatic overloading" works as follows: Each argument of the operation, which is an element of `rectform`, is converted to an expression using the method `"expr"` (see below). Then, the operation is applied and the result is re-converted to an element of `rectform`.

Use the function `expr` to convert an element of `rectform` to an arithmetical expression (as an element of a kernel domain).

The functions `Re` and `Im` return the real and imaginary part of elements of `rectform`.

Operands

An element *z* of `rectform` consists of three operands:

1. the real part of *z*,
2. the imaginary part of *z*,
3. the part of *z*, for that the real and imaginary part cannot be computed (possibly the integer 0, if there are not such subexpressions).

Algorithms

If a subexpression of the form `f(u,..)` occurs in `z` and `f` is a function environment, then `rectform` attempts to call the slot `"rectform"` of `f` to determine the rectangular form of `f(u,..)`. In this way, you can extend the functionality of `rectform` to your own special mathematical functions.

The slot `"rectform"` is called with the arguments `u,..` of `f`. If the slot routine `f::rectform` is not able to determine the rectangular form of `f(u,..)`, then it should return `new(rectform(0,0,f(u,..)))`. See “Example 7” on page 1-1753. If `f` does not have a slot `"rectform"`, then `rectform` returns the object `new(rectform(0,0,f(u,..)))` for the corresponding subexpression.

Similarly, if an element `d` of a library domain`T` occurs as a subexpression of `z`, then `rectform` attempts to call the slot `"rectform"` of that domain with `d` as argument to compute the rectangular form of `d`.

If the slot routine `T::rectform` is not able to determine the rectangular form of `d`, then it should return `new(rectform(0,0,d))`.

If the domain `T` does not have a slot `"rectform"`, then `rectform` returns the object `new(rectform(0,0,d))` for the corresponding subexpression.

rectangularPulse

Rectangular pulse function

Syntax

```
rectangularPulse(a, b, x)

rectangularPulse(x)
```

Description

`rectangularPulse(a, b, x)` represents the rectangular function.

`rectangularPulse(x)` is a shortcut for `rectangularPulse(-1/2, 1/2, x)`.

The rectangular function is also called the rectangle function, box function, Pi function, or gate function.

If `a` and `b` are variables or expressions with variables, `rectangularPulse` assumes that `a < b`. If `a` and `b` are numerical values, such that `a > b`, `rectangularPulse` throws an error.

If `a < x < b`, the rectangular pulse function equals 1. If `x = a` or `x = b`, the rectangular pulse function equals 1/2. Otherwise, it equals 0. See “Example 1” on page 1-1758 and “Example 2” on page 1-1758.

If `a = b`, `rectangularPulse` returns 0. See “Example 3” on page 1-1758.

`rectangularPulse(x)` is equivalent to `rectangularPulse(-1/2, 1/2, x)`. See “Example 4” on page 1-1758.

`rectangularPulse` also accepts infinities as its arguments. See “Example 7” on page 1-1760.

`rectangularPulse` and `rectpulse` are equivalent.

Examples

Example 1

Compute the rectangular pulse function for these input arguments:

```
[rectangularPulse(-1, 1, -2), rectangularPulse(-1, 1, -1),
rectangularPulse(-1, 1, 0), rectangularPulse(-1, 1, 1),
rectangularPulse(-1, 1, 2)]
```

$$\left[0, \frac{1}{2}, 1, \frac{1}{2}, 0\right]$$

Example 2

If `a < b`, the rectangular pulse function for `x = a` and `x = b` equals 1/2:

```
assume(a < b);
[rectangularPulse(a, b, a), rectangularPulse(a, b, b)]
```

$$\left[\frac{1}{2}, \frac{1}{2}\right]$$

Example 3

For `a = b`, the rectangular pulse function returns 0:

```
rectangularPulse(a, a, x)
```

$$0$$

Example 4

Use `rectangularPulse` with one input argument as a shortcut for computing `rectangularPulse(-1/2, 1/2, x)`:

```
rectangularPulse(x)
```

$$\text{rectangularPulse}\left(-\frac{1}{2}, \frac{1}{2}, x\right)$$

```
[rectangularPulse(-1), rectangularPulse(-1/2), rectangularPulse(0),
rectangularPulse(1/2), rectangularPulse(1)]
```

$$\left[0, \frac{1}{2}, 1, \frac{1}{2}, 0\right]$$

Example 5

Rewrite the rectangular pulse function in terms of the Heaviside step function:

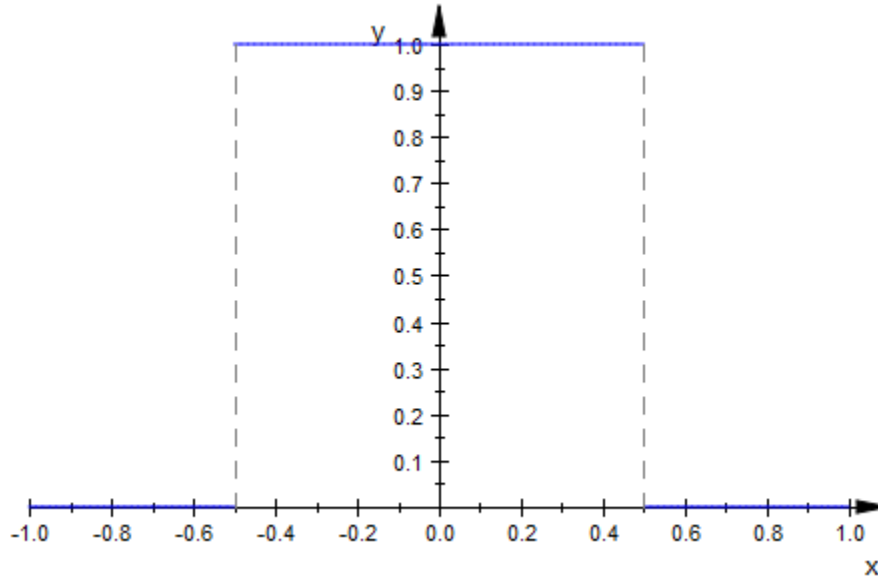
```
rewrite(rectangularPulse(a, b, x), heaviside)
```

$$\text{heaviside}(x-a) - \text{heaviside}(x-b)$$

Example 6

Plot the rectangular pulse function:

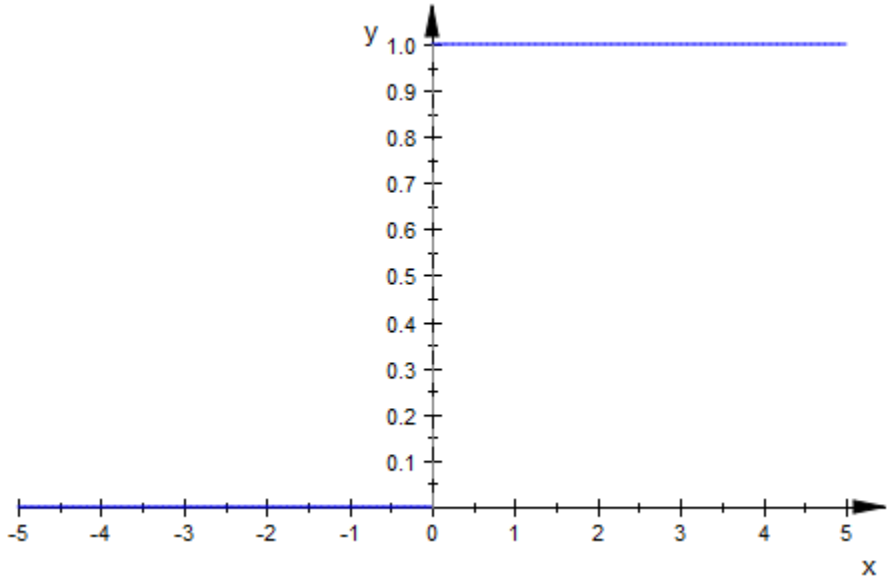
```
plot(rectangularPulse(x), x = -1..1)
```



Example 7

Plot the rectangular pulse function for which the argument b is a positive infinity:

```
plot(rectangularPulse(0, infinity, x))
```



Parameters

a, b, x

Arithmetical expressions.

Return Values

Arithmetical expression.

Overloaded By

x

See Also

MuPAD Functions
`heaviside` | `piecewise` | `triangularPulse`

rectpulse

Rectangular pulse function

Syntax

```
rectpulse(a, b, x)
```

```
rectpulse(x)
```

Description

`rectpulse(a, b, x)` represents the rectangular function.

`rectpulse(x)` is a shortcut for `rectpulse(-1/2, 1/2, x)`.

`rectpulse` and `rectangularPulse` are equivalent. These functions represent the triangular pulse function. For details and examples, see `rectangularPulse`.

Parameters

`a, b, x`

Arithmetical expressions.

Return Values

Arithmetical expression.

Overloaded By

x

See Also

MuPAD Functions

`heaviside` | `piecewise` | `rectangularPulse` | `triangularPulse`

rem

Remainder after division

Syntax

```
rem(a,b)
```

Description

`rem(a,b)` finds the remainder after division. If `b <> 0`, then `rem(a,b) = a - trunc(a/b)*b`. See “Example 1” on page 1-1764 and “Example 2” on page 1-1764.

If `b = 0` or `b = infinity` or `b = -infinity`, then `rem` returns `undefined`.

The `rem` function does not support complex numbers: all values must be real numbers.

Examples

Example 1

Find the remainder after division in case both the dividend and divisor are integers.

Find the modulus after division for these numbers.

```
rem(27, 4), rem(27, -4), rem(-27, 4), rem(-27, -4)
```

```
ans = 3, 3, -3, -3
```

Example 2

Find the remainder after division in case the dividend is a rational number, and the divisor is an integer.

Find the remainder after division for these numbers.

```
rem(22/3, 5), rem(1/2, -7), rem(27/6, -11)
```

$$\frac{7}{3}, \frac{1}{2}, \frac{9}{2}$$

Example 3

Find the remainder after division in case the dividend and divisor are floating-point numbers.

```
rem(2.3, 0.2), rem(-4.5, 1.3), rem(2.7, 1.0)
```

$$0.1, -0.6, 0.7$$

Parameters

a

A real number

b

A real number

Return Values

A number or an arithmetical expression.

Overloaded By

a, b

MuPAD Functions

`/` | `div` | `divide` | `frac` | `gcd` | `gcdex` | `igcd` | `igcdex` | `IntMod` | `mod` | `modp` | `mods` | `powermod`

reset

Re-initialize a session

Syntax

```
reset()
```

Description

`reset()` re-initializes a MuPAD session, so that the current session will behave like a freshly started MuPAD session.

`reset` deletes the values of all identifiers and resets the environment variables to their default values. Finally, the initialization files `sysinit.mu` and `userinit.mu` are read again.

`reset` is permitted only at interactive level. Within a procedure, an error occurs.

Examples

Example 1

`reset` deletes the values of all identifiers and resets environment variables to their default values:

```
a := 1: DIGITS := 5: reset(): a, DIGITS
```

$$a, 10$$

Return Values

Void object `null()` of type `DOM_NULL`.

See Also

MuPAD Functions
`delete`

return

Exit a procedure

Syntax

```
return(x)
```

Description

`return(x)` terminates the execution of a procedure and returns `x`.

Usually, MuPAD ends a procedure when all statements of the procedure body were processed. In this case, the return value of the procedure is the result of the last statement that was executed.

Alternatively, the call `return(x)` inside a procedure leads to immediate exit from the procedure: `x` is evaluated and becomes the return value of the procedure. Execution proceeds after the point where the procedure was invoked.

`x` may be an expression sequence, i.e., calls such as `return(x1, x2, ...)` are allowed.

`return()` returns the void object of type `DOM_NULL`.

Note that `return` is a function, not a keyword. A statement such as `return x;` works in the programming language C, but causes a syntax error in MuPAD.

If called outside a procedure, `return(x)` just returns `x`.

Examples

Example 1

This example shows the implementation of a maximum function (which, in contrast to the system function `max`, accepts only two arguments). If `x` is larger than `y`, the value of `x` is returned and the execution of the procedure `mymax` stops. Otherwise, `return(x)` is not called. Consequently, `y` is the last evaluated object defining the return value:

```
mymax := proc(x : Type::Real, y : Type::Real)
begin
   if x > y then
     return(x)
   end_if;
   y
end_proc:

mymax(3, 2), mymax(4, 5)
```

$$3, 5$$

```
delete mymax:
```

Example 2

`return()` returns the void object:

```
f := x -> return(): type(f(anything))
```

$$\text{DOM\_NULL}$$

```
delete f:
```

Example 3

If `return` is called on the interactive level, the evaluated arguments are returned:

```
x := 1: return(x, y)
```

$$1, y$$

```
delete x:
```

Parameters

x

Any MuPAD object

Return Values

X.

MuPAD Functions
-> | proc

revert

Revert polynomials, lists, character strings and tables, invert series expansions

Syntax

```
revert(object)
```

Description

`revert` reverses the ordering of the elements in a list and the ordering of characters in a string, as well as the ordering of the coefficients in a polynomial. For tables, it swaps indices and entries. For a series expansion, it returns the functional inverse.

`revert` is a general function to compute inverses with respect to functional composition, or to reverse the order of operands. This type of functionality may be extended to further types of objects via overloading.

Currently, the MuPAD library provides functionality for strings, polynomials, lists, and tables, where `revert` reverses the order of the elements, coefficients, or characters, respectively. In tables, entries are turned into indices and vice versa. E.g., `revert(table(x = y, 2 = 4))` yields the table `table(y = x, 4 = 2)`. For series expansions, the functional inverse is returned.

For all other types of MuPAD objects that do not overload `revert`, the symbolic expression `revert(object)` is returned.

Examples

Example 1

`revert` operates on lists and character strings:

```
revert([1, 2, 3, 4, 5])
```

$$[5, 4, 3, 2, 1]$$

```
revert("nuf si DAPuM ni gnimmargorP")
```

"Programming in MuPAD is fun"

`revert` operates on series:

```
revert(series(sin(x), x)) = series(arcsin(x), x)
```

$$x + \frac{x^3}{6} + \frac{3\,x^5}{40} + O(x^7) = x + \frac{x^3}{6} + \frac{3\,x^5}{40} + O(x^7)$$

`revert` operates on tables:

```
t := table():  t[x] := 1: t[y] := 2: t[z] := 3:
T := revert(t): T[1], T[2], T[3]
```

x, y, z

Beware: if an entry is stored under several distinct indices, `revert` reduces the number of table operands:

```
revert(table(x = 1, y = 1, z = 3))
```

1	y
3	z

The functional inverse of the expansion of `exp` around `x = 0` is the expansion of the inverse function `ln` around `x = exp(0) = 1`:

```
revert(series(exp(x), x, 3)) = series(ln(x), x = 1, 2)
```

$$x - 1 - \frac{(x-1)^2}{2} + O((x-1)^3) = x - 1 - \frac{(x-1)^2}{2} + O((x-1)^3)$$

```
delete t, T:
```

Example 2

`revert` computes the reverse of a polynomial:

```
revert(poly(x^3 + 2*x + 5))
```

$$\text{poly}(5\,x^3 + 2\,x^2 + 1, [x])$$

The same works for multivariate polynomials, too:

```
revert(poly(x^3 + 2*x*y + 5*x + 6*y + 7))
```

$$\text{poly}(7\,x^3\,y + 6\,x^3 + 5\,x^2\,y + 2\,x^2 + y, [x, y])$$

We could have achieved the same by substituting all indeterminates by their inverses; however, `revert` works faster.

```
numer(evalp(poly(x^3 + 2*x*y + 5*x + 6*y + 7), x = 1/x, y = 1/y))
```

$$y + 5\,x^2\,y + 7\,x^3\,y + 2\,x^2 + 6\,x^3$$

Example 3

For all other types of objects, a symbolic function call is returned:

```
revert(x + y)
```

$$\text{revert}(x + y)$$

The following series expansion is not of type `Series::Puiseux`. Instead, a generalized expansion of type `Series::gseries` is produced. Consequently, `revert` does not compute an inverse:

```
revert(series(exp(-x)/(1 + x), x = infinity, 3))
```

$$\text{revert}\left(\frac{e^{-x}}{x} - \frac{e^{-x}}{x^2} + \frac{e^{-x}}{x^3} + O\left(\frac{e^{-x}}{x^4}\right)\right)$$

Parameters

`object`

A polynomial, a list, a character string, a table, or a series expansion of type `Series::Puiseux`

Return Values

Object of the same type as the input object, or a symbolic call of type `"revert"`.

MuPAD Functions
`series` | `sort` | `substring`

rewrite

Rewrite an expression

Syntax

```
rewrite(f, target)
```

Description

`rewrite(f, target)` transforms an expression `f` to a mathematically equivalent form, trying to express `f` in terms of the specified target function.

The target indicates the function that is to be used in the desired representation. Symbolic function calls in `f` are replaced by the target function if this is mathematically valid.

With the target `arg`, the function `ln(sign(x))` is rewritten as i $arg(x)$.

With the target `exp`, all trigonometric and hyperbolic functions are rewritten in terms of `exp`. Further, the inverse functions as well as `arg` are rewritten in terms of `ln`.

With the target `sincos`, the functions `tan`, `cot`, `exp`, `sinh`, `cosh`, `tanh`, and `coth` are rewritten in terms of `sin` and `cos`.

With the target `sin`, the same is done as in the case of `sincos`. Additionally, $cos(x)^2$ is rewritten as 1 - $sin(x)^2$. This holds for the target `cos` analogously.

With the target `sinhcosh`, the functions `exp`, `tanh`, `coth`, `sin`, `cos`, `tan`, and `cot` are rewritten in terms of `sinh` and `cosh`. With the targets `sinh` and `cosh`, the same is done, and `cosh(x)^2` is rewritten in terms of `sinh` (or `sinh(x)^2` in terms of `cosh`, respectively.)

With the targets `arcsin`, `arccos`, `arctan`, and `arccot`, the logarithm, all inverse trigonometric functions, and all inverse hyperbolic functions are rewritten in terms of the target function.

With the targets `arcsinh`, `arccosh`, `arctanh`, and `arccoth`, the logarithm, all inverse hyperbolic functions and all inverse trigonometric functions are rewritten in terms of the target function.

With the target `lambertW`, the function `wrightOmega` is rewritten in terms of `lambertW`.

With the target `erf`, the functions `erfc`, `erfi`, and `dawson` are rewritten in terms of `erf`.

With the target `erfc`, the functions `erf`, `erfi`, and `dawson` are rewritten in terms of `erfc`.

With the target `erfi`, the functions `erf`, `erfc`, and `dawson` are rewritten in terms of `erfi`.

With the target `bernoulli`, the function `euler` is rewritten in terms of `bernoulli`.

With the target `diff`, symbolic calls of the differential operator `D` are rewritten in terms of symbolic calls of the function `diff`. E.g., `D(f)(x)` is converted to `diff(f(x), x)`. A univariate expression `D(f)(x)` is rewritten if `x` is an identifier or an indexed identifier. A multivariate expression `D([n1, n2, ...], f)(x1, x2, ...)` is rewritten if `x1`, `x2` are *distinct* identifiers or indexed identifiers. Trying to rewrite a multivariate call `D(f)(x1, x2, ...)` of the univariate dervative `D(f)` raises an error.

With the target `D`, symbolic `diff` calls are rewritten in terms of the differential operator `D`. Derivatives of univariate function calls such as `diff(f(x), x)` are rewritten as `D(f)(x)`. Derivatives of multivariate function calls are expressed via `D([n1, n2, ...], f)`. E.g., `diff(f(x, y), x)` is rewritten as `D([1], f)(x, y)`.

With the target `andor`, the logical operators `xor`, `==>`, and `<=>` are rewritten in terms of `and`, `or`, and `not`.

With the targets `min` and `max`, expressions in `max` and `min` and, for real arguments, `abs` are rewritten in terms of the target function.

The targets `harmonic` and `psi` serve for rewriting symbolic calls of `psi` in terms of `harmonic` and vice versa.

With the target `inverf`, the function `inverfc(x)` is rewritten as `inverf(1 - x)`.

With the target `inverfc`, the function `inverf(x)` is rewritten as `inverfc(1 - x)`.

Examples

Example 1

This example demonstrates the use of `rewrite`:

```
rewrite(D(D(f))(x), diff)
```

$$\frac{\partial^2}{\partial x^2} f(x)$$

```
diff(f(x, x), x) = rewrite(diff(f(x, x), x), D)
```

$$\frac{\partial}{\partial x} f(x, x) = \mathrm{D}_1(f)(x, x) + \mathrm{D}_2(f)(x, x)$$

```
assume(n, Type::PosInt):
rewrite(fact(n), gamma), rewrite(gamma(n), fact);
delete n:
```

$$\Gamma(n+1),\ (n-1)!$$

```
rewrite(sign(x), heaviside), rewrite(heaviside(x), sign);
```

$$2\ \mathrm{heaviside}(x) - 1,\ \frac{\mathrm{sign}(x)}{2} + \frac{1}{2}$$

```
rewrite(heaviside(x), piecewise)
```

$$\begin{cases} \frac{1}{2} & \text{if } x = 0 \\ 1 & \text{if } 0 < x \\ 0 & \text{if } x < 0 \end{cases}$$

Example 2

Trigonometric functions can be rewritten in terms of `exp`, `sin`, `cos` etc.:

```
rewrite(tan(x), exp), rewrite(cot(x), sincos),
rewrite(sin(x), tan)
```

$$-\frac{e^{2xi}i-i}{e^{2xi}+1},\ \frac{\cos(x)}{\sin(x)},\ \frac{2\tan\left(\frac{x}{2}\right)}{\tan\left(\frac{x}{2}\right)^2+1}$$

```
rewrite(arcsinh(x), ln)
```

$$\ln\left(x+\sqrt{x^2+1}\right)$$

Example 3

Inverse trigonometric functions can be rewritten in terms of each other:

```
rewrite(arcsin(x), arctan)
```

$$2\arctan\left(\frac{x}{\sqrt{1-x^2}+1}\right)$$

The following result uses the function `signIm` ("sign of the imaginary part") to make the formula valid throughout the complex plane (apart from the singularities at $x=\pm\sqrt{-1}$):

```
rewrite(arctan(x), arcsin)
```

$$\mathrm{signIm}(x\,i)\left(\frac{\pi}{2}-\arcsin\left(\frac{1}{\sqrt{x^2+1}}\right)\right)$$

Parameters

`f`

An arithmetical or boolean expression

target

The target function to be used in the representation: one of andor, arccos, arccosh, arccot, arccoth, arcsin, arcsinh, arctan, arctanh, arg, bernoulli, cos, cosh, cot, coth, diff, D, erf, erfc, erfi, exp, fact, gamma, harmonic, heaviside, inverf, inverfc, lambertW, ln, max, min, piecewise, psi, sign, sin, sincos, sinh, sinhcosh, tan, or tanh

Return Values

arithmetical expression.

Overloaded By

f

RootOf

Set of roots of a polynomial

Syntax

```
RootOf(f, x)
```

```
RootOf(f)
```

Description

`RootOf(f, x)` represents the symbolic set of roots of the polynomial $f(x)$ with respect to the indeterminate x.

`RootOf` serves as a symbolic representation of the zero set of a polynomial. Since it is generally impossible to represent the roots of a polynomial in terms of radicals, `RootOf` is often the only possible way to represent the roots symbolically. `RootOf` mainly occurs in the output of `solve` or related functions; see "Example 3" on page 1-1783.

The parameter `f` must be either a polynomial, or an arithmetical expression representing a polynomial in `x`, or an equation `p=q`, where `p` and `q` are arithmetical expressions representing polynomials in `x`. In the latter case, `RootOf` represents the roots of `p-q` with respect to `x`.

The polynomial `f` need not be irreducible or even square-free. If `f` has multiple roots, `RootOf` represents each of the roots with its multiplicity.

If `x` is omitted, then `f` must be an arithmetical expression or polynomial equation containing exactly one indeterminate, and `RootOf` represents the roots with respect to this indeterminate.

`x` need not be an identifier or indexed identifier: it may be any expression that is neither rational nor constant.

If `f` contains only one indeterminate, then you can apply `float` to the `RootOf` object to obtain a set of floating-point approximations for all roots; see "Example 3" on page 1-1783.

Examples

Example 1

Each of the following calls represents the roots of the polynomial x^3 - x^2 with respect to x, i.e., the set {0, 1}:

```
RootOf(x^3 - x^2, x), RootOf(x^3 = x^2, x)
```

$$\text{RootOf}(x^3 - x^2, x), \text{RootOf}(x^3 - x^2, x)$$

```
RootOf(x^3 - x^2), RootOf(x^3 = x^2)
```

$$\text{RootOf}(x^3 - x^2, x), \text{RootOf}(x^3 - x^2, x)$$

```
RootOf(poly(x^3 - x^2, [x]), x)
```

$$\text{RootOf}(x^3 - x^2, x)$$

In general, however, `RootOf` is only used when no explicit symbolic representation of the roots is possible.

Example 2

The first argument of `RootOf` may contain parameters:

```
RootOf(y*x^2 - x + y^2, x)
```

$$\text{RootOf}(x^2\, y - x + y^2, x)$$

The set of roots of a polynomial is treated like an expression. For example, it may be differentiated with respect to a free parameter. The result is the set of derivatives of the roots; it is expressed in terms of `RootOf`, by giving a minimal polynomial:

```
diff(%, y)
```

$$\text{RootOf}(4\, x^2\, y^5 - x^2\, y^2 + 4\, x\, y^3 - x + y^4 + 2\, y, x)$$

For reducible polynomials, the result may be a multiple of the correct minimal polynomial.

Example 3

`solve` returns `RootOf` objects when the roots of a polynomial cannot be expressed in terms of radicals:

```
solve(x^5 + x + 7, x)
```

$$\text{RootOf}(z^5 + z + 7, z)$$

You can apply the function `float` to obtain floating-point approximations of all roots:

```
float(%)
```

$$\{-1.410813851,\ -0.508469409 + 1.368616488\,i,\ -0.508469409 - 1.368616488\,i,\ 1.213876335 + 0.9241881109\,i,\ 1.213876335 - 0.9241881109\,i\}$$

Example 4

The function `sum` is able to compute sums over all roots of a given polynomial:

```
sum(i^2, i = RootOf(x^3 + a*x^2 + b*x + c, x))
```

$$a^2 - 2\,b$$

```
sum(1/(z + i), i = RootOf(x^4 - y*x + 1, x))
```

$$\frac{4\,z^3 + y}{z^4 + y\,z + 1}$$

Example 5

A `RootOf` object represents the set of all roots. One can address the individual roots via indexed calls:

```
RootOf(z^3 - 1, z)[i] $ i = 1..3
```

$$\mathrm{RootOf}(z^3-1,\,z)_1,\ \mathrm{RootOf}(z^3-1,\,z)_2,\ \mathrm{RootOf}(z^3-1,\,z)_3$$

```
float(RootOf(z^3 - 1, z)[i]) $ i = 1..3
```

$$1.0,\ -0.5+0.8660254038\,i,\ -0.5-0.8660254038\,i$$

Parameters

f

A polynomial, an arithmetical expression representing a polynomial in `x`, or a polynomial equation in `x`

x

The indeterminate: typically, an identifier or indexed identifier

Return Values

Symbolic `RootOf` call, i.e., an expression of type `"RootOf"`.

MuPAD Functions

`isolate` | `numeric::polyroots` | `poly` | `solve`

Rule

Defining equivalence rules for mathematical expressions

Syntax

```
Rule(pattern, replacement, <conditions>)
```

```
Rule(procedure, <condProc>)
```

Description

`Rule` is a data type. Each object of `Rule` – a rule – describes the equivalence between mathematical expressions. The arguments of a rule are two pattern expressions, that are equivalent, and optional some conditions for the validity of the equivalence.

Rule can be applied to any expression, and returns an expression equivalent to the input, or `FAIL`.

Additionally, a rule can consist of a procedure that returns an equivalent expression to a given expression or `FAIL` *without* using the pattern matcher.

Rules created with `Rule` are mainly used to build a rule base for the new `Simplify`. See the documentation of `Simplify` and "Example 8" on page 1-1792 for a real application of `Rule`. "Example 3" on page 1-1788 shows, how to implement rewriting rules via `Rule`.

All other examples are only given to explain the behavior of rules. In practice, single rules and their manual application is unusual.

There are two kinds of rules: Use the library pattern matcher to determine whether the rule is suitable, or use a user defined procedure to analyze a given expression and return an equivalent expression.

`Rule(pattern, replacement, conditions)` defines a rule that describes the equivalence of the expressions `pattern` and `replacement`.

When this rule is applied to a given expression `ex`, the pattern matcher is called with the arguments

```
match(ex, pattern, Cond = conditions)
```

and returns a set of replacements `S:={var = ex_var, ...}` for each variable `var` of `pattern`, and `ex_var` is the corresponding subexpression of `ex` (see `match` for detailed description).

In this case the result of the substitution `subs(replacement, S)` is returned as equivalent expression to `ex`.

The call to `match` can also return `FAIL`, when `ex` doesn't have the same structure as `pattern`. Then the return value of the rule application is `FAIL`, too.

See “Example 1” on page 1-1787 and “Example 2” on page 1-1787.

See `match` for the description of valid conditions.

Alternatively, a rule can consist of a procedure that is called with a given expression, and must return an equivalent expression or `FAIL`. The “pattern matcher” is not called.

`Rule(procedure, condProc)` defines such a rule that returns an equivalent expression to any given input as return value of `procedure` or `FAIL`.

The optional condition `condProc` must be a procedure, too. This procedure is called *before* the procedure that produces equivalent expressions, with a given expression `ex`. When the call `condProc(ex)` returns `TRUE`, then the return value of the call `procedure(ex)` is returned as the result of the application of the rule, otherwise `FAIL`.

With a rule that consists of a procedure, several relations `pattern <=> result` can be expressed. This is mostly more efficient, than using `match` for each equivalence.

See “Example 6” on page 1-1790 and “Example 7” on page 1-1791.

Note: Rules with expressions as arguments must use identifiers that are protected from any assignment. Those identifiers must be of the form `#X`, where `X` can be any valid variable name. All variables that start with `#` in their names are protected by the kernel from any assignment.

Examples

Example 1

The first rule represents the simplification `sin(X)^2 + cos(X)^2 = 1`. The first argument of the rule is the expression `sin(X)^2 + cos(X)^2`. Each expression, which has the same structure, is found by `match`, and the second argument of the rule `1` is returned as result. There are no conditions for the validity of this equivalence. The identifiers used for defining the rule are write protected, because they have names beginning with #:

```
r := Rule(sin(`#X`)^2 + cos(`#X`)^2, 1):
Rule::apply(r, sin(2*x - 1)^2 + cos(2*x - 1)^2)
```

$$1$$

The next expression doesn't have the right form, the application of the rule fails:

```
Rule::apply(r, sin(2*x - 1)^2 + cos(2*x + 1)^2)
```

$$\text{FAIL}$$

Example 2

The next rule represents the addition theorem `sin(X + Y) = sin(X)*cos(Y) + sin(Y)*cos(X)`. The first argument of the rule is the expression `sin(X + Y)`. Each expression that is a call to `sin` with a sum as argument, is identified by `match`, and the sum `sin(X)*cos(Y) + sin(Y)*cos(X)` is returned, where `X` and `Y` are replaced by the corresponding parts of the given expression. There are no conditions for the validity of this equivalence. The second part of the rule is prevented from evaluation with `hold`. The identifiers used for defining the rule are write protected, because they have names beginning with #:

```
r := Rule(sin(`#X` + `#Y`),
          hold(sin(`#X`)*cos(`#Y`) + sin(`#Y`)*cos(`#X`))):
Rule::apply(r, sin(tan(x) + tan(y)))
```

$$\cos(\tan(x))\,\sin(\tan(y)) + \cos(\tan(y))\,\sin(\tan(x))$$

The matcher identifies the difference of two expressions `a` and `b` as the sum `a + -b`, therefore also the following example works:

```
Rule::apply(r, sin(tan(x) - tan(y)))
```

$$\cos(\tan(y))\,\sin(\tan(x)) - \cos(\tan(x))\,\sin(\tan(y))$$

Example 3

We define two rules based on the trigonometric identies $sin(x)^2 = 1 - cos(x)^2$ and $\tan(x)^2 = \frac{1}{\cos(x)^2} - 1$:

```
myrules := [Rule(sin(`#X`)^`#n`, (1 - cos(`#X`)^2)^(`#n`/2),
                          {`#n` -> is(`#n`, Type::Even)}),
            Rule(tan(`#X`)^`#n`, (1/cos(`#X`)^2 - 1)^(`#n`/2),
                                 {`#n` -> is(`#n`, Type::Even)})
            ]:
```

We wish to apply these rules as rewriting rules to various expressions. We forward `Rule::apply` to all subexpressions of an expression via `misc::maprec`. For convenience, an interface function `myrewrite` is implemented that calls `misc::maprec`:

```
myrewrite:= proc(f, rules)
local _rewrite;
begin
   _rewrite:= proc(x)
   local r, tmp;
   begin
      for r in rules do
         tmp:= Rule::apply(r, x);
         if tmp <> FAIL then
            x:= tmp;
         end;
      end;
      return(x)
    end;
    misc::maprec(f, TRUE = _rewrite);
end:
```

Now we can call `myrewrite(f, myrules)` to apply the rewriting rules to an expression `f`:

```
f:= tan(x) + sin(2*x) - tan(y)^2*sin(x + 3)^6 + sin(x)^2 * tan(23)^4:
myrewrite(f, myrules);
```

$$\sin(2x) + \tan(x) + \left(\frac{1}{\cos(y)^2} - 1\right)(\cos(x+3)^2 - 1)^3 - \left(\frac{1}{\cos(23)^2} - 1\right)^2 (\cos(x)^2 - 1)$$

```
delete myrules, myrewrite, f:
```

Example 4

Another rule represents the simplification `sin(X) = 0`, which is only true, when `X` is an integer multiple of `PI`:

```
r := Rule(sin(`#X`), 0, {`#X` -> is(`#X`/PI, Type::Integer)}):
Rule::apply(r, sin(2*x*PI))
```

FAIL

In the last call, the argument of `sin` doesn't have the necessary property, so the application of the rule fails.

After an assumption to `x`, the expression has the right form:

```
assume(x, Type::Integer):
Rule::apply(r, sin(2*x*PI))
```

0

The next application of the rule checks a constant expression:

```
Rule::apply(r, sin(2*PI))
```

FAIL

Why `FAIL`? The problem is, `sin` simplifies the constant input `2*PI` to `0` itself, so the rule gets `0` as input. However, `0` doesn't have the necessary form, so `FAIL` is returned.

Example 5

Another rule represents the simplification `ln(neg^even*r) = even*ln(-neg) + ln(r)`, which is only true, when `neg` is negative and `even` is an even number:

```
r := Rule(ln(`#Neg`^`#Even`*`#X`),
          `#Even`*ln(-`#Neg`) + ln(`#X`),
          {`#Neg` -> is(`#Neg`, Type::Negative) = TRUE,
           `#Even` -> is(`#Even`, Type::Even) = TRUE}):
delete e, n, x:
Rule::apply(r, ln(n^e*x))
```

$$\ln(n^e\,x)$$

The rule application fails, because the variables doesn't have the necessary properties.

With an assumption `n` should be a negative variable and `e` should be even:

```
assume(n < 0): assume(e, Type::Even):
Rule::apply(r, ln(n^e*x))
```

$$\ln(x) + e\,\ln(-n)$$

Example 6

This rule represents the application of `rewrite` to an expression with the target `exp`, when the expression has subexpressions of type `"sin"` or `"cos"`. The first argument of the rule is a procedure that calls `rewrite` with any expression and target `exp` and returns an expression equivalent to the input (because `rewrite` does it). The second argument is a procedure that checks, whether `sin` or `cos` is contained in the input expression:

```
r := Rule(X -> rewrite(X, exp), X -> has(X, sin) or has(X, cos)):
Rule::apply(r, sin(2*x - 1)^2 + cos(2*x - 1)^2)
```

$$\left(\frac{e^{-2xi+i}}{2} + \frac{e^{2xi-i}}{2}\right)^2 + \left(\frac{e^{-2xi+i}\,i}{2} - \frac{e^{2xi-i}\,i}{2}\right)^2$$

The next expression doesn't have `sin` or `cos`, so the application of the rule fails:

```
Rule::apply(r, tan(2*I*x))
```

FAIL

Example 7

This rule represents the application of `rewrite` to an expression with several targets. The first argument of the rule is a procedure that applies `rewrite` to the given expression, with a target depending on the input. This rule doesn't have a condition procedure:

```
rewProc :=
  proc(ex)
  begin
    rewrite(ex, (if has(ex, exp) then
                   tan
                 elif has(ex, sin) or has(ex, cos) then
                   cot
                 elif has(ex, tan) or has(ex, cot) then
                   sincos
                 else
                   exp
                 end_if))
  end_proc:
r := Rule(rewProc):
Rule::apply(r, exp(2*x))
```

$$-\frac{\tan(x\,i)+i}{\tan(x\,i)-i}$$

The rule is applied again to the last result:

```
Rule::apply(r, %)
```

$$-\frac{\frac{\sin(x\,i)}{\cos(x\,i)}+i}{\frac{\sin(x\,i)}{\cos(x\,i)}-i}$$

The last result should be simplified back to the first expression:

```
Simplify(%)
```

$$e^{2x}$$

Example 8

The new `Simplify` uses a rule base for applying a lot of rewriting rules for finding the simplest form of any given expression.

We want to rewrite only some powers and assume that all used variables are real (without using properties).

The list `PowerRules` consists of several rules. The procedure `powerRules` returns all this rules in a list.

Because of better readability, the names of the used identifiers are short and not protected names:

```
PowerRules :=
  [Rule(A^m*A^n, hold(A^(m + n))),
   Rule(A^m/A^n, hold(A^(m - n))),
   Rule(A^n*B^n, hold((A*B)^n)),
   Rule(A^n/B^n, hold((A/B)^n)),
   Rule(A^n/B^n, hold((B/A)^-n)),
   Rule((A^m)^n, hold(A^(m*n)))]:
powerRules := proc()
              begin
                PowerRules
              end_proc:
```

`Simplify` is called with the option `SelectRules`, and expects a procedure that returns a list of rules, applicable to a given expression. In this case, all of the rules are returned in every case.

`Simplify` applies all rules to a given expression and also to rewritten results, and tries to find the easiest form of the expression with respect to the default valuation procedure `Simplify::complexity`.

Because of the argument `SelectRules = powerRules`, only the given rules are used by `Simplify`:

```
Simplify(T^(1/2)*(R*T)^(-1/2), SelectRules = powerRules)
```

$$\frac{1}{\sqrt{R}}$$

Other expressions cannot be simplified with the same rule base:

```
Simplify(sin(x)^2 + cos(x)^2, SelectRules = powerRules)
```

$$\cos(x)^2 + \sin(x)^2$$

```
delete r, x, powerRules, PowerRules:
```

Parameters

`pattern`

A MuPAD expression; all identifiers are used as pattern variables for the pattern matcher

`replacement`

A MuPAD expression with the same identifiers, as `pattern`; the replacement expression should be protected from evaluation with the function `hold`

`conditions`

A set (of type `DOM_SET`) of procedures and expressions in the pattern variables, or the empty set (see `match` and option `Cond`)

`procedure`

A MuPAD procedure that is called with an expression and must return an equivalent expression or `FAIL`

`condProc`

A procedure that is called with an expression before `procedure`, and must return `TRUE`, when `procedure` should be called with the expression, otherwise `FAIL` is returned immediately

MuPAD Functions
`match` | `Simplify`

save, _save

Save the state of an identifier

Syntax

```
save x1, x2, …

_save(x1, x2, …)
```

Description

In a procedure, the statement "`save x;`" saves the state of the global identifier `x`.

The `save` statement saves the states of identifiers—i.e., their values and properties — during the execution of procedures. The original state of the identifiers is restored when procedure execution is finished. This holds even when an error occurs.

The `save` statement is to be used only inside the body of a procedure. It cannot be called on the interactive level.

The arguments of the `save` statement are evaluated as usual. In the statement '`save x;`', the symbol `x` must evaluate to an identifier `y`, say. It is the state of the identifier `y` that is saved.

The `save` statement is very similar to the `save` declaration for procedures. The main difference to the declaration is that, in order to make the declaration, one has to know the names of the identifiers to be saved in advance. The `save` statement allows to save identifiers which are known only at runtime.

The `save` statement is usually used in order to temporarily change the properties of an identifier, for example by calling the function `assume`. Eventually, the original properties of the identifiers are restored even if an error occurs.

The statement '`save x1, x2, ...;`' is equivalent to the function call `_save(x1, x2, ...)`.

Examples

Example 1

First, we define a property for the identifier y:

```
assume(y < 0)
```

The properties of the identifier stored in x are changed temporarily during the execution of the following procedure p:

```
p := proc(x : DOM_IDENT)
begin
    save x;
    assume(x > 0);
    is(x > 0)
end_proc:
```

From the procedure's result, we see that the properties of y were changed during the execution of p:

```
p(y)
```

```
    TRUE
```

However, the original properties were restored after exiting p. The identifier y has its original properties:

```
is(y > 0), is(y < 0)
```

```
    FALSE, TRUE
```

The restoration of the original properties is guaranteed even if some error occurs inside the procedure. The following procedure q raises an error after changing the identifier given by x:

```
q := proc(x : DOM_IDENT)
begin
    save x;
    assume(x > 0);
    error("some error")
```

```
end_proc:
q(y)

Error: some error [q]
```

Nevertheless, the original assumptions about `y` are restored:

```
is(y > 0), is(y < 0)

    FALSE, TRUE

unassume(y): delete p, q:
```

Parameters

x_1, x_2, …

Symbols evaluating to identifiers

Return Values

Void object of type `DOM_NULL`.

MuPAD Functions
`proc`

select

Select operands

Syntax

```
select(object, f, <p1, p2, …>)
```

Description

`select(object, f)` returns a copy of the object with all operands removed that do not satisfy a criterion defined by the procedure `f`.

`select` is a fast and handy function for picking out elements of lists, sets, tables etc. that satisfy a criterion set by the procedure `f`.

The function `f` must return a value that can be evaluated to one of the Boolean values `TRUE`, `FALSE`, or `UNKNOWN`. It may either return one of these values directly, or it may return an equation or an inequality that can be simplified to one of these values by the function `bool`.

Internally, the function `f` is applied to all operands `x` of the input object via the call `f(x, p1, p2, ...)`. If the result is not `TRUE`, this operand is removed. The original object is not modified in this process.

The output object is of the same type as the input object, i.e., a list yields a list, a set yields a set etc.

An input object that is an expression sequence is not flattened. Cf. “Example 2” on page 1-1800.

Also “atomic” objects such as numbers or identifiers can be passed to `select` as first argument. Such objects are handled like sequences with a single operand.

Examples

Example 1

`select` handles lists and sets. In the first example, we select all true statements from a list of logical statements. The result is again a list:

```
select([1 = 1, 1 = 2, 2 = 1, 2 = 2], bool)
```

$$[1 = 1, 2 = 2]$$

In the following example, we extract the subset of all elements that are recognized as zero by `iszero`:

```
select({0, 1, x, 0.0, 4*x}, iszero)
```

$$\{0.0, 0\}$$

`select` also works on tables:

```
T:= table(1 = "y", 2 = "n", 3 = "n", 4 = "y", 5 = "y"):
select(T, has, "y")
```

1	"y"
4	"y"
5	"y"

The following expression is a sum, i.e., an expression of type `"_plus"`. We extract the sum of all terms that do not contain `x`:

```
select(x^5 + 2*x + y - 4, _not@has, x)
```

$$y - 4$$

We extract all factors containing `x` from the following product. The result is a product with exactly one factor, and therefore, is not of the syntactical type `"_mult"`:

```
select(11*x^2*y*(1 - y), has, x)
```

$$x^2$$

```
delete T:
```

Example 2

`select` works for expression sequences:

```
select((1, -4, 3, 0, -5, -2), testtype, Type::Negative)
```

$$-4, -5, -2$$

The $ command generates such expression sequences:

```
select(i $ i = 1..20, isprime)
```

$$2, 3, 5, 7, 11, 13, 17, 19$$

Atomic objects are treated as expression sequences of length one:

```
select(5, isprime)
```

$$5$$

The following result is the void object `null()` of type `DOM_NULL`:

```
domtype(select(6, isprime))
```

$$\text{DOM\_NULL}$$

Example 3

It is possible to pass an “anonymous procedure” to `select`. This allows to perform more complex actions with one call. In the following example, the command `anames(All)` returns a set of all identifiers that have a value in the current MuPAD session. The `select` statement extracts all identifiers beginning with the letter `"h"`:

```
select(anames(All), x -> expr2text(x)[1] = "h")
```

$$\{\text{has, harmonic, hastype, heaviside, help, hessian, }{}_{h}\text{farray, history, hold, htranspose, hull,}$$
$$\text{hypergeom}\}$$

Parameters

`object`

A list, a set, a table, an expression sequence, or an expression of type `DOM_EXPR`

`f`

A procedure returning a Boolean value

`p1, p2, …`

Any MuPAD objects accepted by `f` as additional parameters

Return Values

Object of the same type as the input object.

Overloaded By

object

series

Compute a generalized series expansion

Syntax

```
series(f, x, <order>, <Left | Right | Real | Undirected>, <NoWarning>, <UseGseries>)
```

```
series(f, x = x0, <order>, <Left | Right | Real | Undirected>, <options>)
```

Description

`series(f, x = x0)` computes the first terms of a series expansion of `f` with respect to the variable `x` around the point x_0.

`series` tries to compute either the Taylor series, the Laurent series, the Puiseux series, or a generalized series expansion of `f` around `x = x0`. See `Series::gseries` for details on generalized series expansions.

The mathematical type of the series returned by `series` can be queried using the type expression `Type::Series`.

If `series` cannot compute a series expansion of `f`, a symbolic function call is returned. This is an expression of type `"series"`. Cf. “Example 11” on page 1-1812.

Mathematically, the expansion computed by `series` is valid in some neighborhood of the expansion point in the complex plane. Usually, this is an open disc centered at x_0. However, if the expansion point is a branch point, then the returned expansion may not approximate the function `f` for values of `x` close to the branch cut. Cf. “Example 12” on page 1-1813.

Using the options `Left` or `Right`, one can compute directed expansions that are valid along the real axis. With the option `Real`, a two-sided expansion along the real axis is computed. See “Example 5” on page 1-1807 and “Example 6” on page 1-1807.

If x_0 is `infinity` or `-infinity`, then a directed series expansion along the real axis from the left to the positive real infinity or from the right to the negative real infinity, respectively, is computed. If x_0 is `complexInfinity` and `dir` is not specified or

`Undirected`, then an undirected series expansion around the complex infinity, i.e., the north pole of the Riemann sphere, is computed. Specifying `x0= infinity` is equivalent to `x0= complexInfinity` and `dir = Left`. Similarly, `x0= -infinity` is equivalent to `x0= complexInfinity` and `dir = Right`. Cf. "Example 7" on page 1-1808.

Such a series expansion is computed as follows: The series variable `x` in `f` is replaced by $x = \frac{1}{u}$ (or $x = -\frac{1}{u}$ for `x0= -infinity`). Then, a series expansion of `f` around $u = 0$ is computed. Finally, $u = \frac{1}{x}$ (or $u = -\frac{1}{x}$, respectively) is substituted in the result.

Mathematically, the result of such a series expansion is a series in $\frac{1}{x}$. However, it may happen that the coefficients of the returned series depend on the series variable. See the corresponding paragraph below.

The number of requested terms for the expansion is the argument `order` if specified. Otherwise, the value of the environment variable `ORDER` is used. One can change the default value 6 by assigning a new value to `ORDER`.

The number of terms is counted from the lowest degree term on for finite expansion points, and from the highest degree term on for expansions around infinity, i.e., "`order`" has to be regarded as a "relative truncation order".

`series` implements a limited amount of precision management to circumvent cancellation. If the number of terms of the computed expansion is less than `order`, a second series computation with a higher value of `order` is tried automatically, and the result of the latter is returned.

Note: Nevertheless, the actual number of terms in the resulting series expansion may differ from the requested number of terms. See "Example 13" on page 1-1814 and "Example 15" on page 1-1816.

Taylor/Laurent/Puiseux expansions (all of domain type `Series::Puiseux`) can be restricted easily to an absolute order term by adding an appropriate `O` term. Cf. "Example 14" on page 1-1815.

Expansions of symbolic integrals can be computed. Cf. "Example 16" on page 1-1817.

If `f` is an expression of type `RootOf`, then `series` returns the set of all non-zero series solutions of the corresponding algebraic equation. Cf. "Example 9" on page 1-1810.

If `order` has the value `infinity`, then the system tries to convert the first argument into a formal infinite series, i.e., it computes a general formula for the n-th coefficient in the Taylor expansion of `f`. The result is an inactive symbolic sum or a polynomial expression. Cf. “Example 10” on page 1-1812.

If `series` returns a series expansion of domain type `Series::Puiseux`, it may happen that the “coefficients” of the returned series depend on the series variable. In this case, the expansion is not a proper Puiseux series in the mathematical sense. See “Example 7” on page 1-1808 and “Example 8” on page 1-1809. However, if the series variable is x and the expansion point is x_0, then the following is valid for each coefficient function $c(x)$ and every positive ε: $c(x)\,(x - x_0)^{\varepsilon}$ converges to zero and $\frac{c(x)}{(x-x_0)^{\varepsilon}}$ is unbounded when x approaches x_0. Similarly, if the expansion point is *infinity*, then, for every positive ε, $\frac{c(x)}{x^{\varepsilon}}$ converges to zero and $c(x)\,x^{\varepsilon}$ is unbounded when x approaches *infinity*.

The function returns a domain object that can be manipulated by the standard arithmetical operations. Moreover, the following methods are available: `ldegree` returns the exponent of the leading term; `Series::Puiseux::order` returns the exponent of the error term; `expr` converts to an arithmetical expression, removing the error term; `coeff(s, n)` returns the coefficient of the term of `s` with exponent `n`; `lcoeff` returns the leading coefficient; `revert` computes the inverse with respect to composition; `diff` and `int` differentiate and integrate a series expansion, respectively; `map` applies a function to all coefficients. See the help pages for `Series::Puiseux` and `Series::gseries` for further details.

Note: `series` works on a symbolic level and should not be called with arguments containing floating point arguments.

Environment Interactions

The function is sensitive to the environment variable `ORDER`, which determines the default number of terms in series computations.

Examples

Example 1

We compute a series expansion of $sin(x)$ around $x = 0$. The result is a Taylor series:

```
s := series(sin(x), x)
```

$$x - \frac{x^3}{6} + \frac{x^5}{120} + O(x^7)$$

Syntactically, the result is an object of domain type `Series::Puiseux`:

```
domtype(s)
```

Series::Puiseux

The mathematical type of the series expansion can be queried using the type expression `Type::Series`:

```
testtype(s, Type::Series(Taylor))
```

TRUE

Various system functions are overloaded to operate on series objects. E.g., the function `coeff` can be used to extract the coefficients of a series expansion:

```
coeff(s, 5)
```

$$\frac{1}{120}$$

The standard arithmetical operators can be used to add or multiply series expansions:

```
s + 2*s, s*s
```

$$3\,x - \frac{x^3}{2} + \frac{x^5}{40} + O(x^7),\ x^2 - \frac{x^4}{3} + \frac{2\,x^6}{45} + O(x^8)$$

```
delete s:
```

Example 2

This example computes the composition of `s` by itself, i.e. the series expansion of $sin(sin(x))$.

```
s := series(sin(x), x): s @ s = series(sin(sin(x)), x)
```

$$x - \frac{x^3}{3} + \frac{x^5}{10} + O(x^7) = x - \frac{x^3}{3} + \frac{x^5}{10} + O(x^7)$$

```
delete s:
```

Example 3

We compute the series expansion of the tangent function around the origin in two ways:

```
series(sin(x), x) / series(cos(x), x) = series(tan(x), x)
```

$$x + \frac{x^3}{3} + \frac{2\,x^5}{15} + O(x^7) = x + \frac{x^3}{3} + \frac{2\,x^5}{15} + O(x^7)$$

```
bool(%)
```

TRUE

Example 4

We compute a Laurent expansion around the point 1:

```
s := series(1/(x^2 - 1), x = 1)
```

$$\frac{1}{2\,(x-1)} - \frac{1}{4} + \frac{x-1}{8} - \frac{(x-1)^2}{16} + \frac{(x-1)^3}{32} - \frac{(x-1)^4}{64} + O((x-1)^5)$$

```
testtype(s, Type::Series(Taylor)),
testtype(s, Type::Series(Laurent))
```

FALSE, TRUE

Example 5

Without an optional argument or with the option `Undirected`, the `sign` function is not expanded:

```
series(x*sign(x^2 + x), x) =
series(x*sign(x^2 + x), x, Undirected)
```

$$x\,\mathrm{sign}(x^2+x)+O(x^7) = x\,\mathrm{sign}(x^2+x)+O(x^7)$$

Some simplification occurs if one requests an expansion that is valid along the real axis only:

```
series(x*sign(x^2 + x), x, Real)
```

$$x\,\mathrm{sign}(x)+O(x^7)$$

The `sign` vanishes from the result if one requests a one-sided expansion along the real axis:

```
series(x*sign(x^2 + x), x, Right),
series(x*sign(x^2 + x), x, Left)
```

$$x+O(x^7),\ -x+O(x^7)$$

Example 6

In MuPAD, the `heaviside` function is defined only on the real axis. Thus an undirected expansion in the complex plane does not make sense:

```
series(x*heaviside(x + 1), x)
```

```
Warning: Cannot find an undirected series expansion. Try the 'Left', 'Right', or 'Real
```

$$\mathrm{series}(x\,\mathrm{heaviside}(x+1),\ x)$$

After specifying corresponding options, the system computes an expansion along the real axis:

```
series(x*heaviside(x + 1), x, Real),
series(x*heaviside(x + 1), x, Right)
```

$$x + O(x^7), x + O(x^7)$$

At the point `I` in the complex plane, the function `heaviside` is not defined, and neither is a series expansion:

```
series(heaviside(x), x = I, Real)
```

$$\text{series}(\text{heaviside}(x), x = \text{i}, \text{Real})$$

Example 7

We compute series expansions around infinity:

```
s1 := series((x + 1)/(x - 1), x = complexInfinity)
```

$$1 + \frac{2}{x} + \frac{2}{x^2} + \frac{2}{x^3} + \frac{2}{x^4} + \frac{2}{x^5} + O\left(\frac{1}{x^6}\right)$$

```
s2 := series(psi(x), x = infinity)
```

$$\ln(x) - \frac{1}{2\,x} - \frac{1}{12\,x^2} + \frac{1}{120\,x^4} + O\left(\frac{1}{x^6}\right)$$

```
domtype(s1), domtype(s2)
```

$$\text{Series::Puiseux}, \text{Series::Puiseux}$$

Although both expansions are of domain type `Series::Puiseux`, `s2` is not a Puiseux series in the mathematical sense, since the first term contains a logarithm, which has an essential singularity at infinity:

```
testtype(s1, Type::Series(Puiseux)),
testtype(s2, Type::Series(Puiseux))
```

TRUE, FALSE

```
coeff(s2)
```

$$\ln(x),\ -\frac{1}{2},\ -\frac{1}{12},\ 0,\ \frac{1}{120}$$

The following expansion is of domain type `Series::gseries`:

```
s3 := series(exp(x)/(1 - x), x = infinity, 4)
```

$$-\frac{e^x}{x}-\frac{e^x}{x^2}-\frac{e^x}{x^3}-\frac{e^x}{x^4}+O\left(\frac{e^x}{x^5}\right)$$

```
domtype(s3)
```

Series::gseries

```
delete s1, s2, s3:
```

Example 8

Oscillating but bounded functions may appear in the "coefficients" of a series expansion as well:

```
s := series(sin(x + 1/x), x = infinity)
```

$$\sin(x)+\frac{\cos(x)}{x}-\frac{\sin(x)}{2\,x^2}-\frac{\cos(x)}{6\,x^3}+\frac{\sin(x)}{24\,x^4}+\frac{\cos(x)}{120\,x^5}+O\left(\frac{1}{x^6}\right)$$

```
domtype(s), testtype(s, Type::Series(Puiseux))
```

Series::Puiseux, FALSE

```
coeff(s, -1)
```

$\cos(x)$

Example 9

The algebraic equation $y^5 - y - x = 0$ cannot be resolved in terms of radicals:

```
solve(y^5 - y - x, y)
```

$$\text{RootOf}(z^5 - z - x,\ z)$$

However, `series` can compute all series solutions of this equation around $x = 0$:

```
series(%, x = 0)
```

$$\left\{-x - x^5 + O(x^7),\ -1 + \frac{x}{4} + \sigma_5 + \sigma_1 + \sigma_4 + \frac{x^5}{4} + O(x^6),\ 1 + \frac{x}{4} - \sigma_5 + \sigma_1 - \sigma_4 + \frac{x^5}{4} + O(x^6),\right.$$
$$\left.-i + \frac{x}{4} - \sigma_3 - \sigma_1 + \sigma_2 + \frac{x^5}{4} + O(x^6),\ i + \frac{x}{4} + \sigma_3 - \sigma_1 - \sigma_2 + \frac{x^5}{4} + O(x^6)\right\}$$

where

$$\sigma_1 = \frac{5x^3}{32}$$

$$\sigma_2 = \frac{385x^4 i}{2048}$$

$$\sigma_3 = \frac{5x^2 i}{32}$$

$$\sigma_4 = \frac{385x^4}{2048}$$

$$\sigma_5 = \frac{5x^2}{32}$$

It may happen that the series solutions themselves are expressed in terms of `RootOf`s:

```
series(RootOf(y^5 -(x + 2*x^2)*y^3 - x^3*y^2
              + (x^3 + x^4)*y + x^4 + x^5, y), x)
```

$$\left\{-\sqrt{x}-\sigma_6+\sigma_5-\sigma_4+\sigma_2-\sigma_1+\sigma_3,\ \sqrt{x}+\sigma_6-\sigma_5+\sigma_4-\sigma_2+\sigma_1+\sigma_3\right\}$$
$$\cup\left\{x\,z+O(x^7)\ \middle|\ z\in \mathrm{RootOf}(z1^3-z1-1,\ z1)\right\}$$

where

$$\sigma_1=\frac{7x^{11/2}}{256}$$

$$\sigma_2=\frac{5x^{9/2}}{128}$$

$$\sigma_3=O\left(x^{13/2}\right)$$

$$\sigma_4=\frac{x^{7/2}}{16}$$

$$\sigma_5=\frac{x^{5/2}}{8}$$

$$\sigma_6=\frac{x^{3/2}}{2}$$

The coefficients of the algebraic equation are allowed to be transcendental. They are internally converted into Puiseux series by `series`:

```
series(RootOf(y^3 - y - exp(x - 1) + 1, y), x = 1, 4)
```

$$\left\{-(x-1)-\frac{(x-1)^2}{2}-\frac{7(x-1)^3}{6}+\sigma_1,\ 1+\frac{x-1}{2}-\frac{(x-1)^2}{8}+\frac{5(x-1)^3}{24}+\sigma_1,\right.$$
$$\left.-1+\frac{x-1}{2}+\frac{5(x-1)^2}{8}+\frac{23(x-1)^3}{24}+\sigma_1\right\}$$

where

$$\sigma_1 = O((x-1)^4)$$

An error occurs if some coefficient cannot be expanded into a Puiseux series:

```
series(RootOf(y^3 - y - exp(x), y), x = infinity)
```

```
Error: Cannot expand the coefficients of 'RootOf(y^3 - y - exp(1/x), y)' into a series
```

Example 10

In this example, we compute a formula for the n-th coefficient a_n in the Taylor expansion of the function $e^{-x} = \sum_{n \geq 0} a_n x^n$ around zero, by specifying `infinity` as `order`. The result is a symbolic sum:

```
series(exp(-x), x, infinity)
```

$$\left(\sum_{k=1}^{\infty} \frac{(-1)^k x^k}{k\,\Gamma(k)}\right) + 1$$

If the input is a polynomial expression, then so is the output:

```
series(x^5 - 1, x = 1, infinity)
```

$$5(x-1) + 10(x-1)^2 + 10(x-1)^3 + 5(x-1)^4 + (x-1)^5$$

Example 11

No asymptotic expansion exists for the Bessel J function of unspecified index, and `series` returns a symbolic function call:

```
series(besselJ(k, x), x=infinity)
```

$$\text{series}\left(J_k(x), x = \infty\right)$$

```
domtype(%), type(%)
```

$$\text{DOM\_EXPR}, \text{"series"}$$

Example 12

The branch cut of the logarithm and the square root is the negative real axis. For a series expansion on the branch cut, `series` uses the function `signIm` to return an expansion that is valid in an open disc around the expansion point:

```
series(ln(x), x = -1, 3)
```

$$\pi\ \text{signIm}(x)\ i - (x+1) - \frac{(x+1)^2}{2} - \frac{(x+1)^3}{3} + O((x+1)^4)$$

```
series(sqrt(x), x = -1, 3)
```

$$(-1)^{\frac{\text{signIm}(x)}{2}} - \frac{(-1)^{\frac{\text{signIm}(x)}{2}}(x+1)}{2} - \frac{(-1)^{\frac{\text{signIm}(x)}{2}}(x+1)^2}{8} + O((x+1)^3)$$

The situation is more intricate when the expansion point is a branch point. The following expansion of the function `arcsin(x + 1)` is valid in an open disc around the branch point 0:

```
series(arcsin(x + 1), x, 4)
```

$$\frac{\pi}{2} - \sqrt{2}\sqrt{-x} - \frac{\sqrt{2}(-x)^{3/2}}{12} - \frac{3\sqrt{2}(-x)^{5/2}}{160} - \frac{5\sqrt{2}(-x)^{7/2}}{896} + O\left(x^{9/2}\right)$$

However, the expansion of `f = ln(x + I*x^3)` around the branch point 0 that is returned by `series` does not approximate `f` for values of `x` that are close to the negative real axis:

```
f := ln(x + I*x^3);
```

```
g := series(f, x, 4);
```

$$\ln(x^3\,\mathrm{i}+x)$$

$$\ln(x)+x^2\,\mathrm{i}+O(x^4)$$

```
DIGITS := 20:
float(subs([f, expr(g)], x = -0.01 + 0.0000001*I));
delete DIGITS:
```

$$[-4.6051701789380914\,16-3.1415026535903362385\,\mathrm{i},\ -4.6051701839380913\,68+3.1416826535897835718\,\mathrm{i}]$$

The situation is similar for algebraic branch points:

```
f := sqrt(x + I*x^3);
g := series(f, x, 4);
```

$$\sqrt{x^3\,\mathrm{i}+x}$$

$$\sqrt{x}+\frac{x^{5/2}\,\mathrm{i}}{2}+O\left(x^{9/2}\right)$$

```
DIGITS := 20:
float(subs([f, expr(g)], x = -0.01 + 0.0000001*I));
delete DIGITS:
```

$$[0.00000449999998719375007\,25-0.10000000025124999\,91\,\mathrm{i},\ -0.00000449999999906875+0.10000000012625\,\mathrm{i}]$$

```
delete f, g:
```

Example 13

The first six terms, including zeroes, of the following two series expansions agree:

```
series(sin(tan(x)), x, 12);
series(tan(sin(x)), x, 12);
```

$$x + \frac{x^3}{6} - \frac{x^5}{40} - \frac{55\,x^7}{1008} - \frac{143\,x^9}{3456} - \frac{968167\,x^{11}}{39916800} + O(x^{13})$$

$$x + \frac{x^3}{6} - \frac{x^5}{40} - \frac{107\,x^7}{5040} - \frac{73\,x^9}{24192} + \frac{41897\,x^{11}}{39916800} + O(x^{13})$$

If we want to compute the series expansion of the difference `sin(tan(x)) - tan(sin(x))`, cancellation happens and produces too few terms in the result. `series` detects this automatically and performs a second series computation with increased precision:

```
series(sin(tan(x)) - tan(sin(x)), x, 6)
```

$$-\frac{x^7}{30} - \frac{29\,x^9}{756} - \frac{1913\,x^{11}}{75600} + O(x^{13})$$

It may nevertheless happen that the result has too few terms; cf. “Example 15” on page 1-1816.

If rational exponents occur in the series expansion, then it may even happen that the result has more than the number of terms requested by the third argument:

```
series(x^2*exp(x) + x*sqrt(sin(x)), x, 3)
```

$$x^{3/2} + x^2 + x^3 - \frac{x^{7/2}}{12} + \frac{x^4}{2} + O(x^5)$$

Example 14

`series`'s control of the order term is based on the concept of `relative order', counting the number of terms beginning with the lowest order that is present in the expansion. An `absolute order' control can be achieved by simply adding an appropriate order term to restrict a result returned by `series`:

```
series(exp(x) + x*sqrt(sin(x)), x, 7)
```

$$1 + x + x^{3/2} + \frac{x^2}{2} + \frac{x^3}{6} - \frac{x^{7/2}}{12} + \frac{x^4}{24} + \frac{x^5}{120} + \frac{x^{11/2}}{1440} + \frac{x^6}{720} + O(x^7)$$

```
series(exp(x) + x*sqrt(sin(x)), x, 7) + O(x^4)
```

$$1 + x + x^{3/2} + \frac{x^2}{2} + \frac{x^3}{6} - \frac{x^{7/2}}{12} + O(x^4)$$

Note, however, that the series must have enough terms for the added order term to have any effect:

```
series(exp(x^2), x, 4)
```

$$1 + x^2 + \frac{x^4}{2} + O(x^6)$$

```
series(exp(x^2), x, 4) + O(x^8)
```

$$1 + x^2 + \frac{x^4}{2} + O(x^6)$$

Example 15

If the specified order for the expansion is too small to compute the reciprocal (due to cancellation), `series` returns a symbolic call:

```
series(exp(x), x, 4)
```

$$1 + x + \frac{x^2}{2} + \frac{x^3}{6} + O(x^4)$$

```
series(1/(exp(x) - 1 - x - x^2/2 - x^3/6), x, 2)
```

$$\text{series}\left(-\frac{1}{x - e^x + \frac{x^2}{2} + \frac{x^3}{6} + 1}, x, 2\right)$$

After increasing the order, an expansion is computed, but possibly with fewer terms:

```
series(1/(exp(x) - 1 - x - x^2/2 - x^3/6), x, 3);
series(1/(exp(x) - 1 - x - x^2/2 - x^3/6), x, 4)
```

$$\frac{24}{x^4} - \frac{24}{5\,x^3} + O\left(\frac{1}{x^2}\right)$$

$$\frac{24}{x^4} - \frac{24}{5\,x^3} + \frac{4}{25\,x^2} + \frac{12}{875\,x} + O(1)$$

Example 16

`series` and `int` support each other. On the one hand, series expansions can be integrated:

```
int(series(1/(2 - x), x), x = 0..1)
```

$$\int_0^1 O(x^6)\,\mathrm{d}x + \frac{1327}{1920}$$

On the other hand, `series` knows how to handle symbolic integrals:

```
int(x^x, x)
```

$$\int x^x\,\mathrm{d}x$$

```
series(%, x = 0, 3)
```

$$x + x^2\left(\frac{\ln(x)}{2} - \frac{1}{4}\right) + x^3\left(\frac{\ln(x)^2}{6} - \frac{\ln(x)}{9} + \frac{1}{27}\right) + O(x^4)$$

```
int(exp(-x*sin(t)), t = 0.. x)
```

$$\int_0^x \mathrm{e}^{-x\sin(t)}\,\mathrm{d}t$$

```
series(%, x = 0)
```

$$x - \frac{x^3}{2} + \frac{5\,x^5}{24} + O(x^7)$$

```
int(cos((x*t^2 + x^2*t))^(1/3), t = 0..2)
```

$$\int_0^2 \cos(t^2 x + t x^2)^{1/3}\, \mathrm{d}t$$

```
series(%, x)
```

$$2 - \frac{16 x^2}{15} - \frac{4 x^3}{3} - \frac{100 x^4}{81} - \frac{16 x^5}{9} + O(x^6)$$

Example 17

Users can extend the power of `series` by implementing `series` attributes (slots) for their own special mathematical functions.

We illustrate how to write such a series attribute, using the case of the exponential function. (Of course, this function already has a `series` attribute in MuPAD, which you can inspect via `expose(exp::series)`.) In order not to overwrite the already existing attribute, we work on a copy of the exponential function called `Exp`.

The `series` attribute must be a procedure with four arguments. This procedure is called whenever a series expansion of `Exp` with an arbitrary argument is to be computed. The first argument is the argument of `Exp` in the `series` call. The second argument is the series variable; the expansion point is always the origin 0; other expansion points are internally moved to the origin by a change of variables. The third and the fourth argument are identical with the `order` and the `dir` argument of `series`, respectively.

For example, the command `series(Exp(x^2 + 2), x, 5)` is internally converted into the call `Exp::series(x^2 + x, x, 5, Undirected)`. Here is an example of a `series` attribute for `Exp`.

```
// The series attribute for Exp. It handles the call
// series(Exp(f), x = 0, order, dir)
ExpSeries := proc(f, x, order, dir)
  local t, x0, s, r, i;
begin
  // Expand the argument into a series.
  t := series(f, x, order, dir);
```

```
  // Determine the order k of the lowest term in t, so that
  // t = c*x^k + higher order terms, for some non-zero c.
  k := ldegree(t);

  if k = FAIL then
    // t consists only of an error term O(..)
    return(FAIL);

  elif k < 0 then
    // This corresponds to an expansion of exp around infinity,
    // which does not exist for the exponential
    // function, since it has an essential singularity. Thus we
    // return FAIL, which makes series return unevaluatedly. For
    // other special functions, you may add an asymptotic
    // expansion here.
    return(FAIL);

  else // k >= 0
    // This corresponds to an expansion of exp around a
    // finite point x0. We write t = x0 + y, where all
    // terms in y have positive order, use the
    // formula exp(x0 + y) = exp(x0)*exp(y) and compute
    // the series expansion of exp(y) as the functional
    // composition of the Taylor series of exp(x) around
    // x = 0 with t - x0. If your special function has
    // any finite singularities, then they should be
    // treated here.
    x0 := coeff(t, x, 0);
    s := Series::Puiseux::create(1, 0, order,
           [1/i! $ i = 0..(order - 1)], x, 0, dir);
    return(Series::Puiseux::scalmult(s @ (t - x0), Exp(x0), 0))
  end_if
end_proc:
```

This special function must be embedded in a function environment. The following command defines `Exp` as a function environment and lets the system function `exp` do the evaluation. The `subs` command applied on the result achieves that `Exp` with symbolic arguments is returned as `Exp` and not as `exp`.

```
Exp := funcenv(x -> subs(exp(x), hold(exp)=hold(Exp))):
Exp(1), Exp(-1.0), Exp(x^2 + x)
```

$$\mathrm{Exp}(1),\ 0.3678794412,\ \mathrm{Exp}(x^2 + x)$$

`series` can already handle this "new" function, but it can only compute a Taylor expansion with symbolic derivatives:

```
ORDER := 3: series(Exp(x), x = 0)
```

$$1 + x\,\mathrm{Exp}'(0) + \frac{x^2\,\mathrm{Exp}''(0)}{2} + O(x^3)$$

One can define the `series` attribute of `Exp` by assigning the procedure above to its `series` slot:

```
Exp::series := ExpSeries:
```

Now we can test the new attribute:

```
series(Exp(x^2 + x), x = 0) = series(exp(x^2 + x), x = 0)
```

$$1 + x + \frac{3\,x^2}{2} + O(x^3) = 1 + x + \frac{3\,x^2}{2} + O(x^3)$$

```
series(Exp(x^2 + x), x = 2) = series(exp(x^2 + x), x = 2)
```

$$\mathrm{Exp}(6) + 5\,\mathrm{Exp}(6)\,(x-2) + \frac{27\,\mathrm{Exp}(6)\,(x-2)^2}{2} + O((x-2)^3) =$$

$$e^6 + 5\,e^6\,(x-2) + \frac{27\,e^6\,(x-2)^2}{2} + O((x-2)^3)$$

```
series(Exp(x^2 + x), x = 0, 1)
```

$$1 + O(x)$$

```
series(Exp(x^2 + x), x = infinity)
```

$$\mathrm{series}(\mathrm{Exp}(x^2 + x), x = \infty)$$

Another possibility to obtain series expansions of user-defined functions is to define the `diff` attribute of the corresponding function environment. This is used by `series` to compute a Taylor expansion when no `series` attribute exists. However, this only works

when a Taylor expansion exists, whilst a `series` attribute can handle more general types of series expansions as well.

```
delete ExpSeries, Exp:
```

Parameters

`f`

An arithmetical expression representing a function in `x`

`x`

An identifier

x_0

The expansion point: an arithmetical expression. If not specified, the default expansion point 0 is used.

`order`

The number of terms to be computed: a nonnegative integer or `infinity`. The default order is given by the environment variable `ORDER` (default value 6).

Options

`Left`, `Real`, `Right`, `Undirected`

If no expansion exists that is valid in the complex plane, this argument can be used to request expansions that only need to be valid along the real line. The default is `Undirected`.

`NoWarning`

Supresses warning messages printed during the series computation. This can be useful if `series` is called within user-defined procedures.

`UseGseries`

Option, specified as `UseGseries = b`

Use `Series::gseries` to compute the series. `b` must be `TRUE` or `FALSE`. Default is `TRUE`. Even if this option is set to `TRUE`, computing a Puiseux expansion will be attempted first.

Return Values

If `order` is a nonnegative integer, then `series` returns either an object of the domain type `Series::Puiseux` or `Series::gseries`, an expression of type `"series"`, or, if `f` is a `RootOf` expression, a set of type `Type::Set`. If `order = infinity`, then `series` returns an arithmetical expression.

Si

Sine integral function

Syntax

```
Si(x)
```

Description

`Si(x)` represents the sine integral $\int_0^x \frac{\sin(t)}{t}\,dt$.

If `x` is a floating-point number, then `Si(x)` returns numerical values. The special values $Si(0) = 0$, $\mathrm{Si}(\infty) = \frac{\pi}{2}$, $\mathrm{Si}(-\infty) = -\frac{\pi}{2}$ are implemented. For all other arguments, `Si` returns symbolic function calls.

The reflection rule $Si(x) = -Si(-x)$ is used if the argument is a negative integer or a negative rational number. It is also used if the argument is a symbolic product involving such a factor. Cf. "Example 2" on page 1-1824.

The float attribute of `Si` is a kernel function, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
Si(0), Si(1), Si(sqrt(2)), Si(x + 1), Si(infinity)
```

$$0,\ \mathrm{Si}(1),\ \mathrm{Si}(\sqrt{2}),\ \mathrm{Si}(x+1),\ \frac{\pi}{2}$$

```
Ssi(0), Ssi(1), Ssi(sqrt(2)), Ssi(x + 1), Ssi(infinity)
```

$$-\frac{\pi}{2},\ \mathrm{Ssi}(1),\ \mathrm{Ssi}(\sqrt{2}),\ \mathrm{Ssi}(x+1),\ 0$$

```
Shi(0), Shi(1), Shi(sqrt(2)), Shi(x + 1), Shi(infinity)
```

$$0,\ \mathrm{Shi}(1),\ \mathrm{Shi}(\sqrt{2}),\ \mathrm{Shi}(x+1),\ \infty$$

Floating point values are computed for floating-point arguments:

```
Si(-5.0), Si(1.0), Si(2.0 + 10.0*I)
```

$$-1.549931245,\ 0.9460830704,\ 1187.409493 - 242.5252717\,i$$

```
Ssi(-5.0), Ssi(1.0), Ssi(2.0 + 10.0*I)
```

$$-3.120727572,\ -0.6247132564,\ 1185.838696 - 242.5252717\,i$$

```
Shi(-5.0), Shi(1.0), Shi(2.0 + 10.0*I)
```

$$-20.09321183,\ 1.057250875,\ -0.225644485 + 1.861300836\,i$$

Example 2

The reflection rule *Si*(- *x*) = - *Si*(*x*), *Ssi*(- *x*) = - *Ssi*(*x*) - π, *Shi*(- *x*) = - *Shi*(*x*) is implemented for negative real numbers and products involving such numbers:

```
Si(-3), Si(-3/7), Si(-sqrt(2)), Si(-x/7), Si(-0.3*x)
```

$$-\mathrm{Si}(3),\ -\mathrm{Si}\left(\frac{3}{7}\right),\ -\mathrm{Si}(\sqrt{2}),\ -\mathrm{Si}\left(\frac{x}{7}\right),\ -\mathrm{Si}(0.3\,x)$$

```
Ssi(-3), Ssi(-3/7), Ssi(-sqrt(2)), Ssi(-x/7), Ssi(-0.3*x)
```

$$-\pi - \mathrm{Ssi}(3),\ -\pi - \mathrm{Ssi}\left(\frac{3}{7}\right),\ -\pi - \mathrm{Ssi}(\sqrt{2}),\ -\pi - \mathrm{Ssi}\left(\frac{x}{7}\right),\ -\mathrm{Ssi}(0.3\,x) - 3.141592654$$

```
Shi(-3), Shi(-3/7), Shi(-sqrt(2)), Shi(-x/7), Shi(-0.3*x)
```

$$-\mathrm{Shi}(3),\ -\mathrm{Shi}\left(\frac{3}{7}\right),\ -\mathrm{Shi}(\sqrt{2}),\ -\mathrm{Shi}\left(\frac{x}{7}\right),\ -\mathrm{Shi}(0.3\,x)$$

No such “normalization” occurs for complex numbers or arguments that are not products:

```
Si(- 3 - I), Si(3 + I), Si(x - 1), Si(1 - x)
```

$$\mathrm{Si}(-3-i),\ \mathrm{Si}(3+i),\ \mathrm{Si}(x-1),\ \mathrm{Si}(1-x)$$

```
Ssi(- 3 - I), Ssi(3 + I), Ssi(x - 1), Ssi(1 - x)
```

$$\mathrm{Ssi}(-3-i),\ \mathrm{Ssi}(3+i),\ \mathrm{Ssi}(x-1),\ \mathrm{Ssi}(1-x)$$

```
Shi(- 3 - I), Shi(3 + I), Shi(x - 1), Shi(1 - x)
```

$$\mathrm{Shi}(-3-i),\ \mathrm{Shi}(3+i),\ \mathrm{Shi}(x-1),\ \mathrm{Shi}(1-x)$$

Example 3

The functions `diff`, `float`, `limit`, and `series` handle expressions involving `Si` and `Shi`:

```
diff(Si(x), x, x, x), float(ln(3 + Si(sqrt(PI))))
```

$$\frac{2\sin(x)}{x^3} - \frac{\sin(x)}{x} - \frac{2\cos(x)}{x^2},\ 1.502020149$$

```
diff(Ssi(x), x, x, x), float(ln(3 + Ssi(sqrt(PI))))
```

$$\frac{2\sin(x)}{x^3} - \frac{\sin(x)}{x} - \frac{2\cos(x)}{x^2},\ 1.071568401$$

```
diff(Shi(x), x, x, x), float(ln(3 + Shi(sqrt(PI))))
```

$$\frac{\sinh(x)}{x} - \frac{2\cosh(x)}{x^2} + \frac{2\sinh(x)}{x^3},\ 1.631702794$$

```
limit(Si(2*x^2/(1+x)), x = infinity)
```

$$\frac{\pi}{2}$$

```
limit(Ssi(2*x^2/(1+x)), x = infinity)
```

$$0$$

```
limit(Shi(2*I*x^2/(1+x)), x = infinity)
```

$$\frac{\pi\, i}{2}$$

```
series(Si(x), x = 0)
```

$$x - \frac{x^3}{18} + \frac{x^5}{600} + O(x^7)$$

```
series(Ssi(x), x = 0)
```

$$-\frac{\pi}{2} + x - \frac{x^3}{18} + \frac{x^5}{600} + O(x^6)$$

```
series(Shi(x), x = 0)
```

$$x + \frac{x^3}{18} + \frac{x^5}{600} + O(x^7)$$

```
series(Si(x), x = infinity, 3)
```

$$\frac{\pi}{2} - \frac{\cos(x)}{x} - \frac{\sin(x)}{x^2} + O\left(\frac{1}{x^3}\right)$$

```
series(Ssi(x), x = infinity, 3)
```

$$-\frac{\cos(x)}{x}-\frac{\sin(x)}{x^2}+\frac{2\cos(x)}{x^3}+O\left(\frac{1}{x^4}\right)$$

```
series(Shi(I*x), x = infinity, 3)
```

$$\frac{\pi\,i}{2}-\frac{\cos(x)\,i}{x}-\frac{\sin(x)\,i}{x^2}+O\left(\frac{1}{x^3}\right)$$

Parameters

x

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

x

Algorithms

Si, *Ssi*, and *Shi* are entire functions.

`Si` and `Ssi` are related by $Ssi(x) = Si(x) - \pi$ for all x in the complex plane.

`Si` and `Shi` are related by $i\,Si(x) = Shi(i\,x)$ for all x in the complex plane.

Ssi

Shifted sine integral function

Syntax

```
Ssi(x)
```

Description

`Ssi(x)` represents the shifted sine integral $\mathrm{Si}(x) - \frac{\pi}{2}$.

The special values $\mathrm{Ssi}(0) = -\frac{\pi}{2}$, $Ssi(\infty) = 0$, $Ssi(-\infty) = -\pi$ are implemented.

The reflection rule $Ssi(x) = -Ssi(-x) - \pi$ is used if the argument is a negative integer or a negative rational number. It is also used if the argument is a symbolic product involving such a factor. Cf. “Example 2” on page 1-1830.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
Si(0), Si(1), Si(sqrt(2)), Si(x + 1), Si(infinity)
```

$$0,\ \mathrm{Si}(1),\ \mathrm{Si}(\sqrt{2}),\ \mathrm{Si}(x+1),\ \frac{\pi}{2}$$

```
Ssi(0), Ssi(1), Ssi(sqrt(2)), Ssi(x + 1), Ssi(infinity)
```

$$-\frac{\pi}{2},\ \mathrm{Ssi}(1),\ \mathrm{Ssi}(\sqrt{2}),\ \mathrm{Ssi}(x+1),\ 0$$

```

```

$$0,\ \mathrm{Shi}(1),\ \mathrm{Shi}(\sqrt{2}),\ \mathrm{Shi}(x+1),\ \infty$$

Floating point values are computed for floating-point arguments:

```
Si(-5.0), Si(1.0), Si(2.0 + 10.0*I)
```

$$-1.549931245,\ 0.9460830704,\ 1187.409493 - 242.5252717\,i$$

```
Ssi(-5.0), Ssi(1.0), Ssi(2.0 + 10.0*I)
```

$$-3.120727572,\ -0.6247132564,\ 1185.838696 - 242.5252717\,i$$

```
Shi(-5.0), Shi(1.0), Shi(2.0 + 10.0*I)
```

$$-20.09321183,\ 1.057250875,\ -0.225644485 + 1.861300836\,i$$

Example 2

The reflection rule *Si*(- *x*) = - *Si*(*x*), *Ssi*(- *x*) = - *Ssi*(*x*) - π, *Shi*(- *x*) = - *Shi*(*x*) is implemented for negative real numbers and products involving such numbers:

```
Si(-3), Si(-3/7), Si(-sqrt(2)), Si(-x/7), Si(-0.3*x)
```

$$-\mathrm{Si}(3),\ -\mathrm{Si}\left(\frac{3}{7}\right),\ -\mathrm{Si}(\sqrt{2}),\ -\mathrm{Si}\left(\frac{x}{7}\right),\ -\mathrm{Si}(0.3\,x)$$

```
Ssi(-3), Ssi(-3/7), Ssi(-sqrt(2)), Ssi(-x/7), Ssi(-0.3*x)
```

$$-\pi - \mathrm{Ssi}(3),\ -\pi - \mathrm{Ssi}\left(\frac{3}{7}\right),\ -\pi - \mathrm{Ssi}(\sqrt{2}),\ -\pi - \mathrm{Ssi}\left(\frac{x}{7}\right),\ -\mathrm{Ssi}(0.3\,x) - 3.141592654$$

```
Shi(-3), Shi(-3/7), Shi(-sqrt(2)), Shi(-x/7), Shi(-0.3*x)
```

$$-\mathrm{Shi}(3),\ -\mathrm{Shi}\left(\frac{3}{7}\right),\ -\mathrm{Shi}(\sqrt{2}),\ -\mathrm{Shi}\left(\frac{x}{7}\right),\ -\mathrm{Shi}(0.3\,x)$$

No such “normalization” occurs for complex numbers or arguments that are not products:

```
Si(- 3 - I), Si(3 + I), Si(x - 1), Si(1 - x)
```

$$\mathrm{Si}(-3-i),\ \mathrm{Si}(3+i),\ \mathrm{Si}(x-1),\ \mathrm{Si}(1-x)$$

```
Ssi(- 3 - I), Ssi(3 + I), Ssi(x - 1), Ssi(1 - x)
```

$$\mathrm{Ssi}(-3-i),\ \mathrm{Ssi}(3+i),\ \mathrm{Ssi}(x-1),\ \mathrm{Ssi}(1-x)$$

```
Shi(- 3 - I), Shi(3 + I), Shi(x - 1), Shi(1 - x)
```

$$\mathrm{Shi}(-3-i),\ \mathrm{Shi}(3+i),\ \mathrm{Shi}(x-1),\ \mathrm{Shi}(1-x)$$

Example 3

The functions `diff`, `float`, `limit`, and `series` handle expressions involving `Si` and `Shi`:

```
diff(Si(x), x, x, x), float(ln(3 + Si(sqrt(PI))))
```

$$\frac{2\sin(x)}{x^3}-\frac{\sin(x)}{x}-\frac{2\cos(x)}{x^2},\ 1.502020149$$

```
diff(Ssi(x), x, x, x), float(ln(3 + Ssi(sqrt(PI))))
```

$$\frac{2\sin(x)}{x^3}-\frac{\sin(x)}{x}-\frac{2\cos(x)}{x^2},\ 1.071568401$$

```
diff(Shi(x), x, x, x), float(ln(3 + Shi(sqrt(PI))))
```

$$\frac{\sinh(x)}{x}-\frac{2\cosh(x)}{x^2}+\frac{2\sinh(x)}{x^3},\ 1.631702794$$

```
limit(Si(2*x^2/(1+x)), x = infinity)
```

$$\frac{\pi}{2}$$

```
limit(Ssi(2*x^2/(1+x)), x = infinity)
```

$$0$$

```
limit(Shi(2*I*x^2/(1+x)), x = infinity)
```

$$\frac{\pi\,\mathrm{i}}{2}$$

```
series(Si(x), x = 0)
```

$$x - \frac{x^3}{18} + \frac{x^5}{600} + O(x^7)$$

```
series(Ssi(x), x = 0)
```

$$-\frac{\pi}{2} + x - \frac{x^3}{18} + \frac{x^5}{600} + O(x^6)$$

```
series(Shi(x), x = 0)
```

$$x + \frac{x^3}{18} + \frac{x^5}{600} + O(x^7)$$

```
series(Si(x), x = infinity, 3)
```

$$\frac{\pi}{2} - \frac{\cos(x)}{x} - \frac{\sin(x)}{x^2} + O\left(\frac{1}{x^3}\right)$$

```
series(Ssi(x), x = infinity, 3)
```

$$-\frac{\cos(x)}{x} - \frac{\sin(x)}{x^2} + \frac{2\cos(x)}{x^3} + O\left(\frac{1}{x^4}\right)$$

```
series(Shi(I*x), x = infinity, 3)
```

$$\frac{\pi\,\mathrm{i}}{2} - \frac{\cos(x)\,\mathrm{i}}{x} - \frac{\sin(x)\,\mathrm{i}}{x^2} + O\left(\frac{1}{x^3}\right)$$

Parameters

x

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

x

Algorithms

Si, *Ssi*, and *Shi* are entire functions.

`Si` and `Ssi` are related by $Ssi(x) = Si(x) - \pi$ for all x in the complex plane.

`Si` and `Shi` are related by $\mathrm{i}\,Si(x) = Shi(\mathrm{i}\,x)$ for all x in the complex plane.

MuPAD Functions

`Chi` | `Ci` | `Ei` | `int` | `Li` | `Shi` | `Si` | `sin`

Shi

Hyperbolic sine integral function

Syntax

```
Shi(x)
```

Description

`Shi(x)` represents the hyperbolic sine integral $\int_0^x \frac{\sinh(t)}{t}\,dt$.

If `x` is a floating-point number, then `Shi(x)` returns numerical values. The special values $Shi(0) = 0$, $Shi(\infty) = \infty$, $Shi(-\infty) = -\infty$ are implemented. For all other arguments, `Shi` returns symbolic function calls.

The reflection rule $Shi(x) = -Shi(-x)$ is used if the argument is a negative integer or a negative rational number. It is also used if the argument is a symbolic product involving such a factor. Cf. "Example 2" on page 1-1835.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
Si(0), Si(1), Si(sqrt(2)), Si(x + 1), Si(infinity)
```

$$0,\ \mathrm{Si}(1),\ \mathrm{Si}(\sqrt{2}),\ \mathrm{Si}(x+1),\ \frac{\pi}{2}$$

```
Ssi(0), Ssi(1), Ssi(sqrt(2)), Ssi(x + 1), Ssi(infinity)
```

$$-\frac{\pi}{2},\ \mathrm{Ssi}(1),\ \mathrm{Ssi}(\sqrt{2}),\ \mathrm{Ssi}(x+1),\ 0$$

```
Shi(0), Shi(1), Shi(sqrt(2)), Shi(x + 1), Shi(infinity)
```

$$0,\ \mathrm{Shi}(1),\ \mathrm{Shi}(\sqrt{2}),\ \mathrm{Shi}(x+1),\ \infty$$

Floating point values are computed for floating-point arguments:

```
Si(-5.0), Si(1.0), Si(2.0 + 10.0*I)
```

$$-1.549931245,\ 0.9460830704,\ 1187.409493 - 242.5252717\,i$$

```
Ssi(-5.0), Ssi(1.0), Ssi(2.0 + 10.0*I)
```

$$-3.120727572,\ -0.6247132564,\ 1185.838696 - 242.5252717\,i$$

```
Shi(-5.0), Shi(1.0), Shi(2.0 + 10.0*I)
```

$$-20.09321183,\ 1.057250875,\ -0.225644485 + 1.861300836\,i$$

Example 2

The reflection rule *Si*(- *x*) = - *Si*(*x*), *Ssi*(- *x*) = - *Ssi*(*x*) - π, *Shi*(- *x*) = - *Shi*(*x*) is implemented for negative real numbers and products involving such numbers:

```
Si(-3), Si(-3/7), Si(-sqrt(2)), Si(-x/7), Si(-0.3*x)
```

$$-\mathrm{Si}(3),\ -\mathrm{Si}\left(\frac{3}{7}\right),\ -\mathrm{Si}(\sqrt{2}),\ -\mathrm{Si}\left(\frac{x}{7}\right),\ -\mathrm{Si}(0.3\,x)$$

```
Ssi(-3), Ssi(-3/7), Ssi(-sqrt(2)), Ssi(-x/7), Ssi(-0.3*x)
```

$$-\pi - \mathrm{Ssi}(3),\ -\pi - \mathrm{Ssi}\left(\frac{3}{7}\right),\ -\pi - \mathrm{Ssi}(\sqrt{2}),\ -\pi - \mathrm{Ssi}\left(\frac{x}{7}\right),\ -\mathrm{Ssi}(0.3\,x) - 3.141592654$$

```
Shi(-3), Shi(-3/7), Shi(-sqrt(2)), Shi(-x/7), Shi(-0.3*x)
```

$$-\mathrm{Shi}(3),\ -\mathrm{Shi}\left(\frac{3}{7}\right),\ -\mathrm{Shi}(\sqrt{2}),\ -\mathrm{Shi}\left(\frac{x}{7}\right),\ -\mathrm{Shi}(0.3\,x)$$

No such “normalization” occurs for complex numbers or arguments that are not products:

```
Si(- 3 - I), Si(3 + I), Si(x - 1), Si(1 - x)
```

$$\mathrm{Si}(-3-i),\ \mathrm{Si}(3+i),\ \mathrm{Si}(x-1),\ \mathrm{Si}(1-x)$$

```
Ssi(- 3 - I), Ssi(3 + I), Ssi(x - 1), Ssi(1 - x)
```

$$\mathrm{Ssi}(-3-i),\ \mathrm{Ssi}(3+i),\ \mathrm{Ssi}(x-1),\ \mathrm{Ssi}(1-x)$$

```
Shi(- 3 - I), Shi(3 + I), Shi(x - 1), Shi(1 - x)
```

$$\mathrm{Shi}(-3-i),\ \mathrm{Shi}(3+i),\ \mathrm{Shi}(x-1),\ \mathrm{Shi}(1-x)$$

Example 3

The functions `diff`, `float`, `limit`, and `series` handle expressions involving `Si` and `Shi`:

```
diff(Si(x), x, x, x), float(ln(3 + Si(sqrt(PI))))
```

$$\frac{2\sin(x)}{x^3}-\frac{\sin(x)}{x}-\frac{2\cos(x)}{x^2},\ 1.502020149$$

```
diff(Ssi(x), x, x, x), float(ln(3 + Ssi(sqrt(PI))))
```

$$\frac{2\sin(x)}{x^3}-\frac{\sin(x)}{x}-\frac{2\cos(x)}{x^2},\ 1.071568401$$

```
diff(Shi(x), x, x, x), float(ln(3 + Shi(sqrt(PI))))
```

$$\frac{\sinh(x)}{x}-\frac{2\cosh(x)}{x^2}+\frac{2\sinh(x)}{x^3},\ 1.631702794$$

```
limit(Si(2*x^2/(1+x)), x = infinity)
```

$$\frac{\pi}{2}$$

```
limit(Ssi(2*x^2/(1+x)), x = infinity)
```

$$0$$

```
limit(Shi(2*I*x^2/(1+x)), x = infinity)
```

$$\frac{\pi\,\mathrm{i}}{2}$$

```
series(Si(x), x = 0)
```

$$x - \frac{x^3}{18} + \frac{x^5}{600} + O(x^7)$$

```
series(Ssi(x), x = 0)
```

$$-\frac{\pi}{2} + x - \frac{x^3}{18} + \frac{x^5}{600} + O(x^6)$$

```
series(Shi(x), x = 0)
```

$$x + \frac{x^3}{18} + \frac{x^5}{600} + O(x^7)$$

```
series(Si(x), x = infinity, 3)
```

$$\frac{\pi}{2} - \frac{\cos(x)}{x} - \frac{\sin(x)}{x^2} + O\left(\frac{1}{x^3}\right)$$

```
series(Ssi(x), x = infinity, 3)
```

$$-\frac{\cos(x)}{x} - \frac{\sin(x)}{x^2} + \frac{2\cos(x)}{x^3} + O\left(\frac{1}{x^4}\right)$$

```
series(Shi(I*x), x = infinity, 3)
```

$$\frac{\pi\,\mathrm{i}}{2} - \frac{\cos(x)\,\mathrm{i}}{x} - \frac{\sin(x)\,\mathrm{i}}{x^2} + O\left(\frac{1}{x^3}\right)$$

Parameters

MuPAD Functions

`Chi` | `Ci` | `Ei` | `int` | `Li` | `Si` | `sin` | `Ssi`

sign

Sign of a real or complex number

Syntax

```
sign(z)
```

Description

`sign(z)` returns the sign of the number `z`.

Mathematically, the sign of a complex number $z \neq 0$ is defined as $\frac{z}{|z|}$. For real numbers, this reduces to 1 or - 1.

`sign()` and `sign(0.0)` return `0`. The user may redefine this value by a direct assignment, e.g.:

```
unprotect(sign): sign(0) := 1: protect(sign):
```

If the type of `z` is `DOM_INT`, `DOM_RAT`, or `DOM_FLOAT`, a fast kernel function is used to determine the sign. The return value is either - 1, 0, or 1.

If the sign of the expression cannot be determined, a symbolic function call is returned. Certain simplifications are implemented. In particular, numerical factors of symbolic products are simplified. Cf. “Example 2” on page 1-1840.

The `expand` function rewrites the sign of a product to a product of signs. E.g., `expand(sign(x*y))` yields `sign(x)*sign(y)`. Cf. “Example 2” on page 1-1840.

For constant expressions such as `PI - sqrt(2)`, `exp(I*3) - I*sin(3)` etc., internal floating-point evaluation is used to determine, whether the expression represents a non-zero real number. If so, the sign - 1 or 1 is returned. Internally, the floating-point approximation is checked for reliability. Cf. “Example 4” on page 1-1841.

Environment Interactions

`sign` respects properties of identifiers. For real expressions, the result may depend on the value of the environment variable `DIGITS`.

Examples

Example 1

We compute the sign of various real numbers and expressions:

```
sign(-8/3), sign(3.2), sign(exp(3) - sqrt(2)*PI), sign(0)
```

$$-1,\ 1,\ 1,\ 0$$

The sign of a complex number `z` is the complex number `z/abs(z)`:

```
sign(0.5 + 1.1*I), sign(2 + 3*I), sign(exp(sin(2 + 3*I)))
```

$$0.4138029443 + 0.9103664775\,i,\ \sqrt{13}\left(\frac{2}{13}+\frac{3\,i}{13}\right),\ e^{\cos(2)\sinh(3)\,i}$$

Example 2

`sign` yields a symbolic, yet simplified, function call if identifiers are involved:

```
sign(x), sign(2*x*y), sign(2*x + y),  sign(PI*exp(2 + y))
```

$$\mathrm{sign}(x),\ \mathrm{sign}(x\,y),\ \mathrm{sign}(2\,x+y),\ \mathrm{sign}\left(e^{y+2}\right)$$

In special cases, the `expand` function may provide further simplifications:

```
expand(sign(2*x*y)), expand(sign(PI*exp(2 + y)))
```

$$\mathrm{sign}(x)\ \mathrm{sign}(y),\ \mathrm{sign}(e^{y})$$

Example 3

`sign` respects properties of identifiers:

```
sign(x + PI)
```

$$\operatorname{sign}(\pi + x)$$

```
assume(x > -3): sign(x + PI)
```

$$1$$

```
unassume(x):
```

Example 4

The following rational number approximates π to about 30 digits:

```
p:= 392699081698724154807830422 91/125000000000000000000000000000:
```

With the standard precision `DIGITS =10`, the float test inside `sign` does not give a decisive answer, whether `p` is larger or smaller than π:

```
float(PI - p)
```

$$0.0$$

This result is subject to numerical roundoff and does not allow a conclusion on the sign of the number `PI - p`. The float test inside `sign` checks the reliablity of floating-point approximations. In this case, no simplified result is returned:

```
sign(PI - p)
```

$$\operatorname{sign}\left(\pi - \frac{392699081698724154807830422 91}{125000000000000000000000000000}\right)$$

With increased `DIGITS`, a reliable decision can be taken:

```
DIGITS := 30: sign(PI - p)
```

```
     - 1
```

```
delete p, DIGITS:
```

Parameters

z

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

z

See Also

MuPAD Functions

`abs` | `conjugate` | `Im` | `Re`

signIm

Sign of the imaginary part of a complex number

Syntax

```
signIm(z)
```

Description

`signIm(z)` represents the sign of `Im(z)`.

`signIm(z)` indicates whether the complex number `z` lies in the upper or in the lower half plane: `signIm(z)` yields 1 if `Im(z) > 0`, or if `z` is real and `z < 0`. At the origin: `signIm(0)=0`. For all other numerical arguments, - 1 is returned. Thus, `signIm(z)=sign(Im(z))` if `z` is not on the real axis.

If the position of the argument in the complex plane cannot be determined, then a symbolic call is returned. If appropriate, the reflection rule `signIm(-x) = -signIm(x)` is used.

The functions `diff` and `series` treat `signIm` as a constant function. Cf. “Example 2” on page 1-1845.

The following relation holds for arbitrary complex z and p:

$$(-z)^p = z^p \frac{1}{(-1)^{p\,\mathrm{signIm}(z)}}.$$

Further, for arbitrary complex z:

$$\sqrt{z^2} = z\,\mathrm{signIm}(\mathrm{i}\,z)$$

and

$$\ln(-z) = \ln(z) - \mathrm{signIm}(z)\,\pi\,\mathrm{i}.$$

Environment Interactions

Properties of identifiers set via `assume` are taken into account.

Examples

Example 1

For numerical values, the position in the complex plane can always be determined:

```
signIm(2 + I), signIm(- 4 - I*PI), signIm(0.3), signIm(-2/7),
signIm(-sqrt(2) + 3*I*PI)
```

$$1, -1, -1, 1, 1$$

Symbolic arguments without properties lead to symbolic calls:

```
signIm(x), signIm(x - I*sqrt(2))
```

$$\mathrm{signIm}(x),\ \mathrm{signIm}(x - \sqrt{2}\ \mathrm{i})$$

Properties set via `assume` are taken into account:

```
assume(x, Type::Real): signIm(x - I*sqrt(2))
```

$$-1$$

```
assume(x > 0): signIm(x)
```

$$-1$$

```
assume(x < 0): signIm(x)
```

$$1$$

```
assume(x = 0): signIm(x)
```

```
    0
```

```
unassume(x):
```

Example 2

`signIm` is a constant function, apart from the jump discontinuities along the real axis. These discontinuities are ignored by `diff`:

```
diff(signIm(z), z)
```

```
    0
```

Also `series` treats `signIm` as a constant function:

```
series(signIm(z/(1 - z)), z = 0)
```

$$-\mathrm{signIm}\left(\frac{z}{z-1}\right)+O(z^6)$$

Parameters

z

An arithmetical expression representing a complex number

Return Values

Either ± 1, 0, or a symbolic call of type `"signIm"`.

Overloaded By

z

simplify

Simplify an expression

Syntax

```
simplify(f, <target>, options)
```

```
simplify(L, <target>, options)
```

Description

`simplify(f)` tries to simplify the expression `f` by applying term rewriting rules.

`simplify(f, target)` restricts the simplification to term rewriting rules applicable to one or more target functions.

Note: The `cos`, `sin`, `exp`, `ln`, and `sqrt` targets has been removed. Use `simplify` function calls without these targets. Alternatively, use `radsimp` instead of `simplify` with the `sqrt` target.

The `simplify` function performs sequential simplifications. It applies a certain set of term-rewriting rules to the original expression, rewrites the expression according to these rules, takes the result, and applies the next set of term-rewriting rules. The `simplify` function assumes that the output of every rule is "simpler" than the input without further checks. Generally, this method is faster, but less reliable and controllable than the algorithm used by `Simplify`.

If you do not specify a target, `simplify` tries to simplify the whole expression. This first step includes rewriting of products of trigonometric and exponential terms. After that, the function tries to simplify the operands of the expression. If an expression contains special functions, MuPAD calls, the simplification methods available for these functions.

The call `simplify(L, target )` applies simplifications to the operands of the object `L`.

If you specify the `logic` target, the `simplify` function simplifies Boolean expressions. With the `logic` target, `simplify` does not use properties and assumptions specified for the terms of Boolean expressions.

If you specify the `condition` target, the `simplify` function simplifies Boolean expressions. With the `condition` target, `simplify` uses properties and assumptions specified for the terms of Boolean expressions.

Environment Interactions

`simplify` reacts to properties of identifiers.

Examples

Example 1

Use the `simplify` function to simplify the following algebraic expressions:

```
simplify(exp(x)-exp(x/2)^2)
```

$$0$$

```
f := ln(x) + ln(3) - ln(3*x) + (exp(x) - 1)/(exp(x/2) + 1):
simplify(f)
```

$$e^{\frac{x}{2}} - 1$$

Example 2

To simplify Boolean expressions, use the `logic` target:

```
simplify((a and b) or (a and (not b)), logic)
```

$$a$$

Example 3

Alternatively, to simplify Boolean expressions, use the `condition` target. With the `condition` target, `simplify` uses the properties and assumptions specified for the

terms of Boolean expressions. With the `logic` target, `simplify` ignores those properties and assumptions:

```
simplify(x > x, condition), simplify(x > x, logic)
```

$$\text{FALSE}, x < x$$

Example 4

The option `IgnoreAnalyticConstraints` allows you to get simpler results using a set of purely algebraic simplifications:

```
simplify(ln(x^2 + 2*x + 1) - ln(x + 1))
```

$$\ln((x+1)^2) - \ln(x+1)$$

```
simplify(ln(x^2 + 2*x + 1) - ln(x + 1), IgnoreAnalyticConstraints)
```

$$\ln(x+1)$$

If you use this option, the simplifier does not guarantee the equality of the initial expression and the result for all symbolic parameters.

Example 5

To change the number of simplification steps, use the `Steps` option:

```
f := ((exp(-x*i)*i)/2 - (exp(x*i)*i)/2)/(exp(-x*i)/2 + exp(x*i)/2):
simplify(f);
simplify(f, Steps = 10);
simplify(f, Steps = 30)
```

$$-\frac{i\left(e^{2ix}-1\right)}{e^{2ix}+1}$$

$$\frac{2i}{e^{2ix}+1} - i$$

$$-i\tanh(i\,x)$$

Example 6

Your custom functions can have simplification attributes. For example, suppose you know that *f* is an additive function, but you do not know more about *f*. Therefore, you cannot compute the function value of at any point except zero, but you can use the additivity:

```
f := funcenv( x -> if iszero(x) then 0 else procname(x) end):
f::simplify := proc(F)
                 local argument;
                 begin
                   argument := op(F,1);
                   if type(argument) = "_plus" then
                     map(argument, f)
                   else
                     F
                   end
                 end:

f(x + 3*y) - f(3*y) = simplify(f(x + 3*y) - f(3*y))
```

$$f(x+3\,y)-f(3\,y)=f(x)$$

You can refine the simplification attribute of `f` further. For example, you can specify that it must turn `f(3*y)` into `3*f(y)`. The reverse rule (rewriting $f(x) + f(y)$ as $f(x + y)$) is not context-free. Therefore, you cannot implement the reverse rule in a simplification attribute.

Parameters

`f`

An arithmetical expression

`L`

A container object: an array, an hfarray, a list, a matrix, a polynomial, a set, or a table.

target

One of the identifiers `unit`, `logic`, or `condition`

Options

IgnoreAnalyticConstraints

With this option the simplifier applies the following rules to expressions:

- $ln(a) + ln(b) = ln(a\,b)$ for all values of a and b. In particular:

  $(a\,b)^c = e^{c\,\ln(a\,b)} = e^{c\,(\ln(a)+\ln(b))} = a^c\,b^c$ for all values of a, b, and c
- $ln(a^b) = b\,ln(a)$ for all values of a and b. In particular:

  $(a^b)^c = e^{b\,c\,\ln(a)} = e^{\ln(a)^{b\,c}} = a^{b\,c}$ for all values of a, b, and c
- If f and g are standard mathematical functions and $f(g(x)) = x$ for all small positive numbers, $f(g(x)) = x$ is assumed to be valid for all complex x. In Particular:
- - $\ln(e^x) = x$
  - $arcsin(sin(x)) = x$, $arccos(cos(x)) = x$, $arctan(tan(x)) = x$
  - $arcsinh(sinh(x)) = x$, $arccosh(cosh(x)) = x$, $arctanh(tanh(x)) = x$
  - $W_k(x\,e^x) = x$ for all values of k

Using the `IgnoreAnalyticConstraints` option can give you simple results for expressions for which the direct use of the simplifier returns complicated results. With this option the simplifier does not guarantee the equality of the initial expression and the result for all symbolic parameters. See “Example 4” on page 1-1848.

Seconds

Limit the time allowed for the internal simplification process. The value denotes the maximal time in seconds. By default, the simplification time is unlimited.

Steps

Terminate algebraic simplification after the specified number of simplification steps. The value must be a positive integer. the default number of simplification steps is 1.

Return Values

Object of the same type as the input object `f` or `L`, respectively.

Overloaded By

f, L

Simplify

Simplify an expression

Syntax

```
Simplify(f)
```

```
Simplify(f, Steps = numberOfSteps)
```

```
Simplify(f, options)
```

Description

`Simplify(f)` applies term-rewriting rules to `f` and returns the simplest expression it can find.

The methods of searching for the simplest representation of an expression are different for `Simplify` and `simplify`. The `simplify` function performs a linear search trying to improve the result returned by the previous simplification step. The `Simplify` function uses the results returned by all previous simplification steps (the best-first search). The `simplify` function is faster. The `Simplify` function is slower, but more effective and more configurable.

The term “simplest” is defined as follows. One object is simpler than another if it has smaller *valuation*. If two objects have the same valuation, `Simplify` chooses the simpler object using internal heuristics. A valuation is a function that assigns a nonnegative real number to each MuPAD object. To override the default valuation used by `Simplify`, use the `Valuation` option. `Simplify` uses the valuation for the best-first search as for determining the best result at the final step. However, you can define a separate method for the final simplification step by using the `Criterion` option.

The simplification process consists of *steps*. In each step, `Simplify` performs one of the following kinds of tasks for `a := f` or some (previously obtained) object `a` equivalent to `f`. In each step, `Simplify` can produce new objects equivalent to `f` (results) or new tasks to do or both:

- Initial step: Find all *rules* for `a`. The `Simplify` function performs the search for all rules for every new object `a`. This search produces no new result.

- Rewriting step: Apply one rule to `a`. This step can either fail or produce an equivalent object as result.
- Subexpression step: Perform one step in simplifying an operand of `a`. Replace the operand with the returned result (if there are any results). This step can produce a new equivalent object.

Each open task has a priority that determines what to do next. Simplification terminates in any of the following cases:

- There are no more open tasks.
- `Simplify` reached the time limit specified by `Seconds`.
- `Simplify` performed the maximal number of simplification steps specified by `Steps`.
- `Simplify` returned the object specified by `Goal`.

`Simplify` always returns the "simplest" equivalent object found in all simplification steps unless you specify another `OutputType`.

Rules form a particular domain `Rule`. They consist of a pattern (left side), an expression (right side), and options.

MuPAD organizes rules for `Simplify` in *rule bases*. You can change the default rule base by using the `RuleBase` option. You also can define your own rule selection mechanism by using the `SelectRules` option.

Typically, `Simplify` applies the selected rules to the given object `a` as a whole. The following case is an exception from this rule. If the pattern of the rule and the object `a` are both a sum or a product, then `Simplify` applies the rule to each subsum or subproduct of `a` that has the same number of operands as the pattern.

By using the `ApplyRule` option, you can specify your own function that applies a particular rule to a particular object. Otherwise, `Simplify` uses a default method.

The application of a rule to an object `a` fails if the pattern does not match (see `match`) the object `a`. The performance of `Simplify` strongly depends on the number of successful matches. Therefore, if you specify your own rule base, it must dispose of non-matching rules before rule selection.

A simplification step for an operand works like a simplification step on simplifying `f`. The exceptions are as follows. Performing a simplification step for an operand, MuPAD does not apply certain rules (see the details on `SelectRules`).

MuPAD determines priorities of open tasks as follows. The priority of doing the initial step for an expression depends on the valuation of the expression. The priority of doing a simplification step on an operand depends on the ratio between the overall valuation of the expression and the valuation of the operand and the priority of the highest-rank task in the to-do list of the operand. Finally, the priority of applying a rule to an expression equals to the priority of the rule multiplied by the valuation of the expression.

The strategy determines the priority of a rule. See the `Strategy` option for details.

`Simplify` never uses the symmetry of mathematical equivalence of expressions. Therefore, you can use `Simplify` as a general rewriting system.

`Simplify` maps to lists, sets, and tables.

For domain elements `d`, `Simplify` can be overloaded in two ways. First, `Simplify` uses the slot `d::dom::Simplify`. If that slot does not exist, `Simplify` uses `d::dom::simplify`. If the slot that `Simplify` uses is not a list, `Simplify` calls the slot and accepts the result as simple (even if the valuation does not agree). In this case, `Simplify` does not apply any other rules to `d`. However, `Simplify` uses the valuation to decide whether it must replace a domain element that occurs as an operand in another object with its "simplified" version. If the slot is a list, its entries must be rules, and `Simplify` applies them according to their priority.

Examples

Example 1

The easiest way to use `Simplify` is to accept all defaults, and then plug in the expression you want to simplify:

```
Simplify(sin(x)^2 + cos(x)^2)
```

```
1
```

Example 2

By default, `Simplify` returns only one expression that the function considers as simplest. To return a list of all equivalent expressions, use the `All` option:

```
Simplify(sin(x)^2 + cos(x)^2, All)
```

$$[1, \cos(x)^2 + \sin(x)^2]$$

Example 3

The output of the previous example is short because as soon as the simplifier finds 1, it stops immediately. After that, the simplifier does not look for other equivalent expressions. In addition, the simplifier discards the equivalent expressions that are significantly more complicated than the best expression found earlier. You can switch off both mechanisms:

```
Simplify(sin(x)^2 + cos(x)^2, All, Discard = FALSE,
                                   IsSimple = FALSE)
```

$$\left[1,\ \cos(x)^2+\sin(x)^2,\ -\cos(x)^2-\sin(x)^2+2,\ \sin(x)^2+\sigma_5+\frac{1}{2},\ \cos(x)^2-\sigma_5+\frac{1}{2},\right.$$
$$-\cos(x)^2+\sigma_5+\frac{3}{2},\ -\sin(x)^2-\sigma_5+\frac{3}{2},\ \sigma_7+\sigma_8,\ 2-\sigma_8-\sigma_7,\ \sigma_8-\sigma_2+\frac{1}{2},\ \sigma_2-\sigma_8+\frac{3}{2},$$
$$\sigma_2+\sigma_7+\frac{1}{2},\ \frac{3}{2}-\sigma_7-\sigma_2,\ \sigma_3+\sigma_1,\ 2-\sigma_1-\sigma_3,\ \frac{1}{2}-\sigma_6+\sigma_3-\sigma_4,\ \sigma_4+\sigma_6-\sigma_3+\frac{3}{2},$$
$$\left.\sigma_4+\sigma_6+\sigma_1+\frac{1}{2},\ \frac{3}{2}-\sigma_6-\sigma_1-\sigma_4,\ \frac{1}{\sigma_9}+\frac{2\,\sigma_{10}}{\sigma_9}+\frac{\sigma_{11}}{\sigma_9}\right]$$

where

$$\sigma_1=\left(\frac{e^{-x\,i_i}}{2}-\frac{e^{x\,i_i}}{2}\right)^2$$

$$\sigma_2=\frac{\tan(x)^2-1}{2\left(\tan(x)^2+1\right)}$$

$$\sigma_3=\left(\frac{e^{-x\,i}}{2}+\frac{e^{x\,i}}{2}\right)^2$$

$$\sigma_4=\frac{e^{-2\,x\,i}}{4}$$

$$\sigma_5=\frac{\cos(2\,x)}{2}$$

$$\sigma_6=\frac{e^{2\,x\,i}}{4}$$

$$\sigma_7=\frac{\left(\sigma_{10}-1\right)^2}{\left(\sigma_{10}+1\right)^2}$$

$$\sigma_8=\frac{4\,\sigma_{10}}{\left(\sigma_{10}+1\right)^2}$$

$$\sigma_9=\sigma_{11}+2\,\sigma_{10}+1$$

Example 4

By default, `Simplify` uses a valuation that favors expressions with fewer different irrational subexpressions. For example, `Simplify` assumes that an expression containing only `sin(x)` or `cos(x)` is simpler than an expression containing both:

```
Simplify(cos(x)*sin(x))
```

$$\frac{\sin(2\,x)}{2}$$

If you take the `length` as a complexity measure for expressions, `Simplify` returns another result:

```
Simplify(cos(x)*sin(x), Valuation = length)
```

$$\cos(x)\,\sin(x)$$

Example 5

The default number of steps is 100. To change the maximal number of possible simplification steps, use the `Steps` option. For example, decrease (resulting in a speedup) and increase (resulting in a probably better simplification) the number of simplification steps:

```
f := ln(x) + ln(3) - ln(3*x) + (exp(x) - 1)/(exp(x/2) + 1):
Simplify(f, Steps = 8), Simplify(f, Steps = 120)
```

$$\frac{e^{x}}{e^{\frac{x}{2}}+1}-\frac{1}{e^{\frac{x}{2}}+1},\ e^{\frac{x}{2}}-1$$

```
delete f:
```

Example 6

For many expressions, the default number of simplification steps does not allow the simplifier to find a good simplification:

```
Simplify(e^(a* x *(a + 1) + b2* y *(y + b2* x* y)))
```

$$e^{b2\,y\,(y+b2\,x\,y)+a\,x\,(a+1)}$$

Increasing this limit often helps:

```
Simplify(e^(a* x *(a + 1) + b2* y *(y + b2* x* y)), Steps=125)
```

$$e^{b2\,(b2\,x+1)\,y^2+a\,x\,(a+1)}$$

Example 7

By default, simplification functions do not combine logarithms:

```
Simplify(ln(x^3 - 1) - ln(x - 1))
```

$$\ln(x^3-1)-\ln(x-1)$$

Using the `IgnoreAnalyticConstraints` option, you often can get shorter results:

```
Simplify(ln(x^3 - 1) - ln(x - 1), IgnoreAnalyticConstraints)
```

$$\ln(x^2+x+1)$$

Example 8

You can write the same expression in different coordinate systems. For example, use Cartesian and polar coordinates:

```
assume(x/r = cos(Symbol::theta)):
assumeAlso(y/r = sin(Symbol::theta)):
assumeAlso(r = sqrt(x^2+y^2)):
x/sqrt(x^2+y^2) + I*y/sqrt(x^2+y^2) = exp(I*Symbol::theta);
Simplify(%)
```

$$\frac{x}{\sqrt{x^2+y^2}}+\frac{y\,\mathrm{i}}{\sqrt{x^2+y^2}}=\mathrm{e}^{\theta\,\mathrm{i}}$$

TRUE

Example 9

The following expression is equivalent to `exp(x)`:

```
a := -1/(sin(1/2*I*x)^2 + 4*sin(1/4*I*x)^4 -
     4*sin(1/4*I*x)^2 + 1)*(sin(1/2*I*x)^2 -
     4*I*sin(1/2*I*x)*sin(1/4*I*x)^2 + 2*I*sin(1/2*I*x) -
     4*sin(1/4*I*x)^4 + 4*sin(1/4*I*x)^2 - 1)
```

$$-\frac{{\sigma_1}^2-4\,\sigma_1\,\sin\left(\frac{x\,i}{4}\right)^2\,i+2\,\sigma_1\,i-4\,\sin\left(\frac{x\,i}{4}\right)^4+4\,\sin\left(\frac{x\,i}{4}\right)^2-1}{{\sigma_1}^2+4\,\sin\left(\frac{x\,i}{4}\right)^4-4\,\sin\left(\frac{x\,i}{4}\right)^2+1}$$

where

$$\sigma_1=\sin\left(\frac{x\,i}{2}\right)$$

`Simplify` recognizes the equivalence of `a` and `exp(x)` within 100 steps. To show how the function proves the equivalence at each step, use the `OutputType` option. Note that the proof returned by `Simplify` is not a proof in a strict mathematical sense. `Simplify` uses the rules from the default rule base:

```
Simplify(a, OutputType = "Proof")
```

```
Input was
  -(sin((x*I)/2)^2 - 4*sin((x*I)/2)*sin((x*I)/4)^2*I + 2*sin((x*I)/2)*I - \
4*sin((x*I)/4)^4 + 4*sin((x*I)/4)^2 - 1)/(sin((x*I)/2)^2 + 4*sin((x*I)/4)^\
4 - 4*sin((x*I)/4)^2 + 1)
Applying the rule
  Simplify::combineSinCos
gives
  cos(x*I) - sin(x*I)*I
Applying the rule
  Simplify::expand
gives
  cosh(x) + sinh(x)
```

```
Applying the rule
  X -> rewrite(X, exp)
gives
  exp(x)
END OF PROOF
```

Example 10

You also can use `Simplify` for experiments with formal grammars given by only a few rules. In this case, the better approach is not to use rule bases, but to use a `SelectRules` method that returns a list of all rules. The following example presents a general associative operator `?`. The example computes the number of all possible placements of parentheses. First, define the `operator`, and then attach it to a function that controls its output (see `funcenv`). Specify that the only applicable rule is the associative law. In the call to `Simplify`, set the number of steps to a very large value to perform a complete search. Note that most grammars produce infinitely many words and spend infinite time to finish a complete search:

```
_f := funcenv(() -> procname(args())):
operator("?", _f, Binary, 1000):
R := Rule((X ? Y) ? Z, X ? (Y ? Z)):
selectProc := () -> [R]:
S := Simplify(u ? v ? x ? y ? z, Steps = 10^10,
              SelectRules = selectProc, All):

PRETTYPRINT := FALSE:
print(Plain, S):
PRETTYPRINT := TRUE:

[u ? (v ? (x ? (y ? z))), u ? (v ? ((x ? y) ? z)), u ? ((v ? (x ? y)) ? z)\
, u ? (((v ? x) ? y) ? z), u ? ((v ? x) ? (y ? z)), (u ? (v ? x)) ? (y ? z\
), ((u ? v) ? x) ? (y ? z), (u ? v) ? (x ? (y ? z)), (u ? v) ? ((x ? y) ? \
z), (u ? (v ? (x ? y))) ? z, (u ? ((v ? x) ? y)) ? z, ((u ? (v ? x)) ? y) \
? z, (((u ? v) ? x) ? y) ? z, ((u ? v) ? (x ? y)) ? z]
```

There are 14 possible ways of placing parentheses:

```
nops(S);
delete fout, _f, R, S, selectProc:
operator("?", Delete):

     14
```

Example 11

If you want to specify a larger set of rules, the best approach is to use your own rule base. A classic example is differentiation. Although a heuristic search must be slower than a simple recursive algorithm, this example is suitable for demonstrating some efficiency considerations. Start by defining a function environment `mydiff` that does not do anything:

```
mydiff := funcenv(mydiff):
mydiff::type := "mydiff"
```

```
"mydiff"
```

The goal of this definition is to show that MuPAD sorts rules in rule bases by the types of expressions to which MuPAD applies those rules. Therefore, `mydiff` gets its own type. Now, define a rule base `Myrules` with the usual differentiation rules. Do not use any additional rules:

```
Myrules := newDomain("Myrules"):
Myrules::mydiff :=
     [Rule(mydiff(f, x), 0, {(f, x) -> not has(f, x)}),
      Rule(mydiff(x, x), 1),
      Rule(mydiff(x^n, x), n*x^(n - 1)),
      Rule(mydiff(f*g, x), f*mydiff(g, x) + g*mydiff(f, x)),
      Rule(mydiff(f + g, x), mydiff(f, x) + mydiff(g, x))
     ]:
```

This rule base works for the expression x^2:

```
Simplify(mydiff(x^2, x), RuleBase = Myrules)
```

$$2\,x$$

However, the rule base does not work for the following expression:

```
Simplify(mydiff(x + 3, x), RuleBase = Myrules)
```

$$\mathrm{mydiff}(x+3,\,x)$$

Try to improve that rule base. As a first step, increase the number of simplification steps. Increasing the number of steps does not help in this case:

```
Simplify(mydiff(x + 3, x), RuleBase = Myrules, Steps = 200)
```

$$\text{mydiff}(x+3, x)$$

As a second step, take a closer look on the equivalent expressions returned by `Simplify`. Sometimes, `Simplify` finds the expected result, but does not return it because the valuation of the expected result is higher than the valuation of some other equivalent expression. For the expression `x + 3`, the `Simplify` function does not find the expected result:

```
l := Simplify(mydiff(x + 3, x), RuleBase = Myrules, All)
```

$$[\sigma_1, \text{mydiff}(x, x) + \text{mydiff}(3, x), (x+3)\,\text{mydiff}(1, x) + \sigma_1, 2\,(x+3)\,\text{mydiff}(1, x) + \sigma_1,$$
$$3\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 4\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 5\,(x+3)\,\text{mydiff}(1, x) + \sigma_1,$$
$$6\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 7\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 8\,(x+3)\,\text{mydiff}(1, x) + \sigma_1,$$
$$9\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 10\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 11\,(x+3)\,\text{mydiff}(1, x) + \sigma_1,$$
$$12\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 13\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 14\,(x+3)\,\text{mydiff}(1, x) + \sigma_1,$$
$$15\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 16\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 17\,(x+3)\,\text{mydiff}(1, x) + \sigma_1,$$
$$18\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 19\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 20\,(x+3)\,\text{mydiff}(1, x) + \sigma_1,$$
$$21\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 22\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 23\,(x+3)\,\text{mydiff}(1, x) + \sigma_1,$$
$$24\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 25\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 26\,(x+3)\,\text{mydiff}(1, x) + \sigma_1,$$
$$27\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 28\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 29\,(x+3)\,\text{mydiff}(1, x) + \sigma_1,$$
$$30\,(x+3)\,\text{mydiff}(1, x) + \sigma_1, 31\,(x+3)\,\text{mydiff}(1, x) + \sigma_1]$$

where

$$\sigma_1 = \text{mydiff}(x+3, x)$$

Note that the derivative of 1 appears in the result. Use the `OutputType` option, to check how `Simplify` manipulates the third term `l[3]` and how it proves the equivalence of input and output at each step:

```
Simplify(mydiff(x + 3, x), RuleBase = Myrules,
                           Goal = l[3],
                           OutputType = "Proof")
```

```
Input was
  mydiff(x + 3, x)
Applying the rule
  mydiff(f*g, x) -> f*mydiff(g, x) + g*mydiff(f, x)
gives
  (x + 3)*mydiff(1, x) + mydiff(x + 3, x)
END OF PROOF
```

Now you can see that for each expression f, you must specify the rule for diffentiating products because $f = 1 f$. Modify that rule:

```
(Myrules::mydiff)[4] := Rule(mydiff(f*g, x),
                             f*mydiff(g, x) + g*mydiff(f, x),
                             {(f, g) -> f <> 1 and g <> 1}):
```

The updated rule base works:

```
Simplify(mydiff(x + 3, x), RuleBase=Myrules, Remember=FALSE)
```

```
     1
```

Use a few options to optimize the call to `Simplify`. As a first step, measure how many steps a typical example takes before returning the expected output:

```
Simplify(mydiff(5*x^4 + x^3 + x^2 + x + 1, x),
         RuleBase = Myrules,
         Steps = 2000,
         Goal = 20*x^3 + 3*x^2 + 2*x + 1,
         OutputType = "NumberOfSteps")
```

```
     134
```

Avoid the application of the equality $f = f + 0$. Switch off the remember mechanism. When the remember mechanism works, `Simplify` ignores changes in the rule base:

```
Myrules::mydiff[5] := Rule(mydiff(f + g, x),
                           mydiff(f, x) + mydiff(g, x),
                           {(f, g) -> f <> 0 and g <> 0}):
Simplify(mydiff(5*x^4 + x^3 + x^2 + x + 1, x),
         RuleBase = Myrules,
         Steps = 2000,
         Goal = 20*x^3 + 3*x^2 + 2*x + 1,
         OutputType = "NumberOfSteps",
         Remember = FALSE)
```

```
     129
```

Next, try to change the valuation criteria. For example, use `length`:

```
Simplify(mydiff(5*x^4 + x^3 + x^2 + x + 1, x),
         RuleBase = Myrules,
         Steps = 2000,
         Goal = 20*x^3 + 3*x^2 + 2*x + 1,
         OutputType = "NumberOfSteps",
         Valuation = length)
```

```
     121
```

To optimize the call to `Simplify`, you also can specify your own simplification *strategy*. For example, the first rule seems to provide a very useful simplification whenever it applies. Therefore, assign a high priority to this rule by assuming that on average this rule simplifies its input to 0.03 of the original complexity:

```
Myrules::mydiff[1] := subsop(Myrules::mydiff[1],
                             4 = table("MyStrategy" = 0.03)):
Simplify(mydiff(5*x^4 + x^3 + x^2 + x + 1, x),
         RuleBase = Myrules,
         Steps = 3000,
         Goal = 20*x^3 + 3*x^2 + 2*x + 1,
         OutputType = "NumberOfSteps",
         Strategy = "MyStrategy")
```

```
     124
```

When using the valuation `length`, you get the following result:

```
Simplify(mydiff(5*x^4 + x^3 + x^2 + x + 1, x),
         RuleBase = Myrules,
         Steps = 3000,
         Goal = 20*x^3 + 3*x^2 + 2*x + 1,
         OutputType = "NumberOfSteps",
         Strategy = "MyStrategy",
         Valuation = length)
```

```
     125
```

When you use a matcher-based simplification, most of the rules do not match to most objects. Trying to match all rules to all objects produces many failing rewriting steps. The recommended approach is to discard these failing rules during the initial step. Discarding failling rules decreases the number of steps. It also increases the running time per step by a small amount. Defining a procedure instead of a list of rules can help you to discard the failing rules during an initial step. You can define the rules by using a pattern or a procedure as their first argument:

```
Myrules::mydiff :=
proc(df)
  begin
  [if not has(op(df, 1), op(df, 2)) then
      Rule(X -> 0)
   else
      case type(op(df, 1))
        of "_plus" do
           Rule(X -> map(op(X, 1), mydiff, op(X, 2)));
           break
        of "_mult" do
           Rule(mydiff(f*g, x), f*mydiff(g, x) + g*mydiff(f, x));
           break
        of "_power" do
           Rule(X -> op(X, [1,2])*op(X, [1,1])^(op(X, [1,2]) - 1));
           break
        of DOM_IDENT do
           assert(op(df, 1) = op(df, 2));
           Rule(X -> 1);
           break
        otherwise

         OutputType = "NumberOfSteps")

     35

delete Myrules, mydiff:
```

Parameters

`f`

Any object

Options

`All`

When you use the `All` option, the `Simplify` function returns a list of all equivalent objects that the function can find. This syntax is a shortcut for `OutputType = "All"`.

`ApplyRule`

Option, specified as `ApplyRule = applyFunction`

Specify the function `applyFunction` that `Simplify` calls every time when a rule `R` must be applied to an object `a`. Here, `applyFunction` must be a function of two arguments `R` (a rule) and `a` (an object). It must return the result of applying the rule `R` to an object `a`. If the rule is not applicable, the `applyFunction` function must return `FAIL`.

`Discard`

Option, specified as `Discard = discardFunction`

Specify the function `discardFunction(newvalue, bestvalue)` that `Simplify` calls every time it finds a new object equivalent to `f`. Here `newvalue` is the valuation

of the new object, and `bestvalue` is the minimal valuation among all equivalent objects that `Simplify` found earlier. If Boolean evaluation of the result produces `TRUE`, then `Simplify` discards the new object. By default, `Simplify` discards a result if its valuation exceeds `10×current best valuation + 1`. To prevent the loss of results, switch this mechanism off: `Discard = FALSE`.

`Criterion`

Option, specified as `Criterion = CriterionFunction`

Specify the function `CriterionFunction(a, vala)` that `Simplify` calls at the end of the computation to perform the final sorting of the results. For each result `a` and its valuation `vala`, `CriterionFunction(a, vala)` returns a number. `Simplify` uses that number to sort the results. By default, `Simplify` uses `vala` to sort the results.

`Goal`

Option, specified as `Goal = a`

If the `Simplify` function finds the equivalent object `a`, stop the computation and return `a` even if this object is not the simplest equivalent expression found.

`IgnoreAnalyticConstraints`

With this option the simplifier applies the following rules to expressions:

- $ln(a) + ln(b) = ln(a\,b)$ for all values of a and b. In particular:

  $(a\,b)^c = e^{c\,\ln(a\,b)} = e^{c\,(\ln(a)+\ln(b))} = a^c\,b^c$ for all values of a, b, and c
- $ln(a^b) = b\,ln(a)$ for all values of a and b. In particular:

  $(a^b)^c = e^{b\,c\,\ln(a)} = e^{\ln(a)^{b\,c}} = a^{b\,c}$ for all values of a, b, and c
- If f and g are standard mathematical functions and $f(g(x)) = x$ for all small positive numbers, $f(g(x)) = x$ is assumed to be valid for all complex x. In particular:
- - $\ln(e^x) = x$
  - $arcsin(sin(x)) = x$, $arccos(cos(x)) = x$, $arctan(tan(x)) = x$
  - $arcsinh(sinh(x)) = x$, $arccosh(cosh(x)) = x$, $arctanh(tanh(x)) = x$
  - $W_k(x\,e^x) = x$ for all values of k

With this option, the Simplify function can return simple results for expressions for which Simplify without this option returns more complicated results. With this option the simplifier does not guarantee the equality of the initial expression and the result for all symbolic parameters. See “Example 7” on page 1-1858.

IsSimple

Option, specified as IsSimple = B

Specify the function B(a) that the Simplify function calls for any expression a that is equivalent to any subexpression of the input. If the result of the call is TRUE, then the Simplify function does not simplify this subexpression any further. B must return TRUE or FALSE for every input.

KernelSteps

Option, specified as KernelSteps = n

Limit the effort invested in one simplification step. Here n must be a positive integer. The default value is 100.

OutputType

Option, specified as OutputType = output

Specify the type of return value. The value output must be one of the strings "All", "Best", "NumberOfSteps", or "Proof". This option makes Simplify return all results, the best result, the number of performed simplification steps, or a proof for the equivalence of the input and the best result. By default, Simplify returns the simplest result found.

Even if you specify the output type as "All", Simplify does not return any results discarded due to the Discard option. To get all results, set Discard to FALSE. See “Example 3” on page 1-1855.

If you set this option to "Proof", the Simplify function returns text displaying proof steps and lemmas. Proof steps state that f_{i-1} is equivalent to f_i for $1 \le i \le n$, where $f_0 = f$ is the input and f_n is the result of the simplification. Each proof step is either a rule application or a lemma application. A rule application step shows that applying a rule to f_{i-1} gives f_i. A lemma application steps shows that replacing some operand of f_{i-1} by an equivalent object gives f_i. A lemma consists of the statement that two objects are equivalent, a proof in the above sense, and the END OF LEMMA tag.

Technically, proofs are objects of the same type as the output of `expose`.

`Remember`

Option, specified as `Remember = bool`

The `Remember` option switches the remember mechanism on and off. If you call `Simplify` with the same argument several times, the remember mechanism saves running time. If the argument of one call reappears as a subexpression in the argument of another call, the remember mechanism does not help to save time. By default, `bool` is `TRUE`.

`RuleBase`

Option, specified as `RuleBase = base`

A rule base `base` is a domain that contains its rules for expressions of type `T` in its slot `slot(base, T)`. In addition, the following three slots can contain rules for a rule base: `base::All`, `base::Global`, and `base::Local`. The `base::All` slot contains generally applicable rules. The `base::Global` slot contains rules that the `Simplify` function applies only to expressions. `Simplify` does not apply the rules defined in `base::Global` within a subexpression step. The `base::Local` slot contains rules that the `Simplify` function applies only within a subexpression step. If no slots exist for the type of a given object, MuPAD does not generate any rules for that object. A slot of a rule base is a list of rules or a procedure that returns such a list for any given object of appropriate type. Any rule must be an object of type `Rule`. See the `Rule` help page for details. If you use your own `SelectRules`, you can ignore these conventions. See “Example 11” on page 1-1861.

`Seconds`

Option, specified as `Seconds = t`

When you use the `Seconds` option, the `Simplify` function limits the time allowed for the internal simplification process. The value `t` is the maximal time in seconds. By default, the simplification process never terminates due to a time limitation: `t = infinity`.

`SelectRules`

Option, specified as `SelectRules = selFunction`

When you use the `SelectRules` option, MuPAD lets you specify the function `selFunction(base, ex, global, strat)` that `Simplify` calls to obtain the rules

applicable to ex in the rule base base for strategy strat. The boolean flag global indicates whether ex is the whole expression accepted by Simplify (global = TRUE) or a subexpression of the original expression (global = FALSE). Using the arguments given to selFunction is optional. For example, for small rule bases the easiest method is to return a list of all rules independent of the given expression. See “Example 10” on page 1-1860. However, returning a list of all rules can result in unnecessary rule applications. Applying each unnecessary rule returns FAIL and only affects the performance.

You can define any rule base and use any kind the rules. The only restriction is that selFunction must return a list of rules.

Steps

Option, specified as Steps = numberOfSteps

When you use the Steps option, the Simplify function terminates a simplification after numberOfSteps simplification steps. The default number of steps is 100.

StopIf

Option, specified as StopIf = B

When you use the StopIf option, the Simplify function lets you specify the function B(a) that Simplify calls for any expression a that is equivalent to the original expression. If the result is TRUE, the simplification stops immediately, and the Simplify function returns the expression a as the simplest result regardless of its valuation. The specified function B must return TRUE or FALSE for any input.

Strategy

Option, specified as Strategy = strat

When you use the Strategy option, the Simplify function lets you set the rule selection strategy. The value of strat must be a string. The SelectRules option uses strat as an argument that determines the priority for applying each rule.

By default, Simplify uses the strategy "Default". The default rule base also uses the strategy "Default".

If a particular rule does not recognize the strategy strat, the Simplify function uses the strategy "Default" to determine the priority of that rule. Finally, if no entry for the

default strategy is available, the rule has the priority 1. In this case, expect an output to be as complicated as the input.

If you use the `IgnoreAnalyticConstraints`, `Simplify` uses the strategy that comes with that option instead of using the strategy `"Default"`.

If `Simplify` uses a strategy, that strategy does not affect the valuation of results of rule applications.

`Valuation`

Option, specified as `Valuation = valFunction`

When you use the `Strategy` option, the `Simplify` function lets you specify a function MuPAD uses for computing valuations of returned objects. `Simplify` computes the valuation for many intermediate results. Generally, to compute the valuation, `Simplify` evaluates each node of the expression tree. Therefore, the `Valuation` option can significantly affect the running time.

A good valuation is a compromise between context-free and maximum-type concepts. For a context-free valuation, both the operator of an expression and the valuations of the operands determine the valuation of the expression. For a maximum-type valuation, generally the valuation of an expression equals the maximum of valuations of its operands.

A typical context-free example is `length`. A typical maximum-type example is `X -> 2^nops(indets(X))` .

MuPAD offers a context-free valuation `Simplify::complexity`. This valuation favors usual operators like `exp` over unusual ones like `besselJ` and puts a penalty factor on arguments of unusual operators.

Return Values

`Simplify` returns an object mathematically equivalent to the input. With the option `OutputType = "All"`, the `Simplify` function returns a list of all equivalent objects found during the simplification. With the option `OutputType = "NumberOfSteps"`, the function returns a positive integer. With the option `OutputType = "Proof"`, the function returns a string containing a proof of the equivalence of the input and the result.

More About

- "If You Want to Simplify Results Further"

sin

Sine function

Syntax

```
sin(x)
```

Description

`sin(x)` represents the sine function.

The arguments have to be specified in radians, not in degrees. E.g., use π to specify an angle of 180^o.

All trigonometric functions are defined for complex arguments.

Floating point values are returned for floating-point arguments. Floating point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

Translations by integer multiples of π are eliminated from the argument. Further, arguments that are rational multiples of π lead to simplified results; symmetry relations are used to rewrite the result using an argument from the standard interval $\left[0, \frac{\pi}{2}\right)$.

Explicit expressions are returned for the following arguments:

$$0, \frac{\pi}{2}, \frac{\pi}{3}, \frac{\pi}{4}, \frac{\pi}{5}, \frac{2\pi}{5}, \frac{\pi}{6}, \frac{\pi}{8}, \frac{3\pi}{8}, \frac{\pi}{10}, \frac{3\pi}{10}, \frac{\pi}{12}, \frac{5\pi}{12}.$$

Cf. “Example 2” on page 1-1875.

The result is rewritten in terms of hyperbolic functions, if the argument is a rational multiple of `I`. Cf. “Example 3” on page 1-1875.

The functions `expand` and `combine` implement the addition theorems for the trigonometric functions. Cf. “Example 4” on page 1-1876.

The trigonometric functions do not respond to properties set via `assume`. Use `simplify` to take such properties into account. Cf. “Example 4” on page 1-1876.

Use `rewrite` to rewrite expressions involving `tan` and `cot` in terms of `sin` and `cos`. Cf. “Example 5” on page 1-1877.

The inverse function is implemented by `arcsin`. Cf. “Example 6” on page 1-1877.

The float attributes are kernel functions, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
sin(PI), cos(1), tan(5 + I), csc(PI/2), sec(PI/11), cot(PI/8)
```

$$0,\ \cos(1),\ \tan(5+i),\ 1,\ \frac{1}{\cos\left(\frac{\pi}{11}\right)},\ \sqrt{2}+1$$

```
sin(-x), cos(x + PI), tan(x^2 - 4)
```

$$-\sin(x),\ -\cos(x),\ \tan(x^2-4)$$

Floating point values are computed for floating-point arguments:

```
sin(123.4), cos(5.6 + 7.8*I), cot(1.0/10^20)
```

$$-0.7693905459,\ 946.4239673 + 770.3351731\,i,\ 1.0\ 10^{20}$$

Floating point intervals are computed for interval arguments:

```
sin(0 ... 1), cos(20 ... 30), tan(0 ... 5)
```

$$0.0 \ldots 0.8414709849,\ -1.0 \ldots 1.0,\ \mathrm{RD\_NINF} \ldots \mathrm{RD\_INF}$$

For the functions with discontinuities, the result may be a union of intervals:

```
csc(-1 ... 1), tan(1 ... 2)
```

$$\mathrm{RD\_NINF} \ldots -1.188395105 \cup 1.188395105 \ldots \mathrm{RD\_INF},\ \mathrm{RD\_NINF} \ldots -2.185039863 \cup 1.557407724 \ldots \mathrm{RD\_INF}$$

Example 2

Some special values are implemented:

```
sin(PI/10), cos(2*PI/5), tan(123/8*PI), cot(-PI/12)
```

$$\frac{\sqrt{5}}{4} - \frac{1}{4},\ \frac{\sqrt{5}}{4} - \frac{1}{4},\ \sqrt{2} + 1,\ -\sqrt{3} - 2$$

Translations by integer multiples of π are eliminated from the argument:

```
sin(x + 10*PI), cos(3 - PI), tan(x + PI), cot(2 - 10^100*PI)
```

$$\sin(x),\ -\cos(3),\ \tan(x),\ \cot(2)$$

All arguments that are rational multiples of π are transformed to arguments from the interval $\left[0, \frac{\pi}{2}\right)$:

```
sin(4/7*PI), cos(-20*PI/9), tan(123/11*PI), cot(-PI/13)
```

$$\sin\left(\frac{3\,\pi}{7}\right),\ \cos\left(\frac{2\,\pi}{9}\right),\ \tan\left(\frac{2\,\pi}{11}\right),\ -\cot\left(\frac{\pi}{13}\right)$$

Example 3

Arguments that are rational multiples of `I` are rewritten in terms of hyperbolicfunctions:

```
sin(5*I), cos(5/4*I), tan(-3*I)
```

$$\sinh(5)\,i,\ \cosh\left(\frac{5}{4}\right),\ -\tanh(3)\,i$$

For other complex arguments, use `expand` to rewrite the result:

```
sin(5*I + 2*PI/3), cos(PI/4 - 5/4*I), tan(-3*I + PI/2)
```

$$\sin\left(\frac{2\,\pi}{3}+5\,i\right),\ \cos\left(\frac{\pi}{4}-\frac{5\,i}{4}\right),\ \tan\left(\frac{\pi}{2}-3\,i\right)$$

```
expand(sin(5*I + 2*PI/3)), expand(cos(5/4*I - PI/4)),
expand(tan(-3*I + PI/2))
```

$$\frac{\sqrt{3}\,\cosh(5)}{2}-\frac{\sinh(5)\,i}{2},\ \frac{\sqrt{2}\,\cosh\left(\frac{5}{4}\right)}{2}+\frac{\sqrt{2}\,\sinh\left(\frac{5}{4}\right)i}{2},\ -\frac{i}{\tanh(3)}$$

Example 4

The `expand` function implements the addition theorems:

```
expand(sin(x + PI/2)), expand(cos(x + y))
```

$$\cos(x),\ \cos(x)\cos(y)-\sin(x)\sin(y)$$

The `combine` function uses these theorems in the other direction, trying to rewrite products of trigonometric functions:

```
combine(sin(x)*sin(y), sincos)
```

$$\frac{\cos(x-y)}{2}-\frac{\cos(x+y)}{2}$$

The trigonometric functions do not immediately respond to properties set via `assume`:

```
assume(n, Type::Integer): sin(n*PI), cos(n*PI)
```

$$\sin(\pi\, n),\ \cos(\pi\, n)$$

Use `simplify` to take such properties into account:

```
simplify(sin(n*PI)), simplify(cos(n*PI))
```

$$0,\ (-1)^n$$

```
assume(n, Type::Odd): sin(n*PI + x), simplify(sin(n*PI + x))
```

$$\sin(x+\pi\, n),\ -\sin(x)$$

```
y := cos(x + n*PI) + cos(x - n*PI):  y, simplify(y)
```

$$\cos(x+\pi\, n)+\cos(x-\pi\, n),\ -2\cos(x)$$

```
delete n, y:
```

Example 5

Various relations exist between the trigonometric functions:

```
csc(x), sec(x)
```

$$\frac{1}{\sin(x)},\ \frac{1}{\cos(x)}$$

Use `rewrite` to obtain a representation in terms of a specific target function:

```
rewrite(tan(x)*exp(2*I*x), sincos), rewrite(sin(x), cot)
```

$$\frac{\sin(x)\,(\cos(2\,x)+\sin(2\,x)\,\mathrm{i})}{\cos(x)},\ \frac{2\cot\left(\frac{x}{2}\right)}{\cot\left(\frac{x}{2}\right)^2+1}$$

Example 6

The inverse functions are implemented by `arcsin`, `arccos` etc.:

```
sin(arcsin(x)), sin(arccos(x)), cos(arctan(x))
```

$$x,\ \sqrt{1-x^2},\ \frac{1}{\sqrt{x^2+1}}$$

Note that `arcsin(sin(x))` does not necessarily yield `x`, because `arcsin` produces values with real parts in the interval $\left[-\frac{\pi}{2}, \frac{\pi}{2}\right]$:

```
arcsin(sin(3)), arcsin(sin(1.6 + I))
```

$$\pi - 3,\ 1.541592654 - 1.0\,i$$

Example 7

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the trigonometric functions:

```
diff(sin(x^2), x), float(sin(3)*cot(5 + I))
```

$$2\,x\cos(x^2),\ -0.01668502608 - 0.1112351327\,i$$

```
limit(x*sin(x)/tan(x^2), x = 0)
```

$$1$$

```
series((tan(sin(x)) - sin(tan(x)))/sin(x^7), x = 0)
```

$$\frac{1}{30} + \frac{29\,x^2}{756} + \frac{1913\,x^4}{75600} + O(x^6)$$

Parameters

x

An arithmetical expression or a floating-point interval

Return Values

cos

Cosine function

Syntax

```
cos(x)
```

Description

`cos(x)` represents the cosine function.

The arguments have to be specified in radians, not in degrees. E.g., use π to specify an angle of 180^o.

All trigonometric functions are defined for complex arguments.

Floating point values are returned for floating-point arguments. Floating point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

Translations by integer multiples of π are eliminated from the argument. Further, arguments that are rational multiples of π lead to simplified results; symmetry relations are used to rewrite the result using an argument from the standard interval $\left[0, \frac{\pi}{2}\right)$.

Explicit expressions are returned for the following arguments:

$$0, \frac{\pi}{2}, \frac{\pi}{3}, \frac{\pi}{4}, \frac{\pi}{5}, \frac{2\pi}{5}, \frac{\pi}{6}, \frac{\pi}{8}, \frac{3\pi}{8}, \frac{\pi}{10}, \frac{3\pi}{10}, \frac{\pi}{12}, \frac{5\pi}{12}.$$

Cf. “Example 2” on page 1-1882.

The result is rewritten in terms of hyperbolic functions, if the argument is a rational multiple of `I`. Cf. “Example 3” on page 1-1882.

The functions `expand` and `combine` implement the addition theorems for the trigonometric functions. Cf. “Example 4” on page 1-1883.

The trigonometric functions do not respond to properties set via `assume`. Use `simplify` to take such properties into account. Cf. “Example 4” on page 1-1883.

Use `rewrite` to rewrite expressions involving `tan` and `cot` in terms of `sin` and `cos`. Cf. “Example 5” on page 1-1884.

The inverse function is implemented by `arccos`. Cf. “Example 6” on page 1-1884.

The float attributes are kernel functions, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
sin(PI), cos(1), tan(5 + I), csc(PI/2), sec(PI/11), cot(PI/8)
```

$$0,\ \cos(1),\ \tan(5+i),\ 1,\ \frac{1}{\cos\left(\frac{\pi}{11}\right)},\ \sqrt{2}+1$$

```
sin(-x), cos(x + PI), tan(x^2 - 4)
```

$$-\sin(x),\ -\cos(x),\ \tan(x^2-4)$$

Floating point values are computed for floating-point arguments:

```
sin(123.4), cos(5.6 + 7.8*I), cot(1.0/10^20)
```

$$-0.7693905459,\ 946.4239673 + 770.3351731\ i,\ 1.0\ 10^{20}$$

Floating point intervals are computed for interval arguments:

```
sin(0 ... 1), cos(20 ... 30), tan(0 ... 5)
```

$$0.0 \ldots 0.8414709849,\ -1.0 \ldots 1.0,\ \mathrm{RD\_NINF} \ldots \mathrm{RD\_INF}$$

For the functions with discontinuities, the result may be a union of intervals:

```
csc(-1 ... 1), tan(1 ... 2)
```

$$\mathrm{RD\_NINF} \ldots -1.188395105 \cup 1.188395105 \ldots \mathrm{RD\_INF},\ \mathrm{RD\_NINF} \ldots -2.185039863 \cup 1.557407724 \ldots \mathrm{RD\_INF}$$

Example 2

Some special values are implemented:

```
sin(PI/10), cos(2*PI/5), tan(123/8*PI), cot(-PI/12)
```

$$\frac{\sqrt{5}}{4} - \frac{1}{4},\ \frac{\sqrt{5}}{4} - \frac{1}{4},\ \sqrt{2} + 1,\ -\sqrt{3} - 2$$

Translations by integer multiples of π are eliminated from the argument:

```
sin(x + 10*PI), cos(3 - PI), tan(x + PI), cot(2 - 10^100*PI)
```

$$\sin(x),\ -\cos(3),\ \tan(x),\ \cot(2)$$

All arguments that are rational multiples of π are transformed to arguments from the interval $\left[0, \frac{\pi}{2}\right)$:

```
sin(4/7*PI), cos(-20*PI/9), tan(123/11*PI), cot(-PI/13)
```

$$\sin\left(\frac{3\,\pi}{7}\right),\ \cos\left(\frac{2\,\pi}{9}\right),\ \tan\left(\frac{2\,\pi}{11}\right),\ -\cot\left(\frac{\pi}{13}\right)$$

Example 3

Arguments that are rational multiples of `I` are rewritten in terms of hyperbolicfunctions:

```
sin(5*I), cos(5/4*I), tan(-3*I)
```

$$\sinh(5)\,i,\ \cosh\left(\frac{5}{4}\right),\ -\tanh(3)\,i$$

For other complex arguments, use `expand` to rewrite the result:

```
sin(5*I + 2*PI/3), cos(PI/4 - 5/4*I), tan(-3*I + PI/2)
```

$$\sin\left(\frac{2\,\pi}{3}+5\,i\right),\ \cos\left(\frac{\pi}{4}-\frac{5\,i}{4}\right),\ \tan\left(\frac{\pi}{2}-3\,i\right)$$

```
expand(sin(5*I + 2*PI/3)), expand(cos(5/4*I - PI/4)),
expand(tan(-3*I + PI/2))
```

$$\frac{\sqrt{3}\,\cosh(5)}{2}-\frac{\sinh(5)\,i}{2},\ \frac{\sqrt{2}\,\cosh\left(\frac{5}{4}\right)}{2}+\frac{\sqrt{2}\,\sinh\left(\frac{5}{4}\right)i}{2},\ -\frac{i}{\tanh(3)}$$

Example 4

The `expand` function implements the addition theorems:

```
expand(sin(x + PI/2)), expand(cos(x + y))
```

$$\cos(x),\ \cos(x)\cos(y)-\sin(x)\sin(y)$$

The `combine` function uses these theorems in the other direction, trying to rewrite products of trigonometric functions:

```
combine(sin(x)*sin(y), sincos)
```

$$\frac{\cos(x-y)}{2}-\frac{\cos(x+y)}{2}$$

The trigonometric functions do not immediately respond to properties set via `assume`:

```
assume(n, Type::Integer): sin(n*PI), cos(n*PI)
```

$$\sin(\pi\, n),\ \cos(\pi\, n)$$

Use `simplify` to take such properties into account:

```
simplify(sin(n*PI)), simplify(cos(n*PI))
```

$$0,\ (-1)^n$$

```
assume(n, Type::Odd): sin(n*PI + x), simplify(sin(n*PI + x))
```

$$\sin(x + \pi\, n),\ -\sin(x)$$

```
y := cos(x + n*PI) + cos(x - n*PI):  y, simplify(y)
```

$$\cos(x + \pi\, n) + \cos(x - \pi\, n),\ -2\cos(x)$$

```
delete n, y:
```

Example 5

Various relations exist between the trigonometric functions:

```
csc(x), sec(x)
```

$$\frac{1}{\sin(x)},\ \frac{1}{\cos(x)}$$

Use `rewrite` to obtain a representation in terms of a specific target function:

```
rewrite(tan(x)*exp(2*I*x), sincos), rewrite(sin(x), cot)
```

$$\frac{\sin(x)\,(\cos(2\,x) + \sin(2\,x)\,\mathrm{i})}{\cos(x)},\ \frac{2\cot\left(\frac{x}{2}\right)}{\cot\left(\frac{x}{2}\right)^2 + 1}$$

Example 6

The inverse functions are implemented by `arcsin`, `arccos` etc.:

```
sin(arcsin(x)), sin(arccos(x)), cos(arctan(x))
```

$$x,\ \sqrt{1-x^2},\ \frac{1}{\sqrt{x^2+1}}$$

Note that `arcsin(sin(x))` does not necessarily yield `x`, because `arcsin` produces values with real parts in the interval $\left[-\frac{\pi}{2}, \frac{\pi}{2}\right]$:

```
arcsin(sin(3)), arcsin(sin(1.6 + I))
```

$$\pi - 3,\ 1.541592654 - 1.0\,i$$

Example 7

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the trigonometric functions:

```
diff(sin(x^2), x), float(sin(3)*cot(5 + I))
```

$$2\,x\cos(x^2),\ -0.01668502608 - 0.1112351327\,i$$

```
limit(x*sin(x)/tan(x^2), x = 0)
```

$$1$$

```
series((tan(sin(x)) - sin(tan(x)))/sin(x^7), x = 0)
```

$$\frac{1}{30} + \frac{29\,x^2}{756} + \frac{1913\,x^4}{75600} + O(x^6)$$

Parameters

x

An arithmetical expression or a floating-point interval

MuPAD Functions

`arccos` | `arccot` | `arccsc` | `arcsec` | `arcsin` | `arctan` | `cot` | `csc` | `sec` | `sin` | `tan`

tan

Tangent function

Syntax

```
tan(x)
```

Description

`tan(x)` represents the tangent function `sin(x)/cos(x)`.

The arguments have to be specified in radians, not in degrees. E.g., use π to specify an angle of 180^o.

All trigonometric functions are defined for complex arguments.

Floating point values are returned for floating-point arguments. Floating point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

Translations by integer multiples of π are eliminated from the argument. Further, arguments that are rational multiples of π lead to simplified results; symmetry relations are used to rewrite the result using an argument from the standard interval $\left[0, \frac{\pi}{2}\right)$.

Explicit expressions are returned for the following arguments:

$$0, \frac{\pi}{2}, \frac{\pi}{3}, \frac{\pi}{4}, \frac{\pi}{5}, \frac{2\pi}{5}, \frac{\pi}{6}, \frac{\pi}{8}, \frac{3\pi}{8}, \frac{\pi}{10}, \frac{3\pi}{10}, \frac{\pi}{12}, \frac{5\pi}{12}.$$

Cf. “Example 2” on page 1-1889.

The result is rewritten in terms of hyperbolic functions, if the argument is a rational multiple of `I`. Cf. “Example 3” on page 1-1889.

The functions `expand` and `combine` implement the addition theorems for the trigonometric functions. Cf. “Example 4” on page 1-1890.

The trigonometric functions do not respond to properties set via `assume`. Use `simplify` to take such properties into account. Cf. “Example 4” on page 1-1890.

Use `rewrite` to rewrite expressions involving `tan` and `cot` in terms of `sin` and `cos`. Cf. “Example 5” on page 1-1891.

The inverse function is implemented by `arctan`. Cf. “Example 6” on page 1-1891.

The float attributes are kernel functions, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
sin(PI), cos(1), tan(5 + I), csc(PI/2), sec(PI/11), cot(PI/8)
```

$$0,\ \cos(1),\ \tan(5+i),\ 1,\ \frac{1}{\cos\left(\frac{\pi}{11}\right)},\ \sqrt{2}+1$$

```
sin(-x), cos(x + PI), tan(x^2 - 4)
```

$$-\sin(x),\ -\cos(x),\ \tan(x^2-4)$$

Floating point values are computed for floating-point arguments:

```
sin(123.4), cos(5.6 + 7.8*I), cot(1.0/10^20)
```

$$-0.7693905459,\ 946.4239673 + 770.3351731\ i,\ 1.0\ 10^{20}$$

Floating point intervals are computed for interval arguments:

```
sin(0 ... 1), cos(20 ... 30), tan(0 ... 5)
```

$$0.0 \ldots 0.8414709849,\ -1.0 \ldots 1.0,\ \mathrm{RD\_NINF} \ldots \mathrm{RD\_INF}$$

For the functions with discontinuities, the result may be a union of intervals:

```
csc(-1 ... 1), tan(1 ... 2)
```

$$\mathrm{RD\_NINF} \ldots -1.188395105 \cup 1.188395105 \ldots \mathrm{RD\_INF},\ \mathrm{RD\_NINF} \ldots -2.185039863 \cup 1.557407724 \ldots \mathrm{RD\_INF}$$

Example 2

Some special values are implemented:

```
sin(PI/10), cos(2*PI/5), tan(123/8*PI), cot(-PI/12)
```

$$\frac{\sqrt{5}}{4} - \frac{1}{4},\ \frac{\sqrt{5}}{4} - \frac{1}{4},\ \sqrt{2} + 1,\ -\sqrt{3} - 2$$

Translations by integer multiples of π are eliminated from the argument:

```
sin(x + 10*PI), cos(3 - PI), tan(x + PI), cot(2 - 10^100*PI)
```

$$\sin(x),\ -\cos(3),\ \tan(x),\ \cot(2)$$

All arguments that are rational multiples of π are transformed to arguments from the interval $\left[0, \frac{\pi}{2}\right)$:

```
sin(4/7*PI), cos(-20*PI/9), tan(123/11*PI), cot(-PI/13)
```

$$\sin\left(\frac{3\,\pi}{7}\right),\ \cos\left(\frac{2\,\pi}{9}\right),\ \tan\left(\frac{2\,\pi}{11}\right),\ -\cot\left(\frac{\pi}{13}\right)$$

Example 3

Arguments that are rational multiples of `I` are rewritten in terms of hyperbolicfunctions:

```
sin(5*I), cos(5/4*I), tan(-3*I)
```

$$\sinh(5)\,i,\ \cosh\left(\frac{5}{4}\right),\ -\tanh(3)\,i$$

For other complex arguments, use `expand` to rewrite the result:

```
sin(5*I + 2*PI/3), cos(PI/4 - 5/4*I), tan(-3*I + PI/2)
```

$$\sin\left(\frac{2\,\pi}{3}+5\,i\right),\ \cos\left(\frac{\pi}{4}-\frac{5\,i}{4}\right),\ \tan\left(\frac{\pi}{2}-3\,i\right)$$

```
expand(sin(5*I + 2*PI/3)), expand(cos(5/4*I - PI/4)),
expand(tan(-3*I + PI/2))
```

$$\frac{\sqrt{3}\,\cosh(5)}{2}-\frac{\sinh(5)\,i}{2},\ \frac{\sqrt{2}\,\cosh\left(\frac{5}{4}\right)}{2}+\frac{\sqrt{2}\,\sinh\left(\frac{5}{4}\right)i}{2},\ -\frac{i}{\tanh(3)}$$

Example 4

The `expand` function implements the addition theorems:

```
expand(sin(x + PI/2)), expand(cos(x + y))
```

$$\cos(x),\ \cos(x)\cos(y)-\sin(x)\sin(y)$$

The `combine` function uses these theorems in the other direction, trying to rewrite products of trigonometric functions:

```
combine(sin(x)*sin(y), sincos)
```

$$\frac{\cos(x-y)}{2}-\frac{\cos(x+y)}{2}$$

The trigonometric functions do not immediately respond to properties set via `assume`:

```
assume(n, Type::Integer): sin(n*PI), cos(n*PI)
```

$$\sin(\pi\, n),\ \cos(\pi\, n)$$

Use `simplify` to take such properties into account:

```
simplify(sin(n*PI)), simplify(cos(n*PI))
```

$$0,\ (-1)^n$$

```
assume(n, Type::Odd): sin(n*PI + x), simplify(sin(n*PI + x))
```

$$\sin(x+\pi\, n),\ -\sin(x)$$

```
y := cos(x + n*PI) + cos(x - n*PI):  y, simplify(y)
```

$$\cos(x+\pi\, n)+\cos(x-\pi\, n),\ -2\cos(x)$$

```
delete n, y:
```

Example 5

Various relations exist between the trigonometric functions:

```
csc(x), sec(x)
```

$$\frac{1}{\sin(x)},\ \frac{1}{\cos(x)}$$

Use `rewrite` to obtain a representation in terms of a specific target function:

```
rewrite(tan(x)*exp(2*I*x), sincos), rewrite(sin(x), cot)
```

$$\frac{\sin(x)\,(\cos(2\,x)+\sin(2\,x)\,\mathrm{i})}{\cos(x)},\ \frac{2\cot\left(\frac{x}{2}\right)}{\cot\left(\frac{x}{2}\right)^2+1}$$

Example 6

The inverse functions are implemented by `arcsin`, `arccos` etc.:

```
sin(arcsin(x)), sin(arccos(x)), cos(arctan(x))
```

$$x,\ \sqrt{1-x^2},\ \frac{1}{\sqrt{x^2+1}}$$

Note that `arcsin(sin(x))` does not necessarily yield `x`, because `arcsin` produces values with real parts in the interval $\left[-\frac{\pi}{2}, \frac{\pi}{2}\right]$:

```
arcsin(sin(3)), arcsin(sin(1.6 + I))
```

$$\pi - 3,\ 1.541592654 - 1.0\,i$$

Example 7

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the trigonometric functions:

```
diff(sin(x^2), x), float(sin(3)*cot(5 + I))
```

$$2\,x\cos(x^2),\ -0.01668502608 - 0.1112351327\,i$$

```
limit(x*sin(x)/tan(x^2), x = 0)
```

$$1$$

```
series((tan(sin(x)) - sin(tan(x)))/sin(x^7), x = 0)
```

$$\frac{1}{30} + \frac{29\,x^2}{756} + \frac{1913\,x^4}{75600} + O(x^6)$$

Parameters

x

csc

Cosecant function

Syntax

```
csc(x)
```

Description

`csc(x)` represents the cosecant function `1/sin(x)`.

The arguments have to be specified in radians, not in degrees. E.g., use π to specify an angle of 180^o.

All trigonometric functions are defined for complex arguments.

Floating point values are returned for floating-point arguments. Floating point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

Translations by integer multiples of π are eliminated from the argument. Further, arguments that are rational multiples of π lead to simplified results; symmetry relations are used to rewrite the result using an argument from the standard interval $\left[0, \frac{\pi}{2}\right)$.

Explicit expressions are returned for the following arguments:

$$0, \frac{\pi}{2}, \frac{\pi}{3}, \frac{\pi}{4}, \frac{\pi}{5}, \frac{2\pi}{5}, \frac{\pi}{6}, \frac{\pi}{8}, \frac{3\pi}{8}, \frac{\pi}{10}, \frac{3\pi}{10}, \frac{\pi}{12}, \frac{5\pi}{12}.$$

Cf. “Example 2” on page 1-1896.

The result is rewritten in terms of hyperbolic functions, if the argument is a rational multiple of `I`. Cf. “Example 3” on page 1-1896.

The functions `expand` and `combine` implement the addition theorems for the trigonometric functions. Cf. “Example 4” on page 1-1897.

The trigonometric functions do not respond to properties set via `assume`. Use `simplify` to take such properties into account. Cf. “Example 4” on page 1-1897.

`csc(x)` is immediately rewritten as `1/sin(x)`. Cf. “Example 5” on page 1-1898.

The inverse function is implemented by `arccsc`. Cf. “Example 6” on page 1-1898.

The float attributes are kernel functions, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
sin(PI), cos(1), tan(5 + I), csc(PI/2), sec(PI/11), cot(PI/8)
```

$$0,\ \cos(1),\ \tan(5+i),\ 1,\ \frac{1}{\cos\left(\frac{\pi}{11}\right)},\ \sqrt{2}+1$$

```
sin(-x), cos(x + PI), tan(x^2 - 4)
```

$$-\sin(x),\ -\cos(x),\ \tan(x^2-4)$$

Floating point values are computed for floating-point arguments:

```
sin(123.4), cos(5.6 + 7.8*I), cot(1.0/10^20)
```

$$-0.7693905459,\ 946.4239673 + 770.3351731\ i,\ 1.0\ 10^{20}$$

Floating point intervals are computed for interval arguments:

```
sin(0 ... 1), cos(20 ... 30), tan(0 ... 5)
```

$$0.0 \ldots 0.8414709849,\ -1.0 \ldots 1.0,\ \mathrm{RD\_NINF} \ldots \mathrm{RD\_INF}$$

For the functions with discontinuities, the result may be a union of intervals:

```
csc(-1 ... 1), tan(1 ... 2)
```

$$\mathrm{RD\_NINF} \ldots -1.188395105 \cup 1.188395105 \ldots \mathrm{RD\_INF},\ \mathrm{RD\_NINF} \ldots -2.185039863 \cup 1.557407724 \ldots \mathrm{RD\_INF}$$

Example 2

Some special values are implemented:

```
sin(PI/10), cos(2*PI/5), tan(123/8*PI), cot(-PI/12)
```

$$\frac{\sqrt{5}}{4} - \frac{1}{4},\ \frac{\sqrt{5}}{4} - \frac{1}{4},\ \sqrt{2} + 1,\ -\sqrt{3} - 2$$

Translations by integer multiples of π are eliminated from the argument:

```
sin(x + 10*PI), cos(3 - PI), tan(x + PI), cot(2 - 10^100*PI)
```

$$\sin(x),\ -\cos(3),\ \tan(x),\ \cot(2)$$

All arguments that are rational multiples of π are transformed to arguments from the interval $\left[0, \frac{\pi}{2}\right)$:

```
sin(4/7*PI), cos(-20*PI/9), tan(123/11*PI), cot(-PI/13)
```

$$\sin\left(\frac{3\,\pi}{7}\right),\ \cos\left(\frac{2\,\pi}{9}\right),\ \tan\left(\frac{2\,\pi}{11}\right),\ -\cot\left(\frac{\pi}{13}\right)$$

Example 3

Arguments that are rational multiples of `I` are rewritten in terms of hyperbolicfunctions:

```
sin(5*I), cos(5/4*I), tan(-3*I)
```

$$\sinh(5)\,i,\ \cosh\left(\frac{5}{4}\right),\ -\tanh(3)\,i$$

For other complex arguments, use `expand` to rewrite the result:

```
sin(5*I + 2*PI/3), cos(PI/4 - 5/4*I), tan(-3*I + PI/2)
```

$$\sin\left(\frac{2\,\pi}{3}+5\,i\right),\ \cos\left(\frac{\pi}{4}-\frac{5\,i}{4}\right),\ \tan\left(\frac{\pi}{2}-3\,i\right)$$

```
expand(sin(5*I + 2*PI/3)), expand(cos(5/4*I - PI/4)),
expand(tan(-3*I + PI/2))
```

$$\frac{\sqrt{3}\,\cosh(5)}{2}-\frac{\sinh(5)\,i}{2},\ \frac{\sqrt{2}\,\cosh\left(\frac{5}{4}\right)}{2}+\frac{\sqrt{2}\,\sinh\left(\frac{5}{4}\right)i}{2},\ -\frac{i}{\tanh(3)}$$

Example 4

The `expand` function implements the addition theorems:

```
expand(sin(x + PI/2)), expand(cos(x + y))
```

$$\cos(x),\ \cos(x)\cos(y)-\sin(x)\sin(y)$$

The `combine` function uses these theorems in the other direction, trying to rewrite products of trigonometric functions:

```
combine(sin(x)*sin(y), sincos)
```

$$\frac{\cos(x-y)}{2}-\frac{\cos(x+y)}{2}$$

The trigonometric functions do not immediately respond to properties set via `assume`:

```
assume(n, Type::Integer): sin(n*PI), cos(n*PI)
```

$$\sin(\pi\, n),\ \cos(\pi\, n)$$

Use `simplify` to take such properties into account:

```
simplify(sin(n*PI)), simplify(cos(n*PI))
```

$$0,\ (-1)^n$$

```
assume(n, Type::Odd): sin(n*PI + x), simplify(sin(n*PI + x))
```

$$\sin(x + \pi\, n),\ -\sin(x)$$

```
y := cos(x + n*PI) + cos(x - n*PI):  y, simplify(y)
```

$$\cos(x + \pi\, n) + \cos(x - \pi\, n),\ -2\cos(x)$$

```
delete n, y:
```

Example 5

Various relations exist between the trigonometric functions:

```
csc(x), sec(x)
```

$$\frac{1}{\sin(x)},\ \frac{1}{\cos(x)}$$

Use `rewrite` to obtain a representation in terms of a specific target function:

```
rewrite(tan(x)*exp(2*I*x), sincos), rewrite(sin(x), cot)
```

$$\frac{\sin(x)\,(\cos(2\,x) + \sin(2\,x)\,\mathrm{i})}{\cos(x)},\ \frac{2\cot\left(\frac{x}{2}\right)}{\cot\left(\frac{x}{2}\right)^2 + 1}$$

Example 6

The inverse functions are implemented by `arcsin`, `arccos` etc.:

```
sin(arcsin(x)), sin(arccos(x)), cos(arctan(x))
```

$$x,\ \sqrt{1-x^2},\ \frac{1}{\sqrt{x^2+1}}$$

Note that `arcsin(sin(x))` does not necessarily yield `x`, because `arcsin` produces values with real parts in the interval $\left[-\frac{\pi}{2}, \frac{\pi}{2}\right]$:

```
arcsin(sin(3)), arcsin(sin(1.6 + I))
```

$$\pi - 3,\ 1.541592654 - 1.0\,i$$

Example 7

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the trigonometric functions:

```
diff(sin(x^2), x), float(sin(3)*cot(5 + I))
```

$$2\,x\cos(x^2),\ -0.01668502608 - 0.1112351327\,i$$

```
limit(x*sin(x)/tan(x^2), x = 0)
```

$$1$$

```
series((tan(sin(x)) - sin(tan(x)))/sin(x^7), x = 0)
```

$$\frac{1}{30} + \frac{29\,x^2}{756} + \frac{1913\,x^4}{75600} + O(x^6)$$

Parameters

x

sec

Secant function

Syntax

```
sec(x)
```

Description

`sec(x)` represents the secant function `1/cos(x)`.

The arguments have to be specified in radians, not in degrees. E.g., use π to specify an angle of 180^o.

All trigonometric functions are defined for complex arguments.

Floating point values are returned for floating-point arguments. Floating point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

Translations by integer multiples of π are eliminated from the argument. Further, arguments that are rational multiples of π lead to simplified results; symmetry relations are used to rewrite the result using an argument from the standard interval $\left[0, \frac{\pi}{2}\right)$.

Explicit expressions are returned for the following arguments:

$$0, \frac{\pi}{2}, \frac{\pi}{3}, \frac{\pi}{4}, \frac{\pi}{5}, \frac{2\pi}{5}, \frac{\pi}{6}, \frac{\pi}{8}, \frac{3\pi}{8}, \frac{\pi}{10}, \frac{3\pi}{10}, \frac{\pi}{12}, \frac{5\pi}{12}.$$

Cf. “Example 2” on page 1-1903.

The result is rewritten in terms of hyperbolic functions, if the argument is a rational multiple of `I`. Cf. “Example 3” on page 1-1903.

The functions `expand` and `combine` implement the addition theorems for the trigonometric functions. Cf. “Example 4” on page 1-1904.

The trigonometric functions do not respond to properties set via `assume`. Use `simplify` to take such properties into account. Cf. “Example 4” on page 1-1904.

`sec(x)` is immediately rewritten as `1/cos(x)`. Cf. “Example 5” on page 1-1905.

The inverse function is implemented by `arcsec`. Cf. “Example 6” on page 1-1905.

The float attributes are kernel functions, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
sin(PI), cos(1), tan(5 + I), csc(PI/2), sec(PI/11), cot(PI/8)
```

$$0,\ \cos(1),\ \tan(5+i),\ 1,\ \frac{1}{\cos\left(\frac{\pi}{11}\right)},\ \sqrt{2}+1$$

```
sin(-x), cos(x + PI), tan(x^2 - 4)
```

$$-\sin(x),\ -\cos(x),\ \tan(x^2-4)$$

Floating point values are computed for floating-point arguments:

```
sin(123.4), cos(5.6 + 7.8*I), cot(1.0/10^20)
```

$$-0.7693905459,\ 946.4239673 + 770.3351731\ i,\ 1.0\ 10^{20}$$

Floating point intervals are computed for interval arguments:

```
sin(0 ... 1), cos(20 ... 30), tan(0 ... 5)
```

$$0.0 \ldots 0.8414709849,\ -1.0 \ldots 1.0,\ \mathrm{RD\_NINF} \ldots \mathrm{RD\_INF}$$

For the functions with discontinuities, the result may be a union of intervals:

```
csc(-1 ... 1), tan(1 ... 2)
```

$$\mathrm{RD\_NINF} \ldots -1.188395105 \cup 1.188395105 \ldots \mathrm{RD\_INF},\ \mathrm{RD\_NINF} \ldots -2.185039863 \cup 1.557407724 \ldots \mathrm{RD\_INF}$$

Example 2

Some special values are implemented:

```
sin(PI/10), cos(2*PI/5), tan(123/8*PI), cot(-PI/12)
```

$$\frac{\sqrt{5}}{4} - \frac{1}{4},\ \frac{\sqrt{5}}{4} - \frac{1}{4},\ \sqrt{2} + 1,\ -\sqrt{3} - 2$$

Translations by integer multiples of π are eliminated from the argument:

```
sin(x + 10*PI), cos(3 - PI), tan(x + PI), cot(2 - 10^100*PI)
```

$$\sin(x),\ -\cos(3),\ \tan(x),\ \cot(2)$$

All arguments that are rational multiples of π are transformed to arguments from the interval $\left[0, \frac{\pi}{2}\right)$:

```
sin(4/7*PI), cos(-20*PI/9), tan(123/11*PI), cot(-PI/13)
```

$$\sin\left(\frac{3\,\pi}{7}\right),\ \cos\left(\frac{2\,\pi}{9}\right),\ \tan\left(\frac{2\,\pi}{11}\right),\ -\cot\left(\frac{\pi}{13}\right)$$

Example 3

Arguments that are rational multiples of `I` are rewritten in terms of hyperbolicfunctions:

```
sin(5*I), cos(5/4*I), tan(-3*I)
```

$$\sinh(5)\,i,\ \cosh\left(\frac{5}{4}\right),\ -\tanh(3)\,i$$

For other complex arguments, use `expand` to rewrite the result:

```
sin(5*I + 2*PI/3), cos(PI/4 - 5/4*I), tan(-3*I + PI/2)
```

$$\sin\left(\frac{2\,\pi}{3}+5\,i\right),\ \cos\left(\frac{\pi}{4}-\frac{5\,i}{4}\right),\ \tan\left(\frac{\pi}{2}-3\,i\right)$$

```
expand(sin(5*I + 2*PI/3)), expand(cos(5/4*I - PI/4)),
expand(tan(-3*I + PI/2))
```

$$\frac{\sqrt{3}\,\cosh(5)}{2}-\frac{\sinh(5)\,i}{2},\ \frac{\sqrt{2}\,\cosh\left(\frac{5}{4}\right)}{2}+\frac{\sqrt{2}\,\sinh\left(\frac{5}{4}\right)i}{2},\ -\frac{i}{\tanh(3)}$$

Example 4

The `expand` function implements the addition theorems:

```
expand(sin(x + PI/2)), expand(cos(x + y))
```

$$\cos(x),\ \cos(x)\cos(y)-\sin(x)\sin(y)$$

The `combine` function uses these theorems in the other direction, trying to rewrite products of trigonometric functions:

```
combine(sin(x)*sin(y), sincos)
```

$$\frac{\cos(x-y)}{2}-\frac{\cos(x+y)}{2}$$

The trigonometric functions do not immediately respond to properties set via `assume`:

```
assume(n, Type::Integer): sin(n*PI), cos(n*PI)
```

$$\sin(\pi\, n),\ \cos(\pi\, n)$$

Use `simplify` to take such properties into account:

```
simplify(sin(n*PI)), simplify(cos(n*PI))
```

$$0,\ (-1)^n$$

```
assume(n, Type::Odd): sin(n*PI + x), simplify(sin(n*PI + x))
```

$$\sin(x+\pi\, n),\ -\sin(x)$$

```
y := cos(x + n*PI) + cos(x - n*PI):  y, simplify(y)
```

$$\cos(x+\pi\, n)+\cos(x-\pi\, n),\ -2\,\cos(x)$$

```
delete n, y:
```

Example 5

Various relations exist between the trigonometric functions:

```
csc(x), sec(x)
```

$$\frac{1}{\sin(x)},\ \frac{1}{\cos(x)}$$

Use `rewrite` to obtain a representation in terms of a specific target function:

```
rewrite(tan(x)*exp(2*I*x), sincos), rewrite(sin(x), cot)
```

$$\frac{\sin(x)\,(\cos(2\,x)+\sin(2\,x)\,\mathrm{i})}{\cos(x)},\ \frac{2\,\cot\left(\frac{x}{2}\right)}{\cot\left(\frac{x}{2}\right)^2+1}$$

Example 6

The inverse functions are implemented by `arcsin`, `arccos` etc.:

```
sin(arcsin(x)), sin(arccos(x)), cos(arctan(x))
```

$$x,\ \sqrt{1-x^2},\ \frac{1}{\sqrt{x^2+1}}$$

Note that `arcsin(sin(x))` does not necessarily yield `x`, because `arcsin` produces values with real parts in the interval $\left[-\frac{\pi}{2}, \frac{\pi}{2}\right]$:

```
arcsin(sin(3)), arcsin(sin(1.6 + I))
```

$$\pi - 3,\ 1.541592654 - 1.0\,i$$

Example 7

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the trigonometric functions:

```
diff(sin(x^2), x), float(sin(3)*cot(5 + I))
```

$$2\,x\cos(x^2),\ -0.01668502608 - 0.1112351327\,i$$

```
limit(x*sin(x)/tan(x^2), x = 0)
```

$$1$$

```
series((tan(sin(x)) - sin(tan(x)))/sin(x^7), x = 0)
```

$$\frac{1}{30} + \frac{29\,x^2}{756} + \frac{1913\,x^4}{75600} + O(x^6)$$

Parameters

x

An arithmetical expression or a floating-point interval

Return Values

Arithmetical expression or a floating-point interval

Overloaded By

x

See Also

MuPAD Functions

`arccos` | `arccot` | `arccsc` | `arcsec` | `arcsin` | `arctan` | `cos` | `cot` | `csc` | `sin` | `tan`

cot

Cotangent function

Syntax

```
cot(x)
```

Description

`cot(x)` represents the cotangent function `cos(x)/sin(x)`.

The arguments have to be specified in radians, not in degrees. E.g., use π to specify an angle of 180^o.

All trigonometric functions are defined for complex arguments.

Floating point values are returned for floating-point arguments. Floating point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

Translations by integer multiples of π are eliminated from the argument. Further, arguments that are rational multiples of π lead to simplified results; symmetry relations are used to rewrite the result using an argument from the standard interval $\left[0, \frac{\pi}{2}\right)$.

Explicit expressions are returned for the following arguments:

$$0, \frac{\pi}{2}, \frac{\pi}{3}, \frac{\pi}{4}, \frac{\pi}{5}, \frac{2\,\pi}{5}, \frac{\pi}{6}, \frac{\pi}{8}, \frac{3\,\pi}{8}, \frac{\pi}{10}, \frac{3\,\pi}{10}, \frac{\pi}{12}, \frac{5\,\pi}{12}.$$

Cf. “Example 2” on page 1-1910.

The result is rewritten in terms of hyperbolic functions, if the argument is a rational multiple of `I`. Cf. “Example 3” on page 1-1910.

The functions `expand` and `combine` implement the addition theorems for the trigonometric functions. Cf. “Example 4” on page 1-1911.

The trigonometric functions do not respond to properties set via `assume`. Use `simplify` to take such properties into account. Cf. “Example 4” on page 1-1911.

Use `rewrite` to rewrite expressions involving `tan` and `cot` in terms of `sin` and `cos`. Cf. “Example 5” on page 1-1912.

The inverse function is implemented by `arccot`. Cf. “Example 6” on page 1-1912.

The float attributes are kernel functions, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
sin(PI), cos(1), tan(5 + I), csc(PI/2), sec(PI/11), cot(PI/8)
```

$$0,\ \cos(1),\ \tan(5+i),\ 1,\ \frac{1}{\cos\left(\frac{\pi}{11}\right)},\ \sqrt{2}+1$$

```
sin(-x), cos(x + PI), tan(x^2 - 4)
```

$$-\sin(x),\ -\cos(x),\ \tan(x^2-4)$$

Floating point values are computed for floating-point arguments:

```
sin(123.4), cos(5.6 + 7.8*I), cot(1.0/10^20)
```

$$-0.7693905459,\ 946.4239673 + 770.3351731\,i,\ 1.0\ 10^{20}$$

Floating point intervals are computed for interval arguments:

```
sin(0 ... 1), cos(20 ... 30), tan(0 ... 5)
```

$$0.0 \ldots 0.8414709849,\ -1.0 \ldots 1.0,\ \mathrm{RD\_NINF} \ldots \mathrm{RD\_INF}$$

For the functions with discontinuities, the result may be a union of intervals:

```
csc(-1 ... 1), tan(1 ... 2)
```

$$\mathrm{RD\_NINF} \ldots -1.188395105 \cup 1.188395105 \ldots \mathrm{RD\_INF},\ \mathrm{RD\_NINF} \ldots -2.185039863 \cup 1.557407724 \ldots \mathrm{RD\_INF}$$

Example 2

Some special values are implemented:

```
sin(PI/10), cos(2*PI/5), tan(123/8*PI), cot(-PI/12)
```

$$\frac{\sqrt{5}}{4} - \frac{1}{4},\ \frac{\sqrt{5}}{4} - \frac{1}{4},\ \sqrt{2} + 1,\ -\sqrt{3} - 2$$

Translations by integer multiples of π are eliminated from the argument:

```
sin(x + 10*PI), cos(3 - PI), tan(x + PI), cot(2 - 10^100*PI)
```

$$\sin(x),\ -\cos(3),\ \tan(x),\ \cot(2)$$

All arguments that are rational multiples of π are transformed to arguments from the interval $\left[0, \frac{\pi}{2}\right)$:

```
sin(4/7*PI), cos(-20*PI/9), tan(123/11*PI), cot(-PI/13)
```

$$\sin\left(\frac{3\,\pi}{7}\right),\ \cos\left(\frac{2\,\pi}{9}\right),\ \tan\left(\frac{2\,\pi}{11}\right),\ -\cot\left(\frac{\pi}{13}\right)$$

Example 3

Arguments that are rational multiples of `I` are rewritten in terms of hyperbolicfunctions:

```
sin(5*I), cos(5/4*I), tan(-3*I)
```

$$\sinh(5)\,i,\ \cosh\left(\frac{5}{4}\right),\ -\tanh(3)\,i$$

For other complex arguments, use `expand` to rewrite the result:

```
sin(5*I + 2*PI/3), cos(PI/4 - 5/4*I), tan(-3*I + PI/2)
```

$$\sin\left(\frac{2\,\pi}{3}+5\,i\right),\ \cos\left(\frac{\pi}{4}-\frac{5\,i}{4}\right),\ \tan\left(\frac{\pi}{2}-3\,i\right)$$

```
expand(sin(5*I + 2*PI/3)), expand(cos(5/4*I - PI/4)),
expand(tan(-3*I + PI/2))
```

$$\frac{\sqrt{3}\,\cosh(5)}{2}-\frac{\sinh(5)\,i}{2},\ \frac{\sqrt{2}\,\cosh\left(\frac{5}{4}\right)}{2}+\frac{\sqrt{2}\,\sinh\left(\frac{5}{4}\right)i}{2},\ -\frac{i}{\tanh(3)}$$

Example 4

The `expand` function implements the addition theorems:

```
expand(sin(x + PI/2)), expand(cos(x + y))
```

$$\cos(x),\ \cos(x)\cos(y)-\sin(x)\sin(y)$$

The `combine` function uses these theorems in the other direction, trying to rewrite products of trigonometric functions:

```
combine(sin(x)*sin(y), sincos)
```

$$\frac{\cos(x-y)}{2}-\frac{\cos(x+y)}{2}$$

The trigonometric functions do not immediately respond to properties set via `assume`:

```
assume(n, Type::Integer): sin(n*PI), cos(n*PI)
```

$$\sin(\pi\, n),\ \cos(\pi\, n)$$

Use `simplify` to take such properties into account:

```
simplify(sin(n*PI)), simplify(cos(n*PI))
```

$$0,\ (-1)^n$$

```
assume(n, Type::Odd): sin(n*PI + x), simplify(sin(n*PI + x))
```

$$\sin(x+\pi\, n),\ -\sin(x)$$

```
y := cos(x + n*PI) + cos(x - n*PI):  y, simplify(y)
```

$$\cos(x+\pi\, n)+\cos(x-\pi\, n),\ -2\,\cos(x)$$

```
delete n, y:
```

Example 5

Various relations exist between the trigonometric functions:

```
csc(x), sec(x)
```

$$\frac{1}{\sin(x)},\ \frac{1}{\cos(x)}$$

Use `rewrite` to obtain a representation in terms of a specific target function:

```
rewrite(tan(x)*exp(2*I*x), sincos), rewrite(sin(x), cot)
```

$$\frac{\sin(x)\,(\cos(2\,x)+\sin(2\,x)\,\mathrm{i})}{\cos(x)},\ \frac{2\,\cot\left(\frac{x}{2}\right)}{\cot\left(\frac{x}{2}\right)^2+1}$$

Example 6

The inverse functions are implemented by `arcsin`, `arccos` etc.:

```
sin(arcsin(x)), sin(arccos(x)), cos(arctan(x))
```

$$x,\ \sqrt{1-x^2},\ \frac{1}{\sqrt{x^2+1}}$$

Note that `arcsin(sin(x))` does not necessarily yield `x`, because `arcsin` produces values with real parts in the interval $\left[-\frac{\pi}{2}, \frac{\pi}{2}\right]$:

```
arcsin(sin(3)), arcsin(sin(1.6 + I))
```

$$\pi - 3,\ 1.541592654 - 1.0\,i$$

Example 7

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the trigonometric functions:

```
diff(sin(x^2), x), float(sin(3)*cot(5 + I))
```

$$2\,x\,\cos(x^2),\ -0.01668502608 - 0.1112351327\,i$$

```
limit(x*sin(x)/tan(x^2), x = 0)
```

$$1$$

```
series((tan(sin(x)) - sin(tan(x)))/sin(x^7), x = 0)
```

$$\frac{1}{30} + \frac{29\,x^2}{756} + \frac{1913\,x^4}{75600} + O(x^6)$$

Parameters

x

An arithmetical expression or a floating-point interval

Return Values

Arithmetical expression or a floating-point interval

sinh

Hyperbolic sine function

Syntax

```
sinh(x)
```

Description

`sinh(x)` represents the hyperbolic sine function.

This function is defined for complex arguments.

Floating point values are returned for floating-point arguments. Floating point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

Arguments that are integer multiples of $\frac{i\pi}{2}$ lead to simplified results. If the argument involves a negative numerical factor of `Type::Real`, then symmetry relations are used to make this factor positive. Cf. “Example 2” on page 1-1916.

The special values $sinh(0) = 0$, $sinh(\infty) = \infty$, $sinh(-\infty) = -\infty$ are implemented.

The functions `expand` and `combine` implement the addition theorems for the hyperbolic functions. Cf. “Example 3” on page 1-1917.

`csch(x)` is rewritten as `1/sinh(x)`. Use `expand` or `rewrite` to rewrite expressions involving `tanh` and `coth` in terms of `sinh` and `cosh`. Cf. “Example 4” on page 1-1917.

The inverse function is implemented by `arcsinh`. Cf. “Example 5” on page 1-1918.

The float attributes are kernel functions, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
sinh(I*PI), cosh(1), tanh(5 + I), csch(PI), sech(1/11), coth(8)
```

$$0,\ \cosh(1),\ \tanh(5+i),\ \frac{1}{\sinh(\pi)},\ \frac{1}{\cosh\left(\frac{1}{11}\right)},\ \coth(8)$$

```
sinh(x), cosh(x + I*PI), tanh(x^2 - 4)
```

$$\sinh(x),\ -\cosh(x),\ \tanh(x^2-4)$$

Floating point values are computed for floating-point arguments:

```
sinh(123.4), cosh(5.6 + 7.8*I), coth(1.0/10^20)
```

$$1.953930316\ 10^{53},\ 7.295585032 + 135.0143985\ i,\ 1.0\ 10^{20}$$

For floating-point intervals, intervals enclosing the image are calculated:

```
cosh(-1 ... 1), tanh(-1 ... 1)
```

$$1.0 \ldots 1.543080635,\ -0.761594156 \ldots 0.761594156$$

For functions with discontinuities, evaluation over an interval may result in a union of intervals:

```
coth(-1 ... 1)
```

$$\text{RD\_NINF} \ldots -1.313035285 \cup 1.313035285 \ldots \text{RD\_INF}$$

Example 2

Simplifications are implemented for arguments that are integer multiples of $\frac{i\,\pi}{2}$:

```
sinh(I*PI/2), cosh(40*I*PI), tanh(-10^100*I*PI),
coth(-17/2*I*PI)
```

$$i,\ 1,\ 0,\ 0$$

Negative real numerical factors in the argument are rewritten via symmetry relations:

```
sinh(-5), cosh(-3/2*x), tanh(-x*PI/12), coth(-12/17*x*y*PI)
```

$$-\sinh(5),\ \cosh\left(\frac{3x}{2}\right),\ -\tanh\left(\frac{\pi x}{12}\right),\ -\coth\left(\frac{12\pi xy}{17}\right)$$

Example 3

The `expand` function implements the addition theorems:

```
expand(sinh(x + PI*I)), expand(cosh(x + y))
```

$$-\sinh(x),\ \cosh(x)\cosh(y)+\sinh(x)\sinh(y)$$

The `combine` function uses these theorems in the other direction, trying to rewrite products of hyperbolic functions:

```
combine(sinh(x)*sinh(y), sinhcosh)
```

$$\frac{\cosh(x+y)}{2}-\frac{\cosh(x-y)}{2}$$

Example 4

Various relations exist between the hyperbolic functions:

```
csch(x), sech(x)
```

$$\frac{1}{\sinh(x)},\ \frac{1}{\cosh(x)}$$

Use `rewrite` to obtain a representation in terms of a specific target function:

```
rewrite(tanh(x)*exp(2*x), sinhcosh), rewrite(sinh(x), tanh)
```

$$\frac{\sinh(x)\,(\cosh(2\,x)+\sinh(2\,x))}{\cosh(x)},\ -\frac{2\tanh\left(\frac{x}{2}\right)}{\tanh\left(\frac{x}{2}\right)^2-1}$$

```
rewrite(sinh(x)*coth(y), exp), rewrite(exp(x), coth)
```

$$-\frac{\left(\frac{e^{-x}}{2}-\frac{e^{x}}{2}\right)\left(e^{2\,y}+1\right)}{e^{2\,y}-1},\ \frac{\coth\left(\frac{x}{2}\right)+1}{\coth\left(\frac{x}{2}\right)-1}$$

Example 5

The inverse functions are implemented by `arcsinh`, `arccosh` etc.:

```
sinh(arcsinh(x)), sinh(arccosh(x)), cosh(arctanh(x))
```

$$x,\ \sqrt{x^2-1},\ \frac{1}{\sqrt{1-x}\,\sqrt{x+1}}$$

Note that `arcsinh(sinh(x))` does not necessarily yield `x`, because `arcsinh` produces values with imaginary parts in the interval $\left[-\frac{\pi}{2},\frac{\pi}{2}\right]$:

```
arcsinh(sinh(3)), arcsinh(sinh(1.6 + 100*I))
```

$$3,\ 1.6-0.5309649149\,i$$

Example 6

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the hyperbolic functions:

```
diff(sinh(x^2), x), float(sinh(3)*coth(5 + I))
```

$$2\,x\,\cosh(x^2),\ 10.01749636 - 0.0008270853591\,i$$

```
limit(x*sinh(x)/tanh(x^2), x = 0)
```

$$1$$

```
series((tanh(sinh(x)) - sinh(tanh(x)))/sinh(x^7), x = 0)
```

$$-\frac{1}{30} + \frac{29\,x^2}{756} - \frac{1913\,x^4}{75600} + O(x^6)$$

```
series(tanh(x), x = infinity)
```

$$1 - 2\,e^{-2x} + 2\,e^{-4x} - 2\,e^{-6x} + 2\,e^{-8x} - 2\,e^{-10x} + O\left(e^{-12x}\right)$$

Parameters

x

An arithmetical expression or a floating-point interval

Return Values

Arithmetical expression or a floating-point interval

cosh

Hyperbolic cosine function

Syntax

```
cosh(x)
```

Description

`cosh(x)` represents the hyperbolic cosine function.

This function is defined for complex arguments.

Floating point values are returned for floating-point arguments. Floating point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

Arguments that are integer multiples of $\frac{i\pi}{2}$ lead to simplified results. If the argument involves a negative numerical factor of `Type::Real`, then symmetry relations are used to make this factor positive. Cf. “Example 2” on page 1-1921.

The special values $\cosh(0) = 1$, $\cosh(\infty) = \infty$, $\cosh(-\infty) = \infty$ are implemented.

The functions `expand` and `combine` implement the addition theorems for the hyperbolic functions. Cf. “Example 3” on page 1-1922.

`sech(x)` is rewritten as `1/cosh(x)`. Use `expand` or `rewrite` to rewrite expressions involving `tanh` and `coth` in terms of `sinh` and `cosh`. Cf. “Example 4” on page 1-1922.

The inverse function is implemented by `arccosh`. Cf. “Example 5” on page 1-1923.

The float attributes are kernel functions, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
sinh(I*PI), cosh(1), tanh(5 + I), csch(PI), sech(1/11), coth(8)
```

$$0,\ \cosh(1),\ \tanh(5+i),\ \frac{1}{\sinh(\pi)},\ \frac{1}{\cosh\left(\frac{1}{11}\right)},\ \coth(8)$$

```
sinh(x), cosh(x + I*PI), tanh(x^2 - 4)
```

$$\sinh(x),\ -\cosh(x),\ \tanh(x^2-4)$$

Floating point values are computed for floating-point arguments:

```
sinh(123.4), cosh(5.6 + 7.8*I), coth(1.0/10^20)
```

$$1.953930316\ 10^{53},\ 7.295585032 + 135.0143985\ i,\ 1.0\ 10^{20}$$

For floating-point intervals, intervals enclosing the image are calculated:

```
cosh(-1 ... 1), tanh(-1 ... 1)
```

$$1.0 \ldots 1.543080635,\ -0.761594156 \ldots 0.761594156$$

For functions with discontinuities, evaluation over an interval may result in a union of intervals:

```
coth(-1 ... 1)
```

$$\text{RD\_NINF} \ldots -1.313035285 \cup 1.313035285 \ldots \text{RD\_INF}$$

Example 2

Simplifications are implemented for arguments that are integer multiples of $\frac{i\,\pi}{2}$:

```
sinh(I*PI/2), cosh(40*I*PI), tanh(-10^100*I*PI),
coth(-17/2*I*PI)
```

$$i,\ 1,\ 0,\ 0$$

Negative real numerical factors in the argument are rewritten via symmetry relations:

```
sinh(-5), cosh(-3/2*x), tanh(-x*PI/12), coth(-12/17*x*y*PI)
```

$$-\sinh(5),\ \cosh\left(\frac{3\,x}{2}\right),\ -\tanh\left(\frac{\pi\,x}{12}\right),\ -\coth\left(\frac{12\,\pi\,x\,y}{17}\right)$$

Example 3

The `expand` function implements the addition theorems:

```
expand(sinh(x + PI*I)), expand(cosh(x + y))
```

$$-\sinh(x),\ \cosh(x)\cosh(y)+\sinh(x)\sinh(y)$$

The `combine` function uses these theorems in the other direction, trying to rewrite products of hyperbolic functions:

```
combine(sinh(x)*sinh(y), sinhcosh)
```

$$\frac{\cosh(x+y)}{2}-\frac{\cosh(x-y)}{2}$$

Example 4

Various relations exist between the hyperbolic functions:

```
csch(x), sech(x)
```

$$\frac{1}{\sinh(x)},\ \frac{1}{\cosh(x)}$$

Use `rewrite` to obtain a representation in terms of a specific target function:

```
rewrite(tanh(x)*exp(2*x), sinhcosh), rewrite(sinh(x), tanh)
```

$$\frac{\sinh(x)\,(\cosh(2\,x)+\sinh(2\,x))}{\cosh(x)},\ -\frac{2\tanh\left(\frac{x}{2}\right)}{\tanh\left(\frac{x}{2}\right)^2-1}$$

```
rewrite(sinh(x)*coth(y), exp), rewrite(exp(x), coth)
```

$$-\frac{\left(\frac{e^{-x}}{2}-\frac{e^{x}}{2}\right)\left(e^{2\,y}+1\right)}{e^{2\,y}-1},\ \frac{\coth\left(\frac{x}{2}\right)+1}{\coth\left(\frac{x}{2}\right)-1}$$

Example 5

The inverse functions are implemented by `arcsinh`, `arccosh` etc.:

```
sinh(arcsinh(x)), sinh(arccosh(x)), cosh(arctanh(x))
```

$$x,\ \sqrt{x^2-1},\ \frac{1}{\sqrt{1-x}\,\sqrt{x+1}}$$

Note that `arcsinh(sinh(x))` does not necessarily yield `x`, because `arcsinh` produces values with imaginary parts in the interval $\left[-\frac{\pi}{2},\ \frac{\pi}{2}\right]$:

```
arcsinh(sinh(3)), arcsinh(sinh(1.6 + 100*I))
```

$$3,\ 1.6-0.5309649149\,i$$

Example 6

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the hyperbolic functions:

```
diff(sinh(x^2), x), float(sinh(3)*coth(5 + I))
```

$$2\,x\,\cosh(x^2),\ 10.01749636 - 0.0008270853591\,i$$

```
limit(x*sinh(x)/tanh(x^2), x = 0)
```

$$1$$

```
series((tanh(sinh(x)) - sinh(tanh(x)))/sinh(x^7), x = 0)
```

$$-\frac{1}{30} + \frac{29\,x^2}{756} - \frac{1913\,x^4}{75600} + O(x^6)$$

```
series(tanh(x), x = infinity)
```

$$1 - 2\,e^{-2x} + 2\,e^{-4x} - 2\,e^{-6x} + 2\,e^{-8x} - 2\,e^{-10x} + O\left(e^{-12x}\right)$$

Parameters

x

tanh

Hyperbolic tangent function

Syntax

```
tanh(x)
```

Description

`tanh(x)` represents the hyperbolic tangent function `sinh(x)/cosh(x)`.

This function is defined for complex arguments.

Floating point values are returned for floating-point arguments. Floating point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

Arguments that are integer multiples of $\frac{i\pi}{2}$ lead to simplified results. If the argument involves a negative numerical factor of `Type::Real`, then symmetry relations are used to make this factor positive. Cf. “Example 2” on page 1-1926.

The special values $tanh(0) = 0$, $tanh(\infty) = 1$, $tanh(-\infty) = -1$ are implemented.

The functions `expand` and `combine` implement the addition theorems for the hyperbolic functions. Cf. “Example 3” on page 1-1927.

Use `expand` or `rewrite` to rewrite expressions involving `tanh` and `coth` in terms of `sinh` and `cosh`. Cf. “Example 4” on page 1-1927.

The inverse function is implemented by `arctanh`. Cf. “Example 5” on page 1-1928.

The float attributes are kernel functions, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
sinh(I*PI), cosh(1), tanh(5 + I), csch(PI), sech(1/11), coth(8)
```

$$0,\ \cosh(1),\ \tanh(5+i),\ \frac{1}{\sinh(\pi)},\ \frac{1}{\cosh\left(\frac{1}{11}\right)},\ \coth(8)$$

```
sinh(x), cosh(x + I*PI), tanh(x^2 - 4)
```

$$\sinh(x),\ -\cosh(x),\ \tanh(x^2-4)$$

Floating point values are computed for floating-point arguments:

```
sinh(123.4), cosh(5.6 + 7.8*I), coth(1.0/10^20)
```

$$1.953930316\ 10^{53},\ 7.295585032 + 135.0143985\ i,\ 1.0\ 10^{20}$$

For floating-point intervals, intervals enclosing the image are calculated:

```
cosh(-1 ... 1), tanh(-1 ... 1)
```

$$1.0 \ldots 1.543080635,\ -0.761594156 \ldots 0.761594156$$

For functions with discontinuities, evaluation over an interval may result in a union of intervals:

```
coth(-1 ... 1)
```

$$\text{RD\_NINF} \ldots -1.313035285 \cup 1.313035285 \ldots \text{RD\_INF}$$

Example 2

Simplifications are implemented for arguments that are integer multiples of $\frac{i\,\pi}{2}$:

```
sinh(I*PI/2), cosh(40*I*PI), tanh(-10^100*I*PI),
coth(-17/2*I*PI)
```

$$i,\ 1,\ 0,\ 0$$

Negative real numerical factors in the argument are rewritten via symmetry relations:

```
sinh(-5), cosh(-3/2*x), tanh(-x*PI/12), coth(-12/17*x*y*PI)
```

$$-\sinh(5),\ \cosh\left(\frac{3x}{2}\right),\ -\tanh\left(\frac{\pi x}{12}\right),\ -\coth\left(\frac{12\pi xy}{17}\right)$$

Example 3

The `expand` function implements the addition theorems:

```
expand(sinh(x + PI*I)), expand(cosh(x + y))
```

$$-\sinh(x),\ \cosh(x)\cosh(y)+\sinh(x)\sinh(y)$$

The `combine` function uses these theorems in the other direction, trying to rewrite products of hyperbolic functions:

```
combine(sinh(x)*sinh(y), sinhcosh)
```

$$\frac{\cosh(x+y)}{2}-\frac{\cosh(x-y)}{2}$$

Example 4

Various relations exist between the hyperbolic functions:

```
csch(x), sech(x)
```

$$\frac{1}{\sinh(x)},\ \frac{1}{\cosh(x)}$$

Use `rewrite` to obtain a representation in terms of a specific target function:

```
rewrite(tanh(x)*exp(2*x), sinhcosh), rewrite(sinh(x), tanh)
```

$$\frac{\sinh(x)\,(\cosh(2\,x)+\sinh(2\,x))}{\cosh(x)},\ -\frac{2\tanh\left(\frac{x}{2}\right)}{\tanh\left(\frac{x}{2}\right)^2-1}$$

```
rewrite(sinh(x)*coth(y), exp), rewrite(exp(x), coth)
```

$$-\frac{\left(\frac{e^{-x}}{2}-\frac{e^{x}}{2}\right)\left(e^{2\,y}+1\right)}{e^{2\,y}-1},\ \frac{\coth\left(\frac{x}{2}\right)+1}{\coth\left(\frac{x}{2}\right)-1}$$

Example 5

The inverse functions are implemented by `arcsinh`, `arccosh` etc.:

```
sinh(arcsinh(x)), sinh(arccosh(x)), cosh(arctanh(x))
```

$$x,\ \sqrt{x^2-1},\ \frac{1}{\sqrt{1-x}\,\sqrt{x+1}}$$

Note that `arcsinh(sinh(x))` does not necessarily yield `x`, because `arcsinh` produces values with imaginary parts in the interval $\left[-\frac{\pi}{2},\ \frac{\pi}{2}\right]$:

```
arcsinh(sinh(3)), arcsinh(sinh(1.6 + 100*I))
```

$$3,\ 1.6-0.5309649149\,i$$

Example 6

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the hyperbolic functions:

```
diff(sinh(x^2), x), float(sinh(3)*coth(5 + I))
```

$$2\,x\,\cosh(x^2),\ 10.01749636 - 0.0008270853591\,i$$

```
limit(x*sinh(x)/tanh(x^2), x = 0)
```

$$1$$

```
series((tanh(sinh(x)) - sinh(tanh(x)))/sinh(x^7), x = 0)
```

$$-\frac{1}{30} + \frac{29\,x^2}{756} - \frac{1913\,x^4}{75600} + O(x^6)$$

```
series(tanh(x), x = infinity)
```

$$1 - 2\,e^{-2x} + 2\,e^{-4x} - 2\,e^{-6x} + 2\,e^{-8x} - 2\,e^{-10x} + O\left(e^{-12x}\right)$$

Parameters

x

An arithmetical expression or a floating-point interval

Return Values

Arithmetical expression or a floating-point interval

Overloaded By

x

csch

Hyperbolic cosecant function

Syntax

```
csch(x)
```

Description

`csch(x)` represents the hyperbolic cosecant function `1/sinh(x)`.

This function is defined for complex arguments.

Floating point values are returned for floating-point arguments. Floating point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

Arguments that are integer multiples of $\frac{i\pi}{2}$ lead to simplified results. If the argument involves a negative numerical factor of `Type::Real`, then symmetry relations are used to make this factor positive. Cf. “Example 2” on page 1-1931.

The functions `expand` and `combine` implement the addition theorems for the hyperbolic functions. Cf. “Example 3” on page 1-1932.

`csch(x)` is rewritten as `1/sinh(x)`. Cf. “Example 4” on page 1-1932.

The inverse function is implemented by `arccsch`. Cf. “Example 5” on page 1-1933.

The float attributes are kernel functions, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
sinh(I*PI), cosh(1), tanh(5 + I), csch(PI), sech(1/11), coth(8)
```

$$0,\ \cosh(1),\ \tanh(5+i),\ \frac{1}{\sinh(\pi)},\ \frac{1}{\cosh\left(\frac{1}{11}\right)},\ \coth(8)$$

```
sinh(x), cosh(x + I*PI), tanh(x^2 - 4)
```

$$\sinh(x),\ -\cosh(x),\ \tanh(x^2-4)$$

Floating point values are computed for floating-point arguments:

```
sinh(123.4), cosh(5.6 + 7.8*I), coth(1.0/10^20)
```

$$1.953930316\ 10^{53},\ 7.295585032 + 135.0143985\ i,\ 1.0\ 10^{20}$$

For floating-point intervals, intervals enclosing the image are calculated:

```
cosh(-1 ... 1), tanh(-1 ... 1)
```

$$1.0 \ldots 1.543080635,\ -0.761594156 \ldots 0.761594156$$

For functions with discontinuities, evaluation over an interval may result in a union of intervals:

```
coth(-1 ... 1)
```

$$\text{RD\_NINF} \ldots -1.313035285 \cup 1.313035285 \ldots \text{RD\_INF}$$

Example 2

Simplifications are implemented for arguments that are integer multiples of $\frac{i\,\pi}{2}$:

```
sinh(I*PI/2), cosh(40*I*PI), tanh(-10^100*I*PI),
coth(-17/2*I*PI)
```

$$i,\ 1,\ 0,\ 0$$

Negative real numerical factors in the argument are rewritten via symmetry relations:

```
sinh(-5), cosh(-3/2*x), tanh(-x*PI/12), coth(-12/17*x*y*PI)
```

$$-\sinh(5),\ \cosh\left(\frac{3x}{2}\right),\ -\tanh\left(\frac{\pi x}{12}\right),\ -\coth\left(\frac{12\pi xy}{17}\right)$$

Example 3

The `expand` function implements the addition theorems:

```
expand(sinh(x + PI*I)), expand(cosh(x + y))
```

$$-\sinh(x),\ \cosh(x)\cosh(y)+\sinh(x)\sinh(y)$$

The `combine` function uses these theorems in the other direction, trying to rewrite products of hyperbolic functions:

```
combine(sinh(x)*sinh(y), sinhcosh)
```

$$\frac{\cosh(x+y)}{2}-\frac{\cosh(x-y)}{2}$$

Example 4

Various relations exist between the hyperbolic functions:

```
csch(x), sech(x)
```

$$\frac{1}{\sinh(x)},\ \frac{1}{\cosh(x)}$$

Use `rewrite` to obtain a representation in terms of a specific target function:

```
rewrite(tanh(x)*exp(2*x), sinhcosh), rewrite(sinh(x), tanh)
```

$$\frac{\sinh(x)\,(\cosh(2\,x)+\sinh(2\,x))}{\cosh(x)},\ -\frac{2\tanh\left(\frac{x}{2}\right)}{\tanh\left(\frac{x}{2}\right)^2-1}$$

```
rewrite(sinh(x)*coth(y), exp), rewrite(exp(x), coth)
```

$$-\frac{\left(\frac{e^{-x}}{2}-\frac{e^{x}}{2}\right)\left(e^{2\,y}+1\right)}{e^{2\,y}-1},\ \frac{\coth\left(\frac{x}{2}\right)+1}{\coth\left(\frac{x}{2}\right)-1}$$

Example 5

The inverse functions are implemented by `arcsinh`, `arccosh` etc.:

```
sinh(arcsinh(x)), sinh(arccosh(x)), cosh(arctanh(x))
```

$$x,\ \sqrt{x^2-1},\ \frac{1}{\sqrt{1-x}\,\sqrt{x+1}}$$

Note that `arcsinh(sinh(x))` does not necessarily yield `x`, because `arcsinh` produces values with imaginary parts in the interval $\left[-\frac{\pi}{2},\ \frac{\pi}{2}\right]$:

```
arcsinh(sinh(3)), arcsinh(sinh(1.6 + 100*I))
```

$$3,\ 1.6-0.5309649149\,i$$

Example 6

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the hyperbolic functions:

```
diff(sinh(x^2), x), float(sinh(3)*coth(5 + I))
```

$$2\,x\,\cosh(x^2),\ 10.01749636 - 0.0008270853591\,i$$

```
limit(x*sinh(x)/tanh(x^2), x = 0)
```

$$1$$

```
series((tanh(sinh(x)) - sinh(tanh(x)))/sinh(x^7), x = 0)
```

$$-\frac{1}{30} + \frac{29\,x^2}{756} - \frac{1913\,x^4}{75600} + O(x^6)$$

```
series(tanh(x), x = infinity)
```

$$1 - 2\,e^{-2x} + 2\,e^{-4x} - 2\,e^{-6x} + 2\,e^{-8x} - 2\,e^{-10x} + O\left(e^{-12x}\right)$$

Parameters

x

sech

Hyperbolic secant function

Syntax

```
sech(x)
```

Description

`sech(x)` represents the hyperbolic secant function `1/cosh(x)`.

This function is defined for complex arguments.

Floating point values are returned for floating-point arguments. Floating point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

Arguments that are integer multiples of $\frac{i\pi}{2}$ lead to simplified results. If the argument involves a negative numerical factor of `Type::Real`, then symmetry relations are used to make this factor positive. Cf. “Example 2” on page 1-1936.

The functions `expand` and `combine` implement the addition theorems for the hyperbolic functions. Cf. “Example 3” on page 1-1937.

`sech(x)` is rewritten as `1/cosh(x)`. Cf. “Example 4” on page 1-1937.

The inverse function is implemented by `arcsech`. Cf. “Example 5” on page 1-1938.

The float attributes are kernel functions, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
sinh(I*PI), cosh(1), tanh(5 + I), csch(PI), sech(1/11), coth(8)
```

$$0,\ \cosh(1),\ \tanh(5+i),\ \frac{1}{\sinh(\pi)},\ \frac{1}{\cosh\left(\frac{1}{11}\right)},\ \coth(8)$$

```
sinh(x), cosh(x + I*PI), tanh(x^2 - 4)
```

$$\sinh(x),\ -\cosh(x),\ \tanh(x^2-4)$$

Floating point values are computed for floating-point arguments:

```
sinh(123.4), cosh(5.6 + 7.8*I), coth(1.0/10^20)
```

$$1.953930316\ 10^{53},\ 7.295585032 + 135.0143985\ i,\ 1.0\ 10^{20}$$

coth

Hyperbolic cotangent function

Syntax

```
coth(x)
```

Description

`coth(x)` represents the hyperbolic cotangent function `cosh(x)/sinh(x)`.

This function is defined for complex arguments.

Floating point values are returned for floating-point arguments. Floating point intervals are returned for floating-point interval arguments. Unevaluated function calls are returned for most exact arguments.

Arguments that are integer multiples of $\frac{i\pi}{2}$ lead to simplified results. If the argument involves a negative numerical factor of `Type::Real`, then symmetry relations are used to make this factor positive. Cf. “Example 2” on page 1-1941.

The special values $coth(\infty) = 1$, $coth(-\infty) = -1$ are implemented.

The functions `expand` and `combine` implement the addition theorems for the hyperbolic functions. Cf. “Example 3” on page 1-1942.

Use `expand` or `rewrite` to rewrite expressions involving `tanh` and `coth` in terms of `sinh` and `cosh`. Cf. “Example 4” on page 1-1942.

The inverse function is implemented by `arccoth`. Cf. “Example 5” on page 1-1943.

The float attributes are kernel functions, i.e., floating-point evaluation is fast.

Environment Interactions

When called with a floating-point argument, the functions are sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
sinh(I*PI), cosh(1), tanh(5 + I), csch(PI), sech(1/11), coth(8)
```

$$0,\ \cosh(1),\ \tanh(5+i),\ \frac{1}{\sinh(\pi)},\ \frac{1}{\cosh\left(\frac{1}{11}\right)},\ \coth(8)$$

```
sinh(x), cosh(x + I*PI), tanh(x^2 - 4)
```

$$\sinh(x),\ -\cosh(x),\ \tanh(x^2-4)$$

Floating point values are computed for floating-point arguments:

```
sinh(123.4), cosh(5.6 + 7.8*I), coth(1.0/10^20)
```

$$1.953930316\ 10^{53},\ 7.295585032 + 135.0143985\ i,\ 1.0\ 10^{20}$$

For floating-point intervals, intervals enclosing the image are calculated:

```
cosh(-1 ... 1), tanh(-1 ... 1)
```

$$1.0 \ldots 1.543080635,\ -0.761594156 \ldots 0.761594156$$

For functions with discontinuities, evaluation over an interval may result in a union of intervals:

```
coth(-1 ... 1)
```

$$\text{RD\_NINF} \ldots -1.313035285 \cup 1.313035285 \ldots \text{RD\_INF}$$

Example 2

Simplifications are implemented for arguments that are integer multiples of $\frac{i\pi}{2}$:

```
sinh(I*PI/2), cosh(40*I*PI), tanh(-10^100*I*PI),
coth(-17/2*I*PI)
```

$$i, 1, 0, 0$$

Negative real numerical factors in the argument are rewritten via symmetry relations:

```
sinh(-5), cosh(-3/2*x), tanh(-x*PI/12), coth(-12/17*x*y*PI)
```

$$-\sinh(5),\ \cosh\left(\frac{3x}{2}\right),\ -\tanh\left(\frac{\pi x}{12}\right),\ -\coth\left(\frac{12\,\pi\,x\,y}{17}\right)$$

Example 3

The `expand` function implements the addition theorems:

```
expand(sinh(x + PI*I)), expand(cosh(x + y))
```

$$-\sinh(x),\ \cosh(x)\cosh(y)+\sinh(x)\sinh(y)$$

The `combine` function uses these theorems in the other direction, trying to rewrite products of hyperbolic functions:

```
combine(sinh(x)*sinh(y), sinhcosh)
```

$$\frac{\cosh(x+y)}{2}-\frac{\cosh(x-y)}{2}$$

Example 4

Various relations exist between the hyperbolic functions:

```
csch(x), sech(x)
```

$$\frac{1}{\sinh(x)},\ \frac{1}{\cosh(x)}$$

Use `rewrite` to obtain a representation in terms of a specific target function:

```
rewrite(tanh(x)*exp(2*x), sinhcosh), rewrite(sinh(x), tanh)
```

$$\frac{\sinh(x)\,(\cosh(2\,x)+\sinh(2\,x))}{\cosh(x)},\ -\frac{2\tanh\left(\frac{x}{2}\right)}{\tanh\left(\frac{x}{2}\right)^2-1}$$

```
rewrite(sinh(x)*coth(y), exp), rewrite(exp(x), coth)
```

$$-\frac{\left(\frac{e^{-x}}{2}-\frac{e^{x}}{2}\right)\left(e^{2\,y}+1\right)}{e^{2\,y}-1},\ \frac{\coth\left(\frac{x}{2}\right)+1}{\coth\left(\frac{x}{2}\right)-1}$$

Example 5

The inverse functions are implemented by `arcsinh`, `arccosh` etc.:

```
sinh(arcsinh(x)), sinh(arccosh(x)), cosh(arctanh(x))
```

$$x,\ \sqrt{x^2-1},\ \frac{1}{\sqrt{1-x}\,\sqrt{x+1}}$$

Note that `arcsinh(sinh(x))` does not necessarily yield `x`, because `arcsinh` produces values with imaginary parts in the interval $\left[-\frac{\pi}{2},\frac{\pi}{2}\right]$:

```
arcsinh(sinh(3)), arcsinh(sinh(1.6 + 100*I))
```

$$3,\ 1.6-0.5309649149\,i$$

Example 6

Various system functions such as `diff`, `float`, `limit`, or `series` handle expressions involving the hyperbolic functions:

```
diff(sinh(x^2), x), float(sinh(3)*coth(5 + I))
```

$$2\,x\,\cosh(x^2),\ 10.01749636 - 0.0008270853591\,i$$

```
limit(x*sinh(x)/tanh(x^2), x = 0)
```

$$1$$

```
series((tanh(sinh(x)) - sinh(tanh(x)))/sinh(x^7), x = 0)
```

$$-\frac{1}{30} + \frac{29\,x^2}{756} - \frac{1913\,x^4}{75600} + O(x^6)$$

```
series(tanh(x), x = infinity)
```

$$1 - 2\,e^{-2x} + 2\,e^{-4x} - 2\,e^{-6x} + 2\,e^{-8x} - 2\,e^{-10x} + O\left(e^{-12x}\right)$$

Parameters

x

An arithmetical expression or a floating-point interval

Return Values

Arithmetical expression or a floating-point interval

Overloaded By

x

MuPAD Functions

`arccosh` | `arccoth` | `arccsch` | `arcsech` | `arcsinh` | `arctanh` | `cosh` | `csch` | `sech` | `sinh` | `tanh`

slot

Method or entry of a domain or a function environment

Syntax

```
d::n
```

```
slot(d, "n")
```

```
d::n := v
```

```
slot(d, "n", v)
```

```
object::dom
```

```
slot(object, "dom")
```

Description

`d::n` returns the value of the slot named `"n"` of the object `d`.

`d::n := v` creates or changes the slot `"n"`. The value `v` is assigned to the slot.

The function `slot` is used for defining methods and entries of data types (domains) or for defining attributes of function environments. Such methods, entries, or attributes are called *slots*. They allow to overload system functions by user defined domains and function environments. See the “Background” section below for further information.

Any MuPAD object has a special slot named `"dom"`. It holds the domain the object belongs to: `slot(object, "dom")` is equivalent to `domtype(object)`. The value of this special slot cannot be changed. Cf. “Example 1” on page 1-1946.

Apart from the special slot `"dom"`, only domains and function environments may have further slots.

The call `slot(d, "n")` is equivalent to `d::n`. It returns the value of the slot.

The call `slot(d, "n", v)` returns the object `d` with an added or changed slot `"n"` bearing the value `v`.

For a *function environment*`d`, the call `slot(d, "n", v)` returns `d` with the changed slot `"n"` and changes the function environment `d` as a side-effect. This is the so-called "reference effect" of function environments. Cf. "Example 2" on page 1-1947.

For a *domain*`d`, however, the call `slot(d, "n", v)` modifies `d` as a side-effect and returns the domain. This is the so-called "reference effect" of domains. Cf. "Example 3" on page 1-1947.

If a non-existing slot is accessed, `FAIL` is returned as the value of the slot. Cf. "Example 4" on page 1-1948.

The `::`-operator is a shorthand notation to access a slot.

The expression `d::n`, when not appearing on the left hand side of an assignment, is equivalent to `slot(d, "n")`.

The command `d::n := v` assigns the value `v` to the slot `"n"` of `d`. This assignment is almost equivalent to changing or creating a slot via `slot(d, "n", v)`. Note the following subtle semantical difference between these assignments: in `d::n := v`, the identifier `d` is evaluated with level 1, i.e., the slot `"n"` is attached to the *value* of `d`. In `slot(d, "n", v)`, the identifier `d` is *fully evaluated*. See "Example 6" on page 1-1949.

With `delete d::n` or `delete slot(d,"n")`, the slot `"n"` of the function environment or the domain `d` is deleted. Cf. "Example 5" on page 1-1948. The special slot `"dom"` cannot be deleted.

The first argument of `slot` is not flattened. This allows to access the slots of expression sequences and `null()` objects. Cf. "Example 7" on page 1-1949.

For domains, there is a special mechanism to create new values for slots on demand. If a non existing slot is read, the method `"make_slot"` of the domain is called in order to create the slot. If such a method does not exist, `FAIL` is returned. Cf. "Example 8" on page 1-1950.

Examples

Example 1

Every object has the slot `"dom"`:

```
x::dom = domtype(x),
slot(45, "dom") = domtype(45),
sin::dom = domtype(sin)
```

$$\text{DOM\_IDENT} = \text{DOM\_IDENT},\ \text{DOM\_INT} = \text{DOM\_INT},\ \text{DOM\_FUNC\_ENV} = \text{DOM\_FUNC\_ENV}$$

Example 2

Here we access the existing `"float"` slot of the function environment `sin` implementing the sine function. The float slot is again a function environment and may be called like any MuPAD function. Note, however, the different functionality: in contrast to `sin`, the float slot always tries to compute a floating-point approximation:

```
s := sin::float:  s(1), sin(1)
```

$$0.8414709848,\ \sin(1)$$

With the following commands, `s` becomes the function environment `sin` apart from a changed `"float"` slot. The `slot` call has no effect on the original `sin` function because `slot` returns a copy of the function environment:

```
s := funcenv(sin):
s::float := x -> float(x - x^3/3!):
s(PI/3) = sin(PI/3), s::float(1) <> sin::float(1)
```

$$\frac{\sqrt{3}}{2} = \frac{\sqrt{3}}{2},\ 0.8333333333 \neq 0.8414709848$$

```
delete s:
```

Example 3

If you are using the `slot` function to change slot entries in a domain, you must be aware that you are modifying the domain:

```
old_one := Dom::Float::one
```

$$1.0$$

```
newDomFloat := slot(Dom::Float, "one", 1):
newDomFloat::one, Dom::Float::one
```

```
1, 1
```

We restore the original state:

```
slot(Dom::Float, "one", old_one):  Dom::Float::one
```

```
1.0
```

```
delete old_one, newDomFloat:
```

Example 4

The function environment `sin` does not contain a `"sign"` slot. So accessing this slot yields `FAIL`:

```
slot(sin, "sign"), sin::sign
```

```
FAIL, FAIL
```

Example 5

We define a function environment for a function computing the logarithm to the base `3`:

```
log3 := funcenv(x -> log(3, x)):
```

If the function `info` is to give some information about `log3`, we have to define the `"info"` slot for this function:

```
log3::info := "log3 -- the logarithm to the base 3":

info(log3)
```

```
log3 -- the logarithm to the base 3
```

The `delete` statement is used for deleting a slot:

```
delete log3::info: info(log3)
```

```
log3(x) -- a library procedure [try ?log3 for help]
```

It is not possible to delete the special slot `"dom"`:

```
delete log3::dom
```

```
Error: The argument is invalid. [delete]
```

```
delete log3:
```

Example 6

Here we demonstrate the subtle difference between the `slot` function and the use of the `::`-operator in assignments. The following call adds a `"xyz"` slot to the domain `DOM_INT` of integer numbers:

```
delete b: d := b: b := DOM_INT: slot(d, "xyz", 42):
```

The slot `"xyz"` of `DOM_INT` is changed, because `d` is fully evaluated with the result `DOM_INT`. Hence, the slot `DOM_INT::xyz` is set to 42:

```
slot(d, "xyz"), slot(DOM_INT, "xyz")
```

```
42, 42
```

Here is the result when using the `::`-operator: `d` is only evaluated with level 1, i.e., it is evaluated to the identifier `b`. However, there is no slot `b::xyz`, and an error occurs:

```
delete b: d := b: b := DOM_INT: d::xyz := 42
```

```
Error: Slot 'd::xyz' is unknown. [slot]
```

```
delete b, d:
```

Example 7

The first argument of `slot` is not flattened. This allows access to the slots of expression sequences and `null()` objects:

```
slot((a, b), "dom") = (a,b)::dom,
slot(null(), "dom") = (null())::dom
```

```
DOM_EXPR = DOM_EXPR, DOM_NULL = DOM_NULL
```

Example 8

We give an example for the use of the function `make_slot`. The element `undefined` of the domain `stdlib::Undefined` represents an undefined value. Any function `f` should yield `f(undefined) = undefined`. Inside the implementation of `stdlib::Undefined`, we find:

```
undef := newDomain("stdlib::Undefined"):
undefined := new(undef):
undef::func_call := proc() begin undefined end_proc;
undef::make_slot := undef::func_call:
```

The following mechanism takes place automatically for a function `f` that is overloadable by its first argument: in the call `f(undefined)`, it is checked whether the slot `undef::f` exists. If this is not the case, the `make_slot` function creates this slot "on the fly", producing the value `undefined`. Thus, via overloading, `f(undefined)` returns the value `undefined`.

Example 9

The following example is rather advanced and technical. It demonstrates overloading of the `slot` function to implement slot access and slot assignments for other objects than domains (`DOM_DOMAIN`) or function environments (`DOM_FUNC_ENV`). The following example defines the slots `"numer"` and `"denom"` for rational numbers. The domain `DOM_RAT` of such numbers does not have slots `"numer"` and `"denom"`:

```
domtype(3/4)
```

```
DOM_RAT
```

```
slot(3/4, "numer")
```

```
Error: Slot '(3/4)::numer' is unknown. [slot]
```

We can change `DOM_RAT`, however. For this, we have to unprotect`DOM_RAT` temporarily:

```
unprotect(DOM_RAT):
```

```
DOM_RAT::slot :=
  proc(r : DOM_RAT, n : DOM_STRING, v=null(): DOM_INT)
      local i : DOM_INT;
  begin
      i := contains(["numer", "denom"], n);
      if i = 0 then
         error("Unknown slot \"".expr2text(r)."::".n."\"")
      end;
      if args(0) = 3 then
         subsop(r, i = v)
      else
         op(r, i)
      end
  end_proc:
```

Now, we can access the operands of rational numbers, which are the numerator and the denominator respectively, via our new slots:

```
slot(3/4, "numer"), (3/4)::numer,
slot(3/4, "denom"), (3/4)::denom
```

$$3, 3, 4, 4$$

```
a := 3/4:  slot(a, "numer", 7)
```

$$\frac{7}{4}$$

```
a::numer := 11:  a
```

$$\frac{11}{4}$$

We restore the original behavior:

```
delete DOM_RAT::slot, a: protect(DOM_RAT, Error):
```

Parameters

d

A domain or a function environment

n

The name of the slot: an identifier

v

The new value of the slot: an arbitrary MuPAD object

object

An arbitrary MuPAD object

Return Values

`slot(d, "n")` returns the value of the slot; `slot(d, "n", v)` returns the object `d` with the added or changed slot; `slot(object, "dom")` returns the domain type of the object.

Overloaded By

d

Algorithms

Overloading of system functions by domain elements is typically implemented as follows. If a library function `f`, say, is to be overloadable by user defined data types, a code segment as indicated by the following lines is appropriate. It tests whether the domain `x::dom` of the argument `x` contains a method `f`. If this is the case, this domain method is called:

```
f:= proc(x)
    begin
      // check if f is overloaded by x
      if x::dom::f <> FAIL then
           // use the method of the domain of x
           return(x::dom::f(args()))
      else
```

```
        // execute the code for the function f
    endif
  end_proc:
```

By overloading the function `slot`, slot access and slot assignment can be implemented for other objects than domains or function environments. Cf. “Example 9” on page 1-1950.

In principle, the name `n` of a slot may be an arbitrary MuPAD object. Note, however, that the `::`-operator cannot access slots defined by `slot(d, n, v)` if the the name `n` is not a string.

Strings may be used in conjunction with the `::`-operator: the calls `d::"n"` and `d::n` are equivalent.

MuPAD Domains

`DOM_DOMAIN` | `DOM_FUNC_ENV`

MuPAD Functions

`funcenv` | `newDomain` | `slotAssignCounter`

slotAssignCounter

Counts slot assignments

Syntax

```
slotAssignCounter(key)
```

Description

`slotAssignCounter(key)` returns the number of `slot` assignments with the key `key` since the initialization of the counter. The counter for `key` is initialized with `0` on the first call of `slotAssignCounter(key)`. Previous assignments with the key `key` are not counted.. This function serves a highly technical purpose. Usually, there should be no need for a user to call this function.

`slotAssignCounter` only counts assignments to slots of domains and function environments.

`slotAssignCounter` was introduced as a dependency check function for `prog::remember`. See “Example 2” on page 1-1955.

Examples

Example 1

We initialize slot assignment counting of the slot `"foo"`:

```
slotAssignCounter("foo")
```

```
     0
```

Then we define a function `f` with a slot `"foo"`:

```
f := funcenv(f):
f::foo := bar:
```

Now the counter has the value 1:

```
slotAssignCounter("foo")
```

```
     1
```

Example 2

Here we define a recursing function `foo` which overloads for domain elements. The function remembers computed values with `prog::remember`:

```
foo := x -> (if x::dom::foo <> FAIL then return(x::dom::foo(x)) end_if;
             if x = op(x) then procname(x) else map(x, foo) end_if):
foo := prog::remember(foo):
```

Then we define a domain `bar` which does not overload the slot `"foo"`:

```
bar := newDomain("bar"):
bar::new := x -> new(bar, x):
bar::print := x -> hold(bar)(extop(x)):
bar::op := id:
foo(bar(2))
```

```
     foo(bar(2))
```

Now we add a `"foo"` slot to `bar`:

```
bar::foo := x -> 4:
foo(bar(2))
```

```
     foo(bar(2))
```

The new slot was not used, because `foo` took the result from its remember table. If we use a dependency function with `slotAssignCounter` in `prog::remember`, we can make `foo` aware of changes in `"foo"`-slots of other functions and domains:

```
foo := x -> (if x::dom::foo <> FAIL then return(x::dom::foo(x)) end_if;
             if x = op(x) then x else map(x, foo) end_if):
foo := prog::remember(foo, () -> slotAssignCounter("foo")):
foo(bar(2));
bar::foo := x -> 5:
```

```
foo(bar(2))
```

```
    4
```

```
    5
```

```
delete foo, bar:
```

Parameters

`key`

Any MuPAD object

Return Values

Non-negative number of type `DOM_INT`.

MuPAD Functions

`prog::remember` | `slot`

solve

Solve equations and inequalities

Syntax

```
solve(eq, x, options)

solve(eq, x = a .. b, options)

solve(eq, vars, options)

solve(eq, options)

solve(eqs, x, options)

solve(eqs, vars, options)

solve(eqs, options)

solve(ODE)

solve(REC)
```

Description

`solve(eq, x)` returns the set of all complex solutions of an equation or inequality `eq` with respect to `x`.

`solve(eq, x = a..b)` returns the set of all solutions in the closed interval `Dom::Interval([a, b])`.

`solve(eq, vars)` solves an equation for the variables `vars`.

`solve(eqs, x)` solves a system `eqs` for the variable `x`.

`solve(eqs, vars)` solves a system `eqs` of equations for the variables `vars`.

The `solve` function provides a unified interface to a variety of specialized solvers. See Choosing a Solver.

If you do not specify indeterminates for which you want to solve an equation, inequality or system, the solver uses a set of all indeterminates. Indeterminates must be identifiers or indexed identifiers. You cannot use mathematical constants, such as PI, EULER, and so on, as indeterminates. The solver discards indeterminates that appear only inside function names or indices. See “Example 12” on page 1-1966.

If you specify a list of indeterminates for which you want to solve an equation, an inequality, or a system, the solver sorts the components of the resulting solution vectors according to the order of the indeterminates that you used. If you specify indeterminates as a set, MuPAD can change the order of the indeterminates.

`solve(eq, vars)` is equivalent to `solve([eq], vars)`.

The solver can return the following types of sets:

- Finite sets (type `DOM_SET`).
- Symbolic calls to `solve`.
- Zero sets of polynomials (type `RootOf`). The solver returns a set of this type if it cannot solve an equation explicitly in terms of radicals. The solver also can return this type of set when you use the `MaxDegree` option.
- Set-theoretic expressions, such as `"_union"`, `"_intersect"`, and `"_minus"`.
- Symbolic calls to `solvelib::Union`. These calls represent unions over parametrized systems of sets.
- The $\mathbb{C}$, $\mathbb{R}$, $\mathbb{Q}$, and $\mathbb{Z}$ (type `solvelib::BasicSet`) sets.
- Intervals (type `Dom::Interval`).
- Image sets of functions (type `Dom::ImageSet`).
- Piecewise objects in which every branch defines a set of one of the valid types (type `piecewise`).

MuPAD can use sets of these types, excluding intervals and basic sets, to represent sets of vectors (for solutions of systems). When solving a system, MuPAD also can return a solution in the form S^n (the n-fold cartesian power of the set S of scalars). Here S is a set of any type returned by `solve`.

For returned solution sets, you can use the set-theoretic operations, such as `intersect`, `union`, and `minus`. Also, you can use pointwise-defined arithmetical operations, such as `+`, `*`, and so on. To extract elements of a set, use the `solvelib::getElement` function. To test whether the solution set returned by `solve` is finite, use the function `solvelib::isFinite`. See “Example 2” on page 1-1960

For systems, the solver returns a set of vectors or a set of lists of equations. To specify that the solver must return a set of vectors, use the `VectorFormat` option. See “Example 10” on page 1-1964.

By default, `solve(eq, x)` returns only the solutions consistent with the properties of `x`. To ignore the properties of `x`, use the `IgnoreProperties` option. This option is helpful when you solve a system of equations for more than one variable. See “Example 13” on page 1-1966.

An inequality `a <= b` or `a < b` holds only when both sides represent real numbers. In particular, `a = b` does not imply that `a <= b` for complex numbers.

You can write custom domains for equations of special types, and then overload `solve` for these domains. MuPAD uses this feature for differential and recurrence equations. See the `ode`, `ode::solve`, and `rec` help pages.

The `solve` function is a symbolic solver. If you want to use numeric methods, see the `numeric::solve` help page for available options and examples.

If the input contains floating-point numbers, the solver replaces them by approximate rational values. The accuracy of these approximate values depends on the environment variable `DIGITS`. If `solve` finds a solution, MuPAD internally calls the `float` function for that solution, and then returns the result. If the symbolic solver returns `unevaluated`, MuPAD calls `numeric::solve`. See “Example 16” on page 1-1967.

If a numerator contains a factored polynomial with the multiplicities greater than 1, the solver does not check the multiple roots for zeros in the denominator. See “Example 17” on page 1-1968.

Environment Interactions

`solve` reacts to properties of identifiers.

Examples

Example 1

Solve the following equation. Typically, for equations with a finite number of solutions, the solver returns a set of the `DOM_SET` type:

```
solve(x^4 - 5*x^2 + 6*x = 2, x)
```

$$\{1, -\sqrt{3} - 1, \sqrt{3} - 1\}$$

Example 2

The solver can also return an infinite discrete set of solutions:

```
S := solve(sin(x*PI/7) = 0, x)
```

$$\{7\,k \mid k \in \mathbb{Z}\}$$

To select the solutions in a particular finite interval, find the intersection of the solution set with the interval:

```
S intersect Dom::Interval(-22, 22)
```

$$\{-21, -14, -7, 0, 7, 14, 21\}$$

Alternatively, specify the interval when calling the solver. For example, compute the solutions in the interval [- 22, 22]:

```
solve(sin(x*PI/7) = 0, x = -22..22)
```

$$\{-21, -14, -7, 0, 7, 14, 21\}$$

```
delete S:
```

Example 3

Use the `solve` function to solve inequalities. Typically, the solution set of an inequality is an interval or a union of intervals:

```
solve(x^2 > 5, x)
```

$$(-\infty, -\sqrt{5}) \cup (\sqrt{5}, \infty)$$

Example 4

Solve the following inequality. The solution includes the set of all complex numbers, excluding $\sqrt{7}$ and $-\sqrt{7}$:

```
solve(x^2 <> 7, x)
```

$$\mathbb{C} \setminus \{\sqrt{7}, -\sqrt{7}\}$$

Example 5

The solver can return a solution as a union of an infinite family of sets. The `solvelib::Union` function represents such infinite unions in MuPAD:

```
solve(sin(x)*cos(x) > 1/4, x, Real)
```

$$\bigcup_{k \in \mathbb{Z}} \left(\frac{\pi}{12} + \pi\, k, \frac{5\,\pi}{12} + \pi\, k \right)$$

Example 6

If an equation contains symbolic parameters, the solver returns a piecewise solution. For example, solve the quadratic equation $ax^2 + bx + c = 0$:

```
S := solve(a*x^2 + b*x + c, x)
```

$$\begin{cases} \left\{ -\frac{b+\sigma_1}{2\,a}, -\frac{b-\sigma_1}{2\,a} \right\} & \text{if } a \neq 0 \\ \left\{ -\frac{c}{b} \right\} & \text{if } a = 0 \wedge b \neq 0 \\ \mathbb{C} & \text{if } a = 0 \wedge b = 0 \wedge c = 0 \\ \varnothing & \text{if } a = 0 \wedge b = 0 \wedge c \neq 0 \end{cases}$$

where

$$\sigma_1 = \sqrt{b^2 - 4\,a\,c}$$

Now, evaluate the solution assuming that a is not equal to 0:

```
assume(a <> 0): S
```

$$\left\{-\frac{b+\sqrt{b^2-4\,a\,c}}{2\,a}, -\frac{b-\sqrt{b^2-4\,a\,c}}{2\,a}\right\}$$

```
delete S: unassume(a):
```

Example 7

By default, the solver tries to find all possible solutions. The following inequality has both real and complex solutions. For example, $x = \sqrt{\frac{3}{4}} + \frac{i}{2}$ is one of the solutions. The solver cannot find a closed-form representation of all possible solutions:

```
solve(x + 1/x > 0, x)
```

$$\text{solve}\left(0 < x + \frac{1}{x}, x\right)$$

With the `Real` option, the solver computes only real solutions. The closed-form representation of all real solutions of that equation is an interval of all real numbers from 0 to infinity:

```
solve(x + 1/x > 0, x, Real)
```

$$(0, \infty)$$

Example 8

Solve this equation. By default, the solver returns a complete, but rather long and complicated solution:

```
solve(x^(7/2) + 1/x^(7/2) = 1, x)
```

$$\left\{\frac{1}{\sigma_1}, \frac{1}{\sigma_2}, \frac{e^{\frac{4\pi i}{7}}}{\sigma_1}, \frac{e^{\frac{4\pi i}{7}}}{\sigma_2}, -\frac{e^{\frac{3\pi i}{7}}}{\sigma_1}, -\frac{e^{\frac{3\pi i}{7}}}{\sigma_2}\right\}$$

where

$$\sigma_1 = \left(\frac{1}{2} - \frac{\sqrt{3}\,i}{2}\right)^{2/7}$$

$$\sigma_2 = \left(\frac{1}{2} + \frac{\sqrt{3}\,i}{2}\right)^{2/7}$$

Using `IgnoreAnalyticConstraints`, you often can get simpler results:

```
solve(x^(7/2) + 1/x^(7/2) = 1, x, IgnoreAnalyticConstraints)
```

$$\left\{\frac{1}{\left(\frac{1}{2} - \frac{\sqrt{3}\,i}{2}\right)^{2/7}}, \frac{1}{\left(\frac{1}{2} + \frac{\sqrt{3}\,i}{2}\right)^{2/7}}\right\}$$

Using this option, you also can get wrong results:

```
solve(arcsin(x) = C, x, IgnoreAnalyticConstraints) assuming C > 10
```

$$\{\sin(C)\}$$

Always check the results obtained with this option:

```
testeq(arcsin(sin(C)), C)
```

FALSE

The `IgnoreAnalyticConstraints` option also can lead to incomplete results:

```
solve(x^(5/2) = 1, x)
```

$$\left\{1, -\frac{\sqrt{5}}{4} - \frac{1}{4} - \frac{\sqrt{2}\sqrt{5-\sqrt{5}}\,i}{4}, -\frac{\sqrt{5}}{4} - \frac{1}{4} + \frac{\sqrt{2}\sqrt{5-\sqrt{5}}\,i}{4}\right\}$$

```
solve(x^(5/2) = 1, x, IgnoreAnalyticConstraints)
```

$$\{1\}$$

Example 9

With the `IgnoreAnalyticConstraints` option, the solver can multiply both sides of an equation by any expression, except `0`. In the following example, the solver multiplies both sides of the equation by $\sqrt{x}\,\sqrt{y}$. The solver does not consider the special case `x = y = 0`:

```
solve(1/sqrt(x) = 1/sqrt(y), IgnoreAnalyticConstraints)
```

$$\{[x = z,\ y = z]\}$$

The result is not valid for `x = y = 0`.

Example 10

When you solve a system of equations, MuPAD tries to represent the solutions as a set of lists of substitutions:

```
solve([x^2 + y = 1, x + y^2 = 1], [x, y])
```

$$\left\{[x = 0,\ y = 1],\ [x = 1,\ y = 0],\ \left[x = -\frac{\sqrt{5}}{2} - \frac{1}{2},\ y = -\frac{\sqrt{5}}{2} - \frac{1}{2}\right],\ \left[x = \frac{\sqrt{5}}{2} - \frac{1}{2},\ y = \frac{\sqrt{5}}{2} - \frac{1}{2}\right]\right\}$$

If you use the `VectorFormat` option, MuPAD returns a solution as a set of vectors:

```
solve([x^2 + y = 1, x + y^2 = 1], [x, y], VectorFormat)
```

$$\left\{\begin{pmatrix}1\\0\end{pmatrix},\ \begin{pmatrix}0\\1\end{pmatrix},\ \begin{pmatrix}-\frac{\sqrt{5}}{2} - \frac{1}{2}\\ -\frac{\sqrt{5}}{2} - \frac{1}{2}\end{pmatrix},\ \begin{pmatrix}\frac{\sqrt{5}}{2} - \frac{1}{2}\\ \frac{\sqrt{5}}{2} - \frac{1}{2}\end{pmatrix}\right\}$$

Right sides of the returned substitutions can contain generated identifiers. In this case, substituting each of these identifiers with a complex number gives a solution of

the system. You can obtain all solutions by substituting generated identifiers with all complex numbers:

```
sys:= [x + y + z = 2, x + y^2 + z^2 = 4]:
solve(sys, [x, y, z])
```

$$\left\{\left[x = \frac{3}{2} - \sigma_1 - z1,\ y = \sigma_1 + \frac{1}{2},\ z = z1\right],\ \left[x = \sigma_1 - z1 + \frac{3}{2},\ y = \frac{1}{2} - \sigma_1,\ z = z1\right]\right\}$$

where

$$\sigma_1 = \frac{\sqrt{-4\,z1^2 + 4\,z1 + 9}}{2}$$

If you use the `VectorFormat` option, the solver returns a solution as an infinite set of vectors, in the usual mathematical notation:

```
solve(sys, [x, y, z], VectorFormat); delete sys:
```

$$\left\{\begin{pmatrix} -z1 + \sigma_1 + \frac{3}{2} \\ -\sigma_1 + \frac{1}{2} \\ z1 \end{pmatrix} \middle|\ z1 \in \mathbb{C}\right\} \cup \left\{\begin{pmatrix} -z1 - \sigma_1 + \frac{3}{2} \\ \sigma_1 + \frac{1}{2} \\ z1 \end{pmatrix} \middle|\ z1 \in \mathbb{C}\right\}$$

where

$$\sigma_1 = \frac{\sqrt{-4\,z1^2 + 4\,z1 + 9}}{2}$$

Example 11

You can specify the variable, for which you want to solve an equation, as a list of one entry. In this case, the solver returns the solution using the output format typically used for systems:

```
solve(x = x, x), solve(x = x, [x])
```

$$\mathbb{C},\ \{[x = z]\}$$

Example 12

If you do not specify indeterminates (the variables for which you want to solve an equation), the solver uses the set of all indeterminates that it can find in that equation:

```
solve(x^2 = 3)
```

$$\{[x = \sqrt{3}], [x = -\sqrt{3}]\}$$

The solver does not regard operators and indices as indeterminates. Therefore, the solver does not treat `f` and `y` as indeterminates in the following equation:

```
solve(f(x[y]) = 7)
```

$$\text{solve}\left(\left[f\left(x_y\right) = 7\right], \left[x_y\right]\right)$$

Example 13

If you set an assumption on the variable for which you want to solve an equation, the solver returns only the results compatible with that assumption. For example, assume that `x` represents a real positive number. Then, solve the following equation:

```
assume(x, Type::Positive): solve(x^4 = 1, x)
```

$$\{1\}$$

Without that assumption, the solver returns all complex solutions:

```
unassume(x): solve(x^4 = 1, x)
```

$$\{-1, 1, -i, i\}$$

Example 14

To obtain the multiplicities of the roots of a polynomial, use the `Multiple` option. For example, the polynomial $x^3 + 2\,x^2 + x$ has two roots. The multiplicity of $x = -1$ is 2. The multiplicity of $x = 0$ is 1:

```
solve(x^3 + 2*x^2 + x, x, Multiple)
```

$$\{[-1, 2], [0, 1]\}$$

Example 15

Suppose, you want to solve the following system of equations for two variables, `x` and `y`. Suppose, you want to avoid backward substitutions while solving this system. To disable backward substitutions, use the option `BackSubstitution = FALSE`. Specify the list of variables so that `x` appears to the right of `y`. Now, the solution for the variable `y` can contain the variable `x`:

```
solve({x^2 + y = 1, x - y = 2}, [y, x], BackSubstitution = FALSE)
```

$$\left\{\left[y = x - 2, x = -\frac{\sqrt{13}}{2} - \frac{1}{2}\right], \left[y = x - 2, x = \frac{\sqrt{13}}{2} - \frac{1}{2}\right]\right\}$$

```
solve({x^2 + y = 1, x - y = 2}, {x, y})
```

$$\left\{\left[x = -\frac{\sqrt{13}}{2} - \frac{1}{2}, y = -\frac{\sqrt{13}}{2} - \frac{5}{2}\right], \left[x = \frac{\sqrt{13}}{2} - \frac{1}{2}, y = \frac{\sqrt{13}}{2} - \frac{5}{2}\right]\right\}$$

If MuPAD cannot express the result as a set of lists, then `BackSubstitution` has no effect:

```
solve({x^2 + y = 1, x - y = 2}, [y, x],
BackSubstitution = FALSE, MaxDegree = 1)
```

$$\begin{pmatrix} y \\ x \end{pmatrix} \in \left\{ \begin{pmatrix} x - 2 \\ z1 \end{pmatrix} \;\middle|\; z1 \in \mathrm{RootOf}(z^2 + z - 3, z) \right\}$$

Example 16

If the input contains floating-point numbers, MuPAD uses the symbolic solver `solve`, and then calls the `float` function for the obtained solution:

```
solve(x^3 + 3.0*x + 1, x)
```

$$\{-0.3221853546, 0.1610926773 + 1.75438096\,i, 0.1610926773 - 1.75438096\,i\}$$

If the symbolic solver fails to solve such equation or system, MuPAD calls the numeric solver `numeric::solve`:

```
solve({sin(x) + 1/2*cos(sqrt(2)*y) = 1, cos(x) + sin(y) = 0.1}, {x, y})
```

$$\{[x = 0.7780082473,\ y = -0.6589827125]\}$$

The numeric solver can return an incomplete set of solutions. For details, see the `numeric::solve` help page.

Example 17

If a numerator contains a factored polynomial with the multiplicities greater than 1, the solutions might give zeros in a denominator:

```
solve((x - 1)^2/(x - 1) = 0, x)
```

$$\{1\}$$

To eliminate these solutions, expand a numerator:

```
f := expand((x - 1)^2): solve(f/(x - 1) = 0, x)
```

$$\varnothing$$

Example 18

You can use the `solve` function to solve Diophantine equations. For example, solve the following linear Diophantine equation:

```
S := solve(30*x + 56*y = 2, [x, y], Domain = Z_)
```

$$\binom{x}{y} \in \left\{ \begin{pmatrix} -28\,k - 13 \\ 15\,k + 7 \end{pmatrix} \,\middle|\, k \in \mathbb{Z} \right\}$$

Example 19

You can use the `solve` function to solve equation given in the form of memberships. For example, solve the following equation:

```
solve(x^2 in Z_, x)
```

$$\{\sqrt{k} \mid k \in \mathbb{Z}\} \cup \{-\sqrt{k} \mid k \in \mathbb{Z}\}$$

Example 20

You can solve an equation with symbolic parameters, thus finding its general solution. Then you can evaluate the solution for any particular values of parameters or plot the solution with respect to the parameter values.

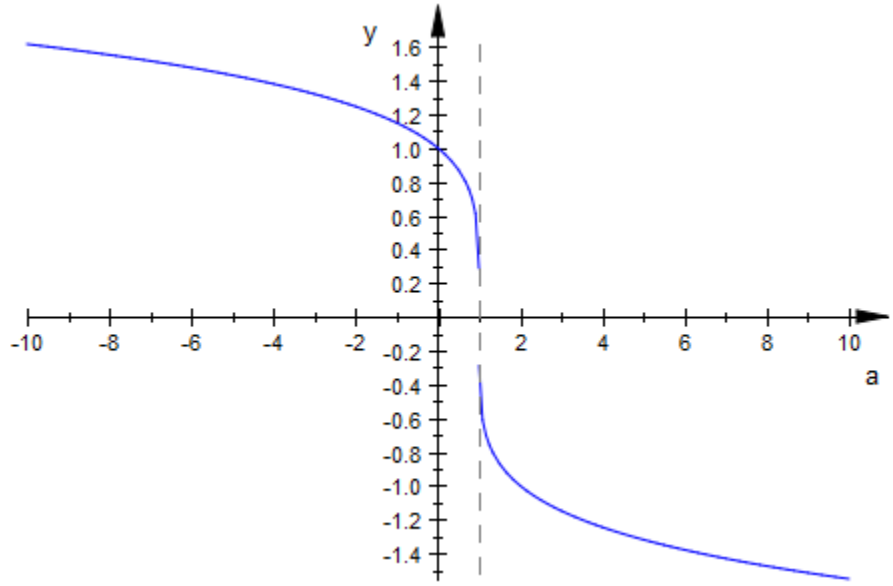
Solve this equation:

```
S := solve(x^5 + a = 1, x, Real)
```

$$\left\{-|a-1|^{1/5}\,\mathrm{sign}(a-1)\right\}$$

Plot the result for the values `-10 < a < 10`:

```
plot(S, a = -10..10)
```



Evaluate the result for `a = 5` using the operator `|` or its functional form `evalAt`:

```
S | a = 5
```

$$\left\{-4^{1/5}\right\}$$

Approximate the result with a floating-point value using `float`:

```
float(%)
```

$$\{-1.319507911\}$$

Parameters

`eq`

A single equation or an inequality of type `"_equal"`, `"_less"`, `"_leequal"`, or `"_unequal"`, or an equation in the form of membership (`_in`). Alternatively, any Boolean expression composed of equations or inequalities by the operators `"_and"`, `"_or"`, and `"_not"`. Also, the solver accepts an arithmetical expression and regards such expression as an equation without the right side. (Internally, the solver assumes that the right side is equal to 0.)

`x`

The indeterminate for which you solve an equation, an inequality of a system: an identifier or an indexed identifier

`a, b`

Arithmetical expressions

`vars`

A nonempty set or list of indeterminates for which you solve an equation, an inequality, or a system

eqs

A set, list, array, or table of equations, inequalities, arithmetical expressions, or any combination of these objects. The solver regards expressions as equations without the right side. (Internally, the solver assumes that the right side is equal to 0.)

ODE

An ordinary differential equation: an object of the `ode` type.

REC

A recurrence equation: an object of the `rec` type.

Options

MaxDegree

Option, specified as `MaxDegree = n`

Do not use explicit formulas that involve radicals when solving polynomial equations of degree larger than `n`. Here `n` is a positive integer. By default, `n = 2`.

This option enables and disables the use of explicit formulas for the roots of polynomials. This option does not affect other methods, such as factorization. For polynomial equations, the given maximal degree `n` refers to the factors of the polynomials, not to the input polynomial.

When you solve a fifth- or higher-order polynomial equation, the solver might be unable to return the solution explicitly. In general, there are no explicit expressions for the roots of polynomials of degrees higher than 4. Setting the `MaxDegree` option to 4 or a higher value makes no difference.

BackSubstitution

Option, specified as `BackSubstitution = b`

Enable or disable backward substitutions when solving algebraic systems. The value `b` must be `TRUE` or `FALSE`. By default, `b = TRUE`.

`BackSubstitution` only affects the results returned as sets of lists.

`Multiple`

With this option, `solve` returns a set of type `Dom::Multiset`, indicating the multiplicity of polynomial roots.

The solver ignores this option if the input is not a polynomial expression or equation, or if the solution is of the `RootOf` type.

`VectorFormat`

Return a set of vectors when solving a system of equations for a list of variables.

`PrincipalValue`

With this option, the solver returns only one solution. The solver returns this solution as a set with one element. If an equation does not have a solution, the solver returns an empty set.

If the solver cannot find any solution and cannot prove that solutions do not exist, it returns an unresolved symbolic call to `solve`. For example, if the set of solutions is a piecewise function, and there are no elements that belongs to all cases, the solver cannot find a solution.

You also can use this option to solve equations for more than one variable. In this case, the solver returns a set that contains one list. This nested structure represents a solution vector.

`Domain`

Option, specified as `Domain = d`

Return the set of all solutions that are elements of `d`. Here `d` must represent a subset of the complex numbers (for example, real numbers `Dom::Real` or integers `Dom::Integer`). Alternatively, `d` can be a domain over which you can factor polynomials (for example, `d` can be a finite field). In this case, you can use this option only when solving polynomial equations. Without this option, the solver returns all solutions in the set of complex numbers.

You can solve an equation or a system over the following domains:

- Subsets of the set of complex numbers `C_`.
- Domains over which you can factor polynomials. You can use these domains only when solving polynomial equations.

A subset of `C_` is any kind of set returned by `solve`. Instead of `C_`, `R_`, `Q_`, and `Z_`, you also can use the corresponding domains of the domains package `Dom::Complex`, `Dom::Real`, `Dom::Rational`, and `Dom::Integer`.

You can overload the solver for your custom domains by adding the `domsolve` method to those domains. If this method does not exist, MuPAD uses the `solve_eq` method to solve equations. The `solve_eq` method does not accept systems as arguments. Finally, if the `solve_eq` method does not exist, MuPAD uses the `solve_poly` method to solve polynomials. The `solve_poly` method accepts only polynomials as first arguments. This method regards any first argument of `solve` that cannot be converted to a polynomial as illegal.

The calling syntax for the `domsolve`, `solve_eq`, and `solve_poly` methods is `domsolve(eq, var, options)`. Here `var` is the same argument as in `solve`, and `options` is a table of options. For the `domsolve` method, `eq` is also the same as in `solve`. For the `solve_eq` method, `eq` must be an arithmetical expression. For `solve_poly`, `eq` must be a polynomial.

You cannot solve equations and systems in more than one variable over domains.

`IgnoreProperties`

Include solutions that are not consistent with the properties of the variable `x`.

`Real`

Return only the solutions for which every subexpression of `eq` represents a real number. Also, assume that every subexpression independent of `x` represents a real number.

With this option, the solver assumes that every subexpression independent of `x` represents a real number. In particular, the solver assumes that all symbolic parameters are real. When you use `Real`, the solver returns only the solutions for which every subexpression of `eq` is real. See “Example 7” on page 1-1962.

When you use this option, MuPAD restricts the domain of every function to real numbers. For example, it does not support the logarithms of negative numbers. For all returned solutions `x`, the input is defined over the real numbers.

This option is particularly useful for solving inequalities. Inequalities hold only when both sides represent real values.

This option does not affect some systems.

IgnoreSpecialCases

If a solution requires case analysis, ignore cases for which one or more parameters in the equation are supposed to be an element of a comparatively small set (for example, with this option, MuPAD can ignore a membership in a fixed finite set or a set of integers $\mathbb{Z}$).

With this option, the solver tries to reduce the number of branches in piecewise objects. MuPAD finds equations and memberships in comparatively small sets. First, MuPAD tries to prove such equations and memberships by using the property mechanism. If the property mechanism proves an equation or a membership is true, MuPAD keeps that statement. Otherwise, MuPAD can replace that statement with the value FALSE. For example, if the property mechanism cannot prove that a denominator is equal to zero, MuPAD regards this denominator as nonzero. This option can significantly reduce the number of piecewise objects in a solution.

IgnoreAnalyticConstraints

Apply purely algebraic simplifications to expressions and equations. With this option, the solver applies the following rules to the expressions on both sides of an equation:

- $ln(a) + ln(b) = ln(a\,b)$ for all values of a and b. In particular:

  $(a\,b)^c = e^{c\,\ln(a\,b)} = e^{c\,(\ln(a)+\ln(b))} = a^c\,b^c$ for all values of a, b, and c.
- $ln(a^b) = b\,ln(a)$ for all values of a and b. In particular:

  $(a^b)^c = e^{b\,c\,\ln(a)} = e^{\ln(a)^{b\,c}} = a^{b\,c}$ for all values of a, b, and c.
- If f and g are standard mathematical functions and $f(g(x)) = x$ for all small positive numbers, $f(g(x)) = x$ is assumed to be valid for all complex x. In particular:
- - $\ln(e^x) = x$.
  - $arcsin(sin(x)) = x$, $arccos(cos(x)) = x$, $arctan(tan(x)) = x$.
  - $arcsinh(sinh(x)) = x$, $arccosh(cosh(x)) = x$, $arctanh(tanh(x)) = x$.
  - $W_k(x\,e^x) = x$ for all values of k.
- The solver can multiply both sides of an equation by any expression except 0.
- The solutions of polynomial equations must be complete.

Using this option, you can get simpler solutions for equations for which the direct call of the solver returns complicated results. Note that with this option the solver does not

verify the correctness and completeness of the result. See “Example 8” on page 1-1962 and “Example 9” on page 1-1964.

`DontRewriteBySystem`

Do not transform an equation to an equivalent system of equations. This option decreases the running time. With this option, the solver cannot solve some equations.

This option does not allow the solver to replace an equation with the equivalent system of equations. Typically, MuPAD replaces an equation by an equivalent system of equations when solving equations with nested roots. Solving the resulting system can be slow. Use this option to improve performance of the solver. When you use `DontRewriteBySystem`, the solver cannot solve some of the equations that it can solve without this option.

`NoWarning`

Suppress all warning messages.

Return Values

If `x` is an identifier, `solve(eq, x)` returns an object that represents a mathematical set (see the “Details” section). If `x` is a set or a list, or if you omit `x`, a call to `solve` returns a set of lists. Each list consists of equations. The left side of each equation is one of the variables for which you solve an equation, an inequality of a system. In this case, `solve` also can return an expression of the form `x in S`, where `x` is a list of variables, and `S` is a set of vectors. When you solve a system providing the list of variables and the `VectorFormat` option, the solver returns a set of vectors.

MuPAD Functions

`isolate` | `linsolve` | `numeric::linsolve` | `numeric::solve` | `RootOf`

sort

Sort a list

Syntax

```
sort(list, <f>)
```

Description

`sort(list)` returns a sorted copy of the list.

`sort` sorts the list in ascending order.

If you do not specify a procedure `f`, the `sort` command uses the following rules for sorting the lists:

- The command sorts a list of real numbers (`Type::Real`) numerically.
- The command sorts a list of character strings alphabetically.
- The command sorts an outer list containing inner lists with numeric first entries by these numeric first entries. See “Example 4” on page 1-1979.
- In all other cases, the command sorts a list according to the internal order: `sort(list)` is equivalent to `sort(list, sysorder)`. All MuPAD sessions use the same internal order. Between different versions of MuPAD, internal order might change.

When you sort strings, uppercase letters have a preference over lowercase letters. For example, `Z` appears before `abc`.

You can specify a procedure `f` to define the sorting criteria. `sort` calls the procedure `f` for every pair of the entries of the list. `f` must return a Boolean expression that the `bool` command can evaluate to `TRUE` or `FALSE`. If for the pair of entries the procedure `f(x, y)` returns `TRUE`, the sorted list displays `x` to the left of `y`. Otherwise, `x` appears to the right of `y`. The entries of the sorted list `L := sort(list, f)` satisfy `bool(f(L[i], L[j])) = TRUE` for `i < j`.

If two entries of a list are equal by the sorting criteria `f`, the `sort` command can swap these entries. For example, if you sort polynomials by their degrees, the `sort` command

can return the polynomials with the same degree in the order different from their order in the input.

`sort` can be overloaded by kernel domains. For example, use the function `DOM_SET::sort` to sort sets. See “Example 3” on page 1-1978

The average runtime to sort a list containing n entries is $O(n\ log(n))$.

Examples

Example 1

The `sort` command sorts real numbers (type `Type::Real`) numerically:

```
sort([4, -1, 2/3, 0.5])
```

$$\left[-1,\ 0.5,\ \frac{2}{3},\ 4\right]$$

The `sort` command sorts strings alphabetically:

```
sort(["chip", "alpha", "Zip"])
```

$$\text{["Zip", "alpha", "chip"]}$$

If a list contains other types of objects the `sort` command sorts a list according to the internal order. The command also applies internal order to sort the lists with mixed types of entries:

```
sort([4, -1, 2/3, 0.5, "alpha"])
```

$$\left[-1,\ 0.5,\ \frac{2}{3},\ 4,\ \text{"alpha"}\right]$$

```
sort([4, -1, 2/3, 0.5, I])
```

$$\left[-1,\ 0.5,\ \frac{2}{3},\ 4,\ i\right]$$

Example 2

Define your own criteria to sort a list. For example, sort the entries by their absolute values:

```
sort([-2, 1, -3, 4], (x, y) -> abs(x) < abs(y))
```

$$[1, -2, -3, 4]$$

Example 3

When sorting sets, the `sort` command returns a list as a result:

```
sort({3, 12, 5, 30, 6, 43})
```

$$[3, 5, 6, 12, 30, 43]$$

The sorted set is equivalent to the corresponding sorted list:

```
bool(sort({3, 12, 5, 30, 6, 43}) = sort([3, 12, 5, 30, 6, 43]))
```

$$\text{TRUE}$$

To sort other data types, implement a `sort`-slot for them:

```
unprotect(DOM_INT):
DOM_INT::sort :=
proc(n)
  local str, i;
begin
  str := expr2text(n);
  text2expr(_concat(op(sort([str[i] $ i = 1..length(str)]))))
end:
sort(1703936)
```

$$133679$$

```
delete DOM_INT::sort:  protect(DOM_INT):
```

Example 4

If the list contains lists as entries, and all the inner lists start with numbers, the `sort` command uses these numbers to sort the outer list:

```
sort([[10 - i, i*x^i] $ i = 1..9])
```

$$[[1, 9\,x^9], [2, 8\,x^8], [3, 7\,x^7], [4, 6\,x^6], [5, 5\,x^5], [6, 4\,x^4], [7, 3\,x^3], [8, 2\,x^2], [9, x]]$$

Compare the sorted list with the internal order of its entries:

```
sort([[10 - i, i*x^i] $ i = 1..9], sysorder)
```

$$[[8, 2\,x^2], [7, 3\,x^3], [6, 4\,x^4], [5, 5\,x^5], [4, 6\,x^6], [3, 7\,x^7], [2, 8\,x^8], [1, 9\,x^9], [9, x]]$$

Parameters

`list`

A list of arbitrary MuPAD objects

`f`

A procedure defining the ordering

Return Values

List.

Overloaded By

list

Algorithms

To implement the `sort` function, MuPAD uses a version of the Quicksort algorithm.

See Also

MuPAD Functions
`prog::sort` | `sysorder`

split

Split an object

Syntax

```
split(object, f, <p1, p2, …>)
```

Description

`split(object, f)` splits the object into a list of three objects. The first list entry is an object consisting of those operands of the input object that satisfy a criterion defined by the procedure `f`. The second list entry is built from the operands that violate the criterion. The third list entry is built from the operands for which it is unknown whether the criterion is satisfied.

The function `f` must return a value that can be evaluated to one of the Boolean values `TRUE`, `FALSE`, or `UNKNOWN`. It may either return one of these values directly, or it may return an equation or an inequality that can be simplified to one of these values by the function `bool`.

The function `f` is applied to all operands`x` of the input object via the call `f(x, p1, p2, ...)`. Depending on the result `TRUE`, `FALSE`, or `UNKNOWN`, this operand is inserted into the first, the second, or the third output object, respectively.

The output objects are of the same type as the input object, i.e., a list is split into three lists, a set into three sets, a table into three tables etc.

If the input object is an expression sequence, then neither the input sequence nor the output (a list containing three sequences) are flattened.

Also “atomic” objects such as numbers or identifiers can be passed to `split` as first argument. Such objects are handled like sequences with a single operand.

Examples

Example 1

The following command checks which of the integers in the list are prime:

```
split([1, 2, 3, 4, 5, 6, 7, 8, 9, 10], isprime)
```

$$[[2, 3, 5, 7], [1, 4, 6, 8, 9, 10], []]$$

The return value is a list of three lists. The first list contains the prime numbers, the second list contains all other numbers. The third list is empty, because for any number of the input list, it can be decided whether it is prime or not.

Example 2

With the optional arguments `p1, p2, ...` one can use functions that need more than one argument. For example, `contains` is a handy function to be used with `split`. The following call splits a list of sets into those sets that contain `x` and those that do not:

```
split([{a, x, b}, {a}, {1, x}], contains, x)
```

$$[[\{a, b, x\}, \{1, x\}], [\{a\}], []]$$

The elements of the returned list are of of type `DOM_LIST`, because the given expression was a list. If the given expression is of another type, e.g., `DOM_SET`, also the elements of the result are of type `DOM_SET`, too:

```
split({{a, x, b}, {a}, {1, x}}, contains, x)
```

$$[\{\{1, x\}, \{a, b, x\}\}, \{\{a\}\}, \varnothing]$$

Example 3

We use the function `is` to split an expression sequence into sub-sequences. This function returns `UNKNOWN` if it cannot derive the queried property:

```
split((-2, -1, a, 0, b, 1, 2), is, Type::Positive)
```

$$[1, 2, -2, -1, 0, a, b]$$

Example 4

We split a table of people marked as male or female:

```
people := table("Tom" = "m", "Rita" = "f", "Joe" = "m"):
[male, female, dummy] := split(people, has, "m"):

male
```

"Joe"	"m"
"Tom"	"m"

```
female
```

"Rita"	"f"

```
dummy
```

$\top$

```
delete people, male, female, dummy:
```

Parameters

`object`

A list, a set, a table, an expression sequence, or an expression of type `DOM_EXPR`

`f`

A procedure returning a Boolean value

`p1, p2, …`

Any MuPAD objects accepted by `f` as additional parameters

Return Values

List with three objects of the same type as the input object.

Overloaded By

object

MuPAD Functions
`map` | `op` | `select` | `zip`

sqrt

Square root function

Syntax

```
sqrt(z)
```

Description

`sqrt(z)` represents the square root of *z*.

$x = \sqrt{z}$ represents the solution of $x^2 = z$ that has a nonnegative real part. In particular, it represents the positive root for real positive *z*. For real negative *z*, it represents the complex root with positive imaginary part.

A floating-point result is returned for floating-point arguments. Note that the branch cut is chosen as the negative real semi-axis. The values returned by `sqrt` jump when crossing this cut. Cf. “Example 2” on page 1-1986.

Certain simplifications of the argument may occur. In particular, positive integer factors are extracted from some symbolic products. Cf. “Example 3” on page 1-1987.

Note that $\sqrt{z}$ cannot be simplified to *x* for all complex numbers (e.g., $\sqrt{x^2} = -x$ for real $x < 0$). Cf. “Example 4” on page 1-1987.

Mathematically, `sqrt(z)` coincides with `z^(1/2) = _power(z,1/2)`. However, `sqrt` provides more simplifications than `_power`. Cf. “Example 5” on page 1-1987.

Environment Interactions

When called with a floating-point argument, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

We demonstrate some calls with exact and symbolic input data:

```
sqrt(2), sqrt(4), sqrt(36*7), sqrt(127)
```

$$\sqrt{2},\ 2,\ 6\sqrt{7},\ \sqrt{127}$$

```
sqrt(1/4), sqrt(1/2), sqrt(3/4), sqrt(25/36/7), sqrt(4/127)
```

$$\frac{1}{2},\ \frac{\sqrt{2}}{2},\ \frac{\sqrt{3}}{2},\ \frac{5\sqrt{7}}{42},\ \frac{2\sqrt{127}}{127}$$

```
sqrt(-4), sqrt(-1/2), sqrt(1 + I)
```

$$2\,i,\ \frac{\sqrt{2}\,i}{2},\ \sqrt{1+i}$$

```
sqrt(x), sqrt(4*x^(4/7)), sqrt(4*x/3), sqrt(4*(x + I))
```

$$\sqrt{x},\ 2\,x^{2/7},\ \sqrt{\frac{4\,x}{3}},\ 2\sqrt{x+i}$$

Example 2

Floating point values are computed for floating-point arguments:

```
sqrt(1234.5), sqrt(-1234.5), sqrt(-2.0 + 3.0*I)
```

$$35.13545218,\ 35.13545218\,i,\ 0.8959774761 + 1.674149228\,i$$

A jump occurs when crossing the negative real semi axis:

```
sqrt(-4.0), sqrt(-4.0 + I/10^100), sqrt(-4.0 - I/10^100)
```

$$2.0\,i,\ 2.5\,10^{-101}+2.0\,i,\ 2.5\,10^{-101}-2.0\,i$$

Example 3

The square root of symbolic products involving positive integer factors is simplified:

```
sqrt(20*x*y*z)
```

$$2\sqrt{5}\sqrt{x\,y\,z}$$

Example 4

Square roots of squares are not simplified, unless the argument is real and its sign is known:

```
sqrt(x^2*y^4)
```

$$\sqrt{x^2\,y^4}$$

```
assume(x > 0): sqrt(x^2*y^4)
```

$$x\sqrt{y^4}$$

```
assume(x < 0): sqrt(x^2*y^4)
```

$$-x\sqrt{y^4}$$

Example 5

`sqrt` provides more simplifications than the `_power` function:

```
sqrt(4*x), (4*x)^(1/2) = _power(4*x, 1/2)
```

$$2\sqrt{x},\ \sqrt{4x} = \sqrt{4x}$$

Parameters

z

An arithmetical expression

Return Values

Arithmetical expression.

Overloaded By

z

See Also

MuPAD Functions

`_power` | `isqrt` | `numlib::issqr` | `surd`

strmatch

Match pattern in character string

Syntax

```
strmatch(text, pattern, <Index>, <ReturnMatches>, <All>)
```

Description

`strmatch(text, pattern)` checks whether `text` matches the regular expression `pattern`.

`strmatch` performs regular expression matching on strings, via the ICU library. The pattern can contain wildcards forming a perl-compatible regular expression. In these expressions, most characters represent themselves. For example, `"a"` matches `"a"`. For the list of exceptions, see “Algorithms” on page 1-2002.

The library `stringlib` provides more functions for handling strings. For details, see “Operations on Strings”.

Examples

Example 1

Most characters simply match themselves:

```
s := "Hamburg": strmatch(s, "Hamburg")
```

```
     TRUE
```

`strmatch` typically matches substrings:

```
strmatch(s, "Ham"), strmatch(s, "burg")
```

```
     TRUE, TRUE
```

```
strmatch("Ham", "Hamburg")
```

```
    FALSE
```

```
delete s:
```

Example 2

A dot (`.`) is a placeholder for any character except `"\n"`:

```
strmatch("abcd", "a.c"), strmatch("ab\ncd", "ab.")
```

```
    TRUE, FALSE
```

To match an actual dot, use `"\\."`:

```
strmatch("abcd", "a\\.c"),
strmatch("a.cd", "a\\.c")
```

```
    FALSE, TRUE
```

A dot, like all special characters, has its special role only in the second argument of `strmatch`:

```
strmatch("a.c", "abc")
```

```
    FALSE
```

With the `s` modifier, you can use a dot to match newlines:

```
strmatch("abcd", "(?s)a.c"), strmatch("ab\ncd", "(?s)ab.")
```

```
    TRUE, TRUE
```

A dot matches only a single character:

```
strmatch("abcd", "a.d"), strmatch("abcd", "a.b")
```

```
    FALSE, FALSE
```

Example 3

By default, `strmatch` only checks for a match and returns a Boolean value:

```
strmatch("aaaba", "a"), strmatch("aaaba", "c")
```

```
TRUE, FALSE
```

To return the first place where a match occurs, use `Index`:

```
strmatch("aaaba", "a", Index),
strmatch("aaaba", "c", Index)
```

```
[1, 1], FALSE
```

To return the matched substrings, use `ReturnMatches`. This option is helpful when you match complicated expressions.

```
strmatch("aaaba", "a", ReturnMatches),
strmatch("aaaba", "c", ReturnMatches)
```

```
"a", FALSE
```

To find more than one match, use `All`:

```
strmatch("aaaba", "a", All),
strmatch("aaaba", "c", All)
```

```
{"a"}, ∅
```

This expression has several matches because a dot matches any character:

```
strmatch("aaaba", "a.", All)
```

```
{"aa", "ab"}
```

`All` implies `ReturnMatches` unless you also use `Index`:

```
strmatch("aaaba", "a", All, Index)
```

```
{[1, 1], [2, 2], [3, 3], [5, 5]}
```

Combine all three options:

```
strmatch("aaaba", "a", All, Index, ReturnMatches)
```

```
{[1, 1, "a"], [2, 2, "a"], [3, 3, "a"], [5, 5, "a"]}
```

Example 4

By default, `strmatch` matches substrings. To look only for matches at the beginning and end of the string, use the caret (^) and dollar ($) characters, respectively:

```
strmatch("abcd", "a"),
strmatch("abcd", "c"),
strmatch("abcd", "d"),
strmatch("abcd", "abcd")
```

```
TRUE, TRUE, TRUE, TRUE
```

```
strmatch("abcd", "^a"),
strmatch("abcd", "^c"),
strmatch("abcd", "^d"),
strmatch("abcd", "^abcd")
```

```
TRUE, FALSE, FALSE, TRUE
```

```
strmatch("abcd", "a$"),
strmatch("abcd", "c$"),
strmatch("abcd", "d$"),
strmatch("abcd", "abcd$")
```

```
FALSE, FALSE, TRUE, TRUE
```

```
strmatch("abcd", "^a$"),
strmatch("abcd", "^c$"),
strmatch("abcd", "^d$"),
strmatch("abcd", "^abcd$")
```

```
FALSE, FALSE, FALSE, TRUE
```

Using the `m` modifier, you can change the meaning from the beginning or end of a string to the beginning or end of a line:

```
s := "ab\ncd":

strmatch(s, "b$"),
strmatch(s, "(?m)b$")
```

```
FALSE, TRUE
```

Example 5

Specify alternative patterns to match by using the vertical bar (|):

```
strmatch("abcd", "abc|xyz")
```

```
TRUE
```

```
strmatch("abcd", "a|f|j")
```

```
TRUE
```

`strmatch` treats all characters between the vertical bars as one of the alternative patterns. To limit the extent of alternatives, use parentheses:

```
strmatch("abcd", "ab(c|xy)z"),
strmatch("abcd", "ab(c|xy)(z|d)")
```

```
FALSE, TRUE
```

When you use the `ReturnMatches` option, `strmatch` returns the substrings matched by each pair of parentheses:

```
strmatch("abcd", "ab(c|xy)(z|d)", ReturnMatches)
```

```
["abcd", "c", "d"]
```

With alternatives, `strmatch` can find several matches:

```
strmatch("abracadabra", "a(b|c|d)", All)
```

```
{["ab", "b"], ["ac", "c"], ["ad", "d"]}
```

To group alternatives without returning matches, use `(?:...)`:

```
strmatch("abracadabra", "a(?:b|c|d)", All)
```

```
{"ab", "ac", "ad"}
```

To match for the characters `"|"`, `"("`, and `")"`, use `\\` before the character when you specify the pattern to match:

```
strmatch("ab(c)d", "\\((c|d)\\)", ReturnMatches)
```

```
["(c)", "c"]
```

Example 6

Use a question mark (?) to indicate that a subexpression (a single character or a group of characters in parentheses or brackets) is optional:

```
strmatch("abcd", "abc?d"),
strmatch("abd", "abc?d")
```

```
TRUE, TRUE
```

Use an asterisk (*) to indicate that a subexpression can be repeated an arbitrary number of times, including zero:

```
strmatch("abcd", "a.*d"),
strmatch("abcd", "a.*c")
```

```
TRUE, TRUE
```

Use a plus sign (+) to indicate that a subexpression can be repeated an arbitrary number of times, excluding zero:

```
strmatch("abcd", "a.+d"),
strmatch("abcd", "a.+b")
```

```
TRUE, FALSE
```

When you use the asterisk or the plus sign in the pattern to match, `strmatch` finds the first match going from left to right, and then returns the longest substring that satisfies the matching pattern:

```
strmatch("abracadabra", "a.*a", ReturnMatches)
```

```
"abracadabra"
```

By appending another question mark, you can switch the asterisk and plus sign to “non-greedy” matching:

```
strmatch("abracadabra", "a.*?a", ReturnMatches)
```

```
"abra"
```

This does not return the shortest match (which would have been `"aca"` or `"ada"`). The call returns the first match looking from left to right from the starting position.

Example 7

Use curly braces to specify a number of repetitions of a subexpression:

```
strmatch("abracadabra", "(a(b|c|d)){2}"),
strmatch("abracadabra", "(a(b|c|d)){3}"),
strmatch("abracadabra", "(a(b|c|d)){4}")
```

```
TRUE, TRUE, FALSE
```

These repetitions must be adjacent:

```
strmatch("abracadabra", "(abr){2}")
```

```
FALSE
```

To get nonadjacent repetitions, use `".*"`. This combination means "anything without newlines".

```
strmatch("abracadabra", "(abr.*){2}")
```

```
    TRUE
```

Example 8

To indicate a range of possible repetitions, use a comma inside curly braces. For example, select the expressions representing binary numbers with three to five digits:

```
select(["11001", "1100111", "11", "11021"], strmatch, "^((0|1){3,5})$")
```

```
    ["11001"]
```

Here `{3,5}` specifies the range. You can omit the second number to remove the upper bound. For example, `{3,}` indicates that there must be three or more repetitions.

The following regular expression checks whether there is an `"a"` followed by at least three letters `"b"` followed by a `"c"` somewhere in the input string:

```
strmatch("abcd", "ab{3,}c"),
strmatch("abbbcd", "ab{3,}c"),
strmatch("abcdabbbc", "ab{3,}c")
```

```
    FALSE, TRUE, TRUE
```

By default, when `strmatch` looks for repetitions, it returns the longest matching substring. Use a question mark to return the first match instead of the longest one:

```
strmatch("abcdabcdabcd", "a.{2,8}d", ReturnMatches),
strmatch("abcdabcdabcd", "a.{2,8}?d", ReturnMatches)
```

```
    "abcdabcd", "abcd"
```

Example 9

Characters enclosed in brackets ([ ]) form a "character class", which matches any of the characters in the class. This behavior is similar to an alternation between these characters.

```
strmatch("abc", "ab[cde]"),
strmatch("abd", "ab[cde]"),
strmatch("aba", "ab[cde]")
```

```
TRUE, TRUE, FALSE
```

Inside character classes, special characters are completely different. Dots, asterisks, plus and dollar signs, parentheses, and curly braces match themselves, but a character class starting with a caret is "negated" and matches any character *not* listed:

```
strmatch("abcd", "[^ab]", All)
```

```
{"c", "d"}
```

If a caret is not the first character in a class, then it represents itself:

```
strmatch("x^2", "[*^]2")
```

```
TRUE
```

If a dash (-) is not the first character in a class (apart from the caret), then it specifies a range of characters. Thus, to find a number with at least five digits, you can specify the pattern as follows:

```
strmatch("x = 123456...", "[0-9]{5,}", ReturnMatches)
```

```
"123456"
```

The exact meaning of a range depends on the language settings of your computer. Technically, it depends on the "collating", which can be different for the same language on different versions of the same operating system. For example, `"[a-z]"` can match only lowercase ASCII characters on one computer, while on the second one it also matches the uppercase characters from A through Y, and on the third one includes the uppercase characters from B through Z. For this reason, the best practice is using the named character classes instead:

```
strmatch("some words", "[[:word:]]+", All)
```

```
{"some", "words"}
```

Example 10

Some character classes have a short form, such as `"\\x"`, where `x` is `w`, `W`, `s`, `S`, `d`, or `D`. The uppercase letters mean the negation of the lowercase letters.

```
strmatch("abcd", "\\w"),
strmatch("abcd", "\\W"),
strmatch("abcd", "\\d"),
strmatch("abcd", "\\D")
```

```
TRUE, FALSE, FALSE, TRUE
```

Here, negation means that a character does not match whatever is negated:

```
strmatch("abcd 1", "\\w"),
strmatch("abcd 1", "\\W"),
strmatch("abcd 1", "\\d"),
strmatch("abcd 1", "\\D")
```

```
TRUE, TRUE, TRUE, TRUE
```

Use `"\\b"` to look for words starting with an `a`. The pattern `"\\b"` is a zero-width expression matching the place between a "word" and the spaces surrounding it (or the beginning and end of string).

```
strmatch("abc cbd cba (aa) b", "\\ba\\w*", All)
```

```
{"aa", "abc"}
```

You can also use `"\\b"` to match the end of a word:

```
strmatch("abc cbd cba (aa) b", "\\w*a\\b", All)
```

```
{"aa", "cba"}
```

Example 11

You can change the behavior of `strmatch` with modifier flags. For example, the `i` modifier enables case-insensitive matching. (The precise effects of case-insensitive

matching depend on your language settings, for example, most English computers do not treat the German umlauts ä and Ä as being the same up to case.) To enable case-insensitive matching for the whole expression, prefix it with "(?i)":

```
strmatch("ABC", "(?i)ab")
```

```
TRUE
```

To limit the effect of the modifier to some part of the expression, use "(?i:...)":

```
strmatch("ABC", "(?i:a)b"),
strmatch("abc", "(?i:a)b"),
strmatch("Abc", "(?i:a)b")
```

```
FALSE, TRUE, TRUE
```

Example 12

`strmatch` with `ReturnMatches` or `All` (without `Index`) returns the matched substrings. You can also return parts of those substrings. For example, extract all function names from this expression. To identify function names, note that an opening parenthesis or a space and an opening parenthesis follows every function name.

```
s := "f(sin (x) + abc + def(x))":
strmatch(s, "\\b\\w+\\s*\\(", All)
```

```
{"def(", "f(", "sin ("}
```

To extract the function names themselves, use this command:

```
map(strmatch(s, "\\b(\\w+)\\s*\\(", All), op, 2)
```

```
{"def", "f", "sin"}
```

Regular expressions can contain zero-width assertions. These assertions ensure that something does or does not follow, without actually including it or moving the conceptual pointer behind it. Therefore, the more efficient approach is to wrap the corresponding expression in "(?=...)":

```
strmatch(s, "\\b\\w+(?=\\s*\\()", All)
```

```
{"def", "f", "sin"}
```

Example 13

Regular expressions can also make zero-width assertions with respect to the preceding text. Such assertions must have a fixed width. For example, extract the amount of money mentioned in this string:

```
s := "In March 2005, we've spent $1192.23 on light.":
strmatch(s, "(?<=\\$)\\d+(?:\\.\\d\\d)?", All)
```

```
{"1192.23"}
```

Example 14

To detect the positions of the matches in the input string, use the `Index` option. The returned list contains two numbers: the beginning and end of the match.

```
strmatch("abc", "b", Index)
```

```
[2, 2]
```

If no match is found, `strmatch` returns `FALSE`:

```
strmatch("abc", "d", Index)
```

```
FALSE
```

If you use both `Index` and `ReturnMatches`, then `strmatch` returns indices followed by the matched subexpressions:

```
strmatch("abc", "b.", ReturnMatches, Index)
```

```
[2, 3, "bc"]
```

Example 15

If you use `All`, then the return value is a set:

```
strmatch("abc", ".", All),
strmatch("abc", ".", Index, All),
strmatch("abc", ".", ReturnMatches, All)
```

```
{"a", "b", "c"}, {[1, 1], [2, 2], [3, 3]}, {"a", "b", "c"}
```

Parameters

`text`, `pattern`

character strings

Options

`Index`

Return the position of the match. If there are no matches, `strmatch` returns `FALSE`. Otherwise, it returns the position of the match as a list of two integers, `[i, j]`, such that `text[i..j]` is the matched substring.

`ReturnMatches`

Return the matched substrings. If the regular expression contains groups (subexpressions in parentheses), then `strmatch` returns lists containing the matched substring and the strings matched by the groups, in order of opening parentheses.

`All`

Return all matches that `strprint` can find. By default, `strmatch` returns only the first match. If you do not use `Index`, then the `All` option also implies `ReturnMatches`.

Return Values

Without options, `TRUE` or `FALSE` is returned. With `Index`, a list of two nonnegative integers or `FALSE` is returned. With option `ReturnMatches`, a string or a list of strings is returned, depending on whether the pattern contains groups. With both `Index` and

`ReturnMatches`, a list starting with the indices of the match, followed by the string or strings of `ReturnMatches`, is returned. With option `All`, a set is returned.

pattern, text

Algorithms

- A dot (`.`) matches any character, except `"\n"`. With the `s` modifier, a dot matches any character. See “Example 2” on page 1-1990.
- A caret (`^`) matches the beginning of a line. A dollar (`$`) matches the end of a line. Typically, `^` and `$` mark the beginning and end of the string, but with the `m` modifier they also can appear after or before a `"\n"`. See “Example 4” on page 1-1992.
- A pattern enclosed in parentheses (`()`) is considered “grouped.”
- A vertical bar (`|`) between two characters or groups (sub-regexes) lets you specify alternative matching patterns. Any one of the alternatives matching is sufficient. See “Example 5” on page 1-1993.
- A sub-regex followed by a number *n* enclosed in `{}` must match exactly *n* times.

  A sub-regex followed by `{n,}` must match at least *n* times.

  A sub-regex followed by `{n,m}` must match at least *n* and at most *m* times.

  In any other context, `{` and `}` are treated as normal characters.

  See “Example 7” on page 1-1995.
- Following a sub-regex, a question mark (`?`) works as `{0,1}`, making the sub-regex optional.

  A plus sign (`+`) in this context works as `{1,}` and allows an arbitrary positive number of repetitions.

  An asterisk after an expression is equivalent to `{0,}` and allows an arbitrary number of repetitions, including zero.

  See “Example 6” on page 1-1994.

- By default, `{n,}` and its three shorthand forms match as many characters as possible. By following them with another question mark (for example, `"a(b[cd]){2,}?bd"`, `"(0|1)*?12"`), you can specify that `strmatch` must return the lowest number of characters consistent with the remainder of the pattern.
- While a backslash (which must be typed as `"\\"`) escapes any special character (including itself), it makes some characters following it special. See “Example 10” on page 1-1998.
  - `"\\w"` matches a “word” character (alphanumeric or underline).
  - `"\\W"` matches a character not matched by `"\\w"`.
  - `"\\s"` matches a white-space character (space, or tabulator, or, if the `s` modifier is active, also an end-of-line character).
  - `"\\S"` matches a character not matched by `"\\s"`.
  - `"\\d"` matches a digit.
  - `"\\D"` matches a nondigit.
  - `"\\b"` matches the place between a word character and a nonword character, for example, the place where a word starts or ends.
  - `"\\B"` is also zero-width, but matches those places where `"\\b"` does not.
  - `"\\A"` and `"\\Z"` match at the beginning and end of the string, respectively. `"\\Z"` ignores a `"\n"` at the end of the string; `"\\z"` behaves like `"\\Z"`, but does not ignore a trailing `"\n"`.
  - `'\\X'` matches a grapheme cluster. For example, the letter `a̅` is a grapheme cluster: it consists of `a` and `̅`. `'\\X'` lets you access `a̅` as one entity.
- Characters enclosed between `[` and `]` form a character class. See “Example 9” on page 1-1996.

  A character class starting with `^` is negated, and matches all the characters not listed. The symbol `^` at any other place in the character class has no special meaning.

  Inside a character class, the special characters, except for a hyphen, do not have any special meaning. If a hyphen (`-`) is not the first character, then it creates a range of characters. The language settings of your operating system (technically speaking, the current locale) affect how `strmatch` interprets this range. Likely, in every language setting `"[0-9]"` represents any digit.

  To specify character classes independent of language settings, use named access to POSIX character classes:

- `"[[:digit:]]"` for any digit.
- `"[[:alpha:]]"` for characters (the language settings define what makes a character).
- `"[[:alnum:]]"` for alphanumerical characters.
- `"[[:word:]]"` for alphanumerical characters plus the underline (_).
- `"[[:punct:]]"` for punctuation characters, such as a dot or a comma.
- `"[[:ascii:]]"` for characters in the ASCII range (decimal codes 32 through 127).
- `"[[:blank:]]"` for horizontal spaces, such as`[ \t]`.
- `"[[:space:]]"` for spaces, including end-of-line.
- `"[[:cntrl:]]"` for control characters, such as newlines. Note that you cannot type most control characters in MuPAD, but they can occur in strings read from files.
- `"[[:graph:]]"` for the class of alphanumeric or punctuation characters, that is, characters with visual graphical representation.
- `"[[:print:]]"` is equivalent to `"[ [:graph:]]"`. It adds the space character to the `graph` class.
- `"[[:lower:]]"` and `"[[:upper:]]"` for the characters that your language settings consider lowercase and uppercase letters. For example, a German system is more likely to know about ä being a lowercase letter than a U.S. system.
- `"[[:xdigit:]]"` matches hexadecimal digits. It is equivalent to `[0123456789aAbBcCdDeEfF]`.

You combine these classes with one another or add characters from one class to another class. For example, you can match septendecimal digits with `"[[:xdigit:]gG]"`.

You can negate posix character classes using a caret. For example, `"[[:^digit:]]"` matches nondigits. This is equivalent to `"[^[:digit:]]"`, but `"[0[:^digit:]]"` to allow any nondigit or zero is more difficult to express otherwise.

- Groups starting with `(?` have special meanings:
  - Groups starting with `(?:` behave like other groups, but do not create output matches for the `ReturnMatches` option.
  - `"(?#text)"` is a comment and effectively ignored.

- Groups starting with `(?X:`, where `X` is one of `i`, `m`, `s`, `x`, locally apply modifiers:
  - `i` causes all pattern matching to be case-insensitive (as defined by the system's locale).
  - `m` causes a “multiline” match, where `^` and `$` match after/before `"\n"` characters in the string.
  - `s` makes the dot match newlines.
  - `x` allows perl-style comments in the pattern. In this case, `strmatch` ignores spaces in most contexts. The # characters start comments that extend to the end of the line.

  When using these options in an outer group, you can disable them by preceding them with a minus sign, as in `"(?-i:aB)"`.
- The string `"(?X)"`, where `X` is one of the characters listed above, switches the corresponding setting on up to the end of the enclosing group.
- `(?=` starts a positive zero-width lookahead assertion. This is a zero-width item (and therefore does not add something to the output) that matches if its contents match at the current position. See “Example 12” on page 1-1999.
- `(?!` starts a zero-width negative look-ahead assertion. It behaves almost identical to `(?=` except it matches if and only if `(?=` does not.
- `(?<=` starts a positive zero-width look-behind assertion, which is like `(?=`, but looking in the other direction. Look-behind assertions must have a fixed width. See “Example 13” on page 1-2000.
- `(?<!` starts a negative zero-width look-behind assertion, which matches if and only if a `(?<=` at the same place does not match.

strprint

Print into string

Syntax

```
strprint(<All>, <Unquoted>, <NoNL>, <KeepOrder>, object1, object2, …)
```

Description

`strprint(objects)` returns the string `print(objects)` would display on the screen.

`strprint` returns a string that contains the output `print` would have sent to the screen for the same arguments. This string contains `` `\n' `` characters if the output would have consisted of multiple lines.

On Windows systems, each `\n` is preceded by `\r`, because that is the traditional end-of-line combination since that is the end-of-line combination inherited from CP/M. The examples in this documentation assume a system like UNIX. Also note that with Typesetting activated, `\r`, `\n`, `\t`, and `\b` will not be displayed in a string.

All options and dependencies on variables are interpreted as described in the documentation of `print`. Especially, this means `PRETTYPRINT` affects the output of `strprint`. Overloading of `print` is taken into account. See `?print` for details.

Environment Interactions

`strprint` is sensitive to the environment variables `DIGITS`, `PRETTYPRINT`, and `TEXTWIDTH`, and to the output preferences `Pref::floatFormat`, `Pref::keepOrder`, and `Pref::trailingZeroes`.

Examples

Example 1

The string returned by `strprint`, when printed with option `Unquoted`, yields the same output as the operands would have in the first place:

```
s := strprint(a*x^2-7):
print(Unquoted, s)
```

```
   2
a x  - 7
```

This can be used to combine multiple outputs:

```
s1 := strprint(a*x^2-7):
s2 := _concat("-" $ TEXTWIDTH)."\n":
s3 := strprint(sin(1/x)):
print(Unquoted, s1.s2.s3)
```

```
   2
a x  - 7
--------------------------------------------------------------------------------
   / 1 \
sin| - |
   \ x /
```

In the example above, you can see that the output of `strprint` does not contain the spaces usually used for centering. The output in the first example was centered, because it used only a fraction of the text width, while the string `s1.s2.s3` in the second example spans the whole width of the line and is therefore printed flush left.

Example 2

For demonstrative purposes, let us write a domain that puts an expression into a box. We make use of the fact that `strprint` returns strings starting with a newline, of `output::fence` and of indexed assignment to strings:

```
domain box
  print := proc(e)
```

```
            local ex, str, w;
            save TEXTWIDTH;
          begin
            if TEXTWIDTH > 15 then
              TEXTWIDTH := TEXTWIDTH - 4;
            end_if;
            ex := extop(e, 1);
            str := strprint(All, ex);
            w := str[5]+4;
            str := output::fence("| ", " |",
                                 "\n".str[1]."\n",
                                 str[5], str[6]+1);
            str[1..w]     := "+"._concat("-"$w-2)."+";
            str[-w-1..-2] := "+"._concat("-"$w-2)."+";
            str;
          end_proc;

   new := x -> new(dom, x);
end_domain

print(Plain, box(a), box(sin(1/x)))
```

```
       +----------+
+---+  |    / 1 \ |
| a |, | sin| - | |
+---+  |    \ x / |
       +----------+
```

```
print(Plain, box(box(hold(E=m*c^2))))
```

```
+--------------+
| +----------+ |
| |        2 | |
| | E = m c  | |
| +----------+ |
+--------------+
```

Example 3

As a last example, we implement a print-method for matrices over $\mathbb{Z}_5$:

```
M5 := Dom::Matrix(Dom::IntegerMod(5))
```

```
Dom::Matrix(Dom::IntegerMod(5))
```

The standard output function simply puts “mod 5” behind every entry, inherited from the output method of `Dom::IntegerMod(5)`:

```
A := M5([[1,2,3,4],[5,6,7,8],[-2,-3,0,1]])
```

$$\begin{pmatrix} 1 \bmod 5 & 2 \bmod 5 & 3 \bmod 5 & 4 \bmod 5 \\ 0 \bmod 5 & 1 \bmod 5 & 2 \bmod 5 & 3 \bmod 5 \\ 3 \bmod 5 & 2 \bmod 5 & 0 \bmod 5 & 1 \bmod 5 \end{pmatrix}$$

We now replace this method:

```
M5::print := proc(A)
               local str, h1, w1, h, w, b;
             begin
               [str, h1, w1, h, w, b] := strprint(All, expr(A));
               _concat(str, " " $ w, "[mod 5]");
             end_proc:

print(A):

/ 1, 2, 3, 4 \
|            |
| 0, 1, 2, 3 |
|            |
\ 3, 2, 0, 1 /
              [mod 5]
```

Alternatively, we can set the `[mod 5]` right beneath the brackets:

```
M5::print := proc(A)
               local str;
             begin
               str := strprint(expr(A));
               str[-1..-1] := " [mod 5]";
               str
             end_proc:

print(A):
```

```
/ 1, 2, 3, 4 \
|            |
| 0, 1, 2, 3 |
|            |
\ 3, 2, 0, 1 / [mod 5]
```

Parameters

$object_1$, $object_2$, …

Any MuPAD objects

Options

All

When the option `All` is given, `strprint` returns additional information on the string generated by printing. More specifically, it returns a list consisting of

1. the formatted string,
2. the height (in characters) of the first line,
3. the width of the first line,
4. the height of the complete string,
5. the width of the complete string,
6. the baseline, counted from top to bottom.

"Example 2" on page 1-2007 contains sample code that makes use of this information.

Unquoted

Display character strings without quotation marks and with expanded control characters `'\n'`, `'\t'`, and `'\b'`.

NoNL

Like `Unquoted`, but no newline is put at the end. `PRETTYPRINT` is implicitly set to `FALSE`.

KeepOrder

Display operands of sums (of type `"_plus"`) always in the internal order.

Return Values

`DOM_STRING` or a list of a `DOM_STRING` and five integers.

subs

Substitute into an object

Syntax

```
subs(f, old = new, <Unsimplified>)
subs(f, old1 = new1, old2 = new2, …, options)
subs(f, [old1 = new1, old2 = new2, …], options)
subs(f, {old1 = new1, old2 = new2, …}, options)
subs(f, table(old1 = new1, old2 = new2, …), options)
subs(f, s1, s2, …, options)
```

Description

`subs(f, old = new)` searches `f` for operands matching `old`, and replaces `old` with `new`. See “Example 1” on page 1-2013.

The `subs` function returns a modified copy of the object. The function does not change the object itself.

By default, the `subs` function does not evaluate the result of a substitution. To enforce evaluation of all modified subexpressions, use the `EvalChanges` option. Also, you can reevaluate the whole returned result by using the `eval` function. Evaluation of the returned result is slower and less efficient than evaluation of the modified subexpressions. See “Example 3” on page 1-2014 and “Example 4” on page 1-2015.

The call `subs(f, old1 = new1, old2 = new2, ...)` applies the specified substitutions in a sequence from left to right (sequential substituton). This call applies each substitution (except for the first substitution) to the result of the previous substitution. See “Example 5” on page 1-2015.

The call `subs(f, [old1 = new1, old2 = new2, ...])` applies all specified substitutions to the operands of the original input object `f` (parallel substitution). This call does not use the results of any previous substitutions. If you specify multiple

substitutions of the same operand, this call computes only the first substitution. Specifying substitutions by lists, sets, or tables invokes parallel substitution. See “Example 6” on page 1-2016.

The call `subs(f, s1, s2, ...)` is a general form of substitution that can combine sequential and parallel substitutions. This call is equivalent to `subs(... subs(subs(f, s1), s2), ...)`. MuPAD treats each substitution step as a sequential or a parallel substitution depending on the form of the parameters `s1`, `s2`, ... See “Example 7” on page 1-2017.

`subs` replaces only those operands that you can access via the function `op` (“syntactical substitution”). To apply a more “semantical” substitution, use the `subsex` function. The `subsex` function also identifies and replaces partial sums and products. See “Example 8” on page 1-2017.

You can use `subs` to replace operands of expression sequences. The `subs` function does not flatten such objects. See “Example 9” on page 1-2018.

If you do not specify substitutions, `subs` returns the original expression without modifications. For example, `subs(f)` returns `f`.

Examples

Example 1

Use the `subs` function to substitute the operands in the following expressions:

```
subs(a + b*a, a = 4)
```

$$4\,b + 4$$

```
subs([a * (b + c), sin(b +c)], b + c = a)
```

$$[a^2, \sin(a)]$$

Example 2

When replacing the sine function in an expression, use the `hold` command to prevent the evaluation of the identifier `sin`:

```
subs(sin(x), hold(sin) = cos);
domtype(hold(sin))
```

$$\cos(x)$$

DOM_IDENT

Otherwise, MuPAD replaces `sin` by its value. The function environment (see `funcenv`) defines the value of `sin`:

```
subs(sin(x), sin = cos);
domtype(sin)
```

$$\sin(x)$$

DOM_FUNC_ENV

Inside the expression `sin(x)`, the 0-th operand `sin` is the identifier, not the function environment:

```
domtype(op(sin(x), 0))
```

DOM_IDENT

Example 3

The `subs` function evaluates the original expression, performs a substitution, but does not evaluate the modified expression:

```
subs(y^2 + sin(x), x = PI)
```

$$y^2 + \sin(\pi)$$

To evaluate the modified subexpression, use the `EvalChanges` option:

```
subs(y^2 + sin(x), x = PI, EvalChanges)
```

$$y^2$$

Alternatively, use the `eval` function to evaluate the result returned by `subs`:

```
S := subs(y^2 + sin(x), x = PI):
eval(S)
```

$$y^2$$

Example 4

The `subs` function with the `EvalChanges` option returns the same results as the evaluation of the whole expression:

```
eval(subs(sin(x + 3 - PI)*numeric::int(_plus(sin(k/y) $ k = 1..5),
                                       y = 0..1), x=-3));
subs(sin(x + 3 - PI)*numeric::int(_plus(sin(k/y) $ k = 1..5),
                                  y = 0..1), x = -3, EvalChanges)
```

$$0$$

$$0$$

The evaluation of the returned result is slower and less efficient than the evaluation of the modified subexpressions:

```
time(eval(subs(sin(x + 3 - PI)*numeric::int(_plus(sin(k/y) $ k = 1..5),
                                            y = 0..1), x = -3)));
time(subs(sin(x + 3 - PI)*numeric::int(_plus(sin(k/y) $ k = 1..5),
                                       y = 0..1), x = -3, EvalChanges))
```

$$12218.75$$

$$6265.625$$

Example 5

The following call results in the sequential substitution $x \to y \to z$:

```
subs(x^3 + y*z, x = y, y = z)
```

$$z^3 + z^2$$

Example 6

The `subs` function lets you use sequential and parallel substitutions. For example, substitute the operand in the following expressions sequentiallly:

```
subs(a^2 + b^3, a = b, b = a)
```

$$a^3 + a^2$$

```
subs(a^2 + b^3, b = a, a = b)
```

$$b^3 + b^2$$

For the same expression, parallel substitution swaps the identifiers:

```
subs(a^2 + b^3, [a = b, b = a])
```

$$a^3 + b^2$$

In the following call, the substitution of `y + x` for `a` yields the intermediate result `y + 2*x`. From there, the substitution of `z` for `x` results in `y + 2 z`:

```
subs(a + x, a = x + y, x = z)
```

$$y + 2\,z$$

Parallel substitution produces a different result. The following call substitues `a` with `x + y`. Simultaneously, this call substitutes the operand `x` *of the original expression* `a + x` with `z`:

```
subs(a + x, [a = x + y, x = z])
```

$$x + y + z$$

If you specify the substitutions using a set of a table of equations, the `subs` function also performs a parallel substitution:

```
subs(a + x, {a = x + y, x = z})
```

$$x+y+z$$

```
T := table(): T[a] := x + y: T[x] := z: T
```

a	$x+y$
x	z

```
subs(a + x, T)
```

$$x+y+z$$

```
delete T:
```

Example 7

You can combine sequential and parallel substitutions:

```
subs(a + x, {a = x + y, x = z}, x = y)
```

$$2\,y+z$$

Example 8

The `subs` function replaces only those operands that the `op` function can return. The following expression contains the subexpression `x + y` as the operand `op(f, [1, 2])`:

```
f := sin(z*(x + y)): op(f, [1, 2]);
```

$$x+y$$

Consequently, the `subs` function replaces this subexpression:

```
subs(f, x + y = z)
```

$$\sin(z^2)$$

Syntactically, the following sum does not contain the subexpression `x + y`. Therefore, the `subs` function does not replace it:

```
subs(x + y + z, x + y = z)
```

$$x + y + z$$

In contrast to `subs`, the `subsex` function finds and replaces partial sums and products:

```
subsex(x + y + z, x + y = z)
```

$$2\,z$$

```
subs(a*b*c, a*c = 5), subsex(a*b*c, a*c = 5)
```

$$a\,b\,c,\ 5\,b$$

```
delete f:
```

Example 9

You can substitute operands of expression sequences. Enclose sequences in parentheses:

```
subs((a, b, a*b), a = x)
```

$$x,\ b,\ b\,x$$

Example 10

The `Unsimplified` option suppresses simplification:

```
subs(a + b + 2, a = 1, b = 0, Unsimplified)
```

$$1 + 0 + 2$$

Example 11

If you try to substitute something in a domain, MuPAD ignores the substitution. For example, define a new domain with the methods `"foo"` and `"bar"`:

```
mydomain := newDomain("Test"):
mydomain::foo := x -> 4*x:
mydomain::bar := x -> 4*x^2:
```

Now try to replace every number 4 inside the domain with the number 3:

```
mydomain := subs(mydomain, 4 = 3):
```

That substitution does not have any effect:

```
mydomain::foo(x), mydomain::bar(x)
```

$$4\,x,\ 4\,x^2$$

To substitute objects in a domain method, you must substitute in the individual methods:

```
mydomain::foo := subs(mydomain::foo, 4 = 3):
mydomain::bar := subs(mydomain::bar, 4 = 3):
mydomain::foo(x), mydomain::bar(x)
```

$$3\,x,\ 3\,x^2$$

```
delete mydomain:
```

Parameters

`f`

An arbitrary MuPAD object

`old`, $\texttt{old}_1$, $\texttt{old}_2$, …

Arbitrary MuPAD objects

`new`, $\texttt{new}_1$, $\texttt{new}_2$, …

Arbitrary MuPAD objects

s_1, s_2, …

Either equations `old = new`, or lists or sets of such equations, or tables whose entries are interpreted as such equations.

Options

`EvalChanges`

After substitution, evaluate all modified subexpressions.

By default, the `subs` function does not evaluate the modified object. The `EvalChanges` option enforces the evaluation of all modified subexpressions. See “Example 3” on page 1-2014 and “Example 4” on page 1-2015.

`Unsimplified`

Do not simplify the result of a substitution.

As the last step of a substitution, MuPAD automatically simplifies (but does not evaluate) the modified object. The `Unsimplified` option suppresses the final simplification. See “Example 10” on page 1-2018.

Return Values

Copy of the input object with replaced operands.

Overloaded By

f

subset, _subset, _notsubset

Relation “is a subset of”

Syntax

```
A subset B
```

```
_subset(A, B)
```

```
not A subset B
```

```
_notsubset(A, B)
```

Description

`A subset B` represents the expression $A \subset B$.

A is a subset of B if $x \in A \Rightarrow x \in B$.

The function `_notsubset` exists for typesetting purposes. It is returned as the result of negating a `subset` expression. See “Example 4” on page 1-2022.

If called with symbolic arguments (anything but sets), these functions return a symbolic expression of type _in or the unevaluated input.

Examples

Example 1

When called with two sets, these functions return a Boolean value:

```
{1} subset {1,2,3},
{} subset {1},
{1} subset {1},
{1} subset {}
```

```
TRUE, TRUE, TRUE, FALSE
```

Example 2

Note: identifiers in sets are not assumed to be place-holders. See `?=` for details on syntactic equality.

```
{x} subset {1,2}
```

FALSE

Example 3

If one of the arguments is not a set, these functions return an equivalent symbolic expression:

```
{1} subset A, A subset {1}
```

$1 \in A, A \subset \{1\}$

Example 4

For “pretty typesetting”, the negation of `subset`is implemented in a special function environment:

```
not A subset B
```

$A \not\subset B$

```
type(%)
```

"_notsubset"

Parameters

A, B

MuPAD expressions

Return Values

TRUE, FALSE, or an expression.

Overloaded By

A, B

See Also

MuPAD Functions
`in` | `intersect` | `minus` | `union`

subsex

Extended substitution

Syntax

```
subsex(f, old = new, <Unsimplified>)
subsex(f, old1 = new1, old2 = new2, …, <Unsimplified>)
subsex(f, [old1 = new1, old2 = new2, …], <Unsimplified>)
subsex(f, {old1 = new1, old2 = new2, …}, <Unsimplified>)
subsex(f, table(old1 = new1, old2 = new2, …), <Unsimplified>)
subsex(f, s1, s2, …, <Unsimplified>)
```

Description

`subsex(f, old = new)` returns a copy of the object `f` in which all expressions matching `old` are replaced by the value `new`. In contrast to the function `subs`, `subsex` also replaces "incomplete" subexpressions.

`subsex` returns a modified copy of the object, but does not change the object itself.

`subsex(f, old = new)` searches `f` for subexpressions matching `old`. Each such subexpression is replaced by `new`.

In most cases, `subsex` leads to the same result as `subs`. However, in contrast to `subs`, `subsex` allows to replace "incomplete" subexpressions such as `a + b` in a sum `a + b + c`. In general, combinations of the operands of the n-ary "operators" `+`, `*`, `and`, `_exprseq`, `intersect`, `or`, `_lazy_and`, `_lazy_or`, and `union` can be replaced. In particular, partial sums and partial products can be replaced. Note that these operations are assumed to be commutative, e.g., `subsex(a*b*c, a*c = new)` does replace the partial product `a*c` by `new`. See "Example 1" on page 1-2025 and "Example 2" on page 1-2026.

`subsex` additionally replaces powers with the same base, if the exponent of the expression is an integer multiple of the replacement power, e.g. like in `subsex(a^4,`

`a^2 = new)`. This rule also matches inverted expressions like in `subsex(1/sqrt(x), sqrt(x)=new)`, which is internally equivalent to `subsex(x^(-1/2), x^(1/2)=new)`. Cf. “Example 3” on page 1-2026.

`subsex` is much slower than `subs`! If `subs` can do the substitution, use `subs` rather than `subsex`.

The call `subsex(f, old1 = new1, old2 = new2, ...)` invokes a “sequential substitution”. See the `subs` help page for details.

The call `subsex(f, [old1 = new1, old2 = new2, ...])` invokes a “parallel substitution”. See the `subs` help page for details.

The call `subsex(f, s1, s2, ...)` describes the most general form of substitution which may combine sequential and parallel substitutions. This call is equivalent to `subsex(... subsex(subsex(f, s1), s2), ...)`. Depending on the form of `s1`, `s2`, ..., sequential or parallel substitutions are carried out in each step. An example can be found on the `subs` help page.

After substitution, the result is not evaluated. Use the function `eval` to enforce evaluation. Cf. “Example 5” on page 1-2028.

Operands of expression sequences can be replaced by `subsex`. Such objects are not flattened. Cf. “Example 6” on page 1-2028.

The call `subsex(f)` is allowed; it returns `f` without modifications.

Examples

Example 1

We demonstrate some simple substitutions; `subsex` finds and replaces partial sums and products:

```
subsex(a + b + c, a + c = x)
```

$$b + x$$

```
subsex(a*b*c, a*c = x)
```

$$b\,x$$

```
subsex(a * (b + c) + b + c, b + c = a)
```

$$a^2 + a$$

```
subsex(a + b*c*d + b*d, b*d = c);
```

$$c^2 + c + a$$

Example 2

We replace subexpressions inside an expression sequence and a symbolic union of sets:

```
subsex((a, b, c, d), (b, d) = w)
```

$$a, c, w$$

```
subsex(a union b union c, a union b = w)
```

$$c \cup w$$

The same can be achieved by using the functional equivalent `union` of the operator `union`:

```
subsex(_union(a, b, c), _union(a, b) = w)
```

$$c \cup w$$

Example 3

`subsex` replaces powers with with the same base, if the exponent of the expression is an integer multiple of the replacement power:

```
subsex(1/a^4, a^2 = X)
```

$$\frac{1}{X^2}$$

This holds even for exponents which are expressions:

```
subsex(1/a^(6*x), a^(2*x) = X)
```

$$\frac{1}{X^3}$$

`1/sqrt(x)` is internally `x^(-1/2)`, so the replacement of `sqrt(x)` which is internally `x^(1/2)` works, too:

```
subsex(1/sqrt(n), sqrt(n) = X)
```

$$\frac{1}{X}$$

Example 4

`subsex` (and also `subs`) are often useful to convert the output of one command into a form required by the next one. As an example, we compute the Laplace transform of the two-dimensional ODE

$$x'(t) = x(t) + 2\,y(t),\ x(0) = 1$$

,

$$y'(t) = 5\,x(t) + 2\,y(t),\ y(0) = -2$$

,

and transform the result into a form suitable for calling `solve` by replacing the unknown Laplace transforms by symbolic names:

```
xfrm1 := laplace(x'(t) = x(t) + 2*y(t), t, s);
xfrm2 := laplace(y'(t) = 5*x(t) + 2*y(t), t, s)
```

$$s\,\mathrm{laplace}(x(t), t, s) - x(0) = \mathrm{laplace}(x(t), t, s) + 2\,\mathrm{laplace}(y(t), t, s)$$

$$s\,\mathrm{laplace}(y(t), t, s) - y(0) = 5\,\mathrm{laplace}(x(t), t, s) + 2\,\mathrm{laplace}(y(t), t, s)$$

For readability, we give names to both substitutions:

```
sub_x := laplace(x(t),t,s) = X:
sub_y := laplace(y(t),t,s) = Y:
```

```
Leqn1 := subs(xfrm1, sub_x, sub_y, x(0) = 1);
Leqn2 := subs(xfrm2, sub_x, sub_y, y(0) =-2)
```

$$X\,s - 1 = X + 2\,Y$$

$$Y\,s + 2 = 5\,X + 2\,Y$$

```
solve({Leqn1, Leqn2}, {X, Y})
```

$$\begin{cases} \varnothing & \text{if } s^2 = 3\,s + 8 \\ \left\{\left[X = -\frac{s-6}{-s^2+3\,s+8},\ Y = \frac{2\,s-7}{-s^2+3\,s+8}\right]\right\} & \text{if } s^2 \neq 3\,s + 8 \end{cases}$$

(This example was suggested by MuPAD user Brad Cooper.)

Example 5

The result of `subsex` is not evaluated. In the following call, the identifier `sin` is not replaced by its value, i.e., by the procedure defining the behavior of the system's sine function. Consequently, `sin(2*PI)` is not simplified to 0 by this procedure:

```
subsex(sin(2*x*y), x*y = PI)
```

$$\sin(2\,\pi)$$

The function `eval` enforces evaluation:

```
eval(subsex(sin(2*x*y), x*y = PI))
```

$$0$$

Example 6

Operands of expression sequences can be subtituted. Note that sequences need to be enclosed in brackets:

```
subsex((a, b, a*b*c), a*b = x)
```

$$a, b, c\,x$$

Example 7

The option `Unsimplified` suppresses simplification:

```
subsex(2 + a + b, a + b = 0, Unsimplified)
```

$$2 + 0$$

Parameters

`f`

An arbitrary MuPAD object

`old`, $\texttt{old}_1$, $\texttt{old}_2$, …

Arbitrary MuPAD objects

`new`, $\texttt{new}_1$, $\texttt{new}_2$, …

Arbitrary MuPAD objects

$\texttt{s}_1$, $\texttt{s}_2$, …

Either equations `old = new`, or lists or sets of such equations, or tables whose entries are interpreted as such equations.

Options

`Unsimplified`

Prevents simplification of the returned object after substitution

As the last step of a substitution, the modified object is simplified (however, not evaluated). This option suppresses this final simplification. An example can be found on the `subs` help page.

Return Values

Copy of the input object with replaced operands.

Overloaded By

f

See Also

MuPAD Functions

`evalAt` | `extnops` | `extop` | `extsubsop` | `has` | `map` | `match` | `op` | `subs` | `subsop`

subsop

Replace operands

Syntax

```
subsop(object, i1 = new1, i2 = new2, …, <Unsimplified>)
```

Description

`subsop` returns a modified copy of the object, but does not change the object itself.

`subsop(object, i = new)` replaces the operand `op(object, i)` by `new`. Operands are specified in the same way as with the function `op`: `i` may be an integer or a list of integers. E.g., `subsop(object, [j, k] = new)` replaces the suboperand `op(op(object, j), k)`. Cf. “Example 2” on page 1-2032. In contrast to `op`, ranges cannot be used in `subsop` to specify more than one operand to replace. Several substitution equations have to be specified instead.

If several operands are to be replaced, the specified substitutions are processed in sequence from left to right. Each substitution is carried out and the result is processed further with the next substitution. The intermediate objects are not simplified.

The result of `subsop` is not evaluated further. It can be evaluated via the function `eval`. Cf. “Example 3” on page 1-2033.

Operands of expression sequences can be replaced by `subsop`. Such objects are not flattened.

Note that the order of the operands may change by replacing operands and evaluating the result. Cf. “Example 4” on page 1-2033.

`FAIL` is returned if an operand cannot be accessed.

Substitution via `subsop` is faster than via `subs` or `subsex`.

The call `subsop(object)` is allowed; it returns the object without modifications.

Examples

Example 1

We demonstrate how to replace one or more operands of an expression:

```
x := a + b: subsop(x, 2 = c)
```

$$a + c$$

```
subsop(x, 1 = 2, 2 = c)
```

$$c + 2$$

Also the 0-th operand of an expression (the “operator”) can be replaced:

```
subsop(x, 0 = _mult)
```

$$a\,b$$

The variable `x` itself was not affected by the substitutions:

```
x
```

$$a + b$$

```
delete x:
```

Example 2

The following call specifies the suboperand `c` by a list of integers:

```
subsop([a, b, f(c)], [3, 1] = x)
```

$$[a, b, f(x)]$$

Example 3

This example demonstrates the effect of simplification. The following substitution replaces the first operand `a` by 2. The result simplifies to 3:

```
subsop(a + 1, 1 = 2)
```

$$3$$

The option `Unsimplified` suppresses the simplification:

```
subsop(a + 1, 1 = 2, Unsimplified)
```

$$2 + 1$$

The next call demonstrates the difference between *simplification* and *evaluation*. After substitution of `PI` for `x`, the identifier `sin` is not evaluated, i.e., the body of the system function `sin` is not executed:

```
subsop(sin(x),  1 = PI)
```

$$\sin(\pi)$$

Evaluation of `sin` simplifies the result:

```
eval(%)
```

$$0$$

Example 4

The order of operands may change by substitutions. Substituting `z` for the identifier `b` changes the internal order of the terms in `x`:

```
x := a + b + c: op(x)
```

$$a,\ b,\ c$$

```
x := subsop(x, 2 = z): op(x)
```

$$a, c, z$$

```
delete x:
```

Parameters

`object`

Any MuPAD object

i_1, i_2, …

Integers or lists of integers

new_1, new_2, …

Arbitrary MuPAD objects

Options

`Unsimplified`

As the last step of a substitution, the modified object is simplified (however, not evaluated). This option suppresses this final simplification. Cf. “Example 3” on page 1-2033.

Return Values

Input object with replaced operands or `FAIL`.

Overloaded By

object

Algorithms

For overloading `subsop`, it is sufficient to handle the cases `subsop(object)` and `subsop(object, i = new)`.

The case where the position of the operand to be replaced is given by a list is always handled recursively: First, `op` is called with the list bar the last element to find the object to substitute in (using the overloading of `op` if present, storing all the intermediate results), then the substitution is performed on that sub-object (using the overloading of `subsop` of the form `subsop(subobj, i = new)`). The result is substituted into the last-but-one result of the recursive `op` call, again respecting any overloading of `subsop`, and so on up to the front of the list.

See Also

MuPAD Functions

substring

Extract a substring from a string

Syntax

```
substring(string, i)

substring(string, i, l)

substring(string, i .. j)
```

Description

`substring(string, i)` returns the *i*-th character of a string.

`substring(string, i, l)` returns the substring of length `l` starting with the *i*-th character of the string.

`substring(string, i..j)` returns the substring consisting of the characters *i* through *j*, inclusive.

The empty string `""` is returned if the length `l = 0` is specified.

`substring` is considered obsolete. You should use index access to strings instead.

Examples

Example 1

We extract individual characters from a string:

```
substring("123456789", i) $ i = 1..9
```

```
"1", "2", "3", "4", "5", "6", "7", "8", "9"
```

Substrings of various lengths are extracted:

```
substring("123456789", 1, 2), substring("123456789", 4, 4)
```

```
"12", "4567"
```

Substrings of length 0 are empty strings:

```
substring("123456789", 4, 0)
```

```
""
```

Ranges may be used to specify the substrings:

```
substring("123456789", 1..9)
```

```
"123456789"
```

Example 2

The following `while` loop removes all trailing blank characters from a string:

```
string := "MuPAD       ":
while substring(string, length(string)) = " " do
  string := substring(string, 1..length(string) - 1)
end_while
```

```
"MuPAD"
```

Parameters

`string`

A nonempty character string

`i`

An integer between 1 and `length(string)`

`l`

An integer between `1` and `length(string)`

`j`

An integer between `i` and `length(string)`

Return Values

Character string

See Also

MuPAD Functions
`length` | `stringlib::subs` | `strmatch`

_subtract

Subtract expressions

Syntax

```
_subtract(x, y)
```

Description

`_subtract(x, y)` subtracts `y` from `x`.

The difference operator `-` does not call `_subtract(x, y)`. The difference `x - y` is equivalent to `x + (-y) = _plus (x, _negate(y))`.

To implement the slot `d::_subtract` for your domain `d`, use the following convention:

- If both `x` and `y` are elements of `d`, the slot must return an appropriate difference of type `d`.
- If `x` or `y` is not an element of `d` and cannot be converted to an element of `d`, the slot must return `FAIL`.
- If `x` or `y` is not an element of `d`, but can be converted to type `d`, use the following approach. This object must be converted to an element of `d` only if the mathematical semantics is obvious to all users of `d`, including the users who treat this domain as a "black box". For example, you can regard integers as rational numbers because of the natural mathematical embedding, but you must make sure that all users are aware of this approach. Otherwise, the `"_subtract"` method must return `FAIL` instead of using implicit conversions. If you use implicit conversions for the elements of your domain, document these conversions.

In the MuPAD standard installation, most of the library domains comply with this convention.

`_subtract` can subtract polynomials of the `DOM_POLY` type from a polynomial of the same type. The polynomials must have the same indeterminates and the same coefficient ring.

`_subtract` can subtract finite sets from a finite set. For finite sets `X` and `Y`, the difference is the set $\{x - y \mid x \in X, y \in Y\}$.

Examples

Example 1

Compute the difference of the following arithmetical expressions by using the `_subtract` method. Then, compute the difference of the same expressions by using the difference operator:

```
_subtract(x, y), x - y
```

$$x - y, x - y$$

Although both `_subtract` and the difference operator return the same result for these expressions, the `_subtract` call is not equivalent to `x - y`:

```
type(hold(x - y)), type(hold(_subtract(x, y)))
```

"_plus", "_subtract"

Example 2

Use the `_subtract` function when combining the following lists:

```
zip([a, b, c, d], [1, 2, 3, 4], _subtract)
```

$$[a - 1, b - 2, c - 3, d - 4]$$

Parameters

x, y

arithmetical expressions, polynomials of type `DOM_POLY`, or sets

Return Values

arithmetical expression, a polynomial, or a set.

Overloaded By

x, y

See Also

MuPAD Functions

`*` | `+` | `-` | `/` | `^` | `_invert` | `poly` | `Pref::keepOrder`

sum

Definite and indefinite summation

Syntax

```
sum(f, i)

sum(f, i = a .. b)

sum(f, i = RootOf(p, x))
```

Description

`sum(f, i)` computes a symbolic antidifference of $f(i)$ with respect to i.

`sum(f, i = a..b)` tries to find a closed form representation of the sum $\sum_{i=a}^{b} f(i)$.

`sum` serves for simplifying *symbolic* sums (the discrete analog of integration). It should *not* be used for simply adding a finite number of terms: if `a` and `b` are integers of type `DOM_INT`, the call `_plus(f $ i = a..b)` gives the desired result, while `sum(f, i = a..b)` may return unevaluated. `expand` may be used to sum such an unevaluated finite sum. See "Example 3" on page 1-2044.

`sum(f, i)` computes the indefinite sum of `f` with respect to `i`. This is an expression `g` such that $f(i) = g(i + 1) - g(i)$.

It is implicitly assumed that `i` runs through integers only.

`sum(f, i = a..b)` computes the definite sum with `i` running from `a` to `b`.

If `a` and `b` are numbers, then they must be integers.

If `b - a` is a nonnegative integer, then the explicit sum $f(a) + f(a + 1) + \ldots + f(b)$ is returned, provided that this sum has no more than 1000 terms.

`sum(f, i = RootOf(p, x))` computes the sum with `i` extending over all roots of the polynomial `p` with respect to `x`.

If `f` is a rational function of `i`, a closed form of the sum will be found.

See “Example 2” on page 1-2044.

The system returns a symbolic call of `sum` if it cannot compute a closed form representation of the sum.

Infinite symbolic sums without symbolic parameters can be evaluated numerically via `float` or `numeric::sum`. Cf. “Example 4” on page 1-2046.

Examples

Example 1

We compute some indefinite sums:

```
sum(1/(i^2 - 1), i)
```

$$-\frac{1}{2\,(i-1)}-\frac{1}{2\,i}$$

```
sum(1/i/(i + 2)^2, i)
```

$$\frac{\psi'(i+2)}{2}-\frac{1}{4\,i+4}-\frac{1}{4\,i}$$

```
sum(binomial(n + i, i), i)
```

$$\begin{cases} 0 & \text{if } n=-1 \\ \dfrac{i\binom{i+n}{i}}{n+1} & \text{if } n\neq -1 \end{cases}$$

We compute some definite sums. Note that $\pm\infty$ are valid boundaries:

```
sum(1/(i^2 + 21*i), i = 1..infinity)
```

$$\frac{18858053}{108636528}$$

```
sum(1/i, i = a .. a + 3)
```

$$\psi(a+4) - \psi(a)$$

```
expand(%)
```

$$\frac{1}{a+1} + \frac{1}{a+2} + \frac{1}{a+3} + \frac{1}{a}$$

Example 2

We compute some sums over all roots of a polynomial:

```
sum(i^2, i = RootOf(x^3 + a*x^2 + b*x + c, x))
```

$$a^2 - 2\,b$$

```
sum(1/(z + i), i = RootOf(x^4 - y*x + 1, x))
```

$$\frac{4\,z^3 + y}{z^4 + y\,z + 1}$$

Example 3

`sum` can compute finite sums if indefinite summation succeeds:

```
sum(1/(i^2 + i), i = 1..100)
```

$$\frac{100}{101}$$

`_plus` yields the same result more quickly if the number of summands is small:

```
_plus(1/(i^2 + i) $ i = 1..100)
```

$$\frac{100}{101}$$

In such cases, `sum` is much more efficient than `_plus` if the number of summands is large:

```
sum(1/(i^2 + i), i = 1..10^30)
```

$$\frac{1000000000000000000000000000000}{1000000000000000000000000000001}$$

Finite sums for which no indefinite summation is possible are expanded if they have no more than 1000 terms:

```
sum(binomial(n, i), i = 0..4)
```

$$n + \binom{n}{2} + \binom{n}{3} + \binom{n}{4} + 1$$

An application of `expand` is necessary to expand the binomials:

```
expand(%)
```

$$\frac{n^4}{24} - \frac{n^3}{12} + \frac{11\,n^2}{24} + \frac{7\,n}{12} + 1$$

Finite sums with more than 1000 terms are not expanded:

```
sum(binomial(n, i), i = 0..1000)
```

$$\sum_{i=0}^{1000} \binom{n}{i}$$

You might use `expand` here to expand the sum and obtain a huge expression. If you really want to do that, we recommend using `_plus` directly.

However, if one of the boundaries is symbolic, then `_plus` cannot be used:

```
_plus(1/(i^2 + i) $ i = 1..n)
```

$$\_plus\left(\frac{1}{i^2+i}\ \$\ i = 1..n\right)$$

```
_plus(binomial(n, i) $ i = 0..n)
```

$$\_plus\left(\binom{n}{i}\ \$\ i = 0..n\right)$$

```
sum(1/(i^2 + i), i = 1..n), sum(binomial(n, i), i = 0..n)
```

$$\frac{n}{n+1},\ 2^n$$

Example 4

The following infinite sum cannot be computed symbolically:

```
sum(ln(i)/i^5, i = 1..infinity)
```

$$\sum_{i=1}^{\infty} \frac{\ln(i)}{i^5}$$

We obtain a floating-point approximation via `float`:

```
float(%)
```

$$0.02857378051$$

Alternatively, the function `numeric::sum` can be used directly. This is usually much faster than applying `float`, since it avoids the overhead of `sum` attempting to compute a symbolic representation:

```
numeric::sum(ln(i)/i^5, i = 1..infinity)
```

$$0.02857378051$$

Parameters

f

An arithmetical expression depending on `i`

i

The summation index: an identifier or indexed identifier

a, b

The boundaries: arithmetical expressions

p

A polynomial of type `DOM_POLY` or a polynomial expression

x

An indeterminate of `p`

Return Values

arithmetical expression.

Algorithms

The function `sum` implements Abramov's algorithm for rational expressions, Gosper's algorithm for hypergeometric expressions, and Zeilberger's algorithm for the definite summation of holonomic expressions.

MuPAD Functions

`+` | `_plus` | `int` | `numeric::sum` | `product` | `rec` | `sum::addpattern`

sum::addpattern

Add patterns for definite and indefinite summation

Syntax

```
sum::addpattern(pat, k, res, <[var, …], <[cond, …]>>)
```

```
sum::addpattern(pat, k = a .. b, res, <[var, …], <[cond, …]>>)
```

Description

`sum::addpattern(pat, k, res)` teaches `sum` to make use of $\sum_k \text{pat} = \text{res}$.

`sum::addpattern(pat, k=a..b, res)` teaches `sum` that $\sum_{x=a}^{b} \text{pat} = \text{res}$.

A part of a computer algebra system's summation abilities stems from mathematical pattern matching. The MuPAD pattern matcher can be extended at runtime with `sum::addpattern`.

For definite summation, each bound is either an arithmetical expression which may contain pattern variables, or an identifier which can be used as a variable in the result and condition terms.

Users can include pattern variables and conditions on these by giving additional arguments. These conditions, as well as the result, are protected from premature evaluation, i.e., it is not necessary to write `hold( _not @ iszero )(a^2-b)`, a simple `not iszero(a^2-b)` suffices.

The difference between `not iszero(a^2-b)` and `a^2-b <> 0` when given as a condition is that the latter takes into account assumptions on the identifiers encountered, while the first does not. Cf. “Example 4” on page 1-2050.

Patterns introduced by `sum::addpattern` are also used in recursive calls of `sum` and are automatically extended to include simple applications of summation by change of variables. Cf. “Example 1” on page 1-2049.

Environment Interactions

Calling `sum::addpattern` changes the expressions returned by future calls to `sum`.

Examples

Example 1

Not surprisingly, MuPAD does not know how to do an indefinite summation with the function *foo*:

```
sum(foo(n), n)
```

$$\sum_n \text{foo}(n)$$

We add a pattern for this function:

```
sum::addpattern(foo(k), k, bar(k))
```

```
sum(foo(n), n)
```

$$\text{bar}(n)$$

Note that this pattern is also used indirectly:

```
sum(foo(k+3),k)
```

$$\text{bar}(k+3)$$

Example 2

Definite sums can be added similarly:

```
sum::addpattern(foo(k), k=1..infinity, bar(k))
```

```
sum(foo(k), k=1..infinity)
```

$$\text{bar}(k)$$

The above pattern will also match this definite sum with different bounds:

```
sum(foo(k), k=3..infinity)
```

$$\mathrm{bar}(k) - \mathrm{foo}(2) - \mathrm{foo}(1)$$

Note that this pattern is also used indirectly:

```
sum(foo(k)+1/k^3, k=1..infinity)
```

$$\zeta(3) + \mathrm{bar}(k)$$

The bounds may also be variables occurring in the pattern or the result:

```
sum::addpattern(foo(k,a), k=0..a, bar(a), [a])
```

```
sum(foo(k,7), k=0..7)
```

$$\mathrm{bar}(7)$$

Example 3

The name of the summation variable used in the call to `sum::addpattern` does not restrict later calls to `sum`:

```
sum::addpattern(x^(2*i+1)/(2*i+1), i=0..infinity,
                piecewise([abs(x) < 1,
                           arccoth(x) + PI/2*sqrt(-1/x^2)*x]),
                [x])
```

```
sum(x^(2*n+1)/(2*n+1),n=0..infinity)
```

$$\begin{cases} \mathrm{arccoth}(x) + \dfrac{\pi x \sqrt{-\frac{1}{x^2}}}{2} & \text{if } |x| < 1 \end{cases}$$

Example 4

Conditions are checked using `is` and therefore react to assumptions:

```
sum::addpattern(binomial(-1/2, k)*x^(2*k^2 + 1)/(2*k + 1),
                                k = 0..infinity, arcsinh(x),
                                       [x], [abs(x) < 1])
```

```
sum(binomial(-1/2, k)*x^(2*k^2 + 1)/(2*k + 1),
    k = 0..infinity) assuming -1 < x < 1
```

$$\operatorname{arcsinh}(x)$$

```
sum(binomial(-1/2, k)*x^(2*k^2 + 1)/(2*k + 1),
    k = 0..infinity) assuming x > 1
```

$$\sum_{k=0}^{\infty} \frac{x^{2k^2+1}\binom{-\frac{1}{2}}{k}}{2k+1}$$

If MuPAD cannot decide whether the conditions are satisfied, a piecewise defined object is returned:

```
sum(binomial(-1/2, k) * x^(2*k^2+1)/(2*k+1),
    k = 0..infinity)
```

$$\begin{cases} \operatorname{arcsinh}(x) & \text{if } |x| < 1 \end{cases}$$

If either the conditions are not satisfied or substituting the values into the result yields an error, the pattern is ignored. There is no need to include a condition to guard against an error, MuPAD simply computes the sum as usual:

```
sum::addpattern(c^k, k=0..n, (c^n-1)/(c-1), [c]);
sum(1^k, k=0..n)
```

$$n+1$$

Parameters

pat

The pattern to match: an arithmetical expression in `k`.

k

The summation index: an identifier.

a .. b

The boundaries for a definite summation: arithmetical expressions or identifiers.

res

The pattern for the result of the summation: an arithmetical expression

var, …

"pattern variables": placeholders in `pat` and `ret`, i.e., identifiers or indexed identifiers. They do not represent themselves but almost arbitrary MuPAD expressions not containing `k`. You may restrict them by the conditions in the 5th parameter.

cond, …

Conditions on the pattern variables

Return Values

Object of type `DOM_NULL`

See Also

MuPAD Functions

`sum`

surd

N -th root

Syntax

```
surd(x, n)
```

Description

For a complex number `x` and integer `n`, `surd(x, n)` returns the n-th root of x whose (complex) argument is closest to that of `x`.

If `x` is a positive real number, `surd(x, n)` coincides with `x^(1/n)`. If `x` is a negative real number and `n` is odd, then `surd(x, n)` coincides with `-|x|^(1/n)`.

`surd(x, n)` returns that complex solution y of $y^n = x$ with polar angle closest to that of x; among two equally distant y's, the one with smaller argument is chosen. In contrast, `x^(1/n)` represents the solution with the smallest absolute value of the polar angle in the range $(-\pi, \pi]$.

If `n` is a numerical value, it must be a non-zero integer. If it is symbolic, it is understood to represent a non-zero integer.

`surd(x, 2)` is mathematically equivalent to `sqrt(x)`. Unlike `sqrt`, however, `surd` may return an unevaluated symbolic call.

Environment Interactions

When called with a floating-point argument, the function is sensitive to the environment variable `DIGITS` which determines the numerical working precision.

Examples

Example 1

If n is odd and x is real, then `surd(x, n)` is real, too. On the other hand, `x^(1/n)` is not real if x is negative:

```
surd(-27, 3), surd(-27.0, 3), (-27)^(1/3), (-27.0)^(1/3)
```

$$-3,\ -3.0,\ 3\,(-1)^{1/3},\ 1.5 + 2.598076211\,i$$

Example 2

`surd` may be called with symbolic arguments:

```
surd(3, n)
```

$$3^{1/n}$$

Sometimes, `surd` returns an unevaluated function call:

```
surd(x, 3), surd(x, n^2 + n)
```

$$\sqrt[3]{x},\ \sqrt[n^2+n]{x}$$

Parameters

x

An arithmetical expression

n

An arithmetical expression

Return Values

Arithmetical expression.

See Also

MuPAD Functions

`_power` | `sqrt`

sysname

Name of the operating system

Syntax

```
sysname(<Arch>)
```

Description

`sysname()` returns information on the operating system on which MuPAD is currently executed. It can return one of the following strings:

- `"UNIX"` for UNIX operating systems including Mac OS X and Linux,
- `"MSDOS"` for MS-DOS® operating systems including Microsoft Windows,

`sysname(Arch)` returns a more specific name of the operating system as a character string.

Examples

Example 1

On a 64-bit Microsoft Windows operating system, `sysname` returns the following values:

```
sysname(), sysname(Arch)
```

```
"MSDOS", "win64"
```

On a 32-bit Microsoft Windows operating system, `sysname(Arch)` returns:

```
sysname(Arch)
```

```
"win32"
```

Example 2

On a 64-bit Linux operating system, `sysname` returns the following values:

```
sysname(), sysname(Arch)
```

```
"UNIX", "glnxa64"
```

Example 3

On a 64-bit Apple Macintosh operating system, `sysname` returns the following values:

```
sysname(), sysname(Arch)
```

```
"UNIX", "maci64"
```

Options

`Arch`

Makes `sysname` return more specific information on the architecture

Return Values

character string.

See Also

MuPAD Functions

`system`

sysorder

Compare objects according to the internal order

Syntax

```
sysorder(object1, object2)
```

Description

`sysorder(object1, object2)` returns `TRUE` if the MuPAD internal order of `object1` is less than or equal to the order of `object2`. Otherwise, `FALSE` is returned.

Note: The exceptions are domains.

One should not try and use the internal order to sort objects according to specific criteria. E.g., its does not necessarily reflect the natural ordering of numbers or strings. Further, the internal order may differ between different MuPAD versions.

The only feature one may rely upon is its uniqueness. Cf. “Example 2” on page 1-2059.

Examples

Example 1

We give some examples how `sysorder` behaves in the current MuPAD version. For numbers, the internal order is equal to the natural order:

```
sysorder(3, 4) = bool(3 <= 4),
sysorder(45, 33) = bool(45 <= 33),
sysorder(0, 4) = bool(0 <= 4)
```

$$\text{TRUE} = \text{TRUE},\ \text{FALSE} = \text{FALSE},\ \text{TRUE} = \text{TRUE}$$

```
sysorder(1/3, 1/4) = bool(1/3 <= 1/4),
sysorder(-4, 2) = bool(-4 <= 2),
sysorder(-4, -2) =  bool(-4 <= -2)
```

$$\text{FALSE} = \text{FALSE},\ \text{TRUE} = \text{TRUE},\ \text{TRUE} = \text{TRUE}$$

Example 2

We give a simple application of `sysorder`. Suppose, we want to implement a function `f`, say, whose only known property is its skewness `f(-x) = -f(x)`. Expressions involving `f` should be simplified automatically, e.g., `f(x) + f(-x)` should yield zero for any argument `x`. To achieve this, we use `sysorder` to decide, whether a call `f(x)` should return `f(x)` or `-f(-x)`:

```
f := proc(x) begin
       if sysorder(x, -x) then
            return(-procname(-x))
       else return(procname(x))
       end_if;
     end_proc:
```

For numerical arguments, `f` prefers to rewrite itself with positive arguments:

```
f(-3), f(3), f(-4.5), f(4.5), f(-2/3), f(2/3)
```

$$-f(3),\ f(3),\ -f(4.5),\ f(4.5),\ -f\left(\frac{2}{3}\right),\ f\left(\frac{2}{3}\right)$$

For other arguments, the result is difficult to predict:

```
f(x), f(-x), f(sqrt(2) + 1), f(-sqrt(2) - 1)
```

$$-f(-x),\ f(-x),\ f(\sqrt{2}+1),\ -f(\sqrt{2}+1)$$

With this implementation, expressions involving `f` simplify automatically:

```
f(x) + f(-x) - f(3)*f(x) + f(-3)*f(-x) + sin(f(7)) + sin(f(-7))
```

$$0$$

```
delete f:
```

Parameters

object1, object2

Arbitrary MuPAD objects

Return Values

TRUE or FALSE.

See Also

MuPAD Functions

`_less` | `listlib::removeDupSorted` | `sort`

system

Execute a command of the operating system

Syntax

```
! command
```

```
system(command)
```

Description

`system("command")` executes a command of the operating system or a program, respectively.

`!command` is equivalent to `system("command"):`; note that `!command` will suppress output of its return value.

The syntax `!command` is allowed during interactive input only, not when reading MuPAD input from a file. "`!`" must be the first character on the input line.

`system` is not available in all MuPAD versions. If not available, a call to `system` results in the following error message:

```
Error: Function not available for this client [system].
```

`system("command")` sends the command to the operating system. E.g., this command may start another application program on the computer. The return value 0 indicates that the command was executed successfully. Otherwise, an integer error code is returned which depends on the operating system and the command.

If the called command writes output to `stderr` on UNIX systems, the output will go to the MuPAD `stderr`. Outputs on the standard output channel will be inserted in the command's output, but are not accessible programmatically.

Examples

Example 1

On a UNIX system, the `date` command is executed. The command output is printed to the screen, the error code 0 for successful execution is returned to the MuPAD session:

```
errorcode := system("date"):
```

```
Fri Sep 29 14:42:13 MEST 2000
```

```
errorcode
```

```
    0
```

Now the `date` command is called with the command line option `'+%m'` in order to display the current month only:

```
errorcode := system("date '+%m'"):
```

```
09
```

Missing the prefix `'+'` in the command line option of `date`, `date` and therefore `system` returns an error code. Note that the error output goes to `stderr`:

```
system("date '%m'")
```

```
    1
```

```
delete errorcode:
```

Example 2

The output of a program started with the `system` command cannot be accessed in MuPAD directly, but it can be redirected into a file and then be read using the `read` or `ftextinput` command:

```
system("echo communication example > comm_file"):
ftextinput("comm_file")
```

```
"communication example"
```

```
system("rm -f comm_file"):
```

Parameters

`command`

A command of the operating system or a name of a program as a MuPAD character string

Return Values

“error code”: an integer.

See Also

MuPAD Functions

`sysname`

table

Create a table

Syntax

```
table()
```

```
table(index1 = entry1, index2 = entry2, …, <default>)
```

```
table(<list>, <set>, <tab>, …, <default>)
```

Description

`table()` creates a new empty table.

`table(index1 = entry1, index2 = entry2, ...)` creates a new table with the given indices and entries.

In MuPAD, tables are the most flexible objects for storing data. In contrast to arrays or lists, arbitrary MuPAD objects can be used as indices. Indexed access to table entries is fast and nearly independent of the size of the table. Thus, tables are suitable containers for large data.

For a table`T`, say, an indexed call `T[index]` returns the corresponding entry. If no such entry exists, the default value of the table is returned, if the table has one. If no default value has been set and, the indexed expression `T[index]` is returned symbolically.

An indexed assignment of the form `T[index] := entry` adds a new entry to an existing table `T` or overwrites an existing entry associated with the index.

`table` can be used to create tables from other tables, lists or sets of equations. Cf. “Example 2” on page 1-2066.

`table` is used for the explicit creation of a table. There also is the following mechanism for creating a table implicitly.

If the value of an identifier `T`, say, is neither a table nor an array nor an hfarray nor a list, then an indexed assignment `T[index] := entry` is equivalent to `T :=`

`table(index = entry)`. I.e., implicitly, a new table with one entry is created. Cf. “Example 3” on page 1-2067.

If the value of `T` was either a table or an array or an hfarray or a list, then the indexed assignment only inserts a new entry without changing the type of `T` implicitly.

Table entries can be deleted with the function `delete`. Cf. “Example 4” on page 1-2067.

Examples

Example 1

The following call creates a table with two entries:

```
T := table(a = 13, c = 42)
```

a	13
c	42

The data may be accessed via indexed calls. Note the symbolic result for the index `b` which does not have a corresponding entry in the table:

```
T[a], T[b], T[c]
```

$$13,\ T_b,\ 42$$

Entries of a table may be changed via indexed assignments:

```
T[a] := T[a] + 10: T
```

a	23
c	42

Expression sequences may be used as indices or entries, respectively. Note, however, that they have to be enclosed in brackets when using them as input parameters for `table`:

```
T := table((a, b) = "hello", a + b = (50, 70))
```

$a + b$	50, 70
a, b	"hello"

```
T[a + b]
```

50, 70

Indexed access does not require additional brackets:

```
T[a, b] := T[a, b]." world": T
```

$a + b$	50, 70
a, b	"hello world"

```
delete T:
```

Example 2

A `table` can be created from other tables, lists or sets:

```
table(table(a = 1, b = 2),
      {a = 3, c = 4},
      [b = 5, e = 6])
```

a	3
b	5
c	4
e	6

Please note that a set has no order of operands. When a set contains several values under the same index, the table entry is chosen “randomly”:

```
table({a = 3, a = 4});
table({a = 4, a = 3})
```

a	4

Example 3

Below, a new table is created implicitly by an indexed assignment using an identifier `T` without a value:

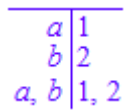
```
delete T: T[4] := 7: T
```

```
delete T:
```

Example 4

Use `delete` to delete entries:

```
T := table(a = 1, b = 2, (a, b) = (1, 2))
```



```
delete T[b], T[a, b]: T
```

```
delete T:
```

Example 5

One of the uses of tables is to count the number of occurrences of some objects. In this situation, an implementation not using default values would have to look like this:

```
T := table():
L := [1,2,3,a,b,c,a,b,a]:
for i in L do
```

```
  if contains(T, i) then
    T[i] := T[i] + 1;
  else
    T[i] := 1;
  end_if;
end_for:
T
```

1	1
2	1
3	1
a	3
b	2
c	1

Note the test whether `T[i]` has already been set. If it has not, we cannot use its previous value, because that would remain symbolic:

```
T := table():
T[a] := T[a] + 1:
T
```

a	$T_a + 1$

By creating `T` as `table(0)` instead of `table()`, we can tell MuPAD to regard `T[i]` as `0` if it has not been told anything else and the code from above becomes substantially shorter and, much more important, much easier to read:

```
T := table(0):
L := [1,2,3,a,b,c,a,b,a]:
for i in L do
  T[i] := T[i] + 1;
end_for:
T
```

1	1
2	1
3	1
a	3
b	2
c	1

A slightly more complicated version counting all identifiers in an expression:

```
ex := sin(a*x+b)-cos(c+x):
cnt := table(0):
misc::maprec(ex,
  {DOM_IDENT} = (x -> (cnt[x] := cnt[x]+1; x))):
cnt
```

_mult	2
_plus	3
a	1
b	1
c	1
cos	1
sin	1
x	2

Parameters

$\mathtt{index}_1$, $\mathtt{index}_2$, …

The indices: arbitrary MuPAD objects

$\mathtt{entry}_1$, $\mathtt{entry}_2$, …

The corresponding entries: arbitrary MuPAD objects

`list`

A list of equations

`set`

A set of equations

`tab`

A table

`default`

The default value: A MuPAD object which is not an equation, a list, a set, nor a table

Return Values

Object of type DOM_TABLE.

taylor

Compute a Taylor series expansion

Syntax

```
taylor(f, x, <order>, <mode>)

taylor(f, x = x0, <order>, <mode>)

taylor(f, x, <AbsoluteOrder = order>)

taylor(f, x = x0, <AbsoluteOrder = order>)

taylor(f, x, <RelativeOrder = order>)

taylor(f, x = x0, <RelativeOrder = order>)
```

Description

`taylor(f, x = x0)` computes the first terms of the Taylor series of `f` with respect to the variable `x` around the point `x0`.

If `taylor` finds the corresponding Taylor series, the result is a series expansion of domain type `Series::Puiseux`. Use `expr` to convert it to an arithmetical expression of domain type `DOM_EXPR`. See “Example 1” on page 1-2072.

If a Taylor series does not exist or if `taylor` cannot find it, then `taylor` throws an error. See “Example 2” on page 1-2073 and “Example 3” on page 1-2074.

Mathematically, the expansion computed by `taylor` is valid in some open disc around the expansion point in the complex plane.

If `x0` is `complexInfinity`, then an expansion around the complex infinity, i.e., the north pole of the Riemann sphere, is computed. If `x0` is `infinity` or `-infinity`, a directed series expansion valid along the real axis is computed.

Such an expansion is computed as follows: The series variable `x` in `f` is replaced by $x = \pm\frac{1}{u}$. Then a directed series expansion at $u = 0$ from the right is computed. If `x0 =`

`complexInfinity`, then an undirected expansion around $u = 0$ is computed. Finally, $u = \pm\frac{1}{x}$ is substituted in the result.

Mathematically, the result of an expansion around `complexInfinity` or ±`infinity` is a power series in $\frac{1}{x}$. See “Example 4” on page 1-2074.

With the default mode `RelativeOrder`, the number of requested terms for the expansion is `order` if specified. If no `order` is specified, the value of the environment variable `ORDER` used. You can change the default value 6 by assigning a new value to `ORDER`.

The number of terms is counted from the lowest degree term on for finite expansion points, and from the highest degree term on for expansions around infinity, i.e., “`order`” has to be regarded as a “relative truncation order”.

If `AbsoluteOrder` is specified, `order` represents the truncation order of the series (i.e., the `x` power in the Big-Oh term).

`taylor` uses the more general series function `series` to compute the Taylor expansion. See the corresponding help page for `series` for details about the parameters and the data structure of a Taylor series expansion.

Environment Interactions

The function is sensitive to the environment variable `ORDER`, which determines the default number of terms in series computations.

Examples

Example 1

Compute a Taylor series around the default point 0:

```
s := taylor(exp(x^2), x)
```

$$1 + x^2 + \frac{x^4}{2} + O(x^6)$$

The result of `taylor` is of the following domain type:

```
domtype(s)
```

```
Series::Puiseux
```

If you apply the function `expr` to a series, the result is an arithmetical expression without the order term:

```
expr(s)
```

$$\frac{x^4}{2} + x^2 + 1$$

```
domtype(%)
```

```
DOM_EXPR
```

```
delete s:
```

Example 2

A Taylor series expansion of $f(x) = \frac{1}{x^2-1}$ around $x = 1$ does not exist. Therefore, `taylor` throws an error:

```
taylor(1/(x^2 - 1), x = 1)
```

```
Error: Cannot compute a Taylor expansion of '1/(x^2 - 1)'. Try 'series' for a more gene
```

Call `series` to compute a more general series expansion. A Laurent expansion does exist:

```
series(1/(x^2 - 1), x = 1)
```

$$\frac{1}{2\,(x-1)} - \frac{1}{4} + \frac{x-1}{8} - \frac{(x-1)^2}{16} + \frac{(x-1)^3}{32} - \frac{(x-1)^4}{64} + O((x-1)^5)$$

Example 3

If `taylor` cannot find a Taylor series expansion, it also throws an error.

```
taylor(psi(1/x), x = 0)
```

```
Error: Cannot compute a Taylor expansion of 'psi(1/x)'. Try 'series' with the 'Left',
```

Call `series` with the optional argument. In this case, `series` returns a more general type of expansion. In cases where `series` cannot find a series expansion, it returns the symbolic function call.

```
series(psi(1/x), x = 0, Right)
```

$$-\ln(x) - \frac{x}{2} - \frac{x^2}{12} + \frac{x^4}{120} + O(x^6)$$

Example 4

This is an example of a directed Taylor expansion along the real axis around `infinity`:

```
taylor(exp(1/x), x = infinity)
```

$$1 + \frac{1}{x} + \frac{1}{2\,x^2} + \frac{1}{6\,x^3} + \frac{1}{24\,x^4} + \frac{1}{120\,x^5} + O\left(\frac{1}{x^6}\right)$$

In fact, this is even an undirected expansion:

```
taylor(exp(1/x), x = complexInfinity)
```

$$1 + \frac{1}{x} + \frac{1}{2\,x^2} + \frac{1}{6\,x^3} + \frac{1}{24\,x^4} + \frac{1}{120\,x^5} + O\left(\frac{1}{x^6}\right)$$

Parameters

`f`

An arithmetical expression representing a function in `x`

`x`

An identifier or an indexed identifier

`x0`

The expansion point: an arithmetical expression. Also expressions involving `infinity` or `complexInfinity` are accepted.

If not specified, the default expansion point 0 is used.

`order`

The truncation order (in conjunction with `AbsoluteOrder`) or, in conjunction with `RelativeOrder`, the number of terms to be computed, respectively. A nonnegative integer; the default order is given by the environment variable `ORDER` (default value 6).

`mode`

One of the flags `AbsoluteOrder` or `RelativeOrder`. The default is `RelativeOrder`.

Options

`AbsoluteOrder`

With this flag, the integer value `order` is the truncation order of the computed series (i.e., the exponent of `x` in the Big-Oh term).

`RelativeOrder`

With this flag, the exponents of `x` in the computed series range from some leading order `v` to the highest exponent `v + order - 1` (i.e., the exponent of `x` in the Big-Oh term is `v + order`). In this case, `order` essentially is the "number of `x` powers" in the computed series if the series involves all integer powers of `x`.

Return Values

Object of domain type `Series::Puiseux` or a symbolic expression of type `"taylor"`.

tbl2text

Concatenate the strings in a table

Syntax

```
tbl2text(strtab)
```

Description

`tbl2text` concatenates all entries of a table of character strings.

The table must be indexed by 1, 2, 3 etc. All entries must be character strings. They are concatenated in the order of their indices.

`tbl2text` restores strings split by `text2tbl`.

Examples

Example 1

A character string can be created from an arbitrary number of table entries:

```
tbl2text(table(1 = "Hell", 2 = "o", 3 = " ", 4 = "world."))
```

```
"Hello world."
```

Parameters

`strtab`

A table of character strings

Return Values

Character string.

See Also

MuPAD Functions

`_concat` | `coerce` | `expr2text` | `int2text` | `text2expr` | `text2list` | `text2tbl`

tcoeff

Trailing coefficient of a polynomial

Syntax

```
tcoeff(p, <order>)
```

```
tcoeff(f, <vars>, <order>)
```

Description

`tcoeff(p)` returns the trailing coefficient of the polynomial `p`.

The returned coefficient is "trailing" with respect to the lexicographical ordering, unless a different ordering is specified via the argument `order`. Cf. "Example 1" on page 1-2079.

A polynomial expression `f` is first converted to a polynomial with the variables given by `vars`. If no variables are given, they are searched for in `f`. See `poly` about details of the conversion. The result is returned as polynomial expression. `FAIL` is returned if `f` cannot be converted to a polynomial. Cf. "Example 3" on page 1-2080.

The result of `tcoeff` is not fully evaluated. Evaluation can be enforced by the function `eval`. Cf. "Example 2" on page 1-2080.

Examples

Example 1

We demonstrate how various orderings influence the result:

```
p := poly(5*x^2*y^3 + 4*x^3*y*z + 3*x*y^4*z, [x, y, z]):
tcoeff(p), tcoeff(p, DegreeOrder), tcoeff(p, DegInvLexOrder)
```

```
3, 5, 4
```

The following call uses the reverse lexicographical order on 3 indeterminates:

```
tcoeff(p, Dom::MonomOrdering(RevLex(3)))
```

$$4$$

```
delete p:
```

Example 2

The result of `tcoeff` is not fully evaluated:

```
p := poly(27*x^2 + a*x, [x]): a := 5:
tcoeff(p), eval(tcoeff(p))
```

$$a, 5$$

```
delete p, a:
```

Example 3

The expression `1/x` may not be regarded as polynomial:

```
lterm(1/x)
```

$$\text{FAIL}$$

Parameters

`p`

A polynomial of type `DOM_POLY`

`f`

A polynomial expression

`vars`

A list of indeterminates of the polynomial: typically, identifiers or indexed identifiers

`order`

The term ordering: either `LexOrder`, or `DegreeOrder`, or `DegInvLexOrder`, or a user-defined term ordering of type `Dom::MonomOrdering`. The default is the lexicographical ordering `LexOrder`.

Return Values

Element of the coefficient domain of the polynomial or `FAIL`.

Overloaded By

p

testargs

Decide whether procedure arguments should be tested

Syntax

```
testargs()
```

```
testargs(b)
```

Description

Inside a procedure, `testargs` indicates whether the procedure should check its arguments.

Checking the input parameters of a procedure may be costly. For this reason, most functions of the MuPAD libraries are implemented according to the following philosophy:

If a procedure is called on the interactive level, i.e., if its parameters are supplied interactively by the user, then the parameters should be checked. If the input parameters do not comply with the documented specification of the procedure, then appropriate error messages should be returned to notify the user of wrong usage.

If the procedure is called by another procedure, then no check of the parameters should be performed to improve efficiency. The calling procedure is supposed to make sure that appropriate parameters are passed.

`testargs` is the tool to check whether the arguments should be tested: called inside the body of a procedure, `testargs()` returns `TRUE` if the procedure was called on the interactive level. Otherwise, it returns `FALSE`.

`testargs` has two modes. In the “standard mode”, its functionality is as described above. In the “argument checking mode”, the call `testargs()` always returns `TRUE`. This supports the debugging of procedures: any function using `testargs` checks its parameters and returns useful error messages if called in an inappropriate way.

The call `testargs(TRUE)` switches to the “argument checking mode”, i.e., parameter testing is switched on globally.

The call `testargs(FALSE)` switches to the “standard mode”, i.e., parameter testing is used only on the interactive level.

The call `testargs(b)` returns the previously set value.

`testargs` should not be used to change the behavior of a function other than performing type-checks, since the user may have switched to “argument checking mode”.

Checking the input parameters of a procedure can also be controlled with the function `Pref::typeCheck`.

Examples

Example 1

The following example demonstrates how `testargs` should be used inside a procedure. The function `p` is to generate a sequence of `n` zeroes; its argument should be a positive integer:

```
p := proc(n)
begin
   if testargs() then
       if not testtype(n, Type::PosInt) then
          error("expecting a positive integer");
       end_if;
   end_if;
   return(0 $ n)
end_proc:
```

Its argument is checked when `p` is called on the interactive level:

```
p(13/2)
```

```
Error: expecting a positive integer [p]
```

Calling `p` from within a procedure with an inappropriate parameter does not invoke the argument testing. The following strange output is caused by the attempt to evaluate `0 $ n`:

```
f := proc(n) begin p(n) end_proc:  f(13/2)
```

$$0\ \$\ \frac{13}{2}$$

We switch on the “argument checking mode” of `testargs`:

```
testargs(TRUE):
```

Now also a non-interactive call to `p` produces an informative error message:

```
f(13/2)
```

```
Error: expecting a positive integer [p]
```

We clean up, restoring the “standard mode” of `testargs`:

```
testargs(FALSE): delete f, g:
```

Parameters

b

TRUE or FALSE

Return Values

TRUE or FALSE.

MuPAD Functions

`Pref::typeCheck` | `proc` | `testtype`

testeq

Check the mathematical equivalence of expressions

Syntax

```
testeq(ex1, options)

testeq(ex1, ex2, options)
```

Description

`testeq(ex1, ex2)` checks whether the expressions `ex1` and `ex2` are mathematically equivalent.

`testeq(ex1, ex2)` returns `TRUE` if the difference `ex1 - ex2` can be simplified to zero.

`testeq` returns `FALSE` if `ex1` and `ex2` attain different values for at least one choice of variables contained in them.

By default, `testeq` performs five random tests. If randomly chosen values of the variables are inconsistent with the assumptions on these variables or the test returns the value `undefined`, the `testeq` function performs an additional test. The number of additional tests cannot exceed the number of initial tests. By default, the maximal total number of tests is 10. See “Example 4” on page 1-2087.

If the equivalence of `ex1` and `ex2` cannot be decided, `testeq` returns `UNKNOWN`.

If only one expression is passed to `testeq`, it is checked whether this expression is equivalent to zero.

`testeq` uses `Simplify(ex1 - ex2)` and `is(ex1 - ex2 = 0)` to determine its result. The result `UNKNOWN` can be caused by weaknesses of `Simplify` and `is`.

Using the options, the simplification process can be made stronger at the cost of increased run time.

Examples

Example 1

Check the mathematical equivalence of expressions:

```
testeq(sin(x)^2, 1 - cos(x)^2)
```

```
    TRUE
```

```
testeq(sin(2*x), 2*sin(x)*cos(x))
```

```
    TRUE
```

```
testeq((cos(a) + sin(a))^2, 2*(cos(PI/4 - a)^2))
```

```
    TRUE
```

In order to be equivalent, two expressions must be equivalent for all values their variables can attain. For certain values of the parameter `a` the following two expressions are equivalent, but for other values they are not; therefore, they are not equivalent:

```
testeq((cos(a) + sin(a))^2, 3*(cos(PI/4 - a)^2))
```

```
    FALSE
```

Example 2

Applying `expand` and `rewrite` to an expression always produces an equivalent expression. However, with the default setting of `100` steps for the internal simplification procedure, the equivalence is not recognized in the following example:

```
f:= exp(arcsin(I*sin(x))):
g:= rewrite(expand(f), ln):
testeq(f, g)
```

```
    UNKNOWN
```

After 1000 steps, however, the expressions are recognized as being equivalent:

```
testeq(f, g, Steps = 1000);
delete f, g:
```

```
    TRUE
```

Example 3

When trying to prove the equivalence of two expressions, the `testeq` command runs random tests before applying `IgnoreAnalyticConstraints`. If tests for random values of identifiers show that expressions are not equivalent, `testeq` disregards the `IgnoreAnalyticConstraints` option and returns FALSE:

```
testeq(x^(ln(a))*x^(ln(b)) = x^(ln(a*b)),
               IgnoreAnalyticConstraints)
```

```
    FALSE
```

If, for a given number of attempts, random tests do not find the inequality between expressions, `testeq` applies the `IgnoreAnalyticConstraints` option:

```
testeq(ln(a) + ln(b) = ln(a*b), IgnoreAnalyticConstraints)
```

```
    TRUE
```

By default, random tests check the equality of expressions for five random sets of values of identifiers. Increasing the number of attempts can prove inequality:

```
testeq(ln(a) + ln(b) = ln(a*b), NumberOfRandomTests = 10,
                                IgnoreAnalyticConstraints)
```

```
    FALSE
```

Example 4

When `testeq` performs tests, it takes into account the assumptions on variables that you specify:

```
testeq(x, abs(x)) assuming x > 0
```

```
TRUE
```

If `testeq` chooses values of the variables that are inconsistent with the assumptions on these variables, it performs an additional test. The number of tests cannot exceed `2n`, where `n` is the original number of tests defined by the `NumberOfRandomTests` option. If `testeq` performs `2n` tests and all values of the variables are inconsistent with the assumptions on the variables, `testeq` returns `UNKNOWN`:

```
testeq(x, abs(x)) assuming x^2 + x + 7 = x^13 + 11
```

```
UNKNOWN
```

For this particular assumption, MuPAD cannot find a closed-form expression to substitute for `x`:

```
solve(x^2 + x + 7 = x^13 + 11, x)
```

$$\mathrm{RootOf}(z^{13} - z^2 - z + 4,\ z)$$

Therefore, increasing the number of tests does not help `testeq` decide if the expressions are equivalent:

```
testeq(x, abs(x), NumberOfRandomTests = 100)
            assuming x^2 + x + 7 = x^13 + 11
```

```
UNKNOWN
```

Parameters

`ex1, ex2`

Any MuPAD expressions

Options

`Steps`

Option, specified as `Steps = n`

This option is directly passed to `Simplify` and determines the maximum number of steps allowed for the internal simplification process. The default value of `n` is `100`. Increasing the number of steps can give you a simpler result, often at the costs of increased runtime. For details, see the `Simplify` help page.

`Seconds`

Option, specified as `Seconds = t`

This option is directly passed to `Simplify` and sets a time limit `t` in seconds for the internal simplification process. The default setting is `infinity`, i.e., the simplification process will not terminate due to a time limitation, but due to other internal stopping criteria. See the documentation of `Simplify` for details.

`RuleBase`

Option, specified as `RuleBase = base`

This option is directly passed to `Simplify` and determines the rule base that is used for the internal simplification process. See the documentation of `Simplify` for details.

The default value of `base` is `Simplify`.

The advanced user can specify her own rule base (see `Simplify`). This allows the construction of specialized and fast tests for special classes of expressions.

`NumberOfRandomTests`

Option, specified as `NumberOfRandomTests = n`

This option determines the number of times `testeq` tries to disprove the equivalence of `ex1` and `ex2` by plugging in some random values for all identifiers.

The default value of `n` is 5. If randomly chosen values of the variables are inconsistent with the assumptions on these variables or the test returns the value `undefined`, the `testeq` function performs an additional test. The total number of tests does not exceed `2n`. See “Example 4” on page 1-2087.

`IgnoreAnalyticConstraints`

This option applies purely algebraic simplifications to expressions `ex1` and `ex2`. For the list of rules, see the documentation of `Simplify`. These simplification rules are not generally valid.

Note that random tests have higher priority than `IgnoreAnalyticConstraints`. When trying to prove the equivalence of two expressions, the `testeq` command runs random tests before applying the `IgnoreAnalyticConstraints` option. If random tests prove the expressions are not equivalent, `testeq` returns the value FALSE. See "Example 3" on page 1-2087.

Return Values

TRUE, FALSE, or UNKNOWN

More About

- "Test Results"

testtype

Syntactical type checking

Syntax

```
testtype(object, T)
```

Description

`testtype(object, T)` checks whether the object is syntactically of type `T`.

The type object `T` may be either a domain type such as `DOM_INT`, `DOM_EXPR` etc., a string as returned by the function `type`, or a Type object. The latter are probably the most useful predefined values for the argument `T`.

Note: `testtype` performs a purely syntactical check. Use `is` for semantical checks taking into account properties of identifiers!

See the Algorithms section below for details on the overloading mechanism.

Examples

Example 1

The following call tests, whether the first argument is an expression. Expressions are basic objects of domain type `DOM_EXPR`:

```
testtype(x + y, DOM_EXPR)
```

```
TRUE
```

The `type` function distinguishes expressions. The corresponding type string is a valid type object for `testtype`:

```
type(x + y), testtype(x + y, "_plus")
```

```
"_plus", TRUE
```

The following call tests, whether the first argument is an integer by querying, whether it is of domain type `DOM_INT`:

```
testtype(7, DOM_INT)
```

```
TRUE
```

Note that `testtype` performs a purely syntactical test. Mathematically, the integer 7 is a rational number. However, the domain type `DOM_RAT` does not encompass `DOM_INT`:

```
testtype(7, DOM_RAT)
```

```
FALSE
```

The Type library provides more flexible type objects. E.g., `Type::Rational` represents the union of `DOM_INT` and `DOM_RAT`:

```
testtype(7, Type::Rational)
```

```
TRUE
```

The number 7 matches other types as well:

```
testtype(7, Type::PosInt), testtype(7, Type::Prime),
testtype(7, Type::Numeric), testtype(7, Type::Odd)
```

```
TRUE, TRUE, TRUE, TRUE
```

Example 2

Subtypes of expressions can be specified via character strings:

```
type(f(x)),  type(sin(x))
```

```
"function", "sin"
```

```
testtype(sin(x), "function"), testtype(sin(x), "sin"),
testtype(sin(x), "cos")
```

```
TRUE, TRUE, FALSE
```

Example 3

We demonstrate how to implement a customized type object "`div3`" which is to represent integer multiples of 3. One has to create a new domain with a "`testtypeDom`" attribute:

```
div3 := newDomain("divisible by 3?"):
div3::testtypeDom := x -> testtype(x/3, Type::Integer):
```

Via overloading, the command `testtype(object, div3)` calls this slot:

```
testtype(5, div3), testtype(6, div3), testtype(sin(1), div3)
```

```
FALSE, TRUE, FALSE
```

```
delete div3:
```

Parameters

`object`

Any MuPAD object

`T`

A type object

Return Values

TRUE or FALSE.

Overloaded By

object, T

Algorithms

Overloading of `testtype` works as follows: First, it is checked whether `domtype(object) = T` or `type(object) = T` holds. If so, `testtype` returns `TRUE`.

Next, the method `"testtype"` of the domain `object::dom` is called with the arguments `object, T`. If this method returns a result other than `FAIL`, then `testtype` returns this value.

If the method `object::dom::testtype` does not exist or if this method returns `FAIL`, then overloading by the second argument is used:

- If `T` is a domain, then the method `"testtypeDom"` of `T` is called with the arguments `object, T`.
- If `T` is not a domain, then the method `"testtypeDom"` of `T::dom` is called with the arguments `object, T`.

text2expr

Convert a character string to an expression

Syntax

```
text2expr(text)
```

Description

`text2expr(text)` interprets the character string `text` as MuPAD input and generates the corresponding object.

The text must correspond to syntactically correct MuPAD input. Otherwise, `text2expr` produces an error. Typically, strings created from MuPAD objects via `expr2text` can be reconverted to corresponding objects.

The object is returned without being further evaluated. Evaluation can be enforced using the function `eval`.

The `text` does not need to be terminated with a "`;`" or a "`:`" character, respectively.

`text` cannot refer to local variables of an enclosing procedure by their name. The text is parsed as if entered interactively. Cf. "Example 4" on page 1-2097.

Examples

Example 1

A character string is converted to a simple expression. The newly created expression is not evaluated automatically:

```
text2expr("21 + 21")
```

$$21 + 21$$

It may be evaluated via `eval`:

```
eval(%)
```

```
     42
```

Example 2

A character string is converted to a statement sequence:

```
text2expr("x:= 3; x + 2 + 1"); eval(%)
```

```
(x := 3;
x + 2 + 1)
```

```
     6
```

```
x
```

```
     3
```

```
delete x:
```

Example 3

A matrix is converted to a string:

```
matrix([[a11, a12], [a21, a22]])
```

$$\begin{pmatrix} a11 & a12 \\ a21 & a22 \end{pmatrix}$$

```
expr2text(%)
```

```
     "matrix([[a11, a12], [a21, a22]])"
```

The string is reconverted to a matrix:

```
text2expr(%)
```

$$\begin{pmatrix} a11 & a12 \\ a21 & a22 \end{pmatrix}$$

```
eval(%)
```

$$\begin{pmatrix} a11 & a12 \\ a21 & a22 \end{pmatrix}$$

Example 4

`text2expr` will not create a `DOM_VAR` of an enclosing procedure from its name:

```
a := "global identifier":
g := proc()
       local a;
     begin
       a := "local variable";
       print(a);
       print(eval(text2expr("a")));
     end_proc:
g();
```

"local variable"

"global identifier"

Parameters

`text`

A character string

Return Values

MuPAD object.

text2int

Convert a character string to an integer

Syntax

```
text2int(text, <b>)
```

Description

`text2int(text, b)` converts a character string corresponding to an integer in `b`-adic representation to an integer of type `DOM_INT`.

It must consist of the first `b` characters in 0, 1, …, 9, *A*, *B*, …, *Z*, *a*, *b*, …, *z*. The letters are used to represent the `b`-adic digits larger than 9.

For bases larger than 10 but smaller than 37 the letters are not case sensitive. The lower case letters *a*, *b*, …, *z* are accepted: $a = A = 10, \ldots, z = Z = 35$.

`text2int` is the inverse of `int2text`.

Examples

Example 1

Relative to the default base 10, `text2int` provides a mere datatype conversion from `DOM_STRING` to `DOM_INT`:

```
text2int("123"), text2int("-45678")
```

$$123, -45678$$

Example 2

The characters of the input string are interpreted as digits with respect to the specified base, the return value is a standard MuPAD integer represented with respect to the

decimal system. The following example converts integers from the base 2 and 16, respectively, to the base 10:

```
text2int("101", 2), text2int("101", 16)
```

```
5, 257
```

The digit "3" does not exist in a binary representation:

```
text2int("103", 2)
```

```
Error: The argument is invalid. [text2int]
```

Example 3

For bases larger than 10 but smaller than 37, the letters are not case-sensitive:

```
text2int("3B9ACA00", 16), text2int("Z", 36) = text2int("z", 36)
```

```
1000000000, 35 = 35
```

For bases larger than 37 however, the case makes a difference:

```
text2int("Z", 62) <> text2int("z", 62)
```

```
35 ≠ 61
```

Parameters

`text`

A character string

`b`

The base: an integer between 2 and 62. The default base is 10.

Return Values

Integer.
