The CPM Phase Recovery block recovers the carrier phase of the input signal using the 2P-Power method. This feedforward, non-data-aided, clock-aided method is suitable for systems that use these types of baseband modulation: continuous phase modulation (CPM), minimum shift keying (MSK), continuous phase frequency shift keying (CPFSK), and Gaussian minimum shift keying (GMSK). This block is suitable for use with blocks in the Baseband Continuous Phase Modulation library.

If you express the modulation index for CPM as a proper fraction, h = K / P, then P is the number to which the name "2P-Power" refers. The observation interval parameter must be an integer multiple of the input signal vector length.

The 2P-Power method assumes that the carrier phase is constant over a series of consecutive symbols, and returns an estimate of the carrier phase for the series. The **Observation interval** parameter is the number of symbols for which the carrier phase is assumed constant. This number must be an integer multiple of the input signal's vector length.

Input and Output Signals

This block accepts a scalar or column vector input signal of type `double` or `single`. The input signal represents a baseband signal at the symbol rate, so it must be complex-valued and must contain one sample per symbol.

The outputs are as follows:

- The output port labeled `Sig` gives the result of rotating the input signal counterclockwise, where the amount of rotation equals the carrier phase estimate. The `Sig` output is thus a corrected version of the input signal, and has the same sample time and vector size as the input signal.
- The output port labeled `Ph` outputs the carrier phase estimate, in degrees, for all symbols in the observation interval. The `Ph` output is a scalar signal.

> **Note** Because the block internally computes the argument of a complex number, the carrier phase estimate has an inherent ambiguity. The carrier phase estimate is between -90/P and 90/P degrees and might differ from the actual carrier phase by an integer multiple of 180/P degrees.

Delays and Latency

The block's algorithm requires it to collect symbols during a period of length **Observation interval** before computing a single estimate of the carrier phase. Therefore, each estimate is delayed by

Observation interval symbols and the corrected signal has a latency of **Observation interval** symbols, relative to the input signal.

Parameters

P

The denominator of the modulation index for CPM (h = K / P) when expressed as a proper fraction.

Observation interval

The number of symbols for which the carrier phase is assumed constant. The observation interval parameter must be an integer multiple of the input signal vector length.

When this parameter is exactly equal to the vector length of the input signal, then the block always works. When the integer multiple is not equal to `1`, on the **Simulation** tab, select **Model Settings**. Then in the **Solver** > **Solver selection** section, choose **Type:** `Fixed-step` and clear the **Treat each discrete rate as a separate task** checkbox.

Algorithm

If the symbols occurring during the observation interval are x(1), x(2), x(3),..., x(L), then the resulting carrier phase estimate is

$$\frac{1}{2P}\arg\left\{\sum_{k=1}^{L}(x(k))^{2P}\right\}$$

where the arg function returns values between -180 degrees and 180 degrees.

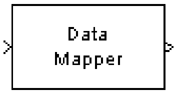
Data Mapper

Map integer symbols from one coding scheme to another
Library: Communications Toolbox / Utility Blocks



Description

The Data Mapper block accepts integer inputs and maps them to integer outputs. The mapping types include: binary to Gray coded, Gray coded to binary, and user defined. Additionally, a pass through option is available.

Gray coding is an ordering of binary numbers such that all adjacent numbers differ by only one bit.

Input/Output Ports

Input

`Port_1` — Input port
scalar | column vector | matrix

Input signal, specified as a scalar, vector, or matrix of integers. Elements of the input signal must be nonnegative values. The block truncates noninteger values to integer values. When the input is a matrix, the columns are treated as independent channels.

Data Types: `double` | `single` | `int8` | `int16` | `int32` | `uint8` | `uint16` | `uint32`

Output

`Port_2` — Output signal
scalar | column vector | matrix

Output signal, returned as a scalar, column vector, or matrix. The dimensions of the output signal match those of the input signal.

Data Types: `double` | `single` | `int8` | `int16` | `int32` | `uint8` | `uint16` | `uint32`

Parameters

`Mapping mode` — Mapping mode
`Binary to Gray` (default) | `Gray to Binary` | `User Defined` | `Straight through`

Mapping mode, specified as one of the four options. The mapping for the `Binary to Gray` and the `Gray to Binary` modes are shown in the following table when the inputs range from 0 to 7.

Binary to Gray Mode		Gray to Binary Mode	
Input	**Output**	**Input**	**Output**
0	0 *(000)*	0 *(000)*	0
1	1 *(001)*	1 *(001)*	1
2	3 *(011)*	2 *(010)*	3
3	2 *(010)*	3 *(011)*	2
4	6 *(110)*	4 *(100)*	7
5	7 *(111)*	5 *(101)*	6
6	5 *(101)*	6 *(110)*	4
7	4 *(100)*	7 *(111)*	5

When you select the `User Defined` mode, you can use any arbitrary mapping by providing a vector to specify the output ordering. When you select the `Straight Through` mode, the output equals the input.

`Symbol set size (M)` — Symbol set size
8 (default) | positive integer

Symbol set size, specified as a positive integer. This parameter restricts the inputs and outputs to integers in the range of 0 to M-1.

`Mapping vector` — Maps input elements to the output elements
`[0 1 3 2 7 6 4 5]` (default) | vector

Mapping vector, specified as vector of nonnegative integers whose length equals . This parameter defines the relationship between the input and output integers. For example, the vector `[1 5 0 4 2 3]` defines the following mapping:

0 → 1
1 → 5
2 → 0
3 → 4
4 → 2
5 → 3

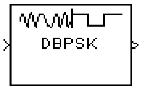
"Phase Modulation"

Introduced before R2006a

DBPSK Demodulator Baseband

Demodulate DBPSK-modulated data



Library

PM, in Digital Baseband sublibrary of Modulation

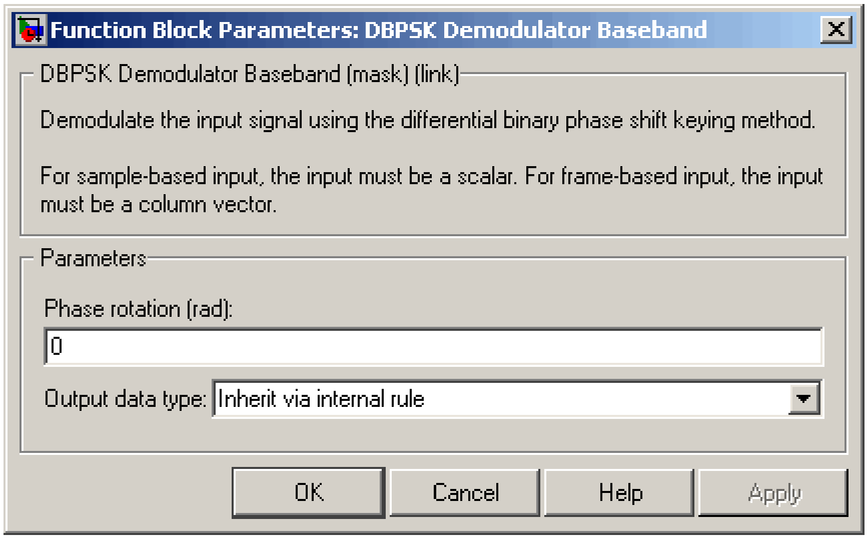
Description

The DBPSK Demodulator Baseband block demodulates a signal that was modulated using the differential binary phase shift keying method. The input is a baseband representation of the modulated signal.

The input must be a discrete-time complex signal. The block compares the current symbol to the previous symbol. It maps phase differences of θ and π+θ, respectively, to outputs of 0 and 1, respectively, where θ is the **Phase rotation** parameter. The first element of the block's output is the initial condition of zero because there is no previous symbol with which to compare the first symbol.

This block accepts a scalar or column vector input signal. The input signal can be of data types `single` and `double`. For information about the data types each block port supports, see "Supported Data Types" on page 5-164.

Dialog Box



Function Block Parameters: DBPSK Demodulator Baseband

DBPSK Demodulator Baseband (mask) (link)

Demodulate the input signal using the differential binary phase shift keying method.

For sample-based input, the input must be a scalar. For frame-based input, the input must be a column vector.

Parameters

Phase rotation (rad): 0

Output data type: Inherit via internal rule

Phase rotation (rad)

This phase difference between the current and previous modulated symbols results in an output of zero.

Output data type

When the parameter is set to `'Inherit via internal rule'` (default setting), the block will inherit the output data type from the input port. The output data type will be the same as the input data type if the input is of type `single` or `double`.

For additional information, see “Supported Data Types” on page 5-164.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point
Output	• Double-precision floating point • Single-precision floating point • Boolean • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers

DBPSK Modulator Baseband

Modulate using differential binary phase shift keying method

Library

PM, in Digital Baseband sublibrary of Modulation

Description

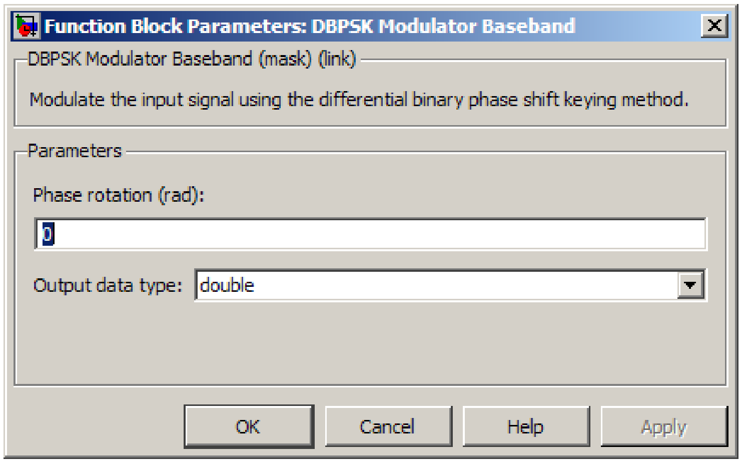
The DBPSK Modulator Baseband block modulates using the differential binary phase shift keying method. The output is a baseband representation of the modulated signal.

This block accepts a scalar or column vector input signal. The input must be a discrete-time binary-valued signal. For information about the data types each block port supports, see “Supported Data Types” on page 5-166.

The following rules govern this modulation method when the **Phase rotation** parameter is θ:

- If the first input bit is 0 or 1, respectively, then the first modulated symbol is exp(jθ) or -exp(jθ), respectively.
- If a successive input bit is 0 or 1, respectively, then the modulated symbol is the previous modulated symbol multiplied by exp(jθ) or -exp(jθ), respectively.

Dialog Box



DBPSK Modulator Baseband (mask) (link)

Modulate the input signal using the differential binary phase shift keying method.

Parameters

Phase rotation (rad): 0

Output data type: double

Phase rotation (rad)

The phase difference between the previous and current modulated symbols when the input is zero.

Output Data type

The output data type can be either `single` or `double`. By default, the block sets this to `double`.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point • Boolean • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers
Output	• Double-precision floating point • Single-precision floating point

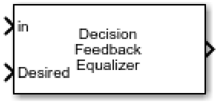
Decision Feedback Equalizer

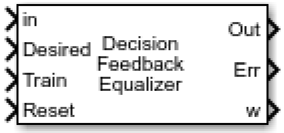
Equalize modulated signals using decision feedback filtering
Library: Communications Toolbox / Equalizers



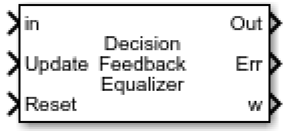
Description

The Decision Feedback Equalizer block uses a decision feedback filter tap delay line with a weighted sum to equalize modulated signals transmitted through a dispersive channel. Using an estimate of the channel modeled as a finite input response (FIR) filter, the block processes input frames and outputs the estimated signal.

This icon shows the block with all ports enabled for configurations that use the LMS or RLS adaptive algorithm.



This icon shows the block with all ports enabled for configurations that use the CMA adaptive algorithm.



Ports

Input

`in` — Input signal

column vector

Input signal, specified as a column vector. The vector length of **in** must be equal to an integer multiple of the **Number of input samples per symbol** parameter. For more information, see “Symbol Tap Spacing” on page 5-456.

Data Types: `double`
Complex Number Support: Yes

`Desired` — Training symbols

column vector

Training symbols, specified as a column vector. The vector length of **Desired** must be less than or equal to the length of input **in**. The **Desired** input port is ignored when the **Train** input port is `0`.

Dependencies

To enable this port, set the **Adaptive algorithm** parameter to `LMS` or `RLS`.

Data Types: `double`
Complex Number Support: Yes

`Train` — Train equalizer flag
boolean scalar

Train equalizer flag, specified as `1` or `0`. The block starts training when this value changes from `0` to `1` (at the rising edge). The block trains until all symbols in the **Desired** input port are processed.

Dependencies

To enable this port, set the **Adaptive algorithm** parameter to `LMS` or `RLS` and select the **Enable training control input** parameter.

Data Types: `Boolean`

`Update` — Update tap weights flag
`1` | `0`

Update tap weights flag, specified as `1` or `0`. The tap weights are updated when this value is `1`.

Dependencies

To enable this port, set the **Adaptive algorithm** parameter to `CMA` and the **Source of adapt weights flag** parameter to `Input port`.

Data Types: `Boolean`

`Reset` — Reset equalizer flag
`1` | `0`

Reset equalizer flag, specified as `1` or `0`. If **Reset** is set to `1`, the block resets the tap weights before processing the incoming signal. The block performs initial training until all symbols in the **Desired** input port are processed.

Dependencies

To enable this port, select the **Enable reset input** parameter.

Data Types: `Boolean`

Output

`Out` — Equalized symbols
column vector

Equalized symbols, returned as a column vector that has the same length as input signal **in**.

This port is unnamed until you select the **Output error signal** or **Output taps weights** parameter.

`Err` — Error signal
column vector

Error signal, returned as a column vector that has the same length as input signal **in**.

`w` — Tap weights

column vector

Tap weights, returned as an N_{Taps}-by-1 vector, where N_{Taps} is equal to the sum of the **Number of forward taps** and **Number of feedback taps** parameter values. **w** contains the tap weights from the last tap weight update.

Parameters

Structure parameters

`Number of forward taps` — Number of forward equalizer taps

`5` (default) | positive integer

Number of forward equalizer taps, specified as a positive integer. The number of forward equalizer taps must be greater than or equal to the value of the **Number of input samples per symbol** parameter.

`Number of feedback taps` — Number of feedback equalizer taps

`3` (default) | positive integer

Number of feedback equalizer taps, specified as a positive integer.

`Signal constellation` — Signal constellation

`pskmod(0:3,4,pi/4)` (default) | vector

Signal constellation, specified as a vector. The default value is a QPSK constellation generated using this code: `pskmod(0:3,4,pi/4)`.

Tunable: Yes

`Number of input samples per symbol` — Number of input samples per symbol

`1` (default) | positive integer

Number of input samples per symbol, specified as a positive integer. Setting this parameter to any number greater than `1` effectively creates a fractionally spaced equalizer. For more information, see “Symbol Tap Spacing” on page 5-456.

Algorithm parameters

`Adaptive algorithm` — Adaptive algorithm

`LMS` (default) | `RLS` | `CMA`

Adaptive algorithm used for equalization, specified as one of these values:

- `LMS` — Update the equalizer tap weights using the “Least Mean Square (LMS) Algorithm” on page 5-457.
- `RLS` — Update the equalizer tap weights using the “Recursive Least Square (RLS) Algorithm” on page 5-457.
- `CMA` — Update the equalizer tap weights using the “Constant Modulus Algorithm (CMA)” on page 5-458.

`Step size` — Step size

`0.01` (default) | positive scalar

Step size used by the adaptive algorithm, specified as a positive scalar. Increasing the step size reduces the equalizer convergence time but causes the equalizer output estimates to be less stable.

Tunable: Yes

Dependencies

To enable this parameter, set **Adaptive algorithm** to `LMS` or `CMA`.

`Forgetting factor` — Forgetting factor

`0.99` (default) | scalar in the range (0, 1]

Forgetting factor used by the adaptive algorithm, specified as a scalar in the range (0, 1]. Decreasing the forgetting factor reduces the equalizer convergence time but causes the equalizer output estimates to be less stable.

Tunable: Yes

Dependencies

To enable this parameter, set **Adaptive algorithm** to `RLS`.

`Initial inverse correlation matrix` — Initial inverse correlation matrix

`0.1` (default) | scalar | matrix

Initial inverse correlation matrix, specified as a scalar or an N_{Taps}-by-N_{Taps} matrix. N_{Taps} is equal to the sum of the **Number of forward taps** and **Number of feedback taps** parameter values. If you specify this value as a scalar, *a*, the equalizer sets the initial inverse correlation matrix to *a* times the identity matrix: a(`eye`(N_{Taps})).

Tunable: Yes

Dependencies

To enable this parameter, set **Adaptive algorithm** to `RLS`.

Control parameters

`Reference tap` — Reference tap

`3` (default) | positive integer

Reference tap, specified as a positive integer less than or equal to the **Number of forward taps** parameter value. The equalizer uses the reference tap location to track the main energy of the channel.

`Input signal delay (samples)` — Input signal delay

`0` (default) | nonnegative integer

Input signal delay in samples relative to the reset time of the equalizer, specified as a nonnegative integer. If the input signal is a vector of length greater than 1, then the input delay is relative to the start of the input vector. If the input signal is a scalar, then the input delay is relative to the first call of the block and to the first call of the block after the **Reset** input port toggles to `1`.

Dependencies

To enable this parameter, set **Adaptive algorithm** to `LMS` or `RLS`.

`Source of adapt weights flag` — Source of adapt tap weights request

`Property` (default) | `Input port`

Source of the adapt tap weights request, specified as one of these values:

- `Property` — Specify this value to use the **Adaptive algorithm** parameter to control when the block adapts tap weights.
- `Input port` — Specify this value to use the **Update** input port to control when the block adapts tap weights.

Dependencies

To enable this parameter, set **Adaptive algorithm** to `CMA`.

`Adapt tap weights` — Adapt tap weights

`on` (default) | `off`

Select this parameter to adaptively update the equalizer tap weights. If this parameter is cleared, the block keeps the equalizer tap weights unchanged.

Tunable: Yes

Dependencies

To enable this parameter, set **Adaptive algorithm** to `CMA` and **Source of adapt weights flag** to `Property`.

`Initial tap weights source` — Source for initial tap weights

`Auto` (default) | `Property`

Source for initial tap weights, specified as one of these values:

- `Auto` — Initialize the tap weights to the algorithm-specific default values, as described in the **Initial weights** parameter.
- `Property` — Initialize the tap weights using the **Initial weights** parameter value.

`Initial weights` — Initial tap weights

`0` or `[0;0;1;0;0]` (default) | scalar | column vector

Initial tap weights used by the adaptive algorithm, specified as a scalar or an N_{Taps}-by-1 vector. N_{Taps} is equal to the sum of the **Number of forward taps** and **Number of feedback taps** parameter values. The default is `0` when the **Adaptive algorithm** parameter is set to `LMS` or `RLS`. The default is `[0;0;1;0;0]` when the **Adaptive algorithm** parameter is set to `CMA`.

If you specify **Initial weights** as a vector, the vector length must be N_{Taps}. If you specify **Initial weights** as a scalar, the equalizer uses scalar expansion to create a vector of length N_{Taps} with all values set to **Initial weights**.

Tunable: Yes

Dependencies

To enable this parameter, set **Initial tap weights source** to `Property`.

`Tap weight update period (symbols)` — Tap weight update period

`1` (default) | positive integer

Tap weight update period in symbols, specified as a positive integer. The equalizer updates the tap weights after processing this number of symbols.

`Enable training control input` — Enable training control input

`off` (default) | `on`

Select this parameter to enable input port **Train**. If this parameter is cleared, the block does not reenter training mode after the initial tap training.

Tunable: Yes

Dependencies

To enable this parameter, set **Adaptive algorithm** to `LMS` or `RLS`.

`Update tap weights when not training` — Update tap weights when not training

`on` (default) | `off`

Select this parameter to use decision directed mode to update equalizer tap weights. If this parameter is cleared, the block keeps the equalizer tap weights unchanged after training.

Tunable: Yes

Dependencies

To enable this parameter, set **Adaptive algorithm** to `LMS` or `RLS`.

`Enable reset input` — Enable reset input

`off` (default) | `on`

Select this parameter to enable input port **Train**. If this parameter is cleared, the block does not reenter training mode after the initial tap training.

Tunable: Yes

Diagnostic parameters

`Output error signal` — Enable error signal output

`off` (default) | `on`

Select this parameter to enable output port **Err** containing the equalizer error signal.

Tunable: Yes

`Output taps weights` — Enable tap weights output

`off` (default) | `on`

Select this parameter to enable output port **w** containing tap weights from the last tap weight update.

Tunable: Yes

`Simulate using` — Type of simulation to run

`Code generation` (default) | `Interpreted execution`

Type of simulation to run, specified as `Code generation` or `Interpreted execution`.

- `Code generation` –– Simulate the model by using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations unless the model changes. This option requires additional startup time, but the speed of the subsequent simulations is faster than `Interpreted execution`.
- `Interpreted execution` –– Simulate the model by using the MATLAB interpreter. This option requires less startup time than the `Code generation` method, but the speed of subsequent simulations is slower. In this mode, you can debug the source code of the block.

Block Characteristics

Data Types	`double` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`yes`

More About

Symbol Tap Spacing

You can configure the equalizer to operate as a symbol-spaced equalizer or as a fractional symbol-spaced equalizer.

- To operate the equalizer at a symbol-spaced rate, specify the number of samples per symbol as `1`. Symbol-rate equalizers have taps spaced at the symbol duration. Symbol-rate equalizers are sensitive to timing phase.
- To operate the equalizer at a fractional symbol-spaced rate, specify the number of input samples per symbol as an integer greater than `1` and provide an input signal oversampled at that sampling rate. Fractional symbol-spaced equalizers have taps spaced at an integer fraction of the input symbol duration. Fractional symbol-spaced equalizers are not sensitive to timing phase.

Algorithms

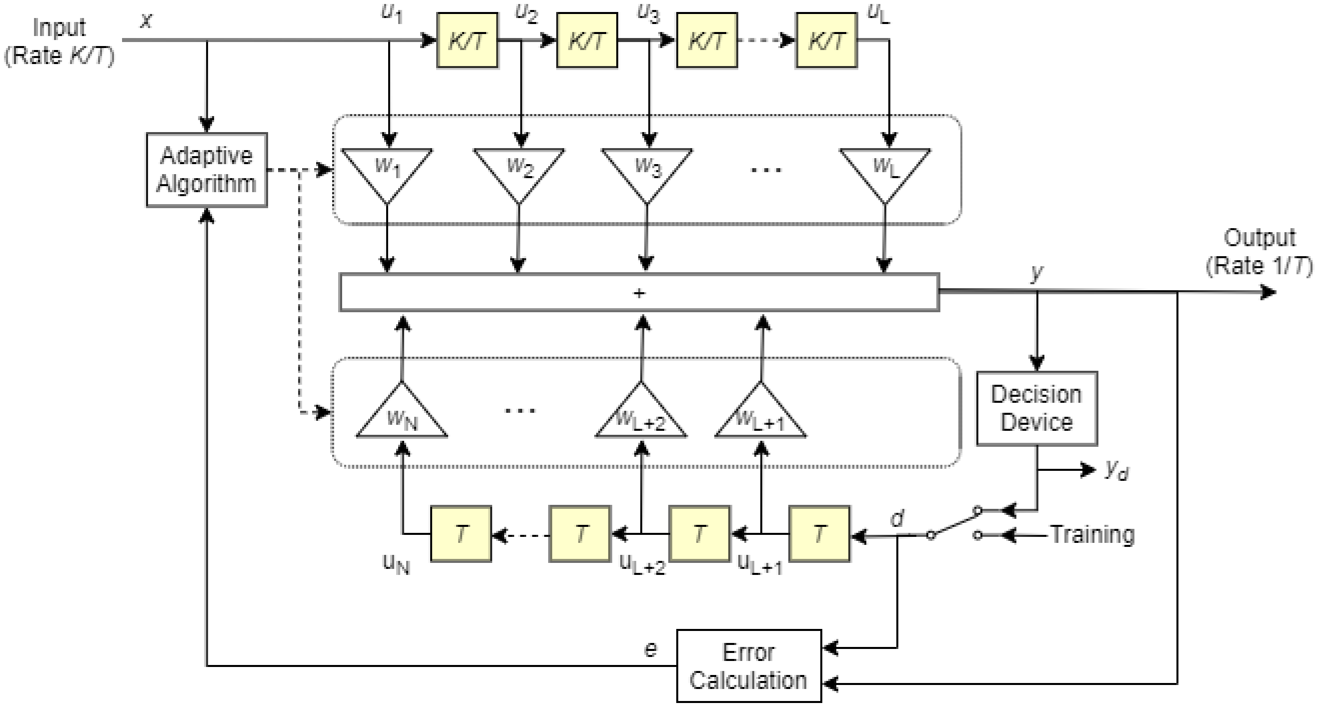
Decision Feedback Equalizers

A decision feedback equalizer (DFE) is a nonlinear equalizer that reduces intersymbol interference (ISI) in frequency-selective channels. If a null exists in the frequency response of a channel, DFEs do not enhance the noise. A DFE consists of a tapped delay line that stores samples from the input signal and contains a forward filter and a feedback filter. The forward filter is similar to a linear equalizer. The feedback filter contains a tapped delay line whose inputs are the decisions made on the equalized signal. Once per symbol period, the equalizer outputs a weighted sum of the values in the delay line and updates the weights to prepare for the next symbol period.

DFEs can be symbol-spaced or fractional symbol-spaced.

- For a symbol-spaced equalizer, the number of samples per symbol, K, is 1. The output sample rate equals the input sample rate.
- For a fractional symbol-spaced equalizer, the number of samples per symbol, K, is an integer greater than 1. Typically, K is 4 for fractional symbol-spaced equalizers. The output sample rate is $1/T$ and the input sample rate is K/T. Tap weight updating occurs at the output rate.

This schematic shows a fractional symbol-spaced DFE with a total of *N* weights, a symbol period of *T*, and *K* samples per symbol. The filter has *L* forward weights and *N*-*L* feedback weights. The forward filter is at the top, and the feedback filter is at the bottom. If *K* is 1, the result is a symbol-spaced DFE instead of a fractional symbol-spaced DFE.



In each symbol period, the equalizer receives *K* input samples at the forward filter and one decision or training sample at the feedback filter. The equalizer then outputs a weighted sum of the values in the forward and feedback delay lines and updates the weights to prepare for the next symbol period.

Note The algorithm for the Adaptive Algorithm block in the schematic jointly optimizes the forward and feedback weights. Joint optimization is especially important for convergence in the recursive least square (RLS) algorithm.

For more information, see “Equalization”.

Least Mean Square (LMS) Algorithm

For the LMS algorithm, in the previous schematic, *w* is a vector of all weights w_i, and *u* is a vector of all inputs u_i. Based on the current set of weights, the LMS algorithm creates the new set of weights as

$$w_{\text{new}} = w_{\text{current}} + (StepSize)\, ue^*.$$

The step size used by the adaptive algorithm is specified as a positive scalar. Increasing the step size reduces the equalizer convergence time but causes the equalized output signal to be less stable. To determine the maximum step size allowed when using the LMS adaptive algorithm, use the `maxstep` object function. The * operator denotes the complex conjugate and the error calculation $e = d - y$.

Recursive Least Square (RLS) Algorithm

For the RLS algorithm, in the previous schematic, w is the vector of all weights w_i, and u is the vector of all inputs u_i. Based on the current set of inputs, u, and the inverse correlation matrix, P, the RLS algorithm first computes the Kalman gain vector, K, as

$$K = \frac{Pu}{(ForgettingFactor) + u^H Pu}.$$

The forgetting factor used by the adaptive algorithm is specified as a scalar in the range (0, 1]. Decreasing the forgetting factor reduces the equalizer convergence time but causes the equalized output signal to be less stable. H denotes the Hermitian transpose. Based on the current inverse correlation matrix, the new inverse correlation matrix is

$$P_{\text{new}} = \frac{(1 - Ku^H)P_{\text{current}}}{ForgettingFactor}.$$

Based on the current set of weights, the RLS algorithm creates the new set of weights as

$w_{\text{new}} = w_{\text{current}}+K^*e.$

The * operator denotes the complex conjugate and the error calculation $e = d - y$.

Constant Modulus Algorithm (CMA)

For the CMA adaptive algorithm, in the previous schematic, w is the vector of all weights w_i, and u is the vector of all inputs u_i. Based on the current set of weights, the CMA adaptive algorithm creates the new set of weights as

$w_{\text{new}} = w_{\text{current}} + (StepSize)\ u^*e.$

The step size used by the adaptive algorithm is specified as a positive scalar. Increasing the step size reduces the equalizer convergence time but causes the equalized output signal to be less stable. To determine the maximum step size allowed by the CMA adaptive algorithm, use the `maxstep` object function. The * operator denotes the complex conjugate and the error calculation $e = y(R - |y|^2)$, where R is a constant related to the signal constellation.

Deinterlacer

Distribute elements of input vector alternately between two output vectors
Library: Communications Toolbox / Sequence Operations

Deinterlacer
O
E

Description

The Deinterlacer block accepts an even length column vector input signal. The block alternately places the elements in two output vectors. As a result, each output vector size is half the input vector size. The outputs inherit the sample time from the **Sample time** parameter of the input block.

Ports

Input

In — Input signal
column vector

Input signal, specified as an even length column vector.

Data Types: `double` | `single`

Output

0 — Odd-numbered elements
vector

Odd-numbered elements of the input vector, returned as a vector. If the input is a vector of length *N*, the output length is *N*/2.

E — Even-numbered elements
vector

Even-numbered elements of the input vector, returned as a vector. If the input is a vector of length *N*, the output length is *N*/2.

Derepeat

Reduce sampling rate by averaging consecutive samples
Library: Communications Toolbox / Sequence Operations

Description

The Derepeat block resamples the discrete input at a rate 1/*N* times the input sample rate by averaging *N* consecutive samples. *N* represents the `Derepeat factor, N` parameter.

Ports

Input

`In` — Input signal
scalar | vector | matrix

Input signal, specified as a scalar, vector, or matrix.

Data Types: `double`
Complex Number Support: Yes

Output

`Out` — Output signal
scalar | vector | matrix

Output signal, returned as a scalar or column vector.

Data Types: `double`
Complex Number Support: Yes

For more information on the processing rates, see “Single-Rate Processing” on page 5-180, and “Multirate Processing” on page 5-181.

Parameters

`Derepeat factor, N` — Derepeat factor
5 (default) | integer

Derepeat factor, specified as an integer. The derepeat factor is the number of consecutive input samples to average to produce each output sample.

Data Types: `double`

`Input processing` — Input processing control
`Columns as channels (frame based)` (default) | `Elements as channels (sample based)`

Input processing control, specified as one of these options:

- `Columns as channels (frame based)` — The block treats each column of the input as a separate channel.
- `Elements as channels (sample based)` — The block treats each element of the input as a separate channel.

`Rate options` — Block processing rate
`Allow multirate processing` (default) | `Enforce single-rate processing`

Block processing rate, specified as one of these options:

- `Allow multirate processing` — The block downsamples the signal such that the output sample rate is `Derepeat factor, N` times slower than the input sample rate. For more information, see "Multirate Processing" on page 5-181.
- `Enforce single-rate processing` — The block maintains the input sample rate by decreasing the output frame size by a factor equal to the `Derepeat factor, N` parameter value. Also, in single-rate processing mode you can use this block in a triggered subsystem. For more information, see "Single-Rate Processing" on page 5-180

`Initial condition` — Initial condition
0 (default) | scalar | vector | matrix

Initial condition, specified as a scalar, vector, or matrix. This parameter specifies values that are output when it is too early for the input data to show up in the output. If the dimensions of the **Initial condition** parameter match the output dimensions, then the parameter represents the initial output value. If **Initial condition** is a scalar, then it represents the initial value of each element in the output. The block does not support empty matrices for initial conditions.

Data Types: `double`

More About

Single-Rate Processing

The block derepeats each frame, treating distinct channels independently. Each element of the output is the average of *N* consecutive elements along a *column* of the input matrix. *N* must be less than the frame size. *N* represents the `Derepeat factor, N` parameter.

When you set the `Rate options` parameter to `Enforce single-rate processing`, the input and output of the block have the same sample rate. The block reduces the sampling rate by using a proportionally smaller frame *size* than the input. To process all input values, *N* must be an integer factor of the number of rows in the input vector or matrix. For derepetition by a factor of *N*, the output frame size is 1/*N* times the input frame size, but the input and output frame rates are equal.

When you use this option, the `Initial condition` parameter does not apply and the block incurs no delay, because the input data immediately shows up in the output.

For example, for a single-channel input with 64 elements that is derepeated by a factor of 4, the block outputs 16 elements. The input and output frame periods are equal.

Also, in single-rate processing mode you can use this block in a triggered subsystem.

Multirate Processing

When you set the `Rate options` parameter to `Allow multirate processing`, the input and output of the block are the same size, but the sample rate of the output is *N* times slower than the input. *N* represents the `Derepeat factor, N` parameter.

- When you set the `Input processing` parameter to `Elements as channels (sample based)`, the block assumes that the input is a vector or matrix whose elements represent samples from independent channels. The block averages samples from each channel independently over time. The output period is *N* times the input period, and the input and output sizes are identical. The output is delayed by one output period, and the first output value is the `Initial condition` value. If you set `Rate options` to `Enforce single-rate processing`, the block generates an error message.
- When you set the `Input processing` parameter to `Columns as channels (frame based)`, the block reduces the sampling rate by using a proportionally longer frame *period* at the output port than at the input port. For derepetition by a factor of *N*, the output frame period is *N* times the input frame period, but the input and output frame sizes are equal. The output is delayed by one output frame, and the first output frame is the `Initial condition` value. The block derepeats each frame, treating distinct channels independently. Each element of the output is the average of *N* consecutive elements along a *column* of the input matrix. The derepeat factor must be less than the frame size.

  For example, for a single-channel input with a frame period of 1 second that is derepeated by a factor of 4, the output has a frame period of 4 seconds. The input and output frame sizes are equal.

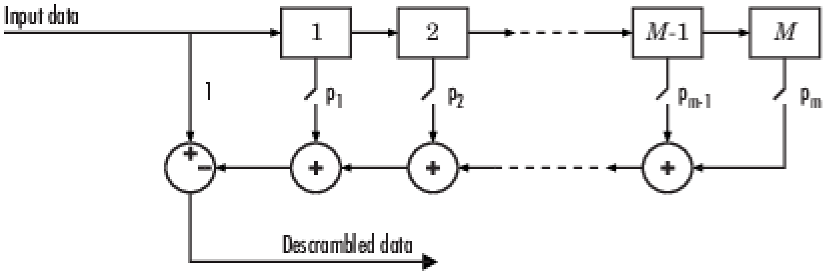
Descrambler

Descramble input signal
Library: Communications Toolbox / Sequence Operations

Description

The Descrambler block descrambles a scalar or column vector input signal. The Descrambler block is the inverse of the Scrambler block. If you use the Scrambler block in a transmitter, then you use the Descrambler block in the related receiver.

This schematic shows the descrambler operation. The adders and subtracter operate modulo *N*, where *N* is the value specified by the Calculation base parameter.



At each time step, the input causes the contents of the registers to shift sequentially. Using the Scramble polynomial parameter, you specify the on or off state for each switch in the descrambler. To make the Descrambler block reverse the operation of the Scrambler block, use the same parameter settings in both blocks. If there is no signal delay between the scrambler and the descrambler, then the **Initial states** in the two blocks must be the same.

To achieve repeatable initial descrambler conditions, you can use one of these optional input ports:

- Select the Reset on nonzero input via port parameter and reset the scrambler with Rst.
- Set the Initial states source parameter to `Input port` and provide the initial states with ISt.

This block can accept input sequences that vary in length during simulation. For more information about sequences that vary in length, see “Variable-Size Signal Basics” (Simulink).

Ports

Input

`in` — Input data signal

vector

Input data signal, specified as an N_S-by-1 vector. N_S represents the number of samples in the input signal. The input values must be integers from `0` to Calculation base – `1`.

Data Types: `double`

`Rst` — Reset scrambler

scalar

Reset scrambler, specified as a scalar. The scrambler is reset if a nonzero input is applied to the port.

Dependencies

To enable this port, set Initial states source to `Dialog Parameter` and select Reset on nonzero input via port.

`ISt` — Initial states

scalar

Initial states of the descrambler registers when the simulation starts, specified as a nonnegative integer vector. The length of **ISt** must equal the order of the Scramble polynomial parameter. The vector element values must be integers from `0` to Calculation base – `1`.

Dependencies

To enable this port, set Initial states source to `Input port`.

Output

`Out1` — Output descrambled data

vector

Output descrambled data, returned as an N_S-by-1 vector. N_S equals the number of samples in the input signal.

Data Types: `double`

Parameters

`Calculation base` — Calculation base

4 (default) | nonnegative integer

Calculation base used in the descrambler for modulo operations, specified as a nonnegative integer. The input and output of this block are integers from `0` to **Calculation base** – `1`.

`Scramble polynomial` — Polynomial that defines connections in descrambler

`'1 + z^-1 + z^-2 + z^-4'` (default) | character vector | integer vector | binary vector

Polynomial that defines the connections in the descrambler, specified as a character vector, integer vector, or binary vector. The **Scramble polynomial** parameter defines if each switch in the descrambler is on or off. Specify the polynomial as:

- A character vector, such as `'1 + z^-6 + z^-8'`. For more details on specifying polynomials in this way, see Character Representation of Polynomials.
- An integer vector, such as `[0 -6 -8]`, listing the descrambler coefficients in order of descending powers of z^{-1}, where $p(z^{-1}) = 1 + p_1 z^{-1} + p_2 z^{-2} + \ldots$
- A binary vector, such as `[1 0 0 0 0 0 1 0 1]`, listing the powers of *z* that appear in the polynomial that has a coefficient of 1. In this case, the order of the descramble polynomial is one less than the binary vector length.

Example: '1 + z^-6 + z^-8', [0 -6 -8], and [1 0 0 0 0 0 1 0 1] all represent this polynomial:

$p(z^{-1}) = 1 + z^{-6} + z^{-8}$

Initial states source — Set the source for descrambler initial states
Dialog Parameter (default) | Input port

- Dialog Parameter – Specify descrambler initial states by using the Initial states parameter.
- Input port – Specify descrambler initial states by using the ISt port.

Initial states — Initial states of descrambler registers
[0 1 2 3] (default) | nonnegative integer vector

Initial states of descrambler registers when the simulation starts, specified as a nonnegative integer vector. The length of **Initial states** must equal the order of the Scramble polynomial parameter. The vector element values must be integers from 0 to Calculation base – 1.

Dependencies

This parameter is available when Initial states source is set to Dialog Parameter.

Reset on nonzero input via port — Reset descrambler via input port
off (default) | on

Select this parameter to reset the Descrambler block via input port Rst.

Dependencies

This parameter is available when Initial states source is set to Dialog Parameter.

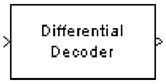
Differential Decoder

Decode binary signal using differential coding



Library

Source Coding

Description

The Differential Decoder block decodes the binary input signal. The output is the logical difference between the consecutive input element within a channel. More specifically, the block's input and output are related by

$m(i_0)$ = $d(i_0)$ XOR **Initial condition** parameter value

$m(i_k) = d(i_k)$ XOR $d(i_{k-1})$

where

- d is the differentially encoded input.
- m is the output message.
- i_k is the kth element.
- XOR is the logical exclusive-or operator.

This block accepts a scalar, column vector, or matrix input signal and treats columns as channels.

Parameters

Initial conditions

The logical exclusive-or of this value with the initial input value forms the initial output value.

Supported Data Type

Port	Supported Data Types
In	• double • single • boolean • integer • fixed-point

Port	Supported Data Types
Out	- double - single - boolean - integer - fixed-point

Differential Encoder

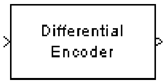
Encode binary signal using differential coding



Library

Source Coding

Description

The Differential Encoder block encodes the binary input signal within a channel. The output is the logical difference between the current input element and the previous output element. More specifically, the input and output are related by

$d(i_0)$ = $m(i_0)$ XOR **Initial condition** parameter value

$d(i_k) = d(i_{k-1})$ XOR $m(i_k)$

where

- m is the input message.
- d is the differentially encoded output.
- i_k is the kth element.
- XOR is the logical exclusive-or operator.

This block accepts a scalar or column vector input signal and treats columns as channels.

Parameters

Initial conditions

The logical exclusive-or of this value with the initial input value forms the initial output value.

Discrete-Time VCO

Implement voltage-controlled oscillator in discrete time

Library

Components sublibrary of Synchronization

Description

The Discrete-Time VCO (voltage-controlled oscillator) block generates a signal whose frequency shift from the **Quiescent frequency** parameter is proportional to the input signal. The input signal is interpreted as a voltage. If the input signal is $u(t)$, then the output signal is

$$y(t) = A_c\cos\left(2\pi f_c t + 2\pi k_c\int_0^t u(\tau)d\tau + \varphi\right)$$

where A_c is the **Output amplitude**, f_c is the **Quiescent frequency**, k_c is the **Input sensitivity**, and φ is the **Initial phase**

This block uses a discrete-time integrator to interpret the equation above.

This block accepts a scalar-valued input signal with a data type of `single` or `double`. The output signal inherits its data type from the input signal. The block supports double precision only for code generation.

Parameters

Output amplitude

The amplitude of the output.

Quiescent frequency (Hz)

The frequency of the oscillator output when the input signal is zero.

Input sensitivity

This value scales the input voltage and, consequently, the shift from the **Quiescent frequency** value. The units of **Input sensitivity** are Hertz per volt.

Initial phase (rad)

The initial phase of the oscillator in radians.

Sample time

The calculation sample time.

DPD

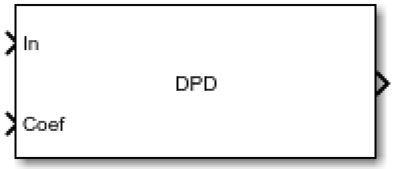
Digital predistorter

Library: Communications Toolbox / RF Impairments Correction

Description

Apply digital predistortion (DPD) to a complex baseband signal using a memory polynomial to compensate for nonlinearities in a power amplifier. For more information, see “Digital Predistortion” on page 5-194.

This icon shows the block with all ports enabled.



Ports

Input

`In` — Input baseband signal
column vector

Input baseband signal, specified as a column vector. This port is unnamed until the **Coefficient source** parameter is set to `Input port`.

Data Types: `double`
Complex Number Support: Yes

`Coef` — Memory-polynomial coefficients
matrix

Memory-polynomial coefficients, specified as a matrix. The number of rows in the matrix must equal the memory depth of the memory polynomial.

- If the **Polynomial type** parameter is set to `Memory polynomial`, the number of columns in the matrix is the degree of the memory polynomial.
- If **Polynomial type** is set to `Cross-term memory polynomial`, the number of columns in the matrix must equal $m(n\text{-}1)+1$. m is the memory depth of the polynomial, and n is the degree of the memory polynomial.

Example: `complex([1 0 0 0 0; 0 0 0 0 0; 0 0 0 0 0])`

Dependencies

To enable this port, set the **Coefficient source** parameter to `Input port`.

Data Types: `double`
Complex Number Support: Yes

Output

`Out` — Predistorted baseband signal
column vector

Predistorted baseband signal, returned as a column vector of the same length as the input signal.

Parameters

`Polynomial type` — Polynomial type
`Memory polynomial` (default) | `Cross-term memory polynomial`

Polynomial type used for predistortion, specified as one of these values:

- `Memory polynomial` — Computes predistortion coefficients by using a memory polynomial without cross terms
- `Cross-term memory polynomial` — Computes predistortion coefficients by using a memory polynomial with cross terms

For more information, see "Digital Predistortion" on page 5-194.

`Coefficient source` — Source of memory-polynomial coefficients
`Property` (default) | `Input port`

Source of the memory polynomial coefficients, specified as one of these values:

- `Property` — Specify this value to use the **Coefficients** parameter to define the memory-polynomial coefficients
- `Input port` — Specify this value to use the **Coef** input port to define the memory-polynomial coefficients

`Coefficients` — Memory-polynomial coefficients
`complex([1 0 0 0 0; 0 0 0 0 0; 0 0 0 0 0])` (default) | matrix

Memory-polynomial coefficients, specified as a matrix. The number of rows must equal the memory depth of the memory polynomial.

- If the **Polynomial type** is set to `Memory polynomial`, the number of columns is the degree of the memory polynomial.
- If the **Polynomial type** is set to `Cross-term memory polynomial`, the number of columns must equal $m(n\text{-}1)+1$. m is the memory depth of the polynomial, and n is the degree of the memory polynomial.

For more information, see "Digital Predistortion" on page 5-194.

Dependencies

To enable this parameter, set **Coefficient source** to `Property`.

Data Types: `double`
Complex Number Support: Yes

`Simulate using` — Type of simulation to run
`Code generation` (default) | `Interpreted execution`

Type of simulation to run, specified as `Code generation` or `Interpreted execution`.

- `Code generation` –– Simulate the model by using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations unless the model changes. This option requires additional startup time, but the speed of the subsequent simulations is faster than `Interpreted execution`.
- `Interpreted execution` –– Simulate the model by using the MATLAB interpreter. This option requires less startup time than the `Code generation` method, but the speed of subsequent simulations is slower. In this mode, you can debug the source code of the block.

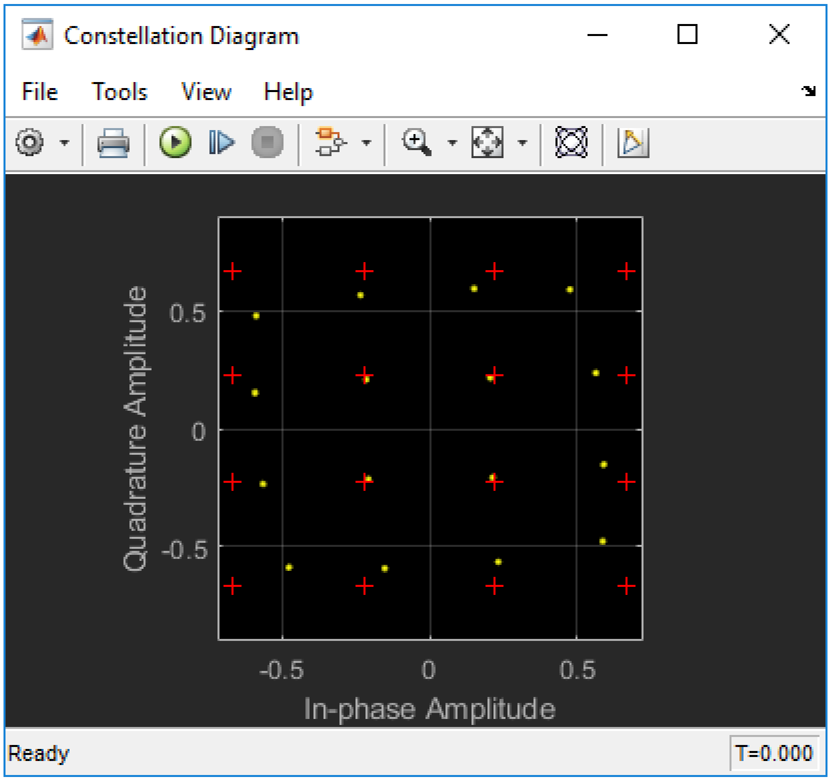
Block Characteristics

Data Types	`double` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`yes`

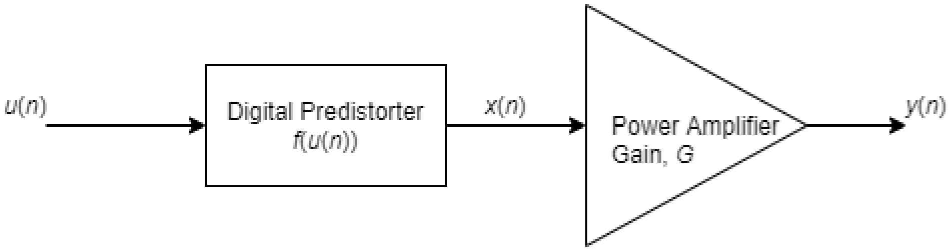
More About

Digital Predistortion

Wireless communication transmissions commonly require wide bandwidth signal transmission over a wide signal dynamic range. To transmit signals over a wide dynamic range and achieve high efficiency, RF power amplifiers (PAs) commonly operate in their nonlinear region. As this constellation diagram shows, the nonlinear behavior of a PA causes signal constellation distortions that pinch the amplitude (AM-AM distortion) and twist phase (AM-PM distortion) of constellation points proportional to the amplitude of the constellation point.



The goal of digital predistortion is to find a nonlinear function that linearizes the net effect of the PA nonlinear behavior at the PA output across the PA operating range. When the PA input is $x(n)$, and the predistortion function is $f(u(n))$, where $u(n)$ is the true signal to be amplified, the PA output is approximately equal to $G\times u(n)$, where G is the desired amplitude gain of the PA.



The digital predistorter can be configured to use a memory polynomial with or without cross terms.

- The memory polynomial with cross terms predistorts the input signal as

$$x(n) = f(u(n)) \triangleq \sum_{m=0}^{M-1} c_m \times u(n\text{-}m) + \sum_{m=0}^{M-1}\sum_{j=0}^{M-1}\sum_{k=0}^{K-1} a_{mjk} \times u(n\text{-}m) \times \left|u(n\text{-}j)\right|^k .$$

  The memory polynomial with cross terms has (M+M×M×(K-1)) coefficients for c_m and a_{mjk}.
- The memory polynomial without cross terms predistorts the input signal as

$$x(n) = f(u(n)) \triangleq \sum_{m=0}^{M-1}\sum_{k=0}^{K-1} a_{mk} \times u(n\text{-}m) \times \left|u(n\text{-}m)\right|^k .$$

The polynomial without cross terms has $M \times K$ coefficients for a_{mk}.

Estimating Predistortion Function and Coefficients

The DPD coefficient estimation uses an indirect learning architecture to find function $f(u(n))$ to predistort input signal $u(n)$ which precedes the PA input.

The DPD coefficient estimation algorithm models nonlinear PA memory effects based on the work in reference papers by Morgan, et al [1], and by Schetzen [2], using the theoretical foundation developed for Volterra systems.

Specifically, the inverse mapping from the PA output normalized by the PA gain, $\{y(n)/G\}$, to the PA input, $\{x(n)\}$, provides a good approximation to the function $f(u(n))$, needed to predistort $\{u(n)\}$ to produce $\{x(n)\}$.

Referring to the memory polynomial equations above, estimates are computed for the memory-polynomial coefficients:

- c_m and a_{mjk} for a memory polynomial with cross terms
- a_{mk} for a memory polynomial without cross terms

The memory-polynomial coefficients are estimated by using a least squares fit algorithm or a recursive least squares algorithm. The least squares fit algorithm or a recursive least squares algorithms use the memory polynomial equations above for a memory polynomial with or without cross terms, by replacing $\{u(n)\}$ with $\{y(n)/G\}$. The function order and dimension of the coefficient matrix are defined by the degree and depth of the memory polynomial.

For an example that details the process of accurately estimating memory-polynomial coefficients and predistorting a PA input signal, see “Digital Predistortion to Compensate for Power Amplifier Nonlinearities”.

For background reference material, see the works listed in [1] and [2].

PA In
PA Out
DPD
Coefficient Estimator
Forgetting Factor

Ports

Input

`PA In` — Power amplifier baseband-equivalent input
column vector

Power amplifier baseband-equivalent input, specified as a column vector.

Data Types: `double`
Complex Number Support: Yes

`PA Out` — Power amplifier baseband-equivalent output
column vector

Power amplifier baseband-equivalent output, specified as a column vector of the same length as **PA In**.

Data Types: `double`
Complex Number Support: Yes

`Forgetting Factor` — Forgetting factor
scalar in the range (0, 1]

Forgetting factor used by the recursive least squares algorithm, specified as a scalar in the range (0, 1]. Decreasing the forgetting factor reduces the convergence time but causes the output estimates to be less stable.

Dependencies

To enable this port, set **Algorithm** to `Recursive least squares` and set **Forgetting factor source** to `Input port`.

Data Types: `double`

Output

`Out` — Memory-polynomial coefficients
matrix

Memory-polynomial coefficients, returned as a matrix. For more information, see “Digital Predistortion” on page 5-201.

Parameters

`Desired amplitude gain (dB)` — Desired amplitude gain
`10` (default) | scalar

Desired amplitude gain in dB, specified as a scalar. This parameter value expresses the desired signal gain at the compensated amplifier output.

Tunable: Yes

Data Types: `double`

`Polynomial type` — Polynomial type
`Memory polynomial` (default) | `Cross-term memory polynomial`

Polynomial type used for predistortion, specified as one of these values:

- `Memory polynomial` — Computes predistortion coefficients by using a memory polynomial without cross terms
- `Cross-term memory polynomial` — Computes predistortion coefficients by using a memory polynomial with cross terms

For more information, see “Digital Predistortion” on page 5-201.

`Degree` — Memory-polynomial degree
`5` (default) | positive integer

Memory-polynomial degree, specified as a positive integer.

Data Types: `double`

`Memory depth` — Memory-polynomial depth
`3` (default) | positive integer

Memory-polynomial depth in samples, specified as a positive integer.

Data Types: `double`

`Algorithm` — Estimation algorithm
`Least squares` (default) | `Recursive least squares`

Adaptive algorithm used for equalization, specified as one of these values:

- `Least squares` — Estimate the memory-polynomial coefficients by using a least squares algorithm
- `Recursive least squares` — Estimate the memory-polynomial coefficients by using a recursive least squares algorithm

For algorithm reference material, see the works listed in [1] and [2].

Data Types: `char` | `string`

`Forgetting factor source` — Source of forgetting factor

`Property` (default) | `Input port`

Source of the forgetting factor, specified as one of these values:

- `Property` — Specify this value to use the **Forgetting factor** parameter to specify the forgetting factor.
- `Input port` — Specify this value to use the **Forgetting Factor** input port to specify the forgetting factor.

Dependencies

To enable this parameter, set **Algorithm** to `Recursive least squares`.

Data Types: `double`

`Forgetting factor` — Forgetting factor

`0.99` (default) | scalar in the range (0, 1]

Forgetting factor used by the recursive least squares algorithm, specified as a scalar in the range (0, 1]. Decreasing the forgetting factor reduces the convergence time but causes the output estimates to be less stable.

Dependencies

To enable this parameter, set **Algorithm** to `Recursive least squares` and set **Forgetting factor source** to `Property`.

Data Types: `double`

`Initial coefficient estimate` — Initial coefficient estimate

`[]` (default) | matrix

Initial coefficient estimate for the recursive least squares algorithm, specified as a matrix.

- If you specify this value as an empty matrix, the initial coefficient estimate for the recursive least squares algorithm is chosen automatically to correspond to a memory polynomial that is an identity function, so that the output is equal to input.
- If you specify this value as a nonempty matrix, the number of rows must be equal to the **Memory depth** parameter value.
  - If the **Polynomial type** parameter is set to `Memory polynomial`, the number of columns is the degree of the memory polynomial.
  - If the **Polynomial type** parameter is set to `Cross-term memory polynomial`, the number of columns must equal $m(n\text{-}1)+1$. m is the memory depth of the polynomial, and n is the degree of the memory polynomial.

For more information, see “Digital Predistortion” on page 5-201.

Dependencies

To enable this parameter, set **Algorithm** to `Recursive least squares`.

Data Types: `double`
Complex Number Support: Yes

`Simulate using` — Type of simulation to run

`Code generation` (default) | `Interpreted execution`

Type of simulation to run, specified as `Code generation` or `Interpreted execution`.

- `Code generation` –– Simulate the model by using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations unless the model changes. This option requires additional startup time, but the speed of the subsequent simulations is faster than `Interpreted execution`.
- `Interpreted execution` –– Simulate the model by using the MATLAB interpreter. This option requires less startup time than the `Code generation` method, but the speed of subsequent simulations is slower. In this mode, you can debug the source code of the block.

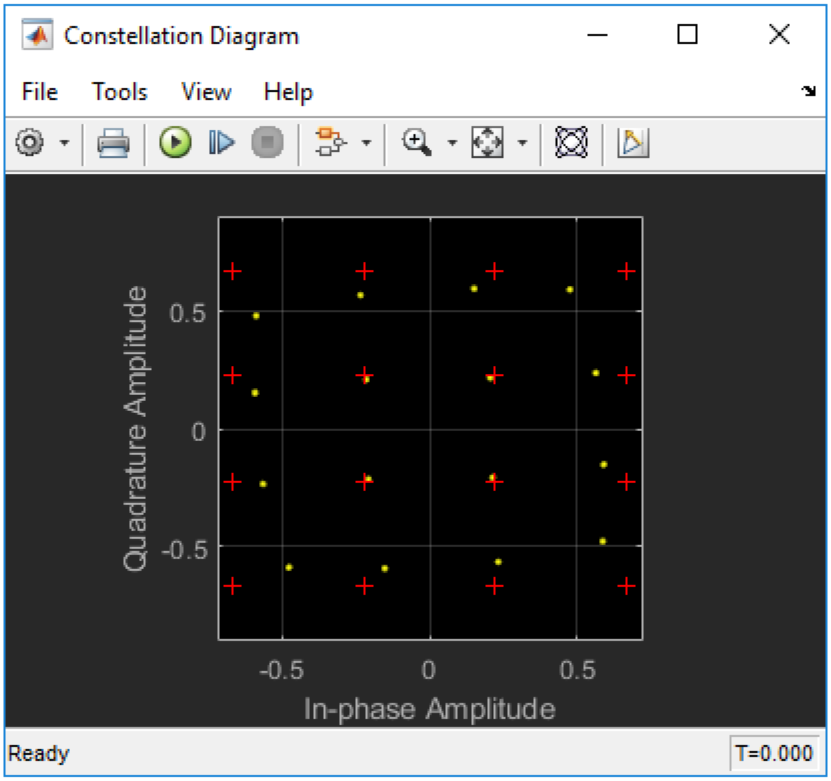
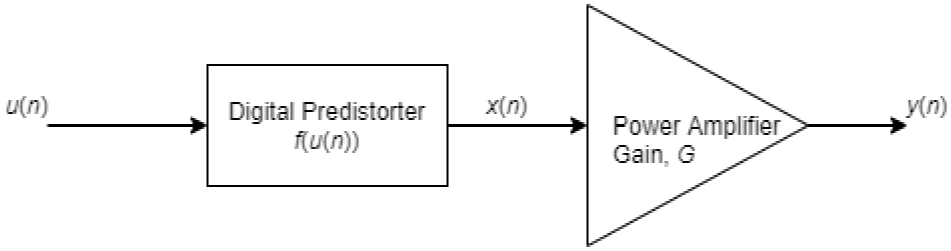
More About

Digital Predistortion

Wireless communication transmissions commonly require wide bandwidth signal transmission over a wide signal dynamic range. To transmit signals over a wide dynamic range and achieve high efficiency, RF power amplifiers (PAs) commonly operate in their nonlinear region. As this constellation diagram shows, the nonlinear behavior of a PA causes signal constellation distortions that pinch the amplitude (AM-AM distortion) and twist phase (AM-PM distortion) of constellation points proportional to the amplitude of the constellation point.



The goal of digital predistortion is to find a nonlinear function that linearizes the net effect of the PA nonlinear behavior at the PA output across the PA operating range. When the PA input is $x(n)$, and the predistortion function is $f(u(n))$, where $u(n)$ is the true signal to be amplified, the PA output is approximately equal to $G\times u(n)$, where G is the desired amplitude gain of the PA.



The digital predistorter can be configured to use a memory polynomial with or without cross terms.

- The memory polynomial with cross terms predistorts the input signal as

$$x(n) = f(u(n)) \triangleq \sum_{m=0}^{M-1} c_m \times u(n\text{-}m) + \sum_{m=0}^{M-1}\sum_{j=0}^{M-1}\sum_{k=0}^{K-1} a_{mjk} \times u(n\text{-}m) \times \left|u(n\text{-}j)\right|^k .$$

  The memory polynomial with cross terms has $(M+M\times M\times(K\text{-}1))$ coefficients for c_m and a_{mjk}.
- The memory polynomial without cross terms predistorts the input signal as

$$x(n) = f(u(n)) \triangleq \sum_{m=0}^{M-1}\sum_{k=0}^{K-1} a_{mk} \times u(n\text{-}m) \times \left|u(n\text{-}m)\right|^k .$$

The polynomial without cross terms has $M \times K$ coefficients for a_{mk}.

Estimating Predistortion Function and Coefficients

The DPD coefficient estimation uses an indirect learning architecture to find function $f(u(n))$ to predistort input signal $u(n)$ which precedes the PA input.

The DPD coefficient estimation algorithm models nonlinear PA memory effects based on the work in reference papers by Morgan, et al [1], and by Schetzen [2], using the theoretical foundation developed for Volterra systems.

Specifically, the inverse mapping from the PA output normalized by the PA gain, $\{y(n)/G\}$, to the PA input, $\{x(n)\}$, provides a good approximation to the function $f(u(n))$, needed to predistort $\{u(n)\}$ to produce $\{x(n)\}$.

Referring to the memory polynomial equations above, estimates are computed for the memory-polynomial coefficients:

- c_m and a_{mjk} for a memory polynomial with cross terms
- a_{mk} for a memory polynomial without cross terms

The memory-polynomial coefficients are estimated by using a least squares fit algorithm or a recursive least squares algorithm. The least squares fit algorithm or a recursive least squares algorithms use the memory polynomial equations above for a memory polynomial with or without cross terms, by replacing $\{u(n)\}$ with $\{y(n)/G\}$. The function order and dimension of the coefficient matrix are defined by the degree and depth of the memory polynomial.

For an example that details the process of accurately estimating memory-polynomial coefficients and predistorting a PA input signal, see “Digital Predistortion to Compensate for Power Amplifier Nonlinearities”.

For background reference material, see the works listed in [1] and [2].

DQPSK Demodulator Baseband

Demodulate DQPSK-modulated data

Library

PM, in Digital Baseband sublibrary of Modulation

Description

The DQPSK Demodulator Baseband block demodulates a signal that was modulated using the differential quadrature phase shift keying method. The input is a baseband representation of the modulated signal.

The input must be a discrete-time complex signal. The output depends on the phase difference between the current symbol and the previous symbol. The first integer (or binary pair, if you set the **Output type** parameter to `Bit`) at the block output is the initial condition of zero because there is no previous symbol.

This block accepts either a scalar or column vector input signal. For information about the data types each block port supports, see “Supported Data Types” on page 5-206.

Outputs and Constellation Types

When you set **Output type** parameter to `Integer`, the block maps a phase difference of

$\theta + \pi m/2$

to *m*, where θ represents the **Phase rotation** parameter and *m* is 0, 1, 2, or 3.

When you set the **Output type** parameter to `Bit`, then the output contains pairs of binary values. The reference page for the DQPSK Modulator Baseband block shows which phase differences map to each binary pair, for the cases when the **Constellation ordering** parameter is either `Binary` or `Gray`.

Function Block Parameters: DQPSK Demodulator Baseband

DQPSK Demodulator Baseband (mask) (link)

Demodulate the input signal using the differential quaternary phase shift keying method.

Parameters

Output type: Integer

Constellation ordering: Gray

Phase rotation (rad):

pi/4

Output data type: Inherit via internal rule

Output type

Determines whether the output consists of integers or pairs of bits.

Constellation ordering

Determines how the block maps each integer to a pair of output bits.

Phase rotation (rad)

This phase difference between the current and previous modulated symbols results in an output of zero.

Output data type

When the parameter is set to `'Inherit via internal rule'` (default setting), the block will inherit the output data type from the input port. The output data type will be the same as the input data type if the input is of type `single` or `double`.

For integer outputs, this block can output the data types `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `single`, and `double`. For bit outputs, output can be `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, or `double`.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point
Output	• Double-precision floating point • Single-precision floating point • Boolean when **Output type** is`Bit` • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers

DQPSK Modulator Baseband

Modulate using differential quadrature phase shift keying method

Library

PM, in Digital Baseband sublibrary of Modulation

Description

The DQPSK Modulator Baseband block modulates using the differential quadrature phase shift keying method. The output is a baseband representation of the modulated signal.

The input must be a discrete-time signal. For information about the data types each block port supports, see “Supported Data Types” on page 5-210.

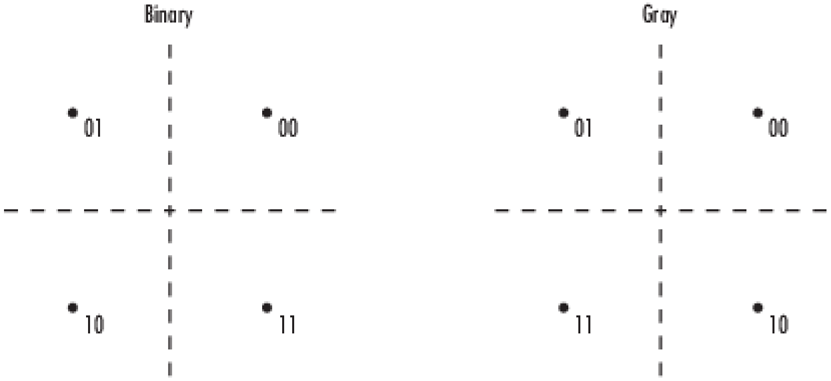
Integer-Valued Signals and Binary-Valued Signals

When you set the **Input type** parameter to `Integer`, the valid input values are 0, 1, 2, and 3. In this case, the block accepts a scalar or column vector input signal. If the first input is *m*, then the modulated symbol is

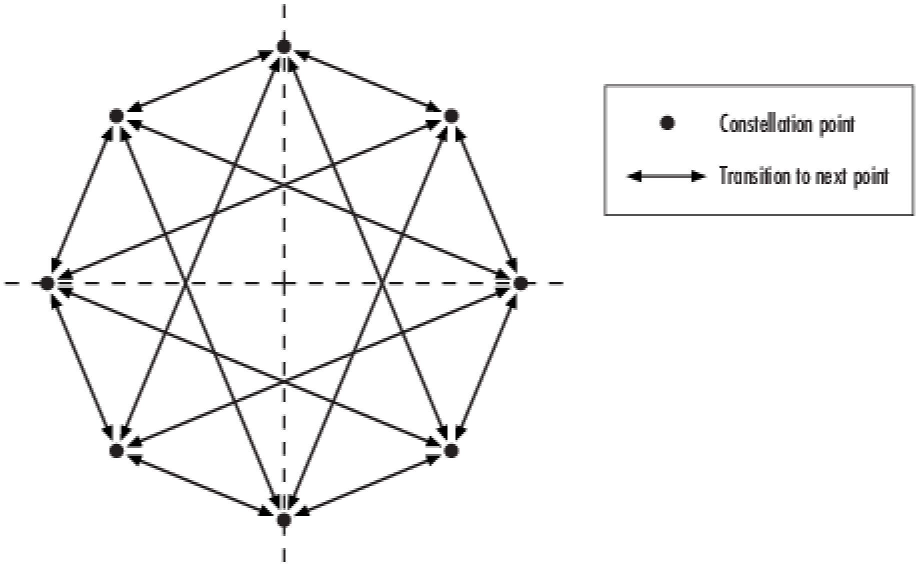
$\exp(j\theta + j\pi m/2)$

where θ represents the **Phase rotation** parameter. If a successive input is *m*, then the modulated symbol is the previous modulated symbol multiplied by $\exp(j\theta + j\pi m/2)$.

When you set the **Input type** parameter to `Bit`, the input contains pairs of binary values. In this case, the block accepts a column vector whose length is an even integer. The following figure shows the complex numbers by which the block multiples the previous symbol to compute the current symbol, depending on whether you set the **Constellation ordering** parameter to `Binary` or `Gray`. The following figure assumes that you set the **Phase rotation** parameter to $\frac{\Pi}{4}$; in other cases, the two schematics would be rotated accordingly.

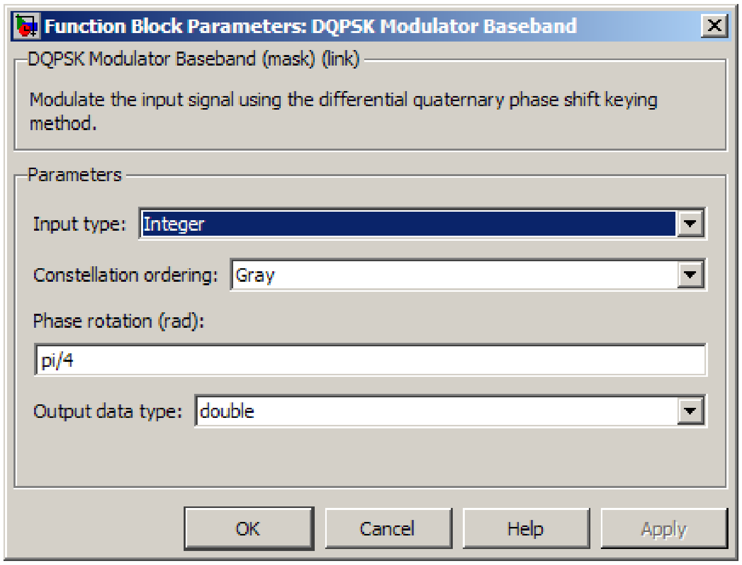


The following figure shows the signal constellation for the DQPSK modulation method when you set the **Phase rotation** parameter to $\frac{\Pi}{4}$. The arrows indicate the four possible transitions from each symbol to the next symbol. The `Binary` and `Gray` options determine which transition is associated with each pair of input values.



More generally, if the **Phase rotation** parameter has the form $\frac{\Pi}{k}$for some integer k, then the signal constellation has $2k$ points.

Dialog Box



Function Block Parameters: DQPSK Modulator Baseband

DQPSK Modulator Baseband (mask) (link)

Modulate the input signal using the differential quaternary phase shift keying method.

Parameters

Input type: Integer

Constellation ordering: Gray

Phase rotation (rad):

pi/4

Output data type: double

Input type

Indicates whether the input consists of integers or pairs of bits.

Constellation ordering

Determines how the block maps each pair of input bits to a corresponding integer, using either a Binary or Gray mapping scheme.

Phase rotation (rad)

The phase difference between the previous and current modulated symbols when the input is zero.

Output Data type

The output data type can be either `single` or `double`. By default, the block sets this to `double`.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point • Boolean when **Input type** is `Bit` • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers
Output	• Double-precision floating point • Single-precision floating point

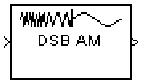
DSB AM Demodulator Passband

Demodulate DSB-AM-modulated data



Library

Analog Passband Modulation, in Modulation

Description

The DSB AM Demodulator Passband block demodulates a signal that was modulated using double-sideband amplitude modulation. The block uses the envelope detection method. The input is a passband representation of the modulated signal. Both the input and output signals are real scalar signals.

In the course of demodulating, this block uses a filter whose order, coefficients, passband ripple and stopband ripple are described by their respective lowpass filter parameters.

Typically, an appropriate **Carrier frequency** value is much higher than the highest frequency of the input signal. By the Nyquist sampling theorem, the reciprocal of the model's sample time (defined by the model's signal source) must exceed twice the **Carrier frequency** parameter.

This block works only with real inputs of type `double`. This block does not work inside a triggered subsystem.

Parameters

Input signal offset

The same as the **Input signal offset** parameter in the corresponding DSB AM Modulator Passband block.

Carrier frequency (Hz)

The frequency of the carrier in the corresponding DSB AM Modulator Passband block.

Initial phase (rad)

The initial phase of the carrier in radians.

Lowpass filter design method

The method used to generate the filter. Available methods are Butterworth, Chebyshev type I, Chebyshev type II, and Elliptic.

Filter order

The order of the lowpass digital filter specified in the **Lowpass filter design method** field .

Cutoff frequency (Hz)

The cutoff frequency of the lowpass digital filter specified in the **Lowpass filter design method** field in Hertz.

Passband ripple (dB)

Applies to Chebyshev type I and Elliptic filters only. This is peak-to-peak ripple in the passband in dB.

Stopband ripple (dB)

Applies to Chebyshev type II and Elliptic filters only. This is the peak-to-peak ripple in the stopband in dB.

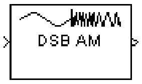
Pair Block

DSB AM Modulator Passband

Introduced before R2006a

DSB AM Modulator Passband

Modulate using double-sideband amplitude modulation



Library

Analog Passband Modulation, in Modulation

Description

The DSB AM Modulator Passband block modulates using double-sideband amplitude modulation. The output is a passband representation of the modulated signal. Both the input and output signals are real scalar signals.

If the input is $u(t)$ as a function of time t, then the output is

$$(u(t) + k)\cos(2\pi f_c t + \theta)$$

where:

- k is the **Input signal offset** parameter.
- f_c is the **Carrier frequency** parameter.
- θ is the **Initial phase** parameter.

It is common to set the value of k to the maximum absolute value of the negative part of the input signal $u(t)$.

Typically, an appropriate **Carrier frequency** value is much higher than the highest frequency of the input signal. By the Nyquist sampling theorem, the reciprocal of the model's sample time (defined by the model's signal source) must exceed twice the **Carrier frequency** parameter.

This block works only with real inputs of type `double`. This block does not work inside a triggered subsystem.

Parameters

Input signal offset

The offset factor k. This value should be greater than or equal to the absolute value of the minimum of the input signal.

Carrier frequency (Hz)

The frequency of the carrier.

Initial phase (rad)

The initial phase of the carrier.

DSBSC AM Demodulator Passband

Demodulate DSBSC-AM-modulated data

Library

Analog Passband Modulation, in Modulation

Description

The DSBSC AM Demodulator Passband block demodulates a signal that was modulated using double-sideband suppressed-carrier amplitude modulation. The input is a passband representation of the modulated signal. Both the input and output signals are real scalar signals.

In the course of demodulating, this block uses a filter whose order, coefficients, passband ripple and stopband ripple are described by the their respective lowpass filter parameters.

Typically, an appropriate **Carrier frequency** value is much higher than the highest frequency of the input signal. By the Nyquist sampling theorem, the reciprocal of the model's sample time (defined by the model's signal source) must exceed twice the **Carrier frequency** parameter.

This block works only with real inputs of type `double`. This block does not work inside a triggered subsystem.

Parameters

Carrier frequency (Hz)

The carrier frequency in the corresponding DSBSC AM Modulator Passband block.

Initial phase (rad)

The initial phase of the carrier in radians.

Lowpass filter design method

The method used to generate the filter. Available methods are Butterworth, Chebyshev type I, Chebyshev type II, and Elliptic.

Filter order

The order of the lowpass digital filter specified in the **Lowpass filter design method** field .

Cutoff frequency (Hz)

The cutoff frequency of the lowpass digital filter specified in the Lowpass filter design method field in Hertz.

Passband Ripple (dB)

Applies to Chebyshev type I and Elliptic filters only. This is peak-to-peak ripple in the passband in dB.

Stopband Ripple (dB)

Applies to Chebyshev type II and Elliptic filters only. This is the peak-to-peak ripple in the stopband in dB.

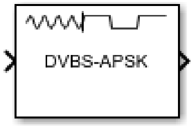
DVBS-APSK Demodulator Baseband

DVB-S2/S2X/SH standard-specific amplitude phase shift keying (APSK) demodulation

Library: Communications Toolbox / Modulation / Digital Baseband Modulation / APM
Communications Toolbox / Modulation / Digital Baseband Modulation / Standard-Compliant



Description

The DVBS-APSK Demodulator Baseband block demodulates the input signal using Digital Video Broadcasting (“DVB-S2/S2X/SH” on page 5-223) standard-specific amplitude phase shift keying (APSK) demodulation. For a description of DVB-compliant APSK demodulation, see “DVB Compliant APSK Hard Demodulation” on page 5-224 and “DVB Compliant APSK Soft Demodulation” on page 5-224.

This icon shows the block with all ports enabled:

In
DVBS-APSK
Var

Ports

Input

In — DVB-S2/S2X/SH standard-specific APSK modulated signal
scalar | vector | matrix

DVB-S2/S2X/SH standard-specific APSK modulated signal, specified as a scalar, vector, or matrix. When this input is a matrix, each column is treated as an independent channel. This port is unnamed until the Var port is enabled.

Data Types: double | single
Complex Number Support: Yes

Var — Noise variance
positive scalar | vector of positive values

Noise variance, specified as a positive scalar or vector of positive values. When the noise variance or signal power result in computations involving extreme positive or negative magnitudes, see “DVB Compliant APSK Soft Demodulation” on page 5-224 for demodulation decision type considerations.

Dependencies

This parameter applies when Noise variance source is set to Input port.

Data Types: double | single

Output

Out — Demodulated signal
scalar | vector | matrix

Demodulated signal, returned as a scalar, vector, or matrix. The dimensions of the demodulated signal depend on the specified Output type and Decision type. This port is unnamed on the block.

Output type	Decision type	Demodulated Signal Description	Dimensions of Demodulated Signal
Integer	—	Demodulated integer values in the range [0, (M – 1)]	The output signal has the same dimensions as the input signal.
Bit	Hard decision	Demodulated bits	The number of rows in the output signal is $\log_2(M)$ times the number of rows in the input signal. Each demodulated symbol is mapped to a group of $\log_2(M)$ elements in a column, where the first element represents the MSB and the last element represents the LSB.
	Log-likelihood ratio	Log-likelihood ratio value for each bit	
	Approximate log-likelihood ratio	Approximate log-likelihood ratio value for each bit	
M is the value of Modulation order.			

Use Output data type to specify the output data type.

Parameters

DVB standard suffix — Standard suffix
S2 | S2X | SH

Standard suffix for DVB modulation variant, specified as S2, S2X, or SH.

Frame length — Frame length
Normal (default) | Short

Frame length, specified as Normal or Short.

Dependencies

This parameter applies only when DVB standard suffix is set to S2 or S2X.

Modulation order — Modulation order
16 (default) | integer

Modulation order, specified as a power of two. The modulation order specifies the total number of points in the constellation of the input signal. The list of valid modulation orders varies depending on the setting for DVB standard suffix and Frame length.

DVB standard suffix	Frame length	Modulation order Options
S2	Normal or Short	16 or 32
S2X	Normal	8, 16, 32, 64, or 256
	Short	16 or 32
SH	Not applicable	16

Code identifier — Code identifier

2/3 | character vector

Code identifier, specified as a character vector. The list of valid code identifier values varies depending on the setting for DVB standard suffix, Frame length, and Modulation order. This table lists the available options for **Code identifier** values.

Modulation order	DVB standard suffix	Frame length	Code identifier Options
8	S2X	Normal	100/180 or 104/180
16	S2 or S2X	Normal	2/3, 3/4, 4/5, 5/6, 8/9, or 9/10
		Short	2/3, 3/4, 4/5, 5/6, or 8/9
16	S2X	Normal	26/45, 3/5, 28/45, 23/36, 25/36, 13/18, 140/180, 154/180, 100/180, 96/180, 90/180, 18/30, or 20/30
		Short	7/15, 8/16, 26/45, 3/5, or 32/45
32	S2 or S2X	Normal	3/4, 4/5, 5/6, 8/9, or 9/10
		Short	3/4, 4/5, 5/6, or 8/9
32	S2X	Normal	128/180, 132/180, 140/180, or 2/3
		Short	2/3 or 32/45
64	S2X	Normal	128/180 , 132/180, 7/9, 4/5, or 5/6
128	S2X	Normal	135/180 or 140/180
256	S2X	Normal	116/180, 124/180, 128/180, 20/30, or 135/180

For more information, refer to Tables 9 and 10 in the DVB-S2 standard [1] and Table 17a in the DVB-S2X standard [2].

Dependencies

This parameter applies only when **DVB standard suffix** is set to S2 or S2X.

Constellation scaling — Constellation scaling

Outer radius as 1 (default) | Unit average power

Constellation scaling, specified as Outer radius as 1 or Unit average power.

Dependencies

This input argument applies only when DVB standard suffix is set to S2 or S2X.

Output type — Output type

Integer (default) | Bit

Output type, specified as Integer or Bit.

Data Types: char | string

Decision type — Demodulation decision type

Hard decision (default) | Log-likelihood ratio | Approximate log-likelihood ratio

Demodulation decision type, specified as Hard decision, Log-likelihood ratio, or Approximate log-likelihood ratio. See "DVB Compliant APSK Soft Demodulation" on page 5-224 for algorithm selection considerations.

Dependencies

This parameter applies when Output type is set to Bit.

Noise variance source — Noise variance source

Property (default) | Input port

Noise variance source, specified as:

- Property — The noise variance is set using the Noise variance parameter.
- Input port — The noise variance is set using the Var input port.

Noise variance — Noise variance

1 (default) | positive scalar | vector of positive values

Noise variance, specified as a positive scalar or vector of positive values.

- When specified as a scalar, that value is used on all elements in the input signal.
- When specified as a vector, the vector length must be equal to the number of columns in the input signal. Each noise variance vector element is applied to its corresponding column in the input signal.

When the noise variance or signal power result in computations involving extreme positive or negative magnitudes, see "DVB Compliant APSK Soft Demodulation" on page 5-224 for demodulation decision type considerations.

Dependencies

This parameter applies when Noise variance source is set to Property and Decision type is set to either Log-likelihood ratio or Approximate log-likelihood ratio.

Data Types: double

Output data type — Output data type

double (default) | ...

Output data type, specified as one of the acceptable values from this table. Acceptable **Output data type** values depend on the Output type and Decision type parameter values.

Output type	Decision type	Output data type Options
Integer	Not applicable	double, single, int8, uint8, int16, uint16, int32, or uint32
Bit	Hard decision	double, single, int8, uint8, int16, uint16, int32, uint32, or logical
	Log-likelihood ratio or Approximate log-likelihood ratio	The output signal is the same data type as the input signal.

Dependencies

This parameter applies only when Output type is set to Integer or when Output type is set to Bit and Decision type is set to Hard decision.

Simulate using — Type of simulation to run

Interpreted execution (default) | Code generation

Type of simulation to run, specified as:

- Code generation –– Simulate the model using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations as long as the model does not change. This option requires additional startup time.
- Interpreted execution –– Simulate the model using the MATLAB interpreter. This option shortens startup time. In Interpreted execution mode, you can debug the source code of the block.

For information on execution speed, see “Tips” on page 5-225.

Block Characteristics

Data Types	Boolean | double | integer | single
Multidimensional Signals	yes
Variable-Size Signals	no

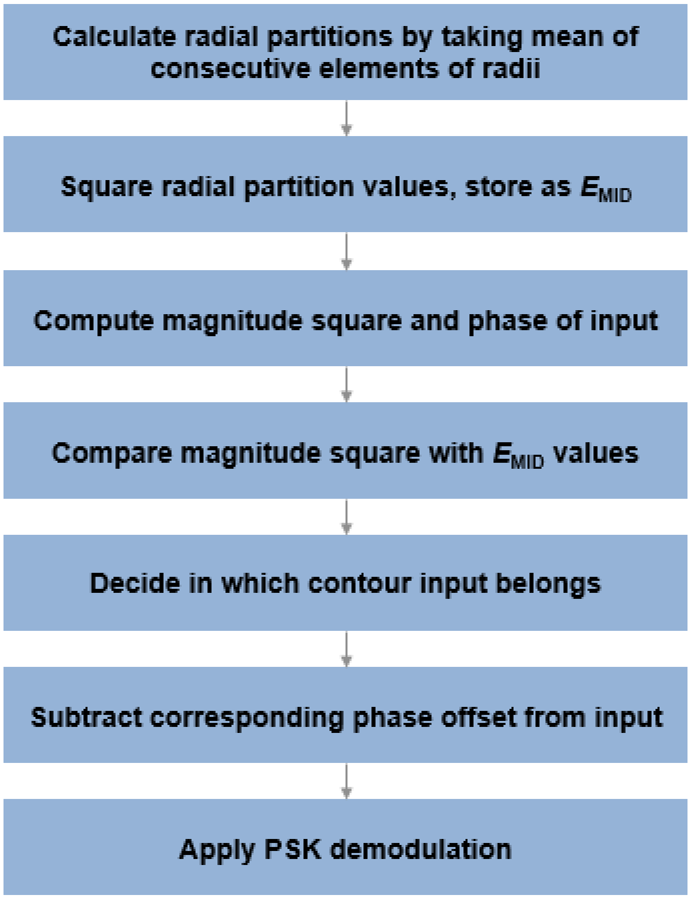
More About

DVB-S2/S2X/SH

Digital video broadcasting (DVB) standards specify S2, S2X, and SH standard-specific amplitude phase shift keying (APSK) modulation. For further information on the DVB-S2/S2X/SH standards, see [1], [2], and [3], respectively.

DVB Compliant APSK Hard Demodulation

The hard demodulation algorithm applies amplitude phase decoding as described in [4].



Calculate radial partitions by taking mean of consecutive elements of radii
Square radial partition values, store as E_{MID}
Compute magnitude square and phase of input
Compare magnitude square with E_{MID} values
Decide in which contour input belongs
Subtract corresponding phase offset from input
Apply PSK demodulation

DVB Compliant APSK Soft Demodulation

For soft demodulation, two soft-decision log-likelihood ratio (LLR) algorithms are available: exact LLR and approximate LLR. This table compares these algorithms.

Algorithm	Accuracy	Execution Speed
Exact LLR	more accurate	slower execution
Approximate LLR	less accurate	faster execution

For further description of these algorithms, see “Exact LLR Algorithm” and “Approximate LLR Algorithm”.

Note The exact LLR algorithm computes exponentials using finite precision arithmetic. Computation of exponentials with very large positive or negative magnitudes might yield:

- `Inf` or `-Inf` if the noise variance is a very large value

- NaN if both the noise variance and signal power are very small values

When the output returns any of these values, try using the approximate LLR algorithm because it does not compute exponentials.

Tips

- For faster execution of the DVBS-APSK Demodulator Baseband block, set the Simulate using parameter to:
  - `Code generation` when using hard decision demodulation.
  - `Interpreted execution` when using soft decision demodulation.

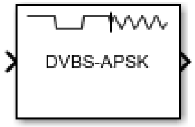
Communications Toolbox / Modulation / Digital Baseband Modulation / Standard-Compliant



Description

The DVBS-APSK Modulator Baseband block modulates the input signal using Digital Video Broadcasting ("DVB-S2/S2X/SH" on page 5-229) standard-specific amplitude phase shift keying (APSK) modulation.

Ports

Input

In — Input signal
scalar | vector | matrix

Input signal, specified as a scalar, vector, or matrix. The input signal must be binary values or integers in the range [0, (M – 1)], where M is the Modulation order. This port is unnamed on the block.

Note To process the input signal as binary elements, set the Input type parameter value to `Bit`. For binary inputs, the number of rows must be an integer multiple of $\log_2(M)$. Groups of $\log_2(M)$ bits in a column are mapped onto a symbol, with the first bit representing the MSB and the last bit representing the LSB.

Data Types: `single` | `double` | `int8` | `int16` | `int32` | `uint8` | `uint16` | `uint32` | `Boolean`

Output

`Out` — DVB-S2/S2X/SH standard-specific APSK modulated signal
scalar | vector | matrix

DVB-S2/S2X/SH standard-specific APSK modulated signal, returned as a complex scalar, vector, or matrix. The output signal dimensions depend on the specified Input type value. This port is unnamed on the block.

Input type	Dimensions of Output Signal
`Integer`	The output signal has the same dimensions as the input signal.

Input type	Dimensions of Output Signal
Bit	The number of rows in the output signal equals the number of rows in the input signal divided by $\log_2(M)$, where M is the Modulation order.

Use Output data type to specify the output data type.

Parameters

DVB standard suffix — Standard suffix

S2 (default) | S2X | SH

Standard suffix for DVB modulation variant, specified as S2, S2X, or SH.

Frame length — Frame length

Normal (default) | Short

Frame length, specified as Normal or Short.

Dependencies

This parameter applies only when DVB standard suffix is set to S2 or S2X.

Modulation order — Modulation order

16 (default) | 8 | 32 | 64 | 256

Modulation order, M, specified as a power of two. The modulation order specifies the total number of points in the constellation of the output signal. The list of valid modulation orders varies depending on the values of DVB standard suffix and Frame length.

DVB standard suffix	Frame length	Modulation order Options
S2	Normal or Short	16 or 32
S2X	Normal	8, 16, 32, 64, or 256
	Short	16 or 32
SH	Not applicable	16

Code identifier — Code identifier

2/3 | character vector

Code identifier, specified as a character vector. The list of valid code identifier values varies depending on the specified values of DVB standard suffix, Frame length, and Modulation order. This table lists the options for **Code identifier** values.

Modulation order	DVB standard suffix	Frame length	Code identifier Options
8	S2X	Normal	100/180 or 104/180
16	S2 or S2X	Normal	2/3, 3/4, 4/5, 5/6, 8/9, or 9/10
		Short	2/3, 3/4, 4/5, 5/6, or 8/9

Modulation order	DVB standard suffix	Frame length	Code identifier Options
16	S2X	Normal	26/45, 3/5, 28/45, 23/36, 25/36, 13/18, 140/180, 154/180, 100/180, 96/180, 90/180, 18/30, or 20/30
		Short	7/15, 8/16, 26/45, 3/5, or 32/45
32	S2 or S2X	Normal	3/4, 4/5, 5/6, 8/9, or 9/10
		Short	3/4, 4/5, 5/6, or 8/9
32	S2X	Normal	128/180, 132/180, 140/180, or 2/3
		Short	2/3 or 32/45
64	S2X	Normal	128/180 , 132/180, 7/9, 4/5, or 5/6
128	S2X	Normal	135/180 or 140/180
256	S2X	Normal	116/180, 124/180, 128/180, 20/30, or 135/180

For more information, refer to Tables 9 and 10 in the DVB-S2 standard [1] and Table 17a in the DVB-S2X standard [2].

Dependencies

This parameter applies only when **DVB standard suffix** is set to S2 or S2X.

Constellation scaling — Constellation scaling

Outer radius as 1 (default) | Unit average power

Constellation scaling, specified as Outer radius as 1 or Unit average power.

Dependencies

This parameter applies only when DVB standard suffix is set to S2 or S2X.

Input type — Input type

Integer (default) | Bit

Input type, specified as Integer or Bit. To use Integer, the input signal must consist of integers in the range [0, (M – 1)]. To use Bit, the input data must contain binary values, and the number of rows must be an integer multiple of $\log_2(M)$, where M is the Modulation order.

Output data type — Output data type

double (default) | single

Output data type, specified as double or single.

`View Constellation` — Plot reference constellation

`button`

To plot the reference constellation, click the **View Constellation** button.

`Simulate using` — Type of simulation to run

`Code generation` (default) | `Interpreted execution`

Type of simulation to run, specified as:

- `Code generation` –– Simulate the model using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations as long as the model does not change. This option requires additional startup time.
- `Interpreted execution` –– Simulate the model using the MATLAB interpreter. This option shortens startup time. In `Interpreted execution` mode, you can debug the source code of the block.

Block Characteristics

Data Types	`Boolean` | `double` | `integer` | `single`
Multidimensional Signals	`yes`
Variable-Size Signals	`no`

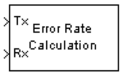
Error Rate Calculation

Compute bit error rate or symbol error rate of input data



Library

Comm Sinks

Description

The Error Rate Calculation block compares input data from a transmitter with input data from a receiver. It calculates the error rate as a running statistic, by dividing the total number of unequal pairs of data elements by the total number of input data elements from one source.

Use this block to compute either symbol or bit error rate, because it does not consider the magnitude of the difference between input data elements. If the inputs are bits, then the block computes the bit error rate. If the inputs are symbols, then it computes the symbol error rate.

Note When you set the **Output data** parameter to `Workspace`, the block generates no code. Similarly, no data is saved to the workspace if the **Simulation mode** is set to `Accelerator` or `Rapid Accelerator`. If you need error rate information in these cases, set **Output data** to `Port`.

Input Data

This block has between two and four input ports, depending on how you set the dialog parameters. The input ports marked `Tx` and `Rx` accept transmitted and received signals, respectively. The `Tx` and `Rx` signals must share the same sampling rate.

The `Tx` and `Rx` input ports accept scalar or column vector signals. For information about the data types each block port supports, see the “Supported Data Types” on page 5-235 table on this page.

If `Tx` is a scalar and `Rx` is a vector, or vice-versa, then the block compares the scalar with each element of the vector. In this case, the block behaves as if you had preprocessed the scalar signal by using the Repeat block with the **Rate options** parameter set to `Enforce single rate`.

If you select **Reset port**, then an additional input port appears, labeled `Rst`. The `Rst` input accepts only a scalar signal (of type `double` or `boolean`) and must have the same port sample time as the `Tx` and `Rx` ports. When the `Rst` input is nonzero, the block clears and then recomputes the error statistics.

If you set the **Computation mode** parameter to `Select samples from port`, then an additional input port appears, labeled `Sel`. The `Sel` input indicates which elements of a frame are relevant for the computation. The `Sel` input can be a column vector of type `double`.

The guidelines below indicate how you should configure the inputs and the dialog parameters depending on how you want this block to interpret your `Tx` and `Rx` data.

- If both data signals are scalar, then this block compares the Tx scalar signal with the Rx scalar signal. For this configuration, use the **Computation mode** parameter default value, `Entire frame`.
- If both data signals are vectors, then this block compares some or all of the Tx and Rx data:
  - If you set the **Computation mode** parameter to `Entire frame`, then the block compares all of the Tx frame with all of the Rx frame.
  - If you set the **Computation mode** parameter to `Select samples from mask`, then the **Selected samples from frame** field appears in the dialog. This parameter field accepts a vector that lists the indices of those elements of the Rx frame that you want the block to consider. For example, to consider only the first and last elements of a length-six receiver frame, set the **Selected samples from frame** parameter to `[1 6]`. If the **Selected samples from frame** vector includes zeros, then the block ignores them.
  - If you set the **Computation mode** parameter to `Select samples from port`, then an additional input port, labeled `Sel`, appears on the block icon. The data at this input port must have the same format as that of the **Selected samples from frame** parameter described above.
- If one data signal is a scalar and the other is a vector, then the scalar is with each entry of the vector. In this case, if Rx is a scalar, then the phrase “Rx frame” above refers to the vector expansion of Rx.

Note This block does not support variable-size signals. If you choose the `Select samples from port` option and want the number of elements in the subframe to vary during the simulation, then you should pad the `Sel` signal with zeros. The Error Rate Calculation block ignores zeros in the `Sel` signal.

Output Data

This block produces a vector of length three, whose entries correspond to:

- The error rate
- The total number of errors, that is, the number of instances that an Rx element does not match the corresponding Tx element
- The total number of comparisons that the block made

The block sends this output data to the base MATLAB workspace or to an output port, depending on how you set the **Output data** parameter:

- If you set the **Output data** parameter to `Workspace` and fill in the **Variable name** parameter, then that variable in the base MATLAB workspace contains the current value when the simulation *ends*. Pausing the simulation does not cause the block to write interim data to the variable.

  If you plan to use this block along with the Simulink Coder software, then you should not use the `Workspace` option. Instead, use the `Port` option and connect the output port to a Simulink To Workspace block.
- If you set the **Output data** parameter to `Port`, then an output port appears. This output port contains the *running* error statistics.

Delays

The **Receive delay** and **Computation delay** parameters implement two different types of delays for this block. One delay is useful if you want this block to compensate for the delay in the received signal. The other is useful if you want to ignore the initial transient behavior of both input signals.

- The **Receive delay** parameter represents the number of samples by which the received data lags behind the transmitted data. The transmit signal is implicitly delayed by that same amount before the block compares it to the received data. This value is helpful when you delay the transmit signal so that it aligns with the received signal. The receive delay persists throughout the simulation.
- The **Computation delay** parameter represents the number of samples the block ignores at the beginning of the comparison.

Use the Find Delay block to determine the delay, and then set the **Receive delay** to the delay reported by the Find Delay block.

If you use the `Select samples from mask` or `Select samples from port` option, then each delay parameter refers to the number of samples that the block receives, whether the block ultimately ignores some of them or not.

If using the **Sel** port to calculate errors on a delayed signal, the delay must be added to the **Sel** indices. For more information, see “Calculate Errors for Delayed Selected Samples”.

Stopping the Simulation Based on Error Statistics

You can configure this block so that its error statistics control the duration of simulation. This is useful for computing reliable steady-state error statistics without knowing in advance how long transient effects might last. To use this mode, check **Stop simulation**. The block attempts to run the simulation until it detects the number of errors the **Target number of errors** parameter specifies. However, the simulation stops before detecting enough errors if the time reaches the model's **Stop time** setting (in the **Configuration Parameters** dialog box), if the Error Rate Calculation block makes **Maximum number of symbols** comparisons, or if another block in the model directs the simulation to stop.

To ignore either of the two stopping criteria in this block, set the corresponding parameter (**Target number of errors** or **Maximum number of symbols**) to `Inf`. For example, to reach a target number of errors without stopping the simulation early, set **Maximum number of symbols** to `Inf` and set the model's **Stop time** to `Inf`.

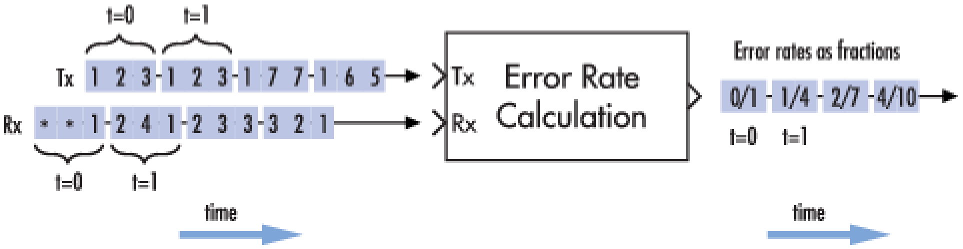
Tuning Parameters in an RSim Executable (Simulink Coder Software)

If you use the Simulink Coder rapid simulation (RSim) target to build an RSim executable, then you can tune the **Target number of errors** and **Maximum number of symbols** parameters without recompiling the model. This is useful for Monte Carlo simulations in which you run the simulation multiple times (perhaps on multiple computers) with different amounts of noise.

Examples

Full Frame Error Calculation

The figure below shows how the block compares pairs of elements and counts the number of error events. The `Tx` and `Rx` inputs are column vectors.



This example assumes that the sample time of each input signal is 1 second and that the block's parameters are as follows:

- **Receive delay** = 2
- **Computation delay** = `0`
- **Computation mode** = `Entire frame`

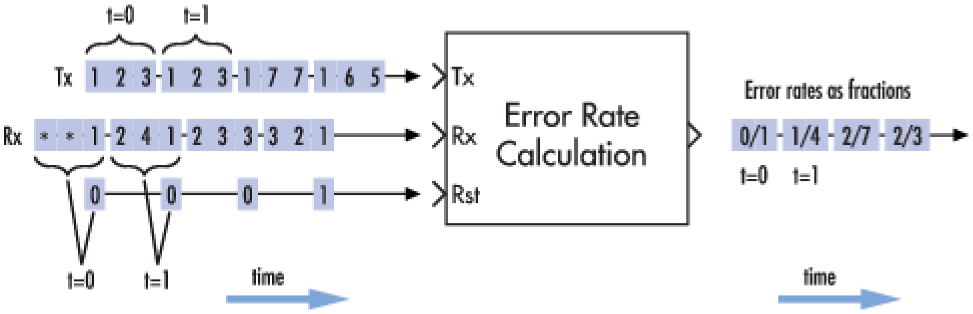
Both input signals are column vectors of length three. However, the schematic arranges each column vector horizontally and aligns pairs of vectors so as to reflect a receive delay of two samples. At each time step, the block compares elements of the Rx signal with those of the Tx signal that appear directly above them in the schematic. For instance, at time 1, the block compares 2, 4, and 1 from the Rx signal with 2, 3, and 1 from the Tx signal.

The values of the first two elements of Rx appear as asterisks because they do not influence the output. Similarly, the 6 and 5 in the Tx signal do not influence the output up to time 3, though they *would* influence the output at time 4.

In the error rates on the right side of the figure, each numerator at time *t* reflects the number of errors when considering the elements of Rx up through time *t*.

Full Frame Error Calculation with Reset

If the block's **Reset port** box had been checked and a reset had occurred at time = 3 seconds, then the last error rate would have been 2/3 instead of 4/10. This value 2/3 would reflect the comparison of 3, 2, and 1 from the Rx signal with 7, 7, and 1 from the Tx signal. The figure below illustrates this scenario. The Tx and Rx inputs are column vectors.



Error Calculation on Selected Samples in the Frame

If using the **Sel** port to calculate errors on a delayed signal, the delay must be added to the **Sel** indices. For more information, see “Calculate Errors for Delayed Selected Samples”.

Parameters

Receive delay

Number of samples by which the received data lags behind the transmitted data. (If Tx or Rx is a vector, then each entry represents a sample.)

Computation delay

Number of samples that the block should ignore at the beginning of the comparison.

Computation mode

Either `Entire frame`, `Select samples from mask`, or `Select samples from port`, depending on whether the block should consider all or only part of the input frames.

Selected samples from frame

A vector that lists the indices of the elements of the Rx frame vector that the block should consider when making comparisons. This field appears only if **Computation mode** is set to `Select samples from mask`.

Output data

Either `Workspace` or `Port`, depending on where you want to send the output data.

Variable name

Name of variable for the output data vector in the base MATLAB workspace. This field appears only if **Output data** is set to `Workspace`.

Reset port

If you check this box, then an additional input port appears, labeled `Rst`.

Stop simulation

If you check this box, then the simulation runs only until this block detects a specified number of errors or performs a specified number of comparisons, whichever comes first.

Target number of errors

The simulation stops after detecting this number of errors. This field is active only if **Stop simulation** is checked.

Maximum number of symbols

The simulation stops after making this number of comparisons. This field is active only if **Stop simulation** is checked.

Supported Data Types

Port	Supported Data Types
Tx	• Double-precision floating point • Single-precision floating point • Boolean • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers

Port	Supported Data Types
Rx	• Double-precision floating point • Single-precision floating point • Boolean • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers
Sel	• Double-precision floating point
Reset	• Double-precision floating point • Boolean

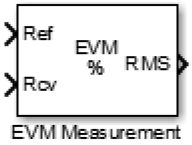
EVM Measurement

Measure error vector magnitude



Library

Utility Blocks

Description

The EVM Measurement block measures the error vector magnitude (EVM), which is an indication of modulator or demodulator performance.

The block has one or two input signals: a received signal and, optionally, a reference signal. You must select if the block uses a reference from an input port or from a reference constellation.

The block normalizes to the average reference signal power, average constellation power, or peak constellation power. For RMS EVM, maximum EVM, and *X*-percentile EVM, the output computations reflect the normalization method.

The default EVM output is the RMS EVM in percent, with an option of maximum EVM or *X*-percentile EVM values. The maximum EVM represents the worst-case EVM value per burst. For the *X*-percentile option, you can enable an output port that returns the number of symbols processed in the percentile computations.

The table shows the output type, the parameter that selects the output type, the computation units, and the corresponding measurement interval.

Output	Activation Parameter	Units	Measurement Interval
RMS EVM	None (output by default)	Percentage	`Current length` | `Entire history` | `Custom` | `Custom with periodic reset`
Maximum EVM	**Output maximum EVM**	Percentage	`Current length` | `Entire history` | `Custom` | `Custom with periodic reset`
Percentile EVM	**Output X-percentile EVM**	Percentage	`Entire history`

Output	Activation Parameter	Units	Measurement Interval
Number of symbols	**Output X-percentile EVM** and **Output the number of symbols processed**	None	`Entire history`

Data Type

The block accepts double, single, and fixed-point data types. The output of the block is always `double`.

Parameters

Normalize RMS error vector by

Selects the method by which the block normalizes measurements:

- `Average reference signal power`
- `Average constellation power`
- `Peak constellation power`

The default is `Average reference signal power`.

Average constellation power

Normalizes EVM measurement by the average constellation power. This parameter is available only when you set **Normalize RMS error vector** to `Average constellation power`.

Peak constellation power

Normalizes EVM measurement by the peak constellation power. This parameter only is available if you set **Normalize RMS error vector** to `Peak constellation power`.

Reference signal

Specifies the reference signal source as either `Input port` or `Estimated from reference constellation`.

Reference constellation

Specifies the reference constellation points as a vector. This parameter is available only when **Reference signal** is `Estimated from reference constellation`. The default is `constellation(comm.QPSKModulator)`.

Measurement interval

Specify the measurement interval as: `Input length`, `Entire history`, `Custom`, or `Custom with periodic reset`. This parameter affects the RMS and maximum EVM outputs only.

- To calculate EVM using only the current samples, set this parameter to `'Input length'`.
- To calculate EVM for all samples, set this parameter to `'Entire history'`.
- To calculate EVM over an interval you specify and to use a sliding window, set this parameter to `'Custom'`.
- To calculate EVM over an interval you specify and to reset the object each time the measurement interval is filled, set this parameter to `'Custom with periodic reset'`.

Custom measurement interval

Specify the custom measurement interval in samples as a real positive integer. This is the interval over which the EVM is calculated. This parameter is available when **Measurement interval** is `Custom` or `Custom with periodic reset`. The default is `100`.

Averaging dimensions

Averaging dimensions over which to average the EVM measurements, specified as an integer or row vector of integers with element values in the range [1, 3]. For example, to average across the rows, set this parameter to `2`. The default is `1`.

This block supports var-size inputs of the dimensions in which the averaging takes place. However, the input size for the nonaveraged dimensions must be constant. For example, if the input size is `[1000 3 2]` and **Averaging dimensions** is `[1 3]`, then the output size is `[1 3 1]`. The number of elements in the second dimension is fixed at 3.

Output maximum EVM

Outputs the maximum EVM of an input vector or frame.

Output X-percentile EVM

Enables an output *X*-percentile EVM measurement. When you select this option, specify **X-percentile value (%)**.

X-percentile value (%)

This parameter is available only when you select **Output X-percentile EVM**. The *X*th percentile is the EVM value below which X% of all the computed EVM values lie. The parameter defaults to the 95th percentile. That is, 95% of all EVM values are below this value.

Output the number of symbols processed

Outputs the number of symbols that the block uses to compute the *X*-percentile value. This parameter is available only when you select **Output X-percentile EVM**.

Simulate using

Select the simulation mode.

`Code generation`

On the first model run, simulate and generate code. If the structure of the block does not change, subsequent model runs do not regenerate the code.

If the simulation mode is `Code generation`, System objects corresponding to the blocks accept a maximum of nine inputs.

`Interpreted execution`

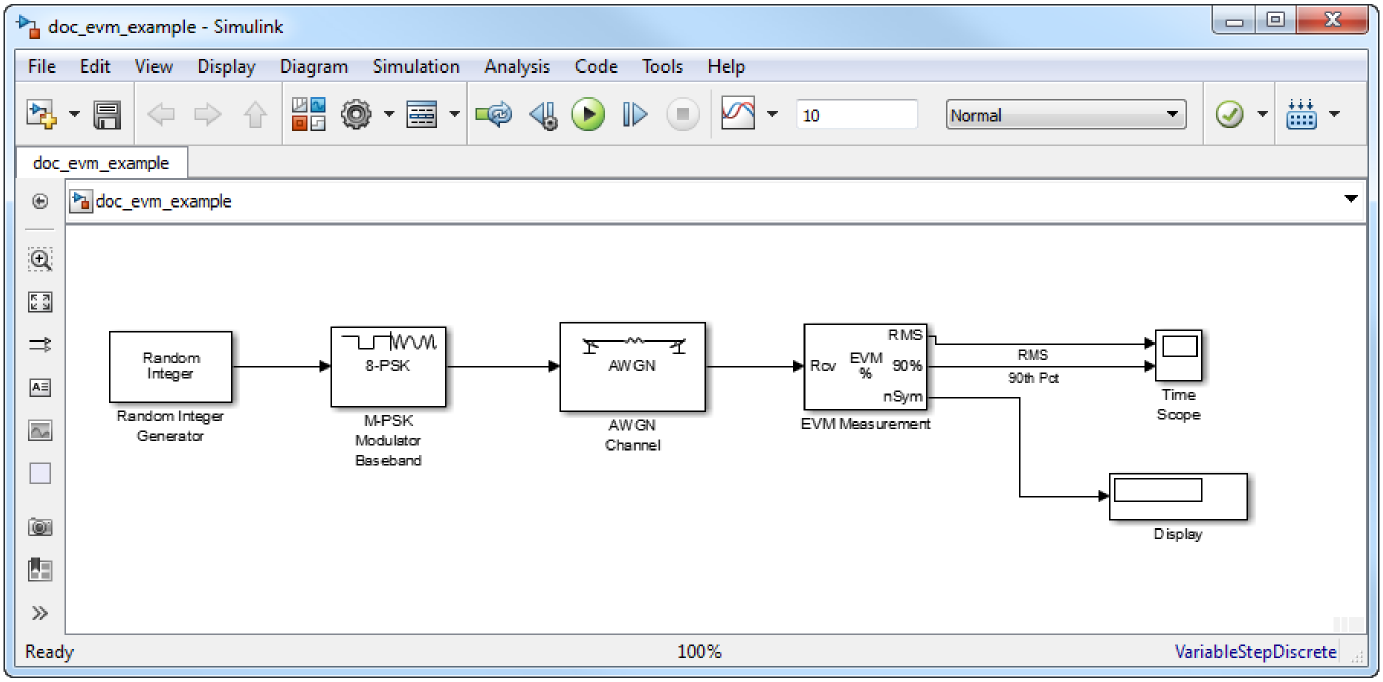
Simulate model without generating code. This option results in faster start times but can slow subsequent simulation performance.

Examples

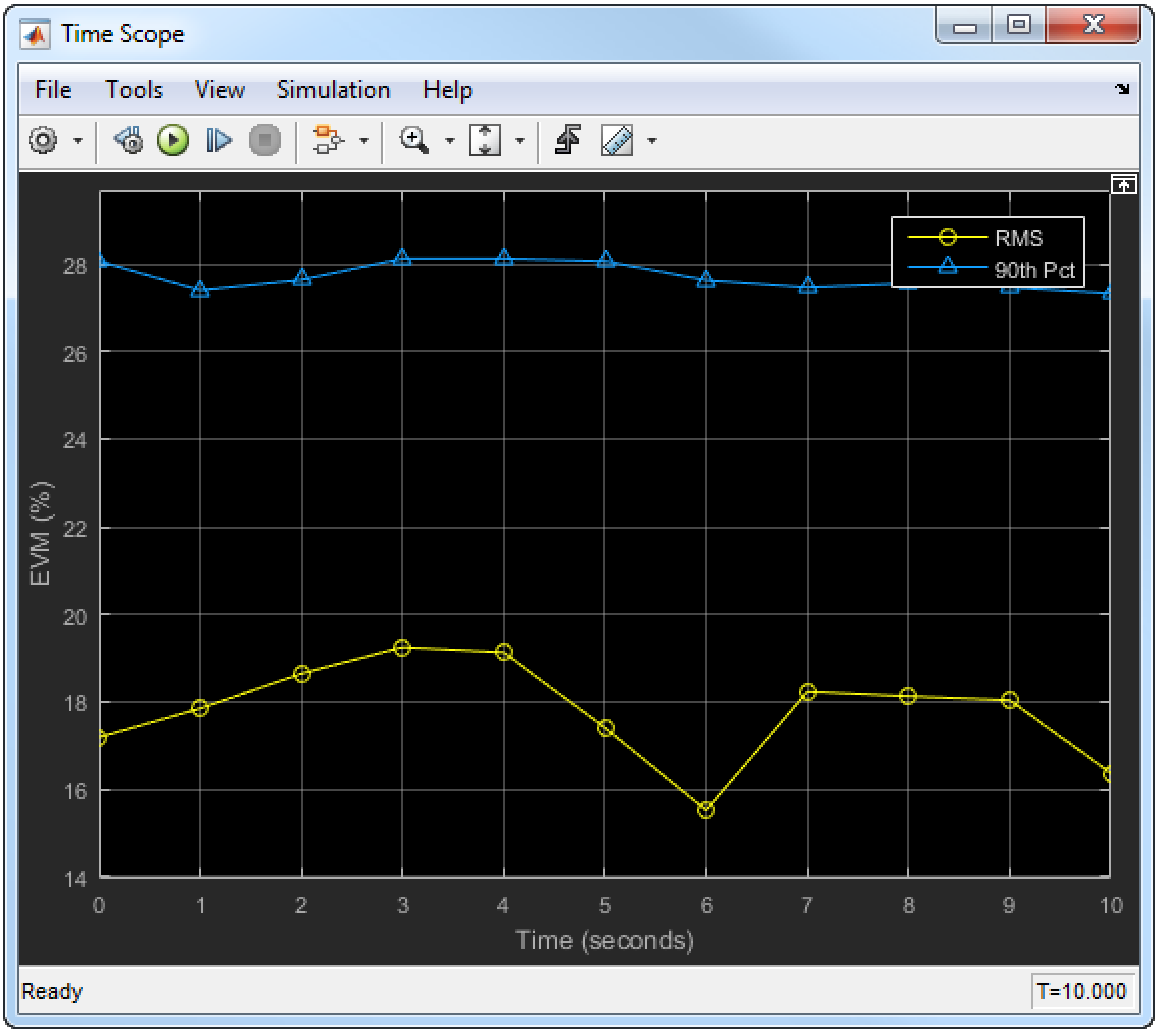
Measure RMS and 90th Percentile EVM

Measure the RMS and 90th percentile EVM for an 8-PSK signal in an AWGN channel.

Open the model by typing doc_evm_example on the command line.



Run the model. The Display block shows the number of symbols used to estimate the EVM. The Time Scope shows the RMS and 90th percentile EVM values.



Observe that 90% of the symbols had an EVM value of less than 28% and that the average EVM is approximately 17%.

Experiment with the model by changing the signal-to-noise ratio in the AWGN Channel block. Examine its effect on the EVM values.

Algorithms

Both the EVM block and the EVM object provide three normalization methods. You can normalize measurements according to the average power of the reference signal, average constellation power, or peak constellation power. Different industry standards follow one of these normalization methods.

The block or object calculates the RMS EVM value differently for each normalization method.

EVM Normalization Method	Algorithm
Reference signal	$EVM_{RMS} = \sqrt{\dfrac{\frac{1}{N}\sum_{k=1}^{N}(e_k)}{\frac{1}{N}\sum_{k=1}^{N}(I_k^2 + Q_k^2)}} * 100$
Average power	$\mathrm{EVM}_{\mathrm{RMS}}(\%) = 100\sqrt{\dfrac{\frac{1}{N}\sum_{k=1}^{N}(e_k)}{P_{\mathrm{avg}}}}$
Peak power	$\mathrm{EVM}_{\mathrm{RMS}}(\%) = 100\sqrt{\dfrac{\frac{1}{N}\sum_{k=1}^{N}(e_k)}{P_{\mathrm{max}}}}$

Where:

- $e_k = e_k = (I_k - \tilde{I}_k)^2 + (Q_k - \tilde{Q}_k)^2$
- I_k = In-phase measurement of the kth symbol in the burst
- Q_k = Quadrature phase measurement of the kth symbol in the burst
- N = Input vector length
- P_{avg} = The value for **Average constellation power**
- P_{max} = The value for **Peak constellation power**
- I_k and Q_k represent ideal (reference) values. $\tilde{I}_k$ and $\tilde{Q}_k$ represent measured (received) symbols.

The max EVM is the maximum EVM value in a frame or $\mathrm{EVM}_{\mathrm{max}} = \max\limits_{k \in [1,\ldots,N]} \{\mathrm{EVM}_k\}$, where k is the kth symbol in a burst of length N.

The definition for EVM_k varies depending upon which normalization method you select for computing measurements. The block or object supports these algorithms.

EVM Normalization	Algorithm
Reference signal	$EVM_k = \sqrt{\dfrac{e_k}{\frac{1}{N}\sum_{k=1}^{N}(I_k^2 + Q_k^2)}} * 100$
Average power	$\mathrm{EVM}_k = 100\sqrt{\dfrac{e_k}{P_{\mathrm{avg}}}}$
Peak power	$\mathrm{EVM}_k = 100\sqrt{\dfrac{e_k}{P_{\mathrm{max}}}}$

The block or object computes the X-percentile EVM by creating a histogram of all the incoming EVM_k values. The output provides the EVM value below which X% of the EVM values fall.

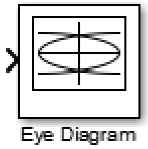
Eye Diagram Scope

Display eye diagram of time-domain signal

Library: Communications Toolbox / Comm Sinks
Communications Toolbox HDL Support / Comm Sinks
Mixed-Signal Blockset / Utilities
SerDes Toolbox / Utilities

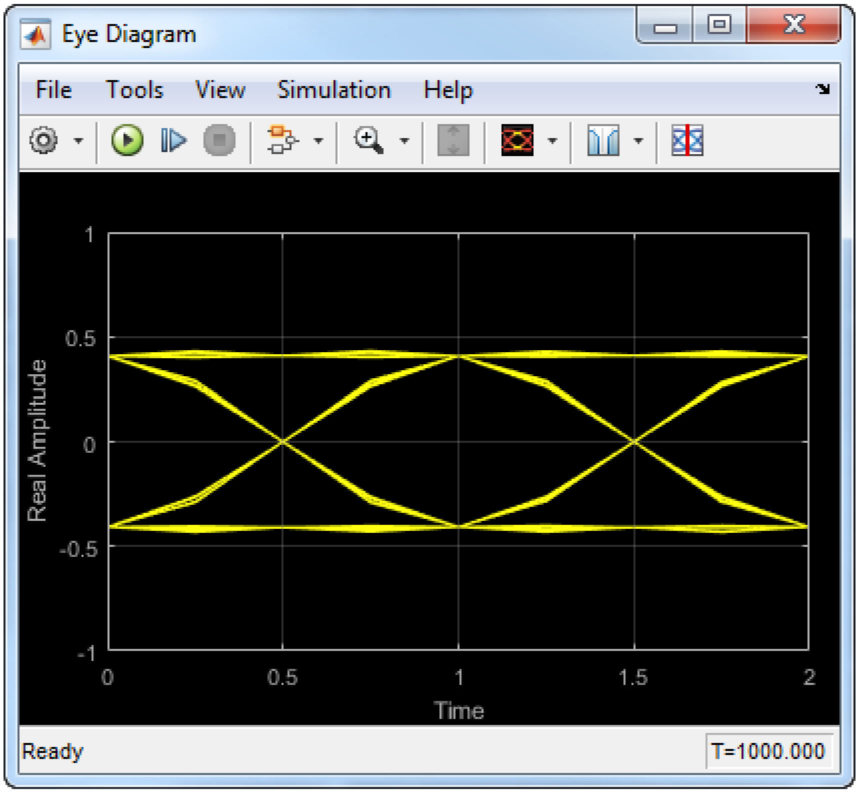


Description

The Eye Diagram block displays multiple traces of a modulated signal to produce an eye diagram. You can use the block to reveal the modulation characteristics of the signal, such as the effects of pulse shaping or channel distortions. For more information, see “Eye Diagram Analysis”.

The Eye Diagram block has one input port. This block accepts a column vector or scalar input signal. The block accepts a signal with the following data types: double, single, base integer, and fixed point. All data types are cast as double before the block displays results.

To modify the eye diagram display, select **View > Configuration Properties** or click the **Configuration Properties** button (⚙). Then select the **Main**, **2D color histogram**, **Axes**, or **Export** tabs and modify the settings.



Ports

Input

In — Input signal
scalar | column vector

Input signal, specified as a scalar or column vector.

Data Types: `double`

Parameters

Main Tab

`Display mode` — Display mode
`Line plot` (default) | `2D color Histogram`

Display mode of the eye diagram, specified as `Line plot` or `2D color histogram`. Selecting `2D color histogram` makes the histogram tab available.

Tunable: Yes

`Enable measurements` — Enable measurements
`off` (default) | `on`

Select this check box to enable eye measurements of the input signal.

`Show horizontal (jitter) histogram` — Display jitter histogram

`off` (default) | `on`

Select this radio button to display the jitter histogram. This can also be accessed by using the histogram button drop down on the toolbar.

Dependencies

This parameter is available when **Display mode** is `2D color histogram` and **Enable measurements** is selected.

`Show vertical (noise) histogram` — Display noise histogram

`off` (default) | `on`

Select this radio button to display the noise histogram. This can also be accessed by using the histogram button drop down on the toolbar.

Dependencies

This parameter is available when **Display mode** is `2D color histogram` and **Enable measurements** is selected.

`Do not show horizontal or vertical histogram` — Do not show horizontal or vertical histogram

`on` (default) | `off`

Select this radio button to display neither the histogram noise nor the histogram jitter.

Dependencies

This parameter is available when **Display mode** is `2D color histogram` and **Enable measurements** is selected.

`Show horizontal bathtub curve` — Show horizontal bathtub curve

`off` (default) | `on`

Select this check box to display the horizontal bathtub curve. This can also be accessed by using the bathtub curve button on the toolbar.

Dependencies

This parameter is available when **Enable measurements** is selected.

`Show vertical bathtub curve` — Show vertical bathtub curve

`off` (default) | `on`

Select this check box to display the vertical bathtub curve. This can also be accessed by using the bathtub curve button on the toolbar.

Dependencies

This parameter is available when **Enable measurements** is selected.

`Eye diagram to display` — Eye diagram to display

`Real only` (default) | `Real and imaginary`

Select either `Real only` or `Real and imaginary` to display one or both eye diagrams. To make eye measurements, this parameter must be `Real only`.

Tunable: Yes

`Color fading` — Color fading

`off` (default) | `on`

Select this check box to fade the points in the display as the interval of time after they are first plotted increases.

Tunable: Yes

Dependencies

This parameter is available only when the **Display mode** is `Line plot`.

`Samples per symbol` — Samples per symbol

8 (default) | positive integer

Number of samples per symbol, specified as a positive integer. Use with **Symbols per trace** to determine the number of samples per trace.

Tunable: Yes

`Sample offset` — Sample offset

0 (default) | nonnegative integer

Sample offset, specified as a nonnegative integer smaller than the product of **Samples per symbol** and **Symbols per trace**. The offset provides the number of samples to omit before plotting the first point.

Tunable: Yes

`Symbols per trace` — Symbols per trace

2 (default) | positive integer

Number of symbols plotted per trace, specified as a positive integer.

Tunable: Yes

`Traces to display` — Number of traces to display

40 (default) | positive integer

Number of traces plotted, specified as a positive integer.

Tunable: Yes

Dependencies

This parameter is available only when the **Display mode** is `Line plot`

Axes Tab

`Title` — Title label

None (default)

Label that appears above the eye diagram plot.

Tunable: Yes

`Show grid` — Toggle scope grid

`on` (default) | `off`

Toggle this check box to turn the grid on and off.

Tunable: Yes

`Y-limits (Minimum)` — Lower limit of *y*-axis

`-1.1` (default) | scalar

Minimum value of the *y*-axis.

Tunable: Yes

`Y-limits (Maximum)` — Upper limit of *y*-axis

`1.1` (default) | scalar

Maximum value of the *y*-axis.

Tunable: Yes

`Real axis label` — Real axis label

`Real Amplitude` (default)

Text that the scope displays along the real axis.

Tunable: Yes

`Imaginary axis label` — Imaginary axis label

`Imaginary Amplitude` (default)

Text that the scope displays along the imaginary axis.

Tunable: Yes

2D Histogram Tab

The 2D histogram tab is available when you click the histogram button or when the display mode is set to `2D color histogram`.

`Oversampling method` — Oversampling method

`None` (default) | `Input interpolation` | `Histogram interpolation`

Oversampling method, specified as `None`, `Input interpolation`, or `Histogram interpolation`.

To plot eye diagrams as quickly as possible, set the **Oversampling method** to `None`. The drawback to not oversampling is that the plots look pixelated when the number of samples per trace is small. To create smoother, less-pixelated plots using a small number of samples per trace, set the **Oversampling method** to `Input interpolation` or `Histogram interpolation`. `Input interpolation` is the faster of the two interpolation methods and produces good results when the signal-to-noise ratio (SNR) is high. With a lower SNR, this oversampling method is not recommended because it introduces a bias to the centers of the histogram ranges. `Histogram interpolation` is not as fast as the other techniques, but it provides good results even when the SNR is low.

Tunable: Yes

`Color scale` — Color scale
`Linear` (default) | `Logarithmic`

Color scale of the histogram plot, specified as either `Linear` or `Logarithmic`. Set **Color scale** to `Logarithmic` if certain areas of the eye diagram include a disproportionate number of points.

Tunable: Yes

The toolbar contains a histogram reset button ↻, which resets the internal histogram buffers and clears the display. This button is not available when the display mode is set to `Line plot`.

Export Tab

`Export measurements, histograms and bathtub curves` — Export measurements, histograms and bathtub curves
`Off` (default) | `off`

Select this check box export the eye diagram measurements to the MATLAB workspace.

Tunable: Yes

`Variable name` — Variable name
`EyeData` (default)

Specify the name of the variable to which the eye diagram measurements are saved. The data is saved as a structure having these fields:

- `MeasurementSettings`
- `Measurements`
- `JitterHistogram`
- `NoiseHistogram`
- `HorizontalBathtub`
- `VerticalBathtub`
- `BlockName`

Tunable: Yes

Style Dialog Box

In the **Style** dialog box, you can customize the style of the active display. You can change the color of the figure containing the displays, the background and foreground colors of display axes, and properties of lines in a display. To open this dialog box, select **View** > **Style**.

`Figure color` — Figure color
`black` (default)

Specify the background color of the scope figure.

`Axes colors` — Axes colors
`black` | `gray` (default)

Specify the fill and line colors for the axes.

`Line` — Line style, thickness and color for line plots

`continuous` | `0.5` | `yellow` (default)

Specify the line style, line width, and line color for the displayed signal.

Dependencies

This parameter is available only when the **Display mode** is `Line plot`.

`Marker` — Data point marker

None (default) | ...

Data point marker for the selected signal, specified as one of the choices in this table data point markers. This parameter is similar to the `Marker` property for MATLAB Handle Graphics® plot objects.

Specifier	Marker Type
none	No marker (default)
○	Circle
□	Square
×	Cross
•	Point
+	Plus sign
*	Asterisk
◇	Diamond
▽	Downward-pointing triangle
△	Upward-pointing triangle
◁	Left-pointing triangle
▷	Right-pointing triangle
☆	Five-pointed star (pentagram)
✡	Six-pointed star (hexagram)

Dependencies

This parameter is available only when the **Display mode** is `Line plot`.

`Colormap` — Colormap for histograms

`Hot` (default) | `Parula` | `Jet` | `HSV` | `Cool` | `SpringSummer` | `Autumn` | `Winter` | `Gray` | `Bone` | `Copper` | `Pink` | `Lines` | `Custom`

Specify the colormap of the histogram plots as one of these schemes: `Parula`, `Jet`, `HSV`, `Hot`, `Cool`, `Spring`, `Summer`, `Autumn`, `Winter`, `Gray`, `Bone`, `Copper`, `Pink`, `Lines`, or `Custom`. If you select `Custom`, a dialog box pops up from which you can enter code to specify your own colormap.

Dependencies

This parameter is available only when the **Display mode** is `2D color histogram`.

Measurement Settings Pane

To change measurement settings, first select **Enable measurements**. Then, in the **Eye Measurements** pane, click the arrow next to **Settings**. You can control these measurement settings.

`Eye level boundaries` — Time range for calculating eye levels
`[40 60]` (default) | two-element vector

Time range for calculating eye levels, specified as a two-element vector. These values are expressed as a percentage of the symbol duration.

Tunable: Yes

`Decision boundary` — Amplitude level threshold
`0` (default) | scalar

Amplitude level threshold in V, specified as a scalar. This parameter separates the different signaling regions for horizontal (jitter) histograms. This parameter is tunable, but the jitter histograms reset when the parameter changes.

For non-return-to-zero (NRZ) signals, set **Decision boundary** to 0. For return-to-zero (RZ) signals, set **Decision boundary** to half the maximum amplitude.

Tunable: Yes

`Rise/Fall thresholds` — Amplitude levels of the rise and fall transitions
`[10 90]` (default) | two-element vector

Amplitude levels of the rise and fall transitions, specified as a two-element vector. These values are expressed as a percentage of the eye amplitude. This parameter is tunable, but the crossing histograms of the rise and fall thresholds reset when the parameter changes.

Tunable: Yes

`Hysteresis` — Amplitude tolerance of the horizontal crossings
`0` (default) | scalar

Amplitude tolerance of the horizontal crossings in V, specified as a scalar. Increase hysteresis to provide more tolerance to spurious crossings due to noise. This parameter is tunable, but the jitter and the rise and fall histograms reset when the parameter changes.

Tunable: Yes

`BER threshold` — BER used for eye measurements
`1e-12` (default) | nonnegative scalar from 0 to 0.5

BER used for eye measurements, specified as a nonnegative scalar from 0 to 0.5. The value is used to make measurements of random jitter, total jitter, horizontal eye openings, and vertical eye openings.

Tunable: Yes

`Bathtub BERs` — BER values used to calculate openings of bathtub curves
`[0.5 0.1 0.01 0.001 0.0001 1e-05 1e-06 1e-07 1e-08 1e-09 1e-10 1e-11 1e-12]` (default) | vector

BER values used to calculate openings of bathtub curves, specified as a vector whose elements range from 0 to 0.5. Horizontal and vertical eye openings are calculated for each of the values specified by this parameter.

Tunable: Yes

Dependencies

To enable this parameter, select **Show horizontal bathtub curve**, **Show vertical bathtub curve**, or both.

`Measurement delay` — Duration of initial data discarded from measurements

`0` (default) | nonnegative scalar

Duration of initial data discarded from measurements, in seconds, specified as a nonnegative scalar.

Block Characteristics

Data Types	`Boolean` | `double` | `enumerated` | `fixed point` | `integer` | `single`
Direct Feedthrough	`no`
Multidimensional Signals	`no`
Variable-Size Signals	`no`
Zero-Crossing Detection	`no`

More About

Using Eye Diagram in Conditionally Executed Subsystems

When an Eye Diagram block is placed in a conditionally executed subsystem, for example in a triggered or enabled subsystem:

- Input size must be an integer multiple of `SamplesPerSymbol` * `SymbolsPerTrace`
- Sample offset must be zero
- The rightmost part of the display is intentionally omitted. This figure compares typical eye diagram display when placed in a normal system versus one placed in a conditionally executed subsystem.

Eye Diagram Plot in Normal System	Eye Diagram Plot in Conditionally Executed Subsystem
	In a regular Eye Diagram, the rightmost part is a line between the last sample of a trace and the first sample of the next trace.	In conditionally executed subsystems, these traces may be non-contiguous, thus this rightmost segment could corrupt the display and is omitted.

Measurements

Measurements assume that the eye diagram object has valid data. A valid eye diagram has two distinct eye crossing points and two distinct eye levels.

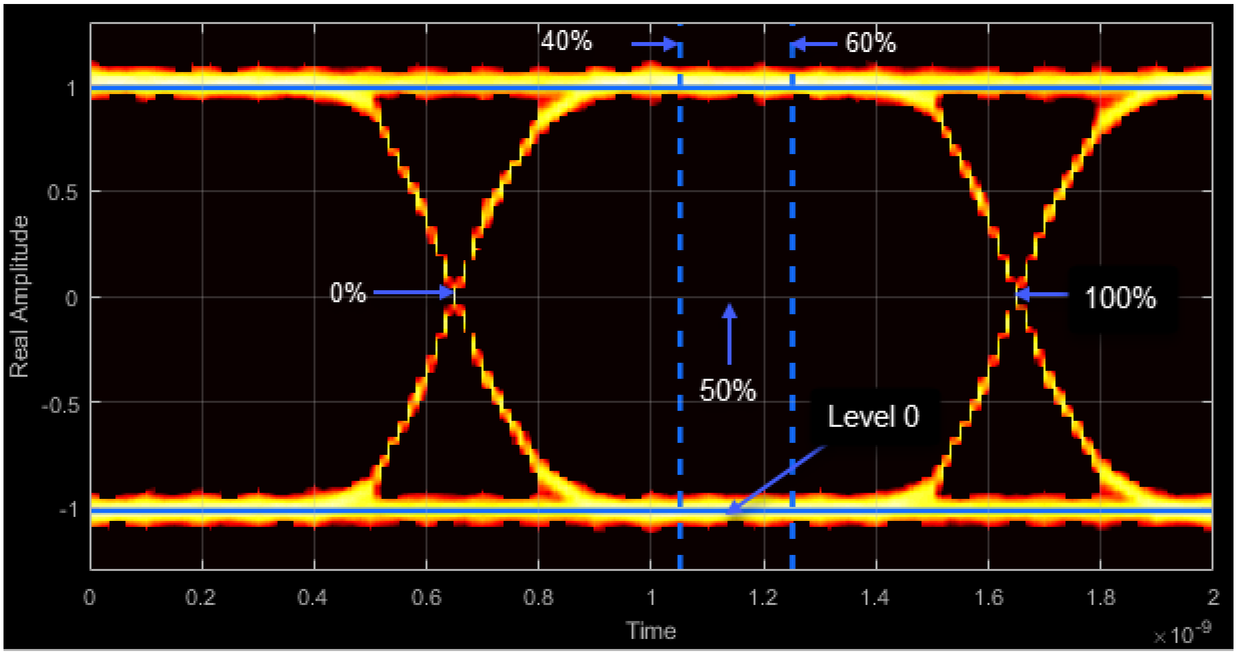
To open the measurements pane, click on the **Eye Measurements** button or select **Tools > Measurements > Eye Measurements** from the toolbar menu.

Note

- For amplitude measurements, at least one bin per vertical histogram must reach 10 hits before the measurement is taken, ensuring higher accuracy.
- For time measurements, at least one bin per horizontal histogram must reach 10 hits before the measurement is taken.
- When an eye crossing time measurement falls within the [-0.5/Fs, 0) seconds interval, the time measurement wraps to the end of the eye diagram, i.e., the measurement wraps by 2×T_s seconds (where T_s is the symbol time). For a complex signal case, the analyze method issues a warning if the crossing time measurement of the in-phase branch wraps while that of the quadrature branch does not (or vice versa). To avoid time-wrapping or a warning, add a half-symbol duration delay to the current value in the `MeasurementDelay` property of the eye diagram object. This additional delay repositions the eye in the approximate center of the scope.

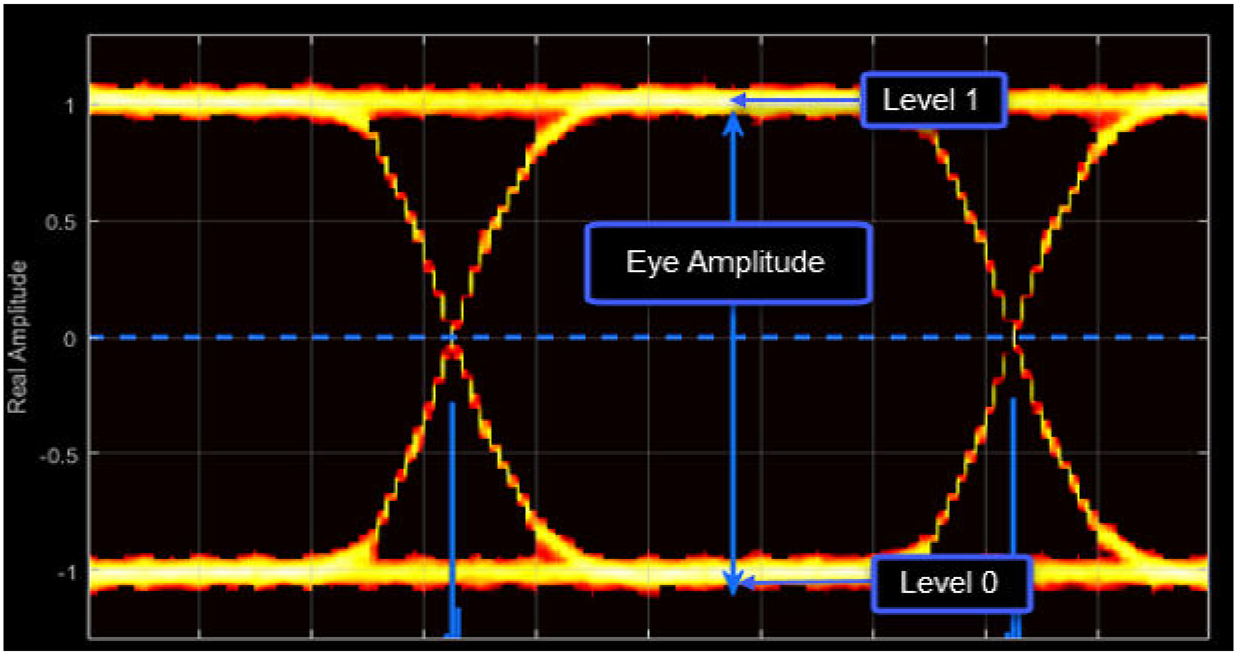
Eye Levels - Amplitude level used to represent data bits

Eye level is the amplitude level used to represent data bits. For the displayed NRZ signal, the levels are –1 V and +1 V. The eye levels are calculated by averaging the 2-D histogram within the eye level boundaries. For example, when the EyeLevelBoundaries property is set to `[40 60]`, that is, 40% and 60% of the symbol duration, the eye levels are calculated by estimating the mean value of the vertical histogram in this window marked by the eye level boundaries.



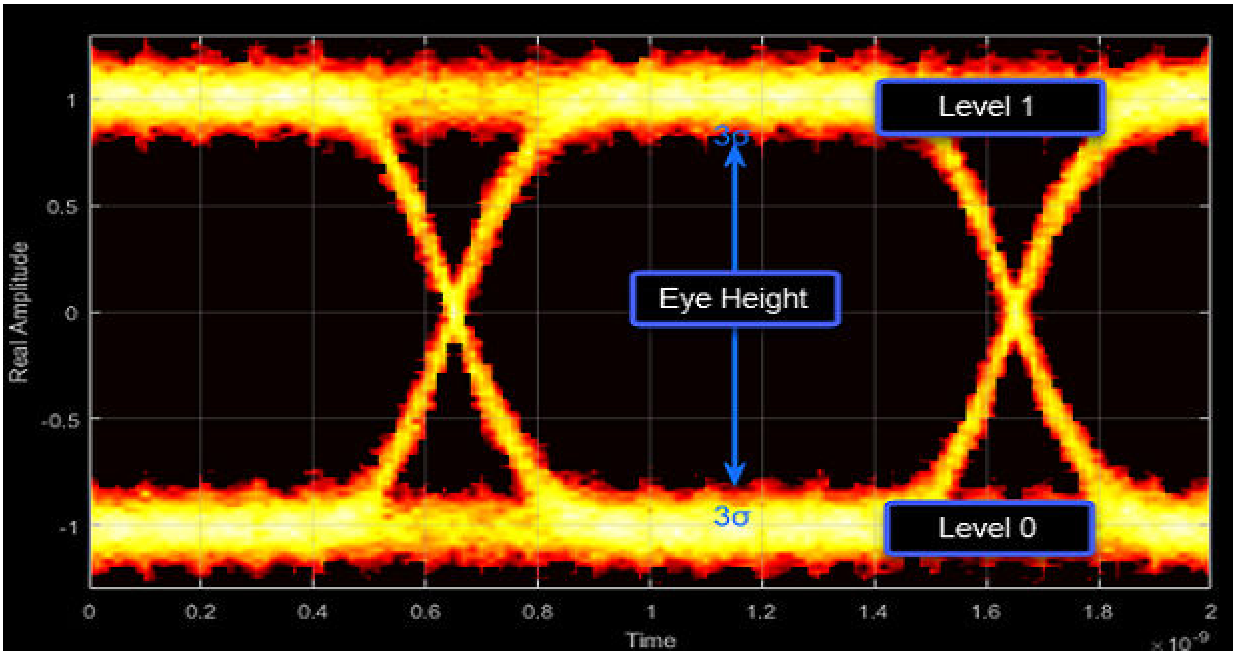
Eye Amplitude - Distance between eye levels

Eye amplitude is the distance in V between the mean value of two eye levels.



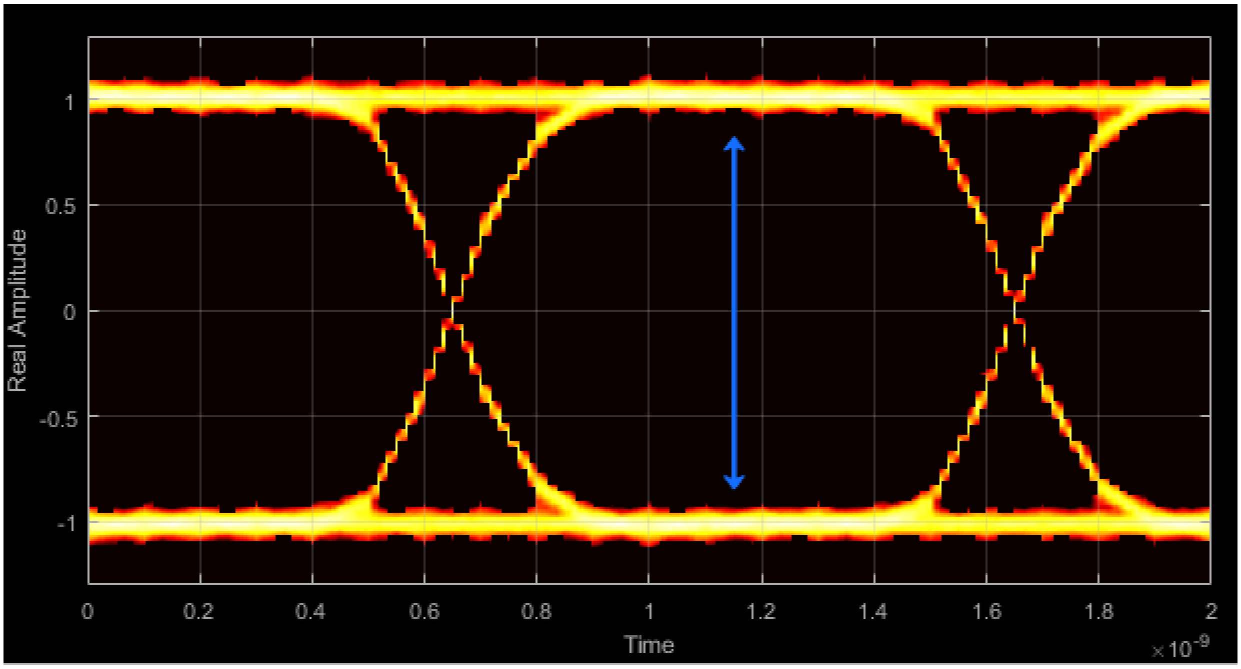
Eye Height - Statistical minimum distance between eye levels

Eye height is the distance between μ – 3σ of the upper eye level and μ + 3σ of the lower eye level. μ is the mean of the eye level, and σ is the standard deviation.



Vertical Opening - Distance between BER threshold points

The vertical opening is the distance between the two points that correspond to the BERThreshold property. For example, for a BER threshold of 10^{-12}, these points correspond to the 7σ distance from each eye level.



Eye SNR - Signal-to-noise ratio

The eye SNR is the ratio of the eye level difference to the difference of the vertical standard deviations corresponding to each eye level:

$$\text{SNR} = \frac{L_1 - L_0}{\sigma_1 - \sigma_0},$$

where L_1 and L_0 represent the means of the upper and lower eye levels and σ_1 and σ_0 represent their standard deviations.

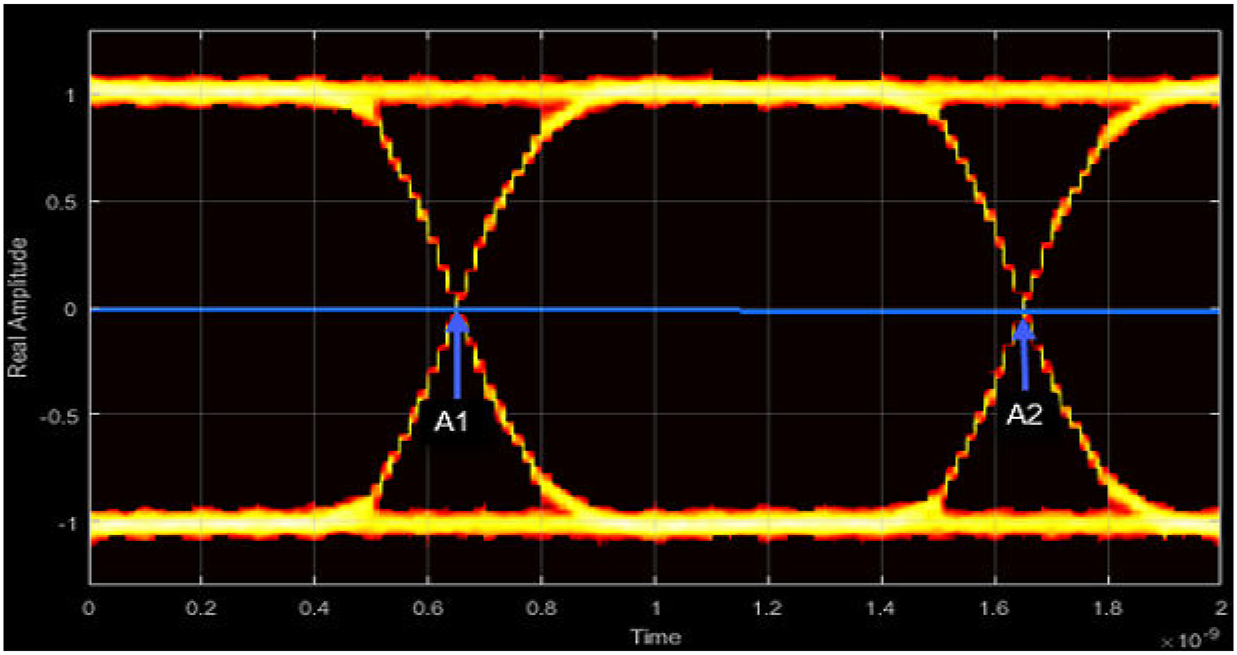
Q Factor - Quality factor

The Q factor is the quality factor and is calculated using the same formula as the eye SNR. However, the standard deviations of the vertical histograms are replaced with those computed with the dual-Dirac analysis.

Crossing Levels - Amplitude levels for eye crossings

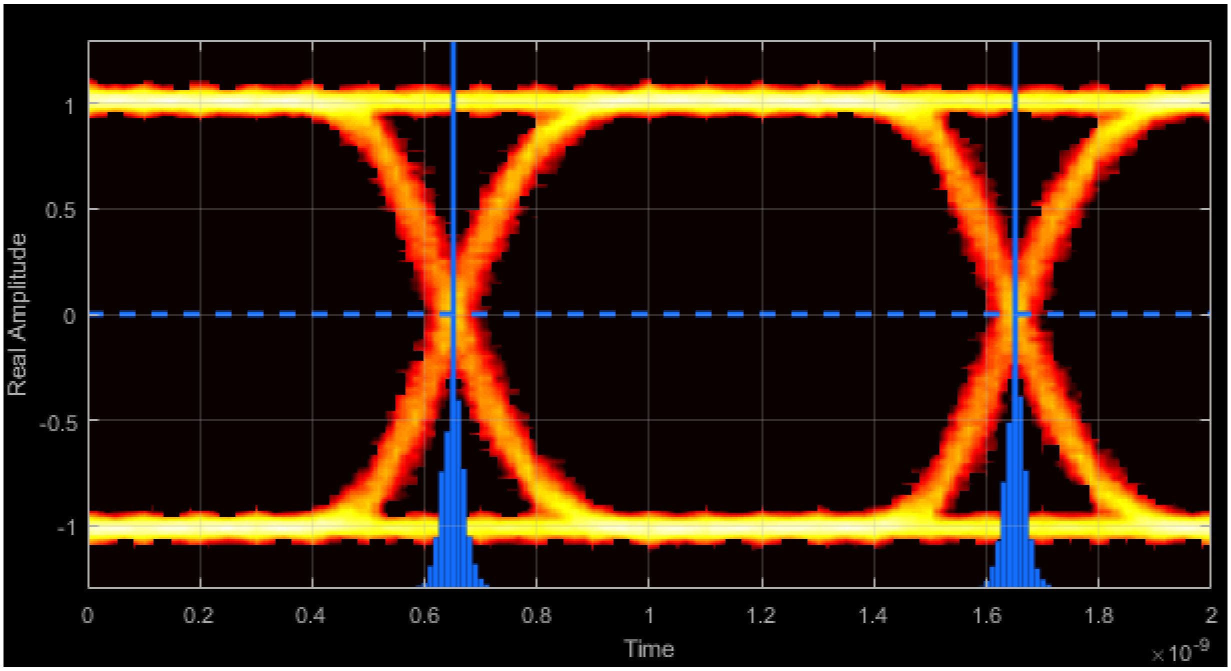
The crossing levels are the amplitude levels at which the eye crossings occur.

The level at which the input signal crosses the amplitude value is specified by the DecisionBoundary property.



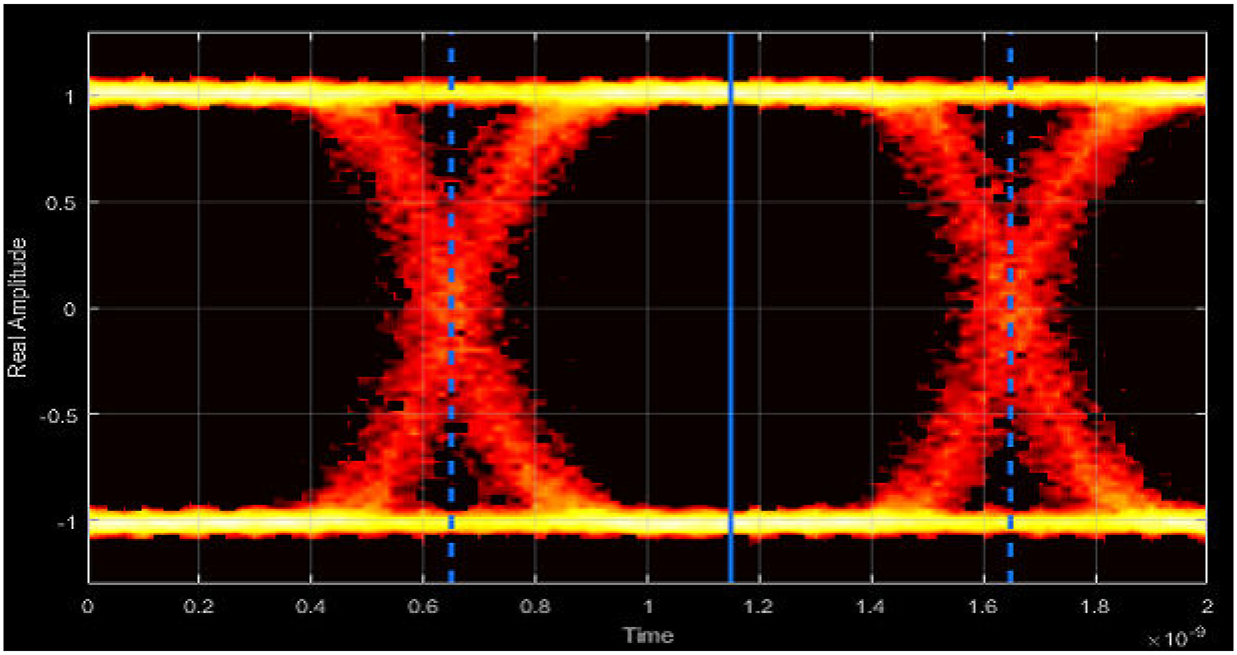
Crossing Times - Times for which crossings occur

The crossing times are the times at which the crossings occur. The times are computed as the mean values of the horizontal (jitter) histograms.



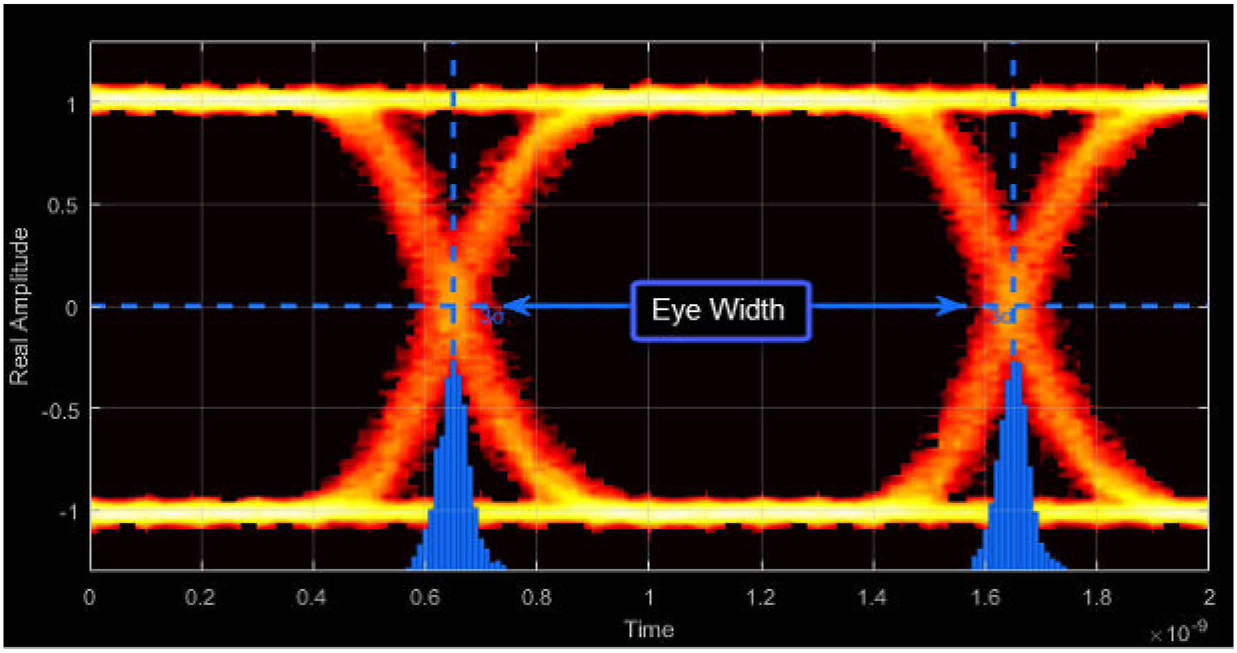
Eye Delay - Mean time between eye crossings

Eye delay is the midpoint between the two crossing times.



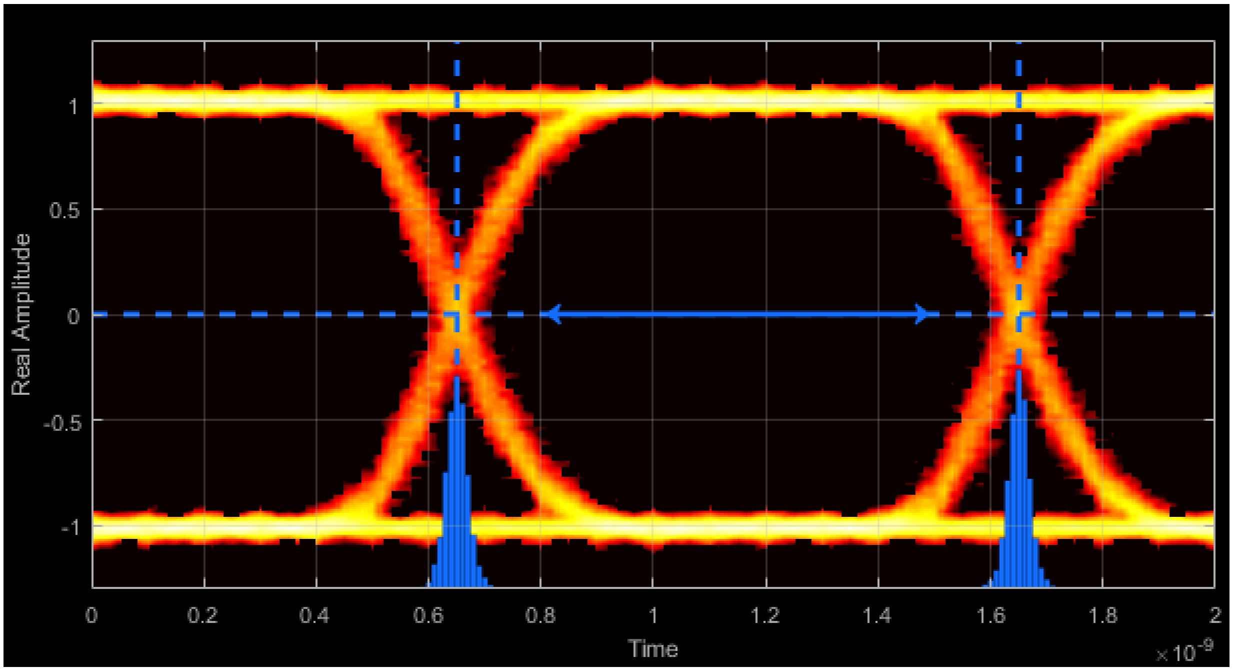
Eye Width - Statistical minimum time between eye crossings

Eye width is the horizontal distance between μ + 3σ of the left crossing time and μ – 3σ of the right crossing time. μ is the mean of the jitter histogram, and σ is the standard deviation.



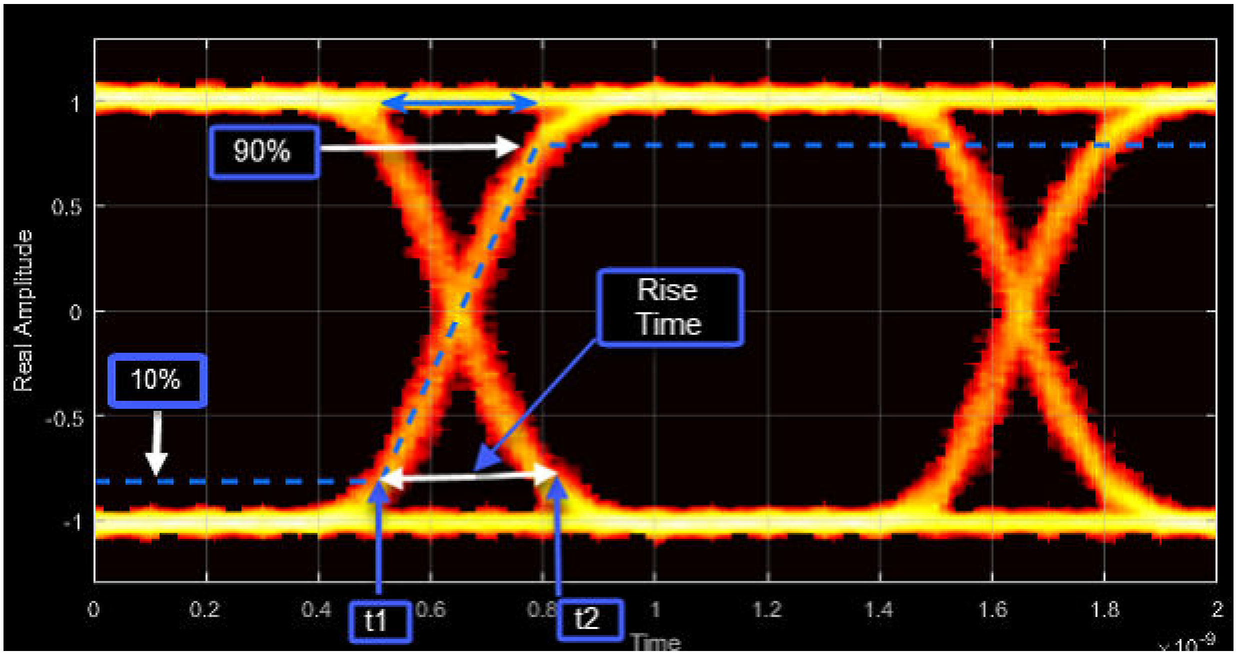
Horizontal Opening - Time between BER threshold points

The horizontal opening is the distance between the two points that correspond to the BERThreshold property. For example, for a 10^{-12} BER, these two points correspond to the 7σ distance from each crossing time.



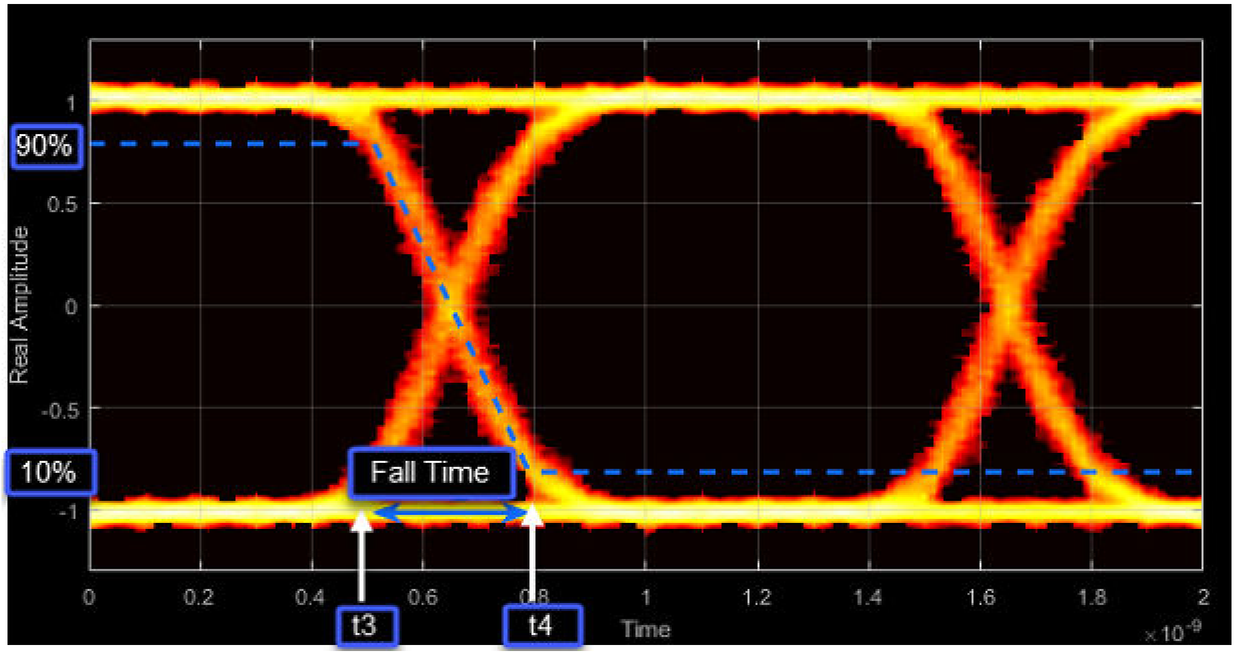
Rise Time - Time to transition from low to high

Rise time is the mean time between the low and high rise/fall thresholds defined in the eye diagram. The default thresholds are 10% and 90% of the eye amplitude.



Fall Time - Time to transition from high to low

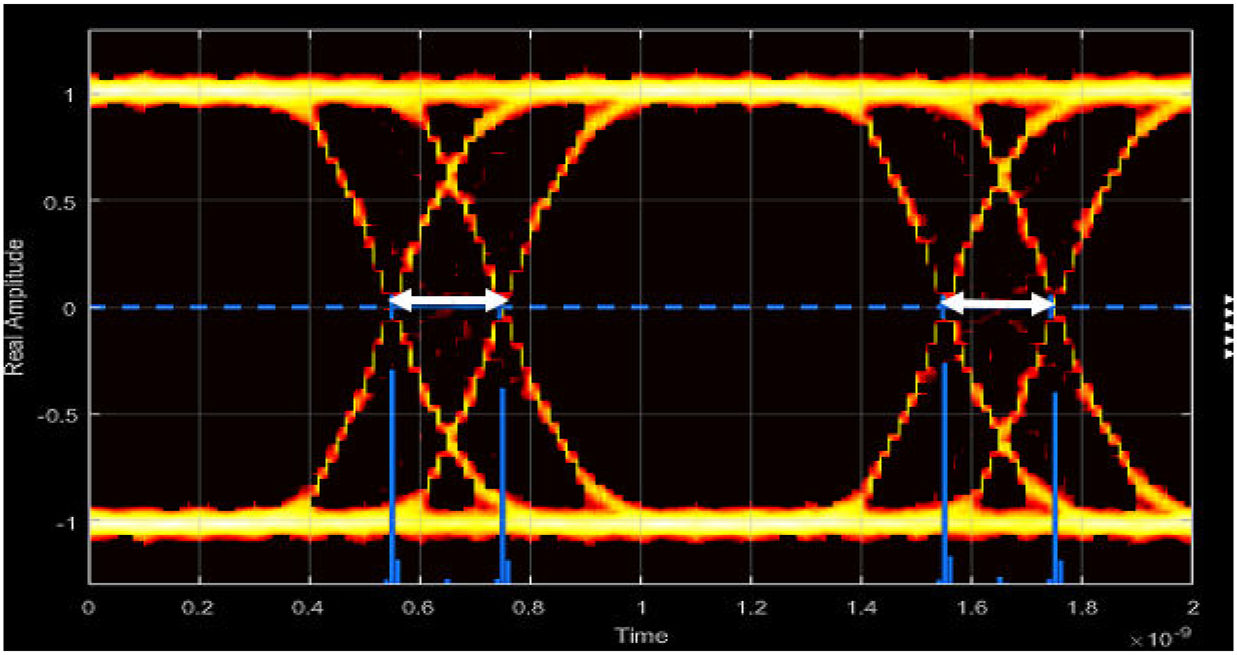
Fall time is the mean time between the high and low rise/fall thresholds defined in the eye diagram. The default thresholds are 10% and 90% of the eye amplitude.



Deterministic Jitter - Deterministic deviation from ideal signal timing

Jitter is the deviation of a signal’s timing event from its intended (ideal) occurrence in time [2]. Jitter can be represented with a dual-Dirac model. A dual-Dirac model assumes that the jitter has two components: deterministic jitter (DJ) and random jitter (RJ).

DJ is the distance between the two peaks of the dual-Dirac histograms. The probability density function (PDF) of DJ is composed of two delta functions.



Random Jitter - Random deviation from ideal signal timing

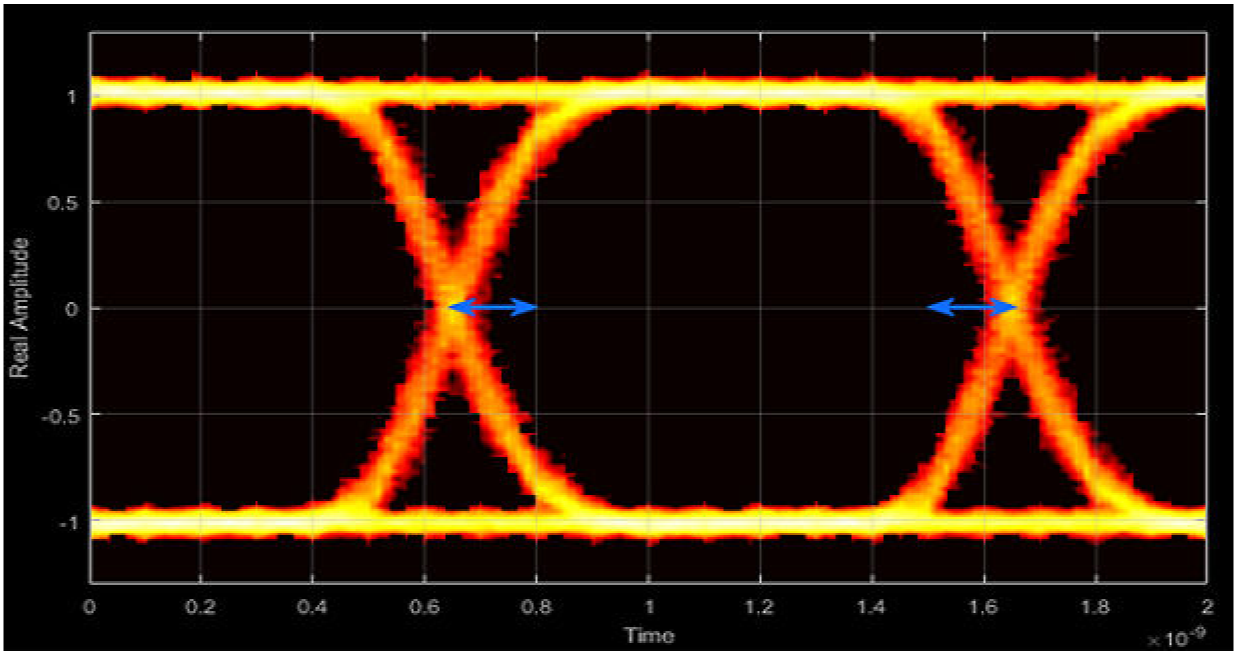
RJ is the Gaussian unbounded jitter component. The random component of jitter is modeled as a zero-mean Gaussian random variable with a specified standard-deviation of σ. The RJ is computed as:

$$\mathrm{RJ} = (Q_L + Q_R)\sigma\,,$$

where

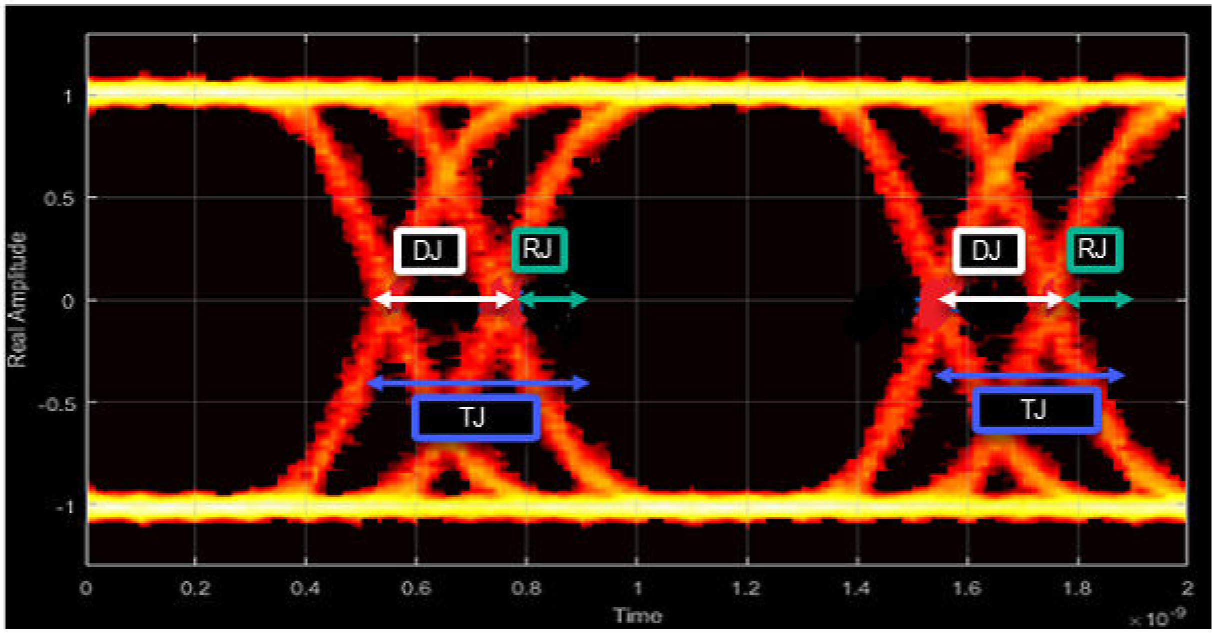
$$Q = \sqrt{2}\mathrm{erfc}^{-1}\left(2\frac{BER}{\rho}\right)\,.$$

BER is the specified BER threshold. ρ is the amplitude of the left and right Dirac function, which is determined from the bin counts of the jitter histograms.

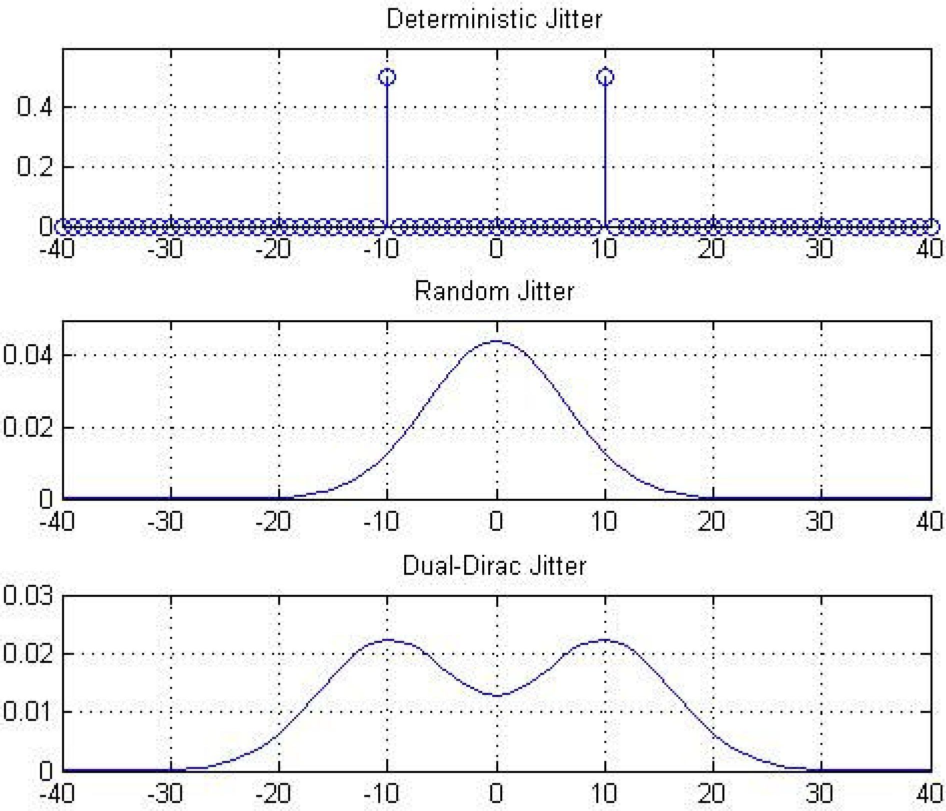


Total Jitter - Deviation from ideal signal timing

Total jitter (TJ) is the sum of the deterministic and random jitter, such that TJ = DJ + RJ.

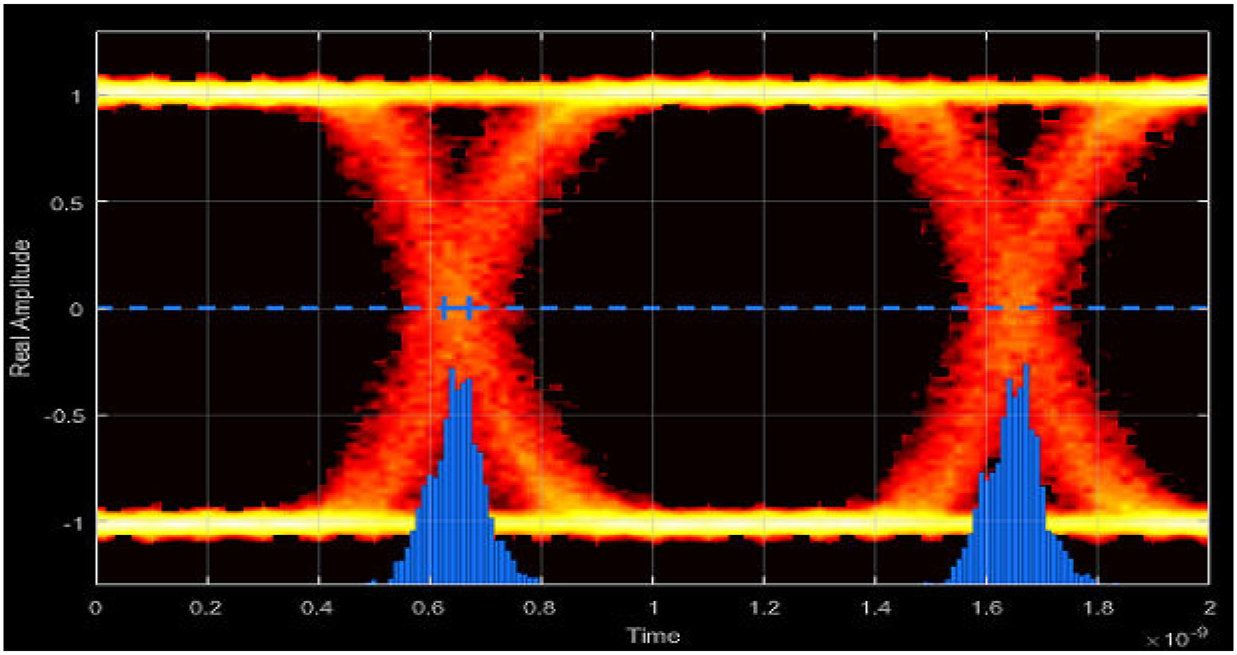


The total jitter PDF is the convolution of the DJ PDF and the RJ PDF.



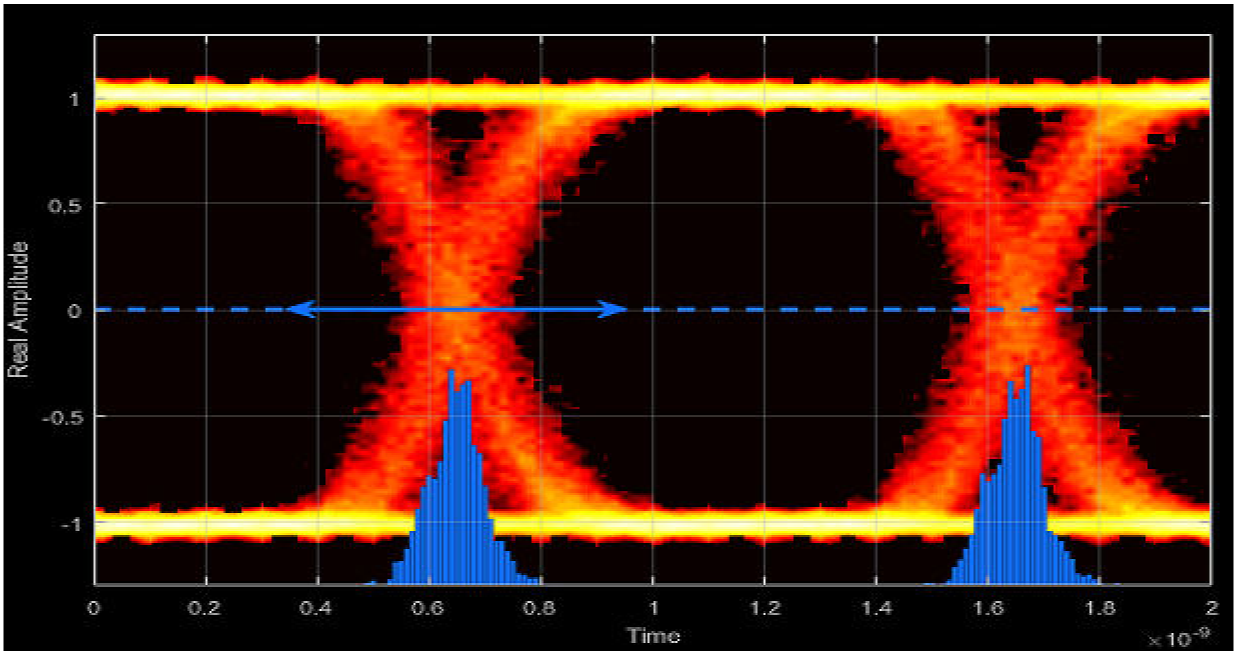
RMS Jitter - Standard deviation of jitter

RMS jitter is the standard deviation of the jitter calculated in the horizontal (jitter) histogram at the decision boundary.



Peak-to-Peak Jitter - Distance between extreme data points of histogram

Peak-to-peak jitter is the maximum horizontal distance between the left and right nonzero values in the horizontal histogram of each crossing time.

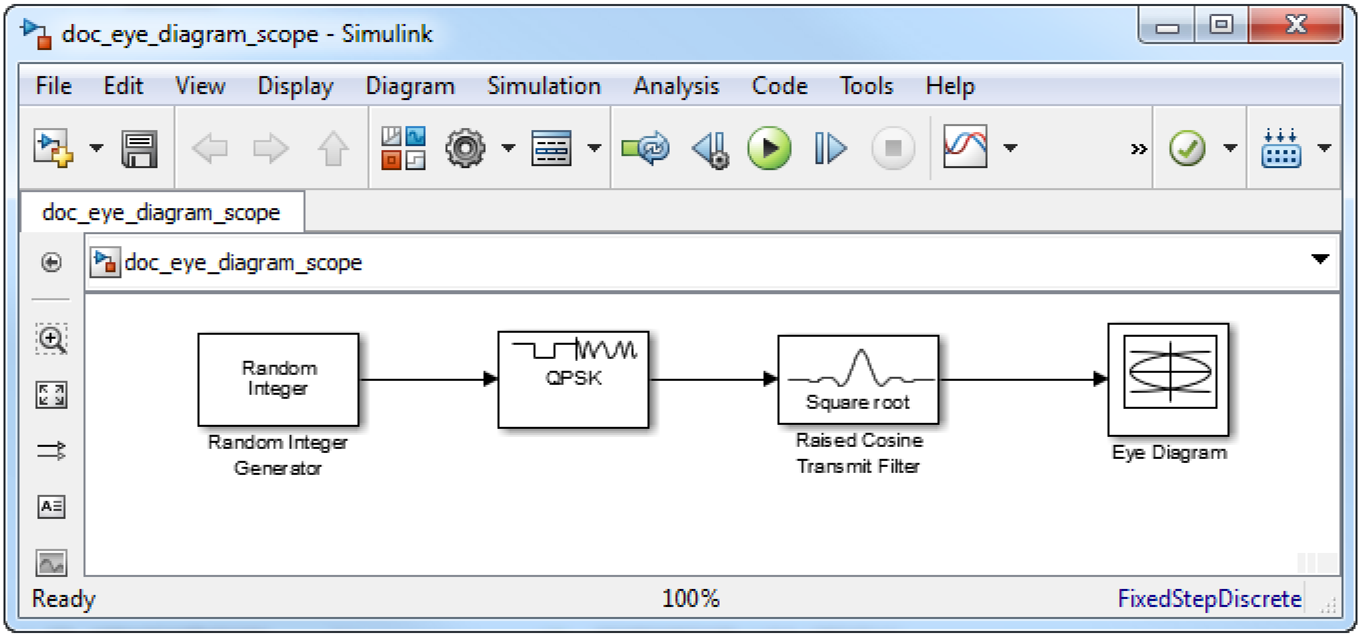


View Eye Diagram

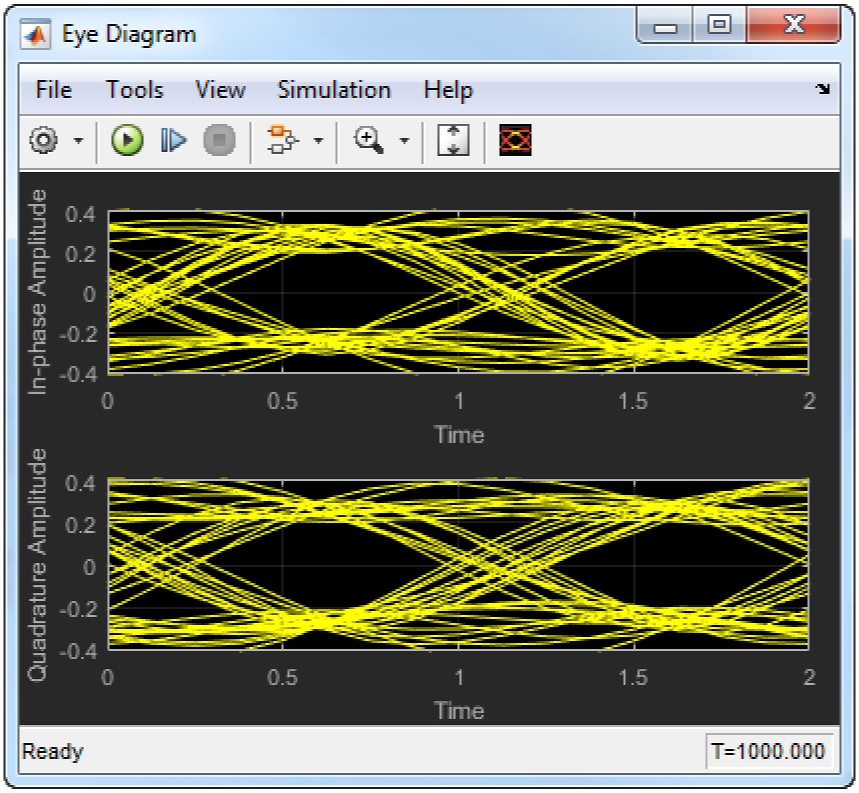
Display the eye diagram of a filtered QPSK signal using the Eye Diagram block.

Load the doc_eye_diagram_scope model from the MATLAB command prompt.

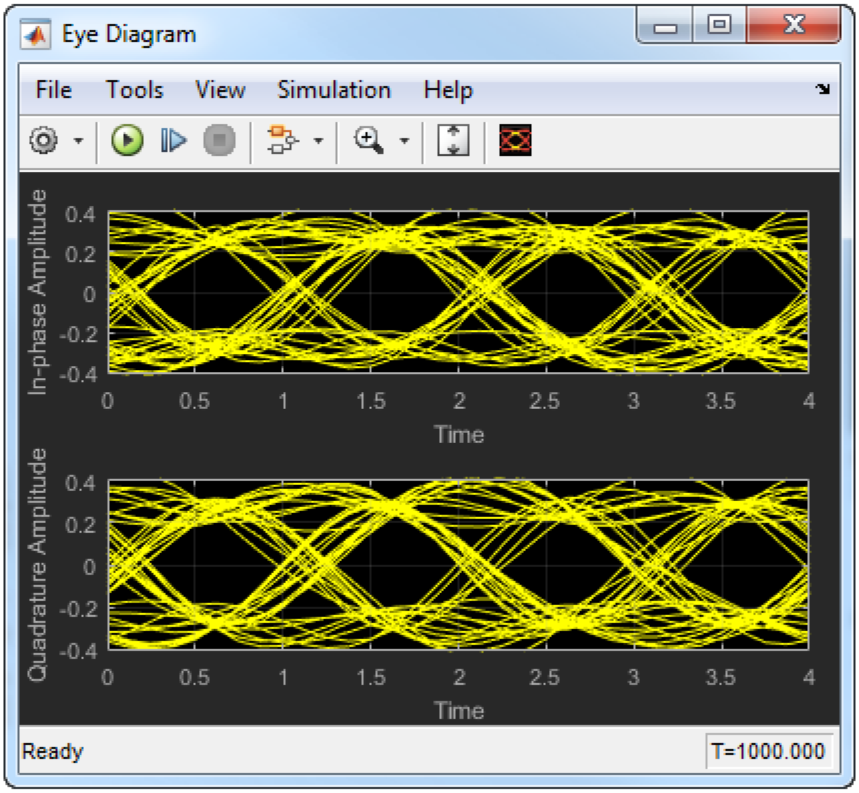
```
doc_eye_diagram_scope
```



Run the model and observe that two symbols are displayed.



Open the configuration parameters dialog box. Change the **Symbols per trace** parameter to 4. Run the simulation and observe that four symbols are displayed.



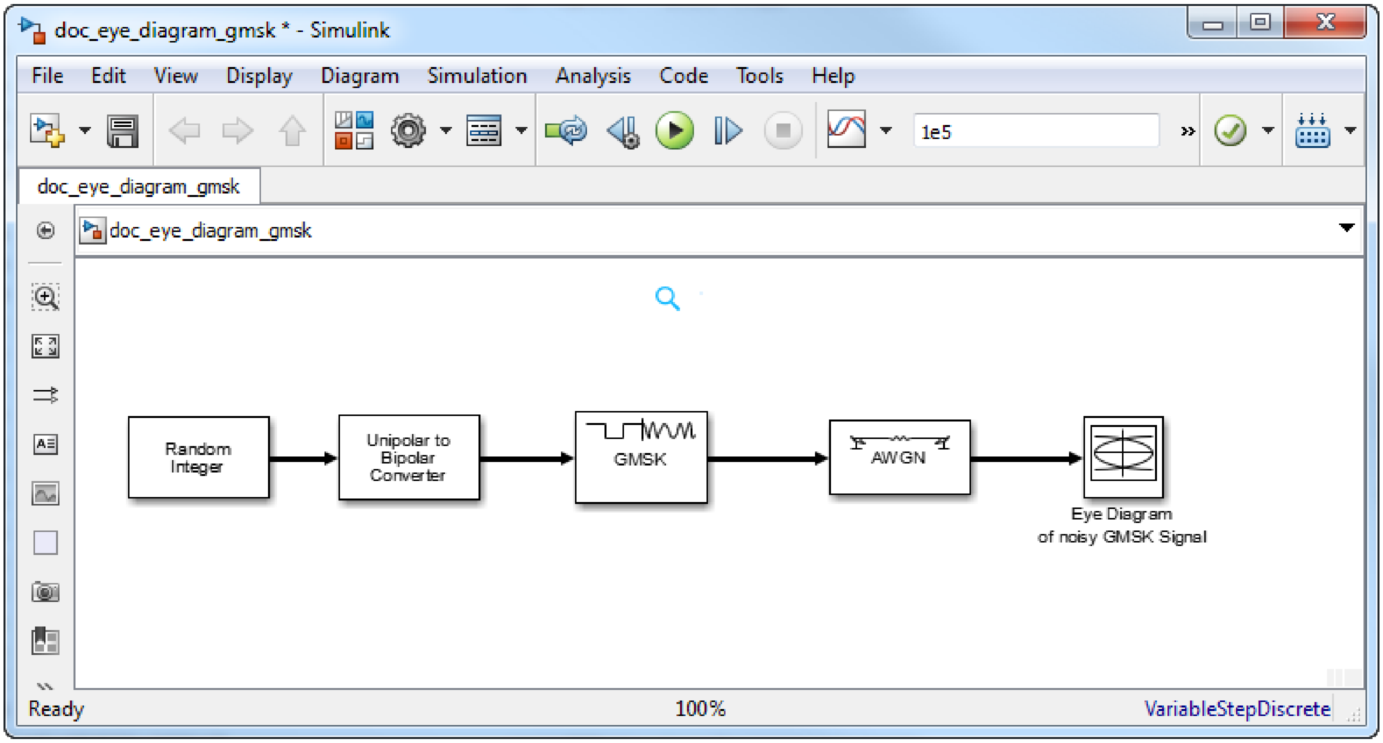
Try changing the Raised Cosine Transmit Filter parameters or changing additional Eye Diagram parameters to see their effects on the eye diagram.

Histogram Plots

Display histogram plots of a noisy GMSK signal.

Load the doc_eye_diagram_gmsk model from the MATLAB command prompt.

```
doc_eye_diagram_gmsk
```



doc_eye_diagram_gmsk * - Simulink

doc_eye_diagram_gmsk
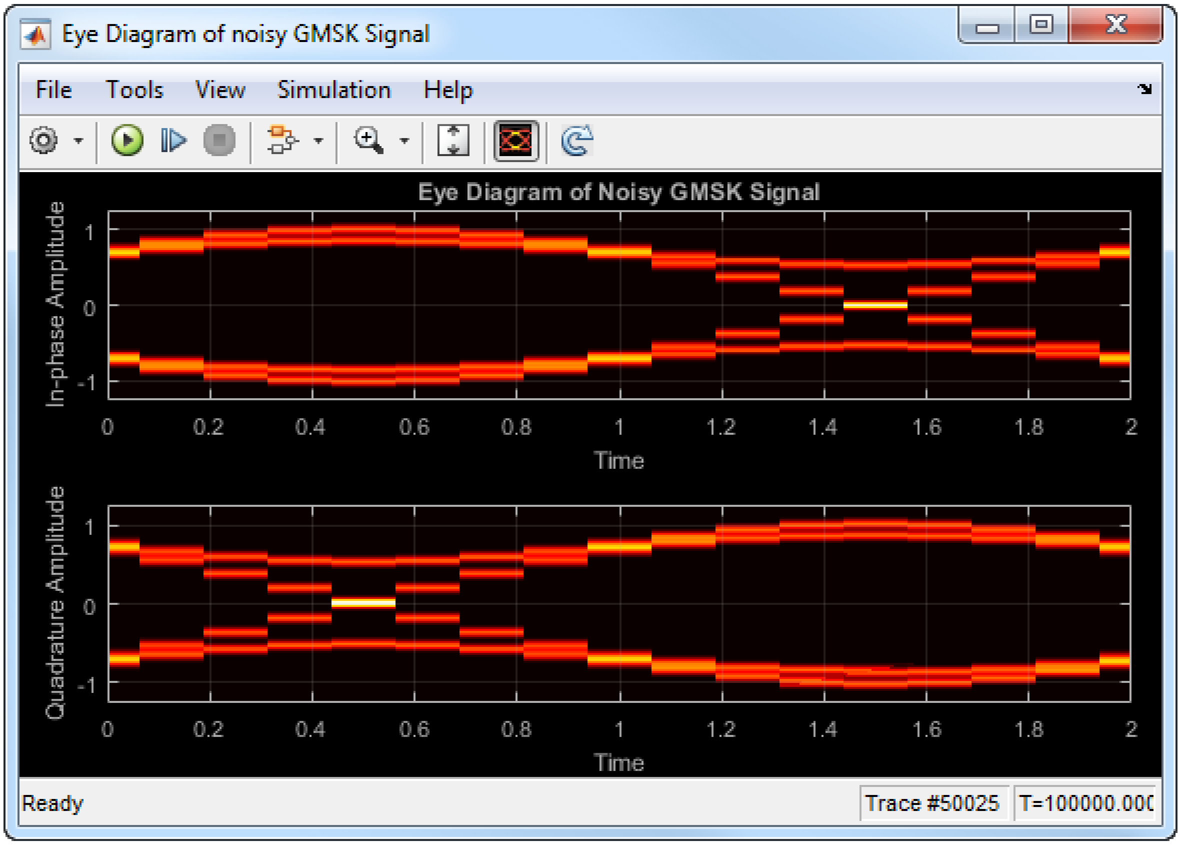
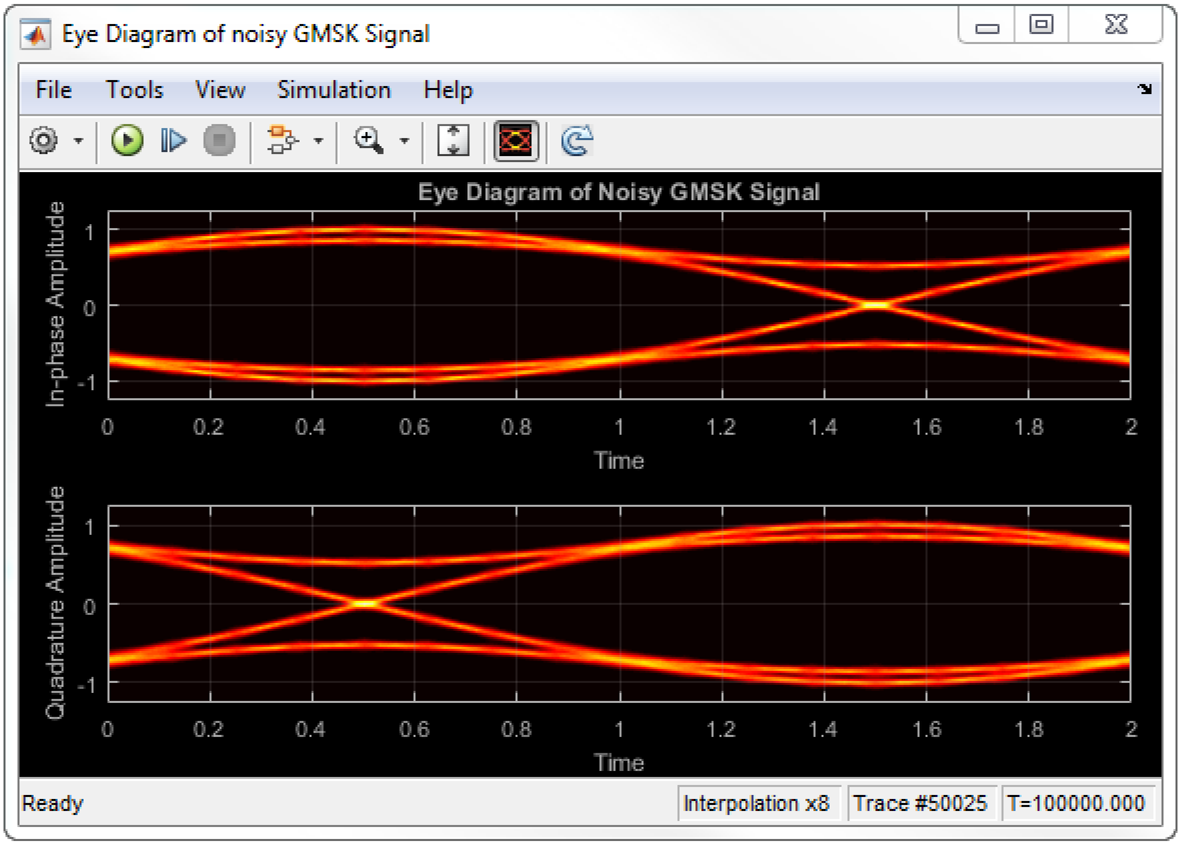
Random Integer
Unipolar to Bipolar Converter
GMSK
AWGN
Eye Diagram of noisy GMSK Signal
Ready
100%
VariableStepDiscrete

Run the model. The eye diagram is configured to show a histogram without interpolation.



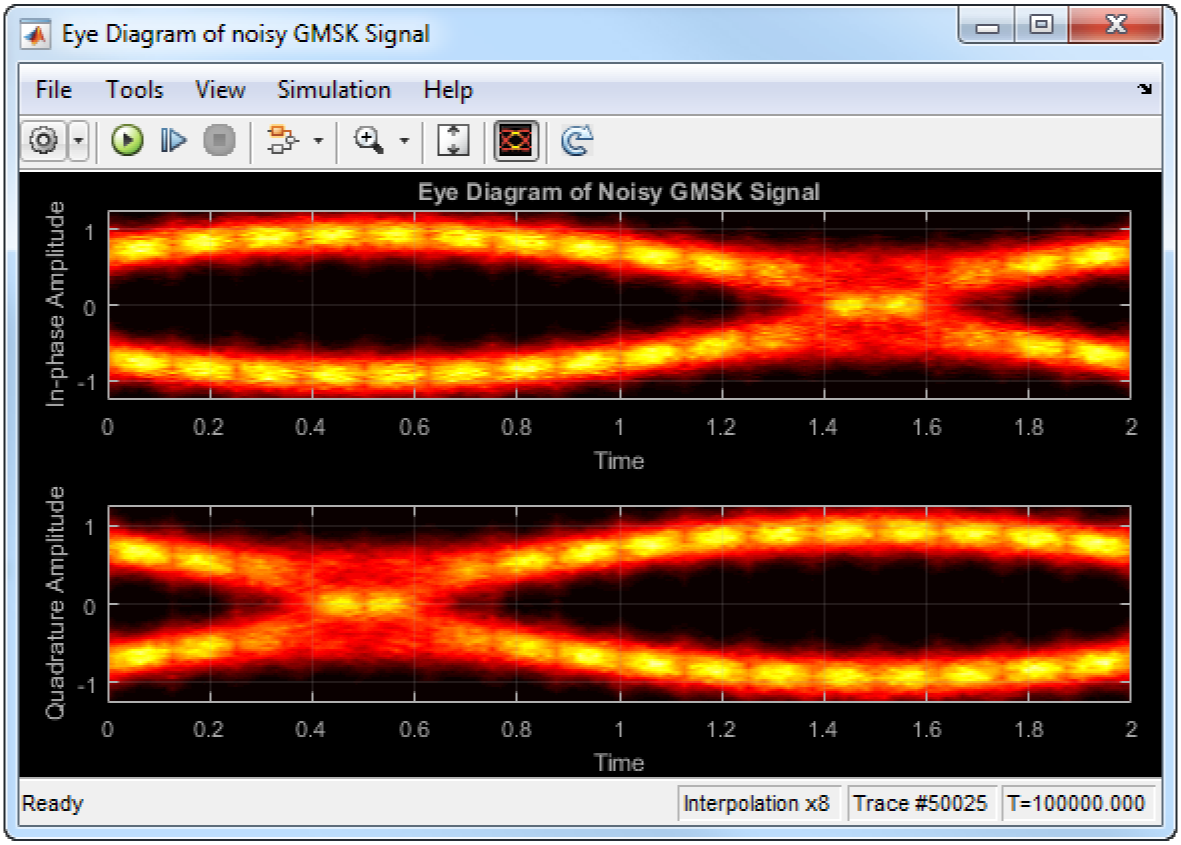
The lack of interpolation results in a plot having piecewise-continuous behavior.

Open the **2D Histogram** tab of the Configuration Properties dialog box. Set the **Oversampling method** to `Input interpolation`. Run the model.



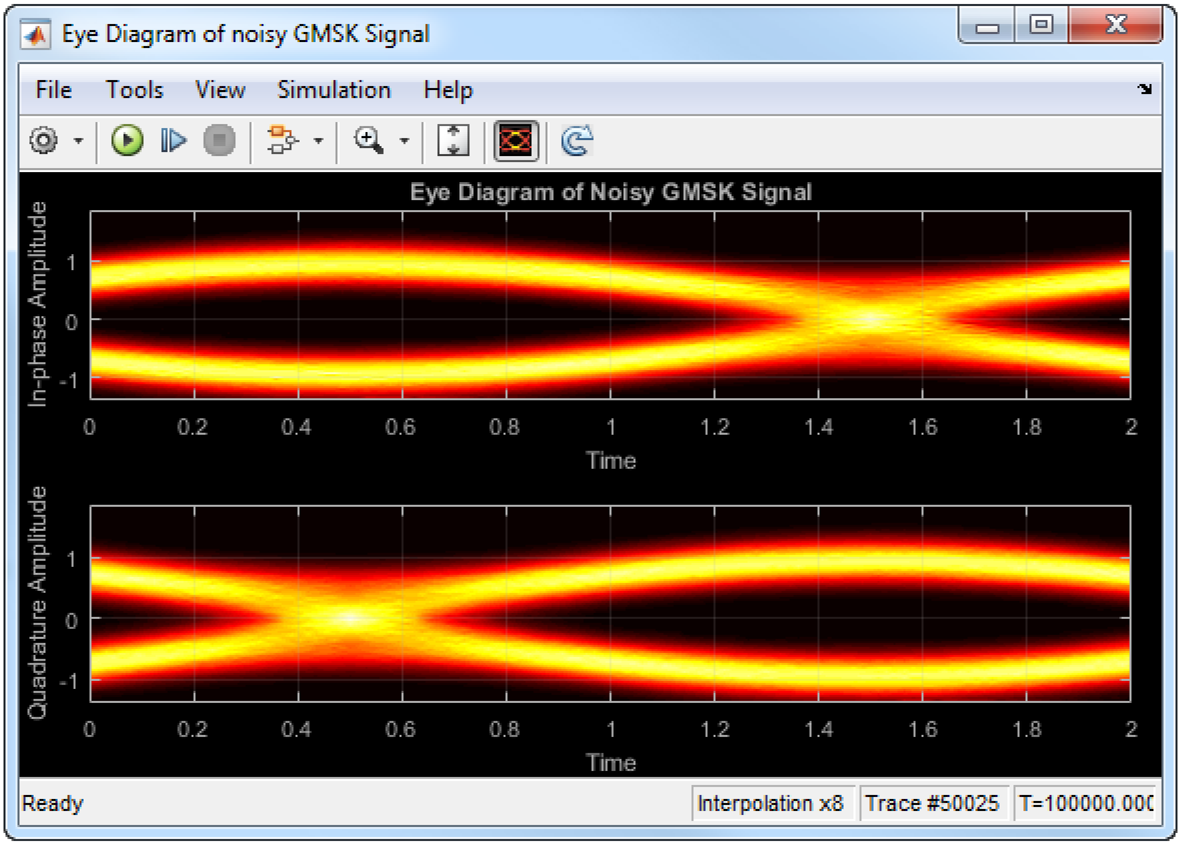
The interpolation smooths the eye diagram.

On the AWGN Channel block, change **SNR (dB)** from `25` to `10`. Run the model.



Observe that vertical striping is present in the eye diagram. This striping is the result of input interpolation, which has limited accuracy in low-SNR conditions.

Set the **Oversampling method** to `Histogram interpolation`. Run the model.



The eye diagram plot now renders accurately because the histogram interpolation method works for all SNR values. This method is not as fast as the other techniques and results in increased execution time.

Programmatic Configuration

You can programmatically configure the scope properties with callbacks or within scripts by using a scope configuration object as describe in “Control Scope Blocks Programmatically” (Simulink).

Find Delay

Find delay between two signals
Library: Communications Toolbox / Utility Blocks

Description

The Find Delay block finds the delay between a signal and a delayed, and possibly distorted, version of itself. This is useful when you want to compare a transmitted and received signal to find the bit error rate, but do not know the delay in the received signal. This block accepts a column vector or matrix input signal. For a matrix input, the block outputs a row vector, and finds the delay in each channel of the matrix independently. See “Delays” for more information about signal delays.

Ports

Input

`sRef` — Reference signal
vector | matrix

Original reference signal, specified as a vector or matrix. Dimensions and sample times of **sRef** and **sDel** must match.

Data Types: `double`

`sDel` — Delayed signal
vector | matrix

Delayed or distorted version of reference signal, specified as a vector or matrix. Dimensions and sample times of **sRef** and **sDel** must match.

Data Types: `double`

Output

`delay` — Delay output
scalar | vector

The output port labeled **delay** outputs the delay in units of samples.

For a matrix input, the output is a row vector, and finds the delay in each channel of the matrix independently

The delay output is a nonnegative integer less than the **Correlation window length**.

Data Types: `double`

`chg` — Delay flag
`0` | `1`

The **chg** output port outputs `1` when there is a change from the delay computed at the previous sample, and `0` when there is no change

Dependencies

This output port becomes visible only when `Include "change signal" output port` is selected.

Data Types: `Boolean`

Parameters

`Correlation window length (samples)` — Number of samples

`200` (default) | positive integer

The number of samples the block uses to calculate the cross-correlations of the two signals.

As the **Correlation window length** is increased, the reliability of the computed delay also increases. However, the processing time to compute the delay increases as well.

`Include "change signal" output port` — Enable chg port

`off` (default) | `on`

If you select this option, then the block has an extra output port that emits a value of 1 when the current computed delay differs from the previous computed delay and emits a value of 0 when there is no delay.

`Disable recurring updates` — Disable recurring updates

`off` (default) | `on`

Selecting this option causes the block to stop computing the delay after it computes the same delay value for a specified number of samples.

`Number of constant delay outputs to disable updates` — Number of constant delay outputs to disable updates

`3` (default) | positive integer

A positive integer specifying how many times the block must compute the same delay before ceasing to update.

Dependencies

This field becomes visible only when **Disable recurring updates** is selected.

Block Characteristics

Data Types	`double` | `enumerated` | `integer`[a] | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`no`

[a] Signed integers only.

More About

Finding the Delay Before Calculating an Error Rate

A typical use of this block is to determine the correct **Receive delay** parameter in the Error Rate Calculation block. This is illustrated in “Use the Find Delay Block”. In that example, the modulation/ demodulation operation introduces a computational delay into the received signal and the Find Delay block determines that the delay is 6 samples. This value of 6 becomes a parameter in the Error Rate Calculation block, which computes the bit error rate of the system.

Another example of this usage is in “Delays”.

Finding the Delay to Help Align Words

Another typical use of this block is to determine how to align the boundaries of frames with the boundaries of codewords or other types of data blocks. “Delays” describes when such alignment is necessary and also illustrates, in the “Aligning Words of a Block Code” discussion, how to use the Find Delay block to solve the problem.

Tips for Using the Block Effectively

- Set **Correlation window length** sufficiently large so that the computed delay eventually stabilizes at a constant value. When this occurs, the signal from the optional `chg` output port stabilizes at the constant value of zero. If the computed delay is not constant, you should increase **Correlation window length**. If the increased value of **Correlation window length** exceeds the duration of the simulation, then you should also increase the duration of the simulation accordingly. If you can roughly estimate the delay, then the **Correlation window length** will produce a stable delay estimate at four times that value.
- If the cross-correlation between the two signals is broad, then the **Correlation window length** value should be much larger than the expected delay, or else the algorithm might stabilize at an incorrect value. For example, a CPM signal has a broad autocorrelation, so it has a broad cross-correlation with a delayed version of itself. In this case, the **Correlation window length** value should be much larger than the expected delay.
- If the block calculates a delay that is greater than 75 percent of the **Correlation window length**, the signal `sRef` is probably delayed relative to the signal `sDel`. In this case, you should switch the signal lines leading into the two input ports.
- You can make the Find Delay block stop updating the delay after it computes the same delay value for a specified number of samples. To do so, select **Disable recurring updates**, and enter a positive integer in the **Number of constant delay outputs to disable updates** field. For example, if you set **Number of constant delay outputs to disable updates** to `20`, the block will stop recalculating and updating the delay after it calculates the same value `20` times in succession. Disabling recurring updates causes the simulation to run faster after the target number of constant delays occurs.

Algorithms

The Find Delay block finds the delay by calculating the cross-correlations of the first signal with time-shifted versions of the second signal, and then finding the index at which the cross-correlation is maximized.

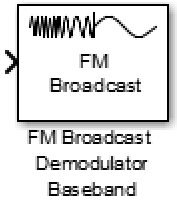
FM Broadcast Demodulator Baseband

Demodulate using broadcast FM method



Library

Modulation > Analog Baseband Modulation

Description

The FM Broadcast Demodulator Baseband block demodulates a complex baseband FM signal by using the conjugate delay method, and filters the signal by using a de-emphasis filter. To demodulate stereo audio using 38 kHz, enable stereo demodulation. To demodulate RBDS signals from the 57 kHz band, enable RBDS demodulation.

Parameters

Sample rate (Hz)

Specify the input signal sample rate as a positive real scalar.

Frequency deviation (Hz)

Specify the frequency deviation of the modulator in Hz as a positive real scalar. The system bandwidth is equal to twice the sum of the frequency deviation and the message bandwidth. FM broadcast standards specify a value of 75 kHz in the United States and 50 kHz in Europe.

De-emphasis filter time constant (s)

Specify the de-emphasis lowpass filter time constant in seconds as a positive real scalar. FM broadcast standards specify a value of 75 μs in the United States and 50 μs in Europe.

Output audio sample rate (Hz)

Specify the output audio sample rate as a positive real scalar.

Play audio device

Select this check box to play sound from a default audio device.

Buffer size (samples)

Specify the buffer size the block uses to communicate with an audio device as a positive integer scalar. This parameter is available only when the **Play audio device** check box is selected.

Stereo audio

Select this check box to enable demodulation of a stereo audio signal. If not selected, the audio signal is assumed to be monophonic.

RBDS demodulation

Select this check box to demodulate the RBDS signal from the input complex baseband FM signal. By default, this check box is not selected.

Number of samples per RBDS symbol

Specify the number of samples of the RBDS output as a positive integer. The RBDS sample rate is given by **Number of samples per RBDS symbol** × `1187.5` Hz. According to the RBDS standard, the sample rate of each bit is 1187.5 Hz.

This parameter appears when you select the **RBDS demodulation** check box.

The default is 10.

RBDS Costas loop

Specify whether a Costas loop is used to recover the phase of the RBDS signal. Select this check box for radio stations that do not lock the `57` kHz RBDS signal in phase with the third harmonic of the `19` kHz pilot tone.

This parameter appears when you select the **RBDS demodulation** check box.

By default, this check box is not selected.

Simulate using

Select the type of simulation to run.

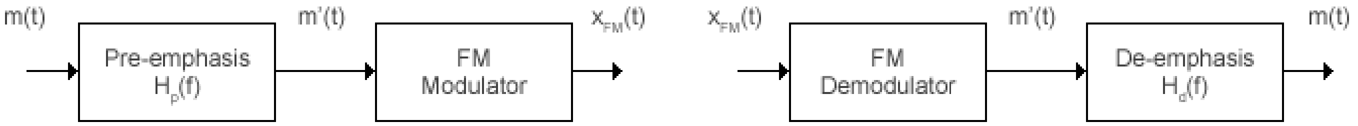
- `Code generation`. Simulate model using generate C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations, as long as the model does not change. This option requires additional startup time but provides faster simulation speed than `Interpreted execution`.
- `Interpreted execution`. Simulate model using the MATLAB interpreter. This option shortens startup time but has slower simulation speed than `Code generation`.

Algorithms

The FM Broadcast demodulator includes the functionality of the baseband FM demodulator, de-emphasis filtering, and the ability to receive stereophonic signals. The algorithms which govern basic FM modulation and demodulation are covered in `comm.FMDemodulator`.

Filtering

FM amplifies high-frequency noise and degrades the overall signal-to-noise ratio. To compensate, FM broadcasters insert a pre-emphasis filter prior to FM modulation to amplify the high-frequency content. The FM receiver has a reciprocal de-emphasis filter after the FM demodulator to attenuate high-frequency noise and restore a flat signal spectrum.



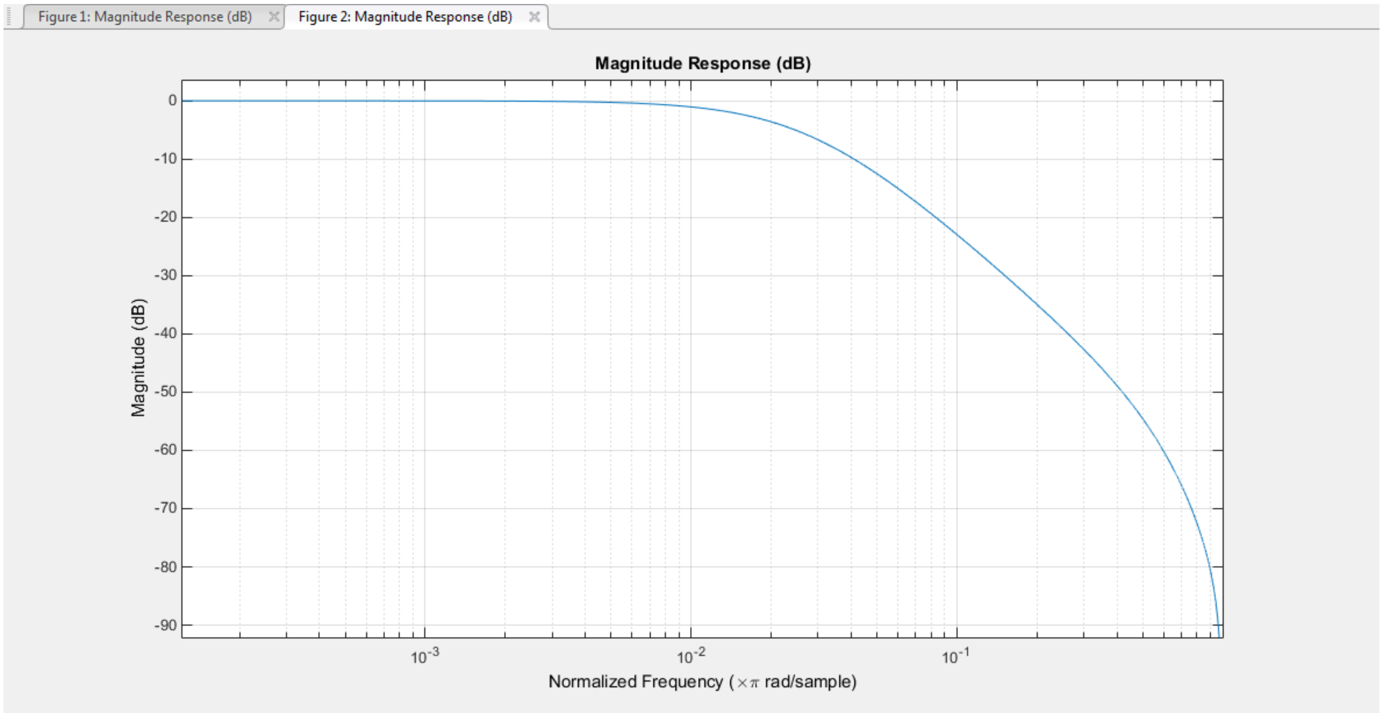
The pre-emphasis filter has a highpass characteristic transfer function given by

$$H_p(f) = 1 + j2\pi f\tau_s\,,$$

where τ_s is the filter time constant. The time constant is 50 µs in Europe and 75 µs in the United States. Similarly, the transfer function for the lowpass de-emphasis filter is given by

$$H_d(f) = \frac{1}{1 + j2\pi f\tau_s}\;.$$

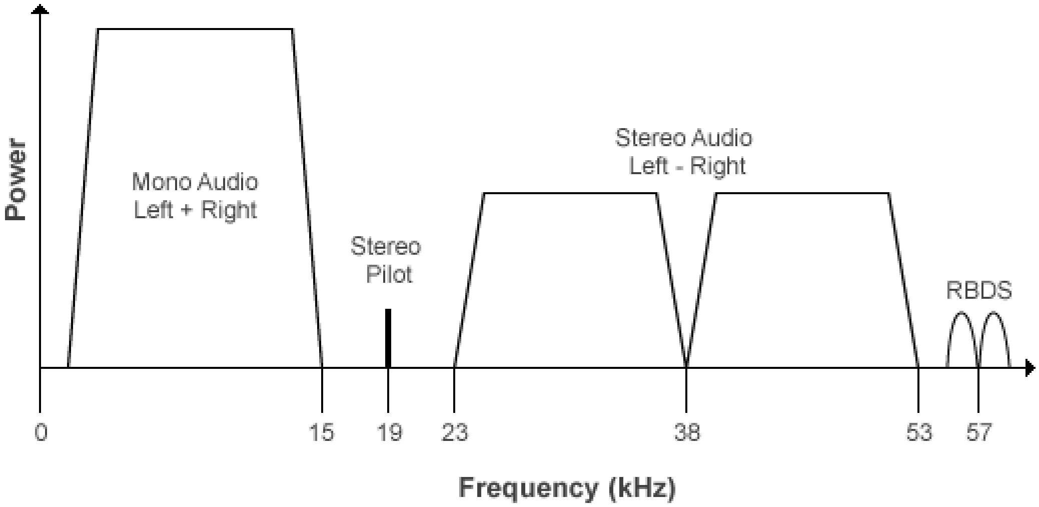
For an audio sample rate of 44.1 kHz, the de-emphasis filter has the following response.



Stereo and RDS/RBDS FM — Multiplex Signal

The FM broadcast demodulator supports stereophonic and monophonic operations. To support stereo transmission, the left (L) and right (R) channel information (L+R) is assigned to the mono portion of the spectrum (0 to 15 kHz). The (L-R) information is amplitude modulated onto the 23 to 53 kHz region of the baseband spectrum using a 38 kHz subcarrier signal. A pilot tone at 19 kHz in the multiplexed signal enables the FM receiver to coherently demodulate the stereo and RDS/RBDS signals.

Here is the spectrum of the multiplex baseband signal, *m(t)*.



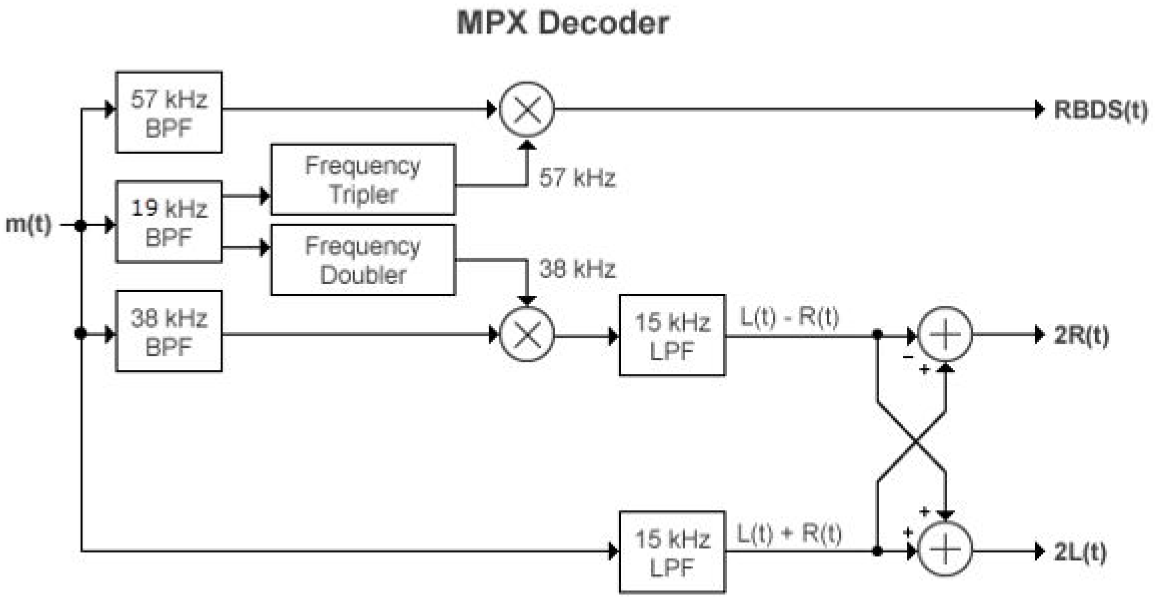
m(t) is given by

$$m(t) = C_0[L(t) + R(t)] + C_1\cos(2\pi \times 19kHz \times t) + C_0[L(t) - R(t)]\cos(2\pi \times 38kHz \times t) + C_2RBDS(t)\cos(2\pi \times 57kHz \times t)\,,$$

where C_0, C_1, and C_2 are gains. To generate the appropriate modulation level, these gains scale the amplitudes of the (*L(t)*±*R(t)*) signals, the 19 kHz pilot tone, and the RDS/RBDS subcarrier, respectively.

The demodulator applies *m(t)* to three bandpass filters with center frequencies at 19, 38, and 57 kHz, and to a lowpass filter with a 3-dB cutoff frequency of 15 kHz. The 19 kHz bandpass filter extracts the pilot tone from the modulated signal. The recovered pilot tone is doubled and tripled in frequency to produce the 38 kHz and 57 kHz signals, which demodulate the (*L* – *R*) and RDS/RBDS signals, respectively. To generate a scaled version of the left and right channels that produce the stereo sound, the (*L* + *R*) and (*L* – *R*) signals are added and subtracted. The RDS/RBDS signal is recovered by mixing with the 57 kHz signal.

Here is the block diagram of the FM broadcast demodulator.



Examples

Modulate and Demodulate an Audio Signal

Load an audio input file, modulate and demodulate using the FM broadcast blocks. Compare the input signal spectrum with the demodulated signal spectrum.

FM Broadcast Modulator Baseband

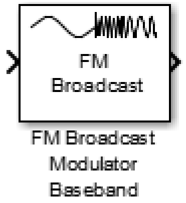
Modulate using broadcast FM method



Library

Modulation > Analog Baseband Modulation

Description

The FM Broadcast Modulator Baseband block pre-emphasizes an audio signal and modulates it onto a baseband FM signal. If you select the **Stereo audio** check box, the block modulates the stereo audio (*L*–*R*) at the 38 kHz band, in addition to the baseband (*L*+*R*). If you select the **RBDS modulation** check box, the block also modulates a baseband RBDS signal at 57 kHz. For more details, see "Algorithms" on page 5-283.

Parameters

Sample rate (Hz)

Specify the output signal sample rate as a positive real scalar.

Frequency deviation (Hz)

Specify the frequency deviation of the modulator in Hz as a positive real scalar. The system bandwidth is equal to twice the sum of the frequency deviation and the message bandwidth. FM broadcast standards specify a value of 75 kHz in the United States and 50 kHz in Europe.

Pre-emphasis filter time constant (s)

Specify the pre-emphasis highpass filter time constant as a positive real scalar. FM broadcast standards specify a value of 75 μs in the United States and 50 μs in Europe.

Sample rate of audio input signal (Hz)

Specify the input audio sample rate as a positive real scalar.

Stereo audio

Select this check box if the input signal is a stereophonic audio signal.

RBDS modulation

Select this check box to modulate a baseband RBDS signal at 57 kHz. By default, this check box is not selected.

Oversampling factor of RBDS input

Specify the number of samples per RBDS symbol as a positive integer. The RBDS sample rate is given by **Oversampling factor of RBDS input** × `1187.5` Hz. According to the RBDS standard, the sample rate of each bit is 1187.5 Hz.

This parameter appears when you select the **RBDS modulation** check box.

The default is 10.

Simulate using

Select the type of simulation to run.

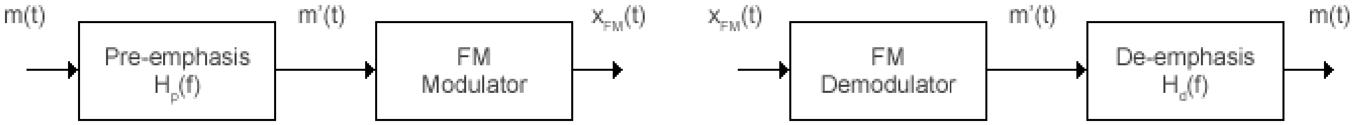
- `Code generation`. Simulate model using generate C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations, as long as the model does not change. This option requires additional startup time but provides faster simulation speed than `Interpreted execution`.
- `Interpreted execution`. Simulate model using the MATLAB interpreter. This option shortens startup time but has slower simulation speed than `Code generation`.

Algorithms

The FM Broadcast modulator includes the functionality of the baseband FM modulator, pre-emphasis filtering, and the ability to transmit stereophonic signals. The algorithms which govern basic FM modulation and demodulation are covered in `comm.FMModulator`.

Filtering

FM amplifies high-frequency noise and degrades the overall signal-to-noise ratio. To compensate, FM broadcasters insert a pre-emphasis filter prior to FM modulation to amplify the high-frequency content. The FM receiver has a reciprocal de-emphasis filter after the FM demodulator to attenuate high-frequency noise and restore a flat signal spectrum.



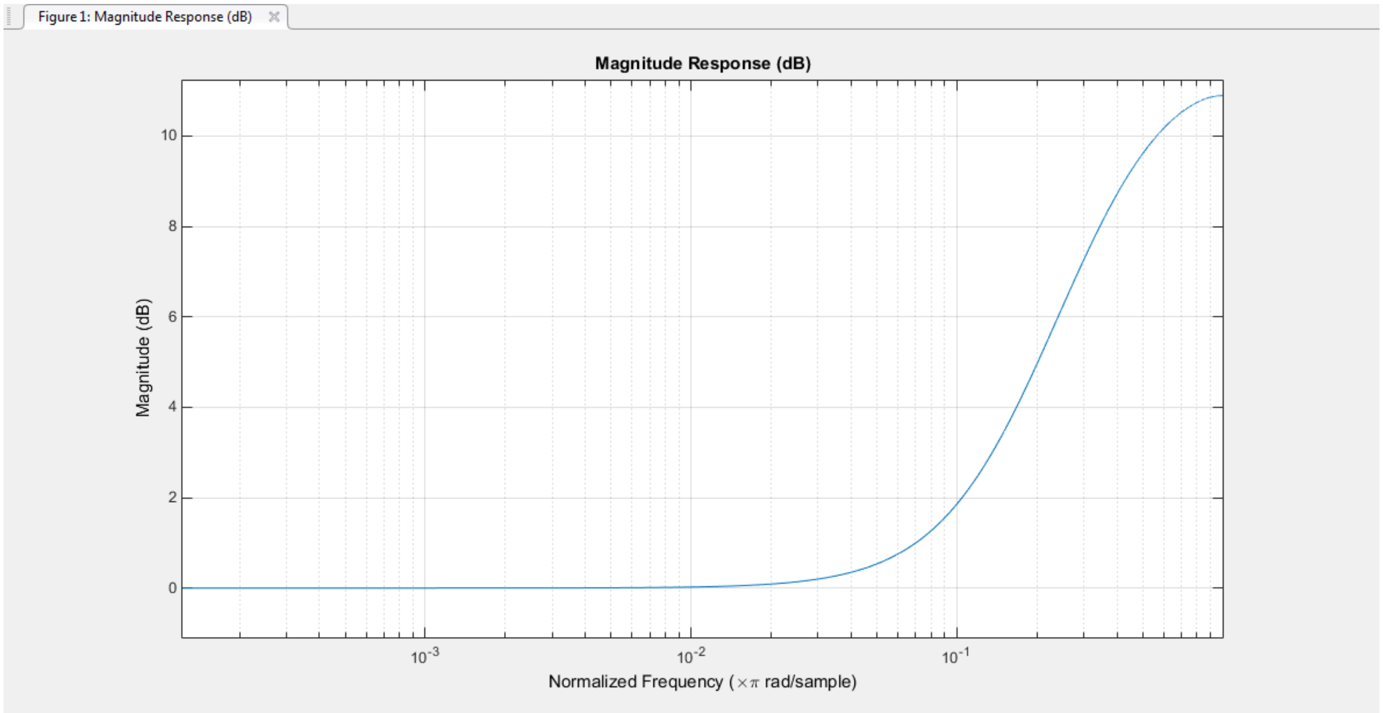
The pre-emphasis filter has a highpass characteristic transfer function given by

$$H_p(f) = 1 + j2\pi f\tau_s\,,$$

where τ_s is the filter time constant. The time constant is 50 µs in Europe and 75 µs in the United States. Similarly, the transfer function for the lowpass de-emphasis filter is given by

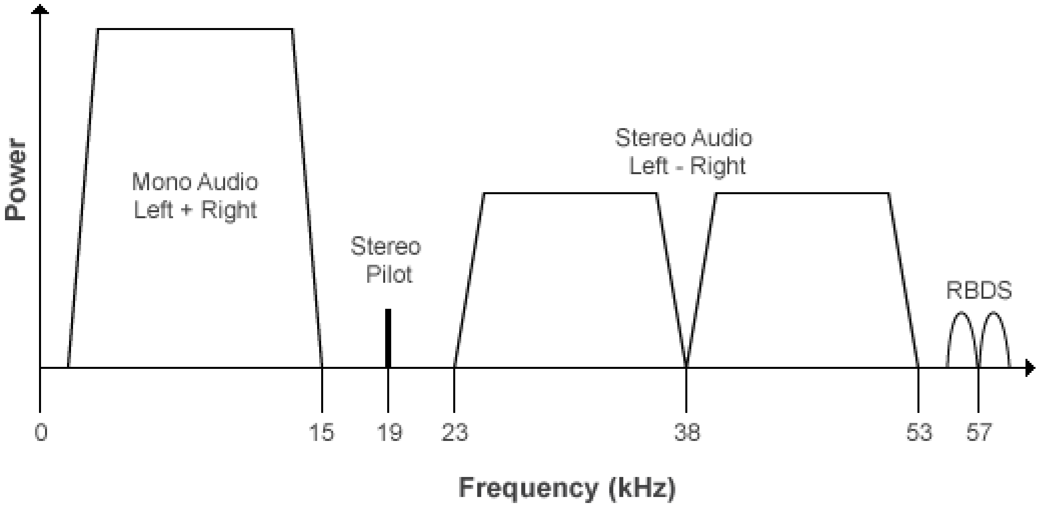
$$H_d(f) = \frac{1}{1 + j2\pi f\tau_s}\ .$$

Irrespective of the audio sampling rate, the signal is converted to a 152 kHz output sampling rate. For an audio sample rate of 44.1 kHz, the pre-emphasis filter has the following response.

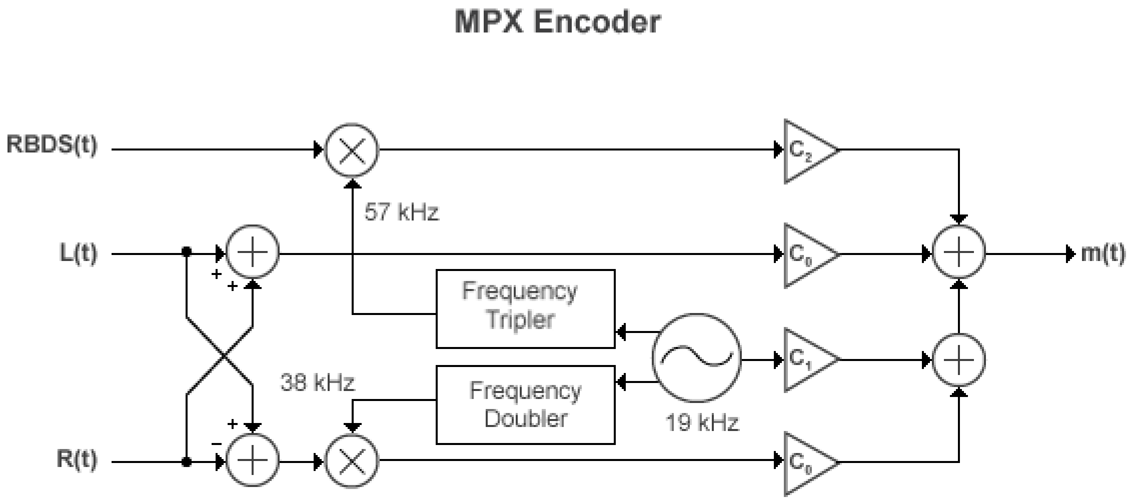


Stereo and RDS/RBDS FM – Multiplex Signal

The FM broadcast modulator supports stereophonic and monophonic operations. To support stereo transmission, the left (L) and right (R) channel information (L+R) is assigned to the mono portion of the spectrum (0 to 15 kHz). The (L-R) information is amplitude modulated onto the 23 to 53 kHz region of the baseband spectrum using a 38 kHz subcarrier signal. A pilot tone at 19 kHz in the multiplexed signal enables the FM receiver to coherently demodulate the stereo and RDS/RBDS signals. Here is the spectrum of the multiplex baseband signal.



Here is the block diagram of the FM broadcast modulator, which is used to generate the multiplex baseband signal. *L(t)* and *R(t)* denote the time-domain waveforms from the left and right channels. *RBDS(t)* denotes the time-domain waveform of the RDS/RBDS signal.



The multiplex message signal, *m(t)* is given by

$$m(t) = C_0[L(t) + R(t)] + C_1\cos(2\pi \times 19kHz \times t) + C_0[L(t) - R(t)]\cos(2\pi \times 38kHz \times t) + C_2RBDS(t)\cos(2\pi \times 57kHz \times t)\,,$$

where C_0, C_1, and C_2 are gains. To generate the appropriate modulation level, these gains scale the amplitudes of the (*L(t)*±*R(t)*) signals, the 19 kHz pilot tone, and the RDS/RBDS subcarrier, respectively.

Limitations

- If you select the **RBDS modulation** check box, both the audio and RBDS inputs must satisfy the following equation:

$$\frac{audioLength}{audioSampleRate} = \frac{RBDSLength}{RBDSSampleRate}$$

- The input length of the audio signal must be an integer multiple of the audio decimation factor. The input length of the RBDS signal must be an integer multiple of the RBDS decimation factor.

Examples

Modulate and Demodulate an Audio Signal

Load an audio input file, modulate and demodulate using the FM broadcast blocks. Compare the input signal spectrum with the demodulated signal spectrum.

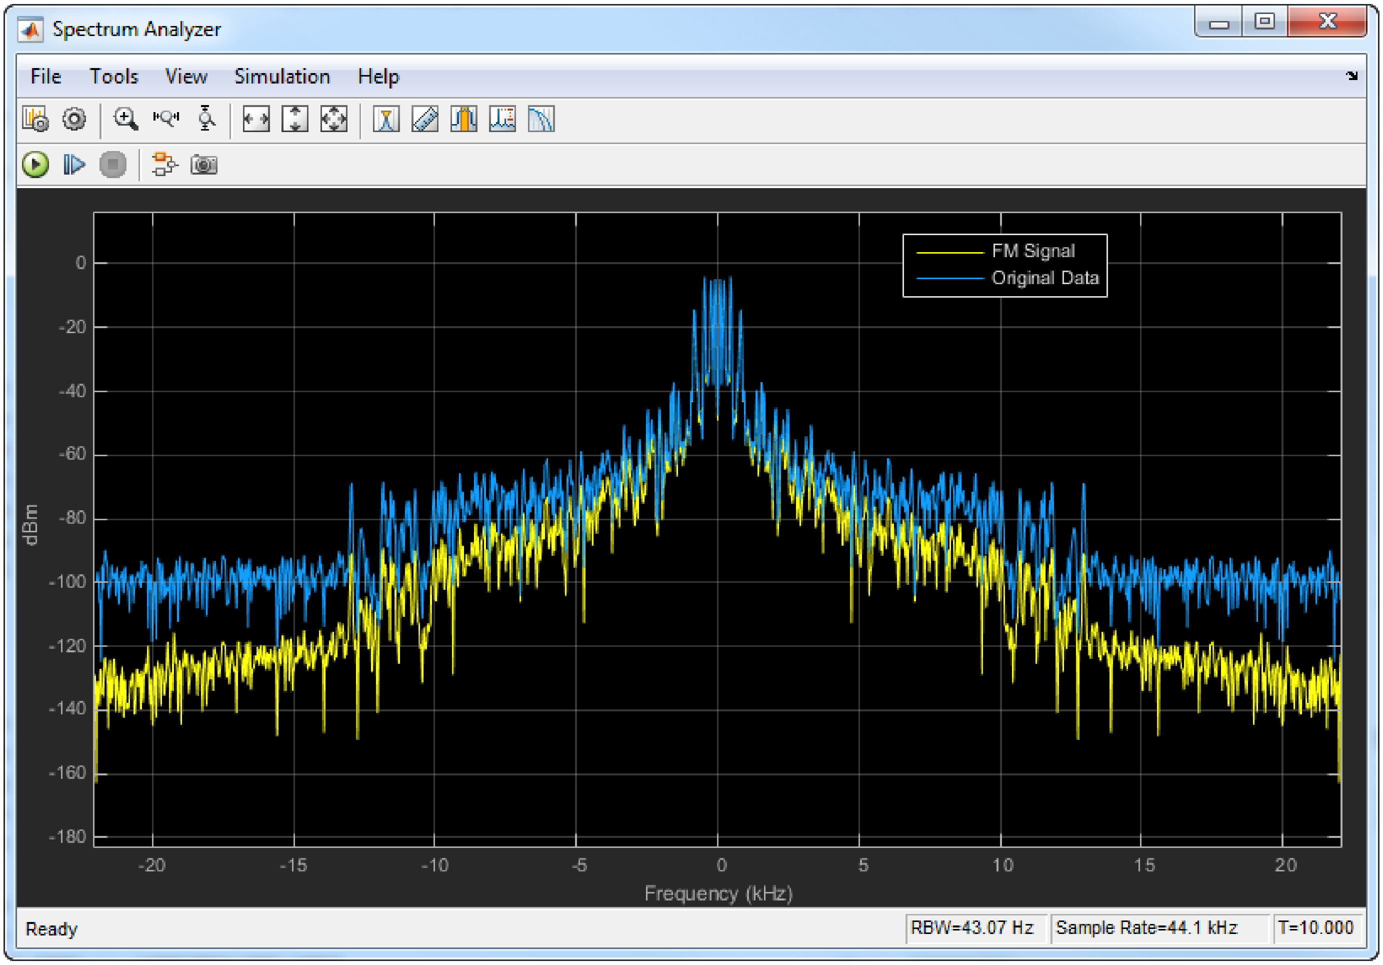
Run the model. The spectrum of the baseband FM signal is attenuated at the higher frequencies relative to the original waveform.



Experiment with the model by changing the **Frequency deviation (Hz)** and the **Pre-emphasis filter time constant (s)** parameters on the modulator and demodulator and observe the impact on the FM signal spectrum.

Supported Data Types

Port	Supported Data Types
Signal Input	• Double-precision floating point • Single-precision floating point
Signal Output	• Double-precision floating point • Single-precision floating point

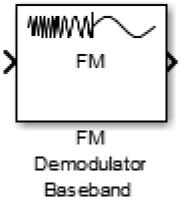
FM Demodulator Baseband

Demodulate using FM method

Library: Communications Toolbox / Modulation / Analog Baseband Modulation



Description

The FM Demodulator Baseband block demodulates a complex input signal and returns a real output signal.

Ports

Input

In — Input data signal
scalar | vector | matrix

Input signal, specified as a real scalar, vector, or matrix.

Data Types: double | single

Output

Out — Output data signal
scalar | vector | matrix

Output signal, returned as a real scalar, vector, or matrix. The data at this port has the same data type and size as the input signal.

Data Types: double | single

Parameters

Frequency deviation (Hz) — Frequency deviation of demodulator
75e3 (default) | positive scalar

Frequency deviation of the demodulator, in Hz, specified as a positive scalar. The system bandwidth is equal to twice the sum of the frequency deviation and the message bandwidth.

Simulate using — Type of simulation to run
Code generation (default) | Interpreted execution

Type of simulation to run, specified as `Code generation` or `Interpreted execution`.

- `Code generation` –– Simulate the model by using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations unless the model changes. This option requires additional startup time, but the speed of the subsequent simulations is faster than `Interpreted execution`.
- `Interpreted execution` –– Simulate the model by using the MATLAB interpreter. This option requires less startup time than the `Code generation` method, but the speed of subsequent simulations is slower. In this mode, you can debug the source code of the block.

Block Characteristics

Data Types	`double` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`no`

Algorithms

Represent a frequency modulated passband signal, *Y(t)*, as

$$Y(t) = A\cos\left(2\pi f_c t + 2\pi f_\Delta \int_0^t x(\tau)d\tau\right),$$

where *A* is the carrier amplitude, f_c is the carrier frequency, *x(τ)* is the baseband input signal, and f_Δ is the frequency deviation in Hz. The frequency deviation is the maximum shift from f_c in one direction, assuming |*x(t)*| ≤ 1.

A baseband FM signal can be derived from the passband representation by downconverting it by f_c such that

$$\begin{aligned} y_s(t) = Y(t)e^{-j2\pi f_c t} &= \frac{A}{2}\left[e^{j\left(2\pi f_c t + 2\pi f_\Delta \int_0^t x(\tau)d\tau\right)} + e^{-j\left(2\pi f_c t + 2\pi f_\Delta \int_0^t x(\tau)d\tau\right)}\right]e^{-j2\pi f_c t} \\ &= \frac{A}{2}\left[e^{j2\pi f_\Delta \int_0^t x(\tau)d\tau} + e^{-j4\pi f_c t - j2\pi f_\Delta \int_0^t x(\tau)d\tau}\right]. \end{aligned}$$

Removing the component at -2f_c from $y_s(t)$ leaves the baseband signal representation, *y(t)*, which is expressed as

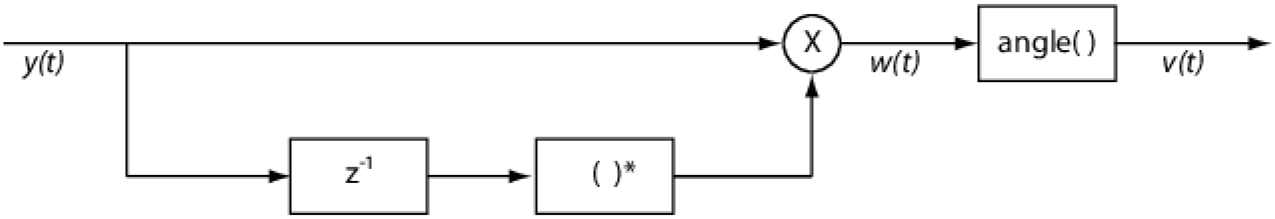
$$y(t) = \frac{A}{2}e^{j2\pi f_\Delta \int_0^t x(\tau)d\tau}.$$

The expression for *y(t)* is rewritten as

$$y(t) = \frac{A}{2}e^{j\phi(t)},$$

where $\phi(t) = 2\pi f_\Delta \int_0^t x(\tau)d\tau$, which implies that the input signal is a scaled version of the derivative of the phase, *ϕ(t)*.

A baseband delay demodulator is used to recover the input signal from *y(t)*.



A delayed and conjugated copy of the received signal is subtracted from the signal itself,

$$w(t) = \frac{A^2}{4} e^{j\phi(t)} e^{-j\phi(t-T)} = \frac{A^2}{4} e^{j[\phi(t) - \phi(t-T)]},$$

where T is the sample period. In discrete terms, w_n=$w(nT)$, and

$$w_n = \frac{A^2}{4} e^{j[\phi_n - \phi_{n-1}]},$$

$$v_n = \phi_n - \phi_{n-1} .$$

The signal v_n is the approximate derivative of ϕ_n, such that $v_n \approx x_n$.

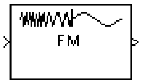
FM Demodulator Passband

Demodulate FM-modulated data



Library

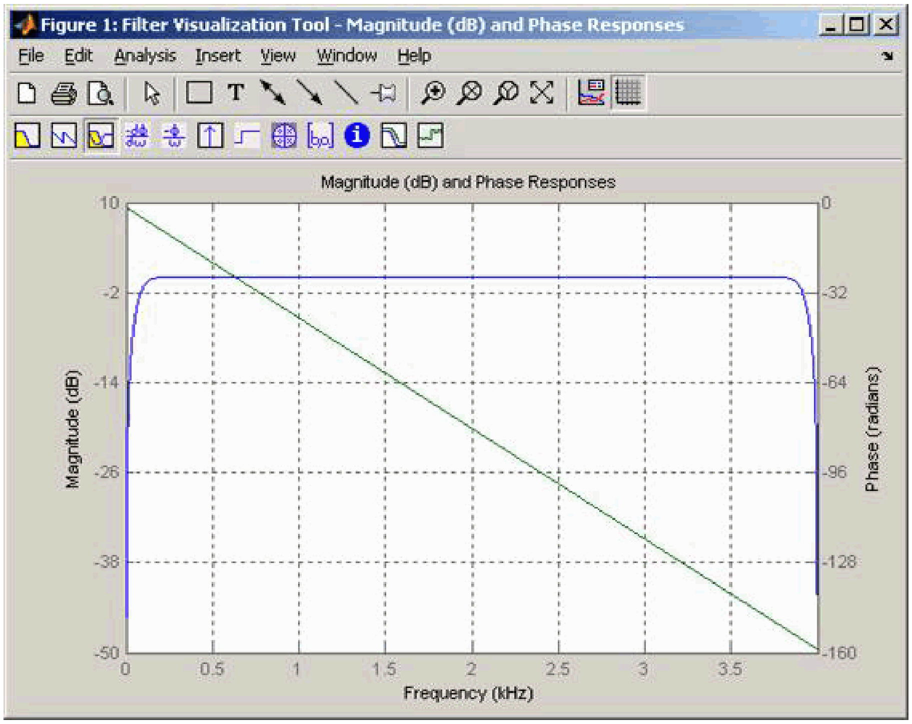
Analog Passband Modulation, in Modulation

Description

The FM Demodulator Passband block demodulates a signal that was modulated using frequency modulation. The input is a passband representation of the modulated signal. Both the input and output signals are real scalar signals.

For best results, use a carrier frequency which is estimated to be larger than 10% of the reciprocal of your input signal's sample rate. This is due to the implementation of the Hilbert transform by means of a filter.

In the following example, we sample a 10Hz input signal at 8000 samples per second. We then designate a Hilbert Transform filter of order 100. Below is the response of the Hilbert Transform filter as returned by `fvtool`.



Note the bandwidth of the filter's magnitude response. By choosing a carrier frequency larger than 10% (but less than 90%) of the reciprocal of your input signal's sample time (8000 samples per second, in this example) or equivalently, a carrier frequency larger than 400Hz, we ensure that the Hilbert Transform Filter will be operating in the flat section of the filter's magnitude response (shown in blue), and that our modulated signal will have the desired magnitude and form.

Typically, an appropriate **Carrier frequency** value is much higher than the highest frequency of the input signal. By the Nyquist sampling theorem, the reciprocal of the model's sample time (defined by the model's signal source) must exceed twice the **Carrier frequency** parameter.

This block works only with real inputs of type `double`. This block does not work inside a triggered subsystem.

Parameters

Carrier frequency (Hz)

The frequency of the carrier.

Initial phase (rad)

The initial phase of the carrier in radians.

Frequency deviation (Hz)

The frequency deviation of the carrier frequency in Hertz. Sometimes it is referred to as the "variation" in the frequency.

Hilbert transform filter order

The length of the FIR filter used to compute the Hilbert transform.

FM Modulator Passband

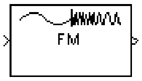
Modulate using frequency modulation



Library

Analog Passband Modulation, in Modulation

Description

The FM Modulator Passband block modulates using frequency modulation. The output is a passband representation of the modulated signal. The output signal's frequency varies with the input signal's amplitude. Both the input and output signals are real scalar signals.

If the input is $u(t)$ as a function of time t, then the output is

$$\cos\left(2\pi f_c t + 2\pi K_c \int_0^t u(\tau) d\tau + \theta\right)$$

where:

- f_c represents the **Carrier frequency** parameter.
- θ represents the **Initial phase** parameter.
- K_c represents the **Frequency deviation** parameter.

Typically, an appropriate **Carrier frequency** value is much higher than the highest frequency of the input signal.

By the Nyquist sampling theorem, the reciprocal of the model's sample time (defined by the model's signal source) must exceed twice the **Carrier frequency** parameter.

This block works only with real inputs of type `double`. This block does not work inside a triggered subsystem.

Parameters

Carrier frequency (Hz)

The frequency of the carrier.

Initial phase (rad)

The initial phase of the carrier in radians.

Frequency deviation (Hz)

The frequency deviation of the carrier frequency in Hertz. Sometimes it is referred to as the "variation" in the frequency.

Free Space Path Loss

Apply free space path loss to complex signal
Library: Communications Toolbox / RF Impairments

Description

The Free Space Path Loss block applies a free space path loss to a complex signal. The block simulates the loss of signal power due to the distance between the transmitter and receiver. The **Mode** parameter indicates whether you specify the loss in decibels or as a computation that is based on distance and the RF signal frequency.

Ports

Input

`In1` — Complex signal
scalar | column vector

Complex signal, specified as a scalar or column vector.

Data Types: `double` | `single`
Complex Number Support: Yes

Output

`Out1` — Output signal
scalar | vector

Output signal, returned as a scalar or column vector. This output is the same dimension and data type as the input signal.

Parameters

`Mode` — Loss calculation mode
`Decibels` (default) | `Distance and Frequency`

Loss calculation mode, specified as one of these options.

- `Decibels` — The loss is specified using the **Loss (dB)** parameter.
- `Distance and Frequency` — The loss is computed using the **Distance (km)** and **Carrier frequency (MHz)** parameters.

`Loss (dB)` — Power loss
`10` (default) | scalar

Power loss in decibels, specified as a scalar. The decibel amount shown on the block icon is rounded for display purposes only.

Dependencies

To enable this parameter, set the **Mode** parameter to `Decibels`.

`Distance (km)` — Distance between transmitter and receiver

`0.100` (default) | scalar

Distance between the transmitter and receiver in kilometers, specified as a scalar.

Dependencies

To enable this parameter, set the **Mode** parameter to `Distance and Frequency`.

`Carrier frequency (MHz)` — Carrier frequency

`1920` (default) | scalar

Carrier frequency in megahertz, specified as a scalar.

Dependencies

To enable this parameter, set the **Mode** parameter to `Distance and Frequency`.

Block Characteristics

Data Types	`double` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`no`

Algorithms

The free-space path loss, L, in decibels is:

$L = 20\log_{10}(4\pi R/\lambda)$.

This formula assumes that the target is in the far-field of the transmitting element or array. In the near-field, the free-space path loss formula is not valid and can result in a loss smaller than 0 dB, equivalent to a signal gain. For this reason, the loss is set to 0 dB for range values $R \leq \lambda/4\pi$.

Gaussian Noise Generator

(To be removed) Generate Gaussian distributed noise with given mean and variance values

Note Gaussian Noise Generator will be removed in a future release. Use the MATLAB Function block and `randn` function instead.

Library

Noise Generators sublibrary of Comm Sources

Description

The Gaussian Noise Generator block generates discrete-time white Gaussian noise. You must specify the **Initial seed** vector in the simulation.

The **Mean Value** and the **Variance** can be either scalars or vectors. If either of these is a scalar, then the block applies the same value to each element of a sample-based output or each column of a frame-based output. Individual elements or columns, respectively, are uncorrelated with each other.

When the **Variance** is a vector, its length must be the same as that of the **Initial seed** vector. In this case, the covariance matrix is a diagonal matrix whose diagonal elements come from the **Variance** vector. Since the off-diagonal elements are zero, the output Gaussian random variables are uncorrelated.

When the **Variance** is a square matrix, it represents the covariance matrix. Its off-diagonal elements are the correlations between pairs of output Gaussian random variables. In this case, the **Variance** matrix must be positive definite, and it must be `N`-by-`N`, where `N` is the length of the **Initial seed**.

The probability density function of *n*-dimensional Gaussian noise is

$$f(x) = \left((2\pi)^n \det K\right)^{-1/2} \exp\left(-(x-\mu)^T K^{-1}(x-\mu)/2\right)$$

where *x* is a length-*n* vector, *K* is the *n*-by-*n* covariance matrix, μ is the mean value vector, and the superscript *T* indicates matrix transpose.

Initial Seed

The **Initial seed** parameter initializes the random number generator that the Gaussian Noise Generator block uses to add noise to the input signal. When multiple blocks in a model have the **Initial seed** parameter, you can choose different initial seeds for each block to ensure different random streams are used in each block. Set **Initial seed** to an integer value for repeatable results or use the `randi` function to randomize your results.

Attributes of Output Signal

The output signal can be a frame-based matrix, a sample-based row or column vector, or a sample-based one-dimensional array. These attributes are controlled by the **Frame-based outputs**, **Samples per frame**, and **Interpret vector parameters as 1-D** parameters. For additional information, see “Sources and Sinks”.

If the **Initial seed** parameter is a vector, then its length becomes the number of columns in a frame-based output or the number of elements in a sample-based vector output. In this case, the shape (row or column) of the **Initial seed** parameter becomes the shape of a sample-based two-dimensional output signal. If the **Initial seed** parameter is a scalar but either the **Mean value** or **Variance** parameter is a vector, then the vector length determines the output attributes mentioned above.

Parameters

Mean value

The mean value of the random variable output.

Variance

The covariance among the output random variables.

Initial seed

The initial seed value for the random number generator.

Sample time

The period of each sample-based vector or each row of a frame-based matrix.

Frame-based outputs

Determines whether the output is frame-based or sample-based. This box is active only if **Interpret vector parameters as 1-D** is unchecked.

Samples per frame

The number of samples in each column of a frame-based output signal. This field is active only if **Frame-based outputs** is checked.

Interpret vector parameters as 1-D

If this box is checked, then the output is a one-dimensional signal. Otherwise, the output is a two-dimensional signal. This box is active only if **Frame-based outputs** is unchecked.

Output data type

The output can be set to `double` or `single` data types.

General Block Deinterleaver

Restore ordering of symbols in input vector

Library

Block sublibrary of Interleaving

Description

The General Block Deinterleaver block rearranges the elements of its input vector without repeating or omitting any elements. If the input contains *N* elements, then the **Permutation vector** parameter is a column vector of length *N*. The column vector indicates the indices, in order, of the output elements that came from the input vector. That is, for each integer *k* between 1 and *N*,

Output(**Permutation vector**(*k*)) = Input(*k*)

The **Permutation vector** parameter must contain unique integers between 1 and *N*.

Both the input and the **Permutation vector** parameter must be column vector signals.

This block can output sequences that vary in length during simulation. For more information about sequences that vary in length, or variable-size signals, see “Variable-Size Signal Basics” (Simulink).

This block accept the following data types: `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, `double`, and fixed-point. The output signal inherits its data type from the input signal.

To use this block as an inverse of the General Block Interleaver block, use the same **Permutation vector** parameter in both blocks. In that case, the two blocks are inverses in the sense that applying the General Block Interleaver block followed by the General Block Deinterleaver block leaves data unchanged.

Parameters

Permutation vector source

A selection that specifies the source of the permutation vector. The source can be either `Dialog` or `Input port`. The default value is `Dialog`.

Permutation vector

A vector of length N that lists the indices of the output elements that came from the input vector. This parameter is available only when **Permutation vector source** is set to `Dialog`.

Examples

This example reverses the operation in the example on the General Block Interleaver block reference page. If you set **Permutation vector** to `[4,1,3,2]'` and you set the General Block Deinterleaver block input to `[1;40;59;32]`, then the output of the General Block Deinterleaver block is `[40;32;59;1]`.

General Block Interleaver

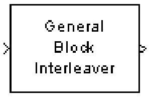
Reorder symbols in input vector



Library

Block sublibrary of Interleaving

Description

The General Block Interleaver block rearranges the elements of its input vector without repeating or omitting any elements. If the input contains *N* elements, then the **Permutation vector** parameter is a column vector of length *N*. The column vector indicates the indices, in order, of the input elements that form the length-*N* output vector; that is,

Output(*k*) = Input(**Permutation vector**(k))

for each integer *k* between 1 and *N*. The contents of **Permutation vector** must be integers between 1 and N, and must have no repetitions.

Both the input and the **Permutation vector** parameter must be column vector signals.

This block can output sequences that vary in length during simulation. For more information about sequences that vary in length, or variable-size signals, see “Variable-Size Signal Basics” (Simulink).

This block accept the following data types: `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, `double`, and fixed-point. The output signal inherits its data type from the input signal.

Parameters

Permutation vector source

A selection that specifies the source of the permutation vector. The source can be either `Dialog` or `Input port`. The default value is `Dialog`.

Permutation vector

A vector of length N that lists the indices of the output elements that came from the input vector. This parameter is available only when **Permutation vector source** is set to `Dialog`.

Examples

If **Permutation vector** is `[4;1;3;2]` and the input vector is `[40;32;59;1]`, then the output vector is `[1;40;59;32]`. Notice that all of these vectors have the same length and that the vector **Permutation vector** is a permutation of the vector `[1:4]'`.

General CRC Generator

Generate CRC code bits according to generator polynomial and append to input data frames

Library: Communications Toolbox / Error Detection and Correction / CRC

Description

The General CRC Generator block generates cyclic redundancy check (CRC) code bits for each input data frame and appends them to the frame. For more information, see “CRC Generator Operation” on page 5-309.

Ports

Input

`In` — Input signal
binary column vector

Input signal, specified as a binary column vector. The length of the input frame must be a multiple of the value of the **Checksums per frame** parameter.

Data Types: `double` | `Boolean`

Output

`Out` — Output codeword frame
binary column vector

Output codeword frame, returned as a binary column vector that inherits the data type of the input signal. The output contains the input data frames with the CRC bit sequences appended to them.

The length of the output frame is $m + k * r$, where m is the size of the input frame, k is the number of checksums per frame, and r is the degree of the generator polynomial.

Parameters

`Generator polynomial` — Generator polynomial
`'z^16 + z^12 + z^5 + 1'` (default) | polynomial character vector | binary row vector | integer row vector

Generator polynomial for the CRC algorithm, specified as one of the following:

- A polynomial character vector such as `'z^3 + z^2 + 1'`.
- A binary row vector that represents the coefficients of the generator polynomial in order of descending power. The length of this vector is (N+1), where N is the degree of the generator polynomial. For example, `[1 1 0 1]` represents the polynomial x^3+ z^2+ 1.

- An integer row vector containing the exponents of z for the nonzero terms in the polynomial in descending order. For example, [3 2 0] represents the polynomial $z^3 + z^2 + 1$.

For more information, see "Character Representation of Polynomials".

Some commonly used generator polynomials include:

CRC method	Generator polynomial
CRC-32	'z^32 + z^26 + z^23 + z^22 + z^16 + z^12 + z^11 + z^10 + z^8 + z^7 + z^5 + z^4 + z^2 + z + 1'
CRC-24	'z^24 + z^23 + z^14 + z^12 + z^8 + 1'
CRC-16	'z^16 + z^15 + z^2 + 1'
Reversed CRC-16	'z^16 + z^14 + z + 1'
CRC-8	'z^8 + z^7 + z^6 + z^4 + z^2 + 1'
CRC-4	'z^4 + z^3 + z^2 + z + 1'

Example: 'z^7 + z^2 + 1', [1 0 0 0 0 1 0 1], and [7 2 0] represent the same polynomial, $p(z) = z^7 + z^2 + 1$.

Initial states — Initial states of internal shift register
0 (default) | 1 | binary row vector

Initial states of the internal shift register, specified as a binary scalar or a binary row vector with a length equal to the degree of the generator polynomial. A scalar value is expanded to a row vector of equal length to the degree of the generator polynomial.

Direct method — Use direct algorithm for CRC checksum calculations
off (default) | on

Select to use the direct algorithm for CRC checksum calculations. When cleared, the block uses the non-direct algorithm for CRC checksum calculations.

For more information on direct and non-direct algorithms, see "Error Detection and Correction".

Reflect input bytes — Reflect input bytes
off (default) | on

Select to flip the input data on a bytewise basis before entering the data into the shift register. When **Reflect input bytes** is selected, the input frame length divided by the value of the **Checksums per frame** parameter must be an integer and a multiple of 8. When **Reflect input bytes** is cleared, the block does not flip the input data.

Reflect checksums before final XOR — Reflect checksums before final XOR
off (default) | on

Select to flip the CRC checksums around their centers after the input data are completely through the shift register. When **Reflect checksums before final XOR** is cleared, the block does not flip the CRC checksums.

Final XOR — Final XOR
0 (default) | 1 | binary row vector

Final XOR, specified as a binary scalar or a binary row vector with a length equal to the degree of the generator polynomial. The XOR operation runs using the value of the **Final XOR** parameter the CRC checksum before appending the CRC to the input data. A scalar value is expanded to a row vector of equal length to the degree of the generator polynomial. A setting of `0` is equivalent to no XOR operation.

`Checksums per frame` — Number of checksums calculated for each frame
1 (default) | positive integer

Number of checksums calculated for each frame, specified as a positive integer.

Block Characteristics

Data Types	`Boolean` | `double`
Multidimensional Signals	`no`
Variable-Size Signals	`yes`

More About

Cyclic Redundancy Check Coding

Cyclic redundancy check (CRC) coding is an error-control coding technique for detecting errors that occur when a data frame is transmitted. Unlike block or convolutional codes, CRC codes do not have a built-in error-correction capability. Instead, when a communications system detects an error in a received codeword, the receiver requests the sender to retransmit the codeword.

In CRC coding, the transmitter applies a rule to each data frame to create extra CRC bits, called the *checksum* or *syndrome*, and then appends the checksum to the data frame. After receiving a transmitted codeword, the receiver applies the same rule to the received codeword. If the resulting checksum is nonzero, an error has occurred and the transmitter should resend the data frame.

When the number of checksums per frame is greater than 1, the input data frame is divided into subframes, the rule is applied to each data subframe, and individual checksums are appended to each subframe. The subframe codewords are concatenated to output one frame.

For a discussion of the supported CRC algorithms, see “Cyclic Redundancy Check Codes”.

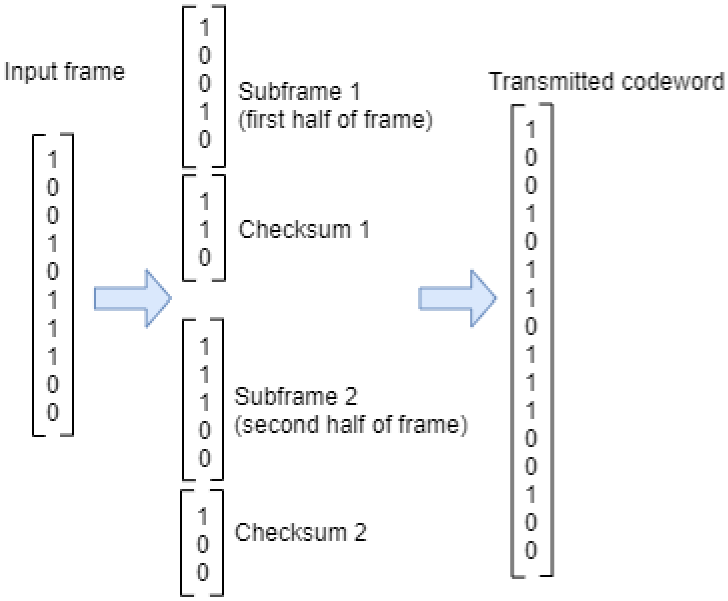
CRC Generator Operation

The CRC generator appends CRC checksums to the input frame according to the specified generator polynomial and number of checksums per frame.

For a specific initial state of the internal shift register and *k* checksums per input frame:

1. The input signal is divided into *k* subframes of equal size.
2. Each of the *k* subframes are prefixed with the initial states vector.
3. The CRC algorithm is applied to each subframe.
4. The resulting checksums are appended to the end of each subframe.
5. The subframes are concatenated and output as a column vector.

For the scenario shown here, a 10-bit frame is input, a third degree generator polynomial computes the CRC checksum, the initial state is 0, and the number of checksums per frame is 2.



The input frame is divided into two subframes of size 5 and checksums of size 3 are computed and appended to each subframe. The initial states are not shown, because an initial state of `[0]` does not affect the output of the CRC algorithm. The output transmitted codeword frame has the size 5 + 3 + 5 + 3 = 16.

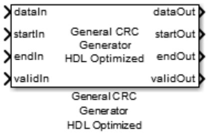
General CRC Generator HDL Optimized

Generate CRC code bits and append them to input data

Library: Communications Toolbox HDL Support / Error Detection and Correction / CRC
Communications Toolbox / Error Detection and Correction / CRC



Description

The General CRC Generator HDL Optimized block, which is similar to the General CRC Generator block, generates a cyclic redundancy check (CRC) checksum and appends it to the input message. The General CRC Generator HDL Optimized block processing is optimized for HDL code generation. Instead of processing an entire frame at once, the block accepts and returns a data sample stream with accompanying control signals. The control signals indicate the validity of the samples and the boundaries of the frame. To achieve higher throughput, the block accepts vector data up to the CRC length and implements a parallel architecture.

Ports

Input

`dataIn` — Input data
scalar | vector

Input data, specified as one of these options.

- Scalar – Specify an integer representing several bits. For this case, the block supports an unsigned integer (`uint8`, `uint16`, or `uint32`) or `fixdt(0,N,0)` data type.
- Vector – Specify a vector of binary values. For this case, the block supports a `double` or `Boolean` data type.

The data width must be less than or equal to the CRC length, and the CRC length must be divisible by the data width. For CRC-CCITT/CRC-16, the valid data widths are 16, 8, 4, 2, and 1.

Example: The `uint8` vector input `[0 0 0 1 0 0 1 1]` is equivalent to 19.

Data Types: `double` | `uint8` | `uint16` | `uint32` | `fixed point` | `Boolean`

`startIn` — Start of input frame indicator
Boolean scalar

Start of input frame indicator, specified as a Boolean scalar.

Data Types: `Boolean`

`endIn` — End of input frame indicator
Boolean scalar

End of input frame indicator, specified as a Boolean scalar.

Data Types: `Boolean`

`validIn` — Valid input data indicator
Boolean scalar

Valid input data indicator, specified as a Boolean scalar.

This is a control signal that indicates if the data on the **dataIn** port is valid.

Data Types: `Boolean`

Output

`dataOut` — Output data
scalar | vector

Output data with appended checksum, returned as a scalar or vector. The output data type and size are the same as the input data.

Data Types: `double` | `uint8` | `uint16` | `uint32` | `Boolean` | `fixed point`

`startOut` — Start of output frame indicator
scalar

Start of output frame indicator, returned as a Boolean scalar.

Data Types: `Boolean`

`endOut` — End of output frame indicator
scalar

End of output frame indicator, returned as a Boolean scalar.

Data Types: `Boolean`

`validOut` — Valid output data indicator
scalar

Valid output data indicator, returned as a Boolean scalar.

This port is a control signal that indicates if the data on the **dataOut** port is valid.

Data Types: `Boolean`

Parameters

`Polynomial` — Generator polynomial
`[1 0 0 0 1 0 0 0 0 0 0 1 0 0 0 0 1]` (default) | binary vector

Specify the generator polynomial as a binary vector with coefficients in descending order of powers. The vector length is equal to the degree of the polynomial plus 1.

`Initial state` — Initial conditions of shift register
`0` (default) | binary scalar | binary vector

Specify initial conditions of the internal shift register as a binary, double-precision, or single-precision scalar or vector. For vector inputs, the length of the initial state must be equal to the degree of the generator polynomial.

`Direct method` — Method of calculating checksum
`off` (default) | `on`

Specify the direct or indirect method for calculating the checksum.

- Select this parameter for the block to use the direct algorithm for CRC checksum calculations.
- Clear this parameter for the block to use the nondirect algorithm for CRC checksum calculations.

For more information about direct and nondirect algorithms, see "Cyclic Redundancy Check Codes".

`Reflect input` — Input byte order
`off` (default) | `on`

Specify the input byte order.

- Select this parameter for the block to flip each input byte before it enters the shift register.
- Clear this parameter for the block to pass the message data to the shift register unchanged.

The input data width must be a multiple of 8.

`Reflect CRC checksum` — Checksum byte order
`off` (default) | `on`

Specify the checksum byte order.

- Select this parameter for the block to flip each checksum byte before passing it to the final XOR stage.
- Clear this parameter for the block to pass the checksum byte to the final XOR stage unchanged.

The input data width must be a multiple of 8.

`Final XOR value` — Checksum
`0` (default) | binary scalar | binary vector

Specify the checksum as a binary, double-precision, or single-precision data type scalar or vector. The block performs XOR operation on the CRC checksum with this value before appending it to the input data.

If you specify a vector input, the vector length must be equal to the degree of the generator polynomial.

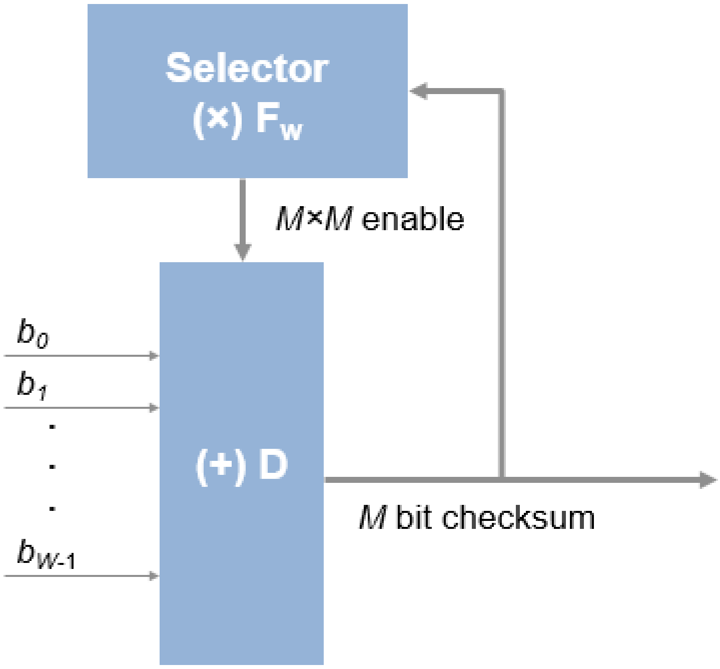
Algorithms

When you use a vector or integer input, the block implements a parallel CRC algorithm [1].

To provide high throughput for modern communications systems, the block implements the CRC algorithm with a parallel architecture. This architecture recursively calculates M bits of a CRC checksum for each W input bits. At the end of the frame, the final checksum result is appended to the message. For a polynomial length of M, the recursive checksum calculation for W bits in parallel is

$$X' = F_W(\times)X(+)D.$$

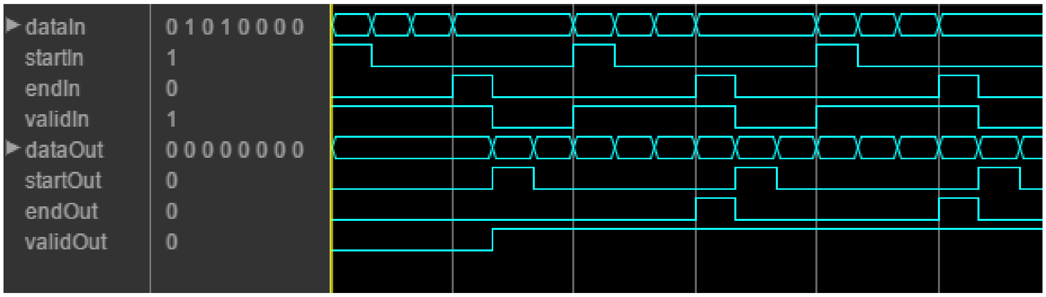
F_W is an M-by-M matrix that selects elements of the current state for the polynomial calculation with the new input bits. D is an M-element vector that provides the new input bits, ordered in relation to the generator polynomial and padded with zeros. The block implements the (×) with logical AND and (+) with logical XOR.



Timing Diagram

This waveform shows streaming data and the accompanying control signals for a CRC16 with an 8-bit binary vector input. To insert the checksum word, input frames must have enough space between the.

This waveform diagram shows continuous input data. The block also supports noncontinuous data. The output valid signal matches the input valid pattern.



```
▶ dataIn    0 1 0 1 0 0 0 0
  startIn   1
  endIn     0
  validIn   1
▶ dataOut   0 0 0 0 0 0 0 0
  startOut  0
  endOut    0
  validOut  0
```

Initial Delay

The General CRC Generator HDL Optimized block introduces a latency on the output. Assuming the input data is continuous, you can compute the latency by using the equation.

```
initialdelay = (CRC length/input data width) + 2.
```

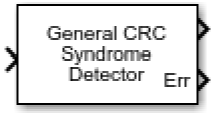
General CRC Syndrome Detector

Detect errors in received codeword frames according to generator polynomial

Library: Communications Toolbox / Error Detection and Correction / CRC



Description

The General CRC Syndrome Detector block computes cyclic redundancy check (CRC) checksums for received codeword frames. For successful CRC detection in a communications system link, you must align the parameter settings of the General CRC Syndrome Detector block with the paired General CRC Generator block.

For more information, see “CRC Syndrome Detector Operation” on page 5-320.

Ports

Input

`In` — Received codeword
binary column vector

Received codeword, specified as a binary column vector.

Data Types: `double` | `Boolean`

Output

`Out` — Output frame
binary column vector

Output frame, returned as a binary column vector that inherits the data type of the input signal. The output frame contains the received codeword with the checksums removed.

The length of the output frame is n - k * r bits, where n is the size of the received codeword, k is the number of checksums per frame, and r is the degree of the generator polynomial.

`Err` — Checksum error signal
binary column vector

Checksum error signal, returned as a binary column vector that inherits the data type of the input signal. The length of `Err` equals the value of **Checksums per frame**. For each checksum computation, an element value of 0 in `Err` indicates no checksum error, and an element value of 1 in `Err` indicates a checksum error.

Parameters

`Generator polynomial` — Generator polynomial

`'z^16 + z^12 + z^5 + 1'` (default) | polynomial character vector | binary row vector | integer row vector

Generator polynomial for the CRC algorithm, specified as one of the following:

- A polynomial character vector such as `'z^3 + z^2 + 1'`.
- A binary row vector that represents the coefficients of the generator polynomial in order of descending power. The length of this vector is (N+1), where N is the degree of the generator polynomial. For example, `[1 1 0 1]` represents the polynomial $x^3+ z^2+ 1$.
- An integer row vector containing the exponents of z for the nonzero terms in the polynomial in descending order. For example, `[3 2 0]` represents the polynomial $z^3 + z^2 + 1$.

For more information, see “Character Representation of Polynomials”.

Some commonly used generator polynomials include:

CRC method	Generator polynomial
CRC-32	`'z^32 + z^26 + z^23 + z^22 + z^16 + z^12 + z^11 + z^10 + z^8 + z^7 + z^5 + z^4 + z^2 + z + 1'`
CRC-24	`'z^24 + z^23 + z^14 + z^12 + z^8 + 1'`
CRC-16	`'z^16 + z^15 + z^2 + 1'`
Reversed CRC-16	`'z^16 + z^14 + z + 1'`
CRC-8	`'z^8 + z^7 + z^6 + z^4 + z^2 + 1'`
CRC-4	`'z^4 + z^3 + z^2 + z + 1'`

Example: `'z^7 + z^2 + 1'`, `[1 0 0 0 0 1 0 1]`, and `[7 2 0]` represent the same polynomial, $p(z) = z^7 + z^2 + 1$.

`Initial states` — Initial states of internal shift register

`0` (default) | `1` | binary row vector

Initial states of the internal shift register, specified as a binary scalar or a binary row vector with a length equal to the degree of the generator polynomial. A scalar value is expanded to a row vector of equal length to the degree of the generator polynomial.

`Direct method` — Use direct algorithm for CRC checksum calculations

`off` (default) | `on`

Select to use the direct algorithm for CRC checksum calculations. When cleared, the block uses the non-direct algorithm for CRC checksum calculations.

For more information on direct and non-direct algorithms, see “Error Detection and Correction”.

`Reflect input bytes` — Reflect input bytes

`off` (default) | `on`

Select to flip the received codeword on a bytewise basis before entering the data into the shift register. When **Reflect input bytes** is selected, the received codeword length divided by the value of the **Checksums per frame** parameter must be an integer and a multiple of 8. When **Reflect input bytes** is cleared, the block does not flip the input data.

`Reflect checksums before final XOR` — Reflect checksums before final XOR

`off` (default) | `on`

Select **Reflect checksums before final XOR** to flip the CRC checksums around their centers after the input data are completely through the shift register. When **Reflect checksums before final XOR** is cleared, the block does not flip the CRC checksums.

`Final XOR` — Final XOR

`0` (default) | `1` | binary row vector

Final XOR, specified as a binary scalar or a binary row vector with a length equal to the degree of the generator polynomial. The XOR operation runs using the value of the **Final XOR** parameter and the CRC checksum before comparing with the input checksum. A scalar value is expanded to a row vector of equal length to the degree of the generator polynomial. A setting of `0` is equivalent to no XOR operation.

`Checksums per frame` — Number of checksums calculated for each frame

`1` (default) | positive integer

Number of checksums calculated for each frame, specified as a positive integer.

Block Characteristics

Data Types	`Boolean` | `double`
Multidimensional Signals	`no`
Variable-Size Signals	`yes`

More About

Cyclic Redundancy Check Coding

Cyclic redundancy check (CRC) coding is an error-control coding technique for detecting errors that occur when a data frame is transmitted. Unlike block or convolutional codes, CRC codes do not have a built-in error-correction capability. Instead, when a communications system detects an error in a received codeword, the receiver requests the sender to retransmit the codeword.

In CRC coding, the transmitter applies a rule to each data frame to create extra CRC bits, called the *checksum* or *syndrome*, and then appends the checksum to the data frame. After receiving a transmitted codeword, the receiver applies the same rule to the received codeword. If the resulting checksum is nonzero, an error has occurred and the transmitter should resend the data frame.

When the number of checksums per frame is greater than 1, the input data frame is divided into subframes, the rule is applied to each data subframe, and individual checksums are appended to each subframe. The subframe codewords are concatenated to output one frame.

For a discussion of the supported CRC algorithms, see “Cyclic Redundancy Check Codes”.

CRC Syndrome Detector Operation

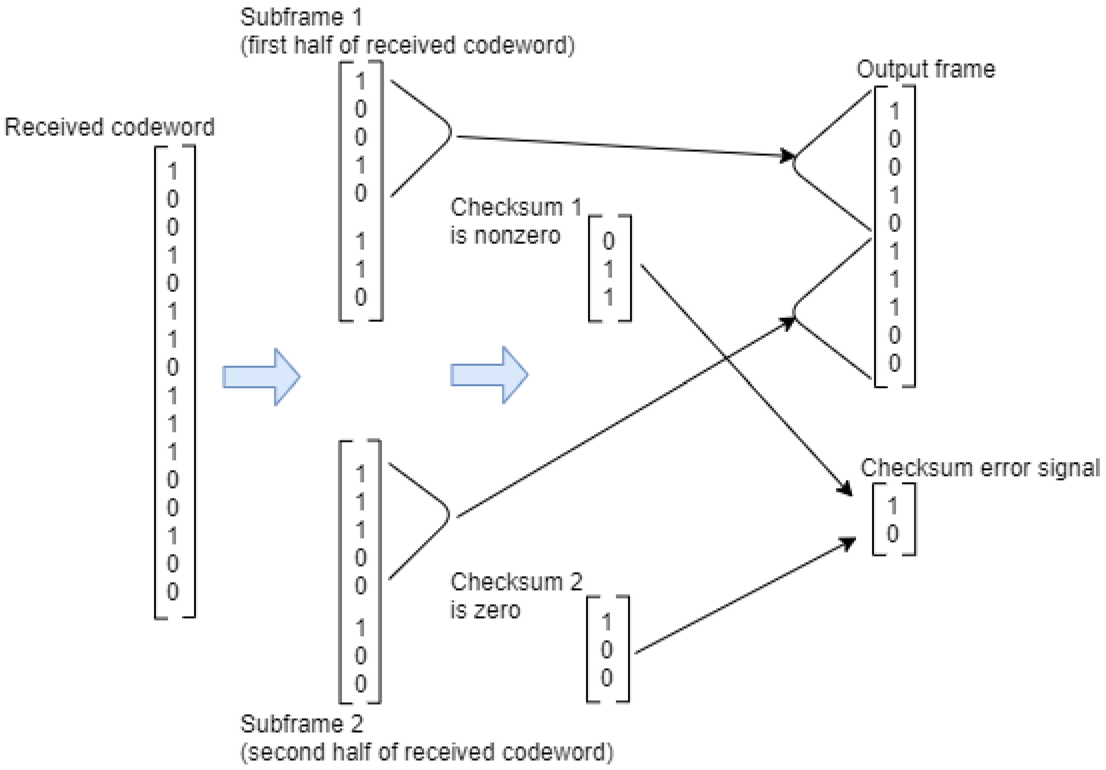
The CRC syndrome detector outputs the received message frame and a checksum error vector according to the specified generator polynomial and number of checksums per frame.

The checksum bits are removed from each subframe, so that the resulting the output frame length is *n* - *k* × *r*, where *n* is the size of the received codeword, *k* is the number of checksums per frame, and *r* is the degree of the generator polynomial. The input frame must be evenly divisible by *k*.

For a specific initial state of the internal shift register:

1. The received codeword is divided into *k* equal sized subframes.
2. The CRC is removed from each of the *k* subframes and compared to the checksum calculated on the received codeword subframes.
3. The output frame is assembled by concatenating the subframe bits of the *k* subframes and then output as a column vector.
4. The checksum error is output as a binary column vector of length *k*. An element value of 0 indicates an error-free received subframe, and an element value of 1 indicates an error occurred in the received subframe.

For the scenario shown here, a 16-bit codeword is received, a third degree generator polynomial computes the CRC checksum, the initial state is 0, and the number of checksums per frame is 2.



Since the number of checksums per frame is 2 and the generator polynomial degree is 3, the received codeword is split in half and two checksums of size 3 are computed, one for each half of the received codeword. The initial states are not shown, because an initial state of `[0]` does not affect the output of the CRC algorithm. The output frame contains the concatenation of the two halves of the received codeword as a single vector of size 10. The checksum error signal output contains a 2-by-1 binary frame vector whose entries depend on whether the computed checksums are zero. As shown in the figure, the first checksum is nonzero and the second checksum is zero, indicating an error occurred in reception of the first half of the codeword.

General CRC Syndrome Detector HDL Optimized

Description

The General CRC Syndrome Detector HDL Optimized block performs a cyclic redundancy check (CRC) on data and compares the resulting checksum with the appended checksum. The General CRC Syndrome Detector HDL Optimized block processing is optimized for HDL code generation. If the two checksums do not match, the block reports an error. Instead of processing an entire frame at once, the block accepts and returns a data sample stream with accompanying control signals. The control signals indicate the validity of the samples and the boundaries of the frame. To achieve higher throughput, the block accepts vector data up to the CRC length and implements a parallel architecture.

Ports

Input

`dataIn` — Input data
scalar | vector

Input data, specified as one of these options.

- Scalar – Specify an integer representing several bits. For this case, the block supports an unsigned integer (`uint8`, `uint16`, or `uint32`) or `fixdt(0,N,0)` data type.
- Vector – Specify a vector of binary values. For this case, the block supports a `double` or `Boolean` data type.

The data width must be less than or equal to the CRC length, and the CRC length must be divisible by the data width. For CRC-CCITT/CRC-16, the valid data widths are 16, 8, 4, 2, and 1.

Example: The `uint8` vector input `[0 0 0 1 0 0 1 1]` is equivalent to 19.

Data Types: `double` | `uint8` | `uint16` | `uint32` | `fixed point` | `Boolean`

`startIn` — Start of input frame indicator
scalar

Start of input frame indicator, specified as a Boolean scalar.

Data Types: `Boolean`

`endIn` — End of input frame indicator

scalar

End of input frame indicator, specified as a Boolean scalar.

Data Types: `Boolean`

`validIn` — Valid input data indicator

scalar

Valid input data indicator, specified as a Boolean scalar.

This a control signal that indicates if the data on the **dataIn** port is valid.

Data Types: `Boolean`

Output

`dataOut` — Output data

scalar | vector

Output data, returned as a scalar or vector. The output data type and size are the same as the input data.

Data Types: `double` | `uint8` | `uint16` | `uint32` | `Boolean` | `fixed point`

`startOut` — Start of output frame indicator

scalar

Start of output frame indicator, returned as a Boolean scalar.

Data Types: `Boolean`

`endOut` — End of output frame indicator

scalar

End of output frame indicator, returned as a `Boolean` scalar.

Data Types: `Boolean`

`validOut` — Valid output data indicator

scalar

Valid output data indicator, returned as a Boolean scalar.

This is a control signal that indicates if the data on the **dataOut** port is valid.

Data Types: `Boolean`

`err` — Error indicator

scalar

Error indicator for the corruption of the received data, returned as a Boolean scalar.

When this value is `1`, the message contains at least one error. When this value is `0`, the message contains zero errors.

Data Types: `Boolean`

Parameters

`Polynomial` — Generator polynomial

`[1 0 0 0 1 0 0 0 0 0 0 1 0 0 0 0 1]` (default) | binary vector

Specify the generator polynomial as a binary vector with coefficients in descending order of powers. The vector length is equal to the degree of the polynomial plus 1.

`Initial state` — Initial conditions of shift register

`0` (default) | binary scalar | binary vector

Specify initial conditions of the internal shift register as a binary, double-precision, or single-precision scalar or vector. For vector inputs, the length of the initial state must be equal to the degree of the generator polynomial.

`Direct method` — Method of calculating checksum

`off` (default) | `on`

Specify the method of calculating checksum as a Boolean scalar.

- Select this parameter to use the direct algorithm for CRC checksum calculations.
- Clear this parameter to use the nondirect algorithm for CRC checksum calculations.

To learn about the direct and non-direct algorithms, see “Cyclic Redundancy Check Codes”.

`Reflect input` — Input byte order

`off` (default) | `on`

Specify the input byte order.

- Select this parameter for the block to flip each input byte before it enters the shift register.
- Clear this parameter for the block to pass the message data to the shift register unchanged.

The input data width must be a multiple of 8.

`Reflect CRC checksum` — Checksum byte order

`off` (default) | `on`

Specify the checksum byte order.

- Select this parameter for the block to flip each checksum byte before passing it to the final XOR stage.
- Clear this parameter for the block to pass the checksum byte to the final XOR stage unchanged.

The input data width must be a multiple of 8.

`Final XOR value` — Checksum

`0` (default) | binary scalar | binary vector

Specify the checksum as a binary, double-precision, or single-precision data type scalar or vector. The block performs XOR operation on the CRC checksum with this value before appending it to the input data.

If you specify a vector input, the vector length must be equal to the degree of the generator polynomial.

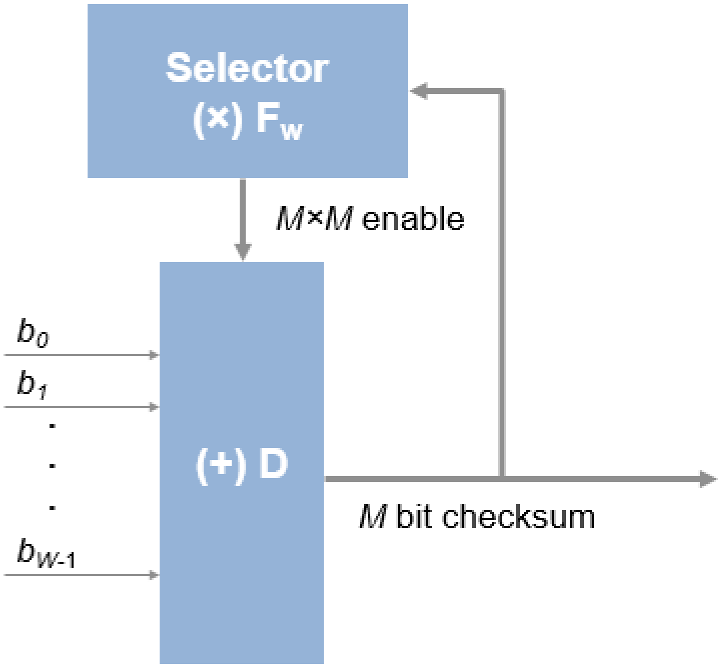
Algorithms

When you use vector or integer input, the block implements a parallel CRC algorithm [1].

To provide high throughput for modern communications systems, the block implements the CRC algorithm with a parallel architecture. This architecture recursively calculates *M* bits of a CRC checksum for each *W* input bits. At the end of the frame, the final checksum result is appended to the message. For a polynomial length of *M*, the recursive checksum calculation for *W* bits in parallel is

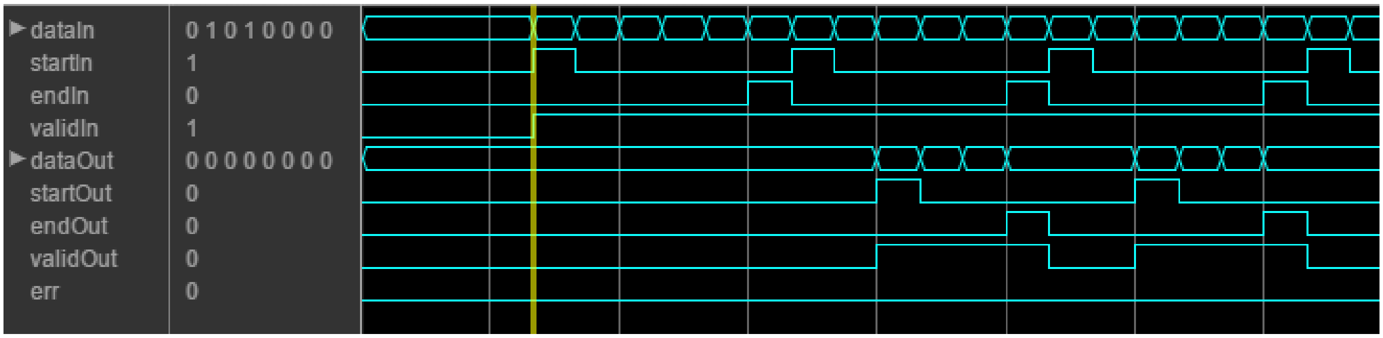
$$X' = F_W(\times)X(+)D .$$

F_W is an *M*-by-*M* matrix that selects elements of the current state for the polynomial calculation with the new input bits. *D* is an *M*-element vector that provides the new input bits, ordered in relation to the generator polynomial and padded with zeros. The block implements the (×) with logical AND and (+) with logical XOR.



Timing Diagram

This waveform shows streaming data and the accompanying control signals for a CRC16 with 8-bit binary vector input. The input frames are contiguous. The output frames include space between them because the detector block removes the checksum word.



This waveform diagram shows continuous input data. Non-continuous data is also supported.

Initial Delay

The General CRC Syndrome Detector HDL Optimized block introduces a latency on the output. This latency can be computed with the following equation, assuming the input data is continuous:

```
initialdelay = 3 * (CRC length/input data width) + 2.
```

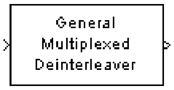
General Multiplexed Deinterleaver

Restore ordering of symbols using specified-delay shift registers



Library

Convolutional sublibrary of Interleaving

Description

The General Multiplexed Deinterleaver block restores the original ordering of a sequence that was interleaved using the General Multiplexed Interleaver block.

In typical usage, the parameters in the two blocks have the same values. As a result, the **Interleaver delay** parameter, *V*, specifies the delays for each shift register in the corresponding *interleaver*, so that the delays of the deinterleaver's shift registers are actually `max(V)-V`.

This block accepts a scalar or column vector input signal, which can be real or complex. The output signal has the same sample time as the input signal.

The block can accept the data types `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, `double`, and fixed-point. The data type of the output will be the same as that of the input signal.

Parameters

Interleaver delay (samples)

A vector that lists the number of symbols that fit in each shift register of the corresponding interleaver. The length of this vector is the number of shift registers.

Initial conditions

The values that fill each shift register when the simulation begins.

Pair Block

General Multiplexed Interleaver

C/C++ Code Generation
Generate C and C++ code using Simulink® Coder™.

HDL Code Generation
Generate Verilog and VHDL code for FPGA and ASIC designs using HDL Coder™.

HDL Coder provides additional configuration options that affect HDL implementation and synthesized logic.

HDL Architecture

The implementation for the General Multiplexed Deinterleaver block is shift register based. If you want to suppress generation of reset logic, set the implementation parameter `ResetType` tonone.

When you set `ResetType` to `none`, reset is not applied to the shift registers. When registers are not fully loaded, mismatches between Simulink and the generated code occur for some number of samples during the initial phase. To avoid spurious test bench errors, determine the number of samples required to fill the shift registers. Set the **Ignore output data checking (number of samples)** option accordingly. (If you are using the command-line interface, you can use the `IgnoreDataChecking` property for this purpose.)

HDL Block Properties

ConstrainedOutputPipeline	Number of registers to place at the outputs by moving existing delays within your design. Distributed pipelining does not redistribute these registers. The default is `0`. For more details, see "ConstrainedOutputPipeline" (HDL Coder).
InputPipeline	Number of input pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see "InputPipeline" (HDL Coder).
OutputPipeline	Number of output pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see "OutputPipeline" (HDL Coder).
ResetType	Suppress reset logic generation. The default is `default`, which generates reset logic. See also "ResetType" (HDL Coder).

Convolutional sublibrary of Interleaving

Description

The General Multiplexed Interleaver block permutes the symbols in the input signal. Internally, it uses a set of shift registers, each with its own delay value.

This block accepts a scalar or column vector input signal, which can be real or complex. The input and output signals have the same sample time.

The block can accept the data types `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, `double`, and fixed-point. The output signal has the same data type as the input signal.

Parameters

Interleaver delay (samples)

A column vector listing the number of symbols that fit into each shift register. The length of this vector is the number of shift registers. (In sample-based mode, it can also be a row vector.)

Initial conditions

The values that fill each shift register at the beginning of the simulation.

If **Initial conditions** is a scalar, then its value fills all shift registers. If **Initial conditions** is a column vector, then each entry fills the corresponding shift register. (In sample-based mode, **Initial conditions** can also be a row vector.) If a given shift register has zero delay, then the value of the corresponding entry in the **Initial conditions** vector is unimportant.

Pair Block

General Multiplexed Deinterleaver

Extended Capabilities

C/C++ Code Generation

Generate C and C++ code using Simulink® Coder™.

HDL Code Generation

Generate Verilog and VHDL code for FPGA and ASIC designs using HDL Coder™.

HDL Coder provides additional configuration options that affect HDL implementation and synthesized logic.

HDL Architecture

The implementation for the General Multiplexed Interleaver block is shift register based. If you want to suppress generation of reset logic, set the implementation parameter `ResetType` to`'none'`.

When you set `ResetType` to`'none'`, reset is not applied to the shift registers. Mismatches between Simulink and the generated code occur for some number of samples during the initial phase, when registers are not fully loaded. To avoid spurious test bench errors, determine the number of samples required to fill the shift registers. Then, set the **Ignore output data checking (number of samples)** option accordingly. (You can use the `IgnoreDataChecking` property for this purpose, if you are using the command-line interface.)

HDL Block Properties

ConstrainedOutputPipeline	Number of registers to place at the outputs by moving existing delays within your design. Distributed pipelining does not redistribute these registers. The default is `0`. For more details, see “ConstrainedOutputPipeline” (HDL Coder).
InputPipeline	Number of input pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see “InputPipeline” (HDL Coder).
OutputPipeline	Number of output pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see “OutputPipeline” (HDL Coder).
ResetType	Suppress reset logic generation. The default is `default`, which generates reset logic. See also “ResetType” (HDL Coder).

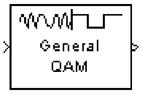
Introduced before R2006a

General QAM Demodulator Baseband

Demodulate QAM-modulated data



Library

AM, in Digital Baseband sublibrary of Modulation

Description

The General QAM Demodulator Baseband block demodulates a signal that was modulated using quadrature amplitude modulation. The input is a baseband representation of the modulated signal.

The input must be a discrete-time complex signal. The **Signal constellation** parameter defines the constellation by listing its points in a length-M vector of complex numbers. The block maps the *m*th point in the **Signal constellation** vector to the integer *m*-1.

This block accepts a scalar or column vector input signal. For information about the data types each block port supports, see the “Supported Data Types” on page 5-338 table on this page.

Parameters

Signal constellation

A real or complex vector that lists the constellation points.

Output type

Determines whether the block produces integers or binary representations of integers.

If you set this parameter to `Integer`, the block produces integers.

If you set this parameter to `Bit`, the block produces a group of K bits, called a *binary word*, for each symbol, when **Decision type** is set to `Hard decision`. If **Decision type** is set to `Log-likelihood ratio` or `Approximate log-likelihood ratio`, the block outputs bitwise LLR and approximate LLR, respectively.

Decision type

This field appears when `Bit` is selected in the pull-down list **Output type**.

Specifies the use of hard decision, LLR, or approximate LLR during demodulation. See “Exact LLR Algorithm” and “Approximate LLR Algorithm” in the *Communications Toolbox User's Guide* for algorithm details.

Noise variance source

This field appears when you set `Approximate log-likelihood ratio` or `Log-likelihood ratio` for **Decision type**.

When you set this parameter to `Dialog`, you can then specify the noise variance in the **Noise variance** field. When you set this option to `Port`, a port appears on the block through which the noise variance can be input.

Noise variance

This parameter appears when the **Noise variance source** is set to `Dialog` and specifies the noise variance in the input signal. This parameter is tunable in normal mode, Accelerator mode and Rapid Accelerator mode.

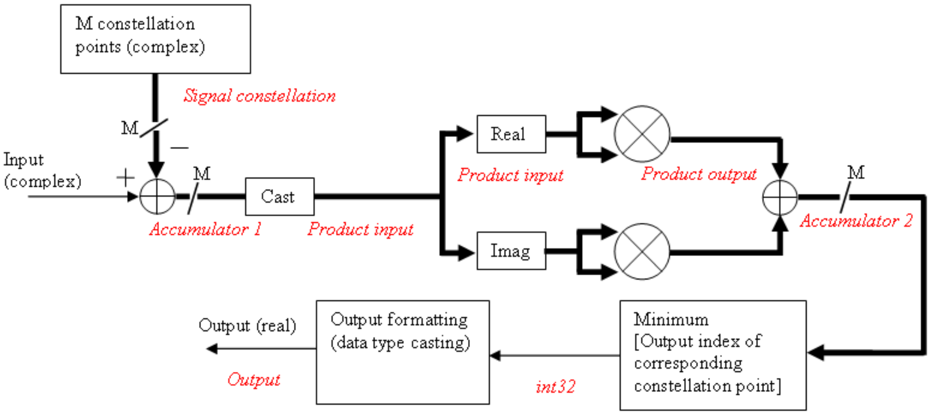
If you use the Simulink Coder rapid simulation (RSIM) target to build an RSIM executable, then you can tune the parameter without recompiling the model. This is useful for Monte Carlo simulations in which you run the simulation multiple times (perhaps on multiple computers) with different amounts of noise.

The LLR algorithm involves computing exponentials of very large or very small numbers using finite precision arithmetic and would yield:

- `Inf` to `-Inf` if **Noise variance** is very high
- `NaN` if **Noise variance** and signal power are both very small

In such cases, use approximate LLR, as its algorithm does not involve computing exponentials.

Fixed-Point Signal Flow Diagrams



Fixed-Point Signal Flow Diagram for Hard Decision Mode

Note In the figure above, *M* represents the size of the **Signal constellation** .

The general QAM Demodulator Baseband block supports fixed-point operations for computing Hard Decision (**Output** type set to `Bit` and **Decision type** is set to `Hard decision`) and Approximate LLR (**Output type** is set to `Bit` and **Decision type** is set to `Approximate Log-Likelihood ratio`) output values. The input values must have fixed-point data type for fixed-point operations.

Note Fixed-Point operations are NOT yet supported for Exact LLR output values.

Data Types Attributes

Output

The block supports the following Output options:

When you set the parameter to `Inherit via internal rule` (default setting), the block inherits the output data type from the input port. The output data type is the same as the input data type if the input is of type `single` or `double`.

For integer outputs, you can set this block's output to `Inherit via internal rule` (default setting), `Smallest unsigned integer`, `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `single`, and `double`.

For bit outputs, when you set **Decision type** to `Hard decision`, you can set the output to `Inherit via internal rule`, `Smallest unsigned integer`, `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, or `double`.

When you set **Decision type** to `Hard decision` or `Approximate log-likelihood ratio` and the input is a floating point data type, then the output inherits its data type from the input. For example, if the input is of data type `double`, the output is also of data type `double`. When you set **Decision type** to `Hard decision` or `Approximate log-likelihood ratio`, and the input is a fixed-point signal, the **Output** parameter, located in the Fixed-Point algorithm parameters region of the Data-Type tab, specifies the output data type.

When you set the parameter to `Smallest unsigned integer`, the output data type is selected based on the settings used in the **Hardware Implementation** pane of the Configuration Parameters dialog box. If you select `ASIC/FPGA` in the **Hardware Implementation** pane, the output data type is the ideal minimum size, i.e., `ufix(1)` for bit outputs, and $ufix(\lceil \log_2 M \rceil)$ for integer outputs. For all other choices, the **Output** data type is an unsigned integer with the smallest available word length large enough to fit the ideal minimum size, usually corresponding to the size of a char (e.g., `uint8`).

Rounding Mode Parameter

Use this parameter to specify the rounding method to be used when the result of a fixed-point calculation does not map exactly to a number representable by the data type and scaling storing the result.

For more information, see “Rounding Modes” or “Rounding Mode: Simplest” (Fixed-Point Designer).

Saturate on integer overflow

Use this parameter to specify the method to be used if the magnitude of a fixed-point calculation result does not fit into the range of the data type and scaling that stores the result:

- Saturate represents positive overflows as the largest positive number in the range being used, and negative overflows as the largest negative number in the range being used.
- Wrap uses modulo arithmetic to cast an overflow back into the representable range of the data type. See Modulo Arithmetic (Fixed-Point Designer) for more information.

For more information, see the **Saturate on integer overflow** parameter subsection of “Specify Fixed-Point Attributes for Blocks”.

Signal constellation

Use this parameter to define the data type of the **Signal constellation** parameter.

- When you select `Same word length as input` the word length of the **Signal constellation** parameter matches that of the input to the block. The fraction length is computed to provide the best precision for given signal constellation values.
- When you select `Specify word length`, the **Word Length** field appears, and you may enter a value for the word length. The fraction length is computed to provide the best precision for given signal constellation values.

Accumulator 1

Use this parameter to specify the data type for **Accumulator 1**:

- When you select `Inherit via internal rule`, the block automatically calculates the output word and fraction lengths. For more information, see the “Inherit via Internal Rule” subsection of the *DSP System Toolbox™ User's Guide*.
- When you select `Binary point scaling`, you can enter the word length and the fraction length of **Accumulator 1**, in bits.

Product Input

Use this parameter to specify the data type for **Product input**.

- When you select `Same as accumulator 1`, the **Product Input** characteristics match those of **Accumulator 1**.
- When you select `Binary point scaling` you can enter the word length and the fraction length of **Product input**, in bits.

Product Output

Use this parameter to select the data type for Product output.

- When you select `Inherit via internal rule`, the block automatically calculates the output signal type. For more information, see the `Inherit via Internal Rule` subsection of the *DSP System Toolbox User's Guide*.
- When you select `Binary point scaling` enter the word length and the fraction length for **Product output**, in bits.

Accumulator 2

Use this parameter to specify the data type for **Accumulator 2**:

- When you select `Inherit via internal rule`, the block automatically calculates the accumulator data type. The internal rule calculates the ideal, full-precision word length and fraction length as follows:

  $WL_{\text{ideal accumulator 2}} = WL_{\text{input to accumulator 2}}$

  $FL_{\text{ideal accumulator 2}} = FL_{\text{ input to accumulator 2}}$

  After the full-precision result is calculated, your particular hardware may still affect the final word and fraction lengths set by the internal rule. For more information, see The Effect of the

Hardware Implementation Pane on the Internal Rule subsection of the *DSP System Toolbox User's Guide*.

The internal rule always sets the sign of data-type to `Unsigned` .

- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of **Accumulator 2**, in bits.

The settings for the following fixed-point parameters only apply when you set **Decision type** to `Approximate log-likelihood ratio`.

Accumulator 3

When you select `Inherit via internal rule`, the block automatically calculates the accumulator data type. The internal rule first calculates ideal, full-precision word length and fraction length as follows:

$WL_{\text{ideal accumulator 3}} = WL_{\text{input to accumulator 3}} + 1$

$FL_{\text{ideal accumulator 3}} = FL_{\text{input to accumulator 3}}$.

After the full-precision result is calculated, your particular hardware may still affect the final word and fraction lengths set by the internal rule. For more information, see The Effect of the Hardware Implementation Pane on the Internal Rule subsection of the *DSP System Toolbox User's Guide*.

The internal rule always sets the sign of data-type to `Signed`.

Noise scaling input

- When you select `Same as accumulator 3`, the **Noise scaling input** characteristics match those of **Accumulator 3**.
- When you select `Binary point scaling` you are able to enter the word length and the fraction length of **Noise scaling input**, in bits.

Inverse noise variance

This field appears when **Noise variance** source is set to Dialog.

- When you select `Same word length as input` the word length of the **Inverse noise variance** parameter matches that of the input to the block. The fraction length is computed to provide the best precision for a given inverse noise variance value.
- When you select `Specify word length`, the **Word Length** field appears, and you may enter a value for the word length. The fraction length is computed to provide the best precision for a given inverse noise variance value.

Output

When you select `Inherit via internal rule` , the **Output data type** is automatically set for you.

If you set the **Noise variance source** parameter to `Dialog`, the output is a result of product operation as shown in the Noise Variance Operation Modes Signal Flow Diagram “Fixed-Point Signal Flow Diagram for Approximate LLR Mode: Noise Variance Operation Modes” on page 5-334. In this case, it follows the internal rule for Product data types specified in the Inherit via Internal Rule subsection of the *DSP System Toolbox User's Guide*.

If the **Noise variance source** parameter is set to `Port`, the output is a result of division operation as shown in the signal flow diagram. In this case, the internal rule calculates the ideal, full-precision word length and fraction length as follows:

$WL_{\text{output}} = \max(WL_{\text{Noise scaling input}}, WL_{\text{Noise variance}})$

$FL_{\text{output}} = FL_{\text{Noise scaling input (dividend)}} - FL_{\text{Noise variance (divisor)}}$.

After the full-precision result is calculated, your particular hardware may still affect the final word and fraction lengths set by the internal rule. For more information, see “The Effect of the Hardware Implementation Pane on the Internal Rule” subsection of the *DSP System Toolbox User's Guide*.

The internal rule for **Output** always sets the sign of data-type to `Signed`.

For additional information about the parameters pertaining to fixed-point applications, see “Specify Fixed-Point Attributes for Blocks”.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point • Signed fixed–point when **Output type** is `Integer` or **Output type** is `Bit` and **Decision type** is either `Hard-decision` or `Approximate LLR`
Var	• Double-precision floating point • Single-precision floating point
Output	• Double-precision floating point • Single-precision floating point • Boolean when **Output type** is `Bit` and **Decision type** is `Hard-decision`. • 8-, 16-, and 32-bit signed integers when **Output type** is `Integer` or **Output type** is `Bit` and **Decision type** is `Hard-decision` • 8-, 16-, and 32-bit unsigned integers when **Output type** is `Integer` or **Output type** is `Bit` and **Decision type** is `Hard-decision` • ufix(1) in ASIC/FPGA when **Output type** is `Bit` and **Decision type** is `Hard-decision` • $ufix(\lceil \log_2 M \rceil)$ in ASIC/FPGA when **Output type** is `Integer` • Signed fixed-point when **Output type** is `Bit` and **Decision type** is `Approximate LLR`

General QAM Modulator Baseband

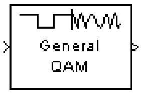
Modulate using quadrature amplitude modulation



Library

AM, in Digital Baseband sublibrary of Modulation

Description

The General QAM Modulator Baseband block modulates using quadrature amplitude modulation. The output is a baseband representation of the modulated signal.

The **Signal constellation** parameter defines the constellation by listing its points in a length-M vector of complex numbers. The input signal values must be integers between 0 and M-1. The block maps an input integer m to the (m+1)st value in the **Signal constellation** vector.

This block accepts a scalar or column vector input signal. For information about the data types each block port supports, see the “Supported Data Types” on page 5-341 table on this page.

Constellation Visualization

The General QAM Modulator Baseband block provides the capability to visualize a signal constellation from the block mask. This Constellation Visualization feature allows you to visualize a signal constellation for specific block parameters. For more information, see the Constellation Visualization section of the *Communications Toolbox User's Guide*.

Parameters

Signal constellation

A real or complex vector that lists the constellation points.

Output data type

The output data type can be set to `double`, `single`, `Fixed-point`, `User-defined`, or `Inherit via back propagation`.

Setting this to `Fixed-point` or `User-defined` will enable fields in which you can further specify details. Setting this to `Inherit via back propagation`, sets the output data type and scaling to match the following block..

Output word length

Specify the word length, in bits, of the fixed-point output data type. This parameter is only visible when you select `Fixed-point` for the **Output data type** parameter.

User-defined data type

Specify any signed built-in or signed fixed-point data type. You can specify fixed-point data types using the `sfix`, `sint`, `sfrac`, and `fixdt` functions from Fixed-Point Designer software. This parameter is only visible when you select `User-defined` for the **Output data type** parameter.

Set output fraction length to

Specify the scaling of the fixed-point output by either of the following two methods:

- Choose `Best precision` to have the output scaling automatically set such that the output signal has the best possible precision.
- Choose `User-defined` to specify the output scaling in the **Output fraction length** parameter.

This parameter is only visible when you select `Fixed-point` for the **Output data type** parameter, or when you select `User-defined` and the specified output data type is a fixed-point data type.

Output fraction length

For fixed-point output data types, specify the number of fractional bits, or bits to the right of the binary point. This parameter is only visible when you select `Fixed-point` or `User-defined` for the **Output data type** parameter and `User-defined` for the **Set output fraction length to** parameter.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point • 8-, 16-, 32-bit signed integers • 8-, 16-, 32-bit unsigned integers • $ufix(\lceil \log_2 M \rceil)$
Output	• Double-precision floating point • Single-precision floating point • Signed fixed-point

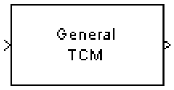
General TCM Decoder

Decode trellis-coded modulation data, mapped using arbitrary constellation



Library

TCM, in Digital Baseband sublibrary of Modulation

Description

The General TCM Decoder block uses the Viterbi algorithm to decode a trellis-coded modulation (TCM) signal that was previously modulated using an arbitrary signal constellation.

The **Trellis structure** and **Signal constellation** parameters in this block should match those in the General TCM Encoder block, to ensure proper decoding. In particular, the **Signal constellation** parameter must be in set-partitioned order.

Input and Output Signals

This block accepts a column vector input signal containing complex numbers. The input signal must be `double` or `single`. The reset port signal must be `double` or `Boolean`. For information about the data types each block port supports, see “Supported Data Types” on page 5-344.

If the convolutional encoder described by the trellis structure represents a rate *k*/*n* code, then the General TCM Decoder block's output is a binary column vector whose length is *k* times the vector length of the input signal.

Operation Modes

The block has three possible methods for transitioning between successive frames. The **Operation mode** parameter controls which method the block uses. This parameter also affects the range of possible values for the **Traceback depth** parameter, D.

- In `Continuous` mode, the block initializes all state metrics to zero at the beginning of the simulation, waits until it accumulates D symbols, and then uses a sequence of D symbols to compute each of the traceback paths. D can be any positive integer. At the end of each frame, the block saves its internal state metric for use with the next frame.

  If you select **Enable the reset input port**, the block displays another input port, labeled `Rst`. This port receives an integer scalar signal. Whenever the value at the `Rst` port is nonzero, the block resets all state metrics to zero and sets the traceback memory to zero.
- In `Truncated` mode, the block treats each frame independently. The traceback path starts at the state with the lowest metric. D must be less than or equal to the vector length of the input.
- In `Terminated` mode, the block treats each frame independently. The traceback path always starts at the all-zeros state. D must be less than or equal to the vector length of the input. If you

know that each frame of data typically ends at the all-zeros state, then this mode is an appropriate choice.

Decoding Delay

If you set **Operation mode** to `Continuous`, then this block introduces a decoding delay equal to **Traceback depth***k bits for a rate k/n convolutional code. The decoding delay is the number of zeros that precede the first decoded bit in the output.

The block incurs no delay for other values of **Operation mode**.

Parameters

Trellis structure

MATLAB structure that contains the trellis description of the convolutional encoder.

Signal constellation

A complex vector that lists the points in the signal constellation in set-partitioned order.

Traceback depth

The number of trellis branches (equivalently, the number of symbols) the block uses in the Viterbi algorithm to construct each traceback path.

Operation mode

The operation mode of the Viterbi decoder. The choices are `Continuous`, `Truncated`, and `Terminated`.

Enable the reset input port

When you select this check box, the block has a second input port labeled `Rst`. Providing a nonzero value to this port causes the block to set its internal memory to the initial state before processing the input data. This field appears only if you set **Operation mode** to `Continuous`.

Output data type

Select the data type for the block output signal as `boolean` or `single`. By default, the block sets this to `double`.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point
Reset	• Double-precision floating point • Boolean
Output	• Double-precision floating point • Boolean

General TCM Encoder

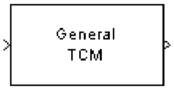
Convolutionally encode binary data and map using arbitrary constellation



Library

TCM, in Digital Baseband sublibrary of Modulation

Description

The General TCM Encoder block implements trellis-coded modulation (TCM) by convolutionally encoding the binary input signal and mapping the result to an arbitrary signal constellation. The **Signal constellation** parameter lists the signal constellation points in set-partitioned order. This parameter is a complex vector with a length, *M*, equal to the number of possible output symbols from the convolutional encoder. (That is, $\log_2 M$ is equal to n for a rate *k*/*n* convolutional code.)

Input Signals and Output Signals

If the convolutional encoder represents a rate *k*/*n* code, then the General TCM Encoder block's input must be a binary column vector with a length of *L***k* for some positive integer *L*.

This block accepts a binary-valued input signal. The output signal is a complex column vector of length *L*. For information about the data types each block port supports, see “Supported Data Types” on page 5-348.

Specifying the Encoder

To define the convolutional encoder, use the **Trellis structure** parameter. This parameter is a MATLAB structure whose format is described in “Trellis Description of a Convolutional Code”. You can use this parameter field in two ways:

- If you want to specify the encoder using its constraint length, generator polynomials, and possibly feedback connection polynomials, then use a `poly2trellis` command within the **Trellis structure** field. For example, to use an encoder with a constraint length of 7, code generator polynomials of 171 and 133 (in octal numbers), and a feedback connection of 171 (in octal), set the **Trellis structure** parameter to

  ```
  poly2trellis(7,[171 133],171)
  ```
- If you have a variable in the MATLAB workspace that contains the trellis structure, then enter its name as the **Trellis structure** parameter. This way is faster because it causes Simulink software to spend less time updating the diagram at the beginning of each simulation, compared to the usage in the previous bulleted item.

The encoder registers begin in the all-zeros state. You can configure the encoder so that it resets its registers to the all-zeros state during the course of the simulation. To do this, set the `Operation`

mode to **Reset on nonzero input via port**. The block then opens a second input port, labeled Rst. The signal at the Rst port is a scalar signal. When it is nonzero, the encoder resets before processing the data at the first input port.

Signal Constellations

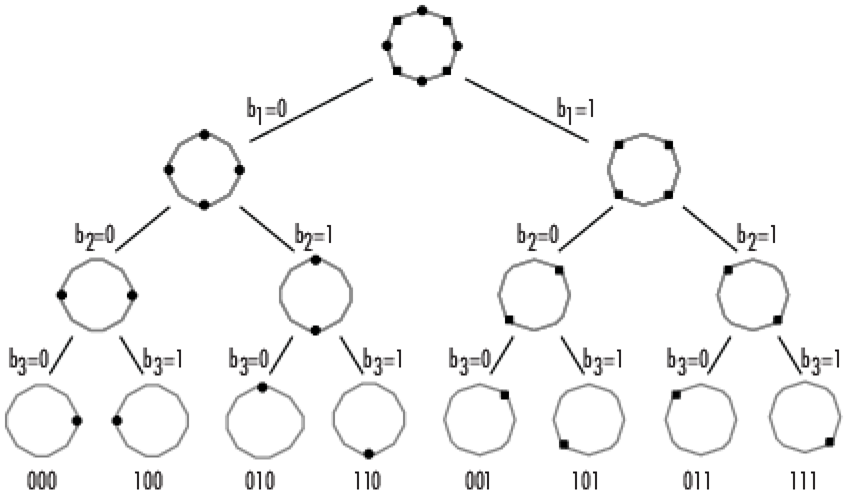
The trellis-coded modulation technique partitions the constellation into subsets called cosets so as to maximize the minimum distance between pairs of points in each coset.

Note When you set the **Signal constellation** parameter, you must ensure that the constellation vector is already in set-partitioned order. Otherwise, the block might produce unexpected or suboptimal results.

As an example, the diagram below shows one way to devise a set-partitioned order for the points for an 8-PSK signal constellation. The figure at the top of the tree is the entire 8-PSK signal constellation, while the eight figures at the bottom of the tree contain one constellation point each. Each level of the tree corresponds to a different bit in a binary sequence (b_3,b_2,b_1), while each branch in a given level of the tree corresponds to a particular value for that bit. Listing the constellation points using the sequence at the bottom of the tree leads to the vector

```
exp(2*pi*j*[0 4 2 6 1 5 3 7]/8)
```

which is a valid value for the **Signal constellation** parameter in this block.



For other examples of signal constellations in set-partitioned order, see [1] or the reference pages for the M-PSK TCM Encoder and Rectangular QAM TCM Encoder blocks.

Coding Gains

Coding gains of 3 to 6 decibels, relative to the uncoded case can be achieved in the presence of AWGN with multiphase trellis codes [3].

Parameters

Trellis structure

MATLAB structure that contains the trellis description of the convolutional encoder.

Operation mode

In `Continuous` mode (default setting), the block retains the encoder states at the end of each frame, for use with the next frame.

In `Truncated (reset every frame)` mode, the block treats each frame independently. I.e., the encoder states are reset to all-zeros state at the start of each frame.

In `Terminate trellis by appending bits` mode, the block treats each frame independently. For each input frame, extra bits are used to set the encoder states to all-zeros state at the end of the frame. The output length is given by $y = n \cdot (x + s)/k$, where x is the number of input bits, and s = constraint length − 1 (or, in the case of multiple constraint lengths, s =`sum(ConstraintLength(i)-1)`). The block supports this mode for column vector input signals.

In `Reset on nonzero input via port` mode, the block has an additional input port, labeled `Rst`. When the `Rst` input is nonzero, the encoder resets to the all-zeros state.

Signal constellation

A complex vector that lists the points in the signal constellation in set-partitioned order.

Output data type

The output type of the block can be specified as a `single` or `double`. By default, the block sets this to `double`.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point • Boolean • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers • ufix(1)
Output	• Double-precision floating point • Single-precision floating point

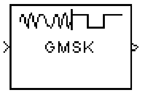
GMSK Demodulator Baseband

Demodulate GMSK-modulated data



Library

CPM, in Digital Baseband sublibrary of Modulation

Description

The GMSK Demodulator Baseband block uses a Viterbi algorithm to demodulate a signal that was modulated using the Gaussian minimum shift keying method. The input to this block is a baseband representation of the modulated signal.

Integer-Valued Signals and Binary-Valued Signals

This block accepts a scalar-valued or column vector input signal with a data type of `single` or `double`. If you set the **Output type** parameter to `Integer`, then the block produces values of 1 and -1. If you set the **Output type** parameter to `Bit`, then the block produces values of 0 and 1.

Single-Rate Processing

In single-rate processing mode, the input and output signals have the same port sample time. The block implicitly implements the rate change by making a size change at the output when compared to the input. The input width must be an integer multiple of the **Samples per symbol** parameter value, and the input can be a column vector.

- When you set **Output type** to `Bit`, the output width is two times the number of input symbols.
- When you set **Output type** to `Integer`, the output width is the number of input symbols.

For a column vector input signal, the width of the input equals the product of the number of symbols and the value for the **Samples per symbol** parameter.

Multirate Processing

In multirate processing mode, the input and output signals have different port sample times. The input must be a scalar. The output symbol time is the product of the input sample time and the **Samples per symbol** parameter value.

- When you set **Output type** to `Bit`, the output width equals the number of bits per symbol.
- When you set **Output type** to `Integer`, the output is a scalar.

Traceback Depth and Output Delays

Internally, this block creates a trellis description of the modulation scheme and uses the Viterbi algorithm. The **Traceback depth** parameter, D, in this block is the number of trellis branches used to construct each traceback path. D influences the output delay, which is the number of zero symbols that precede the first meaningful demodulated value in the output.

- When you set the **Rate options** parameter to `Allow multirate processing`, and the model uses a variable-step solver or a fixed-step solver with the **Tasking Mode** parameter set to `SingleTasking`, then the delay consists of D+1 zero symbols.
- When you set the **Rate options** parameter to `Enforce single-rate processing`, then the delay consists of D zero symbols.

The optimal **Traceback depth** parameter value is dependent on minimum squared Euclidean distance calculations. Alternatively, a typical value, dependent on the number of states, can be chosen using the five-times-the-constraint-length rule, which corresponds to 5 · log2(*numStates*). The number of states is determined by the following equation:

$$numStates = \begin{Bmatrix} p \cdot 2^{(L-1)}, \ for\,even\,m \\ 2p \cdot 2^{(L-1)}, \ for\,odd\,m \end{Bmatrix}$$

where:

- $h = m/p$ is the modulation index in proper rational form
  - m = numerator of modulation index
  - p = denominator of modulation index
- L is the Pulse length

Parameters

Output type

Determines whether the output consists of bipolar or binary values.

BT product

The product of bandwidth and time.

Pulse length (symbol intervals)

The length of the frequency pulse shape.

Symbol prehistory

The data symbols the modulator uses before the start of the simulation.

Phase offset (rad)

The initial phase of the modulated waveform.

Samples per symbol

The number of input samples that represent each modulated symbol, which must be a positive integer. For more information, see “Upsample Signals and Rate Changes” in *Communications Toolbox User's Guide*.

Rate options

Select the rate processing method for the block.

- `Enforce single-rate processing` — When you select this option, the input and output signals have the same port sample time. The block implements the rate change by making a size change at the output when compared to the input. The output width is the number of symbols (which is given by dividing the input length by the **Samples per symbol** parameter value when the **Output type** parameter is set to `Integer`).

- `Allow multirate processing` — When you select this option, the input and output signals have different port sample times. The output period is the same as the symbol period and equals the product of the input period and the **Samples per symbol** parameter value.

For more information, see Single-Rate Processing and Multirate Processing in the Description section of this page.

Traceback depth

The number of trellis branches that the GMSK Demodulator Baseband block uses to construct each traceback path.

Output data type

The output data type can be `boolean`, `int8`, `int16`, `int32`, or `double`.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point
Output	• Double-precision floating point • Boolean (When **Output type** set to `Bit`) • 8-, 16-, and 32-bit signed integers (When **Output type** set to `Integer`)

GMSK Modulator Baseband

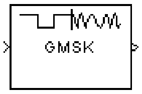
Modulate using Gaussian minimum shift keying method



Library

CPM, in Digital Baseband sublibrary of Modulation

Description

The GMSK Modulator Baseband block modulates using the Gaussian minimum shift keying method. The output is a baseband representation of the modulated signal.

The **BT product** parameter represents bandwidth multiplied by time. This parameter is a nonnegative scalar. It is used to reduce the bandwidth at the expense of increased intersymbol interference. The **Pulse length** parameter measures the length of the Gaussian pulse shape, in symbol intervals. For an explanation of the pulse shape, see the work by Anderson, Aulin, and Sundberg among the references on page 5-355 listed below. The frequency pulse shape is defined by the following equations.

$$g(t) = \frac{1}{2T}\left\{Q\left[2\pi B_b\frac{t-\frac{T}{2}}{\sqrt{\ln(2)}}\right] - Q\left[2\pi B_b\frac{t+\frac{T}{2}}{\sqrt{\ln(2)}}\right]\right\}$$

$$Q(t) = \int_t^\infty \frac{1}{\sqrt{2\pi}}e^{-\tau^2/2}d\tau$$

For this block, an input symbol of 1 causes a phase shift of π/2 radians.

The group delay is the number of samples between the start of a filter's response and its peak. The group delay that the block introduces is **Pulse length**/2 * **Samples per symbol** (using a reference of output sample periods). For GMSK, **Pulse length** denotes the truncated frequency pulse length in symbols. The net delay effect at the receiver (demodulator) is due to the **Traceback depth** parameter, which in most cases would be larger than the group delay.

Integer-Valued Signals and Binary-Valued Signals

When you set the **Input type** parameter to `Integer`, then the block accepts values of 1 and -1.

When you set the **Input type** parameter to `Bit`, then the block accepts values of 0 and 1.

This block accepts a scalar-valued or column vector input signal. For a column vector input signal, the width of the output equals the product of the number of symbols and the value for the **Samples per symbol** parameter.

Single-Rate Processing

In single-rate processing mode, the input and output signals have the same port sample time. The block implicitly implements the rate change by making a size change at the output when compared to the input. In this mode, the input to the block can be multiple symbols.

- When you set **Input type** to `Integer`, the input can be a column vector, the length of which is the number of input symbols.
- When you set **Input type** to `Bit`, the input width must be an integer multiple of 2.

The output width equals the product of the number of input symbols and the **Samples per symbol** parameter value.

Multirate Processing

In multirate processing mode, the input and output signals have different port sample times. In this mode, the input to the block must be one symbol.

- When you set **Input type** to `Integer`, the input must be a scalar.
- When you set **Input type** to `Bit`, the input width must equal the number of bits per symbol.

The output sample time equals the symbol period divided by the **Samples per symbol** parameter value.

Parameters

Input type

Indicates whether the input consists of bipolar or binary values.

BT product

The product of bandwidth and time.

The block uses this parameter to reduce bandwidth at the expense of increased intersymbol interference. Enter a nonnegative scalar value for this parameter.

Pulse length (symbol intervals)

The length of the frequency pulse shape.

Symbol prehistory

A scalar or vector value that specifies the data symbols the block uses before the start of the simulation, in reverse chronological order. If it is a vector, then its length must be one less than the **Pulse length** parameter.

Phase offset (rad)

The initial phase of the output waveform, measured in radians.

Samples per symbol

The number of output samples that the block produces for each integer or bit in the input, which must be a positive integer. For all non-binary schemes, as defined by the pulse shapes, this value must be greater than 1.

For more information, see “Upsample Signals and Rate Changes”.

Rate options

Select the rate processing option for the block.

- `Enforce single-rate processing` — When you select this option, the input and output signals have the same port sample time. The block implements the rate change by making a size change at the output when compared to the input. The output width equals the product of the number of symbols and the **Samples per symbol** parameter value.
- `Allow multirate processing` — When you select this option, the input and output signals have different port sample times. The output sample time equals the symbol period divided by the **Samples per symbol** parameter value.

Output data type

The output type of the block can be specified as a `single` or `double`. By default, the block sets this to `double`.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Boolean (When **Input type** set to `Bit`) • 8-, 16-, and 32-bit signed integers (When **Input type** set to `Integer`)
Output	• Double-precision floating point • Single-precision floating point

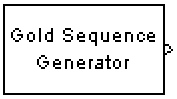
Gold Sequence Generator

Generate Gold sequence from set of sequences

Library: Communications Toolbox / Comm Sources / Sequence Generators



Description

The Gold Sequence Generator block generates a binary sequence with small periodic cross-correlation properties from a bounded set of sequences. For more information on Gold sequences, see “Gold Sequences” on page 5-360.

This block can output sequences that vary in length during simulation. For more information about variable-size signals, see “Variable-Size Signal Basics” (Simulink).

Ports

Input

`oSiz` — Current output size

scalar | two-element row vector

Current output size, specified as a scalar or a two-element row vector. The second element of the vector must be `1`.

Example: `[10 1]` indicates the current output column vector will be of size 10-by-1.

Dependencies

To enable this port select the **Output variable-size signals** parameter and set **Maximum output size source** to `Dialog parameter`.

Data Types: `double`

`Ref` — Reference input signal

scalar | column vector

Reference input signal, specified as a scalar, column vector.

Dependencies

To enable this port select the **Output variable-size signals** parameter and set **Maximum output size source** to `Inherit from reference input`.

Data Types: `double`

`Rst` — Reset signal

scalar | column vector

Reset signal, specified in one of these forms.

- When the output size is variable specify as a scalar.
- Otherwise, specify as a scalar or a 2-D column vector with a length equal to **Samples per frame**.

The output signal resets for nonzero **Rst** input values. For more information, see “Reset Behavior” on page 5-362

Dependencies

To enable this port, select the **Reset on nonzero input** parameter.

Data Types: `double`

Output

`Out` — Output signal

binary column vector

Output signal, returned as a binary column vector. At least one element of the **Initial states (1)** or **Initial states (2)** vector must be nonzero in order for the block to generate a nonzero sequence.

Data Types: `double`

Parameters

`Preferred polynomial (1)` — First sequence polynomial

`'z^6 + z + 1'` (default) | polynomial character vector | binary row vector | integer row vector

First sequence polynomial, specified in one of these forms.

- A polynomial character vector such as `'z^3 + z^2 + 1'`.
- A binary row vector that represents the coefficients of the generator polynomial in order of descending power. The length of this vector is (N+1), where N is the degree of the generator polynomial. For example, `[1 1 0 1]` represents the polynomial x^3+ z^2+ 1.
- An integer row vector containing the exponents of z for the nonzero terms in the polynomial in descending order. For example, `[3 2 0]` represents the polynomial $z^3 + z^2 + 1$.

For more information, see “Character Representation of Polynomials” and “Preferred Pairs of Sequences” on page 5-363.

`Initial states (1)` — Initial states for first sequence polynomial

`[0 0 0 0 0 1]` (default) | binary vector

Initial states of the shift register for first sequence polynomial of the preferred pair, specified as a binary vector with length equal to the degree of **Preferred polynomial (1)**.

`Preferred polynomial (2)` — Second sequence polynomial

`'z^6 + z^5 + z^2 + z + 1'` (default) | polynomial character vector | binary row vector | integer row vector

Second sequence polynomial, specified in one of these forms.

- A polynomial character vector such as `'z^3 + z^2 + 1'`.
- A binary row vector that represents the coefficients of the generator polynomial in order of descending power. The length of this vector is (N+1), where N is the degree of the generator polynomial. For example, `[1 1 0 1]` represents the polynomial x^3+ z^2+ 1.

- An integer row vector containing the exponents of z for the nonzero terms in the polynomial in descending order. For example, `[3 2 0]` represents the polynomial $z^3 + z^2 + 1$.

For more information, see “Character Representation of Polynomials”.

`Initial states (2)` — Initial states for second sequence polynomial

`[0 0 0 0 0 1]` (default) | binary vector

Initial states of the shift register for second sequence polynomial of the preferred pair, specified as a binary vector with length equal to the degree of **Preferred polynomial (2)**.

`Sequence index` — Sequence index

`0` (default) | integer scalar in the range [–2, 2^n–2]

Sequence index of the output sequence from the set of sequences, specified as an integer scalar in the range [–2, 2^n–2]. n is the degree of the preferred polynomials.

`Shift` — Offset of Gold sequence

`0` (default) | integer scalar

Offset of Gold sequence from the initial time, specified as an integer scalar.

`Output variable-size signals` — Output variable-size signals

off (default) | on

Select this parameter to permit variable length output sequences during simulation. When set to `off`, fixed-length sequences are output. When set to `on`, variable-length sequences can be output. For information about variable-size signals, see “Variable-Size Signal Basics” (Simulink).

`Maximum output size source` — Maximum output size source

`Dialog parameter` (default) | `Inherit from reference port`

Maximum output size source, which indicates how the maximum sequence output size is specified.

- `Dialog parameter` configures the block to use the **Maximum output size** parameter setting as the maximum permitted output sequence length. When you make this selection, the **oSiz** input port specifies the current size of the output signal and the block output inherits sample time from the input signal. The input value of **oSiz** must be less than or equal to the **Maximum output size** parameter.
- `Inherit from reference port` adds the `Ref` input port and configures the block to inherit the sample time, maximum size, and the current output size from the variable-sized signal at the `Ref` input port to set the maximum permitted output sequence length.

Dependencies

To enable this parameter, select **Output variable-size signals**.

`Maximum output size` — Maximum output size

`[10 1]` (default) | two-element row vector

Maximum output size, specified as a two-element row vector that denotes the maximum output size for the block. The second element of the vector must be `1`.

Example: `[10 1]` gives a 10-by-1 maximum sized output signal.

Dependencies

To enable this parameter select **Output variable-size signals** and set **Maximum output size source** to `Dialog parameter`.

Data Types: `double`

`Sample time` — Output sample time

`1` (default)

Output sample time, specified as `-1` or a positive scalar that represents the time between each sample of the output signal. If **Sample time** is set to `-1`, the sample time is inherited from downstream. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-360.

Dependencies

To enable this parameter do not select **Output variable-size signals**.

`Samples per frame` — Samples per frame

`1` (default) | positive integer

Samples per frame, specified as a positive integer indicating the number of samples per frame in one channel of the output data. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-360.

Dependencies

To enable this parameter do not select **Output variable-size signals**.

`Reset on nonzero input` — Reset output signal

`off` (default) | `on`

Select this parameter to enable the **Rst** port. When a nonzero value is input at the **Rst** port, the internal shift registers are reset to the original values of the **Initial states (1)** and **Initial states (2)** parameters.

`Output data type` — Output data type

`double` (default) | `boolean` | `Smallest unsigned integer`

Output data type, specified as `boolean`, `double`, or `Smallest unsigned integer`.

When set to `Smallest unsigned integer`, the output data type is selected based on the settings used in the “Hardware Implementation Pane” (Simulink) of the Configuration Parameters dialog box of the model. If ASIC/FPGA is selected in the Hardware Implementation pane, the output data type is the ideal minimum one-bit size (ufix(1)). For all other selections, it is an unsigned integer with the smallest available word length large enough to fit one bit, usually corresponding to the size of a char (uint8).

Block Characteristics

Data Types	`Boolean` | `double` | `fixed point`
Multidimensional Signals	`no`

Variable-Size Signals	yes

More About

Sample Timing

The time between output updates is equal to the product of **Samples per frame** and **Sample time**. For example, if **Sample time** and **Samples per frame** equal one, the block outputs a sample every second. If **Samples per frame** is increased to 10, then a 10-by-1 vector is output every 10 seconds. This ensures that the equivalent output rate is not dependent on the **Samples per frame** parameter.

Gold Sequences

The characteristic cross-correlation properties of Gold sequences make them useful when multiple devices are broadcasting in the same frequency range. The Gold sequences are defined using a specified pair of sequences *u* and *v*, of period $N = 2^n - 1$, called a preferred pair, as defined in “Preferred Pairs of Sequences” on page 5-363. The set $G(u, v)$ of Gold sequences is defined by

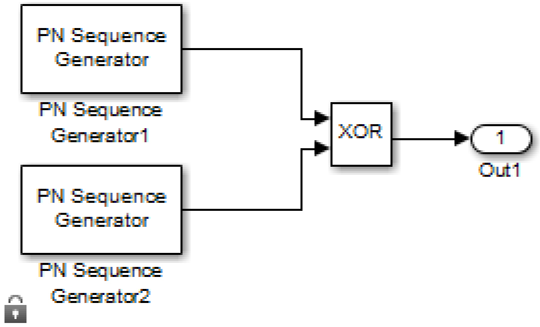
$$G(u,v) = \left\{u, v, u \oplus v, u \oplus Tv, u \oplus T^2 v, \ldots, u \oplus T^{N-1} v\right\}$$

where *T* represents the operator that shifts vectors cyclically to the left by one place, and ⊕ represents addition modulo 2. Note that $G(u,v)$ contains $N + 2$ sequences of period *N*. The Gold Sequence Generator block outputs one Gold sequence according to the configured parameters and inputs.

Gold sequences have the property that the cross-correlation between any two, or between shifted versions of them, takes on one of three values: $-t(n)$, -1, or $t(n) - 2$, where

$$t(n) = \begin{cases} 1 + 2^{(n+1)/2} & n \text{ even} \\ 1 + 2^{(n+2)/2} & n \text{ odd} \end{cases}$$

The Gold Sequence Generator block uses two PN Sequence Generator blocks to generate the preferred pair of sequences, and then XORs these sequences to produce the output sequence, as shown in the following diagram.



You can specify the preferred pair by the **Preferred polynomial (1)** and **Preferred polynomial (2)** parameters in the dialog for the Gold Sequence Generator block. These polynomials, both of which must have degree *n*, describe the shift registers that the PN Sequence Generator blocks use to generate their output. For more details on how these sequences are generated, see the reference page for the PN Sequence Generator block. You can specify the preferred polynomials using these formats:

- A polynomial character vector that includes the number `1`, for example, `'z^4 + z + 1'`.
- A vector that lists the coefficients of the polynomial in descending order of powers. The first and last entries must be 1. Note that the length of this vector is one more than the degree of the generator polynomial.
- A vector containing the exponents of *z* for the nonzero terms of the polynomial in descending order of powers. The last entry must be `0`.

For example, the polynomial $z^5 + z^2 + 1$ can be represented by the character vector `'z^5 + z^2 + 1'`, the vector `[5 2 0]`, and the vector `[1 0 0 1 0 1]`.

The following table provides a short list of preferred pairs.

n	N	Preferred Polynomial (1)	Preferred Polynomial (2)
5	31	`[5 2 0]`	`[5 4 3 2 0]`
6	63	`[6 1 0]`	`[6 5 2 1 0]`
7	127	`[7 3 0]`	`[7 3 2 1 0]`
9	511	`[9 4 0]`	`[9 6 4 3 0]`
10	1023	`[10 3 0]`	`[10 8 3 2 0]`
11	2047	`[11 2 0]`	`[11 8 5 2 0]`

The **Initial states (1)** and **Initial states (2)** parameters are vectors specifying the initial values of the registers corresponding to **Preferred polynomial (1)** and **Preferred polynomial (2)**, respectively. These parameters must satisfy these criteria:

- All elements of the **Initial states (1)** and **Initial states (2)** vectors must be binary numbers.
- The length of the **Initial states (1)** vector must equal the degree of the **Preferred polynomial (1)**, and the length of the **Initial states (2)** vector must equal the degree of the **Preferred polynomial (2)**.

Note At least one element of the initial states vectors (**Initial states (1)** or **Initial states (2)**) must be nonzero in order for the block to generate a nonzero sequence. Specifically, the initial state of at least one of the registers must be nonzero.

The **Sequence index** parameter specifies which Gold sequence in the set $G(u, v)$ is output. The range of **Sequence index** is $[–2, –1, 0, 1, 2, ..., 2^n–2]$, where *n* is the degree of the generator polynomials specified by the **Preferred polynomial (1)** and **Preferred polynomial (2)** parameters. This table shows the correspondence between **Sequence index** and the output sequence.

Sequence Index	Output Sequence
–2	u
–1	v
0	$u \oplus v$
1	$u \oplus Tv$

Sequence Index	Output Sequence
2	$u \oplus T^{2}v$
…	…
2^{n} –2	$u \oplus T^{2^{n}-2}v$

T represents the operator that shifts vectors cyclically to the left by one place, and ⊕ represents addition modulo 2.

You can shift the starting point of the Gold sequence with the **Shift** parameter, which is an integer representing the length of the shift.

You can use an external signal to reset the values of the internal shift register to the initial state by selecting **Reset on nonzero input**. This creates an input port for the external signal in the Gold Sequence Generator block. The way the block resets the internal shift register depends on whether its output signal and the reset signal are scalar or vector. For more information, see “Reset Behavior” on page 5-362.

Reset Behavior

To reset the generator sequence, you must first select **Reset on nonzero input** to add the `Rst` input. Suppose that the Gold Sequence Generator block outputs `[1 0 0 1 1 0 1 1]` when there is no reset. The following table shows the effect on the Gold Sequence Generator block output for the property values indicated.

	Reset Signal Properties	Gold Sequence Generator block	Reset Signal Output Signal
No reset	**Sample time** = 1 **Samples per frame** = 1 **Rst** = `[0 0 0 0 0 0 0 0]`	**Sample time** = 1 **Samples per frame** = 1 **Out** = `[1 0 0 1 1 0 1 1]`	 Rst 0 0 0 0 0 0 0 0 Out 1 0 0 1 1 0 1 1
Scalar reset signal	**Sample time** = 1 **Samples per frame** = 1 **Rst** = `[0 0 0 1 0 0 0 0]`	**Sample time** = 1 **Samples per frame** = 1	 Reset Rst 0 0 0 1 0 0 0 0 Out 1 0 0 1 0 0 1 1
Vector reset signal	**Sample time** = 1 **Samples per frame** = 8 **Rst** = `[0 0 0 1 0 0 0 0]`	**Sample time** = 1 **Samples per frame** = 8	

For the no reset case, the sequence is output without being reset. For the scalar and vector reset signal cases, the reset signal `[0 0 0 1 0 0 0 0]` is input to the `Rst` port. The sequence output is reset at the fourth bit, because the fourth bit of the reset signal is a 1 and the **Sample time** is 1.

For variable-sized outputs, the block only supports scalar reset signal inputs.

The “Gold Sequence Generator Reset Behavior” example demonstrates the reset behavior in a Simulink model.

Preferred Pairs of Sequences

The requirements for a pair of sequences u, v of period $N = 2^n–1$ to be a preferred pair are as follows:

- n is not divisible by 4
- $v = u[q]$, where
  - q is odd
  - $q = 2^k+1$ or $q = 2^{2k}–2^k+1$
  - v is obtained by sampling every qth symbol of u
- $\gcd(n, k) = \begin{cases} 1 & n \equiv 1 \mathrm{mod} 2 \\ 2 & n \equiv 2 \mathrm{mod} 4 \end{cases}$

Compatibility Considerations

Existing models automatically update this block to current version

Behavior changed in R2020a

Starting in R2020a, Simulink no longer allows you to use the Gold Sequence Generator block version available before R2015b.

Existing models automatically update to load the Gold Sequence Generator block version announced in “Source blocks output frames of contiguous time samples but do not use the frame attribute” in the R2015b Release Notes. For more information on block forwarding, see “Forwarding Tables” (Simulink).

Hadamard Code Generator

Generate Hadamard code from orthogonal set of codes

Library

Sequence Generators sublibrary of Comm Sources

Description

The Hadamard Code Generator block generates a Hadamard code from a Hadamard matrix, whose rows form an orthogonal set of codes. Orthogonal codes can be used for spreading in communication systems in which the receiver is perfectly synchronized with the transmitter. In these systems, the despreading operation is ideal, as the codes are decorrelated completely.

The Hadamard codes are the individual rows of a Hadamard matrix. Hadamard matrices are square matrices whose entries are +1 or -1, and whose rows and columns are mutually orthogonal. If *N* is a nonnegative power of 2, the*N*-by-*N* Hadamard matrix, denoted H_N, is defined recursively as follows.

$$H_1 = [1]$$

$$H_{2N} = \begin{bmatrix} H_N & H_N \\ H_N & -H_N \end{bmatrix}$$

The N-by-N Hadamard matrix has the property that

$H_N H_N^T = NI_N$

where I_N is the *N*-by-*N* identity matrix.

The Hadamard Code Generator block outputs a row of H_N. The output is bipolar. You specify the length of the code, *N*,by the **Code length** parameter. The **Code length** must be a power of 2. You specify the index of the row of the Hadamard matrix, which is an integer in the range [0, 1, ... , *N*-1], by the **Code index** parameter.

Parameters

Code length

A positive integer that is a power of two specifying the length of the Hadamard code.

Code index

An integer between 0 and *N*-1, where *N* is the **Code length**, specifying a row of the Hadamard matrix.

Sample time

Output sample time, specified as `-1` or a positive scalar that represents the time between each sample of the output signal. If **Sample time** is set to `-1`, the sample time is inherited from downstream. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-368.

Samples per frame

Samples per frame, specified as a positive integer indicating the number of samples per frame in one channel of the output data. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-368.

Output data type

The output type of the block can be specified as an `int8` or `double`. By default, the block sets this to `double`.

Simulate using

Select the simulation mode.

`Code generation`

On the first model run, simulate and generate code. If the structure of the block does not change, subsequent model runs do not regenerate the code.

If the simulation mode is `Code generation`, System objects corresponding to the blocks accept a maximum of nine inputs.

`Interpreted execution`

Simulate model without generating code. This option results in faster start times but can slow subsequent simulation performance.

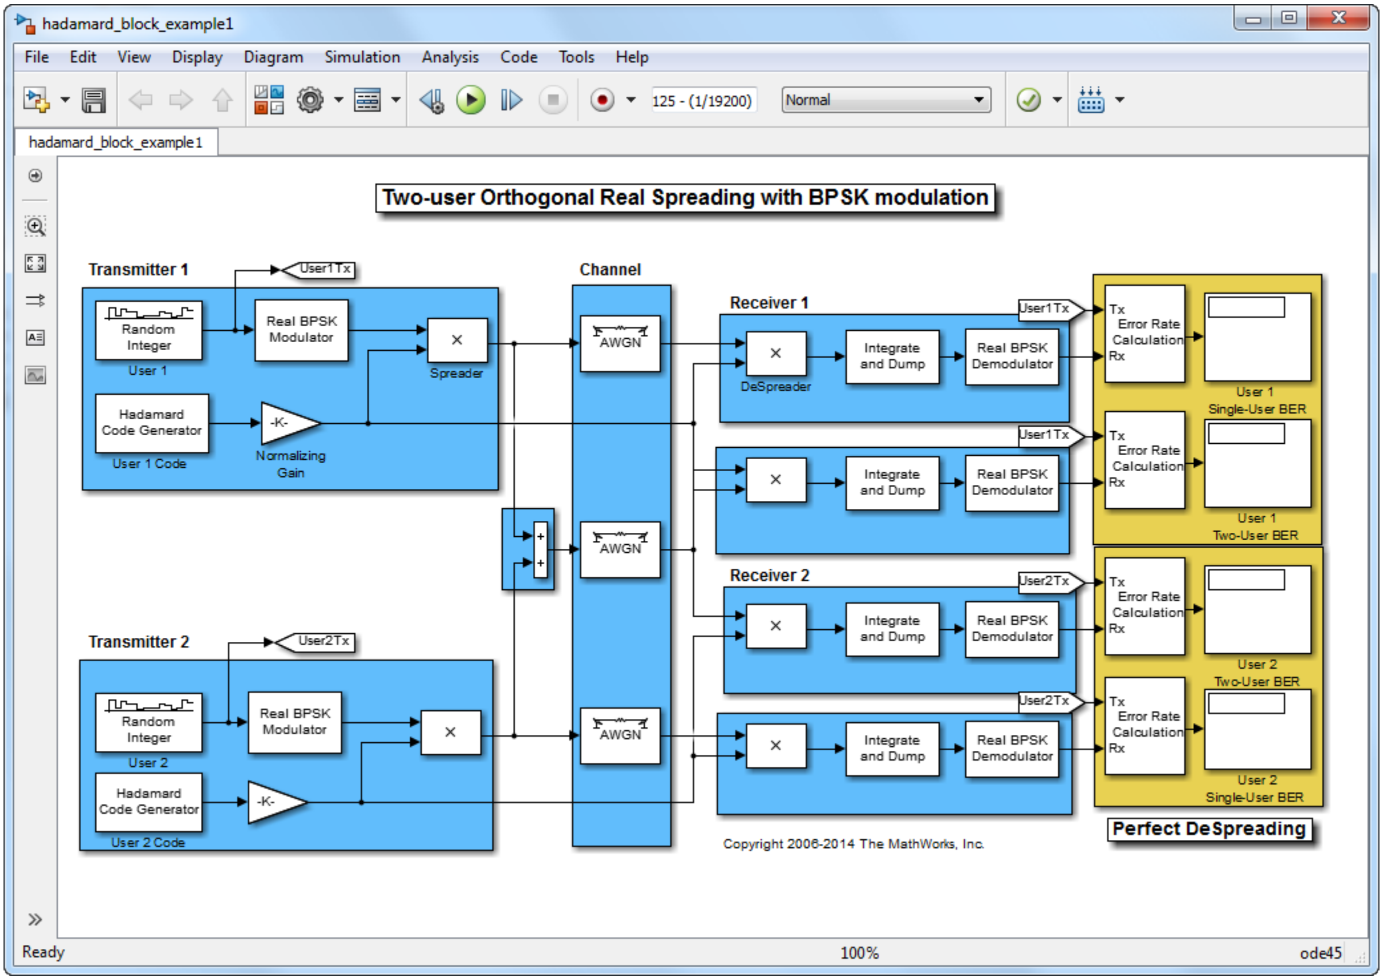
Examples

Orthogonal Spreading - Single-User vs. Two-User Comparison

This example model compares a single-user system vs. a two-user data transmission system with the two data streams being independently spread by different orthogonal codes.

The model uses random binary data which is BPSK modulated (real), spread by Hadamard codes of length 64 and then transmitted over an AWGN channel. The receiver consists of a despreader followed by a BPSK demodulator. Open the model here: hadamard_block_example1.

```
modelname = 'hadamard_block_example1';
open_system(modelname);
sim(modelname);
```



For the same data and channel settings, the model calculates the performance for one- and two-user transmissions.

Note that for the individual users, the error rates are exactly the same in both cases. This shows that perfect despreading is possible due to the ideal cross-correlation properties of the Hadamard codes.

To experiment with this model further, specify a different **Code length** or **Code index** for the individual users to examine the variations in relative performance.

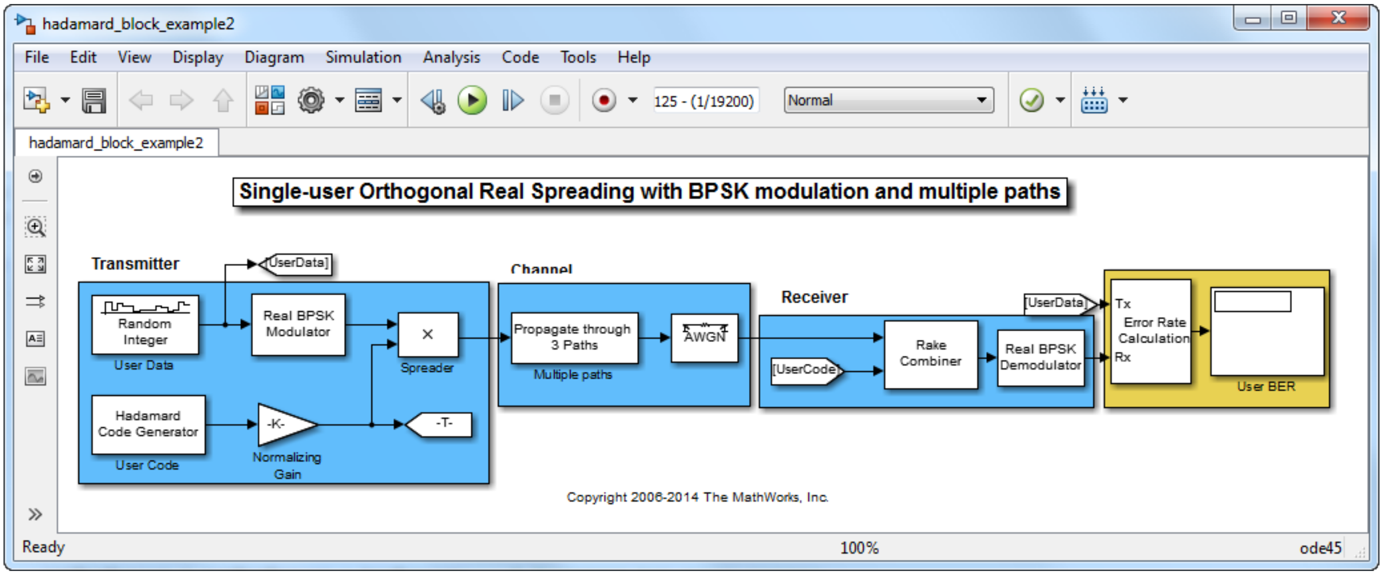
```
close_system(modelname, 0);
```

Orthogonal Spreading - Multipath Scenario

This example model considers a single-user system in which the signal is transmitted over multiple paths. This is similar to a mobile channel environment where the signals are received over multiple paths, each of which have different amplitudes and delays. To take advantage of the multipath transmission, the receiver employs diversity reception which combines the independent paths coherently.

Note, to keep the system simple, no shadowing effects are considered and the receiver has *a priori* knowledge of the number of paths and their respective delays. Open the model here: hadamard_block_example2.

```
modelname = 'hadamard_block_example2';
open_system(modelname);
sim(modelname);
```



For the data transmission with the same spreading code that was used in the first example, we now see deterioration in performance when compared with that example (compare the 180 errors with 81 in the previous case). This can be attributed to the non-ideal auto-correlation values of the orthogonal spreading codes chosen, which prevents perfect resolution of the individual paths. Consequently, we don't see the merits of diversity combining.

To experiment with this model further, try selecting other path delays to see how the performance varies for the same code. Also try different codes with the same delays.

```
close_system(modelname, 0);
```

More About

Sample Timing

The time between output updates is equal to the product of **Samples per frame** and **Sample time**. For example, if **Sample time** and **Samples per frame** equal one, the block outputs a sample every second. If **Samples per frame** is increased to 10, then a 10-by-1 vector is output every 10 seconds. This ensures that the equivalent output rate is not dependent on the **Samples per frame** parameter.

Compatibility Considerations

Existing models automatically update this block to current version

Behavior changed in R2020a

Starting in R2020a, Simulink no longer allows you to use the Hadamard Code Generator block version available before R2015b.

Existing models automatically update to load the Hadamard Code Generator block version announced in “Source blocks output frames of contiguous time samples but do not use the frame attribute” in the

R2015b Release Notes. For more information on block forwarding, see “Forwarding Tables” (Simulink).

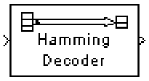
Hamming Decoder

Decode Hamming code to recover binary vector data



Library

Block sublibrary of Error Detection and Correction

Description

The Hamming Decoder block recovers a binary message vector from a binary Hamming codeword vector. For proper decoding, the parameter values in this block should match those in the corresponding Hamming Encoder block.

If the Hamming code has message length *K* and codeword length *N*, then *N* must have the form 2^M-1 for some integer *M* greater than or equal to 3. Also, *K* must equal *N*-*M*.

This block accepts a column vector input signal of length *N*. The output signal is a column vector of length *K*.

The coding scheme uses elements of the finite field GF(2^M). You can either specify the primitive polynomial that the algorithm should use, or you can rely on the default setting:

- To use the default primitive polynomial, simply enter *N* and *K* as the first and second dialog parameters, respectively. The algorithm uses `gfprimdf(M)` as the primitive polynomial for GF(2^M).
- To specify the primitive polynomial, enter *N* as the first parameter and a binary vector as the second parameter. The vector represents the primitive polynomial by listing its coefficients in order of ascending exponents. You can create primitive polynomials using the Communications Toolbox `gfprimfd` function.
- In addition, you can specify the primitive polynomial as a character vector, for example, `'D^3 + D + 1'`.

For information about the data types each block port supports, see the “Supported Data Type” on page 5-371 table on this page.

Parameters

Codeword length N

The codeword length *N*, which is also the input vector length.

Message length K, or M-degree primitive polynomial

The message length, which is also the input vector length or a binary vector that represents a primitive polynomial for GF(2^M) or a polynomial character vector.

Supported Data Type

Port	Supported Data Types
In	• Double-precision floating point • Single-precision floating point • Boolean • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers • Fixed-point

Hamming Encoder

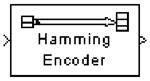
Create Hamming code from binary vector data



Library

Block sublibrary of Error Detection and Correction

Description

The Hamming Encoder block creates a Hamming code with message length *K* and codeword length *N*. The number *N* must have the form 2^M-1, where *M* is an integer greater than or equal to 3. Then *K* equals *N*-*M*.

This block accepts a column vector input signal of length *K*. The output signal is a column vector of length *N*.

The coding scheme uses elements of the finite field GF(2^M). You can either specify the primitive polynomial that the algorithm should use, or you can rely on the default setting:

- To use the default primitive polynomial, simply enter *N* and *K* as the first and second dialog parameters, respectively. The algorithm uses `gfprimdf(M)` as the primitive polynomial for GF(2^M).
- To specify the primitive polynomial, enter *N* as the first parameter and a binary vector as the second parameter. The vector represents the primitive polynomial by listing its coefficients in order of ascending exponents. You can create primitive polynomials using the Communications Toolbox `gfprimfd` function.
- In addition, you can specify the primitive polynomial as a character vector, for example, `'D^3 + D + 1'`.

For information about the data types each block port supports, see the “Supported Data Type” on page 5-373 table on this page.

Parameters

Codeword length N

The codeword length, which is also the output vector length.

Message length K, or M-degree primitive polynomial

The message length, which is also the input vector length or a binary vector that represents a primitive polynomial for GF(2^M) or a polynomial character vector.

Helical Deinterleaver

Restore ordering of symbols permuted by helical interleaver

Library

Convolutional sublibrary of Interleaving

Description

The Helical Deinterleaver block permutes the symbols in the input signal by placing them in an array row by row and then selecting groups in a helical fashion to send to the output port.

The block uses the array internally for its computations. If *C* is the **Number of columns in helical array** parameter, then the array has *C* columns and unlimited rows. If *N* is the **Group size** parameter, then the block accepts an input of length $C{\cdot}N$ at each time step and inserts them into the next *N* rows of the array. The block also places the **Initial condition** parameter into certain positions in the top few rows of the array (not only to accommodate the helical pattern but also to preserve the vector indices of symbols that pass through the Helical Interleaver and Helical Deinterleaver blocks in turn).

The output consists of consecutive groups of *N* symbols. Counting from the beginning of the simulation, the block selects the kth output group in the array from column *k* mod *C*. The selection is helical because of the reduction modulo C and because the first symbol in the k^{th} group is in row 1+(*k*-1)*s, where *s* is the **Helical array step size** parameter.

This block accepts a column vector input signal containing $C{\cdot}N$ elements.

The block can accept the data types `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, `double`, and fixed-point. The data type of this output will be the same as that of the input signal.

Delay of Interleaver-Deinterleaver Pair

After processing a message with the Helical Interleaver block and the Helical Deinterleaver block, the deinterleaved data lags the original message by

$$CN\left\lceil \frac{s(C-1)}{N} \right\rceil$$

samples. Before this delay elapses, the deinterleaver output is either the **Initial condition** parameter in the Helical Deinterleaver block or the **Initial condition** parameter in the Helical Interleaver block.

If your model incurs an additional delay between the interleaver output and the deinterleaver input, then the restored sequence lags the original sequence by the sum of the additional delay and the amount in the formula above. For proper synchronization, the delay between the interleaver and deinterleaver must be m$\cdot$ $C \cdot N$ for some nonnegative integer *m*. You can use the DSP System Toolbox Delay block to adjust delays manually, if necessary.

Parameters

Number of columns in helical array

The number of columns, *C*, in the helical array.

Group size

The size, *N*, of each group of symbols. The input width is *C* times *N*.

Helical array step size

The number of rows of separation between consecutive output groups as the block selects them from their respective columns of the helical array.

Initial conditions

A scalar that fills the array before the first input is placed.

General Multiplexed Deinterleaver | Helical Interleaver

Introduced before R2006a

Helical Interleaver

Permute input symbols using helical array

Library

Convolutional sublibrary of Interleaving

Description

The Helical Interleaver block permutes the symbols in the input signal by placing them in an array in a helical fashion and then sending rows of the array to the output port.

The block uses the array internally for its computations. If *C* is the **Number of columns in helical array** parameter, then the array has *C* columns and unlimited rows. If *N* is the **Group size** parameter, then the block accepts an input of length $C \cdot N$ at each time step and partitions the input into consecutive groups of *N* symbols. Counting from the beginning of the simulation, the block places the k^{th} group in the array along column *k* mod *C*. The placement is helical because of the reduction modulo *C* and because the first symbol in the k^{th} group is in row $1+(k\text{-}1)\cdot s$, where *s* is the **Helical array step size** parameter. Positions in the array that do not contain input symbols have default contents specified by the **Initial condition** parameter.

The block sends $C \cdot N$ symbols from the array to the output port by reading the next *N* rows sequentially. At a given time step, the output symbols might be the **Initial condition** parameter value, symbols from that time step's input vector, or symbols left in the array from a previous time step.

This block accepts a column vector input signal containing $C \cdot N$ elements.

The block can accept the data types `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, `double`, and fixed-point. The data type of this output will be the same as that of the input signal.

Parameters

Number of columns in helical array

The number of columns, C, in the helical array.

Group size

The size, N, of each group of input symbols. The input width is C times N.

Helical array step size

The number of rows of separation between consecutive input groups in their respective columns of the helical array.

Initial conditions

A scalar that fills the array before the first input is placed.

Examples

Suppose that C = 3, N = 2, the **Helical array step size** parameter is 1, and the **Initial condition** parameter is -1. After receiving inputs of `[1:6]'`, `[7:12]'`, and `[13:18]'`, the block's internal array looks like the schematic below. The coloring of the inputs and the array indicate how the input symbols are placed within the array. The outputs at the first three time steps are `[1; -1; -1; 2; 3; -1]`, `[7; 4; 5; 8; 9; 6]`, and `[13; 10; 11; 14; 15; 12]`. (The outputs are not color-coded in the schematic.)

Ideal Rectangular Pulse Filter

Shape input signal using ideal rectangular pulses

Library

Comm Filters

Description

The Ideal Rectangular Pulse Filter block upsamples and shapes the input signal using rectangular pulses. The block replicates each input sample N times, where N is the **Pulse length** parameter. After replicating input samples, the block can also normalize the output signal and/or apply a linear amplitude gain.

If the **Pulse delay** parameter is nonzero, then the block outputs that number of zeros at the beginning of the simulation, before starting to replicate any of the input values.

This block accepts a scalar, column vector, or matrix input signal. For information about the data types each block port supports, see the “Supported Data Type” on page 5-381 table on this page.

The vector size, the pulse length, and the pulse delay are mutually independent. They do not need to satisfy any conditions with respect to each other.

Single-Rate Processing

When you set the **Rate options** parameter to `Enforce single-rate processing`, the input and output of the block have the same sample rate. To generate the output while maintaining the input sample rate, the block resamples the data in each column of the input such that the frame size of the output (M_o) is L times larger than that of the input ($M_o = M_i*L$), where L is the **Pulse length (number of samples)** parameter value.

Multirate Processing

When you set the **Rate options** parameter to `Allow multirate processing`, the input and output of the block are the same size. However, the sample rate of the output is L times faster than that of the input (i.e. the output sample time is 1/N times the input sample time). When the block is in multirate processing mode, you must also specify a value for the **Input processing** parameter:

- When you set the **Input processing** parameter to `Elements as channels (sample based)`, the block treats an M-by-N matrix input as $M*N$ independent channels, and processes each channel over time. The output sample period (T_{so}) is L times shorter than the input sample period ($T_{so} = T_{si}/L$), while the input and output sizes remain identical.
- When you set the **Input processing** parameter to `Columns as channels (frame based)`, the block treats an M_i-by-N matrix input as N independent channels. The block processes each column of the input over time by keeping the frame size constant (M_i=M_o), while making the output frame period (T_{fo}) L times shorter than the input frame period ($T_{fo} = T_{fi}/L$).

Normalization Methods

You determine the block's normalization behavior using the **Normalize output signal** and **Linear amplitude gain** parameters.

- If you clear **Normalize output signal**, then the block multiplies the set of replicated values by the **Linear amplitude gain** parameter. This parameter must be a scalar.
- If you select **Normalize output signal**, then the **Normalization method** parameter appears. The block scales the set of replicated values so that one of these conditions is true:
  - The sum of the samples in each pulse equals the original input value that the block replicated.
  - The energy in each pulse equals the energy of the original input value that the block replicated. That is, the sum of the squared samples in each pulse equals the square of the input value.

After the block applies the scaling specified in the **Normalization method** parameter, it multiplies the scaled signal by the constant scalar value specified in the **Linear amplitude gain** parameter.

The output is scaled by $\sqrt{N}$. If the output of this block feeds the input to the AWGN Channel block, specify the AWGN signal power parameter to be 1/N.

Parameters

Pulse length (number of samples)

The number of samples in each output pulse; that is, the number of times the block replicates each input value when creating the output signal.

Pulse delay (number of samples)

The number of zeros that appear in the output at the beginning of the simulation, before the block replicates any input values.

Input processing

Specify how the block processes the input signal. You can set this parameter to one of the following options:

- `Columns as channels (frame based)` — When you select this option, the block treats each column of the input as a separate channel.
- `Elements as channels (sample based)` — When you select this option, the block treats each element of the input as a separate channel.

Rate options

Specify the method by which the block should upsample and shape the input signal. You can select one of the following options:

- `Enforce single-rate processing` — When you select this option, the block maintains the input sample rate, and processes the signal by increasing the output frame size by a factor of *L*. To select this option, you must set the **Input processing** parameter to `Columns as channels (frame based)`.
- `Allow multirate processing` — When you select this option, the block processes the signal such that the output sample rate is *L* times faster than the input sample rate.

Normalize output signal

If you select this, then the block scales the set of replicated values before applying the linear amplitude gain.

Normalization method

The quantity that the block considers when scaling the set of replicated values. Choices are `Sum of samples` and `Energy per pulse`. This field appears only if you select **Normalize method**.

Linear amplitude gain

A positive scalar used to scale the output signal.

Rounding mode

Use this parameter to specify the rounding method to be used when the result of a fixed-point calculation does not map exactly to a number representable by the data type and scaling storing the result. The filter coefficients do not obey this parameter; they always round to `Nearest`.

For more information, see Rounding Modes or “Rounding Mode: Simplest” (Fixed-Point Designer).

Saturate on integer overflow

Select the overflow mode for fixed-point operations. The filter coefficients do not obey this parameter; they are always saturated.

Coefficients

Choose how you specify the word length and the fraction length of the filter coefficients (numerator and/or denominator). See “Filter Structure Diagrams” in *DSP System Toolbox Reference Guide* for illustrations depicting the use of the coefficient data types in this block:

- When you select `Same word length as input`, the word length of the filter coefficients match that of the input to the block. In this mode, the fraction length of the coefficients is automatically set to the binary-point only scaling that provides you with the best precision possible given the value and word length of the coefficients.
- When you select `Specify word length`, you are able to enter the word length of the coefficients, in bits. In this mode, the fraction length of the coefficients is automatically set to the binary-point only scaling that provides you with the best precision possible given the value and word length of the coefficients.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the coefficients, in bits. If applicable, you are able to enter separate fraction lengths for the numerator and denominator coefficients.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the coefficients. If applicable, you are able to enter separate slopes for the numerator and denominator coefficients. This block requires power-of-two slope and a bias of zero.
- The filter coefficients do not obey the **Rounding mode** and the **Saturate on integer overflow** parameters; they are always saturated and rounded to `Nearest`.

Product output

Use this parameter to specify how you would like to designate the product output word and fraction lengths. See “Filter Structure Diagrams” and “Multiplication Data Types” in *DSP System Toolbox Reference Guide* for illustrations depicting the use of the product output data type in this block:

- When you select `Same as input`, these characteristics match those of the input to the block.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the product output, in bits.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the product output. This block requires power-of-two slope and a bias of zero.

Accumulator

Use this parameter to specify how you would like to designate the accumulator word and fraction lengths. See “Filter Structure Diagrams” and “Multiplication Data Types” for illustrations depicting the use of the accumulator data type in this block:

- When you select `Same as input`, these characteristics match those of the input to the block.
- When you select `Same as product output`, these characteristics match those of the product output.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the accumulator, in bits.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the accumulator. This block requires power-of-two slope and a bias of zero.

Output

Choose how you specify the output word length and fraction length:

- When you select `Same as input`, these characteristics match those of the input to the block.
- When you select `Same as accumulator`, these characteristics match those of the accumulator.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the output, in bits.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the output. This block requires power-of-two slope and a bias of zero.

Lock scaling against changes by the autoscaling tool

Select this check box to prevent any fixed-point scaling you specify in the block mask from being overridden by the autoscaling tool in the Fixed-Point Tool.

Supported Data Type

Port	Supported Data Types
In	• Double-precision floating point • Single-precision floating point • Fixed-point
Out	• Double-precision floating point • Single-precision floating point • Signed fixed-point

Examples

If **Pulse length** is 4 and **Pulse delay** is the scalar 3, then the table below shows how the block treats the beginning of a ramp (1, 2, 3,...) in several situations. (The values shown in the table do not reflect vector sizes but merely indicate numerical values.)

Normalization Method, If Any	Linear Amplitude Gain	First Several Output Values
None (**Normalize output signal** cleared)	1	0, 0, 0, 1, 1, 1, 1, 2, 2, 2, 2, 3, 3, 3, 3,...
None (**Normalize output signal** cleared)	10	0, 0, 0, 10, 10, 10, 10, 20, 20, 20, 20, 30, 30, 30, 30,...
Sum of samples	1	0, 0, 0, 0.25, 0.25, 0.25, 0.25, 0.5, 0.5, 0.5, 0.5, 0.75, 0.75, 0.75, 0.75,..., where 0.25*4=1
Sum of samples	10	0, 0, 0, 2.5, 2.5, 2.5, 2.5, 5, 5, 5, 5, 7.5, 7.5, 7.5, 7.5, ...
Energy per pulse	1	0, 0, 0, 0.5, 0.5, 0.5, 0.5, 1.0, 1.0, 1.0, 1.0, 1.5, 1.5, 1.5, 1.5,..., where (0.5)^2*4=1^2
Energy per pulse	10	0, 0, 0, 5, 5, 5, 5, 10, 10, 10, 10, 15, 15, 15, 15,...

Insert Zero

(To be removed) Distribute input elements in output vector

Note will be removed in a future release. Use MATLAB® code in a MATLAB Function block instead. For more information, see “Compatibility Considerations”.

Library

Sequence Operations

Description

The Insert Zero block constructs an output vector by inserting zeros among the elements of the input vector. The input signal can be real or complex. Both the input signal and the **Insert zero vector** parameter are column vector signals. The number of 1s in the **Insert zero vector** parameter must be evenly divisible by the input data length. If the input vector length is greater than the number of 1s in the **Insert zero vector** parameter, then the block repeats the insertion pattern until it has placed all input elements in the output vector.

The block determines where to place the zeros by using the **Insert zero vector** parameter.

- For each 1 the block places the *next* element of the input vector in the output vector
- For each 0 the block places a 0 in the output vector

The block accepts the following data types: `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, `double`, and fixed-point. The output signal inherits its data type from the input signal.

To implement punctured coding using the Puncture and Insert Zero blocks, use the same vector for the **Insert zero vector** parameter in this block and for the **Puncture vector** parameter in the Puncture block.

Parameters

Insert zero vector

A binary vector with a pattern of 0s and 1s that indicate where the block places either 0s or input vector elements in the output vector.

Compatibility Considerations

Insert Zero will be removed

Not recommended starting in R2020a

- Insert Zero will be removed in a future release. Use MATLAB code in a MATLAB Function block instead.
- This code can be used in a MATLAB Function block to insert zeros into a data stream.

  ```
  function y = fcn(u,insertZeroVector)
      numSeg = length(u)/sum(insertZeroVector);
      c = zeros(length(insertZeroVector), numSeg,'like',u);
      c(logical(insertZeroVector),:) = reshape(u,[],numSeg);
      y = c(:);
  end
  ```

  As with Insert Zero, the input length must be an integer multiple of the number of ones in the **Insert zero vector** parameter.
- For an example using this code, see “Insert Zeros into a Random Number Stream”.

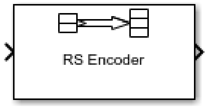
Integer-Input RS Encoder

Create Reed-Solomon code from integer vector data

Library: Communications Toolbox / Error Detection and Correction / Block



Description

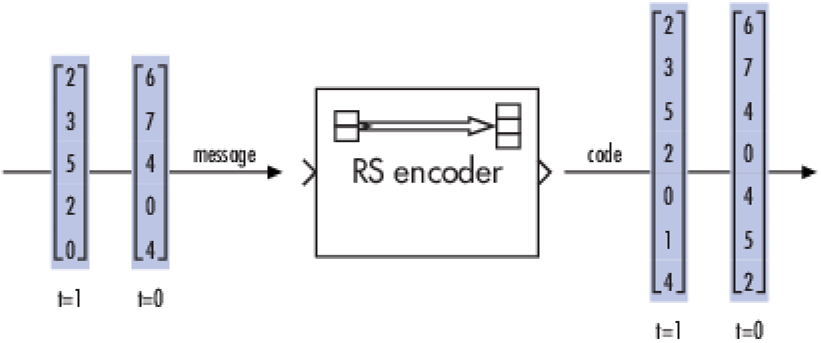
The Integer-Input RS Encoder block creates a Reed-Solomon code.

The symbols for the code are integers between 0 and 2^M-1, which represent elements of the finite field $GF(2^M)$. The default value of M is the smallest integer that is greater than or equal to log2(N+1), that is, `ceil(log2(N+1))`. You can change the default value of M by specifying the primitive polynomial for $GF(2^M)$, as described in “Specify the Primitive Polynomial” on page 5-389 below. Restrictions on M and N are described in “Restrictions on M and the Codeword Length N” on page 5-389.

The input and output are integer-valued signals that represent messages and codewords, respectively. For more information, see “Input and Output Signal Length in RS Blocks” on page 5-388.

An (N, K) Reed-Solomon code can correct up to `floor((N-K)/2)` symbol errors (not bit errors) in each codeword.

Suppose M = 3, N = 2^3-1 = 7, and K = 5. Then a message is a vector of length 5 whose entries are integers between 0 and 7. A corresponding codeword is a vector of length 7 whose entries are integers between 0 and 7. The following figure illustrates possible input and output signals to this block when **Codeword length N** is set to `7`, **Message length K** is set to `5`, and the default primitive and generator polynomials are used.



Ports

Input

In — Message
integer column vector

Message, specified as one of the following:

- When there is no message shortening, a (N_C×K)-by-1 integer column vector.
- When there is message shortening, a (N_C×S)-by-1 integer column vector.

N_C is the number of message words, K is the **Message length K**, and S is the **Shortened message length S**.

Note The number of decoded message words equals the number of codewords.

For more information, see “Input and Output Signal Length in RS Blocks” on page 5-388.

Data Types: `single` | `double` | `int8` | `int16` | `int32` | `uint8` | `uint16` | `uint32`

Output

`Out` — Reed-Solomon codeword

integer column vector

Reed-Solomon codeword, returned as an (N_C×(N – K + S – P)-by-1 integer column vector. N_C is the number of codewords, N is the **Codeword length N**, K is the **Message length K**, S is the **Shortened message length S**, P is the number of punctures per codeword.

For more information, see “Input and Output Signal Length in RS Blocks” on page 5-388.

Data Types: `single` | `double` | `int8` | `int16` | `int32` | `uint8` | `uint16` | `uint32`

For more information, see “Supported Data Types” on page 5-390.

Parameters

`Codeword length N` — Codeword length

7 (default) | integer

Codeword length, specified as an integer.

For more information, see “Restrictions on M and the Codeword Length N” on page 5-389 and “Input and Output Signal Length in RS Blocks” on page 5-388.

`Message length K` — Message word length

3 (default) | integer

Message word length, specified as an integer in the range [1, N–2], where N is the codeword length.

`Shortened message length S` — Shortened message word length

3 (default) | integer

Shortened message word length, specified as an integer, such that $S \leq K$. When **Shortened message length S < Message length K**, the Reed-Solomon code is shortened.

You still specify N and K values for the full-length (N, K) code but the decoding is shortened to an (N–K+S, S) code.

Dependencies

To enable this parameter, select **Specify shortened message length**.

`Generator polynomial` — Generator polynomial

`rsgenpoly(7, 3, [], [], 'double')` (default) | polynomial character vector | binary row vector | binary Galois row vector

Generator polynomial with values in the range [0 to 2^M–1], in order of descending power, specified as one of the following:

- A polynomial character vector. For more information, see “Character Representation of Polynomials”.
- An integer row vector that represents the coefficients of the generator polynomial in order of descending power.
- An integer Galois row vector that represents the coefficients of the generator polynomial in order of descending power.

Each coefficient is an element of the Galois field defined by the primitive polynomial. For more information, see “Specify the Generator Polynomial” on page 5-389.

Example: `[1 3 1 2 3]`, which is equivalent to `rsgenpoly(7,3)`

Dependencies

To enable this parameter, select **Specify generator polynomial**.

`Primitive polynomial` — Primitive polynomial

`'X^3 + X + 1'` (default) | polynomial character vector | binary row vector

Primitive polynomial in order of descending power. This polynomial is of order *M* and defines the finite Galois field GF(2^M) corresponding to the integers that form message words and codewords. Specify the primitive polynomial as one of the following:

- A polynomial character vector. For more information, see “Character Representation of Polynomials”.
- A binary row vector that represents the coefficients of the generator polynomial.

For more information, see “Specify the Primitive Polynomial” on page 5-389.

Example: `'X^3 + X + 1'`, which is the primitive polynomial used for a (7,3) code, `de2bi(primpoly(3,'nodisplay'),'left-msb')`

Dependencies

To enable this parameter, select **Specify primitive polynomial**.

`Puncture vector` — Puncture vector

`[ones(2,1); zeros(2,1)]` (default) | binary column vector

Puncture vector, specified as an (*N*–*K*)-by-1 binary column vector. Element indices with `1`s represent data symbol indices that pass through the block unaltered. Element indices with `0`s represent data symbol indices that get punctured, or removed, from the data stream. For more information, see “Puncturing and Erasures” on page 5-390.

Note If the encoder is processing multiple codewords per frame, then the same puncture pattern holds for all codewords.

Dependencies

To enable this parameter, select **Puncture code**.

Block Characteristics

Data Types	`double` | `integer` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`no`

More About

Input and Output Signal Length in RS Blocks

The Reed-Solomon code has a message word length, K, or shortened message word length, S. The codeword length is $N - K + S - P$, where N is the full codeword length and P is the number of punctures per codeword. When there is no message shortening, the codeword length expression reduces to $N - P$, because $K = S$. If the decoder is processing multiple codewords per frame, then the same puncture pattern holds for all codewords.

This table provides expressions for the input and output signal lengths for the Reed-Solomon encoder and decoder.

The notation $y = N_C \times x$ denotes that y is an integer multiple of x.

	Input, Erasure, and Output Vector Lengths	
RS Block Coder	**No Message Shortening Used**	**Message Shortening Used**

Integer-Input RS Encoder	**Input Length (symbols):**
	$N_C \times K$
	Output Length (symbols):
	$N_C \times (N–P)$
		Input Length (symbols):
		$N_C \times S$
		Output Length (symbols):
		$N_C \times (N–K+S–P)$

Integer-Output RS Decoder	**Input Length (symbols):**
	$N_C \times (N–P)$
	Erasures Length (symbols):
	$N_C \times (N–P)$
	Output Length (symbols):
	$N_C \times K$
		Input Length (symbols):
		$N_C \times (N–K+S–P)$
		Erasures Length (symbols):
		$N_C \times (N–K+S–P)$
		Output Length (symbols):
		$N_C \times S$

- *N* is the codeword length.
- *K* is the message word length.
- *S* is the shortened message word length.
- N_C is the number of codewords (and message words).
- *P* is the number of punctures, and is equal to the number of zeros in the puncture vector.
- *M* is the degree of the primitive polynomial. Each group of *M* bits represents an integer between `0` and $2^M–1$ that belongs to the finite Galois field `GF(`2^M`)`.

For more information on representing data for Reed-Solomon codes, see “Integer Format (Reed-Solomon Only)”.

Restrictions on M and the Codeword Length N

- If you do not select **Specify primitive polynomial**, valid values for the codeword length, *N*, are from 7 to 65535. In this case, the block uses the default primitive polynomial of degree `M = ceil(log2(N+1))`. You can display the default primitive polynomial by running `primpoly(ceil(log2(N+1)))`.
- If you select **Specify primitive polynomial**, valid values for the primitive polynomial degree, *M*, are from 3 to 16. The valid values for *N* in this case are from 7 to $2^M–1$. Selecting **Specify primitive polynomial** enables you to specify the primitive polynomial that defines the finite field $GF(2^M)$, which corresponds to the values that form message words and codewords.

Specify the Primitive Polynomial

You can specify the primitive polynomial that defines the finite field $GF(2^M)$, corresponding to the integers that form messages and codewords. To do so, first select **Specify primitive polynomial**. Then, in the **Primitive polynomial** text box, enter a binary row vector that represents a primitive polynomial over $GF(2^M)$, in descending order of powers. For example, to specify the polynomial x^3+x+1, enter the vector `[1 0 1 1]`.

If you do not select **Specify primitive polynomial**, the block uses the default primitive polynomial of degree M = ceil(log2(N+1)). You can display the default polynomial by entering `primpoly(ceil(log2(N+1)))` at the MATLAB prompt.

Specify the Generator Polynomial

Select **Specify generator polynomial** to enable the **Generator polynomial** parameter for specifying the generator polynomial of the Reed-Solomon code. Enter an integer row vector with element values from 0 to 2^M-1. The vector represents a polynomial, in descending order of powers, whose coefficients are elements of $GF(2^M)$ represented in integer format. For more information about integer and binary format, see “Integer Format (Reed-Solomon Only)”. The generator polynomial must be equal to a polynomial with this factored form:

$$g(x) = (x+\alpha^{b})(x+\alpha^{b+1})(x+\alpha^{b+2})...(x+\alpha^{b+N-K-1})$$

α is the primitive element of the Galois field over which the input message is defined, and *b* is an integer.

If you do not select **Specify generator polynomial**, the block uses the default generator polynomial, corresponding to *b*=1, for Reed-Solomon encoding. You can display the default generator polynomial by running `rsgenpoly`.

- If you are using the default primitive polynomial (**Specify primitive polynomial** is not selected), the default generator polynomial is `rsgenpoly(N,K)`, where `N = 2`^{M}`-1`.
- If you are not using the default primitive polynomial (**Specify primitive polynomial** is selected) and you specify the primitive polynomial as `poly`, the generator polynomial is `rsgenpoly(N,K,poly)`.

Note The degree of the generator polynomial is $N - K$, where N is the codeword length and K is the message word length.

Puncturing and Erasures

`1`s and `0`s have precisely opposite meanings for the puncture and erasure vectors.

In a puncture vector,

- `1` means that the data symbol is passed through the block unaltered.
- `0` means that the data symbol is to be punctured, or removed, from the data stream.

In an erasure vector,

- `1` means that the data symbol is to be replaced with an erasure symbol.
- `0` means that the data symbol is passed through the block unaltered.

These conventions apply to both the encoder and the decoder. For more information, see “Shortening, Puncturing, and Erasures”.

Supported Data Types

Port	Supported Data Types
In	• Double-precision floating point • Single-precision floating point • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers
Out	• Double-precision floating point • Single-precision floating point • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers

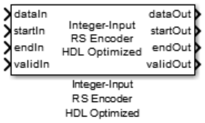
Integer-Input RS Encoder HDL Optimized

Encode data using a Reed-Solomon encoder

Library: Communications Toolbox HDL Support / Error Detection and Correction / Block
Communications Toolbox / Error Detection and Correction / Block



Description

The Integer-Input RS Encoder HDL Optimized decodes data using the RS encoder. The RS encoding follows the same standards as any other cyclic redundancy code. Use this block to model communications system forward error correction (FEC) codes.

For more about the RS encoder, see the Integer-Input RS Encoder block. For more information on representing data for RS codes, see “Integer Format (Reed-Solomon Only)”.

Ports

Input

`dataIn` — Input data
scalar

Input data, specified as a scalar representing one symbol. For binary point scaling, the input data type must be an integer or `fixdt`. The word length of each symbol must be equal to `ceil`($\log_2$(**Codeword length (N)**) + 1. The `double` data type is allowed for simulation, but not for HDL code generation.

Data Types: `double` | `int8` | `int16` | `int32` | `int64` | `fixed point`

`startIn` — Start of input frame indicator
scalar

Start of input frame indicator, specified as a Boolean scalar.

Data Types: `Boolean`

`endIn` — End of input frame indicator
scalar

End of input frame indicator, specified as a Boolean scalar.

Data Types: `Boolean`

`validIn` — Valid input data indicator
scalar

Valid input data indicator, specified as a Boolean scalar.

This is a control signal that indicates if the data on the **dataIn** port is valid.

Data Types: `Boolean`

Output

`dataOut` — Output data
scalar

Output data, returned as a scalar. This output data width is the same size as the input data.

Data Types: `double` | `int8` | `int16` | `int32` | `int64` | `fixed point`

`startOut` — Start of output frame indicator
scalar

Start of output frame indicator, returned as a Boolean scalar.

Data Types: `Boolean`

`endOut` — End of output frame indicator
scalar

End of output frame indicator, returned as a Boolean scalar.

Data Types: `Boolean`

`validOut` — Valid output data indicator
scalar

Valid output data indicator, returned as a Boolean scalar.

This is a control signal that indicates if the data on the **dataOut** port is valid.

Data Types: `Boolean`

Parameters

`Codeword length` — Length of codeword
`7` (default) | range from 7 to 65, 535

Specify the codeword length.

The codeword length `N` must be an integer equal to 2^M – 1, where M is an integer in the range from 3 to 16. For more information on representing data for RS codes, see “Integer Format (Reed-Solomon Only)”.

`Message length` — Length of message
`3` (default) | positive integer

Specify the length of the message.

For more information on representing data for RS codes, see “Integer Format (Reed-Solomon Only)”.

Each input frame, that is, the number of valid data samples between **startIn** and **endIn** port values, must contain more than *N*– *K* symbols and less than or equal to *K* symbols. A shortened code is inferred anytime the number of input data samples in a frame is less than *K*.

`Source of primitive polynomial` — Primitive polynomial source

`Auto` (default) | `Property`

Specify the source of the primitive polynomial.

- Select `Auto` to specify the primitive polynomial based on the **Codeword length (N)** parameter value. The degree of the primitive polynomial is calculated as *M* = `ceil`($\log_2$(**Codeword length (N)**). .
- Select `Property` to specify the primitive polynomial using the **Primitive polynomial** parameter.

`Primitive polynomial` — Primitive polynomial provider

`[ 1 0 1 1 ]` (default) | binary row vector

Specify a binary row vector representing the primitive polynomial in descending order of powers.

For more information on how to specify a primitive polynomial, see “Primitive Polynomials and Element Representations”.

Dependencies

To enable this parameter, set the **Source of primitive polynomial** parameter to `Property`.

`Source of puncture pattern` — Puncture pattern source

`None` (default) | `Property`

Select `Property` to enable the **Puncture pattern vector** parameter.

`Puncture pattern vector` — Puncture vector

`[ones(2,1); zeros(2,1)]` (default) | binary column vector

Specify a column vector of length *N*– *K*. In a puncture vector, a value of `1` represents that the data symbol passes unaltered. A value of `0` represents that the data symbol is punctured, or removed, from the data stream.

Dependencies

To enable this parameter, set the **Source of puncture pattern** parameter to `Property`.

`Source of B, the starting power for roots of the primitive polynomial` — Starting power for roots of primitive polynomial

`Auto` (default) | `Property`

Specify the source of the starting power for roots of the primitive polynomial.

- Select `Property` to enable the **B value** parameter.
- Select `Auto`, to use the **B value** parameter default value of `1`.

`B value` — Starting exponent of roots

`1` (default) | positive integer

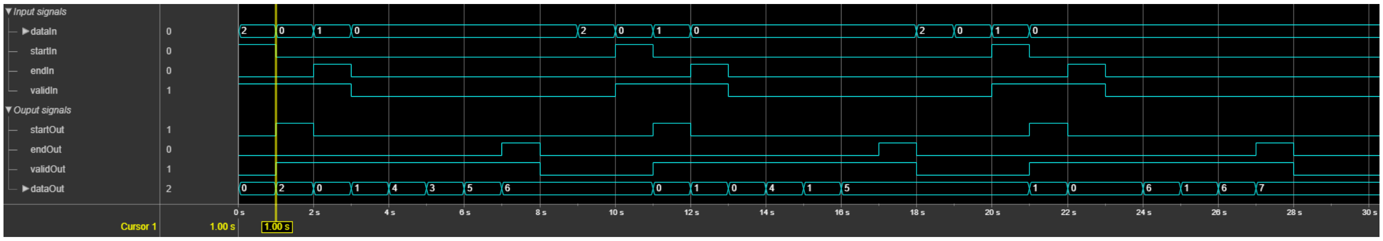
The starting exponent of the roots.

Dependencies

To enable this parameter, set the **Source of B, the starting power for roots of the primitive polynomial** parameter to `Property`.

Algorithms

This figure shows a sample output of the Integer-Input RS Encoder HDL Optimized block with a default configuration.



Extended Capabilities

C/C++ Code Generation

Generate C and C++ code using Simulink® Coder™.

Not recommended for production code.

HDL Code Generation

Generate Verilog and VHDL code for FPGA and ASIC designs using HDL Coder™.

HDL Coder provides additional configuration options that affect HDL implementation and synthesized logic.

HDL Architecture

This block has a single, default HDL architecture.

HDL Block Properties

ConstrainedOutputPipeline	Number of registers to place at the outputs by moving existing delays within your design. Distributed pipelining does not redistribute these registers. The default is `0`. For more details, see “ConstrainedOutputPipeline” (HDL Coder).
InputPipeline	Number of input pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see “InputPipeline” (HDL Coder).
OutputPipeline	Number of output pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see “OutputPipeline” (HDL Coder).

Restrictions

- You cannot generate HDL for this block inside a Resettable Synchronous Subsystem.

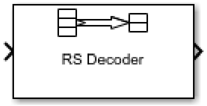
Integer-Output RS Decoder

Decode Reed-Solomon code to recover integer vector data

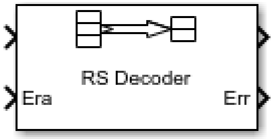
Library: Communications Toolbox / Error Detection and Correction / Block



Description

The Integer-Output RS Decoder block recovers a message vector from a Reed-Solomon codeword vector. For proper decoding, the parameter values in this block must match those in the corresponding Integer-Input RS Encoder block.

The Reed-Solomon code has message length *K*, and codeword length *N* – *number of punctures*. You specify *N* and *K* directly in the block dialog. The symbols for the code are integers in the range [0, 2^{M}-1], which represent elements of the finite field *GF*(2^{M}). Restrictions on *M* and *N* are described in “Restrictions on the M and the Codeword Length N” on page 5-402 below.



This icon shows optional ports.

The input and output are integer-valued signals that represent codewords and messages, respectively. For more information, see “Input and Output Signal Length in RS Blocks” on page 5-401. The block inherits the output data type from the input data type. For information about the data types each block port supports, see “Supported Data Types” on page 5-403.

For more information on representing data for Reed-Solomon codes, see the section “Integer Format (Reed-Solomon Only)”.

If the decoder is processing multiple codewords per frame, then the same puncture pattern holds for all codewords.

The default value of M is `ceil(log2(N+1))`, that is, the smallest integer greater than or equal to log2(N+1). You can change the value of M from the default by specifying the primitive polynomial for GF(2^{M}), as described in “Specify the Primitive Polynomial” on page 5-402 below.

You can also specify the generator polynomial for the Reed-Solomon code, as described in “Specify the Generator Polynomial” on page 5-402.

An (*N*, *K*) Reed-Solomon code can correct up to `floor((N-K)/2)` symbol errors (*not* bit errors) in each codeword.

If decoding fails, the message portion of the decoder input is returned unchanged as the decoder output.

The sample times of the input and output signals are equal.

Ports

Input

`In` — Reed-Solomon codeword
integer column vector

Reed-Solomon codeword, specified as an (N_C×(N – K + S – P)-by-1 integer column vector. N_C is the number of codewords, N is the **Codeword length N**, K is the **Message length K**, S is the **Shortened message length S**, P is the number of punctures per codeword.

For more information, see “Input and Output Signal Length in RS Blocks” on page 5-401.

Data Types: `single` | `double` | `integer`

`Era` — Erasure vector
binary column vector

Erasure vector, specified as a binary column vector input signal with the same size as the input Reed-Solomon codeword.

Erasure values of 1 correspond to erased bits in the same position in the codeword. Values of 0 correspond to bits that are not erased. For more information, see “Puncturing and Erasures” on page 5-403.

Dependencies

To enable this port, select **Enable erasures input port**.

Data Types: `double` | `Boolean`

Output

`Out` — Decoded message
integer column vector

Decoded message, returned as one of the following:

- When there is no message shortening, a (N_C×K)-by-1 integer column vector.
- When there is message shortening, a (N_C×S)-by-1 integer column vector.

N_C is the number of message words, K is the **Message length K (symbols)**, and S is the **Shortened message length S (symbols)**.

Note The number of decoded message words equals the number of codewords.

For more information, see “Input and Output Signal Length in RS Blocks” on page 5-401.

`Err` — Decoding errors
integer vector

Symbol decoding errors, returned as an integer vector with N_C elements, where N_C is the number of codewords. This port indicates the number of symbol errors detected during decoding of each codeword. A negative integer indicates that the block detected more errors than it could correct by using the specified coding scheme.

Note An (*N*,*K*) Reed-Solomon code can correct up to `floor((N-K)/2)` symbol errors (not bit errors) in each codeword. When a received codeword contains more than (*N*-*K*)/2 symbol errors, a decoding failure occurs.

Dependencies

To enable this port, select **Output number of corrected symbol errors**.

Data Types: `double`

For more information, see “Supported Data Types” on page 5-403.

Parameters

`Codeword length N` — Codeword length

7 (default) | integer

Codeword length, specified as an integer.

For more information, see“Restrictions on the M and the Codeword Length N” on page 5-402 and “Input and Output Signal Length in RS Blocks” on page 5-401.

`Message length K` — Message word length

3 (default) | integer

Message word length, specified as an integer in the range [1, *N*–2], where *N* is the codeword length.

`Shortened message length S` — Shortened message word length

3 (default) | integer

Shortened message word length, specified as an integer, such that $S \leq K$. When **Shortened message length S < Message length K**, the Reed-Solomon code is shortened.

You still specify *N* and *K* values for the full-length (*N*, *K*) code but the decoding is shortened to an (*N*–*K*+*S*, *S*) code.

Dependencies

To enable this parameter, select **Specify shortened message length**.

`Generator polynomial` — Generator polynomial

`rsgenpoly(7, 3, [], [], 'double')` (default) | polynomial character vector | binary row vector | binary Galois row vector

Generator polynomial with values in the range [0, 2^M–1], in order of descending power, specified as one of the following:

- A polynomial character vector. For more information, see “Character Representation of Polynomials”.
- An integer row vector that represents the coefficients of the generator polynomial in order of descending power.

- An integer Galois row vector that represents the coefficients of the generator polynomial in order of descending power.

Each coefficient is an element of the Galois field defined by the primitive polynomial. For more information, see “Specify the Generator Polynomial” on page 5-389.

Example: `[1 3 1 2 3]`, which is equivalent to `rsgenpoly(7,3)`

Dependencies

To enable this parameter, select **Specify generator polynomial**.

`Primitive polynomial` — Primitive polynomial

`'X^3 + X + 1'` (default) | polynomial character vector | binary row vector

Primitive polynomial in order of descending power. This polynomial is of order *M* and defines the finite Galois field GF(2^M) corresponding to the integers that form message words and codewords. Specify the primitive polynomial as one of the following:

- A polynomial character vector. For more information, see “Character Representation of Polynomials”.
- A binary row vector that represents the coefficients of the generator polynomial.

For more information, see “Specify the Primitive Polynomial” on page 5-389.

Example: `'X^3 + X + 1'`, which is the primitive polynomial used for a (7,3) code, `de2bi(primpoly(3,'nodisplay'),'left-msb')`

Dependencies

To enable this parameter, select **Specify primitive polynomial**.

`Puncture vector` — Puncture vector

`[ones(2,1); zeros(2,1)]` (default) | binary column vector

Puncture vector, specified as an (*N*–*K*)-by-1 binary column vector. Element indices with `1`s represent data symbol indices that pass through the block unaltered. Element indices with `0`s represent data symbol indices that get punctured, or removed, from the data stream. For more information, see “Puncturing and Erasures” on page 5-403.

Note If the encoder is processing multiple codewords per frame, then the same puncture pattern holds for all codewords.

Dependencies

To enable this parameter, select **Puncture code**.

`Enable erasures input port` — Enable erasures input port

off (default) | on

Selecting this check box enables the erasures port, **Era**. For more information, see “Puncturing and Erasures” on page 5-403.

`Output number of corrected symbol errors` — Enable port to output number of corrected symbol errors

off (default) | on

Selecting this check box enables an additional output port, **Err**, which indicates the number of symbol errors the block corrected in the input codeword.

Block Characteristics

Data Types	`double` | `integer` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`no`

More About

Input and Output Signal Length in RS Blocks

The Reed-Solomon code has a message word length, *K*, or shortened message word length, *S*. The codeword length is $N – K + S – P$, where *N* is the full codeword length and *P* is the number of punctures per codeword. When there is no message shortening, the codeword length expression reduces to $N – P$, because $K = S$. If the decoder is processing multiple codewords per frame, then the same puncture pattern holds for all codewords.

This table provides expressions for the input and output signal lengths for the Reed-Solomon encoder and decoder.

The notation $y = N_C \times x$ denotes that *y* is an integer multiple of *x*.

	Input, Erasure, and Output Vector Lengths	
RS Block Coder	**No Message Shortening Used**	**Message Shortening Used**

Integer-Input RS Encoder	**Input Length (symbols):**
	$N_C \times K$
	Output Length (symbols):
	$N_C \times (N–P)$
		Input Length (symbols):
		$N_C \times S$
		Output Length (symbols):
		$N_C \times (N–K+S–P)$

Integer-Output RS Decoder	**Input Length (symbols):**
	$N_C \times (N–P)$
	Erasures Length (symbols):
	$N_C \times (N–P)$
	Output Length (symbols):
	$N_C \times K$
		Input Length (symbols):
		$N_C \times (N–K+S–P)$
		Erasures Length (symbols):
		$N_C \times (N–K+S–P)$
		Output Length (symbols):
		$N_C \times S$

- *N* is the codeword length.

- *K* is the message word length.
- *S* is the shortened message word length.
- N_C is the number of codewords (and message words).
- *P* is the number of punctures, and is equal to the number of zeros in the puncture vector.
- *M* is the degree of the primitive polynomial. Each group of *M* bits represents an integer between `0` and `2`^{M}`–1` that belongs to the finite Galois field `GF(2`^{M}`)`.

For more information on representing data for Reed-Solomon codes, see "Integer Format (Reed-Solomon Only)".

Restrictions on the M and the Codeword Length N

- If you do not select **Specify primitive polynomial**, valid values for the codeword length, *N*, are from 7 to 65535. In this case, the block uses the default primitive polynomial of degree `M = ceil(log2(N+1))`. You can display the default primitive polynomial by running `primpoly(ceil(log2(N+1)))`.
- If you select **Specify primitive polynomial**, valid values for the primitive polynomial degree, *M*, are from 3 to 16. The valid values for *N* in this case are from 7 to 2^{M}–1. Selecting **Specify primitive polynomial** enables you to specify the primitive polynomial that defines the finite field *GF*(2^{M}), which corresponds to the values that form message words and codewords.

Specify the Primitive Polynomial

You can specify the primitive polynomial that defines the finite field *GF*(2^{M}), corresponding to the integers that form messages and codewords. To do so, first select **Specify primitive polynomial**. Then, in the **Primitive polynomial** text box, enter a binary row vector that represents a primitive polynomial over *GF*(2^{M}), in descending order of powers. For example, to specify the polynomial x^3+x +1, enter the vector `[1 0 1 1]`.

If you do not select **Specify primitive polynomial**, the block uses the default primitive polynomial of degree M = ceil(log2(N+1)). You can display the default polynomial by entering `primpoly(ceil(log2(N+1)))` at the MATLAB prompt.

Specify the Generator Polynomial

Select **Specify generator polynomial** to enable the **Generator polynomial** parameter for specifying the generator polynomial of the Reed-Solomon code. Enter an integer row vector with element values from 0 to 2^{M}-1. The vector represents a polynomial, in descending order of powers, whose coefficients are elements of *GF*(2^{M}) represented in integer format. For more information about integer and binary format, see "Integer Format (Reed-Solomon Only)". The generator polynomial must be equal to a polynomial with this factored form:

$$g(x) = (x+\alpha^{b})(x+\alpha^{b+1})(x+\alpha^{b+2})...(x+\alpha^{b+N-K-1})$$

α is the primitive element of the Galois field over which the input message is defined, and *b* is an integer.

If you do not select **Specify generator polynomial**, the block uses the default generator polynomial, corresponding to *b*=1, for Reed-Solomon encoding. You can display the default generator polynomial by running `rsgenpoly`.

- If you are using the default primitive polynomial (**Specify primitive polynomial** is not selected), the default generator polynomial is `rsgenpoly(N,K)`, where `N = 2`^{M}`-1`.

- If you are not using the default primitive polynomial (**Specify primitive polynomial** is selected) and you specify the primitive polynomial as `poly`, the generator polynomial is `rsgenpoly(N,K,poly)`.

Note The degree of the generator polynomial is $N - K$, where N is the codeword length and K is the message word length.

Puncturing and Erasures

`1`s and `0`s have precisely opposite meanings for the puncture and erasure vectors.

In a puncture vector,

- `1` means that the data symbol is passed through the block unaltered.
- `0` means that the data symbol is to be punctured, or removed, from the data stream.

In an erasure vector,

- `1` means that the data symbol is to be replaced with an erasure symbol.
- `0` means that the data symbol is passed through the block unaltered.

These conventions apply to both the encoder and the decoder. For more information, see “Shortening, Puncturing, and Erasures”.

Supported Data Types

Port	Supported Data Types
In	• Double-precision floating point • Single-precision floating point • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers
Out	• Double-precision floating point • Single-precision floating point • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers
Era	• Double-precision floating point • Boolean
Err	• Double-precision floating point • Single-precision floating point • 8-, 16-, and 32-bit signed integers • If the input is uint8, uint16, or uint32, then the number of errors output datatype is int8, int16, or int32, respectively.

Pair Block

Integer-Input RS Encoder

Algorithms

This block uses the Berlekamp-Massey decoding algorithm. For information about this algorithm, see “Algorithms for BCH and RS Errors-only Decoding”.

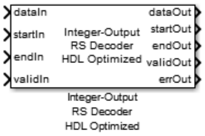
Decode data using Reed-Solomon (RS) decoder

Library: Communications Toolbox HDL Support / Error Detection and Correction / Block
Communications Toolbox / Error Detection and Correction / Block



Description

The Integer-Output RS Decoder HDL Optimized decodes data using RS decoder. The RS decoding follows the same standards as any other cyclic redundancy code. Use this block to model communications system forward error correction (FEC) codes.

For more information about the RS decoder, see the Integer-Output RS Decoder block. For more information on representing data for RS codes, see “Integer Format (Reed-Solomon Only)”.

Ports

Input

`dataIn` — Input data
scalar

Input data, specified as a scalar representing one symbol. For binary point scaling, the input data type must be an integer or `fixdt`. The `double` data type is allowed for simulation, but not for HDL code generation.

Data Types: `double` | `int8` | `int16` | `int32` | `int64` | `fixed point`

`startIn` — Start of input frame indicator
scalar

Start of input frame indicator, specified as a Boolean scalar.

Data Types: `Boolean`

`endIn` — End of input frame indicator
scalar

End of input frame indicator, specified as a Boolean scalar.

Data Types: `Boolean`

`validIn` — Valid input data indicator
scalar

Valid input data indicator, specified as a Boolean scalar.

This is a control signal that indicates if the data on the **dataIn** port is valid.

Data Types: `Boolean`

Output

`dataOut` — Decoded message data
scalar

Decoded message data, returned as a scalar. This output data width is the same size as the input data.

Data Types: `double` | `int8` | `int16` | `int32` | `int64` | `fixed point`

`startOut` — Start of output frame indicator
scalar

Start of output frame indicator, returned as a Boolean scalar.

Data Types: `Boolean`

`endOut` — End of output frame indicator
scalar

End of output frame indicator, returned as a Boolean scalar.

Data Types: `Boolean`

`validOut` — Valid output data indicator
scalar

Valid output data indicator, returned as a Boolean scalar.

This is a control signal that indicates if the data on the **dataOut** port is valid.

Data Types: `Boolean`

`errOut` — Indications of corruption of received data
scalar

Indications of corruption of the received data, returned as a Boolean scalar.

Data Types: `Boolean`

`numErrors` — Number of detected errors
nonnegative scalar

Number of detected errors, returned as a nonnegative scalar.

Dependencies

To enable this port, select the **Output number of corrected symbol errors** parameter.

Data Types: `uint8`

Parameters

`Codeword length` — Length of codeword
7 (default) | range from 7 to 65, 535

Specify the codeword length.

The codeword length N must be an integer equal to 2^M – 1, where M is an integer in the range from 3 to 16. For more information on representing data for RS codes, see “Integer Format (Reed-Solomon Only)”.

Message length — Length of message

3 (default) | positive integer

Specify the length of the message.

For more information on representing data for RS codes, see “Integer Format (Reed-Solomon Only)”.

Source of primitive polynomial — Primitive polynomial source

Auto (default) | Property

Specify the source of the primitive polynomial.

- Select Auto to specify the primitive polynomial based on the **Codeword length (N)** parameter value. The degree of the primitive polynomial is calculated as M = ceil(log$_2$(**Codeword length (N)**). .
- Select Property to specify the primitive polynomial using the **Primitive polynomial** parameter.

Primitive polynomial — Primitive polynomial

[1 0 1 1] (default) | binary row vector

Specify a binary row vector representing the primitive polynomial in descending order of powers.

For more information on how to specify a primitive polynomial, see “Primitive Polynomials and Element Representations”.

Dependencies

To enable this parameter, set the **Source of primitive polynomial** parameter to Property.

Source of B, the starting power for roots of the primitive polynomial — Source of starting power for roots of primitive polynomial

Auto (default) | Property

Specify the source of the starting power for roots of the primitive polynomial.

- Select Property to enable the **B value** parameter.
- Select Auto, to use the **B value** parameter default value of 1.

B value — Starting exponent of roots

1 (default) | positive integer

The starting exponent of the roots.

Dependencies

To enable this parameter, set the **Source of B, the starting power for roots of the primitive polynomial** parameter to Property.

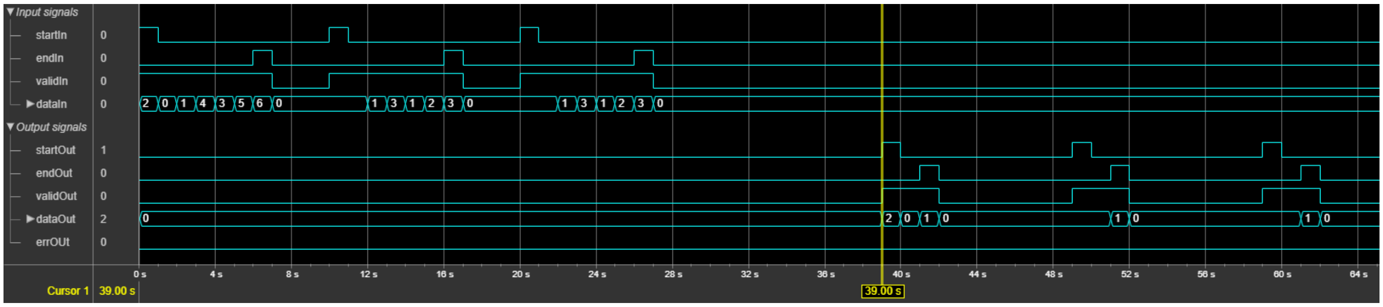
Output number of corrected symbol errors — Number of corrected symbol errors

off (default) | on

Select this parameter to enable the **numErrors** output port. This port outputs the detected symbol error count.

Algorithms

This figure shows a sample output of the Integer-Output RS Decoder HDL Optimized block with a default configuration.



Troubleshooting

- Each input frame must contain more than (*N*– *K*) x 2 symbols and less than or equal to *N* symbols. A shortened code is inferred when the number of valid data samples between **startIn** and **endIn** is less than *N*. A shortened code still requires *N* cycles to perform the Chien search. If the input is less than *N* symbols, leave a guard interval of at least `N-size` inactive cycles before starting the next frame.
- The decoder can operate on up to four messages at a time. If the block receives the start of a fifth message before completely decoding the first message, the block drops data samples from the first message. To avoid this issue, increase the number of inactive cycles between input messages.
- The generator polynomial is not specified explicitly. However, it is defined by the codeword length, message length, and the **B value** for the starting exponent of the roots.

Extended Capabilities

C/C++ Code Generation

Generate C and C++ code using Simulink® Coder™.

Not recommended for production code.

HDL Code Generation

Generate Verilog and VHDL code for FPGA and ASIC designs using HDL Coder™.

HDL Coder provides additional configuration options that affect HDL implementation and synthesized logic.

HDL Architecture

This block has a single, default HDL architecture.

HDL Block Properties

ConstrainedOutputPipeline	Number of registers to place at the outputs by moving existing delays within your design. Distributed pipelining does not redistribute these registers. The default is `0`. For more details, see “ConstrainedOutputPipeline” (HDL Coder).
InputPipeline	Number of input pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see “InputPipeline” (HDL Coder).
OutputPipeline	Number of output pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see “OutputPipeline” (HDL Coder).

Restrictions

- You cannot generate HDL for this block inside a Resettable Synchronous Subsystem.

Introduced in R2012b

Integer to Bit Converter

Map vector of integers to vector of bits
Library: Communications Toolbox / Utility Blocks

Description

The Integer to Bit Converter block maps each integer (or fixed-point value) in the input vector to a group of bits in the output vector.

This block is single-rate and single-channel. The block maps each integer value (or stored integer when you use a fixed point input) to a group of *M* bits, using the selection for the **Output bit order** to determine the most significant bit. The resulting output vector length is *M* times the input vector length.

Ports

Input

`In` — Input signal
integer | integer column vector

Input signal, specified as an integer or a length *N* column vector of integers.

If *M* is specified by the **Number of bits per integer(M)** parameter:

- When the **Number of bits per integer** parameter is set to `Unsigned`, input values must be integers in the range [0, (2^{M} – 1)].
- When the **Number of bits per integer** parameter is set to `Signed`, input values must be integers in the range [(–2^{M-1}), ($2^{M - 1}$ – 1)].

During simulation, the block performs a run-time check and issues an error if any input value is outside of the appropriate range. When the block generates code, it does not perform this run-time check.

Data Types: `double`

Output

`Out` — Output signal
bit scalar | bit column vector

Output signal, returned as a scalar or column vector of bits of length $M \cdot N$.

Parameters

`Number of bits per integer(M)` — Number of bits per integer

3 (default) | integer in the range [1, 32]

Number of input bits mapped to each integer in the input, specified as an integer in the range [1, 32].

`Treat input values as` — Treat input values as

`Unsigned` (default) | `Signed`

Indicate if the integer value input ranges should be treated as signed or unsigned.

`Output bit order` — Output bit order

`MSB first` (default) | `LSB first`

Define whether the first bit of the output signal is the most significant bit (MSB) or the least significant bit (LSB).

`Output data type` — Output data type

`Inherit via internal rule` (default) | `Smallest unsigned integer` | `Same as input` | `double` | `single` | `int8` | `uint8` | `int16` | `uint16` | `int32` | `uint32` | `boolean`

Specify the data type of the output bits. You can choose one of the following **Output data type** options:

- `Inherit via internal rule` –– The block determines the output data type based on the input data type.
  - If the input signal is floating-point (either `single` or `double`), the output data type is the same as the input data type.
  - If the input data type is not floating-point, the output data type is determined as if the parameter is set to `Smallest integer`.
- `Smallest integer` ––The block selects the output data type based on settings used in the “Hardware Implementation Pane” (Simulink) of the Configuration Parameters dialog box.
  - If you select `ASIC/FPGA` for the device vendor, the output data type is the ideal one-bit size (ufix1).
  - For all other device vendor selections, the output data type is an unsigned integer with the smallest available word length, as defined in the Hardware Implementation settings (for example, uint8)
- `Same as input`
- `double`
- `single`
- `uint8`
- `uint16`
- `uint32`

Block Characteristics

Data Types	`Boolean` | `double` | `fixed point`[a] | `integer` | `single`

Multidimensional Signals	`no`
Variable-Size Signals	`yes`

a. ufix(1) only at the output when ASIC/FPGA is selected in the Hardware Implementation Pane.

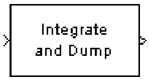
Integrate and Dump

Integrate discrete-time signal, resetting to zero periodically



Library

Comm Filters

Description

The Integrate and Dump block creates a cumulative sum of the discrete-time input signal, while resetting the sum to zero according to a fixed schedule. When the simulation begins, the block discards the number of samples specified in the **Offset** parameter. After this initial period, the block sums the input signal along columns and resets the sum to zero every *N* input samples, where *N* is the **Integration period** parameter value. The reset occurs after the block produces its output at that time step.

Receiver models often use the integrate-and-dump operation when the system's transmitter uses a simple square-pulse model. Fiber optics and in spread-spectrum communication systems, such as CDMA (code division multiple access) applications, also use the operation.

This block accepts a scalar, column vector, or matrix input signal. When the input signal is not a scalar value, it must contain $k \cdot N$ rows for some positive integer *k*. For these input signals, the block processes each column independently.

Selecting **Output intermediate values** affects the contents, dimensions, and sample time as follows:

- If you clear the check box, then the block outputs the cumulative sum at each reset time.
  - If the input is a scalar value, then the output sample time is *N* times the input sample time and the block experiences a delay whose duration is one output sample period. In this case, the output dimensions match the input dimensions.
  - If the input is a ($k \cdot N$)-by-*n* matrix, then the output is *k*-by-*n*. In this case, the block experiences no delay and the output period matches the input period.
- If you select the check box, then the block outputs the cumulative sum at each time step. The output has the same sample time and the same matrix dimensions as the input.

Transients and Delays

A nonzero value in the **Offset** parameter causes the block to output one or more zeros during the initial period while it discards input samples. If the input is a matrix with *n* columns and the **Offset** parameter is a length-*n* vector, then the m^{th} element of the **Offset** vector is the offset for the m^{th} column of data. If **Offset** is a scalar, then the block applies the same offset to each column of data. The output of initial zeros due to a nonzero **Offset** value is a transient effect, not a persistent delay.

When you clear **Output intermediate values**, the block's output is delayed, relative to its input, throughout the simulation:

- If the input is a scalar value, then the output is delayed by one sample after any transient effect is over. That is, after removing transients from the input and output, you can see the result of the *m*th integration period in the output sample indexed by m+1.
- If the input is a column vector or matrix and the **Offset** parameter is nonzero, then after the transient effect is over, the result of each integration period appears in the output frame corresponding to the *last* input sample of that integration period. This is one frame later than the output frame corresponding to the first input sample of that integration period, in cases where an integration period spans two input frames. For an example of this situation, see "Example of Transient and Delay" on page 5-416.

Parameters

Integration period

The number of input samples between resets.

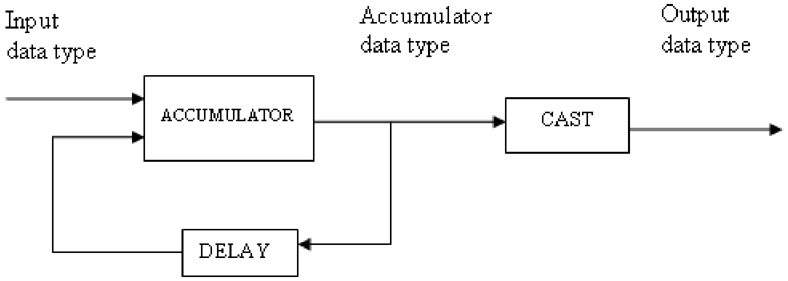
Offset

A nonnegative integer vector or scalar specifying the number of input samples to discard from each column of input data at the beginning of the simulation.

Output intermediate values

Determines whether the block outputs the intermediate cumulative sums between successive resets.

Fixed-Point Signal Flow Diagram



Fixed-Point Attributes

The settings for the following parameters only apply when block inputs are fixed-point signals.

Rounding mode

Use this parameter to specify the rounding method to be used when the result of a fixed-point calculation does not map exactly to a number representable by the data type and scaling storing the result.

For more information, see "Rounding Modes" or "Rounding Mode: Simplest" (Fixed-Point Designer).

Saturate on integer overflow

Use this parameter to specify the method to be used if the magnitude of a fixed-point calculation result does not fit into the range of the data type and scaling that stores the result:

- Saturate represents positive overflows as the largest positive number in the range being used, and negative overflows as the largest negative number in the range being used.
- Wrap uses modulo arithmetic to cast an overflow back into the representable range of the data type. See “Modulo Arithmetic” (Fixed-Point Designer) for more information.

Accumulator—Mode

Use the **Accumulator—Mode** parameter to specify how you would like to designate the accumulator word and fraction lengths:

- When you select `Inherit via internal rule`, the block automatically calculates the accumulator output word and fraction lengths.
- When you select `Same as input`, these characteristics match those of the input to the block.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the accumulator, in bits.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the accumulator.

Output

Use the **Output** parameter to choose how you specify the word length and fraction length of the output of the block:

- When you select `Same as accumulator`, these characteristics match those of the accumulator.
- When you select `Same as input`, these characteristics match those of the input to the block.
- When you select `Binary point scaling`, enter the word length and the fraction length of the output, in bits.
- When you select `Slope and bias scaling`, enter the word length, in bits, and the slope of the output.

For additional information about the parameters pertaining to fixed-point applications, see “Specify Fixed-Point Attributes for Blocks”.

Supported Data Type

Port	Supported Data Types
In	• Double-precision floating point • Single-precision floating point • Fixed-point
Out	• Double-precision floating point • Single-precision floating point • Fixed-point

Examples

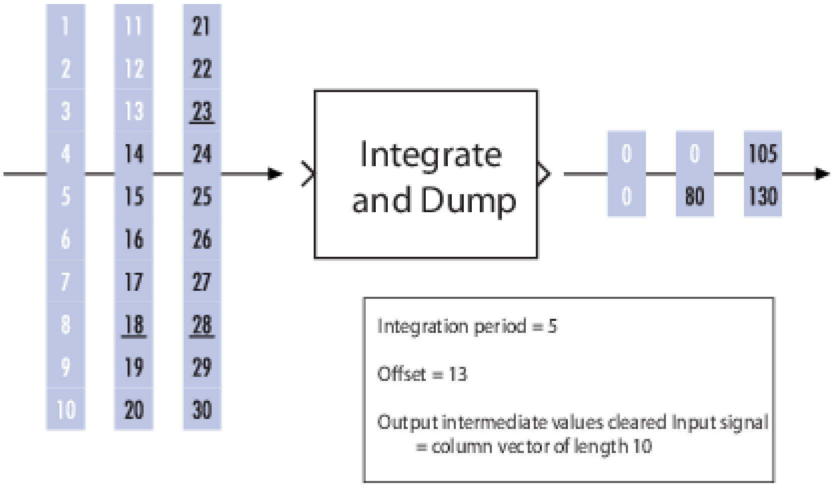
If **Integration period** is 4 and **Offset** is the scalar 3, then the table below shows how the block treats the beginning of a ramp (1, 2, 3, 4,...) in several situations. (The values shown in the table do not reflect vector sizes but merely indicate numerical values.)

Output intermediate values Check Box	Input Signal Properties	First Several Output Values
Cleared	Scalar	0, 0, 4+5+6+7, and 8+9+10+11, where one 0 is an initial transient value and the other 0 is a delay value that results from the cleared check box and scalar value input.
Cleared	Column vector of length 4	0, 4+5+6+7, and 8+9+10+11, where 0 is an initial delay value that results from the nonzero offset. The output is a scalar value.
Selected	Scalar	0, 0, 0, 4, 4+5, 4+5+6, 4+5+6+7, 8, 8+9, 8+9+10, 8+9+10+11, and 12, where the three 0s are initial transient values.
Selected	Column vector of length 4	0, 0, 0, 4, 4+5, 4+5+6, 4+5+6+7, 8, 8+9, 8+9+10, 8+9+10+11, and 12, where the three 0s are initial transient values. The output is a column vector of length 4.

In all cases, the block discards the first three input samples (1, 2, and 3).

Example of Transient and Delay

The figure below illustrates a situation in which the block exhibits both a transient effect for three output samples, as well as a one-sample delay in alternate subsequent output samples for the rest of the simulation. The figure also indicates how the input and output values are organized as column vectors. In each vector in the figure, the last sample of each integration period is underlined, discarded input samples are white, and transient zeros in the output are white.



The transient effect lasts for ceil(13/5) output samples because the block discards 13 input samples and the integration period is 5. The first output sample after the transient effect is over, 80, corresponds to the sum 14+15+16+17+18 and appears at the time of the input sample 18. The next output sample, 105, corresponds to the sum 19+20+21+22+23 and appears at the time of the input sample 23. Notice that the input sample 23 is one frame later than the input sample 19; that is, this five-sample integration period spans two input frames. As a result, the output of 105 is delayed compared to the first input (19) that contributes to that sum.

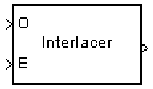
Interlacer

Alternately select elements from two input vectors to generate output vector
Library: Communications Toolbox / Sequence Operations



Description

The Interlacer block accepts two vector with the size, complexity, and sample time. It produces one output vector by alternating elements from the first input (labeled O for odd) and the second input (labeled E for even) .

Ports

Input

O — Odd-numbered elements
vector

Odd-numbered elements, specified as a vector. The complexity of inputs O and E must match.

Data Types: double | single

E — Even-numbered elements
vector

Even-numbered elements, specified as a vector. The complexity of inputs O and E must match.

Data Types: double | single

Output

Out — Output signal
column vector

Output signal, returned as an even length column vector. Odd numbered elements in the output vector contain the elements from input O and even numbered elements in the output vector contain the elements from input E. The output vector has the same data type and sample time as the input.

Block Characteristics

Data Types	Boolean | double | enumerated | fixed point | integer | single

I/Q Imbalance

Apply I/Q imbalances to complex signal
Library: Communications Toolbox / RF Impairments

Description

The I/Q Imbalance block applies in-phase and quadrature imbalances to a complex signal. This block applies an amplitude imbalance, a phase imbalance, and a DC offset to the in-phase and quadrature signal components. For more information, see “I/Q Imbalance Implementation” on page 5-421 and “Algorithms” on page 5-421.

Ports

Input

`In1` — Complex signal
scalar | vector

Complex signal, specified as a scalar or vector.

Data Types: `double` | `single`
Complex Number Support: Yes

Output

`Out1` — Output signal
scalar | vector

Output signal, returned as a scalar or vector. This output is the same dimension and data type as the input signal.

Parameters

`I/Q amplitude imbalance (dB)` — I/Q amplitude imbalance
`0` (default) | scalar

I/Q amplitude imbalance in decibels of signal power, specified as a scalar. For more information, see “Algorithms” on page 5-421.

`I/Q phase imbalance (deg)` — I/Q phase imbalance
`0` (default) | scalar

I/Q amplitude imbalance in degrees, specified as a scalar.

`I dc offset` — In-phase component DC offset
`0` (default) | scalar

In-phase component DC offset, specified as a scalar.

`Q dc offset` — Quadrature component DC offset

`0` (default) | scalar

Quadrature component DC offset, specified as a scalar.

Block Characteristics

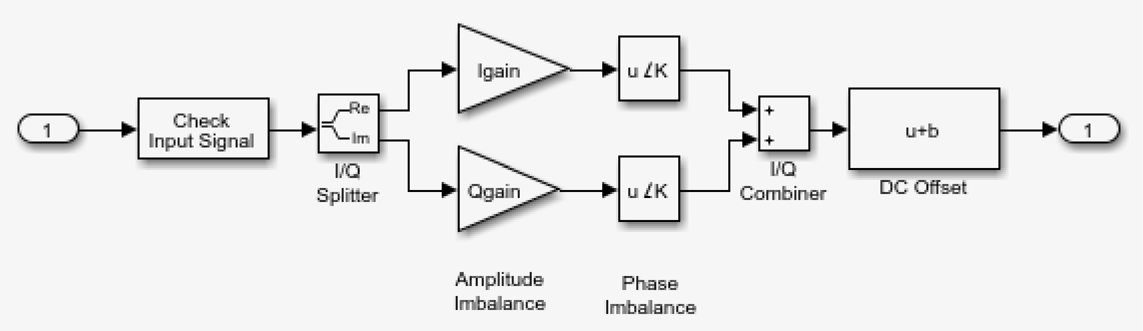
Data Types	`double` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`no`

More About

I/Q Imbalance Implementation

The I/Q Imbalance block applies amplitude imbalance, phase imbalance, and DC offsets to the in-phase and quadrature components of the complex input signal.

The block performs these operations consecutively, as shown by the subsystem in this model diagram. You can view the subsystem by right-clicking the block and selecting **Mask > Look under mask**.



To apply the impairments, the block follows this workflow.

1. Separate the signal into its in-phase and quadrature components.
2. Apply amplitude imbalance, specified by the **I/Q amplitude imbalance (dB)** parameter.
3. Apply phase imbalance, specified by the **I/Q phase imbalance (deg)** parameter.
4. Recombine the in-phase and quadrature components into a complex signal.
5. Apply an in-phase DC offset, specified by the **I dc offset** parameter, and a quadrature DC offset, specified by the **Q dc offset** parameter, to the signal.

For more information, see “Algorithms” on page 5-421.

Algorithms

The I/Q amplitude imbalance, I/Q phase imbalance, and DC offset impairments are described sequentially in the section.

1. For an I/Q amplitude imbalance, I_{a}, the impairment is applied to the input signal, $x_{\mathrm{r}}+\mathrm{j}x_{\mathrm{i}}$ and $y_{\mathrm{AmplitudeImbalance}}$ is an intermediate output.

   $$y_{\mathrm{AmplitudeImbalance}} \triangleq y_{\mathrm{r}_{\mathrm{AmplitudeImbalance}}} + jy_{\mathrm{i}_{\mathrm{AmplitudeImbalance}}}$$

   $$y_{\mathrm{AmplitudeImbalance}} = \left(10^{(0.5I_{\mathrm{a}}/20)}x_{\mathrm{r}}\right) + j\left(10^{(-0.5I_{\mathrm{a}}/20)}x_{\mathrm{i}}\right)$$

2. For an I/Q phase imbalance, I_{p}, the impairment is applied to $y_{\mathrm{AmplitudeImbalance}}$ and $y_{\mathrm{PhaseImbalance}}$ is an intermediate output.

   $$y_{\mathrm{PhaseImbalance}} \triangleq y_{\mathrm{r}_{\mathrm{PhaseImbalance}}} + jy_{\mathrm{i}_{\mathrm{PhaseImbalance}}}$$

   $$y_{\mathrm{PhaseImbalance}} = \left(e\left(j\left(-0.5\pi\frac{Ip}{180}\right)\right)y_{\mathrm{r}_{\mathrm{AmplitudeImbalance}}}\right) + \left(e\left(j\left(\frac{\pi}{2} + 0.5\pi\frac{I\mathrm{p}}{180}\right)\right)y_{\mathrm{r}_{\mathrm{AmplitudeImbalance}}}\right)$$

3. For DC offsets, I_{DC} and Q_{DC}, the impairment is applied to $y_{\mathrm{PhaseImbalance}}$ and y is the final output.

   $$y = (y_{\mathrm{r}_{\mathrm{PhaseImbalance}}} + I_{\mathrm{DC}}) + j(y_{\mathrm{i}_{\mathrm{PhaseImbalance}}} + Q_{\mathrm{DC}})$$

Variables for these calculations are defined in this list.

- I_{a} is the I/Q amplitude imbalance.
- I_{p} is the I/Q phase imbalance.
- I_{DC} is the in-phase DC offset.
- Q_{DC} is the quadrature DC offset.
- x is the complex input signal and is given by $x_{\mathrm{r}} + jx_{\mathrm{i}}$.
  - x_{r} and x_{i} are the real and imaginary parts, respectively, of x.
- y is the complex output signal and is given by $y_{\mathrm{r}} + jy_{\mathrm{i}}$.
  - y_r and y_i are the real and imaginary parts, respectively, of y.

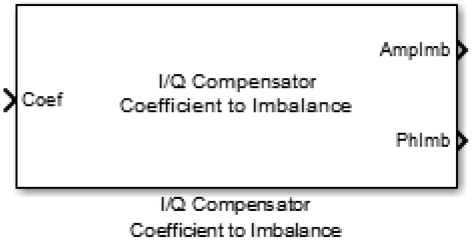
I/Q Compensator Coefficient to Imbalance

Convert compensator coefficient into amplitude and phase imbalance



Library

RF Impairments Correction

Description

The I/Q Compensator Coefficient to Imbalance block converts a compensator coefficient into its equivalent amplitude and phase imbalance.

This block has a single input port, which accepts a complex coefficient or a vector of coefficients. There are amplitude and phase imbalance output ports both of which are real. The amplitude imbalance is expressed in dB while the phase imbalance is expressed in degrees.

Algorithms

See the `iqcoef2imbal` function reference page for more information on the inputs, outputs, and algorithms.

Supported Data Types

I/Q Imbalance Compensator

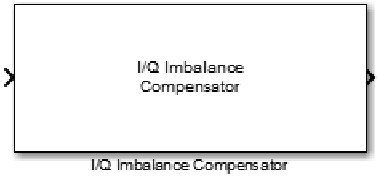
Compensate for imbalance between in-phase and quadrature components



Library

RF Impairments Correction

Description

The I/Q Imbalance Compensator mitigates the effects of an amplitude and phase imbalance between the in-phase and quadrature components of a modulated signal. The supported modulation schemes include OFDM, M-PSK, and M-QAM, where M > 2.

This block accepts up to three input ports, of which one is the input signal. When you set the **Source of compensator coefficient** parameter to `Estimated from input signal`, two additional input ports are enabled. The first is enabled when you set the **Source of adaptation step size** parameter to `Input port` and the second is enabled when you check the **Coefficient adaptation input port** box. The two options are independent. Additionally, you can check the **Estimated coefficient output port** box to create an optional output port from which the estimated compensator coefficients are made available.

When you set the **Source of compensator coefficient** parameter to `Input port`, only one possible configuration is possible (input signal port, coefficient input port, and output signal port).

Parameters

Source of compensator coefficient

Specify the source of the compensator coefficients as `Estimated from input signal` or `Input port`. If set to `Estimated from input signal`, the compensator calculates the coefficients from the input signal. If set to `Input port`, all other properties are disabled and you must provide the coefficients through the input port. The default value is `Estimated from input signal`.

Initial compensator coefficient

Specify the initial coefficient used by the internal algorithm to compensate for the I/Q imbalance. The default value is `0+0j`.

Source of adaptation step size

Specify the source of the adaptation step size as `Property` or `Input port`. If set to `Property`, specify the step size in the **Adaptation step size** field. If set to `Input port`, you must specify the step size through an input port. The default value is `Property`.

Adaptation step size

Specify the step size of the adaptation algorithm as a real scalar. This parameter is available only when **Source of adaptation step size** is set to `Property`. The default value is `0.00001`.

Coefficient adaptation input port

Select this check box to create an input port that permits a signal to control the adaptation process. If the check box is selected and if the input signal is `true`, the estimated compensation coefficients are updated. If the adaptation port is not enabled or if the input signal is `false`, the compensation coefficients do not change. By default, the check box is not selected.

Estimated coefficient output port

Select this check box to provide the estimated compensation coefficients to an output port. By default, the check box is not selected.

Algorithms

This block implements the algorithm, inputs, and outputs described on the `comm.IQImbalanceCompensator` reference page. The object properties correspond to the block parameters.

Examples

Compensate for I/Q Imbalance

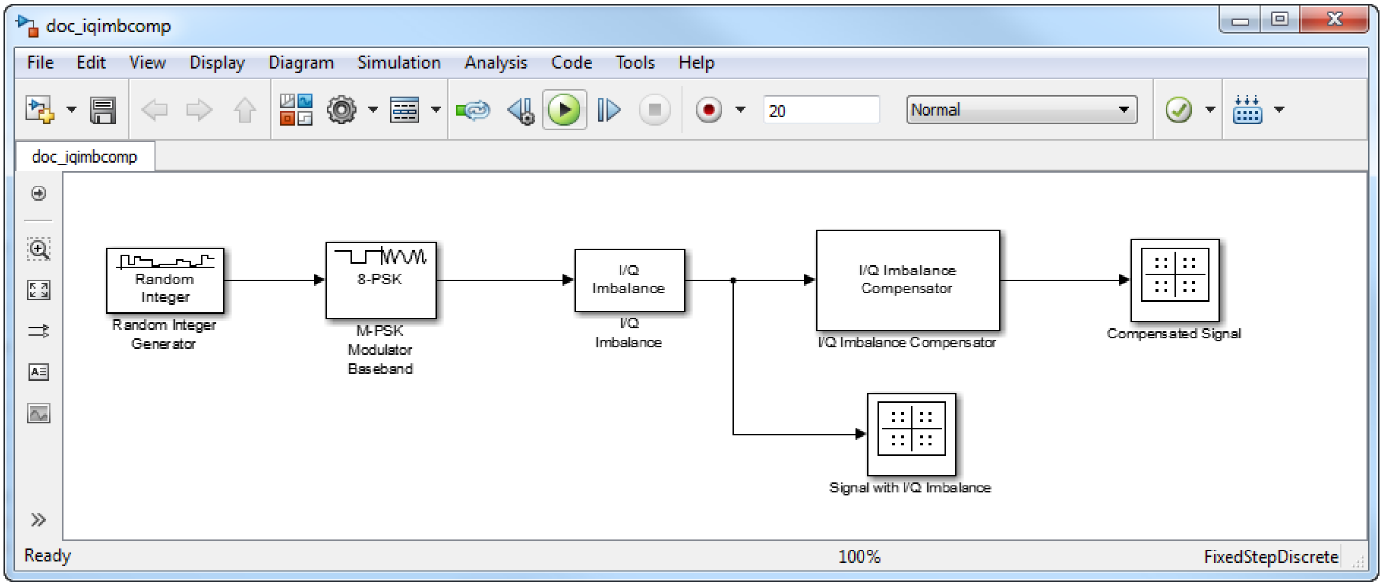
This example shows how to use the I/Q Imbalance Compensator block to remove the effects of an amplitude and phase imbalance on a modulated signal.

Open the model, doc_iqimbcomp, from the MATLAB command prompt.

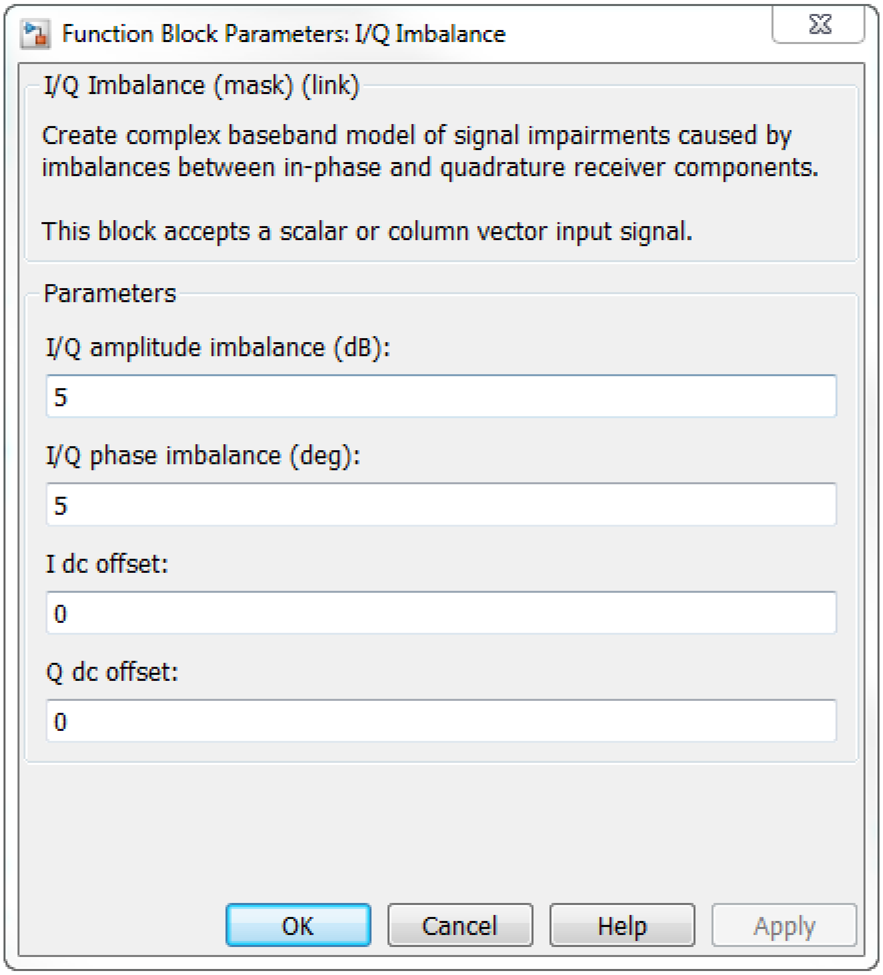
```
doc_iqimbcomp
```

The model includes these blocks:

- Random Integer Generator
- M-PSK Modulator Baseband
- I/Q Imbalance
- I/Q Imbalance Compensator
- Constellation Diagram



Double-click the I/Q Imbalance block. You can see that the **I/Q amplitude imbalance (dB)** parameter is set to 5 and the **I/Q phase imbalance (deg)** parameter is also set to 5.



Function Block Parameters: I/Q Imbalance

I/Q Imbalance (mask) (link)

Create complex baseband model of signal impairments caused by imbalances between in-phase and quadrature receiver components.

This block accepts a scalar or column vector input signal.

Parameters

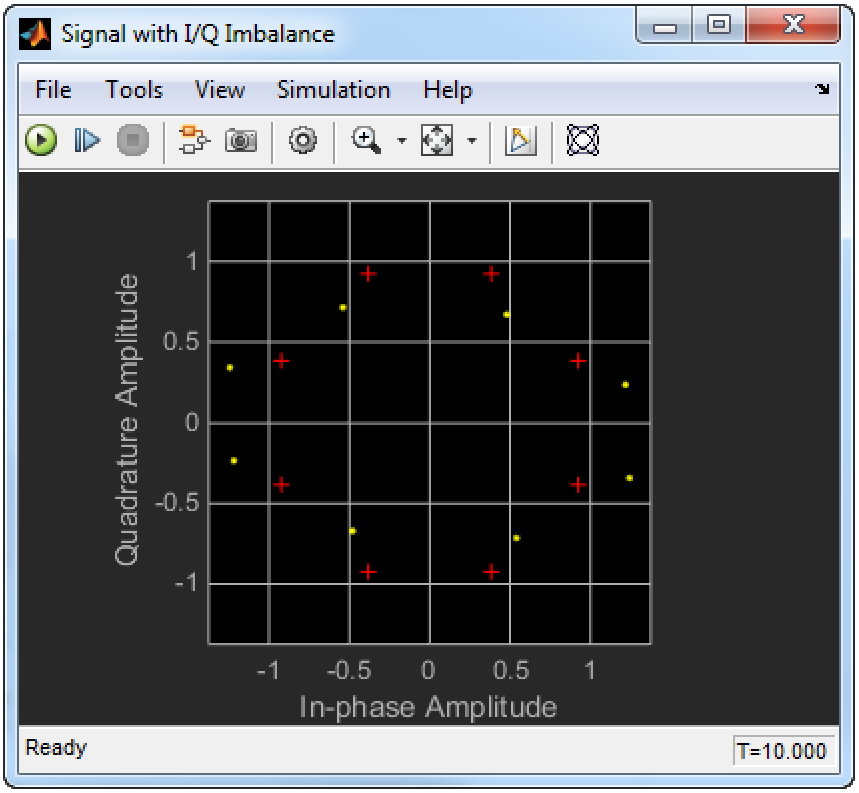
I/Q amplitude imbalance (dB): 5

I/Q phase imbalance (deg): 5

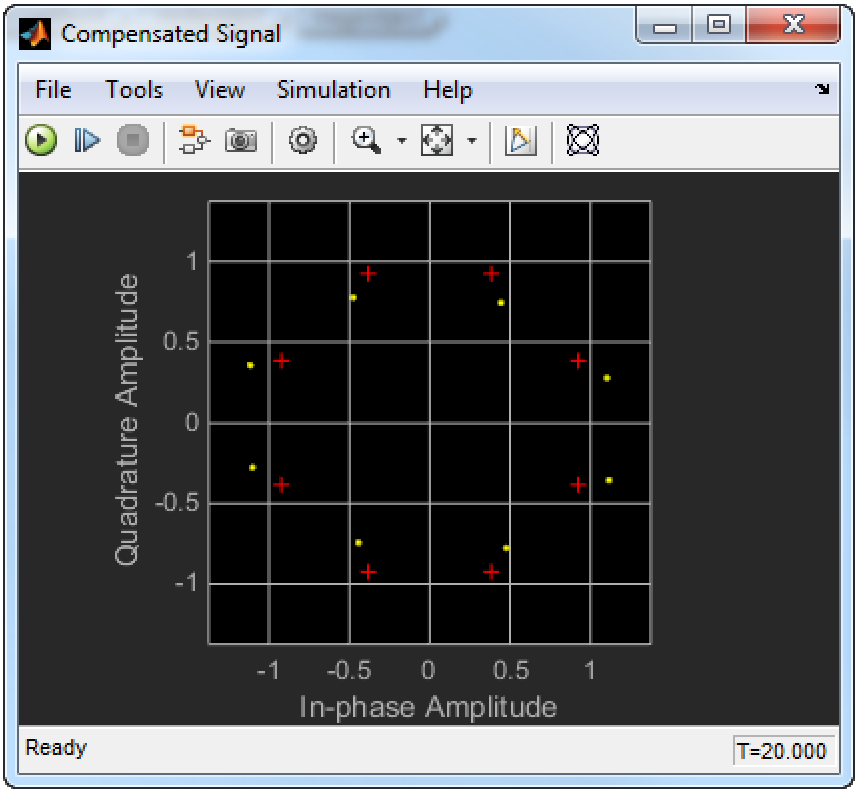
I dc offset: 0

Q dc offset: 0

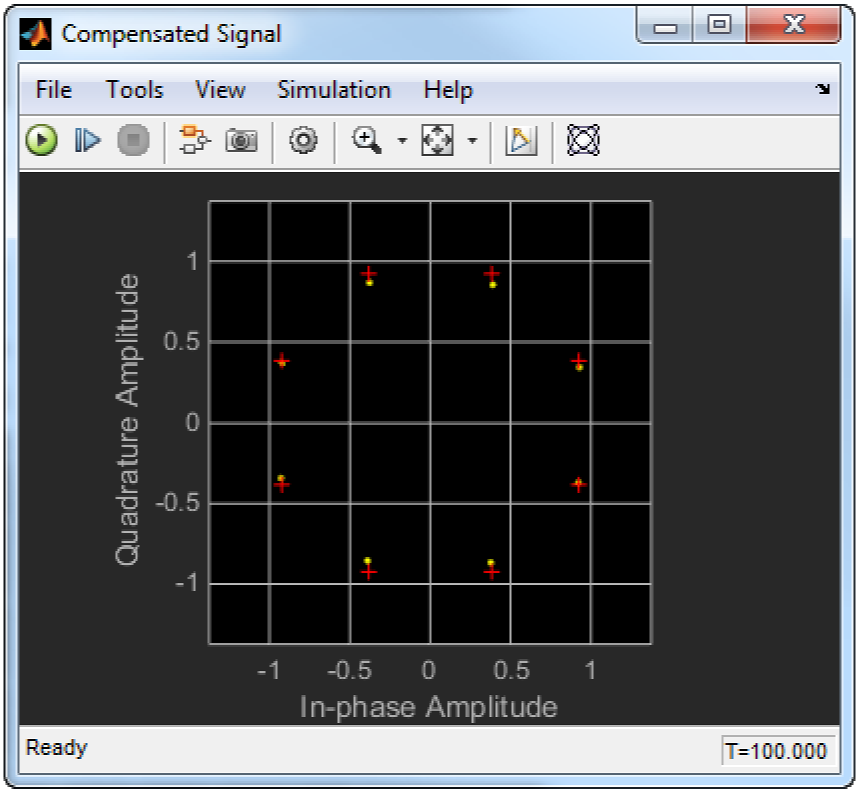
Run the model. In the *Signal with I/Q Imbalance* constellation diagram, observe the effects of the amplitude imbalance and phase imbalance on the 8-PSK signal.



Look at the *Compensated Signal* constellation diagram. Observe that the signal is not well aligned with the reference constellation (shown in red).



Increase the simulation time from 20 seconds to 100 seconds and run the model again. You can see that the constellation is now well aligned with the reference constellation. This is because the compensation algorithm is adaptive; consequently, it requires time to accurately estimate the I/Q imbalance.



Try changing other simulation parameters such as the step size in the I/Q Imbalance Compensator block, the amplitude and phase imbalance in the I/Q Imbalance block, the modulation type etc. Observe the effects on the *Compensated Signal* constellation diagram.

Supported Data Types

Port	Supported Data Types

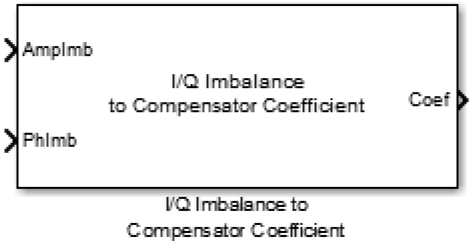
I/Q Imbalance to Compensator Coefficient

Converts amplitude and phase imbalance into I/Q compensator coefficient



Library

RF Impairments Correction

Description

The I/Q Imbalance to Compensator Coefficient block returns a complex coefficient to compensate for amplitude and phase imbalance.

This block has an amplitude imbalance input port and a phase imbalance input port, where the amplitude imbalance is a real number expressed in dB and the phase imbalance is a real number expressed in degrees. The imbalance inputs are vectors. The complex coefficients are returned from a single output port.

Algorithms

See `iqimbal2coef` for more information on the inputs, outputs, and algorithms.

Supported Data Types

Port	Supported Data Types
Compensator Coefficient	• Double-precision, complex floating point • Single-precision, complex floating point
Amplitude Imbalance (dB)	• Double-precision floating point • Single-precision floating point
Phase Imbalance (deg)	• Double-precision floating point • Single-precision floating point

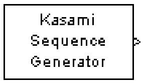
Kasami Sequence Generator

Generate Kasami sequence from set of Kasami sequences



Library

Sequence Generators sublibrary of Comm Sources

Description

The Kasami Sequence Generator block generates a sequence from the set of Kasami sequences. The Kasami sequences are a set of sequences that have good cross-correlation properties.

This block can output sequences that vary in length during simulation. For more information about variable-size signals, see “Variable-Size Signal Basics” (Simulink).

Kasami Sequences

There are two sets of Kasami sequences: the *small set* and the *large set*. The large set contains all the sequences in the small set. Only the small set is optimal in the sense of matching Welch's lower bound for correlation functions.

Kasami sequences have period $N = 2^n - 1$, where n is a nonnegative, even integer. Let u be a binary sequence of length N, and let w be the sequence obtained by decimating u by $2^{n/2} +1$. The small set of Kasami sequences is defined by the following formulas, in which T denotes the left shift operator, m is the shift parameter for w, and ⊕ denotes addition modulo 2.

$$K_S(u, n, m) = \begin{cases} u & m = -1 \\ u \oplus T^m w & m = 0, \ldots, 2^{n/2} - 2 \end{cases}$$

Small Set of Kasami Sequences for n Even

Note that the small set contains $2^{n/2}$ sequences.

For mod(n, 4) = 2, the large set of Kasami sequences is defined as follows. Let v be the sequence formed by decimating the sequence u by $2^{n/2 + 1}+ 1$. The large set is defined by the following table, in which k and m are the shift parameters for the sequences v and w, respectively.

$$K_L(u,n,k,m) = \begin{cases} u & k = -2;\ m = -1 \\ v & k = -1;\ m = -1 \\ u \oplus T^k v & k = 0, \dots, 2^n - 2;\ m = -1 \\ u \oplus T^m w & k = -2;\ m = 0, \dots, 2^{n/2} - 2 \\ v \oplus T^m w & k = -1;\ m = 0, \dots, 2^{n/2} - 2 \\ u \oplus T^k v \oplus T^m w & k = 0, \dots, 2^n - 2;\ m = 0, \dots, 2^{n/2} - 2 \end{cases}$$

Large Set of Kasami Sequences for mod(n, 4) = 2

The sequences described in the first three rows of the preceding figure correspond to the Gold sequences for mod(n, 4) = 2. See the reference page for the Gold Sequence Generator block for a description of Gold sequences. However, the Kasami sequences form a larger set than the Gold sequences.

The correlation functions for the sequences takes on the values

{-$t(n)$, -$s(n)$, -1, $s(n)$ -2 , $t(n)$ - 2}

where

$$t(n) = 1 + 2^{(n+2)/2},\ n \text{ even}$$

$$s(n) = \frac{1}{2}(t(n) + 1)$$

Block Parameters

The **Generator polynomial** parameter specifies the generator polynomial, which determines the connections in the shift register that generates the sequence *u*. You can specify the **Generator polynomial** parameter using these formats:

- A polynomial character vector that includes the number `1`, for example, `'z^4 + z + 1'`.
- A vector that lists the coefficients of the polynomial in descending order of powers. The first and last entries must be 1. Note that the length of this vector is one more than the degree of the generator polynomial.
- A vector containing the exponents of *z* for the nonzero terms of the polynomial in descending order of powers. The last entry must be `0`.

For example, `'z^8 + z^2 + 1'`, `[1 0 0 0 0 0 1 0 1]`, and `[8 2 0]` represent the same polynomial, p(z) = z^8+z^2+1.

The **Initial states** parameter specifies the initial states of the shift register that generates the sequence u. **Initial States** is a binary scalar or row vector of length equal to the degree of the **Generator polynomial**. If you choose a binary scalar, the block expands the scalar to a row vector of length equal to the degree of the **Generator polynomial**, all of whose entries equal the scalar.

The **Sequence index** parameter specifies the shifts of the sequences *v* and *w* used to generate the output sequence. You can specify the parameter in either of two ways:

- To generate sequences from the small set, for *n* is even, you can specify the **Sequence index** as an integer *m*. The range of *m* is [-1, ..., $2^{n/2}$ - 2]. The following table describes the output sequences corresponding to **Sequence index** `m`:

Sequence Index	Range of Indices	Output Sequence
`-1`	$m = -1$	u
`m`	$m = 0, \dots, 2^{n/2} - 2$	$u \oplus T^m w$

- To generate sequences from the large set, for mod (n, 4) = 2, where n is the degree of the **Generator polynomial**, you can specify **Sequence index** as an integer vector [k m]. In this case, the output sequence is from the large set. The range for k is [-2, ..., 2^n - 2], and the range for m is [-1, ..., $2^{n/2}$ - 2]. The following table describes the output sequences corresponding to **Sequence index** [k m]:

Sequence Index [k m]	Range of Indices	Output Sequence
`[-2 -1]`	$k = -2$, $m = -1$	u
`[-1 -1]`	$k = -1$, $m = -1$	v
`[k -1]`	$k = 0, 1, \dots, 2^n - 2$ $m = -1$	$u \oplus T^k v$
`[-2 m]`	$k = -2$ $m = 0, 1, \dots, 2^{n/2} - 2$	$u \oplus T^m w$
`[-1 m]`	$k = -1$ $m = 0, \dots, 2^{n/2} - 2$	$v \oplus T^m w$
`[k m]`	$k = 0, \dots, 2^n - 2$ $m = 0, \dots, 2^{n/2} - 2$	$u \oplus T^k v \oplus T^m w$

You can shift the starting point of the Kasami sequence with the **Shift** parameter, which is an integer representing the length of the shift.

You can use an external signal to reset the values of the internal shift register to the initial state by selecting **Reset on nonzero input**. This creates an input port for the external signal in the Kasami Sequence Generator block. The way the block resets the internal shift register depends on whether its output signal and the reset signal are sample-based or frame-based. See “Reset Behavior” on page 5-663 for an example.

Polynomials for Generating Kasami Sequences

The following table lists some of the polynomials that you can use to generate the Kasami set of sequences.

n	N	Polynomial	Set
4	15	[4 1 0]	Small
6	63	[6 1 0]	Large
8	255	[8 4 3 2 0]	Small
10	1023	[10 3 0]	Large
12	4095	[12 6 4 1 0]	Small

Parameters

Generator polynomial

Character vector or binary vector specifying the generator polynomial for the sequence *u*.

Initial states

Binary scalar or row vector of length equal to the degree of the **Generator polynomial**, which specifies the initial states of the shift register that generates the sequence *u*.

Sequence index

Integer or vector specifying the shifts of the sequences *v* and *w* used to generate the output sequence.

Shift

Integer scalar that determines the offset of the Kasami sequence from the initial time.

Output variable-size signals

Select this if you want the output sequences to vary in length during simulation. The default selection outputs fixed-length signals.

Maximum output size source

Specify how the block defines maximum output size for a signal.

- When you select `Dialog parameter`, the value you enter in the **Maximum output size** parameter specifies the maximum size of the output. When you make this selection, the `oSiz` input port specifies the current size of the output signal and the block output inherits sample time from the input signal. The input value must be less than or equal to the **Maximum output size** parameter.
- When you select `Inherit from reference port`, the block output inherits sample time, maximum size, and current size from the variable-sized signal at the Ref input port.

This parameter only appears when you select **Output variable-size signals**. The default selection is `Dialog parameter`.

Maximum output size

Specify a two-element row vector denoting the maximum output size for the block. The second element of the vector must be 1. For example, [10 1] gives a 10-by-1 maximum sized output signal. This parameter only appears when you select **Output variable-size signals**.

Sample time

Output sample time, specified as `-1` or a positive scalar that represents the time between each sample of the output signal. If **Sample time** is set to `-1`, the sample time is inherited from downstream. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-440.

Samples per frame

Samples per frame, specified as a positive integer indicating the number of samples per frame in one channel of the output data. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-440.

Reset on nonzero input

When selected, you can specify an input signal that resets the internal shift registers to the original values of the **Initial states**.

Output data type

The output type of the block can be specified as a `boolean` or `double`. By default, the block sets this to `double`.

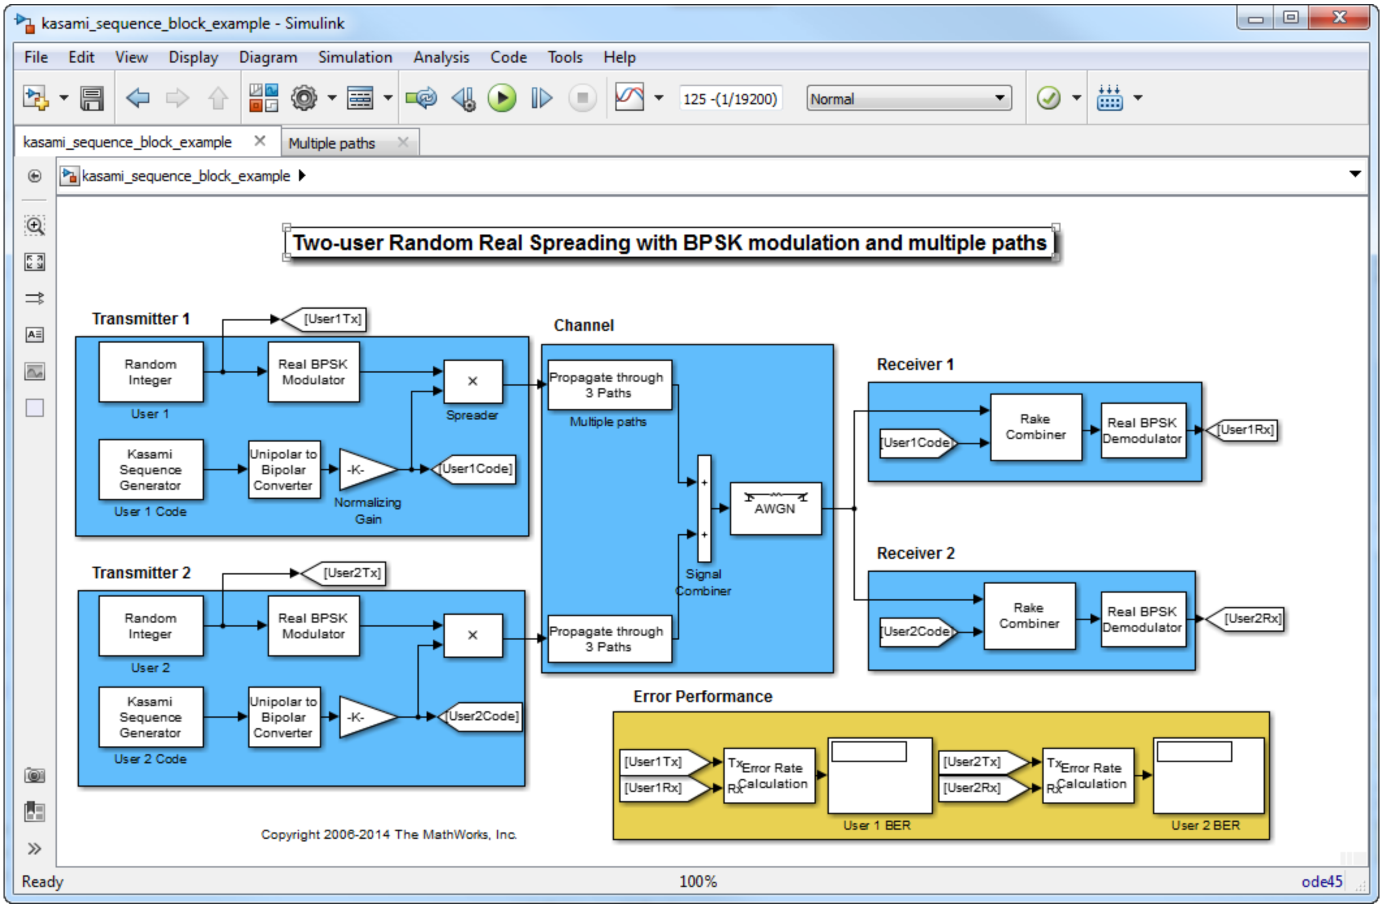
Example

Kasami Spreading with Two Users and Multipath

This model considers Kasami spreading for a combined two-user transmission in a multipath environment.

Open the model here: kasami_sequence_block_example

```
modelname = 'kasami_sequence_block_example';
open_system(modelname);
sim(modelname);
```



You can see very good user separation over multiple paths with the gains of combining. This can be attributed to the "good" correlation properties of Kasami sequences, which provide a balance between the ideal cross-correlation properties of orthogonal codes and the ideal auto-correlation properties of PN sequences. See the relevant examples on the Hadamard Code Generator and PN Sequence Generator reference pages.

To experiment with this model further, try selecting other path delays to see how the performance varies for the same code. Also try different codes with the same delays.

```
close_system(modelname, 0);
```

Blocks
Gold Sequence Generator | Hadamard Code Generator | PN Sequence Generator

More About

Sample Timing

The time between output updates is equal to the product of **Samples per frame** and **Sample time**. For example, if **Sample time** and **Samples per frame** equal one, the block outputs a sample every second. If **Samples per frame** is increased to 10, then a 10-by-1 vector is output every 10 seconds. This ensures that the equivalent output rate is not dependent on the **Samples per frame** parameter.

Reset Behavior

To reset the generator sequence, you must first select **Reset on nonzero input** to add the `Rst` input. Suppose that the Kasami Sequence Generator block outputs `[1 0 0 1 1 0 1 1]` when there is no reset. The following table shows the effect on the Kasami Sequence Generator block output for the property values indicated.

	Reset Signal Properties	Kasami Sequence Generator block	Reset Signal Output Signal
No reset	**Sample time** = 1 **Samples per frame** = 1 **Rst** = `[0 0 0 0 0 0 0 0]`	**Sample time** = 1 **Samples per frame** = 1 **Out** = `[1 0 0 1 1 0 1 1]`	 Rst 0 0 0 0 0 0 0 0 Out 1 0 0 1 1 0 1 1
Scalar reset signal	**Sample time** = 1 **Samples per frame** = 1 **Rst** = `[0 0 0 1 0 0 0 0]`	**Sample time** = 1 **Samples per frame** = 1	 Reset Rst 0 0 0 1 0 0 0 0 Out 1 0 0 1 0 0 1 1

	Reset Signal Properties	Kasami Sequence Generator block	Reset Signal Output Signal
Vector reset signal	**Sample time** = 1 **Samples per frame** = 8 **Rst** = [0 0 0 1 0 0 0 0]	**Sample time** = 1 **Samples per frame** = 8	

For the no reset case, the sequence is output without being reset. For the scalar and vector reset signal cases, the reset signal [0 0 0 1 0 0 0 0] is input to the Rst port. The sequence output is reset at the fourth bit, because the fourth bit of the reset signal is a 1 and the **Sample time** is 1.

For variable-sized outputs, the block only supports scalar reset signal inputs.

Compatibility Considerations

Existing models automatically update this block to current version

Behavior changed in R2020a

Starting in R2020a, Simulink no longer allows you to use the Kasami Sequence Generator block version available before R2015b.

Existing models automatically update to load the Kasami Sequence Generator block version announced in “Source blocks output frames of contiguous time samples but do not use the frame attribute” in the R2015b Release Notes. For more information on block forwarding, see “Forwarding Tables” (Simulink).

Extended Capabilities

C/C++ Code Generation

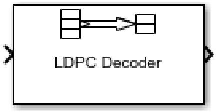
Generate C and C++ code using Simulink® Coder™.

Introduced before R2006a

LDPC Decoder

Decode binary low-density parity-check (LDPC) code

Library: Communications Toolbox / Error Detection and Correction / Block



Description

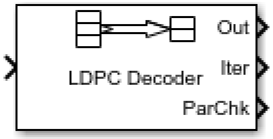
The LDPC Decoder block uses the belief propagation algorithm to decode a binary LDPC code, which is input to the block as the soft-decision output (log-likelihood ratio of received bits) from demodulation. The block decodes generic binary LDPC codes where no patterns in the parity-check matrix are assumed. For more information, see “Belief Propagation Decoding” on page 5-445.

The input and output are discrete-time signals. The ratio of the output sample time to the input sample time is:

- *N/K* when only the information-part of the codeword is decoded
- 1 when the entire codeword is decoded

N is the length of the received signal and must be in the range (0, 2^{31}). *K* is the length of the uncoded message and must be less than *N*.

This icon shows all ports, including optional ports, for the LDPC Decoder block.



Ports

Input

In — Log-likelihood ratios

column vector

Log-likelihood ratios, specified as an *N*-by-1 column vector containing the soft-decision output from demodulation. *N* is the number of bits in the LDPC codeword before modulation. Each element is the log-likelihood ratio for a received bit and the value is more likely to be `0` if the log-likelihood ratio is positive. The first *K* elements correspond to the information-part of the input message.

Data Types: `double`

Output

Out — Decoded data

column vector

Decoded data, returned as a column vector. The **Decision type** parameter specifies whether the block outputs hard decisions or soft decisions (log-likelihood ratios).

- If the **Output format** parameter is set to `Information part`, the output includes only the information-part of the received codeword.
- If the **Output format** parameter is set to `Whole codeword`, the output includes the whole log-likelihood ratio vector.

Data Types: `double` | `Boolean`

`Iter` — Number of executed decoding iterations

positive integer

Number of executed decoding iterations, returned as a positive integer.

Dependencies

To enable this port, select the **Output number of iterations executed** parameter.

Data Types: `double`

`ParChk` — Final parity checks

column vector

Final parity checks after decoding the input LDPC code, returned as an (*N*-*K*)-by-1 column vector. *N* is the number of bits in the LDPC codeword before modulation. *K* is the length of the uncoded message.

Dependencies

To enable this port, select the **Output final parity checks** parameter.

Parameters

`Parity-check matrix (sparse binary (N-K)-by-N matrix)` — Parity-check matrix

`dvbs2ldpc(1/2)` (default) | sparse binary matrix | nonsparse index matrix

Parity-check matrix, specified as a sparse $(N - K)$-by-N binary-valued matrix. N is the length of the received signal and must be in the range $(0, 2^{31})$. K is the length of the uncoded message and must be less than N. The last $(N - K)$ columns in the parity-check matrix must be an invertible matrix in the Galois field of order 2, `gf`(2).

You can also specify the parity-check matrix as a two-column nonsparse index matrix, `I`, that defines the row and column indices of the `1`s in the parity-check matrix such that `sparse(I(:,1),I(:,2),1)`.

This parameter accepts numeric data types. When you set this parameter to a sparse binary matrix, this parameter also accepts the `Boolean` data type.

The default value uses the `dvbs2ldpc` function to configure a sparse parity-check matrix for half-rate LDPC coding, as specified in the DVB-S.2 standard.

Example: `dvbs2ldpc(R,'indices')` configures the index matrix for the DVB-S.2 standard, where `R` is the code rate, and `'indices'` specifies the output format of `dvbs2ldpc` as a two-column double-precision matrix that defines the row and column indices of the `1`s in the parity-check matrix.

Data Types: `double` | `Boolean`

`Output format` — Output value format

`Information part` (default) | `Whole codeword`

Output value format, specified as one of these values:

- `Information part` — The block outputs a *K*-by-1 column vector containing only the information-part of the received log-likelihood ratio vector. *K* is the length of the uncoded message.
- `Whole codeword` — The block outputs an *N*-by-1 column vector containing the whole log-likelihood ratio vector. *N* is the length of the received signal.

  N and *K* must align with the dimension of the (*N*–*K*)-by-*K* parity-check matrix.

`Decision type` — Decision method

`Hard decision` (default) | `Soft decision`

Decision method used for decoding, specified as one of these values:

- `Hard decision` — The block outputs decoded data of data type `double` or `boolean`. Specify this data type using the **Output data type** parameter.
- `Soft decision` — The block outputs log-likelihood ratios of data type `double`.

`Output data type` — Output value data type

`double` (default) | `boolean`

Output value data type, specified as `double` or `boolean`.

Dependencies

To enable this parameter, set the **Decision type** parameter to `Hard decision`.

`Number of iterations` — Maximum number of decoding iterations

`50` (default) | positive integer

Maximum number of decoding iterations, specified as a positive integer.

`Stop iterating when all parity-checks are satisfied` — Condition for iteration termination

`off` (default) | `on`

Select this parameter to terminate decoding after all parity checks are satisfied. If not all parity checks are satisfied, decoding terminates after the number of iterations specified by the **Number of iterations** parameter.

`Output number of iterations executed` — Output number of iterations executed

`off` (default) | `on`

Select this parameter to enable the **Iter** output port.

`Output final parity-checks` — Output number of iterations executed

`off` (default) | `on`

Select this parameter to enable the **ParChk** output port.

Block Characteristics

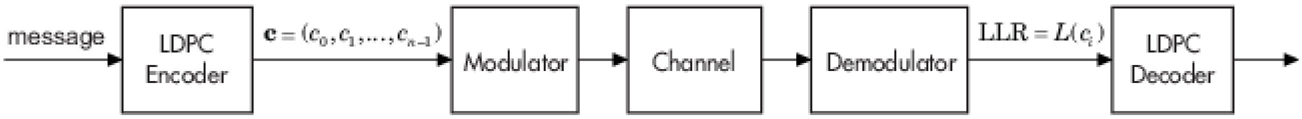
Data Types	`Boolean` | `double`
Multidimensional Signals	`no`
Variable-Size Signals	`no`

Algorithms

This block performs LDPC decoding using the belief propagation algorithm, also known as a message-passing algorithm.

Belief Propagation Decoding

The implementation of the belief propagation algorithm is based on the decoding algorithm presented by Gallager.



For transmitted LDPC-encoded codeword $c = c_0, c_1, \ldots, c_{n-1}$, the input to the LDPC decoder is the log-likelihood ratio (LLR) value $L(c_i) = \log\left(\frac{\Pr(c_i = 0 \mid \text{channel output for } c_i)}{\Pr(c_i = 1 \mid \text{channel output for } c_i)}\right)$.

In each iteration, the key components of the algorithm are updated based on these equations:

$$L(r_{ji}) = 2\,\text{atanh}\left(\prod_{i' \in V_j \backslash i} \tanh\left(\frac{1}{2}L(q_{i'j})\right)\right),$$

$L(q_{ij}) = L(c_i) + \sum_{j' \in C_i \backslash j} L(r_{j'i})$, initialized as $L(q_{ij}) = L(c_i)$ before the first iteration, and

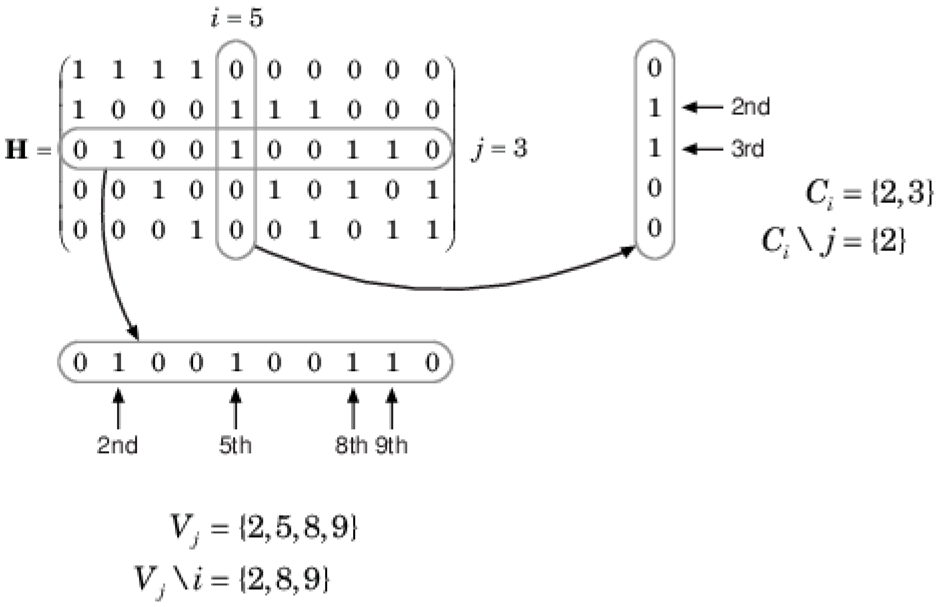
$$L(Q_i) = L(c_i) + \sum_{j' \in C_i} L(r_{j'i}).$$

At the end of each iteration, $L(Q_i)$ contains the updated estimate of the LLR value for transmitted bit c_i. The value $L(Q_i)$ is the soft-decision output for c_i. If $L(Q_i) < 0$, the hard-decision output for c_i is 1. Otherwise, the hard-decision output for c_i is 0.

If configured to stop when all parity checks are satisfied, the algorithm verifies the parity-check equation ($H\,c' = 0$) at the end of each iteration. When all parity checks are satisfied, or if the maximum number of iterations is reached, decoding stops.

Index sets $C_i \backslash j$ and $V_j \backslash i$ are based on the parity-check matrix (PCM). Index sets C_i and V_j correspond to all nonzero elements in column i and row j of the PCM, respectively.

This figure highlights the computation of these index sets in a given PCM for $i = 5$ and $j = 3$.



To avoid infinite numbers in the algorithm equations, atanh(1) and atanh(-1) are set to 19.07 and –19.07, respectively. Due to finite precision, MATLAB returns 1 for tanh(19.07) and –1 for tanh(-19.07).

LDPC Encoder

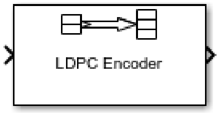
Encode binary low-density parity-check (LDPC) code

Library: Communications Toolbox / Error Detection and Correction / Block



Description

The LDPC Encoder block applies LDPC coding to a binary input message. LDPC codes are linear error control codes with sparse parity-check matrices and long block lengths that can attain performance near the Shannon limit.

The input and output are discrete-time signals. The ratio of the output sample time to the input sample time is *K/N*, where:

- *N* is the length of the received signal and must be in the range (0, 2^{31}).
- *K* is the length of the uncoded message and must be less than *N*.

Ports

Input

In — Input message

binary column vector

Input message, specified as a *K*-by-1 column vector containing binary-valued elements. *K* is the length of the uncoded message.

Data Types: `double` | `Boolean`

Output

Out — LDPC codeword

column vector

LDPC codeword, returned as an *N*-by-1 column vector. *N* is the number of bits in the LDPC codeword. The output signal inherits its data type from the input signal. The LDPC codeword output is a solution to the parity-check equation. The input message comprises the first *K* bits of the LDPC codeword output, and the parity check comprises the remaining (*N* – *K*) bits.

Data Types: `double` | `Boolean`

Parameters

`Parity-check matrix (sparse binary (N-K)-by-N matrix)` — Parity-check matrix

`dvbs2ldpc(1/2)` (default) | sparse binary matrix | nonsparse index matrix

Parity-check matrix, specified as a sparse (*N* – *K*)-by-*N* binary-valued matrix. *N* is the length of the output LDPC codeword and must be in the range (0, 2^{31}). *K* is the length of the uncoded message and must be less than *N*. The last (*N* – *K*) columns in the parity-check matrix must be an invertible matrix in the Galois field of order 2, `gf`(2).

You can also specify the parity-check matrix as a two-column nonsparse index matrix, `I`, that defines the row and column indices of the `1`s in the parity-check matrix such that `sparse(I(:,1),I(:,2),1)`.

This parameter accepts numeric data types. When you set this parameter to a sparse binary matrix, this parameter also accepts the `Boolean` data type.

The default value uses the `dvbs2ldpc` function to configure a sparse parity-check matrix for half-rate LDPC coding, as specified in the DVB-S.2 standard.

Note

- When the last (*N* – *K*) columns of the parity-check matrix form a triangular matrix, forward or backward substitution is performed to solve the parity-check equation.
- When the last (*N* – *K*) columns of the parity-check matrix do not form a triangular matrix, a matrix inversion is performed to solve the parity-check equation. If a large matrix needs to be inverted, initializations or updates take more time.

Example: `dvbs2ldpc(R,'indices')` configures the index matrix for the DVB-S.2 standard, where `R` is the code rate, and `'indices'` specifies the output format of `dvbs2ldpc` as a two-column double-precision matrix that defines the row and column indices of the `1`s in the parity-check matrix.

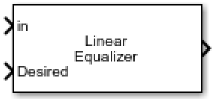
Linear Equalizer

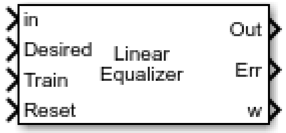
Equalize modulated signals using linear filtering
Library: Communications Toolbox / Equalizers



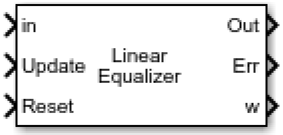
Description

The Linear Equalizer block uses a tapped delay line filter to equalize a linearly modulated signal through a dispersive channel. Using an estimate of the channel modeled as a finite input response (FIR) filter, the block processes input frames and outputs the estimated signal.

This icon shows the block with all ports enabled for configurations that use the LMS or RLS adaptive algorithm.



This icon shows the block with all ports enabled for configurations that use the CMA adaptive algorithm.



Ports

Input

`in` — Input signal

column vector

Input signal, specified as a column vector. The vector length of **in** must be equal to an integer multiple of the **Number of input samples per symbol** parameter. For more information, see “Symbol Tap Spacing” on page 5-456.

Data Types: `double`
Complex Number Support: Yes

`Desired` — Training symbols

column vector

Training symbols, specified as a column vector. The vector length of **Desired** must be less than or equal to the length of input **in**. The **Desired** input port is ignored when the **Train** input port is `0`.

Dependencies

To enable this port, set the **Adaptive algorithm** parameter to `LMS` or `RLS`.

Data Types: `double`
Complex Number Support: Yes

`Train` — Train equalizer flag
`1` | `0`

Train equalizer flag, specified as `1` or `0`. The block starts training when this value changes from `0` to `1` (at the rising edge). The block trains until all symbols in the **Desired** input port are processed.

Dependencies

To enable this port, set the **Adaptive algorithm** parameter to `LMS` or `RLS` and select the **Enable training control input** parameter.

Data Types: `Boolean`

`Update` — Update tap weights flag
`1` | `0`

Update tap weights flag, specified as `1` or `0`. The tap weights are updated when this value is `1`.

Dependencies

To enable this port, set the **Adaptive algorithm** parameter to `CMA` and the **Source of adapt weights flag** parameter to `Input port`.

Data Types: `Boolean`

`Reset` — Reset equalizer flag
`1` | `0`

Reset equalizer flag, specified as `1` or `0`. If **Reset** is set to `1`, the block resets the tap weights before processing the incoming signal. The block performs initial training until all symbols in the **Desired** input port are processed.

Dependencies

To enable this port, select the **Enable reset input** parameter.

Data Types: `Boolean`

Output

`Out` — Equalized symbols
column vector

Equalized symbols, returned as a column vector that has the same length as input signal **in**.

This port is unnamed until you select the **Output error signal** or **Output taps weights** parameter.

`Err` — Error signal
column vector

Error signal, returned as a column vector that has the same length as input signal **in**.

`w` — Tap weights

column vector

Tap weights, returned as an N_{Taps}-by-1 vector, where N_{Taps} is the value of the **Number of Taps** parameter. **w** contains the tap weights from the last tap weight update.

Parameters

Structure parameters

`Number of taps` — Number of equalizer taps

`5` (default) | positive integer

Number of equalizer taps, specified as a positive integer. The number of equalizer taps must be greater than or equal to the value of the **Number of input samples per symbol** parameter.

`Signal constellation` — Signal constellation

`pskmod(0:3,4,pi/4)` (default) | vector

Signal constellation, specified as a vector. The default value is a QPSK constellation generated using this code: `pskmod(0:3,4,pi/4)`.

Tunable: Yes

`Number of input samples per symbol` — Number of input samples per symbol

`1` (default) | positive integer

Number of input samples per symbol, specified as a positive integer. Setting this parameter to any number greater than `1` effectively creates a fractionally spaced equalizer. For more information, see “Symbol Tap Spacing” on page 5-456.

Algorithm parameters

`Adaptive algorithm` — Adaptive algorithm

`LMS` (default) | `RLS` | `CMA`

Adaptive algorithm used for equalization, specified as one of these values:

- `LMS` — Update the equalizer tap weights using the “Least Mean Square (LMS) Algorithm” on page 5-457.
- `RLS` — Update the equalizer tap weights using the “Recursive Least Square (RLS) Algorithm” on page 5-457.
- `CMA` — Update the equalizer tap weights using the “Constant Modulus Algorithm (CMA)” on page 5-458.

`Step size` — Step size

`0.01` (default) | positive scalar

Step size used by the adaptive algorithm, specified as a positive scalar. Increasing the step size reduces the equalizer convergence time but causes the equalizer output estimates to be less stable.

Tunable: Yes

Dependencies

To enable this parameter, set **Adaptive algorithm** to `LMS` or `CMA`.

`Forgetting factor` — Forgetting factor

`0.99` (default) | scalar in the range (0, 1]

Forgetting factor used by the adaptive algorithm, specified as a scalar in the range (0, 1]. Decreasing the forgetting factor reduces the equalizer convergence time but causes the equalizer output estimates to be less stable.

Tunable: Yes

Dependencies

To enable this parameter, set **Adaptive algorithm** to `RLS`.

`Initial inverse correlation matrix` — Initial inverse correlation matrix

`0.1` (default) | scalar | matrix

Initial inverse correlation matrix, specified as a scalar or an N_{Taps}-by-N_{Taps} matrix. N_{Taps} is equal to the **Number of Taps** parameter value. If you specify this value as a scalar, *a*, the equalizer sets the initial inverse correlation matrix to *a* times the identity matrix: a(`eye`(N_{Taps})).

Tunable: Yes

Dependencies

To enable this parameter, set **Adaptive algorithm** to `RLS`.

Control parameters

`Reference tap` — Reference tap

`3` (default) | positive integer

Reference tap, specified as a positive integer less than or equal to the **Number of Taps** parameter value. The equalizer uses the reference tap location to track the main energy of the channel.

`Input signal delay (samples)` — Input signal delay

`0` (default) | nonnegative integer

Input signal delay in samples relative to the reset time of the equalizer, specified as a nonnegative integer. If the input signal is a vector of length greater than 1, then the input delay is relative to the start of the input vector. If the input signal is a scalar, then the input delay is relative to the first call of the block and to the first call of the block after the **Reset** input port toggles to `1`.

Dependencies

To enable this parameter, set **Adaptive algorithm** to `LMS` or `RLS`.

`Source of adapt weights flag` — Source of adapt tap weights request

`Property` (default) | `Input port`

Source of the adapt tap weights request, specified as one of these values:

- `Property` — Specify this value to use the **Adaptive algorithm** parameter to control when the block adapts tap weights.

- `Input port` — Specify this value to use the **Update** input port to control when the block adapts tap weights.

Dependencies

To enable this parameter, set **Adaptive algorithm** to `CMA`.

`Adapt tap weights` — Adapt tap weights

`on` (default) | `off`

Select this parameter to adaptively update the equalizer tap weights. If this parameter is cleared, the block keeps the equalizer tap weights unchanged.

Tunable: Yes

Dependencies

To enable this parameter, set **Adaptive algorithm** to `CMA` and **Source of adapt weights flag** to `Property`.

`Initial tap weights source` — Source for initial tap weights

`Auto` (default) | `Property`

Source for initial tap weights, specified as one of these values:

- `Auto` — Initialize the tap weights to the algorithm-specific default values, as described in the **Initial weights** parameter.
- `Property` — Initialize the tap weights using the **Initial weights** parameter value.

`Initial weights` — Initial tap weights

`0` or `[0;0;1;0;0]` (default) | scalar | column vector

Initial tap weights used by the adaptive algorithm, specified as a scalar or an N_{Taps}-by-1 vector. N_{Taps} is equal to the **Number of Taps** parameter value. The default is `0` when the **Adaptive algorithm** parameter is set to `LMS` or `RLS`. The default is `[0;0;1;0;0]` when the **Adaptive algorithm** parameter is set to `CMA`.

If you specify **Initial weights** as a vector, the vector length must be equal to the **Number of Taps** parameter value. If you specify **Initial weights** as a scalar, the equalizer uses scalar expansion to create a vector of length **Number of Taps** with all values set to **Initial weights**.

Tunable: Yes

Dependencies

To enable this parameter, set **Initial tap weights source** to `Property`.

`Tap weight update period (symbols)` — Tap weight update period

`1` (default) | positive integer

Tap weight update period in symbols, specified as a positive integer. The equalizer updates the tap weights after processing this number of symbols.

`Enable training control input` — Enable training control input

`off` (default) | `on`

Select this parameter to enable input port **Train**. If this parameter is cleared, the block does not reenter training mode after the initial tap training.

Tunable: Yes

Dependencies

To enable this parameter, set **Adaptive algorithm** to `LMS` or `RLS`.

`Update tap weights when not training` — Update tap weights when not training

`on` (default) | `off`

Select this parameter to use decision directed mode to update equalizer tap weights. If this parameter is cleared, the block keeps the equalizer tap weights unchanged after training.

Tunable: Yes

Dependencies

To enable this parameter, set **Adaptive algorithm** to `LMS` or `RLS`.

`Enable reset input` — Enable reset input

`off` (default) | `on`

Select this parameter to enable input port **Train**. If this parameter is cleared, the block does not reenter training mode after the initial tap training.

Tunable: Yes

Diagnostic parameters

`Output error signal` — Enable error signal output

`off` (default) | `on`

Select this parameter to enable output port **Err** containing the equalizer error signal.

Tunable: Yes

`Output taps weights` — Enable tap weights output

`off` (default) | `on`

Select this parameter to enable output port **w** containing tap weights from the last tap weight update.

Tunable: Yes

`Simulate using` — Type of simulation to run

`Code generation` (default) | `Interpreted execution`

Type of simulation to run, specified as `Code generation` or `Interpreted execution`.

- `Code generation` –- Simulate the model by using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations unless the model changes. This option requires additional startup time, but the speed of the subsequent simulations is faster than `Interpreted execution`.
- `Interpreted execution` –- Simulate the model by using the MATLAB interpreter. This option requires less startup time than the `Code generation` method, but the speed of subsequent simulations is slower. In this mode, you can debug the source code of the block.

Block Characteristics

Data Types	`double` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`yes`

More About

Symbol Tap Spacing

You can configure the equalizer to operate as a symbol-spaced equalizer or as a fractional symbol-spaced equalizer.

- To operate the equalizer at a symbol-spaced rate, specify the number of samples per symbol as `1`. Symbol-rate equalizers have taps spaced at the symbol duration. Symbol-rate equalizers are sensitive to timing phase.
- To operate the equalizer at a fractional symbol-spaced rate, specify the number of input samples per symbol as an integer greater than `1` and provide an input signal oversampled at that sampling rate. Fractional symbol-spaced equalizers have taps spaced at an integer fraction of the input symbol duration. Fractional symbol-spaced equalizers are not sensitive to timing phase.

Algorithms

Linear Equalizers

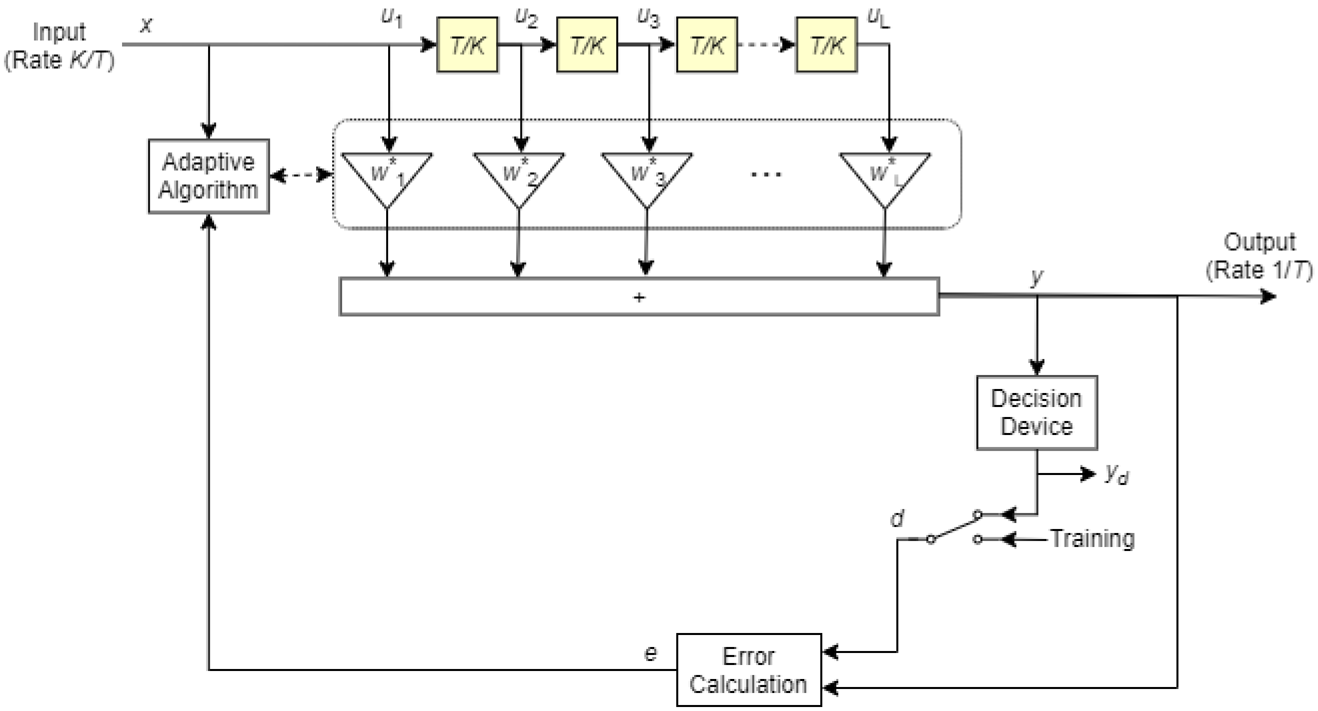
Linear equalizers can remove intersymbol interference (ISI) when the frequency response of a channel has no null. If a null exists in the frequency response of a channel, linear equalizers tend to enhance the noise. In this case, use decision feedback equalizers to avoid enhancing the noise.

A linear equalizer consists of a tapped delay line that stores samples from the input signal. Once per symbol period, the equalizer outputs a weighted sum of the values in the delay line and updates the weights to prepare for the next symbol period.

Linear equalizers can be symbol-spaced or fractional symbol-spaced.

- For a symbol-spaced equalizer, the number of samples per symbol, *K*, is 1. The output sample rate equals the input sample rate.
- For a fractional symbol-spaced equalizer, the number of samples per symbol, *K*, is an integer greater than 1. Typically, *K* is 4 for fractionally spaced equalizers. The output sample rate is 1/*T* and the input sample rate is *K*/*T*, where *T* is the symbol period. Tap-weight updating occurs at the output rate.

This schematic shows a linear equalizer with *L* weights, a symbol period of *T*, and *K* samples per symbol. If *K* is 1, the result is a symbol-spaced linear equalizer instead of a fractional symbol-spaced linear equalizer.



In each symbol period, the equalizer receives *K* input samples at the tapped delay line. The equalizer then outputs a weighted sum of the values in the tapped delay line and updates the weights to prepare for the next symbol period.

For more information, see “Equalization”.

Least Mean Square (LMS) Algorithm

For the LMS algorithm, in the previous schematic, *w* is a vector of all weights w_i, and *u* is a vector of all inputs u_i. Based on the current set of weights, the LMS algorithm creates the new set of weights as

$$w_{\text{new}} = w_{\text{current}} + (StepSize)\ ue^*.$$

The step size used by the adaptive algorithm is specified as a positive scalar. Increasing the step size reduces the equalizer convergence time but causes the equalized output signal to be less stable. To determine the maximum step size allowed when using the LMS adaptive algorithm, use the `maxstep` object function. The * operator denotes the complex conjugate and the error calculation $e = d - y$.

Recursive Least Square (RLS) Algorithm

For the RLS algorithm, in the previous schematic, *w* is the vector of all weights w_i, and *u* is the vector of all inputs u_i. Based on the current set of inputs, *u*, and the inverse correlation matrix, *P*, the RLS algorithm first computes the Kalman gain vector, *K*, as

$$K = \frac{Pu}{(ForgettingFactor) + u^H Pu}.$$

The forgetting factor used by the adaptive algorithm is specified as a scalar in the range (0, 1]. Decreasing the forgetting factor reduces the equalizer convergence time but causes the equalized output signal to be less stable. *H* denotes the Hermitian transpose. Based on the current inverse correlation matrix, the new inverse correlation matrix is

$$P_{\text{new}} = \frac{(1 - Ku^{H})P_{\text{current}}}{ForgettingFactor}.$$

Based on the current set of weights, the RLS algorithm creates the new set of weights as

$w_{\text{new}} = w_{\text{current}} + K^{*}e$.

The * operator denotes the complex conjugate and the error calculation $e = d - y$.

Constant Modulus Algorithm (CMA)

For the CMA adaptive algorithm, in the previous schematic, w is the vector of all weights w_i, and u is the vector of all inputs u_i. Based on the current set of weights, the CMA adaptive algorithm creates the new set of weights as

$w_{\text{new}} = w_{\text{current}} + (StepSize)\ u^{*}e$.

The step size used by the adaptive algorithm is specified as a positive scalar. Increasing the step size reduces the equalizer convergence time but causes the equalized output signal to be less stable. To determine the maximum step size allowed by the CMA adaptive algorithm, use the `maxstep` object function. The * operator denotes the complex conjugate and the error calculation $e = y(R - |y|^{2})$, where R is a constant related to the signal constellation.

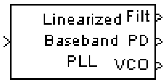
Linearized Baseband PLL

Implement linearized version of baseband phase-locked loop



Library

Components sublibrary of Synchronization

Description

The Linearized Baseband PLL block is a feedback control system that automatically adjusts the phase of a locally generated signal to match the phase of an input signal. Unlike the Phase-Locked Loop block, this block uses a baseband model method. Unlike the Baseband PLL block, which uses a nonlinear model, this block simplifies the computations by using *x* to approximate sin(*x*). The baseband PLL model depends on the amplitude of the incoming signal but does not depend on a carrier frequency.

This PLL has these three components:

- An integrator used as a phase detector.
- A filter. You specify the filter's transfer function using the **Lowpass filter numerator** and **Lowpass filter denominator** parameters. Each is a vector that gives the respective polynomial's coefficients in order of descending powers of *s*.

  To design a filter, you can use functions such as `butter`, `cheby1`, and `cheby2` in Signal Processing Toolbox software. The default filter is a Chebyshev type II filter whose transfer function arises from the command below.

  ```
  [num, den] = cheby2(3,40,100,'s')
  ```
- A voltage-controlled oscillator (VCO). You specify the sensitivity of the VCO signal to its input using the **VCO input sensitivity** parameter. This parameter, measured in Hertz per volt, is a scale factor that determines how much the VCO shifts from its quiescent frequency.

This block accepts a sample-based scalar input signal. The input signal represents the received signal. The three output ports produce:

- The output of the filter
- The output of the phase detector
- The output of the VCO

Parameters

Lowpass filter numerator

The numerator of the lowpass filter transfer function, represented as a vector that lists the coefficients in order of descending powers of *s*.

Lowpass filter denominator

The denominator of the lowpass filter transfer function, represented as a vector that lists the coefficients in order of descending powers of *s*.

VCO input sensitivity (Hz/V)

This value scales the input to the VCO and, consequently, the shift from the VCO's quiescent frequency.

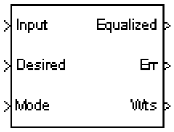
LMS Decision Feedback Equalizer

(To be removed) Equalize using decision feedback equalizer that updates weights with LMS algorithm

Note will be removed in a future release. Use Decision Feedback Equalizer instead.



Library

Equalizers

Description

The LMS Decision Feedback Equalizer block uses a decision feedback equalizer and the LMS algorithm to equalize a linearly modulated baseband signal through a dispersive channel. During the simulation, the block uses the LMS algorithm to update the weights, once per symbol. If the **Number of samples per symbol** parameter is `1`, then the block implements a symbol-spaced equalizer; otherwise, the block implements a fractionally spaced equalizer.

Input and Output Signals

The `Input` port accepts a column vector input signal. The `Desired` port receives a training sequence with a length that is less than or equal to the number of symbols in the `Input` signal. Valid training symbols are those symbols listed in the **Signal constellation** vector.

Set the **Reference tap** parameter so it is greater than zero and less than the value for the **Number of forward taps** parameter.

The port labeled `Equalized` outputs the result of the equalization process.

You can configure the block to have one or more of these extra ports:

- `Mode` input.
- `Err` output for the error signal, which is the difference between the `Equalized` output and the reference signal. The reference signal consists of training symbols in training mode, and detected symbols otherwise.
- `Weights` output.

Decision-Directed Mode and Training Mode

To learn the conditions under which the equalizer operates in training or decision-directed mode, see “Equalization”.

Equalizer Delay

For proper equalization, you should set the **Reference tap** parameter so that it exceeds the delay, in symbols, between the transmitter's modulator output and the equalizer input. When this condition is satisfied, the total delay, in symbols, between the modulator output and the equalizer *output* is equal to

1+(**Reference tap**-1)/(**Number of samples per symbol**)

Because the channel delay is typically unknown, a common practice is to set the reference tap to the center tap of the forward filter.

Parameters

Number of forward taps

The number of taps in the forward filter of the decision feedback equalizer.

Number of feedback taps

The number of taps in the feedback filter of the decision feedback equalizer.

Number of samples per symbol

The number of input samples for each symbol.

Signal constellation

A vector of complex numbers that specifies the constellation for the modulation.

Reference tap

A positive integer less than or equal to the number of forward taps in the equalizer.

Step size

The step size of the LMS algorithm.

Leakage factor

The leakage factor of the LMS algorithm, a number between 0 and 1. A value of 1 corresponds to a conventional weight update algorithm, and a value of 0 corresponds to a memoryless update algorithm.

Initial weights

A vector that concatenates the initial weights for the forward and feedback taps.

Mode input port

If you select this check box, the block has an input port that enables you to toggle between training and decision-directed mode. For training, the mode input must be 1, and for decision directed, the mode must be 0. For every frame in which the mode input is 1 or not present, the equalizer trains at the beginning of the frame for the length of the desired signal.

Output error

If you select this check box, the block outputs the error signal, which is the difference between the equalized signal and the reference signal.

Output weights

If you select this check box, the block outputs the current forward and feedback weights, concatenated into one vector.

Compatibility Considerations

LMS Decision Feedback Equalizer will be removed

Warns starting in R2020a

- LMS Decision Feedback Equalizer will be removed in a future release. Use Decision Feedback Equalizer instead with the adaptive algorithm set to LMS.
- The **Enable training control input** parameter of the Decision Feedback Equalizer block is equivalent to the **Mode input port** parameter of the LMS Decision Feedback Equalizer block.
- The Decision Feedback Equalizer block does not have a leakage factor parameter. This is equivalent to setting the **Leakage factor** parameter to 1 in the LMS Decision Feedback Equalizer block.

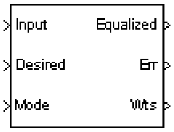
LMS Linear Equalizer

(To be removed) Equalize using linear equalizer that updates weights with LMS algorithm

Note will be removed in a future release. Use Linear Equalizer instead.



Library

Equalizers

Description

The LMS Linear Equalizer block uses a linear equalizer and the LMS algorithm to equalize a linearly modulated baseband signal through a dispersive channel. During the simulation, the block uses the LMS algorithm to update the weights, once per symbol. When you set the **Number of samples per symbol** parameter to `1`, then the block implements a symbol-spaced (i.e. T-spaced) equalizer. When you set the **Number of samples per symbol** parameter to a value greater than one, the block updates the weights once every N^{th} sample for a T/N-spaced equalizer.

Input and Output Signals

The `Input` port accepts a column vector input signal. The `Desired` port receives a training sequence with a length that is less than or equal to the number of symbols in the `Input` signal. Valid training symbols are those symbols listed in the **Signal constellation** vector.

Set the **Reference tap** parameter so it is greater than zero and less than the value for the **Number of taps** parameter.

The `Equalized` port outputs the result of the equalization process.

You can configure the block to have one or more of these extra ports:

- `Mode` input.
- `Err` output for the error signal, which is the difference between the `Equalized` output and the reference signal. The reference signal consists of training symbols in training mode, and detected symbols otherwise.
- `Weights` output.

Decision-Directed Mode and Training Mode

To learn the conditions under which the equalizer operates in training or decision-directed mode, see “Equalization”.

Equalizer Delay

For proper equalization, you should set the **Reference tap** parameter so that it exceeds the delay, in symbols, between the transmitter's modulator output and the equalizer input. When this condition is satisfied, the total delay, in symbols, between the modulator output and the equalizer *output* is equal to

1+(**Reference tap**-1)/(**Number of samples per symbol**)

Because the channel delay is typically unknown, a common practice is to set the reference tap to the center tap.

Parameters

Number of taps

The number of taps in the filter of the linear equalizer.

Number of samples per symbol

The number of input samples for each symbol.

Signal constellation

A vector of complex numbers that specifies the constellation for the modulated signal, as determined by the modulator in your model

Reference tap

A positive integer less than or equal to the number of taps in the equalizer.

Step size

The step size of the LMS algorithm.

Leakage factor

The leakage factor of the LMS algorithm, a number between 0 and 1. A value of 1 corresponds to a conventional weight update algorithm, and a value of 0 corresponds to a memoryless update algorithm.

Initial weights

A vector that lists the initial weights for the taps.

Mode input port

If you select this check box, the block has an input port that allows you to toggle between training and decision-directed mode. For training, the mode input must be 1, and for decision directed, the mode must be 0. For every frame in which the mode input is 1 or not present, the equalizer trains at the beginning of the frame for the length of the desired signal.

Output error

If you select this check box, the block outputs the error signal, which is the difference between the equalized signal and the reference signal.

Output weights

If you select this check box, the block outputs the current weights.

Matrix Deinterleaver

Permute input symbols by filling matrix by columns and emptying it by rows

Library

Block sublibrary of Interleaving

Description

The Matrix Deinterleaver block performs block deinterleaving by filling a matrix with the input symbols column by column and then sending the matrix contents to the output port row by row. The **Number of rows** and **Number of columns** parameters are the dimensions of the matrix that the block uses internally for its computations.

This block accepts a column vector input signal. The length of the input vector must be **Number of rows** times **Number of columns**.

The block accepts the following data types: `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, `double`, and fixed-point. The output signal inherits its data type from the input signal.

Parameters

Number of rows

The number of rows in the matrix that the block uses for its computations.

Number of columns

The number of columns in the matrix that the block uses for its computations.

Examples

If the **Number of rows** and **Number of columns** parameters are 2 and 3, respectively, then the deinterleaver uses a 2-by-3 matrix for its internal computations. Given an input signal of `[1; 2; 3; 4; 5; 6]`, the block produces an output of `[1; 3; 5; 2; 4; 6]`.

Matrix Helical Scan Deinterleaver

Restore ordering of input symbols by filling matrix along diagonals

Library

Block sublibrary of Interleaving

Description

The Matrix Helical Scan Deinterleaver block performs block deinterleaving by filling a matrix with the input symbols in a helical fashion and then sending the matrix contents to the output port row by row. The **Number of rows** and **Number of columns** parameters are the dimensions of the matrix that the block uses internally for its computations.

Helical fashion means that the block places input symbols along diagonals of the matrix. The number of elements in each diagonal matches the **Number of columns** parameter, after the block wraps past the edges of the matrix when necessary. The block traverses diagonals so that the row index and column index both increase. Each diagonal after the first one begins one row below the first element of the previous diagonal.

The **Array step size** parameter is the slope of each diagonal, that is, the amount by which the row index increases as the column index increases by one. This parameter must be an integer between zero and the **Number of rows** parameter. If the **Array step size** parameter is zero, then the block does not deinterleave and the output is the same as the input.

This block accepts a column vector input signal. The number of elements of the input vector must be the product of **Number of rows** and **Number of columns**.

The block accepts the following data types: `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, `double`, and fixed-point. The output signal inherits its data type from the input signal.

Parameters

Number of rows

The number of rows in the matrix that the block uses for its computations.

Number of columns

The number of columns in the matrix that the block uses for its computations.

Array step size

The slope of the diagonals that the block writes.

Matrix Helical Scan Interleaver

Permute input symbols by selecting matrix elements along diagonals

Library

Block sublibrary of Interleaving

Description

The Matrix Helical Scan Interleaver block performs block interleaving by filling a matrix with the input symbols row by row and then sending the matrix contents to the output port in a helical fashion. The **Number of rows** and **Number of columns** parameters are the dimensions of the matrix that the block uses internally for its computations.

Helical fashion means that the block selects output symbols by selecting elements along diagonals of the matrix. The number of elements in each diagonal matches the **Number of columns** parameter, after the block wraps past the edges of the matrix when necessary. The block traverses diagonals so that the row index and column index both increase. Each diagonal after the first one begins one row below the first element of the previous diagonal.

The **Array step size** parameter is the slope of each diagonal, that is, the amount by which the row index increases as the column index increases by one. This parameter must be an integer between zero and the **Number of rows** parameter. If the **Array step size** parameter is zero, then the block does not interleave and the output is the same as the input.

This block accepts a column vector input signal. The number of elements of the input vector must be the product of **Number of rows** and **Number of columns**.

The block accepts the following data types: `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, `double`, and fixed-point. The output signal inherits its data type from the input signal.

Parameters

Number of rows

The number of rows in the matrix that the block uses for its computations.

Number of columns

The number of columns in the matrix that the block uses for its computations.

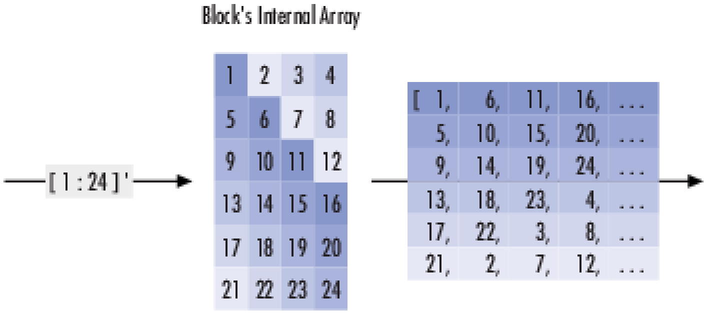
Array step size

The slope of the diagonals that the block reads.

Examples

If the **Number of rows** and **Number of columns** parameters are 6 and 4, respectively, then the interleaver uses a 6-by-4 matrix for its internal computations. If the **Array step size** parameter is 1, then the diagonals are as shown in the figure below. Positions with the same color form part of the same diagonal, and diagonals with darker colors precede those with lighter colors in the output signal.

Given an input signal of `[1:24]'`, the block produces an output of



```
[1; 6; 11; 16; 5; 10; 15; 20; 9; 14; 19; 24; 13; 18; 23;...
4; 17; 22; 3; 8; 21; 2; 7; 12]
```

The **Number of rows** and **Number of columns** parameters are the dimensions of the matrix that the block uses internally for its computations.

This block accepts a column vector input signal. The number of elements of the input vector must be the product of **Number of rows** and **Number of columns**.

The block accepts the following data types: `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, `double`, and fixed-point. The output signal inherits its data type from the input signal.

Parameters

Number of rows

The number of rows in the matrix that the block uses for its computations.

Number of columns

The number of columns in the matrix that the block uses for its computations.

Examples

If the **Number of rows** and **Number of columns** parameters are 2 and 3, respectively, then the interleaver uses a 2-by-3 matrix for its internal computations. Given an input signal of `[1; 2; 3; 4; 5; 6]`, the block produces an output of `[1; 4; 2; 5; 3; 6]`.

M-DPSK Demodulator Baseband

Demodulate DPSK-modulated data

Library

PM, in Digital Baseband sublibrary of Modulation

Description

The M-DPSK Demodulator Baseband block demodulates a signal that was modulated using the M-ary differential phase shift keying method. The input is a baseband representation of the modulated signal. The input and output for this block are discrete-time signals. This block accepts a scalar-valued or column vector input signal. For information about the data types each block port supports, see the “Supported Data Types” on page 5-477 table on this page.

The **M-ary number** parameter, M, is the number of possible output symbols that can immediately follow a given output symbol. The block compares the current symbol to the previous symbol. The block's first output is the initial condition of zero (or a group of zeros, if the **Output type** parameter is set to `Bit`) because there is no previous symbol.

Integer-Valued Signals and Binary-Valued Signals

If you set the **Output type** parameter to `Integer`, then the block demodulates a phase difference of

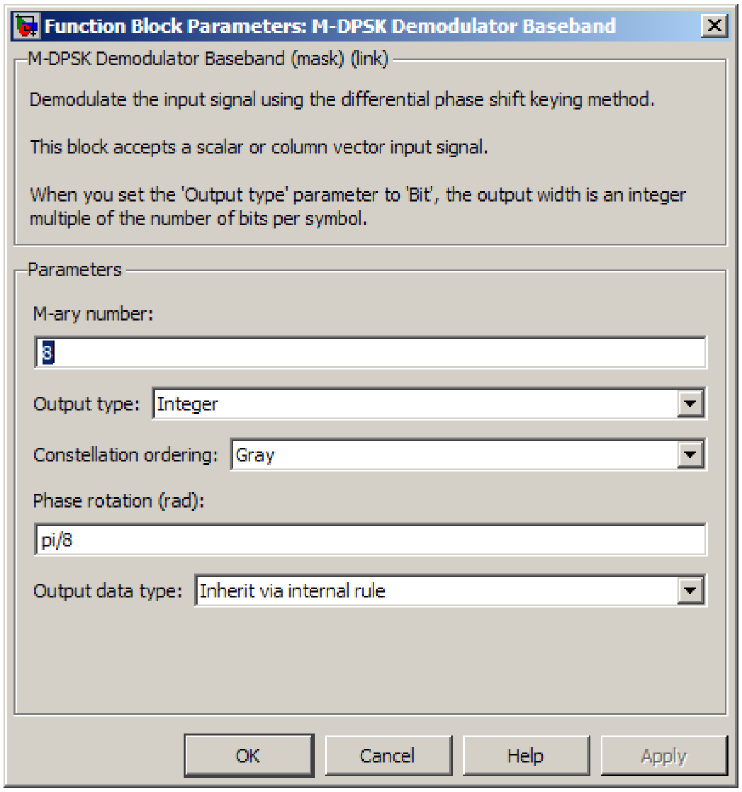
$$\theta + 2\pi k/M$$

to k, where θ represents the **Phase rotation** parameter and k represents an integer between `0` and M-1.

When you set the **Output type** parameter to `Bit`, the block outputs binary-valued signals that represent integers. The block represents each integer using a group of $K = \log_2(M)$ bits, where K represents the number of bits per symbol. The output vector length must be an integer multiple of K.

In binary output mode, the symbols can be either binary-demapped or Gray-demapped. The **Constellation ordering** parameter indicates how the block maps an integer to a corresponding group of K output bits. See the reference pages for the M-DPSK Modulator Baseband and M-PSK Modulator Baseband blocks for details.

Dialog Box



Function Block Parameters: M-DPSK Demodulator Baseband

M-DPSK Demodulator Baseband (mask) (link)

Demodulate the input signal using the differential phase shift keying method.

This block accepts a scalar or column vector input signal.

When you set the 'Output type' parameter to 'Bit', the output width is an integer multiple of the number of bits per symbol.

Parameters

M-ary number: 8

Output type: Integer

Constellation ordering: Gray

Phase rotation (rad): pi/8

Output data type: Inherit via internal rule

M-ary number

The number of possible modulated symbols that can immediately follow a given symbol.

Output type

Determines whether the output consists of integers or groups of bits.

Constellation ordering

Determines how the block maps each integer to a group of output bits.

Phase rotation (rad)

This phase difference between the current and previous modulated symbols that results in an output of zero.

Output data type

When the parameter is set to `'Inherit via internal rule'` (default setting), the block will inherit the output data type from the input port. The output data type will be the same as the input data type if the input is of type `single` or `double`.

For integer outputs, this block can output the data types `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `single`, and `double`. For bit outputs, output can be `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, or `double`.

Supported Data Types

Port	Supported Data Types
Input	- Double-precision floating point - Single-precision floating point
Output	- Double-precision floating point - Single-precision floating point - Boolean when **Output type** set to `Bit` - 8-, 16-, and 32-bit signed integers - 8-, 16-, and 32-bit unsigned integers

M-DPSK Modulator Baseband

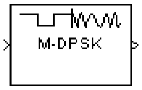
Modulate using M-ary differential phase shift keying method



Library

PM, in Digital Baseband sublibrary of Modulation

Description

The M-DPSK Modulator Baseband block modulates using the M-ary differential phase shift keying method. The output is a baseband representation of the modulated signal. The **M-ary number** parameter, M, is the number of possible output symbols that can immediately follow a given output symbol.

The input must be a discrete-time signal. For integer inputs, the block can accept the data types `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `single`, and `double`. For bit inputs, the block can accept `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, and `double`.

The input can be either bits or integers, which are binary-mapped or Gray-mapped into symbols.

This block accepts column vector input signals. For a bit input, the input width must be an integer multiple of the number of bits per symbol.

Integer-Valued Signals and Binary-Valued Signals

If you set the **Input type** parameter to `Integer`, then valid input values are integers between 0 and M-1. In this case, the input can be either a scalar or a frame-based column vector. If the first input is k_1, then the modulated symbol is

$$\exp\left(j\theta + j2\pi\frac{k_1}{m}\right)$$

where θ represents the **Phase rotation** parameter. If a successive input is *k*, then the modulated symbol is

$$\exp\left(j\theta + j2\pi\frac{k}{m}\right) \cdot \text{(previous modulated symbol)}$$

When you set the **Input type** parameter to `Bit`, the block accepts binary-valued inputs that represent integers. The block collects binary-valued signals into groups of $K = \log_2(M)$ bits

where

K represents the number of bits per symbol.

The input vector length must be an integer multiple of *K*. In this configuration, the block accepts a group of *K* bits and maps that group onto a symbol at the block output. The block outputs one modulated symbol for each group of *K* bits.

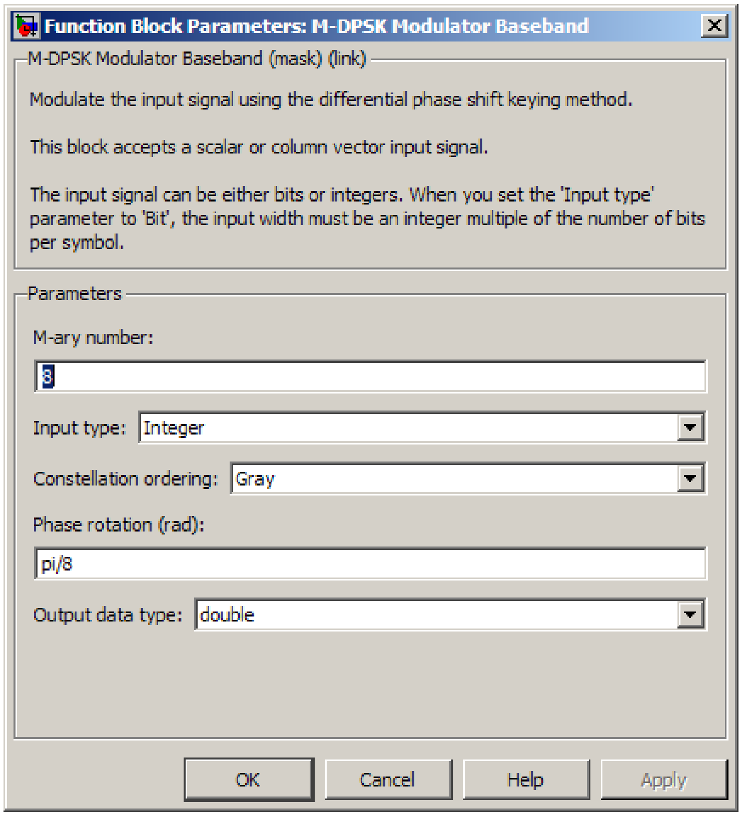
The input can be a column vector with a length that is an integer multiple of *K*.

In binary input mode, the **Constellation ordering** parameter indicates how the block maps a group of *K* input bits to a corresponding phase difference. The `Binary` option uses a natural binary-to-integer mapping, while the `Gray` option uses a Gray-coded assignment of phase differences. For example, the following table indicates the assignment of phase difference to three-bit inputs, for both the `Binary` and `Gray` options. θ is the **Phase rotation** parameter. The phase difference is between the previous symbol and the current symbol.

Current Input	Binary-Coded Phase Difference	Gray-Coded Phase Difference
[0 0 0]	jθ	jθ
[0 0 1]	jθ + jπ/4	jθ + jπ/4
[0 1 0]	jθ + jπ2/4	jθ + jπ3/4
[0 1 1]	jθ + jπ3/4	jθ + jπ2/4
[1 0 0]	jθ + jπ4/4	jθ + jπ7/4
[1 0 1]	jθ + jπ5/4	jθ + jπ6/4
[1 1 0]	jθ + jπ6/4	jθ + jπ4/4
[1 1 1]	jθ + jπ7/4	jθ + jπ5/4

For more details about the `Binary` and `Gray` options, see the reference page for the M-PSK Modulator Baseband block. The signal constellation for that block corresponds to the arrangement of phase differences for this block.

Dialog Box



M-DPSK Modulator Baseband (mask) (link)

Modulate the input signal using the differential phase shift keying method.

This block accepts a scalar or column vector input signal.

The input signal can be either bits or integers. When you set the 'Input type' parameter to 'Bit', the input width must be an integer multiple of the number of bits per symbol.

Parameters

M-ary number: 8

Input type: Integer

Constellation ordering: Gray

Phase rotation (rad): pi/8

Output data type: double

M-ary number

The number of possible output symbols that can immediately follow a given output symbol.

Input type

Indicates whether the input consists of integers or groups of bits. If this parameter is set to `Bit`, then the **M-ary number** parameter must be 2^K for some positive integer K.

Constellation ordering

Determines how the block maps each group of input bits to a corresponding integer.

Phase rotation (rad)

The phase difference between the previous and current modulated symbols when the input is zero.

Output data type

The output data type can be either `single` or `double`. By default, the block sets this to `double`.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point • Boolean (binary input mode only) • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers
Output	• Double-precision floating point • Single-precision floating point

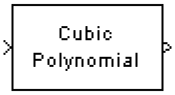
Memoryless Nonlinearity

Apply memoryless nonlinearity to complex baseband signal
Library: Communications Toolbox / RF Impairments



Description

The Memoryless Nonlinearity block applies memoryless nonlinear impairments to a complex baseband signal. Use this block to model memoryless nonlinear impairments caused by signal amplification in the radio frequency (RF) transmitter or receiver. For more information, see “Memoryless Nonlinear Impairments” on page 5-486.

Note All values of power assume a nominal impedance of 1 ohm.

Ports

Input

`In1` — Input RF baseband signal
scalar | column vector

Input RF baseband signal, specified as a scalar or column vector. Values in this input must be complex.

Data Types: `double`
Complex Number Support: Yes

Output

`Out1` — Output RF baseband signal
scalar | column vector

Output RF baseband signal, returned as a scalar or column vector. The output is of the same data type as the input.

Parameters

`Method` — Nonlinearity modeling method
`Cubic polynomial` (default) | `Hyperbolic tangent` | `Saleh model` | `Ghorbani model` | `Rapp model`

Nonlinearity modeling method, specified as `Cubic polynomial`, `Hyperbolic tangent`, `Saleh model`, `Ghorbani model`, `Rapp model`, or `Lookup table`. For more information, see “Memoryless Nonlinear Impairments” on page 5-486.

`Linear gain (dB)` — Linear gain
`0` (default) | scalar

Linear gain in decibels, specified as a scalar. This parameter scales the power gain of the output signal.

Tunable: Yes

Dependencies

To enable this parameter, set the **Method** to `Cubic polynomial`, `Hyperbolic tangent`, or `Rapp model`.

Data Types: `double`

`IIP3 (dBm)` — Third-order input intercept point

`30` (default) | scalar

Third-order input intercept point in dBm, specified as a scalar.

Tunable: Yes

Dependencies

To enable this parameter, set the **Method** to `Cubic polynomial` or `Hyperbolic tangent`.

Data Types: `double`

`AM/PM conversion (degrees per dB)` — AM/PM conversion factor

`10` (default) | scalar

AM/PM conversion factor in degrees per decibel, specified as a scalar. For more information, see “Cubic Polynomial and Hyperbolic Tangent Model Methods” on page 5-487.

Tunable: Yes

Dependencies

To enable this parameter, set the **Method** to `Cubic polynomial` or `Hyperbolic tangent`.

Data Types: `double`

`Lower input power limit for AM/PM conversion (dBm)` — Input power lower limit

`10` (default) | scalar

Input power lower limit in dBm, specified as a scalar less than the **Upper input power limit for AM/PM conversion (dBm)** parameter value. The AM/PM conversion scales linearly for input power values in the range [**Lower input power limit for AM/PM conversion (dBm)**, **Upper input power limit for AM/PM conversion (dBm)**]. If the input signal power is below the input power lower limit, the phase shift resulting from AM/PM conversion is zero. For more information, see “Cubic Polynomial and Hyperbolic Tangent Model Methods” on page 5-487.

Tunable: Yes

Dependencies

To enable this parameter, set the **Method** to `Cubic polynomial` or `Hyperbolic tangent`.

Data Types: `double`

`Upper input power limit for AM/PM conversion (dBm)` — Input power upper limit

`inf` (default) | scalar

Input power upper limit in dBm, specified as a scalar greater than the **Lower input power limit for AM/PM conversion (dBm)** parameter value. The AM/PM conversion scales linearly for input power values in the range [**Lower input power limit for AM/PM conversion (dBm)**, **Upper input power limit for AM/PM conversion (dBm)**]. If the input signal power is below the input power lower limit, the phase shift resulting from AM/PM conversion is zero. For more information, see “Cubic Polynomial and Hyperbolic Tangent Model Methods” on page 5-487.

Tunable: Yes

Dependencies

To enable this parameter, set the **Method** to `Cubic polynomial` or `Hyperbolic tangent`.

Data Types: `double`

`Input scaling (dB)` — Input signal scaling factor

`0` (default) | scalar

Input signal scaling factor in decibels, specified as a scalar. This parameter scales the power gain of the input signal.

Tunable: Yes

Dependencies

To enable this parameter, set the **Method** to `Saleh model` or `Ghorbani model`.

Data Types: `double`

`AM/AM parameters [alpha beta]` — AM/AM parameters for Saleh model

`[2.1587 1.1517]` (default) | two-element vector

AM/AM parameters for Saleh model, used to compute the amplitude gain for an input signal, specified as a two-element vector. For more information, see “Saleh Model Method” on page 5-488.

Tunable: Yes

Dependencies

To enable this parameter, set the **Method** to `Saleh model`.

Data Types: `double`

`AM/PM parameters [alpha beta]` — AM/PM parameters for Saleh model

`[4.0033 9.1040]` (default) | two-element vector

AM/PM parameters for Saleh model, used to compute the phase change for an input signal, specified as a two-element vector. For more information, see “Saleh Model Method” on page 5-488.

Tunable: Yes

Dependencies

To enable this parameter, set the **Method** to `Saleh model`.

`AM/AM parameters [x1 x2 x3 x4]` — AM/AM parameters for Ghorbani model

`[8.1081 1.5413 6.5202 -0.0718]` (default) | four-element vector

AM/AM parameters for Ghorbani model, used to compute the amplitude gain for an input signal, specified as a four-element vector. For more information, see "Ghorbani Model Method" on page 5-488.

Tunable: Yes

Dependencies

To enable this parameter, set the **Method** to `Ghorbani model`.

Data Types: `double`

`AM/PM parameters [y1 y2 y3 y4]` — AM/PM parameters for Ghorbani model

`[4.6645 2.0965 10.88 -0.003]` (default) | four-element vector

AM/PM parameters for Ghorbani model, used to compute the phase change for an input signal, specified as a four-element vector. For more information, see "Ghorbani Model Method" on page 5-488.

Tunable: Yes

Dependencies

To enable this parameter, set the **Method** to `Ghorbani model`.

Data Types: `double`

`Output scaling (dB)` — Output signal scaling factor

`0` (default) | scalar

Output signal scaling factor in decibels, specified as a scalar. This parameter scales the power gain of the output signal.

Tunable: Yes

Dependencies

To enable this parameter, set the **Method** to `Saleh model` or `Ghorbani model`.

Data Types: `double`

`Smoothness factor` — Smoothness factor

`0.5` (default) | scalar

Smoothness factor, specified as a scalar. For more information, see "Rapp Model Method" on page 5-489.

Tunable: Yes

Dependencies

To enable this parameter, set the **Method** to `Rapp model`.

Data Types: `double`

`Output saturation level` — Output saturation level

`1` (default) | scalar

Output saturation level, specified as a scalar. For more information, see “Rapp Model Method” on page 5-489.

Tunable: Yes

Dependencies

To enable this parameter, set the **Method** to `Rapp model`.

Data Types: `double`

Block Characteristics

Data Types	`double` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`no`

More About

Memoryless Nonlinear Impairments

Memoryless nonlinear impairments distort the input signal amplitude and phase. The amplitude distortion is amplitude-to-amplitude modulation (AM/AM) and the phase distortion is amplitude-to-phase modulation (AM/PM).

Model Method	Memoryless Nonlinear Impairment
Cubic polynomial	AM/AM and AM/PM
Hyperbolic tangent	
Saleh model	
Ghorbani model	
Rapp model	AM/AM only

The modeled impairments apply the AM/AM and AM/PM distortions differently, according to the model method you specify. The models apply the memoryless nonlinear impairment to the input signal by following these steps.

1. Multiply the signal by an input gain factor.

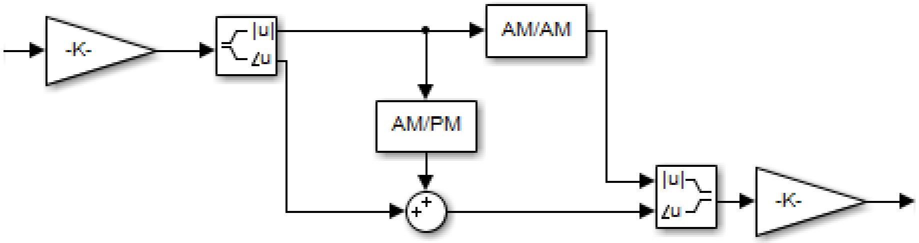
   Note You can normalize the signal to 1 by setting the input scaling gain to the inverse of the input signal amplitude.

2. Split the complex signal into its magnitude and angle components.
3. Apply an AM/AM distortion to the magnitude of the signal, according to the selected model method, to produce the magnitude of the output signal.
4. Apply an AM/PM distortion to the phase of the signal, according to the selected model method, to produce the angle of the output signal.

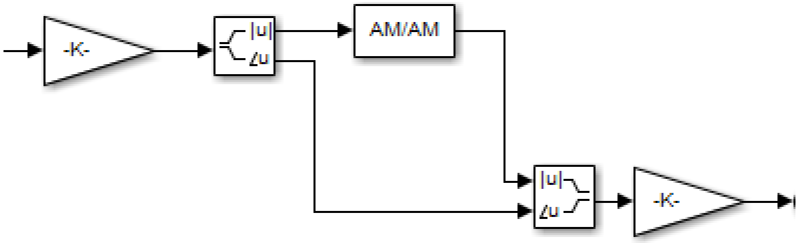
   Note This step does not apply for the Rapp model.

5 Combine the new magnitude and angle components into a complex signal. Then, multiply the result by an output gain factor.

The first four model methods (cubic polynomial, hyperbolic tangent, Saleh model, and Ghorbani model) apply AM/AM and AM/PM impairments as shown in this figure.

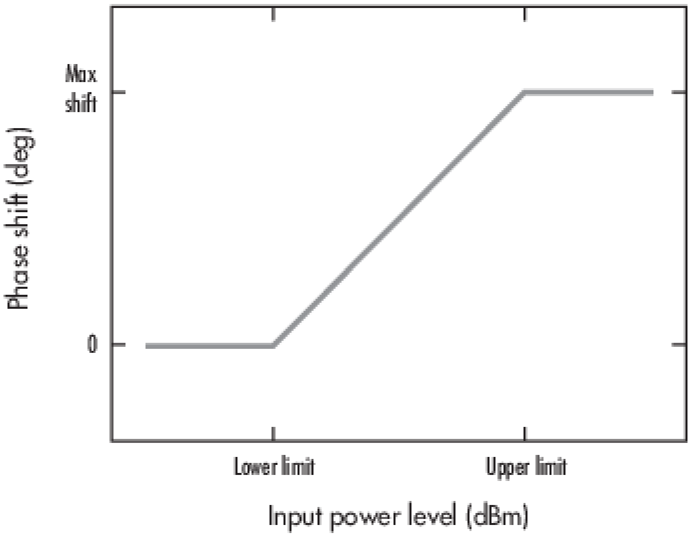


The Rapp model method applies AM/AM distortion as shown in this figure.



Cubic Polynomial and Hyperbolic Tangent Model Methods

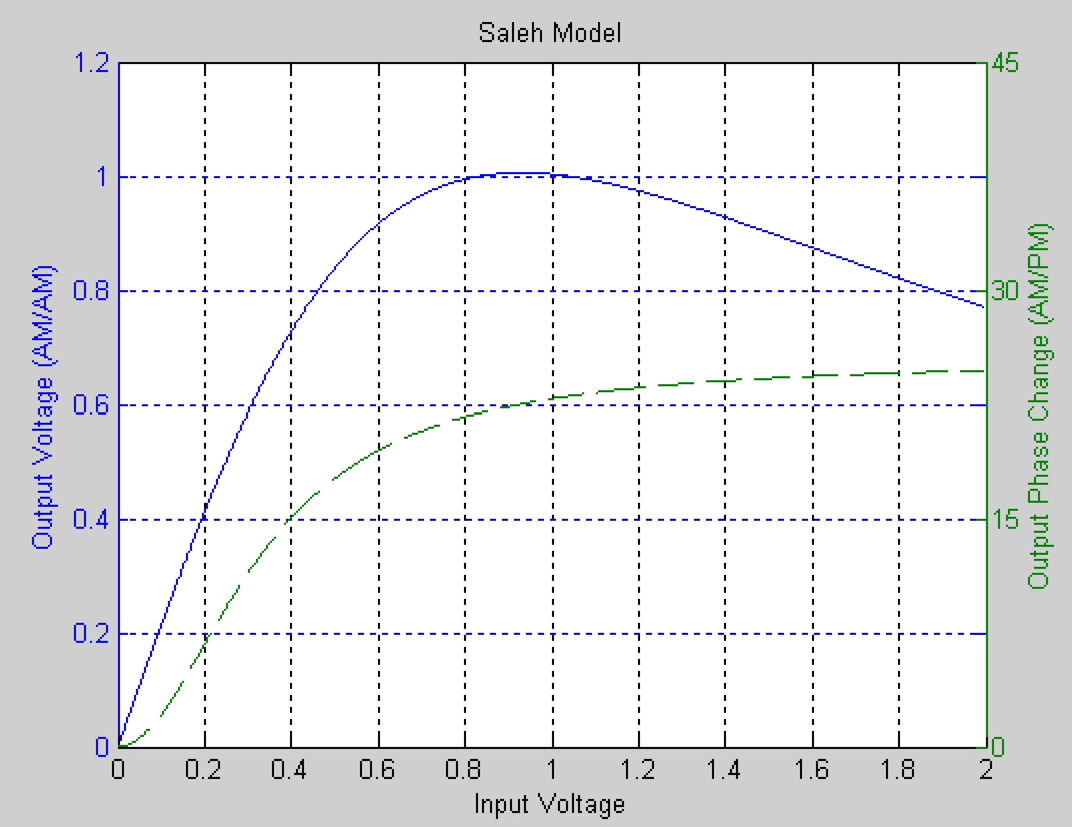
This figure shows the AM/PM conversion behavior for the cubic polynomial and hyperbolic tangent model methods.



The AM/PM conversion scales linearly with an input power value between the lower and upper limits of the input power level. Outside this range, the AM/PM conversion is constant at the values corresponding to the lower and upper input power limits, which are zero and (*AM/PM conversion*) × (*upper input power limit – lower input power limit*), respectively.

Saleh Model Method

This figure shows the AM/AM behavior (output voltage versus input voltage for the AM/AM distortion) and the AM/PM behavior (output phase versus input voltage for the AM/PM distortion) for the Saleh model method.



The AM/AM parameters, α_{AMAM} and β_{AMAM}, are used to compute the amplitude distortion of the input signal by using

$$F_{\mathrm{AMAM}}(u) = \frac{\alpha_{\mathrm{AMAM}} \times u}{1 + \beta_{\mathrm{AMAM}} \times u^2},$$

where u is the magnitude of the scaled signal.

The AM/PM parameters, α_{AMPM} and β_{AMPM}, are used to compute the phase distortion of the input signal by using

$$F_{\mathrm{AMPM}}(u) = \frac{\alpha_{\mathrm{AMPM}} \times u^2}{1 + \beta_{\mathrm{AMPM}} \times u^2},$$

where u is the magnitude of the scaled signal. The α and β parameters for AM/AM and AM/PM are similarly named but distinct.

Ghorbani Model Method

The Ghorbani model method applies AM/AM and AM/PM distortion as described in this section.

The AM/AM parameters (x_1, x_2, x_3, and x_4) are used to compute the amplitude distortion of the input signal by using

$$F_{\mathrm{AMAM}}(u) = \frac{x_1 u^{x_2}}{1 + x_3 u^{x_2}} + x_4 u,$$

where u is the magnitude of the scaled signal.

The AM/PM parameters (y_1, y_2, y_3, and y_4) are used to compute the phase distortion of the input signal by using

$$F_{\mathrm{AMPM}}(u) = \frac{y_1 u^{y_2}}{1 + y_3 u^{y_2}} + y_4 u,$$

where u is the magnitude of the scaled signal.

Rapp Model Method

The Rapp model method applies AM/AM distortion as described in this section. The Rapp model does not apply AM/PM distortion to the input signal.

The smoothness factor and output saturation level are used to compute the amplitude distortion of the input signal given by

$$F_{\mathrm{AMAM}}(u) = \frac{u}{\left(1 + \left(\frac{u}{O_{\mathrm{sat}}}\right)^{2\mathrm{S}}\right)^{1/2\mathrm{S}}},$$

where

- u is the magnitude of the scaled signal.
- S is the smoothness factor.
- O_{sat} is the output saturation level.

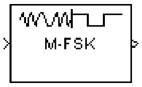
M-FSK Demodulator Baseband

Demodulate FSK-modulated data



Library

FM, in Digital Baseband sublibrary of Modulation

Description

The M-FSK Demodulator Baseband block demodulates a signal that was modulated using the M-ary frequency shift keying method. The input is a baseband representation of the modulated signal. The input and output for this block are discrete-time signals. This block accepts a scalar value or column vector input signal of type `single` or `double`. For information about the data types each block port supports, see "Supported Data Types" on page 5-494.

The **M-ary number** parameter, M, is the number of frequencies in the modulated signal. The **Frequency separation** parameter is the distance, in Hz, between successive frequencies of the modulated signal.

The M-FSK Demodulator Baseband block implements a non-coherent energy detector. To obtain the same BER performance as that of coherent FSK demodulation, use the CPFSK Demodulator Baseband block.

Integer-Valued Signals and Binary-Valued Signals

When you set the **Output type** parameter to `Integer`, the block outputs integer values between `0` and *M*-`1`. *M* represents the **M-ary number** block parameter.

When you set the **Output type** parameter to `Bit`, the block outputs binary-valued signals that represent integers. The block represents each integer using a group of $K = \log_2(M)$ bits, where *K* represents the number of bits per symbol. The output vector length must be an integer multiple of *K*.

The **Symbol set ordering** parameter indicates how the block maps a symbol to a group of *K* output bits. When you set the parameter to `Binary`, the block maps the integer, I, to [*u*(1) *u*(2) ... *u*(K)] bits, where the individual u(i) are given by

$$I = \sum_{i=1}^{K} u(i)2^{K-i}$$

u(1) is the most significant bit.

For example, if *M* = 8, you set **Symbol set ordering** to `Binary`, and the demodulated integer symbol value is 6, then the binary output word is [1 1 0].

When you set **Symbol set ordering** to `Gray`, the block assigns binary outputs from points of a predefined Gray-coded signal constellation. The predefined M-ary Gray-coded signal constellation assigns the binary representation

```
M = 8; P = [0:M-1]';
de2bi(bitxor(P,floor(P/2)), log2(M),'left-msb')
```

to the *P*th integer.

The typical Binary to Gray mapping for *M* = 8 is shown in the following tables.

Binary to Gray Mapping for Bits

Binary Code	Gray Code
000	000
001	001
010	011
011	010
100	110
101	111
110	101
111	100

Binary to Gray Mapping for Integers

Binary Code	Gray Code
0	0
1	1
2	3
3	2
4	6
5	7
6	5
7	4

Whether the output is an integer or a binary representation of an integer, the block maps the highest frequency to the integer 0 and maps the lowest frequency to the integer M-1. In baseband simulation, the lowest frequency is the negative frequency with the largest absolute value.

Single-Rate Processing

In single-rate processing mode, the input and output signals have the same port sample time. The block implicitly implements the rate change by making a size change at the output when compared to the input. The input width must be an integer multiple of the **Samples per symbol** parameter value, and the input can be a column vector.

- When you set **Output type** to `Bit`, the output width is *K* times the number of input symbols.
- When you set **Output type** to `Integer`, the output width is the number of input symbols.

Multirate Processing

In multirate processing mode, the input and output signals have different port sample times. The input must be a scalar. The output symbol time is the product of the input sample time and the **Samples per symbol** parameter value.

- When you set **Output type** to `Bit`, the output width equals the number of bits per symbol.
- When you set **Output type** to `Integer`, the output is a scalar.

To run the M-FSK Demodulator block in multirate mode, clear the **Treat each discrete rate as a separate task** checkbox (in **Simulation > Configuration Parameters > Solver**).

Parameters

M-ary number

The number of frequencies in the modulated signal.

Output type

Determines whether the output consists of integers or groups of bits. If this parameter is set to `Bit`, then the **M-ary number** parameter must be 2^K for some positive integer K.

Symbol set ordering

Determines how the block maps each integer to a group of output bits.

Frequency separation (Hz)

The distance between successive frequencies in the modulated signal.

Samples per symbol

The number of input samples that represent each modulated symbol.

Rate options

Select the rate processing method for the block.

- `Enforce single-rate processing` — When you select this option, the input and output signals have the same port sample times. The block implements the rate change by making a size change at the output when compared to the input. The output width is the number of symbols (which is given by dividing the input length by the **Samples per symbol** parameter value when the **Output type** parameter is set to `Integer`).
- `Allow multirate processing` — When you select this option, the input and output signals have different port sample times. The output period is the same as the symbol period and equals the product of the input period and the **Samples per symbol** parameter value.

For more information, see Single-Rate Processing and Multirate Processing in the Description section of this page.

Output data type

The output type of the block can be specified here as `boolean`, `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, or `double`. By default, the block sets this to `double`.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point
Output	• Double-precision floating point • Boolean • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers

M-FSK Modulator Baseband

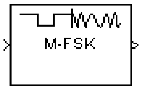
Modulate using M-ary frequency shift keying method



Library

FM, in Digital Baseband sublibrary of Modulation

Description

The M-FSK Modulator Baseband block modulates using the M-ary frequency shift keying method. The output is a baseband representation of the modulated signal. For information about the data types each block port supports, see “Supported Data Types” on page 5-498.

To prevent aliasing from occurring in the output signal, set the sampling frequency greater than the product of *M* and the **Frequency separation** parameter. Sampling frequency is **Samples per symbol** divided by the input symbol period (in seconds).

Integer-Valued Signals and Binary-Valued Signals

The input and output signals for this block are discrete-time signals.

When you set the **Input type** parameter to `Integer`, the block accepts integer values between `0` and *M*-`1`. *M* represents the **M-ary number** block parameter.

When you set the **Input type** parameter to `Bit`, the block accepts binary-valued inputs that represent integers. The block collects binary-valued signals into groups of $K = \log_2(M)$ bits

where

K represents the number of bits per symbol.

The input vector length must be an integer multiple of *K*. In this configuration, the block accepts a group of *K* bits and maps that group onto a symbol at the block output. The block outputs one modulated symbol, oversampled by the **Samples per symbol** parameter value, for each group of *K* bits.

The **Symbol set ordering** parameter indicates how the block maps a group of *K* input bits to a corresponding symbol. When you set the parameter to `Binary`, the block maps [*u*(1) *u*(2) ... *u*(K)] to the integer

$$\sum_{i=1}^{K} u(i)2^{K-i}$$

and assumes that this integer is the input value. *u*(1) is the most significant bit.

If you set M = 8, **Symbol set ordering** to `Binary`, and the binary input word is [1 1 0], the block converts [1 1 0] to the integer 6. The block produces the same output when the input is 6 and the **Input type** parameter is `Integer`.

When you set **Symbol set ordering** to `Gray`, the block uses a Gray-coded arrangement and assigns binary inputs to points of a predefined Gray-coded signal constellation. The predefined M-ary Gray-coded signal constellation assigns the binary representation

```
M = 8; P = [0:M-1]';
de2bi(bitxor(P,floor(P/2)), log2(M),'left-msb')
```

to the P^{th} integer.

The following tables show the typical Binary to Gray mapping for M = 8.

Binary to Gray Mapping for Bits

Binary Code	Gray Code
000	000
001	001
010	011
011	010
100	110
101	111
110	101
111	100

Binary to Gray Mapping for Integers

Binary Code	Gray Code
0	0
1	1
2	3
3	2
4	6
5	7
6	5
7	4

Single-Rate Processing

In single-rate processing mode, the input and output signals have the same port sample time. The block implicitly implements the rate change by making a size change at the output when compared to the input. In this mode, the input to the block can be multiple symbols.

- When you set **Input type** to `Integer`, the input can be a column vector, the length of which is the number of input symbols.
- When you set **Input type** to `Bit`, the input width must be an integer multiple of K, the number of bits per symbol.

The output width equals the product of the number of input symbols and the **Samples per symbol** parameter value.

Multirate Processing

In multirate processing mode, the input and output signals have different port sample times. In this mode, the input to the block must be one symbol.

- When you set **Input type** to `Integer`, the input must be a scalar.
- When you set **Input type** to `Bit`, the input width must equal the number of bits per symbol.

The output sample time equals the symbol period divided by the **Samples per symbol** parameter value.

To run the M-FSK Modulator block in multirate mode, clear the **Treat each discrete rate as a separate task** checkbox (in **Simulation > Configuration Parameters > Solver**).

Parameters

M-ary number

The number of frequencies in the modulated signal.

Input type

Indicates whether the input consists of integers or groups of bits. If you set this parameter to `Bit`, then the **M-ary number** parameter must be 2^K for some positive integer K.

Symbol set ordering

Determines how the block maps each group of input bits to a corresponding integer.

Frequency separation (Hz)

The distance between successive frequencies in the modulated signal.

Phase continuity

Determines whether the modulated signal changes phases in a continuous or discontinuous way.

If you set the **Phase continuity** parameter to `Continuous`, then the modulated signal maintains its phase even when it changes its frequency. If you set the **Phase continuity** parameter to `Discontinuous`, then the modulated signal comprises portions of *M* sinusoids of different frequencies. Thus, a change in the input value sometimes causes a change in the phase of the modulated signal.

Samples per symbol

The number of output samples that the block produces for each integer or binary word in the input.

Rate options

Select the rate processing option for the block.

- `Enforce single-rate processing` — When you select this option, the input and output signals have the same port sample time. The block implements the rate change by making a size change at the output when compared to the input. The output width equals the product of the number of symbols and the **Samples per symbol** parameter value.
- `Allow multirate processing` — When you select this option, the input and output signals have different port sample times. The output sample time equals the symbol period divided by the **Samples per symbol** parameter value.

Output data type

You can specify the output type of the block as either a `double` or a `single`. By default, the block sets this value to `double`.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Boolean (bit input mode only) • 8-, 16-, and 32-bit signed integers (integer input mode only) • 8-, 16-, and 32-bit unsigned integers (integer input mode only)
Output	• Double-precision floating point • Single-precision floating point

MIL-188 QAM Demodulator Baseband

MIL-STD-188-110 B/C standard-specific quadrature amplitude demodulation

Library: Communications Toolbox / Modulation / Digital Baseband Modulation / AM
Communications Toolbox / Modulation / Digital Baseband Modulation / Standard-Compliant

Description

The MIL-188 QAM Demodulator Baseband block demodulates the input signal using “MIL-STD-188-110” on page 5-502 standard-specific quadrature amplitude modulation (QAM). For a description of MIL-STD-188 compliant demodulation, see “MIL-STD-188-110 QAM Hard Demodulation” on page 5-502 and “MIL-STD-188-110 QAM Soft Demodulation” on page 5-503.

This icon shows the block with all ports enabled:

In
MIL-188-QAM
Var

Ports

Input

In — MIL-STD-188 standard-specific QAM modulated signal

scalar | vector | matrix

MIL-STD-188 standard-specific QAM modulated signal, specified as a scalar, vector, or matrix. When this input is a matrix, each column is treated as an independent channel. This port is unnamed until the `Var` port is enabled.

Data Types: `single` | `double`
Complex Number Support: Yes

`Var` — Noise variance

positive scalar | vector of positive values

Noise variance, specified as a positive scalar or vector of positive values. When the noise variance or signal power result in computations involving extreme positive or negative magnitudes, see “MIL-STD-188-110 QAM Soft Demodulation” on page 5-503 for demodulation decision type considerations.

Dependencies

To enable this port set the Noise variance source parameter to `Input port`.

Output

`Out` — Demodulated signal
scalar | vector | matrix

Demodulated signal, returned as a scalar, vector, or matrix. The dimensions of the demodulated signal depend on the specified Output type and Decision type parameter values. This port is unnamed on the block.

Output type	Decision type	Demodulated Signal Description	Dimensions of Demodulated Signal
`Integer`	—	Demodulated integer values in the range [0, (M – 1)]	The output signal has the same dimensions as input signal.
`Bit`	`Hard decision`	Demodulated bits	The number of rows in the output signal is $\log_2(M)$ times the number of rows in the input signal. Each demodulated symbol is mapped to a group of $\log_2(M)$ elements in a column, where the first element represents the MSB, and the last element represents the LSB.
	`Log-likelihood ratio`	Log-likelihood ratio value for each bit	
	`Approximate log-likelihood ratio`	Approximate log-likelihood ratio value for each bit	
M is the value of Modulation order.			

Use Output data type to specify the output data type.

Parameters

`Modulation order` — Modulation order
`16` (default) | `32` | `64` | `256`

Modulation order, M, specified as `16`, `32`, `64`, or `256`. The modulation order specifies the total number of points in the constellation of the input signal.

`Constellation scaling` — Constellation scaling
`As specified in standard` (default) | `Unit average power`

Constellation scaling preference, specified as:

- `As specified in standard` – The block scales the constellation based on specifications in the relevant standard [1].
- `Unit average power` – The block scales the constellation to an average power of 1 watt referenced to 1 ohm.

`Output type` — Input type
`Integer` (default) | `Bit`

Output type, specified as `Integer` or `Bit`. To use `Integer`, the input signal must consist of integers in the range [0, (M – 1)]. To use `Bit`, the input signal must contain binary values, and the number of rows must be an integer multiple of $\log_2(M)$, where M is the Modulation order.

Decision type — Demodulation decision type

Hard decision (default) | Log-likelihood ratio | Approximate log-likelihood ratio

Demodulation decision type, specified as Hard decision, Log-likelihood ratio, or Approximate log-likelihood ratio. See “MIL-STD-188-110 QAM Soft Demodulation” on page 5-503 for algorithm selection considerations.

Dependencies

This parameter applies when Output type is set to Bit.

Noise variance source — Noise variance source

Property (default) | Input port

Noise variance source, specified as:

- Property — The noise variance is set using the Noise variance parameter.
- Input port — The noise variance is set using the Var input port.

Dependencies

This parameter applies only when Decision type is set to either Log-likelihood ratio or Approximate log-likelihood ratio.

Noise variance — Noise variance

1 (default) | positive scalar | vector of positive values

Noise variance, specified as a positive scalar or vector of positive values.

- When specified as a scalar, that value is used on all elements in the input signal.
- When specified as a vector, the vector length must be equal to the number of columns in the input signal. Each noise variance vector element is applied to its corresponding column in the input signal.

When the noise variance or signal power result in computations involving extreme positive or negative magnitudes, see “MIL-STD-188-110 QAM Soft Demodulation” on page 5-503 for demodulation decision type considerations.

Dependencies

This parameter applies only when Noise variance is set to Property and Decision type is set to either Log-likelihood ratio or Approximate log-likelihood ratio.

Data Types: double

Output data type — Output data type

double (default) | ...

Output data type, specified as one of the acceptable values from this table. Acceptable Output data type values depend on the Output type and Decision type parameter values.

Output type	Decision type	Output data type Options
Integer	Not applicable	double, single, int8, uint8, int16, uint16, int32, or uint32

Output type	Decision type	Output data type Options
`Bit`	`Hard decision`	`double`, `single`, `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, or `logical`
	`Log-likelihood ratio` or `Approximate log-likelihood ratio`	The output signal is the same data type as the input signal.

Dependencies

This parameter applies only when Output type is set to `Integer` or when Output type is set to `Bit` and Decision type is set to `Hard decision`.

`Simulate using` — Type of simulation to run

`Interpreted execution` (default) | `Code generation`

Type of simulation to run, specified as:

- `Code generation` –– Simulate the model using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations as long as the model does not change. This option requires additional startup time.
- `Interpreted execution` –– Simulate the model using the MATLAB interpreter. This option shortens startup time. In `Interpreted execution` mode, you can debug the source code of the block.

For information on execution speed, see "Tips" on page 5-503.

Block Characteristics

Data Types	`Boolean` | `double` | `integer` | `single`
Multidimensional Signals	`yes`
Variable-Size Signals	`no`

More About

MIL-STD-188-110

MIL-STD-188-110 is a US Department of Defense standard for HF communications using serial PSK mode of both data and voice signals.

The standard specifies physical layer modulation schemes for tactical and long-haul communications. The modulation scheme specified by the standard is a mix of QAM and APSK. For a detailed description of the modulation scheme, see [1].

MIL-STD-188-110 QAM Hard Demodulation

The hard demodulation algorithm uses optimum decision region-based demodulation. Since all the constellation points are equally probable, maximum a posteriori probability (MAP) detection reduces to a maximum likelihood (ML) detection. The ML detection rule is equivalent to choosing the closest constellation point to the received symbol. The decision region for each constellation point is designed by drawing perpendicular bisectors between adjacent points. A received symbol is mapped to the proper constellation point based on which decision region it lies in.

Since all MIL-STD constellations are quadrant-based symmetric, for each symbol the optimum decision region-based demodulation:

- Maps the received symbol into the first quadrant
- Chooses the decision region for the symbol
- Maps the constellation point back to its original quadrant using the sign of real and imaginary parts of the received symbol

MIL-STD-188-110 QAM Soft Demodulation

For soft demodulation, two soft-decision log-likelihood ratio (LLR) algorithms are available: exact LLR and approximate LLR. This table compares these algorithms.

Algorithm	Accuracy	Execution Speed
Exact LLR	more accurate	slower execution
Approximate LLR	less accurate	faster execution

For further description of these algorithms, see “Exact LLR Algorithm” and “Approximate LLR Algorithm”.

Note The exact LLR algorithm computes exponentials using finite precision arithmetic. Computation of exponentials with very large positive or negative magnitudes might yield:

- `Inf` or `-Inf` if the noise variance is a very large value
- `NaN` if both the noise variance and signal power are very small values

When the output returns any of these values, try using the approximate LLR algorithm because it does not compute exponentials.

Tips

- For faster execution of the MIL-188 QAM Demodulator Baseband block, set the Simulate using parameter to:
  - `Code generation` when using hard decision demodulation.
  - `Interpreted execution` when using soft decision demodulation.

MIL-188 QAM Modulator Baseband

MIL-STD-188-110 B/C standard-specific quadrature amplitude modulation (QAM)

Library: Communications Toolbox / Modulation / Digital Baseband Modulation / AM
Communications Toolbox / Modulation / Digital Baseband Modulation / Standard-Compliant

Description

The MIL-188 QAM Modulator Baseband block modulates the input signal using “MIL-STD-188-110” on page 5-507 standard-specific quadrature amplitude modulation (QAM).

Ports

Input

In — Input signal
scalar | vector | matrix

Input signal, specified as a scalar, vector, or matrix. The input signal must be binary values or integers in the range [0, (*M* – 1)], where *M* is the Modulation order. This port is unnamed on the block.

Note To process the input signal as binary elements, set the Input type parameter value to `Bit`. For binary inputs, the number of rows must be an integer multiple of $\log_2(M)$. Groups of $\log_2(M)$ bits in a column are mapped onto a symbol, with the first bit representing the MSB and the last bit representing the LSB.

Data Types: `single` | `double` | `int8` | `int16` | `int32` | `uint8` | `uint16` | `uint32` | `Boolean`

Output

`Out` — MIL-STD-188 standard-specific QAM modulated signal
scalar | vector | matrix

MIL-STD-188 standard-specific QAM modulated signal, returned as a complex scalar, vector, or matrix. The output signal dimensions depend on the specified Input type parameter value. This port is unnamed on the block.

Input type	Dimensions of Output Signal
`Integer`	The output signal has the same dimensions as the input signal.

Input type	Dimensions of Output Signal
`Bit`	The number of rows in the output signal equals the number of rows in the input signal divided by $\log_2(M)$, where M is the Modulation order.

Parameters

`Modulation order` — Modulation order
16 (default) | 32 | 64 | 256

Modulation order, M, specified as `16`, `32`, `64`, or `256`. The modulation order specifies the total number of points in the constellation of the output signal.

`Constellation scaling` — Constellation scaling
`As specified in standard` (default) | `Unit average power`

Constellation scaling preference, specified as:

- `As specified in standard` – The block scales the constellation based on specifications in the relevant standard [1].
- `Unit average power` – The block scales the constellation to an average power of 1 watt referenced to 1 ohm.

`Input type` — Input type
`Integer` (default) | `Bit`

Input type, specified as `Integer` or `Bit`. To use `Integer`, the input signal must consist of integers in the range [0, (M – 1)]. To use `Bit`, the input signal must contain binary values, and the number of rows must be an integer multiple of $\log_2(M)$, where M is the Modulation order.

`Output data type` — Output data type
`double` (default) | `single`

Output data type, specified as `double` or `single`.

`View Constellation` — Plot reference constellation
`button`

To plot the reference constellation, click the **View Constellation** button.

`Simulate using` — Type of simulation to run
`Code generation` (default) | `Interpreted execution`

Type of simulation to run, specified as:

- `Code generation` –– Simulate the model using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations as long as the model does not change. This option requires additional startup time, but the speed of the subsequent simulations is comparable to `Interpreted execution`.
- `Interpreted execution` –– Simulate the model using the MATLAB interpreter. This option shortens startup time and has a simulation speed comparable to `Code generation`. In `Interpreted execution` mode, you can debug the source code of the block.

Block Characteristics

Data Types	`Boolean` | `double` | `integer` | `single`
Multidimensional Signals	`yes`
Variable-Size Signals	`no`

MIMO Fading Channel

Filter input signal through MIMO multipath fading channel

Library: Communications Toolbox / Channels
Communications Toolbox / MIMO

Description

The MIMO Fading Channel block filters an input signal using a multi-input/multi-output (MIMO) multipath fading channel. This block models both Rayleigh and Rician fading and employs the Kronecker model for modeling the spatial correlation between the links. For processing details, see the Algorithms on page 5-517 section.

Signal Dimensions

The availability and dimensions of input and output port signals depends on:

- The Antenna selection parameter setting on the **Main** tab
- The Initial time source parameter setting on the **Realization** tab
- The Output channel path gains selection on the **Realization** tab

Antenna Selection Parameter	Signal Input (in)	Transmit Selection Input (Tx Sel)	Receive Selection Input (Rx Sel)	Initial Time Offset Input (Init Time)	Signal Output (Out1)	Optional Channel Gain Output (Gain)
`Off`	N_S-by-N_T	N/A	N/A	nonnegative scalar	N_S-by-N_R	N_S-by-N_P-by-N_T-by-N_R
`Tx`	N_S-by-N_{ST}	1-by-N_T	N/A		N_S-by-N_R	
`Rx`	N_S-by-N_T	N/A	1-by-N_R		N_S-by-N_{SR}	
`Tx and Rx`	N_S-by-N_{ST}	1-by-N_T	1-by-N_R		N_S-by-N_{SR}	

- N_S represents the number of samples in the input signal.
- N_T represents the number of transmit antennas, as determined by:
  - Transmit spatial correlation when Specify spatial correlation is set to `Separate Tx Rx`
  - Number of transmit antennas when Specify spatial correlation is set to `None` or `Combined`
- N_R represents the number of receive antennas, as determined by:
  - Receive spatial correlation when Specify spatial correlation is set to `Separate Tx Rx`
  - Number of receive antennas when Specify spatial correlation is set to `None`
  - Combined spatial correlation and Number of transmit antennas when Specify spatial correlation is set to `Combined`

- N_P represents the number of channel paths, as determined by the Discrete path delays (s) or Average path gains (dB).
- N_{ST} represents the number of selected transmit antennas, as determined by the number of elements set to `1` in the vector provided to the Tx Sel input port.
- N_{SR} represents the number of selected receive antennas, as determined by the number of elements set to `1` in the vector provided to the Rx Sel input port.

Ports

Input

`in` — Input data signal

vector

Input data signal, specified as an N_S-by-N_T or N_S-by-N_{ST} matrix.

- N_S represents the number of samples in the input signal.
- N_T represents the number of transmit antennas.
- N_{ST} represents the number of selected transmit antennas.

Data Types: `double` | `single`
Complex Number Support: Yes

`Tx Sel` — Select active transmit antennas

binary vector

Select active transmit antennas, specified as a 1-by-N_T binary vector. N_T represents the number of transmit antennas. Elements set to `1` identify selected antenna indices and `0` identify nonselected antenna indices.

Dependencies

To enable this port, on the **Main** tab, set Antenna selection to `Tx` or `Tx and Rx`.

Data Types: `double`

`Rx Sel` — Select active receive antennas

binary vector

Select active receive antennas, specified as a 1-by-N_R binary vector. N_R represents the number of receive antennas. Elements set to `1` identify selected antenna indices and `0` identify nonselected antenna indices.

Dependencies

To enable this port, on the **Main** tab, set Antenna selection to `Rx` or `Tx and Rx`.

Data Types: `double`

`Init Time` — Initial time offset

nonnegative scalar

Initial time offset for the fading model in seconds, specified as a nonnegative scalar.

Init Time must be greater than the last frame end time. When **Init Time** is not a multiple of `1/Sample Rate (Hz)`, it is rounded up to the nearest sample position.

Dependencies

To enable this port, on the **Realization** tab, set Initial time source to `Input port`.

Data Types: `double`

Output

`Out1` — Output data signal for fading channel
vector

Output data signal for the fading channel, returned as an N_S-by-N_R or N_S-by-N_{SR} matrix.

- N_S represents the number of samples in the input signal.
- N_R represents the number of receive antennas.
- N_{SR} represents the number of selected receive antennas.

`Gain` — Discrete path gains
4-D array

Discrete path gains of the underlying fading process, returned as an N_S-by-N_P-by-N_T-by-N_R array.

- N_S represents the number of samples in the input signal.
- N_P represents the number of channel paths.
- N_T represents the number of transmit antennas.
- N_R represents the number of receive antennas.

Entries for nonselected paths are filled with `NaN`.

Dependencies

To enable this port, on the **Realization** tab, select Output channel path gains.

Parameters

Main Tab

Multipath parameters (frequency selectivity)

`Inherit sample rate from input` — Option to inherit the sample rate from input
on (default) | off

Select this parameter to use the sample rate of the input signal when processing. When `Inherit sample rate from input` is selected, the sample rate is N_S/T_S, where N_S is the number of input samples, and T_S is the model sample time.

`Sample rate (Hz)` — Input signal sample rate
1 (default) | positive scalar

Input signal sample rate, specified in hertz as a positive scalar. To match the model settings, set the sample rate to N_S/T_S, where N_S is the number of input samples, and T_S is the model sample time.

Dependencies

This parameter appears when Inherit sample rate from input is not selected.

Data Types: `double`

`Discrete path delays (s)` — Delays for each discrete path

`0` (default) | nonnegative scalar | row vector

Delays for each discrete path in seconds, specified as a nonnegative scalar or row vector.

- When you set **Discrete path delays (s)** to a scalar, the MIMO channel is frequency flat.
- When you set **Discrete path delays (s)** to a vector, the MIMO channel is frequency selective.

Data Types: `double`

`Average path gains (dB)` — Average gain for each discrete path

`0` (default) | scalar | row vector

Average gain for each discrete path in decibels, specified as a scalar or row vector. **Average path gains (dB)** must have the same size as Discrete path delays (s).

Data Types: `double`

`Normalize average path gains to 0 dB` — Option to normalize average path gains to 0 dB

on (default) | off

Select this parameter to normalize the fading processes so that the total power of the path gains, averaged over time, is 0 dB.

`Fading distribution` — Fading distribution of channel

`Rayleigh` (default) | `Rician`

Select the fading distribution of the channel, either `Rayleigh` or `Rician`.

`K-factors` — K-factor of Rician fading channel

`3` (default) | positive scalar | row vector of nonnegative values

K-factor of a Rician fading channel, specified as a positive scalar or a 1-by-N_P vector of nonnegative values. N_P equals the value of the Discrete path delays (s) parameter.

- If you set **K-factors** to a scalar, the first discrete path is a Rician fading process with a Rician K-factor of **K-factors**. Any remaining discrete paths are independent Rayleigh fading processes.
- If you set **K-factors** to a row vector, the discrete path corresponding to a positive element of the **K-factors** vector is a Rician fading process with a Rician K-factor specified by that element. The discrete path corresponding to any zero-valued elements of the **K-factors** vector are Rayleigh fading processes. At least one element value must be nonzero.

Dependencies

This parameter appears when Fading distribution is `Rician`.

Data Types: `double`

`LOS path Doppler shifts (Hz)` — Doppler shifts for line-of-sight components

`0` (default) | scalar | row vector

Doppler shifts for the line-of-sight components of the Rician fading channel in hertz, specified as a scalar or row vector. This parameter must have the same size as K-factors.

- If you set **LOS path Doppler shifts (Hz)** to a scalar, it represents the line-of-sight component Doppler shift of the first discrete path that is a Rician fading process.
- If you set **LOS path Doppler shifts (Hz)** to a row vector, the discrete path that is a Rician fading process has its line-of-sight component Doppler shift specified by the elements of **LOS path Doppler shifts (Hz)** that correspond to positive elements in the K-factors vector.

Dependencies

This parameter appears when Fading distribution is `Rician`.

Data Types: `double`

`LOS path initial phases (rad)` — Initial phases for line-of-sight components

`0` (default) | scalar | row vector

Initial phases for the line-of-sight component of the Rician fading channel in radians, specified as a scalar or row vector. This parameter must have the same size as K-factors.

- If you set **LOS path initial phases (rad)** to a scalar, it is the line-of-sight component initial phase of the first discrete path that is a Rician fading process.
- If you set **LOS path initial phases (rad)** to a row vector, the discrete path that is a Rician fading process has its line-of-sight component initial phase specified by the elements of **LOS path initial phases (rad)** that correspond to positive elements in the K-factors vector.

Dependencies

This parameter appears when Fading distribution is `Rician`.

Data Types: `double`

Doppler parameters (time dispersion)

`Maximum Doppler shift (Hz)` — Maximum Doppler shift for all channel paths

`0.001` (default) | nonnegative scalar

Maximum Doppler shift for all channel paths in hertz, specified as a nonnegative scalar.

Maximum Doppler shift (Hz) must be smaller than (Sample Rate (Hz)/10)/f_c for each path, where f_c is the cutoff frequency factor of the path. For more information, see “Cutoff Frequency Factor” on page 5-517.

Data Types: `double`

`Doppler spectrum` — Doppler spectrum shape for all channel paths

`doppler('Jakes')` (default) | `doppler('Flat')` | `doppler('Rounded', ...)` | `doppler('Bell', ...)` | `doppler('Asymmetric Jakes', ...)` | `doppler('Restricted Jakes', ...)` | `doppler('Gaussian', ...)` | `doppler('BiGaussian', ...)`

Doppler spectrum shape for all channel paths, specified as a single Doppler spectrum structure returned from the `doppler` function or a 1-by-N_P cell array of such structures. The default value of this parameter is the Jakes Doppler spectrum (`doppler('Jakes')`).

- If you assign a single call to `doppler`, all paths have the same specified Doppler spectrum.

- If you assign a 1-by-N_P cell array of calls to `doppler` using any of the specified syntaxes, each path has the Doppler spectrum specified by the corresponding Doppler spectrum structure in the array. In this case, N_P equals the value of the Discrete path delays (s) parameter.

Dependencies

This parameter applies when Maximum Doppler shift (Hz) is greater than zero.

If the Technique for generating fading samples parameter is set to `Sum of sinusoids`, Doppler spectrum must be `doppler('Jakes')`.

Antenna parameters (spatial dispersion)

`Specify spatial correlation` — Spatial correlation mode

`None` (default) | `Separate Tx Rx` | `Combined`

Select the spatial correlation mode: `None`, `Separate Tx Rx`, or `Combined`.

- Choose `'None'` to specify the number of transmit and receive antennas.
- Choose `'Spatial Tx Rx'` to specify the transmit and receive spatial correlation matrices separately. The number of transmit (N_T) and receive (N_R) antennas are derived from the dimensions of the Transmit spatial correlation and Receive spatial correlation parameters, respectively.
- Choose `'Combined'` to specify a single correlation matrix for the whole channel. The product of N_T and N_R is derived from the dimension of Combined spatial correlation.

`Number of transmit antennas` — Number of transmit antennas

2 (default) | positive integer

Number of transmit antennas, specified as a positive integer.

Dependencies

This parameter appears when Specify spatial correlation is `None` or `Combined`.

Data Types: `double`

`Number of receive antennas` — Number of receive antennas

2 (default) | positive integer

Number of receive antennas, specified as a positive integer.

Dependencies

This parameter appears when Specify spatial correlation is `None`.

Data Types: `double`

`Transmit spatial correlation` — Spatial correlation of transmitter

`[1 0; 0 1]` (default) | matrix | 3-D array

Specify the spatial correlation of the transmitter as an N_T-by-N_T matrix or N_T-by-N_T-by-N_P array. N_T is the number of transmit antennas, and N_P equals the value of the Discrete path delays (s) parameter.

- If **Discrete path delays (s)** is a scalar, the channel is frequency flat, and **Transmit spatial correlation** is an N_T-by-N_T Hermitian matrix. The magnitude of any off-diagonal element must be no larger than the geometric mean of the two corresponding diagonal elements.

- If **Discrete path delays (s)** is a vector, the channel is frequency selective, and you can specify **Transmit spatial correlation** as a matrix. Each path has the same transmit spatial correlation matrix.
- Alternatively, you can specify **Transmit spatial correlation** as an N_T-by-N_T-by-N_P array, where each path can have its own different transmit spatial correlation matrix.

Dependencies

This parameter appears when Specify spatial correlation is `Separate Tx Rx`.

Data Types: `double`
Complex Number Support: Yes

`Receive spatial correlation` — Spatial correlation of receiver

`[1 0; 0 1]` (default) | matrix | 3-D array

Specify the spatial correlation of the receiver as an N_R-by-N_R matrix or N_R-by-N_R-by-N_P array. N_R is the number of receive antennas, and N_P equals the value of the Discrete path delays (s) parameter.

- If **Discrete path delays (s)** is a scalar, the channel is frequency flat, and **Receive spatial correlation** is an N_R-by-N_R Hermitian matrix. The magnitude of any off-diagonal element must be no larger than the geometric mean of the two corresponding diagonal elements.
- If **Discrete path delays (s)** is a vector, the channel is frequency selective, and you can specify **Receive spatial correlation** as a matrix. Each path has the same receive spatial correlation matrix.
- Alternatively, you can specify **Receive spatial correlation** as an N_R-by-N_R-by-N_P array, where each path can have its own different receive spatial correlation matrix.

Dependencies

This parameter appears when Specify spatial correlation is `Separate Tx Rx`.

Data Types: `double`
Complex Number Support: Yes

`Combined spatial correlation` — Combined spatial correlation matrix

`[1 0 0 0; 0 1 0 0; 0 0 1 0; 0 0 0 1]` (default) | matrix | 3-D array

Specify the combined spatial correlation matrix as an N_{TR}-by-N_{TR} matrix or N_{TR}-by-N_{TR}-by-N_P array, where N_{TR} = ($N_T \times N_R$), and N_P equals the number of delay paths specified by the Discrete path delays (s) parameter.

- If Discrete path delays (s) is a scalar, the channel is frequency flat, and **Combined spatial correlation** is an N_{TR}-by-N_{TR} Hermitian matrix. The magnitude of any off-diagonal element must be no larger than the geometric mean of the two corresponding diagonal elements.
- If Discrete path delays (s) is a vector, the channel is frequency selective, and you can specify **Combined spatial correlation** as a matrix. Each path has the same spatial correlation matrix.
- Alternatively, you can specify **Combined spatial correlation** as an N_{TR}-by-N_{TR}-by-N_P array, where each path can have its own different combined spatial correlation matrix.

Dependencies

This parameter appears when Specify spatial correlation is `Combined`.

Data Types: `double`

`Normalize outputs by number of receive antennas` — Normalize channel output

on (default) | off

Select this parameter to normalize the channel outputs by the number of receive antennas.

`Simulate using` — Compilation type

`Interpreted execution` (default) | `Code generation`

Compilation type, specified as `Interpreted execution` or `Code generation`.

`Antenna selection` — Antenna mode

`Off` (default) | `Tx` | `Rx` | `Tx and Rx`

The antenna mode you select corresponds to additional input ports on the block.

Antenna selection Setting	Input Ports Added
`Off`	**None**
`Tx`	**Tx Sel**
`Rx`	**Rx Sel**
`Tx and Rx`	**Tx Sel**, **Rx Sel**

Realization Tab

`Technique for generating fading samples` — Channel modeling technique

`Filtered Gaussian noise` (default) | `Sum of sinusoids`

Select the channel modeling technique, either `Filtered Gaussian noise` or `Sum of sinusoids`.

`Number of sinusoids` — Number of sinusoids used

`48` (default) | positive integer

Number of sinusoids used to model the fading process, specified as a positive integer.

Dependencies

This parameter appears when Technique for generating fading samples is `Sum of sinusoids`.

`Initial time source` — Source of initial time offset

`Property` (default) | `Input port`

Indicate the source of the initial time offset for the fading model, either `Property` or `Input port`.

- When you set **Initial time source** to `Property`, use Initial time (s) to set the initial time offset.
- When you set **Initial time source** to `Input port`, use the input port Init Time to set the initial time offset.

Dependencies

This parameter appears when Technique for generating fading samples is `Sum of sinusoids`.

`Initial time (s)` — Initial time offset

`0` (default) | nonnegative scalar

Initial time offset for the fading model, specified as a nonnegative scalar.

When `Initial time (s)` is not a multiple of `1/`Sample Rate (Hz), it is rounded up to the nearest sample position.

Dependencies

This parameter appears when Technique for generating fading samples is `Sum of sinusoids` and Initial time source is set to `Property`.

`Initial seed` — Random number generator initial seed

`73` (default) | nonnegative integer

Random number generator initial seed for this block, specified as a nonnegative integer.

`Output channel path gains` — Option to output channel path gains

off (default) | on

Select this parameter to add the Gain output port to the block and output the channel path gains of the underlying fading process.

Visualization Tab

`Channel visualization` — Select the channel visualization

`Off` (default) | `Impulse response` | `Frequency response` | `Doppler spectrum` | `Impulse and frequency responses`

Select the channel visualization: `Off`, `Impulse response`, `Frequency response`, `Doppler spectrum`, or `Impulse and frequency responses`. When visualization is on, the selected channel characteristics, such as impulse response or Doppler spectrum, display in a separate window. For more information, see Channel Visualization.

`Antenna pair to display` — Transmit-receive antenna pair to display

`[1,1]` (default) | vector

Transmit-receive antenna pair to display, specified as a 1-by-2 vector, where the first element corresponds to the desired transmit antenna and the second corresponds to the desired receive antenna. At this time, only a single pair can be displayed.

Dependencies

This parameter appears when Channel visualization is not `Off`.

`Percentage of samples to display` — Percentage of samples to display

`25%` (default) | `10%` | `50%` | `100%`

Select the percentage of samples to display: `10%`, `25%`, `50%`, or `100%`. Increasing the percentage improves display accuracy at the expense of simulation speed.

Dependencies

This parameter appears when Channel visualization is `Impulse response`, `Frequency response`, or `Impulse and frequency responses`.

`Path for Doppler spectrum display` — Path for which Doppler spectrum is displayed

`1` (default) | positive integer

Path for which the Doppler spectrum is displayed, specified as a positive integer from 1 to N_P, where N_P equals the value of the Discrete path delays (s) parameter.

Dependencies

This parameter appears when Channel visualization is `Doppler spectrum`.

Block Characteristics

Data Types	`double` | `single`
Multidimensional Signals	`yes`
Variable-Size Signals	`yes`

Algorithms

The fading processing per link is described in Methodology for Simulating Multipath Fading Channels and assumes the same parameters for all ($N_T \times N_R$) links of the MIMO channel. Each link comprises all multipaths for that link.

The Kronecker Model

The Kronecker model assumes that the spatial correlations at the transmit and receive sides are separable. Equivalently, the direction of departure (DoD) and directions of arrival (DoA) spectra are assumed to be separable. The full correlation matrix is:

$$R_H = E[R_t \otimes R_r]$$

- The ⊗ symbol represents the Kronecker product.
- R_t represents the correlation matrix at the transmit side: $R_t = E\left[H^H H\right]$, of size N_T-by-N_T.
- R_r represents the correlation matrix at the receive side: $R_r = E\left[H H^H\right]$, of size N_R-by-N_R.

You can obtain a realization of the MIMO channel matrix as:

$$H = R_r^{\frac{1}{2}} A R_t^{\frac{1}{2}}$$

A is an N_R-by-N_T matrix of independent identically distributed complex Gaussian variables with zero mean and unit variance.

Cutoff Frequency Factor

The cutoff frequency factor, f_c, is determined for different Doppler spectrum types.

- For any Doppler spectrum type other than Gaussian and biGaussian, f_c equals 1.
- For a `doppler('Gaussian')` spectrum type, f_c equals `NormalizedStandardDeviation` × $\sqrt{2\log2}$.
- For a `doppler('BiGaussian')` spectrum type:
  - If the `PowerGains(1)` and `NormalizedCenterFrequencies(2)` field values are both `0`, then f_c equals `NormalizedStandardDeviation(1)` × $\sqrt{2\log2}$.
  - If the `PowerGains(2)` and `NormalizedCenterFrequencies(1)` field values are both `0`, then f_c equals `NormalizedStandardDeviation(2)` × $\sqrt{2\log2}$.

- If the `NormalizedCenterFrequencies` field value is `[0,0]` and the `NormalizedStandardDeviation` field has two identical elements, then f_c equals `NormalizedStandardDeviation(1)` × $\sqrt{2\log 2}$.
- In all other cases, f_c equals 1.

Antenna Selection

When the object is in antenna selection mode, it uses the following algorithms to process an input signal:

- All random path gains are always generated and keep evolving for each link, whether or not a given link is selected. The path gain values output for the non-selected links are populated with `NaN`.
- The spatial correlation only applies to the selected transmit and/or receive antennas, and the correlation coefficients are the corresponding entries in the transmit, receive, or combined correlation matrices. In other words, the spatial correlation matrix for the selected transmit or receive antennas is a submatrix of the transmit, receive, or combined spatial correlation matrix property value.
- For signal paths associated with nonactive antennas, a signal with zero power is transmitted to the channel filter.
- Channel output normalization happens over the number of selected receive antennas.

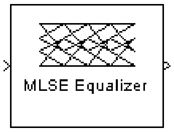
MLSE Equalizer

Equalize using Viterbi algorithm



Library

Equalizer Block

Description

The MLSE Equalizer block uses the Viterbi algorithm to equalize a linearly modulated signal through a dispersive channel. The block processes input frames and outputs the maximum likelihood sequence estimate (MLSE) of the signal, using an estimate of the channel modeled as a finite input response (FIR) filter.

This block supports `single` and `double` data types.

Channel Estimates

The channel estimate takes the form of a column vector containing the coefficients of an FIR filter in descending order of powers. The length of this vector is the channel memory, which must be a multiple of the block's **Samples per input symbol** parameter.

To specify the channel estimate vector, use one of these methods:

- Set **Specify channel via** to `Dialog` and enter the vector in the **Channel coefficients** field.
- Set **Specify channel via** to `Input port` and the block displays an additional input port, labeled `Ch`, which accepts a column vector input signal.

Signal Constellation

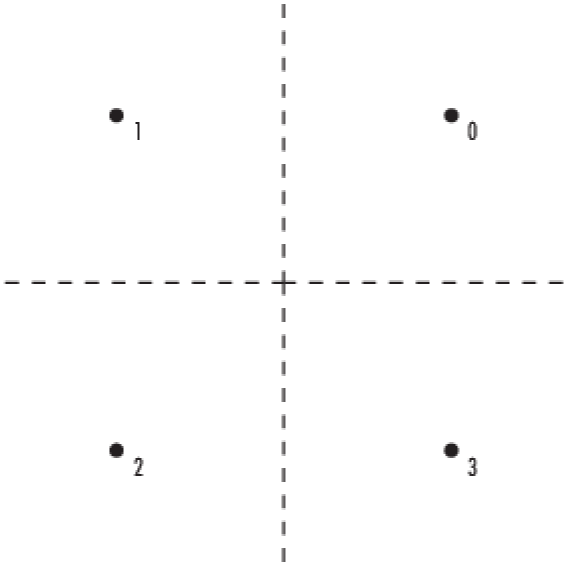
The **Signal constellation** parameter specifies the constellation for the modulated signal, as determined by the modulator in your model. **Signal constellation** is a vector of complex numbers, where the kth complex number in the vector is the constellation point to which the modulator maps the integer k-1.

Note The sequence of constellation points must be consistent between the modulator in your model and the **Signal constellation** parameter in this block.

For example, to specify the constellation given by the mapping

$$
\begin{aligned}
0 &\rightarrow +1+i\\
1 &\rightarrow -1+i\\
2 &\rightarrow -1-i\\
3 &\rightarrow +1-i
\end{aligned}
$$

set **Constellation points** to `[1+i, -1+i, -1-i, 1-i]`. Note that the sequence of numbers in the vector indicates how the modulator maps integers to the set of constellation points. The labeled constellation is shown below.



Preamble and Postamble

If your data is accompanied by a preamble (prefix) or postamble (suffix), then configure the block accordingly:

- If you select **Input contains preamble**, then the **Expected preamble** parameter specifies the preamble that you expect to precede the data in the input signal.
- If you check the **Input contains postamble**, then the **Expected postamble** parameter specifies the postamble that you expect to follow the data in the input signal.

The **Expected preamble** or **Expected postamble** parameter must be a vector of integers between 0 and M-1, where M is the number of constellation points. An integer value of k-1 in the vector corresponds to the kth entry in the **Constellation points** vector and, consequently, to a modulator input of k-1.

The preamble or postamble must already be included at the beginning or end, respectively, of the input signal to this block. If necessary, you can concatenate vectors in Simulink software using the Matrix Concatenation block.

To learn how the block uses the preamble and postamble, see “"Reset Every Frame" Operation Mode” on page 5-521 below.

"Reset Every Frame" Operation Mode

One way that the Viterbi algorithm can transition between successive frames is called `Reset every frame` mode. You can choose this mode using the **Operation mode** parameter.

In `Reset every frame` mode, the block decodes each frame of data independently, resetting the state metric at the end of each frame. The traceback decoding always starts at the state with the minimum state metric.

The initialization of state metrics depends on whether you specify a preamble and/or postamble:

- If you do not specify a preamble, the decoder initializes the metrics of all states to 0 at the beginning of each frame of data.
- If you specify a preamble, the block uses it to initialize the state metrics at the beginning of each frame of data. More specifically, the block decodes the preamble and assigns a metric of 0 to the decoded state. If the preamble does not decode to a unique state -- that is, if the length of the preamble is less than the channel memory -- the decoder assigns a metric of 0 to all states that can be represented by the preamble. Whenever you specify a preamble, the traceback path ends at one of the states represented by the preamble.
- If you do not specify a postamble, the traceback path starts at the state with the smallest metric.
- If you specify a postamble, the traceback path begins at the state represented by the postamble. If the postamble does not decode to a unique state, the decoder identifies the smallest of all possible decoded states that are represented by the postamble and begins traceback decoding at that state.

Note In `Reset every frame` mode, the input to the MLSE Equalizer block must contain at least T symbols, not including an optional preamble, where T is the **Traceback depth** parameter.

Continuous Operation Mode

An alternative way that the Viterbi algorithm can transition between successive frames is called `Continuous with reset option` mode. You can choose this mode using the **Operation mode** parameter.

In `Continuous with reset option` mode, the block initializes the metrics of all states to 0 at the beginning of the simulation. At the end of each frame, the block saves the internal state metric for use in computing the traceback paths in the next frame.

If you select **Enable the reset input port**, the block displays another input port, labeled `Rst`. In this case, the block resets the state metrics whenever the scalar value at the `Rst` port is nonzero.

Decoding Delay

The MLSE Equalizer block introduces an output delay equal to the **Traceback depth** in the `Continuous with reset option` mode, and no delay in the `Reset every frame` mode.

Parameters

Specify channel via

The method for specifying the channel estimate. If you select `Input port`, the block displays a second input port that receives the channel estimate. If you select `Dialog`, you can specify the channel estimate as a vector of coefficients for an FIR filter in the **Channel coefficients** field.

Channel coefficients

Vector containing the coefficients of the FIR filter that the block uses for the channel estimate. This field is visible only if you set **Specify channel via** to `Dialog`.

Signal constellation

Vector of complex numbers that specifies the constellation for the modulation.

Traceback depth

The number of trellis branches (equivalently, the number of symbols) the block uses in the Viterbi algorithm to construct each traceback path.

Operation mode

The operation mode of the Viterbi decoder. Choices are `Continuous with reset option` and `Reset every frame`.

Input contains preamble

When checked, you can set the preamble in the **Expected preamble** field. This option appears only if you set **Operation mode** to `Reset every frame`.

Expected preamble

Vector of integers between 0 and M-1 representing the preamble, where M is the size of the constellation. This field is visible and active only if you set **Operation mode** to `Reset every frame` and then select **Input contains preamble**.

Input contains postamble

When checked, you can set the postamble in the **Expected postamble** field. This option appears only if you set **Operation mode** to `Reset every frame`.

Expected postamble

Vector of integers between 0 and M-1 representing the postamble, where M is the size of the constellation. This field is visible and active only if you set **Operation mode** to `Reset every frame` and then select **Input contains postamble**.

Samples per input symbol

The number of input samples for each constellation point.

Enable the reset input port

When you check this box, the block has a second input port labeled `Rst`. Providing a nonzero input value to this port causes the block to set its internal memory to the initial state before processing the input data. This option appears only if you set **Operation mode** to `Continuous with reset option`.

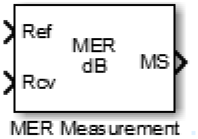
MER Measurement

Measure signal-to-noise ratio (SNR) in digital modulation applications



Library

Utility Blocks

Description

The MER Measurement block outputs the modulation error ratio (MER). MER is a measure of the signal-to-noise ratio (SNR) in digital modulation applications. The block measures all outputs in dB.

The MER Measurement block accepts a received signal at input port `Rcv`. It may use an ideal input signal at reference port `Ref` or, optionally, a reference constellation. The MER block then outputs a measure of the modulation accuracy by comparing these inputs. The modulation error ratio is the ratio of the average reference signal power to the mean square error. This ratio corresponds to the SNR of the AWGN channel.

The block output always outputs MER in dB, with an option to output minimum MER and *X*-percentile MER values. The minimum MER represents the best-case MER value per burst. For the *X*-percentile option, you can select to output the number of symbols processed in the percentile computations.

The table shows the output type, the parameter that selects the output type, the computation units, and the corresponding measurement interval.

Output	Activation Parameter	Units	Measurement Interval
MER	None (output by default)	dB	`Current length` | `Entire history` | `Custom` | `Custom with periodic reset`
Minimum MER	**Output minimum MER**	dB	`Current length` | `Entire history` | `Custom` | `Custom with periodic reset`
Percentile MER	**Output X-percentile EVM**	dB	`Entire history`
Number of symbols	**Output X-percentile EVM** and **Output the number of symbols processed**	None	`Entire history`

Data Type

The block accepts double, single, and fixed-point data types. The output of the block is always double.

Algorithms

Parameters

Reference signal

Specifies the reference signal source as either Input port or Estimated from reference constellation.

Reference constellation

Specifies the reference constellation points as a vector. This parameter is available only when **Reference signal** is Estimated from reference constellation. The default is constellation(comm.QPSKModulator).

Measurement interval

Specify the measurement interval as: Input length, Entire history, Custom, or Custom with periodic reset. This parameter affects the RMS and minimum MER outputs only.

- To calculate MER using only the current samples, set this parameter to 'Input length'.
- To calculate MER for all samples, set this parameter to 'Entire history'.
- To calculate MER over an interval you specify and to use a sliding window, set this parameter to 'Custom'.
- To calculate MER over an interval you specify and to reset the object each time the measurement interval is filled, set this parameter to 'Custom with periodic reset'.

Custom measurement interval

Specify the custom measurement interval in samples as a real positive integer. This is the interval over which the MER is calculated. This parameter is available when **Measurement interval** is Custom or Custom with periodic reset. The default is 100.

Averaging dimensions

Specify the dimensions over which to average the MER measurements as a scalar or row vector whose elements are positive integers. For example, to average across the rows, set this parameter to 2. The default is 1.

This block supports var-size inputs of the dimensions in which the averaging takes place. However, the input size for the nonaveraged dimensions must be constant. For example, if the input size is [1000 3 2] and **Averaging dimensions** is [1 3], then the output size is [1 3 1]. The number of elements in the second dimension is fixed at 3.

Output minimum MER

Outputs the minimum MER of an input vector or frame.

Output X-percentile MER

Enables an output *X*-percentile MER measurement. When you select this option, specify **X-percentile value (%)**.

X-Percentile value (%)

This parameter is available only when you select **Output X-percentile MER**. The Xth percentile is the MER value above which X% of all the computed MER values lie. The parameter defaults to the 95th percentile. That is, 95% of all MER values are above this output.

Output the number of symbols processed

Outputs the number of symbols that the block uses to compute the **Output X-percentile MER**. This parameter is available only when you select **Output X-percentile MER**.

Simulate using

Select the simulation mode.

`Code generation`

On the first model run, simulate and generate code. If the structure of the block does not change, subsequent model runs do not regenerate the code.

If the simulation mode is `Code generation`, System objects corresponding to the blocks accept a maximum of nine inputs.

`Interpreted execution`

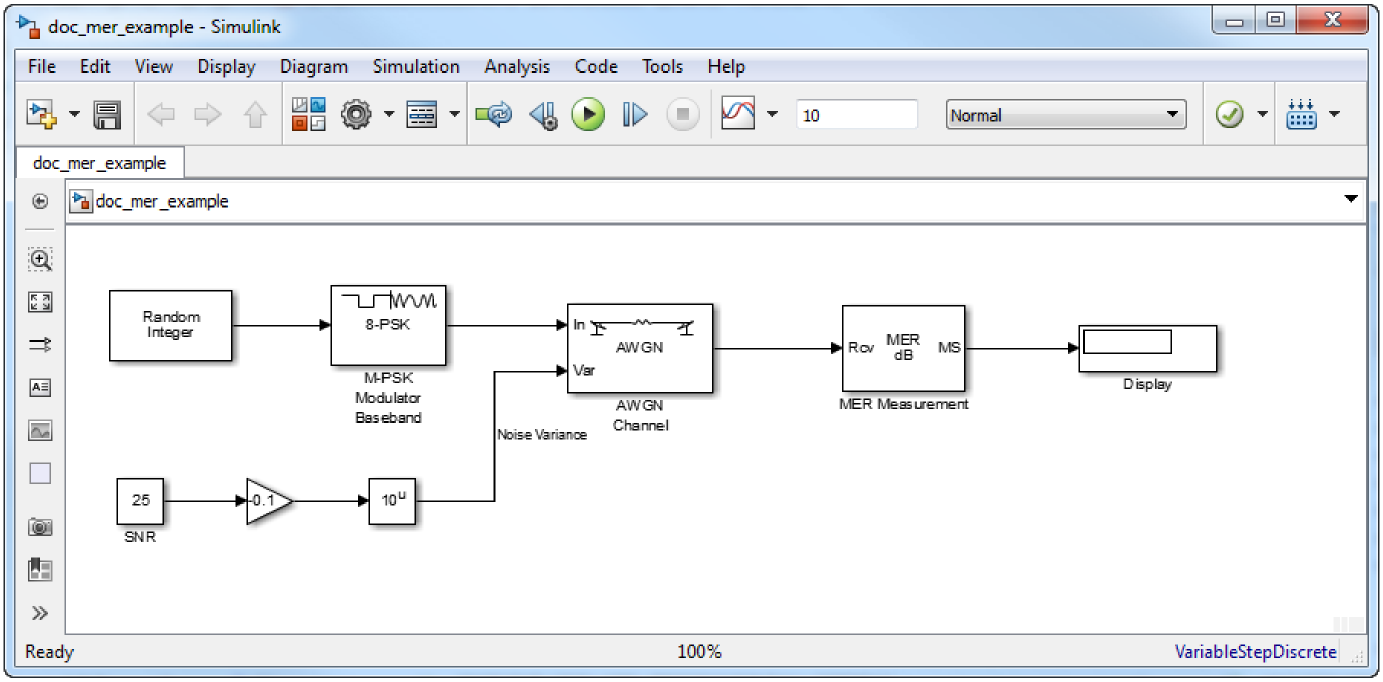
Simulate model without generating code. This option results in faster start times but can slow subsequent simulation performance.

Examples

Measure MER of Noisy PSK Signal

Measure the MER of a noisy 8-PSK signal.

Load the model by typing doc_mer_example at the command line.



Run the model. The MER is shown in the Display block and is approximately equal to the SNR, which is set by using the Constant block. Experiment with different SNR values, and observe the effect on the estimated MER.

Algorithms

MER is a measure of the SNR in a modulated signal calculated in dB. The MER over *N* symbols is

$$\text{MER} = 10 \cdot \log_{10}\left(\frac{\sum_{n=1}^{N}\left(I_k^2 + Q_k^2\right)}{\sum_{n=1}^{N}(e_k)}\right)\text{dB},$$

The MER for the *k*th symbol is

$$MER_k = 10 * \log_{10}\left(\frac{\frac{1}{N}\sum_{n=1}^{N}\left(I_k^2 + Q_k^2\right)}{e_k}\right)\text{dB}.$$

The minimum MER represents the minimum MER value in a burst, or

$$MER_{\min} = \min_{k \in [1, \ldots, N]}\{MER_k\},$$

where:

- $e_k = e_k = (I_k - \tilde{I}_k)^2 + (Q_k - \tilde{Q}_k)^2$
- I_k = In-phase measurement of the *k*th symbol in the burst
- Q_k = Quadrature phase measurement of the *k*th symbol in the burst
- I_k and Q_k represent ideal (reference) values. $\tilde{I}_k$ and $\tilde{Q}_k$ represent measured (received) symbols.

The block computes the *X*-percentile MER by creating a histogram of all the incoming MER_k values. The output provides the MER value above which X% of the MER values fall.

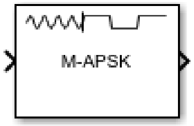
M-APSK Demodulator Baseband

M-ary amplitude phase shift keying (APSK) demodulation

Library: Communications Toolbox / Modulation / Digital Baseband Modulation / APM



Description

The M-APSK Demodulator Baseband block demodulates a baseband representation of an *M*-ary amplitude phase shift keying (APSK) modulated signal. *M* is the “Modulation Order for M-APSK” on page 5-534. For a description of *M*-APSK demodulation, see “APSK Hard Demodulation” on page 5-534 and “APSK Soft Demodulation” on page 5-535.

Note M-APSK Demodulator Baseband specifically applies to multiple ring PSK constellations. For a single ring PSK constellation, use M-PSK Demodulator Baseband.

This icon shows the block with all ports enabled:

In
M-APSK
Var

Ports

Input

In — APSK modulated signal
scalar | vector | matrix

APSK modulated signal, specified as a scalar, vector, or matrix. When this input is a matrix, each column is treated as an independent channel. This port is unnamed until the `Var` port is enabled.

Data Types: `double` | `single`
Complex Number Support: Yes

`Var` — Noise variance
positive scalar | vector of positive values

Noise variance, specified as a positive scalar or vector of positive values. When the noise variance or signal power result in computations involving extreme positive or negative magnitudes, see “APSK Soft Demodulation” on page 5-535 for demodulation decision type considerations.

Dependencies

To enable this port, set Noise variance source to `Input port`.

Data Types: `double` | `single`

Output

`Out` — Demodulated signal

scalar | vector | matrix

Demodulated signal, returned as a scalar, vector, or matrix. The data type and dimensions of the demodulated signal depend on the values specified by the Output type and Decision type parameters. This port is unnamed on the block.

Output type	Decision type	Demodulated Signal Description	Dimensions of Demodulated Signal
`Integer`	—	Demodulated integer values in the range [0, (M – 1)]	The output signal has the same dimensions as the input signal.
`Bit`	`Hard decision`	Demodulated bits	The number of rows in the output signal is $\log_2(M)$ times the number of rows in the input signal. Each demodulated symbol is mapped to a group of $\log_2(M)$ elements in a column, where the first element represents the MSB and the last element represents the LSB.
	`Log-likelihood ratio`	Log-likelihood ratio value for each bit	
	`Approximate log-likelihood ratio`	Approximate log-likelihood ratio value for each bit	
M is the "Modulation Order for M-APSK" on page 5-534.			

Use Output data type to specify the output data type.

Data Types: `single` | `double`

Parameters

`Constellation points per circle` — Constellation points per PSK ring

`[4,12]` (default) | vector

Constellation points per PSK ring, specified as a vector with more than one element. Each vector element indicates the number of constellation points in its corresponding PSK ring. The first element corresponds to the innermost circle, and so on until the last element, which corresponds to the outermost circle. The sum of the elements in **Constellation points per circle** determines the modulation order. Element values must be multiples of four, and the modulation order must be a power of two.

Example: `[4,12,16]` specifies a three PSK ring constellation with a modulation order of 32.

`Radius of each circle` — Radius per PSK ring

`[0.5,1]` (default) | vector

Radius per PSK ring, specified as a vector with the same length as Constellation points per circle. Each vector element indicates the radius of its corresponding PSK ring. The first element corresponds to the innermost circle, and so on until the last element, which corresponds to the outermost circle. These element values must be positive values arranged in increasing order.

Example: `[0.5,1,2]` defines radii for three constellation PSK rings. The inner ring has a radius of 0.5, the second ring has a radius of 1.0, and the outer ring has a radius of 2.0.

`Phase offset of each circle (rad)` — Phase offset per PSK ring

`[pi/4,pi/12]` (default) | scalar | vector

Phase offset per PSK ring in radians, specified as a scalar or vector with the same length as Constellation points per circle. Each vector element indicates the phase offset of its corresponding PSK ring. The first element corresponds to the innermost circle, and so on until the last element, which corresponds to the outermost circle. The **Phase offset of each circle (rad)** can be a scalar only if all the elements of **Constellation points per circle** are the same value.

Example: `[pi/4,pi/12,pi/16]` defines phase offsets for three constellation PSK rings. The inner ring has a phase offset of π/4, the second ring has a phase offset of π/12, and the outer ring has a phase offset of π/16.

`Symbol mapping` — Symbol mapping

`Auto` (default) | `Contourwise-gray` | `Gray` | `User-defined`

Symbol mapping, specified as one of the following:

- `Contourwise-gray` — Uses Gray mapping along the contour in the phase dimension for each PSK ring.
- `Gray` — Uses Gray mapping along the contour in both the amplitude and phase dimensions. For Gray symbol mapping, all elements in Constellation points per circle must be equal, and all elements in Phase offset of each circle (rad) must be equal. For a description of the Gray mapping used, see [2].
- `User-defined` — See Custom symbol mapping.

The default symbol mapping depends on the **Constellation points per circle** and **Phase offset of each circle (rad)** parameters. When all elements in **Constellation points per circle** are equal, and all elements in **Phase offset of each circle (rad)** are equal, the default is `Gray`. For all other cases, the default is `Contourwise-gray`.

`Custom symbol mapping` — Custom symbol mapping

`[0,4,12,8,1,3,2,6,7,5,13,15,14,10,11,9]` (default) | integer vector

Custom symbol mapping, specified as an integer vector. This vector must consist of *M* unique elements with values in the range [0, (*M* – 1)], where *M* is the “Modulation Order for M-APSK” on page 5-534. The first element in **Custom symbol mapping** corresponds to the constellation point in the first quadrant of the innermost circle, with subsequent elements positioned counterclockwise around the PSK rings.

Example: The default value, `[0,4,12,8,1,3,2,6,7,5,13,15,14,10,11,9]`, specifies contourwise-gray symbol mapping. The distribution of constellation points is nonuniform on all contours.

Dependencies

To enable this parameter, set Symbol mapping to `User-defined`.

`Output type` — Output type

`Integer` (default) | `Bit`

Output type, specified as `Integer` or `Bit`.

Data Types: `char` | `string`

`Decision type` — Demodulation decision type

`Hard decision` (default) | `Log-likelihood ratio` | `Approximate log-likelihood ratio`

Demodulation decision type, specified as `Hard decision`, `Log-likelihood ratio`, or `Approximate log-likelihood ratio`. See “APSK Soft Demodulation” on page 5-535 for algorithm selection considerations.

Dependencies

This parameter applies only when Output type is set to `Bit`.

`Noise variance source` — Noise variance source

`Property` (default) | `Input port`

Noise variance source, specified as:

- `Property` — The noise variance is set using the Noise variance parameter.
- `Input port` — The noise variance is set using the Var input port.

Dependencies

This parameter applies only when Decision type is set to either `Log-likelihood ratio` or `Approximate log-likelihood ratio`.

`Noise variance` — Noise variance

`1` (default) | positive scalar | vector of positive values

Noise variance, specified as a positive scalar or vector of positive values.

- When specified as a scalar, that value is used on all elements in the input signal.
- When specified as a vector, the vector length must be equal to the number of columns in the input signal. Each noise variance vector element is applied to its corresponding column in the input signal.

When the noise variance or signal power result in computations involving extreme positive or negative magnitudes, see “APSK Soft Demodulation” on page 5-535 for Decision type specification considerations.

Dependencies

This parameter applies only when Noise variance source is set to `Property` and Decision type is set to either `Log-likelihood ratio` or `Approximate log-likelihood ratio`.

Data Types: `double`

`Output data type` — Output data type

`double` (default) | `...`

Output data type, specified as one of the acceptable values from this table. Acceptable **Output data type** values depend on the Output type and Decision type parameter values.

Output type	Decision type	Output data type Options
`Integer`	Not applicable	`double`, `single`, `int8`, `uint8`, `int16`, `uint16`, `int32`, or `uint32`
`Bit`	`Hard decision`	`double`, `single`, `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, or `logical`
	`Log-likelihood ratio` or `Approximate log-likelihood ratio`	The output signal is the same data type as the input signal.

Dependencies

This parameter applies only when Output type is set to `Integer` or when Output type is set to `Bit` and Decision type is set to `Hard decision`.

`Simulate using` — Type of simulation to run
`Interpreted execution` (default) | `Code generation`

Type of simulation to run, specified as:

- `Code generation` -– Simulate the model using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations as long as the model does not change. This option requires additional startup time.
- `Interpreted execution` -– Simulate the model using the MATLAB interpreter. This option shortens startup time. In `Interpreted execution` mode, you can debug the source code of the block.

For information on execution speed, see “Tips” on page 5-536.

Block Characteristics

Data Types	`Boolean` | `double` | `integer` | `single`
Multidimensional Signals	`yes`
Variable-Size Signals	`no`

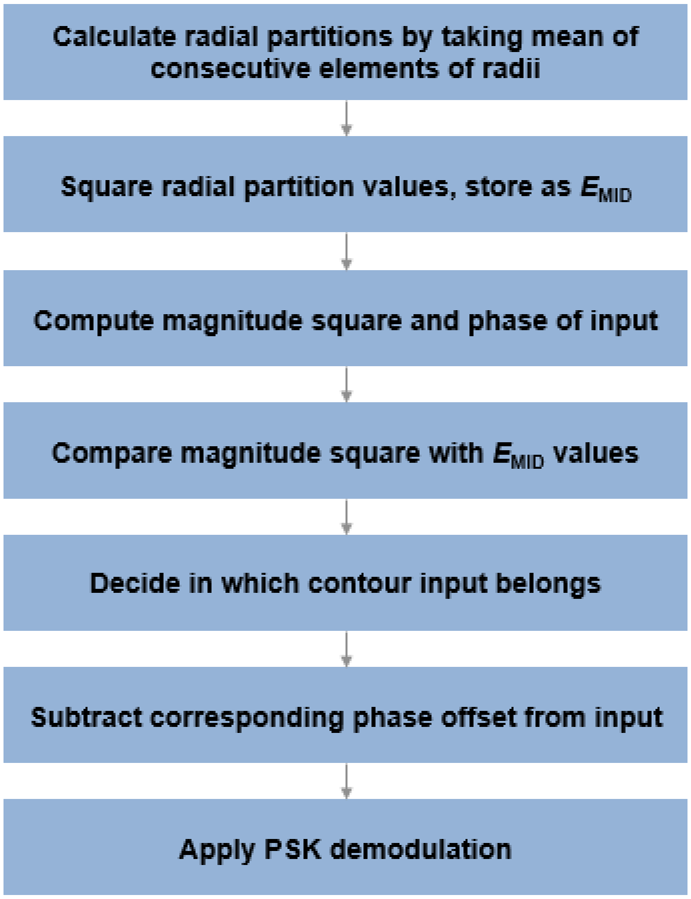
More About

Modulation Order for *M*-APSK

The modulation order, *M*, for *M*-APSK equals the sum of the vector elements in the Constellation points per circle parameter and is the total number of points in the signal constellation. Element values in **Constellation points per circle** must be multiples of four, and *M* must be a power of two.

APSK Hard Demodulation

The hard demodulation algorithm applies amplitude phase decoding, as described in [1].



Calculate radial partitions by taking mean of consecutive elements of radii
Square radial partition values, store as E_{MID}
Compute magnitude square and phase of input
Compare magnitude square with E_{MID} values
Decide in which contour input belongs
Subtract corresponding phase offset from input
Apply PSK demodulation

APSK Soft Demodulation

For soft demodulation, two soft-decision log-likelihood ratio (LLR) algorithms are available: exact LLR and approximate LLR. This table compares these algorithms.

Algorithm	Accuracy	Execution Speed
Exact LLR	more accurate	slower execution
Approximate LLR	less accurate	faster execution

For further description of these algorithms, see “Exact LLR Algorithm” and “Approximate LLR Algorithm”.

Note The exact LLR algorithm computes exponentials using finite precision arithmetic. Computation of exponentials with very large positive or negative magnitudes might yield:

- `Inf` or `-Inf` if the noise variance is a very large value
- `NaN` if both the noise variance and signal power are very small values

When the output returns any of these values, try using the approximate LLR algorithm because it does not compute exponentials.

Tips

- For faster execution of the M-APSK Demodulator Baseband block, set the Simulate using parameter to:
  - `Code generation` when using hard decision demodulation.
  - `Interpreted execution` when using soft decision demodulation.

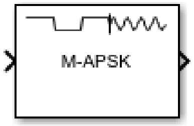
M-APSK Modulator Baseband

M-ary amplitude phase shift keying (APSK) modulation

Library: Communications Toolbox / Modulation / Digital Baseband Modulation / APM



Description

The M-APSK Modulator Baseband block modulates the input signal using *M*-ary amplitude phase shift keying (APSK) modulation. The output is a baseband representation of the modulated signal. *M*, the “Modulation Order for M-APSK” on page 5-540, equals the sum of the elements in Constellation points per circle. For a description of *M*-APSK modulation, see “Algorithms” on page 5-540.

Note M-APSK Modulator Baseband specifically applies to multiple ring PSK constellations. For a single ring PSK constellation, use M-PSK Modulator Baseband.

Ports

Input

`In` — Input signal
scalar | vector | matrix

Input signal, specified as a scalar, vector, or matrix. The input signal must consist of binary values or integers in the range [0, (*M* – 1)], where *M* is the “Modulation Order for M-APSK” on page 5-540. This port is unnamed on the block.

Note To process the input signal as binary elements, set the Input type parameter value to `Bit`. For binary inputs, the number of rows must be an integer multiple of $\log_2(M)$. Groups of $\log_2(M)$ bits in a column are mapped onto a symbol, with the first bit representing the MSB and the last bit representing the LSB.

Data Types: `single` | `double` | `int8` | `int16` | `int32` | `uint8` | `uint16` | `uint32` | `Boolean`

Output

`Out` — APSK modulated signal
scalar | vector | matrix

APSK modulated signal, returned as a complex scalar, vector, or matrix. The output signal dimensions depend on the specified Input type value. This port is unnamed on the block.

Input type	Dimensions of Output Signal
`Integer`	The output signal has the same dimensions as the input signal.
`Bit`	The number of rows in the output signal equals the number of rows in the input signal divided by $\log_2(M)$, where M is the “Modulation Order for M-APSK” on page 5-540.

Use Output data type to specify the output data type.

Parameters

`Constellation points per circle` — Constellation points per PSK ring

`[4,12]` (default) | vector

Constellation points per PSK ring, specified as a vector with more than one element. Each vector element indicates the number of constellation points in its corresponding PSK ring. The first element corresponds to the innermost circle, and so on until the last element, which corresponds to the outermost circle. The sum of the elements in **Constellation points per circle** determines the modulation order. Element values must be multiples of four, and the modulation order must be a power of two.

Example: `[4,12,16]` specifies a three PSK ring constellation with a modulation order of 32.

`Radius of each circle` — Radius per PSK ring

`[0.5,1]` (default) | vector

Radius per PSK ring, specified as a vector with the same length as Constellation points per circle. Each vector element indicates the radius of its corresponding PSK ring. The first element corresponds to the innermost circle, and so on until the last element, which corresponds to the outermost circle. These element values must be positive and arranged in increasing order.

Example: `[0.5,1,2]` defines radii for three constellation PSK rings. The inner ring has a radius of 0.5, the second ring has a radius of 1.0, and the outer ring has a radius of 2.0.

`Phase offset of each circle (rad)` — Phase offset per PSK ring

`[pi/4,pi/12]` (default) | scalar | vector

Phase offset per PSK ring in radians, specified as a scalar or vector with the same length as Constellation points per circle. Each vector element indicates the phase offset of its corresponding PSK ring. The first element corresponds to the innermost circle, and so on until the last element, which corresponds to the outermost circle. The **Phase offset of each circle (rad)** can be a scalar only if all the elements of **Constellation points per circle** are the same value.

Example: `[pi/4,pi/12,pi/16]` defines phase offsets for three constellation PSK rings. The inner ring has a phase offset of π/4, the second ring has a phase offset of π/12, and the outer ring has a phase offset of π/16.

`Symbol mapping` — Symbol mapping

`Auto` (default) | `Contourwise-gray` | `Gray` | `User-defined`

Symbol mapping, specified as one of the following:

- `Contourwise-gray` — Uses Gray mapping along the contour in the phase dimension for each PSK ring.

- `Gray` — Uses Gray mapping along the contour in both the amplitude and phase dimensions. For Gray symbol mapping, all the values for Constellation points per circle must be equal and all the values for Phase offset of each circle (rad) must be equal. For a description of the Gray mapping used, see [2].
- `User-defined` — See Custom symbol mapping.

The default symbol mapping depends on **Constellation points per circle** and **Phase offset of each circle (rad)**. When all the elements of **Constellation points per circle** are equal and all the elements of **Phase offset of each circle (rad)** are equal, the default is `Gray`. For all other cases, the default is `Contourwise-gray`.

`Custom symbol mapping` — Custom symbol mapping

`[0,4,12,8,1,3,2,6,7,5,13,15,14,10,11,9]` (default) | integer vector

Custom symbol mapping, specified as an integer vector. This vector must consist of *M* unique elements with values in the range [0, (*M* – 1)], where *M* is the "Modulation Order for M-APSK" on page 5-540. The first element in **Custom symbol mapping** corresponds to the constellation point in the first quadrant of the innermost circle, with subsequent elements positioned counterclockwise around the PSK rings.

Example: The default value, `[0,4,12,8,1,3,2,6,7,5,13,15,14,10,11,9]`, specifies contourwise-gray symbol mapping. The distribution of constellation points is nonuniform on all contours.

Dependencies

To enable this parameter, set Symbol mapping to `User-defined`.

`Input type` — Input type

`Integer` (default) | `Bit`

Input type, specified as `Integer` or `Bit`. To use `Integer`, the input signal must consist of integers in the range [0, (*M* – 1)]. To use `Bit`, the input signal must contain binary values, and the number of rows must be an integer multiple of $\log_2(M)$, where *M* is the "Modulation Order for M-APSK" on page 5-540.

`Output data type` — Output data type

`double` (default) | `single`

Output data type, specified as `double` or `single`.

`View Constellation` — Plot reference constellation

`button`

To plot the reference constellation, click the **View Constellation** button.

Tip Click **Apply** before clicking the **View Constellation** to view latest parameter values.

`Simulate using` — Type of simulation to run

`Code generation` (default) | `Interpreted execution`

Type of simulation to run, specified as:

- `Code generation` –– Simulate the model using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations as long as the model does not change. This option requires additional startup time.
- `Interpreted execution` –– Simulate the model using the MATLAB interpreter. This option shortens startup time. In `Interpreted execution` mode, you can debug the source code of the block.

Block Characteristics

Data Types	`Boolean` | `double` | `integer` | `single`
Multidimensional Signals	`yes`
Variable-Size Signals	`no`

More About

Modulation Order for *M*-APSK

The modulation order, *M*, for *M*-APSK is the total number of points in the signal constellation. *M* equals the sum of the elements in Constellation points per circle. The element values in **Constellation points per circle** must be multiples of four. *M* must be a power of two.

Algorithms

The block implements a pure APSK constellation.

A pure M-APSK constellation is composed of N_C concentric rings or contours, each with uniformly spaced PSK points. The M-APSK constellation set is

$$\chi = \begin{cases} R_1 \exp\left(j\left(\frac{2\pi}{M_1} i + \theta_1\right)\right), & i = 0, \ldots, M_1 - 1, \\ R_2 \exp\left(j\left(\frac{2\pi}{M_2} i + \theta_2\right)\right), & i = 0, \ldots, M_2 - 1, \\ \quad \vdots & \quad \vdots \\ R_{N_C} \exp\left(j\left(\frac{2\pi}{M_{N_C}} i + \theta_{\mathrm{Nc}}\right)\right), & i = 0, \ldots, M_{N_C} - 1, \end{cases}$$

where

- The modulation order is equal to the sum of all M_l for $l = 1, 2, \ldots, N_C$.
- N_C is the number of concentric rings. $N_C \geq 2$.
- M_l is the number of constellation points in the *l*th ring.
- R_l is the radius of the *l*th ring.
- θ_l is the phase offset of the *l*th ring.
- $j = \sqrt{-1}$

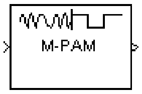
Introduced in R2018b

M-PAM Demodulator Baseband

Demodulate PAM-modulated data



Library

AM, in Digital Baseband sublibrary of Modulation

Description

The M-PAM Demodulator Baseband block demodulates a signal that was modulated using M-ary pulse amplitude modulation. The input is a baseband representation of the modulated signal.

The signal constellation has M points, where M is the **M-ary number** parameter. M must be an even integer. The block scales the signal constellation based on how you set the **Normalization method** parameter. For details on the constellation and its scaling, see the reference page for the M-PAM Modulator Baseband block.

This block accepts a scalar or column vector input signal. For information about the data types each block port supports, see “Supported Data Types” on page 5-547.

Note All values of power assume a nominal impedance of 1 ohm.

Integer-Valued Signals and Binary-Valued Signals

When you set the **Output type** parameter to `Integer`, the block outputs integer values between `0` and *M*-`1`. *M* represents the **M-ary number** block parameter.

When you set the **Output type** parameter to `Bit`, the block outputs binary-valued signals that represent integers. The block represents each integer using a group of $K = \log_2(M)$ bits, where K represents the number of bits per symbol. The output vector length must be an integer multiple of K.

The **Constellation ordering** parameter indicates how the block assigns binary words to points of the signal constellation. More details are on the reference page for the M-PAM Modulator Baseband block.

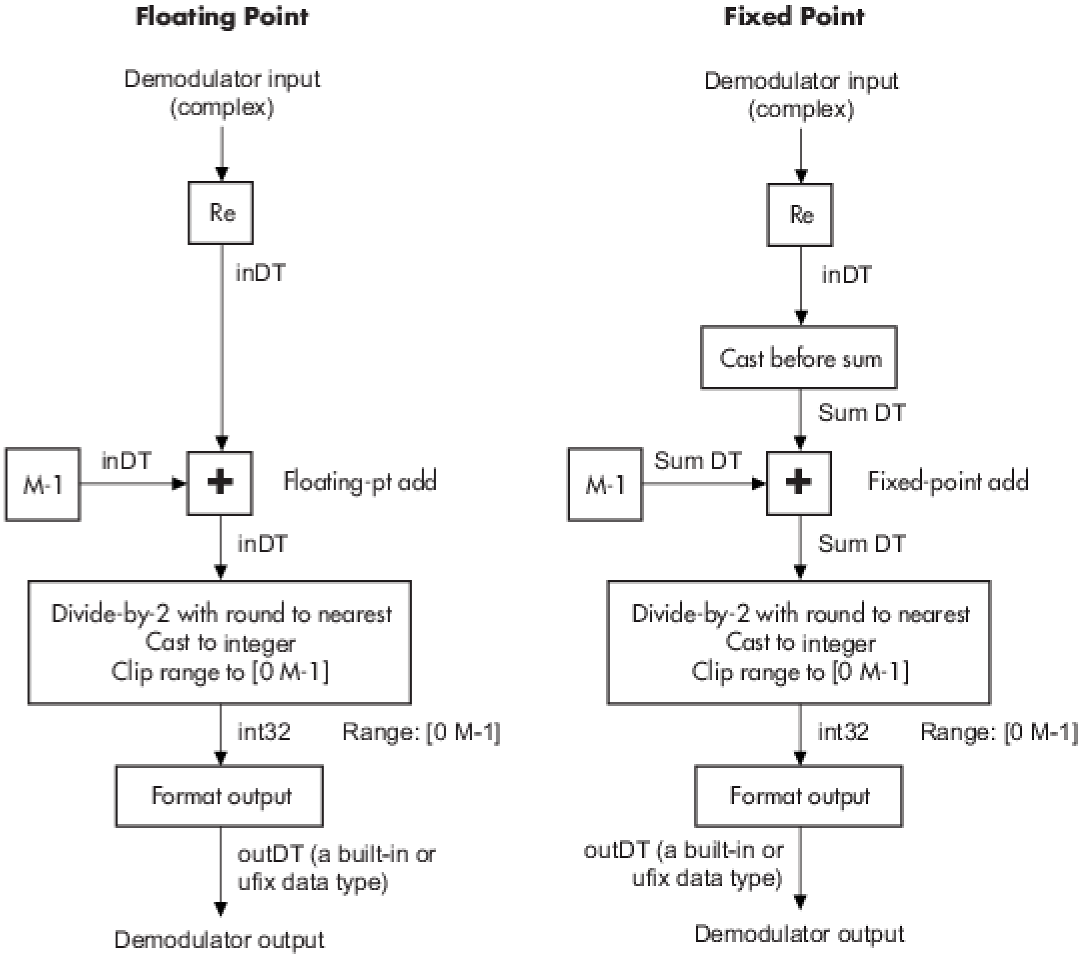
Algorithm

The demodulator algorithm maps received input signal constellation values to M-ary integer symbol indices between 0 and M-1 and then maps these demodulated symbol indices to formatted output values.

The integer symbol index computation is performed by first scaling the real part of the input signal constellation (possibly with noise) by a denormalization factor derived from the **Normalization**

method and related parameters. This denormalized value is added to M-1 to translate it into an approximate range between 0 and 2 x (M-1) plus noise. The resulting value is then rescaled via a divide-by-two (or, equivalently, a right-shift by one bit for fixed-point operation) to obtain a range approximately between 0 and M-1 (plus noise). The noisy index value is rounded to the nearest integer and clipped, via saturation, to the exact range of [0 M-1]. Finally, based on other block parameters, the integer index is mapped to a symbol value that is formatted and cast to the selected **Output data type**.

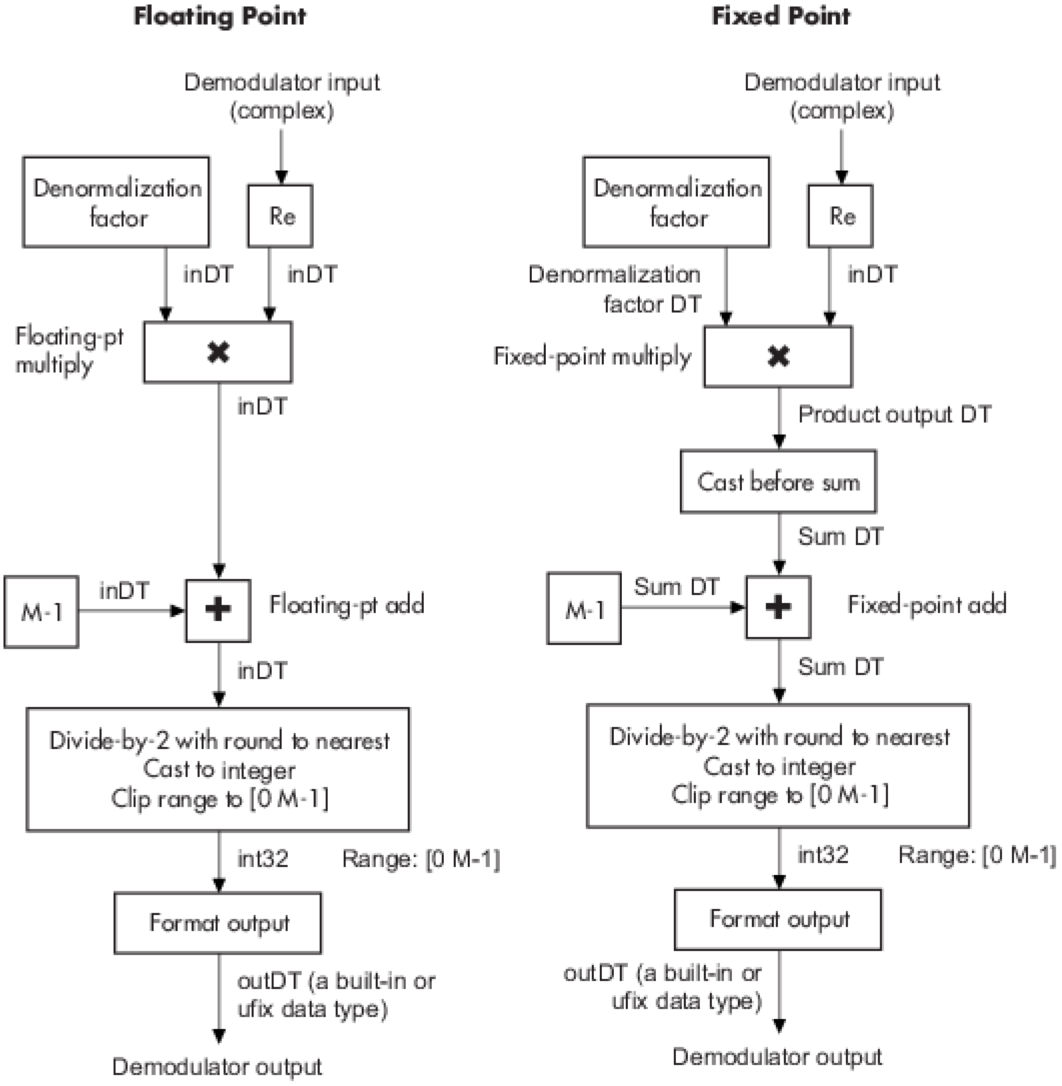
The following figures contains signal flow diagrams for floating-point and fixed-point algorithm operation. The floating-point diagrams apply when the input signal data type is `double` or `single`. The fixed-point diagrams apply when the input signal is a signed fixed-point data type. Note that the diagram is simplified when using normalized constellations (i.e., denormalization factor is 1).



Floating Point

Fixed Point

Signal-Flow Diagrams with Denormalization Factor Equal to 1



Signal-Flow Diagrams with Nonunity Denormalization Factor

Parameters

M-ary number

The number of points in the signal constellation. It must be an even integer.

Output type

Determines whether the output consists of integers or groups of bits. If this parameter is set to `Bit`, then the **M-ary number** parameter must be 2^K for some positive integer K.

Constellation ordering

Determines how the block maps each integer to a group of output bits.

Normalization method

Determines how the block scales the signal constellation. Choices are `Min. distance between symbols`, `Average Power`, and `Peak Power`.

Minimum distance

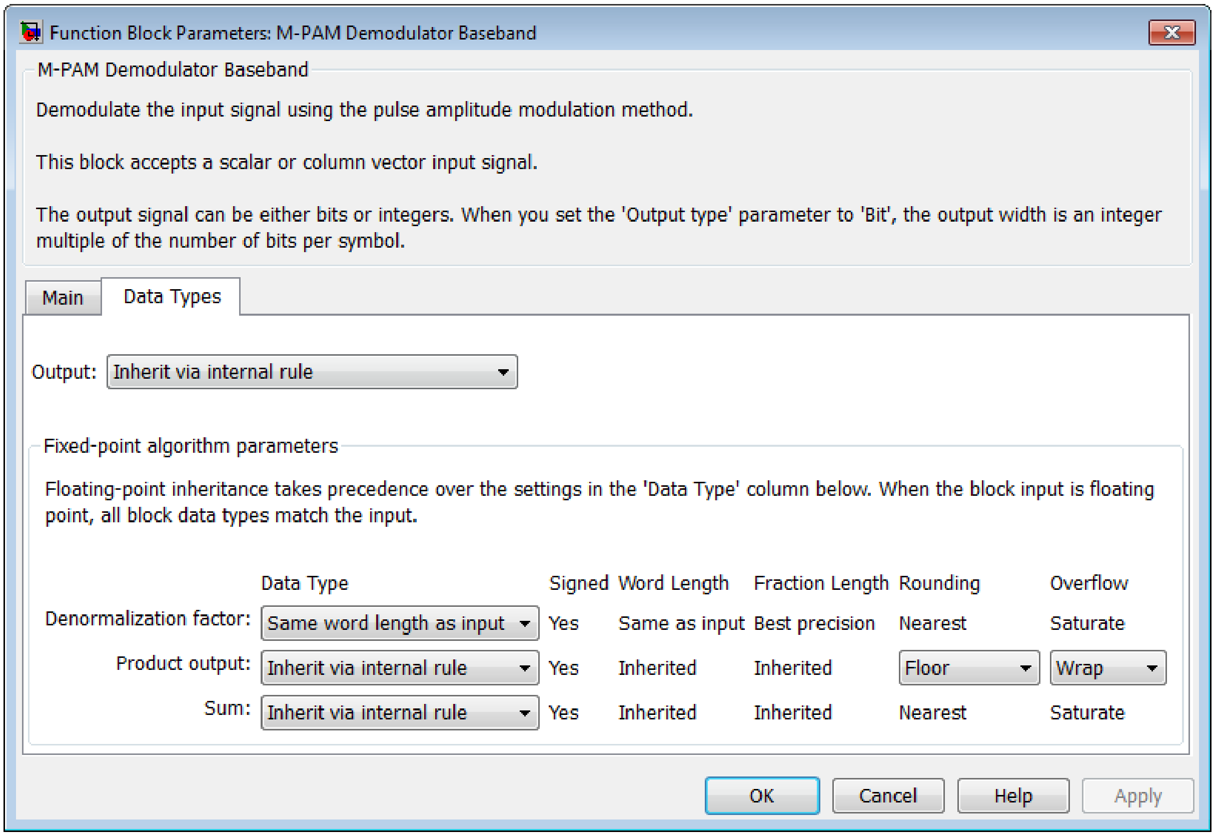
The distance between two nearest constellation points. This field appears only when **Normalization method** is set to `Min. distance between symbols`.

Average power, referenced to 1 ohm (watts)

The average power of the symbols in the constellation, referenced to 1 ohm. This field appears only when **Normalization method** is set to `Average Power`.

Peak power, referenced to 1 ohm (watts)

The maximum power of the symbols in the constellation, referenced to 1 ohm. This field appears only when **Normalization method** is set to `Peak Power`.



M-PAM Demodulator Baseband

Demodulate the input signal using the pulse amplitude modulation method.

This block accepts a scalar or column vector input signal.

The output signal can be either bits or integers. When you set the 'Output type' parameter to 'Bit', the output width is an integer multiple of the number of bits per symbol.

Output: Inherit via internal rule

Fixed-point algorithm parameters

Floating-point inheritance takes precedence over the settings in the 'Data Type' column below. When the block input is floating point, all block data types match the input.

	Data Type	Signed	Word Length	Fraction Length	Rounding	Overflow
Denormalization factor:	Same word length as input	Yes	Same as input	Best precision	Nearest	Saturate
Product output:	Inherit via internal rule	Yes	Inherited	Inherited	Floor	Wrap
Sum:	Inherit via internal rule	Yes	Inherited	Inherited	Nearest	Saturate

Output

When the parameter is set to `'Inherit via internal rule'` (default setting), the block will inherit the output data type from the input port. The output data type will be the same as the input data type if the input is of type `single` or `double`. Otherwise, the output data type will be as if this parameter is set to `'Smallest unsigned integer'`.

When the parameter is set to `'Smallest unsigned integer'`, the output data type is selected based on the settings used in the **Hardware Implementation** pane of the Configuration Parameters dialog box of the model. If `ASIC/FPGA` is selected in the **Hardware Implementation** pane, the output data type is the ideal minimum size, i.e., `ufix(1)` for bit outputs, and `ufix(ceil(log2(M)))` for integer outputs. For all other selections, it is an unsigned integer with the smallest available word length large enough to fit the ideal minimum size, usually corresponding to the size of a char (e.g., `uint8`).

For integer outputs, this parameter can be set to `Smallest unsigned integer`, `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `single`, and `double`. For bit outputs, the options are `Smallest unsigned integer`, `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, or `double`.

Denormalization factor

This parameter applies when a fixed-point input is not normalized. It can be set to `Same word length as input` or `Specify word length`, in which case a field is enabled for user input. A best-precision fraction length is always used.

Product output

This parameter only applies when the input is a fixed-point signal and there is a nonunity (not equal to 1) denormalized factor. It can be set to `Inherit via internal rule` or `Specify word length`, which enables a field for user input.

Setting to `Inherit via internal rule` computes the full-precision product word length and fraction length. Internal Rule for Product Data Types in *DSP System Toolbox User's Guide* describes the full-precision Product output internal rule.

Setting to `Specify word length` allows you to define the word length. The block computes a best-precision fraction length based on the word length specified and the pre-computed worst-case (min/max) real world value **Product output** result. The worst-case **Product output** result is precomputed by multiplying the denormalized factor with the worst-case (min/max) input signal range, purely based on the input signal data type.

The block uses the **Rounding** method when the result of a fixed-point calculation does not map exactly to a number representable by the data type and scaling storing the result. For more information, see “Rounding Modes” or “Rounding Mode: Simplest” (Fixed-Point Designer).

Sum

This parameter only applies when the input is a fixed-point signal. It can be set to `Inherit via internal rule`, `Same as product output`, or `Specify word length`, in which case a field is enabled for user input

Setting `Inherit via internal rule` computes the full-precision sum word length and fraction length, based on the two inputs to the Sum in the fixed-point Hard Decision Algorithm on page 5-542 signal flow diagram. The rule is the same as the fixed-point inherit rule of the internal **Accumulator data type** parameter in the Simulink Sum (Simulink) block.

Setting `Specify word length` allows you to define the word length. A best precision fraction length is computed based on the word length specified in the pre-computed maximum range necessary for the demodulated algorithm to produce accurate results. The signed fixed-point data type that has the best precision fully contains the values in the range 2 * (M-1) for the specified word length.

Setting to `Same as product output` allows the Sum data type to be the same as the **Product output** data type (when **Product output** is used). If the **Product output** is not used, then this setting will be ignored and the `Inherit via internal rule` Sum setting will be used.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point • Signed fixed-point
Output	• Double-precision floating point • Single-precision floating point • Boolean when **Output type** is `Bit` • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers • ufix(1) in ASIC/FPGA when **Output type** is `Bit` • $ufix(\lceil \log_2 M \rceil)$ in ASIC/FPGA when **Output type** is `Integer`

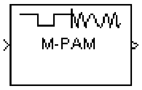
Introduced before R2006a

M-PAM Modulator Baseband

Modulate using M-ary pulse amplitude modulation



Library

AM, in Digital Baseband sublibrary of Modulation

Description

The M-PAM Modulator Baseband block modulates using M-ary pulse amplitude modulation. The output is a baseband representation of the modulated signal. The **M-ary number** parameter, M, is the number of points in the signal constellation. It must be an even integer.

Note All values of power assume a nominal impedance of 1 ohm.

Constellation Size and Scaling

Baseband M-ary pulse amplitude modulation using the block's default signal constellation maps an integer m between 0 and M-1 to the complex value

2m - M + 1

Note This value is actually a real number. The block's output signal is a complex data-type signal whose imaginary part is zero.

The block scales the default signal constellation based on how you set the **Normalization method** parameter. The following table lists the possible scaling conditions.

Value of Normalization Method Parameter	Scaling Condition
`Min. distance between symbols`	The nearest pair of points in the constellation is separated by the value of the **Minimum distance** parameter
`Average Power`	The average power of the symbols in the constellation is the **Average power** parameter
`Peak Power`	The maximum power of the symbols in the constellation is the **Peak power** parameter

Integer-Valued Signals and Binary-Valued Signals

This block accepts a scalar or column vector input signal.

When you set the **Input type** parameter to `Integer`, the block accepts integer values between `0` and *M*-`1`. *M* represents the **M-ary number** block parameter.

When you set the **Input type** parameter to `Bit`, the block accepts binary-valued inputs that represent integers. The block collects binary-valued signals into groups of $K = \log_2(M)$ bits

where

K represents the number of bits per symbol.

The input vector length must be an integer multiple of *K*. In this configuration, the block accepts a group of *K* bits and maps that group onto a symbol at the block output. The block outputs one modulated symbol for each group of *K* bits.

The **Constellation ordering** parameter indicates how the block assigns binary words to points of the signal constellation.

- If **Constellation ordering** is set to `Binary`, then the block uses a natural binary-coded constellation.
- If **Constellation ordering** is set to `Gray`, then the block uses a Gray-coded constellation.

  For details about the Gray coding, see the reference page for the M-PSK Modulator Baseband block.

Constellation Visualization

The M-PAM Modulator Baseband block provides the capability to visualize a signal constellation from the block mask. This Constellation Visualization feature allows you to visualize a signal constellation for specific block parameters. For more information, see the Constellation Visualization section of the *Communications Toolbox User's Guide*.

Parameters

M-ary number

The number of points in the signal constellation. It must be an even integer.

Input type

Indicates whether the input consists of integers or groups of bits. If this parameter is set to `Bit`, then the **M-ary number** parameter must be 2^K for some positive integer K.

Constellation ordering

Determines how the block maps each group of input bits to a corresponding integer.

Normalization method

Determines how the block scales the signal constellation. Choices are `Min. distance between symbols`, `Average Power`, and `Peak Power`.

Minimum distance

The distance between two nearest constellation points. This field appears only when **Normalization method** is set to `Min. distance between symbols`.

Average power, referenced to 1 ohm (watts)

The average power of the symbols in the constellation, referenced to 1 ohm. This field appears only when **Normalization method** is set to `Average Power`.

Peak power, referenced to 1 ohm (watts)

The maximum power of the symbols in the constellation, referenced to 1 ohm. This field appears only when **Normalization method** is set to `Peak Power`.

Output data type

The output data type can be set to `double`, `single`, `Fixed-point`, `User-defined`, or `Inherit via back propagation`.

Setting this parameter to `Fixed-point` or `User-defined` enables fields in which you can further specify details. Setting this parameter to `Inherit via back propagation`, sets the output data type and scaling to match the following block.

Output word length

Specify the word length, in bits, of the fixed-point output data type. This parameter is only visible when you select `Fixed-point` for the **Output data type** parameter.

User-defined data type

Specify any signed built-in or signed fixed-point data type. You can specify fixed-point data types using the `sfix`, `sint`, `sfrac`, and `fixdt` functions from Fixed-Point Designer software. This parameter is only visible when you select `User-defined` for the **Output data type** parameter.

Set output fraction length to

Specify the scaling of the fixed-point output by either of the following methods:

- Choose `Best precision` to have the output scaling automatically set such that the output signal has the best possible precision.
- Choose `User-defined` to specify the output scaling in the **Output fraction length** parameter.

This parameter is only visible when you select `Fixed-point` for the **Output data type** parameter or when you select `User-defined` and the specified output data type is a fixed-point data type.

Output fraction length

For fixed-point output data types, specify the number of fractional bits, or bits to the right of the binary point. This parameter is only visible when you select `Fixed-point` or `User-defined` for the **Output data type** parameter and `User-defined` for the **Set output fraction length to** parameter.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point • Boolean when **Input type** is `Bit` • 8-, 16-, 32-bit signed integers • 8-, 16-, 32-bit unsigned integers • $ufix(\lceil\log_2 M\rceil)$ when **Input type** is `Integer`

Port	Supported Data Types
Output	• Double-precision floating point • Single-precision floating point • Signed fixed-point

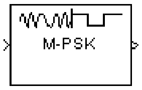
M-PSK Demodulator Baseband

Demodulate PSK-modulated data

Library: Communications Toolbox / Modulation / Digital Baseband Modulation / PM
Communications Toolbox HDL Support / Modulation / PM



Description

The M-PSK Demodulator Baseband block demodulates a baseband representation of a PSK-modulated signal. The modulation order, *M*, is equivalent to the number of points in the signal constellation and is determined by the **M-ary number** parameter. The block accepts scalar or column vector input signals.

Input/Output Ports

Input

`Port_1` — Input signal
scalar | vector

Input port accepting a baseband representation of a PSK-modulated signal.

Data Types: `single` | `double` | `int8` | `int16` | `int32` | `uint8` | `uint16` | `uint32` | `Boolean`

Output

`Port_1` — Output signal
scalar | vector

Output signal, returned as a scalar or vector. The output is a demodulated version of the PSK-modulated signal.

Data Types: `single` | `double` | `fixed point`

Parameters

`M-ary number` — Modulation order of the PSK constellation
8 (default) | scalar

Specify the modulation order as a positive integer power of two.

Example: 2 | 16

`Output type` — Output signal data type
`Integer` (default) | `Bit`

Specify the elements of the input signal as integers or bits. If **Output type** is `Bit`, the number of samples per frame is an integer multiple of the number of bits per symbol, $\log_2(M)$.

`Decision type` — Demodulator output

`Hard decision` (default) | `Log-likelihood ratio` | `Approximate log-likelihood ratio`

Specify the demodulator output to be hard decision, log-likelihood ratio (LLR), or approximate LLR. The LLR and approximate LLR outputs are used with error decoders that support soft-decision inputs such as a Viterbi decoder, to achieve superior performance. This parameter is available when **Output type** is `Bit`.

See “Phase Modulation” for algorithm details. The output values for `Log-likelihood ratio` and `Approximate log-likelihood ratio` decision types are of the same data type as the input values

`Noise variance source` — Source of noise variance

`Dialog` (default) | `Port`

Specify the source of the noise variance estimate. This parameter is available when **Decision type** is `Log-likelihood ratio` or `Approximate log-likelihood ratio`.

- To specify the noise variance from the dialog box, select `Dialog`.
- To input the noise variance from an input port, select `Port`.

`Noise variance` — Estimate of noise variance

`1` (default) | positive scalar

Specify the estimate of the noise variance as a positive scalar. This parameter is available when **Noise variance source** is `Dialog`.

This parameter is tunable in all simulation modes. If you use the Simulink Coder rapid simulation (RSIM) target to build an RSIM executable, then you can tune the parameter without recompiling the model. Avoiding recompilation is useful for Monte Carlo simulations in which you run the simulation multiple times (perhaps on multiple computers) with different amounts of noise.

Note The exact LLR algorithm computes exponentials using finite precision arithmetic. Computation of exponentials with very large positive or negative magnitudes might yield:

- `Inf` or `-Inf` if the noise variance is a very large value
- `NaN` if both the noise variance and signal power are very small values

When the output returns any of these values, try using the approximate LLR algorithm because it does not compute exponentials.

`Constellation ordering` — Symbol mapping

`Gray` (default) | `Binary` | `User-defined`

Specify how the integer or group of $\log_2(M)$ bits is mapped to the corresponding symbol.

- When **Constellation ordering** is set to `Gray`, the output symbol is mapped to the input signal using a Gray-encoded signal constellation.

- When **Constellation ordering** is set to `Binary`, the modulated symbol is exp($j\phi+j2\pi m/M$), where ϕ is the phase offset in radians, m is the integer output such that $0 \leq m \leq M - 1$, and M is the modulation order.
- When **Constellation ordering** is `User-defined`, specify a vector of size M, which has unique integer values in the range [0, M–1]. The first element of this vector corresponds to the constellation point having a value of $e^{j\phi}$ with subsequent elements running counterclockwise.

Example: `[0 3 2 1]`

`Constellation mapping` — User-defined symbol mapping

`[0:7]` (default) | vector

Specify the order in which input integers are mapped to output integers. The parameter is available when **Constellation ordering** is `User-defined`, and must be a row or column vector of size M having unique integer values in the range [0, M – 1].

The first element of this vector corresponds to the constellation point at 0 + **Phase offset** angle, with subsequent elements running counterclockwise. The last element corresponds to the -2π/M + **Phase offset** constellation point.

`Phase offset (rad)` — Phase offset in radians

`pi/8` (default) | scalar

Specify, in radians, the phase offset of the initial constellation as a real scalar.

Example: `pi/4`

`Output data type` — Output data type

`Inherit via internal rule` (default) | `Smallest unsigned integer` | `double` | `single` | `int8` | `uint8` | `int16` | `uint16` | `int32` | `uint32`

Specify the data type of the demodulated output signal.

Block Characteristics

Data Types	`Boolean` | `double` | `fixed point`[abc] | `integer` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`yes`

[a] M = 2, 4, 8 only.

[b] Fixed-point inputs must be signed.

[c] When ASIC/FPGA is selected in the Hardware Implementation Pane, output is ufix(1) for bit outputs, and ufix(ceil(log2(M))) for integer outputs.

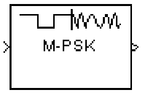
M-PSK Modulator Baseband

Modulate using M-ary phase shift keying

Library: Communications Toolbox / Modulation / Digital Baseband Modulation / PM
Communications Toolbox HDL Support / Modulation / PM



Description

The M-PSK Modulator Baseband block modulates an input signal using M-ary phase shift keying (PSK) and returns a complex baseband output. The modulation order, *M*, which is equivalent to the number of points in the signal constellation, is determined by the **M-ary number** parameter. The block accepts scalar or column vector input signals.

Input/Output Ports

Input

`Port_1` — Input signal
scalar | vector

Specify the input signal as an integer scalar, integer vector, or binary vector.

- When **Input type** is `Integer`, specify the input signal elements as integers from 0 to *M* – 1.
- When **Input type** is `Bit`, specify the input signal as a binary vector in which the number of elements is an integer multiple of the bits per symbol. The bits per symbol is equal to $\log_2(M)$.

Data Types: `single` | `double` | `int8` | `int16` | `int32` | `uint8` | `uint16` | `uint32` | `Boolean`

Output

`Port_1` — Output signal
scalar | vector

Output signal, returned as a complex scalar or vector. The output is the complex baseband representation of the PSK-modulated signal.

Data Types: `single` | `double` | `fixed point`

Parameters

`M-ary number` — Modulation order of the PSK constellation
8 (default) | scalar

Specify the modulation order as a positive integer power of two.

Example: 2 | 16

Input type — Type of input signal

Integer (default) | Bit

Specify the elements of the input signal as integers or bits. If **Input type** is Bit, the number of samples per frame must be an integer multiple of the number of bits per symbol. The number of bits per symbol is $\log_2(M)$.

Constellation ordering — Symbol mapping

Gray (default) | Binary | User-defined

Specify how the integer or group of $\log_2(M)$ bits is mapped to the corresponding symbol.

- When **Constellation ordering** is set to Gray, the input signal is mapped to the output symbols using a Gray-encoded signal constellation.
- When **Constellation ordering** is set to Binary, the modulated symbol is $\exp(j\phi+j2\pi m/M)$, where ϕ is the phase offset in radians, m is the integer input such that $0 \le m \le M - 1$, and M is the modulation order.
- When **Constellation ordering** is User-defined, specify a vector of size M, which has unique integer values in the range $[0, M\text{–}1]$. The first element of this vector corresponds to the constellation point having an value of $e^{j\phi}$ with subsequent elements running counterclockwise.

Example: [0 3 2 1]

Constellation mapping — User-defined symbol mapping

[0:7] (default) | vector

Specify the order in which input integers are mapped to output integers. The parameter is available when **Constellation ordering** is User-defined, and must be a row or column vector of size M having unique integer values in the range $[0, M - 1]$.

The first element of this vector corresponds to the constellation point at 0 + **Phase offset** angle, with subsequent elements running counterclockwise. The last element corresponds to the -2π/M + **Phase offset** constellation point.

Phase offset (rad) — Phase offset in radians

pi/8 (default) | scalar

Specify, in radians, the phase offset of the initial constellation as a real scalar.

Example: pi/4

Output data type — Output data type

double (default) | single | Inherit via back propagation | fixdt(1,16) | fixdt(1,16,0) | <data type expression>

Specify the data type of the modulated output signal. Set this parameter to one of the fixed point options or <data type expression> to enable parameters in which you specify additional details. Set this parameter to Inherit via back propagation, to match the output data type and scaling to the following block in the model.

Block Characteristics

Data Types	Boolean | double | fixed point[ab] | integer | single

Multidimensional Signals	no
Variable-Size Signals	yes

a. ufix(1) at the input if ''input type'' is set to ''bit''. ufix(ceil(log2(M))) at input if ''input type'' is set to ''integer'' for M-ary modulation.

b. Fixed-point outputs must be signed.

Tips

The M-PSK Modulator Baseband block provides the capability to visualize a signal constellation from the block mask. Clicking the **View Constellation** button allows you to visualize a signal constellation for the specified block parameters.

Algorithms

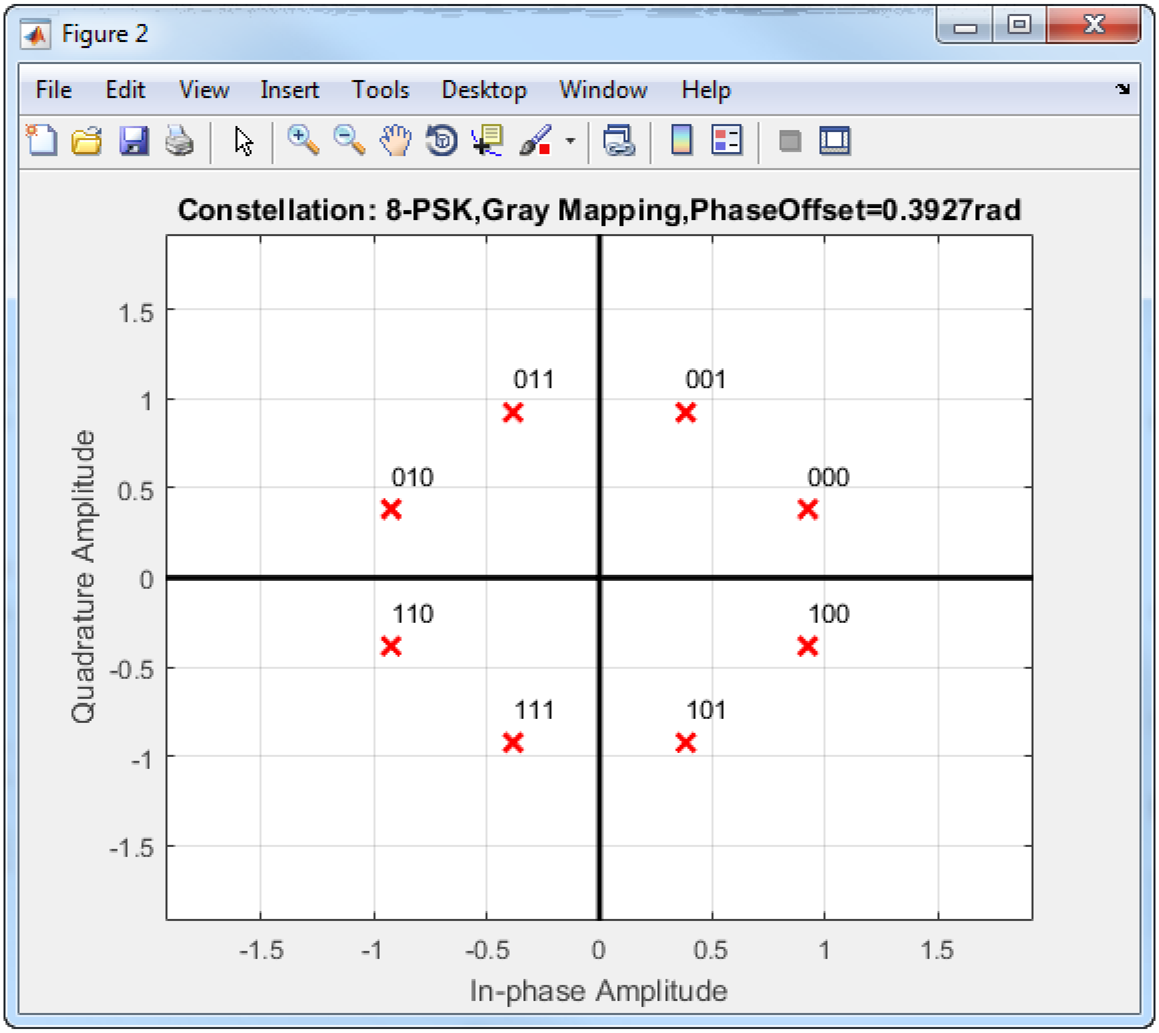
The block outputs a baseband signal by mapping input bits or integers to complex symbols according to the following:

$$s_n(t) = \exp\left(j\pi\left(\frac{2n+1}{M}\right)\right); \quad n \in \left\{0, 1, \ldots, M-1\right\}.$$

This applies when a natural binary ordering is used. Another common mapping is Gray coding, which has the advantage that only one bit changes between adjacent constellation points. This results in better bit error rate performance. For 8-PSK modulation with Gray coding, the mapping between the input and output symbols is shown.

Input	Output
0	0 *(000)*
1	1 *(001)*
2	3 *(011)*
3	2 *(010)*
4	6 *(110)*
5	7 *(111)*
6	5 *(101)*
7	4 *(100)*

The corresponding constellation diagram follows.



When the input signal is composed of bits, the block accepts binary-valued inputs that represent integers. The block collects binary-valued signals into groups of $\log_2(M)$ bits.

M-PSK Phase Recovery

(Removed) Recover carrier phase using M-Power method

Note M-PSK Phase Recovery has been removed. Use the Carrier Synchronizer block instead.

Library

Carrier Phase Recovery sublibrary of Synchronization

Description

The M-PSK Phase Recovery block recovers the carrier phase of the input signal using the M-Power method. This feedforward, non-data-aided, clock-aided method is suitable for systems that use baseband phase shift keying (PSK) modulation. It is also suitable for systems that use baseband quadrature amplitude modulation (QAM), although the results are less accurate than those for comparable PSK systems. The alphabet size for the modulation must be an even integer.

For PSK signals, the **M-ary number** parameter represents the alphabet size. For QAM signals, the **M-ary number** should be 4 regardless of the alphabet size because the 4-power method is the most appropriate for QAM signals.

The M-Power method assumes that the carrier phase is constant over a series of consecutive symbols, and returns an estimate of the carrier phase for the series. The **Observation interval** parameter is the number of symbols for which the carrier phase is assumed constant. This number must be an integer multiple of the input signal's vector length.

Input and Output Signals

This block accepts a scalar or column vector input signal of type `double` or `single`. The input signal represents a baseband signal at the symbol rate, so it must be complex-valued and must contain one sample per symbol.

The outputs are as follows:

- The output port labeled `Sig` gives the result of rotating the input signal counterclockwise, where the amount of rotation equals the carrier phase estimate. The `Sig` output is thus a corrected version of the input signal, and has the same sample time and vector size as the input signal.
- The output port labeled `Ph` outputs the carrier phase estimate, in degrees, for all symbols in the observation interval. The `Ph` output is a scalar signal.

Note Because the block internally computes the argument of a complex number, the carrier phase estimate has an inherent ambiguity. The carrier phase estimate is between -180/M and 180/M degrees and might differ from the actual carrier phase by an integer multiple of 360/M degrees.

Delays and Latency

The block's algorithm requires it to collect symbols during a period of length **Observation interval** before computing a single estimate of the carrier phase. Therefore, each estimate is delayed by

Observation interval symbols and the corrected signal has a latency of **Observation interval** symbols, relative to the input signal.

Parameters

M-ary number

The number of points in the signal constellation of the transmitted PSK signal. This value as an even integer.

Observation interval

The number of symbols for which the carrier phase is assumed constant. The observation interval parameter must be an integer multiple of the input signal vector length.

When this parameter is exactly equal to the vector length of the input signal, then the block always works. When the integer multiple is not equal to `1`, on the **Simulation** tab, select **Model Settings**. Then in the **Solver > Solver selection** section, choose **Type:** `Fixed-step` and clear the **Treat each discrete rate as a separate task** checkbox.

Algorithm

If the symbols occurring during the observation interval are x(1), x(2), x(3),..., x(L), then the resulting carrier phase estimate is

$$\frac{1}{M}\arg\left\{\sum_{k=1}^{L}(x(k))^M\right\}$$

where the arg function returns values between -180 degrees and 180 degrees.

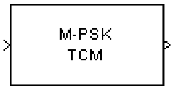
M-PSK TCM Decoder

Decode trellis-coded modulation data, modulated using PSK method



Library

TCM, in Digital Baseband sublibrary of Modulation

Description

The M-PSK TCM Decoder block uses the Viterbi algorithm to decode a trellis-coded modulation (TCM) signal that was previously modulated using a PSK signal constellation.

The **M-ary number** parameter represents the number of points in the signal constellation, which also equals the number of possible output symbols from the convolutional encoder. (That is, $\log_2$(**M-ary number**) is the number of output bit streams from the convolutional encoder.)

The **Trellis structure** and **M-ary number** parameters in this block should match those in the M-PSK TCM Encoder block, to ensure proper decoding.

Input and Output Signals

This block accepts a column vector input signal containing complex numbers. The input signal must be `double` or `single`. The reset port signal must be `double` or `Boolean`. For information about the data types each block port supports, see “Supported Data Types” on page 5-571.

If the convolutional encoder described by the trellis structure represents a rate *k*/*n* code, then the M-PSK TCM Decoder block's output is a binary column vector whose length is *k* times the vector length of the input signal.

Operation Modes

The block has three possible methods for transitioning between successive frames. The **Operation mode** parameter controls which method the block uses. This parameter also affects the range of possible values for the **Traceback depth** parameter, D.

- In `Continuous` mode, the block initializes all state metrics to zero at the beginning of the simulation, waits until it accumulates D symbols, and then uses a sequence of D symbols to compute each of the traceback paths. D can be any positive integer. At the end of each frame, the block saves its internal state metric for use with the next frame.

  If you select **Enable the reset input**, the block displays another input port, labeled `Rst`. This port receives an integer scalar signal. Whenever the value at the `Rst` port is nonzero, the block resets all state metrics to zero and sets the traceback memory to zero.
- In `Truncated` mode, the block treats each frame independently. The traceback path starts at the state with the lowest metric. D must be less than or equal to the vector length of the input.

- In `Terminated` mode, the block treats each frame independently. The traceback path always starts at the all-zeros state. D must be less than or equal to the vector length of the input. If you know that each frame of data typically ends at the all-zeros state, then this mode is an appropriate choice.

Decoding Delay

If you set **Operation mode** to `Continuous`, then this block introduces a decoding delay equal to **Traceback depth***k bits, for a rate k/n convolutional code. The decoding delay is the number of zeros that precede the first decoded bit in the output.

The block incurs no delay for other values of **Operation mode**.

Parameters

Trellis structure

MATLAB structure that contains the trellis description of the convolutional encoder.

M-ary number

The number of points in the signal constellation.

Traceback depth

The number of trellis branches (equivalently, the number of symbols) the block uses in the Viterbi algorithm to construct each traceback path.

Operation mode

The operation mode of the Viterbi decoder. Choices are `Continuous`, `Truncated`, and `Terminated`.

Enable the reset input port

When you check this box, the block has a second input port labeled `Rst`. Providing a nonzero input value to this port causes the block to set its internal memory to the initial state before processing the input data. This option appears only if you set **Operation mode** to `Continuous`.

Output data type

The output type of the block can be specified as a `boolean` or `double`. By default, the block sets this to `double`.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point
Reset	• Double-precision floating point • Boolean

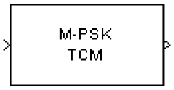
`poly2trellis`

Introduced before R2006a

M-PSK TCM Encoder

Convolutionally encode binary data and modulate using PSK method



Library

TCM, in Digital Baseband sublibrary of Modulation

Description

The M-PSK TCM Encoder block implements trellis-coded modulation (TCM) by convolutionally encoding the binary input signal and mapping the result to a PSK signal constellation.

The **M-ary number** parameter is the number of points in the signal constellation, which also equals the number of possible output symbols from the convolutional encoder. (That is, $\log_2$(**M-ary number**) is equal to n for a rate k/n convolutional code.)

Input Signals and Output Signals

If the convolutional encoder described by the trellis structure represents a rate *k*/*n* code, then the block input signal must be a binary column vector with a length of *L***k* for some positive integer *L*.

This block accepts a binary-valued input signal. The output signal is a complex column vector of length *L*.

Specifying the Encoder

To define the convolutional encoder, use the **Trellis structure** parameter. This parameter is a MATLAB structure whose format is described in “Trellis Description of a Convolutional Code”. You can use this parameter field in two ways:

- If you want to specify the encoder using its constraint length, generator polynomials, and possibly feedback connection polynomials, then use a `poly2trellis` command within the **Trellis structure** field. For example, to use an encoder with a constraint length of 7, code generator polynomials of 171 and 133 (in octal numbers), and a feedback connection of 171 (in octal), set the **Trellis structure** parameter to

  ```
  poly2trellis(7,[171 133],171)
  ```
- If you have a variable in the MATLAB workspace that contains the trellis structure, then enter its name as the **Trellis structure** parameter. This way is faster because it causes Simulink software to spend less time updating the diagram at the beginning of each simulation, compared to the usage in the previous bulleted item.

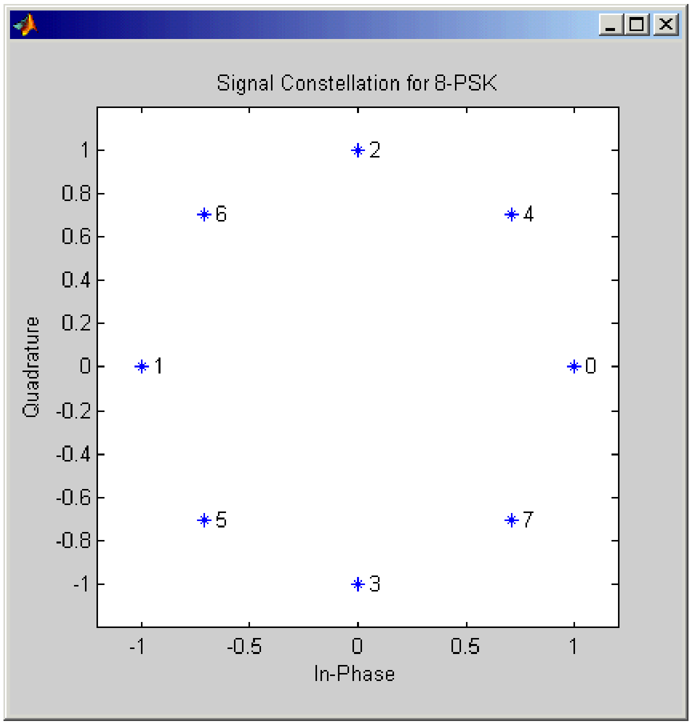
The encoder registers begin in the all-zeros state. You can configure the encoder so that it resets its registers to the all-zeros state during the course of the simulation. To do this, set the `Operation`

mode to **Reset on nonzero input via port**. The block then opens a second input port, labeled Rst. The signal at the Rst port is a scalar signal. When it is nonzero, the encoder resets before processing the data at the first input port.

Signal Constellations

The trellis-coded modulation technique partitions the constellation into subsets called cosets, so as to maximize the minimum distance between pairs of points in each coset. This block internally forms a valid partition based on the value you choose for the **M-ary number** parameter.

The figure below shows the labeled set-partitioned signal constellation that the block uses when **M-ary number** is 8. For constellations of other sizes, see [1].



Coding Gains

Coding gains of 3 to 6 decibels, relative to the uncoded case can be achieved in the presence of AWGN with multiphase trellis codes [3].

Parameters

Trellis structure

MATLAB structure that contains the trellis description of the convolutional encoder.

Operation mode

In Continuous mode (default setting), the block retains the encoder states at the end of each frame, for use with the next frame.

In Truncated (reset every frame) mode, the block treats each frame independently. I.e., the encoder states are reset to all-zeros state at the start of each frame.

In `Terminate trellis by appending bits` mode, the block treats each frame independently. For each input frame, extra bits are used to set the encoder states to all-zeros state at the end of the frame. The output length is given by $y = n \cdot (x + s)/k$, where x is the number of input bits, and s = constraint length − 1 (or, in the case of multiple constraint lengths, s =`sum(ConstraintLength(i)-1)`). The block supports this mode for column vector input signals.

In `Reset on nonzero input via port` mode, the block has an additional input port, labeled `Rst`. When the `Rst` input is nonzero, the encoder resets to the all-zeros state.

M-ary number

The number of points in the signal constellation.

Output data type

The output type of the block can be specified as a `single` or `double`. By default, the block sets this to `double`.

MSK Demodulator Baseband

Demodulate differentially encoded MSK-modulated data

Library

CPM, in Digital Baseband sublibrary of Modulation

Description

The MSK Demodulator Baseband block demodulates a signal that was modulated using the differentially encoded minimum shift keying method. The block expects the input signal to be a baseband representation of a coherent modulated signal with no precoding. The **Phase offset** parameter represents the initial phase of the modulated waveform.

Pulse Shape Filtering

Differentially encoded minimum shift keying modulation uses pulse shaping to smooth the phase transitions of the modulated signal. The function $q(t)$ is the phase response obtained from the frequency pulse, $g(t)$, through this relation: $q(t) = \int_{-\infty}^{t} g(t)dt$

The specified frequency pulse shape corresponds to this rectangular pulse shape expression, $g(t)$.

Pulse Shape	Expression
`Rectangular`	$g(t) = \begin{cases} \frac{1}{2LT}, & 0 \le t \le LT \\ 0 & \text{otherwise} \end{cases}$

- L_{main} is the main lobe pulse duration in symbol intervals.
- The duration of the pulse, LT, is the pulse length in symbol intervals.

Integer-Valued Signals and Binary-Valued Signals

This block accepts a scalar-valued or column vector input signal with a data type of `single` or `double`. If you set the **Output type** parameter to `Integer`, then the block produces values of 1 and -1. If you set the **Output type** parameter to `Bit`, then the block produces values of 0 and 1.

Single-Rate Processing

In single-rate processing mode, the input and output signals have the same port sample time. The block implicitly implements the rate change by making a size change at the output when compared to the input. The input width must be an integer multiple of the **Samples per symbol** parameter value, and the input can be a column vector.

- When you set **Output type** to `Bit`, the output width is *K* times the number of input symbols.
- When you set **Output type** to `Integer`, the output width is the number of input symbols.

Multirate Processing

In multirate processing mode, the input and output signals have different port sample times. The input must be a scalar. The output symbol time is the product of the input sample time and the **Samples per symbol** parameter value.

- When you set **Output type** to `Bit`, the output width equals the number of bits per symbol.
- When you set **Output type** to `Integer`, the output is a scalar.

Traceback Depth and Output Delays

Internally, this block creates a trellis description of the modulation scheme and uses the Viterbi algorithm. The **Traceback depth** parameter, D, in this block is the number of trellis branches used to construct each traceback path. D influences the output delay, which is the number of zero symbols that precede the first meaningful demodulated value in the output.

- When you set the **Rate options** parameter to `Allow multirate processing`, and the model uses a variable-step solver or a fixed-step solver with the **Tasking Mode** parameter set to `SingleTasking`, then the delay consists of D+1 zero symbols.
- When you set the **Rate options** parameter to `Enforce single-rate processing`, then the delay consists of D zero symbols.

The optimal **Traceback depth** parameter value is dependent on minimum squared Euclidean distance calculations. Alternatively, a typical value, dependent on the number of states, can be chosen using the “five-times-the-constraint-length” rule, which corresponds to 5×log2(*numStates*). The number of states is determined by the following equation:

$$numStates = \begin{Bmatrix} p \cdot 2^{(L-1)}, \ for\, even\, m \\ 2p \cdot 2^{(L-1)}, \ for\, odd\, m \end{Bmatrix}$$

where:

- *h* = m/p is the modulation index proper rational form
  - *m* = numerator of modulation index
  - *p* = denominator of modulation index
- *L* is the Pulse length

Parameters

Output type

Determines whether the output consists of bipolar or binary values.

Phase offset (rad)

The initial phase of the modulated waveform.

Samples per symbol

The number of input samples that represent each modulated symbol, which must be a positive integer. For more information, see “Upsample Signals and Rate Changes”.

Rate options

Select the rate processing method for the block.

- `Enforce single-rate processing` — When you select this option, the input and output signals have the same port sample time. The block implements the rate change by making a size change at the output when compared to the input. The output width is the number of symbols (which is given by dividing the input length by the **Samples per symbol** parameter value when the **Output type** parameter is set to `Integer`).
- `Allow multirate processing` — When you select this option, the input and output signals have different port sample times. The output period is the same as the symbol period and equals the product of the input period and the **Samples per symbol** parameter value.

For more information, see Single-Rate Processing and Multirate Processing in the Description section of this page.

Traceback depth

The number of trellis branches that the MSK Demodulator Baseband block uses to construct each traceback path.

Output data type

The output data type can be `boolean`, `int8`, `int16`, `int32`, or `double`.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point
Output	• Double-precision floating point • Boolean (When **Output type** set to `Bit`) • 8-, 16-, and 32-bit signed integers (When **Output type** set to `Integer`)

MSK Modulator Baseband

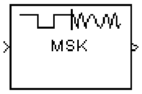
Modulate using differentially encoded minimum shift keying method



Library

CPM, in Digital Baseband sublibrary of Modulation

Description

The MSK Modulator Baseband block modulates using the differentially encoded minimum shift keying method. The output is a baseband representation of the modulated signal.

This block accepts a scalar-valued or column vector input signal. For a column vector input signal, the width of the output equals the product of the number of symbols and the value for the **Samples per symbol** parameter.

Pulse Shape Filtering

Differentially encoded minimum shift keying modulation uses pulse shaping to smooth the phase transitions of the modulated signal. The function *q*(*t*) is the phase response obtained from the frequency pulse, *g*(*t*), through this relation: $q(t) = \int_{-\infty}^{t} g(t)dt$

The specified frequency pulse shape corresponds to this rectangular pulse shape expression, *g*(*t*).

Pulse Shape	Expression
`Rectangular`	$g(t) = \begin{cases} \frac{1}{2LT}, & 0 \le t \le LT \\ 0 & \text{otherwise} \end{cases}$

- L_{main} is the main lobe pulse duration in symbol intervals.
- The duration of the pulse, *LT*, is the pulse length in symbol intervals.

Integer-Valued Signals and Binary-Valued Signals

When you set the **Input type** parameter to `Integer`, then the block accepts values of 1 and -1.

When you set the **Input type** parameter to `Bit`, then the block accepts values of 0 and 1.

For information about the data types each block port supports, see the “Supported Data Types” on page 5-582 table on this page.

Single-Rate Processing

In single-rate processing mode, the input and output signals have the same port sample time. The block implicitly implements the rate change by making a size change at the output when compared to the input. In this mode, the input to the block can be multiple symbols.

- When you set **Input type** to `Integer`, the input can be a column vector, the length of which is the number of input symbols.
- When you set **Input type** to `Bit`, the input width must be an integer multiple of *K*, the number of bits per symbol.

The output width equals the product of the number of input symbols and the **Samples per symbol** parameter value.

Multirate Processing

In multirate processing mode, the input and output signals have different port sample times. In this mode, the input to the block must be one symbol.

- When you set **Input type** to `Integer`, the input must be a scalar.
- When you set **Input type** to `Bit`, the input width must equal the number of bits per symbol.

The output sample time equals the symbol period divided by the **Samples per symbol** parameter value.

Parameters

Input type

Indicates whether the input consists of bipolar or binary values.

Phase offset (rad)

The initial phase of the output waveform, measured in radians.

Samples per symbol

The number of output samples that the block produces for each integer or binary word in the input, which must be a positive integer. For all non-binary schemes, as defined by the pulse shapes, this value must be greater than 1.

For more information, see “Upsample Signals and Rate Changes”.

Rate options

Select the rate processing option for the block.

- `Enforce single-rate processing` — When you select this option, the input and output signals have the same port sample time. The block implements the rate change by making a size change at the output when compared to the input. The output width equals the product of the number of symbols and the **Samples per symbol** parameter value.
- `Allow multirate processing` — When you select this option, the input and output signals have different port sample times. The output sample time equals the symbol period divided by the **Samples per symbol** parameter value.

Output data type

Specify the block output data type as `double` and `single`. By default, the block sets this to `double`.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Boolean (when **Input type** set to `Bit`) • 8-, 16-, and 32-bit signed integers (when **Input type** set to `Integer`)
Output	• Double-precision floating point • Single-precision floating point

MSK-Type Signal Timing Recovery

Recover symbol timing phase using fourth-order nonlinearity method

Library

Timing Phase Recovery sublibrary of Synchronization

Description

The MSK-Type Signal Timing Recovery block recovers the symbol timing phase of the input signal using a fourth-order nonlinearity method. This block implements a general non-data-aided feedback method that is independent of carrier phase recovery but requires prior compensation for the carrier frequency offset. This block is suitable for systems that use baseband minimum shift keying (MSK) modulation or Gaussian minimum shift keying (GMSK) modulation.

Inputs

By default, the block has one input port. The input signal could be (but is not required to be) the output of a receive filter that is matched to the transmitting pulse shape, or the output of a lowpass filter that limits the amount of noise entering this block.

This block accepts a scalar-valued or column vector input signal. The input uses *N* samples to represent each symbol, where $N > 1$ is the **Samples per symbol** parameter.

- For a column vector input signal, the block operates in single-rate processing mode. In this mode, the output signal inherits its sample rate from the input signal. The input length must be a multiple of *N*.
- For a scalar input signal, the block operates in multirate processing mode. In this mode, the input and output signals have different sample rates. The output sample rate equals *N* multiplied by the input sample rate.
- This block accepts input signals of type Double or Single

If you set the **Reset** parameter to `On nonzero input via port`, then the block has a second input port, labeled `Rst`. The `Rst` input determines when the timing estimation process restarts, and must be a scalar.

- If the input signal is a scalar value, the sample time of the `Rst` input equals the symbol period
- If the input signal is a column vector, the sample time of the `Rst` input equals the input port sample time
- This block accepts reset signals of type Double or Boolean

Outputs

The block has two output ports, labeled `Sym` and `Ph`:

- The `Sym` output is the result of applying the estimated phase correction to the input signal. This output is the signal value for each symbol, which can be used for decision purposes. The values in the `Sym` output occur at the symbol rate:
  - For a column vector input signal of length *N***R*, the `Sym` output is a column vector of length *R* having the same sample rate as the input signal.
  - For a scalar input signal, the sample rate of the `Sym` output equals *N* multiplied by the input sample rate.
- The `Ph` output gives the phase estimate for each symbol in the input.

  The `Ph` output contains nonnegative real numbers less than *N*. Noninteger values for the phase estimate correspond to interpolated values that lie between two values of the input signal. The sample time of the `Ph` output is the same as that of the `Sym` output.

  Note If the `Ph` output is very close to either zero or **Samples per symbol**, or if the actual timing phase offset in your input signal is very close to zero, then the block's accuracy might be compromised by small amounts of noise or jitter. The block works well when the timing phase offset is significant rather than very close to zero.
- The output signal inherits its data type from the input signal.

Delays

When the input signal is a vector, this block incurs a delay of two symbols. When the input signal is a scalar, this block incurs a delay of three symbols.

Parameters

Modulation type

The type of modulation in the system. Choices are `MSK` and `GMSK`.

Samples per symbol

The number of samples, N, that represent each symbol in the input signal. This must be greater than 1.

Error update gain

A positive real number representing the step size that the block uses for updating successive phase estimates. Typically, this number is less than 1/N, which corresponds to a slowly varying phase.

This parameter is tunable in normal mode, Accelerator mode and Rapid Accelerator mode. If you use the Simulink Coder rapid simulation (RSIM) target to build an RSIM executable, then you can tune the parameter without recompiling the model. For more information, see Tunable Parameters (Simulink).

Reset

Determines whether and under what circumstances the block restarts the phase estimation process. Choices are `None`, `Every frame`, and `On nonzero input via port`. The last option causes the block to have a second input port, labeled `Rst`.

Algorithm

This block's algorithm extracts timing information by passing the sampled baseband signal through a fourth-order nonlinearity followed by a digital differentiator whose output is smoothed to yield an error signal. The algorithm then uses the error signal to make the sampling adjustments.

More specifically, this block uses a timing error detector whose result for the kth symbol is e(k), given in [2] by

$$
\begin{aligned}
&e(k) = (^{-}\mathrm{Re}\left\{r^2(kT - T_s + d_{k-1})r^{*2}((k-1)T - T_s + d_{k-2})\right\} \\
&-(^{-}\mathrm{Re}\left\{r^2(kT + T_s + d_{k-1})r^{*2}((k-1)T + T_s + d_{k-1})\right\}
\end{aligned}
$$

where

- r is the block's input signal
- T is the symbol period
- T_s is the sampling period
- * means complex conjugate
- d_k is the phase estimate for the kth symbol
- D is 1 for MSK and 2 for Gaussian MSK modulation

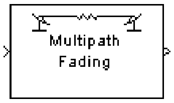
Multipath Rayleigh Fading Channel

(To be removed) Simulate multipath Rayleigh fading propagation channel

Note Multipath Rayleigh Fading Channel will be removed in a future release. Use SISO Fading Channel instead.



Multipath Rayleigh Fading Channel

Library

Channels

Description

The Multipath Rayleigh Fading Channel block implements a baseband simulation of a multipath Rayleigh fading propagation channel. You can use this block to model mobile wireless communication systems. For details about fading channels, see the references listed below.

This block accepts a scalar value or column vector input signal. The block inherits sample time from the input signal. The input signal must have a discrete sample time greater than 0.

Relative motion between the transmitter and receiver causes Doppler shifts in the signal frequency. You can specify the Doppler spectrum of the Rayleigh process using the **Doppler spectrum type** parameter. For channels with multiple paths, you can assign each path a different Doppler spectrum, by entering a vector of `doppler` objects in the **Doppler spectrum** field.

Because a multipath channel reflects signals at multiple places, a transmitted signal travels to the receiver along several paths, each of which may have differing lengths and associated time delays. In the block's parameter dialog box, the **Discrete path delay vector** specifies the time delay for each path. If you do not check **Normalize gain vector to 0 dB overall gain**, then the **Average path gain vector** specifies the gain for each path. When you check the box, the block uses a multiple of **Average path gain vector** instead of the **Average path gain vector** itself, choosing the scaling factor so that the channel's effective gain, considering all paths, is 0 dB.

The number of paths is implicitly indicated via the number of elements in **Discrete path delay vector** or **Average path gain vector**. If both of these parameters are vectors, then they must have the same length; if exactly one of these parameters contains a scalar value, then the block expands it into a vector whose size matches that of the other vector parameter.

The block multiplies the input signal by samples of a Rayleigh-distributed complex random process. The scalar **Initial seed** parameter seeds the random number generator and the block generates random numbers using the Ziggurat method.

Double-clicking this block during simulation or selecting **Open channel visualization at start of simulation** plots the channel characteristics using the channel visualization tool. For more information, see “Channel Visualization”.

Parameters

Maximum Doppler shift (Hz)

A positive scalar value that indicates the maximum Doppler shift.

Doppler spectrum type

Specifies the Doppler spectrum of the Rayleigh process.

This parameter defaults to `Jakes` Doppler spectrum. Alternatively, you can also choose any of the following types:

- Flat on page 2-290
- Gaussian on page 2-292
- Rounded on page 2-300
- Restricted Jakes on page 2-297
- Asymmetrical Jakes on page 2-282
- Bi-Gaussian on page 2-287
- Bell on page 2-285

For all Doppler spectrum types except `Jakes` and `Flat`, you can choose one or more parameters to control the shape of the spectrum.

You can also select `Specify as dialog parameter` for the **Doppler spectrum type**. Specify the Doppler spectrum by entering an object in the **Doppler spectrum** field. See the `doppler` function reference for details on how to construct Doppler objects, and also for the meaning of the parameters associated with the various Doppler spectrum types.

Discrete path delay vector (s)

A vector that specifies the propagation delay for each path.

Average path gain vector (dB)

A vector that specifies the gain for each path.

Normalize gain vector to 0 dB overall gain

Checking this box causes the block to scale the **Gain vector** parameter so that the channel's effective gain (considering all paths) is 0 dB.

Initial seed

The scalar seed for the Gaussian noise generator.

Open channel visualization at start of simulation

Select this check box to open the channel visualization tool when a simulation begins.

Complex path gains port

Select this check box to create a port that outputs the values of the complex path gains for each path. In this *N*-by-*M* multichannel output, *N* represents the number of samples the input signal contains and *M* represents the number of discrete paths (number of delays).

Channel filter delay port

Select this check box to create a port that outputs the value of the delay (in samples) that results from the filtering operation of this block. This delay is zero if only one path is simulated, but can be greater than zero if more than one path is present. See “Methodology for Simulating Multipath Fading Channels” for a definition of this delay, where it is denoted as N_1.

Algorithm

This implementation is based on the direct-form simulator described in Reference [1]. A detailed explanation of the implementation, including a review of the different Doppler spectra, can be found in [4].

Some wireless applications prefer to specify Doppler shifts in terms of the speed of the mobile. If the mobile moves at speed *v* making an angle of θ with the direction of wave motion, then the Doppler shift is

$f_\mathrm{d} = (vf/c)\cos\theta$

where *f* is the transmission carrier frequency and *c* is the speed of light. The Doppler frequency represents the maximum Doppler shift arising from motion of the mobile.

Example

Generating Ideal Theoretical BER Results for a Rayleigh Fading Channel

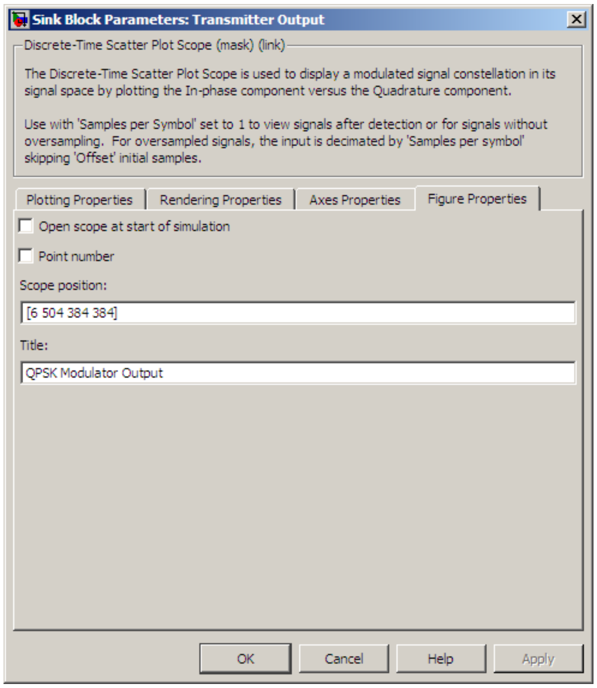
This example illustrates how to generate ideal theoretical BER results for a flat Rayleigh fading channel. The model reproduces known theoretical results and shows the correct BER performance for a flat Rayleigh fading channel. In this example, you will run the model and compare the simulation results to the BERTool theoretical results for verification purposes. Note that the EbNo value for the model's AWGN block is 5 dB. You can change the noise power by double-clicking the AWGN block and entering another numeric value in the EbNo parameter.

Opening the Model

You can open the model by clicking here in the MATLAB Help browser. Alternatively, you can type `doc_qpsk_rayleigh_derotated` at the MATLAB command line.

Running the Model and Comparing Results

1. To run the example, select **Run** in the **Simulate** of the **Simulation**, **Debug**, or **Modeling** tab.
2. After the model collects more than 5000 errors, click the stop button.
3. Close the three scopes.
4. In the Simulink model window, double-click the Transmitter Output block. In the mask window, click the **Figure Properties** tab, uncheck **Open scope at start of Simulation**, then click **OK**.



Sink Block Parameters: Transmitter Output

Discrete-Time Scatter Plot Scope (mask) (link)

The Discrete-Time Scatter Plot Scope is used to display a modulated signal constellation in its signal space by plotting the In-phase component versus the Quadrature component.

Use with 'Samples per Symbol' set to 1 to view signals after detection or for signals without oversampling. For oversampled signals, the input is decimated by 'Samples per symbol' skipping 'Offset' initial samples.

□ Open scope at start of simulation

□ Point number

Scope position: [6 504 384 384]

Title: QPSK Modulator Output

5 In the Simulink model window, double-click the Rayleigh Channel Output block. In the mask window, click the **Figure Properties** tab, uncheck **Open scope at start of Simulation**, then click **OK**.

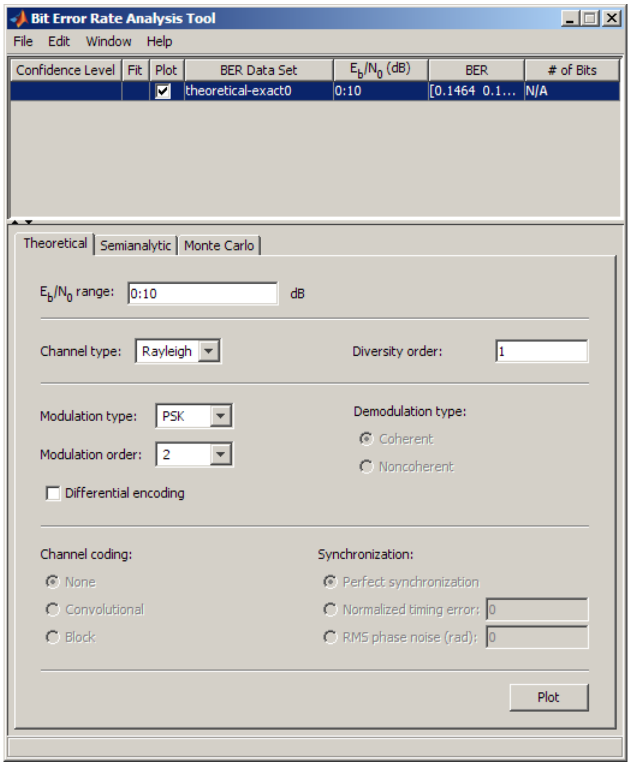
6 In the Simulink model window, double-click the Noisy Rayleigh Channel Output block. In the mask window, click the **Figure Properties** tab, uncheck **Open scope at start of Simulation**, then click **OK**.

7 In the Simulink model window, double-click the Error Rate Calculation block, check **Stop simulation**, enter `5000` for **Target number of error**, then click **OK**.

8 Click the play button to rerun the example.

9 Open BERTool by typing `bertool` at the MATLAB command line.

10 In BERTool, click the **Theoretical** tab and make the following selections:



Confidence Level	Fit	Plot	BER Data Set	E_b/N_0 (dB)	BER	# of Bits
		☑	theoretical-exact0	0:10	[0.1464 0.1...	N/A

E_b/N_0 range: 0:10 dB

Channel type: Rayleigh

Diversity order: 1

Modulation type: PSK

Modulation order: 2

□ Differential encoding

Demodulation type:
● Coherent
○ Noncoherent

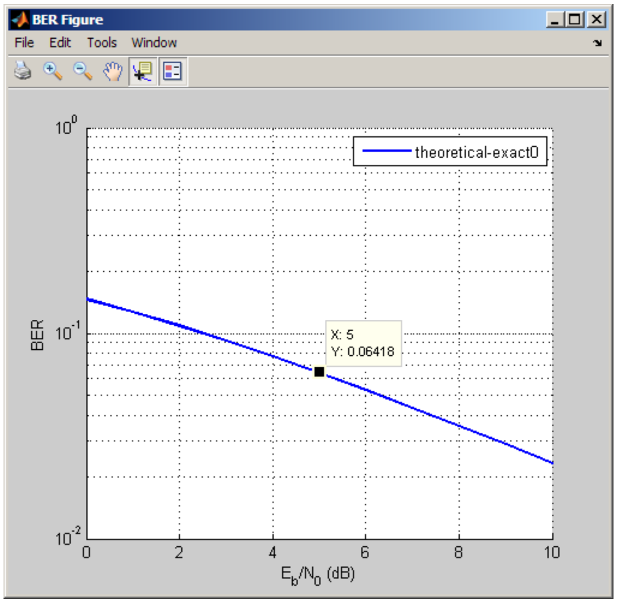
Channel coding:
● None
○ Convolutional
○ Block

Synchronization:
● Perfect synchronization
○ Normalized timing error: 0
○ RMS phase noise (rad): 0

- For **Eb/No range** enter `0:10`
- For **Channel type**, select `Rayleigh`
- For **Diversity Order** enter 1
- For **Modulation Type**, select PSK
- For **Modulation order**, select 4

11 Click **Plot**.

12 Since the Simulink model uses an EbNo value of 5 dB, verify the probability of error on the BERTool curve at 5 dB. The two values should be approximately equal.



Click the Data Cursor button (second from right) and click on the BERTool curve at 5dB.

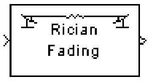
Multipath Rician Fading Channel

(To be removed) Simulate multipath Rician fading propagation channel

Note Multipath Rician Fading Channel will be removed in a future release. Use SISO Fading Channel instead.



Library

Channels

Description

The Multipath Rician Fading Channel block implements a baseband simulation of a multipath Rician fading propagation channel. You can use this block to model mobile wireless communication systems when the transmitted signal can travel to the receiver along a dominant line-of-sight or direct path. For more details, see “Fading Channels”.

This block accepts a scalar value or column vector input signal. The block inherits sample time from the input signal. The input signal must have a discrete sample time greater than 0.

Relative motion between the transmitter and receiver causes Doppler shifts in the signal frequency. You can specify the Doppler spectrum of the Rician process using the **Doppler spectrum type** pop-up menu. For channels with multiple paths, you can assign each path a different Doppler spectrum, by entering a vector of doppler objects in the **Doppler spectrum** field.

Because a multipath channel reflects signals at multiple places, a transmitted signal travels to the receiver along several paths, each of which may have differing lengths and associated time delays. In the block's parameter dialog box, the **Discrete path delay vector** specifies the time delay for each path. If you do not check the **Normalize gain vector to 0 dB overall gain** box, then the **Average path gain vector** specifies the gain for each path. When you check the box, the block uses a multiple of **Average path gain vector** instead of the **Average path gain vector** itself, choosing the scaling factor so that the channel's effective gain considering all paths is 0 dB.

The number of paths is implicitly indicated via the number of elements in **Discrete path delay vector** or **Average path gain vector**. If both of these parameters are vectors, they must have the same length; if exactly one of these parameters contains a scalar value, the block expands it into a vector whose size matches that of the other vector parameter.

Fading causes the signal to become diffuse. The **K-factor** parameter, which is part of the statistical description of the Rician distribution, represents the ratio between the power in the line-of-sight component and the power in the diffuse component. The ratio is expressed linearly, not in decibels. While the Average path gain vector parameter controls the overall gain through the channel, the **K-factor** parameter controls the gain's partition into line-of-sight and diffuse components.

You can specify the **K-factor** parameter as a scalar or a vector. If the **K-factor** parameter is a scalar, then the first discrete path of the channel is a Rician fading process (it contains a line-of-sight component) with the specified **K-factor**, while the remaining discrete paths indicate independent Rayleigh fading processes (with no line-of-sight component). If the **K-factor** parameter is a vector of the same size as **Discrete path delay vector**, then each discrete path is a Rician fading process with a **K-factor** given by the corresponding element of the vector. You can attribute the line-of-sight component a Doppler shift, through the **Doppler shift(s) of line-of-sight component(s)** parameter, and an initial phase, through the **Initial phase(s) of line-of-sight component(s)**. The **Doppler shift(s) of line-of-sight component(s)** and **Initial phase(s) of line-of-sight component(s)** parameters must be of the same size as the K-factor parameter.

The block multiplies the input signal by samples of a Rician-distributed complex random process. The scalar **Initial seed** parameter seeds the random number generator and the block generates random numbers using the Ziggurat method.

Double-clicking this block during simulation or selecting the block dialog's check box labeled **Open channel visualization at start of simulation** plots the channel characteristics using the channel visualization tool. For more information, see “Channel Visualization”.

Parameters

K-factor

The ratio of power in the line-of-sight component to the power in the diffuse component. The ratio is expressed linearly, not in decibels. If **K-factor** is a scalar value, then the first discrete path is a Rician fading process (it contains a line-of-sight component) with the specified K-factor, while the remaining discrete paths are independent Rayleigh fading processes (with no line-of-sight component). If **K-factor** is a vector of the same size as **Discrete path delay vector**, then each discrete path is a Rician fading process with a **K-factor** given by the corresponding element of the vector.

Doppler shift(s) of line-of-sight components(s) (Hz)

The Doppler shift of the line-of-sight component. It must be a scalar (if **K-factor** is a scalar) or a vector of the same size as **K-factor**. If this parameter contains a scalar value, then the line-of-sight component of the first discrete path has the specified Doppler shift, while the remaining discrete paths become independent Rayleigh fading processes. If the parameter contains a vector, then the line-of-sight component of each discrete path has a Doppler shift given by the corresponding element of the vector.

Initial phase(s) of line-of-sight component(s) (rad)

The initial phase of the line-of-sight component. It must be either a scalar (if **K-factor** is a scalar value) or a vector of the same size as **K-factor**.

Maximum diffuse Doppler shift (Hz)

A positive scalar value that indicates the maximum diffuse Doppler shift.

Doppler spectrum type

Specifies the Doppler spectrum of the Rician process.

This parameter defaults to `Jakes` Doppler spectrum. Alternately, you can choose any of the following types:

- Flat on page 2-290
- Gaussian on page 2-292

- Rounded on page 2-300
- Restricted Jakes on page 2-297
- Asymmetrical Jakes on page 2-282
- Bi-Gaussian on page 2-287
- Bell on page 2-285

For all Doppler spectrum types except `Jakes` and `Flat`, You can use one or more parameters to control the shape of the spectrum.

You can also select `Specify as dialog parameter` for the **Doppler spectrum type**. Specify the Doppler spectrum by entering an object in the **Doppler spectrum** field. See the `doppler` function reference for details on how to construct doppler objects, and for the meaning of the parameters associated with the various Doppler spectrum types.

Discrete delay vector(s)

A vector that specifies the propagation delay for each path.

Average path gain vector (dB)

A vector that specifies the gain for each path.

Initial seed

The scalar seed for the Gaussian noise generator.

Open channel visualization at start of simulation

Select this check box to open the channel visualization tool when a simulation begins. This block supports channel visualization for a column vector input signal.

Complex path gains port

Select this check box to create a port that outputs the values of the complex path gains for each path. In this N-by-M multichannel output, N represents the number of samples the input contains and M represents the number of discrete paths (number of delays).

Channel filter delay port

Select this check box to create a port that outputs the value of the delay (in samples) that results from the filtering operation of this block. This delay is zero if only one path is simulated, but can be greater than zero if more than one path is present. See “Methodology for Simulating Multipath Fading Channels” for a definition of this delay, where it is denoted as N_1.

Algorithm

This implementation is based on the direct form simulator described in Reference [1]. A detailed explanation of the implementation, including a review of the different Doppler spectra, can be found in [4].

Some wireless applications prefer to specify Doppler shifts in terms of the speed of the mobile. If the mobile moves at speed v making an angle of θ with the direction of wave motion, the Doppler shift is

$$f_d = (vf/c)\cos\theta$$

where f is the transmission carrier frequency and c is the speed of light. The Doppler frequency is the maximum Doppler shift arising from the motion of the mobile.

Mu-Law Compressor

Implement µ-law compressor for source coding

Library

Source Coding

Description

The Mu-Law Compressor block implements a µ-law compressor for the input signal. The formula for the µ-law compressor is

$$y = \frac{V\log(1 + \mu|x|/V)}{\log(1 + \mu)}\mathrm{sgn}(x)$$

where µ is the µ-law parameter of the compressor, V is the peak magnitude of x, log is the natural logarithm, and sgn is the signum function (`sign` in MATLAB).

The input can have any shape or frame status. This block processes each vector element independently.

Parameters

mu value

The µ-law parameter of the compressor.

Peak signal magnitude

The peak value of the input signal. This is also the peak value of the output.

Supported Data Type

Mu-Law Expander

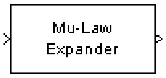
Implement µ-law expander for source coding



Library

Source Coding

Description

The Mu-Law Expander block recovers data that the Mu-Law Compressor block compressed. The formula for the µ-law expander, shown below, is the inverse of the compressor function.

$$x = \frac{V}{\mu}\left(e^{|y|\log(1 + \mu)/V} - 1\right)\mathrm{sgn}(y)$$

The input can have any shape or frame status. This block processes each vector element independently.

Parameters

mu value

The µ-law parameter of the compressor.

Peak signal magnitude

The peak value of the input signal. This is also the peak value of the output.

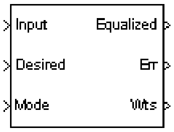
Normalized LMS Decision Feedback Equalizer

(To be removed) Equalize using decision feedback equalizer that updates weights with normalized LMS algorithm

Note will be removed in a future release. Consider using Decision Feedback Equalizer instead.



Library

Equalizer Block

Description

The Normalized LMS Decision Feedback Equalizer block uses a decision feedback equalizer and the normalized LMS algorithm to equalize a linearly modulated baseband signal through a dispersive channel. During the simulation, the block uses the normalized LMS algorithm to update the weights, once per symbol. When you set the **Number of samples per symbol** parameter to `1`, then the block implements a symbol-spaced (i.e. T-spaced) equalizer. When you set the **Number of samples per symbol** parameter to a value greater than 1, , the weights are updated once every N^{th} sample, for a *T*/*N*-spaced equalizer.

Input and Output Signals

The `Input` port accepts a column vector input signal. The `Desired` port receives a training sequence with a length that is less than or equal to the number of symbols in the `Input` signal. Valid training symbols are those symbols listed in the **Signal constellation** vector.

Set the **Reference tap** parameter so it is greater than zero and less than the value for the **Number of forward taps** parameter.

The port labeled `Equalized` outputs the result of the equalization process.

You can configure the block to have one or more of these extra ports:

- `Mode` input.
- `Err` output for the error signal, which is the difference between the `Equalized` output and the reference signal. The reference signal consists of training symbols in training mode, and detected symbols otherwise.
- `Weights` output.

Decision-Directed Mode and Training Mode

To learn the conditions under which the equalizer operates in training or decision-directed mode, see “Equalization”.

Equalizer Delay

For proper equalization, you should set the **Reference tap** parameter so that it exceeds the delay, in symbols, between the transmitter's modulator output and the equalizer input. When this condition is satisfied, the total delay, in symbols, between the modulator output and the equalizer *output* is equal to

1+(**Reference tap**-1)/(**Number of samples per symbol**)

Because the channel delay is typically unknown, a common practice is to set the reference tap to the center tap of the forward filter.

Parameters

Number of forward taps

The number of taps in the forward filter of the decision feedback equalizer.

Number of feedback taps

The number of taps in the feedback filter of the decision feedback equalizer.

Number of samples per symbol

The number of input samples for each symbol.

Signal constellation

A vector of complex numbers that specifies the constellation for the modulation.

Reference tap

A positive integer less than or equal to the number of forward taps in the equalizer.

Step size

The step size of the normalized LMS algorithm.

Leakage factor

The leakage factor of the normalized LMS algorithm, a number between 0 and 1. A value of 1 corresponds to a conventional weight update algorithm, and a value of 0 corresponds to a memoryless update algorithm.

Bias

The bias parameter of the normalized LMS algorithm, a nonnegative real number. This parameter is used to overcome difficulties when the algorithm's input signal is small.

Initial weights

A vector that concatenates the initial weights for the forward and feedback taps.

Mode input port

If you select this check box, the block has an input port that enables you to toggle between training and decision-directed mode. For training, the mode input must be 1, for decision directed, the mode should be 0. The equalizer will train for the length of the Desired signal. If the mode input is not present, the equalizer will train at the beginning of every frame for the length of the Desired signal.

Output error

If you select this check box, the block outputs the error signal, which is the difference between the equalized signal and the reference signal.

Output weights

If you select this check box, the block outputs the current forward and feedback weights, concatenated into one vector.

Compatibility Considerations

Normalized LMS Decision Feedback Equalizer will be removed

Warns starting in R2020a

- Normalized LMS Decision Feedback Equalizer will be removed in a future release. Consider using Decision Feedback Equalizer instead with the adaptive algorithm set to LMS.
- The **Enable training control input** parameter of the Decision Feedback Equalizer block is equivalent to the **Mode input port** parameter of the Normalized LMS Decision Feedback Equalizer block.
- The Decision Feedback Equalizer block does not have a leakage factor parameter. This is equivalent to setting the **Leakage factor** parameter to 1 in the Normalized LMS Decision Feedback Equalizer block.

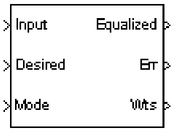
Normalized LMS Linear Equalizer

(To be removed) Equalize using linear equalizer that updates weights with normalized LMS algorithm

Note will be removed in a future release. Consider using Linear Equalizer instead.



Library

Equalizers

Description

The Normalized LMS Linear Equalizer block uses a linear equalizer and the normalized LMS algorithm to equalize a linearly modulated baseband signal through a dispersive channel. During the simulation, the block uses the normalized LMS algorithm to update the weights, once per symbol. When you set the **Number of samples per symbol** parameter to `1`, the block implements a symbol-spaced (i.e. T-spaced) equalizer and updates the filter weights once for each symbol. When you set the **Number of samples per symbol** parameter to a value greater than `1`, the weights are updated once every N^{th} sample, for a *T*/*N*-spaced equalizer.

Input and Output Signals

The `Input` port accepts a column vector input signal. The `Desired` port receives a training sequence with a length that is less than or equal to the number of symbols in the `Input` signal. Valid training symbols are those symbols listed in the **Signal constellation** vector.

Set the **Reference tap** parameter so it is greater than zero and less than the value for the **Number of taps** parameter.

The port labeled `Equalized` outputs the result of the equalization process.

You can configure the block to have one or more of these extra ports:

- `Mode` input.
- `Err` output for the error signal, which is the difference between the `Equalized` output and the reference signal. The reference signal consists of training symbols in training mode, and detected symbols otherwise.
- `Weights` output.

Decision-Directed Mode and Training Mode

To learn the conditions under which the equalizer operates in training or decision-directed mode, see “Equalization”.

Equalizer Delay

For proper equalization, you should set the **Reference tap** parameter so that it exceeds the delay, in symbols, between the transmitter's modulator output and the equalizer input. When this condition is satisfied, the total delay, in symbols, between the modulator output and the equalizer *output* is equal to

1+(**Reference tap**-1)/(**Number of samples per symbol**)

Because the channel delay is typically unknown, a common practice is to set the reference tap to the center tap.

Parameters

Number of taps

The number of taps in the filter of the linear equalizer.

Number of samples per symbol

The number of input samples for each symbol.

Signal constellation

A vector of complex numbers that specifies the constellation for the modulation.

Reference tap

A positive integer less than or equal to the number of taps in the equalizer.

Step size

The step size of the normalized LMS algorithm.

Leakage factor

The leakage factor of the normalized LMS algorithm, a number between 0 and 1. A value of 1 corresponds to a conventional weight update algorithm, and a value of 0 corresponds to a memoryless update algorithm.

Bias

The bias parameter of the normalized LMS algorithm, a nonnegative real number. This parameter is used to overcome difficulties when the algorithm's input signal is small.

Initial weights

A vector that lists the initial weights for the taps.

Mode input port

When you select this check box, the block has an input port that allows you to toggle between training and decision-directed mode. For training, the mode input must be 1, for decision directed, the mode should be 0. For every frame in which the mode input is 1 or not present, the equalizer trains at the beginning of the frame for the length of the desired signal.

Output error

If you check this box, the block outputs the error signal, which is the difference between the equalized signal and the reference signal.

Output weights

If you check this box, the block outputs the current weights.

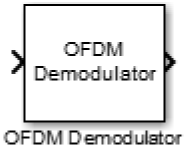
OFDM Demodulator Baseband

Demodulate orthogonal frequency division modulated data



Library

OFDM, in Digital Baseband sublibrary of Modulation

Description

The Orthogonal Frequency Division Modulation (OFDM) Demodulator Baseband block demodulates an OFDM input signal. The block accepts a single input and has one or two output ports, depending on the status of **Pilot output port**.

Signal Dimensions

Pilot Output Port	Pilot Carrier Indices	Signal Input	Signal Output	Pilot Output
false	N/A	$N_{CPTotal}$ $+N_{FFT}×N_{sym}$-by-N_r	N_{data}-by-N_{sym}-by-N_r	N/A
true	2-D			N_{pilot}-by-N_{sym}-by-N_r
	3-D			N_{pilot}-by-N_{sym}-by-N_t-by-N_r

where

- N_{CP} represents the cyclic prefix length as determined by **Cyclic prefix length**.
- $N_{CPTotal}$ represents the cyclic prefix length over all the symbols. When N_{CP} is a scalar, $N_{CPTotal} = N_{CP} \times N_{sym}$. When N_{CP} is a row vector, $N_{CPTotal} = \sum N_{CP}$.
- N_{FFT} represents the number of subcarriers as determined by **FFT length**.
- N_{sym} represents the number of symbols as determined by **Number of OFDM symbols**.
- N_r represents the number of receive antennas as determined by **Number of receive antennas**.
- N_{data} represents the number of data subcarriers. For further information on how N_{data} is determined, see the `info` reference page.
- N_{pilot} represents the number of pilot symbols determined by the second dimension in the **Pilot subcarrier indices** array.
- N_t represents the number of transmit antennas. This parameter is derived from the third dimension of the **Pilot subcarrier indices** array.

Parameters

FFT Length

Specify the FFT length, which is equivalent to the number of subcarriers. The length of the FFT, N_{FFT}, must be greater than or equal to 8.

Number of guard bands

Assign the number of subcarriers to the left, N_{leftG}, and right, N_{rightG}, guard bands. The input is a 2-by-1 vector. The number of subcarriers must fall within $[0,N_{FFT}/2 - 1]$.

Remove DC carrier

Select to remove the DC subcarrier.

Pilot output port

Select to separate the data from the pilot signal and output the demodulated pilot signal.

Pilot subcarrier indices

Specify the pilot subcarrier indices. This field is available only when the **Pilot output port** check box is selected. You can assign the indices can be assigned to the same or different subcarriers for each symbol. Similarly, the pilot carrier indices can differ across multiple transmit antennas. Depending on the desired level of control for index assignments, the dimensions of the indices' array vary from 1 to 3. Valid pilot indices fall in the range

$$[N_{\mathrm{leftG}} + 1,\ N_{\mathrm{FFT}}/2] \cup \left[N_{\mathrm{FFT}}/2 + 2,\ N_{\mathrm{FFT}} - N_{\mathrm{rightG}}\right],$$

where the index value cannot exceed the number of subcarriers. If the number of transmit antennas is greater than one, ensure that the indices per symbol are mutually distinct across antennas to minimize interference.

Cyclic prefix length

Specify the length of the cyclic prefix. If you specify a scalar, the prefix length is the same for all symbols through all antennas. If you specify a row vector of length N_{sym}, the prefix length can vary across symbols but remains the same length through all antennas.

Number of OFDM symbols

Specify the number of OFDM symbols, N_{sym}, in the time-frequency grid.

Number of receive antennas

Specify the number of receive antennas, N_r, as a positive integer such that $N_r \le 64$.

Simulate using

Select the simulation type from these choices:

- `Code generation`
- `Interpreted execution`

Algorithms

This block implements the algorithm, inputs, and outputs described in the `OFDM Demodulator` System object reference page. The object properties correspond to the block parameters.

Supported Data Types

Port	Supported Data Types
Input	- Double-precision floating point
Pilot (optional)	- Double-precision floating point
Output	- Double-precision floating point

OFDM Modulator Baseband

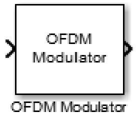
Modulate using orthogonal frequency division modulation

Library: Communications Toolbox / Modulation / Digital Baseband Modulation / OFDM



Description

The OFDM Modulator Baseband block applies Orthogonal Frequency Division Multiplexing modulation to an incoming data signal. The output is a baseband representation of the OFDM modulated signal.

Ports

Input

In — Input signal
3-D array

Input signal, specified as a 3D vector. The block accepts one or two inputs depending on the state of the **Pilot input port**. The input signal dimensions are :

Pilot Input Port	Signal Input	Pilot Input
off	N $_{data}$ -by-N $_{sym}$ -by-N $_{t}$	N/A
on		N $_{pilot}$ -by-N $_{sym}$ -by-N $_{t}$

where

- N_{data} represents the number of data subcarriers. For further information on how N_{data} is determined, see the `info` reference page.
- N_{sym} represents the number of symbols determined by **Number of OFDM symbols**.
- N_{t} represents the number of transmit antennas determined by **Number of transmit antennas**.
- N_{pilot} represents the number of pilot symbols determined by the first dimension size in the **Pilot subcarrier indices** array.
- N_{CP} represents the cyclic prefix length as determined by **Cyclic prefix length**.
- $N_{CPTotal}$ represents the cyclic prefix length over all the symbols. When N_{CP} is a scalar, $N_{CPTotal} = N_{CP} \times N_{sym}$. When N_{CP} is a row vector, $N_{CPTotal} = \sum N_{CP}$.
- N_{FFT} represents the number of subcarriers as determined by **FFT length**.

Data Types: `double`
Complex Number Support: Yes

Output

`Out` — Baseband modulated signal
2-D array

Baseband modulated signal, returned as a 2D array. The datatype of the output follows the input datatype. The output signal has dimension (N $_{CP}$ +N $_{FFT}$) ×N $_{sym}$ -by-N $_{t}$.

Parameters

`FFT Length` — Number of DFT points
64 (default) | positive integer

Number of DFT points, specified as a positive integer. The length of the FFT, N_{FFT}, must be greater than or equal to 8 and is equivalent to the number of subcarriers.

`Number of guard bands` — Number of subcarriers to the left and right guard bands
`[6;5]` (default) | 2-by-1 integer-valued vector

Number of subcarriers allocated to the left and right guard bands, specified as a 2-by-1 integer-valued vector. The number of subcarriers must fall within $[0,\lfloor N_{FFT}/2\rfloor - 1]$ where you specify the left, N_{leftG}, and right, N_{rightG}, guard bands independently in a 2-by-1 column vector.

`Insert DC null` — Option to insert DC null
`off` (default) | `on`

Select this parameter to insert a null on the DC subcarrier.

`Pilot input port` — Option to specify pilot input port
`off` (default) | `on`

Select this parameter to allow the specifying of pilot input port.

`Pilot subcarrier indices` — Pilot subcarrier indices
`[12; 26; 40; 54]` (default) | column vector

Pilot subcarrier indices, specified as a column vector. This field is available only when the **Pilot input port** check box is selected. You can assign the indices to the same or different subcarriers for each symbol. Similarly, the pilot carrier indices can differ across multiple transmit antennas. Depending on the desired level of control for index assignments, the dimensions of the indices array vary. Valid pilot indices fall in the range

$$[N_{\mathrm{leftG}} + 1,\ N_{\mathrm{FFT}}/2] \cup \left[N_{\mathrm{FFT}}/2 + 2,\ N_{\mathrm{FFT}} - N_{\mathrm{rightG}}\right],$$

where the index value cannot exceed the number of subcarriers. When the pilot indices are the same for every symbol and transmit antenna, the property has dimensions N_{pilot}-by-1. When the pilot indices vary across symbols, the property has dimensions of N_{pilot}-by-N_{sym}. If there is only one symbol but multiple transmit antennas, the property has dimensions of N_{pilot}-by-1-by-N_t. If the indices vary across the number of symbols and transmit antennas, the property will have dimensions of N_{pilot}-by-N_{sym}-by-N_t. If the number of transmit antennas is greater than one, ensure that the indices per symbol are mutually distinct across antennas to minimize interference. The default value is `[12; 26; 40; 54]`.

`Cyclic prefix length` — Length of cyclic prefix
16 (default) | positive scalar | positive vector

Length of cyclic prefix, specified as a positive integer. If you specify a scalar, the prefix length is the same for all symbols through all antennas. If you specify a row vector of length N_{sym}, the prefix length can vary across symbols but remains the same through all antennas.

Apply raised cosine windowing between OFDM symbols — Option to apply raised cosine window between OFDM symbols

off (default) | on

Select this parameter to apply raised cosine windowing between OFDM symbols. Windowing is the process in which the OFDM symbol is multiplied by a raised cosine window before transmission to reduce the power of out-of-band subcarriers, which serves to reduce spectral regrowth.

Window length — Length of raised cosine window

1 (default) | positive scalar

Length of raised cosine window, specified as a positive scalar. This field is available only when **Apply raised cosine windowing between OFDM symbols** is selected. Use positive integers having a maximum value no greater than the minimum cyclic prefix length. For example, in a configuration in which there are four symbols with cyclic prefix lengths of [12 16 14 18], the window length cannot exceed 12.

Number of OFDM symbols — Number of OFDM symbols

1 (default) | positive scalar

Number of OFDM symbols in the time-frequency grid, specified as a positive scalar.

Number of transmit antennas — Number of transmit antennas

1 (default) | positive scalar

Number of transmit antennas, specified as a real positive scalar. Specify the number of transmit antennas, N_t, as a positive integer such that $N_t \leq 64$.

Simulate using — Type of simulation to run

Code generation (default) | Interpreted execution

Type of simulation to run, specified as Code generation or Interpreted execution.

- Code generation –– Simulate the model by using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations unless the model changes. This option requires additional startup time, but the speed of the subsequent simulations is faster than Interpreted execution.
- Interpreted execution –– Simulate the model by using the MATLAB interpreter. This option requires less startup time than the Code generation method, but the speed of subsequent simulations is slower. In this mode, you can debug the source code of the block.

Block Characteristics

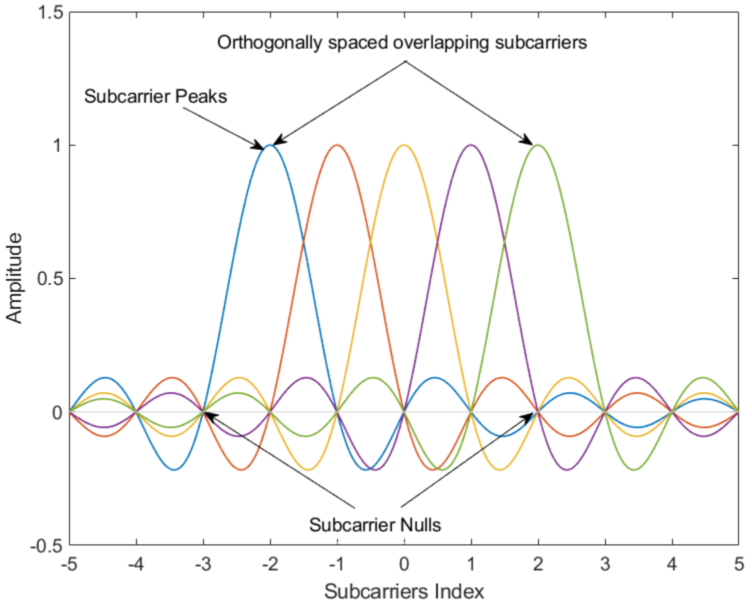
Data Types	double
Multidimensional Signals	yes
Variable-Size Signals	no

More About

Orthogonal Frequency Division Modulation

OFDM operation divides a high-rate data stream into lower data rate substreams by decomposing the transmission frequency band into N contiguous individually modulated subcarriers. Multiple parallel and orthogonal subcarriers carry the samples with almost the same bandwidth as a wideband channel. By using narrow orthogonal subcarriers, the OFDM signal gains robustness over a frequency-selective fading channel and eliminates adjacent subcarrier interference. Intersymbol interference (ISI) is reduced because the lower data rate substreams have symbol durations larger than the channel delay spread.

The Frequency domain representation of orthogonal subcarriers in an OFDM waveform looks as follows:



The transmitter applies inverse fast Fourier transform (IFFT) to N symbols at a time. The output of the IFFT is the sum of the N orthogonal sinusoids:

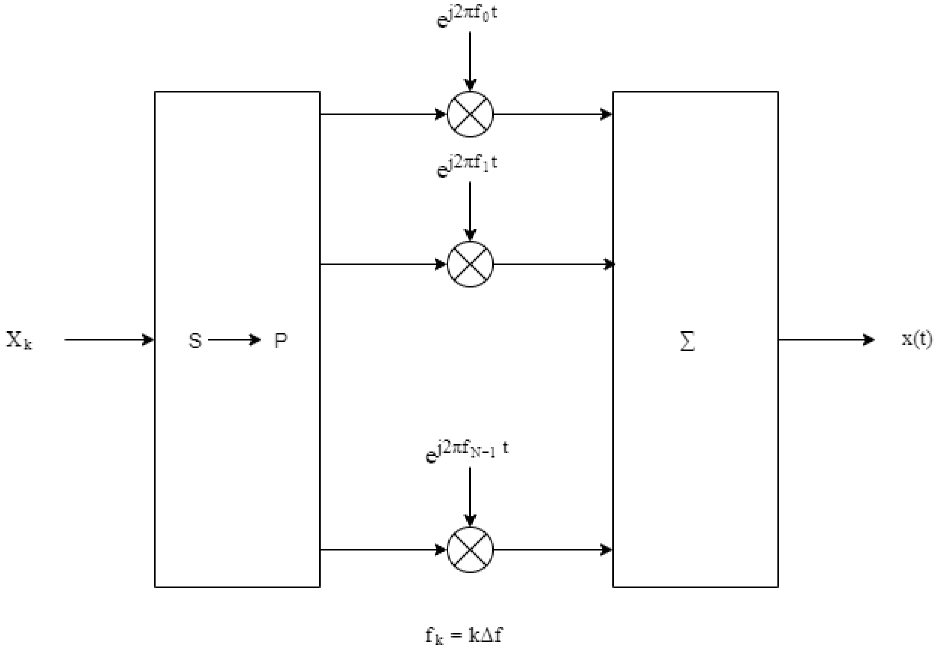
$$x(t) = \sum_{k=0}^{N-1} X_k e^{j2\pi k \Delta f t}, \quad 0 \le t \le T,$$

where $\{X_k\}$ are data symbols, and T is the OFDM symbol time. The data symbols X_k are typically complex and can be from any digital modulation alphabet (for example, QPSK, 16-QAM, 64-QAM).

The subcarrier spacing is $\Delta f = 1/T$; ensuring that the subcarriers are orthogonal over each symbol period, as shown below:

$$\frac{1}{T}\int_0^T \left(e^{j2\pi m \Delta f t}\right)^* \left(e^{j2\pi n \Delta f t}\right) dt = \frac{1}{T}\int_0^T e^{j2\pi(m-n)\Delta f t}\, dt = 0 \quad \text{for } m \ne n\,.$$

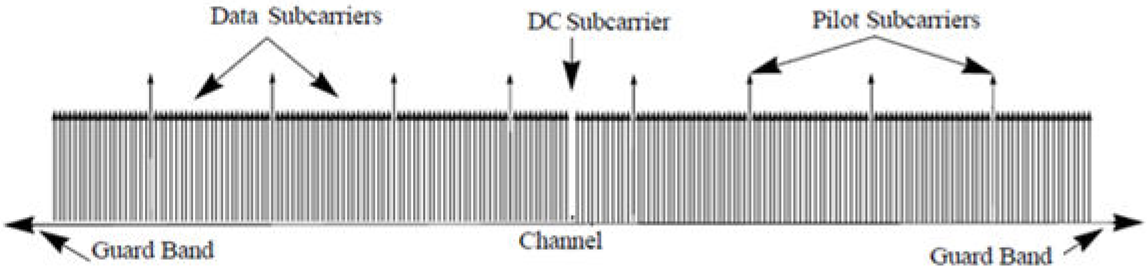
An OFDM modulator consists of a serial-to-parallel conversion followed by a bank of N complex modulators, individually corresponding to each OFDM subcarrier.



Subcarrier Allocation, Guard Bands and Guard Intervals

Individual OFDM subcarriers are allocated as data, pilot, or null subcarriers.

As shown here, subcarriers are designated as data, DC, pilot, or guard band subcarriers.

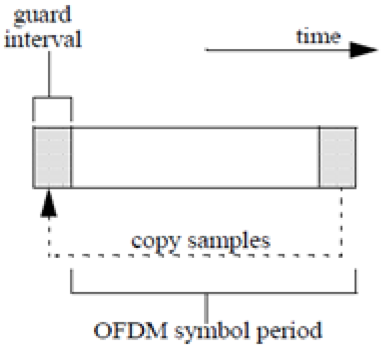


- Data subcarriers transmit user data.
- Pilot subcarriers are used for channel estimation.
- Null subcarriers transmit no data. Subcarriers with no data are used to provide a DC null and serve as buffers between OFDM resource blocks.
  - The null DC subcarrier is the center of the frequency band with an index value of (`nfft`/2 + 1) if `nfft` is even, or ((`nfft` + 1) / 2) if `nfft` is odd.
  - The guard bands provide buffers between consecutive OFDM symbols to protect the integrity of transmitted signals by reducing intersymbol interference.

Null subcarriers enable you to model guard bands and DC subcarrier locations for specific standards, such as the various 802.11 formats, LTE, WiMAX, or for custom allocations. You can allocate the location of nulls by assigning a vector of null subcarrier indices.

Similar to guard bands, guard intervals are used in OFDM to protect the integrity of transmitted signals by reducing intersymbol interference.

Assignment of guard intervals is analogous to the assignment of guard bands. You can model guard intervals to provide temporal separation between OFDM symbols. The guard intervals help preserve intersymbol orthogonality after the signal passes through time-dispersive channels. Guard intervals are created by using cyclic prefixes. Cyclic prefix insertion copies the last part of an OFDM symbol as the first part of the OFDM symbol.



As long as the span of the time dispersion does not exceed the duration of the cyclic prefix, the benefit of cyclic prefix insertion is maintained.

Inserting a cyclic prefix results in a fractional reduction of user data throughput because the cyclic prefix occupies bandwidth that could be used for data transmission.

Raised Cosine Windowing

While the cyclic prefix creates a guard period in time domain to preserve orthogonality, an OFDM symbol rarely begins with the same amplitude and phase exhibited at the end of the prior OFDM symbol causing spectral regrowth and therefore, spreading of signal bandwidth due to intermodulation distortion. To limit this spectral regrowth, it is desired to create a smooth transition between the last sample of a symbol and the first sample of the next symbol. This can be done by using a cyclic suffix and raised cosine windowing.

To create the cyclic suffix, the first N_{WIN} samples of a given symbol are appended to the end of that symbol. However, in order to comply with the 802.11g standard, for example, the length of a symbol cannot be arbitrarily lengthened. Instead, the cyclic suffix must overlap in time and is effectively summed with the cyclic prefix of the following symbol. This overlapped segment is where windowing is applied. Two windows are applied, one of which is the mathematical inverse of the other. The first raised cosine window is applied to the cyclic suffix of symbol k and decreases from 1 to 0 over its duration. The second raised cosine window is applied to the cyclic prefix of symbol k+1 and increases from 0 to 1 over its duration. This process provides a smooth transition from one symbol to the next.

The raised cosine window, $w(t)$, in the time domain can be expressed as:

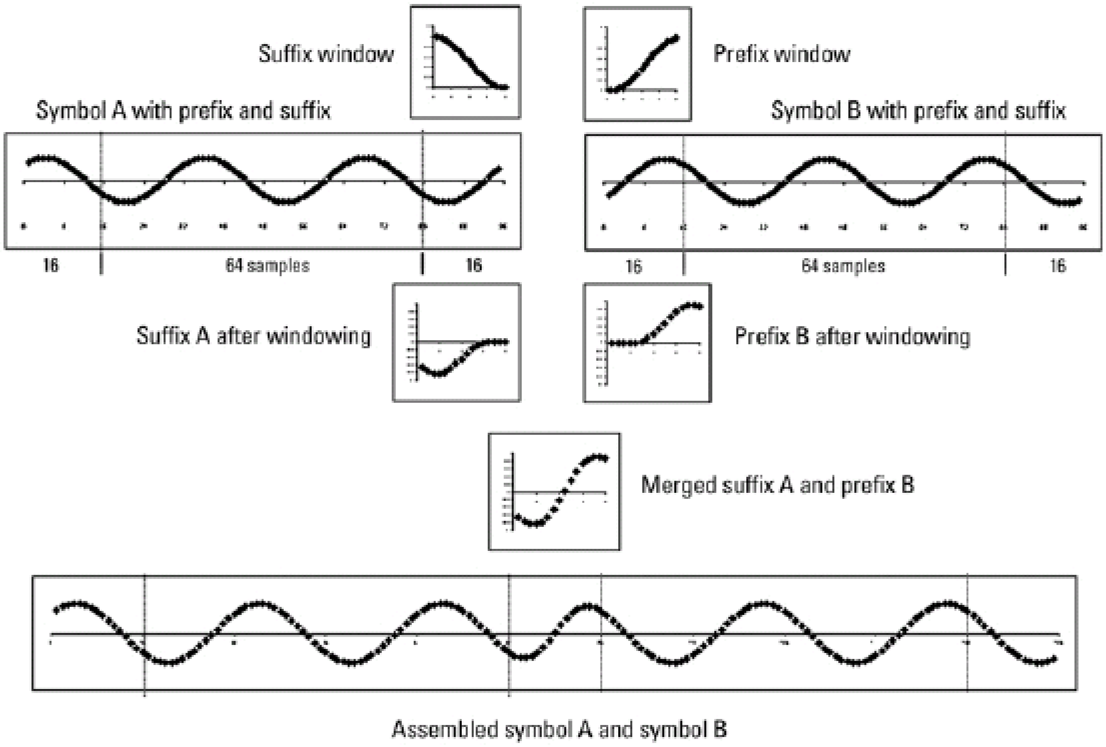
$$w(t) = \begin{cases} 1,\ 0 \le |t| < \dfrac{T - T_W}{2} \\ \dfrac{1}{2}\left\{1 + \cos\left[\dfrac{\pi}{T_W}\left(|t| - \dfrac{T - T_W}{2}\right)\right]\right\}, \dfrac{T - T_W}{2} \le |t| \le \dfrac{T + T_W}{2} \\ 0, \text{otherwise} \end{cases}$$

where:

- T is the OFDM symbol duration including the guard interval.
- T_W is the duration of the window.

Adjust the length of the cyclic suffix via the window length setting property, with suffix lengths set between 1 and the minimum cyclic prefix length. While windowing improves spectral regrowth, it does so at the expense of multipath fading immunity. This occurs because redundancy in the guard band is reduced because the guard band sample values are compromised by the smoothing.

The following figures display the application of raised cosine windowing.



Suffix window

Objects

`comm.OFDMModulator`

Introduced in R2014a

OQPSK Demodulator Baseband

Demodulation using OQPSK method

Library: Communications Toolbox / Modulation / Digital Baseband Modulation / PM

Description

The OQPSK Demodulator Baseband block applies pulse shape filtering to the input waveform and demodulates it using the offset quadrature phase shift keying (OQPSK) method. For more information, see “Pulse Shaping Filter” on page 5-621. The input is a baseband representation of the modulated signal.

For information about delays incurred by modulator-demodulator pair processing, see “Modulation Delays” on page 5-620.

Ports

Input

`In` — Input baseband waveform
scalar | column vector

Input baseband waveform, specified as a discrete-time complex scalar or column vector.

The block processes the input signal based on the Output type setting.

Data Types: `double`
Complex Number Support: Yes

Output

`Out` — Output data
integer column vector | bit column vector

Output data, returned as an integer or bit column vector.

Parameters

Modulation

`Output type` — Output type
`Integer` (default) | `Bit`

Output type, specified as `Integer` or `Bit`.

- When you set **Output type** to `Integer`, the block outputs a vector of integer symbols with values from 0 to 3, the length of which is the number of output symbols.
- When you set **Output type** to `Bit`, the block outputs a 2-bit binary representation of integers, in a binary-valued, even-length vector.

The input period for each integer or bit pair is the Samples per symbol times the output sample period.

`Phase offset (rad)` — Phase of zeroth point of signal constellation

`0` (default) | scalar

Phase offset from π/4, specified as a scalar in radians. The phase offset is applied to the zeroth point of the signal constellation before delay of quadrature component. After the OQPSK imaginary-component delay the signal is normalized with unity power.

Example: Setting **Phase offset (rad)** to `pi/4` aligns the zeroth point of the QPSK signal constellation point on the axes, {(1,0), (0,j), (-1,0), (0,-j)}.

`Symbol mapping` — Signal constellation bit mapping

`Gray` (default) | `Binary` | custom 4-element numeric vector of integers with values from 0 to 3

Signal constellation bit mapping, specified as `Gray`, `Binary`, or a custom 4-element numeric vector of integers with values from 0 to 3.

Setting	Constellation Mapping for Integers	Constellation Mapping for Bits	Comment
`Gray`			The signal constellation mapping is Gray-encoded.
`Binary`			The signal constellation mapping for the input integer `m` (0 ≤ `m` ≤ 3) is the complex value $e^{(j*(PhaseOffset+\pi/4) + j*2*\pi*m/4)}$.
Custom 4-element numeric vector of integers with values from 0 to 3			Elements [a b c d] must be composed of the set of values [0, 1, 2, 3] in any order.

Filtering

`Pulse shape` — Filtering pulse shape

`Half sine` (default) | `Normal raised cosine` | `Root raised cosine` | `Custom`

Select the filtering pulse shape: `Half sine`, `Normal raised cosine`, `Root raised cosine`, or `Custom`.

`Rolloff factor` — Raised cosine filter rolloff factor

`0.2` (default) | scalar

Raised cosine filter rolloff factor, specified as a scalar from `0` to `1`.

Dependencies

This property is enabled when Pulse shape is `Normal raised cosine` or `Root raised cosine`.

Data Types: `double`

`Filter span (in symbols)` — Filter length

`10` (default) | scalar

Filter length in symbols, specified as a scalar. An ideal raised cosine filter has an infinite impulse response. However, to realize a practical implementation of this filter, the object truncates the impulse response to **Filter span (in symbols)** symbols.

Dependencies

This property is enabled when Pulse shape is `Normal raised cosine` or `Root raised cosine`.

Data Types: `double`

`Filter numerator` — Filter numerator

`[0.7071 0.7071]` (default) | row vector

Filter numerator, specified as a row vector.

Dependencies

This parameter is enabled when Pulse shape is `Custom`.

Data Types: `double`

`Samples per symbol` — Number of samples per symbol

`4` (default) | positive even integer

Number of samples per symbol, specified as a positive even integer.

Data Types: `double`

Other Parameters

`Rate options` — Processing rate option

`Enforce single-rate processing` (default) | `Allow multirate processing`

- `Enforce single-rate processing` — Executes the model, ensuring that the input and output signals have the same port sample time. The block implements the rate change by making a size change at the output when compared to the input. For integer outputs, the output width equals 1/Samples per symbol times the input width.

  For more information, see Single-Rate Processing with OQPSK Demodulator Block.
- `Allow multirate processing` — Executes the model, allowing the input and output signals to have different port sample times. The output symbol time is Samples per symbol times the input sample time.

  For more information, see Multirate Processing with OQPSK Demodulator Block.

`Output data type` — Output data type

`double` (default) | `single` | `uint8`

Select the output data type: `double`, `single`, or `uint8`.

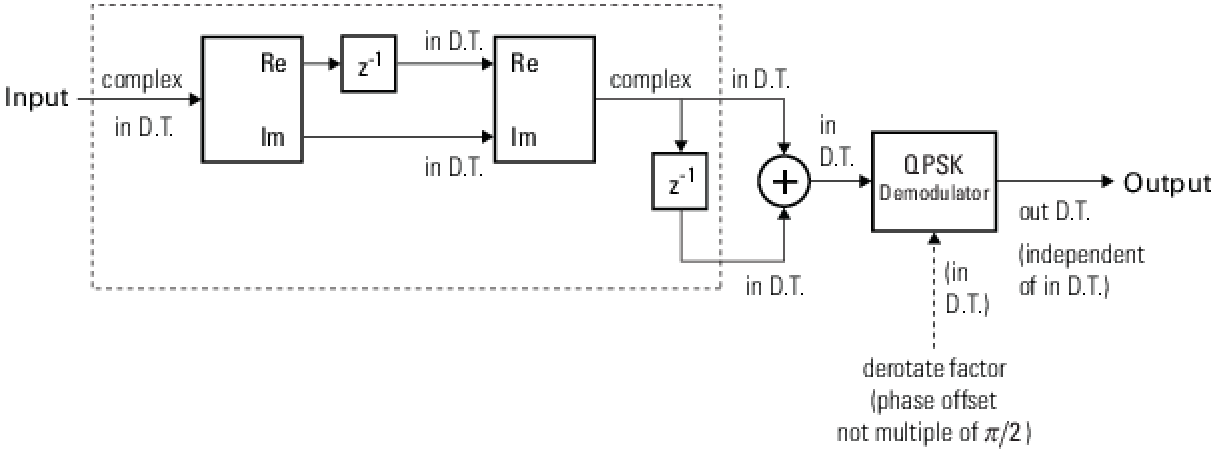
Block Characteristics

Data Types	`Boolean` | `double` | `integer` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`no`

More About

OQPSK Signal Flow Diagram

Every Samples per symbol input samples produce one output symbol. In this figure, the dotted line represents the region comprising the input sample processing.



Modulation Delays

Digital modulation and demodulation blocks incur delays between their inputs and outputs that result in an offset in the arrival time of the received data. Data that enters a modulation or demodulation block at time *T* appears in the output at time *T*+delay. Take system delays into account when comparing transmitted data with received data, such as in overlaid plots or when computing error statistics. As shown here, the OQPSK modulation-demodulation delay varies depending on the pulse shaping filter, input/output data setting, and simulation configuration.

Pulse Shape	Rate Options	Treat Each Discrete Rate as a Separate Task?	Input/Output Data (*)	End-to-End Delay Incurred by an OQPSK Modulator-Demodulator Block Pair (in samples)
`Half sine` or `Custom`	`Enforce single-rate operation`	N/A	`Integer`	1
			`Bit`	2
	`Allow multirate processing`	`false` (single tasking)	`Integer`	length(data) + 1 + 1
			`Bit`	length(data) + 2 + 2
		`true` (multitasking)	`Integer`	length(data) + 1 + 2
			`Bit`	length(data) + 2 + 4
`Normal raised cosine` or `Root raised cosine`	`Enforce single-rate operation`	N/A	`Integer`	**Filter span (in symbols)**
			`Bit`	2***Filter span (in symbols)**
	`Allow multirate processing`	`false` (single tasking)	`Integer`	length(data) + **Filter span (in symbols)** + 1
			`Bit`	length(data) + 2***Filter span (in symbols)** + 2
		`true` (multitasking)	`Integer`	2*length(data) + **Filter span (in symbols)** + 2
			`Bit`	2*length(data) + 2***Filter span (in symbols)** + 4
(*) The data type parameter is **Input type** for modulation and **Output type** for demodulation.				

Pulse Shaping Filter

The OQPSK modulation scheme requires oversampling of two or greater in order to delay (or offset) the quadrature channel by 90 degrees. This oversampling is achieved through interpolation filtering implemented by pulse shaping.

OQPSK Modulator Baseband

Modulation using OQPSK method

Library: Communications Toolbox / Modulation / Digital Baseband Modulation / PM

Description

The OQPSK Modulator Baseband block modulates the input signal using the offset quadrature phase shift keying (OQPSK) method and applies pulse shape filtering to the waveform. For more information, see “Pulse Shaping Filter” on page 5-627. The output is a baseband representation of the modulated signal.

For information about delays incurred by modulator-demodulator pair processing, see “Modulation Delays” on page 5-626.

Ports

Input

`In` — Input data
integer column vector | bit column vector

Input data, specified as an integer or bit column vector.

The input signal is processed based on the setting selected for Input type.

Data Types: `double`

Output

`Out` — Output baseband waveform
column vector

Output baseband waveform, returned as a column vector of complex data.

Parameters

Modulation

`Input type` — Input type
`Integer` (default) | `Bit`

Input type, specified as `Integer` or `Bit`.

- When you set **Input type** to `Integer`, the input can be a scalar value or column vector, the length of which is the number of input symbols.

- When you set **Input type** to `Bit`, the input width must be an integer multiple of two.

The output sample period is the period of each integer or bit pair in the input divided by Samples per symbol.

`Phase offset (rad)` — Phase of zeroth point of signal constellation

`0` (default) | scalar

Phase offset from π/4, specified as a scalar in radians. The phase offset is applied to the zeroth point of the signal constellation before delay of quadrature component. After the OQPSK imaginary-component delay, the signal is normalized with unity power.

Example: Setting **Phase offset (rad)** to `pi/4` aligns the zeroth point of the QPSK signal constellation point on the axes, {(1,0), (0,j), (-1,0), (0,-j)}.

`Symbol mapping` — Signal constellation bit mapping

`Gray` (default) | `Binary` | custom 4-element numeric vector of integers with values from 0 to 3

Signal constellation bit mapping, specified as `Gray`, `Binary`, or a custom 4-element numeric vector of integers with values from 0 to 3.

Setting	Constellation Mapping for Integers	Constellation Mapping for Bits	Comment
`Gray`			The signal constellation mapping is Gray-encoded.
`Binary`			The signal constellation mapping for the input integer `m` (0 ≤ `m` ≤ 3) is the complex value $e^{(j*(PhaseOffset+\pi/4) + j*2*\pi*m/4)}$.
Custom 4-element numeric vector of integers with values from 0 to 3			Elements [a b c d] must be composed of the set of values [0, 1, 2, 3] in any order.

Filtering

`Pulse shape` — Filtering pulse shape

`Half sine` (default) | `Normal raised cosine` | `Root raised cosine` | `Custom`

Select the filtering pulse shape: `Half sine`, `Normal raised cosine`, `Root raised cosine`, or `Custom`.

`Rolloff factor` — Raised cosine filter rolloff factor

`0.2` (default) | scalar

Raised cosine filter rolloff factor, specified as a scalar in the range [0, 1].

Dependencies

This property is enabled when Pulse shape is `Normal raised cosine` or `Root raised cosine`.

Data Types: `double`

`Filter span (in symbols)` — Filter length

`10` (default) | scalar

Filter length in symbols, specified as a scalar. An ideal raised cosine filter has an infinite impulse response. However, to realize a practical implementation of this filter, the object truncates the impulse response to **Filter span (in symbols)** symbols.

Dependencies

This property is enabled when Pulse shape is `Normal raised cosine` or `Root raised cosine`.

Data Types: `double`

`Filter numerator` — Filter numerator

`[0.7071 0.7071]` (default) | row vector

Filter numerator, specified as a row vector.

Dependencies

This parameter is enabled when Pulse shape is `Custom`.

Data Types: `double`

`Samples per symbol` — Number of samples per symbol

`4` (default) | positive even integer

Number of samples per symbol, specified as a positive even integer.

Data Types: `double`

Other Parameters

`Rate options` — Processing rate option

`Enforce single-rate processing` (default) | `Allow multirate processing`

- `Enforce single-rate processing` — Executes the model, ensuring that the input and output signals have the same port sample time. The block implements the rate change by making a size change at the output when compared to the input. For integer inputs, the output width equals Samples per symbol times the number of symbols.

  For more information, see Single-Rate Processing with OQPSK Modulator Block.
- `Allow multirate processing` — Executes the model, allowing the input and output signals to have different port sample times. The output sample time equals the symbol period divided by Samples per symbol.

For more information, see Single-Rate Processing with OQPSK Modulator Block.

`Output data type` — Output data type

`double` (default) | `single`

Select the output data type: `double` or `single`.

Block Characteristics

Data Types	`Boolean` | `double` | `integer` | `single`

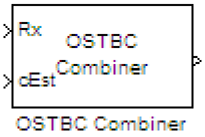
OSTBC Combiner

Combine inputs for received signals and channel estimate according to orthogonal space-time block code (OSTBC)



Library

MIMO

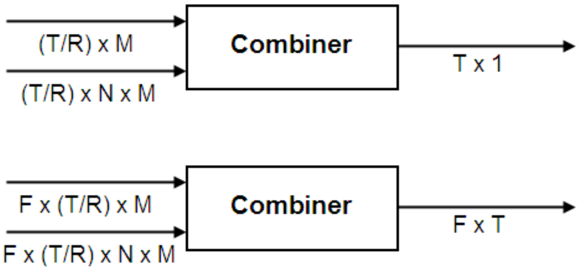
Description

The OSTBC Combiner block combines the input signal (from all of the receive antennas) and the channel estimate signal to extract the soft information of the symbols that were encoded using an OSTBC. The input channel estimate may not be constant during each codeword block transmission and the combining algorithm uses only the estimate for the first symbol period per codeword block. A symbol demodulator or decoder would follow the Combiner block in a MIMO communications system.

The block conducts the combining operation for each symbol independently. The combining algorithm depends on the structure of the OSTBC. For more information, see the OSTBC Combining Algorithms on page 5-630 section of this help page.

Dimension

Along with the time and spatial domains for OSTBC transmission, the block supports an optional dimension, over which the combining calculation is independent. This dimension can be thought of as the frequency domain for OFDM-based applications. The following illustration indicates the supported dimensions for inputs and output of the OSTBC Combiner block.



The following table describes each variable for the block.

Variable	Description
F	The additional dimension; typically the frequency dimension. The combining calculation is independent of this dimension.

Variable	Description
N	Number of transmit antennas.
M	Number of receive antennas.
T	Output symbol sequence length in time domain.
R	Symbol rate of the code.

Note On the two inputs, T/R is the symbol sequence length in the time domain.

F can be any positive integers. *M* can be 1 through 8, indicated by the **Number of receive antennas** parameter. *N* can be 2, 3 or 4, indicated by the **Number of transmit antennas** parameter. The time domain length T/R must be a multiple of the codeword block length (2 for Alamouti; 4 for all other OSTBC). For $N = 2$, T/R must be a multiple of 2. When $N > 2$, T/R must be a multiple of 4. *R* defaults to 1 for 2 antennas. *R* can be either $\frac{3}{4}$ or $\frac{1}{2}$ for more than 2 antennas.

The supported dimensions for the block depend upon the values of *F* and *M*. For one receive antenna ($M = 1$), the received signal input must be a column vector or a full 2–D matrix, depending on the value for *F*. The corresponding channel estimate input must be a full 2-D or 3-D matrix.

For more than one receive antenna ($M > 1$), the received signal input must be a full 2-D or 3-D matrix, depending on the value for *F*. Correspondingly, the channel estimate input must be a 3-D or 4-D matrix, depending on the value for *F*.

To understand the block's dimension propagation, refer to the following table.

	Input 1 (Received Signal)	Input 2 (Channel Estimate)	Output
F = 1 and M = 1	Column vector	2-D	Column vector
F = 1 and M > 1	2-D	3-D	Column vector
F > 1 and M = 1	2-D	3-D	2-D
F > 1 and M > 1	3-D	4-D	2-D

Data Type

For information about the data types each block port supports, see the “Supported Data Type” on page 5-633 table on this page. The output signal inherits the data type from the inputs. The block supports different fixed-point properties for the two inputs. For fixed-point signals, the output word length and fractional length depend on the block’s mask parameter settings. See Fixed-Point Signals for more information about fixed-point data propagation of this block.

Frames

The output inherits the frameness of the received signal input. For either column vector or full 2-D matrix input signal, the input can be either frame-based or sample-based. A 3–D or 4–D matrix input signal must have sample-based input.

OSTBC Combining Algorithms

The OSTBC Combiner block supports five different OSTBC combining computation algorithms. Depending on the selection for **Rate** and **Number of transmit antennas**, you can select one of the algorithms shown in the following table.

Transmit Antenna	Rate	Computational Algorithm per Codeword Block Length
2	1	$\begin{pmatrix} \widehat{s}_1 \\ \widehat{s}_2 \end{pmatrix} = \frac{1}{\lVert H \rVert^2} \sum_{j=1}^{M} \begin{pmatrix} h^*_{1,j} r_{1,j} + h_{2,j} r^*_{2,j} \\ h^*_{2,j} r_{1,j} - h_{1,j} r^*_{2,j} \end{pmatrix}.$
3	1/2	$\begin{pmatrix} \widehat{s}_1 \\ \widehat{s}_2 \end{pmatrix} = \frac{1}{\lVert H \rVert^2} \sum_{j=1}^{M} \begin{pmatrix} h^*_{1,j} r_{1,j} + h_{2,j} r^*_{2,j} + h^*_{3,j} r_{3,j} \\ h^*_{2,j} r_{1,j} - h_{1,j} r^*_{2,j} - h_{3,j} r^*_{4,j} \end{pmatrix}.$
3	3/4	$\begin{pmatrix} \widehat{s}_1 \\ \widehat{s}_2 \\ \widehat{s}_3 \end{pmatrix} = \frac{1}{\lVert H \rVert^2} \sum_{j=1}^{M} \begin{pmatrix} h^*_{1,j} r_{1,j} + h_{2,j} r^*_{2,j} - h_{3,j} r^*_{3,j} \\ h^*_{2,j} r_{1,j} - h_{1,j} r^*_{2,j} - h_{3,j} r^*_{4,j} \\ h^*_{3,j} r_{1,j} + h_{1,j} r^*_{3,j} + h_{2,j} r^*_{4,j} \end{pmatrix}.$
4	1/2	$\begin{pmatrix} \widehat{s}_1 \\ \widehat{s}_2 \end{pmatrix} = \frac{1}{\lVert H \rVert^2} \sum_{j=1}^{M} \begin{pmatrix} h^*_{1,j} r_{1,j} + h_{2,j} r^*_{2,j} + h^*_{3,j3,j} r_{3,j} + h_{4,j} r^*_{4,j} \\ h^*_{2,j} r_{1,j} - h_{1,j} r^*_{2,j} + h^*_{4,j} r_{3,j} - h_{3,j} r^*_{4,j} \end{pmatrix}.$
4	3/4	$\begin{pmatrix} \widehat{s}_1 \\ \widehat{s}_2 \\ \widehat{s}_3 \end{pmatrix} = \frac{1}{\lVert H \rVert^2} \sum_{j=1}^{M} \begin{pmatrix} h^*_{1,j} r_{1,j} + h_{2,j} r^*_{2,j} - h_{3,j} r^*_{3,j} - h^*_{4,j} r_{4j} \\ h^*_{2,j} r_{1j} - h_{1,j} r^*_{2,j} + h^*_{4,j} r_{3,j} - h_{3,j} r^*_{4,j} \\ h^*_{3,j} r_{1j} + h^*_{4,j} r_{2,j} + h_{1,j} r^*_{3,j} + h_{2,j} r^*_{4,j} \end{pmatrix}.$

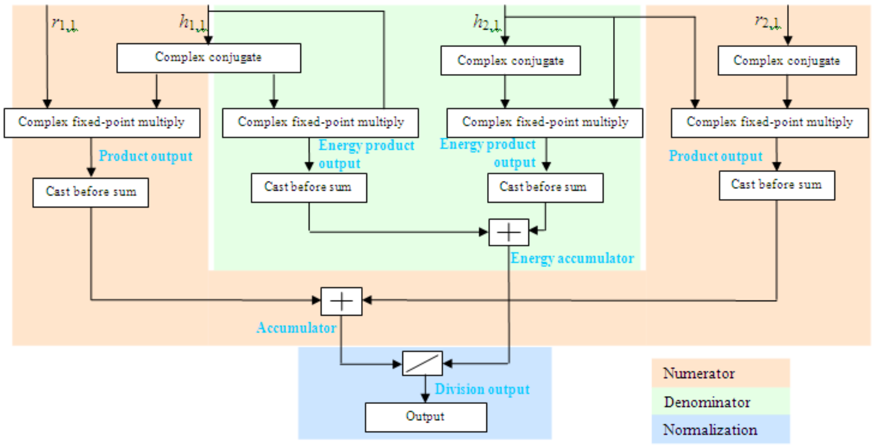
$\widehat{s}_k$ represents the estimated *k*th symbol in the OSTBC codeword matrix. h_{ij} represents the estimate for the channel from the *i*th transmit antenna and the *j*th receive antenna. The values of *i* and *j* can range from 1 to *N* (the number of transmit antennas) and to *M* (the number of receive antennas) respectively. r_{lj} represents the *l*th symbol at the *j*th receive antenna per codeword block. The value of *l* can range from 1 to the codeword block length. $\lVert H \rVert^2$ represents the summation of channel power per link, i.e., $\lVert H \rVert^2 = \sum_{i=1}^{N} \sum_{j=1}^{M} \lVert h_{ij} \rVert^2$

Fixed-Point Signals

Use the following formula for $\widehat{s}_1$ for Alamouti code with 1 receive antenna to highlight the data types used for fixed-point signals.

$$\widehat{s}_1 = \frac{h^*_{1,1,}\ r_{1,1} + h_{2,1,} r^*_{2,1}}{\lVert H \rVert^2} = \frac{h^*_{1,1,}\ r_{1,1} + h_{2,1,} r^*_{2,1}}{h_{1,1} h^*_{1,1,} + h_{2,1,} h^*_{2,1}}$$

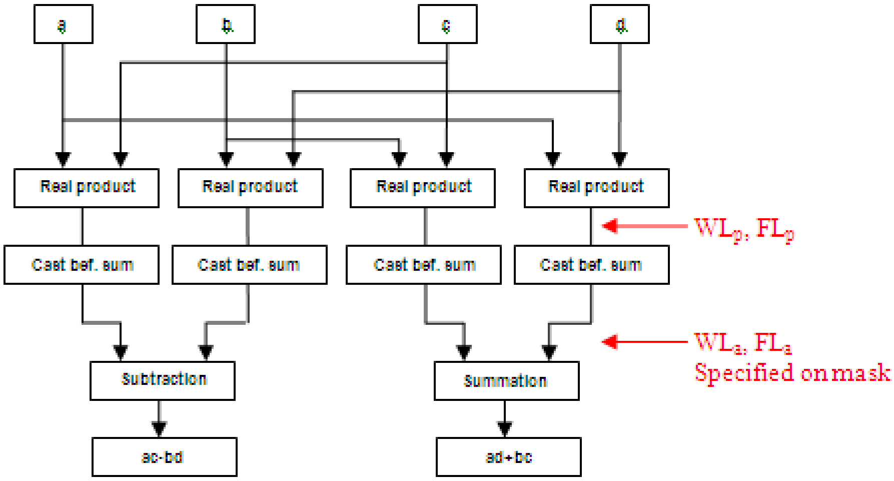
In this equation, the data types for **Product output** and **Accumulator** correspond to the product and summation in the numerator. Similarly, the types for **Energy product output** and **Energy accumulator** correspond to the product and summation in the denominator.



Signal Flow Diagram for s_1 Combining Calculation of Alamouti Code with One Receive Antenna

The following formula shows the data types used within the OSTBC Combiner block for fixed-point signals for more than one receive antenna for Alamouti code, where *M* represents the number of receive antennas.

$$\widehat{s}_1 = \frac{h^*_{1,1,}\ r_{1,1} + h_{2,1,} r^*_{2,1} + h^*_{1,2} r_{1,2} + h_{2,2} r^*_{2,2} + \ldots + h^*_{1,M,}\ r_{1,M} + h_{2,M} r^*_{2,M}}{h_{1,1} h^*_{1,1} +\ h_{2,1} h^*_{2,1} + h_{1,2} h^*_{1,2} +\ h_{2,2} h^*_{2,2} + \ldots + h_{1,M} h^*_{1,M} +\ h_{2,M,} h^*_{2,M}}$$



Signal Flow Diagram for Complex Multiply of *a* + *ib* and *c* + *id*

For Binary point scaling, you cannot specify WL_p and FL_p. Instead, the blocks determine these values implicitly from WL_a and FL_a

The Internal Rule for **Product output** and **Energy product output** are:

- When you select `Inherit via internal rule`, the internal rule determines WL_p and FL_p. Therefore, $WL_a = WL_p + 1$ and $FL_a = FL_p$
- For `Binary point scaling`, you specify WL_a and FL_a. Therefore, $WL_p = WL_a - 1$ and $FL_a = FL_p$.

For information on how the Internal Rule applies to the **Accumulator** and **Energy Accumulator**, see Inherit via Internal Rule.

Parameters

Number of transmit antennas

Sets the number of transmit antennas. The block supports 2, 3, or 4 transmit antennas. This value defaults to 2.

Rate

Sets the symbol rate of the code. You can specify either 3/4 or 1/2. This field only appears when you use more than 2 transmit antennas. This field defaults to $\frac{3}{4}$ for more than 2 transmit antennas. For 2 transmit antennas, there is no rate option and the implicit (default) rate defaults to 1.

Number of receive antennas

The number of antennas the block uses to receive signal streams. The block supports from 1 to 8 receive antennas. This value defaults to 1.

Rounding mode

Sets the rounding mode for fixed-point calculations. The block uses the rounding mode if a value cannot be represented exactly by the specified data type and scaling. When this occurs, the value is rounded to a representable number. For more information refer to Rounding (Fixed-Point Designer).

Saturate on integer overflow

Sets the overflow mode for fixed-point calculations. Use this parameter to specify the method to be used if the magnitude of a fixed-point calculation result does not fit into the range of the data type and scaling that stores the result. For more information refer to Precision and Range.

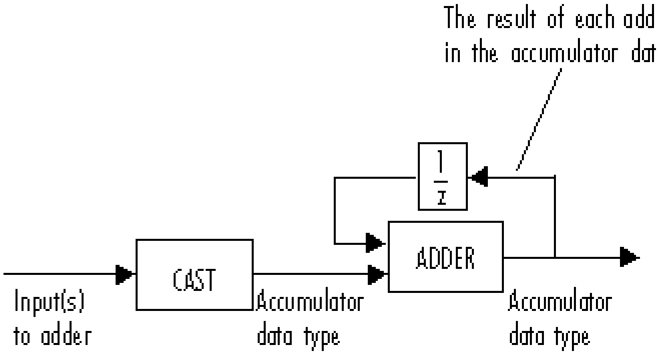
Product Output

Complex product in the numerator for the diversity combining. For more information refer to the Fixed-Point Signals section of this help page.

Accumulator

Summation in the numerator for the diversity combining.

Fixed-point Communications Toolbox blocks that must hold summation results for further calculation usually allow you to specify the data type and scaling of the accumulator. Most such blocks cast to the accumulator data type prior to summation:



Use the **Accumulator—Mode** parameter to specify how you would like to designate the accumulator word and fraction lengths:

- When you select `Inherit via internal rule`, the accumulator output word and fraction lengths are automatically calculated for you. Refer to Inherit via Internal Rule for more information.
- When you select `Same as product output`, these characteristics match those of the product output.
- When you select `Same as input`, these characteristics match those of the first input to the block.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the accumulator, in bits.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the accumulator. The bias of all signals in DSP System Toolbox software is zero.

Energy product output

Complex product in the denominator for calculating total energy in the MIMO channel .

Energy accumulator

Summation in the denominator for calculating total energy in the MIMO channel.

Division output

Normalized diversity combining by total energy in the MIMO channel.

Supported Data Type

Port	Supported Data Types
Rx	• Double-precision floating point • Single-precision floating point • Signed Fixed-point
cEst	• Double-precision floating point • Single-precision floating point • Signed Fixed-point
Out	• Double-precision floating point • Single-precision floating point • Signed Fixed-point

Examples

For an example of this block in use, see OSTBC Over 3x2 Rayleigh Fading Channel. The model shows the use of a rate ¾ OSTBC for 3 transmit and 2 receive antennas with BPSK modulation using independent fading links and AWGN.

You can also see the block in the Concatenated OSTBC with TCM example by typing `commtcmostbc` at the MATLAB command line.

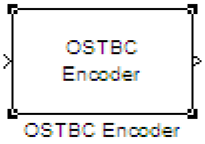
OSTBC Encoder

Introduced in R2009a

OSTBC Encoder

Encode input message using orthogonal space-time block code (OSTBC)



Library

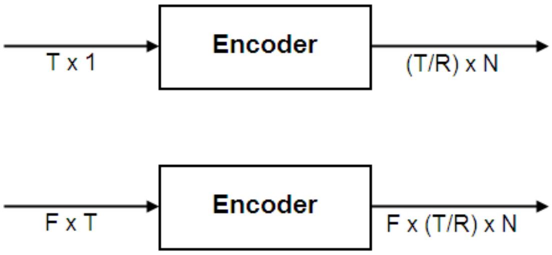
MIMO

Description

The OSTBC Encoder block encodes an input symbol sequence using orthogonal space-time block code (OSTBC). The block maps the input symbols block-wise and concatenates the output codeword matrices in the time domain. For more information, see the OSTBC Encoding Algorithms on page 5-636 section of this help page.

Dimension

The block supports time and spatial domains for OSTBC transmission. It also supports an optional dimension, over which the encoding calculation is independent. This dimension can be thought of as the frequency domain. The following illustration indicates the supported dimensions for the inputs and output of the OSTBC Encoder block.



The following table describes the variables.

Variable	Description
F	The additional dimension; typically the frequency domain. The encoding does not depend on this dimension.
T	Input symbol sequence length for the time domain.
R	Symbol rate of the code.
N	Number of transmit antennas.

Note On the output, T/R is the symbol sequence length in time domain.

F can be any positive integer. *N* can be 2, 3 or 4, indicated by **Number of transmit antennas**. For *N* = 2, *R* must be 1. For *N* = 3 or 4, *R* can be 3/4 or 1/2, indicated by **Rate**. The time domain length *T* must be a multiple of the number of symbols in each codeword matrix. Specifically, for *N* = 2 or *R* = 1/2, *T* must be a multiple of 2 and when *R* = 3/4, *T* must be a multiple of 3.

To understand the block's dimension propagation, refer to the following table.

Dimension	Input	Output
F = 1	Column vector	2-D
F > 1	2-D	3-D

Data Type

For information about the data types each block port supports, see the "Supported Data Type" on page 5-637 table on this page. The output signal inherits the data type from the input signal. For fixed-point signals, the complex conjugation may cause overflows which the fixed-point parameter **Saturate on integer overflow** must handle.

Frames

The output signal inherits frame type from the input signal. A column vector input requires either frame-based or sample-based input; otherwise, the input must be sample-based.

OSTBC Encoding Algorithms

The OSTBC Encoder block supports five different OSTBC encoding algorithms. Depending on the selection for **Rate** and **Number of transmit antennas**, the block implements one of the algorithms in the following table:

Transmit Antenna	Rate	OSTBC Codeword Matrix
2	1	$\begin{pmatrix} s_1 & s_2 \\ -s_2^* & s_1^* \end{pmatrix}$
3	1/2	$\begin{pmatrix} s_1 & s_2 & 0 \\ -s_2^* & s_1^* & 0 \\ 0 & 0 & s_1 \\ 0 & 0 & -s_2^* \end{pmatrix}$
3	3/4	$\begin{pmatrix} s_1 & s_2 & s_3 \\ -s_2^* & s_1^* & 0 \\ s_3^* & 0 & -s_1^* \\ 0 & s_3^* & -s_2^* \end{pmatrix}$

Transmit Antenna	Rate	OSTBC Codeword Matrix
4	1/2	$\begin{pmatrix} s_1 & s_2 & 0 & 0 \\ -s_2^* & s_1^* & 0 & 0 \\ 0 & 0 & s_1 & s_2 \\ 0 & 0 & -s_2^* & s_1^* \end{pmatrix}$
4	3/4	$\begin{pmatrix} s_1 & s_2 & s_3 & 0 \\ -s_2^* & s_1^* & 0 & s_3 \\ s_3^* & 0 & -s_1^* & s_2 \\ 0 & s_3^* & -s_2^* & -s_1 \end{pmatrix}$

In each matrix, its (l, i) entry indicates the symbol transmitted from the ith antenna in the lth time slot of the block. The value of i can range from 1 to N (the number of transmit antennas). The value of l can range from 1 to the codeword block length.

Parameters

Number of transmit antennas

Sets the number of antennas at the transmitter side. The block supports 2, 3, or 4 transmit antennas. The value defaults to 2.

Rate

Sets the symbol rate of the code. You can specify either 3/4 or 1/2. This field only appears when using more than 2 transmit antennas. This field defaults to $\frac{3}{4}$ for more than 2 transmit antennas. For 2 transmit antennas, there is no rate option and the rate defaults to 1.

Saturate on integer overflow

Sets the overflow mode for fixed-point calculations. Use this parameter to specify the method to be used if the magnitude of a fixed-point calculation result does not fit into the range of the data type and scaling that stores the result. For more information refer to “Precision and Range”.

Supported Data Type

Port	Supported Data Types
In	• Double-precision floating point • Single-precision floating point • Signed Fixed-point
Out	• Double-precision floating point • Single-precision floating point • Signed Fixed-point

Examples

For an example of this block in use, see “OSTBC Over 3x2 Rayleigh Fading Channel” . The model shows the use of a rate ¾ OSTBC for 3 transmit and 2 receive antennas with BPSK modulation using independent fading links and AWGN

You can also see the block in the Concatenated OSTBC with TCM example by typing `commtcmostbc` at the MATLAB command line.

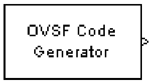
OSTBC Combiner

Introduced in R2009a

OVSF Code Generator

Generate orthogonal variable spreading factor (OVSF) code from set of orthogonal codes



Library

Spreading Codes

Description

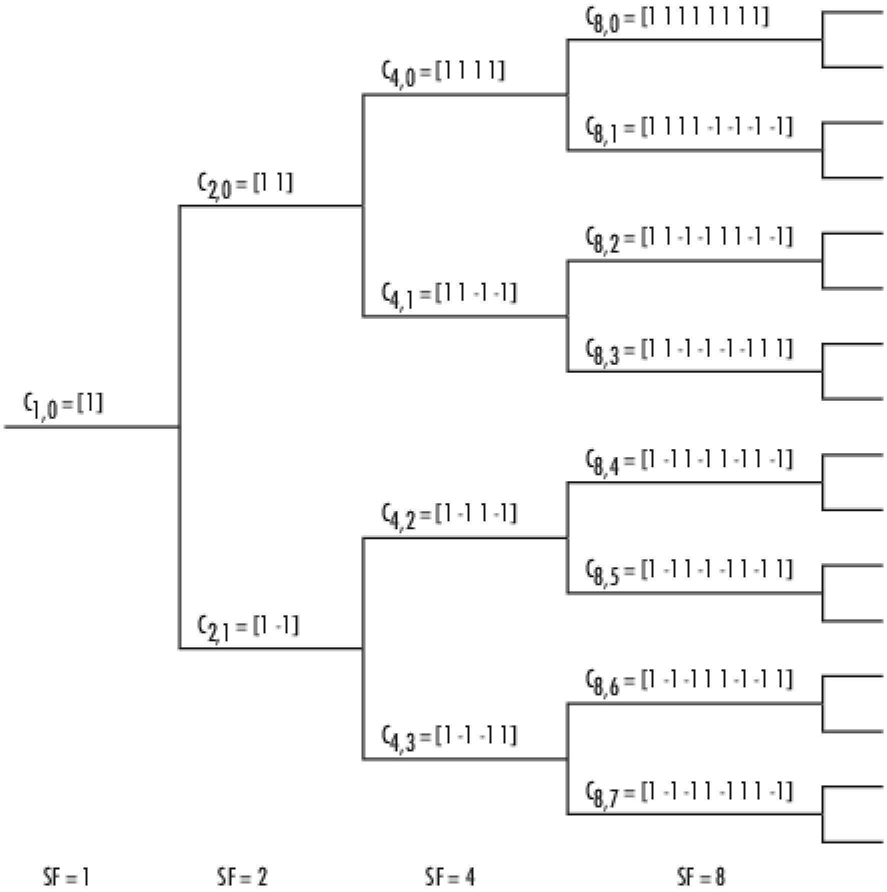
The OVSF Code Generator block generates an OVSF code from a set of orthogonal codes. OVSF codes were first introduced for 3G communication systems. OVSF codes are primarily used to preserve orthogonality between different channels in a communication system.

OVSF codes are defined as the rows of an N-by-N matrix, C_N, which is defined recursively as follows. First, define C_1 = [1]. Next, assume that C_N is defined and let $C_N(k)$ denote the kth row of C_N. Define C_{2N} by

$$C_{2N} = \begin{bmatrix} C_N(0) & C_N(0) \\ C_N(0) & -C_N(0) \\ C_N(1) & C_N(1) \\ C_N(1) & -C_N(1) \\ \ldots & \ldots \\ C_N(N-1) & C_N(N-1) \\ C_N(N-1) & -C_N(N-1) \end{bmatrix}$$

Note that C_N is only defined for N a power of 2. It follows by induction that the rows of C_N are orthogonal.

The OVSF codes can also be defined recursively by a tree structure, as shown in the following figure.



$C_{8,0}$ = [1 1 1 1 1 1 1 1]
$C_{4,0}$ = [1 1 1 1]
$C_{8,1}$ = [1 1 1 1 -1 -1 -1 -1]
$C_{2,0}$ = [1 1]
$C_{8,2}$ = [1 1 -1 -1 1 1 -1 -1]
$C_{4,1}$ = [1 1 -1 -1]
$C_{8,3}$ = [1 1 -1 -1 -1 -1 1 1]
$C_{1,0}$ = [1]
$C_{8,4}$ = [1 -1 1 -1 1 -1 1 -1]
$C_{4,2}$ = [1 -1 1 -1]
$C_{8,5}$ = [1 -1 1 -1 -1 1 -1 1]
$C_{2,1}$ = [1 -1]
$C_{8,6}$ = [1 -1 -1 1 1 -1 -1 1]
$C_{4,3}$ = [1 -1 -1 1]
$C_{8,7}$ = [1 -1 -1 1 -1 1 1 -1]
SF = 1
SF = 2
SF = 4
SF = 8

If [C] is a code length 2^r at depth r in the tree, where the root has depth 0, the two branches leading out of C are labeled by the sequences [C C] and [C -C], which have length 2^{r+1}. The codes at depth r in the tree are the rows of the matrix C_N, where N = 2^r.

Note that two OVSF codes are orthogonal if and only if neither code lies on the path from the other code to the root. Since codes assigned to different users in the same cell must be orthogonal, this restricts the number of available codes for a given cell. For example, if the code C_{41} in the tree is assigned to a user, the codes C_{10}, C_{20}, C_{82}, C_{83}, and so on, cannot be assigned to any other user in the same cell.

Block Parameters

You specify the code the OVSF Code Generator block outputs by two parameters in the block's dialog: the **Spreading factor**, which is the length of the code, and the **Code index**, which must be an integer in the range [0, 1, ... , N - 1], where N is the spreading factor. If the code appears at depth r in the preceding tree, the **Spreading factor** is 2^r. The **Code index** specifies how far down the column of the tree at depth r the code appears, counting from 0 to *N* - 1. For $C_{N,\ k}$ in the preceding diagram, *N* is the **Spreading factor** and *k* is the **Code index**.

You can recover the code from the **Spreading factor** and the **Code index** as follows. Convert the **Code index** to the corresponding binary number, and then add 0s to the left, if necessary, so that the resulting binary sequence $x_1\ x_2 \ldots x_r$ has length *r*, where *r* is the logarithm base 2 of the **Spreading factor**. This sequence describes the path from the root to the code. The path takes the upper branch from the code at depth *i* if $x_i = 0$, and the lower branch if $x_i = 1$.

To reconstruct the code, recursively define a sequence of codes C_i for as follows. Let C_0 be the root [1]. Assuming that C_i has been defined, for *i* < *r*, define C_{i+1} by

$$C_{i+1} = \begin{cases} C_i C_i & \text{if } x_i = 0 \\ C_i(-C_i) & \text{if } x_i = 1 \end{cases}$$

The code C_N has the specified **Spreading factor** and **Code index**.

For example, to find the code with **Spreading factor** 16 and **Code index** 6, do the following:

1. Convert 6 to the binary number 110.
2. Add one 0 to the left to obtain 0110, which has length 4 = $\log_2$ 16.
3. Construct the sequences C_i according to the following table.

i	x_i	C_i
0		C_0 = [1]
1	0	$C_1 = C_0\ C_0$ = [1] [1]
2	1	$C_2 = C_1\ {-C_1}$ = [1 1] [-1 -1]
3	1	$C_3 = C_2\ {-C_2}$ = [1 1 -1 -1] [-1 -1 1 1]
4	0	$C_4 = C_3\ C_3$ = [1 1 -1 -1 -1 -1 1 1] [1 1 -1 -1 -1 -1 1 1]

The code C_4 has **Spreading factor** 16 and **Code index** 6.

Parameters

Spreading factor

Positive integer that is a power of 2, specifying the length of the code.

Code index

Integer in the range [0, 1, ... , N - 1] specifying the code, where N is the **Spreading factor**.

Sample time

Output sample time, specified as `-1` or a positive scalar that represents the time between each sample of the output signal. If **Sample time** is set to `-1`, the sample time is inherited from downstream. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-642.

Samples per frame

Samples per frame, specified as a positive integer indicating the number of samples per frame in one channel of the output data. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-642.

Output data type

The output type of the block can be specified as an `int8` or `double`. By default, the block sets this to `double`.

Simulate using

Select the simulation mode.

`Code generation`

On the first model run, simulate and generate code. If the structure of the block does not change, subsequent model runs do not regenerate the code.

If the simulation mode is `Code generation`, System objects corresponding to the blocks accept a maximum of nine inputs.

`Interpreted execution`

Simulate model without generating code. This option results in faster start times but can slow subsequent simulation performance.

More About

Sample Timing

The time between output updates is equal to the product of **Samples per frame** and **Sample time**. For example, if **Sample time** and **Samples per frame** equal one, the block outputs a sample every second. If **Samples per frame** is increased to 10, then a 10-by-1 vector is output every 10 seconds. This ensures that the equivalent output rate is not dependent on the **Samples per frame** parameter.

Compatibility Considerations

Existing models automatically update this block to current version

Behavior changed in R2020a

Starting in R2020a, Simulink no longer allows you to use the OVSF Code Generator block version available before R2015b.

Existing models automatically update to load the OVSF Code Generator block version announced in “Source blocks output frames of contiguous time samples but do not use the frame attribute” in the R2015b Release Notes. For more information on block forwarding, see “Forwarding Tables” (Simulink).

Phase/Frequency Offset

Apply phase and frequency offsets to complex baseband signal

Library: Communications Toolbox / RF Impairments Correction
Communications Toolbox / RF Impairments

Description

The Phase/Frequency Offset block applies phase and frequency offsets to a complex signal.

This icon shows the block with all ports enabled.

In
Phase/
Frequency
Frq
Offset

Ports

Input

`In` — Complex signal

scalar | vector | matrix

Complex signal, specified as a scalar, vector, or matrix. The port is unnamed until you enable the **Frequency offset from port** parameter.

Data Types: `double` | `single`
Complex Number Support: Yes

`Frq` — Frequency offset

scalar | vector | matrix

Frequency offset, specified as a scalar, a vector with the same number of rows or columns as the input signal, or a matrix with the same dimensions as the input signal. For more information, see "Interdependent Parameter-Port Dimensions" on page 5-644.

Dependencies

To enable this port, select the **Frequency offset from port** parameter.

Data Types: `double` | `single`

Output

`Out1` — Output signal

scalar | vector | matrix

Output signal, returned as a scalar, vector, or matrix. This output is the same dimension and data type as the input signal.

Parameters

`Phase offset (deg)` — Phase offset

`0` (default) | scalar | vector | matrix

Phase offset in degrees, specified as a scalar, vector, or matrix.

If **Phase offset (deg)** and **Frequency offset (Hz)** are both nonscalar, they must be the same size.

Tunable: Yes

`Frequency offset from port` — Option to add port to set frequency offset

`off` (default) | on

Select this parameter to add the **Frq** port.

- When you select this parameter, the **Frq** port specifies the frequency offset.
- When you clear this parameter, the **Frequency offset (Hz)** parameter specifies the frequency offset.

`Frequency offset (Hz)` — Frequency offset

`0` (default) | scalar | vector | matrix

Frequency offset in hertz, specified as a scalar, a vector with the same number of rows or columns as the input signal, or a matrix with the same dimensions as the input signal. For more information, see “Interdependent Parameter-Port Dimensions” on page 5-644.

If **Phase offset (deg)** and **Frequency offset (Hz)** are both nonscalar, they must be the same size.

Tunable: Yes

Dependencies

To enable this port, clear the **Frequency offset from port** parameter.

Block Characteristics

Data Types	`double` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`no`

More About

Interdependent Parameter-Port Dimensions

This table outlines the interdependency of parameter-to-port dimensions.

Number of Dimensions	Data I/O Dimension	Frame Size	Number of Channels	Frequency/Phase Offset Parameter Dimension	Frequency Offset Input Port Dimension
Any	Scalar	1	1	Scalar	Scalar

Number of Dimensions	Data I/O Dimension	Frame Size	Number of Channels	Frequency/Phase Offset Parameter Dimension	Frequency Offset Input Port Dimension
2	*M*-by-1	*M*	1	*M*-by-1 1-by-*M* 1-by-1	*M* *M*-by-1 1 1-by-1
2	1-by-*N*	1	*N*	*N*-by-1 1-by-*N* 1-by-1	*N* 1-by-*N* 1 1-by-1
2	*M*-by-*N*	*M*	*N*	*M*-by-*N* *N*-by-1 1-by-*N* *M*-by-1 1-by-*M* 1-by-1	*M*-by-*N* *N* 1-by-*N* 1 1-by-1 *M* *M*-by-1

For example:

- When you specify a scalar offset parameter, the block applies the same offset to all elements of the input signal
- When you specify a 2-by-1 offset parameter for a 2-by-3 input signal (one offset value per sample), the block applies the same sample offset across the three channels.
- When you specify a 1-by-3 offset parameter for a 2-by-3 input signal (one offset value per channel), the same channel offset is applied across the two samples of a channel.
- When you specify a 2-by-3 offset parameter for a 2-by-3 input signal (one offset value per sample for each channel), the offsets are applied element-wise to the input signal.

Algorithms

If the input signal is $u(t)$, then the output signal is

$$y(t) = u(t)\cdot\left(\cos\left(2\pi\int_0^t f(\tau)d\tau + \varphi(t)\right) + j\sin\left(2\pi\int_0^t f(\tau)d\tau + \varphi(t)\right)\right),$$

where $f(t)$ is the frequency offset, and $\varphi(t)$ is the phase offset.

The discrete-time output is given by

$y(0) = u(0)(\cos(\varphi(0)) + j\sin(\varphi(0)))$ and

$$y(i) = u(i)\left(\cos\left(2\pi\sum_{n=0}^{i-1} f(n)\Delta t + \varphi(i)\right) + j\sin\left(2\pi\sum_{n=0}^{i-1} f(n)\Delta t + \varphi(i)\right)\right),$$

where $i > 0$, and Δt is the sample time.

Extended Capabilities

C/C++ Code Generation

Generate C and C++ code using Simulink® Coder™.

The **Frequency offset (Hz)** and **Phase offset (deg)** parameters are tunable in Normal mode, Accelerator mode, and Rapid Accelerator mode. If you use the Simulink Coder rapid simulation (RSIM) target to build an RSIM executable, then you can tune these parameters without recompiling the model. For more information, see Tunable Parameters (Simulink).

Introduced before R2006a

Phase-Locked Loop

Implement phase-locked loop to recover phase of input signal

Filt
PLL
PD
VCO

Library

Components sublibrary of Synchronization

Description

The Phase-Locked Loop (PLL) block is a feedback control system that automatically adjusts the phase of a locally generated signal to match the phase of an input signal. This block is most appropriate when the input is a narrowband signal.

This PLL has these three components:

- A multiplier used as a phase detector.
- A filter. You specify the filter transfer function using the **Lowpass filter numerator** and **Lowpass filter denominator** parameters. Each is a vector that gives the respective polynomial's coefficients in order of descending powers of *s*.

  To design a filter, you can use functions such as `butter`, `cheby1`, and `cheby2` in Signal Processing Toolbox software. The default filter is a Chebyshev type II filter whose transfer function arises from the command below.

  ```
  [num, den] = cheby2(3,40,100,'s')
  ```
- A voltage-controlled oscillator (VCO). You specify characteristics of the VCO using the **VCO quiescent frequency**, **VCO initial phase**, and **VCO output amplitude** parameters.

This block accepts a sample-based scalar input signal. The input signal represents the received signal. The three output ports produce:

- The output of the filter
- The output of the phase detector
- The output of the VCO

Parameters

Lowpass filter numerator

The numerator of the lowpass filter transfer function, represented as a vector that lists the coefficients in order of descending powers of *s*.

Lowpass filter denominator

The denominator of the lowpass filter transfer function, represented as a vector that lists the coefficients in order of descending powers of *s*.

VCO input sensitivity (Hz/V)

This value scales the input to the VCO and, consequently, the shift from the **VCO quiescent frequency** value. The units of **VCO input sensitivity** are Hertz per volt.

VCO quiescent frequency (Hz)

The frequency of the VCO signal when the voltage applied to it is zero. This should match the carrier frequency of the input signal.

VCO initial phase (rad)

The initial phase of the VCO signal.

VCO output amplitude

The amplitude of the VCO signal.

Phase Noise

Apply receiver phase noise to complex baseband signal
Library: Communications Toolbox / RF Impairments

Description

The Phase Noise block adds phase noise to a complex signal. This block emulates impairments introduced by the local oscillator of a wireless communication transmitter or receiver. The block generates filtered phase noise according to the specified spectral mask and adds it to the input signal. For a description of the phase noise modeling, see “Algorithms” on page 5-651.

Ports

Input

`In` — Input signal
complex column vector

Input signal, specified as an N_S-by-1 vector of complex values. N_S represents the number of samples in the input signal.

Data Types: `double`
Complex Number Support: Yes

Output

`Out` — Output signal
complex column vector

Output signal, returned as an N_S-by-1 vector of complex values. N_S equals the number of samples in the input signal.

Data Types: `double`
Complex Number Support: Yes

Parameters

`Phase noise level (dBc/Hz)` — Phase noise level
`[-60 -80]` (default) | vector of negative scalars

Phase noise level in decibels relative to carrier per hertz (dBc/Hz), specified as a vector of negative scalars. The **Phase noise level (dBc/Hz)** and **Frequency offset (Hz)** parameters must have the same length.

Tunable: Yes

`Frequency offset (Hz)` — Frequency offset

`[20 200]` (default) | vector of positive increasing values

Frequency offset in Hz, specified as a vector of positive increasing values. The **Phase noise level (dBc/Hz)** and **Frequency offset (Hz)** parameters must have the same length.

Tunable: Yes

Data Types: `double`

`Sample rate (Hz)` — Sample rate

`1024` (default) | positive scalar

Sample rate in samples per second, specified as a positive scalar. To avoid aliasing, the sample rate must be greater than twice the largest value specified by **Frequency offset (Hz)**.

Tunable: Yes

Data Types: `double`

`Initial seed` — Initial seed of noise generator

`2137` (default) | positive scalar

Initial seed of noise generator, specified as a positive scalar.

This block uses the Random Source block to generate noise. The block generates random numbers using the Ziggurat method (V5 RANDN algorithm). Every time you rerun the simulation, the block reuses the same initial seed. That way, the block outputs the same signal each time you run a simulation.

Tunable: Yes

Data Types: `double`

`View Filter Response` — Display magnitude response of filter

button

Display magnitude response of filter defined by the Phase Noise block. The block uses the `fvtool` function to display the magnitude response.

`Simulate using` — Specify type of simulation to run

`Interpreted execution` (default) | `Code generation`

- `Interpreted execution` -– Simulate model using the MATLAB interpreter. This option shortens startup time speed, but the speed of the subsequent simulations is slower than `Code generation`. In this mode, you can debug the source code of the block.
- `Code generation` -– Simulate model using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations, as long as the model does not change. This option requires additional startup time, but the speed of the subsequent simulations is faster than `Interpreted execution`.

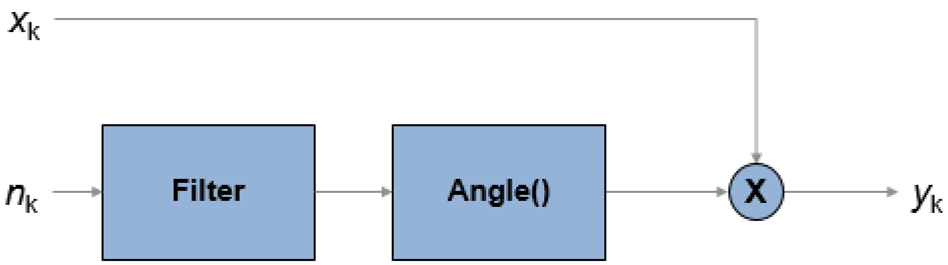
Block Characteristics

Data Types	`double` | `single`

Multidimensional Signals	no
Variable-Size Signals	no

Algorithms

The output signal, y_k, is related to input sequence x_k by $y_k = x_k e^{j\varphi_k}$, where φ_k is the phase noise. The phase noise is filtered Gaussian noise such that $\varphi_k = f(n_k)$, where n_k is the noise sequence and f represents a filtering operation.



To model the phase noise, define the power spectrum density (PSD) mask characteristic by specifying scalar or vector values for the frequency offset and phase noise level.

- For a scalar frequency offset and phase noise level specification, an IIR digital filter computes the spectrum mask. The spectrum mask has a 1/*f* characteristic that passes through the specified point.
- For a vector frequency offset and phase noise level specification, an FIR filter computes the spectrum mask. The spectrum mask is interpolated across log10(*f*). It is flat from DC to the lowest frequency offset, and from the highest frequency offset to half the sample rate.

IIR Digital Filter

For the IIR digital filter, the numerator coefficient is

$$\lambda = \sqrt{2\pi f_{offset} 10^{L/10}},$$

where f_{offset} is the frequency offset in Hz and L is the phase noise level in dBc/Hz. The denominator coefficients, γ_i, are recursively determined as

$$\gamma_i = (i - 2.5)\frac{\gamma_{i-1}}{i-1},$$

where $\gamma_1 = 1$, $i = \{1, 2,..., N_t\}$, and N_t is the number of filter coefficients. N_t is a power of 2, from 2^7 to 2^{19}. The value of N_t grows as the phase noise offset decreases towards 0 Hz.

FIR Filter

For the FIR filter, the phase noise level is determined through log10(*f*) interpolation for frequency offsets over the range [*df*, f_s / 2], where *df* is the frequency resolution and f_s is the sample rate. The phase noise is flat from 0 Hz to the smallest frequency offset, and from the largest frequency offset to f_s / 2. The frequency resolution is equal to $\frac{f_s}{2}\left(\frac{1}{N_t}\right)$, where N_t is the number of coefficients, and is a power of 2 less than or equal to 2^{16}. If $N_t < 2^8$, a time domain FIR filter is used. Otherwise, a frequency domain FIR filter is used.

The algorithm increases N_t until these conditions are met:

- The frequency resolution is less than the minimum value of the frequency offset vector.
- The frequency resolution is less than the minimum difference between two consecutive frequencies in the frequency offset vector.
- The maximum number of FIR filter taps is 2^{16}.

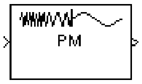
PM Demodulator Passband

Demodulate PM-modulated data



Library

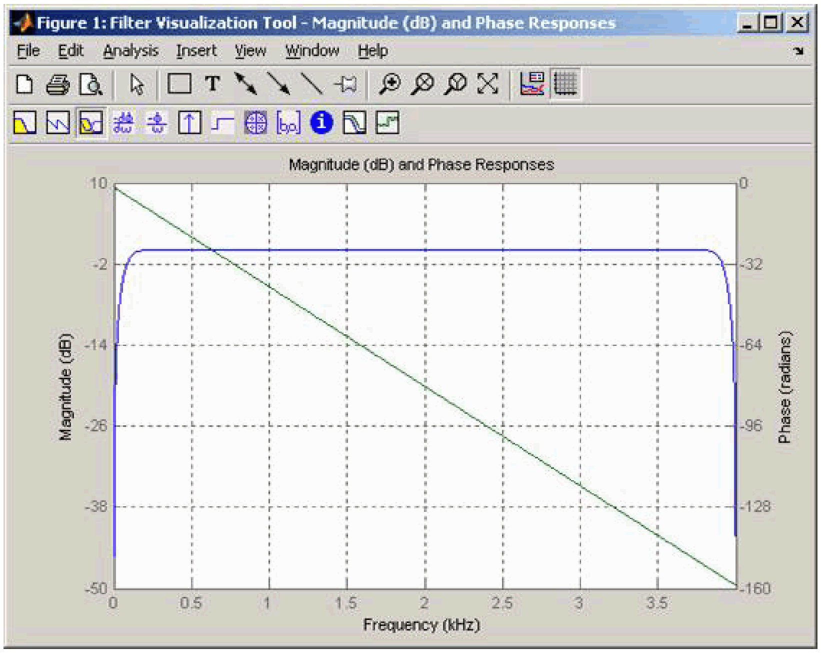
Analog Passband Modulation, in Modulation

Description

The PM Demodulator Passband block demodulates a signal that was modulated using phase modulation. The input is a passband representation of the modulated signal. Both the input and output signals are real scalar signals.

For best results, use a carrier frequency which is estimated to be larger than 10% of your input signal's sample rate. This is due to the implementation of the Hilbert transform by means of a filter.

In the following example, we sample a 10Hz input signal at 8000 samples per second. We then designate a Hilbert Transform filter of order 100. Below is the response of the Hilbert Transform filter as returned by `fvtool`.



Note the bandwidth of the filter's magnitude response. By choosing a carrier frequency larger than 10% (but less than 90%) of the input signal's sample rate (8000 samples per second, in this example) or equivalently, a carrier frequency larger than 400Hz, we ensure that the Hilbert Transform Filter will be operating in the flat section of the filter's magnitude response (shown in blue), and that our modulated signal will have the desired magnitude and form.

Typically, an appropriate **Carrier frequency** value is much higher than the highest frequency of the input signal. By the Nyquist sampling theorem, the reciprocal of the model's sample time (defined by the model's signal source) must exceed twice the **Carrier frequency** parameter.

This block works only with real inputs of type `double`. This block does not work inside a triggered subsystem.

Parameters

Carrier frequency (Hz)

The frequency of the carrier.

Initial phase (rad)

The initial phase of the carrier in radians.

Phase deviation (rad)

The phase deviation of the carrier frequency in radians. Sometimes it is referred to as the "variation" in the phase.

Hilbert transform filter order

The length of the FIR filter used to compute the Hilbert transform.

PM Modulator Passband

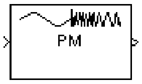
Modulate using phase modulation



Library

Analog Passband Modulation, in Modulation

Description

The PM Modulator Passband block modulates using phase modulation. The output is a passband representation of the modulated signal. The output signal's frequency varies with the input signal's amplitude. Both the input and output signals are real scalar signals.

If the input is $u(t)$ as a function of time t, then the output is

$$\cos(2\pi f_c t + K_c u(t) + \theta)$$

where

- f_c represents the **Carrier frequency** parameter
- θ represents the **Initial phase** parameter
- K_c represents the **Phase deviation** parameter

An appropriate **Carrier frequency** value is generally much higher than the highest frequency of the input signal. By the Nyquist sampling theorem, the reciprocal of the model's sample time (defined by the model's signal source) must exceed twice the **Carrier frequency** parameter.

This block works only with real inputs of type `double`. This block does not work inside a triggered subsystem.

Parameters

Carrier frequency (Hz)

The frequency of the carrier.

Initial phase (rad)

The initial phase of the carrier in radians.

Phase deviation (rad)

The phase deviation of the carrier frequency in radians. This is sometimes referred to as the "variation" in the phase.

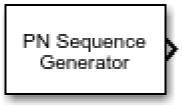
PN Sequence Generator

Generate pseudonoise sequence

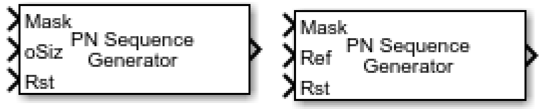
Library: Communications Toolbox / Comm Sources / Sequence Generators
Communications Toolbox HDL Support / Comm Sources



Description

The PN Sequence Generator block generates a sequence of pseudorandom binary numbers using a linear-feedback shift register (LFSR). Pseudonoise sequences are typically used for pseudorandom scrambling, and in direct-sequence spread-spectrum systems. For more information, see “More About” on page 5-662.

These icons shows the block with all ports enabled.



Ports

Input

`Mask` — Output mask
binary vector

Output mask to delay the PN sequence from initial time, specified as a binary vector with *N* elements. *N* is the degree of the generator polynomial.

Dependencies

To enable this port, set **Output mask source** to `Input port`.

Data Types: `double` | `uint8` | `ufix1`

`oSiz` — Output size
integer

Output size for variable-size output signals, specified as an integer. For information about variable-size signals, see “Variable-Size Signal Basics” (Simulink).

Dependencies

To enable this port, select **Output variable-size signals** and set **Maximum output size source** to `Dialog parameter`.

Data Types: `double`

`Ref` — Reference input

column vector

Reference input, specified as a column vector that determines the maximum and current output sequence length. The **Ref** input must be a variable-size signal. For information about variable-size signals, see “Variable-Size Signal Basics” (Simulink).

Dependencies

To enable this port, select **Output variable-size signals** and set **Maximum output size source** to `Inherit from reference input`.

Data Types: `double`

`Rst` — Reset sequence generator

0 | 1

Reset sequence generator, specified as `0` or `1`. For more information, see “Reset Behavior” on page 5-663.

Dependencies

To enable this port, select **Reset on nonzero input**.

Data Types: `Boolean`

Output

`Out` — Pseudorandom noise sequence

binary vector

PN sequence, returned as a binary vector.

Parameters

`Generator polynomial` — Generator polynomial

`'z^6 + z + 1'` (default) | polynomial character vector | binary row vector

Generator polynomial, specified as one of the following:

- A polynomial character vector that includes the number `1`.
- A binary row vector that represents the coefficients of the generator polynomial in order of descending power. The first and last entries must be `1`. The length of this vector is (N+1), where N is the degree of the generator polynomial.
- A vector containing the exponents of z for the nonzero terms of the polynomial in descending order of powers. The last entry must be `0`.

For more information, see “Character Representation of Polynomials”.

Example: `'z^8 + z^2 + 1'`, `[1 0 0 0 0 0 1 0 1]`, and `[8 2 0]` represent the same polynomial, $p(z) = z^8 + z^2 + 1$.

Data Types: `double` | `char`

`Initial states` — Initial shift register states

`[0 0 0 0 0 1]` (default) | binary row vector

Initial shift register states, specified as a binary row vector of length *N*, where *N* is the degree of the generator polynomial.

Note For the block to generate a nonzero sequence, the **Initial states** vector must contain at least one nonzero element.

Data Types: `double`

`Output mask source` — Output mask source

`Dialog parameter` (default) | `Input port`

Output mask source that indicates how the output mask information is given to the block, specified as:

- `Dialog parameter` to use the `Output mask vector (or scalar shift value)` parameter setting.
- `Input port` to add and use the `Mask` input port.

`Output mask vector (or scalar shift value)` — Output mask vector or scalar shift value

0 (default) | integer scalar | binary vector

Output mask vector or scalar shift value, specified as an integer scalar or binary row vector of length *N*, where *N* is the degree of the generator polynomial. This parameter determines the delay of the PN sequence from the initial time. For more information, see “Shifting PN Sequence Starting Point” on page 5-663.

Dependencies

To enable this parameter, set **Output mask source** to `Dialog parameter`.

Data Types: `double`

`Output variable-size signals` — Output variable-size signals

off (default) | on

Select this parameter to permit variable length output sequences during simulation. When set to `off`, fixed-length sequences are output. When set to `on`, variable-length sequences can be output. For information about variable-size signals, see “Variable-Size Signal Basics” (Simulink).

`Maximum output size source` — Maximum output size source

`Dialog parameter` (default) | `Inherit from reference port`

Maximum output size source, which indicates how the maximum sequence output size is specified.

- `Dialog parameter` configures the block to use the **Maximum output size** parameter setting as the maximum permitted output sequence length. When you make this selection, the **oSiz** input port specifies the current size of the output signal and the block output inherits sample time from the input signal. The input value of **oSiz** must be less than or equal to the **Maximum output size** parameter.
- `Inherit from reference port` adds the `Ref` input port and configures the block to inherit the sample time, maximum size, and the current output size from the variable-sized signal at the `Ref` input port to set the maximum permitted output sequence length.

Dependencies

To enable this parameter, select **Output variable-size signals**.

`Maximum output size` — Maximum output size

`[10 1]` (default) | two-element row vector

Maximum output size, specified as a two-element row vector that denotes the maximum output size for the block. The second element of the vector must be `1`.

Example: `[10 1]` gives a 10-by-1 maximum sized output signal.

Dependencies

To enable this parameter select **Output variable-size signals** and set **Maximum output size source** to `Dialog parameter`.

Data Types: `double`

`Sample time` — Output sample time

`1` (default) | -1 | positive scalar

Output sample time, specified as `-1` or a positive scalar that represents the time between each sample of the output signal. If **Sample time** is set to `-1`, the sample time is inherited from downstream. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-665.

Example: `1` specifies a sample time of 1 second.

Dependencies

To enable this parameter, clear **Output variable-size signals**.

Data Types: `double`

`Samples per frame` — Samples per frame

`1` (default) | positive integer

Samples per frame in one channel of the output signal, specified as a positive integer. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-665.

Dependencies

To enable this parameter, clear **Output variable-size signals**.

Data Types: `double`

`Reset on nonzero input` — Reset on nonzero input

off (default) | on

Select this parameter to add the `Rst` input port. For more information, see “Reset Behavior” on page 5-663.

`Enable bit-packed outputs` — Enable bit-packed outputs

off (default) | on

Select this parameter to make the **Number of packed bits** and **Interpret bit-packed values as signed** parameters available.

When this parameter is selected, the object outputs a column vector of length *M*, which contains most-significant-bit (MSB) first integer representations of bit words of length *P*. *M* is the number of samples per frame specified in the **Samples per frame** parameter. *P* is the size of the bit-packed words specified in the **Number of packed bits** parameter.

Note The first bit from the left in the bit-packed word contains the most significant bit for the integer representation.

`Number of packed bits` — Number of packed bits

8 (default) | integer in the range [1, 32]

Number of packed bits, specified as an integer in the range [1, 32].

Dependencies

To enable this parameter, select **Enable bit-packed outputs**.

Data Types: `double`

`Interpret bit-packed values as signed` — Interpret bit-packed values as signed

off (default) | on

Interpret bit-packed values as signed integer data values when selected or unsigned integer data values when cleared. When selected, a 1 in the most significant bit (sign bit) indicates a negative value.

Dependencies

To enable this parameter, select **Enable bit-packed outputs**.

`Output data type` — Output data type

`double` (default) | `boolean` | `Smallest unsigned integer`

Output data type, specified as `double`, `boolean`, or `Smallest unsigned integer`.

- When **Enable bit-packed outputs** is cleared, the output data type can be specified as a `double`, `boolean`, or `Smallest unsigned integer`. When the **Output data type** parameter is set to `Smallest unsigned integer`, the output data type is selected based on the settings used in the **Hardware Implementation** pane of the Configuration Parameters dialog box of the model. If `ASIC/FPGA` is selected in the **Hardware Implementation** pane, the output data type `ufix(1)` = ideal minimum one-bit size. For all other selections, it is an unsigned integer with the smallest available word length large enough to fit one bit, usually corresponding to the size of a char (for example, `uint8`).
- When **Enable bit-packed outputs** is selected, the output data type can be specified as `double` or `Smallest unsigned integer`. When the **Output data type** parameter is set to `Smallest unsigned integer`, the output data type is selected based on the **Interpret bit-packed values as signed** and **Number of packed bits** parameters, and the settings used in the **Hardware Implementation** pane of the Configuration Parameters dialog box of the model. If `ASIC/FPGA` is selected in the **Hardware Implementation** pane, the output data type is the ideal minimum *n*-bit size, such as `sfix(n)` or `ufix(n)`, based on the **Interpret bit-packed values as signed** parameter. For all other selections, it is a signed or unsigned integer with the smallest available word length large enough to fit *n* bits.

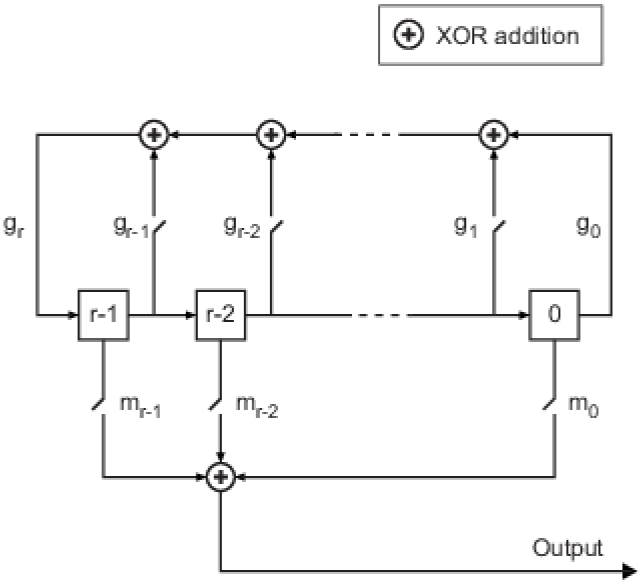
Block Characteristics

Data Types	`Boolean` | `double` | `fixed point`
Multidimensional Signals	`no`
Variable-Size Signals	`yes`

More About

Simple Shift Register Generator

A linear-feedback shift register (LFSR), implemented as a simple shift register generator (SSRG), is used to generate PN sequences. This type of shift register is also known as a Fibonacci implementation. For an example, see “Model PN Sequence Generation With Linear Feedback Shift Register”.



The **Generator Polynomial** parameter determines the feedback connections of the shift register. It is a primitive binary polynomial in z, $g_r z^r + g_{r-1} z^{r-1} + g_{r-2} z^{r-2} + \ldots + g_0$. For the coefficient, $g_{k=0 \text{ to } r}$, the coefficient g_k is 1 if there is a connection from the kth register to the adder. The leading term, g_r, and the constant term, g_0, of the **Generator Polynomial** parameter must be 1 because the polynomial must be primitive. The **Initial states** parameter specifies the initial values of the registers. For example, the following table indicates two sets of parameter values that correspond to a generator polynomial of $p(z) = z^8 + z^2 + 1$.

Quantity	Example 1	Example 2
Generator polynomial	`g1 = [1 0 0 0 0 0 1 0 1]`	`g2 = [8 2 0]`
Degree of generator polynomial	8, which is `length(g1)-1`	8
Initial states	`[1 0 0 0 0 0 1 0]`	`[1 0 0 0 0 0 1 0]`

At each time step, all *r* registers in the generator update their values according to the value of the incoming arrow to the shift register. The adders perform addition modulo 2. The output of the LFSR reflects the sum of all connections in the *m* mask vector.

The **Output mask vector (or scalar shift value)** parameter, *m*, determines the shift of the PN sequence starting point. For more information, see “Shifting PN Sequence Starting Point” on page 5-663.

Shifting PN Sequence Starting Point

To shift the starting point of the PN sequence, specify the **Output mask vector (or scalar shift value)** parameter as:

- An integer representing the length of the shift.

  The default **Output mask vector (or scalar shift value)** setting of 0 corresponds to no shift. As illustrated in the LFSR shift register diagram in “Simple Shift Register Generator” on page 5-662, there is no shift when the only connection is along the arrow labeled m_0.

  This table shows the shift that occurs when you set **Output mask vector (or scalar shift value)** to 0 versus a positive integer *d*.

	T = 0	**T = 1**	**T = 2**	**…**	**T = *d***	**T = *d*+1**
Shift = 0	x_0	x_1	x_2	…	x_d	x_{d+1}
Shift = *d*	x_d	x_{d+1}	x_{d+2}	…	x_{2d}	x_{2d+1}

- A binary vector whose length is equal to the degree of the generator polynomial. The LFSR shift register diagram in “Simple Shift Register Generator” on page 5-662 shows **Output mask vector (or scalar shift value)** specified as a mask vector, *m*. The binary vector must have *N* elements, where *N* is the degree of the generator polynomial. To calculate the mask vector, use the `shift2mask` function.

  The binary vector corresponds to a polynomial in *z*, $m_{r-1}z^{r-1} + m_{r-2}z^{r-2} + \dots + m_1z + m_0$, of degree at most r–1. The mask vector that correspond to a shift of *d* is the vector that represents $m(z) = z^d$ modulo $g(z)$, where $g(z)$ is the generator polynomial.

  For example, if the degree of the generator polynomial is 4, then the mask vector that corresponds to $d = 2$ is `[0 1 0 0]`, which represents the polynomial $m(z) = z^2$.

Reset Behavior

To reset the generator sequence, you must first select **Reset on nonzero input** to add the `Rst` input. Suppose that the PN Sequence Generator block outputs `[1 0 0 1 1 0 1 1]` when there is no reset. The following table shows the effect on the PN Sequence Generator block output for the property values indicated.

	Reset Signal Properties	PN Sequence Generator block	Reset Signal Output Signal
No reset	**Sample time** = 1 **Samples per frame** = 1 **Rst** = `[0 0 0 0 0 0 0 0]`	**Sample time** = 1 **Samples per frame** = 1 **Out** = `[1 0 0 1 1 0 1 1]`	 Rst 0 0 0 0 0 0 0 0 Out 1 0 0 1 1 0 1 1
Scalar reset signal	**Sample time** = 1 **Samples per frame** = 1 **Rst** = `[0 0 0 1 0 0 0 0]`	**Sample time** = 1 **Samples per frame** = 1	 Reset Rst 0 0 0 1 0 0 0 0 Out 1 0 0 1 0 0 1 1
Vector reset signal	**Sample time** = 1 **Samples per frame** = 8 **Rst** = `[0 0 0 1 0 0 0 0]`	**Sample time** = 1 **Samples per frame** = 8	

For the no reset case, the sequence is output without being reset. For the scalar and vector reset signal cases, the reset signal `[0 0 0 1 0 0 0 0]` is input to the `Rst` port. The sequence output is reset at the fourth bit, because the fourth bit of the reset signal is a 1 and the **Sample time** is 1.

For variable-sized outputs, the block only supports scalar reset signal inputs.

Sequences of Maximum Length

To generate a maximum length sequence for a generator polynomial that has the degree *r*, set **Generator polynomial** to a value from the following table. The maximum sequence length is $2^r - 1$.

r	Generator Polynomial	r	Generator Polynomial	r	Generator Polynomial	r	Generator Polynomial
2	`[2 1 0]`	15	`[15 14 0]`	28	`[28 25 0]`	41	`[41 3 0]`
3	`[3 2 0]`	16	`[16 15 13 4 0]`	29	`[29 27 0]`	42	`[42 23 22 1 0]`
4	`[4 3 0]`	17	`[17 14 0]`	30	`[30 29 28 7 0]`	43	`[43 6 4 3 0]`
5	`[5 3 0]`	18	`[18 11 0]`	31	`[31 28 0]`	44	`[44 6 5 2 0]`
6	`[6 5 0]`	19	`[19 18 17 14 0]`	32	`[32 31 30 10 0]`	45	`[45 4 3 1 0]`
7	`[7 6 0]`	20	`[20 17 0]`	33	`[33 20 0]`	46	`[46 21 10 1 0]`
8	`[8 6 5 4 0]`	21	`[21 19 0]`	34	`[34 15 14 1 0]`	47	[47 14 0]
9	`[9 5 0]`	22	`[22 21 0]`	35	`[35 2 0]`	48	[48 28 27 1 0]
10	`[10 7 0]`	23	`[23 18 0]`	36	`[36 11 0]`	49	[49 9 0]

r	Generator Polynomial	r	Generator Polynomial	r	Generator Polynomial	r	Generator Polynomial
11	[11 9 0]	24	[24 23 22 17 0]	37	[37 12 10 2 0]	50	[50 4 3 2 0]
12	[12 11 8 6 0]	25	[25 22 0]	38	[38 6 5 1 0]	51	[51 6 3 1 0]
13	[13 12 10 9 0]	26	[26 25 24 20 0]	39	[39 8 0]	52	[52 3 0]
14	[14 13 8 4 0]	27	[27 26 25 22 0]	40	[40 5 4 3 0]	53	[53 6 2 1 0]

For more information about the shift-register configurations that these polynomials represent, see *Digital Communications* by John Proakis.[1].

Sample Timing

The time between output updates is equal to the product of **Samples per frame** and **Sample time**. For example, if **Sample time** and **Samples per frame** equal one, the block outputs a sample every second. If **Samples per frame** is increased to 10, then a 10-by-1 vector is output every 10 seconds. This ensures that the equivalent output rate is not dependent on the **Samples per frame** parameter.

Compatibility Considerations

Existing models automatically update this block to current version

Behavior changed in R2020a

Starting in R2020a, Simulink no longer allows you to use the PN Sequence Generator block version available before R2015b.

Existing models automatically update to load the PN Sequence Generator block version announced in “Source blocks output frames of contiguous time samples but do not use the frame attribute” in the R2015b Release Notes. For more information on block forwarding, see “Forwarding Tables” (Simulink).

Extended Capabilities

C/C++ Code Generation

Generate C and C++ code using Simulink® Coder™.

HDL Code Generation

Generate Verilog and VHDL code for FPGA and ASIC designs using HDL Coder™.

HDL Coder provides additional configuration options that affect HDL implementation and synthesized logic.

HDL Architecture

This block has a single, default HDL architecture.

HDL Block Properties

ConstrainedOutputPipeline	Number of registers to place at the outputs by moving existing delays within your design. Distributed pipelining does not redistribute these registers. The default is `0`. For more details, see “ConstrainedOutputPipeline” (HDL Coder).
InputPipeline	Number of input pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see “InputPipeline” (HDL Coder).
OutputPipeline	Number of output pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see “OutputPipeline” (HDL Coder).

Restrictions

- You can select `Input port` as the **Output mask source** on the block. In this case, the `Mask` input signal must be a vector of data type `ufix1`.
- If you select **Reset on nonzero input**, the input to the `Rst` port must have data type `Boolean`.
- Outputs of type `double` are not supported for HDL code generation. All other output types (including bit-packed outputs) are supported.
- You cannot generate HDL for this block inside a Resettable Synchronous Subsystem.
- You cannot generate HDL for this block inside a Triggered Subsystem if the **Use trigger signal as clock** option is selected. See “Using Triggered Subsystems for HDL Code Generation” (HDL Coder).

Poisson Integer Generator

Generate Poisson-distributed random integers

Library

Random Data Sources sublibrary of Comm Sources

Description

The Poisson Integer Generator block generates random integers using a Poisson distribution. The probability of generating a nonnegative integer *k* is

$$\lambda^{k}\exp(-\lambda)/(k!)$$

where λ is a positive number known as the Poisson parameter.

You can use the Poisson Integer Generator to generate noise in a binary transmission channel. In this case, the Poisson parameter **Lambda** should be less than 1, usually much less.

Attributes of Output Signal

The output signal can be a column or row vector, a two-dimensional matrix, or a scalar. The number of rows in the output signal corresponds to the number of samples in one frame and is determined by the **Samples per frame** parameter. The number of columns in the output signal corresponds to the number of channels and is determined by the number of elements in the **Lambda** parameter. See "Sources and Sinks" in *Communications Toolbox User's Guide* for more details.

Parameters

Lambda

The Poisson parameter λ. Specify λ as a scalar or row vector whose elements are real numbers. If **Lambda** is a scalar, then every element in the output vector shares the same Poisson parameter. If **Lambda** is a row vector, then the number of elements correspond to the number of independent channels output from the block.

Source of initial seed

The source of the initial seed for the random number generator. Specify the source as either `Auto` or `Parameter`. When set to `Auto`, the block uses the global random number stream.

> **Note** When **Source of initial seed** is `Auto` in `Code generation` mode, the random number generator uses an initial seed of zero. Therefore, the block generates the same random numbers each time it is started. Use `Interpreted execution` to ensure that the model uses different initial seeds. If `Interpreted execution` is run in `Rapid accelerator` mode, then it behaves the same as `Code generation` mode.

Initial seed

The initial seed value for the random number generator. Specify the seed as a nonnegative integer scalar. **Initial seed** is available when the **Source of initial seed** parameter is set to `Parameter`.

Sample time

Output sample time, specified as `-1` or a positive scalar that represents the time between each sample of the output signal. If **Sample time** is set to `-1`, the sample time is inherited from downstream. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-668.

Samples per frame

Samples per frame, specified as a positive integer indicating the number of samples per frame in one channel of the output data. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-668.

Output data type

The output type of the block can be specified as a `boolean`, `uint8`, `uint16`, `uint32`, `single`, or `double`. The default is `double`.

Simulate using

Select the simulation mode.

`Code generation`

On the first model run, simulate and generate code. If the structure of the block does not change, subsequent model runs do not regenerate the code.

If the simulation mode is `Code generation`, System objects corresponding to the blocks accept a maximum of nine inputs.

`Interpreted execution`

Simulate model without generating code. This option results in faster start times but can slow subsequent simulation performance.

More About

Sample Timing

The time between output updates is equal to the product of **Samples per frame** and **Sample time**. For example, if **Sample time** and **Samples per frame** equal one, the block outputs a sample every second. If **Samples per frame** is increased to 10, then a 10-by-1 vector is output every 10 seconds. This ensures that the equivalent output rate is not dependent on the **Samples per frame** parameter.

Compatibility Considerations

Existing models automatically update this block to current version

Behavior changed in R2020a

Starting in R2020a, Simulink no longer allows you to use the Poisson Integer Generator block version available before R2015b.

- Existing models automatically update to load the Poisson Integer Generator block version announced in R2015b. For more information on block forwarding, see “Forwarding Tables” (Simulink).

- Behavior of the random number generator is changed. The statistics are improved. For more information, see “Source blocks output frames of contiguous time samples but do not use the frame attribute” in the R2015b Release Notes.

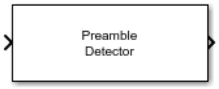
Preamble Detector

Detect preamble in data packet

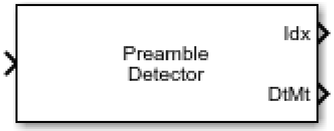
Library: Communications Toolbox / Synchronization



Description

The Preamble Detector block detects the end of preambles in data packets. A preamble is a set of symbols or bits used in packet-based communications systems to indicate the start of a packet. Packets consist of preamble data and user data. The length of the user data portion of the packet can vary during a simulation run.

This icon shows the block with all ports enabled:



Input/Output Ports

Input

In — Input data
scalar | column vector

Input data of symbols or bits, specified as a scalar or column vector. The input data can contain multiple packets. This port is unnamed on the block.

Data Types: `single` | `double` | `Boolean` | `int8` | `uint8`

Output

`Idx` — Index of last preamble symbol
scalar | column vector

Index of the last preamble symbol, returned as a scalar or column vector of the same size and data type as the input data.

- When the Detections parameter is set to `All`, `Idx` outputs the index corresponding to the last element of each detected preamble.
- When the Detections parameter is set to `First`, `Idx` outputs the index corresponding to the last element of the first detected preamble.

This port is unnamed until the `DtMt` port is enabled.

`DtMt` — Detection metric
scalar | column vector

Detection metric, returned as a scalar or column vector of the same size and data type as the input data packet.

- If either the preamble or input data is complex, the detection metric is the absolute value of the cross-correlation of the preamble and the input data.
- If both the preamble and input data are real, the detection metric is the cross-correlation of the preamble and the input data.

Dependencies

To enable this port, set the Input parameter to `Symbol`, and select the Output detection metric parameter.

Parameters

`Input` — Input type

`Symbol` (default) | `Bit`

Input type, specified as `Symbol` or `Bit`.

- For binary inputs, set this parameter to `Bit`.
- For all other inputs, set this parameter to `Symbol`.

For information on execution speed, see “Tips” on page 5-672.

`Preamble` — Preamble sequence

`[1 + 1i; 1 - 1i]` (default) | column vector

Preamble sequence, specified as a column vector.

- If the **Input** parameter is set to `Bit`, the preamble must be binary.
- If the **Input** parameter is set to `Symbol`, the preamble can be any real or complex sequence.

`Detection threshold` — Detection threshold

3 (default) | nonnegative scalar

Detection threshold, specified as a nonnegative scalar. When the detection metric is greater than or equal to the threshold, the block detects the preamble and updates `Idx`.

Tunable: Yes

Dependencies

To enable this parameter, set the Input parameter to `Symbol`.

`Output detection metric` — Option to output detection metric

`off` (default) | `on`

Select this parameter to output the detection metric and enable the `DtMt` output port.

Dependencies

To enable this parameter, set the Input parameter to `Symbol`.

`Detections` — Detections returned

`All` (default) | `First`

Detections returned, specified as `All` or `First`. Specifying `All` returns all detected preambles. Specifying `First` returns only the first detected preamble.

Tunable: Yes

`Simulate using` — Type of simulation to run
`Code generation` (default) | `Interpreted execution`

Type of simulation to run, specified as:

- `Code generation` -- Simulate the model using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations as long as the model does not change. This option requires additional startup time.
- `Interpreted execution` -- Simulate the model using the MATLAB interpreter. This option shortens startup time. In `Interpreted execution` mode, you can debug the source code of the block.

For information on execution speed, see “Tips” on page 5-672.

Block Characteristics

Data Types	`Boolean` | `double` | `integer` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`yes`

Tips

- For faster execution of the Preamble Detector block, set the Simulate using parameter to:
  - `Code generation` when the Input parameter is set to `Symbol`
  - `Interpreted execution` when the Input parameter is set to `Bit`

Algorithms

Bit Inputs

When the input data is composed of bits, the preamble detector uses an exact pattern match.

Symbol Inputs

When the input data is composed of symbols, the preamble detector uses a cross-correlation algorithm. A finite impulse response (FIR) filter, in which the coefficients are specified from the preamble, computes the cross-correlation between the input data and the preamble. When a sequence of input samples match the preamble, the filter output reaches its peak. The index of the peak corresponds to the end of the preamble sequence in the input data. See Discrete FIR Filter for further information on the FIR filter algorithm.

The cross-correlation values that are greater than or equal to the specified threshold are reported as peaks.

- If the detection threshold is too low, the algorithm will detect false peaks, or, in the extreme case, detect as many detected peaks as there are input samples.
- If the detection threshold is too high, the algorithm will miss detecting peaks, or, in the extreme case, detect no peaks.

Consequently, the selection of the detection threshold is critical.

Objects

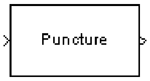
`comm.PreambleDetector`

Introduced in R2016b

Puncture

Output elements that correspond to 1s in binary puncture vector

Library: Communications Toolbox / Sequence Operations



Description

The Puncture block creates an output vector by removing selected elements of the input vector and preserving others. The block determines which elements to remove and preserve by using the binary **Puncture vector** parameter. The block repeats the puncturing pattern, as necessary, to include all input elements. The preserved elements appear in the output vector in the same order in which they appear in the input vector.

Ports

Input

`In` — Input signal

column vector

Input signal, specified as a column vector. The input length must be an integer multiple of the **Puncture vector** parameter length.

Data Types: `double` | `single`

Output

`Out` — Output signal

column vector

Output signal, returned as a column vector. The length of the output vector is an integer multiple of the number of 1s in the **Puncture vector** parameter. The output signal contains only elements from the input signal that align with integer multiples of the element location of 1s in the **Puncture vector**.

Parameters

`Puncture vector` — Puncture pattern

`[1 1 0 1 0 1]'` (default) | column vector of binary values

Puncture pattern, specified as a column vector of binary values. The input signal length must be an integer multiple of the **Puncture vector** parameter length. The block repeats the puncturing pattern, as necessary, to include all input elements.

- The element locations of 0s in **Puncture vector** indicate which elements are removed from the input signal to construct the output signal.

- The element locations of 1s in **Puncture vector** indicate which elements are preserved from the input signal to construct the output signal.

QPSK Demodulator Baseband

Demodulate QPSK-modulated data

Library

PM, in Digital Baseband sublibrary of Modulation

Description

The QPSK Demodulator Baseband block demodulates a signal that was modulated using the quadrature phase shift keying method. The input is a baseband representation of the modulated signal.

The input must be a complex signal. This block accepts a scalar or column vector input signal. For information about the data types each block port supports, see “Supported Data Types” on page 5-682.

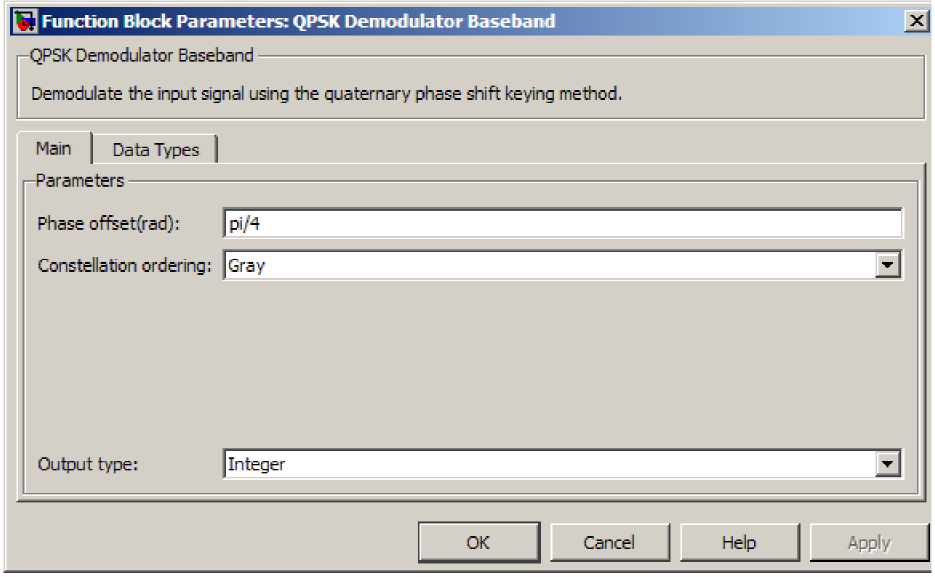
Dialog Box



Function Block Parameters: QPSK Demodulator Baseband

QPSK Demodulator Baseband

Demodulate the input signal using the quaternary phase shift keying method.

Main | Data Types

Parameters

Phase offset(rad): pi/4

Constellation ordering: Gray

Output type: Integer

Phase offset (rad)

The phase of the zeroth point of the signal constellation.

Constellation ordering

Determines how the block maps each integer to a pair of output bits.

Output type

Determines whether the output consists of integers or bits.

If the **Output type** parameter is set to `Integer` and **Constellation ordering** is set to `Binary`, then the block maps the point

$\exp(j\theta + j\pi m/2)$

to m, where θ is the **Phase offset** parameter and m is 0, 1, 2, or 3.

The reference page for the QPSK Modulator Baseband block shows the signal constellations for the cases when **Constellation ordering** is set to either `Binary` or `Gray`.

If the **Output type** is set to `Bit`, then the output contains pairs of binary values if **Decision type** is set to `Hard decision`. The most significant bit (i.e. the left-most bit in the vector), is the first bit the block outputs.

If the **Decision type** is set to `Log-likelihood ratio` or `Approximate log-likelihood ratio`, then the output contains bitwise LLR or approximate LLR values, respectively.

Decision type

Specifies the use of hard decision, LLR, or approximate LLR during demodulation. This parameter appears when you select `Bit` from the **Output type** drop-down list. The output values for Log-likelihood ratio and Approximate log-likelihood ratio decision types are of the same data type as the input values. For integer output, the block always performs Hard decision demodulation.

See “Exact LLR Algorithm” and “Approximate LLR Algorithm” for algorithm details.

Noise variance source

This field appears when `Approximate log-likelihood ratio` or `Log-likelihood ratio` is selected for **Decision type**.

When set to `Dialog`, the noise variance can be specified in the **Noise variance** field. When set to `Port`, a port appears on the block through which the noise variance can be input.

Noise variance

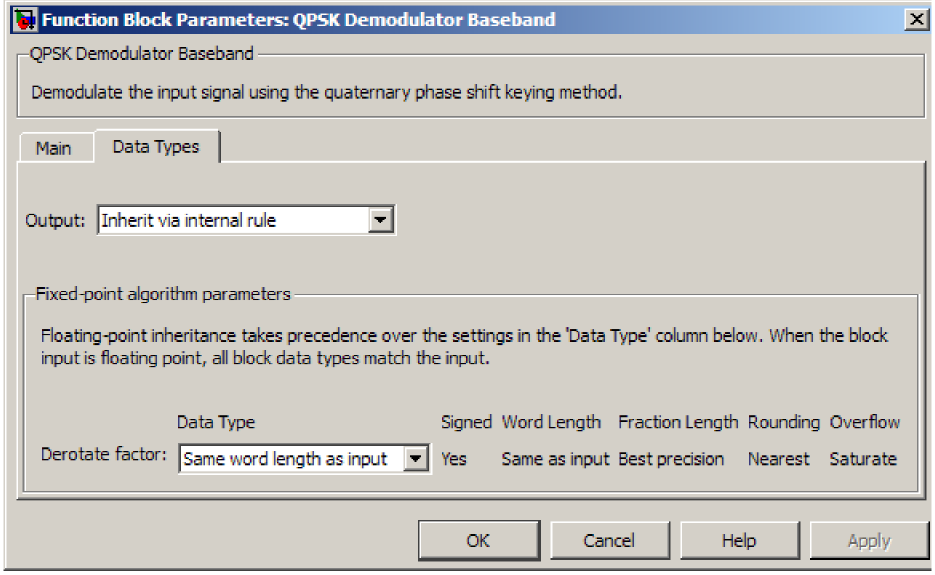
This parameter appears when the **Noise variance source** is set to `Dialog` and specifies the noise variance in the input signal. This parameter is tunable in normal mode, Accelerator mode and Rapid Accelerator mode.

If you use the Simulink Coder rapid simulation (RSIM) target to build an RSIM executable, then you can tune the parameter without recompiling the model. This is useful for Monte Carlo simulations in which you run the simulation multiple times (perhaps on multiple computers) with different amounts of noise.

The LLR algorithm involves computing exponentials of very large or very small numbers using finite precision arithmetic and would yield:

- `Inf` to `-Inf` if **Noise variance** is very high
- `NaN` if **Noise variance** and signal power are both very small

In such cases, use approximate LLR, as its algorithm does not involve computing exponentials.



Function Block Parameters: QPSK Demodulator Baseband

QPSK Demodulator Baseband

Demodulate the input signal using the quaternary phase shift keying method.

Output: Inherit via internal rule

Fixed-point algorithm parameters

Floating-point inheritance takes precedence over the settings in the 'Data Type' column below. When the block input is floating point, all block data types match the input.

	Data Type	Signed	Word Length	Fraction Length	Rounding	Overflow
Derotate factor:	Same word length as input	Yes	Same as input	Best precision	Nearest	Saturate

Data Types Pane for Hard-Decision

Output

For bit outputs, when **Decision type** is set to `Hard decision`, the output data type can be set to `'Inherit via internal rule'`, `'Smallest unsigned integer'`, `double`, `single`, `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, or `boolean`.

For integer outputs, the output data type can be set to `'Inherit via internal rule'`, `'Smallest unsigned integer'`, `double`, `single`, `int8`, `uint8`, `int16`, `uint16`, `int32`, or `uint32`.

When this parameter is set to `'Inherit via internal rule'` (default setting), the block will inherit the output data type from the input port. The output data type will be the same as the input data type if the input is a floating-point type (`single` or `double`). If the input data type is fixed-point, the output data type will work as if this parameter is set to `'Smallest unsigned integer'`.

When this parameter is set to `'Smallest unsigned integer'`, the output data type is selected based on the settings used in the **Hardware Implementation** pane of the Configuration Parameters dialog box of the model.

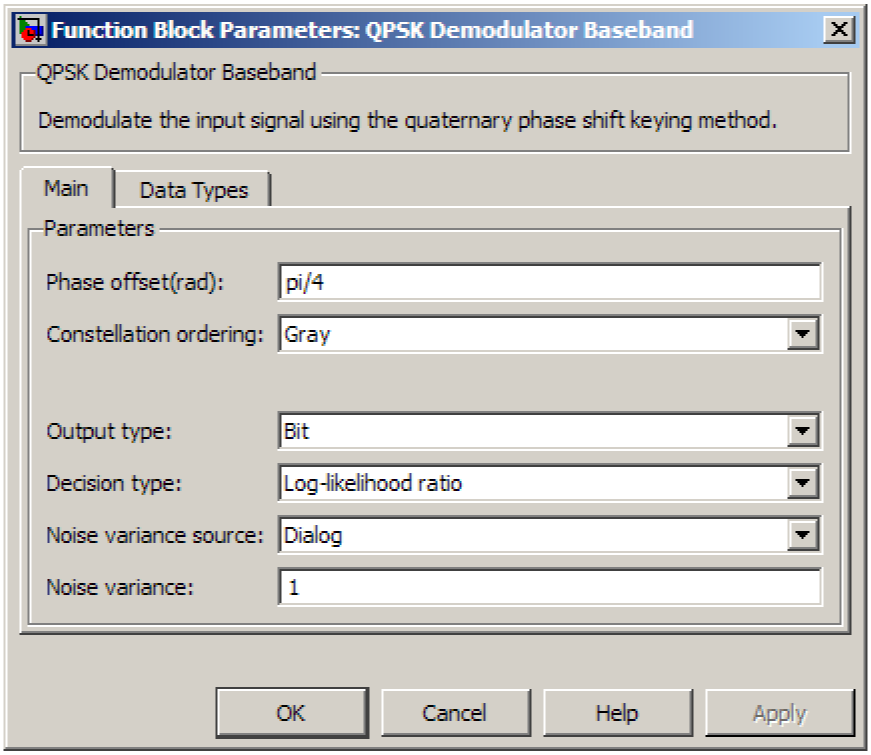
If `ASIC/FPGA` is selected in the **Hardware Implementation** pane, and **Output type** is `Bit`, the output data type is the ideal minimum one-bit size, i.e., `ufix(1)`. For all other selections, it is an unsigned integer with the smallest available word length large enough to fit one bit, usually corresponding to the size of a char (e.g., `uint8`).

If `ASIC/FPGA` is selected in the **Hardware Implementation** pane, and **Output type** is `Integer`, the output data type is the ideal minimum two-bit size, i.e., `ufix(2)`. For all other selections, it is an unsigned integer with the smallest available word length large enough to fit two bits, usually corresponding to the size of a char (e.g., `uint8`).

Derotate factor

This parameter only applies when the input is fixed-point and **Phase offset** is not an even multiple of π/4.

You can select `Same word length as input` or `Specify word length`, in which case you define the word length using an input field.



Function Block Parameters: QPSK Demodulator Baseband

QPSK Demodulator Baseband

Demodulate the input signal using the quaternary phase shift keying method.

Main | Data Types

Parameters

Phase offset(rad): pi/4

Constellation ordering: Gray

Output type: Bit

Decision type: Log-likelihood ratio

Noise variance source: Dialog

Noise variance: 1

Data Types Pane for Soft-Decision

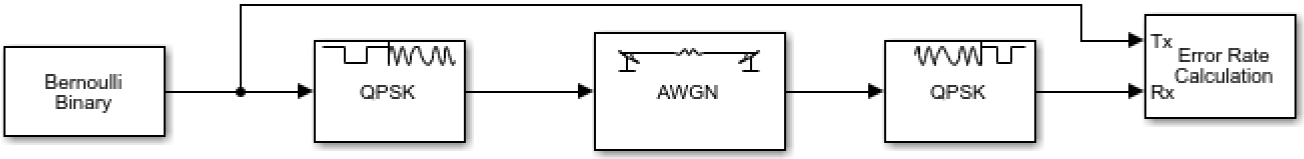
For bit outputs, when **Decision type** is set to `Log-likelihood ratio` or `Approximate log-likelihood ratio`, the output data type is inherited from the input (e.g., if the input is of data type `double`, the output is also of data type `double`).

Examples

Demodulate Noisy QPSK Signal

Modulate and demodulate a noisy QPSK signal.

Open the QPSK demodulation model.



Run the simulation. The results are saved to the base workspace, where the variable `ErrorVec` is a 1-by-3 row vector. The BER is found in the first element.

Display the error statistics. For the Eb/No provided, 4.3 dB, the resultant BER is approximately 0.01. Your results may vary slightly.

```
ans =

    0.0112
```

Increase the Eb/No to 7 dB. Rerun the simulation, and observe that the BER has decreased.

```
ans =

   1.0000e-03
```

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point • Signed fixed-point when: • **Output type** is `Integer` • **Output type** is `Bit` and **Decision type** is `Hard-decision`
Var	• Double-precision floating point • Single-precision floating point

Port	Supported Data Types
Output	• Double-precision floating point • Single-precision floating point • Boolean when **Output type** is `Bit` and **Decision type** is `Hard-decision` • 8-, 16-, 32- bit signed integers • 8-, 16-, 32- bit unsigned integers • ufix(1) in ASIC/FPGA when **Output type** is `Bit` • ufix(2) in ASIC/FPGA when **Output type** is `Integer`

QPSK Modulator Baseband

Modulate using quadrature phase shift keying method

Library

PM in Digital Baseband sublibrary of Modulation

Description

The QPSK Modulator Baseband block modulates using the quadrature phase shift keying method. The output is a baseband representation of the modulated signal.

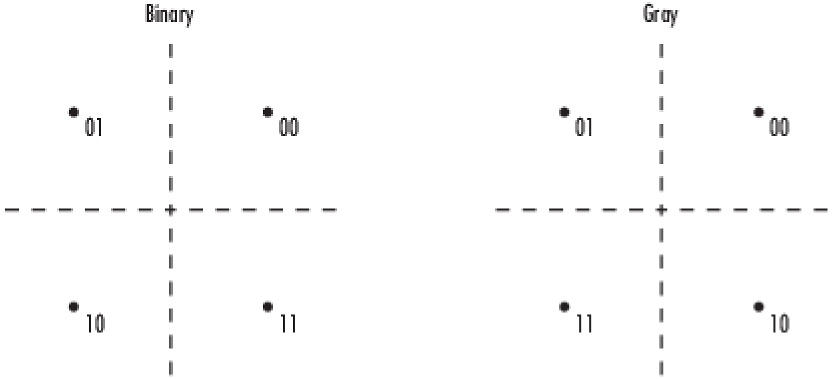
Integer-Valued Signals and Binary-Valued Signals

If you set the **Input type** parameter to `Integer`, then valid input values are 0, 1, 2, and 3. When you set **Constellation ordering** to `Binary` for input *m* the output symbol is

$\exp(j\theta + j\pi m/2)$

where θ represents the **Phase offset** parameter (see the following figure for Gray constellation ordering). In this case, the block accepts a scalar or column vector signal.

If you set the **Input type** parameter to `Bit`, then the input contains pairs of binary values. For this configuration, the block accepts column vectors with even lengths. When you set the **Phase offset** parameter to $\frac{\Pi}{4}$, then the block uses one of the signal constellations in the following figure, depending on whether you set the **Constellation ordering** parameter to `Binary` or `Gray`.

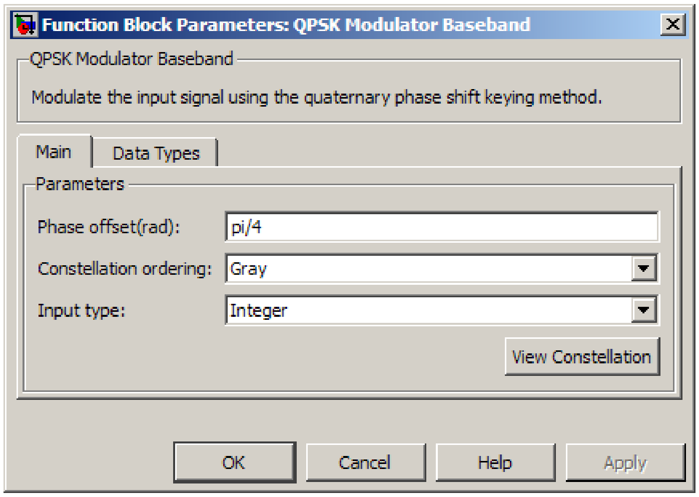


In the previous figure, the most significant bit (i.e. the left-most bit), is the first bit input to the block. For additional information about Gray mapping, see the M-PSK Modulator Baseband help page.

Constellation Visualization

The QPSK Modulator Baseband block provides the capability to visualize a signal constellation from the block mask. This Constellation Visualization feature allows you to visualize a signal constellation for specific block parameters. For more information, see the Constellation Visualization section of the *Communications Toolbox User's Guide*.

Dialog Box



Function Block Parameters: QPSK Modulator Baseband

QPSK Modulator Baseband

Modulate the input signal using the quaternary phase shift keying method.

Parameters

Phase offset(rad): pi/4

Constellation ordering: Gray

Input type: Integer

Phase offset (rad)

The phase of the zeroth point of the signal constellation.

Constellation ordering

Determines how the block maps each pair of input bits or input integers to constellation symbols.

Input type

Indicates whether the input consists of integers or pairs of bits.

Output data type

The output data type can be set to `double`, `single`, `Fixed-point`, `User-defined`, or `Inherit via back propagation`.

Setting this parameter to `Fixed-point` or `User-defined` enables fields in which you can further specify details. Setting this parameter to `Inherit via back propagation`, sets the output data type and scaling to match the following block.

Output word length

Specify the word length, in bits, of the fixed-point output data type. This parameter is only visible when you select `Fixed-point` for the **Output data type** parameter.

Set output fraction length to

Specify the scaling of the fixed-point output by either of the following methods:

- Choose `Best precision` to have the output scaling automatically set such that the output signal has the best possible precision.
- Choose `User-defined` to specify the output scaling in the **Output fraction length** parameter.

This parameter is only visible when you select `Fixed-point` for the **Output data type** parameter or when you select `User-defined` and the specified output data type is a fixed-point data type.

User-defined data type

Specify any signed built-in or signed fixed-point data type. You can specify fixed-point data types using the `sfix`, `sint`, `sfrac`, and `fixdt` functions from Fixed-Point Designer. This parameter is only visible when you select `User-defined` for the **Output data type** parameter.

Output fraction length

For fixed-point output data types, specify the number of fractional bits or bits to the right of the binary point. This parameter is only visible when you select `Fixed-point` or `User-defined` for the **Output data type** parameter and `User-defined` for the **Set output fraction length to** parameter.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point • Boolean when **Input type** is `Bit` • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers • ufix(1) when **Input type** is `Bit` • ufix(2) when **Input type** is `Integer`
Output	• Double-precision floating point • Single-precision floating point • Signed fixed point

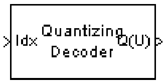
Quantizing Decoder

Decode quantization index according to codebook



Library

Source Coding

Description

The Quantizing Decoder block converts quantization indices to the corresponding codebook values. The **Quantization codebook** parameter, a vector of length N, prescribes the possible output values. If the input is an integer k between 0 and N-1, then the output is the (k+1)st element of **Quantization codebook**.

The input must be a discrete-time signal. This block processes each vector element independently. For information about the data types each block port supports, see the “Supported Data Type” on page 5-689 table on this page.

Note The Quantizing Encoder block also uses a **Quantization codebook** parameter. The first output of that block corresponds to the input of Quantizing Decoder, while the second output of that block corresponds to the output of Quantizing Decoder.

Parameters

Quantization codebook

A real vector that prescribes the output value corresponding to each nonnegative integer of the input.

Quantized output data type

Select the output data type.

Supported Data Type

Port	Supported Data Types
Idx	• Double-precision floating point • Single-precision floating point • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers

Port	Supported Data Types

Quantizing Encoder

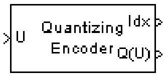
Quantize signal using partition and codebook



Library

Source Coding

Description

The Quantizing Encoder block quantizes the input signal according to the **Partition** vector and encodes the input signal according to the **Codebook** vector. This block processes each vector element independently. The input must be a discrete-time signal. This block processes each vector element independently. For information about the data types each block port supports, see the “Supported Data Type” on page 5-692 table on this page.

The first output is the quantization index. The second output is the quantized signal. The values for the quantized signal are taken from the **Codebook** vector.

The **Quantization partition** parameter, *P*, is a real vector of length n whose entries are in strictly ascending order. The quantization index (second output signal value) corresponding to an input value of *x* is

- 0 if $x \leq P(1)$
- m if $P(\mathrm{m}) < x \leq P(\mathrm{m}+1)$
- n if $P(\mathrm{n}) < x$

The **Quantization codebook** parameter, whose length is n+1, prescribes a value for each partition in the quantization. The first element of **Quantization codebook** is the value for the interval between negative infinity and the first element of *P*. The second output signal from this block contains the quantization of the input signal based on the quantization indices and prescribed values.

Use the `lloyds` function with a representative sample of your data as training data, to obtain appropriate partition and codebook parameters.

Parameters

Quantization partition

The vector of endpoints of the partition intervals.

Quantization codebook

The vector of output values assigned to each partition.

Index output data type

Select the output data type.

Supported Data Type

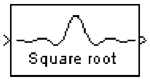
Raised Cosine Receive Filter

Apply pulse shaping by downsampling signal using raised cosine FIR filter



Library

Comm Filters

Description

The Raised Cosine Receive Filter block filters the input signal using a normal raised cosine FIR filter or a square root raised cosine FIR filter. It also downsamples the filtered signal if you set the **Output mode** parameter to `Downsampling`. The FIR Decimation block implements this functionality. The Raised Cosine Receive Filter block's icon shows the filter's impulse response.

Characteristics of the Filter

Characteristics of the raised cosine filter are the same as in the Raised Cosine Transmit Filter block, except that the length of the filter's input response has a slightly different expression: *L* * **Filter span in symbols** + 1, where *L* is the value of the **Input samples per symbol** parameter (not the **Output samples per symbol** parameter, as in the case of the Raised Cosine Transmit Filter block).

The block normalizes the filter coefficients to unit energy. If you specify a **Linear amplitude filter gain** other than `1`, then the block scales the normalized filter coefficients using the gain value you specify.

Decimating the Filtered Signal

To have the block decimate the filtered signal, set the **Decimation factor** parameter to a value greater than `1`.

If `K` represents the **Decimation factor** parameter value, then the block retains 1/*K* of the samples, choosing them as follows:

- If the **Decimation offset** parameter is zero, then the block selects the samples of the filtered signal indexed by 1, *K*+1, 2**K*+1, 3**K*+1, etc.
- If the **Decimation offset** parameter is a positive integer less than M, then the block initially discards that number of samples from the filtered signal and downsamples the remaining data as in the previous case.

To preserve the entire filtered signal and avoid decimation, set **Decimation factor** to `1`. This setting is appropriate, for example, when the output from the filter block forms the input to a timing phase recovery block such as Symbol Synchronizer. The timing phase recovery block performs the downsampling in that case.

Input Signals and Output Signals

This block accepts a column vector or matrix input signal. For information about the data types each block port supports, see the “Supported Data Type” on page 5-697 table on this page.

If you set **Decimation factor** to `1`, then the input and output signals share the same sampling mode, sample time, and vector length.

If you set **Decimation factor** to *K*, which is greater than `1`, then *K* and the input sampling mode determine characteristics of the output signal:

Single-Rate Processing

When you set the **Rate options** parameter to `Enforce single-rate processing`, the input and output of the block have the same sample rate. To generate the output while maintaining the input sample rate, the block resamples the data in each column of the input such that the frame size of the output (M_o) is $1/K$ times that of the input ($M_o = M_i/K$), In this mode, the input frame size, M_i, must be a multiple of *K*.

Multirate Processing

When you set the **Rate options** parameter to `Allow multirate processing`, the input and output of the block are the same size, but the sample rate of the output is *K* times slower than that of the input. When the block is in multirate processing mode, you must also specify a value for the **Input processing** parameter:

- When you set the **Input processing** parameter to `Elements as channels (sample based)`, the block treats an *M*-by-*N* matrix input as *M*N* independent channels, and processes each channel over time. The output sample period (T_{so}) is *K* times longer than the input sample period ($T_{so} = K*T_{si}$), and the input and output sizes are identical.
- When you set the **Input processing** parameter to `Columns as channels (frame based)`, the block treats an M_i-by-*N* matrix input as *N* independent channels. The block processes each column of the input over time by keeping the frame size constant (M_i=M_o), and making the output frame period (T_{fo}) *K* times longer than the input frame period ($T_{fo} = K*T_{fi}$).

Exporting Filter Coefficients to the MATLAB Workspace

To examine or manipulate the coefficients of the filter that this block designs, select **Export filter coefficients to workspace**. Then set the **Coefficient variable name** parameter to the name of a variable that you want the block to create in the MATLAB workspace. Running the simulation causes the block to create the variable, overwriting any previous contents in case the variable already exists.

Latency

For information pertaining to the latency of the block, see details in FIR Decimation.

Parameters

Filter shape

Specify the filter shape as `Square root` or `Normal`.

Rolloff factor

Specify the rolloff factor of the filter. Use a real number between `0` and `1`.

Filter span in symbols

Specify the number of symbols the filter spans as an even, integer-valued positive scalar. The default is `10`. Because the ideal raised cosine filter has an infinite impulse response, the block truncates the impulse response to the number of symbols that this parameter specifies.

Input samples per symbol

An integer greater than 1 representing the number of samples that represent one symbol in the input signal.

Decimation factor

Specify the decimation factor the block applies to the input signal. The output samples per symbol equals the value of the input samples per symbol divided by the decimation factor. If the decimation factor is one, then the block only applies filtering. There is no decimation.

Decimation offset

Specify the decimation offset in samples. Use a value between `0` and **Decimation factor** `-1`.

Linear amplitude filter gain

Specify a positive scalar value that the block uses to scale the filter coefficients. By default, the block normalizes filter coefficients to provide unit energy gain. If you specify a gain other than `1`, the block scales the normalized filter coefficients using the gain value you specify.

Input processing

Specify how the block processes the input signal. You can set this parameter to one of the following options:

- `Columns as channels (frame based)` — When you select this option, the block treats each column of the input as a separate channel.
- `Elements as channels (sample based)` — When you select this option, the block treats each element of the input as a separate channel.

Rate options

Specify the method by which the block should filter and downsample the input signal. You can select one of the following options:

- `Enforce single-rate processing` — When you select this option, the block maintains the input sample rate and processes the signal by decreasing the output frame size by a factor of *K*. To select this option, you must set the **Input processing** parameter to `Columns as channels (frame based)`.
- `Allow multirate processing` — When you select this option, the block processes the signal such that the output sample rate is *K* times slower than the input sample rate.

Export filter coefficients to workspace

Select this check box to create a variable in the MATLAB workspace that contains the filter coefficients.

Coefficient variable name

The name of the variable to create in the MATLAB workspace. This field appears only if **Export filter coefficients to workspace** is selected.

Visualize filter with FVTool

If you click this button, then MATLAB launches the Filter Visualization Tool, `fvtool`, to analyze the raised cosine filter whenever you apply any changes to the block's parameters. If you launch `fvtool` for the filter, and subsequently change parameters in the mask, `fvtool` will not update.

You will need to launch a new `fvtool` in order to see the new filter characteristics. Also note that if you have launched `fvtool`, then it will remain open even after the model is closed.

Rounding mode

Select the rounding mode for fixed-point operations. The block uses the **Rounding mode** when the result of a fixed-point calculation does not map exactly to a number representable by the data type and scaling storing the result. The filter coefficients do not obey this parameter; they always round to `Nearest`. For more information, see Rounding Modes or "Rounding Mode: Simplest" (Fixed-Point Designer).

Saturate on integer overflow

Select the overflow mode for fixed-point operations. The filter coefficients do not obey this parameter; they are always saturated.

Coefficients

Choose how you specify the word length and the fraction length of the filter coefficients (numerator and/or denominator).

See the Coefficients section of the FIR Decimation help page and "Filter Structure Diagrams" for illustrations depicting the use of the coefficient data types in this block:

See the Coefficients subsection of the Digital Filter help page for descriptions of parameter settings.

- When you select `Same word length as input`, the word length of the filter coefficients match that of the input to the block. In this mode, the fraction length of the coefficients is automatically set to the binary-point only scaling that provides you with the best precision possible given the value and word length of the coefficients.
- When you select `Specify word length`, you are able to enter the word length of the coefficients, in bits. In this mode, the fraction length of the coefficients is automatically set to the binary-point only scaling that provides you with the best precision possible given the value and word length of the coefficients.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the coefficients, in bits. If applicable, you are able to enter separate fraction lengths for the numerator and denominator coefficients.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the coefficients. If applicable, you are able to enter separate slopes for the numerator and denominator coefficients. This block requires power-of-two slope and a bias of zero.
- The filter coefficients do not obey the **Rounding mode** and the **Saturate on integer overflow** parameters; they are always saturated and rounded to `Nearest`.

Product output

Use this parameter to specify how you would like to designate the product output word and fraction lengths. See "Filter Structure Diagrams" and "Multiplication Data Types" for illustrations depicting the use of the product output data type in this block:

- When you select `Same as input`, these characteristics match those of the input to the block.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the product output, in bits.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the product output. This block requires power-of-two slope and a bias of zero.

Accumulator

Use this parameter to specify how you would like to designate the accumulator word and fraction lengths. See “Filter Structure Diagrams” and “Multiplication Data Types” for illustrations depicting the use of the accumulator data type in this block:

- When you select `Same as input`, these characteristics match those of the input to the block.
- When you select `Same as product output`, these characteristics match those of the product output.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the accumulator, in bits.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the accumulator. This block requires power-of-two slope and a bias of zero.

Output

Choose how you specify the output word length and fraction length:

- When you select `Same as input`, these characteristics match those of the input to the block.
- When you select `Same as accumulator`, these characteristics match those of the accumulator.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the output, in bits.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the output. This block requires power-of-two slope and a bias of zero.

Lock data type settings against changes by the fixed-point tools

Select this parameter to prevent any fixed-point scaling you specify in this block mask from being overridden by the autoscaling tool in the Fixed-Point Tool.

Supported Data Type

Port	Supported Data Types
In	• Double-precision floating point • Single-precision floating point • Signed fixed-point
Out	• Double-precision floating point • Single-precision floating point • Signed fixed-point

Raised Cosine Transmit Filter

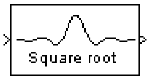
Apply pulse shaping by upsampling signal using raised cosine FIR filter



Library

Comm Filters

Description

The Raised Cosine Transmit Filter block upsamples and filters the input signal using a normal raised cosine FIR filter or a square root raised cosine FIR filter. The block's icon shows the filter's impulse response.

Characteristics of the Filter

The **Filter shape** parameter determines which type of filter the block uses; choices are `Normal` and `Square root`.

The impulse response of a normal raised cosine filter with rolloff factor R and symbol period T is

$$h(t) = \frac{\sin(\pi t/T)}{(\pi t/T)} \cdot \frac{\cos(\pi R t/T)}{(1 - 4R^2 t^2/T^2)}$$

The impulse response of a square root raised cosine filter with rolloff factor R is

$$h(t) = 4R\frac{\cos((1+R)\pi t/T) + \frac{\sin((1-R)\pi t/T)}{(4Rt/T)}}{\pi\sqrt{T}\left(1 - (4Rt/T)^2\right)}$$

The impulse response of a square root raised cosine filter convolved with itself is approximately equal to the impulse response of a normal raised cosine filter.

Because the ideal raised cosine filter has an infinite impulse response, the block truncates the impulse response to the number of symbols that the **Filter span in symbols** parameter specifies. The **Filter span in symbols**, N, and the **Output samples per symbol**, L, determine the length of the filter's impulse response, which is *L* * **Filter span in symbols** + 1.

The **Rolloff factor** parameter is the filter's rolloff factor. It must be a real number between 0 and 1. The rolloff factor determines the excess bandwidth of the filter. For example, a rolloff factor of .5 means that the bandwidth of the filter is 1.5 times the input sampling frequency.

The block normalizes the filter coefficients to unit energy. If you specify a **Linear amplitude filter gain** other than `1`, then the block scales the normalized filter coefficients using the gain value you specify.

Input Signals and Output Signals

The input must be a discrete-time signal. This block accepts a column vector or matrix input signal. For information about the data types each block port supports, see the "Supported Data Type" on page 5-703 table on this page.

The **Rate options** method and the value of the **Output samples per symbol**, *L*, parameter determine the characteristics of the output signal:

Single-Rate Processing

When you set the **Rate options** parameter to `Enforce single-rate processing`, the input and output of the block have the same sample rate. To generate the output while maintaining the input sample rate, the block resamples the data in each column of the input such that the frame size of the output (M_o) is *L* times larger than that of the input ($M_o = M_i*L$), where *L* represents the value of the **Output samples per symbol** parameter.

Multirate Processing

When you set the **Rate options** parameter to `Allow multirate processing`, the input and output of the block are the same size. However, the sample rate of the output is *L* times faster than that of the input (i.e. the output sample time is 1/L times the input sample time). When the block is in multirate processing mode, you must also specify a value for the **Input processing** parameter:

- When you set the **Input processing** parameter to `Elements as channels (sample based)`, the block treats an *M*-by-*L* matrix input as *M**N* independent channels, and processes each channel over time. The output sample period (T_{so}) is *L* times shorter than the input sample period ($T_{so} = T_{si}/L$), while the input and output sizes remain identical.
- When you set the **Input processing** parameter to `Columns as channels (frame based)`, the block treats an M_i-by-*N* matrix input as *N* independent channels. The block processes each column of the input over time by keeping the frame size constant ($M_i=M_o$), while making the output frame period (T_{fo}) *L* times shorter than the input frame period ($T_{fo} = T_{fi}/L$).

Exporting Filter Coefficients to the MATLAB Workspace

To examine or manipulate the coefficients of the filter that this block designs, select **Export filter coefficients to workspace**. Then set the **Coefficient variable name** parameter to the name of a variable that you want the block to create in the MATLAB workspace. Running the simulation causes the block to create the variable, overwriting any previous contents in case the variable already exists.

Parameters

Filter shape

Specify the filter shape as `Square root` or `Normal`.

Rolloff factor

Specify the rolloff factor of the filter. Use a real number between `0` and `1`.

Filter span in symbols

Specify the number of symbols the filter spans as an even, integer-valued positive scalar. The default is `10`. Because the ideal raised cosine filter has an infinite impulse response, the block truncates the impulse response to the number of symbols that this parameter specifies.

Output samples per symbol

Specify the number of output samples for each input symbol. The default is 8. This property accepts an integer-valued, positive scalar. The number of taps for the raised cosine filter equals the value of this parameter multiplied by the value of the **Filter span in symbols** parameter.

Linear amplitude filter gain

Specify a positive scalar value that the block uses to scale the filter coefficients. By default, the block normalizes filter coefficients to provide unit energy gain. If you specify a gain other than `1`, the block scales the normalized filter coefficients using the gain value you specify.

Input processing

Specify how the block processes the input signal. You can set this parameter to one of the following options:

- `Columns as channels (frame based)` — When you select this option, the block treats each column of the input as a separate channel.
- `Elements as channels (sample based)` — When you select this option, the block treats each element of the input as a separate channel.

Rate options

Specify the method by which the block should upsample and filter the input signal. You can select one of the following options:

- `Enforce single-rate processing` — When you select this option, the block maintains the input sample rate, and processes the signal by increasing the output frame size by a factor of *N*. To select this option, you must set the **Input processing** parameter to `Columns as channels (frame based)`.
- `Allow multirate processing` — When you select this option, the block processes the signal such that the output sample rate is *N* times faster than the input sample rate.

Export filter coefficients to workspace

Select this check box to create a variable in the MATLAB workspace that contains the filter coefficients.

Visualize filter with FVTool

If you click this button, then MATLAB launches the Filter Visualization Tool, `fvtool`, to analyze the raised cosine filter whenever you apply any changes to the block's parameters. If you launch `fvtool` for the filter, and subsequently change parameters in the mask, `fvtool` will not update. You will need to launch a new `fvtool` in order to see the new filter characteristics. Also note that if you have launched `fvtool`, then it will remain open even after the model is closed.

Rounding mode

Select the rounding mode for fixed-point operations. The block uses the **Rounding mode** when the result of a fixed-point calculation does not map exactly to a number representable by the data type and scaling storing the result. The filter coefficients do not obey this parameter; they always round to `Nearest`. For more information, see Rounding Modes or “Rounding Mode: Simplest” (Fixed-Point Designer).

Saturate on integer overflow

Select the overflow mode for fixed-point operations. The filter coefficients do not obey this parameter; they are always saturated.

Coefficients

Choose how you specify the word length and the fraction length of the filter coefficients (numerator and/or denominator). See “Filter Structure Diagrams” for illustrations depicting the use of the coefficient data types in this block:

- When you select `Same word length as input`, the word length of the filter coefficients match that of the input to the block. In this mode, the fraction length of the coefficients is automatically set to the binary-point only scaling that provides you with the best precision possible given the value and word length of the coefficients.
- When you select `Specify word length`, you are able to enter the word length of the coefficients, in bits. In this mode, the fraction length of the coefficients is automatically set to the binary-point only scaling that provides you with the best precision possible given the value and word length of the coefficients.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the coefficients, in bits. If applicable, you are able to enter separate fraction lengths for the numerator and denominator coefficients.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the coefficients. If applicable, you are able to enter separate slopes for the numerator and denominator coefficients. This block requires power-of-two slope and a bias of zero.
- The filter coefficients do not obey the **Rounding mode** and the **Saturate on integer overflow** parameters; they are always saturated and rounded to `Nearest`.

Product output

Use this parameter to specify how you would like to designate the product output word and fraction lengths. See “Filter Structure Diagrams” and “Multiplication Data Types” for illustrations depicting the use of the product output data type in this block:

- When you select `Same as input`, these characteristics match those of the input to the block.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the product output, in bits.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the product output. This block requires power-of-two slope and a bias of zero.

Accumulator

Use this parameter to specify how you would like to designate the accumulator word and fraction lengths. See “Filter Structure Diagrams” and “Multiplication Data Types” for illustrations depicting the use of the accumulator data type in this block:

- When you select `Same as input`, these characteristics match those of the input to the block.
- When you select `Same as product output`, these characteristics match those of the product output.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the accumulator, in bits.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the accumulator. This block requires power-of-two slope and a bias of zero.

Output

Choose how you specify the output word length and fraction length:

- When you select `Same as input`, these characteristics match those of the input to the block.
- When you select `Same as accumulator`, these characteristics match those of the accumulator.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the output, in bits.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the output. This block requires power-of-two slope and a bias of zero.

Lock data type settings against changes by the fixed-point tools

Select this parameter to prevent any fixed-point scaling you specify in this block mask from being overridden by the autoscaling tool in the Fixed-Point Tool.

Random Deinterleaver

Restore ordering of input symbols using random permutation

Library

Block sublibrary of Interleaving

Description

The Random Deinterleaver block rearranges the elements of its input vector using a random permutation. The **Initial seed** parameter initializes the random number generator that the block uses to determine the permutation. If this block and the Random Interleaver block have the same value for **Initial seed**, then the two blocks are inverses of each other.

This block accepts a column vector input signal. The **Number of elements** parameter indicates how many numbers are in the input vector.

The block accepts the following data types `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, `double`, and fixed-point. The output signal inherits its data type from the input signal.

Parameters

Number of elements

The number of elements in the input vector.

Initial seed

The initial seed value for the random number generator.

Pair Block

Random Integer Generator

Generate integers randomly distributed in specified range

Library: Communications Toolbox / Comm Sources / Random Data Sources

Description

The Random Integer Generator block generates uniformly distributed random integers in the range [0, *M*-1], where *M* is specified by the Set size parameter. Use this block to generate random binary-valued or integer-valued data.

To ensure that the model uses different initial seeds, set the Simulate using parameter to `Interpreted execution`, and run the simulation in Normal or Accelerator mode. For more information, see “Limitations” on page 5-707.

Limitations

- In Rapid Accelerator simulation mode, when you set Simulate using to `Interpreted execution` and Source of initial seed to `Auto`, the block generates the same numbers every time the simulation runs. This behavior is equivalent to setting Source of initial seed to `Parameter` and setting Initial seed to `0`.
- In all simulation modes (Normal, Accelerator, and Rapid Accelerator), when you set Simulate using to `Code generation` and Source of initial seed to `Auto`, the block generates the same numbers every time the simulation runs. This behavior is equivalent to setting Source of initial seed to `Parameter` and Initial seed to `0`.

For more information, see “Choosing a Simulation Mode” (Simulink).

Ports

Output

`Out` — Random integer output
scalar | vector | matrix

Random integer output, returned as a scalar, vector, or matrix. This port is unnamed on the block. The data type is set using the Output data type parameter.

The number of rows in the output data equals the value of the Samples per frame parameter and corresponds to the number of samples in one frame. The number of columns in the output data equals the number of elements in the Set size parameter and corresponds to the number of channels.

Parameters

Set size — Set size

8 (default) | positive integer | row vector of positive integers

Set size,*M*, specified as a positive integer or row vector of positive integers. The block generates integers in the range [0, (*M* – 1)]. The number of elements in **Set size** corresponds to the number of independent channels output from the block.

- If **Set size** is a scalar, then all output random variables are independent and identically distributed (i.i.d.).
- If **Set size** is a vector, then the length of the vector determines the number of output channels. The channels can have differing output ranges.

Source of initial seed — Source of initial seed

Auto (default) | Parameter

Source of the initial seed for the random number generator, specified as either:

- Auto –– the block uses the global random number stream
- Parameter –– the block sets the random number generator seed to **Initial seed**

Initial seed — Initial seed value

0 (default) | nonnegative integer

Initial seed value for the random number generator, specified as a nonnegative integer. If the **Initial seed** parameter is a constant, then the resulting sequence is repeatable.

Dependencies

To enable this parameter, set the **Source of initial seed** parameter to Parameter.

Sample time — Sample time

1 (default) | -1 | positive scalar

Output sample time, specified as -1 or a positive scalar that represents the time between each sample of the output signal. If **Sample time** is set to -1, the sample time is inherited from downstream. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-709.

Samples per frame — Samples per frame

1 (default) | positive integer

Samples per frame, specified as a positive integer indicating the number of samples per frame in one channel of the output data. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-709.

Output data type — Output data type

double (default) | single | uint8 | uint16 | uint32 | boolean

Output data type, specified as double, single, uint8, uint16, uint32, or boolean. If this parameter is set to boolean, you must set the Set size parameter to 2.

Simulate using — Type of simulation to run

Interpreted execution (default) | Code generation

Type of simulation to run, specified as:

- `Code generation` –– Simulate the model using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations as long as the model does not change. This option requires additional startup time.
- `Interpreted execution` –– Simulate the model using the MATLAB interpreter. This option shortens startup time. In `Interpreted execution` mode, you can debug the source code of the block.

Block Characteristics

Data Types	`Boolean` | `double` | `integer` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`no`

More About

Sample Timing

The time between output updates is equal to the product of **Samples per frame** and **Sample time**. For example, if **Sample time** and **Samples per frame** equal one, the block outputs a sample every second. If **Samples per frame** is increased to 10, then a 10-by-1 vector is output every 10 seconds. This ensures that the equivalent output rate is not dependent on the **Samples per frame** parameter.

Compatibility Considerations

Random Integer Generator block update supported in Upgrade Advisor
Behavior changed in R2020a

Starting in R2020a, Random Integer Generator block allows you to use the Upgrade Advisor. You can update to the block version announced in R2015b or keep the block version available before R2015b.

- Use the Upgrade Advisor to update existing models that include the Random Integer Generator block.
- Behavior of the random number generator is changed. The statistics are improved. For more information, see “Source blocks output frames of contiguous time samples but do not use the frame attribute” in the R2015b Release Notes.

Rayleigh Noise Generator

(To be removed) Generate Rayleigh distributed noise

Note Rayleigh Noise Generator will be removed in a future release. Use the MATLAB Function block and `randn` function instead.

Library

Noise Generators sublibrary of Comm Sources

Description

The Rayleigh Noise Generator block generates Rayleigh distributed noise. The Rayleigh probability density function is given by

$$f(x) = \begin{cases} \dfrac{x}{\sigma^2}\exp\left(-\dfrac{x^2}{2\sigma^2}\right) & x \geq 0 \\ 0 & x < 0 \end{cases}$$

where σ^2 is known as the *fading envelope* of the Rayleigh distribution.

The block requires you to specify the **Initial seed** for the random number generator. If it is a constant, then the resulting noise is repeatable. The **sigma** parameter can be either a vector of the same length as the **Initial seed**, or a scalar. When **sigma** is a scalar, every element of the output signal shares that same value.

Initial Seed

The **Initial seed** parameter initializes the random number generator that the Rayleigh Noise Generator block uses to add noise to the input signal. When multiple blocks in a model have the **Initial seed** parameter, you can choose different initial seeds for each block to ensure different random streams are used in each block. Set **Initial seed** to an integer value for repeatable results or use the `randi` function to randomize your results.

Attributes of Output Signal

The output signal can be a frame-based matrix, a sample-based row or column vector, or a sample-based one-dimensional array. These attributes are controlled by the **Frame-based outputs**, **Samples per frame**, and **Interpret vector parameters as 1-D** parameters. See “Sources and Sinks” for more details.

The number of elements in the **Initial seed** parameter becomes the number of columns in a frame-based output or the number of elements in a sample-based vector output. Also, the shape (row or column) of the **Initial seed** parameter becomes the shape of a sample-based two-dimensional output signal.

Parameters

Sigma

Specify σ as defined in the Rayleigh probability density function.

Initial seed

The initial seed value for the random number generator.

Sample time

The period of each sample-based vector or each row of a frame-based matrix.

Frame-based outputs

Determines whether the output is frame-based or sample-based. This box is active only if **Interpret vector parameters as 1-D** is unchecked.

Samples per frame

The number of samples in each column of a frame-based output signal. This field is active only if **Frame-based outputs** is checked.

Interpret vector parameters as 1-D

If this box is checked, then the output is a one-dimensional signal. Otherwise, the output is a two-dimensional signal. This box is active only if **Frame-based outputs** is unchecked.

Output data type

The output can be set to `double` or `single` data types.

Receiver Thermal Noise

Apply receiver thermal noise to complex signal
Library: Communications Toolbox / RF Impairments

Description

The Receiver Thermal Noise block applies receiver thermal noise to a complex signal. The block simulates the effects of thermal noise on a complex signal. The **Specification method** parameter enables specification of thermal noise based on noise temperature, noise figure, or noise factor.

Ports

Input

`In1` — Complex signal

scalar | column vector

Complex signal, specified as a scalar or column vector.

Data Types: `double` | `single`
Complex Number Support: Yes

Output

`Out1` — Output signal

scalar | column vector

Output signal, returned as a scalar or column vector. This output is the same dimension and data type as the input signal.

Parameters

`Specification method` — Thermal noise specification method

`Noise temperature` (default) | `Noise figure` | `Noise factor`

Thermal noise specification method, specified as one of these options.

- `Noise temperature` specifies the noise in degrees K.
- `Noise figure` specifies the added receiver noise in dB relative to an input noise temperature of 290 K. The noise figure is the decibel equivalent of the noise factor.
- `Noise factor` specifies the added receiver noise relative to an input noise temperature of 290 K. The noise factor is the linear equivalent of the noise figure.

`Noise temperature (K)` — Noise temperature

`290` (default) | scalar

Noise temperature in degrees K, specified as a scalar.

Dependencies

To enable this parameter, set the **Specification method** parameter to `Noise temperature`.

`Noise figure (dB)` — Receiver noise figure

`3.0103` (default) | scalar

Receiver noise figure in dB relative to a noise temperature of 290 degrees K, specified as a scalar.

Note This parameter specifies the noise contribution of the receiver circuitry only. To add the effects of antenna noise, select the **Add 290K antenna noise** parameter.

Dependencies

To enable this parameter, set the **Specification method** parameter to `Noise figure`.

`Noise factor` — Receiver noise factor

`2` (default) | scalar

Receiver noise factor relative to a noise temperature of 290 degrees K, specified as a scalar.

Note This parameter specifies the noise contribution of the receiver circuitry only. To add the effects of antenna noise, select the **Add 290K antenna noise** parameter.

Dependencies

To enable this parameter, set the **Specification method** parameter to `Noise factor`.

`Add 290K antenna noise` — Option to add 290 degrees K antenna noise

`off` (default) | `on`

Select this parameter to add 290 degrees K antenna noise to the signal.

Dependencies

To enable this parameter, set the **Specification method** parameter to `Noise factor` or `Noise factor`.

`Initial seed` — Initial seed value

`67987` (default) | scalar

Initial seed value for the random number generator, specified as a scalar.

Block Characteristics

Data Types	`double` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`no`

Algorithms

Wireless receiver performance is often expressed as a noise factor or figure. The noise factor is defined as the ratio of the input signal-to-noise ratio, S_i/N_i to the output signal-to-noise ratio, S_o/N_o, such that

$$F = \frac{S_i/N_i}{S_o/N_o} \ .$$

Given receiver gain G and receiver noise power N_{ckt}, the noise factor can be expressed as

$$\begin{aligned} F &= \frac{S_i/N_i}{GS_i/(N_{ckt} + GN_i)} \\ &= \frac{N_{ckt} + GN_i}{GN_i} \ . \end{aligned}$$

The IEEE defines the noise factor assuming that noise temperature at the input is T_0, where T_0 = 290 K. The noise factor is then

$$\begin{aligned} F &= \frac{N_{ckt} + GN_i}{GN_i} \\ &= \frac{GkBT_{ckt} + GkBT_0}{GkBT_0} \\ &= \frac{T_{ckt} + T_0}{T_0} \ . \end{aligned}$$

T_{ckt} is the equivalent input noise temperature of the receiver and is expressed as

$$T_{ckt} = T_0(F - 1) \ .$$

The overall noise temperature of an antenna and receiver, T_{sys}, is

$$T_{sys} = T_{ant} + T_{ckt} \, ,$$

where T_{ant} is the antenna noise temperature.

The noise figure, NF, is the dB equivalent of the noise factor and can be expressed as

$$NF = 10\log_{10}(F) \ .$$

Rectangular QAM Demodulator Baseband

Demodulate rectangular-QAM-modulated data

Library

AM, in Digital Baseband sublibrary of Modulation

Description

The Rectangular QAM Demodulator Baseband block demodulates a signal that was modulated using quadrature amplitude modulation with a constellation on a rectangular lattice.

Note All values of power assume a nominal impedance of 1 ohm.

The signal constellation has M points, where M is the **M-ary number** parameter. M must have the form 2^K for some positive integer K. The block scales the signal constellation based on how you set the **Normalization method** parameter. For details, see the reference page for the Rectangular QAM Modulator Baseband block.

This block accepts a scalar or column vector input signal. For information about the data types each block port supports, see the “Supported Data Types” on page 5-726 table on this page.

Hard Decision Algorithm

The demodulator algorithm maps received input signal constellation values to M-ary integer I and Q symbol indices between 0 and $\sqrt{M} - 1$ and then maps these demodulated symbol indices to formatted output values.

The integer symbol index computation is performed by first derotating and scaling the complex input signal constellation (possibly with noise) by a derotate factor and denormalization factor, respectively. These factors are derived from the **Phase offset**, **Normalization method**, and related parameters. These derotated and denormalized values are added to $\sqrt{M} - 1$ to translate them into an approximate range between 0 and $2 \times (\sqrt{M} - 1)$ (plus noise). The resulting values are then rescaled via a divide-by-two (or, equivalently, a right-shift by one bit for fixed-point operation) to obtain a range approximately between 0 and $\sqrt{M} - 1$ (plus noise) for I and Q. The noisy index values are rounded to the nearest integer and clipped, via saturation, and mapped to integer symbol values in the range [0 M-1]. Finally, based on other block parameters, the integer index is mapped to a symbol value that is formatted and cast to the selected **Output data type**.

The following figures contains signal flow diagrams for floating-point and fixed-point algorithm operation. The floating-point diagrams apply when the input signal data type is `double` or `single`. The fixed-point diagrams apply when the input signal is a signed fixed-point data type. Note that the diagram is simplified when **Phase offset** is a multiple of π/2, and/or the derived denormalization factor is 1.

Signal-Flow Diagrams with Nontrivial Phase Offset and Nonunity Denormalization Factor

Parameters

M-ary number

The number of points in the signal constellation. It must have the form 2^K for some positive integer K.

Normalization method

Determines how the block scales the signal constellation. Choices are `Min. distance between symbols`, `Average Power`, and `Peak Power`.

Minimum distance

This parameter appears when **Normalization method** is set to `Min. distance between symbols`.

The distance between two nearest constellation points.

Average power, referenced to 1 ohm (watts)

The average power of the symbols in the constellation, referenced to 1 ohm. This field appears only when **Normalization method** is set to `Average Power`.

Peak power, referenced to 1 ohm (watts)

The maximum power of the symbols in the constellation, referenced to 1 ohm. This field appears only when **Normalization method** is set to `Peak Power`.

Phase offset (rad)

The rotation of the signal constellation, in radians.

Constellation ordering

Determines how the block assigns binary words to points of the signal constellation. More details are on the reference page for the Rectangular QAM Modulator Baseband block.

Selecting `User-defined` displays the field **Constellation mapping**, allowing for user-specified mapping.

Constellation mapping

This parameter appears when `User-defined` is selected in the pull-down list **Constellation ordering**.

This is a row or column vector of size M and must have unique integer values in the range [0, M-1]. The values must be of data type `double`.

The first element of this vector corresponds to the top-leftmost point of the constellation, with subsequent elements running down column-wise, from left to right. The last element corresponds to the bottom-rightmost point.

Output type

Determines whether the block produces integers or binary representations of integers.

If set to `Integer`, the block produces integers.

If set to `Bit`, the block produces a group of K bits, called a *binary word*, for each symbol, when **Decision type** is set to `Hard decision`. If **Decision type** is set to `Log-likelihood ratio` or `Approximate log-likelihood ratio`, the block outputs bitwise LLR and approximate LLR, respectively.

Decision type

This parameter appears when `Bit` is selected in the pull-down list **Output type**.

Specifies the use of hard decision, LLR, or approximate LLR during demodulation. See “Exact LLR Algorithm” and “Approximate LLR Algorithm” in the *Communications Toolbox User's Guide* for algorithm details.

Noise variance source

This parameter appears when `Approximate log-likelihood ratio` or `Log-likelihood ratio` is selected for **Decision type**.

When set to `Dialog`, the noise variance can be specified in the **Noise variance** field. When set to `Port`, a port appears on the block through which the noise variance can be input.

Noise variance

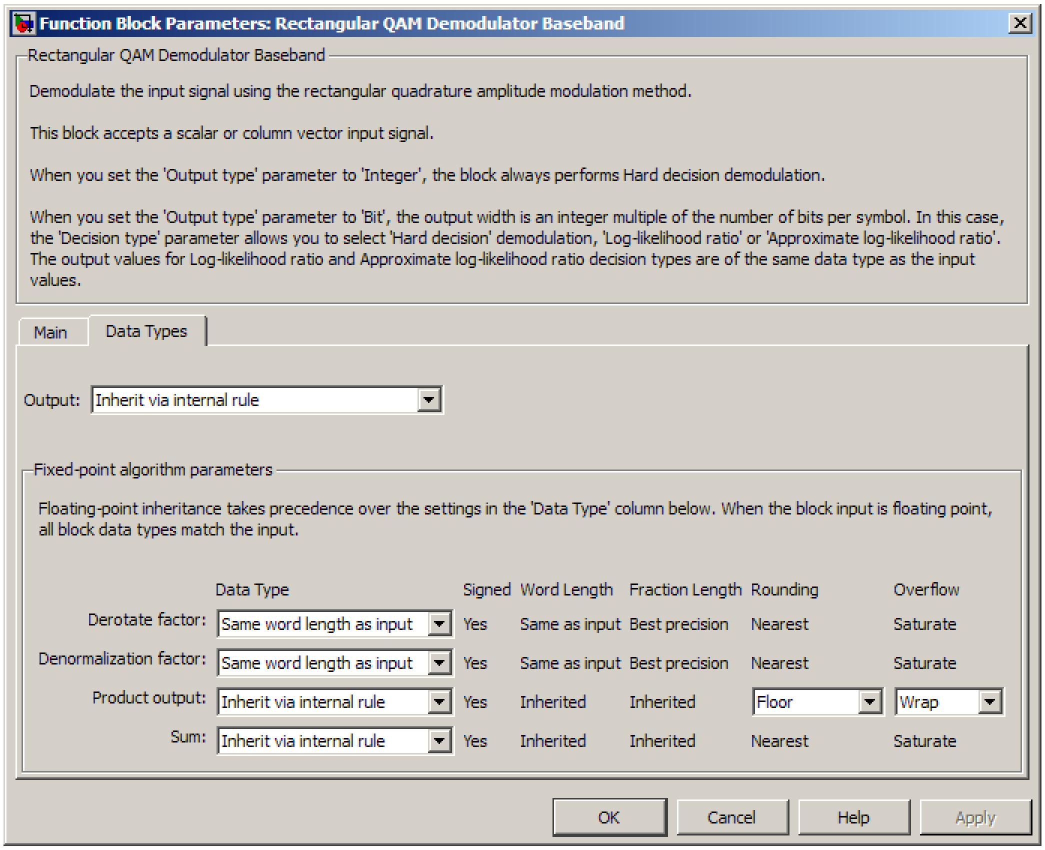
This parameter appears when the **Noise variance source** is set to `Dialog` and specifies the noise variance in the input signal. This parameter is tunable in normal mode, Accelerator mode and Rapid Accelerator mode.

If you use the Simulink Coder rapid simulation (RSIM) target to build an RSIM executable, then you can tune the parameter without recompiling the model. This is useful for Monte Carlo simulations in which you run the simulation multiple times (perhaps on multiple computers) with different amounts of noise.

The LLR algorithm involves computing exponentials of very large or very small numbers using finite precision arithmetic and would yield:

- `Inf` to `-Inf` if **Noise variance** is very high
- `NaN` if **Noise variance** and signal power are both very small

In such cases, use approximate LLR, as its algorithm does not involve computing exponentials.



Function Block Parameters: Rectangular QAM Demodulator Baseband

Apply

Rectangular QAM Demodulator Baseband

Demodulate the input signal using the rectangular quadrature amplitude modulation method.

This block accepts a scalar or column vector input signal.

When you set the 'Output type' parameter to 'Integer', the block always performs Hard decision demodulation.

When you set the 'Output type' parameter to 'Bit', the output width is an integer multiple of the number of bits per symbol. In this case, the 'Decision type' parameter allows you to select 'Hard decision' demodulation, 'Log-likelihood ratio' or 'Approximate log-likelihood ratio'. The output values for Log-likelihood ratio and Approximate log-likelihood ratio decision types are of the same data type as the input values.

Output: Inherit via internal rule

Fixed-point algorithm parameters

Floating-point inheritance takes precedence over the settings in the 'Data Type' column below. When the block input is floating point, all block data types match the input.

	Data Type	Signed	Word Length	Fraction Length	Rounding	Overflow
Derotate factor:	Same word length as input	Yes	Same as input	Best precision	Nearest	Saturate
Denormalization factor:	Same word length as input	Yes	Same as input	Best precision	Nearest	Saturate
Product output:	Inherit via internal rule	Yes	Inherited	Inherited	Floor	Wrap
Sum:	Inherit via internal rule	Yes	Inherited	Inherited	Nearest	Saturate

Output

When the parameter is set to `'Inherit via internal rule'` (default setting), the block will inherit the output data type from the input port. The output data type will be the same as the input data type if the input is of type `single` or `double`. Otherwise, the output data type will be as if this parameter is set to `'Smallest unsigned integer'`.

When the parameter is set to `'Smallest unsigned integer'`, the output data type is selected based on the settings used in the **Hardware Implementation** pane of the Configuration Parameters dialog box of the model. If `ASIC/FPGA` is selected in the **Hardware Implementation** pane, the output data type is the ideal minimum size, i.e., `ufix(1)` for bit outputs, and `ufix(ceil(log2(M)))` for integer outputs. For all other selections, it is an unsigned integer with the smallest available word length large enough to fit the ideal minimum size, usually corresponding to the size of a char (e.g., `uint8`).

For integer outputs, this parameter can be set to `Smallest unsigned integer`, `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `single`, and `double`. For bit outputs, the options are `Smallest unsigned integer`, `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, `boolean`, `single`, or `double`.

Derotate factor

This parameter only applies when the input is fixed-point and **Phase offset** is not a multiple of π/2.

This can be set to `Same word length as input` or `Specify word length`, in which case a field is enabled for user input.

Denormalization factor

This parameter only applies when the input is fixed-point and the derived denormalization factor is nonunity (not equal to 1). This scaling factor is derived from **Normalization method** and other parameter values in the block dialog.

This can be set to `Same word length as input` or `Specify word length`, in which case a field is enabled for user input. A best-precision fraction length is always used.

Product output

This parameter only applies when the input is a fixed-point signal and there is a nonunity (not equal to 1) denormalized factor. It can be set to `Inherit via internal rule` or `Specify word length`, which enables a field for user input.

Setting to `Inherit via internal rule` computes the full-precision product word length and fraction length. Internal Rule for Product Data Types in *DSP System Toolbox User's Guide* describes the full-precision **Product output** internal rule.

Setting to `Specify word length` allows you to define the word length. The block computes a best-precision fraction length based on the word length specified and the pre-computed worst-case (min/max) real world value **Product output** result. The worst-case **Product output** result is precomputed by multiplying the denormalized factor with the worst-case (min/max) input signal range, purely based on the input signal data type.

The block uses the **Rounding mode** when the result of a fixed-point calculation does not map exactly to a number representable by the data type and scaling storing the result. For more information, see “Rounding Modes” or “Rounding Mode: Simplest” (Fixed-Point Designer).

Sum

This parameter only applies when the input is a fixed-point signal. It can be set to `Inherit via internal rule`, `Same as product output`, or `Specify word length`, in which case a field is enabled for user input

Setting to `Inherit via internal rule` computes the full-precision sum word length and fraction length, based on the two inputs to the Sum in the fixed-point Hard Decision Algorithm on page 5-719 signal flow diagram. The rule is the same as the fixed-point inherit rule of the internal **Accumulator data type** parameter in the Simulink Sum (Simulink) block.

Setting to `Specify word length` allows you to define the word length. A best precision fraction length is computed based on the word length specified in the pre-computed maximum range necessary for the demodulated algorithm to produce accurate results. The signed fixed-point data type that has the best precision fully contains the values in the range $2*(\sqrt{M}-1)$ for the specified word length.

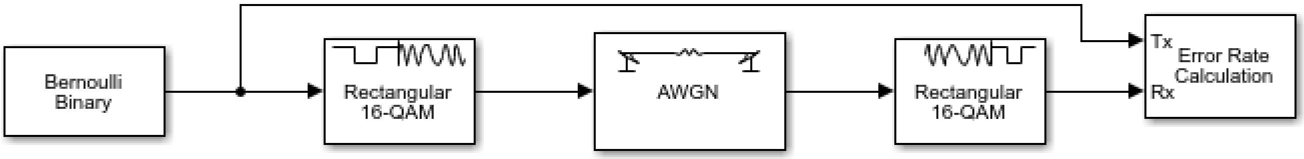
Setting to `Same as product output` allows the Sum data type to be the same as the **Product output** data type (when **Product output** is used). If the **Product output** is not used, then this setting will be ignored and the `Inherit via internal rule` Sum setting will be used.

Examples

Demodulate Noisy QAM Signal

Modulate and demodulate a noisy QAM signal.

Open the QAM demodulation model.



Run the simulation. The results are saved to the base workspace, where the variable `ErrorVec` is a 1-by-3 row vector. The BER is found in the first element.

Display the error statistics. For the Eb/No provided, 2 dB, the resultant BER is approximately 0.1. Your results may vary slightly.

```
ans =

    0.0948
```

Increase the Eb/No to 4 dB. Rerun the simulation, and observe that the BER has decreased.

```
ans =
0.0167
```

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point • Signed fixed–point when **M-ary number** is an even power of 2 and: • **Output type** is `Integer` • **Output type** is `Bit` and **Decision type** is `Hard-decision`
Var	• Double-precision floating point • Single-precision floating point
Output	• Double-precision floating point • Single-precision floating point • Boolean when **Output type** is `Bit` • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers • ufix(1) in ASIC/FPGA when **Output type** is `Bit` • $ufix(\log_2 M)$ in ASIC/FPGA when **Output type** is `Integer`

Extended Capabilities

C/C++ Code Generation

Generate C and C++ code using Simulink® Coder™.

HDL Code Generation

Generate Verilog and VHDL code for FPGA and ASIC designs using HDL Coder™.

HDL Coder provides additional configuration options that affect HDL implementation and synthesized logic.

HDL Architecture

This block has a single, default HDL architecture.

HDL Block Properties

ConstrainedOutputPipeline	Number of registers to place at the outputs by moving existing delays within your design. Distributed pipelining does not redistribute these registers. The default is `0`. For more details, see “ConstrainedOutputPipeline” (HDL Coder).
InputPipeline	Number of input pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see “InputPipeline” (HDL Coder).
OutputPipeline	Number of output pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see “OutputPipeline” (HDL Coder).

Restrictions

- The block does not support `single` or `double` data types for HDL code generation.
- HDL Coder supports the following **Output type** options:
  - `Integer`
  - `Bit` is supported only if the **Decision Type** is `Hard decision`.
- You must set **Normalization Method** to `Minimum Distance Between Symbols`, with a **Minimum distance** of 2.
- You must set **Phase offset (rad)** to a value that is a multiple of `pi`/4.

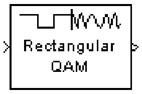
Rectangular QAM Modulator Baseband

Modulate using rectangular quadrature amplitude modulation



Library

AM, in Digital Baseband sublibrary of Modulation

Description

The Rectangular QAM Modulator Baseband block modulates using M-ary quadrature amplitude modulation with a constellation on a rectangular lattice. The output is a baseband representation of the modulated signal. This block accepts a scalar or column vector input signal. For information about the data types each block port supports, see “Supported Data Types” on page 5-733.

Note All values of power assume a nominal impedance of 1 ohm.

Integer-Valued Signals and Binary-Valued Signals

When you set the **Input type** parameter to `Integer`, the block accepts integer values between `0` and *M*-`1`. *M* represents the **M-ary number** block parameter.

When you set the **Input type** parameter to `Bit`, the block accepts binary-valued inputs that represent integers. The block collects binary-valued signals into groups of $K = \log_2(M)$ bits

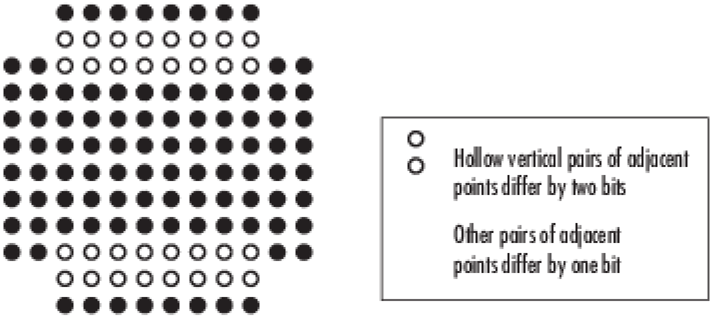
where

K represents the number of bits per symbol.

The input vector length must be an integer multiple of *K*. In this configuration, the block accepts a group of *K* bits and maps that group onto a symbol at the block output. The block outputs one modulated symbol for each group of *K* bits.

The **Constellation ordering** parameter indicates how the block assigns binary words to points of the signal constellation. Such assignments apply independently to the in-phase and quadrature components of the input:

- If **Constellation ordering** is set to `Binary`, the block uses a natural binary-coded constellation.
- If **Constellation ordering** is set to `Gray` and K is even, the block uses a Gray-coded constellation.
- If **Constellation ordering** is set to `Gray` and K is odd, the block codes the constellation so that pairs of nearest points differ in one or two bits. The constellation is cross-shaped, and the schematic below indicates which pairs of points differ in two bits. The schematic uses M = 128, but suggests the general case.



Hollow vertical pairs of adjacent points differ by two bits
Other pairs of adjacent points differ by one bit

For details about the Gray coding, see the reference page for the M-PSK Modulator Baseband block and the paper listed in References on page 5-734. Because the in-phase and quadrature components are assigned independently, the Gray and binary orderings coincide when M = 4.

Constellation Size and Scaling

The signal constellation has M points, where M is the **M-ary number** parameter. M must have the form 2^K for some positive integer K. The block scales the signal constellation based on how you set the **Normalization method** parameter. The following table lists the possible scaling conditions.

Value of Normalization Method Parameter	Scaling Condition
`Min. distance between symbols`	The nearest pair of points in the constellation is separated by the value of the **Minimum distance** parameter
`Average Power`	The average power of the symbols in the constellation is the **Average power** parameter
`Peak Power`	The maximum power of the symbols in the constellation is the **Peak power** parameter

Constellation Visualization

The Rectangular QAM Modulator Baseband block provides the capability to visualize a signal constellation from the block mask. This Constellation Visualization feature allows you to visualize a signal constellation for specific block parameters. For more information, see the Constellation Visualization section of the *Communications Toolbox User's Guide*.

Parameters

M-ary number

The number of points in the signal constellation. It must have the form 2^K for some positive integer K.

Input type

Indicates whether the input consists of integers or groups of bits.

Constellation ordering

Determines how the block maps each symbol to a group of output bits or integer.

Selecting `User-defined` displays the field **Constellation mapping**, which allows for user-specified mapping.

Constellation mapping

This parameter is a row or column vector of size M and must have unique integer values in the range [0, M-1]. The values must be of data type `double`.

The first element of this vector corresponds to the top-leftmost point of the constellation, with subsequent elements running down column-wise, from left to right. The last element corresponds to the bottom-rightmost point.

This field appears when `User-defined` is selected in the drop-down list **Constellation ordering**.

Normalization method

Determines how the block scales the signal constellation. Choices are `Min. distance between symbols`, `Average Power`, and `Peak Power`.

Minimum distance

The distance between two nearest constellation points. This field appears only when **Normalization method** is set to `Min. distance between symbols`.

Average power, referenced to 1 ohm (watts)

The average power of the symbols in the constellation, referenced to 1 ohm. This field appears only when **Normalization method** is set to `Average Power`.

Peak power, referenced to 1 ohm (watts)

The maximum power of the symbols in the constellation, referenced to 1 ohm. This field appears only when **Normalization method** is set to `Peak Power`.

Phase offset (rad)

The rotation of the signal constellation, in radians.

Output data type

The output data type can be set to `double`, `single`, `Fixed-point`, `User-defined`, or `Inherit via back propagation`.

Setting this parameter to `Fixed-point` or `User-defined` enables fields in which you can further specify details. Setting this parameter to `Inherit via back propagation`, sets the output data type and scaling to match the following block.

Output word length

Specify the word length, in bits, of the fixed-point output data type. This parameter is only visible when you select `Fixed-point` for the **Output data type** parameter.

User-defined data type

Specify any signed built-in or signed fixed-point data type. You can specify fixed-point data types using the `sfix`, `sint`, `sfrac`, and `fixdt` functions from Fixed-Point Designer software. This parameter is only visible when you select `User-defined` for the **Output data type** parameter.

Set output fraction length to

Specify the scaling of the fixed-point output by either of the following methods:

- Choose `Best precision` to have the output scaling automatically set such that the output signal has the best possible precision.
- Choose `User-defined` to specify the output scaling in the **Output fraction length** parameter.

This parameter is only visible when you select `Fixed-point` for the **Output data type** parameter or when you select `User-defined` and the specified output data type is a fixed-point data type.

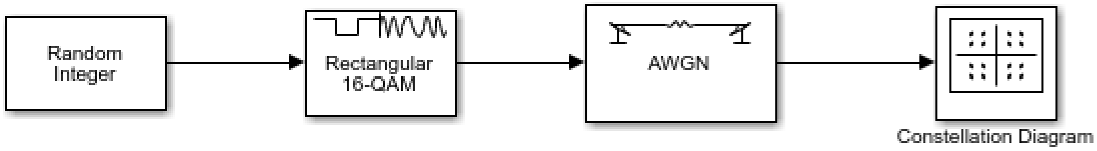
Output fraction length

For fixed-point output data types, specify the number of fractional bits, or bits to the right of the binary point. This parameter is only visible when you select `Fixed-point` or `User-defined` for the **Output data type** parameter and `User-defined` for the **Set output fraction length to** parameter.

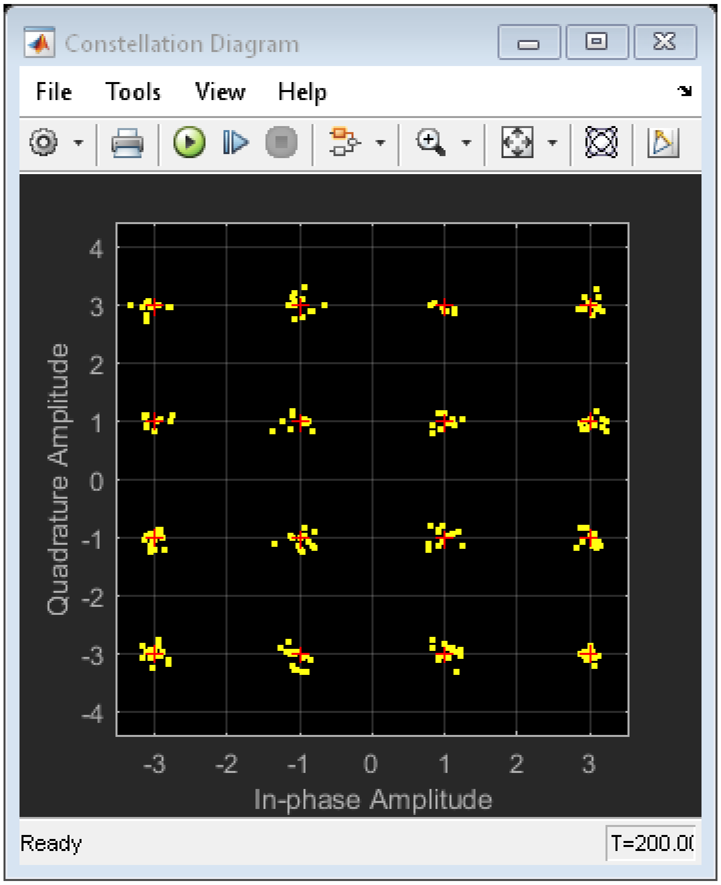
Examples

Plot Noisy 16-QAM Constellation

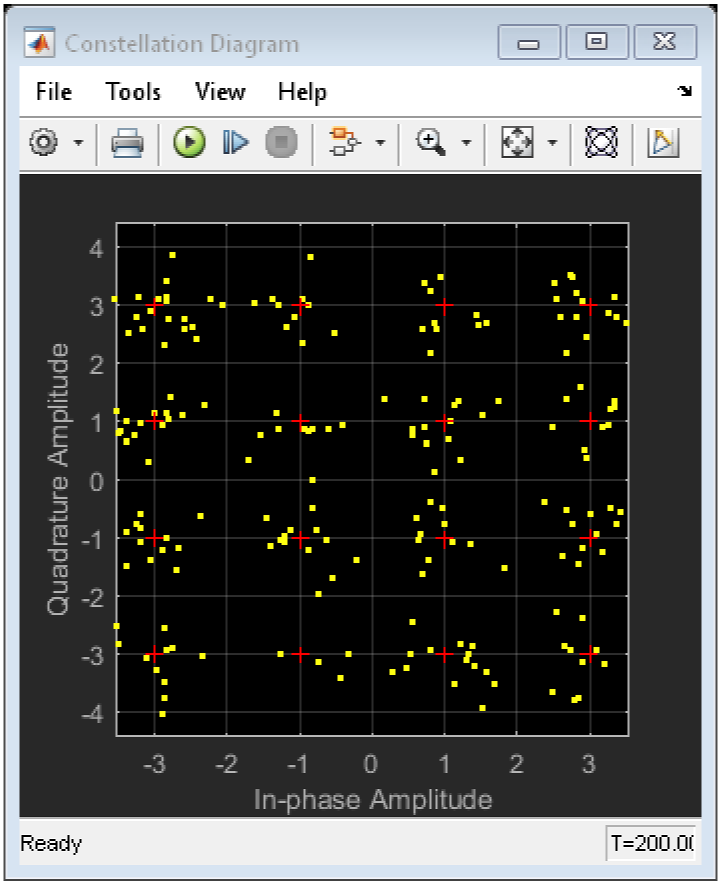
Open the 16-QAM model. The model generates a QAM signal, applies white noise, and displays the resulting constellation diagram.



Run the model.



Change the Eb/No of the AWGN Channel block from 20 dB to 10 dB. Observe the increase in the noise.



Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point • Boolean when **Input type** is `Bit` • 8-, 16-, 32-bit signed integers • 8-, 16-, 32-bit unsigned integers • $ufix(\log_2 M)$ when **Input type** is `Integer`
Output	• Double-precision floating point • Single-precision floating point • Signed fixed-point

Pair Block

Extended Capabilities

C/C++ Code Generation

Generate C and C++ code using Simulink® Coder™.

HDL Code Generation

Generate Verilog and VHDL code for FPGA and ASIC designs using HDL Coder™.

HDL Coder provides additional configuration options that affect HDL implementation and synthesized logic.

HDL Architecture

This block has a single, default HDL architecture.

HDL Block Properties

ConstrainedOutputPipeline	Number of registers to place at the outputs by moving existing delays within your design. Distributed pipelining does not redistribute these registers. The default is `0`. For more details, see “ConstrainedOutputPipeline” (HDL Coder).
InputPipeline	Number of input pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see “InputPipeline” (HDL Coder).
OutputPipeline	Number of output pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see “OutputPipeline” (HDL Coder).

Restrictions

- The block does not support `single` or `double` data types for HDL code generation.
- When **Input Type** is set to `Bit`, the block does not support HDL code generation for input types other than `boolean` or `ufix1`.

When the input type is set to `Bit`, but the block input is actually multibit (`uint16`, for example), the Rectangular QAM Modulator Baseband block does not support HDL code generation.

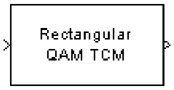
Blocks

General QAM Modulator Baseband | Rectangular QAM Demodulator Baseband

Introduced before R2006a

Rectangular QAM TCM Decoder

Decode trellis-coded modulation data, modulated using QAM method



Library

TCM, in Digital Baseband sublibrary of Modulation

Description

The Rectangular QAM TCM Decoder block uses the Viterbi algorithm to decode a trellis-coded modulation (TCM) signal that was previously modulated using a QAM signal constellation.

The **M-ary number** parameter represents the number of points in the signal constellation, which also equals the number of possible output symbols from the convolutional encoder. (That is, $\log_2$(**M-ary number**) is the number of output bit streams from the convolutional encoder.)

The **Trellis structure** and **M-ary number** parameters in this block should match those in the Rectangular QAM TCM Encoder block, to ensure proper decoding.

Input and Output Signals

This block accepts a column vector input signal containing complex numbers. For information about the data types each block port supports, see “Supported Data Types” on page 5-736.

If the convolutional encoder described by the trellis structure represents a rate *k*/*n* code, then the Rectangular QAM TCM Decoder block's output is a binary column vector with a length of *k* times the vector length of the input signal.

Operation Modes

The block has three possible methods for transitioning between successive frames. The **Operation mode** parameter controls which method the block uses. This parameter also affects the range of possible values for the **Traceback depth** parameter, D.

- In `Continuous` mode, the block initializes all state metrics to zero at the beginning of the simulation, waits until it accumulates D symbols, and then uses a sequence of D symbols to compute each of the traceback paths. D can be any positive integer. At the end of each frame, the block saves its internal state metric for use with the next frame.

  If you select **Enable the reset input**, the block displays another input port, labeled `Rst`. This port receives an integer scalar signal. Whenever the value at the `Rst` port is nonzero, the block resets all state metrics to zero and sets the traceback memory to zero.
- In `Truncated` mode, the block treats each frame independently. The traceback path starts at the state with the lowest metric. D must be less than or equal to the vector length of the input.

- In `Terminated` mode, the block treats each frame independently. The traceback path always starts at the all-zeros state. D must be less than or equal to the vector length of the input. If you know that each frame of data typically ends at the all-zeros state, then this mode is an appropriate choice.

Decoding Delay

If you set **Operation mode** to `Continuous`, then this block introduces a decoding delay equal to **Traceback depth***k bits, for a rate k/n convolutional code. The decoding delay is the number of zeros that precede the first decoded bit in the output.

The block incurs no delay for other values of **Operation mode**.

Parameters

Trellis structure

MATLAB structure that contains the trellis description of the convolutional encoder.

M-ary number

The number of points in the signal constellation.

Traceback depth

The number of trellis branches (equivalently, the number of symbols) the block uses in the Viterbi algorithm to construct each traceback path.

Operation mode

The operation mode of the Viterbi decoder. Choices are `Continuous`, `Truncated`, and `Terminated`.

Enable the reset input port

When you select this check box, the block has a second input port labeled `Rst`. Providing a nonzero input value to this port causes the block to set its internal memory to the initial state before processing the input data. This option appears only if you set **Operation mode** to `Continuous`.

Output data type

Select the data type for the block output signal as `boolean` or `single`. By default, the block sets this to `double`.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point
Reset	• Double-precision floating point • Boolean
Output	• Double-precision floating point • Boolean

`poly2trellis`

Introduced before R2006a

Rectangular QAM TCM Encoder

Convolutionally encode binary data and modulate using QAM method

Library

TCM, in Digital Baseband sublibrary of Modulation

Description

The Rectangular QAM TCM Encoder block implements trellis-coded modulation (TCM) by convolutionally encoding the binary input signal and mapping the result to a QAM signal constellation.

The **M-ary number** parameter is the number of points in the signal constellation, which also equals the number of possible output symbols from the convolutional encoder. (That is, $\log_2$(**M-ary number**) is equal to n for a rate k/n convolutional code.)

Input Signals and Output Signals

If the convolutional encoder described by the trellis structure represents a rate *k*/*n* code, then the Rectangular QAM TCM Encoder block's input must be a binary column vector with a length of *L*k* for some positive integer *L*.

The output from the Rectangular QAM TCM Encoder block is a complex column vector of length *L*.

Specifying the Encoder

To define the convolutional encoder, use the **Trellis structure** parameter. This parameter is a MATLAB structure whose format is described in “Trellis Description of a Convolutional Code”. You can use this parameter field in two ways:

- If you want to specify the encoder using its constraint length, generator polynomials, and possibly feedback connection polynomials, then use a `poly2trellis` command within the **Trellis structure** field. For example, to use an encoder with a constraint length of 7, code generator polynomials of 171 and 133 (in octal numbers), and a feedback connection of 171 (in octal), set the **Trellis structure** parameter to

  ```
  poly2trellis(7,[171 133],171)
  ```
- If you have a variable in the MATLAB workspace that contains the trellis structure, then enter its name as the **Trellis structure** parameter. This way is faster because it causes Simulink to spend less time updating the diagram at the beginning of each simulation, compared to the usage in the previous bulleted item.

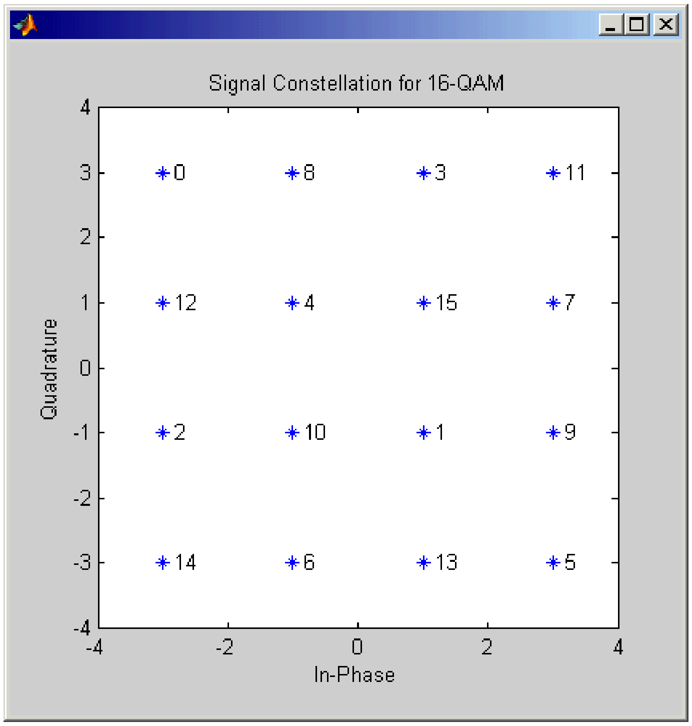
The encoder registers begin in the all-zeros state. You can configure the encoder so that it resets its registers to the all-zeros state during the course of the simulation. To do this, set the `Operation`

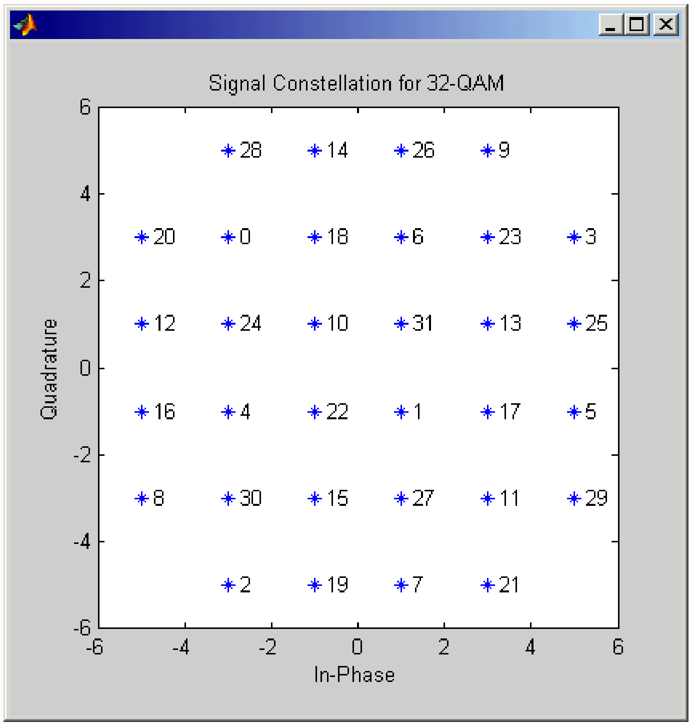
`mode` to **Reset on nonzero input via port**. The block then opens a second input port, labeled `Rst`. The signal at the `Rst` port is a scalar signal. When it is nonzero, the encoder resets before processing the data at the first input port.

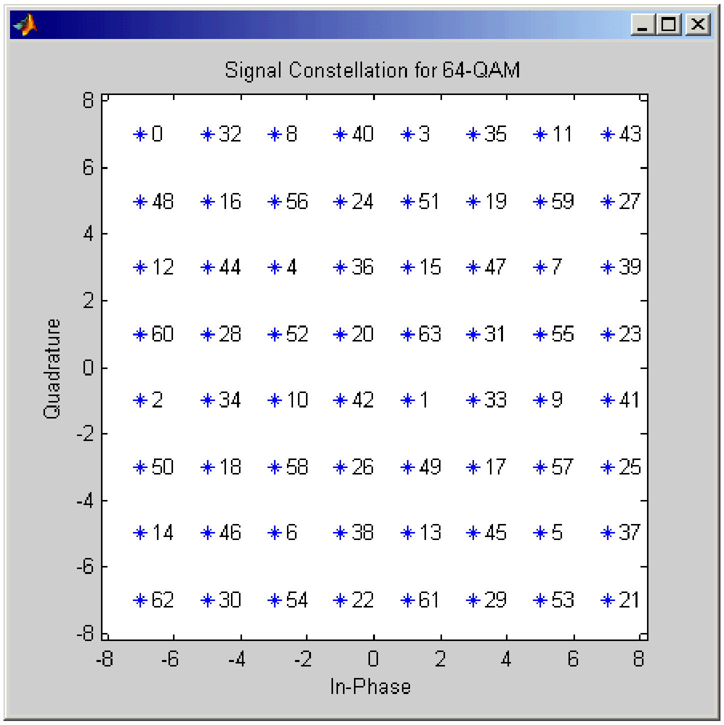
Signal Constellations

The trellis-coded modulation technique partitions the constellation into subsets called cosets, so as to maximize the minimum distance between pairs of points in each coset. This block internally forms a valid partition based on the value you choose for the **M-ary number** parameter.

The figures below show the labeled set-partitioned signal constellations that the block uses when **M-ary number** is `16`, `32`, and `64`. For constellations of other sizes, see Biglieri, E., D. Divsalar, P. J. McLane and M. K. Simon, *Introduction to Trellis-Coded Modulation with Applications*, New York, Macmillan, 1991.







Coding Gains

Coding gains of 3 to 6 decibels, relative to the uncoded case can be achieved in the presence of AWGN with multiphase trellis codes. For more information, see Biglieri, E., D. Divsalar, P. J. McLane and M. K. Simon, *Introduction to Trellis-Coded Modulation with Applications*, New York, Macmillan, 1991.

Parameters

Trellis structure

MATLAB structure that contains the trellis description of the convolutional encoder.

Operation mode

In `Continuous` mode (default setting), the block retains the encoder states at the end of each frame, for use with the next frame.

In `Truncated (reset every frame)` mode, the block treats each frame independently. I.e., the encoder states are reset to all-zeros state at the start of each frame.

In `Terminate trellis by appending bits` mode, the block treats each frame independently. For each input frame, extra bits are used to set the encoder states to all-zeros state at the end of the frame. The output length is given by $y = n \cdot (x + s)/k$, where x is the number of input bits, and s = constraint length – 1 (or, in the case of multiple constraint lengths, s =`sum(ConstraintLength(i)-1)`). The block supports this mode for column vector input signals.

In `Reset on nonzero input via port` mode, the block has an additional input port, labeled `Rst`. When the `Rst` input is nonzero, the encoder resets to the all-zeros state.

M-ary number

The number of points in the signal constellation.

Output data type

The output type of the block can be specified as a `single` or `double`. By default, the block sets this to `double`.

Rician Noise Generator

(To be removed) Generate Rician distributed noise

Note Rician Noise Generator will be removed in a future release. Use the MATLAB Function block and `randn` function instead.

Library

Noise Generators sublibrary of Comm Sources

Description

The Rician Noise Generator block generates Rician distributed noise. The Rician probability density function is given by

$$f(x) = \begin{cases} \dfrac{x}{\sigma^2} I_0\left(\dfrac{mx}{\sigma^2}\right)\exp\left(-\dfrac{x^2 + m^2}{2\sigma^2}\right) & x \ge 0 \\ 0 & x < 0 \end{cases}$$

where:

- σ is the standard deviation of the Gaussian distribution that underlies the Rician distribution noise
- $m^2 = m_I^2 + m_Q^2$, where m_I and m_Q are the mean values of two independent Gaussian components
- I_0 is the modified 0th-order Bessel function of the first kind given by

$$I_0(y) = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{y\cos t} dt$$

Note that *m* and σ are *not* the mean value and standard deviation for the Rician noise.

You must specify the **Initial seed** for the random number generator. When it is a constant, the resulting noise is repeatable. The vector length of the Initial seed parameter should equal the number of columns in a frame-based output or the number of elements in a sample-based output. The set of numerical parameters above the **Initial seed** parameter in the dialog box can consist of vectors having the same length as the **Initial seed**, or scalars.

Initial Seed

The scalar **Initial seed** parameter initializes the random number generator that the block uses to generate its Rician-distributed complex random process. When multiple blocks in a model have the **Initial seed** parameter, you can choose different initial seeds for each block to ensure different random streams are used in each block. Set **Initial seed** to an integer value for repeatable results or use the `randi` function to randomize your results.

Attributes of Output Signal

The output signal can be a frame-based matrix, a sample-based row or column vector, or a sample-based one-dimensional array. These attributes are controlled by the **Frame-based outputs**, **Samples**

per frame, and **Interpret vector parameters as 1-D** parameters. See “Sources and Sinks” in *Communications Toolbox User's Guide* for more details.

The number of elements in the **Initial seed** and **Sigma** parameters becomes the number of columns in a frame-based output or the number of elements in a sample-based vector output. Also, the shape (row or column) of the **Initial seed** and **Sigma** parameters becomes the shape of a sample-based two-dimensional output signal.

Parameters

Specification method

Either `K-factor` or `Quadrature components`.

Rician K-factor

$K = m^2/(2\sigma^2)$, where m is as in the Rician probability density function. This field appears only if **Specification method** is `K-factor`.

In-phase component (mean), Quadrature component (mean)

The mean values m_I and m_Q, respectively, of the Gaussian components. These fields appear only if **Specification method** is `Quadrature components`.

Sigma

The variable σ in the Rician probability density function.

Initial seed

The initial seed value for the random number generator.

Sample time

The period of each sample-based vector or each row of a frame-based matrix.

Frame-based outputs

Determines whether the output is frame-based or sample-based. This box is active only if **Interpret vector parameters as 1-D** is unchecked.

Samples per frame

The number of samples in each column of a frame-based output signal. This field is active only if **Frame-based outputs** is checked.

Interpret vector parameters as 1-D

If this box is checked, then the output is a one-dimensional signal. Otherwise, the output is a two-dimensional signal. This box is active only if **Frame-based outputs** is unchecked.

Output data type

The output can be set to `double` or `single` data types.

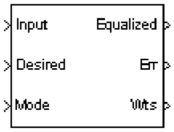
RLS Decision Feedback Equalizer

(To be removed) Equalize using decision feedback equalizer that updates weights with RLS algorithm

Note will be removed in a future release. Use Decision Feedback Equalizer instead.



Library

Equalizers

Description

The RLS Decision Feedback Equalizer block uses a decision feedback equalizer and the RLS algorithm to equalize a linearly modulated baseband signal through a dispersive channel. During the simulation, the block uses the RLS algorithm to update the weights, once per symbol. When you set the **Number of samples per symbol** parameter to `1`, the block implements a symbol-spaced equalizer and updates the filter weights once for each symbol. When you set the **Number of samples per symbol** parameter to a value greater than `1`, the weights are updated once every N^{th} sample, for a fractionally spaced equalizer.

Input and Output Signals

The `Input` port accepts a column vector input signal. The `Desired` port receives a training sequence with a length that is less than or equal to the number of symbols in the `Input` signal. Valid training symbols are those symbols listed in the **Signal constellation** vector.

Set the **Reference tap** parameter so it is greater than zero and less than the value for the **Number of forward taps** parameter.

The port labeled `Equalized` outputs the result of the equalization process.

You can configure the block to have one or more of these extra ports:

- `Mode` input.
- `Err` output for the error signal, which is the difference between the `Equalized` output and the reference signal. The reference signal consists of training symbols in training mode, and detected symbols otherwise.
- `Weights` output.

Decision-Directed Mode and Training Mode

To learn the conditions under which the equalizer operates in training or decision-directed mode, see “Equalization”.

Equalizer Delay

For proper equalization, you should set the **Reference tap** parameter so that it exceeds the delay, in symbols, between the transmitter's modulator output and the equalizer input. When this condition is satisfied, the total delay, in symbols, between the modulator output and the equalizer *output* is equal to

1+(**Reference tap**-1)/(**Number of samples per symbol**)

Because the channel delay is typically unknown, a common practice is to set the reference tap to the center tap of the forward filter.

Parameters

Number of forward taps

The number of taps in the forward filter of the decision feedback equalizer.

Number of feedback taps

The number of taps in the feedback filter of the decision feedback equalizer.

Number of samples per symbol

The number of input samples for each symbol.

Signal constellation

A vector of complex numbers that specifies the constellation for the modulation.

Reference tap

A positive integer less than or equal to the number of forward taps in the equalizer.

Forgetting factor

The forgetting factor of the RLS algorithm, a number between 0 and 1.

Inverse correlation matrix

The initial value for the inverse correlation matrix. The matrix must be N-by-N, where N is the total number of forward and feedback taps.

Initial weights

A vector that concatenates the initial weights for the forward and feedback taps.

Mode input port

When you select this check box, the block has an input port that allows you to toggle between training and decision-directed mode. For training, the mode input must be 1, and for decision directed, the mode must be 0. For every frame in which the mode input is 1 or not present, the equalizer trains at the beginning of the frame for the length of the desired signal.

Output error

When you select this check box, the block outputs the error signal, which is the difference between the equalized signal and the reference signal.

Output weights

When you select this check box, the block outputs the current forward and feedback weights, concatenated into one vector.

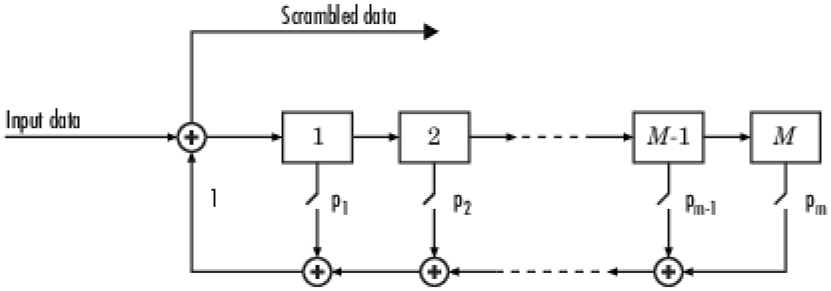
Scrambler

Scramble input signal
Library: Communications Toolbox / Sequence Operations

Description

The Scrambler block scrambles a scalar or column vector input signal.

One purpose of scrambling is to reduce the length of consecutive 0s or 1s in a transmitted signal. Long sequences of 0s or 1s can cause transmission synchronization problems. This schematic shows the scrambler operation. All adders perform addition modulo *N*, where *N* is the value specified by the Calculation base parameter.



At each time step, the input causes the contents of the registers to shift sequentially. Using the Scramble polynomial parameter, you specify the on or off state for each switch in the scrambler.

To achieve repeatable initial scrambler conditions, you can use one of these optional input ports:

- Select the Reset on nonzero input via port parameter and reset the scrambler with Rst.
- Set the Initial states source parameter to `Input port` and provide the initial states with ISt.

This block can accept input sequences that vary in length during simulation. For more information about sequences that vary in length, see Variable-Size Signal Basics (Simulink).

Ports

Input

`in` — Input data signal
vector

Input data signal, specified as an N_S-by-1 vector. N_S represents the number of samples in the input signal. The input values must be integers from `0` to Calculation base – `1`.

Data Types: `double`

`Rst` — Reset scrambler

scalar

Reset scrambler, specified as a scalar. The scrambler is reset if a nonzero input is applied to the port.

Dependencies

To enable this port, set Initial states source to `Dialog Parameter` and select Reset on nonzero input via port.

`ISt` — Initial states

vector

Initial states of the scrambler registers when the simulation starts, specified as a nonnegative integer vector. The length of **ISt** must equal the order of the Scramble polynomial parameter. The vector element values must be integers from `0` to Calculation base – `1`.

Dependencies

To enable this port, set Initial states source to `Input port`.

Output

`Out1` — Output scrambled data

vector

Output scrambled data, returned as an N_S-by-1 vector. N_S equals the number of samples in the input signal.

Data Types: `double`

Parameters

`Calculation base` — Calculation base

4 (default) | nonnegative integer

Calculation base used in the scrambler for modulo operations, specified as a nonnegative integer. The input and output of this block are integers from `0` to **Calculation base** – `1`.

`Scramble polynomial` — Polynomial that defines connections in scrambler

`'1 + z^-1 + z^-2 + z^-4'` (default) | character vector | integer vector | binary vector

Polynomial that defines the connections in the scrambler, specified as a character vector, integer vector, or binary vector. The **Scramble polynomial** parameter defines if each switch in the scrambler is on or off. Specify the polynomial as:

- A character vector, such as `'1 + z^-6 + z^-8'`. For more details on specifying polynomials in this way, see Character Representation of Polynomials.
- An integer vector, such as `[0 -6 -8]`, listing the descrambler coefficients in order of descending powers of z^{-1}, where $p(z^{-1}) = 1 + p_1 z^{-1} + p_2 z^{-2} + \ldots$
- A binary vector, such as `[1 0 0 0 0 0 1 0 1]`, listing the powers of z that appear in the polynomial that has a coefficient of 1. In this case, the order of the scramble polynomial is one less than the binary vector length.

Example: '1 + z^-6 + z^-8', [0 -6 -8], and [1 0 0 0 0 0 1 0 1] all represent this polynomial:

$p(z^{-1}) = 1 + z^{-6} + z^{-8}$

Initial states source — Set the source for scrambler initial states

Dialog Parameter (default) | Input port

- Dialog Parameter – Specify scrambler initial states by using the Initial states parameter.
- Input port – Specify scrambler initial states by using the ISt port.

Initial states — Initial states of scrambler registers

[0 1 2 3] (default) | nonnegative integer vector

Initial states of scrambler registers when the simulation starts, specified as a nonnegative integer vector. The length of **Initial states** must equal the order of the Scramble polynomial parameter. The vector element values must be integers from 0 to Calculation base – 1.

Dependencies

This parameter is available when Initial states source is set to Dialog Parameter.

Reset on nonzero input via port — Reset scrambler via input port

off (default) | on

Select this parameter to reset the Scrambler block via input port Rst.

Dependencies

This parameter is available when Initial states source is set to Dialog Parameter.

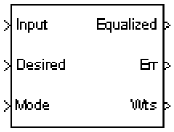
Sign LMS Decision Feedback Equalizer

(To be removed) Equalize using decision feedback equalizer that updates weights with signed LMS algorithm

Note will be removed in a future release. Consider using Decision Feedback Equalizer instead.



Library

Equalizers

Description

The Sign LMS Decision Feedback Equalizer block uses a decision feedback equalizer and an algorithm from the family of signed LMS algorithms to equalize a linearly modulated baseband signal through a dispersive channel.

The supported algorithms, corresponding to the **Update algorithm** parameter, are

- `Sign LMS`
- `Sign Regressor LMS`
- `Sign Sign LMS`

During the simulation, the block uses the particular signed LMS algorithm to update the weights, once per symbol. If the **Number of samples per symbol** parameter is `1`, then the block implements a symbol-spaced equalizer; otherwise, the block implements a fractionally spaced equalizer.

Input and Output Signals

The `Input` port accepts a column vector input signal. The `Desired` port receives a training sequence with a length that is less than or equal to the number of symbols in the `Input` signal. Valid training symbols are those symbols listed in the **Signal constellation** vector.

Set the **Reference tap** parameter so it is greater than zero and less than the value for the **Number of forward taps** parameter.

The port labeled `Equalized` outputs the result of the equalization process.

You can configure the block to have one or more of these extra ports:

- `Mode` input.

- `Err` output for the error signal, which is the difference between the `Equalized` output and the reference signal. The reference signal consists of training symbols in training mode, and detected symbols otherwise.
- `Weights` output.

Decision-Directed Mode and Training Mode

To learn the conditions under which the equalizer operates in training or decision-directed mode, see “Equalization”.

Equalizer Delay

For proper equalization, you should set the **Reference tap** parameter so that it exceeds the delay, in symbols, between the transmitter's modulator output and the equalizer input. When this condition is satisfied, the total delay, in symbols, between the modulator output and the equalizer *output* is equal to

1+(**Reference tap**-1)/(**Number of samples per symbol**)

Because the channel delay is typically unknown, a common practice is to set the reference tap to the center tap of the forward filter.

Parameters

Update algorithm

The specific type of signed LMS algorithm that the block uses to update the equalizer weights.

Number of forward taps

The number of taps in the forward filter of the decision feedback equalizer.

Number of feedback taps

The number of taps in the feedback filter of the decision feedback equalizer.

Number of samples per symbol

The number of input samples for each symbol.

- When you set this parameter to `1`, the filter weights are updated once for each symbol, for a symbol spaced (i.e. T-spaced) equalizer.
- When you set this parameter to a value greater than `1`, the weights are updated once every N^{th} sample, for a T/N-spaced equalizer.

Signal constellation

A vector of complex numbers that specifies the constellation for the modulation.

Reference tap

A positive integer less than or equal to the number of forward taps in the equalizer.

Step size

The step size of the signed LMS algorithm.

Leakage factor

The leakage factor of the signed LMS algorithm, a number between 0 and 1. A value of 1 corresponds to a conventional weight update algorithm, and a value of 0 corresponds to a memoryless update algorithm.

Initial weights

A vector that concatenates the initial weights for the forward and feedback taps.

Mode input port

When you select this check box, the block has an input port that allows you to toggle between training and decision-directed mode. For training, the mode input must be 1, for decision directed, the mode should be 0. For every frame in which the mode input is 1 or not present, the equalizer trains at the beginning of the frame for the length of the desired signal.

Output error

When you select this check box, the block outputs the error signal, which is the difference between the equalized signal and the reference signal.

Output weights

When you select this check box, the block outputs the current forward and feedback weights, concatenated into one vector.

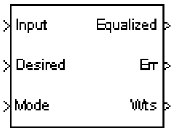
Sign LMS Linear Equalizer

(To be removed) Equalize using linear equalizer that updates weights with signed LMS algorithm

Note will be removed in a future release. Consider using Linear Equalizer instead.



Library

Equalizers

Description

The Sign LMS Linear Equalizer block uses a linear equalizer and an algorithm from the family of signed LMS algorithms to equalize a linearly modulated baseband signal through a dispersive channel. The supported algorithms, corresponding to the **Update algorithm** parameter, are

- `Sign LMS`
- `Sign Regressor LMS`
- `Sign Sign LMS`

During the simulation, the block uses the particular signed LMS algorithm to update the weights, once per symbol. When you set the **Number of samples per symbol** parameter to `1`, then the block implements a symbol-spaced equalizer and updates the filter weights once for each symbol. When you set the **Number of samples per symbol** parameter to a value greater than 1, the weights are updated once every N^{th} sample, for a T/N-spaced equalizer.

Input and Output Signals

The `Input` port accepts a column vector input signal. The `Desired` port receives a training sequence with a length that is less than or equal to the number of symbols in the `Input` signal. Valid training symbols are those symbols listed in the **Signal constellation** vector.

Set the **Reference tap** parameter so it is greater than zero and less than the value for the **Number of taps** parameter.

The `Equalized` port outputs the result of the equalization process.

You can configure the block to have one or more of these extra ports:

- `Mode` input.

- `Err` output for the error signal, which is the difference between the `Equalized` output and the reference signal. The reference signal consists of training symbols in training mode, and detected symbols otherwise.
- `Weights` output.

Decision-Directed Mode and Training Mode

To learn the conditions under which the equalizer operates in training or decision-directed mode, see "Equalization".

Equalizer Delay

For proper equalization, you should set the **Reference tap** parameter so that it exceeds the delay, in symbols, between the transmitter's modulator output and the equalizer input. When this condition is satisfied, the total delay, in symbols, between the modulator output and the equalizer *output* is equal to

1+(**Reference tap**-1)/(**Number of samples per symbol**) (5-1)

Because the channel delay is typically unknown, a common practice is to set the reference tap to the center tap.

Parameters

Update algorithm

The specific type of signed LMS algorithm that the block uses to update the equalizer weights.

Number of taps

The number of taps in the filter of the linear equalizer.

Number of samples per symbol

The number of input samples for each symbol.

Signal constellation

A vector of complex numbers that specifies the constellation for the modulation.

Reference tap

A positive integer less than or equal to the number of taps in the equalizer.

Step size

The step size of the signed LMS algorithm.

Leakage factor

The leakage factor of the signed LMS algorithm, a number between 0 and 1. A value of 1 corresponds to a conventional weight update algorithm, and a value of 0 corresponds to a memoryless update algorithm.

Initial weights

A vector that lists the initial weights for the taps.

Mode input port

When you select this check box, the block has an input port that allows you to toggle between training and decision-directed mode. For training, the mode input must be 1, for decision directed, the mode should be 0. For every frame in which the mode input is 1 or not present, the equalizer trains at the beginning of the frame for the length of the desired signal.

Output error

When you select this check box, the block outputs the error signal, which is the difference between the equalized signal and the reference signal.

Output weights

When you select this check box, the block outputs the current weights.

SISO Fading Channel

Filter input signal through SISO multipath fading channel
Library: Communications Toolbox / Channels

Description

The SISO Fading Channel block filters an input signal using a single-input/single-output (SISO) multipath fading channel. This block models both Rayleigh and Rician fading. For processing details, see the Algorithms on page 5-768 section.

Ports

Input

`in` — Input data signal
vector

Input data signal, specified as an N_S-by-1 vector. N_S represents the number of samples in the input signal.

Data Types: `double` | `single`
Complex Number Support: Yes

Output

`Out1` — Output data signal for fading channel
vector

Output data signal for the fading channel, returned as an N_S-by-1 vector. N_S represents the number of samples in the input signal.

`Gain` — Discrete path gains
matrix

Discrete path gains of the underlying fading process, returned as an N_S-by-N_P matrix.

- N_S represents the number of samples in the input signal.
- N_P represents the number of channel paths.

Dependencies

To enable this port, on the **Main** tab, select Output channel path gains.

`Delay` — Channel filter delay
scalar

Channel filter delay, returned as a scalar.

Dependencies

To enable this port, on the **Main** tab, select Output channel filter delay.

Parameters

Main Tab

Multipath parameters (frequency selectivity)

`Inherit sample rate from input` — Option to inherit the sample rate from input
on (default) | off

Select this parameter to use the sample rate of the input signal when processing. When `Inherit sample rate from input` is selected, the sample rate is N_S/T_S, where N_S is the number of input samples, and T_S is the model sample time.

`Sample rate (Hz)` — Input signal sample rate
`1` (default) | positive scalar

Input signal sample rate in hertz, specified as a positive scalar. To match the model settings, set the sample rate to N_S/T_S, where N_S is the number of input samples, and T_S is the model sample time.

Dependencies

This parameter appears when Inherit sample rate from input is not selected.

Data Types: `double`

`Discrete path delays (s)` — Delays for each discrete path
`0` (default) | nonnegative scalar | row vector

Delays for each discrete path in seconds, specified as a nonnegative scalar or row vector.

- When you set **Discrete path delays (s)** to a scalar, the SISO channel is frequency flat.
- When you set **Discrete path delays (s)** to a vector, the SISO channel is frequency selective.

Data Types: `double`

`Average path gains (dB)` — Average gain for each discrete path
`0` (default) | scalar | row vector

Average gain for each discrete path in decibels, specified as a scalar or row vector. **Average path gains (dB)** must have the same size as Discrete path delays (s).

Data Types: `double`

`Normalize average path gains to 0 dB` — Option to normalize average path gains to 0 dB
on (default) | off

Select this parameter to normalize the fading processes so that the total power of the path gains, averaged over time, is 0 dB.

Fading distribution — Fading distribution of channel

Rayleigh (default) | Rician

Select the fading distribution of the channel, either Rayleigh or Rician.

K-factors — K-factor of Rician fading channel

3 (default) | positive scalar | row vector of nonnegative values

K-factor of a Rician fading channel, specified as a positive scalar or a 1-by-N_P vector of nonnegative values. N_P equals the value of the Discrete path delays (s) parameter.

- If you set **K-factors** to a scalar, the first discrete path is a Rician fading process with a Rician K-factor of **K-factors**. Any remaining discrete paths are independent Rayleigh fading processes.
- If you set **K-factors** to a row vector, the discrete path corresponding to a positive element of the **K-factors** vector is a Rician fading process with a Rician K-factor specified by that element. The discrete path corresponding to any zero-valued elements of the **K-factors** vector are Rayleigh fading processes. At least one element value must be nonzero.

Dependencies

This parameter appears when Fading distribution is Rician.

Data Types: double

LOS path Doppler shifts (Hz) — Doppler shifts for line-of-sight components

0 (default) | scalar | row vector

Doppler shifts for the line-of-sight components of the Rician fading channel in hertz, specified as a scalar or row vector. This parameter must have the same size as K-factors.

- If you set **LOS path Doppler shifts (Hz)** to a scalar, it represents the line-of-sight component Doppler shift of the first discrete path that is a Rician fading process.
- If you set **LOS path Doppler shifts (Hz)** to a row vector, the discrete path that is a Rician fading process has its line-of-sight component Doppler shift specified by the elements of **LOS path Doppler shifts (Hz)** that correspond to positive elements in the K-factors vector.

Dependencies

This parameter appears when Fading distribution is Rician.

Data Types: double

LOS path initial phases (rad) — Initial phases for line-of-sight components

0 (default) | scalar | row vector

Initial phases for the line-of-sight component of the Rician fading channel in radians, specified as a scalar or row vector. This parameter must have the same size as K-factors.

- If you set **LOS path initial phases (rad)** to a scalar, it is the line-of-sight component initial phase of the first discrete path that is a Rician fading process.
- If you set **LOS path initial phases (rad)** to a row vector, the discrete path that is a Rician fading process has its line-of-sight component initial phase specified by the elements of **LOS path initial phases (rad)** that correspond to positive elements in the K-factors vector.

Dependencies

This parameter appears when Fading distribution is `Rician`.

Data Types: `double`

Doppler parameters (time dispersion)

`Maximum Doppler shift (Hz)` — Maximum Doppler shift for all channel paths

`0.001` (default) | nonnegative scalar

Maximum Doppler shift for all channel paths in hertz, specified as a nonnegative scalar.

Maximum Doppler shift (Hz) must be smaller than (f_s/10)/f_c for each path. f_s is the sampling rate at the input to the SISO Fading Channel block. f_c is the cutoff frequency factor of the path. For more information, see Cutoff Frequency Factor on page 5-517.

Data Types: `double`

`Doppler spectrum` — Doppler spectrum shape for all channel paths

`doppler('Jakes')` (default) | `doppler('Flat')` | `doppler('Rounded', ...)` | `doppler('Bell', ...)` | `doppler('Asymmetric Jakes', ...)` | `doppler('Restricted Jakes', ...)` | `doppler('Gaussian', ...)` | `doppler('BiGaussian', ...)`

Doppler spectrum shape for all channel paths, specified as a single Doppler spectrum structure returned from the `doppler` function or a 1-by-N_P cell array of such structures. The default value of this parameter is the Jakes Doppler spectrum (`doppler('Jakes')`).

- If you assign a single call to `doppler`, all paths have the same specified Doppler spectrum.
- If you assign a 1-by-N_P cell array of calls to `doppler` using any of the specified syntaxes, each path has the Doppler spectrum specified by the corresponding Doppler spectrum structure in the array. In this case, N_P equals the value of the Discrete path delays (s) parameter.

Dependencies

This parameter applies when Maximum Doppler shift (Hz) is greater than zero.

Other parameters

`Initial seed` — Random number generator initial seed

`73` (default) | nonnegative integer

Random number generator initial seed for this block, specified as a nonnegative integer.

`Output channel path gains` — Option to output channel path gains

off (default) | on

Select this parameter to add the Gain output port to the block and output the channel path gains of the underlying fading process.

`Output channel filter delay` — Option to output channel filter delay

off (default) | on

Select this parameter to add the Delay output port to the block and output the channel filter delay of the underlying fading process.

`Simulate using` — Compilation type

`Interpreted execution` (default) | `Code generation`

Compilation type, specified as `Interpreted execution` or `Code generation`.

- `Interpreted execution` — Simulate model using the MATLAB interpreter. This option shortens startup time but has slower simulation speed than `Code generation`.
- `Code generation` — Simulate model using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations, as long as the model does not change. This option requires additional startup time but provides faster simulation speed than `Interpreted execution`.

Visualization Tab

`Channel visualization` — Select the channel visualization

`Off` (default) | `Impulse response` | `Frequency response` | `Doppler spectrum` | `Impulse and frequency responses`

Select the channel visualization: `Off`, `Impulse response`, `Frequency response`, `Doppler spectrum`, or `Impulse and frequency responses`. When visualization is on, the selected channel characteristics, such as impulse response or Doppler spectrum, display in a separate window. For more information, see Channel Visualization.

`Percentage of samples to display` — Percentage of samples to display

`25%` (default) | `10%` | `50%` | `100%`

Select the percentage of samples to display: `10%`, `25%`, `50%`, or `100%`. Increasing the percentage improves display accuracy at the expense of simulation speed.

Dependencies

This parameter appears when Channel visualization is `Impulse response`, `Frequency response`, or `Impulse and frequency responses`.

`Path for Doppler spectrum display` — Path for which Doppler spectrum is displayed

`1` (default) | positive integer

Path for which the Doppler spectrum is displayed, specified as a positive integer from 1 to N_P, where N_P equals the value of the Discrete path delays (s) parameter.

Dependencies

This parameter appears when Channel visualization is `Doppler spectrum`.

Block Characteristics

Data Types	`double` | `single`
Multidimensional Signals	`yes`
Variable-Size Signals	`yes`

Algorithms

The fading process for the SISO channel is described in Methodology for Simulating Multipath Fading Channels.

Cutoff Frequency Factor

The cutoff frequency factor, f_c, is determined for different Doppler spectrum types.

- For any Doppler spectrum type other than Gaussian and biGaussian, f_c equals 1.
- For a `doppler('Gaussian')` spectrum type, f_c equals `NormalizedStandardDeviation` × $\sqrt{2\log 2}$.
- For a `doppler('BiGaussian')` spectrum type:
  - If the `PowerGains(1)` and `NormalizedCenterFrequencies(2)` field values are both `0`, then f_c equals `NormalizedStandardDeviation(1)` × $\sqrt{2\log 2}$.
  - If the `PowerGains(2)` and `NormalizedCenterFrequencies(1)` field values are both `0`, then f_c equals `NormalizedStandardDeviation(2)` × $\sqrt{2\log 2}$.
  - If the `NormalizedCenterFrequencies` field value is `[0,0]` and the `NormalizedStandardDeviation` field has two identical elements, then f_c equals `NormalizedStandardDeviation(1)` × $\sqrt{2\log 2}$.
  - In all other cases, f_c equals 1.

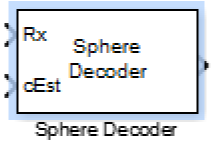
Sphere Decoder

Decode input using a sphere decoder



Library

MIMO

Description

This block decodes the symbols sent over `Nt` antennas using the sphere decoding algorithm.

Data Type

For information about the data types each block port supports, see the “Supported Data Type” on page 5-771 table on this page. The output signal inherits the data type from the inputs.

Algorithm

This block implements the algorithm, inputs, and outputs described on the `comm.SphereDecoder` System object block reference page. The object properties correspond to the block parameters.

Parameters

Signal constellation

Specify the number of points in the signal constellation to which the bits are mapped. This value must be a complex column vector. The length of the vector must be a power of two. The block uses the same constellation for each transmit antenna. The default setting is a QPSK constellation with an average power of 1.

Bit mapping per constellation point

Specify the bit mapping that the block uses for each constellation point. This value must be a numerical matrix. he matrix size must be [ConstellationLength bitsPerSymbol], where ConstellationLength represents the length of the **Signal constellation** parameter value and bitsPerSymbol represents the number of bits that each symbol encodes. The default matrix size is [0 0; 0 1; 1 0; 1 1], which matches the default value of the **Signal constellation** property.

Initial search radius

Specify the initial search radius for the decoding algorithm as `Infinity` or `ZF solution`.

When you select `Infinity`, the block sets the initial search radius to Inf. When you select `ZF solution`, the block 'sets the initial search radius to the zero-forcing solution. The zero-forcing solution is calculated by the pseudo-inverse of the input channel when decoding. Large constellations and/or antenna counts can benefit from the initial reduction in the search radius. In most cases, however, the extra computation of the `ZF Solution` will not provide a benefit.

Decision method

Specify the decoding decision method as `Soft` or `Hard`. When you select `Soft` the block outputs log-likelihood ratios (LLRs), or soft bits. When you select set to `Hard`, the block converts the soft LLRs to bits. The hard decision output logical array follows the mapping of a `0` for a negative LLR and `1` for all other values.

Simulation using

Specify if the block simulates using `Code generation` or `Interpreted execution`. The default is `Interpreted execution`.

Supported Data Type

Port	Supported Data Types
Rx	• Double-precision floating point
cEst	• Double-precision floating point
Output	• Double-precision floating point • Boolean (Hard-decision method)

Limitations

- The output LLR values are not scaled by the noise variance. For coded links employing iterative coding (LDPC or turbo) or MIMO OFDM with Viterbi decoding, the output LLR values should be scaled by the channel state information to achieve better performance.

Algorithms

This block implements the algorithm, inputs, and outputs described on the Sphere Decoder System object reference page. The object properties correspond to the block parameters.

SSB AM Demodulator Passband

Demodulate SSB-AM-modulated data

Library

Analog Passband Modulation, in Modulation

Description

The SSB AM Demodulator Passband block demodulates a signal that was modulated using single-sideband amplitude modulation. The input is a passband representation of the modulated signal. Both the input and output signals are real scalar signals.

This block works only with real inputs of type `double`. This block does not work inside a triggered subsystem.

Parameters

Carrier frequency (Hz)

The carrier frequency in the corresponding SSB AM Modulator Passband block.

Initial phase (rad)

The phase offset, θ, of the modulated signal.

Lowpass filter design method

The method used to generate the filter. Available methods are Butterworth, Chebyshev type I, Chebyshev type II, and Elliptic.

Filter order

The order of the lowpass digital filter specified in the **Lowpass filter design method** field .

Cutoff frequency

The cutoff frequency of the lowpass digital filter specified in the **Lowpass filter design method** field in Hertz.

Passband ripple

Applies to Chebyshev type I and Elliptic filters only. This is peak-to-peak ripple in the passband in dB.

Stopband ripple

Applies to Chebyshev type II and Elliptic filters only. This is the peak-to-peak ripple in the stopband in dB.

SSB AM Modulator Passband

Modulate using single-sideband amplitude modulation

Library

Analog Passband Modulation, in Modulation

Description

The SSB AM Modulator Passband block modulates using single-sideband amplitude modulation with a Hilbert transform filter. The output is a passband representation of the modulated signal. Both the input and output signals are real scalar signals.

SSB AM Modulator Passband transmits either the lower or upper sideband signal, but not both. To control which sideband it transmits, use the **Sideband to modulate** parameter.

If the input is $u(t)$ as a function of time t, then the output is

$$u(t)\cos(f_c t + \theta) \mp \widehat{u}(t)\sin(f_c t + \theta)$$

where:

- f_c is the **Carrier frequency** parameter.
- θ is the **Initial phase** parameter.
- $\hat{u}(t)$is the Hilbert transform of the input $u(t)$.
- The minus sign indicates the upper sideband and the plus sign indicates the lower sideband.

Hilbert Transform Filter

This block uses the Analytic Signal block from the DSP System Toolbox Transforms block library.

The Analytic Signal block computes the complex analytic signal corresponding to each channel of the real M-by-N input, u

$$y = u + jH\{u\}$$

where $j = \sqrt{-1}$ and $H\{\}$denotes the Hilbert transform. The real part of the output in each channel is a replica of the real input in that channel; the imaginary part is the Hilbert transform of the input. In the frequency domain, the analytic signal retains the positive frequency content of the original signal while zeroing-out negative frequencies and doubling the DC component.

The block computes the Hilbert transform using an equiripple FIR filter with the order specified by the Filter order parameter, n. The linear phase filter is designed using the Remez exchange algorithm, and imposes a delay of n/2 on the input samples.

For best results, use a carrier frequency which is estimated to be larger than 10% of your input signal's sample rate. This is due to the implementation of the Hilbert transform by means of a filter.

In the following example, we sample a 10Hz input signal at 8000 samples per second. We then designate a Hilbert Transform filter of order 100. Below is the response of the Hilbert Transform filter as returned by `fvtool`.

Frequency (kHz)

Note the bandwidth of the filter's magnitude response. By choosing a carrier frequency larger than 10% (but less than 90%) of the input signal's sample time (8000 samples per second, in this example) or equivalently, a carrier frequency larger than 400Hz, we ensure that the Hilbert Transform Filter will be operating in the flat section of the filter's magnitude response (shown in blue), and that our modulated signal will have the desired magnitude and form.

Typically, an appropriate **Carrier frequency** value is much higher than the highest frequency of the input signal. By the Nyquist sampling theorem, the reciprocal of the model's sample time (defined by the model's signal source) must exceed twice the **Carrier frequency** parameter.

This block works only with real inputs of type `double`. This block does not work inside a triggered subsystem.

Parameters

Carrier frequency (Hz)

The frequency of the carrier.

Initial phase (rad)

The phase offset, θ, of the modulated signal.

Sideband to modulate

This parameter specifies whether to transmit the upper or lower sideband.

Hilbert Transform filter order

The length of the FIR filter used to compute the Hilbert transform.

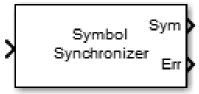
Symbol Synchronizer

Correct symbol timing clock skew
Library: Communications Toolbox / Synchronization



Symbol Synchronizer

Description

The Symbol Synchronizer block corrects symbol timing clock skew for PAM, PSK, QAM, or OQPSK modulation schemes between a single-carrier transmitter and receiver. For more information, see “Symbol Synchronization Overview” on page 5-779.

Note The input signal operates on a sample rate basis, while the output signal operates on a symbol rate basis.

Ports

Input

`samples` — Input samples
scalar (default) | column vector

Input samples, specified as a scalar or column vector of a PAM, PSK, QAM, or OQPSK modulated single-carrier signal. This port in unnamed on the block.

Data Types: `double` | `single`
Complex Number Support: Yes

Output

`Sym` — Output signal symbols
scalar | column vector

Output signal symbols, returned as a variable-size scalar or column vector that has the same data type as the input. For an input with dimensions of N_{samp}-by-1, the output at **Sym** has dimensions of N_{sym}-by-1. N_{sym} is approximately equal to N_{samp} divided by the N_{sps}. N_{sps} is equal to the **Samples per symbol** parameter. If the output exceeds the maximum output size of $\left\lceil \frac{N_{\mathrm{samp}}}{N_{\mathrm{sps}}} \times 1.1 \right\rceil$, it is truncated.

This port is unnamed when **Normalized timing error output port** is not selected.

`Err` — Estimated timing error
scalar | column vector

Estimated timing error for each input sample, returned as a scalar or column vector with values in the range [0, 1]. The estimated timing error is normalized by the input sample time. **Err** has the same data type and size as the input signal.

Dependencies

To enable this port, select **Normalized timing error output port**.

Parameters

`Modulation type` — Modulation type

`PAM/PSK/QAM` (default) | `OQPSK`

Modulation type, specified as `PAM/PSK/QAM`, or `OQPSK`.

`Timing error detector` — Type of timing error detector

`Zero-Crossing (decision-directed)` (default) | `Gardner (non-data-aided)` | `Early-Late (non-data-aided)` | `Mueller-Muller (decision-directed)`

Type of timing error detector, specified as `Zero-Crossing (decision-directed)`, `Gardner (non-data-aided)`, `Early-Late (non-data-aided)`, or `Mueller-Muller (decision-directed)`. This parameter assigns the timing error detection scheme used in the synchronizer.

For more information, see "Timing Error Detection (TED)" on page 5-780.

`Samples per symbol` — Samples per symbol

`2` (default) | positive integer greater than 1

Samples per symbol, specified as a positive integer greater than 1.

Data Types: `double`

`Damping factor` — Damping factor of the loop filter

`1` (default) | positive scalar

Damping factor of the loop filter, specified as a positive scalar. For more information, see "Loop Filter" on page 5-783.

Tunable: Yes

Data Types: `double` | `single`

`Normalized loop bandwidth` — Normalized bandwidth of loop filter

`0.01` (default) | positive scalar less than 1

Normalized bandwidth of the loop filter, specified as a positive scalar less than 1. The loop bandwidth is normalized by the sample rate of the input signal. For more information, see "Loop Filter" on page 5-783.

Note To ensure that the symbol synchronizer locks, set the **Normalized loop bandwidth** parameter to a value less than `0.1`.

Tunable: Yes

Data Types: `double` | `single`

`Detector gain` — Phase detector gain

`2.7` (default) | positive scalar

Phase detector gain, specified as a positive scalar.

Tunable: Yes

Data Types: `double` | `single`

`Normalized timing error output port` — Enable normalized timing error output port
`on` (default) | `off`

Select this parameter to output normalized timing error data at the output port **Err**.

`Simulate using` — Type of simulation to run
`Code generation` (default) | `Interpreted execution`

Type of simulation to run, specified as `Code generation` or `Interpreted execution`.

- `Code generation` –– Simulate the model by using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations unless the model changes. This option requires additional startup time, but the speed of the subsequent simulations is faster than `Interpreted execution`.
- `Interpreted execution` –– Simulate the model by using the MATLAB interpreter. This option requires less startup time than the `Code generation` method, but the speed of subsequent simulations is slower. In this mode, you can debug the source code of the block.

Block Characteristics

Data Types	`double` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`yes`

More About

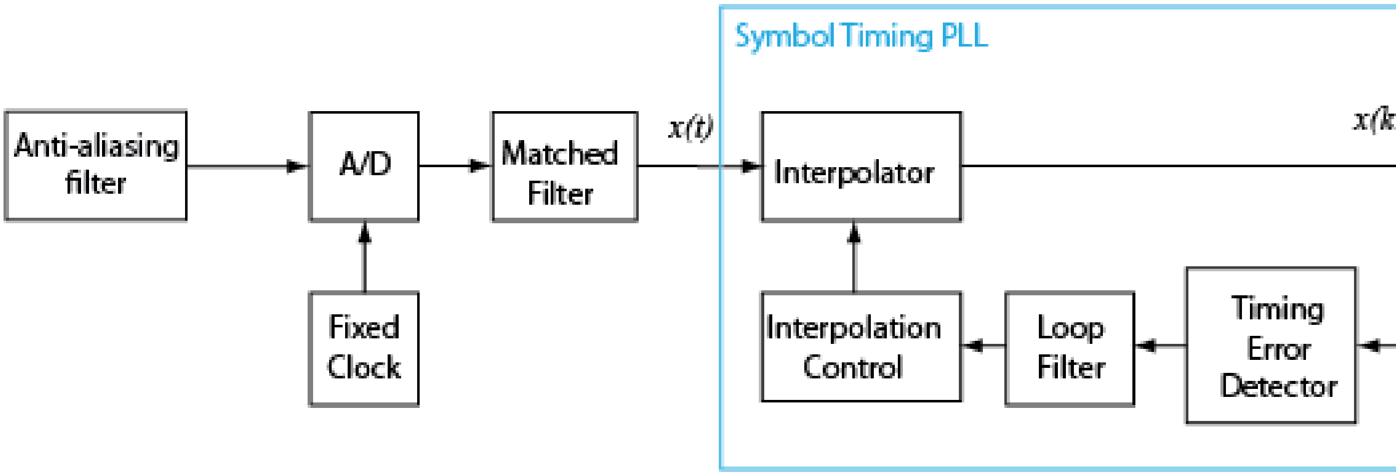
Symbol Synchronization Overview

The symbol timing synchronizer algorithm is based on a phased lock loop (PLL) algorithm that consists of four components:

- A timing error detector (TED)
- An interpolator
- An interpolation controller
- A loop filter

For OQPSK modulation, the in-phase and quadrature signal components are first aligned (as in QPSK modulation) using a state buffer to cache the last half symbol of the previous input. After initial alignment, the remaining synchronization process is the same as for QPSK modulation.

This block diagram shows an example of a timing synchronizer. In the figure, the symbol timing PLL operates on $x(t)$, the received sample signal after matched filtering. The symbol timing PLL outputs the symbol signal, $x(kT_s + \hat{\tau})$, after correcting for the clock skew between the transmitter and receiver.



Timing Error Detection (TED)

The symbol timing synchronizer supports non-data-aided TED and decision-directed TED methods. This table shows the timing estimate expressions for the TED method options.

TED Method	Expression
Zero-crossing (decision-directed)	$e(k) = x((k-1/2)T_s+\hat{\tau})[\hat{a}_0(k-1)-\hat{a}_0(k)] + y((k-1/2)T_s+\hat{\tau})[\hat{a}_1(k-1)-\hat{a}_1(k)]$
Gardner (non-data-aided)	$e(k) = x((k-1/2)T_s+\hat{\tau})[x((k-1)T_s+\hat{\tau}) - x(kT_s+\hat{\tau})] + y((k-1/2)T_s+\hat{\tau})[y((k-1)T_s+\hat{\tau}) - y(kT_s+\hat{\tau})]$
Early-late (non-data-aided)	$e(k) = x(kT_s+\hat{\tau})[x((k+1/2)T_s+\hat{\tau}) - x((k-1/2)T_s+\hat{\tau})] + y(kT_s+\hat{\tau})[y((k+1/2)T_s+\hat{\tau}) - y((k-1/2)T_s+\hat{\tau})]$
Mueller-Muller (decision-directed)	$e(k) = \hat{a}_0(k-1)x(kT_s+\hat{\tau}) - \hat{a}_0(k)x((k-1)T_s+\hat{\tau}) + \hat{a}_1(k-1)y(kT_s+\hat{\tau}) - \hat{a}_1(k)y((k-1)T_s+\hat{\tau})$

Non-data-aided TED uses received samples without any knowledge of the transmitted signal or the results of the channel estimation. Non-data-aided TED is used to estimate the timing error for signals with modulation schemes that have constellation points aligned with the in-phase or quadrature axis. Examples of signals suitable for the Gardner or early-late methods include QPSK-modulated signals with a zero phase offset that has points at {1+0*i*, 0+1*i*, -1+0*i*, 0−1*i*} and BPSK-modulated signals with a zero phase offset.

- **Gardner method** — The Gardner method is a non-data-aided feedback method that is independent of carrier phase recovery. It is used for baseband systems and modulated carrier systems. More specifically, this method is used for systems that use a linear modulation type with Nyquist pulses that have an excess bandwidth between approximately 40% and 100%. Examples include systems that use PAM, PSK, QAM, or OQPSK modulation and that shape the signal using raised cosine filters whose rolloff factor is between 0.4 and 1. In the presence of noise, the performance of this timing recovery method improves as the excess bandwidth increases (or rolloff factor increases in the case of a raised cosine filter). The Gardner method is similar to the early-late gate method.

- **Early-late method** — The early-late method is a non-data-aided feedback method. It is used for systems that use a linear modulation type such as PAM, PSK, QAM, or OQPSK modulation. For example, systems using a raised cosine filter with Nyquist pulses. In the presence of noise, the performance of this timing recovery method improves as the excess bandwidth of the pulse increases (or rolloff factor increases in the case of a raised cosine filter).

The early-late method is similar to the Gardner method. The Gardner method performs better in systems with high SNR values because it has lower self noise than the early-late method.

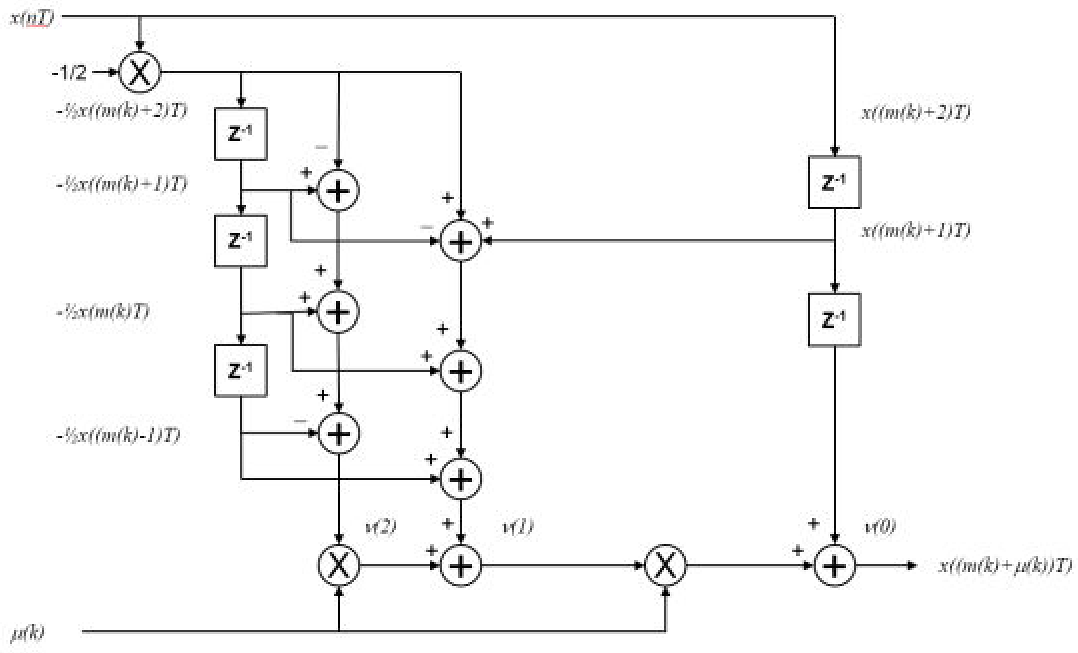
Decision-directed TED uses the `sign` function to estimate the in-phase and quadrature components of received samples, which result in lower computational complexity than non-data-aided TED.

- **Zero-crossing method** — The zero-crossing method is a decision-directed technique that requires 2 samples per symbol at the input to the synchronizer. It is used in low-SNR conditions for all values of excess bandwidth and in moderate-SNR conditions for moderate excess bandwidth factors in the approximate range [0.4, 0.6].
- **Mueller-Muller method** — The Mueller-Muller method is a decision-directed feedback method that requires prior recovery of the carrier phase. When the input signal has Nyquist pulses (for example, when using a raised cosine filter), the Mueller-Muller method has no self noise. For narrowband signaling in the presence of noise, the performance of the Mueller-Muller method improves as the excess bandwidth factor of the pulse decreases.

Because the decision-directed methods (zero-crossing and Mueller-Muller) estimate timing error based on the sign of the in-phase and quadrature components of signals passed to the synchronizer, they are not recommended for constellations that have points with either a zero in-phase or a quadrature component. $x(kT_S + \hat{\tau})$ and $y(kT_S + \hat{\tau})$ are the in-phase and quadrature components of the input signals to the timing error detector, where $\hat{\tau}$ is the estimated timing error. The Mueller-Muller method coefficients $\hat{a}_0(k)$ and $\hat{a}_1(k)$ are the estimates of $x(kT_S + \hat{\tau})$ and $y(kT_S + \hat{\tau})$. The timing estimates are made by applying the `sign` function to the in-phase and quadrature components and are used for only the decision-directed TED methods.

Interpolator

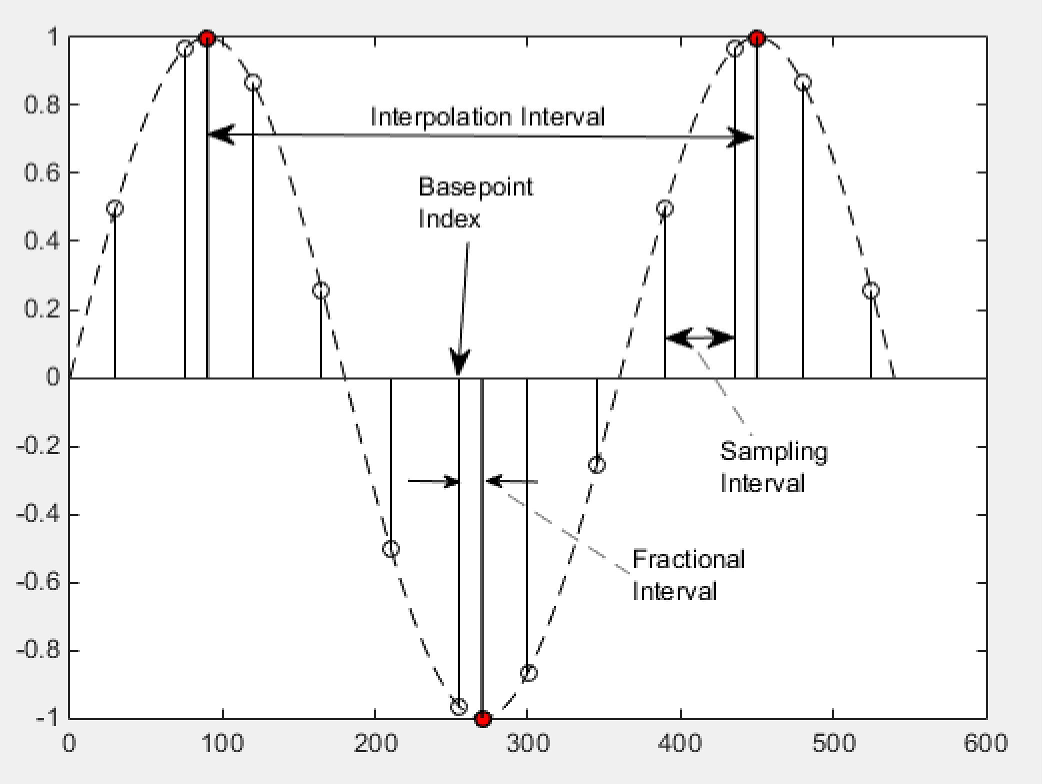
The time delay is estimated from the fixed-rate samples of the matched filter, which are asynchronous with the symbol rate. Because the resulting samples are not aligned with the symbol boundaries, an interpolator is used to "move" the samples. Because the time delay is unknown, the interpolator must be adaptive. Moreover, because the interpolant is a linear combination of the available samples, it can be thought of as the output of a filter.



The interpolator uses a piecewise parabolic interpolator with a Farrow structure and coefficient *α* set to 1/2 (see Rice, Michael, *Digital Communications: A Discrete-Time Approach*).

Interpolation Control

Interpolation control provides the interpolator with the basepoint index and fractional interval. The basepoint index is the sample index nearest to the interpolant. The fractional interval is the ratio of the time between the interpolant and its basepoint index and the interpolation interval.



Interpolation is performed for every sample, and a strobe signal is used to determine if the interpolant is output. The synchronizer uses a modulo-1 counter interpolation control to provide the strobe and the fractional interval for use with the interpolator.

Loop Filter

The synchronizer uses a proportional-plus integrator (PI) loop filter. The proportional gain, K_1, and the integrator gain, K_2, are calculated by

$$K_1 = \frac{-4\zeta\theta}{\left(1 + 2\zeta\theta + \theta^2\right)K_p}$$

and

$$K_2 = \frac{-4\theta^2}{\left(1 + 2\zeta\theta + \theta^2\right)K_p} .$$

The interim term, θ, is given by

$$\theta = \frac{\frac{B_n T_s}{N}}{\zeta + \frac{1}{4\zeta}} ,$$

where:

- N is the number of samples per symbol.

- ζ is the damping factor.
- B_nT_s is the normalized loop bandwidth.
- K_p is the detector gain.

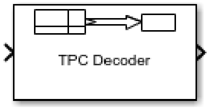
TPC Decoder

Turbo product code (TPC) decoder

Library: Communications Toolbox / Error Detection and Correction / Block



Description

The TPC Decoder block performs 2-D turbo product code (TPC) decoding of the soft input LLRs corresponding to the product code iteratively, using Chase-Pyndiah algorithm. The product code is a 2-D concatenation of linear block codes. The linear block code can be a parity check code, a Hamming code, or a BCH code capable of correcting two errors. Extended and shortened codes can be applied independently on each dimension. For a description of 2-D TPC decoding, see “Turbo Product Code Decoding” on page 5-790.

For information about valid code pairs and the error-correcting capability for each valid code pair, see “Component Code Pairs” on page 5-788.

Ports

Input

In — Log likelihood ratios

column vector

Log likelihood ratios, specified as a column vector.

- For full-length input messages, the length of the column vector is the product of Number of rows in code, Nr and Number of columns in code, Nc.
- For shortened input messages, the length of the column vector is the product of (N_R–K_R+S_R) and (N_C–K_C+S_C), where:
  - N_R is the value of Number of rows in code, Nr.
  - K_R is the value of Number of rows in message, Kr.
  - S_R is the value of Number of rows in shortened message, Sr.
  - N_C is the value of Number of columns in code, Nc.
  - K_C is the value of Number of columns in message, Kc.
  - S_C is the value of Number of columns in shortened message, Sc.

Data Types: `double` | `single`

Output

Out — TPC decoded message

column vector

TPC decoded message, returned as a column vector of binary values.

- For full-length input messages, the length of the column vector is the product of Number of rows in message, Kr and Number of columns in message, Kc.
- For shortened input messages, the length of the column vector is the product of Number of rows in shortened message, Sr and Number of columns in shortened message, Sc.

Data Types: `Boolean`

`Iter` — Actual number of decoding iterations

positive integer

Actual number of decoding iterations, returned as a positive integer.

Dependencies

To enable this port, select Output number of itereations executed.

Data Types: `double`

Parameters

Row TPC parameters

`Extended codes` — Extended codes indicator for TPC row parameters

`on` (default) | `off`

- When Extended codes is selected, the lists for Number of rows in code, Nr and Number of rows in message, Kr contain the valid values for extended individual code pairs (N_R,K_R).
- When Extended codes is cleared, the lists for Number of rows in code, Nr and Number of rows in message, Kr contain the valid values for nonextended individual code pairs (N_R,K_R).

`Number of rows in code, Nr` — Number of rows in product code matrix

`16` (default) | integer

Number of rows in the product code matrix, N_R. The list of integer values varies depending on the setting for Extended codes.

`Number of rows in message, Kr` — Number of rows in message matrix

`11` (default) | integer

Number of rows in the message matrix, K_R. The list of integer values varies depending on the setting for Extended codes and Number of rows in code, Nr.

`Specify shortened message length` — Specify shortened message length for rows

`off` (default) | `on`

Select **Specify shortened message length** to specify a value for Number of rows in shortened message, Sr.

`Number of rows in shortened message, Sr` — Number of rows in shortened message matrix

`9` (default) | integer

Number of rows in the shortened message matrix, S_R, specified as an integer less than or equal to K_R. When you specify this parameter, provide full-length N_R and K_R values to specify the (N_R,K_R) code pair. This code pair is then shortened to the (N_R-K_R+S_R,S_R) code pair, where:

- N_R is the value of Number of rows in code, Nr.
- K_R is the value of Number of rows in message, Kr.
- S_R is the value of Number of rows in shortened message, Sr.

Dependencies

To enable this parameter, select Specify shortened message length.

Data Types: `double`

Column TPC parameters

`Extended codes` — Extended codes indicator for TPC column parameters

`on` (default) | `off`

- When Extended codes is selected, the lists for Number of columns in code, Nc and Number of columns in message, Kc contain the valid values for extended individual code pairs (N_C,K_C).
- When Extended codes is cleared, the lists for Number of columns in code, Nc and Number of columns in message, Kc contain the valid values for nonextended individual code pairs (N_C,K_C).

`Number of columns in code, Nc` — Number of columns in product code matrix

`32` (default) | integer

Number of columns in the product code matrix, N_C. The list of integer values varies depending on the setting for Extended codes.

`Number of columns in message, Kc` — Number of columns in message matrix

`26` (default) | integer

Number of columns in the message matrix, K_C. The list of integer values varies depending on the setting for Extended codes and Number of columns in code, Nc.

`Specify shortened message length` — Specify shortened message length for columns

`off` (default) | `on`

Select **Specify shortened message length** to specify a value for Number of columns in shortened message, Sc.

`Number of columns in shortened message, Sc` — Number of columns in shortened message matrix

`22` (default) | integer

Number of columns in the shortened message matrix, S_C, specified as an integer. When you specify this parameter, provide full-length N_C and K_C values to specify the (N_C,K_C) code pair. This code pair is then shortened to the (N_C-K_C+S_C, S_C) code pair, where:

- N_C is the value of Number of columns in code, Nc.
- K_C is the value of Number of columns in message, Kc.
- S_C is the value of Number of columns in shortened message, Sc.

Dependencies

To enable this parameter, select Specify shortened message length.

Data Types: `double`

`Maximum number of iterations` — Maximum number of decoding iterations
`4` (default) | positive integer

Maximum number of decoding iterations, specified as a positive integer.

Data Types: `double`

`Stop iterating when code converges` — Stop decoding based on the calculated syndrome or parity-check of the component code
`on` (default) | `off`

Select **Stop iterating when code converges** to terminate decoding early if the calculated syndrome or parity-check of the component code evaluates to zero before Maximum number of iterations.

`Output number of iterations executed` — Output number of iterations executed
`off` (default) | `on`

Select this parameter to add the `Iter` output port and output the actual number of TPC decoding iterations performed.

`Simulate using` — Type of simulation to run
`Code generation` (default) | `Interpreted execution`

Type of simulation to run, specified as `Code generation` or `Interpreted execution`.

- `Code generation` –– Simulate the model by using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations unless the model changes. This option requires additional startup time, but the speed of the subsequent simulations is faster than `Interpreted execution`.
- `Interpreted execution` –– Simulate the model by using the MATLAB interpreter. This option requires less startup time than the `Code generation` method, but the speed of subsequent simulations is slower. In this mode, you can debug the source code of the block.

Block Characteristics

Data Types	`Boolean` | `double` | `single`
Multidimensional Signals	`no`
Variable-Size Signals	`no`

More About

Component Code Pairs

This table lists the supported component code pairs for the row (N_R,K_R) and column (N_C,K_C) parameters.

- N_R and K_R represent the number of rows in the product code matrix and message matrix, respectively.
- N_C and K_C represent the number of columns in the product code matrix and message matrix, respectively.

Within each code type, any two component code pairs can form a 2-D TPC code. The table also includes the error-correction capability for each code pair.

Code type	**Component Code Pairs**(N_R,K_R) and (N_C,K_C)	**Error-Correction Capability (*T*)**
Hamming code	(255,247)	1

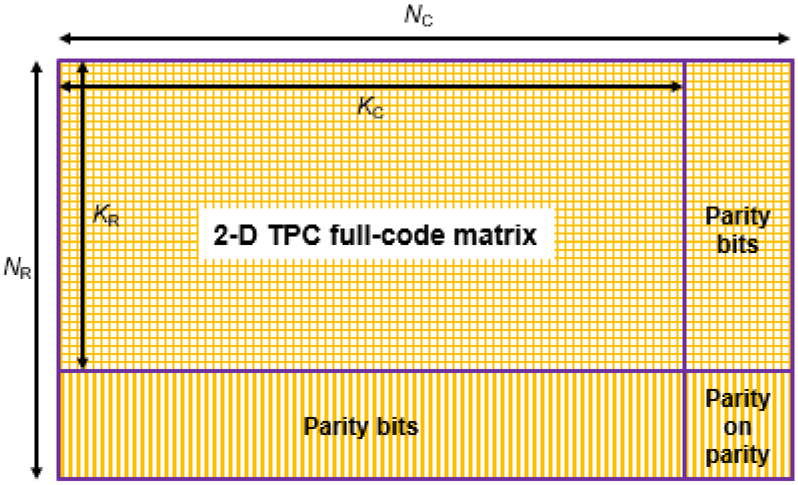
Turbo Product Code Decoding

Turbo product codes (TPC) are a form of concatenated codes used as forward error correcting (FEC) codes. Two or more component block codes, such as systematic linear block codes, are used to construct TPCs. The TPC decoder achieves near-optimum decoding of product codes using Chase decoding and the Pyndiah algorithm to perform iterative soft input, soft output decoding. For a detailed description, see [1] and [2]. This decoder implements an iterative soft input, soft output 2-D product code decoding, as described in [2], using two “Linear Block Codes”. The decoder expects the soft bit log likelihood ratios (LLRs) obtained from digital demodulation as the input signal.

The TPC decoder accepts either full-length or shortened codes.

TPC Decoding Full-Length Messages

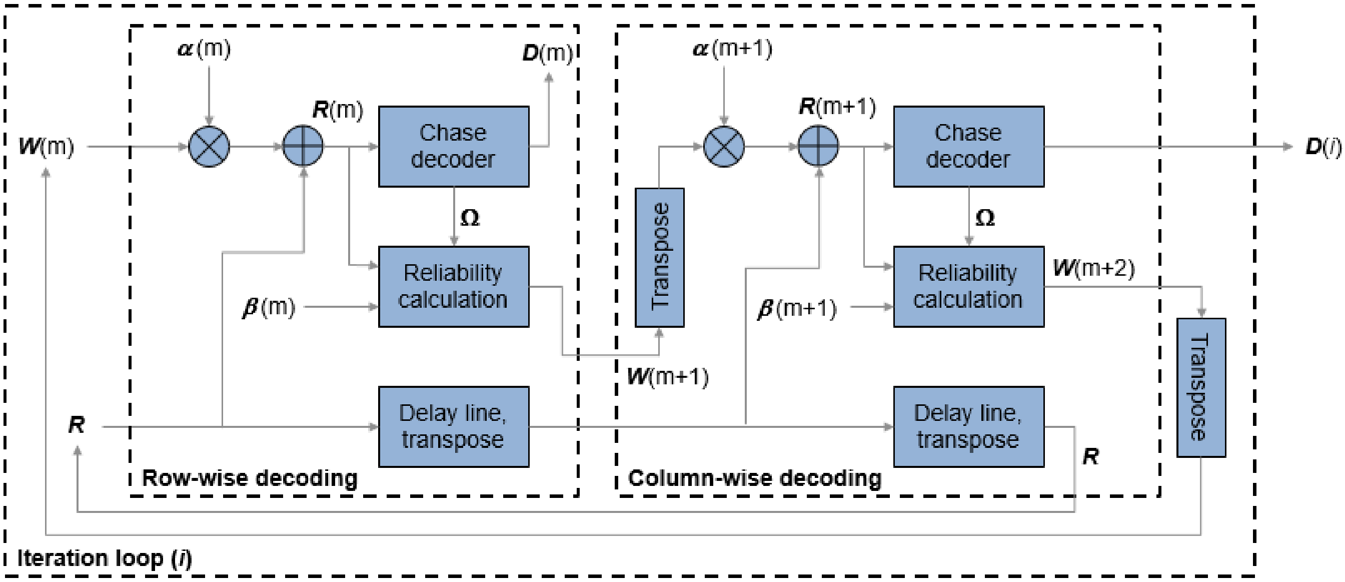
TPC encoded full-length input messages are decoded using specified 2-D TPC code pairs. Row-wise decoding uses the (N_C,K_C) code pair and column-wise decoding uses the (N_R,K_R) code pair. The input vector length must be N_R × N_C. To perform the 2-D TPC decoding, the column vector of the input LLRs, composed of the message and parity bits, is arranged into an N_R-by-N_C matrix.



The TPC decoder achieves near-optimum decoding of product codes using Chase decoding and the Pyndiah algorithm to perform iterative soft input, soft output decoding. Chase decoding forms a set of possible codewords for each row or column. The Pyndiah algorithm calculates soft information required for the next decoding step.

Iterative Soft Input, Soft Output Decoder

The iterative soft input, soft output decoding, as shown in the block diagram, carries out two decoding steps for each iteration.



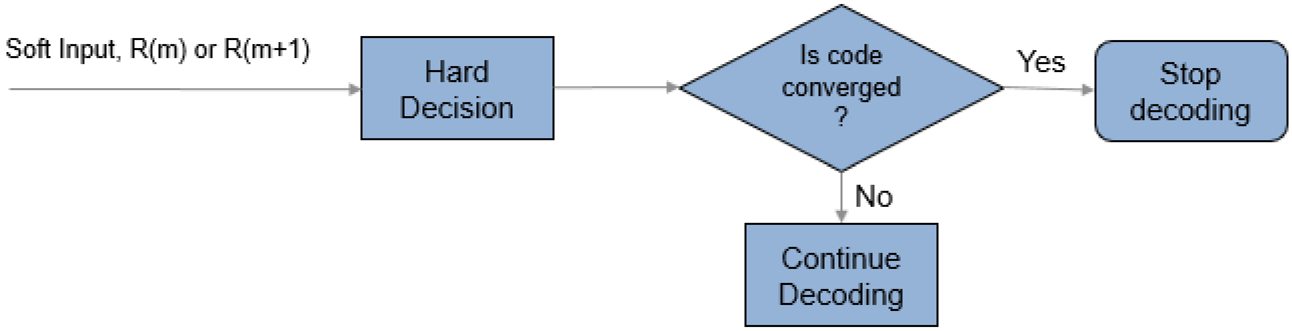
The soft inputs for decoding are $\boldsymbol{R}(m) = \boldsymbol{R} + \alpha(m)\boldsymbol{W}(m)$.

- Iteration loop counter i increments from $i = 1$ to the specified number of iterations.
- $m = 2i - 1$ is the decoding step index.
- $\boldsymbol{R}$ is the received LLR matrix.
- $\boldsymbol{R}(m)$ is the soft input for the mth decoding step.
- $\boldsymbol{W}(m)$ is the input extrinsic information for the mth decoding step.
- $\alpha(m) = [0,0.2,0.3,0.5,0.7,0.9,1,1, \ldots]$, where α is a weighting factor applied based on the decoding step index. For higher decoding steps, $\alpha = 1$.
- $\beta(m) = [0.2,0.4,0.6,0.8,1,1, \ldots]$, where β is a reliability factor applied based on the decoding step index. For higher decoding steps, $\beta = 1$.
- $\boldsymbol{D}$ contains the decoded message bits. The output message bits are formed from $\boldsymbol{D}$ by mapping –1 to 0 and +1 to 1, then reshaping the message block into a column vector.

The output message bits are formed after iterating through the specified number of iterations, or, if early termination is enabled, after code convergence.

Early Termination of TPC Decoding

If early termination is enabled, a code convergence check is performed on the hard decision of the soft input in each row-wise and column-wise decoding step. Early termination can be triggered after either the row-wise decoding or column-wise decoding converges.



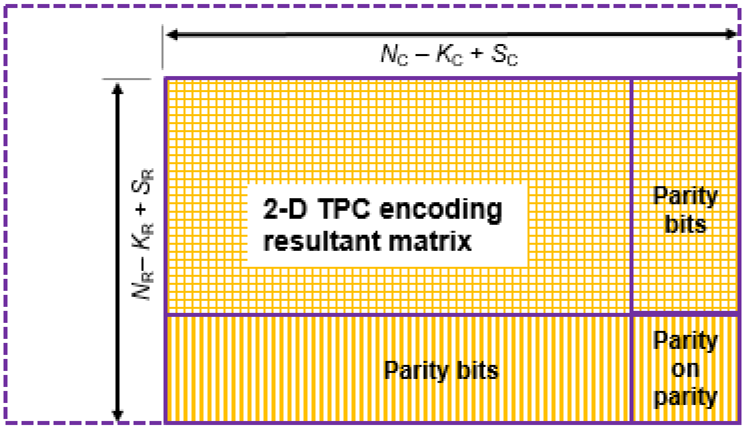
The code is converged if, for all rows or all columns,

- The syndrome evaluates to zero in the codes (Hamming codes, Extended Hamming codes, BCH codes, or Extended BCH codes).
- The parity check is evaluated to zero in parity check codes.

The reported number of iterations evaluates to the iteration value that is currently in progress. For example, if the code convergence check is satisfied after row-wise decoding in the third iteration (after 2.5 decoding steps), then the number of iteration returned is 3.

TPC Decoding Shortened Messages

TPC encoded shortened input messages are decoded using specified 2-D TPC code pairs. Row-wise decoding uses the (N_C - K_C + S_C, S_C) code pair and column-wise decoding uses the (N_R - K_R + S_R, S_R) code pair. The input vector length must be (N_R - K_R + S_R) × (N_C- K_C + S_C). To perform the 2-D TPC decoding of shortened messages, the column vector of the input LLRs, composed of the shortened message and parity bits, is arranged into an (N_R - K_R + S_R)-by-(N_C - K_C + S_C) matrix.



The TPC decoder processes the received shortened message LLRs similar to full length codes, with these exceptions:

- The shortened bit positions in the received codeword are set to –1.
- The Chase algorithm does not consider the shortened bit positions while choosing the least reliable bits.

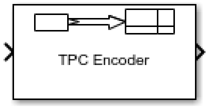
TPC Encoder

Turbo product code (TPC) encoder

Library: Communications Toolbox / Error Detection and Correction / Block



Description

The TPC Encoder block performs 2-D turbo product code (TPC) encoding of an input message. The product code is a 2-D concatenation of linear block codes. The linear block codes can be a parity check code, a Hamming code, or a BCH code capable of correcting two errors. Extended and shortened codes can be applied independently on each dimension. For a description of 2-D TPC encoding, see “Turbo Product Code Construction” on page 5-798.

For information about valid code pairs and the error-correcting capability for each valid code pair, see “Component Code Pairs” on page 5-797.

Ports

Input

In — Message to encode
column vector

Input message bits to encode, specified as a column vector.

- For full-length input messages, the length of the column vector must be the product of Number of rows in message, Kr and Number of columns in message, Kc.
- For shortened input messages, the length of the column vector must be the product of Number of rows in shortened message, Sr and Number of columns in shortened message, Sc.

Data Types: single | double | int8 | int16 | int32 | uint8 | uint16 | uint32 | Boolean

Output

Out — TPC-encoded message
column vector

TPC-encoded message, returned as a column vector with the same data type as the input signal.

- For full-length input messages, the length of the column vector is the product of Number of rows in code, Nr and Number of columns in code, Nc.
- For shortened input messages, the length of the column vector is the product of $(N_{\mathrm{R}}–K_{\mathrm{R}}+S_{\mathrm{R}})$ and $(N_{\mathrm{C}}–K_{\mathrm{C}}+S_{\mathrm{C}})$, where:
  - N_{R} is the value of Number of rows in code, Nr.

- K_R is the value of Number of rows in message, Kr.
- S_R is the value of Number of rows in shortened message, Sr.
- N_C is the value of Number of columns in code, Nc.
- K_C is the value of Number of columns in message, Kc.
- S_C is the value of Number of columns in shortened message, Sc.

Parameters

Row TPC parameters

`Extended codes` — Extended codes indicator for TPC row parameters

`on` (default) | `off`

- When Extended codes is selected, the lists for Number of rows in code, Nr and Number of rows in message, Kr contain the valid values for extended individual code pairs (N_R,K_R).
- When Extended codes is cleared, the lists for Number of rows in code, Nr and Number of rows in message, Kr contain the valid values for nonextended individual code pairs (N_R,K_R).

`Number of rows in code, Nr` — Number of rows in product code matrix

`16` (default) | integer

Number of rows in the product code matrix, N_R. The list of integer values varies depending on the setting for Extended codes.

`Number of rows in message, Kr` — Number of rows in message matrix

`11` (default) | integer

Number of rows in the message matrix, K_R. The list of integer values varies depending on the setting for Extended codes and Number of rows in code, Nr.

`Specify shortened message length` — Specify shortened message length for rows

`off` (default) | `on`

Select **Specify shortened message length** to specify a value for Number of rows in shortened message, Sr.

`Number of rows in shortened message, Sr` — Number of rows in shortened message matrix

`9` (default) | integer

Number of rows in the shortened message matrix, S_R, specified as an integer less than or equal to K_R. When you specify this parameter, provide full-length N_R and K_R values to specify the (N_R,K_R) code pair. This code pair is then shortened to the (N_R-K_R+S_R,S_R) code pair, where:

- N_R is the value of Number of rows in code, Nr.
- K_R is the value of Number of rows in message, Kr.
- S_R is the value of Number of rows in shortened message, Sr.

Dependencies

To enable this parameter, select Specify shortened message length.

Data Types: `double`

Column TPC parameters

`Extended codes` — Extended codes indicator for TPC column parameters

`on` (default) | `off`

- When Extended codes is selected, the lists for Number of columns in code, Nc and Number of columns in message, Kc contain the valid values for extended individual code pairs (N_C,K_C).
- When Extended codes is cleared, the lists for Number of columns in code, Nc and Number of columns in message, Kc contain the valid values for nonextended individual code pairs (N_C,K_C).

`Number of columns in code, Nc` — Number of columns in product code matrix

`32` (default) | integer

Number of columns in the product code matrix, N_C. The list of integer values varies depending on the setting for Extended codes.

`Number of columns in message, Kc` — Number of columns in message matrix

`26` (default) | integer

Number of columns in the message matrix, K_C. The list of integer values varies depending on the setting for Extended codes and Number of columns in code, Nc.

`Specify shortened message length` — Specify shortened message length for columns

`off` (default) | `on`

Select **Specify shortened message length** to specify a value for Number of columns in shortened message, Sc.

`Number of columns in shortened message, Sc` — Number of columns in shortened message matrix

`22` (default) | integer

Number of columns in the shortened message matrix, S_C, specified as an integer. When you specify this parameter, provide full-length N_C and K_C values to specify the (N_C,K_C) code pair. This code pair is then shortened to the (N_C–K_C+S_C, S_C) code pair, where:

- N_C is the value of Number of columns in code, Nc.
- K_C is the value of Number of columns in message, Kc.
- S_C is the value of Number of columns in shortened message, Sc.

Dependencies

To enable this parameter, select Specify shortened message length.

Data Types: `double`

`Simulate using` — Type of simulation to run

`Code generation` (default) | `Interpreted execution`

Type of simulation to run, specified as `Code generation` or `Interpreted execution`.

- `Code generation` –– Simulate the model by using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations unless the model changes. This option requires additional startup time, but the speed of the subsequent simulations is faster than `Interpreted execution`.

- `Interpreted execution` –– Simulate the model by using the MATLAB interpreter. This option requires less startup time than the `Code generation` method, but the speed of subsequent simulations is slower. In this mode, you can debug the source code of the block.

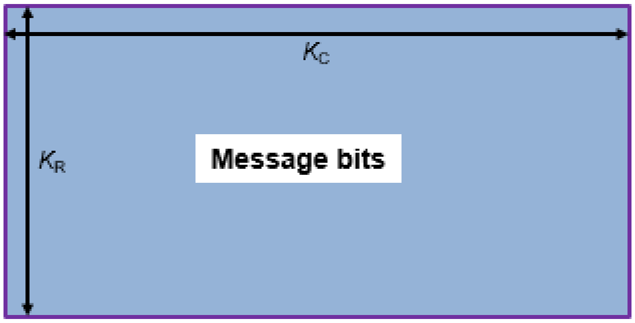
Turbo Product Code Construction

Turbo product codes (TPC) are a form of concatenated codes used as forward error-correcting (FEC) codes. Two or more component block codes, such as systematic linear block codes, are used to construct TPCs. This encoder implements 2-D product code encoding, as described in [1], using two “Linear Block Codes”.

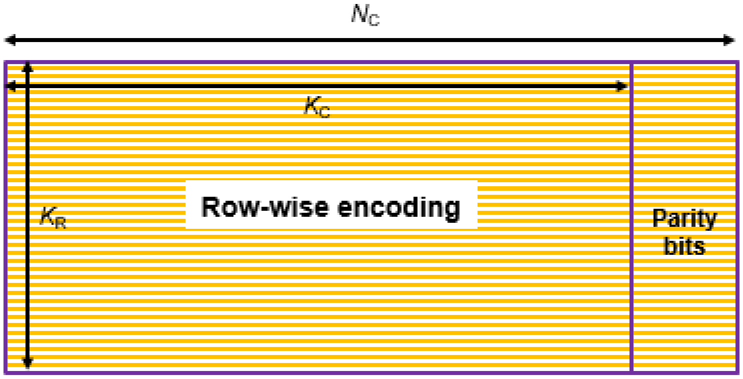
The TPC encoder accepts either full-length or shortened messages.

Construction of Full-Length Message Product Codes

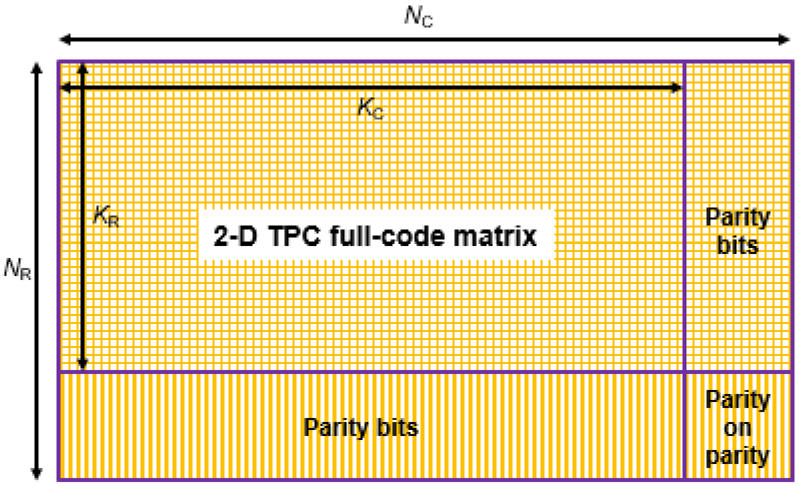
Full-length input messages are encoded using specified 2-D TPC code pairs. Row-wise encoding uses the (N_C,K_C) code pair and column-wise encoding uses the (N_R,K_R) code pair. The input vector length must be $K_R \cdot K_C$. The input message bits vector is arranged into a K_R-by-K_C matrix.



Row-wise encoding uses an (N_C,K_C) systematic linear block encoder with K_C bits per row. The row-wise encoding results in a K_R-by-N_C matrix that includes parity bits added to each row.



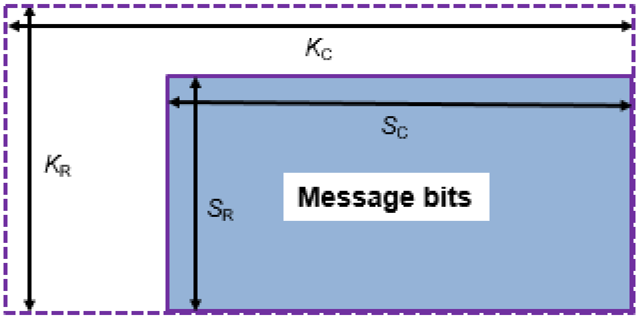
Next, column-wise encoding uses an (N_R,K_R) systematic linear block encoder on each of the N_C columns. Applying this 2-D TPC encoding to the initial K_R-by-K_C matrix results in an N_R-by-N_C matrix that includes parity bits added to each row and column.



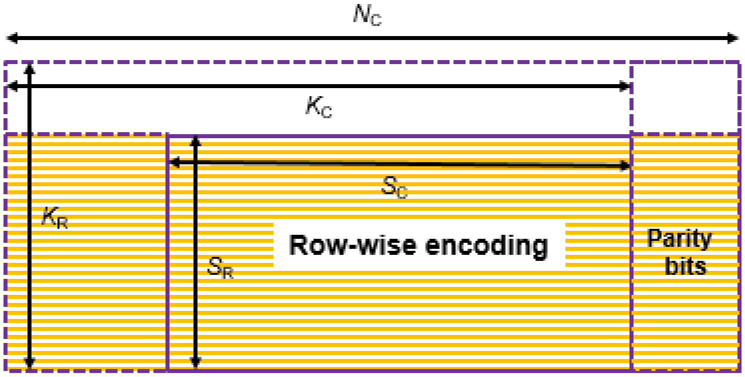
The 2-D TPC full-code matrix is reshaped into a column vector of length $N_R \cdot N_C$ and returned as the TPC-encoded output.

Construction of Shortened Message Product Codes

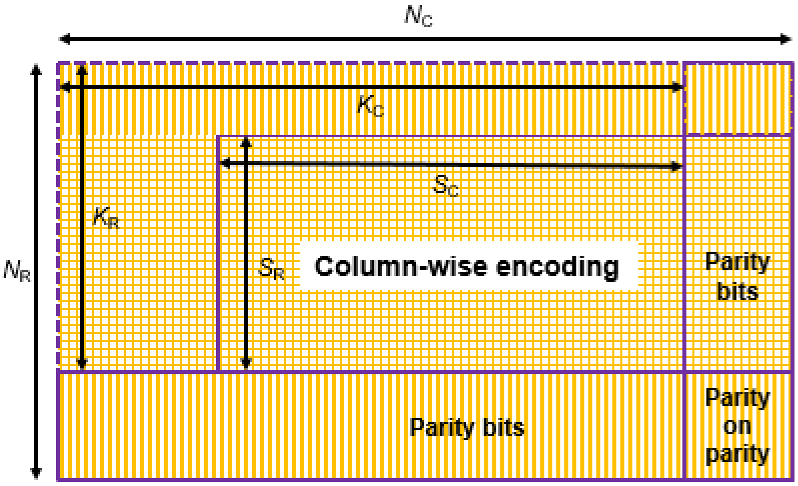
Shortened input messages are encoded using specified 2-D TPC code pairs. Row-wise encoding uses the (N_C,K_C) code pair and column-wise encoding uses an (N_R,K_R) code pair. The input vector length must be $S_R \cdot S_C$. The input shortened message bits vector is arranged into an S_R-by-S_C matrix. The shortened message matrix prepends two dimensions by padding the beginning of the message matrix with zeros. The resulting matrix is a K_R-by-K_C matrix.



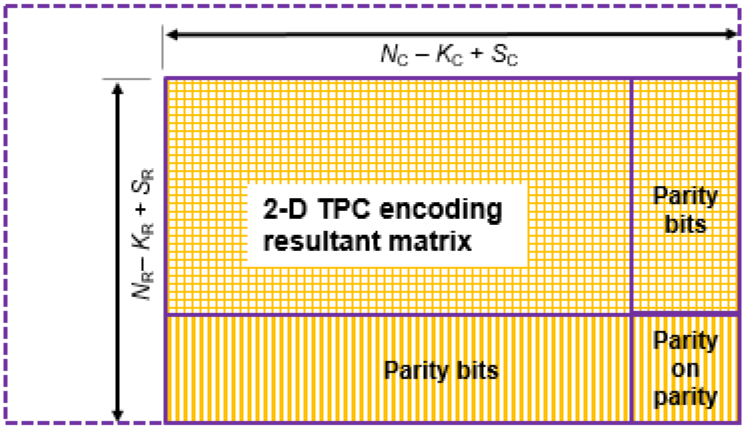
Row-wise encoding uses an (N_C,K_C) systematic linear block encoder with K_C bits per row. The row-wise encoding results in a K_R-by-N_C matrix that includes parity bits added to each row.



Next, the column-wise encoding uses an (N_R,K_R) systematic linear block encoder on each of the N_C columns.



Applying this 2-D TPC encoding to the initial K_R-by-K_C matrix and excluding the zero-padded bits from the output results in an (N_R–K_R+S_R)-by-(N_C–K_C+S_C) matrix. This matrix includes parity bits added to each row and column.



The 2-D TPC shortened-code matrix is reshaped into a column vector of length (N_R–K_R+S_R) · (N_C–K_C+S_C) and returned as the TPC-encoded output.

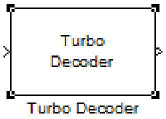
Turbo Decoder

Decode input signal using parallel concatenated decoding scheme



Library

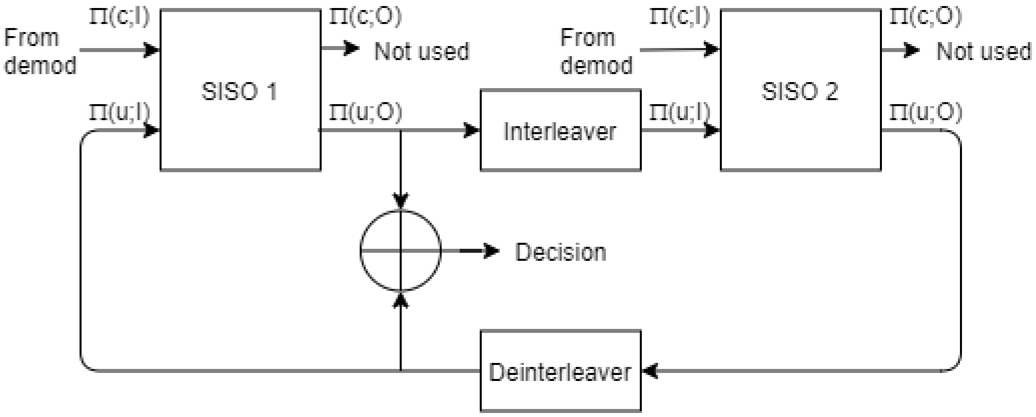
Convolutional sublibrary of Error Detection and Correction

Description

The Turbo Decoder block decodes the input signal using a parallel concatenated decoding scheme. The iterative decoding scheme uses the *a posteriori* probability (APP) decoder as the constituent decoder, an interleaver, and a deinterleaver.

The two constituent decoders use the same trellis structure and decoding algorithm.

Block Diagram of Iterative Turbo Decoding



The previous block diagram illustrates that the APP decoders (labeled as SISO modules in the previous image) output an updated sequence of log-likelihoods of the encoder input bits, π(u;O). This sequence is based on the received sequence of log-likelihoods of the channel (coded) bits, π(c;I), and code parameters.

The decoder block iteratively updates these likelihoods for a fixed number of decoding iterations and then outputs the decision bits. The interleaver (π) that the decoder uses is identical to the one the encoder uses. The deinterleaver (π^{-1}) performs the inverse permutation with respect to the interleaver. The decoder does not assume knowledge of the tail bits and excludes these bits from the iterations.

Dimensions

This block accepts an M-by-1 column vector input signal and outputs an L-by-1 column vector signal. For a given trellis, L and M are related by:

$$L = \frac{(M - 2 \cdot numTails)}{(2 \cdot n - 1)}$$

and

$$M = L \cdot (2 \cdot n - 1) + 2 \cdot numTails$$

where

M = decoder input length

L = decoder output length

n = log2(trellis.NumOutputSymbols), for a rate 1/2 trellis, n = 2

$numTails$ = log2(trellis.numStates) * n

Parameters

Trellis structure

Trellis structure of constituent convolutional code.

Specify the trellis as a MATLAB structure that contains the trellis description of the constituent convolutional code. Alternatively, use the poly2trellis function to create a custom trellis using the constraint length, code generator (octal), and feedback connection (octal).

The default structure is the result of poly2trellis(4, [13 15], 13).

Source of interleaver indices

Specify the source of the interleaver indices as `Property` or `Input port`.

When you set this parameter to `Property`, the block uses the **Interleaver indices** parameter to specify the interleaver indices.

When you set this parameter to `Input port`, the block uses the secondary input port, IntrInd, to specify the interleaver indices.

Interleaver indices

Specify the mapping that the Turbo encoder block uses to permute the input bits as a column vector of integers. The default is `(64:-1:1).'`. This mapping is a vector with the number of elements equal to *L*, the length of the output signal. Each element must be an integer between 1 and *L*, with no repeated values.

Decoding algorithm

Specify the decoding algorithm that the constituent APP decoders use to decode the input signal as `True APP`, `Max*`, `Max`. When you set this parameter to:

- `True APP` – the block implements true *a posteriori* probability decoding
- `Max*` or `Max` – the block uses approximations to increase the speed of the computations.

Number of scaling bits

Specify the number of bits which the constituent APP decoders must use to scale the input data to avoid losing precision during computations. The decoder multiplies the input by `2^`**Number of scaling bits** and divides the pre-output by the same factor. The value for this parameter must be a scalar integer between `0` and `8`. This parameter only applies when you set **Decoding algorithm** to `Max*`. The default is `3`.

Number of decoding iterations

Specify the number of decoding iterations the block uses. The default is `6`. The block iterates and provides updates to the log-likelihood ratios (LLR) of the uncoded output bits. The output of the block is the hard-decision output of the final LLR update.

Simulate using

Specify if the block simulates using `Code generation` or `Interpreted execution`. The default is `Interpreted execution`.

Supported Data Type

Port	Supported Data Types

Turbo Encoder

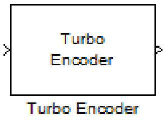
Encode binary data using parallel concatenated encoding scheme



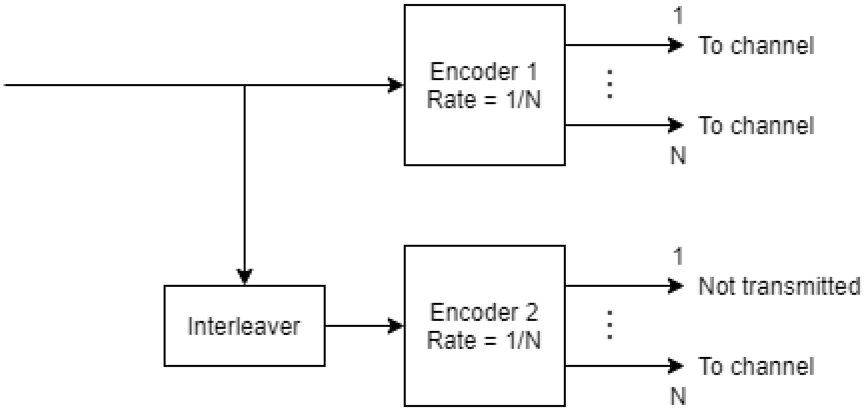
Library

Convolutional sublibrary of Error Detection and Correction

Description

The Turbo Encoder block encodes a binary input signal using a parallel concatenated coding scheme. This coding scheme employs two identical convolutional encoders and one internal interleaver. Each constituent encoder is independently terminated by tail bits.

Block Diagram of Parallel Concatenated Convolutional Code



The previous block diagram illustrates that the output of the Turbo Encoder block consists of the systematic and parity bits streams of the first encoder, and only the parity bit streams of the second encoder.

For a rate one-half constituent encoder, the block interlaces the three streams and multiplexes the tail bits to the end of the encoded data streams.

For more information about tail bits, see the terminate **Operation mode** on the Convolutional Encoder block reference page.

Dimensions

This block accepts an *L*-by-1 column vector input signal and outputs an *M*-by-1 column vector signal. For a given trellis, *M* and *L* are related by:

$$M = L \cdot (2 \cdot n - 1) + 2 \cdot numTails$$

and

$$L = \frac{(M - 2 \cdot numTails)}{(2 \cdot n - 1)}$$

where

L = encoder input length

M = encoder output length

n = log2(trellis.NumOutputSymbols), for a rate 1/2 trellis, n = 2

$numTails$ = log2(trellis.numStates) * n

Encoder Schematic for Rate 1/3 Turbo Code Example

z^-1
z^-1
X'_k

The previous schematic shows the encoder configuration for a trellis specified by the default value of the **Trellis structure** parameter, `poly2trellis(4, [13 15], 13)`. For an input vector length of 64 bits, the output of the encoder block is 204 bits. The first 192 bits correspond to the three 64 bit streams (systematic (X_k) and parity (Z_k) bit streams from the first encoder and the parity (Z'_k) bit stream of the second encoder), interlaced as per X_k, Z_k, Z'_k. The last 12 bits correspond to the tail bits from the two encoders, when the switches are in the lower position corresponding to the dashed lines. The first group of six bits (three systematic bits and three parity bits) are the output tail bits from the first constituent encoder. The second group of six bits (three systematic bits and three parity bits) are the output tail bits from the second constituent encoder.

Due to the tail bits, the encoder output code rate is slightly less than 1/3.

Parameters

Trellis structure

Trellis structure of constituent convolutional code.

Specify the trellis as a MATLAB structure that contains the trellis description of the constituent convolutional code. Alternatively, use the `poly2trellis` function to create a custom trellis using the constraint length, code generator (octal), and feedback connections (octal).

This block supports only rate 1-by-*N* trellises where *N* is an integer.

The default structure is the result of poly2trellis(4, [13 15], 13).

Source of interleaver indices

Specify the source of the interleaver indices as `Property` or `Input port`.

When you set this parameter to `Property`, the block uses the **Interleaver indices** parameter to specify the interleaver indices.

When you set this parameter to `Input port`, the block uses the secondary input port, IntrInd, to specify the interleaver indices.

Interleaver indices

Specify the mapping that the block uses to permute the input bits as a column vector of integers. The default is `(64:-1:1).'`. This mapping is a vector with the number of elements equal to the length, *L*, of the input signal. Each element must be an integer between 1 and *L*, with no repeated values.

Simulate using

Specify if the block simulates using `Code generation` or `Interpreted execution`. The default is `Interpreted execution`.

Uniform Noise Generator

(To be removed) Generate uniformly distributed noise between upper and lower bounds

Note Uniform Noise Generator will be removed in a future release. Use the MATLAB Function block and `rand` function instead.

Library

Noise Generators sublibrary of Comm Sources

Description

The Uniform Noise Generator block generates uniformly distributed noise. The output data of this block is uniformly distributed between the specified lower and upper bounds. The upper bound must be greater than or equal to the lower bound.

You must specify the **Initial seed** in the simulation. When it is a constant, the resulting noise is repeatable.

If all the elements of the output vector are to be independent and identically distributed (i.i.d.), then you can use a scalar for the **Noise lower bound** and **Noise upper bound** parameters. Alternatively, you can specify the range for each element of the output vector individually, by using vectors for the **Noise lower bound** and **Noise upper bound** parameters. If the bounds are vectors, then their length must equal the length of the **Initial seed** parameter.

Attributes of Output Signal

The output signal can be a frame-based matrix, a sample-based row or column vector, or a sample-based one-dimensional array. These attributes are controlled by the **Frame-based outputs**, **Samples per frame**, and **Interpret vector parameters as 1-D** parameters.

The number of elements in the **Initial seed** parameter becomes the number of columns in a frame-based output or the number of elements in a sample-based vector output. Also, the shape (row or column) of the **Initial seed** parameter becomes the shape of a sample-based two-dimensional output signal.

Parameters

Noise lower bound, Noise upper bound

The lower and upper bounds of the interval over which noise is uniformly distributed.

Initial seed

The initial seed value for the random number generator.

Sample time

The period of each sample-based vector or each row of a frame-based matrix.

Frame-based outputs

Determines whether the output is frame-based or sample-based. This box is active only if **Interpret vector parameters as 1-D** is unchecked.

Samples per frame

The number of samples in each column of a frame-based output signal. This field is active only if **Frame-based outputs** is checked.

Interpret vector parameters as 1-D

If this box is checked, then the output is a one-dimensional signal. Otherwise, the output is a two-dimensional signal. This box is active only if **Frame-based outputs** is unchecked.

Output data type

The output can be set to `double` or `single` data types.

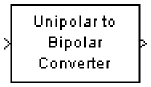
Unipolar to Bipolar Converter

Map unipolar signal in range [0, M-1] into bipolar signal



Library

Utility Blocks

Description

The Unipolar to Bipolar Converter block maps the unipolar input signal to a bipolar output signal. If the input consists of integers between 0 and M-1, where M is the **M-ary number** parameter, then the output consists of integers between -(M-1) and M-1. If M is even, then the output is odd. If M is odd, then the output is even. This block is only designed to work when the input value is within the set {0,1,2...(M-1)}, where M is the **M-ary number** parameter. If the input value is outside of this set of integers the output may not be valid.

The table below shows how the block's mapping depends on the **Polarity** parameter.

Polarity Parameter Value	Output Corresponding to Input Value of k
`Positive`	2k-(M-1)
`Negative`	-2k+(M-1)

Parameters

M-ary number

The number of symbols in the bipolar or unipolar alphabet.

Polarity

A value of `Positive` causes the block to maintain the relative ordering of symbols in the alphabets. A value of `Negative` causes the block to reverse the relative ordering of symbols in the alphabets.

Output Data Type

The type of bipolar signal produced at the block's output.

The block supports the following output data types:

- `Inherit via internal rule`
- `Same as input`
- `double`
- `int8`
- `int16`

- `int32`

When the parameter is set to its default setting, `Inherit via internal rule`, the block determines the output data type based on the input data type.

- If the input signal is floating-point (either `single` or `double`), the output data type is the same as the input data type.
- If the input data type is not floating-point:
  - Based on the **M-ary** number parameter, an ideal signed integer output word length required to contain the range [-(M-1)M-1] is computed as follows:

    ideal word length = ceil(log2(M))+1

    Note The +1 is associated with the need for the sign bit.
  - The block sets the output data type to be a signed integer, based on the smallest word length (in bits) that can fit best the computed ideal word length.

Note The selections in the “Hardware Implementation Pane” (Simulink) pertaining to word length constraints do not affect how this block determines output data types.

Examples

If the input is [0; 1; 2; 3], the **M-ary number** parameter is `4`, and the **Polarity** parameter is `Positive`, then the output is [-3; -1; 1; 3]. Changing the **Polarity** parameter to `Negative` changes the output to [3; 1; -1; -3].

If the value for the **M-ary number** is 2^7 the block gives an output of int8.

If the value for the **M-ary number** is 2^7+1 the block gives an output of int16.

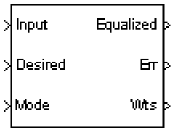
Variable Step LMS Decision Feedback Equalizer

(To be removed) Equalize using decision feedback equalizer that updates weights with variable-step-size LMS algorithm

Note will be removed in a future release. Consider using Decision Feedback Equalizer instead.



Library

Equalizers

Description

The Variable Step LMS Decision Feedback Equalizer block uses a decision feedback equalizer and the variable-step-size LMS algorithm to equalize a linearly modulated baseband signal through a dispersive channel. During the simulation, the block uses the variable-step-size LMS algorithm to update the weights, once per symbol. When you set the **Number of samples per symbol** parameter to `1`, then the block implements a symbol-spaced equalizer and updates the filter weights once for each symbol. When you set the **Number of samples per symbol** parameter to a value greater than 1, the weights are updated once every N^{th} sample, for a *T*/*N*-spaced equalizer.

Input and Output Signals

The `Input` port accepts a column vector input signal. The `Desired` port receives a training sequence with a length that is less than or equal to the number of symbols in the `Input` signal. Valid training symbols are those symbols listed in the **Signal constellation** vector.

Set the **Reference tap** parameter so it is greater than zero and less than the value for the **Number of forward taps** parameter.

The port labeled `Equalized` outputs the result of the equalization process.

You can configure the block to have one or more of these extra ports:

- `Mode` input.
- `Err` output for the error signal, which is the difference between the `Equalized` output and the reference signal. The reference signal consists of training symbols in training mode, and detected symbols otherwise.
- `Weights` output.

Decision-Directed Mode and Training Mode

To learn the conditions under which the equalizer operates in training or decision-directed mode, see "Equalization".

Equalizer Delay

For proper equalization, you should set the **Reference tap** parameter so that it exceeds the delay, in symbols, between the transmitter's modulator output and the equalizer input. When this condition is satisfied, the total delay, in symbols, between the modulator output and the equalizer *output* is equal to

1+(**Reference tap**-1)/(**Number of samples per symbol**)

Because the channel delay is typically unknown, a common practice is to set the reference tap to the center tap of the forward filter.

Parameters

Number of forward taps

The number of taps in the forward filter of the decision feedback equalizer.

Number of feedback taps

The number of taps in the feedback filter of the decision feedback equalizer.

Number of samples per symbol

The number of input samples for each symbol.

Signal constellation

A vector of complex numbers that specifies the constellation for the modulation.

Reference tap

A positive integer less than or equal to the number of forward taps in the equalizer.

Initial step size

The step size that the variable-step-size LMS algorithm uses at the beginning of the simulation.

Increment step size

The increment by which the step size changes from iteration to iteration

Minimum step size

The smallest value that the step size can assume.

Maximum step size

The largest value that the step size can assume.

Leakage factor

The leakage factor of the variable-step-size LMS algorithm, a number between 0 and 1. A value of 1 corresponds to a conventional weight update algorithm, and a value of 0 corresponds to a memoryless update algorithm.

Initial weights

A vector that concatenates the initial weights for the forward and feedback taps.

Mode input port

When you select this check box, the block has an input port that enables you to toggle between training and decision-directed mode. For training, the mode input must be 1, for decision directed, the mode should be 0. The equalizer will train for the length of the Desired signal. If the mode input is not present, the equalizer will train at the beginning of every frame for the length of the Desired signal.

Output error

When you select this check box, the block outputs the error signal, which is the difference between the equalized signal and the reference signal.

Output weights

When you select this check box, the block outputs the current forward and feedback weights, concatenated into one vector.

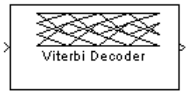
Viterbi Decoder

Decode convolutionally encoded data using Viterbi algorithm



Library

Convolutional sublibrary of Error Detection and Correction

Description

The Viterbi Decoder block decodes input symbols to produce binary output symbols. This block can process several symbols at a time for faster performance.

This block can output sequences that vary in length during simulation. For more information about sequences that vary in length, or variable-size signals, see “Variable-Size Signal Basics” (Simulink).

Input and Output Sizes

If the convolutional code uses an alphabet of 2^n possible symbols, this block's input vector length is L*n for some positive integer L. Similarly, if the decoded data uses an alphabet of 2^k possible output symbols, this block's output vector length is L*k.

This block accepts a column vector input signal with any positive integer value for L. For variable-sized inputs, the L can vary during simulation. The operation of the block is governed by the operation mode parameter.

For information about the data types each block port supports, see the “Supported Data Types” on page 5-828 table on this page.

Input Values and Decision Types

The entries of the input vector are either bipolar, binary, or integer data, depending on the **Decision type** parameter.

Decision type Parameter	Possible Entries in Decoder Input	Interpretation of Values	Branch metric calculation
`Unquantized`	Real numbers	Positive real: logical zero Negative real: logical one	Euclidean distance
`Hard Decision`	0, 1	0: logical zero 1: logical one	Hamming distance

Decision type Parameter	Possible Entries in Decoder Input	Interpretation of Values	Branch metric calculation
`Soft Decision`	Integers between 0 and 2^b-1, where *b* is the **Number of soft decision bits** parameter.	0: most confident decision for logical zero 2^b-1: most confident decision for logical one Other values represent less confident decisions.	Hamming distance

To illustrate the soft decision situation more explicitly, the following table lists interpretations of values for 3-bit soft decisions.

Input Value	Interpretation
0	Most confident zero
1	Second most confident zero
2	Third most confident zero
3	Least confident zero
4	Least confident one
5	Third most confident one
6	Second most confident one
7	Most confident one

Operation Modes for Inputs

The Viterbi decoder block has three possible methods for transitioning between successive input frames. The **Operation mode** parameter controls which method the block uses:

- In `Continuous` mode, the block saves its internal state metric at the end of each input, for use with the next frame. Each traceback path is treated independently.
- In `Truncated` mode, the block treats each input independently. The traceback path starts at the state with the best metric and always ends in the all-zeros state. This mode is appropriate when the corresponding Convolutional Encoder block has its **Operation mode** set to `Truncated (reset every frame)`.
- In `Terminated` mode, the block treats each input independently, and the traceback path always starts and ends in the all-zeros state. This mode is appropriate when the uncoded message signal (that is, the input to the corresponding Convolutional Encoder block) has enough zeros at the end of each input to fill all memory registers of the feed-forward encoder. If the encoder has `k` input streams and constraint length vector `constr` (using the polynomial description), “enough” means `k*max(constr-1)`. For feedback encoders, this mode is appropriate if the corresponding Convolutional Encoder block has **Operation mode** set to `Terminate trellis by appending bits`.

Note When this block outputs sequences that vary in length during simulation and you set the **Operation mode** to `Truncated` or `Terminated`, the block's state resets at every input time step.

Use the `Continuous` mode when the input signal contains only one symbol.

Reset Port

The reset port is usable only when the **Operation mode** parameter is set to `Continuous`. Selecting **Enable reset input port** gives the block an additional input port, labeled `Rst`. When the `Rst` input is nonzero, the decoder returns to its initial state by configuring its internal memory as follows:

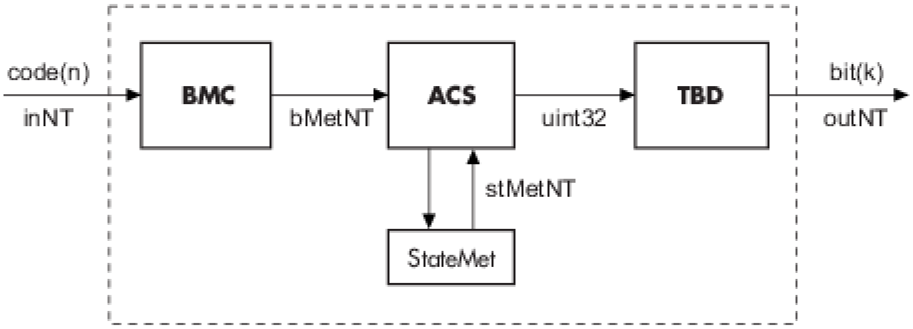
- Sets the all-zeros state metric to zero.
- Sets all other state metrics to the maximum value.
- Sets the traceback memory to zero.

Using a reset port on this block is analogous to setting **Operation mode** in the Convolutional Encoder block to `Reset on nonzero input via port`.

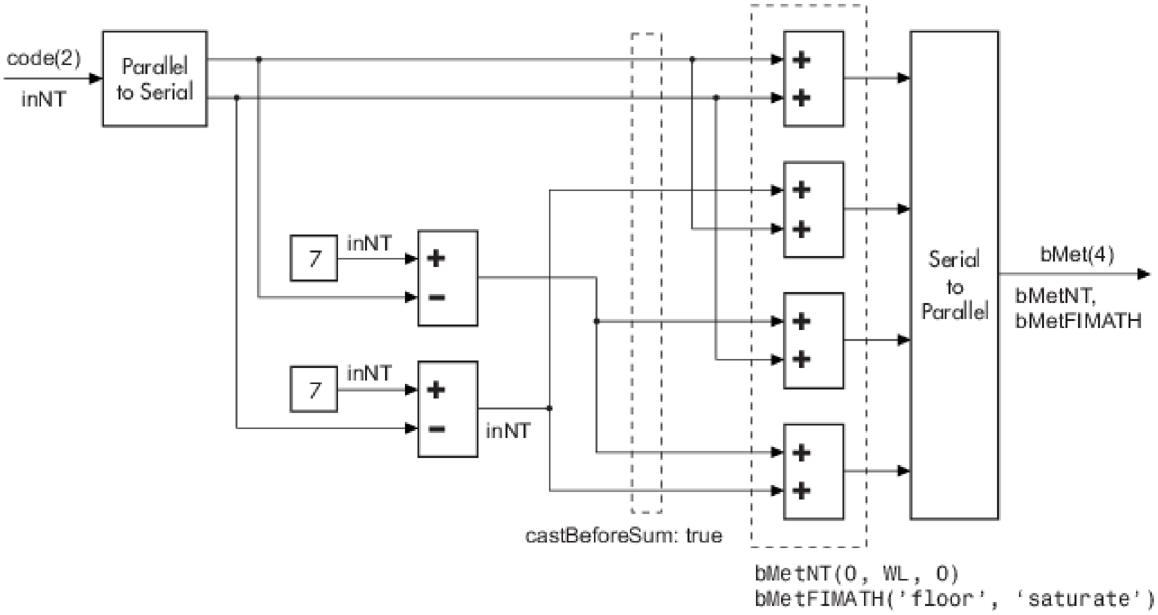
The reset port supports `double` or `boolean` typed signals.

Fixed-Point Signal Flow Diagram

There are three main components to the Viterbi decoding algorithm. They are branch metric computation (BMC), add-compare and select (ACS), and traceback decoding (TBD). The following diagram illustrates the signal flow for a *k/n* rate code.

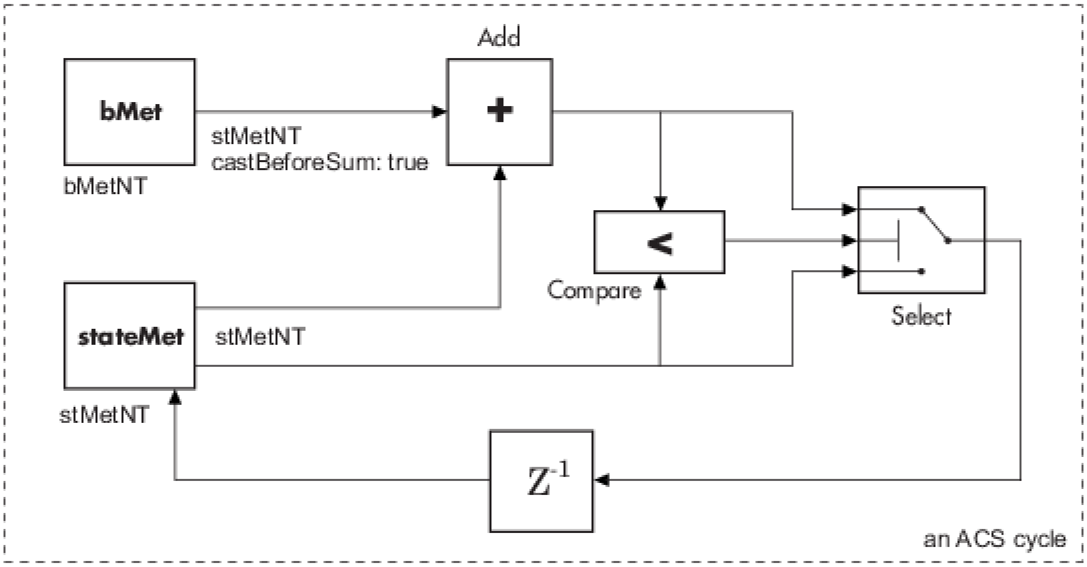


As an example of a BMC diagram, a 1/2 rate, *nsdec* = 3 signal flow would be as follows.



$$\begin{aligned} WL &= nsdec + n - 1 \\ n = 2 &\Rightarrow WL = 4 \end{aligned}$$

The ACS component is generally illustrated as shown in the following diagram.



```
stMetNT(0, WL2, 0)
stMetFIMATH('floor', 'saturate')
```

Where WL2 is specified on the mask by the user.

In the flow diagrams above, inNT, bMetNT , stMetNT, and outNT are `numerictype` (Fixed-Point Designer) objects, and bMetFIMATH and stMetFIMATH, are `fimath (Fixed-Point Designer)` objects.

Puncture Pattern Examples

For some commonly used puncture patterns for specific rates and polynomials, see the last three references.

Fixed-Point Viterbi Decoding Examples

The “Perform Fixed-Point Hard Decision Viterbi Decoding” and “Perform Fixed-Point Soft Decision Viterbi Decoding” examples configure the Viterbi decoder block to use fixed-point processing for hard- and soft-decision convolutional decoding.

The examples highlight the fixed-point modeling attributes of the Viterbi decoder, using a familiar layout.

Overview of the Simulations

The two simulations have a similar structure and have most parameters in common. A data source produces a random binary sequence that is convolutionally encoded, BPSK modulated, and passed through an AWGN channel.

The Convolutional encoder is configured as a rate 1/2 encoder. For every 2 bits, the encoder adds another 2 redundant bits. To accommodate this, and add the correct amount of noise, the **Eb/No (dB)** parameter of the AWGN block is in effect halved by subtracting 10*log10(2).

For the hard-decision case, the BPSK demodulator produces hard decisions, at the receiver, which are passed onto the decoder.

For the soft-decision case, the BPSK demodulator produces soft decisions, at the receiver, using the log-likelihood ratio. These soft outputs are 3-bit quantized and passed onto the decoder.

After the decoding, the simulation compares the received decoded symbols with the original transmitted symbols in order to compute the bit error rate. The simulation ends after processing 100 bit errors or 1e6 bits, whichever comes first.

Fixed-Point Modeling

Fixed-point modeling enables bit-true simulations which take into account hardware implementation considerations and the dynamic range of the data/parameters. For example, if the target hardware is a DSP microprocessor, some of the possible word lengths are 8, 16, or 32 bits, whereas if the target hardware is an ASIC or FPGA, there may be more flexibility in the word length selection.

To enable fixed-point Viterbi decoding, the block input must be of type ufix1 (unsigned integer of word length 1) for hard decisions. Based on this input (either a 0 or a 1), the internal branch metrics are calculated using an unsigned integer of word length = (number of output bits), as specified by the trellis structure (which equals 2 for the hard-decision example).

For soft decisions, the block input must be of type ufixN (unsigned integer of word length N), where N is the number of soft-decision bits, to enable fixed-point decoding. The block inputs must be integers in the range 0 to 2^{N-1}. The internal branch metrics are calculated using an unsigned integer of word length = (N + number of output bits - 1), as specified by the trellis structure (which equals 4 for the soft-decision example).

The **State metric word length** is specified by the user and usually must be greater than the branch metric word length already calculated. You can tune this to be the most suitable value (based on hardware and/or data considerations) by reviewing the logged data for the system.

Enable the logging by selecting **Apps > Fixed-Point Tool**. In the Fixed-Point Setting GUI, set the **Fixed-point instruments mode** to `Minimums, maximums and overflows`, and rerun the simulation. If you see overflows, it implies the data did not fit in the selected container. You could either increase the size of the word length (if your hardware allows it) or try scaling the data prior to processing it. Based on the minimum and maximum values of the data, you are also able to determine whether the selected container is of the appropriate size.

Try running simulations with different values of **State metric word length** to get an idea of its effect on the algorithm. You should be able to narrow down the parameter to a suitable value that has no adverse effect on the BER results.

Comparisons with Double-Precision Data

To run the same model with double precision data, Select **Apps > Fixed-Point Tool**. In the Fixed-Point Tool GUI, select the **Data type override** to be `Double`. This selection overrides all data type settings in all the blocks to use double precision. For the Viterbi Decoder block, as **Output type** was set to `Boolean`, this parameter should also be set to double.

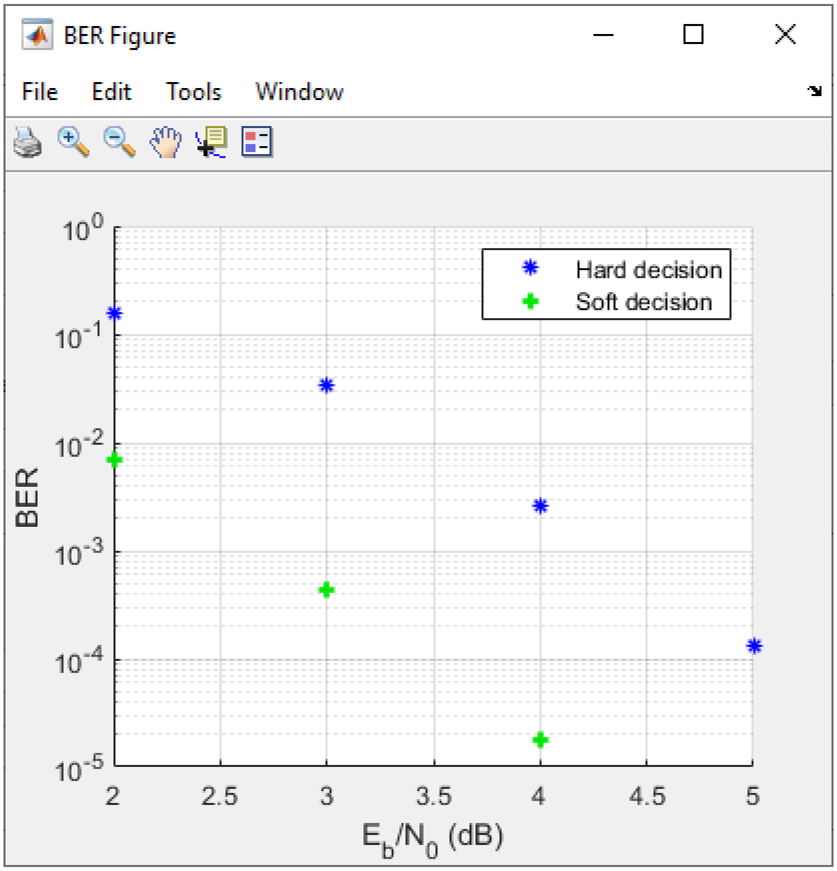
Upon simulating the model, note that the double-precision and fixed-point BER results are the same. They are the same because the fixed-point parameters for the model have been selected to avoid any loss of precision while still being most efficient.

Comparisons Between Hard and Soft-Decision Decoding

The two models are set up to run from within BERTool to generate a simulation curve that compares the BER performance for hard-decision versus soft-decision decoding.

To generate simulation results for “Perform Fixed-Point Hard Decision Viterbi Decoding”, do the following:

1. Open the “Perform Fixed-Point Hard Decision Viterbi Decoding” example to get the simulink model on path.
2. Type `bertool` at the MATLAB command prompt.
3. Go to the **Monte Carlo** pane.
4. Set the **Eb/No range** to `2:5`.
5. Set the **Simulation model** to `cm_viterbi_harddec_fixpt`. Make sure that the model is on path.
6. Set the **BER variable name** to `BER`.
7. Set the **Number of errors** to `100`, and the **Number of bits** to `1e6`.
8. Press **Run** and a plot is generated.



To generate simulation results for “Perform Fixed-Point Soft Decision Viterbi Decoding”, open the example to get simulink model on path, change the change the **Simulation model** to `cm_viterbi_softdec_fixpt`, and press **Run**.

Notice that, as expected, 3-bit soft-decision decoding is better than hard-decision decoding, roughly to the tune of 1.7 dB, and not 2 dB as commonly cited. The difference in the expected results could be attributed to the imperfect quantization of the soft outputs from the demodulator.

Parameters

Trellis structure

MATLAB structure that contains the trellis description of the convolutional encoder. Use the same value here and in the corresponding Convolutional Encoder block.

Punctured code

Select this check box to specify a punctured input code. The field, **Punctured code**, appears.

Puncture vector

Constant puncture pattern vector used at the transmitter (encoder). The puncture vector is a pattern of `1`s and `0`s. The `0`s indicate the punctured bits. When you select **Punctured code**, the **Punctured vector** field appears.

Enable erasures input port

When you check this box, the decoder opens an input port labeled `Era`. Through this port, you can specify an erasure vector pattern of `1`s and `0`s, where the `1`s indicate the erased bits.

For these erasures in the incoming data stream, the decoder does not update the branch metric. The widths and the sample times of the erasure and the input data ports must be the same. The erasure input port can be of data type `double` or `Boolean`.

Decision type

Specifies the use of `Unquantized`, `Hard Decision`, or `Soft Decision` for the branch metric calculation.

- `Unquantized` decision uses the Euclidean distance to calculate the branch metrics.
- `Soft Decision` and `Hard Decision` use the Hamming distance to calculate the branch metrics, where **Number of soft decision bits** equals `1`.

Number of soft decision bits

The number of soft decision bits to represent each input. This field is active only when **Decision type** is set to `Soft Decision`.

Error if quantized input values are out of range

Select this check box to throw an error when quantized input values are out of range. This check box is active only when **Decision type** is set to `Soft Decision` or `Hard Decision`.

Traceback depth

The number of trellis branches to construct each traceback path.

Operation mode

Method for transitioning between successive input frames: `Continuous`, `Terminated`, and `Truncated`.

Note When this block outputs sequences that vary in length during simulation and you set the **Operation mode** to `Truncated` or `Terminated`, the block's state resets at every input time step.

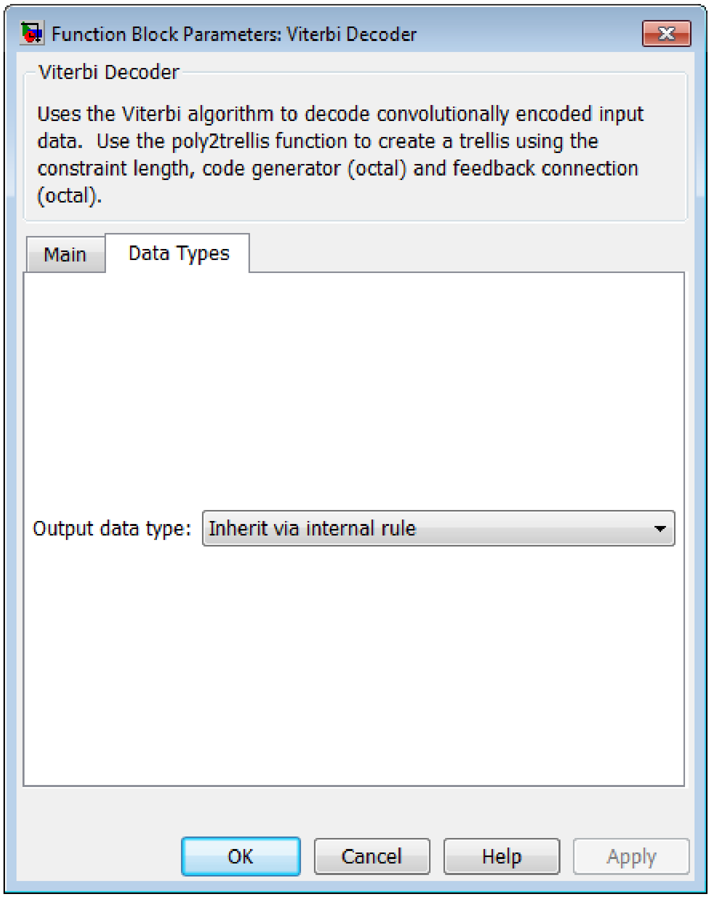
Enable reset input port

When you check this box, the decoder opens an input port labeled `Rst`. Providing a nonzero input value to this port causes the block to set its internal memory to the initial state before processing the input data.

Delay reset action to next time step

When you select this option, the Viterbi Decoder block resets after decoding the encoded data. This option is available only when you set **Operation mode** to `Continuous` and select **Enable reset input port**. You must enable this option for HDL support.

Output data type



Function Block Parameters: Viterbi Decoder

Viterbi Decoder

Uses the Viterbi algorithm to decode convolutionally encoded input data. Use the poly2trellis function to create a trellis using the constraint length, code generator (octal) and feedback connection (octal).

Output data type: Inherit via internal rule

The output signal's data type can be `double`, `single`, `boolean`, `int8`, `uint8`, `int16`, `uint16`, `int32`, `uint32`, or set to `'Inherit via internal rule'` or `'Smallest unsigned integer'`.

When set to `'Smallest unsigned integer'`, the output data type is selected based on the settings used in the **Hardware Implementation** pane of the Configuration Parameters dialog box of the model. If `ASIC/FPGA` is selected in the **Hardware Implementation** pane, the output data type is `ufix(1)`. For all other selections, it is an unsigned integer with the smallest specified wordlength corresponding to the char value (e.g., `uint8`).

When set to `'Inherit via internal rule'` (the default setting), the block selects double-typed outputs for double inputs, single-typed outputs for single inputs, and behaves similarly to the `'Smallest unsigned integer'` option for all other typed inputs.

Supported Data Types

Port	Supported Data Types
Input	• Double-precision floating point • Single-precision floating point • Boolean for `Hard decision` mode • 8-, 16-, and 32-bit signed integers (for `Hard decision` and `Soft decision` modes) • 8-, 16-, and 32-bit unsigned integers (for `Hard decision` and `Soft decision` modes) • ufix(n), where n represents the **Number of soft decision bits**
Output	• Double-precision floating point • Single-precision floating point • Boolean • 8-, 16-, and 32-bit signed integers • 8-, 16-, and 32-bit unsigned integers • ufix(1) for `ASIC/FPGA` mode

More About

Traceback Depth and Decoding Delay

The traceback depth influences the decoding delay. The decoding delay is the number of zero symbols that precede the first decoded symbol in the output.

- For the continuous operating mode, the decoding delay is equal to the number of traceback depth symbols.
- For the truncated or terminated operating mode, the decoding delay is zero. In this case, the traceback depth must be less than or equal to the number of symbols in each input.

Traceback Depth Estimates

As a general estimate, a typical traceback depth value is approximately two to three times (*ConstraintLength* – 1) / (1 – *coderate*). The constraint length of the code, *ConstraintLength*, is equal to (log2(`trellis.numStates`) + 1). The *coderate* is equal to (*K* / *N*) × (length(*PuncturePattern*) / sum(*PuncturePattern*).

K is the number of input symbols, *N* is the number of output symbols, and *PuncturePattern* is the puncture pattern vector.

For example, applying this general estimate, results in these approximate traceback depths.

- A rate 1/2 code has a traceback depth of 5(*ConstraintLength* – 1).
- A rate 2/3 code has a traceback depth of 7.5(*ConstraintLength* – 1).
- A rate 3/4 code has a traceback depth of 10(*ConstraintLength* – 1).
- A rate 5/6 code has a traceback depth of 15(*ConstraintLength* – 1).

For more information, see [7].

Extended Capabilities

C/C++ Code Generation

Generate C and C++ code using Simulink® Coder™.

HDL Code Generation

Generate Verilog and VHDL code for FPGA and ASIC designs using HDL Coder™.

HDL Coder provides additional configuration options that affect HDL implementation and synthesized logic.

Note For decoding data encoded with truncated or terminated modes, or punctured codes, use the Viterbi Decoder block from Wireless HDL Toolbox™.

HDL Coder supports the following features of the Viterbi Decoder block:

- Non-recursive encoder/decoder with feed-forward trellis and simple shift register generation configuration
- Continuous mode
- Sample-based input
- Decoder rates from 1/2 to 1/7
- Constraint length from 3 to 9

When **Decision type** is set to `Soft decision`, the HDL implementation of the Viterbi Decoder block supports fixed-point inputs and output. For input, the fixed-point data type must be `ufixN`. `N` is the number of soft-decision bits. Signed built-in data types (`int8`, `int16`, `int32`) are not supported. For output, the HDL implementation of the Viterbi Decoder block supports block-supported output data types.

When **Decision type** is set to `Hard decision`, the block supports input with data types `ufix1` and `Boolean`. For output, the HDL implementation of the Viterbi Decoder block supports block-supported output data types. The HDL implementation of the Viterbi Decoder block does not support double and single input data types. The block does not support floating point output for fixed-point inputs.

The Viterbi Decoder block decodes every bit by tracing back through a traceback depth that you define for the block. The block implements a complete traceback for each decision bit, using registers to store the minimum state index and branch decision in the traceback decoding unit. There are two methods to optimize the traceback logic: a pipelined register-based implementation or a RAM-based architecture. See the “HDL Code Generation for Viterbi Decoder” example.

Register-Based Traceback

You can specify that the traceback decoding unit be pipelined to improve the speed of the generated circuit. You can add pipeline registers to the traceback unit by specifying the number of traceback stages per pipeline register.

Using the `TracebackStagesPerPipeline` implementation parameter, you can balance the circuit performance based on system requirements. A smaller parameter value indicates the requirement to add more registers to increase the speed of the traceback circuit. Increasing the parameter value results in fewer registers along with a decrease in the circuit speed.

RAM-Based Traceback

Instead of using registers, you can choose to use RAMs to save the survivor branch information. The coder does not support **Enable reset input port** when using RAM-based traceback.

1. Right-click the block and open **HDL Code > HDL Block Properties**. Set the **Architecture** property to `RAM-based Traceback`.
2. Double-click the block and set the **Traceback depth** on the Viterbi Decoder block mask.

RAM-based traceback and register-based traceback differ in the following ways:

- The RAM-based implementation traces back through one set of data to find the initial state to decode the previous set of data. The register-based implementation combines the traceback and decode operations into one step. It uses the best state found from the minimum operation as the decoding initial state.
- RAM-based implementation traces back through M samples, decodes the previous M bits in reverse order, and releases one bit in order at each clock cycle. The register-based implementation decodes one bit after a complete traceback.

Because of the differences in the two traceback algorithms, the RAM-based implementation produces different numerical results than the register-based traceback. A longer traceback depth, for example, 10 times the constraint length, is recommended in the RAM-based traceback. This depth achieves a similar bit error rate (BER) as the register-based implementation. The size of RAM required for the implementation depends on the trellis and the traceback depth.

HDL Block Properties

ConstrainedOutputPipeline	Number of registers to place at the outputs by moving existing delays within your design. Distributed pipelining does not redistribute these registers. The default is `0`. For more details, see “ConstrainedOutputPipeline” (HDL Coder).
InputPipeline	Number of input pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see “InputPipeline” (HDL Coder).
OutputPipeline	Number of output pipeline stages to insert in the generated code. Distributed pipelining and constrained output pipelining can move these registers. The default is `0`. For more details, see “OutputPipeline” (HDL Coder).
TracebackStagesPerPipeline	See “Register-Based Traceback” on page 5-830.

Restrictions

- **Punctured code**: Do not select this option. Punctured code requires frame-based input, which HDL Coder does not support.
- **Decision type**: The coder does not support the `Unquantized` decision type.
- **Error if quantized input values are out of range**: The coder does not support this option.
- **Operation mode**: The coder supports only the `Continuous` mode.
- **Enable reset input port**: When you enable both **Enable reset input port** and **Delay reset action to next time step**, HDL support is provided. You must select `Continuous` operation mode, and use register-based traceback.
- You cannot use the Viterbi Decoder block inside a Resettable Synchronous Subsystem.

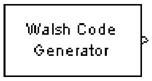
Walsh Code Generator

Generate Walsh code from orthogonal set of codes



Library

Sequence Generators sublibrary of Comm Sources

Description

Walsh codes are defined as a set of *N* codes, denoted W_{j}, for *j* = 0, 1, ... , *N* - 1, which have the following properties:

- W_{j} takes on the values +1 and -1.
- $W_{\mathrm{j}}[0] = 1$ for all *j*.
- W_{j} has exactly *j* zero crossings, for *j* = 0, 1, ... , *N* - 1.
- $$W_j W_k^T = \begin{cases} 0 & j \neq k \\ N & j = k \end{cases}$$
- Each code W*j* is either even or odd with respect to its midpoint.

Walsh codes are defined using a Hadamard matrix of order *N*. The Walsh Code Generator block outputs a row of the Hadamard matrix specified by the **Walsh code index**, which must be an integer in the range [0, ..., *N* - 1]. If you set **Walsh code index** equal to an integer *j*, the output code has exactly *j* zero crossings, for *j* = 0, 1, ... , *N* - 1.

Note, however, that the indexing in the Walsh Code Generator block is different than the indexing in the Hadamard Code Generator block. If you set the **Walsh code index** in the Walsh Code Generator block and the **Code index parameter** in the Hadamard Code Generator block, the two blocks output different codes.

Parameters

Code length

Integer scalar that is a power of 2 specifying the length of the output code.

Code index

Integer scalar in the range [0, 1, ... , N - 1], where N is the **Code length**, specifying the number of zero crossings in the output code.

Sample time

Output sample time, specified as `-1` or a positive scalar that represents the time between each sample of the output signal. If **Sample time** is set to `-1`, the sample time is inherited from downstream. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-833.

Samples per frame

Samples per frame, specified as a positive integer indicating the number of samples per frame in one channel of the output data. If **Samples per frame** is greater than the **Code length**, the code is cyclically repeated. For information on the relationship between **Sample time** and **Samples per frame**, see “Sample Timing” on page 5-833.

Output data type

The output type of the block can be specified as an `int8` or `double`. By default, the block sets this to `double`.

More About

Sample Timing

The time between output updates is equal to the product of **Samples per frame** and **Sample time**. For example, if **Sample time** and **Samples per frame** equal one, the block outputs a sample every second. If **Samples per frame** is increased to 10, then a 10-by-1 vector is output every 10 seconds. This ensures that the equivalent output rate is not dependent on the **Samples per frame** parameter.

Compatibility Considerations

Existing models automatically update this block to current version

Behavior changed in R2020a

Starting in R2020a, Simulink no longer allows you to use the Walsh Code Generator block version available before R2015b.

Existing models automatically update to load the Walsh Code Generator block version announced in “Source blocks output frames of contiguous time samples but do not use the frame attribute” in the R2015b Release Notes. For more information on block forwarding, see “Forwarding Tables” (Simulink).

Extended Capabilities

C/C++ Code Generation

Generate C and C++ code using Simulink® Coder™.

Does not support integer only code generation.

Introduced before R2006a

Windowed Integrator

Integrate over time window of fixed length

Library

Comm Filters

Description

The Windowed Integrator block creates cumulative sums of the input signal values over a sliding time window of fixed length. If the **Integration period** parameter is N and the input samples are denoted by x(1), x(2), x(3),..., then the nth output sample is the sum of the x(k) values for k between n-N+1 and n. In cases where n-N+1 is less than 1, the block uses an initial condition of 0 to represent those samples.

Input and Output Signals

This block accepts scalar, column vector, and *M*-by-*N* matrix input signals. The block filters an *M*-by-*N* input matrix as follows:

- When you set the **Input processing** parameter to `Columns as channels (frame based)`, the block treats each column as a separate channel. In this mode, the block creates *N* instances of the same filter, each with its own independent state buffer. Each of the *N* filters process *M* input samples at every Simulink time step.
- When you set the **Input processing** parameter to `Elements as channels (sample based)`, the block treats each element as a separate channel. In this mode, the block creates *M***N* instances of the same filter, each with its own independent state buffer. Each filter processes one input sample at every Simulink time step.

The output dimensions always equal those of the input signal. For information about the data types each block port supports, see the “Supported Data Type” on page 5-836 table on this page.

Parameters

Integration period

The length of the interval of integration, measured in samples.

Input processing

Specify how the block processes the input signal. You can set this parameter to one of the following options:

- `Columns as channels (frame based)` — When you select this option, the block treats each column of the input as a separate channel.

- `Elements as channels (sample based)` — When you select this option, the block treats each element of the input as a separate channel.

Rounding mode

Select the rounding mode for fixed-point operations. The block uses the **Rounding mode** when the result of a fixed-point calculation does not map exactly to a number representable by the data type and scaling storing the result. The filter coefficients do not obey this parameter; they always round to `Nearest`. For more information, see “Rounding Modes” or “Rounding Mode: Simplest” (Fixed-Point Designer).

Saturate on integer overflow

Select the overflow mode for fixed-point operations. The filter coefficients do not obey this parameter; they are always saturated.

Coefficients

The block implementation uses a Direct-Form FIR filter with all tap weights set to one. The **Coefficients** parameter controls which data type represents the taps (i.e. ones) when the input data is a fixed-point signal.

Choose how you specify the word length and the fraction length of the filter coefficients (numerator and/or denominator). See “Filter Structure Diagrams” for illustrations depicting the use of the coefficient data types in this block:

- When you select `Same word length as input`, the word length of the filter coefficients match that of the input to the block. In this mode, the fraction length of the coefficients is automatically set to the binary-point only scaling that provides you with the best precision possible given the value and word length of the coefficients.
- When you select `Specify word length`, you are able to enter the word length of the coefficients, in bits. In this mode, the fraction length of the coefficients is automatically set to the binary-point only scaling that provides you with the best precision possible given the value and word length of the coefficients.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the coefficients, in bits. If applicable, you are able to enter separate fraction lengths for the numerator and denominator coefficients.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the coefficients. If applicable, you are able to enter separate slopes for the numerator and denominator coefficients. This block requires power-of-two slope and a bias of zero.
- The filter coefficients do not obey the **Rounding mode** and the **Saturate on integer overflow** parameters; they are always saturated and rounded to `Nearest`.

Product output

Use this parameter to specify how you would like to designate the product output word and fraction lengths. See “Filter Structure Diagrams” and “Multiplication Data Types” for illustrations depicting the use of the product output data type in this block:

- When you select `Same as input`, these characteristics match those of the input to the block.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the product output, in bits.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the product output. This block requires power-of-two slope and a bias of zero.

Accumulator

Use this parameter to specify how you would like to designate the accumulator word and fraction lengths. See “Filter Structure Diagrams” and “Multiplication Data Types” for illustrations depicting the use of the accumulator data type in this block:

- When you select `Same as input`, these characteristics match those of the input to the block.
- When you select `Same as product output`, these characteristics match those of the product output.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the accumulator, in bits.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the accumulator. This block requires power-of-two slope and a bias of zero.

Output

Choose how you specify the output word length and fraction length:

- When you select `Same as input`, these characteristics match those of the input to the block.
- When you select `Same as accumulator`, these characteristics match those of the accumulator.
- When you select `Binary point scaling`, you are able to enter the word length and the fraction length of the output, in bits.
- When you select `Slope and bias scaling`, you are able to enter the word length, in bits, and the slope of the output. This block requires power-of-two slope and a bias of zero.

Lock scaling against changes by the autoscaling tool

Select this parameter to prevent any fixed-point scaling you specify in this block mask from being overridden by the autoscaling tool in the Fixed-Point Tool.

Supported Data Type

Port	Supported Data Types
In	• Double-precision floating point • Single-precision floating point • Signed Fixed-point
Out	• Double-precision floating point • Single-precision floating point • Signed fixed-point

Examples

If **Integration period** is `3` and the input signal is a ramp (`1`, `2`, `3`, `4`,...), then some of the sums that form the output of this block are as follows:

- 0+0+1 = 1
- 0+1+2 = 3
- 1+2+3 = 6

- 2+3+4 = 9
- 3+4+5 = 12
- 4+5+6 = 15
- etc.

The zeros in the first few sums represent initial conditions. With the **Input processing** parameter set to `Elements as channels`, then the values 1, 3, 6,... are successive values of the scalar output signal. With the **Input processing** parameter set to `Columns as channels`, the values 1, 3, 6,... are organized into output frames that have the same vector length as the input signal.

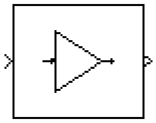
Functions

Introduced before R2006a

Amplifier

Complex baseband model of amplifier with noise and nonlinearities
Library: RF Blockset / Idealized Baseband



Description

The Amplifier block generates a complex baseband model of an amplifier with thermal noise. This block provides four nonlinearity models and three options to specify noise representation.

Note This block assumes a nominal impedance of 1 ohm.

Ports

Input

`Port_1` — Input baseband signal
real scalar | real column | complex scalar | complex column

Input baseband signal, specified as a real scalar, real column, complex scalar, or complex column.

Data Types: `double` | `single`

Output

`Port_1` — Output baseband signal
real scalar | real column | complex scalar | complex column

Output baseband signal, specified as a real scalar, real column, complex scalar, or complex column. The output port mimics the properties of the input port. For example, if the input baseband signal is specified as a real scalar with a data type double, then the output baseband signal is also specified as a real signal with the data type double.

Data Types: `double` | `single`

Parameters

Main Tab

`Model` — Amplifier nonlinearity model
`Cubic polynomial` (default) | `AM/AM - AM/PM` | `Modified Rapp` | `Saleh`

Specify the amplifier nonlinearity model as one of the following:

- `Cubic polynomial`
- `AM/AM - AM/PM`
- `Modified Rapp`
- `Saleh`

`Linear power gain (dB)` — Linear gain of amplifier

`0` (default) | real scalar

Linear gain, specified as a scalar in dB.

`Type of Non-Linearity` — Third - order nonlinearity type

`IIP3` (default) | `OIP3` | `IP1dB` | `OP1dB` | `IPsat` | `OPsat`

Third order nonlinearity type, specified as `IIP3`, `OIP3`, `IP1dB`, `OP1dB`, `IPsat`, or `OPsat`.

IIP3 — Input third-order intercept point

`Inf` (default) | real positive number

Input third-order intercept point, specified as a real positive number in dBm.

Dependencies

To enable this parameter, set **Model** to `Cubic polynomial` and **Type of Non-Linearity** to `IIP3`.

OIP3 — Output third-order intercept point

`Inf` (default) | real positive number

Output third-order intercept point, specified as a real positive number in dBm.

Dependencies

To enable this parameter, set **Model** to `Cubic polynomial` and **Type of Non-Linearity** to `OIP3`.

IP1dB — Input 1 dB compression point

`Inf` (default) | real positive number

Input 1 dB compression point, specified as a real positive number in dBm.

Dependencies

To enable this parameter, set **Model** to `Cubic polynomial` and **Type of Non-Linearity** to `IP1dB`.

OP1dB — Output 1 dB compression point

`Inf` (default) | real positive number

Output 1 dB compression point, specified as a real positive number in dBm.

Dependencies

To enable this parameter, set **Model** to `Cubic polynomial` and **Type of Non-Linearity** to `OP1dB`.

`IPsat` — Input saturation point

`Inf` (default) | real positive number

Input saturation point, specified as a real positive number in dBm.

Dependencies

To enable this parameter, set **Model** to `Cubic polynomial` and **Type of Non-Linearity** to `IPsat`.

`OPsat` — Output saturation point

`Inf` (default) | real positive number

Output saturation point, specified as a positive real number in dBm.

Dependencies

To enable this parameter, set **Model** to `Cubic polynomial` and **Type of Non-Linearity** to `OPsat`.

`Simulate using` — Specify type of simulation to run

`Code generation` (default) | `Interpreted execution`

- `Code generation` – Simulate model using generated C code. The first time you run a simulation, Simulink generates C code for the block. The C code is reused for subsequent simulations, as long as the model does not change. This option requires additional startup time, but the speed of the subsequent simulations is faster than `Interpreted execution`.
- `Interpreted execution` – Simulate model using the MATLAB interpreter. This option shortens startup time speed, but the speed of the subsequent simulations is slower than `Code generation`. In this mode, you can debug the source code of the block.

`Plot power characteristics` — Plot power characteristics

button (default)

This button plots the power characteristics based on the parameters specified on the **Main** tab.

`Lookup table (Pin(dBm), Pout(dBm), deg)` — Stub termination

`[ -25, 5, -1; -10, 20, -2; 0, 27, 5; 5, 28, 12 ]` (default) | real vector

Table lookup entries specified as a real *M*-by-3 matrix. This table expresses the model output power dBm level in matrix column 2 and the model phase change in degrees in matrix column 3 as related to the absolute value of the input signal power of matrix column 1 for the AM/AM - AM/PM model. The column 1 input power must increase monotonically.

Dependencies

To enable this parameter, set **Model** to `AM/AM - AM/PM`

`Output saturation level (V)` — Output saturation level

`1` (default) | real positive number

Voltage output saturation level, specified as a real positive number in dBm.

Dependencies

To enable this parameter, set **Model** to `Modified Rapp`

`Magnitude smoothness factor` — Magnitude smoothness factor

`2` (default) | real positive number

Magnitude smoothness factor for the `Modified Rapp` amplifier model AM/AM calculations, specified as a positive real number.

Dependencies

To enable this parameter, set **Model** to `Modified Rapp`

`Phase gain (rad)` — Phase gain

`-0.45` (default) | real scalar

Phase gain for the `Modified Rapp` amplifier model AM/PM calculations, specified as a real scalar in radians.

Dependencies

To enable this parameter, set **Model** to `Modified Rapp`

`Phase saturation` — Phase saturation

`.88` (default) | real positive number

Phase saturation for the `Modified Rapp` amplifier model AM/PM calculations, specified as a positive real number.

Dependencies

To enable this parameter, set **Model** to `Modified Rapp`

`Phase smoothness factor` — Phase smoothness factor

`3.43` (default) | real positive number

Phase smoothness factor for the `Modified Rapp` amplifier model AM/PM calculations, specified as a positive real number.

Dependencies

To enable this parameter, set **Model** to `Modified Rapp`

`Input scaling (dB)` — Scaling factor for input signal level

`0` (default) | nonnegative real number

Scaling factor for input signal level for the `Saleh` amplifier model, specified as a nonnegative real number in dB.

Dependencies

To enable this parameter, set **Model** to `Saleh`

`AM / AM parameters [alpha beta]` — AM/AM conversion parameters

`[ 2.1587, 1.1517 ]` (default) | two-element vector

AM/AM two-tuple conversion parameters for `Saleh` amplifier model, specified as a two-element vector of nonnegative real numbers.

Dependencies

To enable this parameter, set **Model** to `Saleh`

`AM / PM parameters [alpha beta]` — AM/PM conversion parameters

`[ 4.0033, 9.1040 ]` (default) | two-element vector

AM/PM two-tuple conversion parameters for Saleh amplifier model, specified as a two-element vector of nonnegative real numbers.

Dependencies

To enable this parameter, set **Model** to Saleh

Output scaling (dB) — Scaling factor for output signal level

0 (default) | nonnegative real number

Scaling factor for output signal level for Saleh amplifier model, specified as nonnegative real number in dB.

Dependencies

To enable this parameter, set **Model** to Saleh

Noise Tab

Include Noise — Add noise to system

off (default) | on

Select this parameter to add system noise to the input signal. Once you select this parameter, the parameters associated with the **Noise** tab are displayed.

Specify noise type — Noise representation

Noise temperature (default) | Noise figure | Noise factor

Noise descriptive type, specified as Noise temperature, Noise figure, or Noise factor.

Noise temperature (K) — Noise temperature to model noises in amplifier

290 (default) | nonnegative real number

Noise temperature to model noise in the amplifier, specified as a nonnegative real number in degrees (K).

Dependencies

To enable this parameter, select **Include noise** and set **Specify noise type** to Noise temperature.

Noise figure (dB) — Noise figure to model noise in amplifier

10 * log10(2) (default) | nonnegative real number

Noise figure to model noise in the amplifier, specified as a nonnegative real number in dB.

Dependencies

To enable this parameter, select **Include noise** and set **Specify noise type** to Noise figure.

Noise factor — Noise factor to model noise in amplifier

2 (default) | positive integer scalar greater than or equal to 1

Noise factor to model noise in the amplifier, specified as a positive integer scalar greater than or equal to 1

Dependencies

To enable this parameter, select **Include noise** and set **Specify noise type** to Noise factor.

Seed source — Source of initial seed

Auto (default) | User specified

Source of initial seed used to prepare the Gaussian random number noise generator, specified as one of the following:

- Auto - When **Seed source** is set to Auto, seeds for each amplifier instance are generated using a random number generator. The reset method of the instance has no effect.
- User specified - When **Seed source** is set to User specified, the value provided in the **Seed** is used to initialize the random number generator and the reset method resets the random number generator using the **Seed** property value.

Seed — Seed for random number generator

67987 (default) | nonnegative integer

Seed for the random number generator, specified as a nonnegative integer less than 2^{32}. Use this value to initialize the random number generator.

Dependencies

To enable this parameter, click **Include noise** check box and choose User specified in the **Seed source** parameter.

Algorithms

Model

Cubic Polynomial

- The Cubic polynomial model uses linear power gain to determine the linear coefficient of a third-order polynomial and either IP3, P1dB, or Psat to determine the third - order coefficient of the polynomial.
- The general form of cubic nonlinearity models the AM/AM characteristics as

  $$F_{AM/AM}(u) = c_1 \times u + \frac{3}{4}c_3 \times u^3$$

  where $F_{AM/AM}(u)$ is the magnitude of the output signal, u is the magnitude of the input signal, c_1 is the coefficient of the linear gain term, and c_3 is the coefficient of the cubic gain term.

- The results for IIP3, OIP3, PI,1dB, and Po,1dB are taken from [5] (RF Blockset).
  - If “IIP3” (RF Blockset) is specified, then

    $$c_3 = -\frac{4c_1}{3 \times 10^{[(IIP3-30)/10]}}$$

    where IIP3 is given in dBm.
  - If “OIP3” (RF Blockset) is specified, then

    $$c_3 = -\frac{4c_1^3}{3 \times 10^{[(OIP3-30)/10]}}$$

    where OIP3 is given in dBm.

- If the input 1 dB gain compression power “IP1dB” (RF Blockset) is specified, then

$$c_3 = -\frac{2c_1(10^{19/20} - 10)}{15 \times 10^{[(IP1dB - 30)/10]}}$$

  where IP1dB is given in dBm.
- If the output 1 dB gain compression power “OP1dB” (RF Blockset) is specified, then

$$c_3 = -\frac{2c_1(10^{19/20} - 10)}{15 \times 10^{[(OP1dB - 30 - LGdB + 1)/10]}}$$

  where OP1dB is given in dBm, and LGdB is the linear gain in dB
- If the input saturation power “IPsat” (RF Blockset) is specified, then

$$c_3 = -\frac{4c_1}{9 \times 10^{[(IPsat - 30)/10]}}$$

  where IPsat is given in dBm.
- If the output saturation power “OPsat” (RF Blockset) is specified, then

$$c_3 = -\frac{16c_1^3}{81 \times 10^{[(OPsat - 30)/10]}}$$

  where OPsat is given in dBm.

AM/AM-AM/PM

The `AM/AM-AM/PM` model uses a lookup table to specify the amplifier power characteristics. The table returns interpolated or extrapolated values using linear interpolation. Each row in the table expresses the relationship between output power or phase change as a function of input power.

$$u_{\mathrm{out}} = Table_{AM/AM}(u) \times e^{((Table_{AM/PM}(u) + \angle u) \times i)}$$

where u_{out} is the output signal and u is the magnitude of input signal.

Saleh

- The `Saleh` model is based on normalized transfer function. Use the input / output scaling parameters to adjust signal levels from their normalized values.
- For `Saleh`, the AM/AM parameters $alpha_{AM/AM}$ and $beta_{AM/AM}$ are used to compute the amplitude gain for an input signal using the following equation:

$$F_{AM/AM}(u) = \frac{alpha_{AM/AM} \times |u|}{1 + beta_{AM/AM} \times |u|^2}$$

  where $|u|$ is the magnitude of the scaled signal and `u` is calculated as:

$$u = InputScale \times u_{\mathrm{in}}$$

- For `Saleh`, the AM/PM parameters $alpha_{AM/PM}$ and $beta_{AM/PM}$ are used to compute the phase change for an input signal using the following equation:

$$F_{AM/PM}(u) = \frac{alpha_{AM/PM} \times |u|^2}{1 + beta_{AM/PM} \times |u|^2} + angle(u)$$

where $|u|$ is the magnitude of the scaled signal and *angle* is a MATLAB function that returns the phase angle of *u*.

- The scaled output signal, u_{out} is calculated as:

$$u_{\mathrm{out}} = F_{AM/AM} \times e^{(F_{AM/PM} \times i)} \times OutputScale$$

Modified Rapp

- The `Modified Rapp` model is based on normalized transfer functions. Use the input and output scaling parameters to adjust the signal levels from their normalized values.

  The AM/AM characteristics for `Modified Rapp` are given by:

$$F_{AM/AM}(u) = \frac{g_{lin} \times |u|}{(1 + \left|\frac{g_{lin} \times u}{V_{sat}}\right|^{2p})^{1/2p}}$$

  where $|u|$ is the magnitude of input signal,

  g_{lin} is $10^{(\text{Linear Gain (dB)/20})}$, and is the amplitude gain of the amplifier, V_{sat} is “Output saturation level (V)” (RF Blockset), and p is “Magnitude smoothness factor” (RF Blockset).
- The AM/PM characteristics for `Modified Rapp` is given by

$$F_{AM/PM}(u) = \frac{A \times u^q}{[1 + (\frac{u}{B})^q]} + angle(u)$$

  where u is the magnitude of input signal, A is the “Phase gain (rad)” (RF Blockset), B is “Phase saturation” (RF Blockset), q is “Phase smoothness factor” (RF Blockset) and *angle* is a MATLAB function which returns phase angle of `u`.
- The output signal u_{out} is calculated as:

$$u_{\mathrm{out}} = u_{\mathrm{mag}} \times e^{(u_{angle} \times i)}$$

  where u_{mag} is the magnitude and u_{angle} is the phase of the output signal, respectively.

Thermal Noise Simulation

According to the “Specify noise type” (RF Blockset) parameter, you can specify the amount of thermal noise in three ways,

- `Noise temperature` — Specifies the noise in kelvin.
- `Noise factor` — Specifies the noise by using the equation:

$$Noise\ factor\ =\ 1\ +\ \frac{Noise\ temperature}{290}$$

- `Noise figure` — Specifies the noise in decibels relative to a noise temperature of 290 kelvin. In terms of noise factor

$$\mathit{Noise\ figure} \;=\; 10 \times \log(\mathit{Noise\ factor})$$

Note Some RF Blockset™ blocks require the sample time to perform baseband modeling calculations. To ensure accuracy in these calculations, the Input Port block, as well as the mathematical RF blocks compare the input sample time to the sample time you provide in the mask. If these times do not match, or if the input sample time is missing because the blocks are not connected, an error message appears.

Plot power characteristics

To visualize the functionality of **Plot power characteristics** button, set the to the Amplifier block listed in the table.

Model	Parameters	Power Characteristics Plot
Cubic Polynomial	**Main** tab: • **Linear power gain (dB)**: `7` • **Type of Non-linearity**: `IIP3` • **IIP3 (dBm)**: `33` • **Simulate using**: `Code generation` **Noise** tab: • **Specify noise type**: `Noise temperature` • **Noise temperature**: `290` • **Seed source**: `Auto`	AM/AM - AM/PM	**Main** tab: • **Lookup table (Pin(dBm), Pout(dBm), deg)**: `[-25, 5, -1; -10, 20, -2; 0, 27, 5; 5, 28, 12]` • **Simulate using**: `Code generation` **Noise** tab: • **Specify noise type**: `Noise temperature` • **Noise temperature**: `290` • **Seed source**: `User specified` • **Seed** : `67987`

Application of Nonlinearity

All four subsystems for the amplifier nonlinearity models apply a memoryless nonlinearity to the complex baseband input signal. Each model

1. Multiplies the signal by a gain factor.
2. Splits the complex signal into its magnitude and angle components.
3. Applies an AM/AM conversion to the magnitude of the signal, according to the selected nonlinearity model, to produce the magnitude of the output signal.
4. Applies an AM/PM conversion to the phase of the signal, according to the selected nonlinearity model, and adds the result to the angle of the signal to produce the angle of the output signal.
