Getting Started

Statistics and Machine Learning Toolbox Product Description

Analyze and model data using statistics and machine learning

Statistics and Machine Learning Toolbox provides functions and apps to describe, analyze, and model data. You can use descriptive statistics, visualizations, and clustering for exploratory data analysis, fit probability distributions to data, generate random numbers for Monte Carlo simulations, and perform hypothesis tests. Regression and classification algorithms let you draw inferences from data and build predictive models either interactively, using the Classification and Regression Learner apps, or programmatically, using AutoML.

For multidimensional data analysis and feature extraction, the toolbox provides principal component analysis (PCA), regularization, dimensionality reduction, and feature selection methods that let you identify variables with the best predictive power.

The toolbox provides supervised, semi-supervised and unsupervised machine learning algorithms, including support vector machines (SVMs), boosted decision trees, *k*-means, and other clustering methods. You can apply interpretability techniques such as partial dependence plots and LIME, and automatically generate C/C++ code for embedded deployment. Many toolbox algorithms can be used on data sets that are too big to be stored in memory.

Supported Data Types

Statistics and Machine Learning Toolbox supports the following data types for input arguments:

- Numeric scalars, vectors, matrices, or arrays having single- or double-precision entries. These data forms have data type `single` or `double`. Examples include response variables, predictor variables, and numeric values.
- Cell arrays of character vectors; character, string, logical, or categorical arrays; or numeric vectors for categorical variables representing grouping data. These data forms have data types `cell` (specifically `cellstr`), `char`, `string`, `logical`, `categorical`, and `single` or `double`, respectively. An example is an array of class labels in machine learning.
  - You can also use nominal or ordinal arrays for categorical data. However, the `nominal` and `ordinal` data types are not recommended. To work with nominal or ordinal categorical data, use the `categorical` data type instead.
  - You can use signed or unsigned integers, e.g., `int8` or `uint8`. However:
    - Estimation functions might not support signed or unsigned integer data types for nongrouping data.
    - If you recast a `single` or `double` numeric vector containing `NaN` values to a signed or unsigned integer, then the software converts the `NaN` elements to `0`.
- Some functions support tabular arrays for heterogeneous data (for details, see “Tables”). The `table` data type contains variables of any of the data types previously listed. An example is mixed categorical and numerical predictor data for regression analysis.
  - For some functions, you can also use dataset arrays for heterogeneous data. However, the `dataset` data type is not recommended. To work with heterogeneous data, use the `table` data type if the estimation function supports it.
  - Functions that do not support the `table` data type support sample data of type `single` or `double`, e.g., matrices.
- Some functions accept `gpuArray` input arguments so that they execute on the GPU. For the full list of Statistics and Machine Learning Toolbox functions that accept GPU arrays, see Function List (GPU Arrays).
- Some functions accept `tall` array input arguments to work with large data sets. For the full list of Statistics and Machine Learning Toolbox functions that accept tall arrays, see Function List (Tall Arrays).
- Some functions accept sparse matrices, i.e., matrix `A` such that `issparse(A)` returns `1`. For functions that do not accept sparse matrices, recast the data to a full matrix by using `full`.

Statistics and Machine Learning Toolbox does not support the following data types:

- Complex numbers.
- Custom numeric data types, e.g., a variable that is double precision and an object.
- Signed or unsigned numeric integers for nongrouping data, e.g., `unint8` and `int16`.

Note If you specify data of an unsupported type, then the software might return an error or unexpected results.

Organizing Data

Other MATLAB Functions Supporting Nominal and Ordinal Arrays

Note The `nominal` and `ordinal` array data types are not recommended. To represent ordered and unordered discrete, nonnumeric data, use the "Categorical Arrays" data type instead.

Notable functions that operate on nominal and ordinal arrays are listed in `nominal` and `ordinal`. In addition to these, many other functions in MATLAB operate on nominal and ordinal arrays in much the same way that they operate on other arrays. A few functions might exhibit special behavior when operating on nominal and ordinal arrays:

- If multiple input arguments are nominal or ordinal arrays, the function often requires that they have the same set of categories, including order if ordinal.
- Relational functions, such as `max` and `gt`, require that the input arrays be `ordinal`.

The following table lists MATLAB functions that operate on nominal and ordinal arrays in addition to other arrays.

`size`	`isequal`	`intersect`	`histogram`	`double`
`length`	`isequaln`	`ismember`	`pietimes`	`single`
`ndims`		`setdiff`		`int8`
`numel`	`eq`	`setxor`	`sort`	`int16`
	`ne`	`unique`	`sortrows`	`int32`
`isrow`	`lt`	`union`	`issorted`	`int64`
`iscolumn`	`le`			`uint8`
	`ge`		`permute`	`uint16`
`cat`	`gt`		`reshape`	`uint32`
`horzcat`			`transpose`	`uint64`
`vertcat`	`min`		`ctranspose`	`char`
	`max`			`cellstr`
	`median`			
	`mode`

Create Nominal and Ordinal Arrays

Note The `nominal` and `ordinal` array data types are not recommended. To represent ordered and unordered discrete, nonnumeric data, use the “Categorical Arrays” data type instead.

In this section...

Create Nominal Arrays

This example shows how to create nominal arrays using `nominal`.

Load sample data.

The variable `species` is a 150-by-1 cell array of character vectors containing the species name for each observation. The unique species types are setosa, versicolor, and virginica.

```
load fisheriris
unique(species)
```

```
ans = 3x1 cell
    {'setosa'    }
    {'versicolor'}
    {'virginica' }
```

Create a nominal array.

Convert `species` to a nominal array using the categories occurring in the data.

```
speciesNom = nominal(species);
class(speciesNom)
```

```
ans =
'nominal'
```

Explore category levels.

The nominal array, `speciesNom`, has three levels corresponding to the three unique species. The levels of a nominal array are the set of possible values that its elements can take.

```
getlevels(speciesNom)
```

```
ans = 1x3 nominal
     setosa      versicolor      virginica
```

A nominal array can have more levels than actually appear in the data. For example, a nominal array named `AllSizes` might have levels `small`, `medium`, and `large`, but you might only have observations that are `medium` and `large` in your data. To see which levels of a nominal array are actually present in the data, use `unique`, for instance, `unique(AllSizes)`.

Explore category labels.

Each level has a label. By default, `nominal` labels the category levels with the values occurring in the data. For `speciesNom`, these labels are the species types.

```
getlabels(speciesNom)
```

```
ans = 1x3 cell
    {'setosa'}    {'versicolor'}    {'virginica'}
```

Specify your own category labels.

You can specify your own labels for each category level. You can specify labels when you create the nominal array.

```
speciesNom2 = nominal(species,{'seto','vers','virg'});
getlabels(speciesNom2)
```

```
ans = 1x3 cell
    {'seto'}    {'vers'}    {'virg'}
```

You can also change category labels on an existing nominal array using `setlabels`

Verify new category labels.

Verify that the new labels correspond to the original labels in `speciesNom`.

```
isequal(speciesNom=='setosa',speciesNom2=='seto')
```

```
ans = logical
   1
```

The logical value `1` indicates that the two labels, `'setosa'` and `'seto'`, correspond to the same observations.

Create Ordinal Arrays

This example shows how to create ordinal arrays using `ordinal`.

Load sample data.

```
AllSizes = {'medium','large','small','small','medium',...
            'large','medium','small'};
```

The created variable, `AllSizes`, is a cell array of character vectors containing size measurements on eight objects.

Create an ordinal array.

Create an ordinal array with category levels and labels corresponding to the values in the cell array (the default levels and labels).

```
sizeOrd = ordinal(AllSizes);
getlevels(sizeOrd)
```

```
ans = 1x3 ordinal
     large      medium      small
```

Explore category labels.

By default, `ordinal` uses the original character vectors as category labels. The default order of the categories is ascending alphabetical order.

```
getlabels(sizeOrd)
```

```
ans = 1x3 cell
    {'large'}    {'medium'}    {'small'}
```

Add additional categories.

Suppose that you want to include additional levels for the ordinal array, `xsmall` and `xlarge`, even though they do not occur in the original data. To specify additional levels, use the third input argument to `ordinal`.

```
sizeOrd2 = ordinal(AllSizes,{},...
                   {'xsmall','small','medium','large','xlarge'});
getlevels(sizeOrd2)
```

```
ans = 1x5 ordinal
     xsmall      small      medium      large      xlarge
```

Explore category labels.

To see which levels are actually present in the data, use `unique`.

```
unique(sizeOrd2)
```

```
ans = 1x3 ordinal
     small      medium      large
```

Specify the category order.

Convert `AllSizes` to an ordinal array with categories `small` < `medium` < `large`. Generally, an ordinal array is distinct from a nominal array because there is a natural ordering for levels of an ordinal array. You can use the third input argument to `ordinal` to specify the ascending order of the levels. Here, the order of the levels is smallest to largest.

```
sizeOrd = ordinal(AllSizes,{},{'small','medium','large'});
getlevels(sizeOrd)
```

```
ans = 1x3 ordinal
     small      medium      large
```

The second input argument for `ordinal` is a list of labels for the category levels. When you use braces `{}` for the level labels, `ordinal` uses the labels specified in the third input argument (the labels come from the levels present in the data if only one input argument is used).

Compare elements.

Verify that the first object (with size `medium`) is smaller than the second object (with size `large`).

```
sizeOrd(1) < sizeOrd(2)
```

```
ans = logical
   1
```

The logical value `1` indicates that the inequality holds.

Change Category Labels

Note The `nominal` and `ordinal` array data types are not recommended. To represent ordered and unordered discrete, nonnumeric data, use the “Categorical Arrays” data type instead.

Change Category Labels

This example shows how to change the labels for category levels in categorical arrays using `setlabels`. You also have the option to specify labels when creating a categorical array.

Load sample data.

The variable `Cylinders` contains the number of cylinders in 100 sample cars.

```
load carsmall
unique(Cylinders)
```

```
ans = 3×1

     4
     6
     8
```

The sample has 4-, 6-, and 8-cylinder cars.

Create an ordinal array.

Convert `Cylinders` to a nominal array with the default category labels (taken from the values in the data).

```
cyl  = ordinal(Cylinders);
getlabels(cyl)
```

```
ans = 1x3 cell
    {'4'}    {'6'}    {'8'}
```

`ordinal` created labels using the integer values in `Cylinders`, but you should provide labels for numeric data.

Change category labels.

Relabel the categories in `cyl` to `Four`, `Six`, and `Eight`.

```
cyl = setlabels(cyl ,{'Four','Six','Eight'});
getlabels(cyl)
```

```
ans = 1x3 cell
    {'Four'}    {'Six'}    {'Eight'}
```

Alternatively, you can specify category labels when you create a nominal or ordinal array using the second input argument, for example by specifying `ordinal(Cylinders, {'Four','Six','Eight'})`.

Reorder Category Levels

Note The `nominal` and `ordinal` array data types are not recommended. To represent ordered and unordered discrete, nonnumeric data, use the "Categorical Arrays" data type instead.

In this section...

Reorder Category Levels in Ordinal Arrays

This example shows how to reorder the category levels in an ordinal array using `reorderlevels`.

Load sample data.

```
AllSizes = {'medium','large','small','small','medium',...
            'large','medium','small'};
```

The created variable, `AllSizes`, is a cell array of character vectors containing size measurements on eight objects.

Create an ordinal array.

Convert `AllSizes` to an ordinal array without specifying the order of the category levels.

```
size = ordinal(AllSizes);
getlevels(size)
```

```
ans = 1x3 ordinal
     large      medium      small
```

By default, the categories are ordered by their labels in ascending alphabetical order, `large` < `medium` < `small`.

Compare elements.

Check whether or not the first object (which has size `medium`) is smaller than the second object (which has size `large`).

```
size(1) < size(2)
```

```
ans = logical
   0
```

The logical value `0` indicates that the medium object is not smaller than the large object.

Reorder category levels.

Reorder the category levels so that `small` < `medium` < `large`.

```
size = reorderlevels(size,{'small','medium','large'});
getlevels(size)
```

```
ans = 1x3 ordinal
     small      medium      large
```

Compare elements.

Verify that the first object is now smaller than the second object.

```
size(1) < size(2)
```

```
ans = logical
   1
```

The logical value 1 indicates that the expected inequality now holds.

Reorder Category Levels in Nominal Arrays

This example shows how to reorder the category levels in nominal arrays using `reorderlevels`. By definition, nominal array categories have no natural ordering. However, you might want to change the order of levels for display or analysis purposes. For example, when fitting a regression model with categorical covariates, `fitlm` uses the first level of a nominal independent variable as the reference category.

Load sample data.

The dataset array, `hospital`, contains variables measured on 100 sample patients. The variable `Weight` contains the weight of each patient. The variable `Sex` is a nominal variable containing the gender, `Male` or `Female`, for each patient.

```
load hospital
getlevels(hospital.Sex)
```

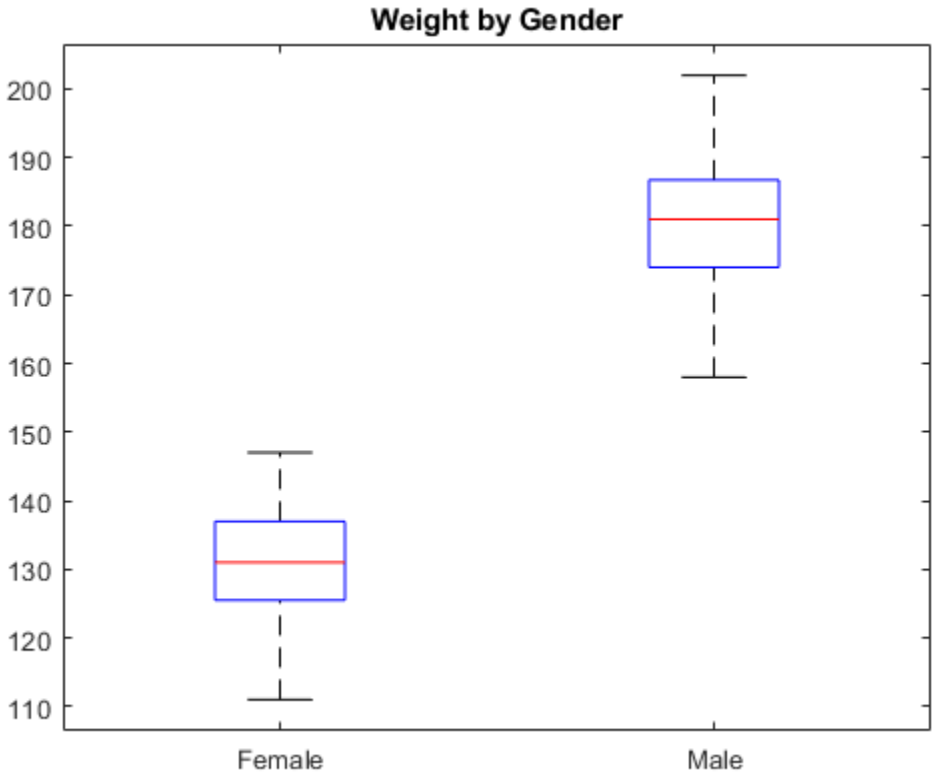
```
ans = 1x2 nominal
     Female      Male
```

By default, the order of the nominal categories is in ascending alphabetical order of the labels.

Plot data grouped by category level.

Draw box plots of weight, grouped by gender.

```
figure
boxplot(hospital.Weight,hospital.Sex)
title('Weight by Gender')
```



The box plots appear in the same alphabetical order returned by `getlevels`.

Change the category order.

Change the order of the category levels.

```
hospital.Sex = reorderlevels(hospital.Sex,{'Male','Female'});
getlevels(hospital.Sex)
```

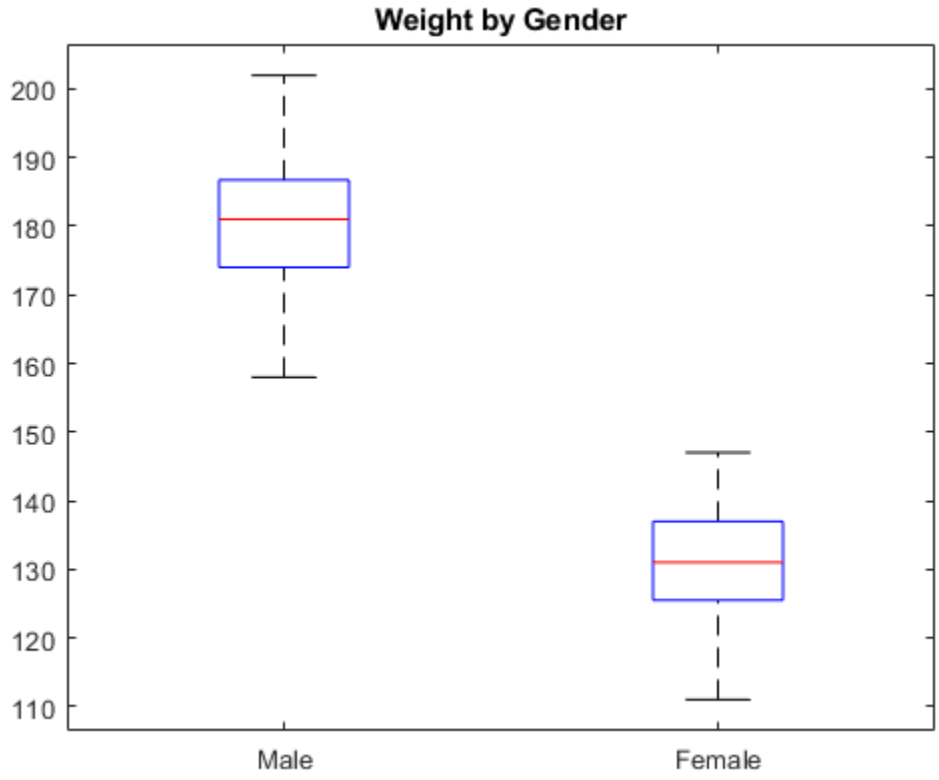
```
ans = 1x2 nominal
     Male      Female
```

The levels are in the newly specified order.

Plot data in new order.

Draw box plots of weight by gender.

```
figure
boxplot(hospital.Weight,hospital.Sex)
title('Weight by Gender')
```



The order of the box plots corresponds to the new level order.

Categorize Numeric Data

Note The `nominal` and `ordinal` array data types are not recommended. To represent ordered and unordered discrete, nonnumeric data, use the “Categorical Arrays” data type instead.

Categorize Numeric Data

This example shows how to categorize numeric data into a categorical ordinal array using `ordinal`. This is useful for discretizing continuous data.

Load sample data.

The dataset array, `hospital`, contains variables measured on a sample of patients. Compute the minimum, median, and maximum of the variable `Age`.

```
load hospital
quantile(hospital.Age,[0,.5,1])
```

```
ans = 1×3

    25    39    50
```

The patient ages range from 25 to 50.

Convert a numeric array to an ordinal array.

Group patients into the age categories `Under 30`, `30-39`, `Over 40`.

```
hospital.AgeCat = ordinal(hospital.Age,{'Under 30','30-39','Over 40'},...
                          [],[25,30,40,50]);
getlevels(hospital.AgeCat)
```

```
ans = 1x3 ordinal
     Under 30      30-39      Over 40
```

The last input argument to `ordinal` has the endpoints for the categories. The first category begins at age 25, the second at age 30, and so on. The last category contains ages 40 and above, so begins at 40 and ends at 50 (the maximum age in the data set). To specify three categories, you must specify four endpoints (the last endpoint is the upper bound of the last category).

Explore categories.

Display the age and age category for the second patient.

```
dataset({hospital.Age(2),'Age'},...
        {hospital.AgeCat(2),'AgeCategory'})
```

```
ans =
    Age    AgeCategory
    43     Over 40
```

When you discretize a numeric array into categories, the categorical array loses all information about the actual numeric values. In this example, `AgeCat` is not numeric, and you cannot recover the raw data values from it.

Categorize a numeric array into quartiles.

The variable `Weight` has weight measurements for the sample patients. Categorize the patient weights into four categories, by quartile.

```
p = 0:.25:1;
breaks = quantile(hospital.Weight,p);
hospital.WeightQ = ordinal(hospital.Weight,{'Q1','Q2','Q3','Q4'},...
                   [],breaks);
getlevels(hospital.WeightQ)

ans = 1x4 ordinal
     Q1      Q2      Q3      Q4
```

Explore categories.

Display the weight and weight quartile for the second patient.

```
dataset({hospital.Weight(2),'Weight'},...
        {hospital.WeightQ(2),'WeightQuartile'})

ans =
    Weight    WeightQuartile
    163       Q3
```

Summary statistics grouped by category levels.

Compute the mean systolic and diastolic blood pressure for each age and weight category.

```
grpstats(hospital,{'AgeCat','WeightQ'},'mean','DataVars','BloodPressure')

ans =
                   AgeCat      WeightQ    GroupCount    mean_BloodPressure
    Under 30_Q1    Under 30    Q1          6            123.17      79.667
    Under 30_Q2    Under 30    Q2          3            120.33      79.667
    Under 30_Q3    Under 30    Q3          2             127.5        86.5
    Under 30_Q4    Under 30    Q4          4               122          78
    30-39_Q1       30-39       Q1         12            121.75       81.75
    30-39_Q2       30-39       Q2          9            119.56      82.556
    30-39_Q3       30-39       Q3          9               121      83.222
    30-39_Q4       30-39       Q4         11            125.55      87.273
    Over 40_Q1     Over 40     Q1          7            122.14      84.714
    Over 40_Q2     Over 40     Q2         13            123.38      79.385
    Over 40_Q3     Over 40     Q3         14            123.07      84.643
    Over 40_Q4     Over 40     Q4         10             124.6        85.1
```

The variable `BloodPressure` is a matrix with two columns. The first column is systolic blood pressure, and the second column is diastolic blood pressure. The group in the sample with the

highest mean diastolic blood pressure, `87.273`, is aged 30–39 and in the highest weight quartile, `30-39_Q4`.

Merge Category Levels

Note The `nominal` and `ordinal` array data types are not recommended. To represent ordered and unordered discrete, nonnumeric data, use the “Categorical Arrays” data type instead.

Merge Category Levels

This example shows how to merge categories in a nominal or ordinal array using `mergelevels`. This is useful for collapsing categories with few observations.

Load sample data.

```
load carsmall
```

Create a nominal array.

The variable `Origin` is a character array containing the country of origin for 100 sample cars. Convert `Origin` to a nominal array.

```
Origin = nominal(Origin);
getlevels(Origin)
```

```
ans = 1x6 nominal
     France      Germany      Italy      Japan      Sweden      USA
```

There are six unique countries of origin in the data.

Tabulate category counts.

Explore the elements of the nominal array.

```
tabulate(Origin)
```

```
    Value    Count   Percent
   France        4      4.00%
  Germany        9      9.00%
    Italy        1      1.00%
    Japan       15     15.00%
   Sweden        2      2.00%
      USA       69     69.00%
```

There are relatively few observations in each European country.

Merge categories.

Merge the categories `France`, `Germany`, `Italy`, and `Sweden` into one category called `Europe`.

```
Origin = mergelevels(Origin,{'France','Germany','Italy','Sweden'},...
                     'Europe');
getlevels(Origin)
```

```
ans = 1x3 nominal
     Europe      Japan      USA
```

The variable `Origin` now has only three category levels.

Tabulate category counts.

Explore the elements of the merged categories.

```
tabulate(Origin)
```

```
   Value    Count   Percent
  Europe       16     16.00%
   Japan       15     15.00%
     USA       69     69.00%
```

The category `Europe` has the 16% of observations that were previously distributed across four countries.

Add and Drop Category Levels

This example shows how to add and drop levels from a nominal or ordinal array.

Note The `nominal` and `ordinal` array data types are not recommended. To represent ordered and unordered discrete, nonnumeric data, use the “Categorical Arrays” data type instead.

Load sample data.

```
load('examgrades')
```

The array `grades` contains exam scores from 0 to 100 on five exams for a sample of 120 students.

Create an ordinal array.

Assign letter grades to each student for each test using these categories.

Grade Range	Letter Grade
100	A+
90–99	A
80–89	B
70–79	C
60–69	D

```
letter = ordinal(grades,{'D','C','B','A','A+'},[],...
                 [60,70,80,90,100,100]);
getlevels(letter)
```

```
ans =

     D      C      B      A      A+
```

There are five grade categories, in the specified order `D < C < B < A < A+`.

Check for undefined categories.

Check whether or not there are any exam scores that do not fall into the five letter categories.

```
any(isundefined(letter))
```

```
ans =

     1     0     1     1     0
```

Recall that there are five exam scores for each student. The previous command returns a logical value for each of the five exams, indicating whether there are any scores that are `<undefined>`. There are scores for the first, third, and fourth exams that are `<undefined>`, that is, missing a category level.

Identify elements in undefined categories.

You can find the exam scores that do not have a letter grade using the `isundefined` logical condition.

```
grades(isundefined(letter))

ans =

    55
    59
    58
    59
    54
    57
    56
    59
    59
    50
    59
    52
```

The exam scores that are in the 50s do not have a letter grade.

Add a new category.

Put all scores that are `<undefined>` into a new category labeled `D-`.

```
letter(isundefined(letter)) = 'D-';
getlevels(letter)

Warning: Categorical level 'D-' being added.
> In categorical.subsasgn at 55

ans =

     D      C      B      A      A+      D-
```

The ordinal variable, `letter`, has a new category added to the end.

Reorder category levels.

Reorder the categories so that `D- < D`.

```
letter = reorderlevels(letter,{'D-','D','C','B','A','A+'});
getlevels(letter)

ans =

     D-      D      C      B      A      A+
```

Compare elements.

Now that all exam scores have a letter grade, count how many students received a higher letter grade on the second test than on the first test.

```
sum(letter(:,2) > letter(:,1))

ans =

    32
```

Thirty-two students improved their letter grade between the first two exams.

Explore categories.

Count the number of A+ scores in each of the five exams.

```
sum(letter=='A+')
```

```
ans =

     0     0     0     0     0
```

There are no A+ scores on any of the five exams.

Drop a category.

Drop the category A+ from the ordinal variable, `letter`.

```
letter = droplevels(letter,'A+');
getlevels(letter)
```

```
ans =

     D-      D      C      B      A
```

Category A+ is no longer in the ordinal variable, `letter`.

Plot Data Grouped by Category

Note The `nominal` and `ordinal` array data types are not recommended. To represent ordered and unordered discrete, nonnumeric data, use the “Categorical Arrays” data type instead.

Plot Data Grouped by Category

This example shows how to plot data grouped by the levels of a categorical variable.

Load sample data.

```
load carsmall
```

The variable `Acceleration` contains acceleration measurements on 100 sample cars. The variable `Origin` is a character array containing the country of origin for each car.

Create a nominal array.

Convert `Origin` to a nominal array.

```
Origin = nominal(Origin);
getlevels(Origin)
```

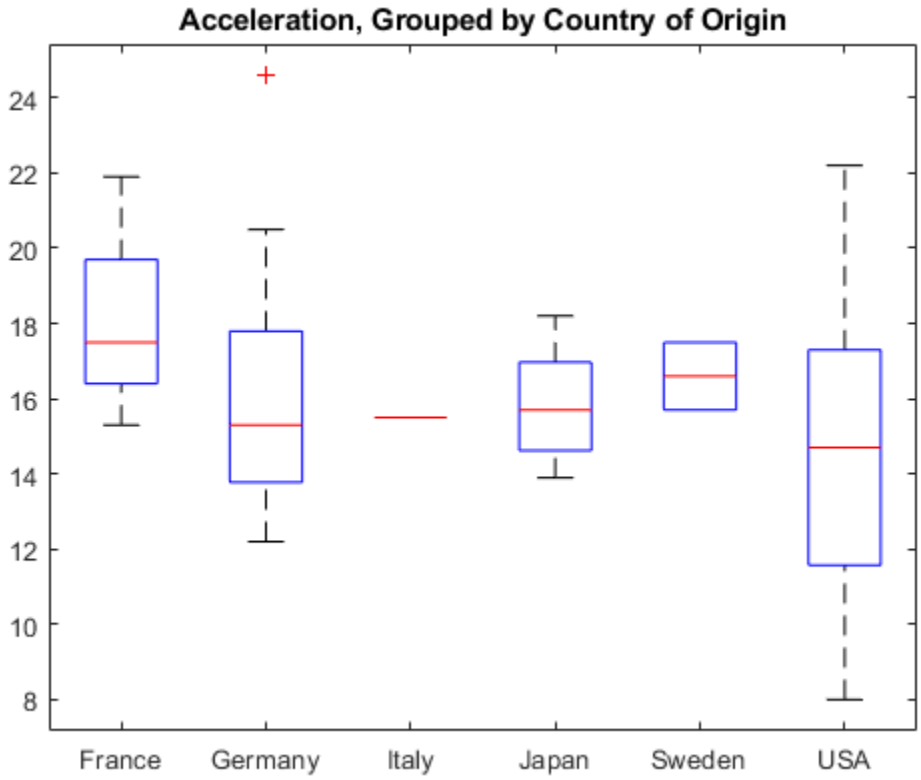
```
ans = 1x6 nominal
     France      Germany      Italy      Japan      Sweden      USA
```

There are six unique countries of origin in the sample. By default, `nominal` orders the countries in ascending alphabetical order.

Plot data grouped by category.

Draw box plots for `Acceleration`, grouped by `Origin`.

```
figure
boxplot(Acceleration,Origin)
title('Acceleration, Grouped by Country of Origin')
```



The box plots appear in the same order as the categorical levels (use `reorderlevels` to change the order of the categories).

Few observations have Italy as the country of origin.

Tabulate category counts.

Tabulate the number of sample cars from each country.

```
tabulate(Origin)
```

```
    Value    Count   Percent
   France        4      4.00%
  Germany        9      9.00%
    Italy        1      1.00%
    Japan       15     15.00%
   Sweden        2      2.00%
      USA       69     69.00%
```

Only one car is made in Italy.

Drop a category.

Delete the Italian car from the sample.

```
Acceleration2 = Acceleration(Origin~='Italy');
Origin2 = Origin(Origin~='Italy');
getlevels(Origin2)
```

```
ans = 1x6 nominal
     France      Germany      Italy      Japan      Sweden      USA
```

Even though the car from Italy is no longer in the sample, the nominal variable, `Origin2`, still has the category `Italy`. Note that this is intentional—the levels of a categorical array do not necessarily coincide with the values.

Drop a category level.

Use `droplevels` to remove the `Italy` category.

```
Origin2 = droplevels(Origin2,'Italy');
tabulate(Origin2)
```

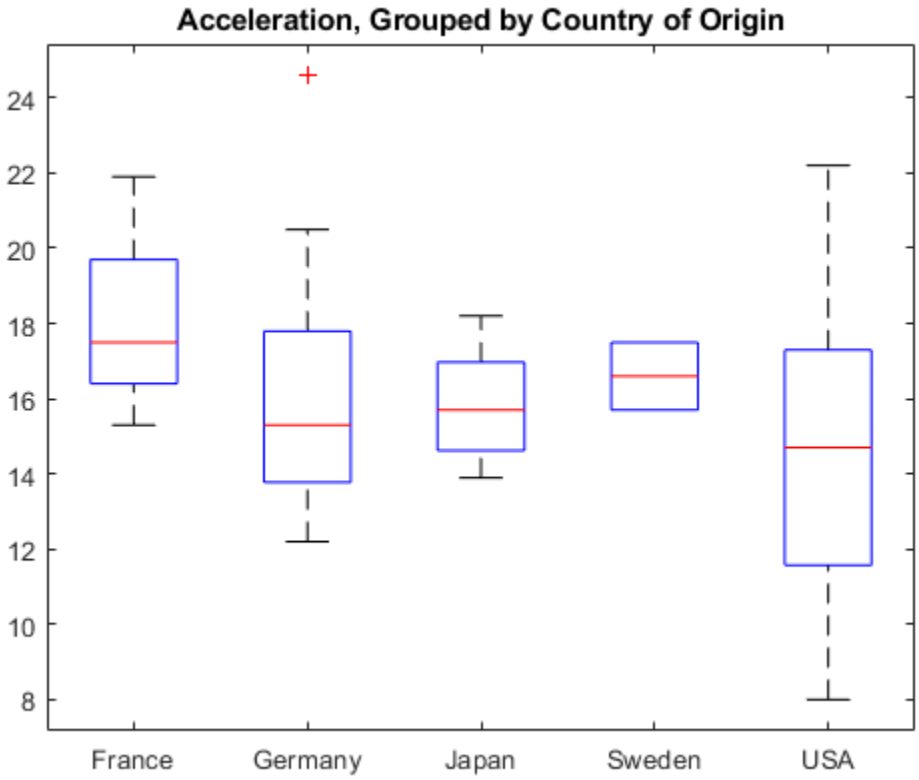
```
    Value    Count   Percent
   France        4      4.04%
  Germany        9      9.09%
    Japan       15     15.15%
   Sweden        2      2.02%
      USA       69     69.70%
```

The `Italy` category is no longer in the nominal array, `Origin2`.

Plot data grouped by category.

Draw box plots of `Acceleration2`, grouped by `Origin2`.

```
figure
boxplot(Acceleration2,Origin2)
title('Acceleration, Grouped by Country of Origin')
```



The plot no longer includes the car from Italy.

Test Differences Between Category Means

This example shows how to test for significant differences between category (group) means using a *t*-test, two-way ANOVA (analysis of variance), and ANOCOVA (analysis of covariance) analysis.

The goal is determining if the expected miles per gallon for a car depends on the decade in which it was manufactured, or the location where it was manufactured.

Note The `nominal` and `ordinal` array data types are not recommended. To represent ordered and unordered discrete, nonnumeric data, use the “Categorical Arrays” data type instead.

Load sample data.

```
load('carsmall')
unique(Model_Year)
```

```
ans =

    70
    76
    82
```

The variable `MPG` has miles per gallon measurements on a sample of 100 cars. The variables `Model_Year` and `Origin` contain the model year and country of origin for each car.

The first factor of interest is the decade of manufacture. There are three manufacturing years in the data.

Create a factor for the decade of manufacture.

Create an ordinal array named `Decade` by merging the observations from years `70` and `76` into a category labeled `1970s`, and putting the observations from `82` into a category labeled `1980s`.

```
Decade = ordinal(Model_Year,{'1970s','1980s'},[],[70 77 82]);
getlevels(Decade)
```

```
ans =

     1970s      1980s
```

Plot data grouped by category.

Draw a box plot of miles per gallon, grouped by the decade of manufacture.

```
figure()
boxplot(MPG,Decade)
title('Miles per Gallon, Grouped by Decade of Manufacture')
```

The box plot suggests that miles per gallon is higher in cars manufactured during the 1980s compared to the 1970s.

Compute summary statistics.

Compute the mean and variance of miles per gallon for each decade.

```
[xbar,s2,grp] = grpstats(MPG,Decade,{'mean','var','gname'})
```

```
xbar =

   19.7857
   31.7097

s2 =

   35.1429
   29.0796

grp =

    '1970s'
    '1980s'
```

This output shows that the mean miles per gallon in the 1980s was `31.71`, compared to `19.79` in the 1970s. The variances in the two groups are similar.

Conduct a two-sample t-test for equal group means.

Conduct a two-sample *t*-test, assuming equal variances, to test for a significant difference between the group means. The hypothesis is

$H_0: \mu_{70} = \mu_{80}$

$H_A: \mu_{70} \neq \mu_{80}$.

```
MPG70 = MPG(Decade=='1970s');
MPG80 = MPG(Decade=='1980s');
[h,p] = ttest2(MPG70,MPG80)
```

```
h =

     1

p =

   3.4809e-15
```

The logical value 1 indicates the null hypothesis is rejected at the default 0.05 significance level. The p-value for the test is very small. There is sufficient evidence that the mean miles per gallon in the 1980s differs from the mean miles per gallon in the 1970s.

Create a factor for the location of manufacture.

The second factor of interest is the location of manufacture. First, convert `Origin` to a nominal array.

```
Location = nominal(Origin);
tabulate(Location)
```

```
tabulate(Location)
    Value    Count   Percent
   France        4      4.00%
  Germany        9      9.00%
    Italy        1      1.00%
    Japan       15     15.00%
   Sweden        2      2.00%
      USA       69     69.00%
```

There are six different countries of manufacture. The European countries have relatively few observations.

Merge categories.

Combine the categories `France`, `Germany`, `Italy`, and `Sweden` into a new category named `Europe`.

```
Location = mergelevels(Location, ...
    {'France','Germany','Italy','Sweden'},'Europe');
tabulate(Location)
```

```
   Value    Count   Percent
   Japan       15     15.00%
     USA       69     69.00%
  Europe       16     16.00%
```

Compute summary statistics.

Compute the mean miles per gallon, grouped by the location of manufacture.

```
[xbar,grp] = grpstats(MPG,Location,{'mean','gname'})
```

```
xbar =

   31.8000
   21.1328
   26.6667

grp =

    'Japan'
    'USA'
    'Europe'
```

This result shows that average miles per gallon is lowest for the sample of cars manufactured in the U.S.

Conduct two-way ANOVA.

Conduct a two-way ANOVA to test for differences in expected miles per gallon between factor levels for `Decade` and `Location`.

The statistical model is

$$MPG_{ij} = \mu + \alpha_i + \beta_j + \varepsilon_{ij}, \quad i = 1, 2; j = 1, 2, 3,$$

where MPG_{ij} is the response, miles per gallon, for cars made in decade i at location j. The treatment effects for the first factor, decade of manufacture, are the α_i terms (constrained to sum to zero). The treatment effects for the second factor, location of manufacture, are the β_j terms (constrained to sum to zero). The ε_{ij} are uncorrelated, normally distributed noise terms.

The hypotheses to test are equality of decade effects,

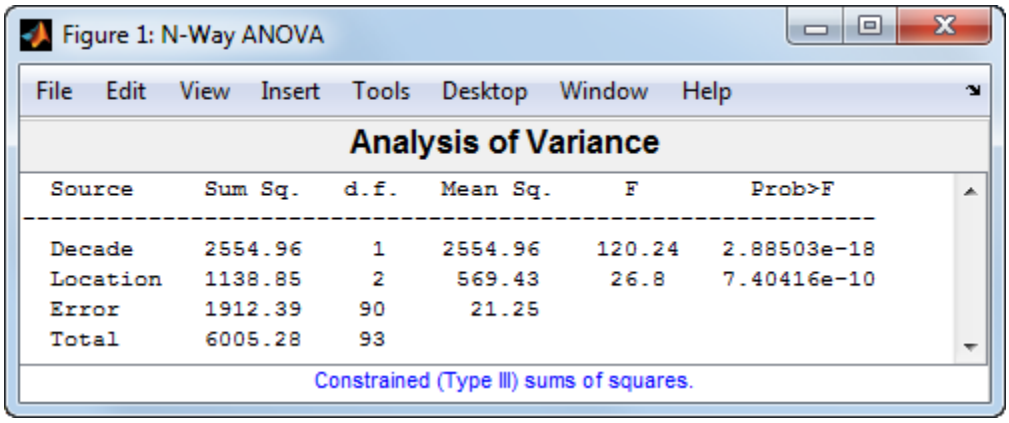
$$H_0: \alpha_1 = \alpha_2 = 0$$
$$H_A: at\ least\ one\ \alpha_i \neq 0,$$

and equality of location effects,

$$H_0: \beta_1 = \beta_2 = \beta_3 = 0$$
$$H_A: at\ least\ one\ \beta_j \neq 0.$$

You can conduct a multiple-factor ANOVA using `anovan`.

```
anovan(MPG,{Decade,Location},'varnames',{'Decade','Location'});
```



This output shows the results of the two-way ANOVA. The p-value for testing the equality of decade effects is `2.88503e-18`, so the null hypothesis is rejected at the 0.05 significance level. The p-value for testing the equality of location effects is `7.40416e-10`, so this null hypothesis is also rejected.

Conduct ANOCOVA analysis.

A potential confounder in this analysis is car weight. Cars with greater weight are expected to have lower gas mileage. Include the variable `Weight` as a continuous covariate in the ANOVA; that is, conduct an ANOCOVA analysis.

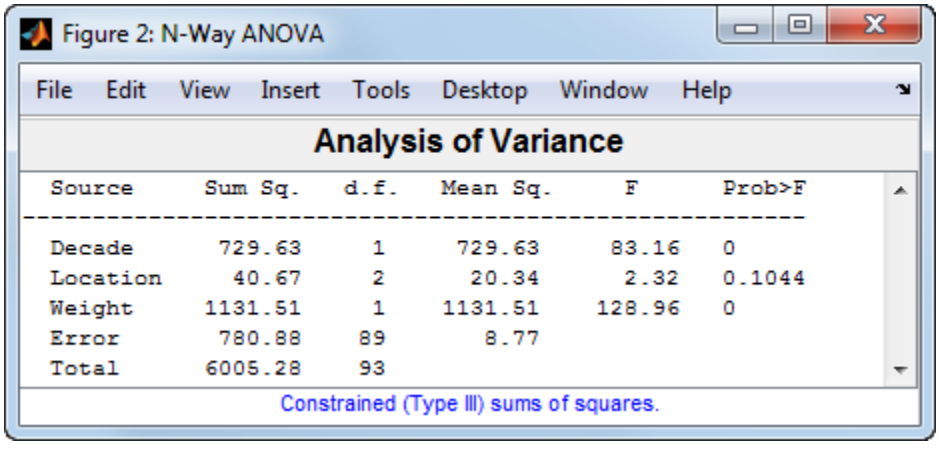
Assuming parallel lines, the statistical model is

$$MPG_{ijk} = \mu + \alpha_i + \beta_j + \gamma Weight_{ijk} + \varepsilon_{ijk}, \quad i = 1, 2; \;\; j = 1, 2, 3; \;\; k = 1, \ldots, 100.$$

The difference between this model and the two-way ANOVA model is the inclusion of the continuous predictor, $Weight_{ijk}$, the weight for the kth car, which was made in the ith decade and in the jth location. The slope parameter is γ.

Add the continuous covariate as a third group in the second `anovan` input argument. Use the name-value pair argument `Continuous` to specify that `Weight` (the third group) is continuous.

```
anovan(MPG,{Decade,Location,Weight},'Continuous',3,...
       'varnames',{'Decade','Location','Weight'});
```



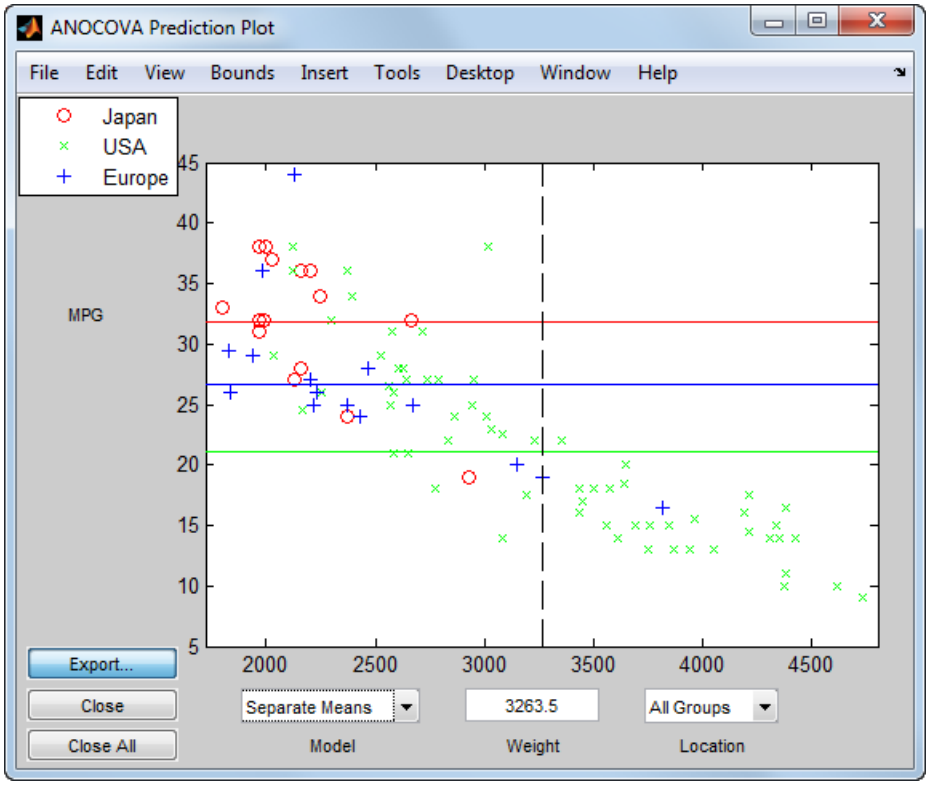
This output shows that when car weight is considered, there is insufficient evidence of a manufacturing location effect (p-value = `0.1044`).

Use interactive tool.

You can use the interactive `aoctool` to explore this result.

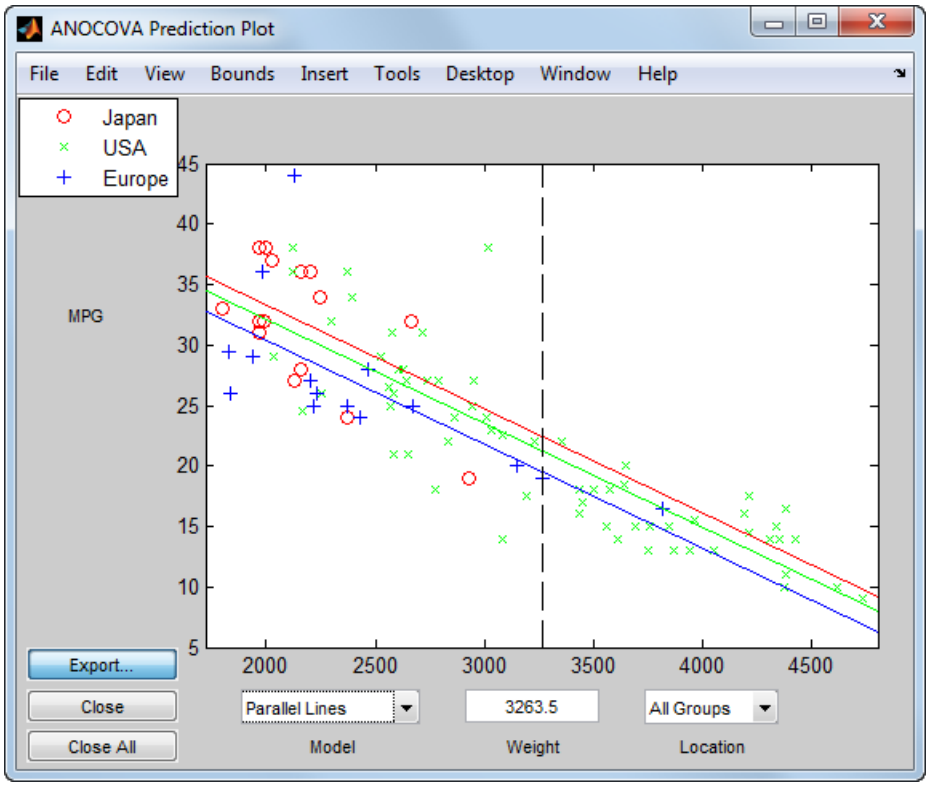
```
aoctool(Weight,MPG,Location);
```

This command opens three dialog boxes. In the ANOCOVA Prediction Plot dialog box, select the **Separate Means** model.



This output shows that when you do not include `Weight` in the model, there are fairly large differences in the expected miles per gallon among the three manufacturing locations. Note that here the model does not adjust for the decade of manufacturing.

Now, select the **Parallel Lines** model.



When you include `Weight` in the model, the difference in expected miles per gallon among the three manufacturing locations is much smaller.

Summary Statistics Grouped by Category

Note The `nominal` and `ordinal` array data types are not recommended. To represent ordered and unordered discrete, nonnumeric data, use the “Categorical Arrays” data type instead.

Summary Statistics Grouped by Category

This example shows how to compute summary statistics grouped by levels of a categorical variable. You can compute group summary statistics for a numeric array or a dataset array using `grpstats`.

Load sample data.

```
load hospital
```

The dataset array, `hospital`, has 7 variables (columns) and 100 observations (rows).

Compute summary statistics by category.

The variable `Sex` is a nominal array with two levels, `Male` and `Female`. Compute the minimum and maximum weights for each gender.

```
stats = grpstats(hospital,'Sex',{'min','max'},'DataVars','Weight')
```

```
stats =
              Sex       GroupCount    min_Weight    max_Weight
    Female    Female    53            111           147
    Male      Male      47            158           202
```

The dataset array, `stats`, has observations corresponding to the levels of the variable `Sex`. The variable `min_Weight` contains the minimum weight for each group, and the variable `max_Weight` contains the maximum weight for each group.

Compute summary statistics by multiple categories.

The variable `Smoker` is a logical array with value `1` for smokers and value `0` for nonsmokers. Compute the minimum and maximum weights for each gender and smoking combination.

```
stats = grpstats(hospital,{'Sex','Smoker'},{'min','max'},...
                 'DataVars','Weight')
```

```
stats =
                Sex       Smoker    GroupCount    min_Weight    max_Weight
    Female_0    Female    false     40            111           147
    Female_1    Female    true      13            115           146
    Male_0      Male      false     26            158           194
    Male_1      Male      true      21            164           202
```

The dataset array, `stats`, has an observation row for each combination of levels of `Sex` and `Smoker` in the original data.

Sort Ordinal Arrays

Note The `nominal` and `ordinal` array data types are not recommended. To represent ordered and unordered discrete, nonnumeric data, use the “Categorical Arrays” data type instead.

Sort Ordinal Arrays

This example shows how to determine sorting order for ordinal arrays.

Load sample data.

```
AllSizes = {'medium','large','small','small','medium',...
            'large','medium','small'};
```

The created variable, `AllSizes`, is a cell array of character vectors containing size measurements on eight objects.

Create an ordinal array.

Convert `AllSizes` to an ordinal array with levels `small` < `medium` < `large`.

```
AllSizes = ordinal(AllSizes,{},{'small','medium','large'});
getlevels(AllSizes)
```

```
ans = 1x3 ordinal
     small      medium      large
```

Sort the ordinal array.

When you sort ordinal arrays, the sorted observations are in the same order as the category levels.

```
sizeSort = sort(AllSizes);
sizeSort(:)
```

```
ans = 8x1 ordinal
     small
     small
     small
     medium
     medium
     medium
     large
     large
```

The sorted ordinal array, `sizeSort`, contains the observations ordered from small to large.

Nominal and Ordinal Arrays

Note The `nominal` and `ordinal` array data types are not recommended. To represent ordered and unordered discrete, nonnumeric data, use the “Categorical Arrays” data type instead.

In this section...

What Are Nominal and Ordinal Arrays?

Nominal and ordinal arrays are Statistics and Machine Learning Toolbox data types for storing categorical values. Nominal and ordinal arrays store data that have a finite set of discrete levels, which might or might not have a natural order.

- `ordinal` arrays store categorical values with ordered levels. For example, an ordinal variable might have levels {small, medium, large}.
- `nominal` arrays store categorical values with unordered levels. For example, a nominal variable might have levels {red, blue, green}.

In experimental design, these variables are often called factors, with ordered or unordered factor levels.

Nominal and ordinal arrays are convenient and memory efficient containers for storing categorical variables. In addition to storing information about which category each observation belongs to, nominal and ordinal arrays store descriptive metadata including category labels and order.

Nominal and ordinal arrays have associated methods that streamline common tasks such as merging categories, adding or dropping levels, and changing level labels.

Nominal and Ordinal Array Conversion

You can easily convert to and from nominal or ordinal arrays. To create a nominal or ordinal array, use `nominal` or `ordinal`, respectively. You can convert these data types to nominal or ordinal arrays:

- Numeric arrays
- Logical arrays
- Character arrays
- String arrays
- Cell arrays of character vectors

Advantages of Using Nominal and Ordinal Arrays

Note The `nominal` and `ordinal` array data types are not recommended. To represent ordered and unordered discrete, nonnumeric data, use the “Categorical Arrays” data type instead.

In this section...

Manipulate Category Levels

When working with categorical variables and their levels, you’ll encounter some typical challenges. This table summarizes the functions you can use with nominal or ordinal arrays to manipulate category levels. For additional functions, type `methods nominal` or `methods ordinal` at the command line, or see the `nominal` and `ordinal` reference pages.

Task	Function
Add new category levels	`addlevels`
Drop category levels	`droplevels`
Combine category levels	`mergelevels`
Reorder category levels	`reorderlevels`
Count the number of observations in each category	`levelcounts`
Change the label or name of category levels	`setlabels`
Create an interaction factor	`times`
Find observations that are not in a defined category	`isundefined`

Analysis Using Nominal and Ordinal Arrays

You can use nominal and ordinal arrays in a variety of statistical analyses. For example, you might want to compute descriptive statistics for data grouped by the category levels, conduct statistical tests on differences between category means, or perform regression analysis using categorical predictors.

Statistics and Machine Learning Toolbox functions that accept a grouping variable as an input argument accept nominal and ordinal arrays. This includes descriptive functions such as:

- `grpstats`
- `gscatter`
- `boxplot`
- `gplotmatrix`

You can also use nominal and ordinal arrays as input arguments to analysis functions and methods based on models, such as:

- `anovan`
- `fitlm`
- `fitglm`

When you use a nominal or ordinal array as a predictor in these functions, the fitting function automatically recognizes the categorical predictor, and constructs appropriate dummy indicator variables for analysis. Alternatively, you can construct your own dummy indicator variables using `dummyvar`.

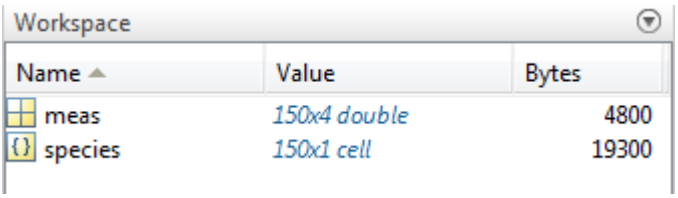
Reduce Memory Requirements

The levels of categorical variables are often defined as text, which can be costly to store and manipulate in a cell array of character vectors or `char` array. Nominal and ordinal arrays separately store category membership and category labels, greatly reducing the amount of memory required to store the variable.

For example, load some sample data:

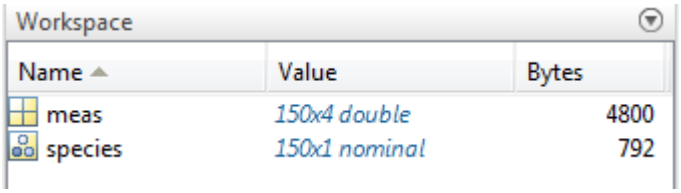
```
load('fisheriris')
```

The variable `species` is a cell array of character vectors requiring 19,300 bytes of memory.



Convert `species` to a nominal array:

```
species = nominal(species);
```



There is a 95% reduction in memory required to store the variable.

Index and Search Using Nominal and Ordinal Arrays

Note The `nominal` and `ordinal` array data types are not recommended. To represent ordered and unordered discrete, nonnumeric data, use the “Categorical Arrays” data type instead.

Index By Category

It is often useful to index and search data by its category, or group. If you store categories as labels inside a cell array of character vectors or `char` array, it can be difficult to index and search the categories. When using nominal or ordinal arrays, you can easily:

- **Index elements from particular categories.** For both nominal and ordinal arrays, you can use the logical operators == and ~= to index the observations that are in, or not in, a particular category. For ordinal arrays, which have an encoded order, you can also use inequalities, >, >=, <, and <=, to find observations in categories above or below a particular category.
- **Search for members of a category.** In addition to the logical operator ==, you can use `ismember` to find observations in a particular group.
- **Find elements that are not in a defined category.** Nominal and ordinal arrays indicate which elements do not belong to a defined category by <undefined>. You can use `isundefined` to find observations missing a category.
- **Delete observations that are in a particular category.** You can use logical operators to include or exclude observations from particular categories. Even if you remove all observations from a category, the category level remains defined unless you remove it using `droplevels`.

Common Indexing and Searching Methods

This example shows several common indexing and searching methods.

Load the sample data.

```
load carsmall;
```

Convert the `char` array, `Origin`, to a nominal array. This variable contains the country of origin, or manufacture, for each sample car.

```
Origin = nominal(Origin);
```

Search for observations in a category. Determine if there are any cars in the sample that were manufactured in Canada.

```
any(Origin=='Canada')
```

```
ans = logical
   0
```

There are no sample cars manufactured in Canada.

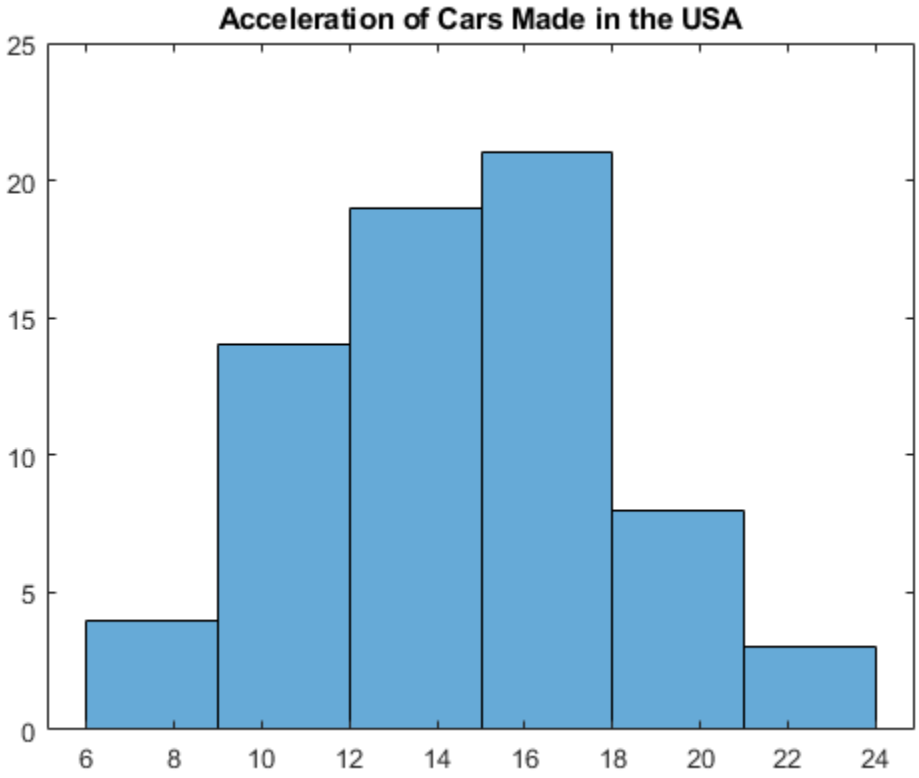
List the countries that are levels of `Origin`.

```
getlevels(Origin)
```

```
ans = 1x6 nominal
     France       Germany       Italy       Japan       Sweden       USA
```

Index elements that are in a particular category. Plot a histogram of the acceleration measurements for cars made in the U.S.

```
figure();
histogram(Acceleration(Origin=='USA'))
title('Acceleration of Cars Made in the USA')
```



Delete observations that are in a particular category. Delete all cars made in Sweden from `Origin`.

```
Origin = Origin(Origin~='Sweden');
any(ismember(Origin,'Sweden'))
```

```
ans = logical
   0
```

The cars made in Sweden are deleted from `Origin`, but `Sweden` is still a level of `Origin`.

```
getlevels(Origin)
```

```
ans = 1x6 nominal
     France       Germany       Italy       Japan       Sweden       USA
```

Remove `Sweden` from the levels of `Origin`.

```
Origin = droplevels(Origin,'Sweden');
getlevels(Origin)
```

```
ans = 1x5 nominal
     France      Germany      Italy      Japan      USA
```

Check for observations not in a defined category. Get the indices for the cars made in France.

```
ix = find(Origin=='France')
```

```
ix = 4×1

    11
    27
    39
    61
```

There are four cars from France. Remove `France` from the levels of `Origin`.

```
Origin = droplevels(Origin,'France');
```

This returns a warning indicating that you are dropping a category level that has elements in it. These observations are no longer in a defined category, indicated by `undefined`.

```
Origin(ix)
```

```
ans = 4x1 nominal
     <undefined>
     <undefined>
     <undefined>
     <undefined>
```

You can use `isundefined` to search for observations with an undefined category.

```
find(isundefined(Origin))
```

```
ans = 4×1

    11
    27
    39
    61
```

These indices correspond to the observations that were in category `France`, before that category was dropped from `Origin`.

Grouping Variables

In this section...

What Are Grouping Variables?

Grouping variables are utility variables used to group, or categorize, observations. Grouping variables are useful for summarizing or visualizing data by group. A grouping variable can be any of these data types:

- Numeric vector
- Logical vector
- Character array
- String array
- Cell array of character vectors
- Categorical vector

A grouping variable must have the same number of observations (rows) as the table, dataset array, or numeric array you are grouping. Observations that have the same grouping variable value belong to the same group.

For example, the following variables comprise the same groups. Each grouping variable divides five observations into two groups. The first group contains the first and fourth observations. The other three observations are in the second group.

Data Type	Grouping Variable
Numeric vector	`[1 2 2 1 2]`
Logical vector	`[0 1 1 0 1]`
String array	`["Male","Female","Female","Male","Female"]`
Cell array of character vectors	`{'Male','Female','Female','Male','Female'}`
Categorical vector	`Male Female Female Male Female`

Use grouping variables with labels to give each group a meaningful name. A categorical vector is an efficient and flexible choice of grouping variable.

Group Definition

Typically, there are as many groups as unique values in the grouping variable. However, categorical vectors can have levels that are not represented in the data. The groups and the order of the groups depend on the data type of the grouping variable. Suppose `G` is a grouping variable.

- If `G` is a numeric or logical vector, then the groups correspond to the distinct values in `G`, in the sorted order of the unique values.

- If `G` is a character array, string array, or cell array of character vectors, then the groups correspond to the distinct elements in `G`, in the order of their first appearance.
- If `G` is a categorical vector, then the groups correspond to the unique category levels in `G`, in the order returned by `categories`.

Some functions, such as `grpstats`, accept multiple grouping variables specified as a cell array of grouping variables, for example, `{G1,G2,G3}`. In this case, the groups are defined by the unique combinations of values in the grouping variables. The order is decided first by the order of the first grouping variable, then by the order of the second grouping variable, and so on.

Analysis Using Grouping Variables

This table lists common tasks you might want to perform using grouping variables.

Grouping Task	Function Accepting Grouping Variable
Draw side-by-side box plots for data in different groups.	`boxplot`
Draw a scatter plot with markers colored by group.	`gscatter`
Draw a scatter plot matrix with markers colored by group.	`gplotmatrix`
Compute summary statistics by group.	`grpstats`
Test for differences between group means.	`anovan`
Create an index vector from a grouping variable.	`grp2idx`

Missing Group Values

Grouping variables can have missing values provided you include a valid indicator.

Grouping Variable Data Type	Missing Value Indicator
Numeric vector	`NaN`
Logical vector	(Cannot be missing)
Character array	Row of spaces
String array	`<missing>` or `""`
Cell array of character vectors	`''`
Categorical vector	`<undefined>`

Dummy Variables

In this section...

This topic provides an introduction to dummy variables, describes how the software creates them for classification and regression problems, and shows how you can create dummy variables by using the `dummyvar` function.

What Are Dummy Variables?

When you perform classification and regression analysis, you often need to include both continuous (quantitative) and categorical (qualitative) predictor variables. A categorical variable must not be included as a numeric array. Numeric arrays have both order and magnitude. A categorical variable can have order (for example, an ordinal variable), but it does not have magnitude. Using a numeric array implies a known “distance” between the categories. The appropriate way to include categorical predictors is as dummy variables. To define dummy variables, use indicator variables that have the values 0 and 1.

The software chooses one of four schemes to define dummy variables based on the type of analysis, as described in the next sections. For example, suppose you have a categorical variable with three categories: `Cool`, `Cooler`, and `Coolest`.

Full Dummy Variables

Represent the categorical variable with three categories using three dummy variables, one variable for each category.

	X_0	X_1	X_2
Cool	1	0	0
Cooler	0	1	0
Coolest	0	0	1

X_0 is a dummy variable that has the value 1 for `Cool`, and 0 otherwise. X_1 is a dummy variable that has the value 1 for `Cooler`, and 0 otherwise. X_2 is a dummy variable that has the value 1 for `Coolest`, and 0 otherwise.

Dummy Variables with Reference Group

Represent the categorical variable with three categories using two dummy variables with a reference group.

	X_1	X_2
Cool	0	0 ← Reference Group
Cooler	1	0
Coolest	0	1

You can distinguish `Cool`, `Cooler`, and `Coolest` using only X_1 and X_2, without X_0. Observations for `Cool` have 0s for both dummy variables. The category represented by all 0s is the reference group.

Dummy Variables for Ordered Categorical Variable

Assume the mathematical ordering of the categories is `Cool` < `Cooler` < `Coolest`. This coding scheme uses 1 and –1 values, and uses more 1s for higher categories, to indicate the ordering.

	X_1	X_2
Cool	-1	-1
Cooler	1	-1
Coolest	1	1

X_1 is a dummy variable that has the value 1 for `Cooler` and `Coolest`, and –1 for `Cool`. X_2 is a dummy variable that has the value 1 for `Coolest`, and –1 otherwise.

You can indicate that a categorical variable has mathematical ordering by using the `'Ordinal'` name-value pair argument of the `categorical` function.

Dummy Variables Created with Effects Coding

Effects coding uses 1, 0, and –1 to create dummy variables. Instead of using 0 values to represent a reference group, as in “Dummy Variables with Reference Group” on page 2-48, effects coding uses –1 to represent the last category.

	X_1	X_2
Cool	1	0
Cooler	0	1
Coolest	-1	-1

Creating Dummy Variables

Automatic Creation of Dummy Variables

Statistics and Machine Learning Toolbox offers several classification and regression fitting functions that accept categorical predictors. Some fitting functions create dummy variables to handle categorical predictors.

The following is the default behavior of the fitting functions in identifying categorical predictors.

- If the predictor data is in a table, the functions assume that a variable is categorical if it is a logical vector, categorical vector, character array, string array, or cell array of character vectors. The fitting functions that use decision trees assume ordered categorical vectors to be continuous variables.
- If the predictor data is a matrix, the functions assume all predictors are continuous.

To identify any other predictors as categorical predictors, specify them by using the `'CategoricalPredictors'` or `'CategoricalVars'` name-value pair argument.

The fitting functions handle the identified categorical predictors as follows:

- `fitckernel`, `fitclinear`, `fitcnet`, `fitcsvm`, `fitrgp`, `fitrkernel`, `fitrlinear`, `fitrnet`, and `fitrsvm` use two different schemes to create dummy variables, depending on whether a categorical variable is unordered or ordered.
  - For an unordered categorical variable, the functions use “Full Dummy Variables” on page 2-48.
  - For an ordered categorical variable, the functions use “Dummy Variables for Ordered Categorical Variable” on page 2-49.
- Parametric regression fitting functions such as `fitlm`, `fitglm`, and `fitcox` use “Dummy Variables with Reference Group” on page 2-48. When the functions include the dummy variables, the estimated coefficients of the dummy variables are relative to the reference group. For an example, see “Linear Regression with Categorical Predictor” on page 33-1984.
- `fitlme`, `fitlmematrix` and `fitglme` allow you to specify the scheme for creating dummy variables by using the `'DummyVarCoding'` name-value pair argument. The functions support three schemes: “Full Dummy Variables” on page 2-48 (`'DummyVarCoding','full'`), “Dummy Variables with Reference Group” on page 2-48 (`'DummyVarCoding','reference'`), and “Dummy Variables Created with Effects Coding” on page 2-49 (`'DummyVarCoding','effects'`). Note that these functions do not offer a name-value pair argument for specifying categorical variables.
- `fitrm` uses “Dummy Variables Created with Effects Coding” on page 2-49.
- Other fitting functions that accept categorical predictors use algorithms that can handle categorical predictors without creating dummy variables.

Manual Creation of Dummy Variables

This example shows how to create your own dummy variable design matrix by using the `dummyvar` function. This function accepts grouping variables and returns a matrix containing zeros and ones, whose columns are dummy variables for the grouping variables.

Create a column vector of categorical data specifying gender.

```
gender = categorical({'Male';'Female';'Female';'Male';'Female'});
```

Create dummy variables for `gender`.

```
dv = dummyvar(gender)
```

```
dv = 5×2

     0     1
     1     0
     1     0
     0     1
     1     0
```

`dv` has five rows corresponding to the number of rows in `gender` and two columns for the unique groups, `Female` and `Male`. Column order corresponds to the order of the levels in `gender`. For categorical arrays, the default order is ascending alphabetical. You can check the order by using the `categories` function.

```
categories(gender)
```

```
ans = 2x1 cell
    {'Female'}
```

```
    {'Male'  }
```

To use the dummy variables in a regression model, you must either delete a column (to create a reference group) or fit a regression model with no intercept term. For the gender example, you need only one dummy variable to represent two genders. Notice what happens if you add an intercept term to the complete design matrix `dv`.

```
X = [ones(5,1) dv]
```

```
X = 5×3

     1     0     1
     1     1     0
     1     1     0
     1     0     1
     1     1     0
```

```
rank(X)
```

```
ans = 2
```

The design matrix with an intercept term is not of full rank and is not invertible. Because of this linear dependence, use only c – 1 indicator variables to represent a categorical variable with c categories in a regression model with an intercept term.

See Also

`categorical` | `dummyvar`

Related Examples

- “Test Differences Between Category Means” on page 2-25

Linear Regression with Categorical Covariates

This example shows how to perform a regression with categorical covariates using categorical arrays and `fitlm`.

Load sample data.

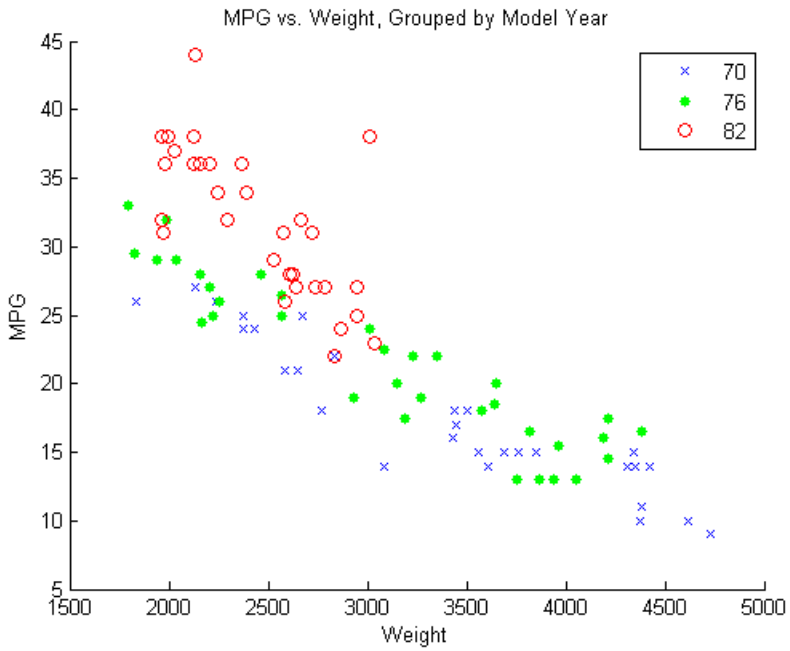
```
load carsmall
```

The variable `MPG` contains measurements on the miles per gallon of 100 sample cars. The model year of each car is in the variable `Model_Year`, and `Weight` contains the weight of each car.

Plot grouped data.

Draw a scatter plot of `MPG` against `Weight`, grouped by model year.

```
figure()
gscatter(Weight,MPG,Model_Year,'bgr','x.o')
title('MPG vs. Weight, Grouped by Model Year')
```



The grouping variable, `Model_Year`, has three unique values, `70`, `76`, and `82`, corresponding to model years 1970, 1976, and 1982.

Create table and categorical array.

Create a table that contains the variables `MPG`, `Weight`, and `Model_Year`. Convert the variable `Model_Year` to a categorical array.

```
cars = table(MPG,Weight,Model_Year);
cars.Model_Year = categorical(cars.Model_Year);
```

Fit a regression model.

Fit a regression model using `fitlm` with `MPG` as the dependent variable, and `Weight` and `Model_Year` as the independent variables. Because `Model_Year` is a categorical covariate with three levels, it should enter the model as two indicator variables.

The scatter plot suggests that the slope of `MPG` against `Weight` might differ for each model year. To assess this, include weight-year interaction terms.

The proposed model is

$$E(MPG) = \beta_0 + \beta_1 Weight + \beta_2 I[1976] + \beta_3 I[1982] + \beta_4 Weight \times I[1976] + \beta_5 Weight \times I[1982],$$

where $I[1976]$ and $I[1982]$ are dummy variables indicating the model years 1976 and 1982, respectively. $I[1976]$ takes the value 1 if model year is 1976 and takes the value 0 if it is not. $I[1982]$ takes the value 1 if model year is 1982 and takes the value 0 if it is not. In this model, 1970 is the reference year.

```
fit = fitlm(cars,'MPG~Weight*Model_Year')
```

```
fit =

Linear regression model:
    MPG ~ 1 + Weight*Model_Year

Estimated Coefficients:
                            Estimate          SE
                           ___________    __________

    (Intercept)                37.399        2.1466
    Weight                  -0.0058437    0.00061765
    Model_Year_76              4.6903        2.8538
    Model_Year_82              21.051         4.157
    Weight:Model_Year_76    -0.00082009    0.00085468
    Weight:Model_Year_82     -0.0050551     0.0015636

                            tStat        pValue
                           ________    __________

    (Intercept)              17.423    2.8607e-30
    Weight                  -9.4612    4.6077e-15
    Model_Year_76            1.6435       0.10384
    Model_Year_82            5.0641    2.2364e-06
    Weight:Model_Year_76    -0.95953       0.33992
    Weight:Model_Year_82     -3.2329     0.0017256

Number of observations: 94, Error degrees of freedom: 88
Root Mean Squared Error: 2.79
R-squared: 0.886,  Adjusted R-Squared: 0.88
F-statistic vs. constant model: 137, p-value = 5.79e-40
```

The regression output shows:

- `fitlm` recognizes `Model_Year` as a categorical variable, and constructs the required indicator (dummy) variables. By default, the first level, `70`, is the reference group (use `reordercats` to change the reference group).
- The model specification, `MPG~Weight*Model_Year`, specifies the first-order terms for `Weight` and `Model_Year`, and all interactions.
- The model $R^2 = 0.886$, meaning the variation in miles per gallon is reduced by 88.6% when you consider weight, model year, and their interactions.
- The fitted model is

  $$\widehat{MPG} = 37.4 - 0.006Weight + 4.7I[1976] + 21.1I[1982] - 0.0008Weight \times I[1976] - 0.005Weight \times I[1982].$$

  Thus, the estimated regression equations for the model years are as follows.

Model Year	Predicted MPG Against Weight
1970	$\widehat{MPG} = 37.4 - 0.006Weight$
1976	$\widehat{MPG} = (37.4 + 4.7) - (0.006 + 0.0008)Weight$
1982	$\widehat{MPG} = (37.4 + 21.1) - (0.006 + 0.005)Weight$

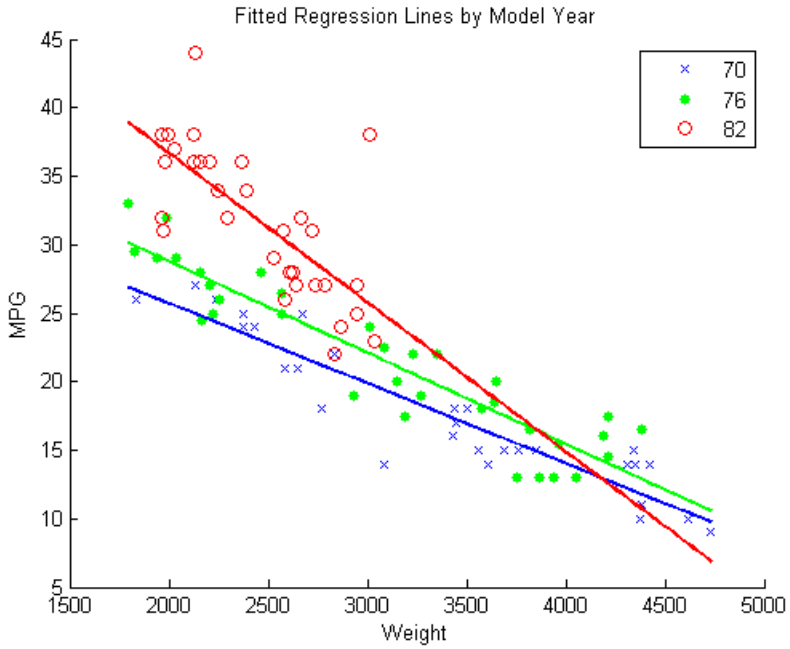
The relationship between `MPG` and `Weight` has an increasingly negative slope as the model year increases.

Plot fitted regression lines.

Plot the data and fitted regression lines.

```
w = linspace(min(Weight),max(Weight));

figure()
gscatter(Weight,MPG,Model_Year,'bgr','x.o')
line(w,feval(fit,w,'70'),'Color','b','LineWidth',2)
line(w,feval(fit,w,'76'),'Color','g','LineWidth',2)
line(w,feval(fit,w,'82'),'Color','r','LineWidth',2)
title('Fitted Regression Lines by Model Year')
```



Test for different slopes.

Test for significant differences between the slopes. This is equivalent to testing the hypothesis

$H_0: \beta_4 = \beta_5 = 0$

$H_A: \beta_i \neq 0$ for at least one i.

```
anova(fit)
```

```
ans =

                       SumSq     DF    MeanSq    F         pValue
    Weight             2050.2     1    2050.2    263.87    3.2055e-28
    Model_Year          807.69    2    403.84    51.976    1.2494e-15
    Weight:Model_Year   81.219    2    40.609    5.2266     0.0071637
    Error               683.74   88    7.7698
```

This output shows that the *p*-value for the test is `0.0072` (from the interaction row, `Weight:Model_Year`), so the null hypothesis is rejected at the 0.05 significance level. The value of the test statistic is `5.2266`. The numerator degrees of freedom for the test is `2`, which is the number of coefficients in the null hypothesis.

There is sufficient evidence that the slopes are not equal for all three model years.

Create a Dataset Array from Workspace Variables

Note The `dataset` data type is not recommended. To work with heterogeneous data, use the MATLAB `table` data type instead. See MATLAB `table` documentation for more information.

In this section...

Create a Dataset Array from a Numeric Array

This example shows how to create a dataset array from a numeric array existing in the MATLAB® workspace.

Load sample data.

```
load fisheriris
```

Two variables load into the workspace: `meas`, a 150-by-4 numeric array, and `species`, a 150-by-1 cell array of species labels.

Create a dataset array.

Use `mat2dataset` to convert the numeric array, `meas`, into a dataset array.

```
ds = mat2dataset(meas);
ds(1:10,:)
```

```
ans =
    meas1    meas2    meas3    meas4
    5.1      3.5      1.4      0.2
    4.9        3      1.4      0.2
    4.7      3.2      1.3      0.2
    4.6      3.1      1.5      0.2
      5      3.6      1.4      0.2
    5.4      3.9      1.7      0.4
    4.6      3.4      1.4      0.3
      5      3.4      1.5      0.2
    4.4      2.9      1.4      0.2
    4.9      3.1      1.5      0.1
```

The array, `meas`, has four columns, so the dataset array, `ds`, has four variables. The default variable names are the array name, `meas`, with column numbers appended.

You can specify your own variable or observation names using the name-value pair arguments `VarNames` and `ObsNames`, respectively.

If you use `dataset` to convert a numeric array to a dataset array, by default, the resulting dataset array has one variable that is an array instead of separate variables for each column.

Examine the dataset array.

Return the size of the dataset array, `ds`.

```
size(ds)
```

```
ans = 1×2

   150     4
```

The dataset array, `ds`, is the same size as the numeric array, `meas`. Variable names and observation names do not factor into the size of a dataset array.

Explore dataset array metadata.

Return the metadata properties of the dataset array, `ds`.

```
ds.Properties
```

```
ans = struct with fields:
       Description: ''
    VarDescription: {}
             Units: {}
          DimNames: {'Observations'  'Variables'}
          UserData: []
          ObsNames: {}
          VarNames: {'meas1'  'meas2'  'meas3'  'meas4'}
```

You can also access the properties individually. For example, you can retrieve the variable names using `ds.Properties.VarNames`.

Access data in a dataset array variable.

You can use variable names with dot indexing to access the data in a dataset array. For example, find the minimum value in the first variable, `meas1`.

```
min(ds.meas1)
```

```
ans = 4.3000
```

Change variable names.

The four variables in `ds` are actually measurements of sepal length, sepal width, petal length, and petal width. Modify the variable names to be more descriptive.

```
ds.Properties.VarNames = {'SLength','SWidth','PLength','PWidth'};
```

Add description.

you can add a description for the dataset array.

```
ds.Properties.Description = 'Fisher iris data';
ds.Properties
```

```
ans = struct with fields:
       Description: 'Fisher iris data'
    VarDescription: {}
```

```
           Units: {}
        DimNames: {'Observations'  'Variables'}
        UserData: []
        ObsNames: {}
        VarNames: {'SLength'  'SWidth'  'PLength'  'PWidth'}
```

The dataset array properties are updated with the new variable names and description.

Add a variable to the dataset array.

The variable `species` is a cell array of species labels. Add `species` to the dataset array, `ds`, as a nominal array named `Species`. Display the first five observations in the dataset array.

```
ds.Species = nominal(species);
ds(1:5,:)
```

```
ans =
    SLength    SWidth    PLength    PWidth    Species
    5.1        3.5       1.4        0.2       setosa
    4.9          3       1.4        0.2       setosa
    4.7        3.2       1.3        0.2       setosa
    4.6        3.1       1.5        0.2       setosa
      5        3.6       1.4        0.2       setosa
```

The dataset array, `ds`, now has the fifth variable, `Species`.

Create Dataset Array from Heterogeneous Workspace Variables

This example shows how to create a dataset array from heterogeneous variables existing in the MATLAB® workspace.

Load sample data.

```
load carsmall
```

Create a dataset array.

Create a dataset array from a subset of the workspace variables.

```
ds = dataset(Origin,Acceleration,Cylinders,MPG);
ds.Properties.VarNames(:)
```

```
ans = 4x1 cell
    {'Origin'      }
    {'Acceleration'}
    {'Cylinders'   }
    {'MPG'         }
```

When creating the dataset array, you do not need to enter variable names. `dataset` automatically uses the name of each workspace variable.

Notice that the dataset array, `ds`, contains a collection of variables with heterogeneous data types. `Origin` is a character array, and the other variables are numeric.

Examine a dataset array.

Display the first five observations in the dataset array.

```
ds(1:5,:)
```

```
ans =
    Origin     Acceleration    Cylinders    MPG
    USA          12            8            18
    USA        11.5            8            15
    USA          11            8            18
    USA          12            8            16
    USA        10.5            8            17
```

Apply a function to a dataset array.

Use `datasetfun` to return the data type of each variable in `ds`.

```
varclass = datasetfun(@class,ds,'UniformOutput',false);
varclass(:)
```

```
ans = 4x1 cell
    {'char'  }
    {'double'}
    {'double'}
    {'double'}
```

You can get additional information about the variables using `summary(ds)`.

Modify a dataset array.

`Cylinders` is a numeric variable that has values 4, 6, and 8 for the number of cylinders. Convert `Cylinders` to a nominal array with levels `four`, `six`, and `eight`.

Display the country of origin and number of cylinders for the first 15 cars.

```
ds.Cylinders = nominal(ds.Cylinders,{'four','six','eight'});
ds(1:15,{'Origin','Cylinders'})
```

```
ans =
    Origin     Cylinders
    USA        eight
    USA        eight
    USA        eight
    USA        eight
    USA        eight
    USA        eight
    USA        eight
    USA        eight
    USA        eight
    USA        eight
    France     four
    USA        eight
    USA        eight
    USA        eight
    USA        eight
```

The variable `Cylinders` has a new data type.

Create a Dataset Array from a File

Note The `dataset` data type is not recommended. To work with heterogeneous data, use the MATLAB `table` data type instead. See MATLAB `table` documentation for more information.

In this section...

Create a Dataset Array from a Tab-Delimited Text File

This example shows how to create a dataset array from the contents of a tab-delimited text file.

Create a dataset array using default settings.

Import the text file `hospitalSmall.txt` as a dataset array using the default settings.

```
ds = dataset('File',fullfile(matlabroot,'help/toolbox/stats/examples','hospitalSmall.txt'))
```

```
ds =

    name              sex        age    wgt    smoke
    'SMITH'           'm'        38     176    1
    'JOHNSON'         'm'        43     163    0
    'WILLIAMS'        'f'        38     131    0
    'JONES'           'f'        40     133    0
    'BROWN'           'f'        49     119    0
    'DAVIS'           'f'        46     142    0
    'MILLER'          'f'        33     142    1
    'WILSON'          'm'        40     180    0
    'MOORE'           'm'        28     183    0
    'TAYLOR'          'f'        31     132    0
    'ANDERSON'        'f'        45     128    0
    'THOMAS'          'f'        42     137    0
    'JACKSON'         'm'        25     174    0
    'WHITE'           'm'        39     202    1
```

By default, `dataset` uses the first row of the text file for variable names. If the first row does not contain variable names, you can specify the optional name-value pair argument `'ReadVarNames',false` to change the default behavior.

The dataset array contains heterogeneous variables. The variables `id`, `name`, and `sex` are cell arrays of character vectors, and the other variables are numeric.

Summarize the dataset array.

You can see the data type and other descriptive statistics for each variable by using `summary` to summarize the dataset array.

```
summary(ds)
```

```
name: [14x1 cell array of character vectors]

sex: [14x1 cell array of character vectors]

age: [14x1 double]

    min    1st quartile    median    3rd quartile    max
    25     33              39.5      43              49

wgt: [14x1 double]

    min    1st quartile    median    3rd quartile    max
    119    132             142       176             202

smoke: [14x1 double]

    min    1st quartile    median    3rd quartile    max
    0      0               0         0               1
```

Import observation names.

Import the text file again, this time specifying that the first column contains observation names.

```
ds = dataset('File',fullfile(matlabroot,'help/toolbox/stats/examples','hospitalSmall.txt'),'ReadO
```

```
ds =

                sex        age    wgt    smoke
    SMITH       'm'        38     176    1
    JOHNSON     'm'        43     163    0
    WILLIAMS    'f'        38     131    0
    JONES       'f'        40     133    0
    BROWN       'f'        49     119    0
    DAVIS       'f'        46     142    0
    MILLER      'f'        33     142    1
    WILSON      'm'        40     180    0
    MOORE       'm'        28     183    0
    TAYLOR      'f'        31     132    0
    ANDERSON    'f'        45     128    0
    THOMAS      'f'        42     137    0
    JACKSON     'm'        25     174    0
    WHITE       'm'        39     202    1
```

The elements of the first column in the text file, last names, are now observation names. Observation names and row names are dataset array properties. You can always add or change the observation names of an existing dataset array by modifying the property `ObsNames`.

Change dataset array properties.

By default, the `DimNames` property of the dataset array has `name` as the descriptor of the observation (row) dimension. `dataset` got this name from the first row of the first column in the text file.

Change the first element of `DimNames` to `LastName`.

```
ds.Properties.DimNames{1} = 'LastName';
ds.Properties
```

```
ans =
```

```
      Description: ''
    VarDescription: {}
             Units: {}
          DimNames: {'LastName'  'Variables'}
          UserData: []
          ObsNames: {14x1 cell}
          VarNames: {'sex'  'age'  'wgt'  'smoke'}
```

Index into dataset array.

You can use observation names to index into a dataset array. For example, return the data for the patient with last name `BROWN`.

```
ds('BROWN',:)
```

```
ans =

              sex         age     wgt     smoke
    BROWN     'f'         49      119     0
```

Note that observation names must be unique.

Create a Dataset Array from a Comma-Separated Text File

This example shows how to create a dataset array from the contents of a comma-separated text file.

Create a dataset array.

Import the file `hospitalSmall.csv` as a dataset array, specifying the comma-delimited format.

```
ds = dataset('File',fullfile(matlabroot,'help/toolbox/stats/examples','hospitalSmall.csv'),'Delim
```

```
ds =

    id                name              sex         age     wgt     smoke
    'YPL-320'         'SMITH'           'm'         38      176     1
    'GLI-532'         'JOHNSON'         'm'         43      163     0
    'PNI-258'         'WILLIAMS'        'f'         38      131     0
    'MIJ-579'         'JONES'           'f'         40      133     0
    'XLK-030'         'BROWN'           'f'         49      119     0
    'TFP-518'         'DAVIS'           'f'         46      142     0
    'LPD-746'         'MILLER'          'f'         33      142     1
    'ATA-945'         'WILSON'          'm'         40      180     0
    'VNL-702'         'MOORE'           'm'         28      183     0
    'LQW-768'         'TAYLOR'          'f'         31      132     0
    'QFY-472'         'ANDERSON'        'f'         45      128     0
    'UJG-627'         'THOMAS'          'f'         42      137     0
    'XUE-826'         'JACKSON'         'm'         25      174     0
    'TRW-072'         'WHITE'           'm'         39      202     1
```

By default, `dataset` uses the first row in the text file as variable names.

Add observation names.

Use the unique identifiers in the variable `id` as observation names. Then, delete the variable `id` from the dataset array.

```
ds.Properties.ObsNames = ds.id;
ds.id = []

ds =

              name              sex        age    wgt    smoke
    YPL-320    'SMITH'           'm'        38     176    1
    GLI-532    'JOHNSON'         'm'        43     163    0
    PNI-258    'WILLIAMS'        'f'        38     131    0
    MIJ-579    'JONES'           'f'        40     133    0
    XLK-030    'BROWN'           'f'        49     119    0
    TFP-518    'DAVIS'           'f'        46     142    0
    LPD-746    'MILLER'          'f'        33     142    1
    ATA-945    'WILSON'          'm'        40     180    0
    VNL-702    'MOORE'           'm'        28     183    0
    LQW-768    'TAYLOR'          'f'        31     132    0
    QFY-472    'ANDERSON'        'f'        45     128    0
    UJG-627    'THOMAS'          'f'        42     137    0
    XUE-826    'JACKSON'         'm'        25     174    0
    TRW-072    'WHITE'           'm'        39     202    1
```

Delete observations.

Delete any patients with the last name `BROWN`. You can use `strcmp` to match `'BROWN'` with the elements of the variable containing last names, `name`.

```
toDelete = strcmp(ds.name,'BROWN');
ds(toDelete,:) = []

ds =

              name              sex        age    wgt    smoke
    YPL-320    'SMITH'           'm'        38     176    1
    GLI-532    'JOHNSON'         'm'        43     163    0
    PNI-258    'WILLIAMS'        'f'        38     131    0
    MIJ-579    'JONES'           'f'        40     133    0
    TFP-518    'DAVIS'           'f'        46     142    0
    LPD-746    'MILLER'          'f'        33     142    1
    ATA-945    'WILSON'          'm'        40     180    0
    VNL-702    'MOORE'           'm'        28     183    0
    LQW-768    'TAYLOR'          'f'        31     132    0
    QFY-472    'ANDERSON'        'f'        45     128    0
    UJG-627    'THOMAS'          'f'        42     137    0
    XUE-826    'JACKSON'         'm'        25     174    0
    TRW-072    'WHITE'           'm'        39     202    1
```

One patient having last name `BROWN` is deleted from the dataset array.

Return size of dataset array.

The array now has 13 observations.

```
size(ds)

ans =

    13     5
```

Note that the row and column corresponding to variable and observation names, respectively, are not included in the size of a `dataset` array.

Create a Dataset Array from an Excel File

This example shows how to create a dataset array from the contents of an Excel® spreadsheet file.

Create a dataset array.

Import the data from the first worksheet in the file `hospitalSmall.xlsx`, specifying that the data file is an Excel spreadsheet.

```
ds = dataset('XLSFile',fullfile(matlabroot,'help/toolbox/stats/examples','hospitalSmall.xlsx'))
```

```
ds =

    id              name              sex        age    wgt    smoke
    'YPL-320'       'SMITH'           'm'        38     176    1
    'GLI-532'       'JOHNSON'         'm'        43     163    0
    'PNI-258'       'WILLIAMS'        'f'        38     131    0
    'MIJ-579'       'JONES'           'f'        40     133    0
    'XLK-030'       'BROWN'           'f'        49     119    0
    'TFP-518'       'DAVIS'           'f'        46     142    0
    'LPD-746'       'MILLER'          'f'        33     142    1
    'ATA-945'       'WILSON'          'm'        40     180    0
    'VNL-702'       'MOORE'           'm'        28     183    0
    'LQW-768'       'TAYLOR'          'f'        31     132    0
    'QFY-472'       'ANDERSON'        'f'        45     128    0
    'UJG-627'       'THOMAS'          'f'        42     137    0
    'XUE-826'       'JACKSON'         'm'        25     174    0
    'TRW-072'       'WHITE'           'm'        39     202    1
```

By default, `dataset` creates variable names using the contents of the first row in the spreadsheet.

Specify which worksheet to import.

Import the data from the second worksheet into a new dataset array.

```
ds2 = dataset('XLSFile',fullfile(matlabroot,'help/toolbox/stats/examples','hospitalSmall.xlsx'),
```

```
ds2 =

    id              name              sex        age    wgt    smoke
    'TRW-072'       'WHITE'           'm'        39     202    1
    'ELG-976'       'HARRIS'          'f'        36     129    0
    'KOQ-996'       'MARTIN'          'm'        48     181    1
    'YUZ-646'       'THOMPSON'        'm'        32     191    1
    'XBR-291'       'GARCIA'          'f'        27     131    1
    'KPW-846'       'MARTINEZ'        'm'        37     179    0
    'XBA-581'       'ROBINSON'        'm'        50     172    0
    'BKD-785'       'CLARK'           'f'        48     133    0
```

Add and Delete Observations

This example shows how to add and delete observations in a dataset array. You can also edit dataset arrays using the Variables editor.

Load sample data.

Import the data from the first worksheet in `hospitalSmall.xlsx` into a dataset array.

```
ds = dataset('XLSFile',fullfile(matlabroot,'help/toolbox/stats/examples','hospitalSmall.xlsx'));
size(ds)
```

```
ans =

    14     6
```

The dataset array, `ds`, has 14 observations (rows) and 6 variables (columns).

Add observations by concatenation.

The second worksheet in `hospitalSmall.xlsx` has additional patient data. Append the observations in this spreadsheet to the end of `ds`.

```
ds2 = dataset('XLSFile',fullfile(matlabroot,'help/toolbox/stats/examples','hospitalSmall.xlsx'),
dsNew = [ds;ds2];
size(dsNew)
```

```
ans =

    22     6
```

The dataset array `dsNew` has 22 observations. In order to vertically concatenate two dataset arrays, both arrays must have the same number of variables, with the same variable names.

Add observations from a cell array.

If you want to append new observations stored in a cell array, first convert the cell array to a dataset array, and then concatenate the dataset arrays.

```
cellObs = {'id','name','sex','age','wgt','smoke';
               'YQR-965','BAKER','M',36,160,0;
               'LFG-497','WALL' ,'F',28,125,1;
               'KSD-003','REED' ,'M',32,187,0};
dsNew = [dsNew;cell2dataset(cellObs)];
size(dsNew)
```

```
ans =

    25     6
```

Add observations from a structure.

You can also append new observations stored in a structure. Convert the structure to a dataset array, and then concatenate the dataset arrays.

```
structObs(1,1).id = 'GHK-842';
structObs(1,1).name = 'GEORGE';
structObs(1,1).sex = 'M';
```

```
structObs(1,1).age = 45;
structObs(1,1).wgt = 182;
structObs(1,1).smoke = 1;

structObs(2,1).id = 'QRH-308';
structObs(2,1).name = 'BAILEY';
structObs(2,1).sex = 'F';
structObs(2,1).age = 29;
structObs(2,1).wgt = 120;
structObs(2,1).smoke = 0;

dsNew = [dsNew;struct2dataset(structObs)];
size(dsNew)

ans =

    27     6
```

Delete duplicate observations.

Use `unique` to delete any observations in a dataset array that are duplicated.

```
dsNew = unique(dsNew);
size(dsNew)

ans =

    21     6
```

One duplicated observation is deleted.

Delete observations by observation number.

Delete observations 18, 20, and 21 from the dataset array.

```
dsNew([18,20,21],:) = [];
size(dsNew)

ans =

    18     6
```

The dataset array has only 18 observations now.

Delete observations by observation name.

First, specify the variable of identifiers, `id`, as observation names. Then, delete the variable `id` from `dsNew`. You can use the observation name to index observations.

```
dsNew.Properties.ObsNames = dsNew.id;
dsNew.id = [];
dsNew('KOQ-996',:) = [];
size(dsNew)

ans =

    17     5
```

The dataset array now has one less observation and one less variable.

Search for observations to delete.

You can also search for observations in the dataset array. For example, delete observations for any patients with the last name `WILLIAMS`.

```
toDelete = strcmp(dsNew.name,'WILLIAMS');
dsNew(toDelete,:) = [];
size(dsNew)
```

```
ans =

    16     5
```

The dataset array now has one less observation.

Add and Delete Variables

This example shows how to add and delete variables in a dataset array. You can also edit dataset arrays using the Variables editor.

Load sample data.

Import the data from the first worksheet in `hospitalSmall.xlsx` into a dataset array.

```
ds = dataset('XLSFile',fullfile(matlabroot,'help/toolbox/stats/examples','hospitalSmall.xlsx'));
size(ds)
```

```
ans =

    14     6
```

The dataset array, `ds`, has 14 observations (rows) and 6 variables (columns).

Add variables by concatenating dataset arrays.

The worksheet `Heights` in `hospitalSmall.xlsx` has heights for the patients on the first worksheet. Concatenate the data in this spreadsheet with `ds`.

```
ds2 = dataset('XLSFile',fullfile(matlabroot,'help/toolbox/stats/examples','hospitalSmall.xlsx'),
ds = [ds ds2];
size(ds)
```

```
ans =

    14     7
```

The dataset array now has seven variables. You can only horizontally concatenate dataset arrays with observations in the same position, or with the same observation names.

```
ds.Properties.VarNames{end}
```

```
ans =

hgt
```

The name of the last variable in `ds` is `hgt`, which `dataset` read from the first row of the imported spreadsheet.

Delete variables by variable name.

First, specify the unique identifiers in the variable `id` as observation names. Then, delete the variable `id` from the dataset array.

```
ds.Properties.ObsNames = ds.id;
ds.id = [];
size(ds)
```

```
ans =

    14     6
```

The dataset array now has six variables. List the variable names.

```
ds.Properties.VarNames(:)

ans =

    'name'
    'sex'
    'age'
    'wgt'
    'smoke'
    'hgt'
```

There is no longer a variable called `id`.

Add a new variable by name.

Add a new variable, `bmi`—which contains the body mass index (BMI) for each patient—to the dataset array. BMI is a function of height and weight. Display the last name, gender, and BMI for each patient.

```
ds.bmi = ds.wgt*703./ds.hgt.^2;
ds(:,{'name','sex','bmi'})

ans =

                name              sex        bmi
    YPL-320     'SMITH'           'm'        24.544
    GLI-532     'JOHNSON'         'm'        24.068
    PNI-258     'WILLIAMS'        'f'        23.958
    MIJ-579     'JONES'           'f'        25.127
    XLK-030     'BROWN'           'f'        21.078
    TFP-518     'DAVIS'           'f'        27.729
    LPD-746     'MILLER'          'f'        26.828
    ATA-945     'WILSON'          'm'         24.41
    VNL-702     'MOORE'           'm'        27.822
    LQW-768     'TAYLOR'          'f'        22.655
    QFY-472     'ANDERSON'        'f'        23.409
    UJG-627     'THOMAS'          'f'        25.883
    XUE-826     'JACKSON'         'm'        24.265
    TRW-072     'WHITE'           'm'        29.827
```

The operators `./` and `.^` in the calculation of BMI indicate element-wise division and exponentiation, respectively.

Delete variables by variable number.

Delete the variable `wgt`, the fourth variable in the dataset array.

```
ds(:,4) = [];
ds.Properties.VarNames(:)

ans =

    'name'
    'sex'
    'age'
    'smoke'
    'hgt'
    'bmi'
```

The variable `wgt` is deleted from the dataset array.

Access Data in Dataset Array Variables

This example shows how to work with dataset array variables and their data.

Access variables by name.

You can access variable data, or select a subset of variables, by using variable (column) names and dot indexing. Load a sample dataset array. Display the names of the variables in `hospital`.

```
load hospital
hospital.Properties.VarNames(:)
```

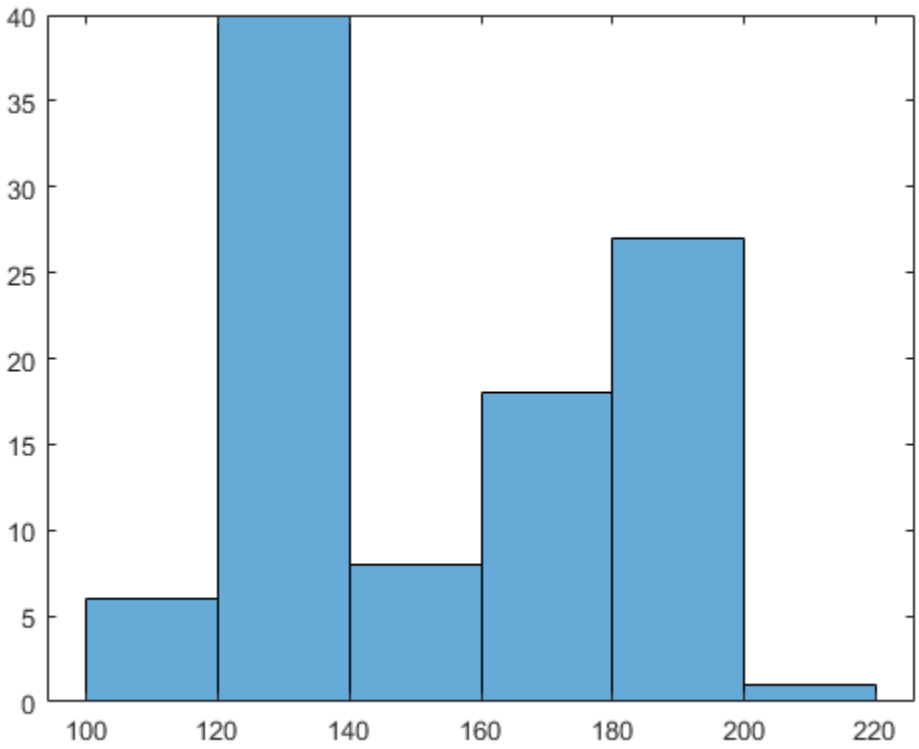
```
ans = 7x1 cell
    {'LastName'     }
    {'Sex'          }
    {'Age'          }
    {'Weight'       }
    {'Smoker'       }
    {'BloodPressure'}
    {'Trials'       }
```

The dataset array has 7 variables (columns) and 100 observations (rows). You can double-click `hospital` in the Workspace window to view the dataset array in the Variables editor.

Plot histogram.

Plot a histogram of the data in the variable `Weight`.

```
figure
histogram(hospital.Weight)
```

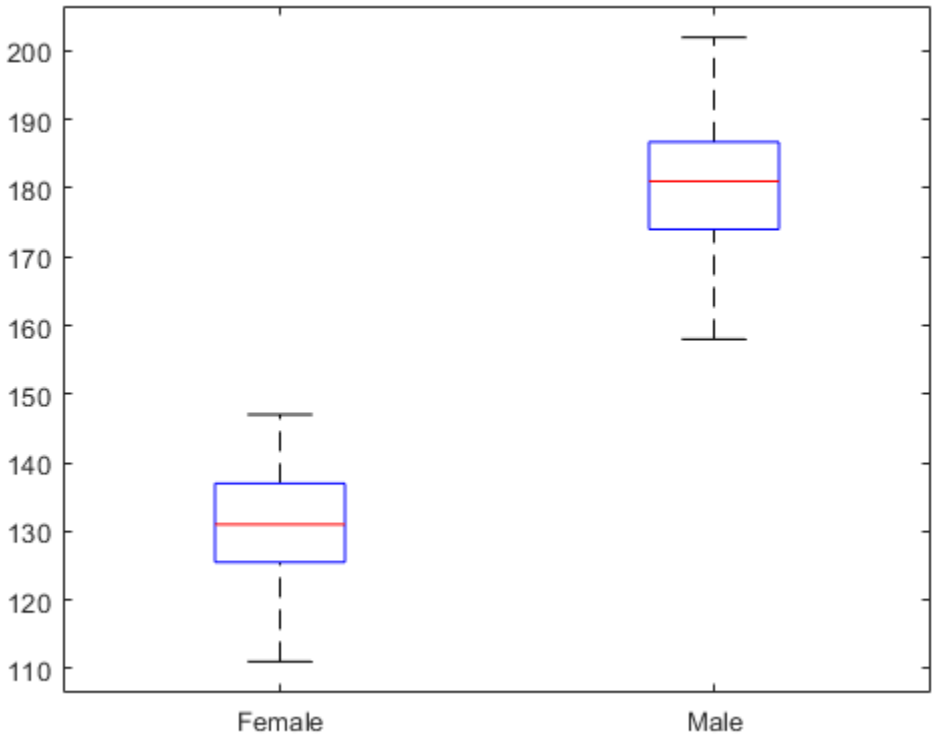


The histogram shows that the weight distribution is bimodal.

Plot data grouped by category.

Draw box plots of `Weight` grouped by the values in `Sex` (Male and Female). That is, use the variable `Sex` as a grouping variable.

```
figure
boxplot(hospital.Weight,hospital.Sex)
```



The box plot suggests that gender accounts for the bimodality in weight.

Select a subset of variables.

Create a new dataset array with only the variables `LastName`, `Sex`, and `Weight`. You can access the variables by name or column number.

```
ds1 = hospital(:,{'LastName','Sex','Weight'});
ds2 = hospital(:,[1,2,4]);
```

The dataset arrays `ds1` and `ds2` are equivalent. Use parentheses `( )` when indexing dataset arrays to preserve the data type; that is, to create a dataset array from a subset of a dataset array. You can also use the Variables editor to create a new dataset array from a subset of variables and observations.

Convert the variable data type.

Convert the data type of the variable `Smoker` from logical to nominal with labels `No` and `Yes`.

```
hospital.Smoker = nominal(hospital.Smoker,{'No','Yes'});
class(hospital.Smoker)
```

```
ans =
'nominal'
```

Explore data.

Display the first 10 elements of `Smoker`.

```
hospital.Smoker(1:10)
```

```
ans = 10x1 nominal
     Yes
     No
     No
     No
     No
     No
     Yes
     No
     No
     No
```

If you want to change the level labels in a nominal array, use `setlabels`.

Add variables.

The variable `BloodPressure` is a 100-by-2 array. The first column corresponds to systolic blood pressure, and the second column to diastolic blood pressure. Separate this array into two new variables, `SysPressure` and `DiaPressure`.

```
hospital.SysPressure = hospital.BloodPressure(:,1);
hospital.DiaPressure = hospital.BloodPressure(:,2);
hospital.Properties.VarNames(:)
```

```
ans = 9x1 cell
    {'LastName'     }
    {'Sex'          }
    {'Age'          }
    {'Weight'       }
    {'Smoker'       }
    {'BloodPressure'}
    {'Trials'       }
    {'SysPressure'  }
    {'DiaPressure'  }
```

The dataset array, `hospital`, has two new variables.

Search for variables by name.

Use `regexp` to find variables in `hospital` with `'Pressure'` in their name. Create a new dataset array containing only these variables.

```
bp = regexp(hospital.Properties.VarNames,'Pressure');
bpIdx = cellfun(@isempty,bp);
bpData = hospital(:,~bpIdx);
bpData.Properties.VarNames(:)
```

```
ans = 3x1 cell
    {'BloodPressure'}
    {'SysPressure'  }
    {'DiaPressure'  }
```

The new dataset array, `bpData`, contains only the blood pressure variables.

Delete variables.

Delete the variable `BloodPressure` from the dataset array, `hospital`.

```
hospital.BloodPressure = [];
hospital.Properties.VarNames(:)
```

```
ans = 8x1 cell
    {'LastName'   }
    {'Sex'        }
    {'Age'        }
    {'Weight'     }
    {'Smoker'     }
    {'Trials'     }
    {'SysPressure'}
    {'DiaPressure'}
```

The variable `BloodPressure` is no longer in the dataset array.

Select Subsets of Observations

This example shows how to select an observation or subset of observations from a dataset array.

Load sample data.

Load the sample dataset array, `hospital`. Dataset arrays can have observation (row) names. This array has observation names corresponding to unique patient identifiers.

```
load hospital
hospital.Properties.ObsNames(1:10)
```

```
ans = 10x1 cell
    {'YPL-320'}
    {'GLI-532'}
    {'PNI-258'}
    {'MIJ-579'}
    {'XLK-030'}
    {'TFP-518'}
    {'LPD-746'}
    {'ATA-945'}
    {'VNL-702'}
    {'LQW-768'}
```

These are the first 10 observation names.

Index an observation by name.

You can use the observation names to index into the dataset array. For example, extract the last name, sex, and age for the patient with identifier `XLK-030`.

```
hospital('XLK-030',{'LastName','Sex','Age'})
```

```
ans =
                LastName         Sex       Age
    XLK-030     {'BROWN'}        Female    49
```

Index a subset of observations by number.

Create a new dataset array containing the first 50 patients.

```
ds50 = hospital(1:50,:);
size(ds50)
```

```
ans = 1×2

    50     7
```

Search observations using a logical condition.

Create a new dataset array containing only male patients. To find the male patients, use a logical condition to search the variable containing gender information.

```
dsMale = hospital(hospital.Sex=='Male',:);
dsMale(1:10,{'LastName','Sex'})
```

```
ans =
                LastName            Sex
    YPL-320    {'SMITH'   }        Male
    GLI-532    {'JOHNSON' }        Male
    ATA-945    {'WILSON'  }        Male
    VNL-702    {'MOORE'   }        Male
    XUE-826    {'JACKSON' }        Male
    TRW-072    {'WHITE'   }        Male
    KOQ-996    {'MARTIN'  }        Male
    YUZ-646    {'THOMPSON'}        Male
    KPW-846    {'MARTINEZ'}        Male
    XBA-581    {'ROBINSON'}        Male
```

Search observations using multiple conditions.

You can use multiple conditions to search the dataset array. For example, create a new dataset array containing only female patients older than 40.

```
dsFemale = hospital(hospital.Sex=='Female' & hospital.Age > 40,:);
dsFemale(1:10,{'LastName','Sex','Age'})
```

```
ans =
                LastName            Sex       Age
    XLK-030    {'BROWN'   }        Female    49
    TFP-518    {'DAVIS'   }        Female    46
    QFY-472    {'ANDERSON'}        Female    45
    UJG-627    {'THOMAS'  }        Female    42
    BKD-785    {'CLARK'   }        Female    48
    VWL-936    {'LEWIS'   }        Female    41
    AAX-056    {'LEE'     }        Female    44
    AFK-336    {'WRIGHT'  }        Female    45
    KKL-155    {'ADAMS'   }        Female    48
    RBA-579    {'SANCHEZ' }        Female    44
```

Select a random subset of observations.

Create a new dataset array containing a random subset of 20 patients from the dataset array `hospital`.

```
rng('default') % For reproducibility
dsRandom = hospital(randsample(length(hospital),20),:);
dsRandom.Properties.ObsNames
```

```
ans = 20x1 cell
    {'DAU-529'}
    {'AGR-528'}
    {'RBO-332'}
    {'QOO-305'}
    {'RVS-253'}
    {'QEQ-082'}
    {'EHE-616'}
    {'HVR-372'}
    {'KOQ-996'}
    {'REV-997'}
    {'PUE-347'}
    {'LQW-768'}
```

```
    {'YLN-495'}
    {'HJQ-495'}
    {'ELG-976'}
    {'XUE-826'}
    {'MEZ-469'}
    {'UDS-151'}
    {'MIJ-579'}
    {'DGC-290'}
```

Delete observations by name.

Delete the data for the patient with observation name `HVR-372`.

```
hospital('HVR-372',:) = [];
size(hospital)
```

```
ans = 1×2

    99     7
```

The dataset array has one less observation.

Sort Observations in Dataset Arrays

This example shows how to sort observations (rows) in a dataset array using the command line. You can also sort rows using the Variables editor.

Sort observations in ascending order.

Load the sample dataset array, `hospital`. Sort the observations by the values in `Age`, in ascending order.

```
load hospital
dsAgeUp = sortrows(hospital,'Age');
dsAgeUp(1:10,{'LastName','Age'})
```

```
ans =
                LastName              Age
    XUE-826    {'JACKSON'  }        25
    FZR-250    {'HALL'     }        25
    PUE-347    {'YOUNG'    }        25
    LIM-480    {'HILL'     }        25
    SCQ-914    {'JAMES'    }        25
    REV-997    {'ALEXANDER'}        25
    XBR-291    {'GARCIA'   }        27
    VNL-702    {'MOORE'    }        28
    DTT-578    {'WALKER'   }        28
    XAX-646    {'COOPER'   }        28
```

The youngest patients are age 25.

Sort observations in descending order.

Sort the observations by `Age` in descending order.

```
dsAgeDown = sortrows(hospital,'Age','descend');
dsAgeDown(1:10,{'LastName','Age'})
```

```
ans =
                LastName             Age
    XBA-581    {'ROBINSON'}        50
    DAU-529    {'REED'    }        50
    XLK-030    {'BROWN'   }        49
    FLJ-908    {'STEWART' }        49
    GGU-691    {'HUGHES'  }        49
    MEZ-469    {'GRIFFIN' }        49
    KOQ-996    {'MARTIN'  }        48
    BKD-785    {'CLARK'   }        48
    KKL-155    {'ADAMS'   }        48
    NSK-403    {'RAMIREZ' }        48
```

The oldest patients are age 50.

Sort observations by the values of two variables.

Sort the observations in `hospital` by `Age`, and then by `LastName`.

```
dsName = sortrows(hospital,{'Age','LastName'});
dsName(1:10,{'LastName','Age'})

ans =
                LastName             Age
    REV-997    {'ALEXANDER'}        25
    FZR-250    {'HALL'     }        25
    LIM-480    {'HILL'     }        25
    XUE-826    {'JACKSON'  }        25
    SCQ-914    {'JAMES'    }        25
    PUE-347    {'YOUNG'    }        25
    XBR-291    {'GARCIA'   }        27
    XAX-646    {'COOPER'   }        28
    QEQ-082    {'COX'      }        28
    NSU-424    {'JENKINS'  }        28
```

Now the names are sorted alphabetically within increasing age groups.

Sort observations in mixed order.

Sort the observations in `hospital` by `Age` in an increasing order, and then by `Weight` in a decreasing order.

```
dsWeight = sortrows(hospital,{'Age','Weight'},{'ascend','descend'});
dsWeight(1:10,{'LastName','Age','Weight'})

ans =
                LastName             Age    Weight
    FZR-250    {'HALL'     }        25     189
    SCQ-914    {'JAMES'    }        25     186
    XUE-826    {'JACKSON'  }        25     174
    REV-997    {'ALEXANDER'}        25     171
    LIM-480    {'HILL'     }        25     138
    PUE-347    {'YOUNG'    }        25     114
    XBR-291    {'GARCIA'   }        27     131
    NSU-424    {'JENKINS'  }        28     189
    VNL-702    {'MOORE'    }        28     183
    XAX-646    {'COOPER'   }        28     127
```

This shows that the maximum weight among patients that are age 25 is 189 lbs.

Sort observations by observation name.

Sort the observations in `hospital` by the observation names.

```
dsObs = sortrows(hospital,'obsnames');
dsObs(1:10,{'LastName','Age'})

ans =
                LastName           Age
    AAX-056    {'LEE'    }        44
    AFB-271    {'PEREZ'  }        44
    AFK-336    {'WRIGHT' }        45
    AGR-528    {'SIMMONS'}        45
    ATA-945    {'WILSON' }        40
    BEZ-311    {'DIAZ'   }        45
    BKD-785    {'CLARK'  }        48
```

```
DAU-529    {'REED'   }        50
DGC-290    {'BUTLER' }        38
DTT-578    {'WALKER' }        28
```

The observations are sorted by observation name in ascending alphabetical order.

Merge Dataset Arrays

This example shows how to merge dataset arrays using `join`.

Load sample data.

Import the data from the first worksheet in `hospitalSmall.xlsx` into a dataset array, then keep only a few of the variables.

```
ds1 = dataset('XLSFile',fullfile(matlabroot,'help/toolbox/stats/examples','hospitalSmall.xlsx'))
ds1 = ds1(:,{'id','name','sex','age'})
```

```
ds1 =

    id              name             sex        age
    'YPL-320'       'SMITH'          'm'        38
    'GLI-532'       'JOHNSON'        'm'        43
    'PNI-258'       'WILLIAMS'       'f'        38
    'MIJ-579'       'JONES'          'f'        40
    'XLK-030'       'BROWN'          'f'        49
    'TFP-518'       'DAVIS'          'f'        46
    'LPD-746'       'MILLER'         'f'        33
    'ATA-945'       'WILSON'         'm'        40
    'VNL-702'       'MOORE'          'm'        28
    'LQW-768'       'TAYLOR'         'f'        31
    'QFY-472'       'ANDERSON'       'f'        45
    'UJG-627'       'THOMAS'         'f'        42
    'XUE-826'       'JACKSON'        'm'        25
    'TRW-072'       'WHITE'          'm'        39
```

The dataset array, `ds1`, has 14 observations (rows) and 4 variables (columns).

Import the data from the worksheet `Heights2` in `hospitalSmall.xlsx`.

```
ds2 = dataset('XLSFile',fullfile(matlabroot,'help/toolbox/stats/examples','hospitalSmall.xlsx'),
```

```
ds2 =

    id              hgt
    'LPD-746'       61
    'PNI-258'       62
    'XUE-826'       71
    'ATA-945'       72
    'XLK-030'       63
```

`ds2` has height measurements for a subset of five individuals from the first dataset array, `ds1`.

Merge only the matching subset of observations.

Use `join` to merge the two dataset arrays, `ds1` and `ds2`, keeping only the subset of observations that are in `ds2`.

```
JoinSmall = join(ds2,ds1)
```

```
JoinSmall =

    id              hgt    name             sex        age
    'LPD-746'       61     'MILLER'         'f'        33
```

```
    'PNI-258'        62     'WILLIAMS'        'f'        38
    'XUE-826'        71     'JACKSON'         'm'        25
    'ATA-945'        72     'WILSON'          'm'        40
    'XLK-030'        63     'BROWN'           'f'        49
```

In `JoinSmall`, the variable `id` only appears once. This is because it is the key variable—the variable that links observations between the two dataset arrays—and has the same variable name in both `ds1` and `ds2`.

Include incomplete observations in the merge.

Merge `ds1` and `ds2` keeping all observations in the larger `ds1`.

```
joinAll = join(ds2,ds1,'type','rightouter','mergekeys',true)
```

```
joinAll =

    id               hgt    name              sex        age
    'ATA-945'         72    'WILSON'          'm'        40
    'GLI-532'        NaN    'JOHNSON'         'm'        43
    'LPD-746'         61    'MILLER'          'f'        33
    'LQW-768'        NaN    'TAYLOR'          'f'        31
    'MIJ-579'        NaN    'JONES'           'f'        40
    'PNI-258'         62    'WILLIAMS'        'f'        38
    'QFY-472'        NaN    'ANDERSON'        'f'        45
    'TFP-518'        NaN    'DAVIS'           'f'        46
    'TRW-072'        NaN    'WHITE'           'm'        39
    'UJG-627'        NaN    'THOMAS'          'f'        42
    'VNL-702'        NaN    'MOORE'           'm'        28
    'XLK-030'         63    'BROWN'           'f'        49
    'XUE-826'         71    'JACKSON'         'm'        25
    'YPL-320'        NaN    'SMITH'           'm'        38
```

Each observation in `ds1` without corresponding height measurements in `ds2` has height value `NaN`. Also, because there is no `id` value in `ds2` for each observation in `ds1`, you need to merge the keys using the option `'MergeKeys',true`. This merges the key variable, `id`.

Merge dataset arrays with different key variable names.

When using `join`, it is not necessary for the key variable to have the same name in the dataset arrays to be merged. Import the data from the worksheet named `Heights3` in `hospitalSmall.xlsx`.

```
ds3 = dataset('XLSFile',fullfile(matlabroot,'help/toolbox/stats/examples','hospitalSmall.xlsx'),
```

```
ds3 =

    identifier       hgt
    'GLI-532'        69
    'QFY-472'        62
    'MIJ-579'        61
    'VNL-702'        68
    'XLK-030'        63
    'LPD-746'        61
    'TFP-518'        60
    'YPL-320'        71
    'ATA-945'        72
    'LQW-768'        64
    'PNI-258'        62
```

```
    'UJG-627'        61
    'XUE-826'        71
    'TRW-072'        69
```

`ds3` has height measurements for each observation in `ds1`. This dataset array has the same patient identifiers as `ds1`, but they are under the variable name `identifier`, instead of `id` (and in a different order).

Specify key variable.

You can easily change the variable name of the key variable in `ds3` by setting `d3.Properties.VarNames` or using the Variables editor, but it is not required to perform a merge. Instead, you can specify the name of the key variable in each dataset array using `LeftKeys` and `RightKeys`.

```
joinDiff = join(ds3,ds1,'LeftKeys','identifier','RightKeys','id')
```

```
joinDiff =

    identifier       hgt    name              sex        age
    'GLI-532'        69     'JOHNSON'         'm'        43
    'QFY-472'        62     'ANDERSON'        'f'        45
    'MIJ-579'        61     'JONES'           'f'        40
    'VNL-702'        68     'MOORE'           'm'        28
    'XLK-030'        63     'BROWN'           'f'        49
    'LPD-746'        61     'MILLER'          'f'        33
    'TFP-518'        60     'DAVIS'           'f'        46
    'YPL-320'        71     'SMITH'           'm'        38
    'ATA-945'        72     'WILSON'          'm'        40
    'LQW-768'        64     'TAYLOR'          'f'        31
    'PNI-258'        62     'WILLIAMS'        'f'        38
    'UJG-627'        61     'THOMAS'          'f'        42
    'XUE-826'        71     'JACKSON'         'm'        25
    'TRW-072'        69     'WHITE'           'm'        39
```

The merged dataset array, `joinDiff`, has the same key variable order and name as the first dataset array input to `join`, `ds3`.

Stack or Unstack Dataset Arrays

This example shows how to reformat dataset arrays using `stack` and `unstack`.

Load sample data.

Import the data from the comma-separated text file `testScores.csv`.

```
ds = dataset('File','testScores.csv','Delimiter',',')
```

```
ds =

    LastName          Sex             Test1    Test2    Test3    Test4
    'HOWARD'          'male'          90       87       93       92
    'WARD'            'male'          87       85       83       90
    'TORRES'          'male'          86       85       88       86
    'PETERSON'        'female'        75       80       72       77
    'GRAY'            'female'        89       86       87       90
    'RAMIREZ'         'female'        96       92       98       95
    'JAMES'           'male'          78       75       77       77
    'WATSON'          'female'        91       94       92       90
    'BROOKS'          'female'        86       83       85       89
    'KELLY'           'male'          79       76       82       80
```

Each of the 10 students has 4 test scores.

Perform calculations on dataset array.

With the data in this format, you can, for example, calculate the average test score for each student. The test scores are in columns 3 to 6.

```
ds.TestAve = mean(double(ds(:,3:6)),2);
ds(:,{'LastName','Sex','TestAve'})
```

```
ans =

    LastName          Sex             TestAve
    'HOWARD'          'male'           90.5
    'WARD'            'male'          86.25
    'TORRES'          'male'          86.25
    'PETERSON'        'female'           76
    'GRAY'            'female'           88
    'RAMIREZ'         'female'        95.25
    'JAMES'           'male'          76.75
    'WATSON'          'female'        91.75
    'BROOKS'          'female'        85.75
    'KELLY'           'male'          79.25
```

A new variable with average test scores is added to the dataset array, `ds`.

Reformat the dataset array.

Stack the test score variables into a new variable, `Scores`.

```
 dsNew = stack(ds,{'Test1','Test2','Test3','Test4'},...
            'newDataVarName','Scores')
```

```
dsNew =
```

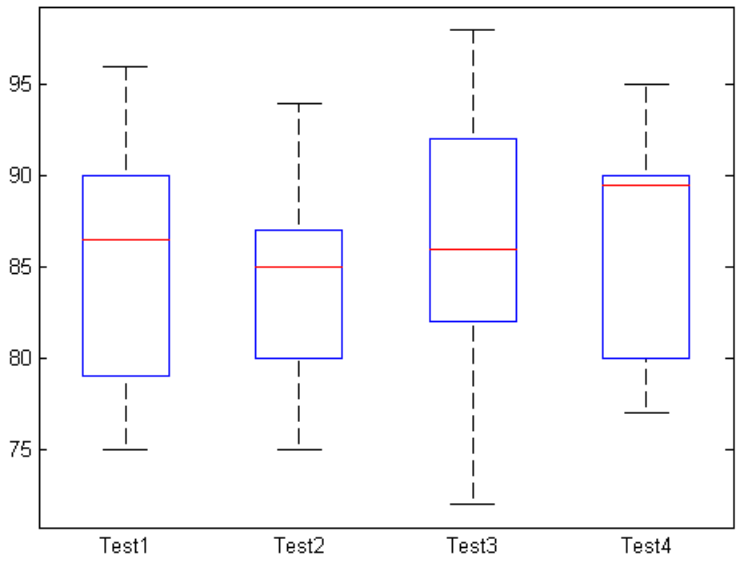
```
    LastName          Sex             TestAve    Scores_Indicator    Scores
    'HOWARD'          'male'           90.5      Test1               90
    'HOWARD'          'male'           90.5      Test2               87
    'HOWARD'          'male'           90.5      Test3               93
    'HOWARD'          'male'           90.5      Test4               92
    'WARD'            'male'          86.25      Test1               87
    'WARD'            'male'          86.25      Test2               85
    'WARD'            'male'          86.25      Test3               83
    'WARD'            'male'          86.25      Test4               90
    'TORRES'          'male'          86.25      Test1               86
    'TORRES'          'male'          86.25      Test2               85
    'TORRES'          'male'          86.25      Test3               88
    'TORRES'          'male'          86.25      Test4               86
    'PETERSON'        'female'           76      Test1               75
    'PETERSON'        'female'           76      Test2               80
    'PETERSON'        'female'           76      Test3               72
    'PETERSON'        'female'           76      Test4               77
    'GRAY'            'female'           88      Test1               89
    'GRAY'            'female'           88      Test2               86
    'GRAY'            'female'           88      Test3               87
    'GRAY'            'female'           88      Test4               90
    'RAMIREZ'         'female'        95.25      Test1               96
    'RAMIREZ'         'female'        95.25      Test2               92
    'RAMIREZ'         'female'        95.25      Test3               98
    'RAMIREZ'         'female'        95.25      Test4               95
    'JAMES'           'male'          76.75      Test1               78
    'JAMES'           'male'          76.75      Test2               75
    'JAMES'           'male'          76.75      Test3               77
    'JAMES'           'male'          76.75      Test4               77
    'WATSON'          'female'        91.75      Test1               91
    'WATSON'          'female'        91.75      Test2               94
    'WATSON'          'female'        91.75      Test3               92
    'WATSON'          'female'        91.75      Test4               90
    'BROOKS'          'female'        85.75      Test1               86
    'BROOKS'          'female'        85.75      Test2               83
    'BROOKS'          'female'        85.75      Test3               85
    'BROOKS'          'female'        85.75      Test4               89
    'KELLY'           'male'          79.25      Test1               79
    'KELLY'           'male'          79.25      Test2               76
    'KELLY'           'male'          79.25      Test3               82
    'KELLY'           'male'          79.25      Test4               80
```

The original test variable names, `Test1`, `Test2`, `Test3`, and `Test4`, appear as levels in the combined test scores indicator variable, `Scores_Indicator`.

Plot data grouped by category.

With the data in this format, you can use `Scores_Indicator` as a grouping variable, and draw box plots of test scores grouped by test.

```
figure()
boxplot(dsNew.Scores,dsNew.Scores_Indicator)
```



Revert the dataset array to the original format.

Reformat `dsNew` back into its original format.

```
dsOrig = unstack(dsNew,'Scores','Scores_Indicator');
dsOrig(:,{'LastName','Test1','Test2','Test3','Test4'})
```

```
ans =

    LastName          Test1    Test2    Test3    Test4
    'HOWARD'          90       87       93       92
    'WARD'            87       85       83       90
    'TORRES'          86       85       88       86
    'PETERSON'        75       80       72       77
    'GRAY'            89       86       87       90
    'RAMIREZ'         96       92       98       95
    'JAMES'           78       75       77       77
    'WATSON'          91       94       92       90
    'BROOKS'          86       83       85       89
    'KELLY'           79       76       82       80
```

The dataset array is back in wide format. `unstack` reassigns the levels of the indicator variable, `Scores_Indicator`, as variable names in the unstacked dataset array.

Calculations on Dataset Arrays

This example shows how to perform calculations on dataset arrays.

Load sample data.

Import the data from the comma-separated text file `testScores.csv`.

```
ds = dataset('File','testScores.csv','Delimiter',',')
```

```
ds =

    LastName          Sex             Test1    Test2    Test3    Test4
    'HOWARD'          'male'          90       87       93       92
    'WARD'            'male'          87       85       83       90
    'TORRES'          'male'          86       85       88       86
    'PETERSON'        'female'        75       80       72       77
    'GRAY'            'female'        89       86       87       90
    'RAMIREZ'         'female'        96       92       98       95
    'JAMES'           'male'          78       75       77       77
    'WATSON'          'female'        91       94       92       90
    'BROOKS'          'female'        86       83       85       89
    'KELLY'           'male'          79       76       82       80
```

There are 4 test scores for each of 10 students, in wide format.

Average dataset array variables.

Compute the average (mean) test score for each student in the dataset array, and store it in a new variable, `TestAvg`. Test scores are in columns 3 to 6.

Use `double` to convert the specified dataset array variables into a numeric array. Then, calculate the mean across the second dimension (across columns) to get the test average for each student.

```
ds.TestAvg = mean(double(ds(:,3:6)),2);
ds(:,{'LastName','TestAvg'})
```

```
ans =

    LastName          TestAvg
    'HOWARD'           90.5
    'WARD'            86.25
    'TORRES'          86.25
    'PETERSON'           76
    'GRAY'               88
    'RAMIREZ'         95.25
    'JAMES'           76.75
    'WATSON'          91.75
    'BROOKS'          85.75
    'KELLY'           79.25
```

Summarize the dataset array using a grouping variable.

Compute the mean and maximum average test scores for each gender.

```
stats = grpstats(ds,'Sex',{'mean','max'},'DataVars','TestAvg')
```

```
stats =
```

```
            Sex             GroupCount    mean_TestAvg    max_TestAvg
    male    'male'          5              83.8            90.5
    female  'female'        5             87.35           95.25
```

This returns a new dataset array containing the specified summary statistics for each level of the grouping variable, `Sex`.

Replace data values.

The denominator for each test score is 100. Convert the test score denominator to 25.

```
scores = double(ds(:,3:6));
newScores = scores*25/100;
ds = replacedata(ds,newScores,3:6)
```

```
ds =

    LastName          Sex             Test1    Test2    Test3    Test4    TestAvg
    'HOWARD'          'male'           22.5    21.75    23.25       23     90.5
    'WARD'            'male'          21.75    21.25    20.75     22.5    86.25
    'TORRES'          'male'           21.5    21.25       22     21.5    86.25
    'PETERSON'        'female'        18.75       20       18    19.25       76
    'GRAY'            'female'        22.25     21.5    21.75     22.5       88
    'RAMIREZ'         'female'           24       23     24.5    23.75    95.25
    'JAMES'           'male'           19.5    18.75    19.25    19.25    76.75
    'WATSON'          'female'        22.75     23.5       23     22.5    91.75
    'BROOKS'          'female'         21.5    20.75    21.25    22.25    85.75
    'KELLY'           'male'          19.75       19     20.5       20    79.25
```

The first two lines of code extract the test data and perform the desired calculation. Then, `replacedata` inserts the new test scores back into the dataset array.

The variable of test score averages, `TestAvg`, is now the final score for each student.

Change variable name.

Change the variable name to `Final`.

```
ds.Properties.VarNames{end} = 'Final';
ds
```

```
ds =

    LastName          Sex             Test1    Test2    Test3    Test4    Final
    'HOWARD'          'male'           22.5    21.75    23.25       23     90.5
    'WARD'            'male'          21.75    21.25    20.75     22.5    86.25
    'TORRES'          'male'           21.5    21.25       22     21.5    86.25
    'PETERSON'        'female'        18.75       20       18    19.25       76
    'GRAY'            'female'        22.25     21.5    21.75     22.5       88
    'RAMIREZ'         'female'           24       23     24.5    23.75    95.25
    'JAMES'           'male'           19.5    18.75    19.25    19.25    76.75
    'WATSON'          'female'        22.75     23.5       23     22.5    91.75
    'BROOKS'          'female'         21.5    20.75    21.25    22.25    85.75
    'KELLY'           'male'          19.75       19     20.5       20    79.25
```

Export Dataset Arrays

This example shows how to export a dataset array from the MATLAB workspace to a text or spreadsheet file.

Load sample data.

```
load('hospital')
```

The dataset array has 100 observations and 7 variables.

Export to a text file.

Export the dataset array, `hospital`, to a text file named `hospital.txt`. By default, `export` writes to a tab-delimited text file with the same name as the dataset array, appended by `.txt`.

```
export(hospital)
```

This creates the file `hospital.txt` in the current working folder, if it does not previously exist. If the file already exists in the current working folder, `export` overwrites the existing file.

By default, variable names are in the first line of the text file. Observation names, if present, are in the first column.

Export without variable names.

Export `hospital` with variable names suppressed to a text file named `NoLabels.txt`.

```
export(hospital,'File','NoLabels.txt','WriteVarNames',false)
```

There are no variable names in the first line of the created text file, `NoLabels.txt`.

Export to a comma-delimited format.

Export `hospital` to a comma-delimited text file, `hospital.csv`.

```
export(hospital,'File','hospital.csv','Delimiter',',')
```

Export to an Excel spreadsheet.

Export `hospital` to an Excel spreadsheet named `hospital.xlsx`.

```
export(hospital,'XLSFile','hospital.xlsx')
```

By default, the first row of `hospital.xlsx` has variable names, and the first column has observation names.

Clean Messy and Missing Data

This example shows how to find, clean, and delete observations with missing data in a dataset array.

Load sample data.

Import the data from the spreadsheet `messy.xlsx`.

```
messyData = dataset('XLSFile',fullfile(matlabroot,'help/toolbox/stats/examples','messy.xlsx'))
```

```
messyData =

    var1          var2          var3         var4          var5
    'afe1'        '3'           'yes'        '3'             3
    'egh3'        '.'           'no'         '7'             7
    'wth4'        '3'           'yes'        '3'             3
    'atn2'        '23'          'no'         '23'           23
    'arg1'        '5'           'yes'        '5'             5
    'jre3'        '34.6'        'yes'        '34.6'       34.6
    'wen9'        '234'         'yes'        '234'         234
    'ple2'        '2'           'no'         '2'             2
    'dbo8'        '5'           'no'         '5'             5
    'oii4'        '5'           'yes'        '5'             5
    'wnk3'        '245'         'yes'        '245'         245
    'abk6'        '563'         ''           '563'         563
    'pnj5'        '463'         'no'         '463'         463
    'wnn3'        '6'           'no'         '6'             6
    'oks9'        '23'          'yes'        '23'           23
    'wba3'        ''            'yes'        'NaN'          14
    'pkn4'        '2'           'no'         '2'             2
    'adw3'        '22'          'no'         '22'           22
    'poj2'        '-99'         'yes'        '-99'         -99
    'bas8'        '23'          'no'         '23'           23
    'gry5'        'NA'          'yes'        'NaN'          21
```

When you import data from a spreadsheet, `dataset` reads any variables with nonnumeric elements as a cell array of character vectors. This is why the variable `var2` is a cell array of character vectors. When importing data from a text file, you have more flexibility to specify which nonnumeric expressions to treat as missing using the option `TreatAsEmpty`.

There are many different missing data indicators in `messy.xlsx`, such as:

- Empty cells
- A period (`.`)
- `NA`
- `NaN`
- `-99`

Find observations with missing values.

Display the subset of observations that have at least one missing value using `ismissing`.

```
ix = ismissing(messyData,'NumericTreatAsMissing',-99,...
                'StringTreatAsMissing',{'NaN','.','NA'});
messyData(any(ix,2),:)
```

```
ans =

    var1          var2         var3         var4         var5
    'egh3'        '.'          'no'         '7'            7
    'abk6'        '563'        ''           '563'        563
    'wba3'        ''           'yes'        'NaN'         14
    'poj2'        '-99'        'yes'        '-99'        -99
    'gry5'        'NA'         'yes'        'NaN'         21
```

By default, `ismissing` recognizes the following missing value indicators:

- `NaN` for numeric arrays
- `''` for character arrays
- `<undefined>` for categorical arrays

Use the `NumericTreatAsMissing` and `StringTreatAsMissing` options to specify other values to treat as missing.

Convert character arrays to double arrays.

You can convert the `char` variables that should be numeric using `str2double`.

```
messyData.var2 = str2double(messyData.var2);
messyData.var4 = str2double(messyData.var4)
```

```
messyData =

    var1          var2    var3         var4    var5
    'afe1'           3    'yes'           3       3
    'egh3'         NaN    'no'            7       7
    'wth4'           3    'yes'           3       3
    'atn2'          23    'no'           23      23
    'arg1'           5    'yes'           5       5
    'jre3'        34.6    'yes'        34.6    34.6
    'wen9'         234    'yes'         234     234
    'ple2'           2    'no'            2       2
    'dbo8'           5    'no'            5       5
    'oii4'           5    'yes'           5       5
    'wnk3'         245    'yes'         245     245
    'abk6'         563    ''            563     563
    'pnj5'         463    'no'          463     463
    'wnn3'           6    'no'            6       6
    'oks9'          23    'yes'          23      23
    'wba3'         NaN    'yes'         NaN      14
    'pkn4'           2    'no'            2       2
    'adw3'          22    'no'           22      22
    'poj2'         -99    'yes'         -99     -99
    'bas8'          23    'no'           23      23
    'gry5'         NaN    'yes'         NaN      21
```

Now, `var2` and `var4` are numeric arrays. During the conversion, `str2double` replaces the nonnumeric elements of the variables `var2` and `var4` with the value `NaN`. However, there are no changes to the numeric missing value indicator, `-99`.

When applying the same function to many dataset array variables, it can sometimes be more convenient to use `datasetfun`. For example, to convert both `var2` and `var4` to numeric arrays simultaneously, you can use:

```
messyData(:,[2,4]) = datasetfun(@str2double,messyData, ...
    'DataVars',[2,4],'DatasetOutput',true);
```

Replace missing value indicators.

Clean the data so that the missing values indicated by the code `-99` have the standard MATLAB numeric missing value indicator, `NaN`.

```
messyData = replaceWithMissing(messyData,'NumericValues',-99)
```

```
messyData =

    var1          var2    var3          var4    var5
    'afe1'           3    'yes'            3       3
    'egh3'         NaN    'no'             7       7
    'wth4'           3    'yes'            3       3
    'atn2'          23    'no'            23      23
    'arg1'           5    'yes'            5       5
    'jre3'        34.6    'yes'         34.6    34.6
    'wen9'         234    'yes'          234     234
    'ple2'           2    'no'             2       2
    'dbo8'           5    'no'             5       5
    'oii4'           5    'yes'            5       5
    'wnk3'         245    'yes'          245     245
    'abk6'         563    ''             563     563
    'pnj5'         463    'no'           463     463
    'wnn3'           6    'no'             6       6
    'oks9'          23    'yes'           23      23
    'wba3'         NaN    'yes'          NaN      14
    'pkn4'           2    'no'             2       2
    'adw3'          22    'no'            22      22
    'poj2'         NaN    'yes'          NaN     NaN
    'bas8'          23    'no'            23      23
    'gry5'         NaN    'yes'          NaN      21
```

Create a dataset array with complete observations.

Create a new dataset array that contains only the complete observations—those without missing data.

```
ix = ismissing(messyData);
completeData = messyData(~any(ix,2),:)
```

```
completeData =

    var1          var2    var3          var4    var5
    'afe1'           3    'yes'            3       3
    'wth4'           3    'yes'            3       3
    'atn2'          23    'no'            23      23
    'arg1'           5    'yes'            5       5
    'jre3'        34.6    'yes'         34.6    34.6
    'wen9'         234    'yes'          234     234
    'ple2'           2    'no'             2       2
    'dbo8'           5    'no'             5       5
    'oii4'           5    'yes'            5       5
    'wnk3'         245    'yes'          245     245
    'pnj5'         463    'no'           463     463
    'wnn3'           6    'no'             6       6
    'oks9'          23    'yes'           23      23
    'pkn4'           2    'no'             2       2
```

```
    'adw3'          22    'no'           22      22
    'bas8'          23    'no'           23      23
```

Dataset Arrays in the Variables Editor

Note The `dataset` data type is not recommended. To work with heterogeneous data, use the MATLAB `table` data type instead. See MATLAB `table` documentation for more information.

In this section...

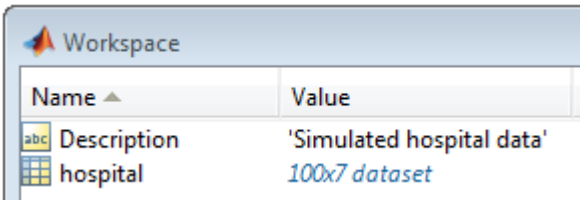
Open Dataset Arrays in the Variables Editor

The MATLAB Variables editor provides a convenient interface for viewing, modifying, and plotting dataset arrays.

First, load the sample data set, `hospital`.

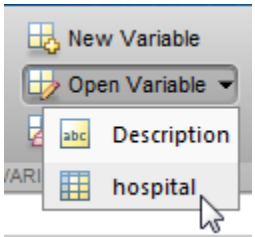
```
load hospital
```

The dataset array, `hospital`, is created in the MATLAB workspace.



The dataset array has 100 observations and 7 variables.

To open `hospital` in the Variables editor, click **Open Variable**, and select `hospital`.



The Variables editor opens, displaying the contents of the dataset array (only the first 10 observations are shown here).

hospital

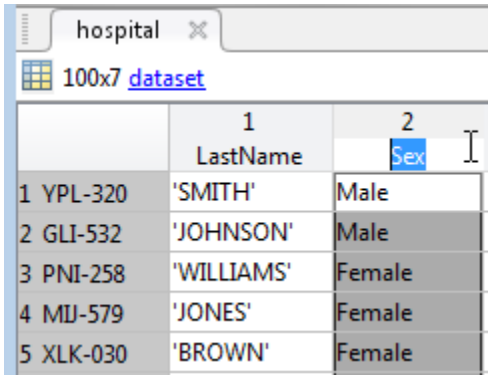
100x7 dataset

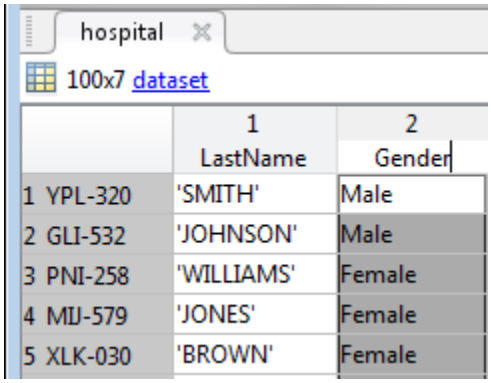
	1 LastName	2 Sex	3 Age	4 Weight	5 Smoker	6 BloodPressure		7 Trials
1	YPL-320	'SMITH'	Male	38	176	1	124	93	18
2	GLI-532	'JOHNSON'	Male	43	163	0	109	77	[11,13,22]
3	PNI-258	'WILLIAMS'	Female	38	131	0	125	83	[]
4	MIJ-579	'JONES'	Female	40	133	0	117	75	[6,12]
5	XLK-030	'BROWN'	Female	49	119	0	122	80	[14,23]
6	TFP-518	'DAVIS'	Female	46	142	0	121	70	19
7	LPD-746	'MILLER'	Female	33	142	1	130	88	13
8	ATA-945	'WILSON'	Male	40	180	0	115	82	[]
9	VNL-702	'MOORE'	Male	28	183	0	115	78	2
10	LQW-768	'TAYLOR'	Female	31	132	0	118	86	11

In the Variables editor, you can see the names of the seven variables along the top row, and the observations names down the first column.

Modify Variable and Observation Names

You can modify variable and observation names by double-clicking a name, and then typing new text.

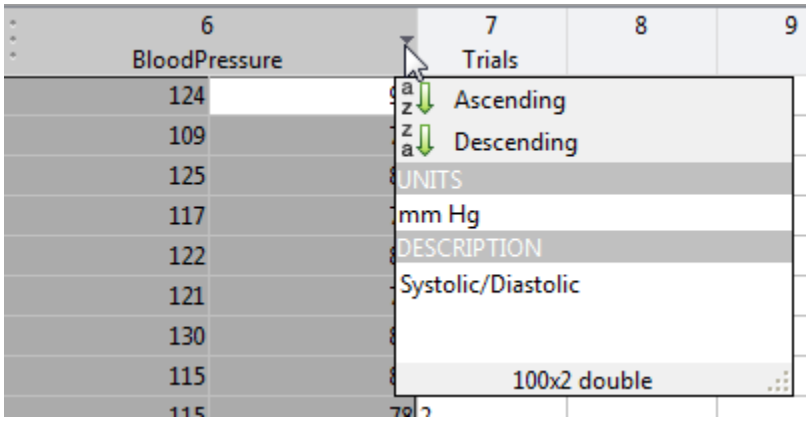




All changes made in the Variables editor are also sent to the command line.

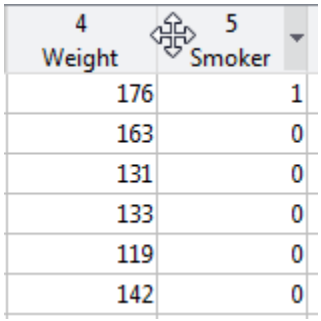
```
Command Window
>> hospital.Properties.VarNames{2} = 'Gender';
>>
```

The sixth variable in the data set, `BloodPressure`, is a numeric array with two columns. The first column shows systolic blood pressure, and the second column shows diastolic blood pressure. Click the arrow that appears on the right side of the variable name cell to see the units and description of the variable. You can type directly in the units and description fields to modify the text. The variable data type and size are shown under the variable description.

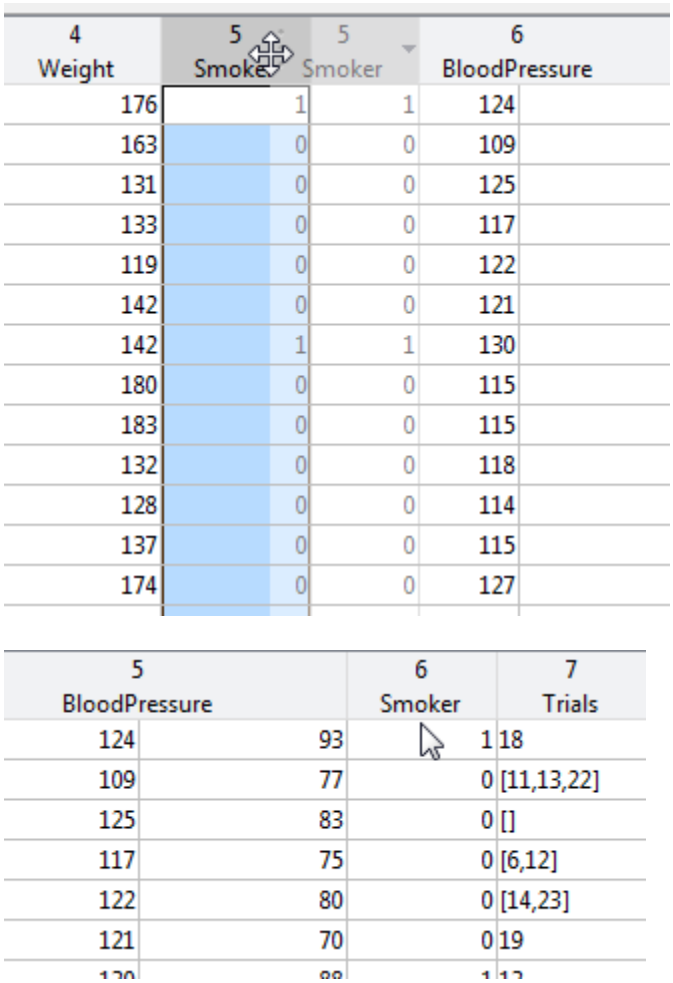


Reorder or Delete Variables

You can reorder variables in a dataset array using the Variables editor. Hover over the left side of a variable name cell until a four-headed arrow appears.



After the arrow appears, click and drag the variable column to a new location.



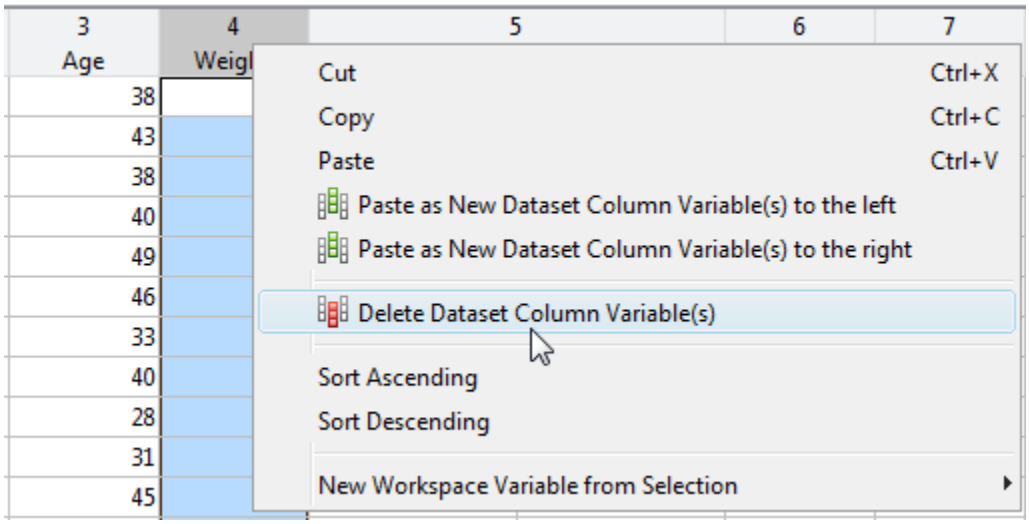
4 Weight	5 Smoke	5 Smoker	6 BloodPressure
176	1	1	124
163	0	0	109
131	0	0	125
133	0	0	117
119	0	0	122
142	0	0	121
142	1	1	130
180	0	0	115
183	0	0	115
132	0	0	118
128	0	0	114
137	0	0	115
174	0	0	127

5 BloodPressure		6 Smoker	7 Trials
124	93	1	18
109	77	0	[11,13,22]
125	83	0	[]
117	75	0	[6,12]
122	80	0	[14,23]
121	70	0	19

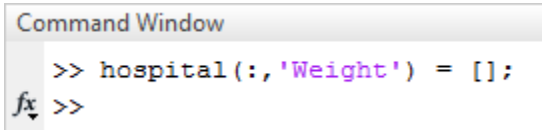
The command for the variable reordering appears in the command line.

```
Command Window
>> hospital = hospital(:,[1:4 6 5 end]);
>>
```

You can delete a variable in the Variables editor by selecting the variable column, right-clicking, and selecting **Delete Column Variable(s)**.

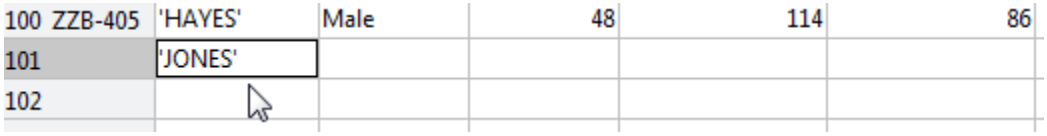


The command for the variable deletion appears in the command line.

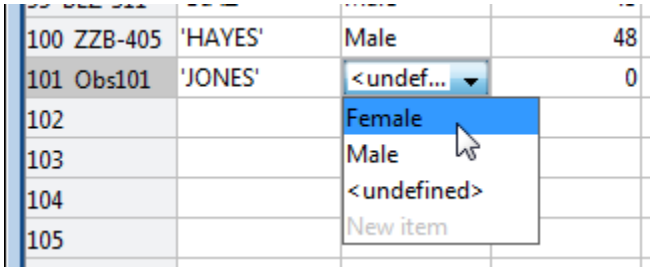


Add New Data

You can enter new data values directly into the Variables editor. For example, you can add a new patient observation to the `hospital` data set. To enter a new last name, add a character vector to the end of the variable `LastName`.



The variable `Gender` is a `nominal` array. The levels of the categorical variable appear in a drop-down list when you double-click a cell in the `Gender` column. You can choose one of the levels previously used, or create a new level by selecting **New Item**.



You can continue to add data for the remaining variables.

To change the observation name, click the observation name and type the new name.

100	ZZB-405	'HAYES'	Male	48
101	Obs101	'JONES'	Female	45
102				

The commands for entering the new data appear at the command line.

```
Command Window
>> hospital.LastName{101} = 'JONES';
Warning: Observations with default values added to dataset
variables.
> In dataset.subsasgn at 584
>> hospital.Sex(101) = 'Female';
>> hospital.Age(101) = 45;
>> hospital.BloodPressure(101,2) = 85;
>> hospital.BloodPressure(101,1) = 120;
>> hospital.Properties.ObsNames{101} = 'QPO-187';
fx >>
```

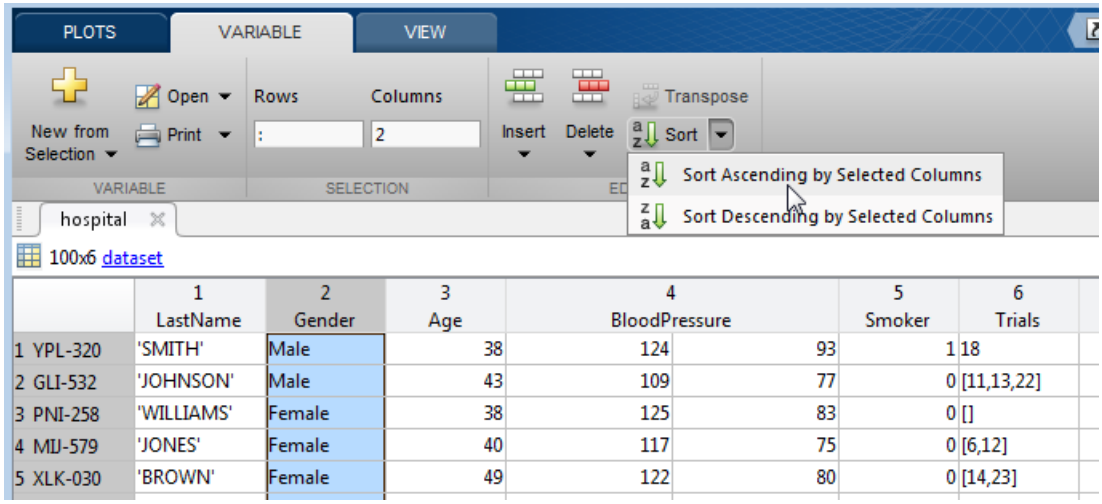
Notice the warning that appears after the first assignment. When you enter the first piece of data in the new observation row—here, the last name—default values are assigned to all other variables. Default assignments are:

- `0` for numeric variables
- `<undefined>` for categorical variables
- `[]` for cell arrays

You can also copy and paste data from one dataset array to another using the Variables editor.

Sort Observations

You can use the Variables editor to sort dataset array observations by the values of one or more variables. To sort by gender, for example, select the variable `Gender`. Then click **Sort**, and choose to sort rows by ascending or descending values of the selected variable.



When sorting by variables that are cell arrays of character vectors or of nominal data type, observations are sorted alphabetically. For ordinal variables, rows are sorted by the ordering of the levels. For example, when the observations of `hospital` are sorted by the values in `Gender`, the females are grouped together, followed by the males.

	1 LastName	2 Gender	3 Age
1	PNI-258	'WILLIAMS'	Female	38
2	MIJ-579	'JONES'	Female	40
3	XLK-030	'BROWN'	Female	49
4	TFP-518	'DAVIS'	Female	46
5	LPD-746	'MILLER'	Female	33
6	LQW-768	'TAYLOR'	Female	31
7	QFY-472	'ANDERSON'	Female	45
8	UJG-627	'THOMAS'	Female	42
9	ELG-976	'HARRIS'	Female	36
10	XBR-291	'GARCIA'	Female	27
11	RKD-785	'CLARK'	Female	48

To sort by the values of multiple variables, press **Ctrl** while you select multiple variables.

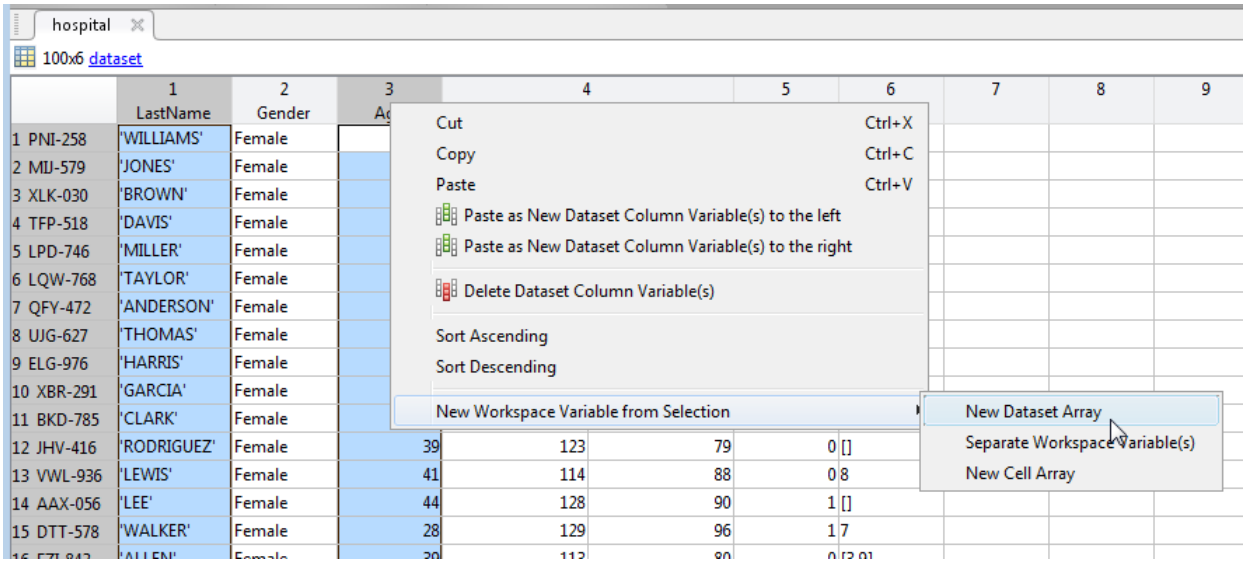
When you use the Variables editor to sort rows, it is the same as calling `sortrows`. You can see this at the command line after executing the sorting.

```
Command Window
>> hospital = sortrows(hospital,'Gender','ascend');
>>
```

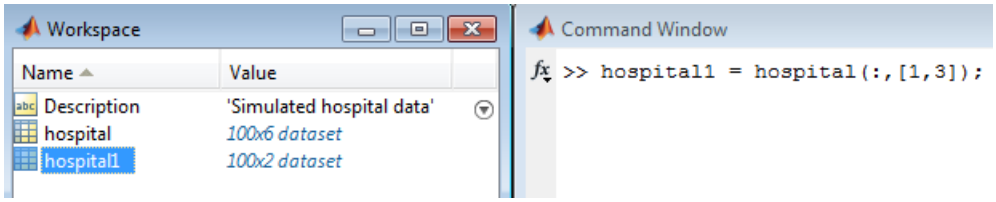
Select a Subset of Data

You can select a subset of data from a dataset array in the Variables editor, and create a new dataset array from the selection. For example, to create a dataset array containing only the variables `LastName` and `Age`:

1. Hold **Ctrl** while you click the variables `LastName` and `Age`.
2. Right-click, and select **New Workspace Variable from Selection** > **New Dataset Array**.



The new dataset array appears in the Workspace window with the name `hospital1`. The Command Window shows the commands that execute the selection.

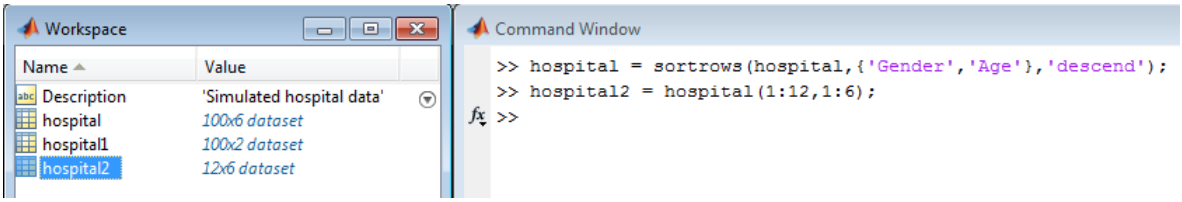


You can use the same steps to select any subset of data. To select observations according to some logical condition, you can use a combination of sorting and selecting. For example, to create a new dataset array containing only males aged 45 and older:

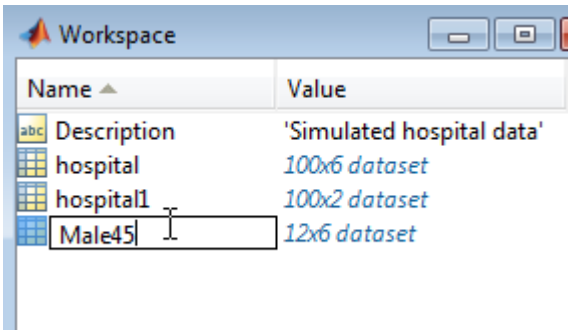
1. Sort the observations of `hospital` by the values in `Gender` and `Age`, descending.
2. Select the male observations with age 45 and older.

	1 LastName	2 Gender	3 Age	4 BloodPressure		5 Smoker	6 Trials
1	XBA-581	'ROBINSON'	Male	50	125	76	0 [20,26,30]
2	DAU-529	'REED'	Male	50	129	89	1 22
3	FLJ-908	'STEWART'	Male	49	129	95	1 15
4	MEZ-469	'GRIFFIN'	Male	49	119	74	0 9
5	KOQ-996	'MARTIN'	Male	48	130	92	1 [13,15,21,27]
6	FCD-425	'GONZALES'	Male	48	123	79	0 []
7	ZZB-405	'HAYES'	Male	48	114	86	0 28
8	YYV-570	'SCOTT'	Male	47	127	84	0 8
9	VDZ-577	'PHILLIPS'	Male	45	117	89	0 [10,15,17,19]
10	WCJ-997	'BELL'	Male	45	138	82	1 7
11	AGR-528	'SIMMONS'	Male	45	124	77	0 [8,18,25]
12	BEZ-311	'DIAZ'	Male	45	136	93	1 []
13	MSL-692	'GREEN'	Male	44	121	92	0 []
14	WTL-804	'BAKER'	Male	44	136	90	1 21
15	AFB-271	'PEREZ'	Male	44	116	80	0 [12,19]
16	RVS-253	'ROBERTS'	Male	44	132	89	1 []
17	HVR-372	'RUSSELL'	Male	44	124	92	1 22

3 Right-click, and select **New Workspace Variables from Selection > New Dataset Array**. The new dataset array, `hospital2`, is created in the Workspace window.



4 You can rename the dataset array in the Workspace window.



Create Plots

You can plot data from a dataset array using plotting options in the Variables editor. Available plot choices depend on the data types of variables to be plotted.

For example, if you select the variable `Age`, you can see in the **Plots** tab some plotting options that are appropriate for a univariate, numeric variable.

	1 LastName	2 Gender	3 Age	4 BloodPressure	
1	XBA-581	'ROBINSON'	Male	50	125	76
2	DAU-529	'REED'	Male	50	129	89
3	FLJ-908	'STEWART'	Male	49	129	95
4	MEZ-469	'GRIFFIN'	Male	49	119	74
5	KOQ-996	'MARTIN'	Male	48	130	92
6	FCD-425	'GONZALES'	Male	48	123	79

Sometimes, there are plot options for multiple variables, depending on their data types. For example, if you select both `Age` and `Gender`, you can draw box plots of age, grouped by gender.

	1 LastName	2 Gender	3 Age
1	XBA-581	'ROBINSON'	Male	50
2	DAU-529	'REED'	Male	50
3	FLJ-908	'STEWART'	Male	49
4	MEZ-469	'GRIFFIN'	Male	49
5	KOQ-996	'MARTIN'	Male	48

Dataset Arrays

Note The `dataset` data type is not recommended. To work with heterogeneous data, use the MATLAB `table` data type instead. See MATLAB `table` documentation for more information.

In this section...

What Are Dataset Arrays?

Statistics and Machine Learning Toolbox has dataset arrays for storing variables with heterogeneous data types. For example, you can combine numeric data, logical data, cell arrays of character vectors, and categorical arrays in one dataset array variable.

Within a dataset array, each variable (column) must be one homogeneous data type, but the different variables can be of heterogeneous data types. A dataset array is usually interpreted as a set of variables measured on many units of observation. That is, each row in a dataset array corresponds to an observation, and each column to a variable. In this sense, a dataset array organizes data like a typical spreadsheet.

Dataset arrays are a unique data type, with a corresponding set of valid operations. Even if a dataset array contains only numeric variables, you cannot operate on the dataset array like a numeric variable. The valid operations for dataset arrays are the methods of the `dataset` class.

Dataset Array Conversion

You can create a dataset array by combining variables that exist in the MATLAB workspace, or directly importing data from a file, such as a text file or spreadsheet. This table summarizes the functions you can use to create dataset arrays.

Data Source	Conversion to Dataset Array
Data from a file	`dataset`
Heterogeneous collection of workspace variables	`dataset`
Numeric array	`mat2dataset`
Cell array	`cell2dataset`
Structure array	`struct2dataset`
Table	`table2dataset`

You can export dataset arrays to text or spreadsheet files using `export`. To convert a dataset array to a cell array or structure array, use `dataset2cell` or `dataset2struct`. To convert a dataset array to a table, use `dataset2table`.

Dataset Array Properties

In addition to storing data in a dataset array, you can store metadata such as:

- Variable and observation names
- Data descriptions
- Units of measurement
- Variable descriptions

This information is stored as dataset array properties. For a dataset array named `ds`, you can view the dataset array metadata by entering `ds.Properties` at the command line. You can access a specific property, such as variable names—property `VarNames`—using `ds.Properties.VarNames`. You can both retrieve and modify property values using this syntax.

Variable and observation names are included in the display of a dataset array. Variable names display across the top row, and observation names, if present, appear in the first column. Note that variable and observation names do not affect the size of a dataset array.

Index and Search Dataset Arrays

Note The `dataset` data type is not recommended. To work with heterogeneous data, use the MATLAB `table` data type instead. See MATLAB `table` documentation for more information.

Ways To Index and Search

There are many ways to index into dataset arrays. For example, for a dataset array, `ds`, you can:

- Use `()` to create a new dataset array from a subset of `ds`. For example, `ds1 = ds(1:5,:)` creates a new dataset array, `ds1`, consisting of the first five rows of `ds`. Metadata, including variable and observation names, transfers to the new dataset array.
- Use variable names with dot notation to index individual variables in a dataset array. For example, `ds.Height` indexes the variable named `Height`.
- Use observation names to index individual observations in a dataset array. For example, `ds('Obs1',:)` gives data for the observation named `Obs1`.
- Use observation or variable numbers. For example, `ds(:,[1,3,5])` gives the data in the first, third, and fifth variables (columns) of `ds`.
- Use logical indexing to search for observations in `ds` that satisfy a logical condition. For example, `ds(ds.Gender=='Male',:)` gives the observations in `ds` where the variable named `Gender`, a nominal array, has the value `Male`.
- Use `ismissing` to find missing data in the dataset array.

Examples

Common Indexing and Searching Methods

This example shows several indexing and searching methods for categorical arrays.

Load the sample data.

```
load hospital;
size(hospital)
```

```
ans = 1×2

   100     7
```

The dataset array has 100 observations and 7 variables.

Index a variable by name. Return the minimum age in the dataset array.

```
min(hospital.Age)
```

```
ans = 25
```

Delete the variable `Trials`.

```
hospital.Trials = [];
size(hospital)
```

```
ans = 1×2

   100     6
```

Index an observation by name. Display measurements on the first five variables for the observation named PUE-347.

```
hospital('PUE-347',1:5)
```

```
ans =
                LastName          Sex       Age    Weight    Smoker
    PUE-347     {'YOUNG'}         Female    25     114       false
```

Index variables by number. Create a new dataset array containing the first four variables of hospital.

```
dsNew = hospital(:,1:4);
dsNew.Properties.VarNames(:)
```

```
ans = 4x1 cell
    {'LastName'}
    {'Sex'     }
    {'Age'     }
    {'Weight'  }
```

Index observations by number. Delete the last 10 observations.

```
hospital(end-9:end,:) = [];
size(hospital)
```

```
ans = 1×2

    90     6
```

Search for observations by logical condition. Create a new dataset array containing only females who smoke.

```
dsFS = hospital(hospital.Sex=='Female' & hospital.Smoker==true,:);
dsFS(:,{'LastName','Sex','Smoker'})
```

```
ans =
                LastName             Sex       Smoker
    LPD-746     {'MILLER'   }        Female    true
    XBR-291     {'GARCIA'   }        Female    true
    AAX-056     {'LEE'      }        Female    true
    DTT-578     {'WALKER'   }        Female    true
    AFK-336     {'WRIGHT'   }        Female    true
    RBA-579     {'SANCHEZ'  }        Female    true
    HAK-381     {'MORRIS'   }        Female    true
    NSK-403     {'RAMIREZ'  }        Female    true
    ILS-109     {'WATSON'   }        Female    true
    JDR-456     {'SANDERS'  }        Female    true
    HWZ-321     {'PATTERSON'}        Female    true
    GGU-691     {'HUGHES'   }        Female    true
```

```
    WUS-105    {'FLORES'   }        Female    true
```

Descriptive Statistics

Measures of Central Tendency

Measures of central tendency locate a distribution of data along an appropriate scale.

The following table lists the functions that calculate the measures of central tendency.

Function Name	Description
`geomean`	Geometric mean
`harmmean`	Harmonic mean
`mean`	Arithmetic average
`median`	50th percentile
`mode`	Most frequent value
`trimmean`	Trimmed mean

The average is a simple and popular estimate of location. If the data sample comes from a normal distribution, then the sample mean is also optimal (minimum variance unbiased estimator (MVUE) of μ).

Unfortunately, outliers, data entry errors, or glitches exist in almost all real data. The sample mean is sensitive to these problems. One bad data value can move the average away from the center of the rest of the data by an arbitrarily large distance.

The median and trimmed mean are two measures that are resistant (robust) to outliers. The median is the 50th percentile of the sample, which will only change slightly if you add a large perturbation to any value. The idea behind the trimmed mean is to ignore a small percentage of the highest and lowest values of a sample when determining the center of the sample.

The geometric mean and harmonic mean, like the average, are not robust to outliers. They are useful when the sample is distributed lognormal or heavily skewed.

Measures of Central Tendency

This example shows how to compute and compare measures of location for sample data that contains one outlier.

Generate sample data that contains one outlier.

```
x = [ones(1,6),100]
```

```
x = 1×7

     1     1     1     1     1     1   100
```

Compute the geometric mean, harmonic mean, mean, median, and trimmed mean for the sample data.

```
locate = [geomean(x) harmmean(x) mean(x) median(x)...
          trimmean(x,25)]
```

```
locate = 1×5
```

```
    1.9307    1.1647   15.1429    1.0000    1.0000
```

The mean (`mean`) is far from any data value because of the influence of the outlier. The geometric mean (`geomean`) and the harmonic mean (`harmmean`) are influenced by the outlier, but not as significantly. The median (`median`) and trimmed mean (`trimmean`) ignore the outlier value and describe the location of the rest of the data values.

Measures of Dispersion

The purpose of measures of dispersion is to find out how spread out the data values are on the number line. Another term for these statistics is measures of spread.

The table gives the function names and descriptions.

Function Name	Description
`iqr`	Interquartile range
`mad`	Mean absolute deviation
`moment`	Central moment of all orders
`range`	Range
`std`	Standard deviation
`var`	Variance

The range (the difference between the maximum and minimum values) is the simplest measure of spread. But if there is an outlier in the data, it will be the minimum or maximum value. Thus, the range is not robust to outliers.

The standard deviation and the variance are popular measures of spread that are optimal for normally distributed samples. The sample variance is the minimum variance unbiased estimator (MVUE) of the normal parameter σ^2. The standard deviation is the square root of the variance and has the desirable property of being in the same units as the data. That is, if the data is in meters, the standard deviation is in meters as well. The variance is in meters^2, which is more difficult to interpret.

Neither the standard deviation nor the variance is robust to outliers. A data value that is separate from the body of the data can increase the value of the statistics by an arbitrarily large amount.

The mean absolute deviation (MAD) is also sensitive to outliers. But the MAD does not move quite as much as the standard deviation or variance in response to bad data.

The interquartile range (IQR) is the difference between the 75th and 25th percentile of the data. Since only the middle 50% of the data affects this measure, it is robust to outliers.

Compare Measures of Dispersion

This example shows how to compute and compare measures of dispersion for sample data that contains one outlier.

Generate sample data that contains one outlier value.

```
x = [ones(1,6),100]
```

```
x = 1×7

     1     1     1     1     1     1   100
```

Compute the interquartile range, mean absolute deviation, range, and standard deviation of the sample data.

```
stats = [iqr(x),mad(x),range(x),std(x)]
```

```
stats = 1×4

         0   24.2449   99.0000   37.4185
```

The interquartile range (`iqr`) is the difference between the 75th and 25th percentile of the sample data, and is robust to outliers. The range (`range`) is the difference between the maximum and minimum values in the data, and is strongly influenced by the presence of an outlier.

Both the mean absolute deviation (`mad`) and the standard deviation (`std`) are sensitive to outliers. However, the mean absolute deviation is less sensitive than the standard deviation.

Quantiles and Percentiles

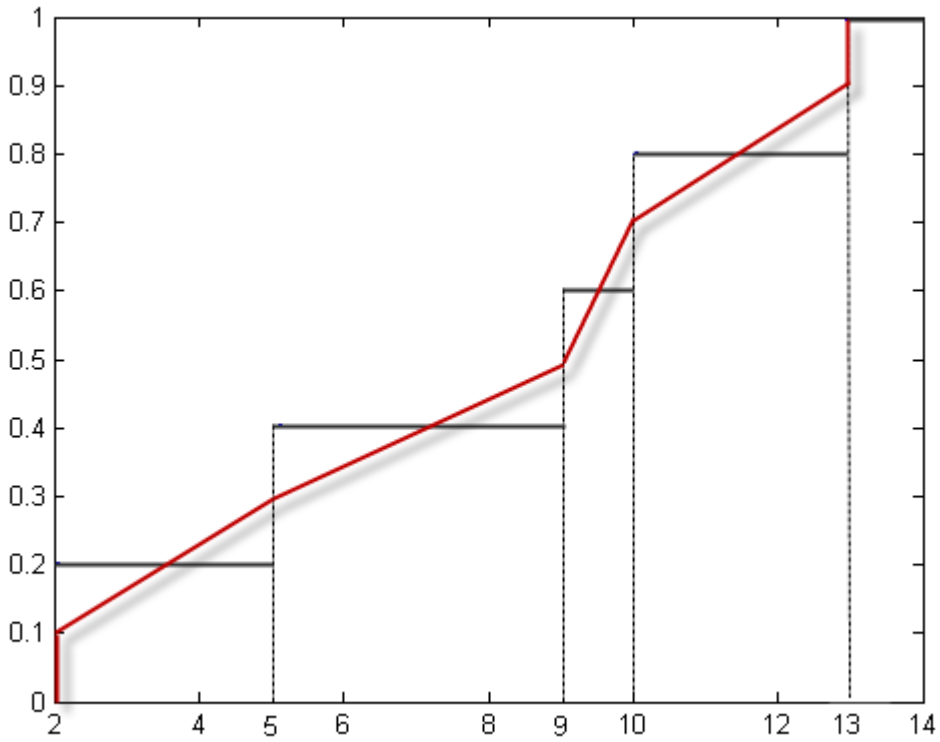
This section explains how the Statistics and Machine Learning Toolbox functions `quantile` and `prctile` compute quantiles and percentiles.

The `prctile` function calculates the percentiles in a similar way as `quantile` calculates quantiles. The following steps in the computation of quantiles are also true for percentiles, given the fact that, for the same data sample, the quantile at the value Q is the same as the percentile at the value P = 100*Q.

1 `quantile` initially assigns the sorted values in X to the (0.5/*n*), (1.5/*n*), ..., ([*n* – 0.5]/*n*) quantiles. For example:

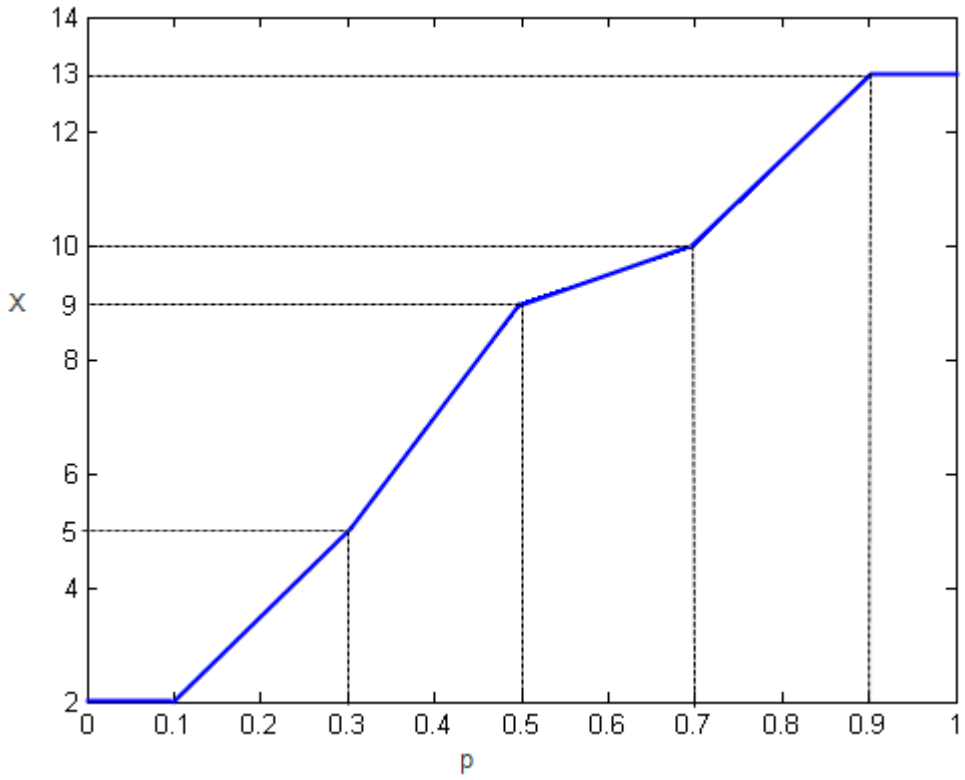
- For a data vector of six elements such as {6, 3, 2, 10, 8, 1}, the sorted elements {1, 2, 3, 6, 8, 10} respectively correspond to the (0.5/6), (1.5/6), (2.5/6), (3.5/6), (4.5/6), and (5.5/6) quantiles.
- For a data vector of five elements such as {2, 10, 5, 9, 13}, the sorted elements {2, 5, 9, 10, 13} respectively correspond to the 0.1, 0.3, 0.5, 0.7, and 0.9 quantiles.

The following figure illustrates this approach for data vector X = {2, 10, 5, 9, 13}. The first observation corresponds to the cumulative probability 1/5 = 0.2, the second observation corresponds to the cumulative probability 2/5 = 0.4, and so on. The step function in this figure shows these cumulative probabilities. `quantile` instead places the observations in midpoints, such that the first corresponds to 0.5/5 = 0.1, the second corresponds to 1.5/5 = 0.3, and so on, and then connects these midpoints. The red lines in the following figure connect the midpoints.



Assigning Observations to Quantiles

By switching the axes, as the next figure, you can see the values of the variable X that correspond to the p quantiles.



Quantiles of *X*

2 `quantile` finds any quantiles between the data values using linear interpolation.

Linear interpolation uses linear polynomials to approximate a function f(x) and construct new data points within the range of a known set of data points. Algebraically, given the data points (x_1, y_1) and (x_2, y_2), where y_1 = f(x_1) and y_2 = f(x_2), linear interpolation finds y = f(x) for a given x between x_1 and x_2 as follows:

$$y = f(x) = y_1 + \frac{(x - x_1)}{(x_2 - x_1)}(y_2 - y_1).$$

Similarly, if the 1.5/n quantile is $y_{1.5/n}$ and the 2.5/n quantile is $y_{2.5/n}$, then linear interpolation finds the 2.3/n quantile $y_{2.3/n}$ as

$$y_{\frac{2.3}{n}} = y_{\frac{1.5}{n}} + \frac{\left(\frac{2.3}{n} - \frac{1.5}{n}\right)}{\left(\frac{2.5}{n} - \frac{1.5}{n}\right)}\left(y_{\frac{2.5}{n}} - y_{\frac{1.5}{n}}\right).$$

3 `quantile` assigns the first and last values of X to the quantiles for probabilities less than (0.5/n) and greater than ([n–0.5]/n), respectively.

Exploratory Analysis of Data

This example shows how to explore the distribution of data using descriptive statistics.

Generate sample data.

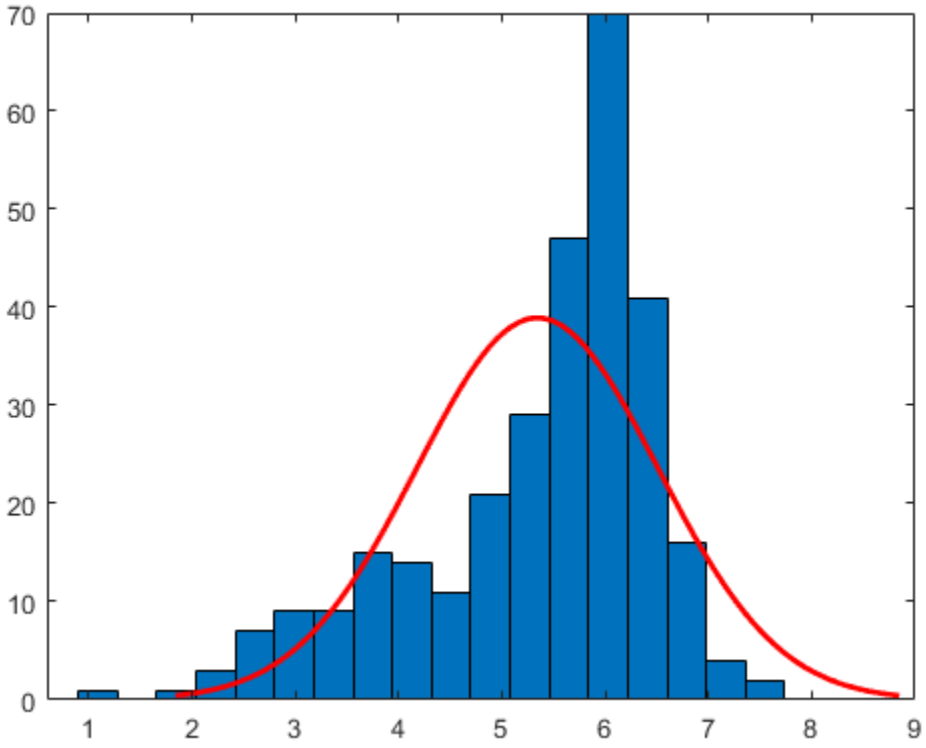
Generate a vector containing randomly-generated sample data.

```
rng default  % For reproducibility
x = [normrnd(4,1,1,100),normrnd(6,0.5,1,200)];
```

Plot a histogram.

Plot a histogram of the sample data with a normal density fit. This provides a visual comparison of the sample data and a normal distribution fitted to the data.

```
histfit(x)
```

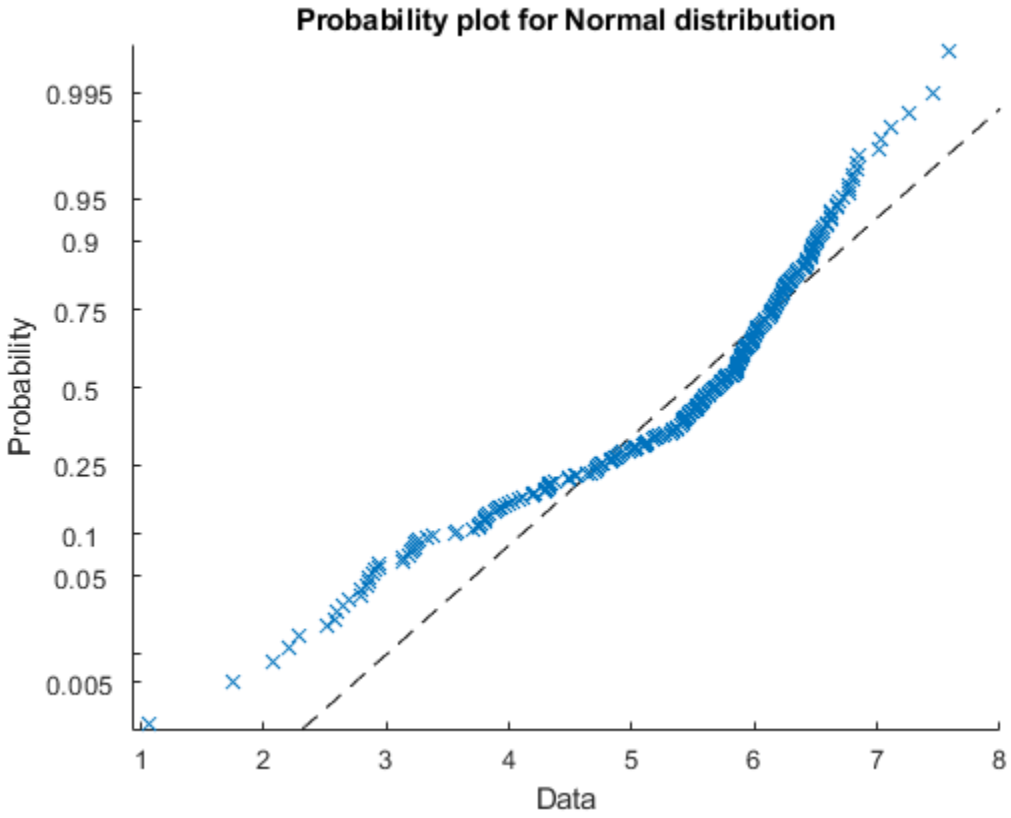


The distribution of the data appears to be left skewed. A normal distribution does not look like a good fit for this sample data.

Obtain a normal probability plot.

Obtain a normal probability plot. This plot provides another way to visually compare the sample data to a normal distribution fitted to the data.

```
probplot('normal',x)
```



The probability plot also shows the deviation of data from normality.

Compute the quantiles.

Compute the quantiles of the sample data.

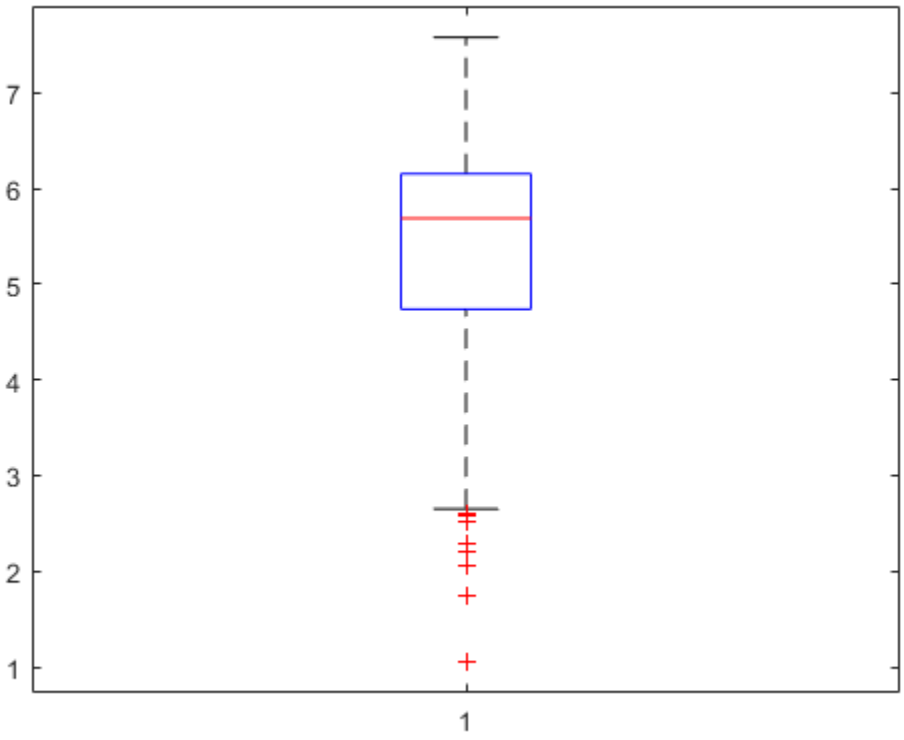
```
p = 0:0.25:1;
y = quantile(x,p);
z = [p;y]
```

```
z = 2×5

         0    0.2500    0.5000    0.7500    1.0000
    1.0557    4.7375    5.6872    6.1526    7.5784
```

Create a box plot to visualize the statistics.

```
boxplot(x)
```



The box plot shows the 0.25, 0.5, and 0.75 quantiles. The long lower tail and plus signs show the lack of symmetry in the sample data values.

Compute descriptive statistics.

Compute the mean and median of the data.

```
y = [mean(x),median(x)]
```

```
y = 1×2

    5.3438    5.6872
```

The mean and median values seem close to each other, but a mean smaller than the median usually indicates that the data is left skewed.

Compute the skewness and kurtosis of the data.

```
y = [skewness(x),kurtosis(x)]
```

```
y = 1×2

   -1.0417    3.5895
```

A negative skewness value means the data is left skewed. The data has a larger peakedness than a normal distribution because the kurtosis value is greater than 3.

Compute z-scores.

Identify possible outliers by computing the z-scores and finding the values that are greater than 3 or less than -3.

```
Z = zscore(x);
find(abs(Z)>3);
```

Based on the z-scores, the 3rd and 35th observations might be outliers.

Resampling Statistics

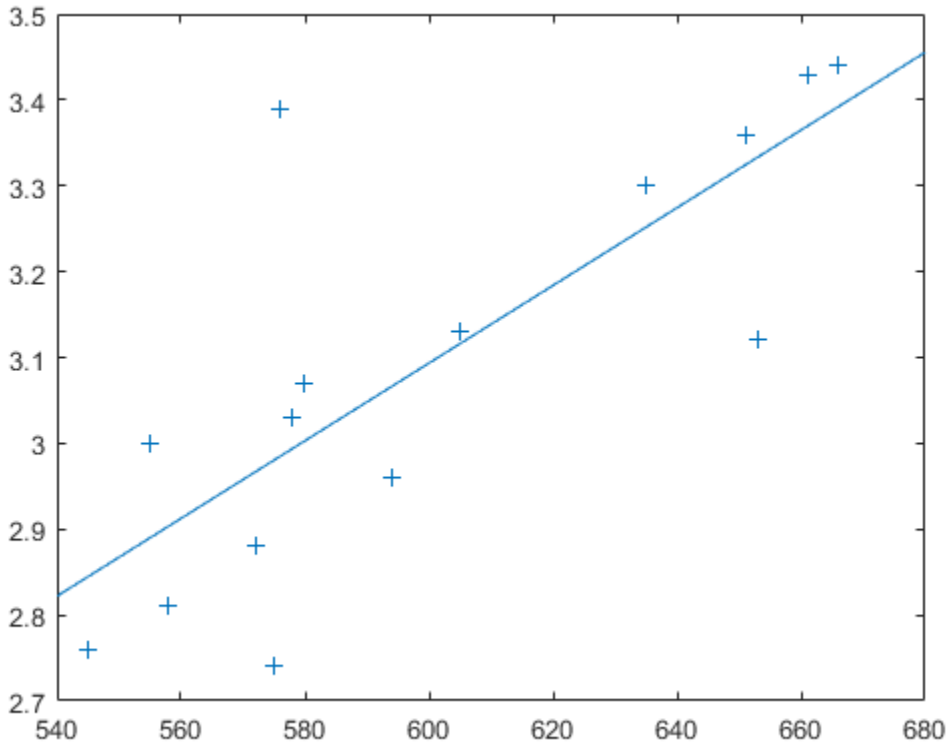
In this section...

Bootstrap Resampling

The bootstrap procedure involves choosing random samples with replacement from a data set and analyzing each sample the same way. Sampling with replacement means that each observation is selected separately at random from the original dataset. So a particular data point from the original data set could appear multiple times in a given bootstrap sample. The number of elements in each bootstrap sample equals the number of elements in the original data set. The range of sample estimates you obtain enables you to establish the uncertainty of the quantity you are estimating.

This example from Efron and Tibshirani compares Law School Admission Test (LSAT) scores and subsequent law school grade point average (GPA) for a sample of 15 law schools.

```
load lawdata
plot(lsat,gpa,'+')
lsline
```



The least-squares fit line indicates that higher LSAT scores go with higher law school GPAs. But how certain is this conclusion? The plot provides some intuition, but nothing quantitative.

You can calculate the correlation coefficient of the variables using the |corr|function.

```
rhohat = corr(lsat,gpa)
```

```
rhohat = 0.7764
```

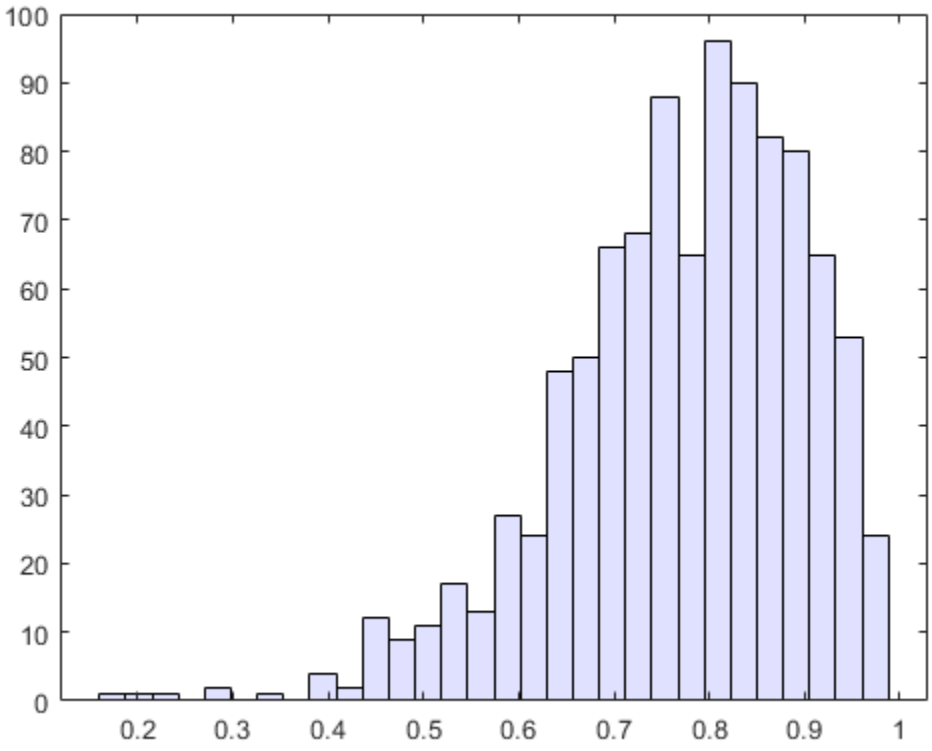
Now you have a number describing the positive connection between LSAT and GPA; though it may seem large, you still do not know if it is statistically significant.

Using the `bootstrp` function you can resample the `lsat` and `gpa` vectors as many times as you like and consider the variation in the resulting correlation coefficients.

```
rng default  % For reproducibility
rhos1000 = bootstrp(1000,'corr',lsat,gpa);
```

This resamples the `lsat` and `gpa` vectors 1000 times and computes the `corr` function on each sample. You can then plot the result in a histogram.

```
histogram(rhos1000,30,'FaceColor',[.8 .8 1])
```



Nearly all the estimates lie on the interval [0.4 1.0].

It is often desirable to construct a confidence interval for a parameter estimate in statistical inferences. Using the `bootci` function, you can use bootstrapping to obtain a confidence interval for the `lsat` and `gpa` data.

```
ci = bootci(5000,@corr,lsat,gpa)
```

```
ci = 2×1

    0.3319
    0.9427
```

Therefore, a 95% confidence interval for the correlation coefficient between LSAT and GPA is [0.33 0.94]. This is strong quantitative evidence that LSAT and subsequent GPA are positively correlated. Moreover, this evidence does not require any strong assumptions about the probability distribution of the correlation coefficient.

Although the `bootci` function computes the Bias Corrected and accelerated (BCa) interval as the default type, it is also able to compute various other types of bootstrap confidence intervals, such as the studentized bootstrap confidence interval.

Jackknife Resampling

Similar to the bootstrap is the jackknife, which uses resampling to estimate the bias of a sample statistic. Sometimes it is also used to estimate standard error of the sample statistic. The jackknife is implemented by the Statistics and Machine Learning Toolbox™ function `jackknife`.

The jackknife resamples systematically, rather than at random as the bootstrap does. For a sample with `n` points, the jackknife computes sample statistics on `n` separate samples of size `n`-1. Each sample is the original data with a single observation omitted.

In the bootstrap example, you measured the uncertainty in estimating the correlation coefficient. You can use the jackknife to estimate the bias, which is the tendency of the sample correlation to over-estimate or under-estimate the true, unknown correlation. First compute the sample correlation on the data.

```
load lawdata
rhohat = corr(lsat,gpa)
```

```
rhohat = 0.7764
```

Next compute the correlations for jackknife samples, and compute their mean.

```
rng default;  % For reproducibility
jackrho = jackknife(@corr,lsat,gpa);
meanrho = mean(jackrho)
```

```
meanrho = 0.7759
```

Now compute an estimate of the bias.

```
n = length(lsat);
biasrho = (n-1) * (meanrho-rhohat)
```

```
biasrho = -0.0065
```

The sample correlation probably underestimates the true correlation by about this amount.

Parallel Computing Support for Resampling Methods

For information on computing resampling statistics in parallel, see Parallel Computing Toolbox™.

Statistical Visualization

Create Scatter Plots Using Grouped Data

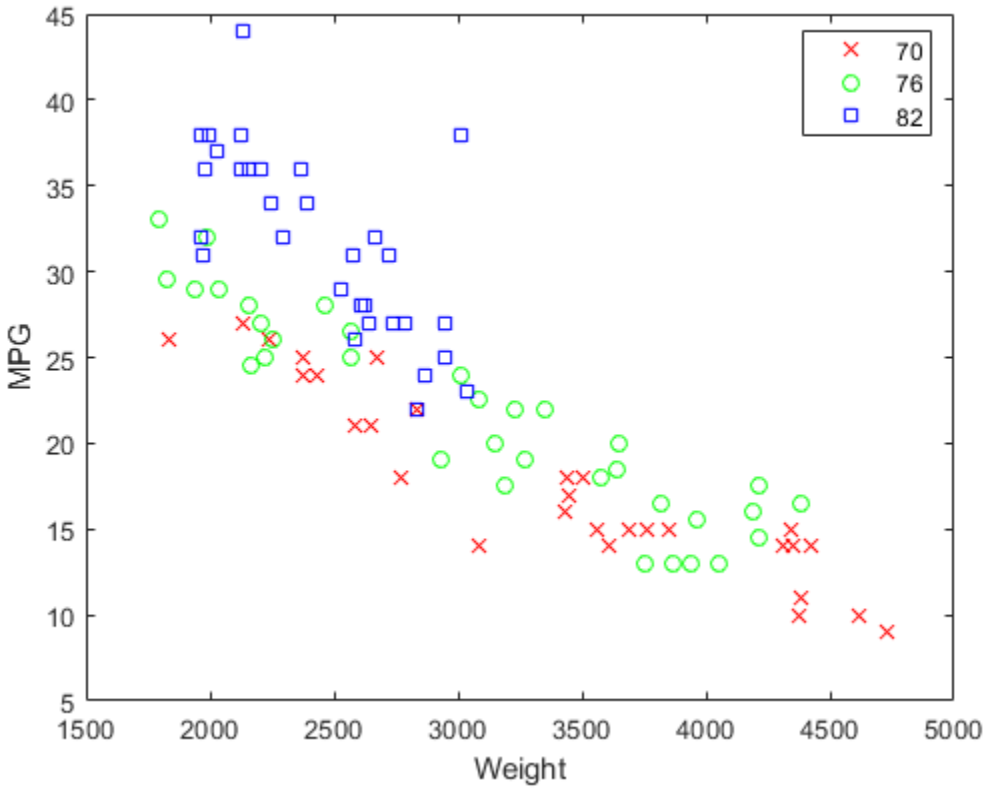
This example shows how to create scatter plots using grouped sample data.

A scatter plot is a simple plot of one variable against another. The MATLAB® functions `plot` and `scatter` produce scatter plots. The MATLAB function `plotmatrix` can produce a matrix of such plots showing the relationship between several pairs of variables.

Statistics and Machine Learning Toolbox™ functions `gscatter` and `gplotmatrix` produce grouped versions of these plots. These functions are useful for determining whether the values of two variables or the relationship between those variables is the same in each group. These functions use different plotting symbols to indicate group membership. You can use `gname` to label points on the plots with a text label or an observation number.

Suppose you want to examine the weight and mileage of cars from three different model years.

```
load carsmall
gscatter(Weight,MPG,Model_Year,'','xos')
```

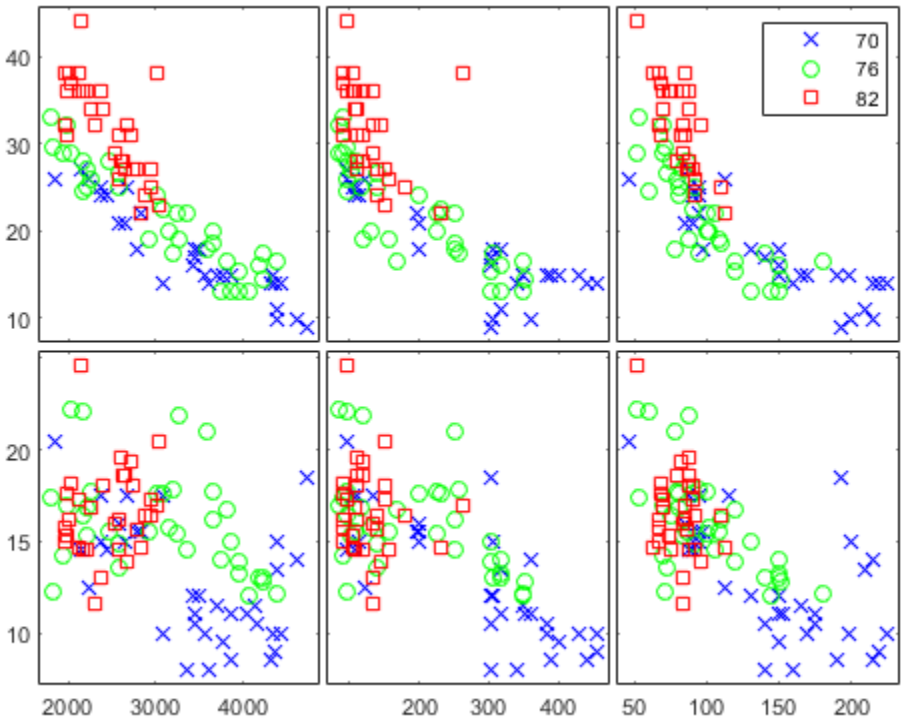


This shows that not only is there a strong relationship between the weight of a car and its mileage, but also that newer cars tend to be lighter and have better gas mileage than older cars.

The default arguments for `gscatter` produce a scatter plot with the different groups shown with the same symbol but different colors. The last two arguments above request that all groups be shown in default colors and with different symbols.

The `carsmall` data set contains other variables that describe different aspects of cars. You can examine several of them in a single display by creating a grouped plot matrix.

```
xvars = [Weight Displacement Horsepower];
yvars = [MPG Acceleration];
gplotmatrix(xvars,yvars,Model_Year,'','xos')
```



The upper right subplot displays `MPG` against `Horsepower`, and shows that over the years the horsepower of the cars has decreased but the gas mileage has improved.

The `gplotmatrix` function can also graph all pairs from a single list of variables, along with histograms for each variable. See “MANOVA” on page 9-49.

- “Grouping Variables” on page 2-45

Compare Grouped Data Using Box Plots

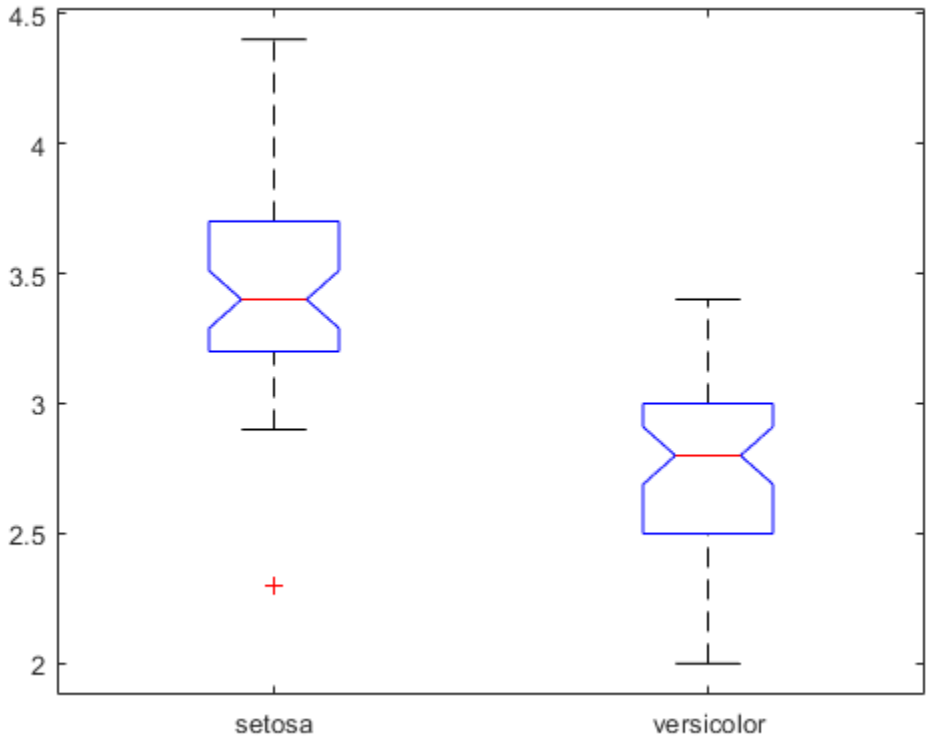
This example shows how to compare two groups of data by creating a notched box plot. Notches display the variability of the median between samples. The width of a notch is computed so that boxes whose notches do not overlap have different medians at the 5% significance level. The significance level is based on a normal distribution assumption, but comparisons of medians are reasonably robust for other distributions. Comparing box plot medians is like a visual hypothesis test, analogous to the *t* test used for means. For more information on the different features of a box plot, see “Box Plot” on page 33-236.

Load the `fisheriris` data set. The data set contains length and width measurements from the sepals and petals of three species of iris flowers. Store the sepal width data for the setosa irises as `s1`, and the sepal width data for the versicolor irises as `s2`.

```
load fisheriris
s1 = meas(1:50,2);
s2 = meas(51:100,2);
```

Create a notched box plot using the sample data, and label each box with the name of the iris species it represents.

```
boxplot([s1 s2],'Notch','on', ...
        'Labels',{'setosa','versicolor'})
```

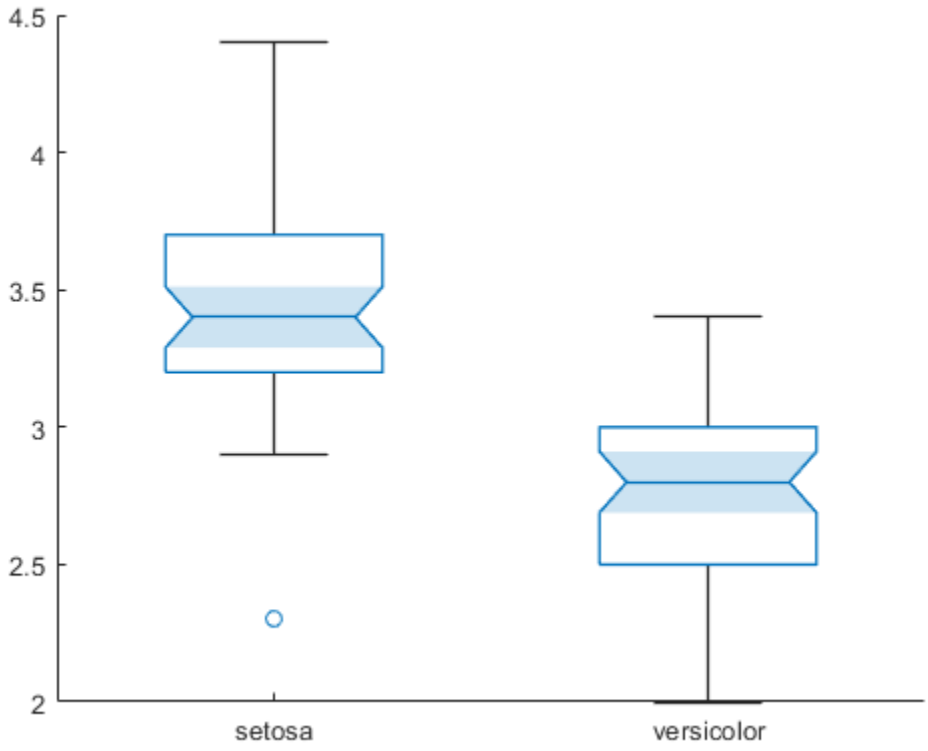


The notches of the two boxes do not overlap, which indicates that the median sepal widths of the setosa and versicolor irises are significantly different at the 5% significance level. Neither the red

median line in the setosa box nor the red median line in the versicolor box appears to be centered inside its box, which indicates that each sample is slightly skewed. Additionally, the setosa data contains one outlier value, while the versicolor data does not contain any outliers.

Instead of using the `boxplot` function, you can use the `boxchart` MATLAB® function to create box plots. Recreate the previous plot by using the `boxchart` function rather than `boxplot`.

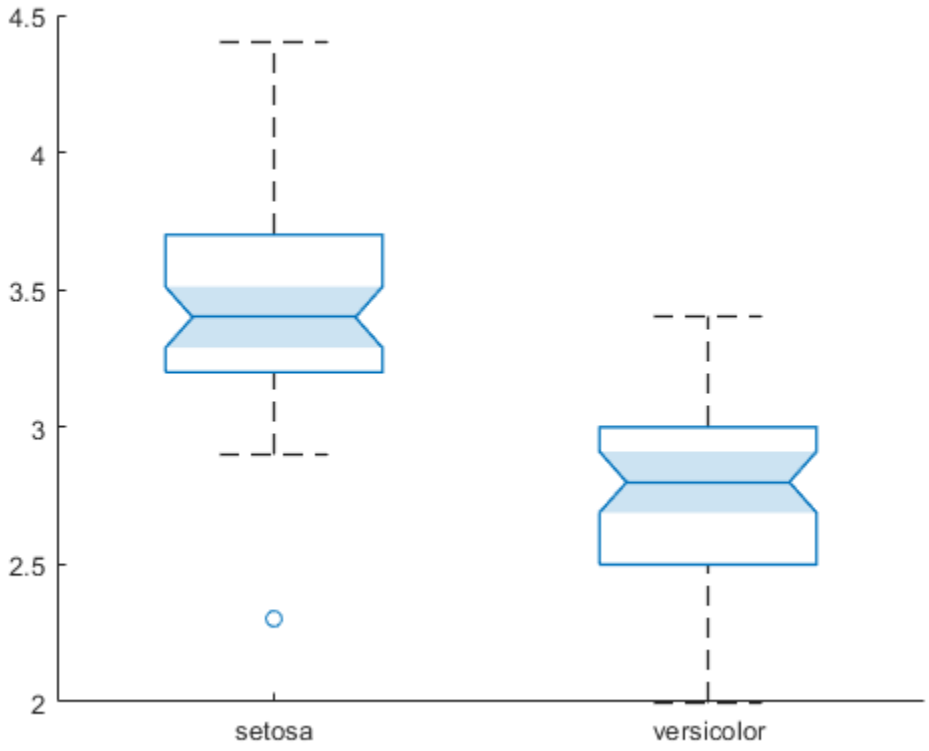
```
speciesName = categorical(species(1:100));
sepalWidth = meas(1:100,2);
b = boxchart(speciesName,sepalWidth,'Notch','on');
```



Each notch created by `boxchart` is a tapered, shaded region around the median line. The shading helps to better identify the notches.

One advantage of using `boxchart` is that the function creates a `BoxChart` object, whose properties you can change easily by using dot notation. For example, you can alter the style of the whiskers by specifying the `WhiskerLineStyle` property of the object `b`.

```
b.WhiskerLineStyle = '--';
```



For more information on the advantages of using `boxchart`, see “Alternative Functionality” on page 33-238.

Distribution Plots

In this section...

Distribution plots visually assess the distribution of sample data by comparing the empirical distribution of the data with the theoretical values expected from a specified distribution. Use distribution plots in addition to more formal hypothesis tests to determine whether the sample data comes from a specified distribution. To learn about hypothesis tests, see “Hypothesis Testing” on page 8-5.

Statistics and Machine Learning Toolbox offers several distribution plot options:

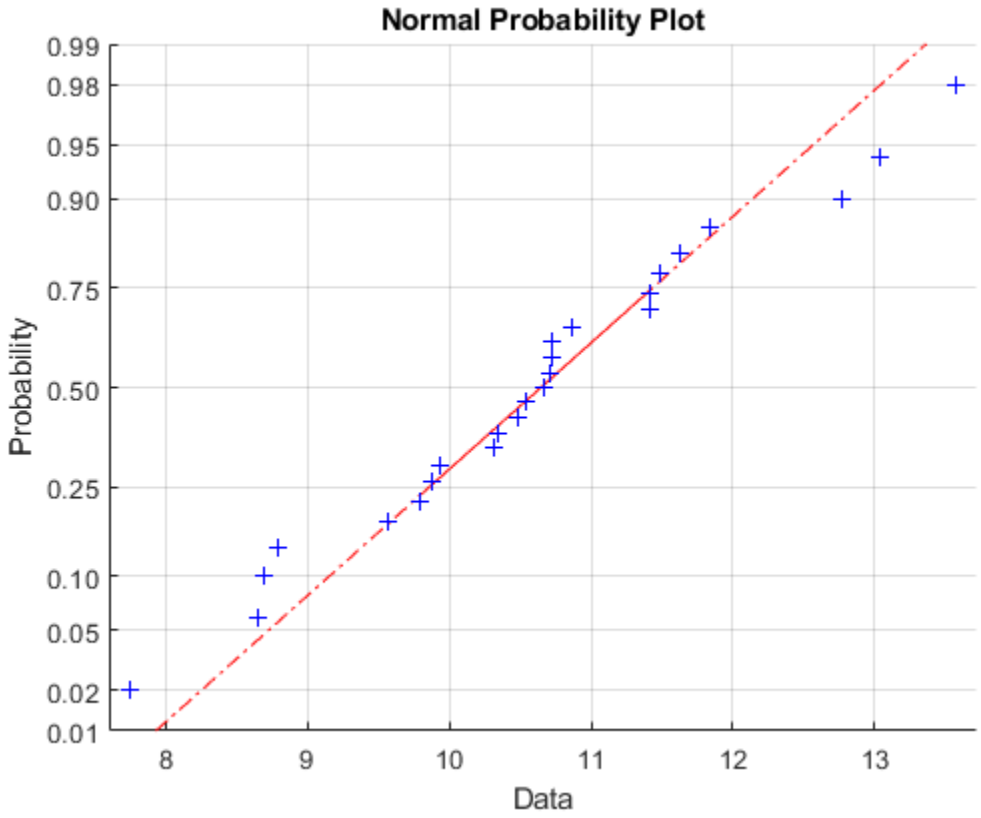
- “Normal Probability Plots” on page 4-7 — Use `normplot` to assess whether sample data comes from a normal distribution. Use `probplot` to create “Probability Plots” on page 4-9 for distributions other than normal, or to explore the distribution of censored data.
- “Quantile-Quantile Plots” on page 4-10 — Use `qqplot` to assess whether two sets of sample data come from the same distribution family. This plot is robust with respect to differences in location and scale.
- “Cumulative Distribution Plots” on page 4-12 — Use `cdfplot` or `ecdf` to display the empirical cumulative distribution function (cdf) of the sample data for visual comparison to the theoretical cdf of a specified distribution.

Normal Probability Plots

Use normal probability plots to assess whether data comes from a normal distribution. Many statistical procedures make the assumption that an underlying distribution is normal. Normal probability plots can provide some assurance to justify this assumption or provide a warning of problems with the assumption. An analysis of normality typically combines normal probability plots with hypothesis tests for normality.

This example generates a data sample of 25 random numbers from a normal distribution with mean 10 and standard deviation 1, and creates a normal probability plot of the data.

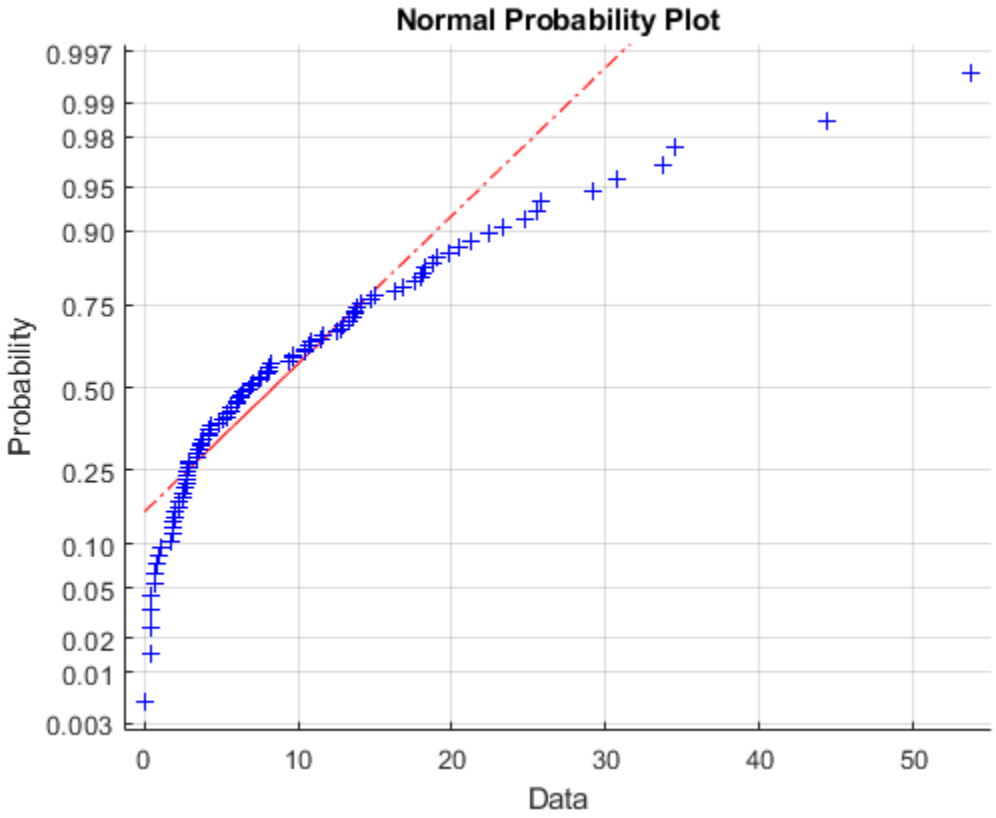
```
rng('default');  % For reproducibility
x = normrnd(10,1,[25,1]);
normplot(x)
```



The plus signs plot the empirical probability versus the data value for each point in the data. A solid line connects the 25th and 75th percentiles in the data, and a dashed line extends it to the ends of the data. The *y*-axis values are probabilities from zero to one, but the scale is not linear. The distance between tick marks on the *y*-axis matches the distance between the quantiles of a normal distribution. The quantiles are close together near the median (50th percentile) and stretch out symmetrically as you move away from the median.

In a normal probability plot, if all the data points fall near the line, an assumption of normality is reasonable. Otherwise, an assumption of normality is not justified. For example, the following generates a data sample of 100 random numbers from an exponential distribution with mean 10, and creates a normal probability plot of the data.

```
x = exprnd(10,100,1);
normplot(x)
```



The plot is strong evidence that the underlying distribution is not normal.

Probability Plots

A probability plot, like the normal probability plot, is just an empirical cdf plot scaled to a particular distribution. The *y*-axis values are probabilities from zero to one, but the scale is not linear. The distance between tick marks is the distance between quantiles of the distribution. In the plot, a line is drawn between the first and third quartiles in the data. If the data falls near the line, it is reasonable to choose the distribution as a model for the data. A distribution analysis typically combines probability plots with hypothesis tests for a particular distribution.

Create Weibull Probability Plot

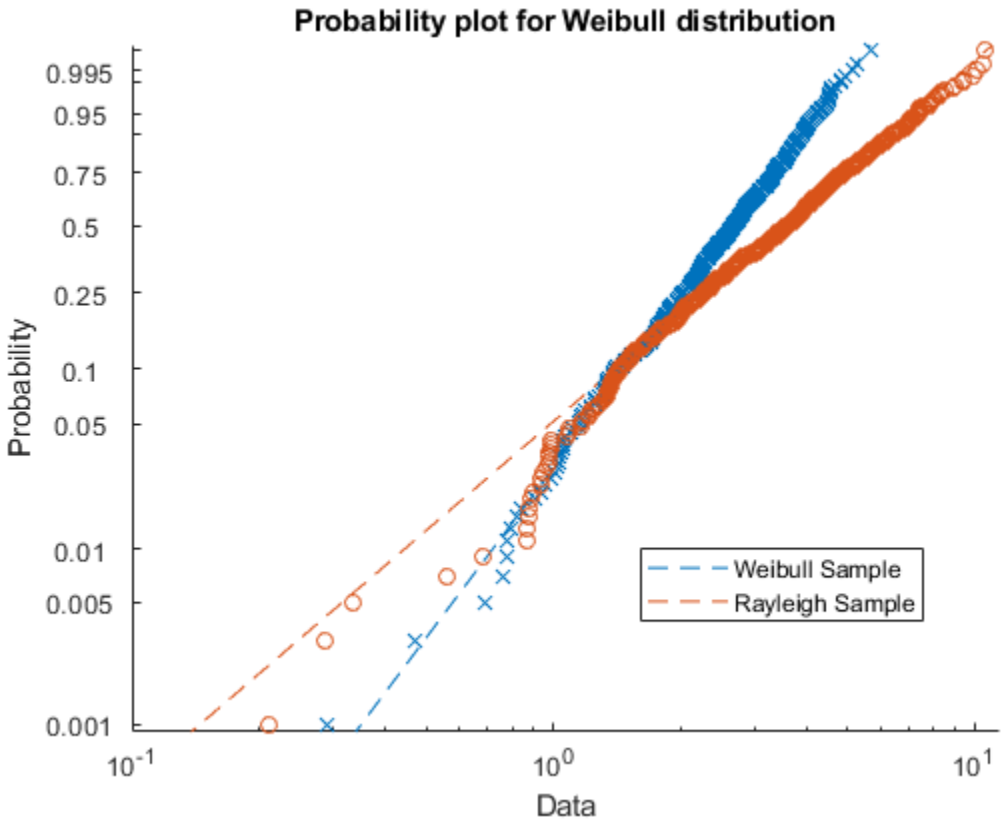
Generate sample data and create a probability plot.

Generate sample data. The sample `x1` contains 500 random numbers from a Weibull distribution with scale parameter `A = 3` and shape parameter `B = 3`. The sample `x2` contains 500 random numbers from a Rayleigh distribution with scale parameter `B = 3`.

```
rng('default');  % For reproducibility
x1 = wblrnd(3,3,[500,1]);
x2 = raylrnd(3,[500,1]);
```

Create a probability plot to assess whether the data in `x1` and `x2` comes from a Weibull distribution.

```
figure
probplot('weibull',[x1 x2])
legend('Weibull Sample','Rayleigh Sample','Location','best')
```



The probability plot shows that the data in `x1` comes from a Weibull distribution, while the data in `x2` does not.

Alternatively, you can use `wblplot` to create a Weibull probability plot.

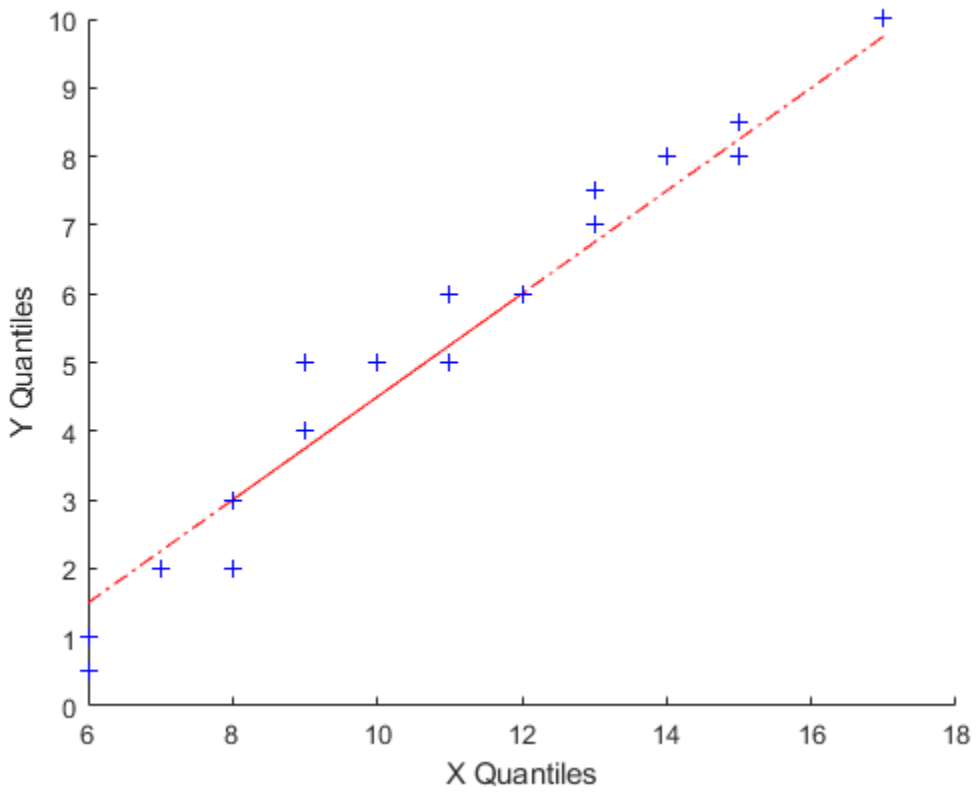
Quantile-Quantile Plots

Use quantile-quantile (q-q) plots to determine whether two samples come from the same distribution family. Q-Q plots are scatter plots of quantiles computed from each sample, with a line drawn between the first and third quartiles. If the data falls near the line, it is reasonable to assume that the two samples come from the same distribution. The method is robust with respect to changes in the location and scale of either distribution.

Create a quantile-quantile plot by using the `qqplot` function.

The following example generates two data samples containing random numbers from Poisson distributions with different parameter values, and creates a quantile-quantile plot. The data in `x` is from a Poisson distribution with mean 10, and the data in `y` is from a Poisson distribution with mean 5.

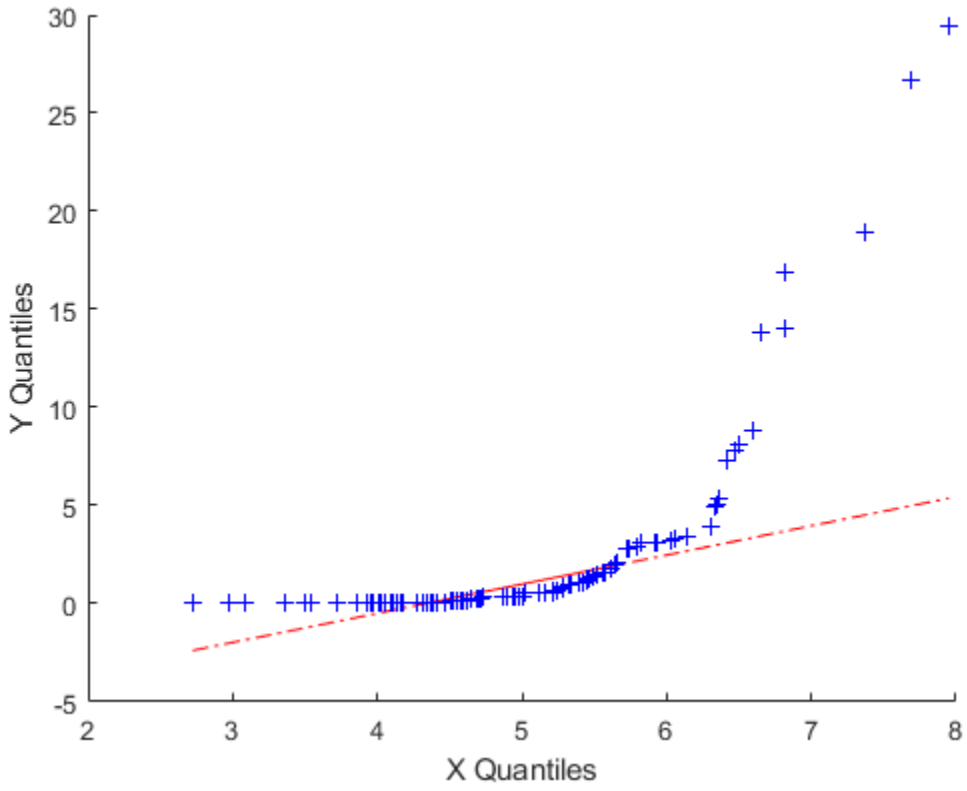
```
x = poissrnd(10,[50,1]);
y = poissrnd(5,[100,1]);
qqplot(x,y)
```



Even though the parameters and sample sizes are different, the approximate linear relationship suggests that the two samples may come from the same distribution family. As with normal probability plots, hypothesis tests can provide additional justification for such an assumption. For statistical procedures that depend on the two samples coming from the same distribution, however, a linear quantile-quantile plot is often sufficient.

The following example shows what happens when the underlying distributions are not the same. Here, `x` contains 100 random numbers generated from a normal distribution with mean 5 and standard deviation 1, while `y` contains 100 random numbers generated from a Weibull distribution with a scale parameter of 2 and a shape parameter of 0.5.

```
x = normrnd(5,1,[100,1]);
y = wblrnd(2,0.5,[100,1]);
qqplot(x,y)
```



The plots indicate that these samples clearly are not from the same distribution family.

Cumulative Distribution Plots

An empirical cumulative distribution function (cdf) plot shows the proportion of data less than or equal to each *x* value, as a function of *x*. The scale on the *y*-axis is linear; in particular, it is not scaled to any particular distribution. Empirical cdf plots are used to compare data cdfs to cdfs for particular distributions.

To create an empirical cdf plot, use the `cdfplot` function or the `ecdf` function.

Compare Empirical cdf to Theoretical cdf

Plot the empirical cdf of a sample data set and compare it to the theoretical cdf of the underlying distribution of the sample data set. In practice, a theoretical cdf can be unknown.

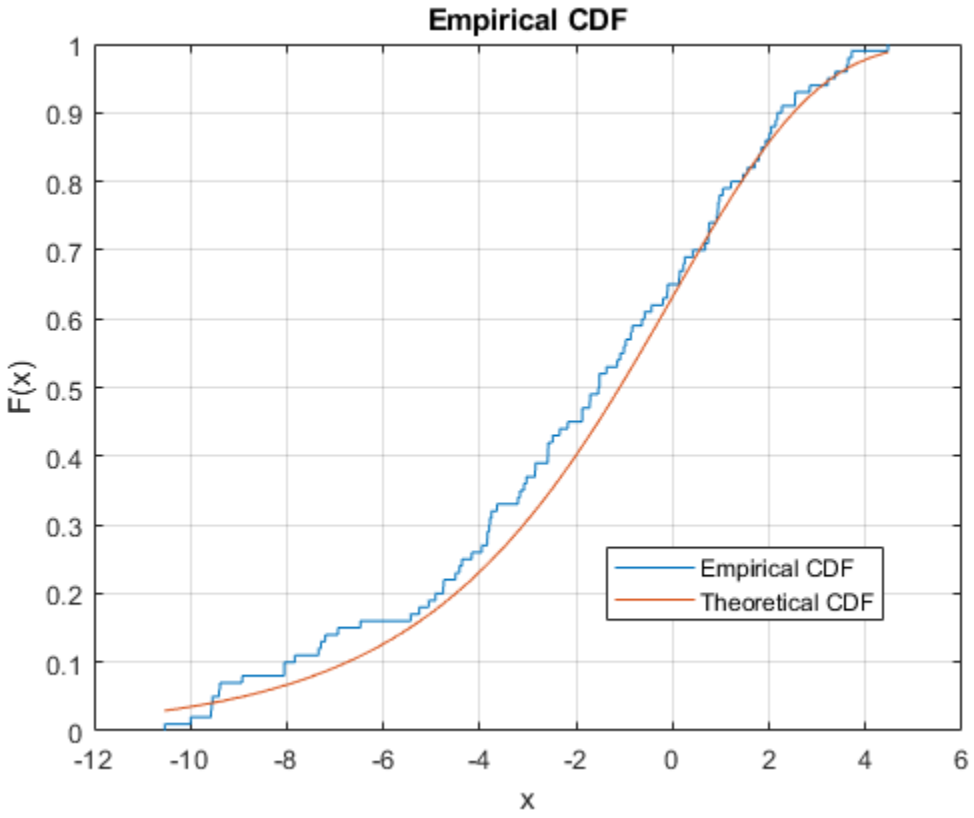
Generate a random sample data set from the extreme value distribution with a location parameter of 0 and a scale parameter of 3.

```
rng('default')  % For reproducibility
y = evrnd(0,3,100,1);
```

Plot the empirical cdf of the sample data set and the theoretical cdf on the same figure.

```
cdfplot(y)
hold on
```

```
x = linspace(min(y),max(y));
plot(x,evcdf(x,0,3))
legend('Empirical CDF','Theoretical CDF','Location','best')
hold off
```



The plot shows the similarity between the empirical cdf and the theoretical cdf.

Alternatively, you can use the `ecdf` function. The `ecdf` function also plots the 95% confidence intervals estimated by using Greenwood's Formula. For details, see “Greenwood’s Formula” on page 33-1279.

```
ecdf(y,'Bounds','on')
hold on
plot(x,evcdf(x,0,3))
grid on
title('Empirical CDF')
legend('Empirical CDF','Lower Confidence Bound','Upper Confidence Bound','Theoretical CDF','Loca
hold off
```

- “Hypothesis Testing” on page 8-5

Visualizing Multivariate Data

This example shows how to visualize multivariate data using various statistical plots. Many statistical analyses involve only two variables: a predictor variable and a response variable. Such data are easy to visualize using 2D scatter plots, bivariate histograms, boxplots, etc. It's also possible to visualize trivariate data with 3D scatter plots, or 2D scatter plots with a third variable encoded with, for example color. However, many datasets involve a larger number of variables, making direct visualization more difficult. This example explores some of the ways to visualize high-dimensional data in MATLAB®, using Statistics and Machine Learning Toolbox™.

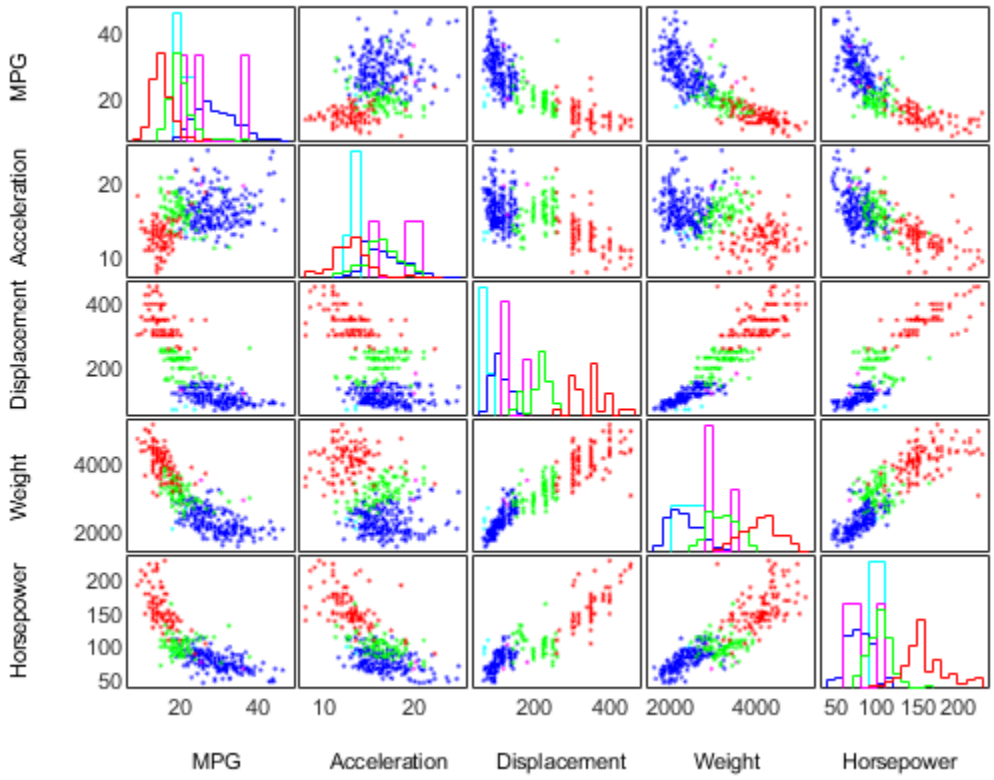
In this example, we'll use the `carbig` dataset, a dataset that contains various measured variables for about 400 automobiles from the 1970's and 1980's. We'll illustrate multivariate visualization using the values for fuel efficiency (in miles per gallon, MPG), acceleration (time from 0-60MPH in sec), engine displacement (in cubic inches), weight, and horsepower. We'll use the number of cylinders to group observations.

```
load carbig
X = [MPG,Acceleration,Displacement,Weight,Horsepower];
varNames = {'MPG'; 'Acceleration'; 'Displacement'; 'Weight'; 'Horsepower'};
```

Scatter Plot Matrices

Viewing slices through lower dimensional subspaces is one way to partially work around the limitation of two or three dimensions. For example, we can use the `gplotmatrix` function to display an array of all the bivariate scatter plots between our five variables, along with a univariate histogram for each variable.

```
figure
gplotmatrix(X,[],Cylinders,['c' 'b' 'm' 'g' 'r'],[],[],false);
text([.08 .24 .43 .66 .83], repmat(-.1,1,5), varNames, 'FontSize',8);
text(repmat(-.12,1,5), [.86 .62 .41 .25 .02], varNames, 'FontSize',8, 'Rotation',90);
```

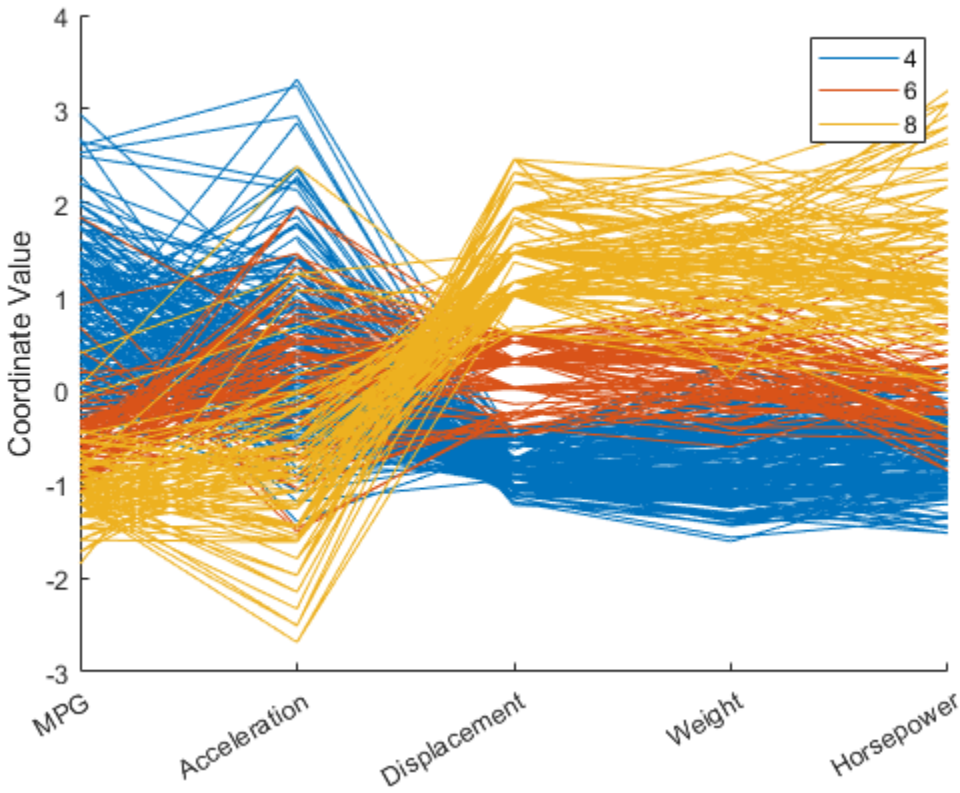


The points in each scatter plot are color-coded by the number of cylinders: blue for 4 cylinders, green for 6, and red for 8. There is also a handful of 5 cylinder cars, and rotary-engined cars are listed as having 3 cylinders. This array of plots makes it easy to pick out patterns in the relationships between pairs of variables. However, there may be important patterns in higher dimensions, and those are not easy to recognize in this plot.

Parallel Coordinates Plots

The scatter plot matrix only displays bivariate relationships. However, there are other alternatives that display all the variables together, allowing you to investigate higher-dimensional relationships among variables. The most straight-forward multivariate plot is the parallel coordinates plot. In this plot, the coordinate axes are all laid out horizontally, instead of using orthogonal axes as in the usual Cartesian graph. Each observation is represented in the plot as a series of connected line segments. For example, we can make a plot of all the cars with 4, 6, or 8 cylinders, and color observations by group.

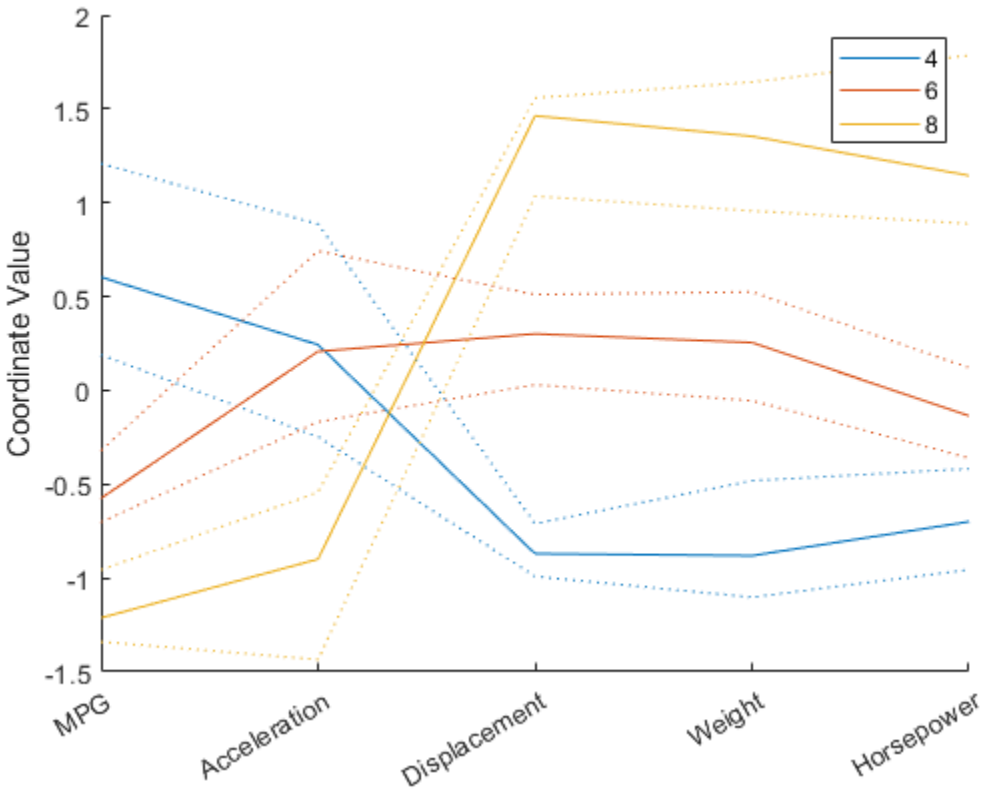
```
Cyl468 = ismember(Cylinders,[4 6 8]);
parallelcoords(X(Cyl468,:), 'group',Cylinders(Cyl468), ...
               'standardize','on', 'labels',varNames)
```



The horizontal direction in this plot represents the coordinate axes, and the vertical direction represents the data. Each observation consists of measurements on five variables, and each measurement is represented as the height at which the corresponding line crosses each coordinate axis. Because the five variables have widely different ranges, this plot was made with standardized values, where each variable has been standardized to have zero mean and unit variance. With the color coding, the graph shows, for example, that 8 cylinder cars typically have low values for MPG and acceleration, and high values for displacement, weight, and horsepower.

Even with color coding by group, a parallel coordinates plot with a large number of observations can be difficult to read. We can also make a parallel coordinates plot where only the median and quartiles (25% and 75% points) for each group are shown. This makes the typical differences and similarities among groups easier to distinguish. On the other hand, it may be the outliers for each group that are most interesting, and this plot does not show them at all.

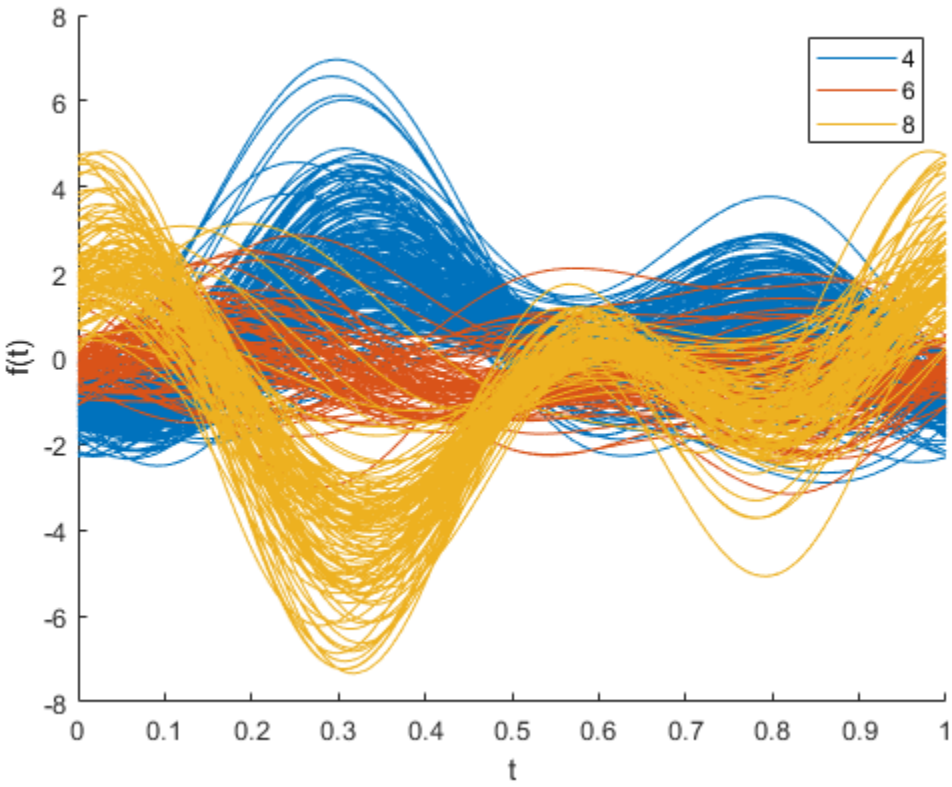
```
parallelcoords(X(Cyl468,:), 'group',Cylinders(Cyl468), ...
               'standardize','on', 'labels',varNames, 'quantile',.25)
```



Andrews Plots

Another similar type of multivariate visualization is the Andrews plot. This plot represents each observation as a smooth function over the interval [0,1].

```
andrewsplot(X(Cyl468,:), 'group',Cylinders(Cyl468), 'standardize','on')
```



Each function is a Fourier series, with coefficients equal to the corresponding observation's values. In this example, the series has five terms: a constant, two sine terms with periods 1 and 1/2, and two similar cosine terms. Effects on the functions' shapes due to the three leading terms are the most apparent in an Andrews plot, so patterns in the first three variables tend to be the ones most easily recognized.

There's a distinct difference between groups at t = 0, indicating that the first variable, MPG, is one of the distinguishing features between 4, 6, and 8 cylinder cars. More interesting is the difference between the three groups at around t = 1/3. Plugging this value into the formula for the Andrews plot functions, we get a set of coefficients that define a linear combination of the variables that distinguishes between groups.

```
t1 = 1/3;
[1/sqrt(2) sin(2*pi*t1) cos(2*pi*t1) sin(4*pi*t1) cos(4*pi*t1)]
```

```
ans =

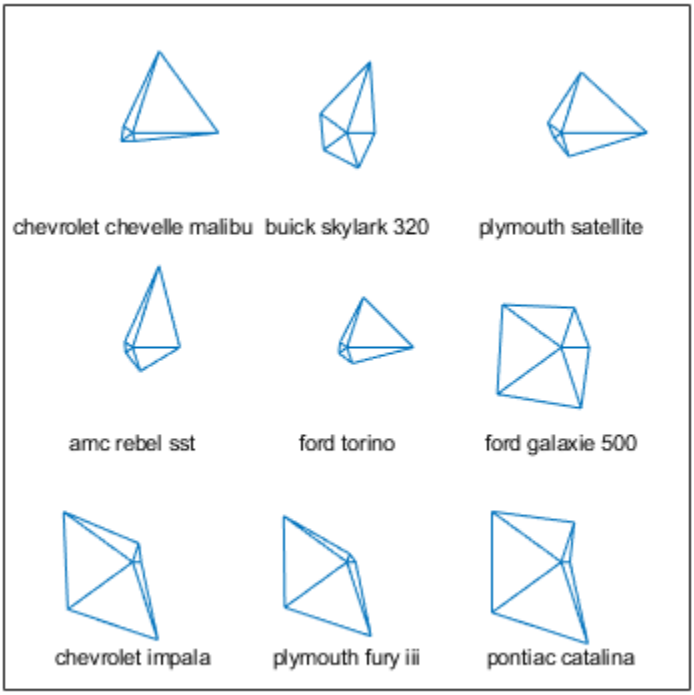
    0.7071    0.8660   -0.5000   -0.8660   -0.5000
```

From these coefficients, we can see that one way to distinguish 4 cylinder cars from 8 cylinder cars is that the former have higher values of MPG and acceleration, and lower values of displacement, horsepower, and particularly weight, while the latter have the opposite. That's the same conclusion we drew from the parallel coordinates plot.

Glyph Plots

Another way to visualize multivariate data is to use "glyphs" to represent the dimensions. The function `glyphplot` supports two types of glyphs: stars, and Chernoff faces. For example, here is a star plot of the first 9 models in the car data. Each spoke in a star represents one variable, and the spoke length is proportional to the value of that variable for that observation.

```
h = glyphplot(X(1:9,:), 'glyph','star', 'varLabels',varNames, 'obslabels',Model(1:9,:));
set(h(:,3),'FontSize',8);
```



In a live MATLAB figure window, this plot would allow interactive exploration of the data values, using data cursors. For example, clicking on the right-hand point of the star for the Ford Torino would show that it has an MPG value of 17.

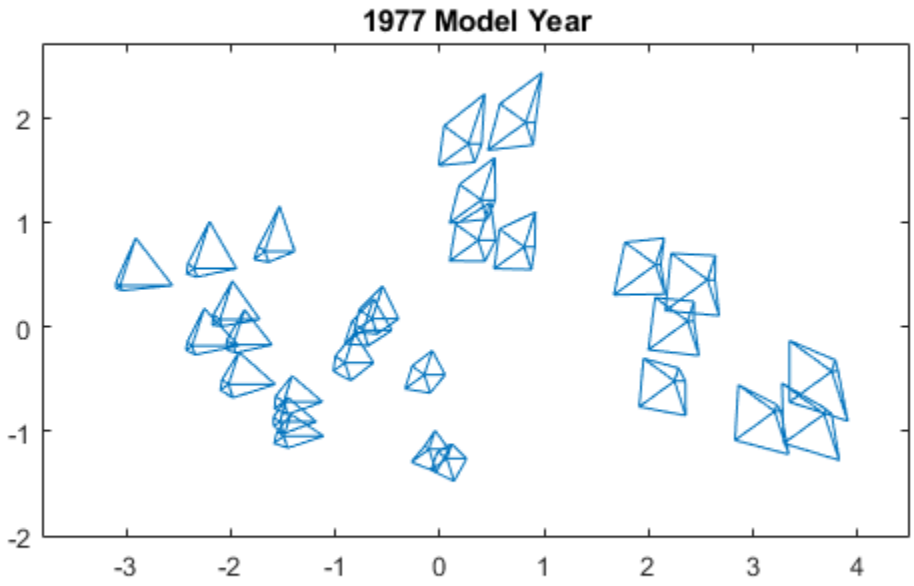
Glyph Plots and Multidimensional Scaling

Plotting stars on a grid, with no particular order, can lead to a figure that is confusing, because adjacent stars can end up quite different-looking. Thus, there may be no smooth pattern for the eye to catch. It's often useful to combine multidimensional scaling (MDS) with a glyph plot. To illustrate, we'll first select all cars from 1977, and use the `zscore` function to standardize each of the five variables to have zero mean and unit variance. Then we'll compute the Euclidean distances among those standardized observations as a measure of dissimilarity. This choice might be too simplistic in a real application, but serves here for purposes of illustration.

```
models77 = find((Model_Year==77));
dissimilarity = pdist(zscore(X(models77,:)));
```

Finally, we use `mdscale` to create a set of locations in two dimensions whose interpoint distances approximate the dissimilarities among the original high-dimensional data, and plot the glyphs using those locations. The distances in this 2D plot may only roughly reproduce the data, but for this type of plot, that's good enough.

```
Y = mdscale(dissimilarity,2);
glyphplot(X(models77,:), 'glyph','star', 'centers',Y, ...
          'varLabels',varNames, 'obslabels',Model(models77,:), 'radius',.5);
title('1977 Model Year');
```

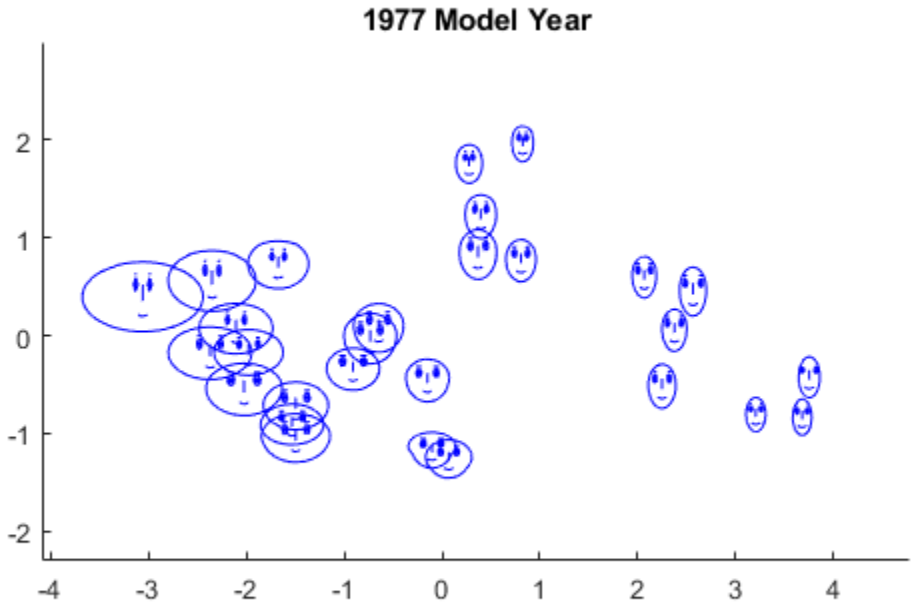


In this plot, we've used MDS as dimension reduction method, to create a 2D plot. Normally that would mean a loss of information, but by plotting the glyphs, we have incorporated all of the high-dimensional information in the data. The purpose of using MDS is to impose some regularity to the variation in the data, so that patterns among the glyphs are easier to see.

Just as with the previous plot, interactive exploration would be possible in a live figure window.

Another type of glyph is the Chernoff face. This glyph encodes the data values for each observation into facial features, such as the size of the face, the shape of the face, position of the eyes, etc.

```
glyphplot(X(models77,:), 'glyph','face', 'centers',Y, ...
          'varLabels',varNames, 'obslabels',Model(models77,:));
title('1977 Model Year');
```



Here, the two most apparent features, face size and relative forehead/jaw size, encode MPG and acceleration, while the forehead and jaw shape encode displacement and weight. Width between eyes encodes horsepower. It's notable that there are few faces with wide foreheads and narrow jaws, or vice-versa, indicating positive linear correlation between the variables displacement and weight. That's also what we saw in the scatter plot matrix.

The correspondence of features to variables determines what relationships are easiest to see, and `glyphplot` allows the choice to be changed easily.

```
close
```

Probability Distributions

Working with Probability Distributions

In this section...

Probability distributions are theoretical distributions based on assumptions about a source population. The distributions assign probability to the event that a random variable has a specific, discrete value, or falls within a specified range of continuous values.

Statistics and Machine Learning Toolbox offers several ways to work with probability distributions.

- Use “Probability Distribution Objects” on page 5-3 to fit a probability distribution object to sample data, or to create a probability distribution object with specified parameter values.
- Use “Probability Distribution Functions” on page 5-6 to work with data input from matrices.
- Use “Probability Distribution Apps and User Interfaces” on page 5-10 to interactively fit, explore, and generate random numbers from probability distributions. Available apps and user interfaces include:
  - The **Distribution Fitter** app
  - The **Probability Distribution Function** user interface
  - The Random Number Generation user interface (`randtool`)

For a list of distributions supported by Statistics and Machine Learning Toolbox, see “Supported Distributions” on page 5-14.

You can define a probability object for a custom distribution and then use the Distribution Fitter app or probability object functions, such as `pdf`, `cdf`, `icdf`, and `random`, to evaluate the distribution, generate random numbers, and so on. For details, see “Define Custom Distributions Using the Distribution Fitter App” on page 5-81. You can also define a custom distribution using a function handle and use the `mle` function to find maximum likelihood estimates. For an example, see “Fit Custom Distribution to Censored Data” on page 33-3970.

Probability Distribution Objects

Probability distribution objects allow you to fit a probability distribution to sample data, or define a distribution by specifying parameter values. You can then perform a variety of analyses on the distribution object.

Create Probability Distribution Objects

Estimate probability distribution parameters from sample data by fitting a probability distribution object to the data using `fitdist`. You can fit a single specified parametric or nonparametric distribution to the sample data. You can also fit multiple distributions of the same type to the sample data based on grouping variables. For most distributions, `fitdist` uses maximum likelihood estimation (MLE) to estimate the distribution parameters from the sample data. For more information and additional syntax options, see `fitdist`.

Alternatively, you can create a probability distribution object with specified parameter values using `makedist`.

Work with Probability Distribution Objects

Once you create a probability distribution object, you can use object functions to:

- Compute confidence intervals for the distribution parameters (`paramci`).
- Compute summary statistics, including mean (`mean`), median (`median`), interquartile range (`iqr`), variance (`var`), and standard deviation (`std`).
- Evaluate the probability density function (`pdf`).
- Evaluate the cumulative distribution function (`cdf`) or the inverse cumulative distribution function (`icdf`).
- Compute the negative loglikelihood (`negloglik`) and profile likelihood function (`proflik`) for the distribution.
- Generate random numbers from the distribution (`random`).
- Truncate the distribution to specified lower and upper limits (`truncate`).

Save a Probability Distribution Object

To save your probability distribution object to a .MAT file:

- In the toolbar, click **Save Workspace**. This option saves all of the variables in your workspace, including any probability distribution objects.
- In the workspace browser, right-click the probability distribution object and select **Save as**. This option saves only the selected probability distribution object, not the other variables in your workspace.

Alternatively, you can save a probability distribution object directly from the command line by using the `save` function. `save` enables you to choose a file name and specify the probability distribution object you want to save. If you do not specify an object (or other variable), MATLAB saves all of the variables in your workspace, including any probability distribution objects, to the specified file name. For more information and additional syntax options, see `save`.

Analyze Distribution Using Probability Distribution Objects

This example shows how to use probability distribution objects to perform a multistep analysis on a fitted distribution.

The analysis illustrates how to:

- Fit a probability distribution to sample data that contains exam grades of 120 students by using `fitdist`.
- Compute the mean of the exam grades by using `mean`.
- Plot a histogram of the exam grade data, overlaid with a plot of the pdf of the fitted distribution, by using `plot` and `pdf`.
- Compute the boundary for the top 10 percent of student grades by using `icdf`.
- Save the fitted probability distribution object by using `save`.

Load the sample data.

```
load examgrades
```

The sample data contains a 120-by-5 matrix of exam grades. The exams are scored on a scale of 0 to 100.

Create a vector containing the first column of exam grade data.

```
x = grades(:,1);
```

Fit a normal distribution to the sample data by using `fitdist` to create a probability distribution object.

```
pd = fitdist(x,'Normal')
```

```
pd =
  NormalDistribution

  Normal distribution
       mu = 75.0083   [73.4321, 76.5846]
    sigma =  8.7202   [7.7391, 9.98843]
```

`fitdist` returns a probability distribution object, `pd`, of the type `NormalDistribution`. This object contains the estimated parameter values, `mu` and `sigma`, for the fitted normal distribution. The intervals next to the parameter estimates are the 95% confidence intervals for the distribution parameters.

Compute the mean of the students' exam grades using the fitted distribution object, `pd`.

```
m = mean(pd)
```

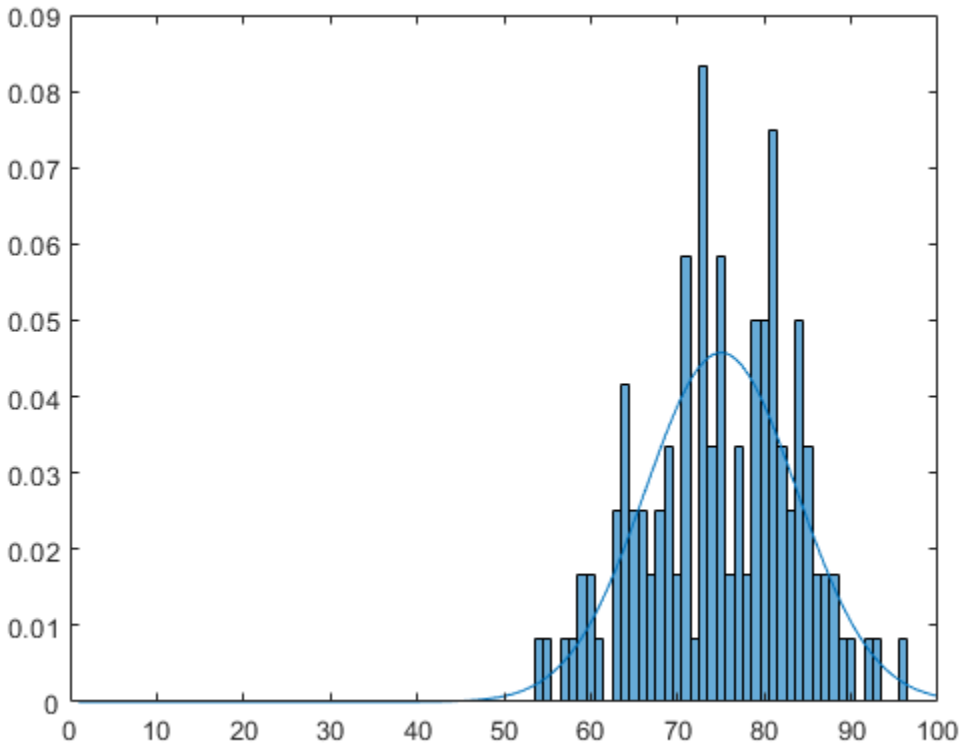
```
m = 75.0083
```

The mean of the exam grades is equal to the `mu` parameter estimated by `fitdist`.

Plot a histogram of the exam grades. Overlay a plot of the fitted pdf to visually compare the fitted normal distribution with the actual exam grades.

```
x_pdf = [1:0.1:100];
y = pdf(pd,x_pdf);

figure
histogram(x,'Normalization','pdf')
line(x_pdf,y)
```



The pdf of the fitted distribution follows the same shape as the histogram of the exam grades.

Determine the boundary for the upper 10 percent of student exam grades by using the inverse cumulative distribution function (`icdf`). This boundary is equivalent to the value at which the cdf of the probability distribution is equal to 0.9. In other words, 90 percent of the exam grades are less than or equal to the boundary value.

```
A = icdf(pd,0.9)
```

```
A = 86.1837
```

Based on the fitted distribution, 10 percent of students received an exam grade greater than 86.1837. Equivalently, 90 percent of students received an exam grade less than or equal to 86.1837.

Save the fitted probability distribution, `pd`, as a file named `myobject.mat`.

```
save('myobject.mat','pd')
```

Probability Distribution Functions

You can also work with probability distributions using distribution-specific functions. These functions are useful for generating random numbers, computing summary statistics inside a loop or script, and passing a cdf or pdf as a function handle to another function. You can also use these functions to perform computations on arrays of parameter values rather than a single set of parameters. For a list of supported probability distributions, see “Supported Distributions” on page 5-14.

Analyze Distribution Using Distribution-Specific Functions

This example shows how to use distribution-specific functions to perform a multistep analysis on a fitted distribution.

The analysis illustrates how to:

- Fit a probability distribution to sample data that contains exam grades of 120 students by using `normfit`.
- Plot a histogram of the exam grade data, overlaid with a plot of the pdf of the fitted distribution, by using `plot` and `normpdf`.
- Compute the boundary for the top 10 percent of student grades by using `norminv`.
- Save the estimated distribution parameters by using `save`.

You can perform the same analysis using a probability distribution object. See “Analyze Distribution Using Probability Distribution Objects” on page 5-4.

Load the sample data.

```
load examgrades
```

The sample data contains a 120-by-5 matrix of exam grades. The exams are scored on a scale of 0 to 100.

Create a vector containing the first column of exam grade data.

```
x = grades(:,1);
```

Fit a normal distribution to the sample data by using `normfit`.

```
[mu,sigma,muCI,sigmaCI] = normfit(x)
```

```
mu = 75.0083

sigma = 8.7202

muCI = 2×1

   73.4321
   76.5846

sigmaCI = 2×1

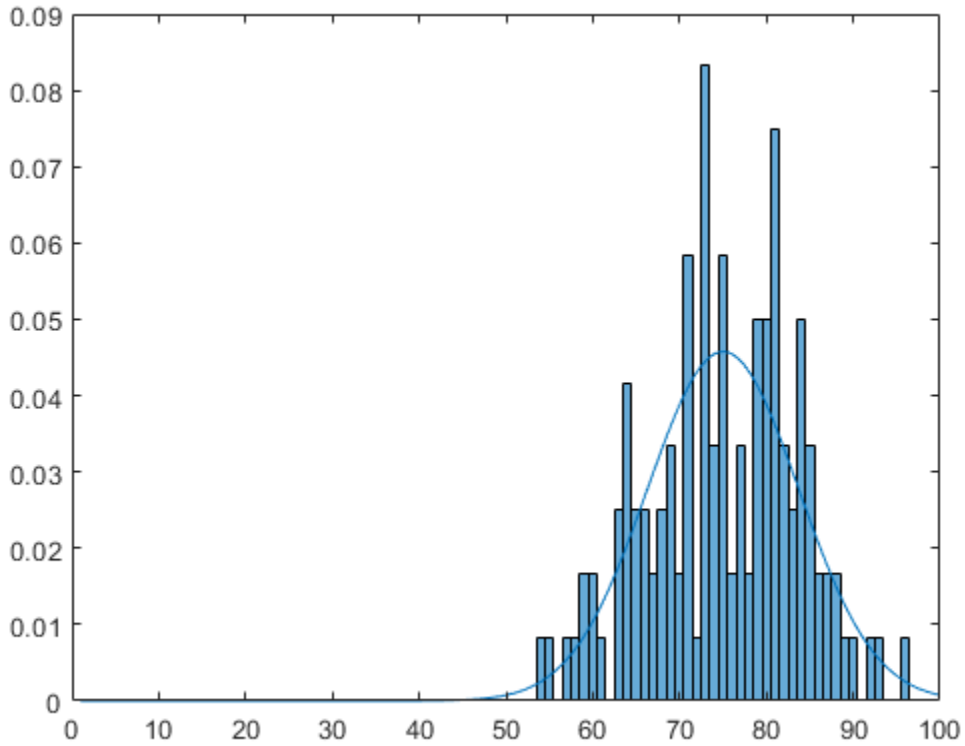
    7.7391
    9.9884
```

The `normfit` function returns the estimates of normal distribution parameters and the 95% confidence intervals for the parameter estimates.

Plot a histogram of the exam grades. Overlay a plot of the fitted pdf to visually compare the fitted normal distribution with the actual exam grades.

```
x_pdf = [1:0.1:100];
y = normpdf(x_pdf,mu,sigma);
```

```
figure
histogram(x,'Normalization','pdf')
line(x_pdf,y)
```



The pdf of the fitted distribution follows the same shape as the histogram of the exam grades.

Determine the boundary for the upper 10 percent of student exam grades by using the normal inverse cumulative distribution function. This boundary is equivalent to the value at which the cdf of the probability distribution is equal to 0.9. In other words, 90 percent of the exam grades are less than or equal to the boundary value.

```
A = norminv(0.9,mu,sigma)
```

```
A = 86.1837
```

Based on the fitted distribution, 10 percent of students received an exam grade greater than 86.1837. Equivalently, 90 percent of students received an exam grade less than or equal to 86.1837.

Save the estimated distribution parameters as a file named `myparameter.mat`.

```
save('myparameter.mat','mu','sigma')
```

Use Probability Distribution Functions as Function Handle

This example shows how to use the probability distribution function `normcdf` as a function handle in the chi-square goodness of fit test (`chi2gof`).

This example tests the null hypothesis that the sample data contained in the input vector, `x`, comes from a normal distribution with parameters μ and σ equal to the mean (`mean`) and standard deviation (`std`) of the sample data, respectively.

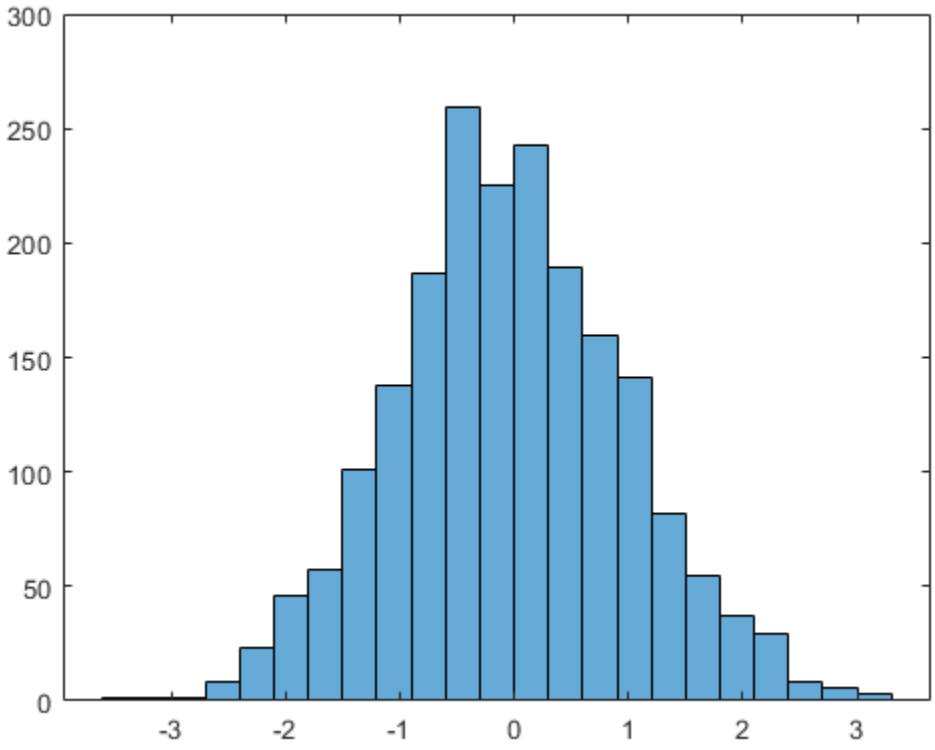
```
rng('default') % For reproducibility
x = normrnd(50,5,100,1);
h = chi2gof(x,'cdf',{@normcdf,mean(x),std(x)})
```

```
h = 0
```

The returned result `h = 0` indicates that `chi2gof` does not reject the null hypothesis at the default 5% significance level.

This next example illustrates how to use probability distribution functions as a function handle in the slice sampler (`slicesample`). The example uses `normpdf` to generate a random sample of 2,000 values from a standard normal distribution, and plots a histogram of the resulting values.

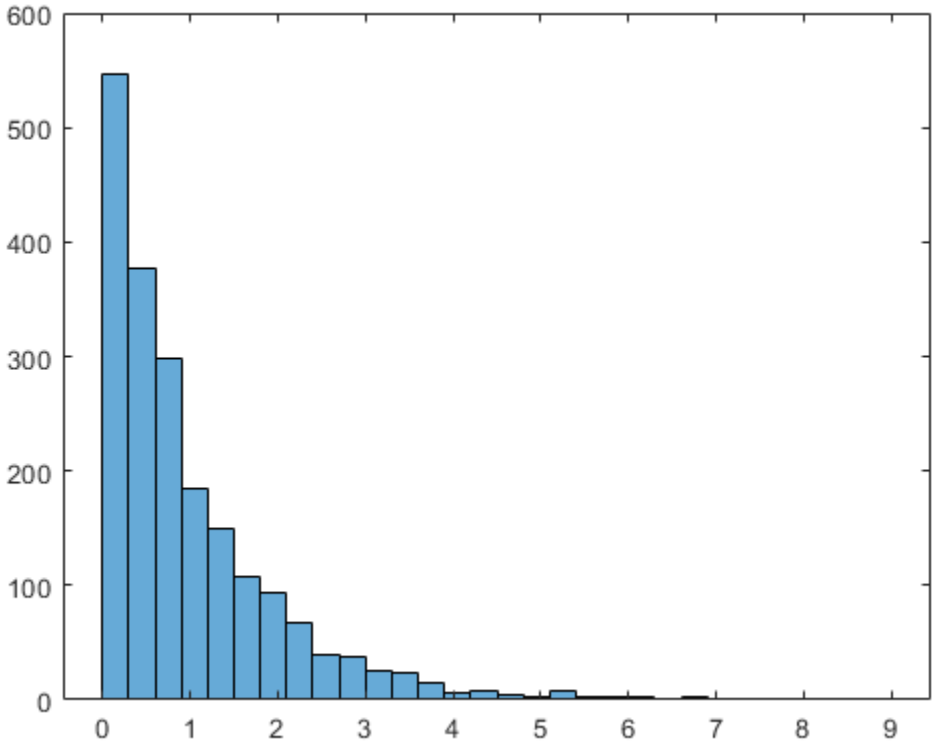
```
rng('default') % For reproducibility
x = slicesample(1,2000,'pdf',@normpdf,'thin',5,'burnin',1000);
histogram(x)
```



The histogram shows that, when using `normpdf`, the resulting random sample has a standard normal distribution.

If you pass the probability distribution function for the exponential distribution pdf (`exppdf`) as a function handle instead of `normpdf`, then `slicesample` generates the 2,000 random samples from an exponential distribution with a default parameter value of μ equal to 1.

```
rng('default') % For reproducibility
x = slicesample(1,2000,'pdf',@exppdf,'thin',5,'burnin',1000);
histogram(x)
```



The histogram shows that the resulting random sample when using `exppdf` has an exponential distribution.

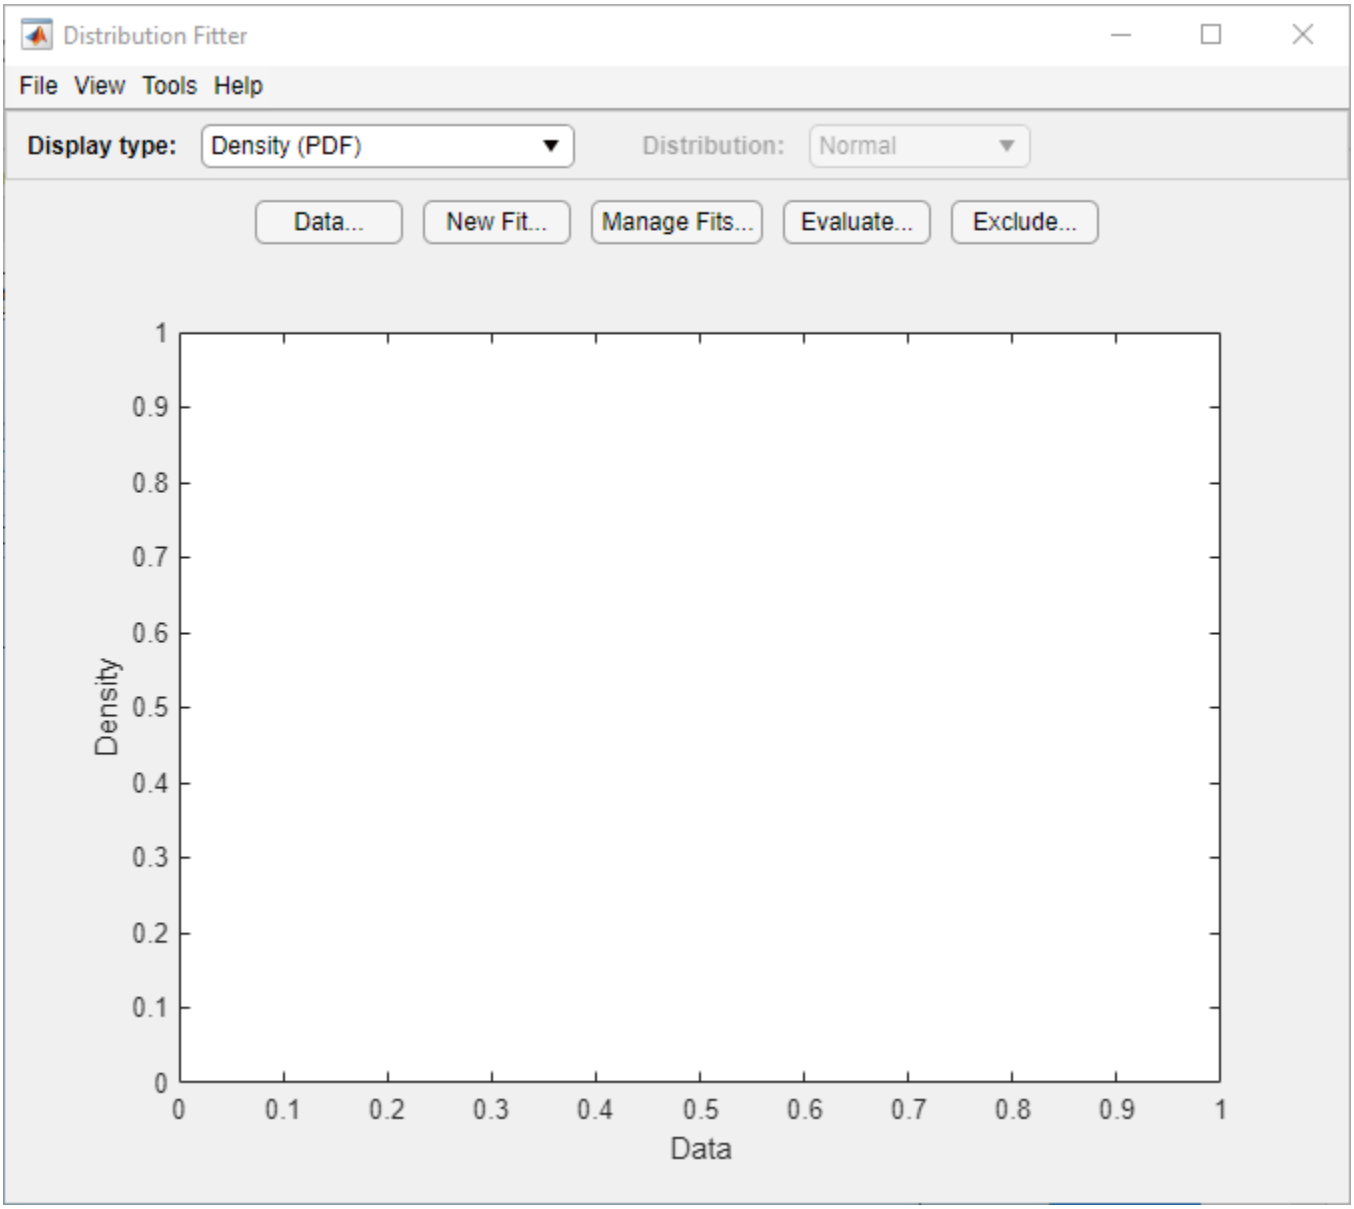
Probability Distribution Apps and User Interfaces

Apps and user interfaces provide an interactive approach to working with parametric and nonparametric probability distributions.

Distribution Fitter App

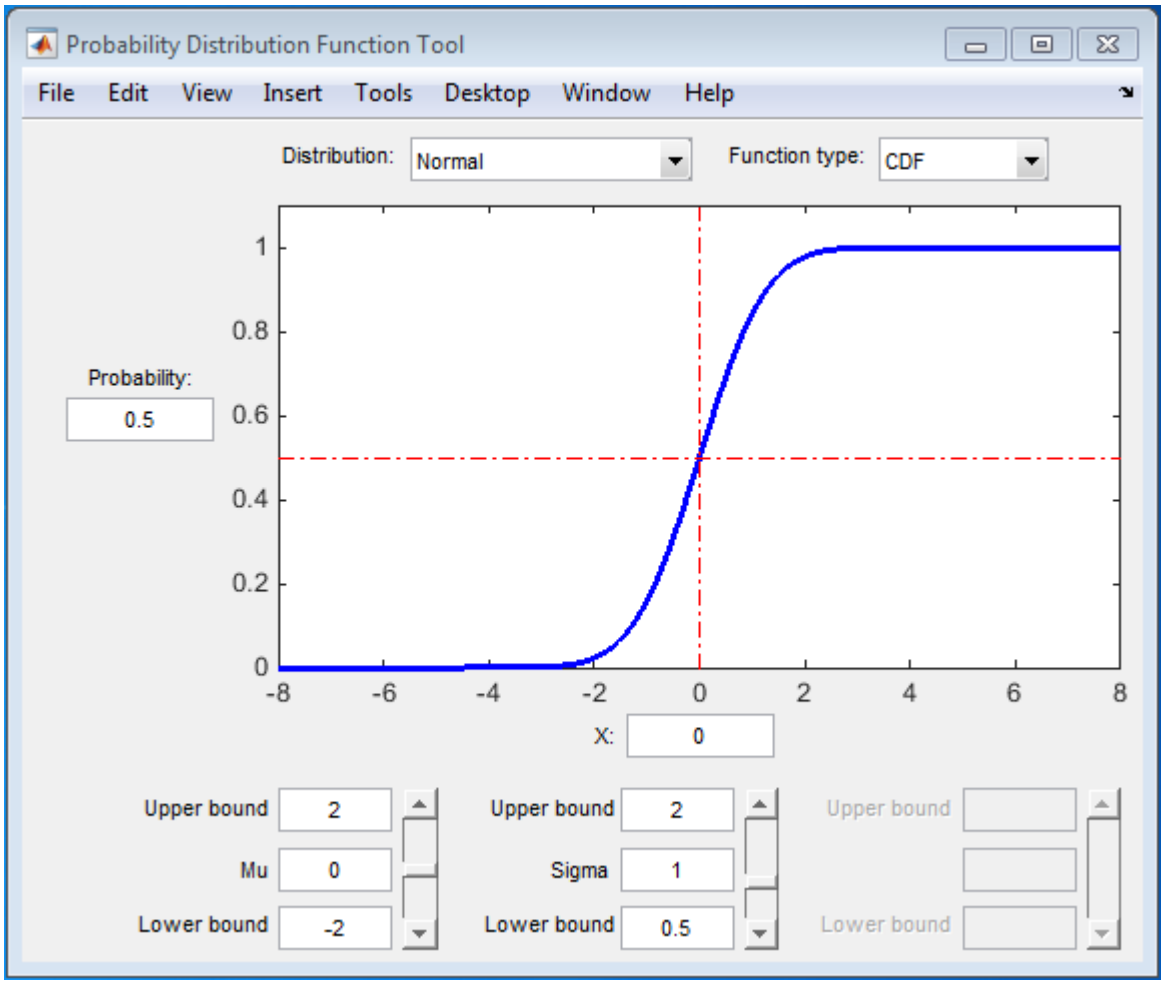
The **Distribution Fitter** app allows you to interactively fit a probability distribution to your data. You can display different types of plots, compute confidence bounds, and evaluate the fit of the data. You can also exclude data from the fit. You can save the data, and export the fit to your workspace as a probability distribution object to perform further analysis.

Load the Distribution Fitter app from the Apps tab, or by entering `distributionFitter` in the command window. For more information, see “Model Data Using the Distribution Fitter App” on page 5-51.



Probability Distribution Function Tool

The **Probability Distribution Function** user interface visually explores probability distributions. You can load the Probability Distribution Function user interface by entering `disttool` in the command window.



Random Number Generation Tool

The Random Number Generation user interface generates random data from a specified distribution and exports the results to your workspace. You can use this tool to explore the effects of changing parameters and sample size on the distributions.

The Random Number Generation user interface allows you to set parameter values for the distribution and change their lower and upper bounds; draw another sample from the same distribution, using the same size and parameters; and export the current random sample to your workspace for use in further analysis. A dialog box enables you to provide a name for the sample.

Supported Distributions

In this section...

Statistics and Machine Learning Toolbox supports more than 30 probability distributions, including parametric, nonparametric, continuous, and discrete distributions.

The toolbox provides several ways to work with probability distributions.

- Use *probability distribution objects* to fit a probability distribution object to sample data, or to create a probability distribution object with specified parameter values. Once you create a probability distribution object, you can use object functions to:
  - Compute confidence intervals for the distribution parameters (`paramci`).
  - Compute summary statistics, including mean (`mean`), median (`median`), interquartile range (`iqr`), variance (`var`), and standard deviation (`std`).
  - Evaluate the probability density function (`pdf`).
  - Evaluate the cumulative distribution function (`cdf`) or the inverse cumulative distribution function (`icdf`).
  - Compute the negative loglikelihood (`negloglik`) and profile likelihood function (`proflik`) for the distribution.
  - Generate random numbers from the distribution (`random`).
  - Truncate the distribution to specified lower and upper limits (`truncate`).

  Each distribution object page provides information about the object’s properties and the functions you can use to work with the object.
- Use *probability distribution functions* to work with data input from matrices. Some of the supported distributions have distribution-specific functions. These functions use the following abbreviations, as in `normpdf`, `normcdf`, `norminv`, `normstat`, `normfit`, `normlike`, and `normrnd`:
  - `pdf` — Probability density functions
  - `cdf` — Cumulative distribution functions
  - `inv` — Inverse cumulative distribution functions
  - `stat` — Distribution statistics functions
  - `fit` — Distribution Fitter functions
  - `like` — Negative loglikelihood functions
  - `rnd` — Random number generators

  You can also use the following generic functions to work with most of the distributions:

  - `pdf` — Probability density function
  - `cdf` — Cumulative distribution function
  - `icdf` — Inverse cumulative distribution function
  - `random` — Random number generating function
  - `mle` — Distribution fitting function
- Use *probability distribution apps and user interfaces* to interactively fit, explore, and generate random numbers from probability distributions. Available apps and user interfaces include:
  - The **Distribution Fitter** app, to interactively fit a distribution to sample data, and export a probability distribution object to the workspace.
  - The **Probability Distribution Function** user interface, to visually explore the effect on the pdf and cdf of changing the distribution parameter values.
  - The Random Number Generation user interface (`randtool`), to interactively generate random numbers from a probability distribution with specified parameter values and export them to the workspace.

For more information on the different ways to work with probability distributions, see “Working with Probability Distributions” on page 5-3.

Maximum Likelihood Estimation

The `mle` function computes maximum likelihood estimates (MLEs) for a distribution specified by its name and for a custom distribution specified by its probability density function (pdf), log pdf, or negative log likelihood function.

For some distributions, MLEs can be given in closed form and computed directly. For other distributions, a search for the maximum likelihood must be employed. The search can be controlled with an `options` input argument, created using the `statset` function. For efficient searches, it is important to choose a reasonable distribution model and set appropriate convergence tolerances.

MLEs can be biased, especially for small samples. As sample size increases, however, MLEs become unbiased minimum variance estimators with approximate normal distributions. This is used to compute confidence bounds for the estimates.

For example, consider the following distribution of means from repeated random samples of an exponential distribution:

```
mu = 1; % Population parameter
n = 1e3; % Sample size
ns = 1e4; % Number of samples

rng('default')  % For reproducibility
samples = exprnd(mu,n,ns); % Population samples
means = mean(samples); % Sample means
```

The Central Limit Theorem says that the means will be approximately normally distributed, regardless of the distribution of the data in the samples. The `mle` function can be used to find the normal distribution that best fits the means:

```
[phat,pci] = mle(means)
```

```
phat = 1×2

    1.0000    0.0315

pci = 2×2

    0.9994    0.0311
    1.0006    0.0319
```

`phat(1)` and `phat(2)` are the MLEs for the mean and standard deviation. `pci(:,1)` and `pci(:,1)` are the corresponding 95% confidence intervals.

Visualize the distribution of sample means together with the fitted normal distribution.

```
numbins = 50;
histogram(means,numbins,'Normalization','pdf')
hold on
x = min(means):0.001:max(means);
y = normpdf(x,phat(1),phat(2));
plot(x,y,'r','LineWidth',2)
```

Negative Loglikelihood Functions

Negative loglikelihood functions for supported Statistics and Machine Learning Toolbox distributions all end with `like`, as in `explike`. Each function represents a parametric family of distributions. Input arguments are lists of parameter values specifying a particular member of the distribution family followed by an array of data. Functions return the negative loglikelihood of the parameters, given the data.

To find maximum likelihood estimates (MLEs), you can use a negative loglikelihood function as an objective function of the optimization problem and solve it by using the MATLAB function `fminsearch` or functions in Optimization Toolbox™ and Global Optimization Toolbox. These functions allow you to choose a search algorithm and exercise low-level control over algorithm execution. By contrast, the `mle` function and the distribution fitting functions that end with `fit`, such as `normfit` and `gamfit`, use preset algorithms with options limited to those set by the `statset` function.

You can specify a parametric family of distributions by using the probability density function (pdf) $f(x|\theta)$, where x represents an outcome of a random variable and θ represents the distribution parameters. When you view $f(x|\theta)$ as a function of θ for a fixed x, the function $f(x|\theta)$ is the likelihood of parameters θ for a single outcome x. The likelihood of parameters θ for an independent and identically distributed random sample data set X is:

$$L(\theta) = \prod_{x \in X} f(x|\theta).$$

Given X, MLEs maximize $L(\theta)$ over all possible θ. Numerical algorithms find MLEs that (equivalently) maximize the loglikelihood function, $\log(L(\theta))$. The logarithm transforms the product of potentially small likelihoods into a sum of logs, which is easier to distinguish from 0 in computation. For convenience, Statistics and Machine Learning Toolbox negative loglikelihood functions return the *negative* of this sum because optimization algorithms typically search for minima rather than maxima.

Find MLEs Using Negative Loglikelihood Function

This example shows how to find MLEs by using the `gamlike` and `fminsearch` functions.

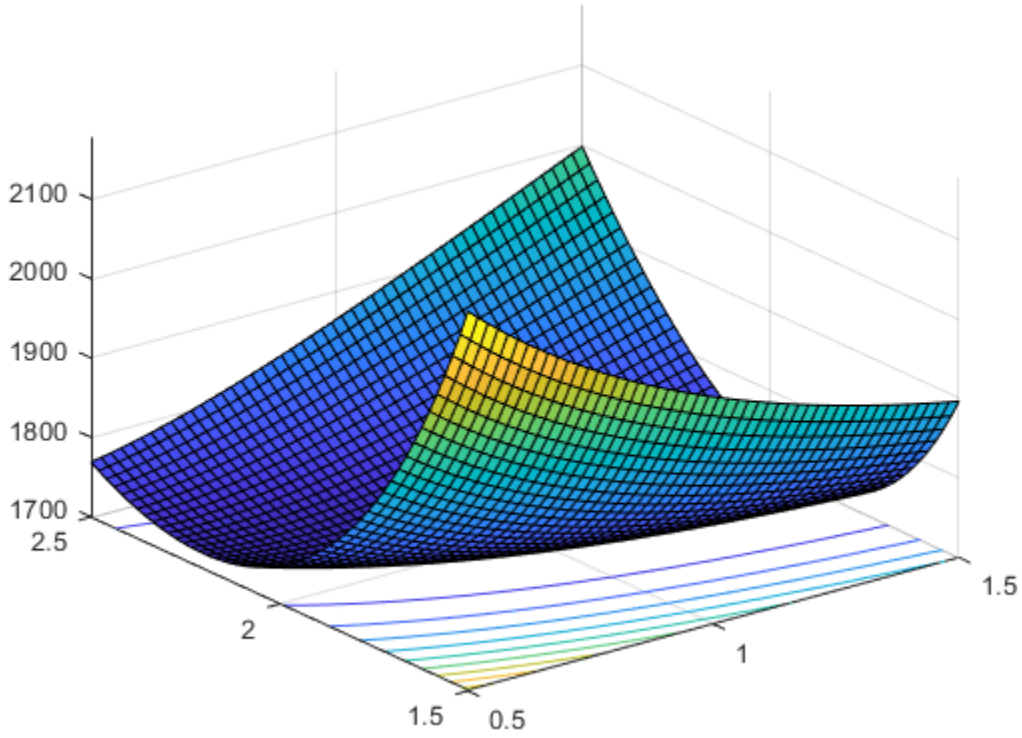
Use the `gamrnd` function to generate a random sample from a specific “Gamma Distribution” on page B-47.

```
rng default;  % For reproducibility
a = [1,2];
X = gamrnd(a(1),a(2),1e3,1);
```

Visualize the likelihood surface in the neighborhood of `a` given `X` by using the `gamlike` function.

```
mesh = 50;
delta = 0.5;
a1 = linspace(a(1)-delta,a(1)+delta,mesh);
a2 = linspace(a(2)-delta,a(2)+delta,mesh);
logL = zeros(mesh); % Preallocate memory
for i = 1:mesh
    for j = 1:mesh
        logL(i,j) = gamlike([a1(i),a2(j)],X);
    end
end
```

```
[A1,A2] = meshgrid(a1,a2);
surfc(A1,A2,logL)
```



Search for the minimum of the likelihood surface by using the `fminsearch` function.

```
LL = @(u)gamlike([u(1),u(2)],X); % Likelihood given X
MLES = fminsearch(LL,[1,2])
```

```
MLES = 1×2

    0.9980    2.0172
```

Compare `MLES` to the estimates returned by the `gamfit` function.

```
ahat = gamfit(X)
```

```
ahat = 1×2

    0.9980    2.0172
```

The difference of each parameter between `MLES` and `ahat` is less than `1e-4`.

Add the MLEs to the surface plot.

```
hold on
plot3(MLES(1),MLES(2),LL(MLES),'ro','MarkerSize',5,'MarkerFaceColor','r')
view([-60 40]) % Rotate to show the minimum
```

Random Number Generation

Statistics and Machine Learning Toolbox supports the generation of random numbers from various distributions. Each random number generator (RNG) represents a parametric family of distributions. RNGs return random numbers from the specified distribution in an array of the specified dimensions.

Other random number generation functions which do not support specific distributions include:

- `cvpartition`
- `datasample`
- `hmmgenerate`
- `lhsdesign`
- `lhsnorm`
- `mhsample`
- `random`
- `randsample`
- `slicesample`

RNGs in Statistics and Machine Learning Toolbox software depend on the default random number stream of MATLAB via the `rand` and `randn` functions. Each RNG uses one of the techniques discussed in “Common Pseudorandom Number Generation Methods” on page 7-2 to generate random numbers from a given distribution.

By controlling the default random number stream and its state, you can control how the RNGs in Statistics and Machine Learning Toolbox software generate random values. For example, to reproduce the same sequence of values from an RNG, you can save and restore the default stream's state, or reset the default stream. For details on managing the default random number stream, see “Managing the Global Stream Using RandStream”.

MATLAB initializes the default random number stream to the same state each time it starts up. Thus, RNGs in Statistics and Machine Learning Toolbox software will generate the same sequence of values for each MATLAB session unless you modify that state at startup. One simple way to do that is to add commands to `startup.m` such as

```
rng shuffle
```

that initialize the default random number stream to a different state for each session.

The following table lists the supported distributions and their respective random number generation functions.

Nonparametric and Empirical Probability Distributions

In this section...

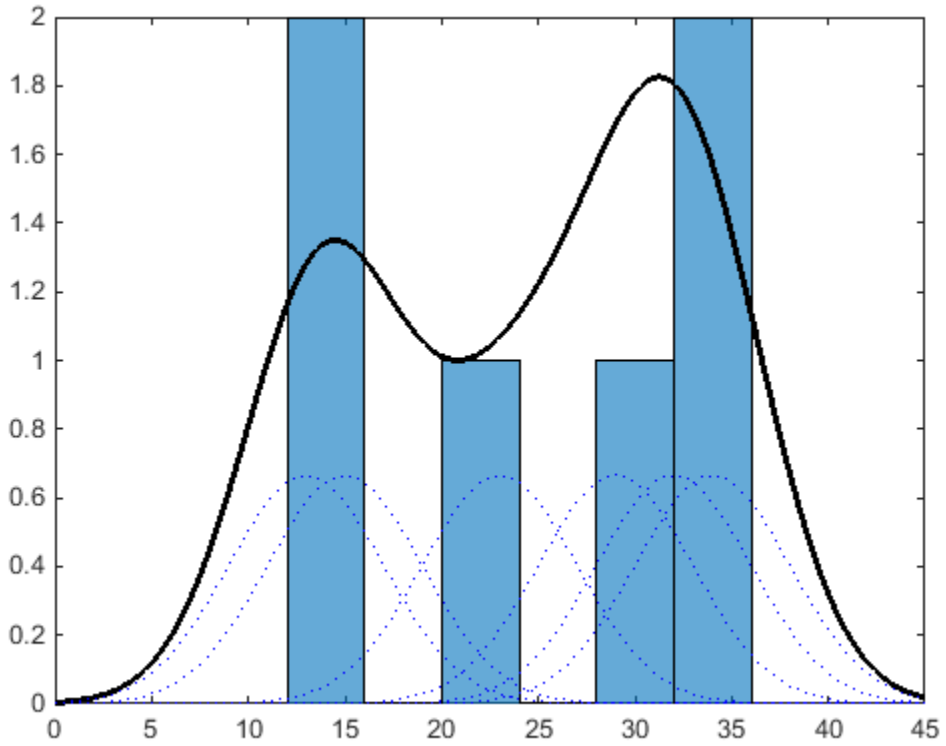
Overview

In some situations, you cannot accurately describe a data sample using a parametric distribution. Instead, the probability density function (pdf) or cumulative distribution function (cdf) must be estimated from the data. Statistics and Machine Learning Toolbox provides several options for estimating the pdf or cdf from sample data.

Kernel Distribution

A kernel distribution on page B-78 produces a nonparametric probability density estimate that adapts itself to the data, rather than selecting a density with a particular parametric form and estimating the parameters. This distribution is defined by a kernel density estimator, a smoothing function that determines the shape of the curve used to generate the pdf, and a bandwidth value that controls the smoothness of the resulting density curve.

Similar to a histogram, the kernel distribution builds a function to represent the probability distribution using the sample data. But unlike a histogram, which places the values into discrete bins, a kernel distribution sums the component smoothing functions for each data value to produce a smooth, continuous probability curve. The following plot shows a visual comparison of a histogram and a kernel distribution generated from the same sample data.



A histogram represents the probability distribution by establishing bins and placing each data value in the appropriate bin. Because of this bin count approach, the histogram produces a discrete probability density function. This might be unsuitable for certain applications, such as generating random numbers from a fitted distribution.

Alternatively, the kernel distribution builds the probability density function (pdf) by creating an individual probability density curve for each data value, then summing the smooth curves. This approach creates one smooth, continuous probability density function for the data set.

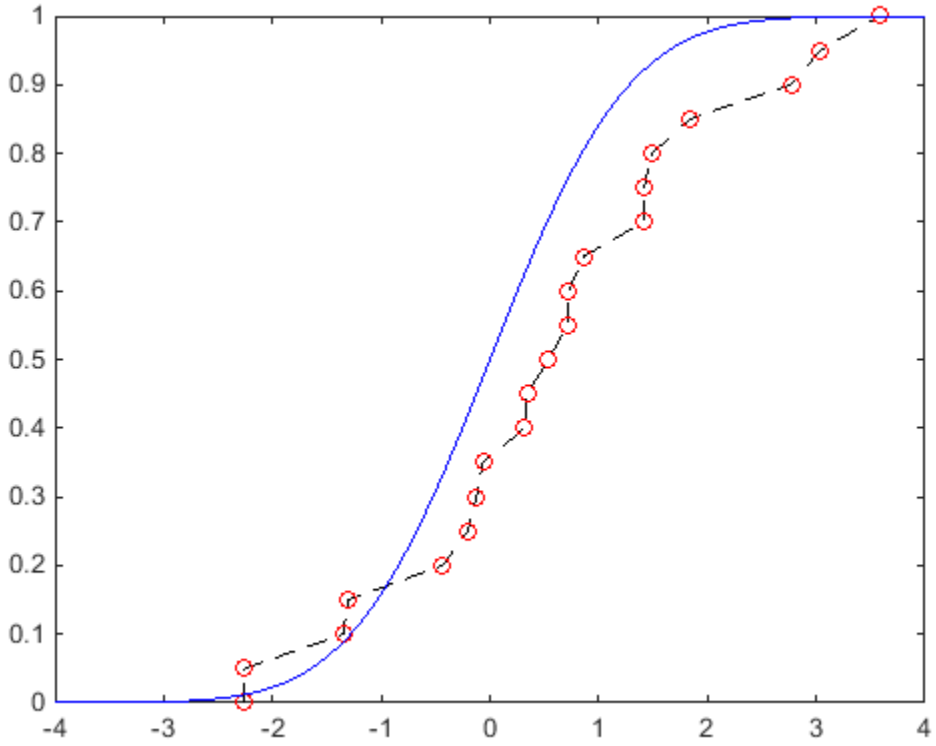
For more general information about kernel distributions, see “Kernel Distribution” on page B-78. For information on how to work with a kernel distribution, see `Using KernelDistribution Objects` and `ksdensity`.

Empirical Cumulative Distribution Function

An empirical cumulative distribution function (`ecdf`) estimates the cdf of a random variable by assigning equal probability to each observation in a sample. Because of this approach, the ecdf is a discrete cumulative distribution function that creates an exact match between the ecdf and the distribution of the sample data.

The following plot shows a visual comparison of the ecdf of 20 random numbers generated from a standard normal distribution, and the theoretical cdf of a standard normal distribution. The circles indicate the value of the ecdf calculated at each sample data point. The dashed line that passes through each circle visually represents the ecdf, although the ecdf is not a continuous function. The

solid line shows the theoretical cdf of the standard normal distribution from which the random numbers in the sample data were drawn.



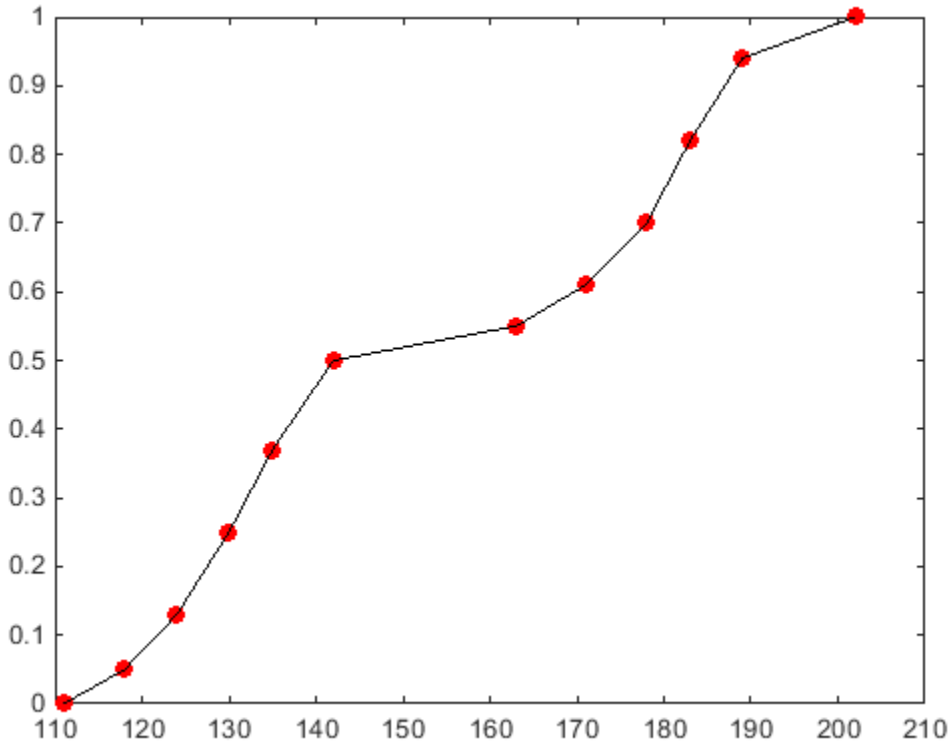
The ecdf is similar in shape to the theoretical cdf, although it is not an exact match. Instead, the ecdf is an exact match to the sample data. The ecdf is a discrete function, and is not smooth, especially in the tails where data might be sparse. You can smooth the distribution with Pareto tails on page 5-33, using the `paretotails` function.

For more information and additional syntax options, see `ecdf`. To construct a continuous function based on cdf values computed from sample data, see “Piecewise Linear Distribution” on page 5-32.

Piecewise Linear Distribution

A piecewise linear distribution on page B-130 estimates an overall cdf for the sample data by computing the cdf value at each individual point, and then linearly connecting these values to form a continuous curve.

The following plot shows the cdf for a piecewise linear distribution based on a sample of hospital patients’ weight measurements. The circles represent each individual data point (weight measurement). The black line that passes through each data point represents the piecewise linear distribution cdf for the sample data.



A piecewise linear distribution linearly connects the cdf values calculated at each sample data point to form a continuous curve. By contrast, an empirical cumulative distribution function on page 5-31 constructed using the `ecdf` function produces a discrete cdf. For example, random numbers generated from the ecdf can only include *x* values contained in the original sample data. Random numbers generated from a piecewise linear distribution can include any *x* value between the lower and upper boundaries of the sample data.

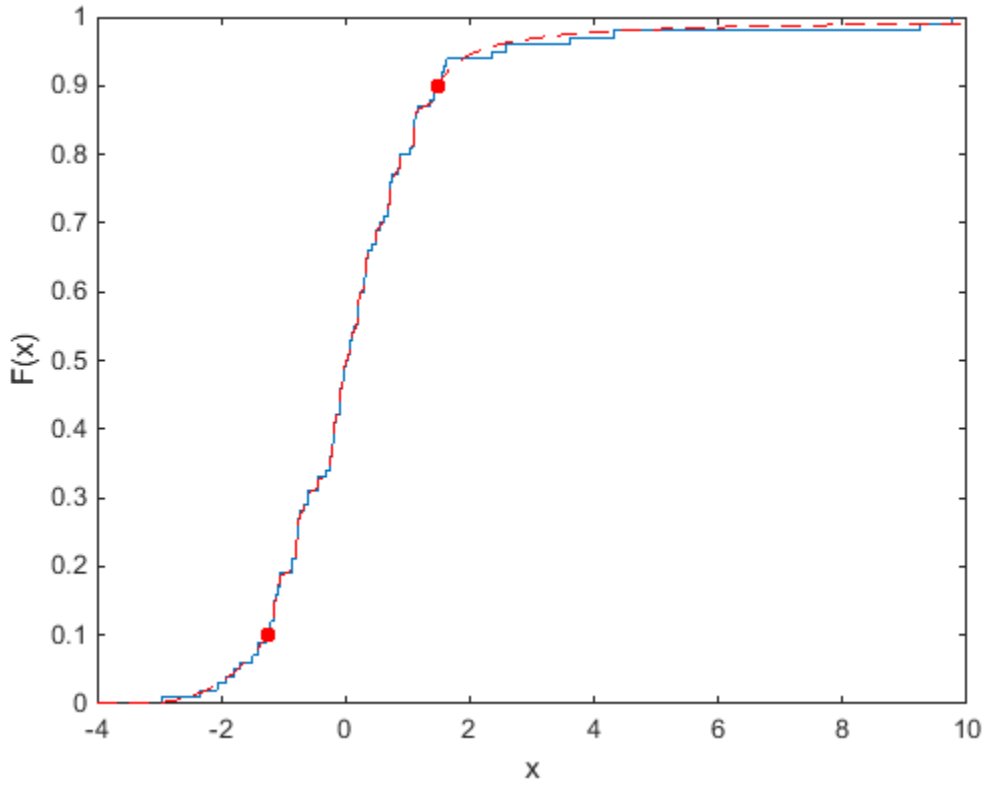
Because the piecewise linear distribution cdf is constructed from the values contained in the sample data, the resulting curve is often not smooth, especially in the tails where data might be sparse. You can smooth the distribution with Pareto tails on page 5-33, using the `paretotails` function.

For information on how to work with a piecewise linear distribution, see Using `PiecewiseLinearDistribution` Objects.

Pareto Tails

Pareto tails use a piecewise approach to improve the fit of a nonparametric cdf by smoothing the tails of the distribution. You can fit a kernel distribution on page 5-30, empirical cdf on page 5-31, or a user-defined estimator to the middle data values, then fit generalized Pareto distribution on page B-59 curves to the tails. This technique is especially useful when the sample data is sparse in the tails.

The following plot shows the empirical cdf (ecdf) of a data sample containing 20 random numbers. The solid line represents the ecdf, and the dashed line represents the empirical cdf with Pareto tails fit to the lower and upper 10 percent of the data. The circles denote the boundaries for the lower and upper 10 percent of the data.

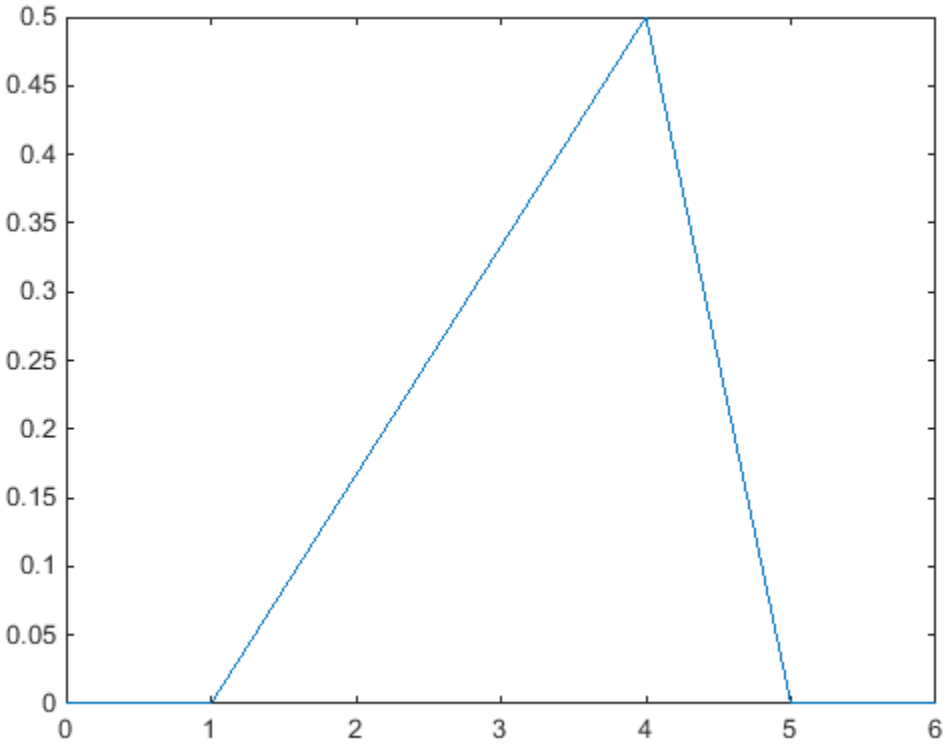


Fitting Pareto tails to the lower and upper 10 percent of the sample data makes the cdf smoother in the tails, where the data is sparse. For more information on working with Pareto tails, see `paretotails`.

Triangular Distribution

A “Triangular Distribution” on page B-158 provides a simplistic representation of the probability distribution when limited sample data is available. This continuous distribution is parameterized by a lower limit, peak location, and upper limit. These points are linearly connected to estimate the pdf of the sample data. You can use the mean, median, or mode of the data as the peak location.

The following plot shows the triangular distribution pdf of a random sample of 10 integers from 0 to 5. The lower limit is the smallest integer in the sample data, and the upper limit is the largest integer. The peak for this plot is at the mode, or most frequently-occurring value, in the sample data.



Business applications such as simulation and project management sometimes use a triangular distribution to create models when limited sample data exists. For more information, see “Triangular Distribution” on page B-158.

Fit Kernel Distribution Object to Data

This example shows how to fit a kernel probability distribution object to sample data.

Step 1. Load sample data.

Load the sample data.

```
load carsmall;
```

This data contains miles per gallon (`MPG`) measurements for different makes and models of cars, grouped by country of origin (`Origin`), model year (`Year`), and other vehicle characteristics.

Step 2. Fit a kernel distribution object.

Use `fitdist` to fit a kernel probability distribution object to the miles per gallon (`MPG`) data for all makes of cars.

```
pd = fitdist(MPG,'Kernel')
```

```
pd =
  KernelDistribution

    Kernel = normal
    Bandwidth = 4.11428
    Support = unbounded
```

This creates a `prob.KernelDistribution` object. By default, `fitdist` uses a normal kernel smoothing function and chooses an optimal bandwidth for estimating normal densities, unless you specify otherwise. You can access information about the fit and perform further calculations using the related object functions.

Step 3. Compute descriptive statistics.

Compute the mean, median, and standard deviation of the fitted kernel distribution.

```
m = mean(pd)
```

```
m = 23.7181
```

```
med = median(pd)
```

```
med = 23.4841
```

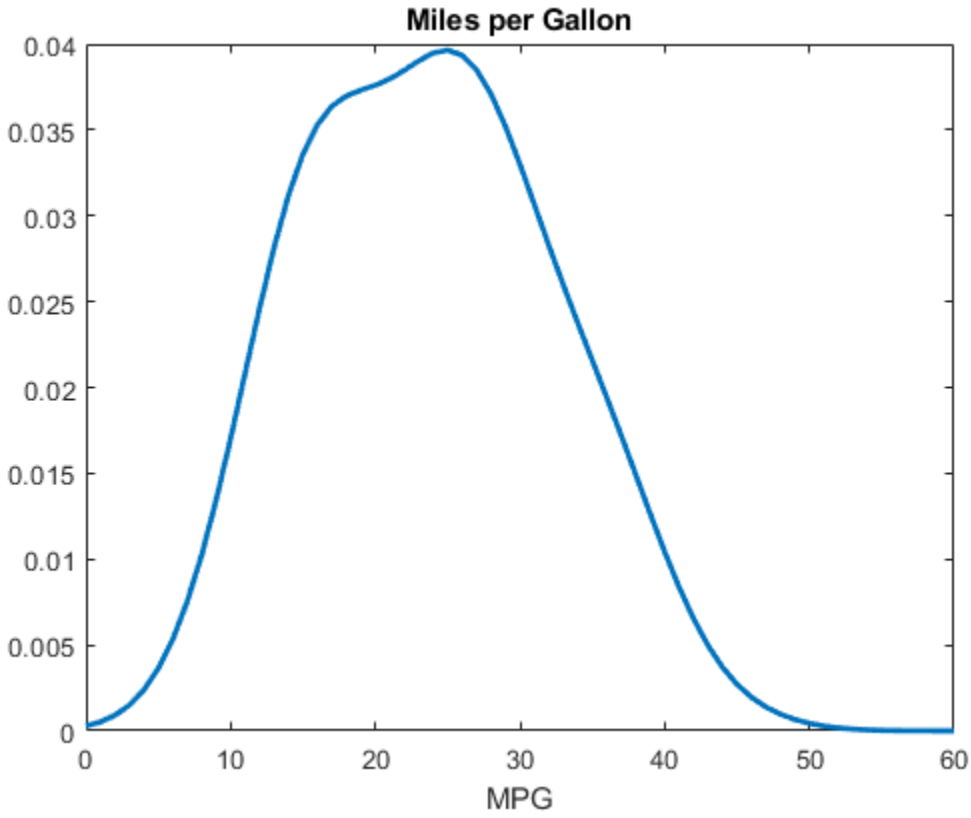
```
s = std(pd)
```

```
s = 8.9896
```

Step 4. Compute and plot the pdf.

Compute and plot the pdf of the fitted kernel distribution.

```
figure
x = 0:1:60;
y = pdf(pd,x);
plot(x,y,'LineWidth',2)
title('Miles per Gallon')
xlabel('MPG')
```

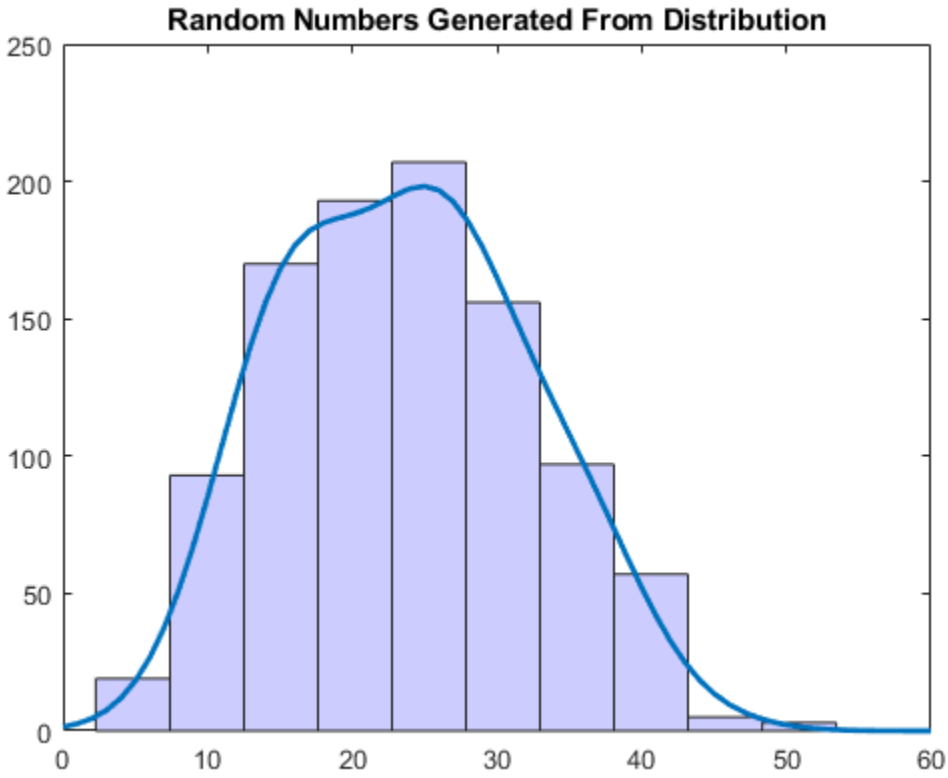


The plot shows the pdf of the kernel distribution fit to the `MPG` data across all makes of cars. The distribution is smooth and fairly symmetrical, although it is slightly skewed with a heavier right tail.

Step 5. Generate random numbers.

Generate a vector of random numbers from the fitted kernel distribution.

```
rng('default')  % For reproducibility
r = random(pd,1000,1);
figure
hist(r);
set(get(gca,'Children'),'FaceColor',[.8 .8 1]);
hold on
y = y*5000;  % Scale pdf to overlay on histogram
plot(x,y,'LineWidth',2)
title('Random Numbers Generated From Distribution')
hold off
```



The histogram has a similar shape to the pdf plot because the random numbers generate from the nonparametric kernel distribution fit to the sample data.

Fit Kernel Distribution Using ksdensity

This example shows how to generate a kernel probability density estimate from sample data using the `ksdensity` function.

Step 1. Load sample data.

Load the sample data.

```
load carsmall;
```

This data contains miles per gallon (`MPG`) measurements for different makes and models of cars, grouped by country of origin (`Origin`), model year (`Year`), and other vehicle characteristics.

Step 2. Generate a kernel probability density estimate.

Use `ksdensity` to generate a kernel probability density estimate for the miles per gallon (`MPG`) data.

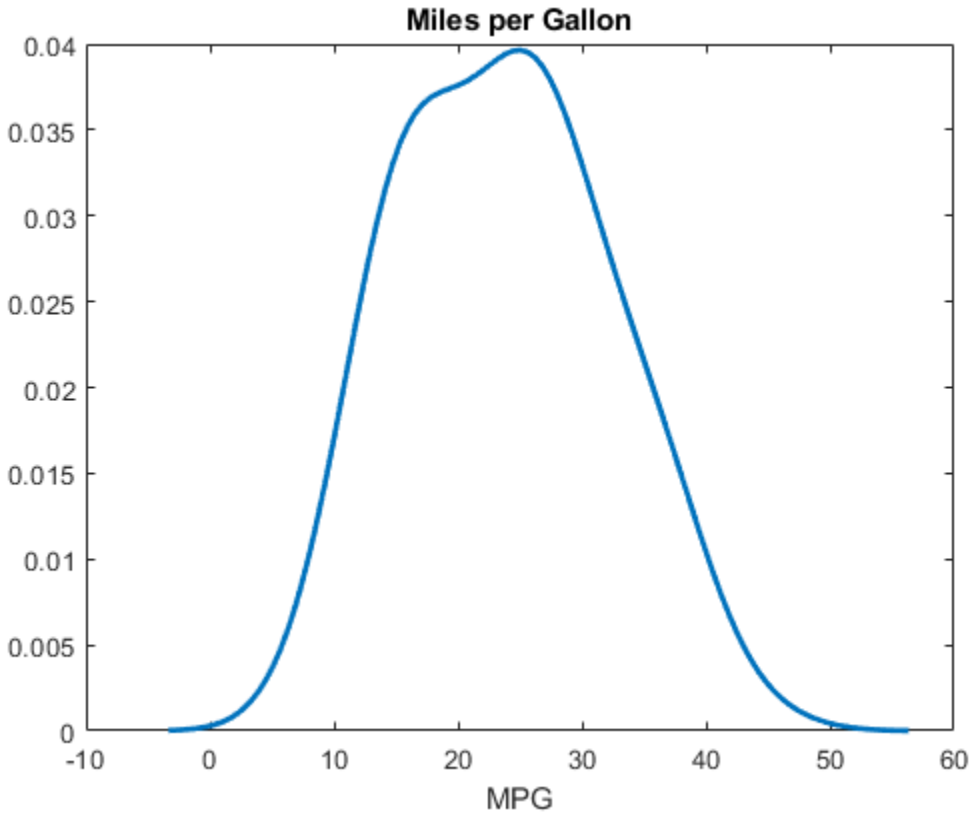
```
[f,xi] = ksdensity(MPG);
```

By default, `ksdensity` uses a normal kernel smoothing function and chooses an optimal bandwidth for estimating normal densities, unless you specify otherwise.

Step 3. Plot the kernel probability density estimate.

Plot the kernel probability density estimate to visualize the `MPG` distribution.

```
plot(xi,f,'LineWidth',2)
title('Miles per Gallon')
xlabel('MPG')
```



The plot shows the pdf of the kernel distribution fit to the `MPG` data across all makes of cars. The distribution is smooth and fairly symmetrical, although it is slightly skewed with a heavier right tail.

Fit Distributions to Grouped Data Using ksdensity

This example shows how to fit kernel distributions to grouped sample data using the `ksdensity` function.

Step 1. Load sample data.

Load the sample data.

```
load carsmall
```

The data contains miles per gallon (`MPG`) measurements for different makes and models of cars, grouped by country of origin (`Origin`), model year (`Model_Year`), and other vehicle characteristics.

Step 2. Group sample data by origin.

Group the `MPG` data by origin (`Origin`) for cars made in the USA, Japan, and Germany.

```
Origin = categorical(cellstr(Origin));
MPG_USA = MPG(Origin=='USA');
MPG_Japan = MPG(Origin=='Japan');
MPG_Germany = MPG(Origin=='Germany');
```

Step 3. Compute and plot the pdf.

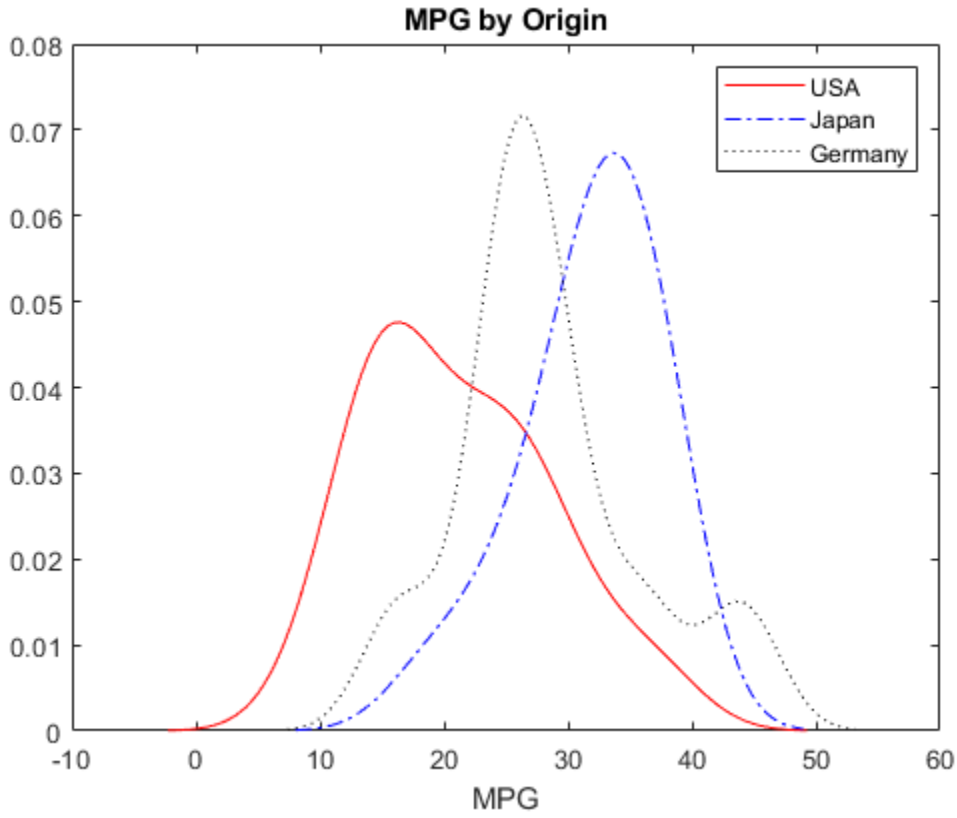
Compute and plot the pdf for each group.

```
[fi,xi] = ksdensity(MPG_USA);
plot(xi,fi,'r-')
hold on

[fj,xj] = ksdensity(MPG_Japan);
plot(xj,fj,'b-.')

[fk,xk] = ksdensity(MPG_Germany);
plot(xk,fk,'k:')

legend('USA','Japan','Germany')
title('MPG by Origin')
xlabel('MPG')
hold off
```



The plot shows how miles per gallon (`MPG`) performance differs by country of origin (`Origin`). Using this data, the USA has the widest distribution, and its peak is at the lowest `MPG` value of the three origins. Japan has the most regular distribution with a slightly heavier left tail, and its peak is at the highest `MPG` value of the three origins. The peak for Germany is between the USA and Japan, and the second bump near 44 miles per gallon suggests that there might be multiple modes in the data.

- “Fit Probability Distribution Objects to Grouped Data” on page 5-92

Fit a Nonparametric Distribution with Pareto Tails

This example shows how to fit a nonparametric probability distribution to sample data using Pareto tails to smooth the distribution in the tails.

Step 1. Generate sample data.

Generate sample data that contains more outliers than expected from a standard normal distribution.

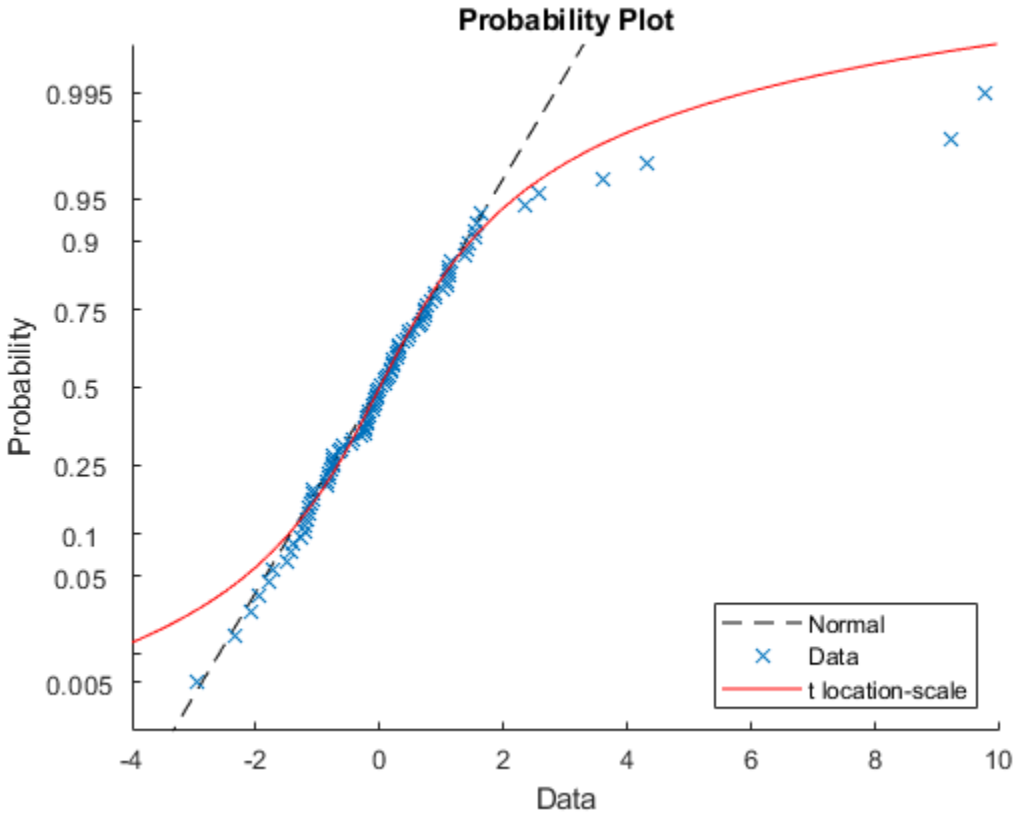
```
rng('default')  % For reproducibility
left_tail = -exprnd(1,10,1);
right_tail = exprnd(5,10,1);
center = randn(80,1);
data = [left_tail;center;right_tail];
```

The data contains 80% values from a standard normal distribution, 10% from an exponential distribution with a mean of 5, and 10% from an exponential distribution with mean of -1. Compared to a standard normal distribution, the exponential values are more likely to be outliers, especially in the upper tail.

Step 2. Fit probability distributions to the data.

Fit a normal distribution and a *t* location-scale distribution to the data, and plot for a visual comparison.

```
probplot(data);
p = fitdist(data,'tlocationscale');
h = probplot(gca,p);
set(h,'color','r','linestyle','-');
title('Probability Plot')
legend('Normal','Data','t location-scale','Location','SE')
```

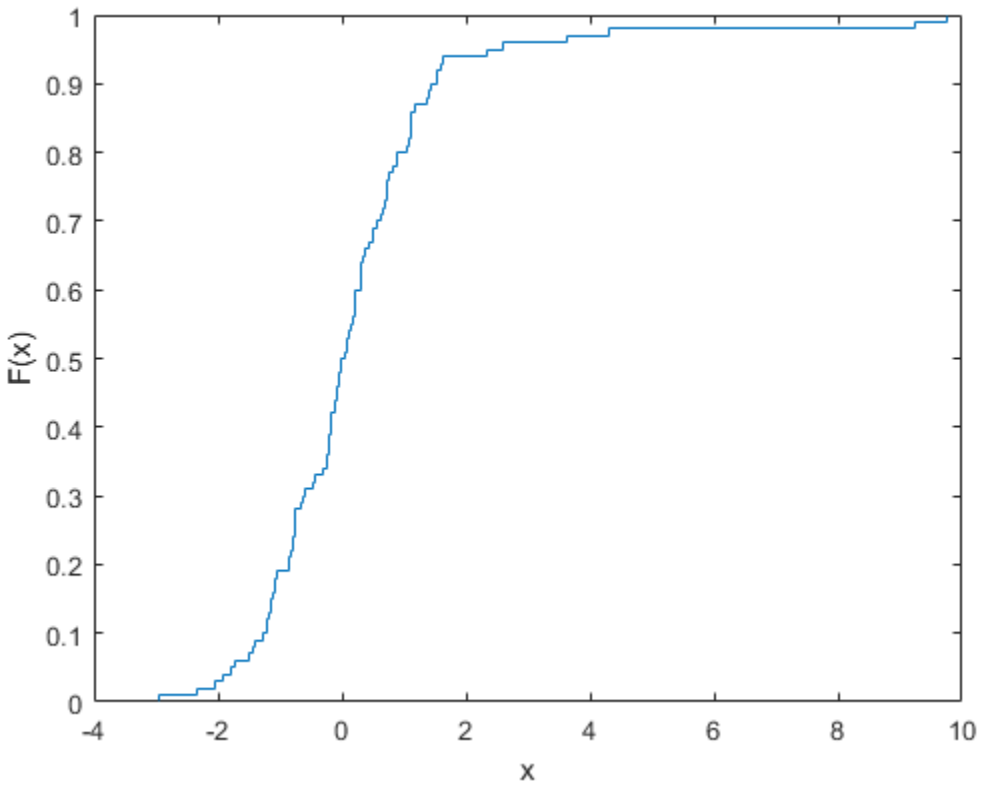


Both distributions appear to fit reasonably well in the center, but neither the normal distribution nor the *t* location-scale distribution fit the tails very well.

Step 3. Generate an empirical distribution.

To obtain a better fit, use `ecdf` to generate an empirical cdf based on the sample data.

```
figure
ecdf(data)
```



The empirical distribution provides a perfect fit, but the outliers make the tails very discrete. Random samples generated from this distribution using the inversion method might include, for example, values near 4.33 and 9.25, but no values in between.

Step 4. Fit a distribution using Pareto tails.

Use `paretotails` to generate an empirical cdf for the middle 80% of the data and fit generalized Pareto distributions to the lower and upper 10%.

```
pfit = paretotails(data,0.1,0.9)
```

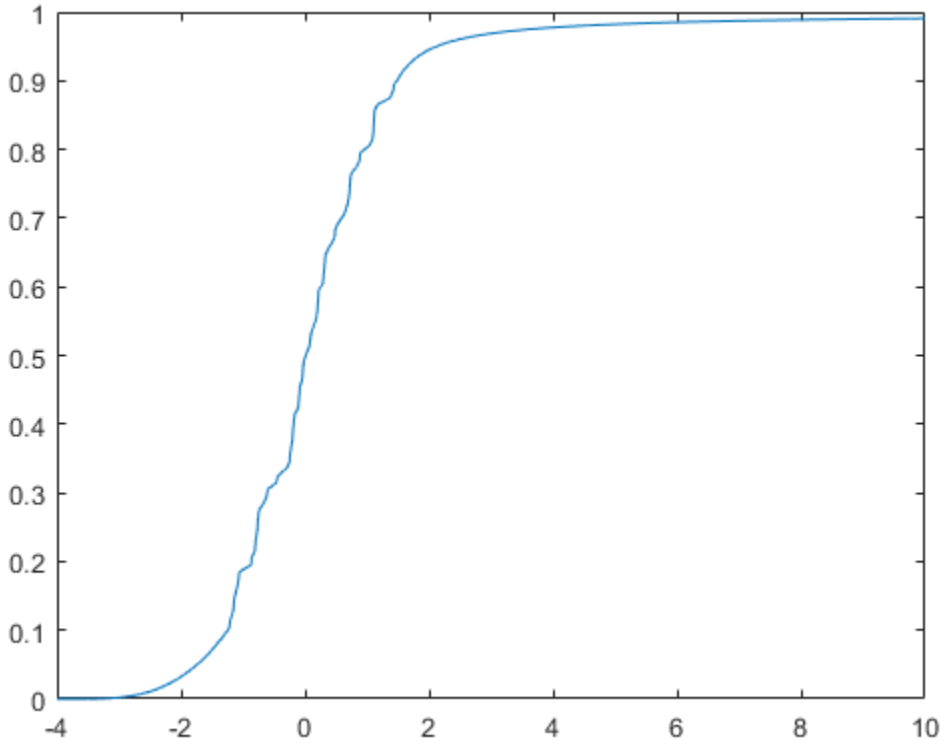
```
pfit =
Piecewise distribution with 3 segments
      -Inf < x < -1.24623    (0 < p < 0.1): lower tail, GPD(-0.334156,0.798745)
   -1.24623 < x < 1.48551  (0.1 < p < 0.9): interpolated empirical cdf
       1.48551 < x < Inf    (0.9 < p < 1): upper tail, GPD(1.23681,0.581868)
```

To obtain a better fit, `paretotails` fits a distribution by piecing together an ecdf or kernel distribution in the center of the sample, and smooth generalized Pareto distributions (GPDs) in the tails. Use `paretotails` to create `paretotails` probability distribution object. You can access information about the fit and perform further calculations on the object using the object functions of the `paretotails` object. For example, you can evaluate the cdf or generate random numbers from the distribution.

Step 5. Compute and plot the cdf.

Compute and plot the cdf of the fitted `paretotails` distribution.

```
x = -4:0.01:10;
plot(x,cdf(pfit,x))
```



The `paretotails` cdf closely fits the data but is smoother in the tails than the ecdf generated in Step 3.

Generate Random Numbers Using the Triangular Distribution

This example shows how to create a triangular probability distribution object based on sample data, and generate random numbers for use in a simulation.

Step 1. Input sample data.

Input the data vector `time`, which contains the observed length of time (in seconds) that 10 different cars stopped at a highway tollbooth.

```
time = [6 14 8 7 16 8 23 6 7 15];
```

The data shows that, while most cars stopped for 6 to 16 seconds, one outlier stopped for 23 seconds.

Step 2. Estimate distribution parameters.

Estimate the triangular distribution parameters from the sample data.

```
lower = min(time);
peak = median(time);
upper = max(time);
```

A triangular distribution provides a simplistic representation of the probability distribution when sample data is limited. Estimate the lower and upper boundaries of the distribution by finding the minimum and maximum values of the sample data. For the peak parameter, the median might provide a better estimate of the mode than the mean, since the data includes an outlier.

Step 3. Create a probability distribution object.

Create a triangular probability distribution object using the estimated parameter values.

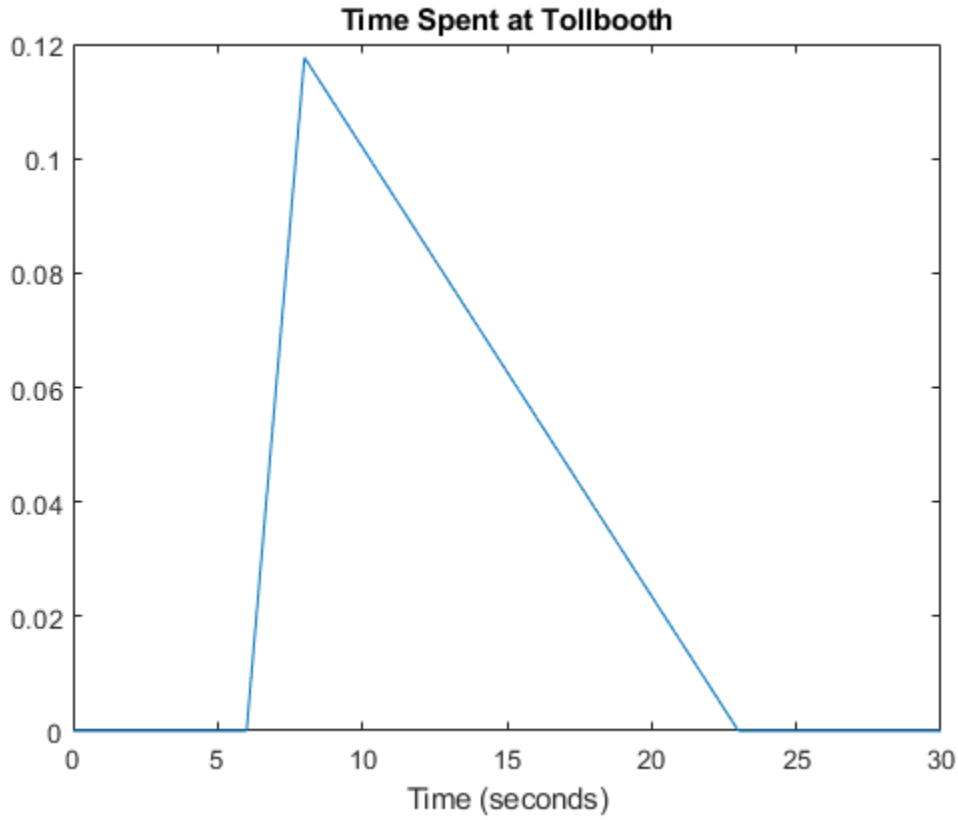
```
pd = makedist('Triangular','a',lower,'b',peak,'c',upper)
```

```
pd =
  TriangularDistribution

A = 6, B = 8, C = 23
```

Compute and plot the pdf of the triangular distribution.

```
x = 0:.1:230;
y = pdf(pd,x);
plot(x,y)
title('Time Spent at Tollbooth')
xlabel('Time (seconds)')
xlim([0 30])
```



The plot shows that this triangular distribution is skewed to the right. However, since the estimated peak value is the sample median, the distribution should be symmetrical about the peak. Because of its skew, this model might, for example, generate random numbers that seem unusually high when compared to the initial sample data.

Step 4. Generate random numbers.

Generate random numbers from this distribution to simulate future traffic flow through the tollbooth.

```
rng('default');  % For reproducibility
r = random(pd,10,1)
```

```
r = 10×1

   16.1265
   18.0987
    8.0796
   18.3001
   13.3176
    7.8211
    9.4360
   12.2508
   19.7082
   20.0078
```

The returned values in `r` are the time in seconds that the next 10 simulated cars spend at the tollbooth. These values seem high compared to the values in the original data vector `time` because

the outlier skewed the distribution to the right. Using the second-highest value as the upper limit parameter might mitigate the effects of the outlier and generate a set of random numbers more similar to the initial sample data.

Step 5. Revise estimated parameters.

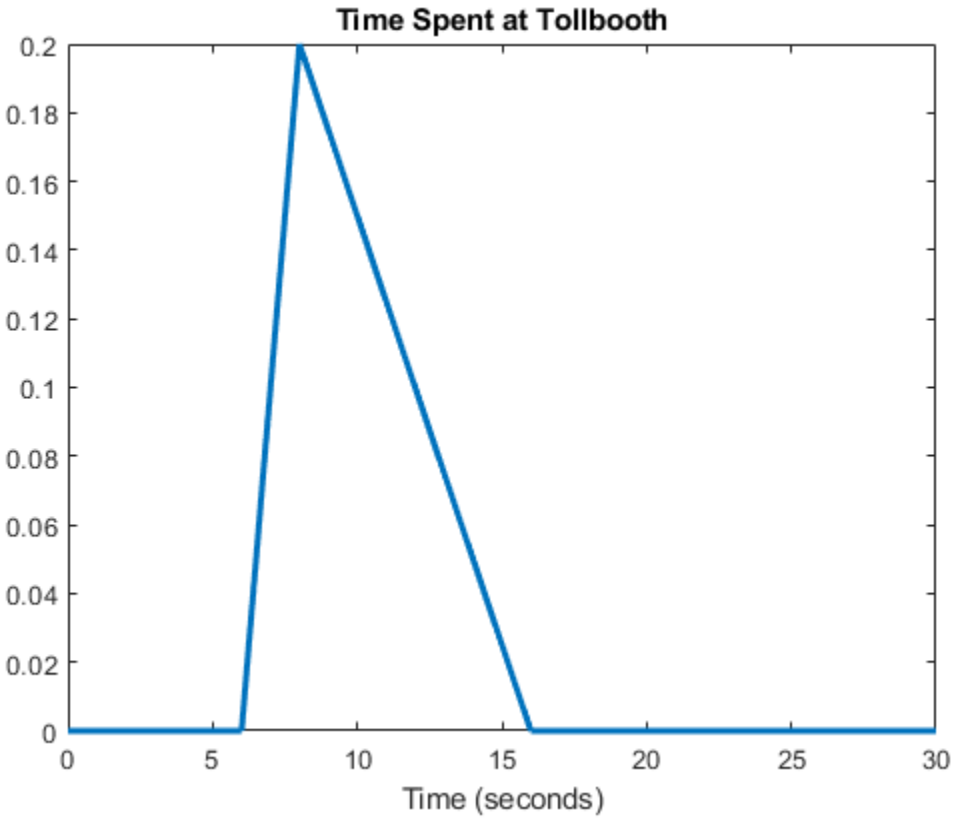
Estimate the upper boundary of the distribution using the second largest value in the sample data.

```
sort_time = sort(time,'descend');
secondLargest = sort_time(2);
```

Step 6. Create a new distribution object and plot the pdf.

Create a new triangular probability distribution object using the revised estimated parameters, and plot its pdf.

```
figure
pd2 = makedist('Triangular','a',lower,'b',peak,'c',secondLargest);
y2 = pdf(pd2,x);
plot(x,y2,'LineWidth',2)
title('Time Spent at Tollbooth')
xlabel('Time (seconds)')
xlim([0 30])
```



The plot shows that this triangular distribution is still slightly skewed to the right. However, it is much more symmetrical about the peak than the distribution that used the maximum sample data value to estimate the upper limit.

Step 7. Generate new random numbers.

Generate new random numbers from the revised distribution.

```
rng('default'); % For reproducibility
r2 = random(pd2,10,1)
```

```
r2 = 10×1

   12.1501
   13.2547
    7.5937
   13.3675
   10.5768
    7.3967
    8.4026
    9.9792
   14.1562
   14.3240
```

These new values more closely resemble those in the original data vector `time`. They are also closer to the sample median than the random numbers generated by the distribution that used the outlier to estimate its upper limit. This example does not remove the outlier from the sample data when computing the median. Other options for parameter estimation include removing outliers from the sample data altogether, or using the mean or mode of the sample data as the peak value.

Model Data Using the Distribution Fitter App

In this section...

The Distribution Fitter app provides a visual, interactive approach to fitting univariate distributions to data.

Explore Probability Distributions Interactively

You can use the Distribution Fitter app to interactively fit probability distributions to data imported from the MATLAB workspace. You can choose from 22 built-in probability distributions, or create your own custom distribution. The app displays the fitted distribution over plots of the empirical distributions, including pdf, cdf, probability plots, and survivor functions. You can export the fit data, including fitted parameter values, to the workspace for further analysis.

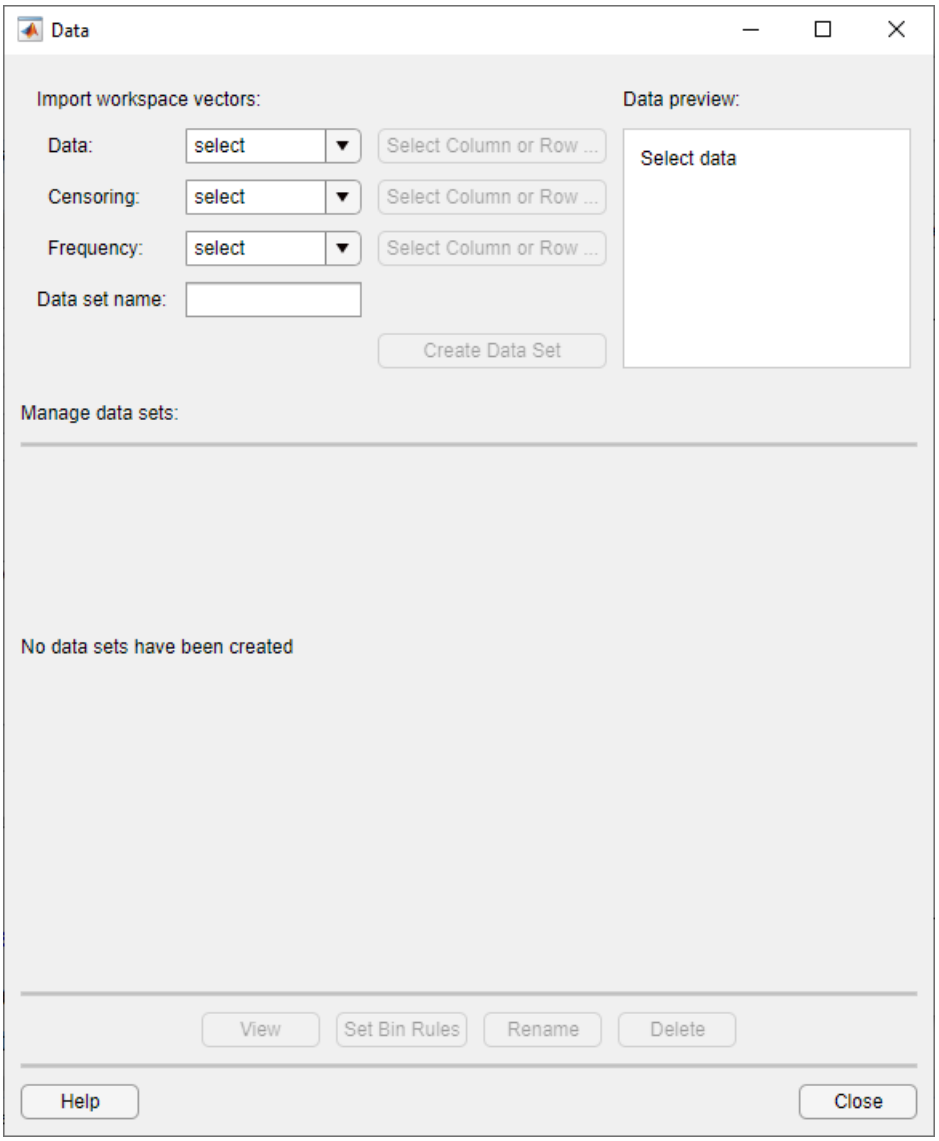
Distribution Fitter App Workflow

To fit a probability distribution to your sample data:

1. On the MATLAB Toolstrip, click the Apps tab. In the Math, Statistics and Optimization group, open the Distribution Fitter app. Alternatively, at the command prompt, enter `distributionFitter`.
2. Import your sample data, or create a data vector directly in the app. You can also manage your data sets and choose which one to fit. See “Create and Manage Data Sets” on page 5-52.
3. Create a new fit for your data. See “Create a New Fit” on page 5-55.
4. Display the results of the fit. You can choose to display the density (pdf), cumulative probability (cdf), quantile (inverse cdf), probability plot (choose one of several distributions), survivor function, and cumulative hazard. See “Display Results” on page 5-59.
5. You can create additional fits, and manage multiple fits from within the app. See “Manage Fits” on page 5-60.
6. Evaluate probability functions for the fit. You can choose to evaluate the density (pdf), cumulative probability (cdf), quantile (inverse cdf), survivor function, and cumulative hazard. See “Evaluate Fits” on page 5-62.
7. Improve the fit by excluding certain data. You can specify bounds for the data to exclude, or you can exclude data graphically using a plot of the values in the sample data. See “Exclude Data” on page 5-64.
8. Save your current Distribution Fitter app session so you can open it later. See “Save and Load Sessions” on page 5-68.

Create and Manage Data Sets

To open the Data dialog box, click the **Data** button in the Distribution Fitter app.



Import Data

Create a data set by importing a vector from the MATLAB workspace using the **Import workspace vectors** pane.

- **Data** — In the **Data** field, the drop-down list contains the names of all matrices and vectors, other than 1-by-1 matrices (scalars) in the MATLAB workspace. Select the array containing the data that you want to fit. The actual data you import must be a vector. If you select a matrix in the **Data** field, the first column of the matrix is imported by default. To select a different column or row of the matrix, click **Select Column or Row**. The matrix displays in the Variables editor. You can select a row or column by highlighting it.

  Alternatively, you can enter any valid MATLAB expression in the **Data** field.

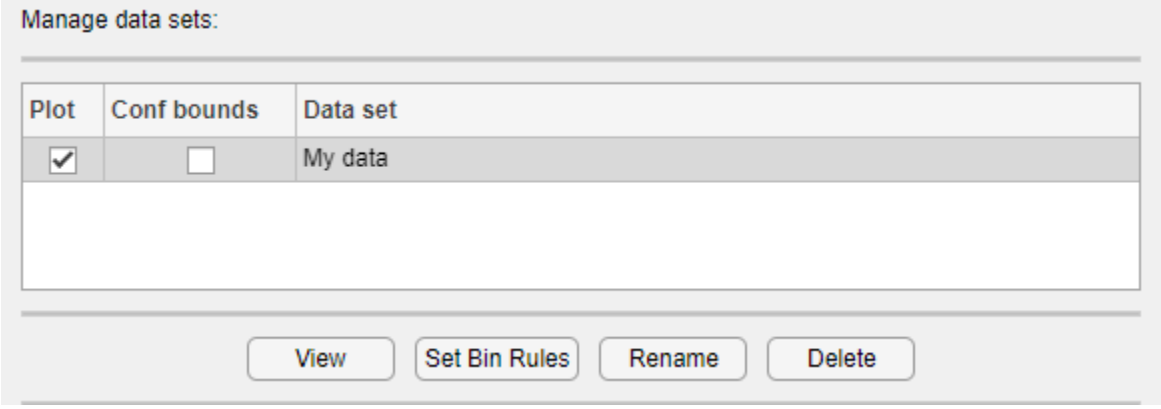
When you select a vector in the **Data** field, a histogram of the data appears in the **Data preview** pane.

- **Censoring** — If some of the points in the data set are censored, enter a Boolean vector of the same size as the data vector, specifying the censored entries of the data. A `1` in the censoring vector specifies that the corresponding entry of the data vector is censored. A `0` specifies that the entry is not censored. If you enter a matrix, you can select a column or row by clicking **Select Column or Row**. If you do not have censored data, leave the **Censoring** field blank.
- **Frequency** — Enter a vector of positive integers of the same size as the data vector to specify the frequency of the corresponding entries of the data vector. For example, a value of 7 in the 15th entry of frequency vector specifies that there are 7 data points corresponding to the value in the 15th entry of the data vector. If all entries of the data vector have frequency 1, leave the **Frequency** field blank.
- **Data set name** — Enter a name for the data set that you import from the workspace, such as `My data`.

After you have entered the information in the preceding fields, click **Create Data Set** to create the data set `My data`.

Manage Data Sets

View and manage the data sets that you create using the **Manage data sets** pane. When you create a data set, its name appears in the **Data sets** list. The following figure shows the **Manage data sets** pane after creating the data set `My data`.



For each data set in the **Data sets** list, you can:

- Select the **Plot** check box to display a plot of the data in the main Distribution Fitter app window. When you create a new data set, **Plot** is selected by default. Clearing the **Plot** check box removes the data from the plot in the main window. You can specify the type of plot displayed in the **Display type** field in the main window.
- If **Plot** is selected, you can also select **Bounds** to display confidence interval bounds for the plot in the main window. These bounds are pointwise confidence bounds around the empirical estimates of these functions. The bounds are displayed only when you set **Display Type** in the main window to one of the following:
  - `Cumulative probability (CDF)`
  - `Survivor function`

- `Cumulative hazard`

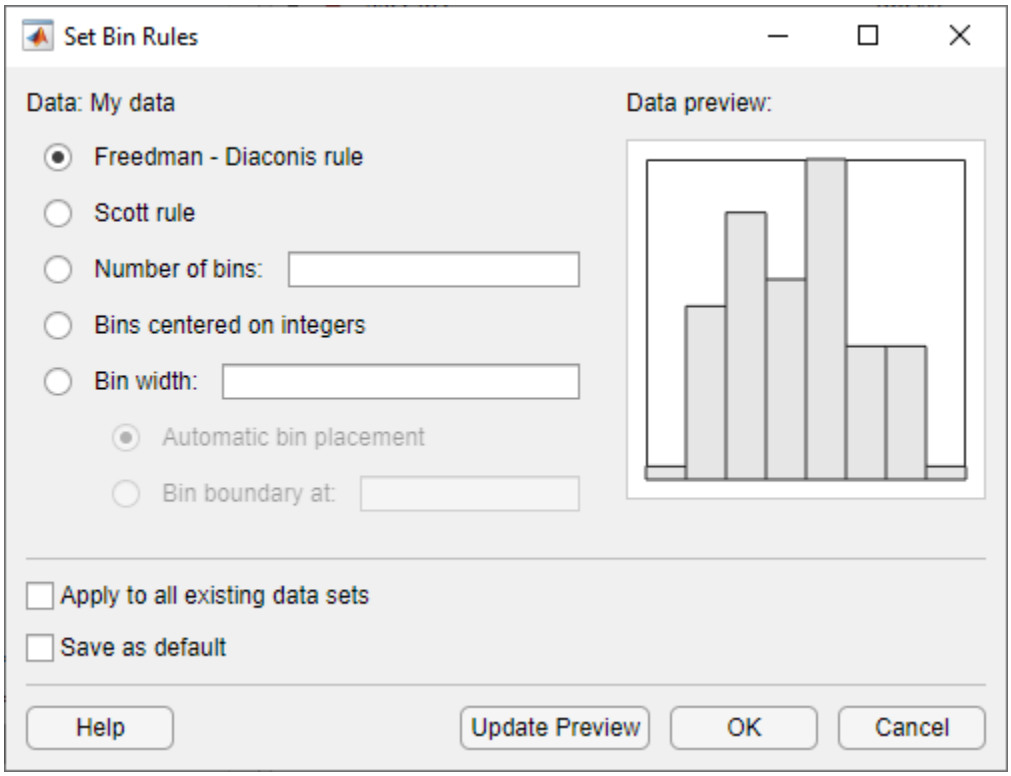
The Distribution Fitter app cannot display confidence bounds on density (`PDF`), quantile (`inverse CDF`), or probability plots. Clearing the **Bounds** check box removes the confidence bounds from the plot in the main window.

When you select a data set from the list, you can access the following buttons:

- **View** — Display the data in a table in a new window.
- **Set Bin Rules** — Defines the histogram bins used in a density (PDF) plot.
- **Rename** — Rename the data set.
- **Delete** — Delete the data set.

Set Bin Rules

To set bin rules for the histogram of a data set, click **Set Bin Rules** to open the **Set Bin Width Rules** dialog box.



You can select from the following rules:

- **Freedman-Diaconis rule** — Algorithm that chooses bin widths and locations automatically, based on the sample size and the spread of the data. This rule, which is the default, is suitable for many kinds of data.
- **Scott rule** — Algorithm intended for data that are approximately normal. The algorithm chooses bin widths and locations automatically.
- **Number of bins** — Enter the number of bins. All bins have equal widths.

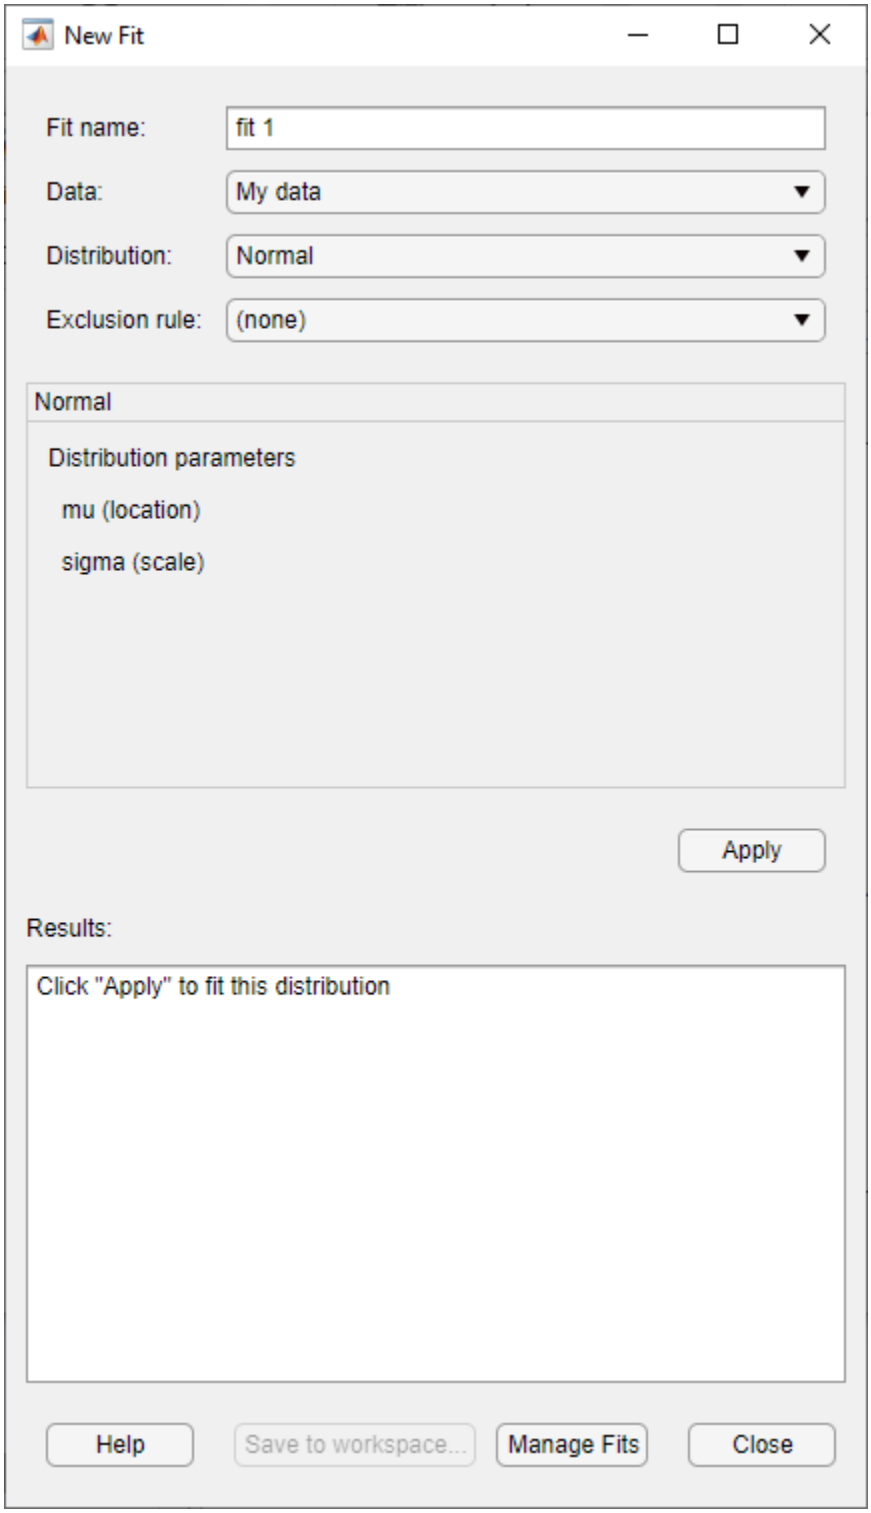
- **Bins centered on integers** — Specifies bins centered on integers.
- **Bin width** — Enter the width of each bin. If you select this option, you can also select:
  - **Automatic bin placement** — Place the edges of the bins at integer multiples of the **Bin width**.
  - **Bin boundary at** — Enter a scalar to specify the boundaries of the bins. The boundary of each bin is equal to this scalar plus an integer multiple of the **Bin width**.

You can also:

- **Apply to all existing data sets** — Apply the rule to all data sets. Otherwise, the rule is applied only to the data set currently selected in the Data dialog box.
- **Save as default** — Apply the current rule to any new data sets that you create. You can set default bin width rules by selecting **Set Default Bin Rules** from the **Tools** menu in the main window.

Create a New Fit

Click the **New Fit** button at the top of the main window to open the New Fit dialog box. If you created the data set `My data`, it appears in the **Data** field.



Field Name	Description
Fit Name	Enter a name for the fit.

Field Name	Description
Data	Select the data set to which you want to fit a distribution from the drop-down list.
Distribution	Select the type of distribution to fit from the **Distribution** drop-down list. Only the distributions that apply to the values of the selected data set appear in the **Distribution** field. For example, when the data include values that are zero or negative, positive distributions are not displayed . You can specify either a parametric or a nonparametric distribution. When you select a parametric distribution from the drop-down list, a description of its parameters appears. Distribution Fitter estimates these parameters to fit the distribution to the data set. If you select the binomial distribution or the generalized extreme value distribution, you must specify a fixed value for one of the parameters. The pane contains a text field into which you can specify that parameter. When you select `Nonparametric fit`, options for the fit appear in the pane, as described in “Further Options for Nonparametric Fits” on page 5-58.
Exclusion rule	Specify a rule to exclude some data. Create an exclusion rule by clicking **Exclude** in the Distribution Fitter app. For more information, see “Exclude Data” on page 5-64.

Apply the New Fit

Click **Apply** to fit the distribution. For a parametric fit, the **Results** pane displays the values of the estimated parameters. For a nonparametric fit, the **Results** pane displays information about the fit.

When you click **Apply**, the Distribution Fitter app displays a plot of the distribution and the corresponding data.

Note When you click **Apply**, the title of the dialog box changes to Edit Fit. You can now make changes to the fit you just created and click **Apply** again to save them. After closing the Edit Fit dialog box, you can reopen it from the Fit Manager dialog box at any time to edit the fit.

After applying the fit, you can save the information to the workspace using probability distribution objects by clicking **Save to workspace**.

Available Distributions

All of the distributions available in the Distribution Fitter app are supported elsewhere in Statistics and Machine Learning Toolbox software. You can use the `fitdist` function to fit any of the distributions supported by the app. Many distributions also have dedicated fitting functions. These functions compute the majority of the fits in the Distribution Fitter app, and are referenced in the following list. Other fits are computed using functions internal to the Distribution Fitter app.

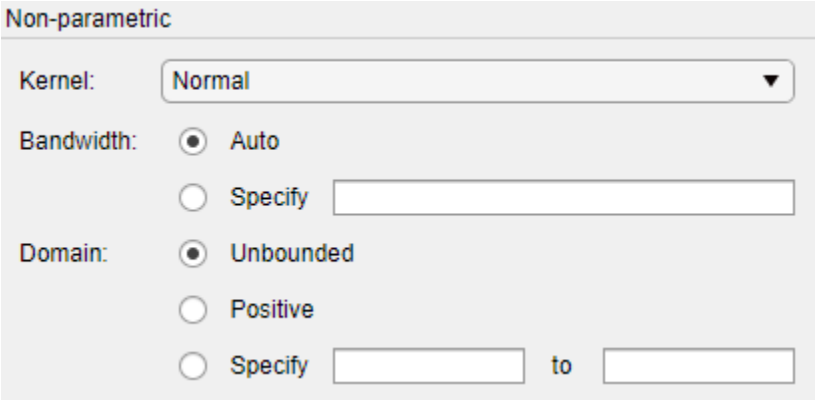
Not all of the distributions listed are available for all data sets. The Distribution Fitter app determines the extent of the data (nonnegative, unit interval, etc.) and displays appropriate distributions in the **Distribution** drop-down list. Distribution data ranges are given parenthetically in the following list.

- Beta on page B-6 (unit interval values) distribution, fit using the function `betafit`.

- Binomial on page B-10 (nonnegative integer values) distribution, fit using the function `binopdf`.
- Birnbaum-Saunders on page B-18 (positive values) distribution.
- Burr Type XII on page B-19 (positive values) distribution.
- Exponential on page B-33 (nonnegative values) distribution, fit using the function `expfit`.
- Extreme value on page B-40 (all values) distribution, fit using the function `evfit`.
- Gamma on page B-47 (positive values) distribution, fit using the function `gamfit`.
- Generalized extreme value on page B-55 (all values) distribution, fit using the function `gevfit`.
- Generalized Pareto on page B-59 (all values) distribution, fit using the function `gpfit`.
- Inverse Gaussian on page B-75 (positive values) distribution.
- Logistic on page B-85 (all values) distribution.
- Loglogistic on page B-86 (positive values) distribution.
- Lognormal on page B-88 (positive values) distribution, fit using the function `lognfit`.
- Nakagami on page B-108 (positive values) distribution.
- Negative binomial on page B-109 (nonnegative integer values) distribution, fit using the function `nbinpdf`.
- Nonparametric on page B-78 (all values) distribution, fit using the function `ksdensity`.
- Normal on page B-119 (all values) distribution, fit using the function `normfit`.
- Poisson on page B-131 (nonnegative integer values) distribution, fit using the function `poisspdf`.
- Rayleigh on page B-137 (positive values) distribution using the function `raylfit`.
- Rician on page B-139 (positive values) distribution.
- *t* location-scale on page B-156 (all values) distribution.
- Weibull on page B-170 (positive values) distribution using the function `wblfit`.

Further Options for Nonparametric Fits

When you select `Non-parametric` in the **Distribution** field, a set of options appears in the **Non-parametric** pane, as shown in the following figure.



The options for nonparametric distributions are:

- **Kernel** — Type of kernel function to use.

  - `Normal`
  - `Box`
  - `Triangle`
  - `Epanechnikov`
- **Bandwidth** — The bandwidth of the kernel smoothing window. Select **Auto** for a default value that is optimal for estimating normal densities. After you click **Apply**, this value appears in the **Fit results** pane. Select **Specify** and enter a smaller value to reveal features such as multiple modes or a larger value to make the fit smoother.
- **Domain** — The allowed *x*-values for the density.
  - **Unbounded** — The density extends over the whole real line.
  - **Positive** — The density is restricted to positive values.
  - **Specify** — Enter lower and upper bounds for the domain of the density.

  When you select **Positive** or **Specify**, the nonparametric fit has zero probability outside the specified domain.

Display Results

The Distribution Fitter app window displays plots of:

- The data sets for which you select **Plot** in the Data dialog box.
- The fits for which you select **Plot** in the Fit Manager dialog box.
- Confidence bounds for:
  - The data sets for which you select **Bounds** in the Data dialog box.
  - The fits for which you select **Bounds** in the Fit Manager dialog box.

The following fields are available.

Display Type

Specify the type of plot to display using the **Display Type** field in the main app window. Each type corresponds to a probability function, for example, a probability density function. You can choose from the following display types:

- `Density (PDF)` — Display a probability density function (PDF) plot for the fitted distribution. The main window displays data sets using a probability histogram, in which the height of each rectangle is the fraction of data points that lie in the bin divided by the width of the bin. This makes the sum of the areas of the rectangles equal to 1.
- `Cumulative probability (CDF)` — Display a cumulative probability plot of the data. The main window displays data sets using a cumulative probability step function. The height of each step is the cumulative sum of the heights of the rectangles in the probability histogram.
- `Quantile (inverse CDF)` — Display a quantile (inverse CDF) plot.
- `Probability plot` — Display a probability plot of the data. Specify the type of distribution used to construct the probability plot in the **Distribution** field. This field is only available when you select `Probability plot`. The choices for the distribution are:
  - `Exponential`

- `Extreme value`
- `Logistic`
- `Log-Logistic`
- `Lognormal`
- `Normal`
- `Rayleigh`
- `Weibull`

You can also create a probability plot against a parametric fit that you create in the **New Fit** pane. When you create these fits, they are added at the bottom of the **Distribution** drop-down list.

- `Survivor function` — Display survivor function plot of the data.
- `Cumulative hazard` — Display cumulative hazard plot of the data.

Note If the plotted data includes `0` or negative values, some distributions are unavailable.

Confidence Bounds

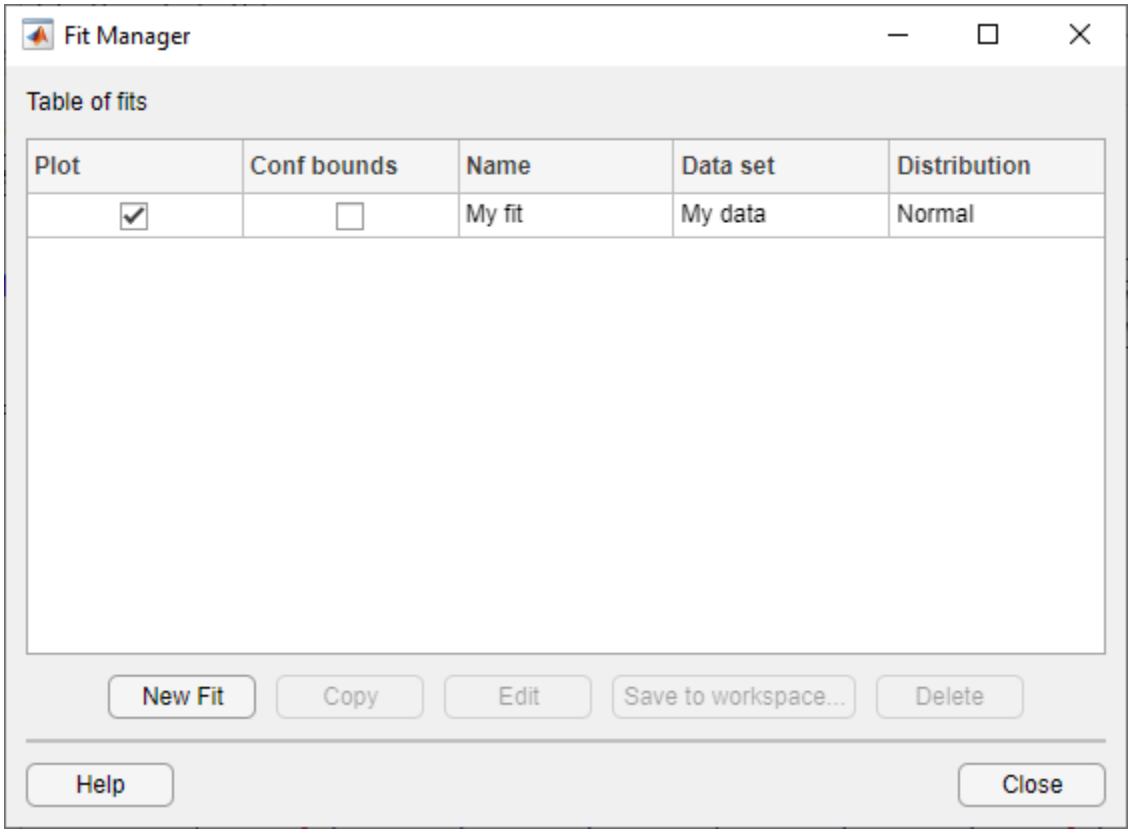
You can display confidence bounds for data sets and fits when you set **Display Type** to `Cumulative probability (CDF)`, `Survivor function`, `Cumulative hazard`, or, for fits only, `Quantile (inverse CDF)`.

- To display bounds for a data set, select **Bounds** next to the data set in the **Data sets** pane of the Data dialog box.
- To display bounds for a fit, select **Bounds** next to the fit in the Fit Manager dialog box. Confidence bounds are not available for all fit types.

To set the confidence level for the bounds, select `Confidence Level` from the **View** menu in the main window and choose from the options.

Manage Fits

Click the **Manage Fits** button to open the **Fit Manager** dialog box.



The **Table of fits** displays a list of the fits that you create, with the following options:

- **Plot** — Displays a plot of the fit in the main window of the Distribution Fitter app. When you create a new fit, **Plot** is selected by default. Clearing the **Plot** check box removes the fit from the plot in the main window.
- **Bounds** — If you select **Plot**, you can also select **Bounds** to display confidence bounds in the plot. The bounds are displayed when you set **Display Type** in the main window to one of the following:

  - `Cumulative probability (CDF)`
  - `Quantile (inverse CDF)`
  - `Survivor function`
  - `Cumulative hazard`

  The Distribution Fitter app cannot display confidence bounds on density (`PDF`) or probability plots. Bounds are not supported for nonparametric fits and some parametric fits.

  Clearing the **Bounds** check box removes the confidence intervals from the plot in the main window.

  When you select a fit in the **Table of fits**, the following buttons are enabled below the table:

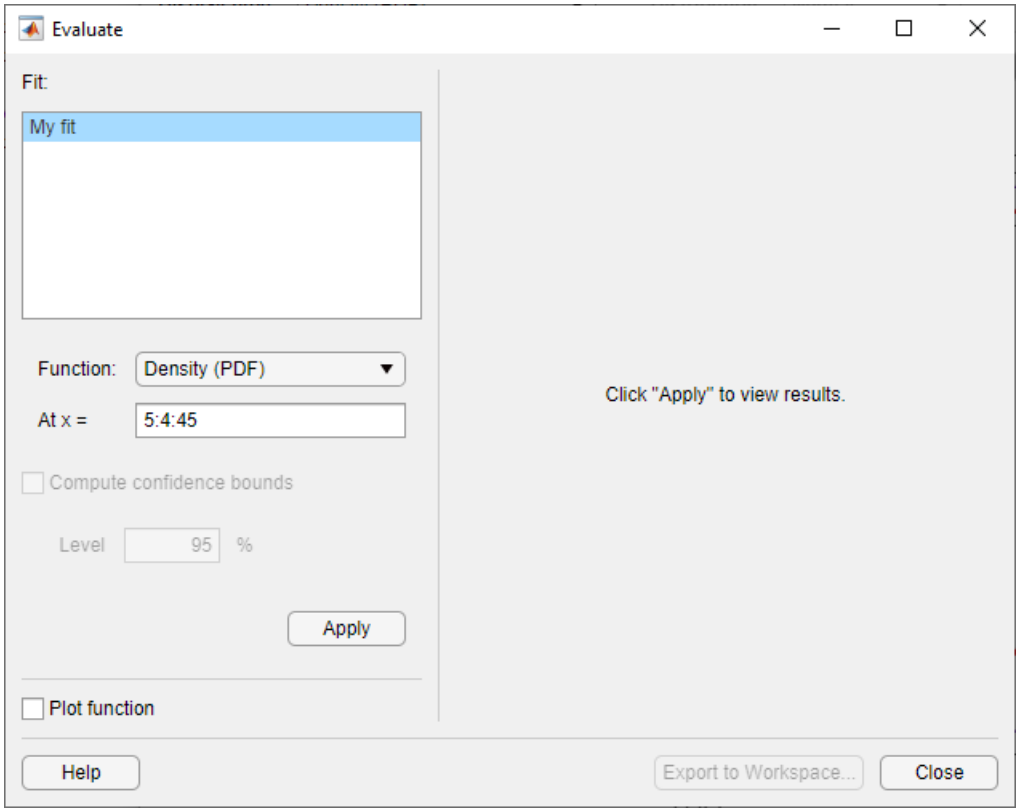
  - **New Fit** — Open a New Fit window.
  - **Copy** — Create a copy of the selected fit.
  - **Edit** — Open an Edit Fit dialog box, to edit the fit.

Note You can edit only the currently selected fit in the Edit Fit dialog box. To edit a different fit, select it in the **Table of fits** and click **Edit** to open another Edit Fit dialog box.

- **Save to workspace** — Save the selected fit as a distribution object.
- **Delete** — Delete the selected fit.

Evaluate Fits

Use the **Evaluate** dialog box to evaluate your fitted distribution at any data points you choose. To open the dialog box, click the **Evaluate** button.



In the **Evaluate** dialog box, choose from the following items:

- **Fit** pane — Display the names of existing fits. Select one or more fits that you want to evaluate. Using your platform specific functionality, you can select multiple fits.
- **Function** — Select the type of probability function that you want to evaluate for the fit. The available functions are:
  - `Density (PDF)` — Computes a probability density function.
  - `Cumulative probability (CDF)` — Computes a cumulative probability function.
  - `Quantile (inverse CDF)` — Computes a quantile (inverse CDF) function.
  - `Survivor function` — Computes a survivor function.
  - `Cumulative hazard` — Computes a cumulative hazard function.
  - `Hazard rate` — Computes the hazard rate.

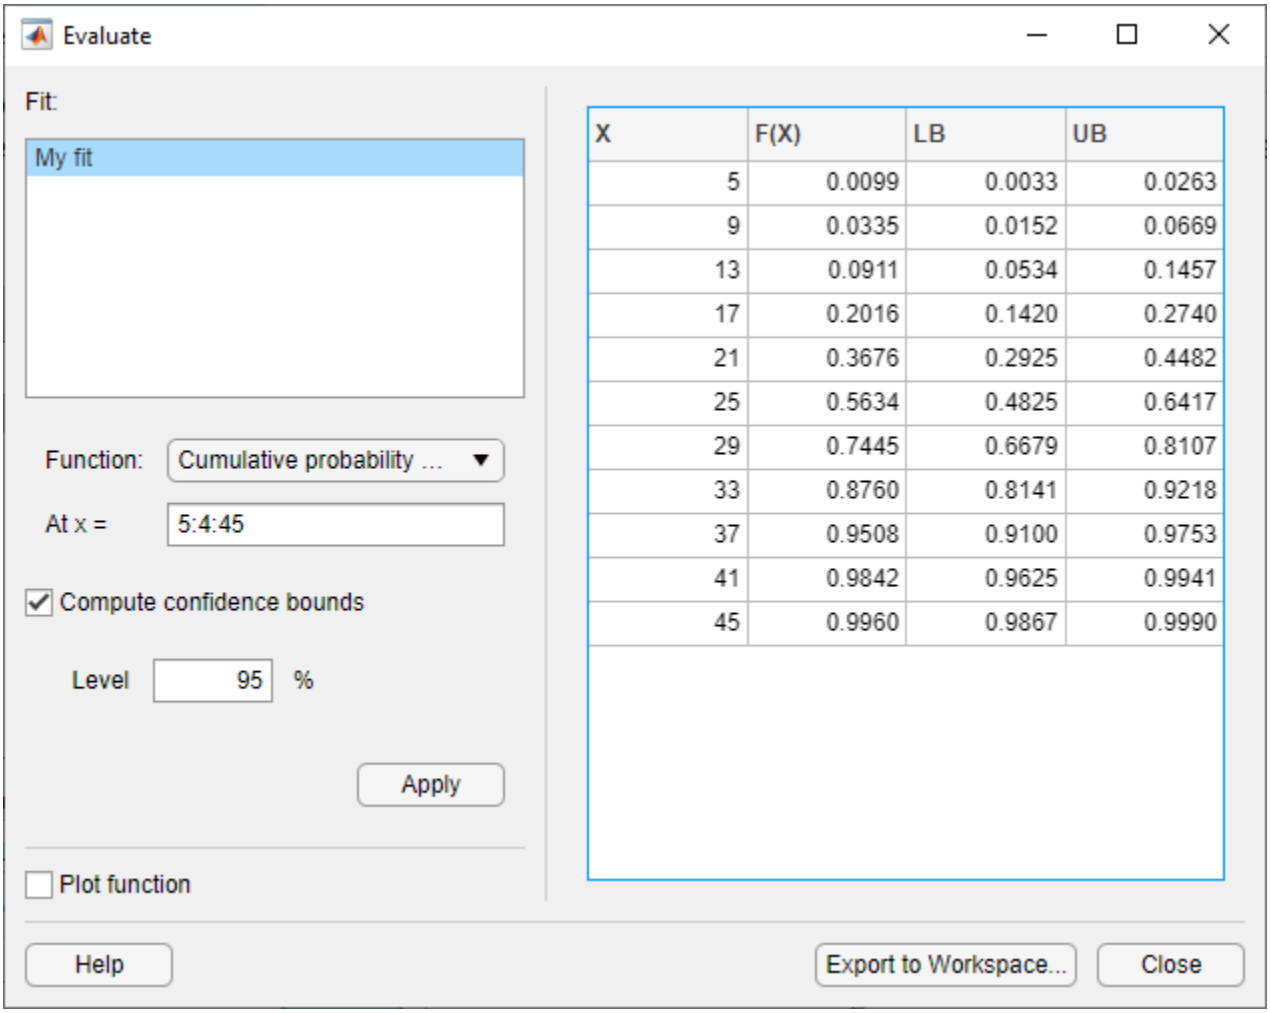
- **At x =** — Enter a vector of points or the name of a workspace variable containing a vector of points at which you want to evaluate the distribution function. If you change **Function** to `Quantile (inverse CDF)`, the field name changes to **At p =**, and you enter a vector of probability values.
- **Compute confidence bounds** — Select this box to compute confidence bounds for the selected fits. The check box is enabled only if you set **Function** to one of the following:

  - `Cumulative probability (CDF)`
  - `Quantile (inverse CDF)`
  - `Survivor function`
  - `Cumulative hazard`

  The Distribution Fitter app cannot compute confidence bounds for nonparametric fits and for some parametric fits. In these cases, it returns `NaN` for the bounds.
- **Level** — Set the level for the confidence bounds.
- **Plot function** — Select this box to display a plot of the distribution function, evaluated at the points you enter in the **At x =** field, in a new window.

Note The settings for **Compute confidence bounds**, **Level**, and **Plot function** do not affect the plots that are displayed in the main window of the Distribution Fitter app. The settings apply only to plots you create by clicking **Plot function** in the Evaluate window.

To apply these evaluation settings to the selected fit, click **Apply**. The following figure shows the results of evaluating the cumulative density function for the fit **My fit**, at the points in the vector `5:4:45`.



X	F(X)	LB	UB
5	0.0099	0.0033	0.0263
9	0.0335	0.0152	0.0669
13	0.0911	0.0534	0.1457
17	0.2016	0.1420	0.2740
21	0.3676	0.2925	0.4482
25	0.5634	0.4825	0.6417
29	0.7445	0.6679	0.8107
33	0.8760	0.8141	0.9218
37	0.9508	0.9100	0.9753
41	0.9842	0.9625	0.9941
45	0.9960	0.9867	0.9990

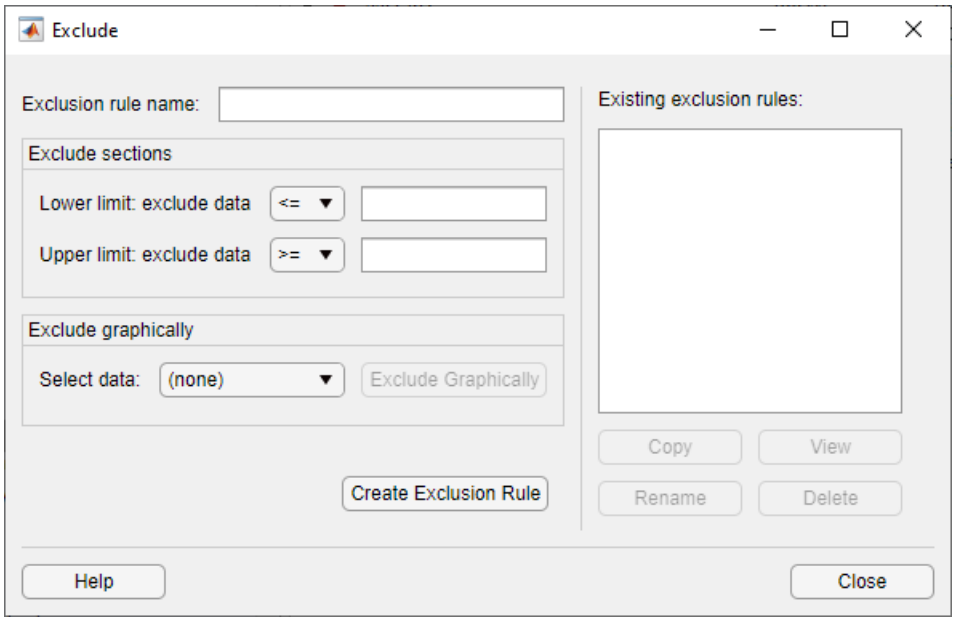
The columns of the table to the right of the **Fit** pane display the following values:

- X — The entries of the vector that you enter in **At x =** field.
- F(X)— The corresponding values of the CDF at the entries of X.
- LB — The lower bounds for the confidence interval, if you select **Compute confidence bounds**.
- UB — The upper bounds for the confidence interval, if you select **Compute confidence bounds**.

To save the data displayed in the table to a matrix in the MATLAB workspace, click **Export to Workspace**.

Exclude Data

To exclude values from fit, open the **Exclude** window by clicking the **Exclude** button. In the **Exclude** window, you can create rules for excluding specified data values. When you create a new fit in the **New Fit** window, you can use these rules to exclude data from the fit.



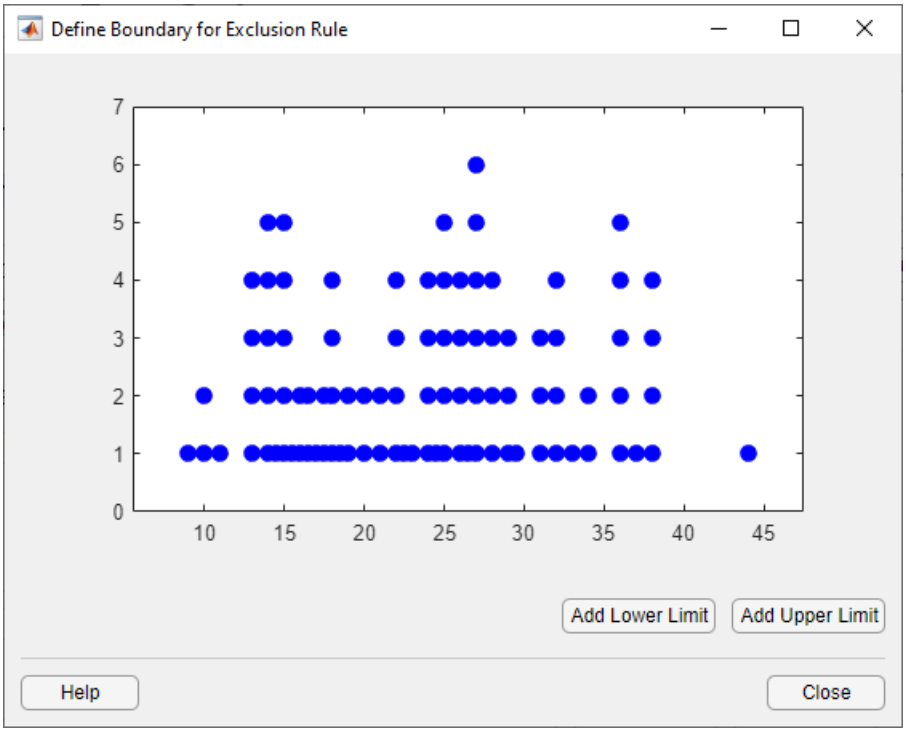
To create an exclusion rule:

1. **Exclusion Rule Name**— Enter a name for the exclusion rule.
2. **Exclude Sections**— Specify bounds for the excluded data:

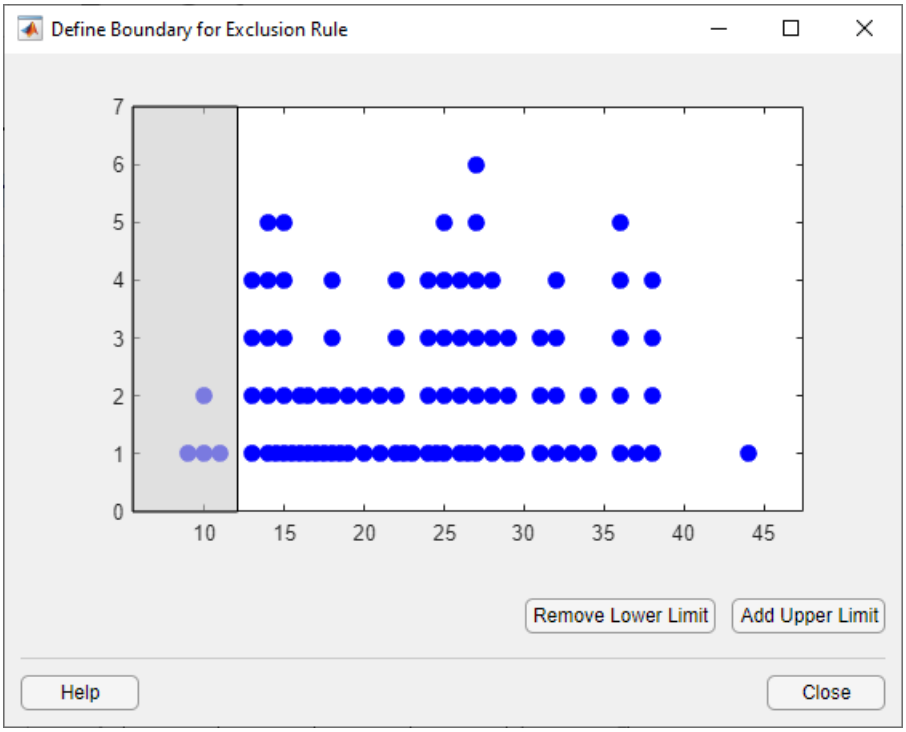
   - In the **Lower limit: exclude data** drop-down list, select <= or < and enter a scalar value in the field to the right. Depending on which operator you select, the app excludes from the fit any data values that are less than or equal to the scalar value, or less than the scalar value, respectively.
   - In the **Upper limit: exclude data** drop-down list, select >= or > and enter a scalar value in the field to the right. Depending on which operator you select, the app excludes from the fit any data values that are greater than or equal to the scalar value, or greater than the scalar value, respectively.

   OR

   Click the **Exclude Graphically** button to define the exclusion rule by displaying a plot of the values in a data set and selecting the bounds for the excluded data. For example, if you created the data set `My data` as described in Create and Manage Data Sets, select it from the drop-down list next to **Exclude graphically**, and then click the **Exclude graphically** button. The app displays the values in `My data` in a new window.



To set a lower limit for the boundary of the excluded region, click **Add Lower Limit**. The app displays a vertical line on the left side of the plot window. Move the line to the point you where you want the lower limit, as shown in the following figure.



Move the vertical line to change the value displayed in the **Lower limit: exclude data** field in the **Exclude** window.

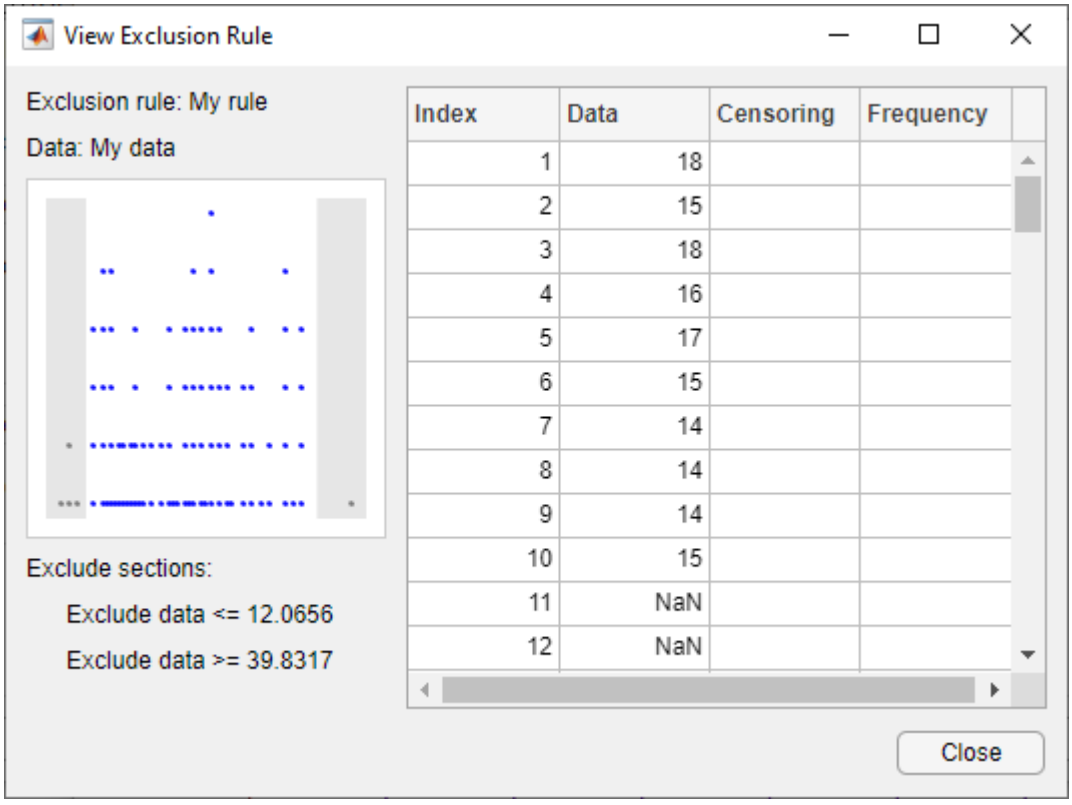
The value displayed corresponds to the *x*-coordinate of the vertical line.

Similarly, you can set the upper limit for the boundary of the excluded region by clicking **Add Upper Limit**, and then moving the vertical line that appears at the right side of the plot window. After setting the lower and upper limits, click **Close** and return to the Exclude window.

3 **Create Exclusion Rule**—Once you have set the lower and upper limits for the boundary of the excluded data, click **Create Exclusion Rule** to create the new rule. The name of the new rule appears in the **Existing exclusion rules** pane.

Selecting an exclusion rule in the **Existing exclusion rules** pane enables the following buttons:

- **Copy** — Creates a copy of the rule, which you can then modify. To save the modified rule under a different name, click **Create Exclusion Rule**.
- **View** — Opens a new window in which you can see the data points excluded by the rule. The following figure shows a typical example.



The shaded areas in the plot graphically display which data points are excluded. The table to the right lists all data points. The shaded rows indicate excluded points.

- **Rename** — Rename the rule.
- **Delete** — Delete the rule.

After you define an exclusion rule, you can use it when you fit a distribution to your data. The rule does not exclude points from the display of the data set.

Save and Load Sessions

Save your work in the current session, and then load it in a subsequent session, so that you can continue working where you left off.

Save a Session

To save the current session, from the **File** menu in the main window, select `Save Session`. A dialog box opens and prompts you to enter a file name, for example`my_session.dfit`. Click **Save** to save the following items created in the current session:

- Data sets
- Fits
- Exclusion rules
- Plot settings
- Bin width rules

Load a Session

To load a previously saved session, from the **File** menu in the main window, select `Load Session`. Enter the name of a previously saved session. Click **Open** to restore the information from the saved session to the current session.

Generate a File to Fit and Plot Distributions

Use the `Generate Code` option in the **File** to create a file that:

- Fits the distributions in the current session to any data vector in the MATLAB workspace.
- Plots the data and the fits.

After you end the current session, you can use the file to create plots in a standard MATLAB figure window, without reopening the Distribution Fitter app.

As an example, if you created the fit described in “Create a New Fit” on page 5-55, do the following steps:

1. From the **File** menu, select `Generate Code`.
2. In the MATLAB Editor window, choose **File > Save as**. Save the file as `normal_fit.m` in a folder on the MATLAB path.

You can then apply the function `normal_fit` to any vector of data in the MATLAB workspace. For example, the following commands:

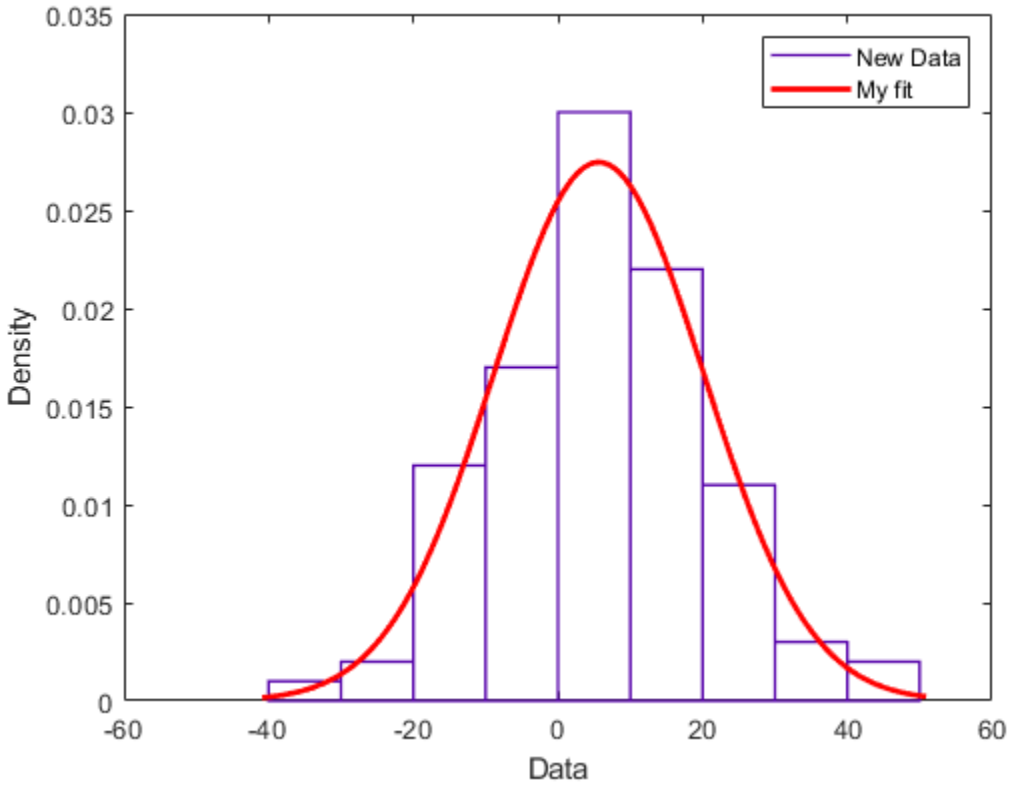
```
new_data = normrnd(4.1, 12.5, 100, 1);
newfit = normal_fit(new_data)
legend('New Data', 'My fit')
```

generate `newfit`, a fitted normal distribution of the data. The commands also generate a plot of the data and the fit.

```
newfit =

  NormalDistribution

  Normal distribution
       mu = 5.63857   [2.7555, 8.52163]
    sigma =   14.53   [12.7574, 16.8791]
```



Note By default, the file labels the data in the legend using the same name as the data set in the Distribution Fitter app. You can change the label using the `legend` command, as illustrated by the preceding example.

Fit a Distribution Using the Distribution Fitter App

In this section...

This example shows how you can use the Distribution Fitter app to interactively fit a probability distribution to data.

Step 1: Load Sample Data

Load the sample data.

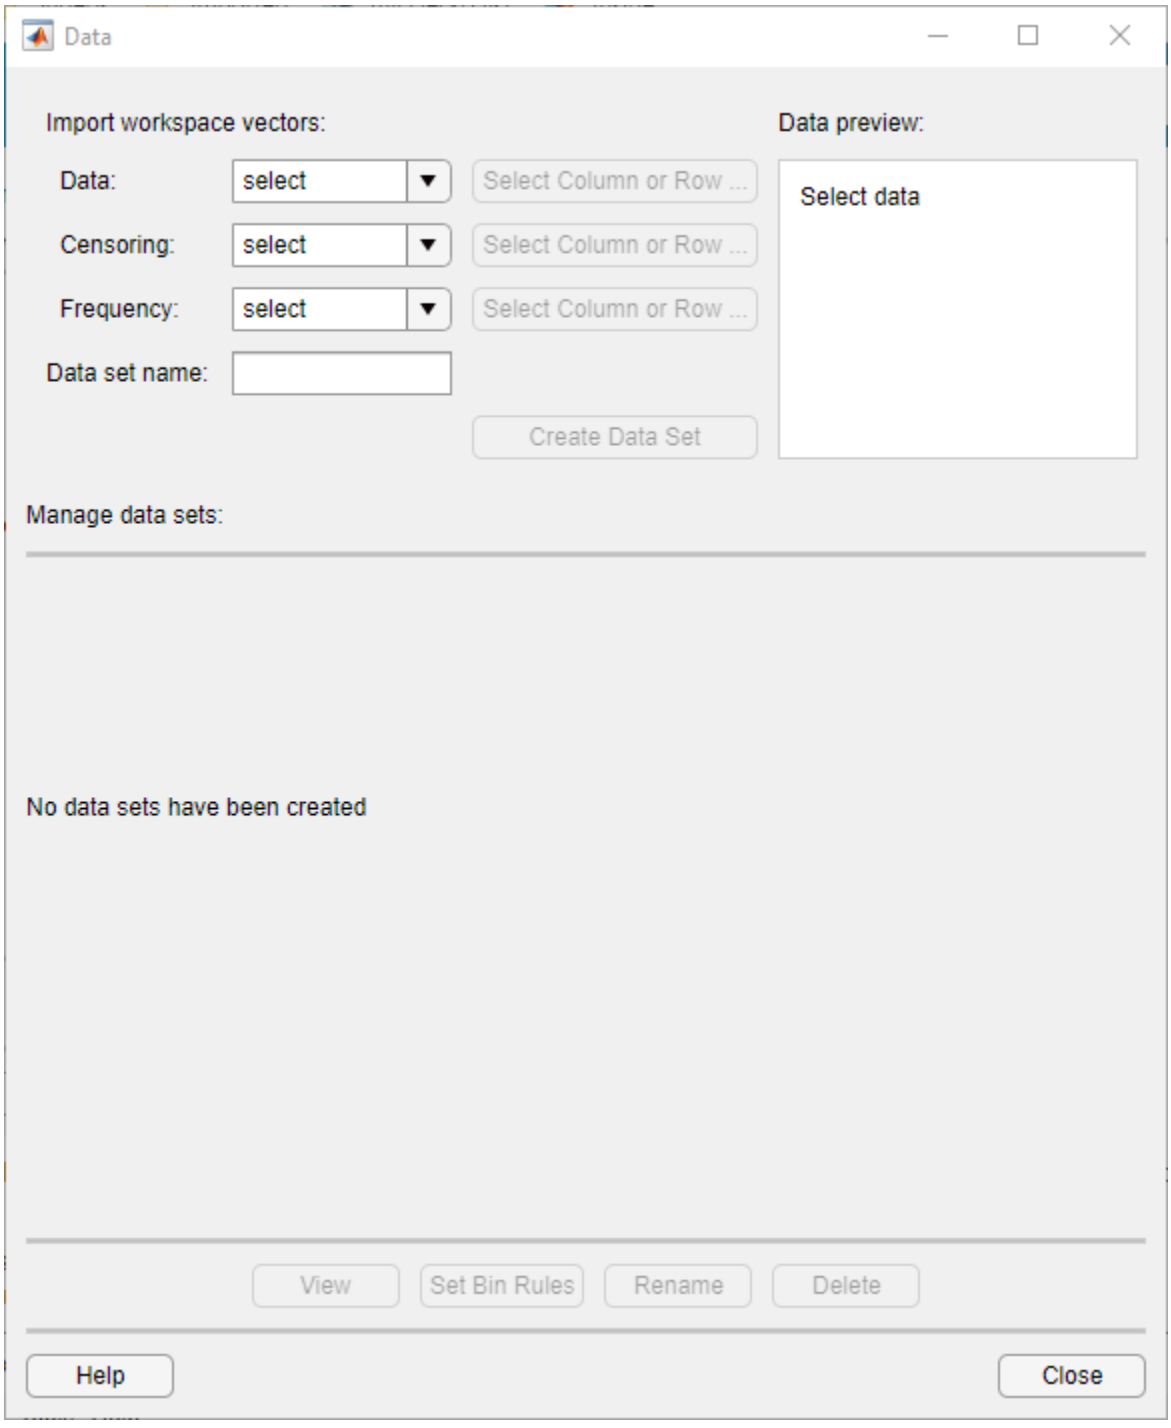
```
load carsmall
```

Step 2: Import Data

Open the Distribution Fitter tool.

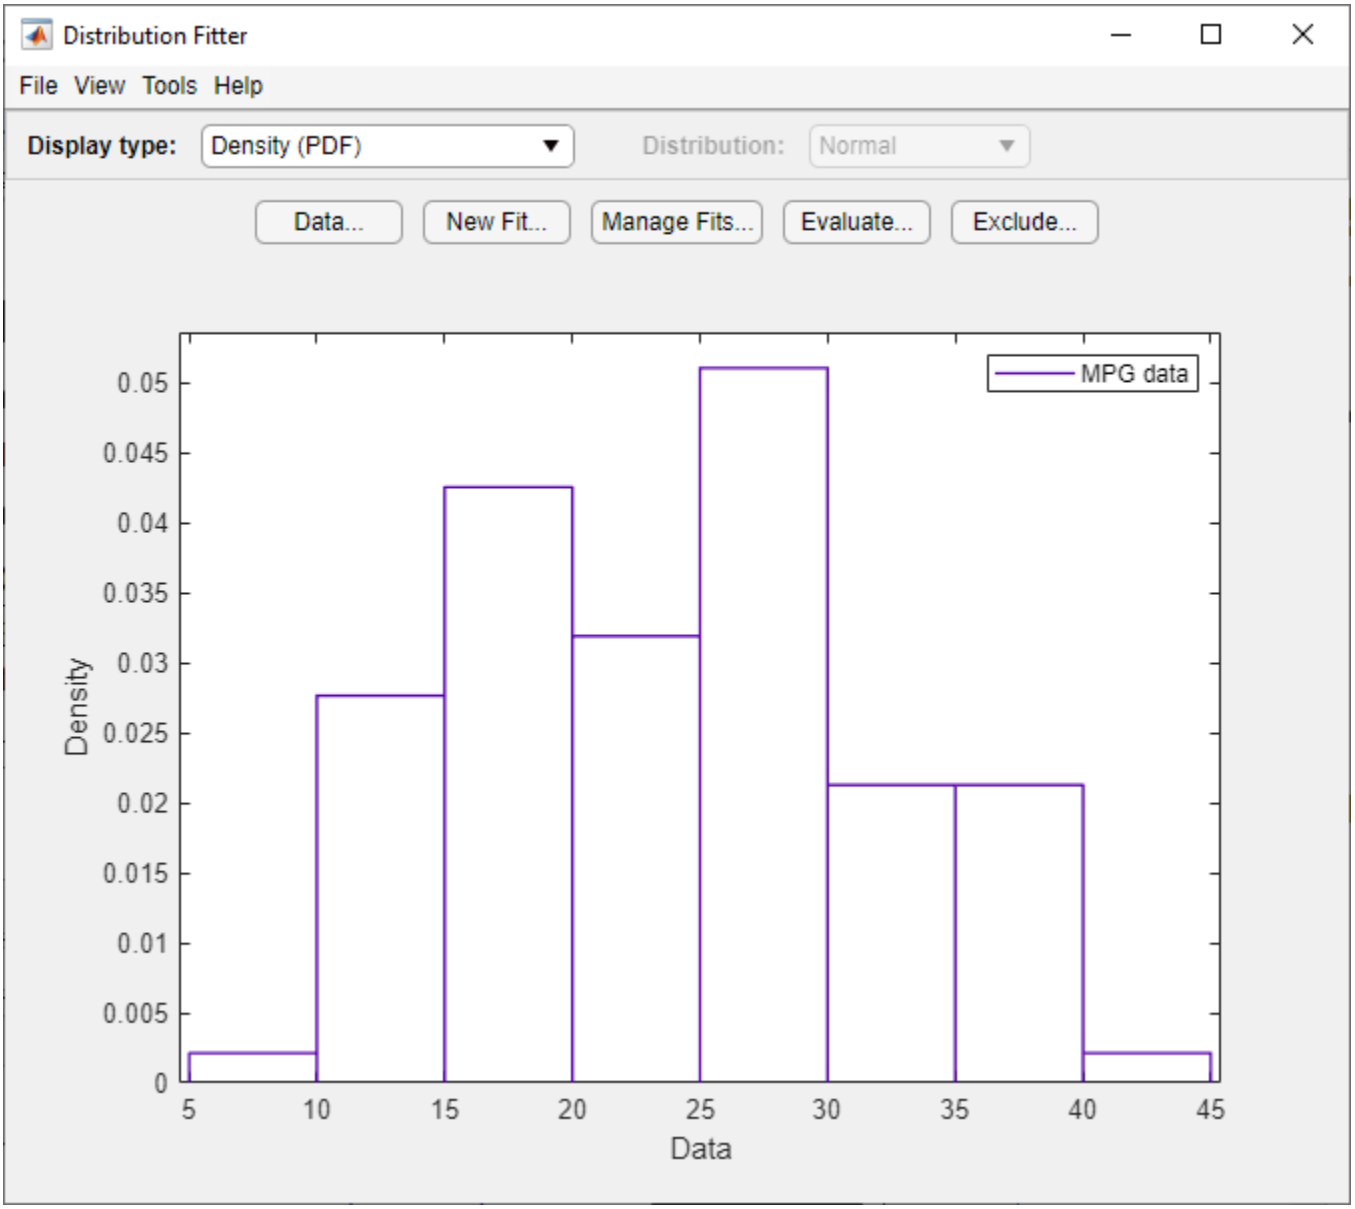
```
distributionFitter
```

To import the vector `MPG` into the Distribution Fitter app, click the **Data** button. The **Data** dialog box opens.



The **Data** field displays all numeric arrays in the MATLAB workspace. From the drop-down list, select `MPG`. A histogram of the selected data appears in the **Data preview** pane.

In the **Data set name** field, type a name for the data set, such as `MPG data`, and click **Create Data Set**. The main window of the Distribution Fitter app now displays a larger version of the histogram in the **Data preview** pane.

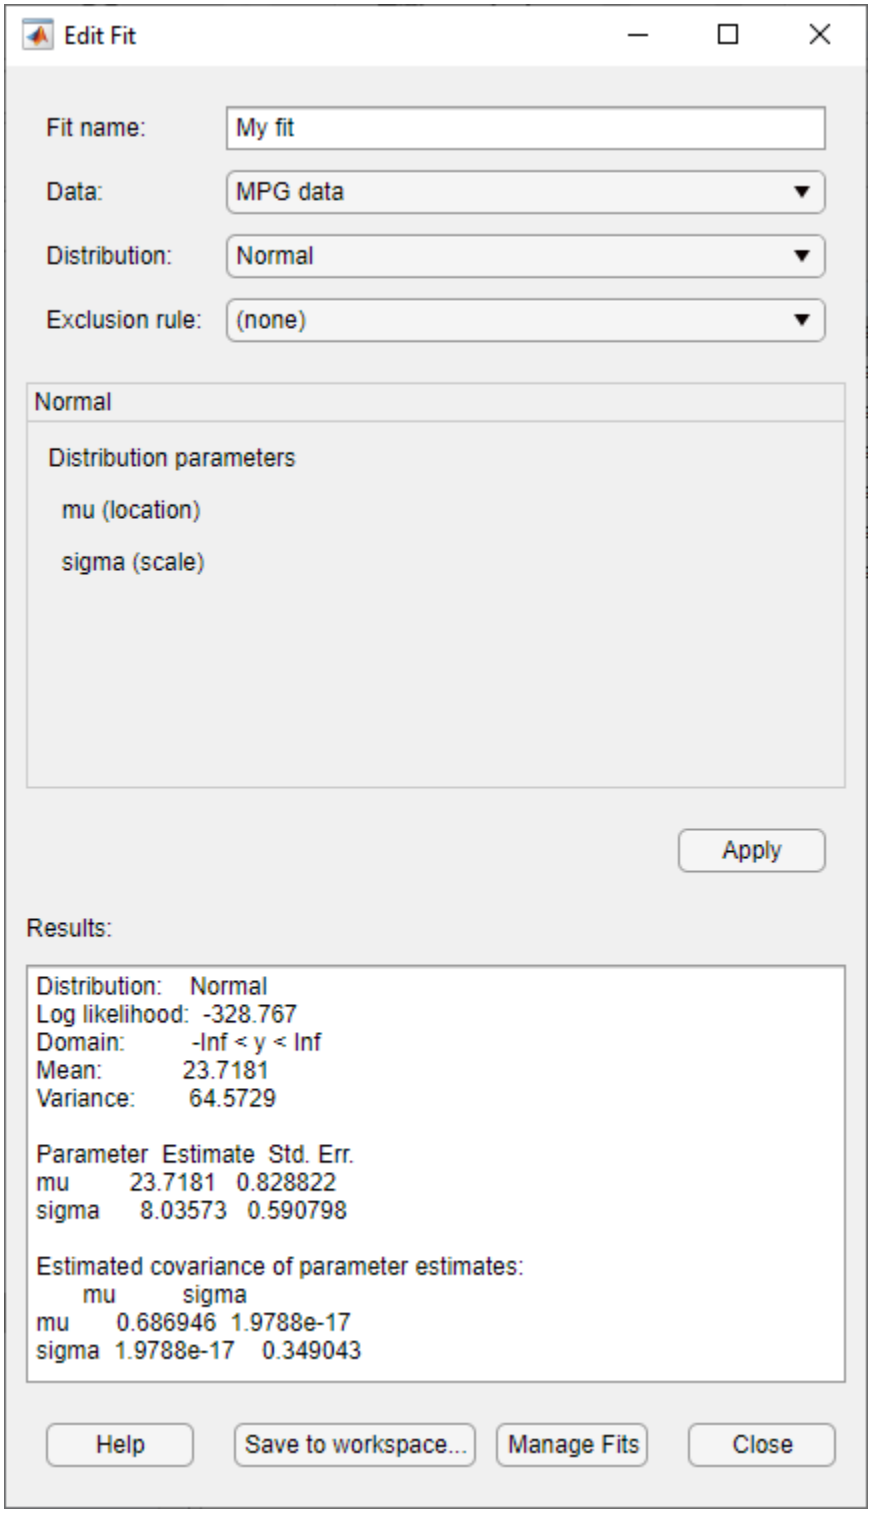


Step 3: Create a New Fit

To fit a distribution to the data, in the main window of the Distribution Fitter app, click **New Fit**.

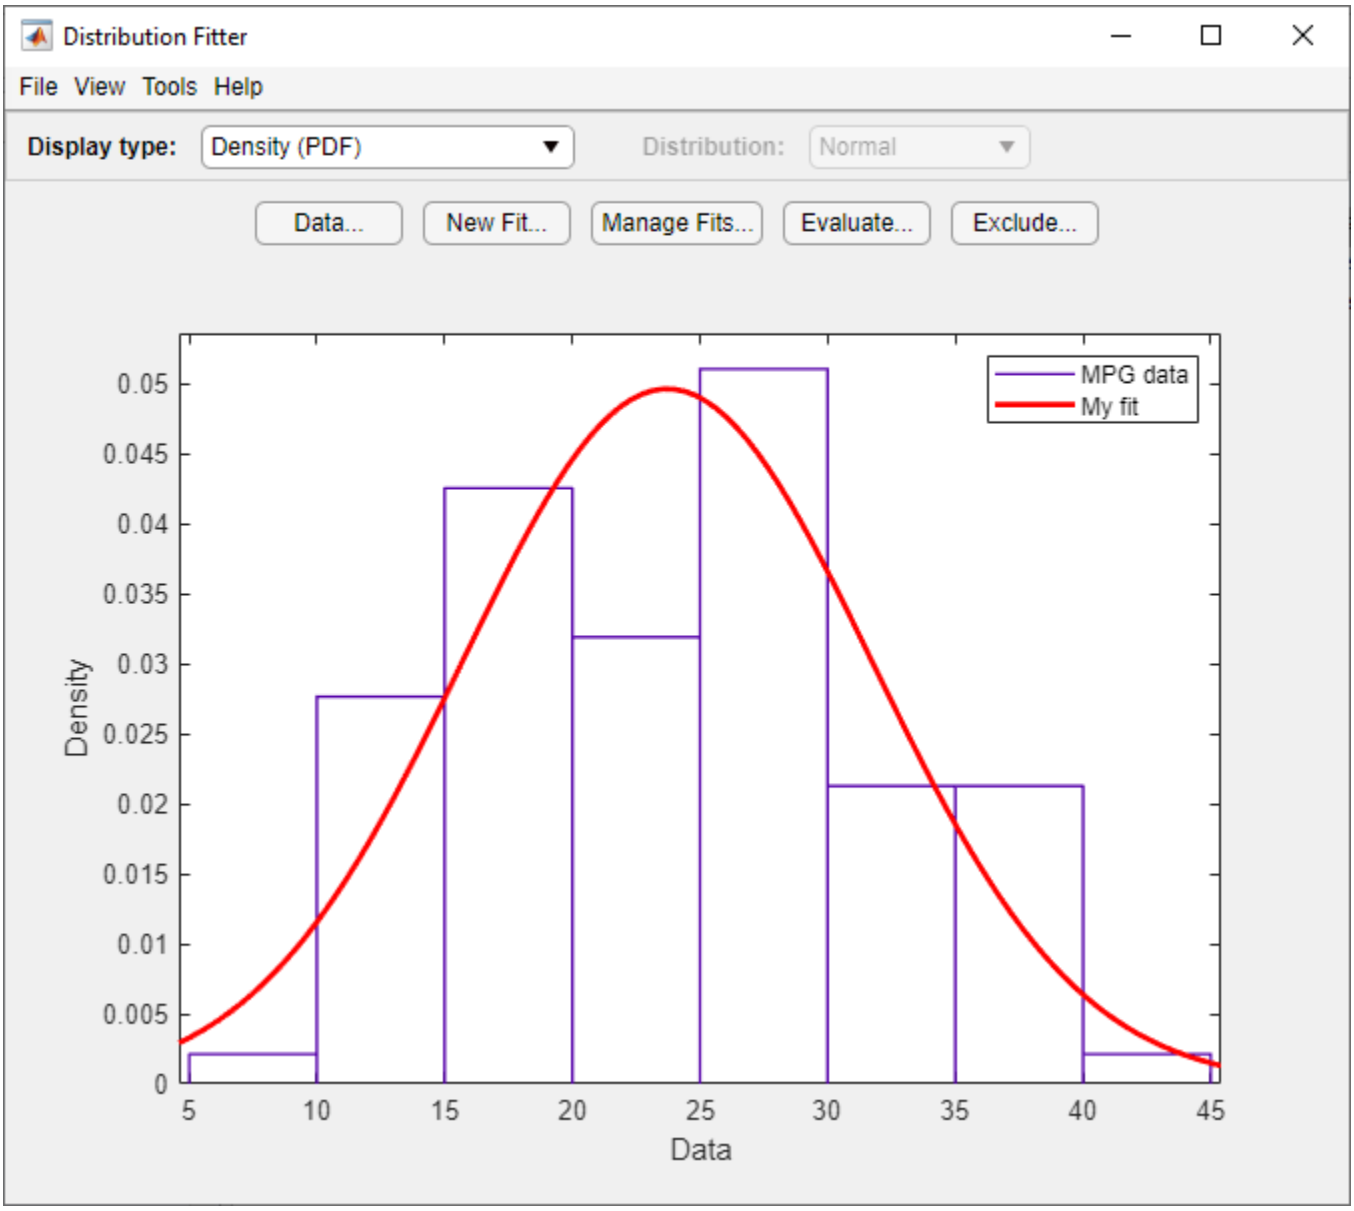
To fit a normal distribution to `MPG data`:

1. In the **Fit name** field, enter a name for the fit, such as `My fit`.
2. From the drop-down list in the **Data** field, select `MPG data`.
3. Confirm that `Normal` is selected from the drop-down menu in the **Distribution** field.
4. Click **Apply**.

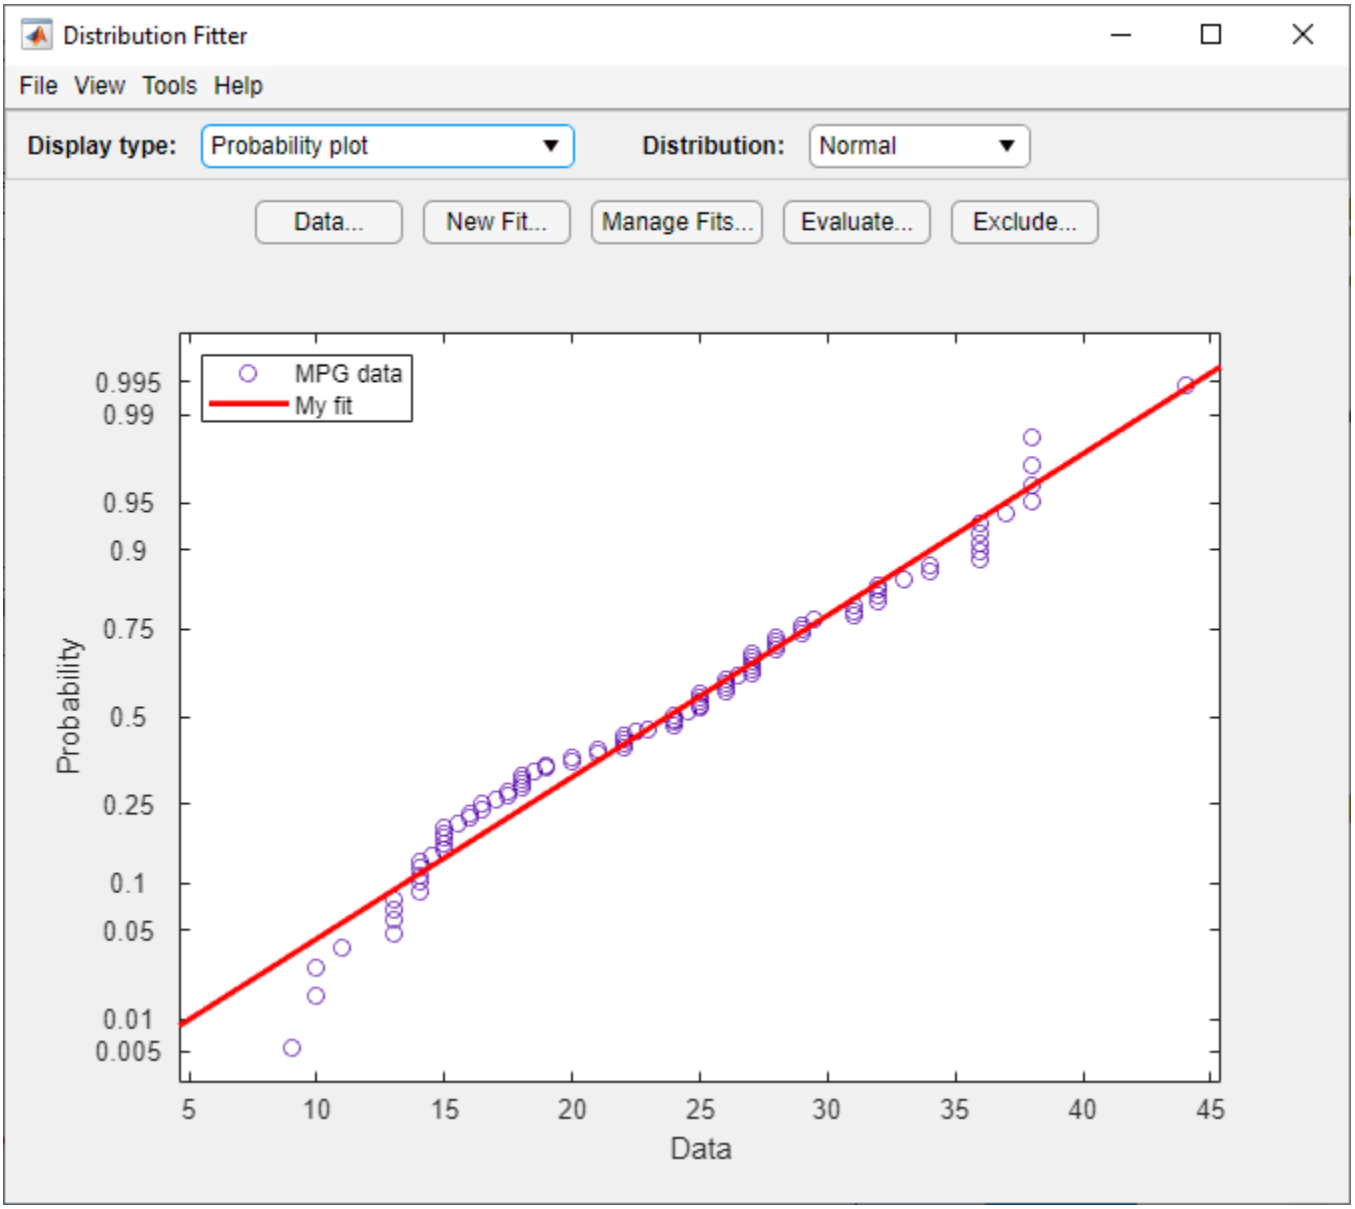


The **Results** pane displays the mean and standard deviation of the normal distribution that best fits `MPG data`.

The Distribution Fitter app main window displays a plot of the normal distribution with this mean and standard deviation.



Based on the plot, a normal distribution does not appear to provide a good fit for the `MPG` data. To obtain a better evaluation, select `Probability plot` from the **Display type** drop-down list. Confirm that the **Distribution** drop-down list is set to `Normal`. The main window displays the following figure.



The normal probability plot shows that the data deviates from normal, especially in the tails.

Step 4: Create and Manage Additional Fits

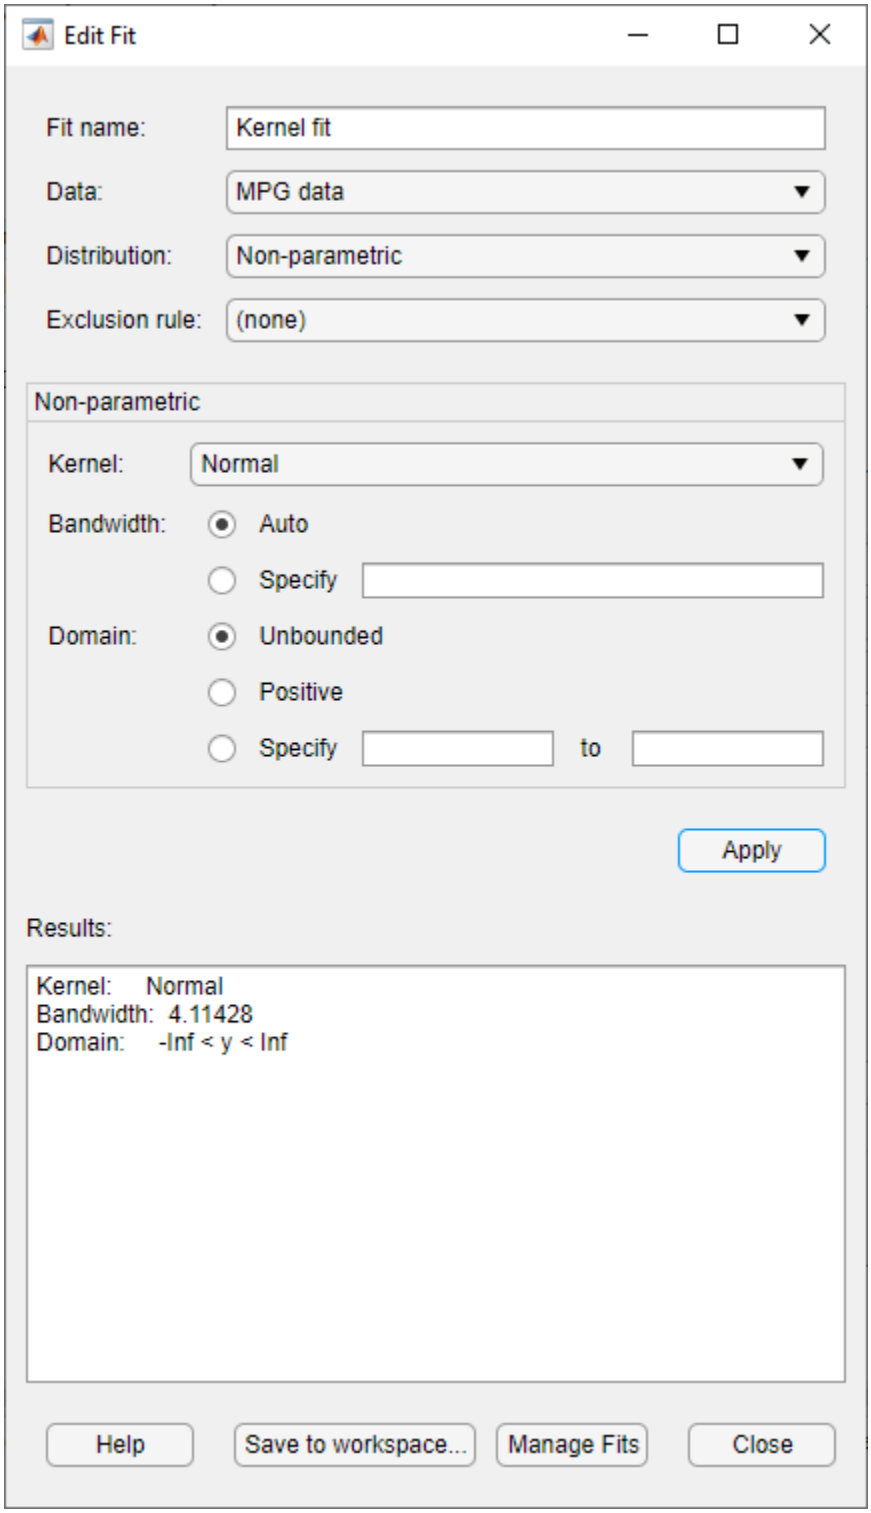
The `MPG` data pdf indicates that the data has two peaks. Try fitting a nonparametric kernel distribution to obtain a better fit for this data.

1. Click **Manage Fits**. In the dialog box, click **New Fit**.
2. In the **Fit name** field, enter a name for the fit, such as `Kernel fit`.
3. From the drop-down list in the **Data** field, select `MPG data`.
4. From the drop-down list in the **Distribution** field, select **Non-parametric**. This enables several options in the **Non-parametric** pane, including **Kernel**, **Bandwidth**, and **Domain**. For now,

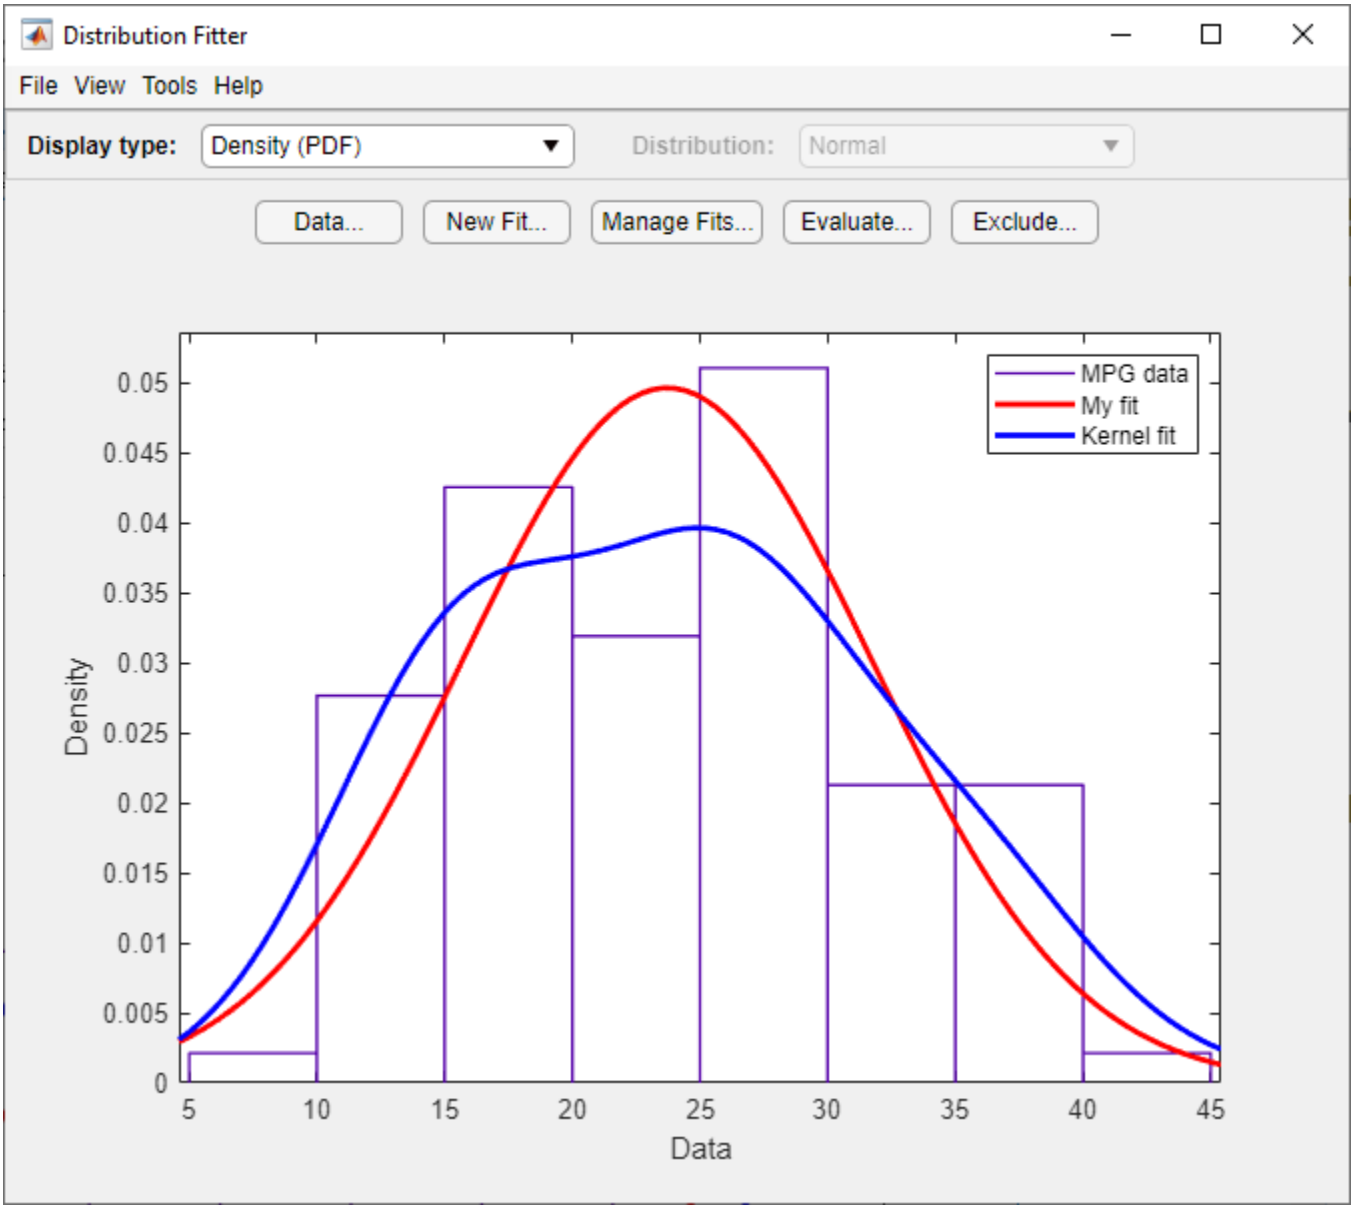
accept the default value to apply a normal kernel shape and automatically determine the kernel bandwidth (using **Auto**). For more information about nonparametric kernel distributions, see “Kernel Distribution” on page B-78.

5 Click **Apply**.

The **Results** pane displays the kernel type, bandwidth, and domain of the nonparametric distribution fit to `MPG data`.



The main window displays plots of the original `MPG data` with the normal distribution and nonparametric kernel distribution overlaid. To visually compare these two fits, select `Density (PDF)` from the **Display type** drop-down list.



To include only the nonparametric kernel fit line (`Kernel fit`) on the plot, click Manage Fits. In the **Table of fits** pane, locate the row for the normal distribution fit (`My fit`) and clear the box in the **Plot** column.

More About

- “Model Data Using the Distribution Fitter App” on page 5-51
- “Define Custom Distributions Using the Distribution Fitter App” on page 5-81

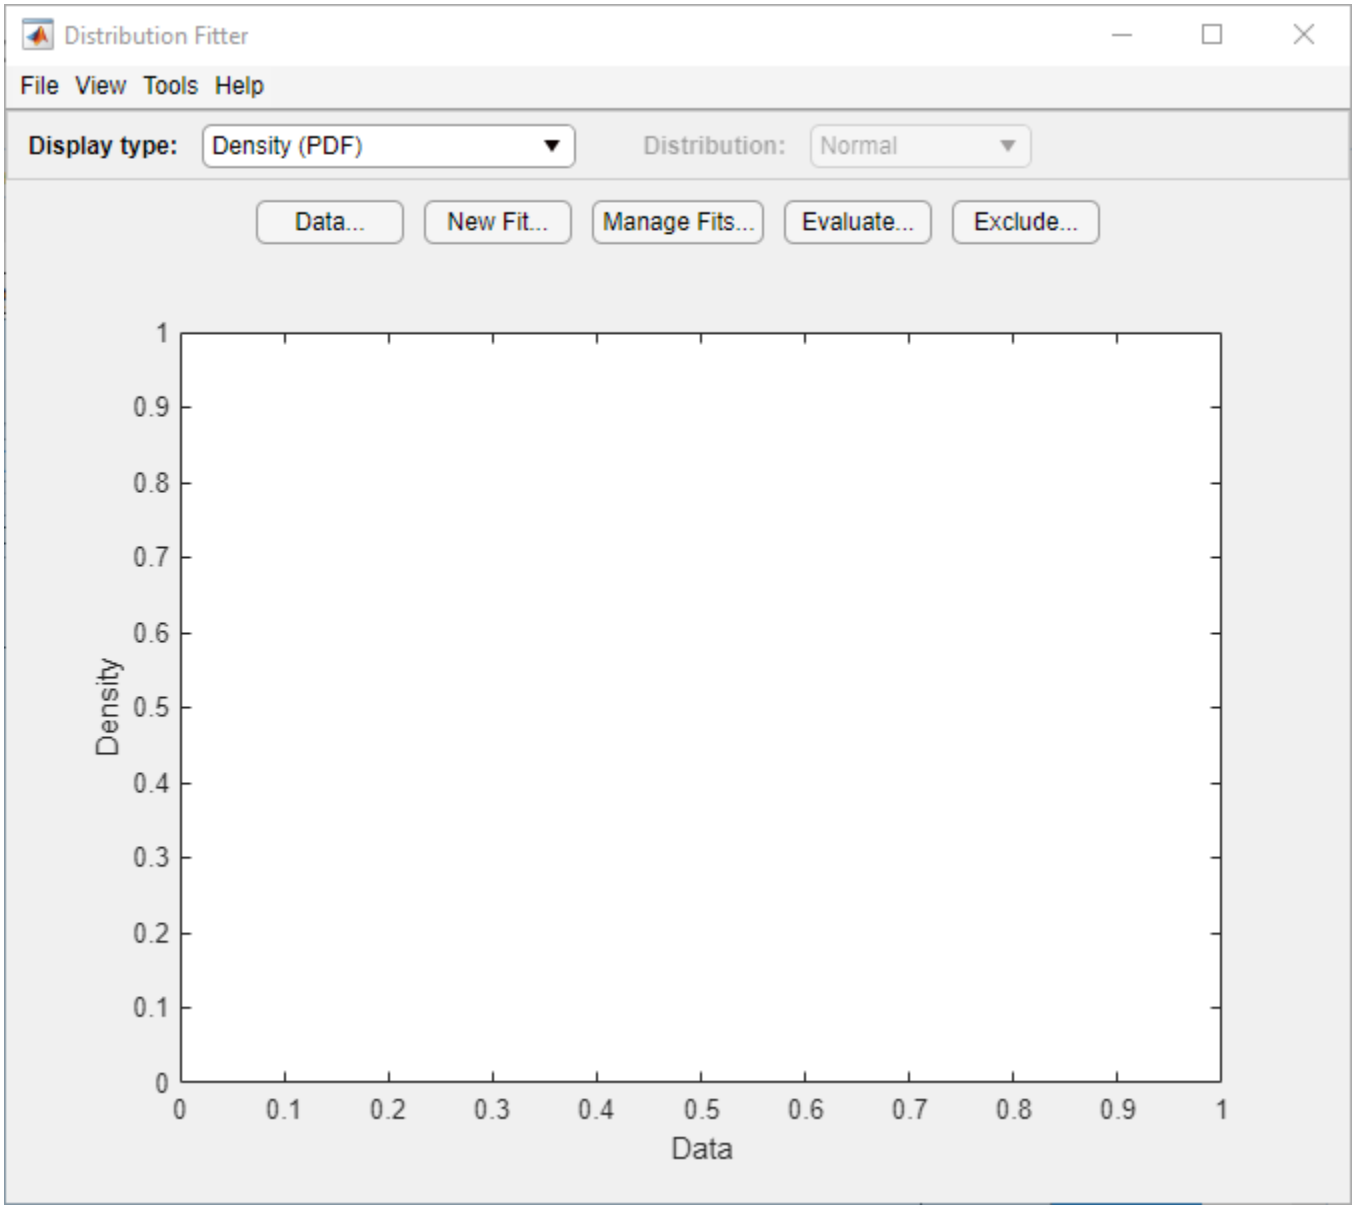
Define Custom Distributions Using the Distribution Fitter App

You can define a probability object for a custom distribution and use the Distribution Fitter app or `fitdist` to fit distributions not supported by Statistics and Machine Learning Toolbox. You can also use a custom probability object as an input argument of probability object functions, such as `pdf`, `cdf`, `icdf`, and `random`, to evaluate the distribution, generate random numbers, and so on.

Open the Distribution Fitter App

- MATLAB Toolstrip: On the **Apps** tab, under **Math, Statistics and Optimization**, click the app icon.
- MATLAB command prompt: Enter `distributionFitter`.

  ```
  distributionFitter
  ```



Define Custom Distribution

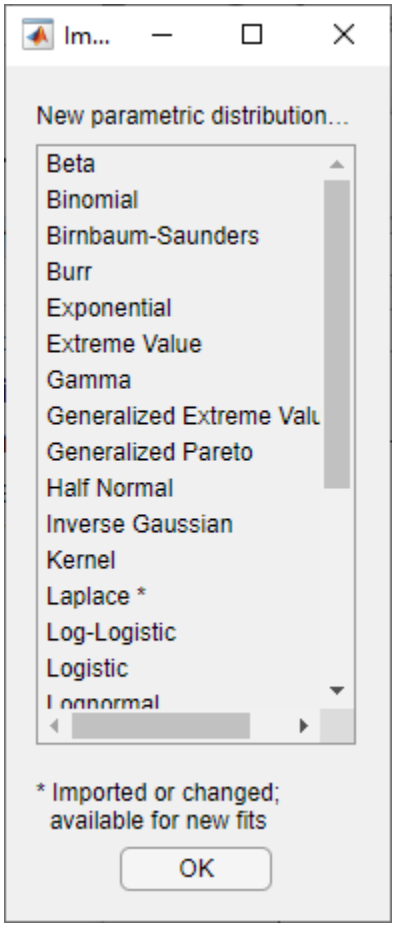
To define a custom distribution using the app, select **File > Define Custom Distributions**. A file template opens in the MATLAB Editor. You then edit this file so that it creates a probability object for the distribution you want.

The template includes sample code that defines a probability object for the Laplace distribution. Follow the instructions in the template to define your own custom distribution.

To save your custom probability object, create a directory named `+prob` on your path. Save the file in this directory using a name that matches your distribution name. For example, save the template as `LaplaceDistribution.m`, and then import the custom distribution as described in the next section.

Import Custom Distribution

To import a custom distribution using the app, select **File > Import Custom Distributions**. The Imported Distributions dialog box opens, in which you can select the file that defines the distribution. For example, if you create the file `LaplaceDistribution.m`, as described in the preceding section, the list in the dialog box includes `Laplace` followed by an asterisk, indicating the file is new or modified and available for fitting.



Alternatively, you can use the `makedist` function to reset the list of distributions so that you do not need to select **File > Import Custom Distributions** in the app.

```
makedist -reset
```

This command resets the list of distributions by searching the path for files contained in a package named `prob` and implementing classes derived from `ProbabilityDistribution`. If you open the app after resetting the list, the distribution list in the app includes the custom distribution that you defined.

Once you import a custom distribution using the Distribution Fitter app or reset the list by using `makedist`, you can use the custom distribution in the app and in the Command Window. The **Distribution** field of the New Fit dialog box, available from the Distribution Fitter app, contains the new custom distribution. In the Command Window, you can create the custom probability distribution object by using `makedist` and fit a data set to the custom distribution by using `fitdist`. Then, you

can use probability object functions, such as `pdf`, `cdf`, `icdf`, and `random`, to evaluate the distribution, generate random numbers, and so on.

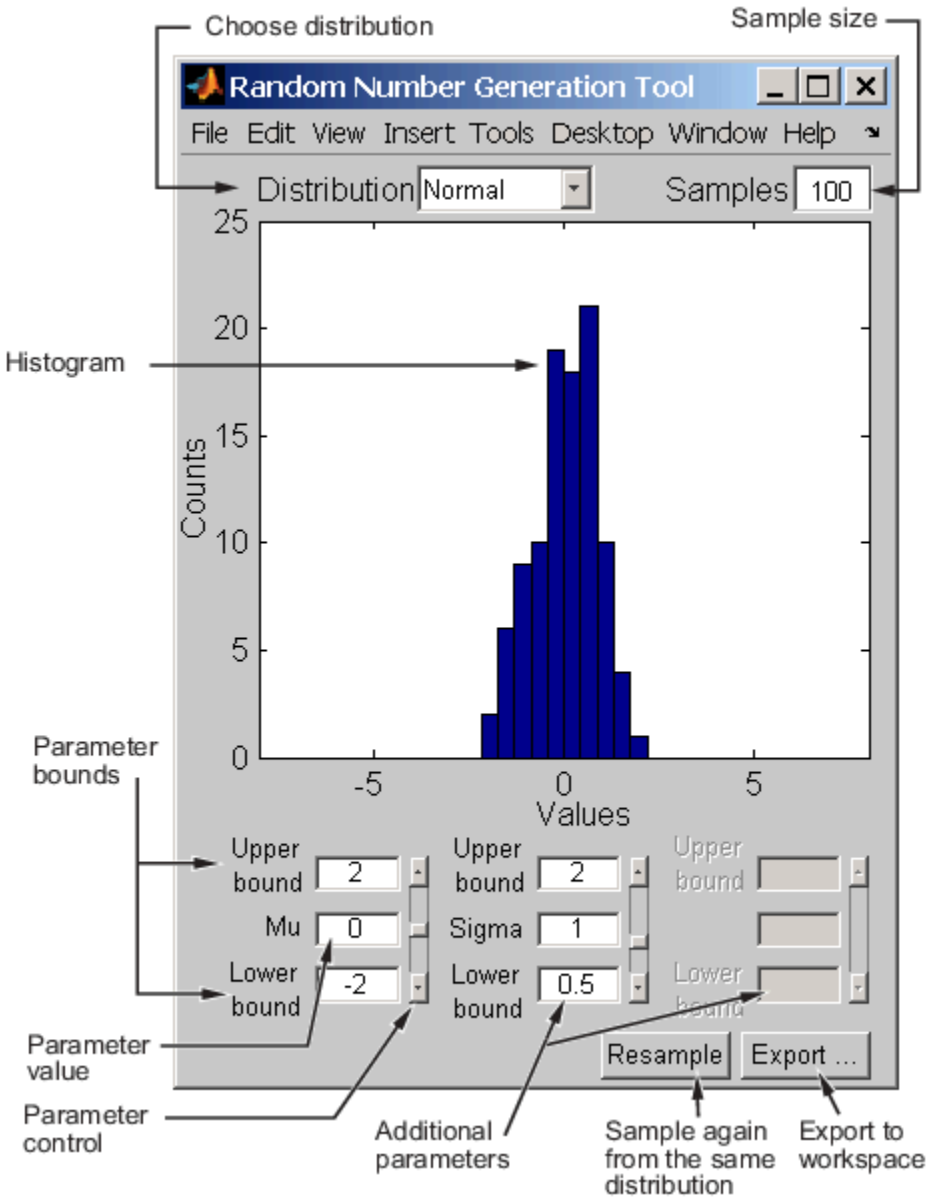
- “Model Data Using the Distribution Fitter App” on page 5-51
- “Fit a Distribution Using the Distribution Fitter App” on page 5-71

Explore the Random Number Generation UI

The Random Number Generation user interface (UI) generates random samples from specified probability distributions, and displays the samples as histograms. Use the interface to explore the effects of changing parameters and sample size on the distributions.

Run the user interface by typing `randtool` at the command line.



Start by selecting a distribution, then enter the desired sample size.

You can also

- Use the controls at the bottom of the window to set parameter values for the distribution and to change their upper and lower bounds.

- Draw another sample from the same distribution, with the same size and parameters.
- Export the current sample to your workspace. A dialog box enables you to provide a name for the sample.

Compare Multiple Distribution Fits

This example shows how to fit multiple probability distribution objects to the same set of sample data, and obtain a visual comparison of how well each distribution fits the data.

Step 1. Load sample data.

Load the sample data.

```
load carsmall
```

This data contains miles per gallon (`MPG`) measurements for different makes and models of cars, grouped by country of origin (`Origin`), model year (`Model_Year`), and other vehicle characteristics.

Step 2. Create a categorical array.

Transform `Origin` into a categorical array and remove the Italian car from the sample data. Since there is only one Italian car, `fitdist` cannot fit a distribution to that group using other than a kernel distribution.

```
Origin = categorical(cellstr(Origin));
MPG2 = MPG(Origin~='Italy');
Origin2 = Origin(Origin~='Italy');
Origin2 = removecats(Origin2,'Italy');
```

Step 3. Fit multiple distributions by group.

Use `fitdist` to fit Weibull, normal, logistic, and kernel distributions to each country of origin group in the `MPG` data.

```
[WeiByOrig,Country] = fitdist(MPG2,'weibull','by',Origin2);
[NormByOrig,Country] = fitdist(MPG2,'normal','by',Origin2);
[LogByOrig,Country] = fitdist(MPG2,'logistic','by',Origin2);
[KerByOrig,Country] = fitdist(MPG2,'kernel','by',Origin2);
```

```
WeiByOrig
```

```
WeiByOrig=1×5 cell array
  Columns 1 through 2

    {1x1 prob.WeibullDistribution}    {1x1 prob.WeibullDistribution}

  Columns 3 through 4

    {1x1 prob.WeibullDistribution}    {1x1 prob.WeibullDistribution}

  Column 5

    {1x1 prob.WeibullDistribution}
```

```
Country
```

```
Country = 5x1 cell
    {'France' }
    {'Germany'}
    {'Japan'  }
    {'Sweden' }
```

```
    {'USA'    }
```

Each country group now has four distribution objects associated with it. For example, the cell array `WeiByOrig` contains five Weibull distribution objects, one for each country represented in the sample data. Likewise, the cell array Norm`ByOrig` contains five normal distribution objects, and so on. Each object contains properties that hold information about the data, distribution, and parameters. The array `Country` lists the country of origin for each group in the same order as the distribution objects are stored in the cell arrays.

Step 4. Compute the pdf for each distribution.

Extract the four probability distribution objects for USA and compute the pdf for each distribution. As shown in Step 3, USA is in position 5 in each cell array.

```
WeiUSA = WeiByOrig{5};
NormUSA = NormByOrig{5};
LogUSA = LogByOrig{5};
KerUSA = KerByOrig{5};

x = 0:1:50;
pdf_Wei = pdf(WeiUSA,x);
pdf_Norm = pdf(NormUSA,x);
pdf_Log = pdf(LogUSA,x);
pdf_Ker = pdf(KerUSA,x);
```

Step 5. Plot pdf the for each distribution.

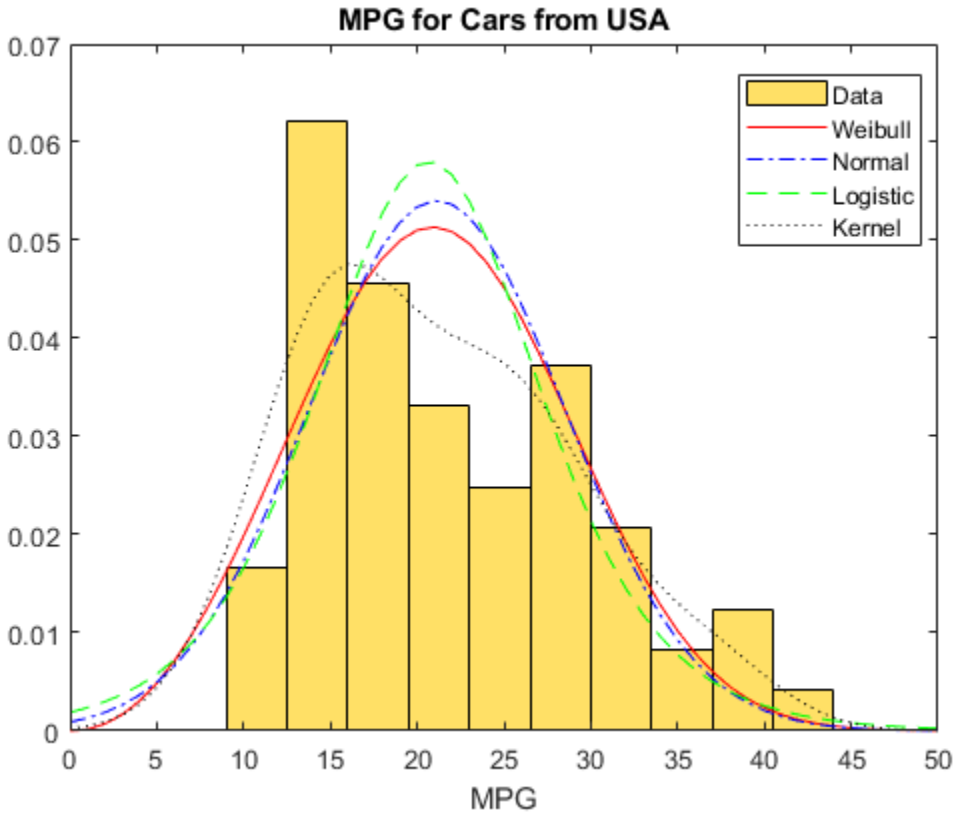
Plot the pdf for each distribution fit to the USA data, superimposed on a histogram of the sample data. Normalize the histogram for easier display.

Create a histogram of the USA sample data.

```
data = MPG(Origin2=='USA');
figure
histogram(data,10,'Normalization','pdf','FaceColor',[1,0.8,0]);
```

Plot the pdf of each fitted distribution.

```
line(x,pdf_Wei,'LineStyle','-','Color','r')
line(x,pdf_Norm,'LineStyle','-.','Color','b')
line(x,pdf_Log,'LineStyle','--','Color','g')
line(x,pdf_Ker,'LineStyle',':','Color','k')
legend('Data','Weibull','Normal','Logistic','Kernel','Location','Best')
title('MPG for Cars from USA')
xlabel('MPG')
```



Superimposing the pdf plots over a histogram of the sample data provides a visual comparison of how well each type of distribution fits the data. Only the nonparametric kernel distribution `KerUSA` comes close to revealing the two modes in the original data.

Step 6. Further group USA data by year.

To investigate the two modes revealed in Step 5, group the `MPG` data by both country of origin (`Origin`) and model year (`Model_Year`), and use `fitdist` to fit kernel distributions to each group.

```
[KerByYearOrig,Names] = fitdist(MPG,'Kernel','By',{Origin Model_Year});
```

Each unique combination of origin and model year now has a kernel distribution object associated with it.

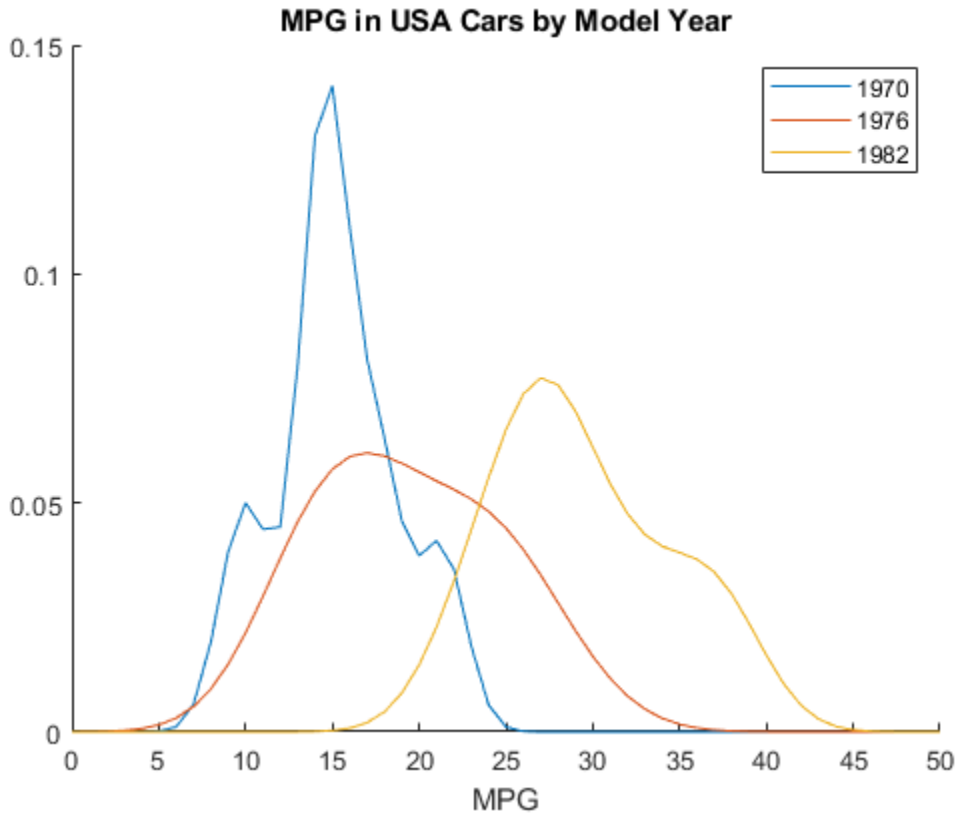
```
Names
```

```
Names = 14x1 cell
    {'France...' }
    {'France...' }
    {'Germany...'}
    {'Germany...'}
    {'Germany...'}
    {'Italy...'  }
    {'Japan...'  }
    {'Japan...'  }
    {'Japan...'  }
    {'Sweden...' }
```

```
    {'Sweden...' }
    {'USA...'    }
    {'USA...'    }
    {'USA...'    }
```

Plot the three probability distributions for each USA model year, which are in positions 12, 13, and 14 in the cell array `KerByYearOrig`.

```
figure
hold on
for i = 12 : 14
    plot(x,pdf(KerByYearOrig{i},x))
end
legend('1970','1976','1982')
title('MPG in USA Cars by Model Year')
xlabel('MPG')
hold off
```



When further grouped by model year, the pdf plots reveal two distinct peaks in the `MPG` data for cars made in the USA — one for the model year 1970 and one for the model year 1982. This explains why the histogram for the combined USA miles per gallon data shows two peaks instead of one.

- “Fit Probability Distribution Objects to Grouped Data” on page 5-92
- “Working with Probability Distributions” on page 5-3
- “Supported Distributions” on page 5-14

Fit Probability Distribution Objects to Grouped Data

This example shows how to fit probability distribution objects to grouped sample data, and create a plot to visually compare the pdf of each group.

Step 1. Load sample data.

Load the sample data.

```
load carsmall;
```

The data contains miles per gallon (`MPG`) measurements for different makes and models of cars, grouped by country of origin (`Origin`), model year (`Model_Year`), and other vehicle characteristics.

Step 2. Create a categorical array.

Transform `Origin` into a categorical array.

```
Origin = categorical(cellstr(Origin));
```

Step 3. Fit kernel distributions to each group.

Use `fitdist` to fit kernel distributions to each country of origin group in the `MPG` data.

```
[KerByOrig,Country] = fitdist(MPG,'Kernel','by',Origin)
```

```
KerByOrig=1×6 cell array
  Columns 1 through 2

    {1x1 prob.KernelDistribution}    {1x1 prob.KernelDistribution}

  Columns 3 through 4

    {1x1 prob.KernelDistribution}    {1x1 prob.KernelDistribution}

  Columns 5 through 6

    {1x1 prob.KernelDistribution}    {1x1 prob.KernelDistribution}

Country = 6x1 cell
    {'France' }
    {'Germany'}
    {'Italy'  }
    {'Japan'  }
    {'Sweden' }
    {'USA'    }
```

The cell array `KerByOrig` contains six kernel distribution objects, one for each country represented in the sample data. Each object contains properties that hold information about the data, the distribution, and the parameters. The array `Country` lists the country of origin for each group in the same order as the distribution objects are stored in `KerByOrig`.

Step 4. Compute the pdf for each group.

Extract the probability distribution objects for Germany, Japan, and USA. Use the positions of each country in `KerByOrig` shown in Step 3, which indicates that Germany is the second country, Japan is the fourth country, and USA is the sixth country. Compute the pdf for each group.

```
Germany = KerByOrig{2};
Japan = KerByOrig{4};
USA = KerByOrig{6};

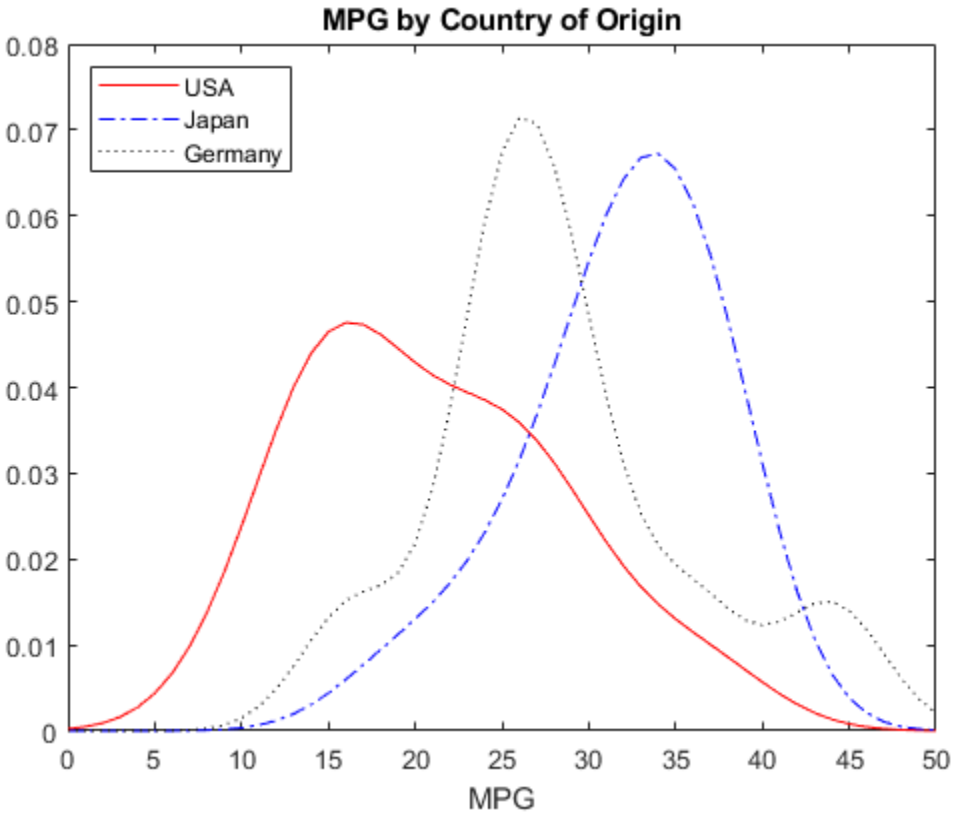
x = 0:1:50;

USA_pdf = pdf(USA,x);
Japan_pdf = pdf(Japan,x);
Germany_pdf = pdf(Germany,x);
```

Step 5. Plot the pdf for each group.

Plot the pdf for each group on the same figure.

```
plot(x,USA_pdf,'r-')
hold on
plot(x,Japan_pdf,'b-.')
plot(x,Germany_pdf,'k:')
legend({'USA','Japan','Germany'},'Location','NW')
title('MPG by Country of Origin')
xlabel('MPG')
```



The resulting plot shows how miles per gallon (`MPG`) performance differs by country of origin (`Origin`). Using this data, the USA has the widest distribution, and its peak is at the lowest `MPG` value of the three origins. Japan has the most regular distribution with a slightly heavier left tail, and its peak is at the highest `MPG` value of the three origins. The peak for Germany is between the USA and Japan, and the second bump near 44 miles per gallon suggests that there might be multiple modes in the data.

Multinomial Probability Distribution Objects

This example shows how to generate random numbers, compute and plot the pdf, and compute descriptive statistics of a multinomial distribution using probability distribution objects.

Step 1. Define the distribution parameters.

Create a vector `p` containing the probability of each outcome. Outcome 1 has a probability of 1/2, outcome 2 has a probability of 1/3, and outcome 3 has a probability of 1/6. The number of trials `n` in each experiment is 5, and the number of repetitions `reps` of the experiment is 8.

```
p = [1/2 1/3 1/6];
n = 5;
reps = 8;
```

Step 2. Create a multinomial probability distribution object.

Create a multinomial probability distribution object using the specified value `p` for the `Probabilities` parameter.

```
pd = makedist('Multinomial','Probabilities',p)
```

```
pd =
  MultinomialDistribution

  Probabilities:
    0.5000    0.3333    0.1667
```

Step 3. Generate one random number.

Generate one random number from the multinomial distribution, which is the outcome of a single trial.

```
rng('default')  % For reproducibility
r = random(pd)
```

```
r = 2
```

This trial resulted in outcome 2.

Step 4. Generate a matrix of random numbers.

You can also generate a matrix of random numbers from the multinomial distribution, which reports the results of multiple experiments that each contain multiple trials. Generate a matrix that contains the outcomes of an experiment with `n = 5` trials and `reps = 8` repetitions.

```
r = random(pd,reps,n)
```

```
r = 8×5

     3     3     3     2     1
     1     1     2     2     1
     3     3     3     1     2
     2     3     2     2     2
     1     1     1     1     1
     1     2     3     2     3
```

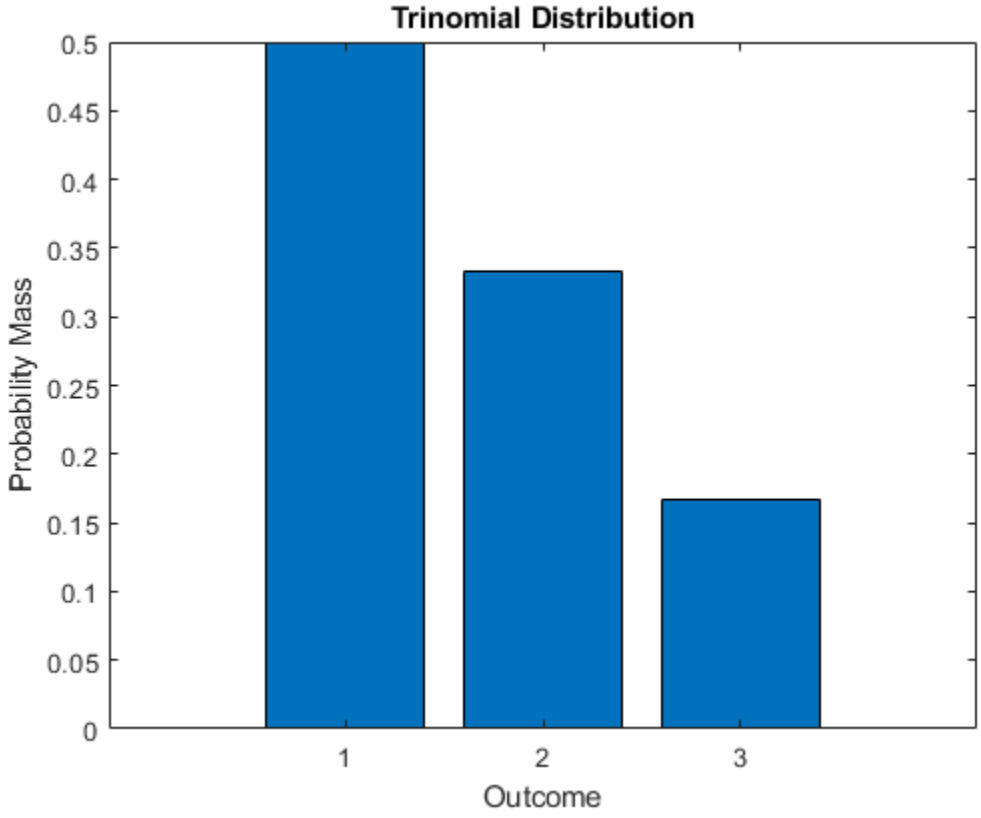
```
     2     1     3     1     1
     3     1     2     1     1
```

Each element in the resulting matrix is the outcome of one trial. The columns correspond to the five trials in each experiment, and the rows correspond to the eight experiments. For example, in the first experiment (corresponding to the first row), one of the five trials resulted in outcome 1, one of the five trials resulted in outcome 2, and three of the five trials resulted in outcome 3.

Step 5. Compute and plot the pdf.

Compute the pdf of the distribution.

```
x = 1:3;
y = pdf(pd,x);
bar(x,y)
xlabel('Outcome')
ylabel('Probability Mass')
title('Trinomial Distribution')
```



The plot shows the probability mass for each k possible outcome. For this distribution, the pdf value for any x other than 1, 2, or 3 is 0.

Step 6. Compute descriptive statistics.

Compute the mean, median, and standard deviation of the distribution.

```
m = mean(pd)
```

```
m = 1.6667
```

```
med = median(pd)
```

```
med = 1
```

```
s = std(pd)
```

```
s = 0.7454
```

- “Working with Probability Distributions” on page 5-3
- “Supported Distributions” on page 5-14

Multinomial Probability Distribution Functions

This example shows how to generate random numbers and compute and plot the pdf of a multinomial distribution using probability distribution functions.

Step 1. Define the distribution parameters.

Create a vector `p` containing the probability of each outcome. Outcome 1 has a probability of 1/2, outcome 2 has a probability of 1/3, and outcome 3 has a probability of 1/6. The number of trials in each experiment `n` is 5, and the number of repetitions of the experiment `reps` is 8.

```
p = [1/2 1/3 1/6];
n = 5;
reps = 8;
```

Step 2. Generate one random number.

Generate one random number from the multinomial distribution, which is the outcome of a single trial.

```
rng('default')  % For reproducibility
r = mnrnd(1,p,1)
```

```
r = 1×3

     0     1     0
```

The returned vector `r` contains three elements, which show the counts for each possible outcome. This single trial resulted in outcome 2.

Step 3. Generate a matrix of random numbers.

You can also generate a matrix of random numbers from the multinomial distribution, which reports the results of multiple experiments that each contain multiple trials. Generate a matrix that contains the outcomes of an experiment with `n = 5` trials and `reps = 8` repetitions.

```
r = mnrnd(n,p,reps)
```

```
r = 8×3

     1     1     3
     3     2     0
     1     1     3
     0     4     1
     5     0     0
     1     2     2
     3     1     1
     3     1     1
```

Each row in the resulting matrix contains counts for each of the *k* multinomial bins. For example, in the first experiment (corresponding to the first row), one of the five trials resulted in outcome 1, one of the five trials resulted in outcome 2, and three of the five trials resulted in outcome 3.

Step 4. Compute the pdf.

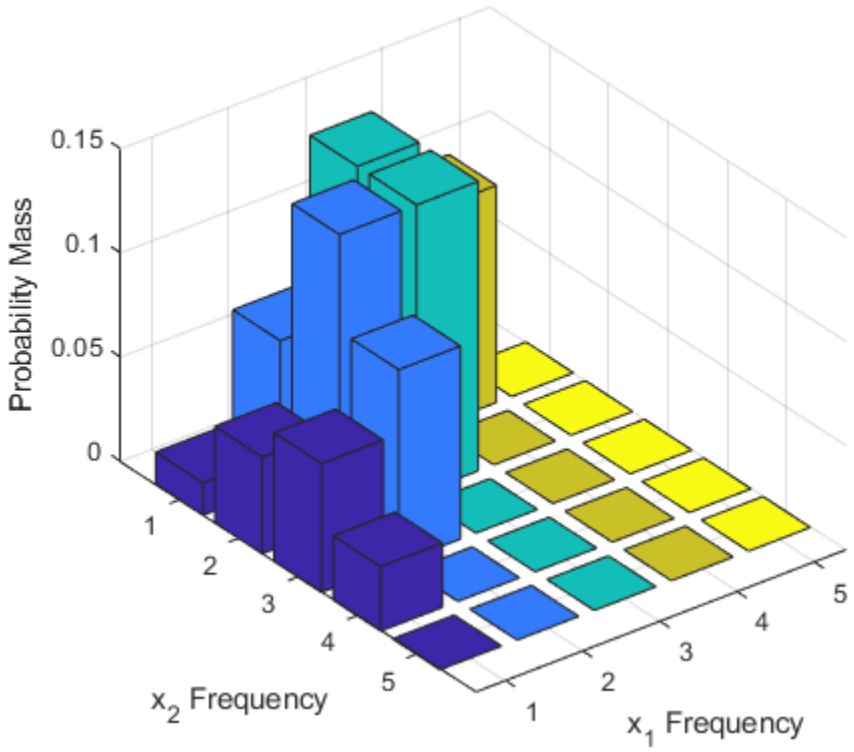
Since multinomial functions work with bin counts, create a multidimensional array of all possible outcome combinations, and compute the pdf using `mnpdf`.

```
count1 = 1:n;
count2 = 1:n;
[x1,x2] = meshgrid(count1,count2);
x3 = n-(x1+x2);
y = mnpdf([x1(:),x2(:),x3(:)],repmat(p,(n)^2,1));
```

Step 5. Plot the pdf.

Create a 3-D bar graph to visualize the pdf for each combination of outcome frequencies.

```
y = reshape(y,n,n);
bar3(y)
set(gca,'XTickLabel',1:n);
set(gca,'YTickLabel',1:n);
xlabel('x_1 Frequency')
ylabel('x_2 Frequency')
zlabel('Probability Mass')
```



The plot shows the probability mass for each possible combination of outcomes. It does not show x_3 , which is determined by the constraint $x_1 + x_2 + x_3 = n$.

Generate Random Numbers Using Uniform Distribution Inversion

This example shows how to generate random numbers using the uniform distribution inversion method. This is useful for distributions when it is possible to compute the inverse cumulative distribution function, but there is no support for sampling from the distribution directly.

Step 1. Generate random numbers from the standard uniform distribution.

Use `rand` to generate 1000 random numbers from the uniform distribution on the interval (0,1).

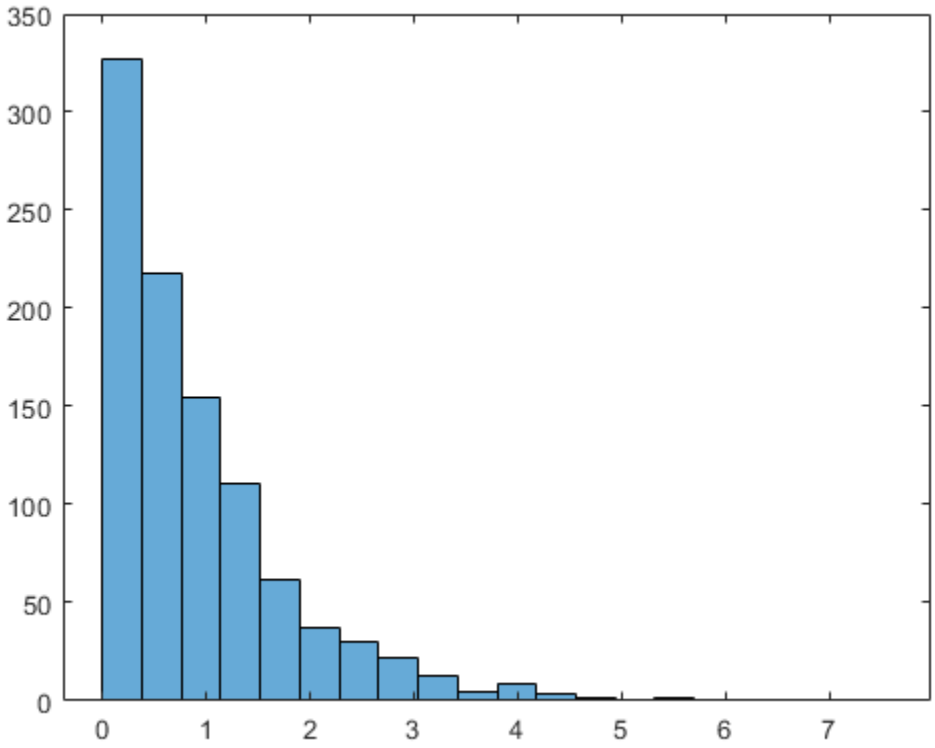
```
rng('default')  % For reproducibility
u = rand(1000,1);
```

The inversion method relies on the principle that continuous cumulative distribution functions (cdfs) range uniformly over the open interval (0,1). If u is a uniform random number on (0,1), then $x = F^{-1}(u)$ generates a random number x from any continuous distribution with the specified cdf `F`.

Step 2. Generate random numbers from the Weibull distribution.

Use the inverse cumulative distribution function to generate the random numbers from a Weibull distribution with parameters `A = 1` and `B = 1` that correspond to the probabilities in `u`. Plot the results.

```
x = wblinv(u,1,1);
histogram(x,20);
```

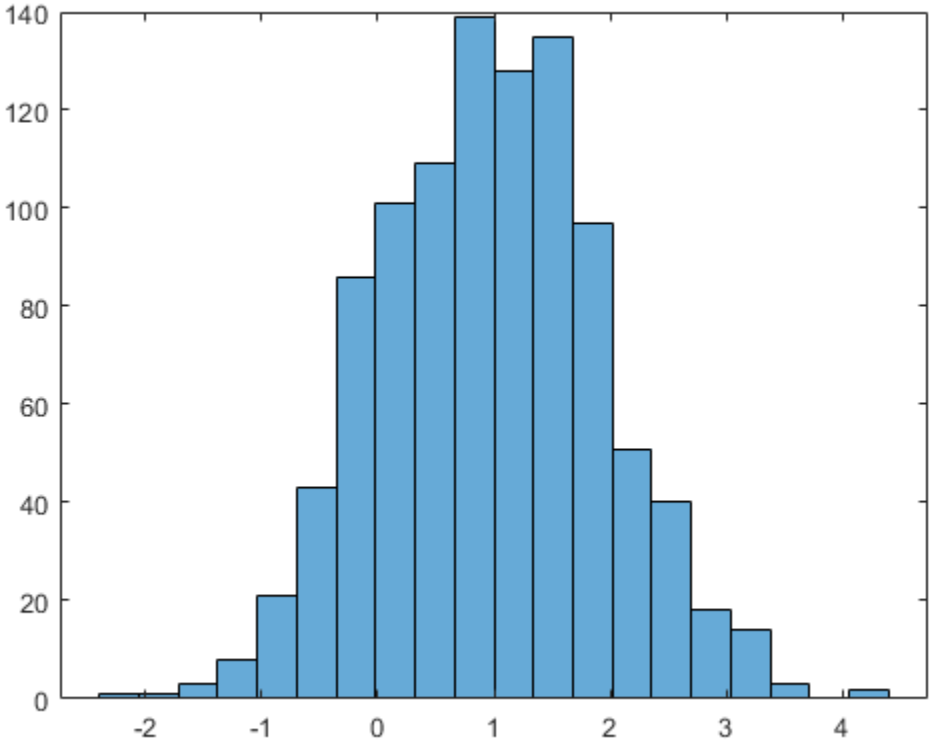


The histogram shows that the random numbers generated using the Weibull inverse cdf function `wblinv` have a Weibull distribution.

Step 3. Generate random numbers from the standard normal distribution.

The same values in `u` can generate random numbers from any distribution, for example the standard normal, by following the same procedure using the inverse cdf of the desired distribution.

```
figure
x_norm = norminv(u,1,1);
histogram(x_norm,20)
```



The histogram shows that, by using the standard normal inverse cdf `norminv`, the random numbers generated from `u` now have a standard normal distribution.

Represent Cauchy Distribution Using t Location-Scale

This example shows how to use the t location-scale probability distribution object to work with a Cauchy distribution with nonstandard parameter values.

Step 1. Create a probability distribution object.

Create a *t* location-scale probability distribution object with degrees of freedom `nu = 1`. Specify `mu = 3` to set the location parameter equal to 3, and `sigma = 1` to set the scale parameter equal to 1.

```
pd = makedist('tLocationScale','mu',3,'sigma',1,'nu',1)
```

```
pd =
  tLocationScaleDistribution

  t Location-Scale distribution
       mu = 3
    sigma = 1
       nu = 1
```

Step 2. Compute descriptive statistics.

Use object functions to compute descriptive statistics for the Cauchy distribution.

```
med = median(pd)
```

```
med = 3
```

```
r = iqr(pd)
```

```
r = 2
```

```
m = mean(pd)
```

```
m = NaN
```

```
s = std(pd)
```

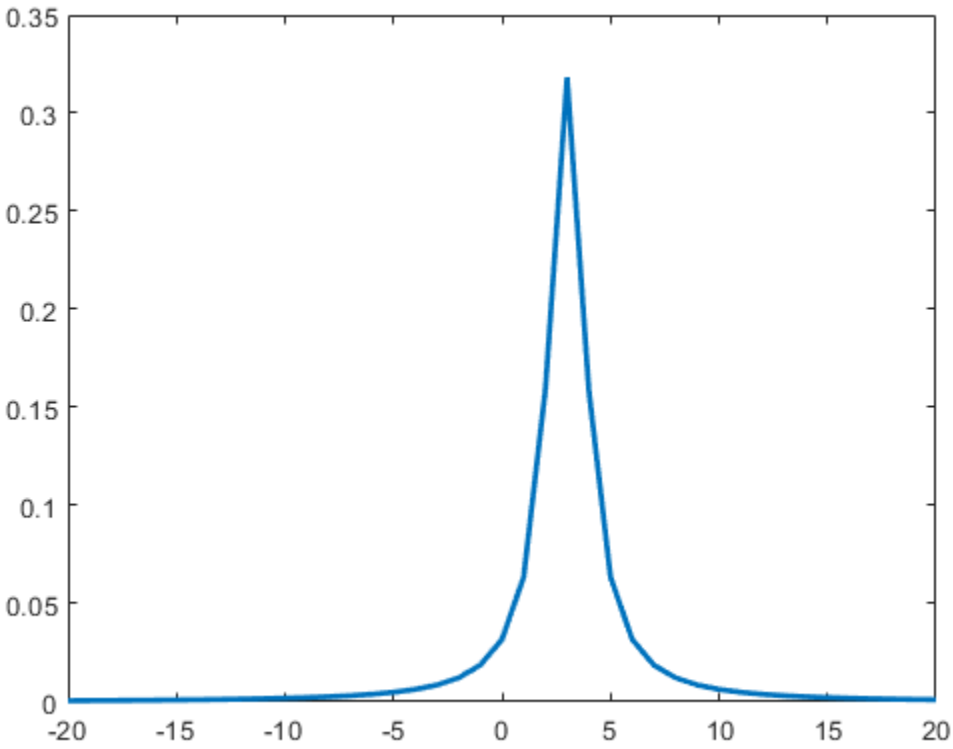
```
s = Inf
```

The median of the Cauchy distribution is equal to its location parameter, and the interquartile range is equal to two times its scale parameter. Its mean and standard deviation are undefined.

Step 3. Compute and plot the pdf.

Compute and plot the pdf of the Cauchy distribution.

```
x = -20:1:20;
y = pdf(pd,x);
plot(x,y,'LineWidth',2)
```



The peak of the pdf is centered at the location parameter `mu = 3`.

Step 4. Generate a vector of Cauchy random numbers.

Generate a column vector containing 10 random numbers from the Cauchy distribution using the `random` function for the *t* location-scale probability distribution object.

```
rng('default');  % For reproducibility
r = random(pd,10,1)
```

```
r = 10×1

Generate Cauchy Random Numbers Using Student's t

This example shows how to use the Student's t distribution to generate random numbers from a standard Cauchy distribution.

Step 1. Generate a vector of random numbers.

Generate a column vector containing 10 random numbers from a standard Cauchy distribution, which has a location parameter `mu = 0` and scale parameter `sigma = 1`. Use `trnd` with degrees of freedom `V = 1`.

```
rng('default');  % For reproducibility
r = trnd(1,10,1)
```

```
r = 10×1

    0.2678
    1.6547
   -0.9396
    1.7322
    0.1810
   -1.3351
   -1.1529
    1.2466
    2.4647
    5.8874
```

Step 2. Generate a matrix of random numbers.

Generate a 5-by-5 matrix of random numbers from a standard Cauchy distribution.

```
r = trnd(1,5,5)
```

```
r = 5×5

   -0.7133   -0.0308   -4.7003    2.5949   -1.0194

Generate Correlated Data Using Rank Correlation

This example shows how to use a copula and rank correlation to generate correlated data from probability distributions that do not have an inverse cdf function available, such as the Pearson flexible distribution family.

Step 1. Generate Pearson random numbers.

Generate 1000 random numbers from two different Pearson distributions, using the `pearsrnd` function. The first distribution has the parameter values mu equal to 0, sigma equal to 1, skew equal to 1, and kurtosis equal to 4. The second distribution has the parameter values mu equal to 0, sigma equal to 1, skew equal to 0.75, and kurtosis equal to 3.

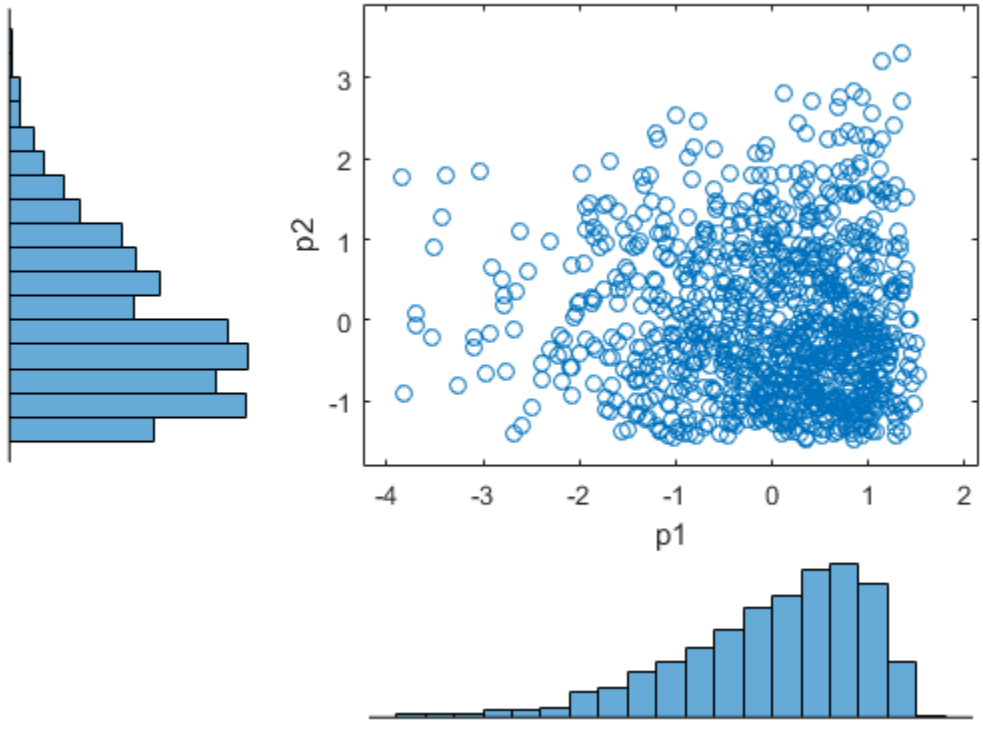
```
rng default  % For reproducibility
p1 = pearsrnd(0,1,-1,4,1000,1);
p2 = pearsrnd(0,1,0.75,3,1000,1);
```

At this stage, `p1` and `p2` are independent samples from their respective Pearson distributions, and are uncorrelated.

Step 2. Plot the Pearson random numbers.

Create a `scatterhist` plot to visualize the Pearson random numbers.

```
figure
scatterhist(p1,p2)
```

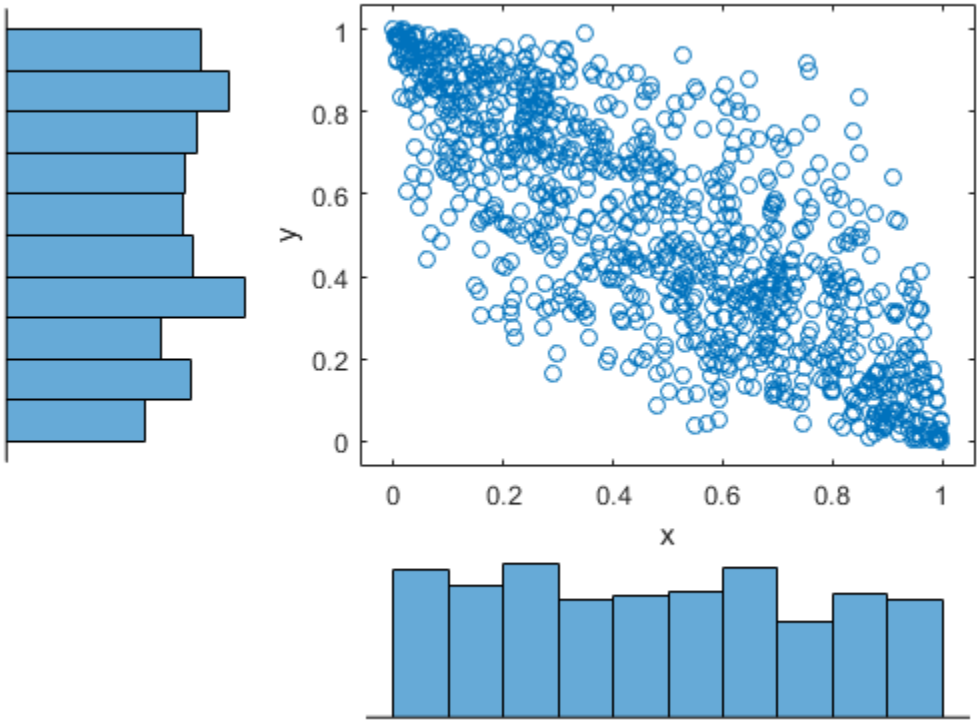


The histograms show the marginal distributions for `p1` and `p2`. The scatterplot shows the joint distribution for `p1` and `p2`. The lack of pattern to the scatterplot shows that `p1` and `p2` are independent.

Step 3. Generate random numbers using a Gaussian copula.

Use `copularnd` to generate 1000 correlated random numbers with a correlation coefficient equal to –0.8, using a Gaussian copula. Create a `scatterhist` plot to visualize the random numbers generated from the copula.

```
u = copularnd('Gaussian',-0.8,1000);
figure
scatterhist(u(:,1),u(:,2))
```



The histograms show that the data in each column of the copula have a marginal uniform distribution. The scatterplot shows that the data in the two columns are negatively correlated.

Step 4. Sort the copula random numbers.

Using Spearman's rank correlation, transform the two independent Pearson samples into correlated data.

Use the `sort` function to sort the copula random numbers from smallest to largest, and to return a vector of indices describing the rearranged order of the numbers.

```
[s1,i1] = sort(u(:,1));
[s2,i2] = sort(u(:,2));
```

`s1` and `s2` contain the numbers from the first and second columns of the copula, `u`, sorted in order from smallest to largest. `i1` and `i2` are index vectors that describe the rearranged order of the elements into `s1` and `s2`. For example, if the first value in the sorted vector `s1` is the third value in the original unsorted vector, then the first value in the index vector `i1` is 3.

Step 5. Transform the Pearson samples using Spearman's rank correlation.

Create two vectors of zeros, `x1` and `x2`, that are the same size as the sorted copula vectors, `s1` and `s2`. Sort the values in `p1` and `p2` from smallest to largest. Place the values into `x1` and `x2`, in the same order as the indices `i1` and `i2` generated by sorting the copula random numbers.

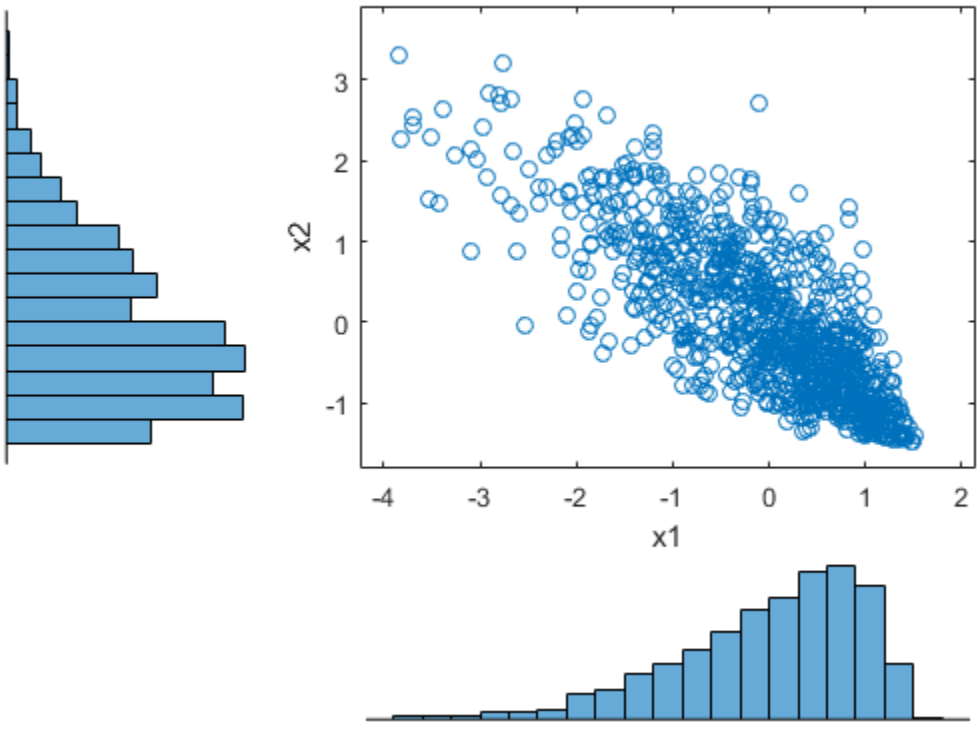
```
x1 = zeros(size(s1));
x2 = zeros(size(s2));

x1(i1) = sort(p1);
x2(i2) = sort(p2);
```

Step 6. Plot the correlated Pearson random numbers.

Create a `scatterhist` plot to visualize the correlated Pearson data.

```
figure
scatterhist(x1,x2)
```



The histograms show the marginal Pearson distributions for each column of data. The scatterplot shows the joint distribution of `p1` and `p2`, and indicates that the data are now negatively correlated.

Step 7. Confirm Spearman rank correlation coefficient values.

Confirm that the Spearman rank correlation coefficient is the same for the copula random numbers and the correlated Pearson random numbers.

```
copula_corr = corr(u,'Type','spearman')
```

```
copula_corr = 2×2

    1.0000   -0.7858
   -0.7858    1.0000
```

```
pearson_corr = corr([x1,x2],'Type','spearman')
```

```
pearson_corr = 2×2

    1.0000   -0.7858
   -0.7858    1.0000
```

The Spearman rank correlation is the same for the copula and the Pearson random numbers.

Create Gaussian Mixture Model

This example shows how to create a known, or fully specified, Gaussian mixture model (GMM) object using `gmdistribution` and by specifying component means, covariances, and mixture proportions. To create a GMM object by fitting data to a GMM, see “Fit Gaussian Mixture Model to Data” on page 5-115.

Specify the component means, covariances, and mixing proportions for a two-component mixture of bivariate Gaussian distributions.

```
mu = [1 2;-3 -5];                    % Means
sigma = cat(3,[2 0;0 .5],[1 0;0 1]); % Covariances
p = ones(1,2)/2;                     % Mixing proportions
```

The rows of `mu` correspond to the component mean vectors, and the pages of `sigma`, `sigma(:,:,J)`, correspond to the component covariance matrices.

Create a GMM object using `gmdistribution`.

```
gm = gmdistribution(mu,sigma,p);
```

Display the properties of the GMM.

```
properties(gm)
```

```
Properties for class gmdistribution:

    NumVariables
    DistributionName
    NumComponents
    ComponentProportion
    SharedCovariance
    NumIterations
    RegularizationValue
    NegativeLogLikelihood
    CovarianceType
    mu
    Sigma
    AIC
    BIC
    Converged
    ProbabilityTolerance
```

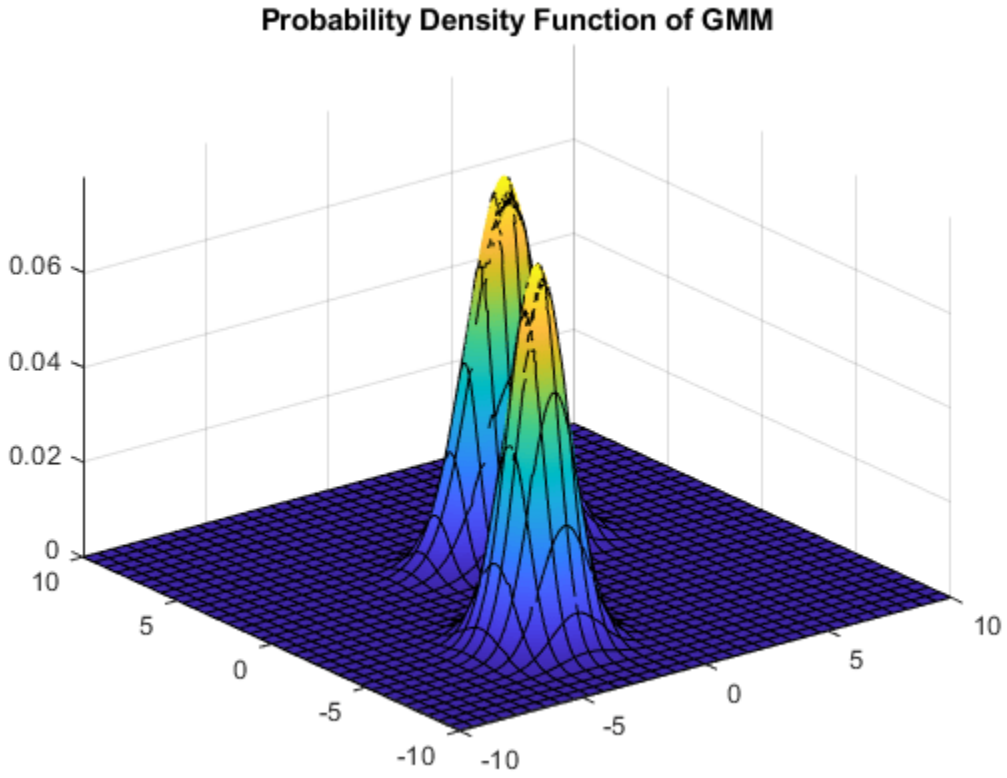
For a description of the properties, see `gmdistribution`. To access the value of a property, use dot notation. For example, access the number of variables of each GMM component.

```
dimension = gm.NumVariables
```

```
dimension = 2
```

Visualize the probability density function (pdf) of the GMM using `pdf` and the MATLAB® function `fsurf`.

```
gmPDF = @(x,y) arrayfun(@(x0,y0) pdf(gm,[x0 y0]),x,y);
fsurf(gmPDF,[-10 10])
title('Probability Density Function of GMM');
```



Visualize the cumulative distribution function (cdf) of the GMM using `cdf` and `fsurf`.

```
gmCDF = @(x,y) arrayfun(@(x0,y0) cdf(gm,[x0 y0]),x,y);
fsurf(gmCDF,[-10 10])
title('Cumulative Distribution Function of GMM');
```

Fit Gaussian Mixture Model to Data

This example shows how to simulate data from a multivariate normal distribution, and then fit a Gaussian mixture model (GMM) to the data using `fitgmdist`. To create a known, or fully specified, GMM object, see “Create Gaussian Mixture Model” on page 5-112.

`fitgmdist` requires a matrix of data and the number of components in the GMM. To create a useful GMM, you must choose `k` carefully. Too few components fails to model the data accurately (i.e., underfitting to the data). Too many components leads to an over-fit model with singular covariance matrices.

Simulate data from a mixture of two bivariate Gaussian distributions using `mvnrnd`.

```
mu1 = [1 2];
sigma1 = [2 0; 0 .5];
mu2 = [-3 -5];
sigma2 = [1 0; 0 1];
rng(1); % For reproducibility
X = [mvnrnd(mu1,sigma1,1000);
     mvnrnd(mu2,sigma2,1000)];
```

Plot the simulated data.

```
scatter(X(:,1),X(:,2),10,'.') % Scatter plot with points of size 10
title('Simulated Data')
```

Fit a two-component GMM. Use the `'Options'` name-value pair argument to display the final output of the fitting algorithm.

```
options = statset('Display','final');
gm = fitgmdist(X,2,'Options',options)
```

```
5 iterations, log-likelihood = -7105.71

gm =

Gaussian mixture distribution with 2 components in 2 dimensions

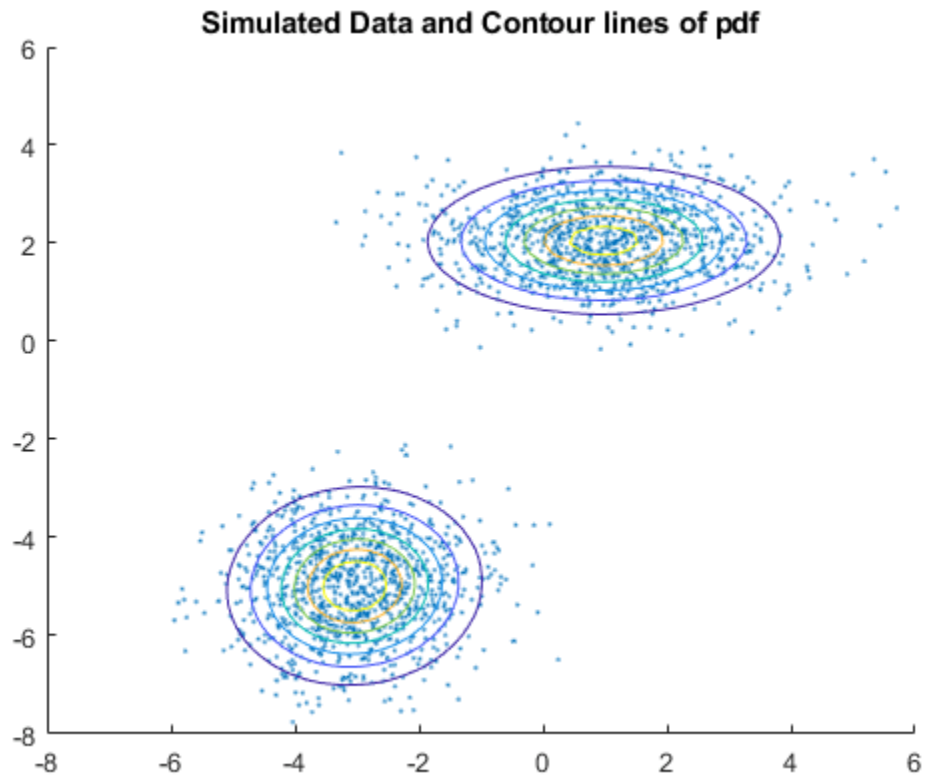
Mixing proportion: 0.500000
Mean:   -3.0377   -4.9859

Component 2:
Mixing proportion: 0.500000
Mean:    0.9812    2.0563
```

Plot the pdf of the fitted GMM.

```
gmPDF = @(x,y) arrayfun(@(x0,y0) pdf(gm,[x0 y0]),x,y);
hold on
h = fcontour(gmPDF,[-8 6]);
title('Simulated Data and Contour lines of pdf');
```



Display the estimates for means, covariances, and mixture proportions

```
ComponentMeans = gm.mu
```

```
ComponentMeans = 2×2

   -3.0377   -4.9859
    0.9812    2.0563
```

```
ComponentCovariances = gm.Sigma
```

```
ComponentCovariances =
ComponentCovariances(:,:,1) =

    1.0132    0.0482
    0.0482    0.9796

ComponentCovariances(:,:,2) =

    1.9919    0.0127
    0.0127    0.5533
```

```
MixtureProportions = gm.ComponentProportion
```

```
MixtureProportions = 1×2

    0.5000    0.5000
```

Fit four models to the data, each with an increasing number of components, and compare the Akaike Information Criterion (AIC) values.

```
AIC = zeros(1,4);
gm = cell(1,4);
for k = 1:4
    gm{k} = fitgmdist(X,k);
    AIC(k)= gm{k}.AIC;
end
```

Display the number of components that minimizes the AIC value.

```
[minAIC,numComponents] = min(AIC);
numComponents
```

```
numComponents = 2
```

The two-component model has the smallest AIC value.

Display the two-component GMM.

```
gm2 = gm{numComponents}
```

```
gm2 =

Gaussian mixture distribution with 2 components in 2 dimensions
Component 1:
Mixing proportion: 0.500000
Mean:   -3.0377   -4.9859
```

```
Component 2:
Mixing proportion: 0.500000
Mean:    0.9812    2.0563
```

Both the AIC and Bayesian information criteria (BIC) are likelihood-based measures of model fit that include a penalty for complexity (specifically, the number of parameters). You can use them to determine an appropriate number of components for a model when the number of components is unspecified.

Simulate Data from Gaussian Mixture Model

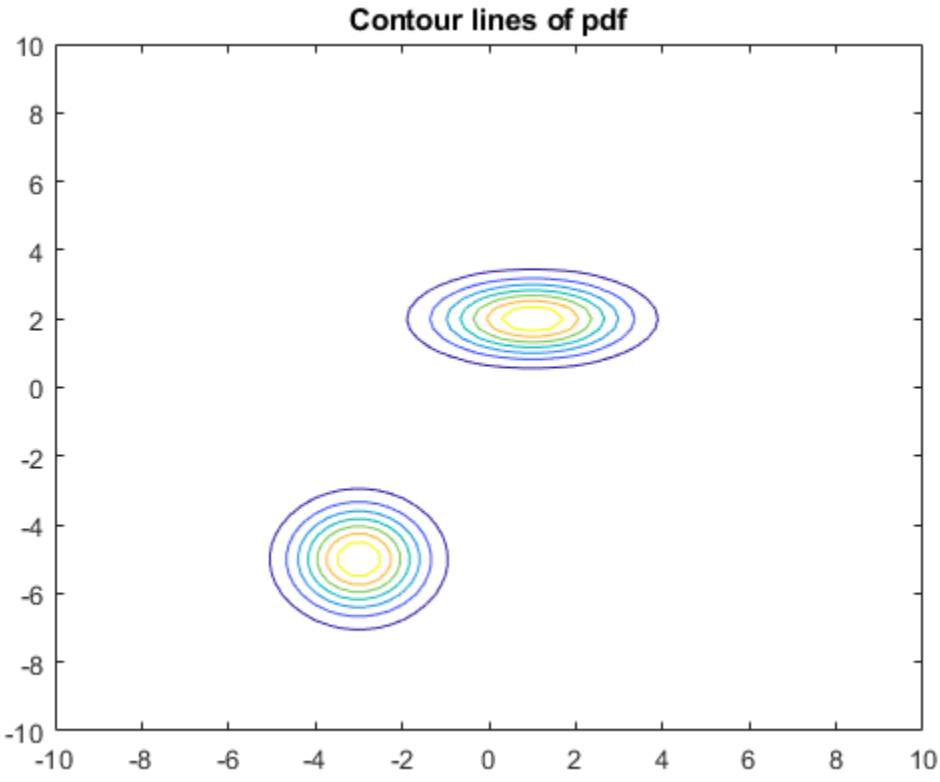
This example shows how to simulate data from a Gaussian mixture model (GMM) using a fully specified `gmdistribution` object and the `random` function.

Create a known, two-component GMM object.

```
mu = [1 2;-3 -5];
sigma = cat(3,[2 0;0 .5],[1 0;0 1]);
p = ones(1,2)/2;
gm = gmdistribution(mu,sigma,p);
```

Plot the contour of the pdf of the GMM.

```
gmPDF = @(x,y) arrayfun(@(x0,y0) pdf(gm,[x0 y0]),x,y);
fcontour(gmPDF,[-10 10]);
title('Contour lines of pdf');
```



Generate 1000 random variates from the GMM.

```
rng('default') % For reproducibility
X = random(gm,1000);
```

Plot the variates with the pdf contours.

```
hold on
scatter(X(:,1),X(:,2),10,'.') % Scatter plot with points of size 10
title('Contour lines of pdf and Simulated Data')
```

Copulas: Generate Correlated Samples

In this section...

Copulas are functions that describe dependencies among variables, and provide a way to create distributions that model correlated multivariate data. Using a copula, you can construct a multivariate distribution by specifying marginal univariate distributions, and then choose a copula to provide a correlation structure between variables. Bivariate distributions, as well as distributions in higher dimensions, are possible.

Determining Dependence Between Simulation Inputs

One of the design decisions for a Monte Carlo simulation is a choice of probability distributions for the random inputs. Selecting a distribution for each individual variable is often straightforward, but deciding what dependencies should exist between the inputs may not be. Ideally, input data to a simulation should reflect what you know about dependence among the real quantities you are modeling. However, there may be little or no information on which to base any dependence in the simulation. In such cases, it is useful to experiment with different possibilities in order to determine the model's sensitivity.

It can be difficult to generate random inputs with dependence when they have distributions that are not from a standard multivariate distribution. Further, some of the standard multivariate distributions can model only limited types of dependence. It is always possible to make the inputs independent, and while that is a simple choice, it is not always sensible and can lead to the wrong conclusions.

For example, a Monte-Carlo simulation of financial risk could have two random inputs that represent different sources of insurance losses. You could model these inputs as lognormal random variables. A reasonable question to ask is how dependence between these two inputs affects the results of the simulation. Indeed, you might know from real data that the same random conditions affect both sources; ignoring that in the simulation could lead to the wrong conclusions.

Generate and Exponentiate Normal Random Variables

The `lognrnd` function simulates independent lognormal random variables. In the following example, the `mvnrnd` function generates `n` pairs of independent normal random variables, and then exponentiates them. Notice that the covariance matrix used here is diagonal.

```
n = 1000;

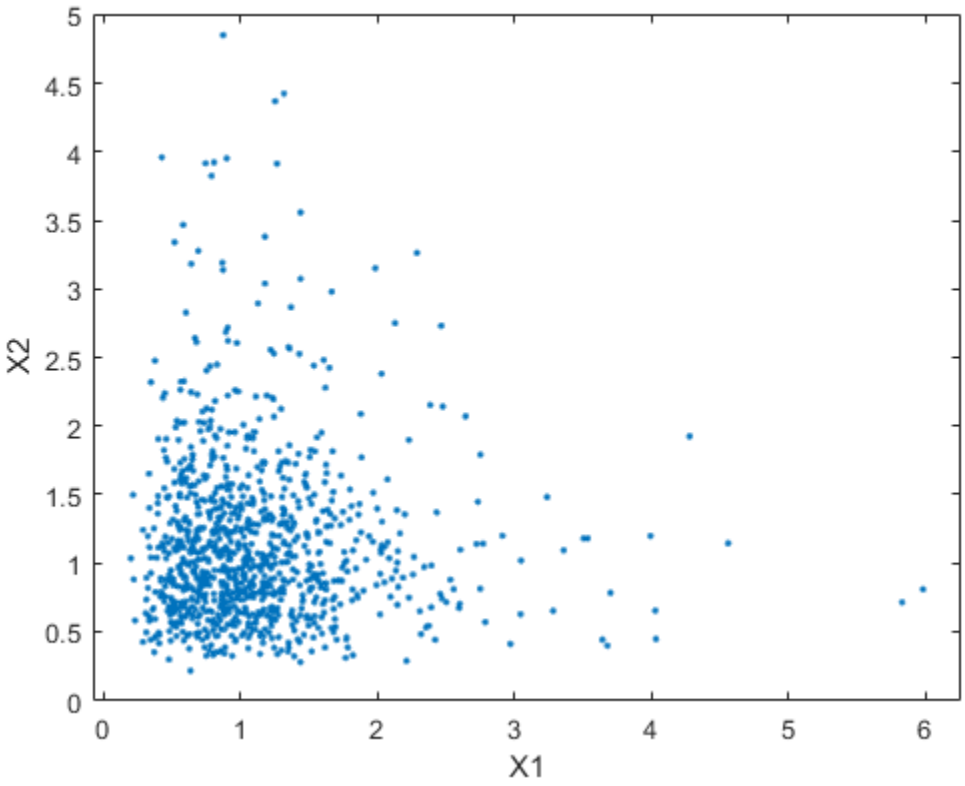
sigma = .5;
SigmaInd = sigma.^2 .* [1 0; 0 1]
```

```
SigmaInd = 2×2

    0.2500         0
         0    0.2500
```

```
rng('default');  % For reproducibility
ZInd = mvnrnd([0 0],SigmaInd,n);
XInd = exp(ZInd);

plot(XInd(:,1),XInd(:,2),'.')
axis([0 5 0 5])
axis equal
xlabel('X1')
ylabel('X2')
```



Dependent bivariate lognormal random variables are also easy to generate using a covariance matrix with nonzero off-diagonal terms.

```
rho = .7;

SigmaDep = sigma.^2 .* [1 rho; rho 1]

SigmaDep = 2×2

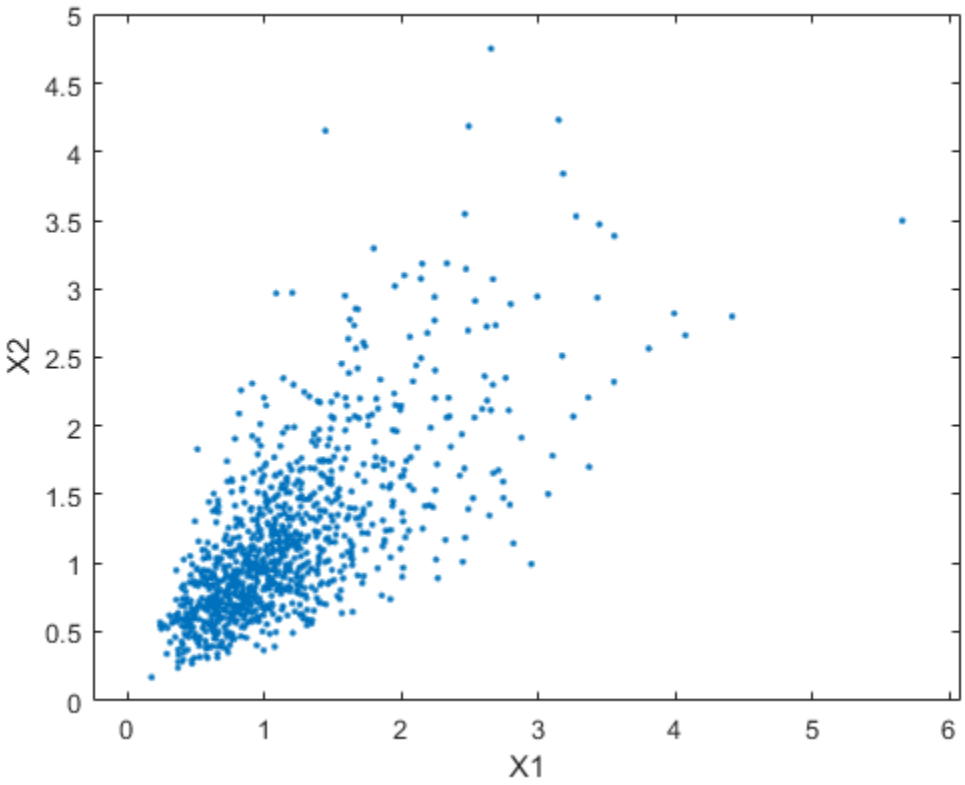
    0.2500    0.1750
```

```
    0.1750    0.2500
```

```
ZDep = mvnrnd([0 0],SigmaDep,n);
XDep = exp(ZDep);
```

A second scatter plot demonstrates the difference between these two bivariate distributions.

```
plot(XDep(:,1),XDep(:,2),'.')
axis([0 5 0 5])
axis equal
xlabel('X1')
ylabel('X2')
```



It is clear that there is a tendency in the second data set for large values of X1 to be associated with large values of X2, and similarly for small values. The correlation parameter ρ of the underlying bivariate normal determines this dependence. The conclusions drawn from the simulation could well depend on whether you generate X1 and X2 with dependence. The bivariate lognormal distribution is a simple solution in this case; it easily generalizes to higher dimensions in cases where the marginal distributions are different lognormals.

Other multivariate distributions also exist. For example, the multivariate *t* and the Dirichlet distributions simulate dependent *t* and beta random variables, respectively. But the list of simple multivariate distributions is not long, and they only apply in cases where the marginals are all in the same family (or even the exact same distributions). This can be a serious limitation in many situations.

Constructing Dependent Bivariate Distributions

Although the construction discussed in the previous section creates a bivariate lognormal that is simple, it serves to illustrate a method that is more generally applicable.

1. Generate pairs of values from a bivariate normal distribution. There is statistical dependence between these two variables, and each has a normal marginal distribution.
2. Apply a transformation (the exponential function) separately to each variable, changing the marginal distributions into lognormals. The transformed variables still have a statistical dependence.

If a suitable transformation can be found, this method can be generalized to create dependent bivariate random vectors with other marginal distributions. In fact, a general method of constructing such a transformation does exist, although it is not as simple as exponentiation alone.

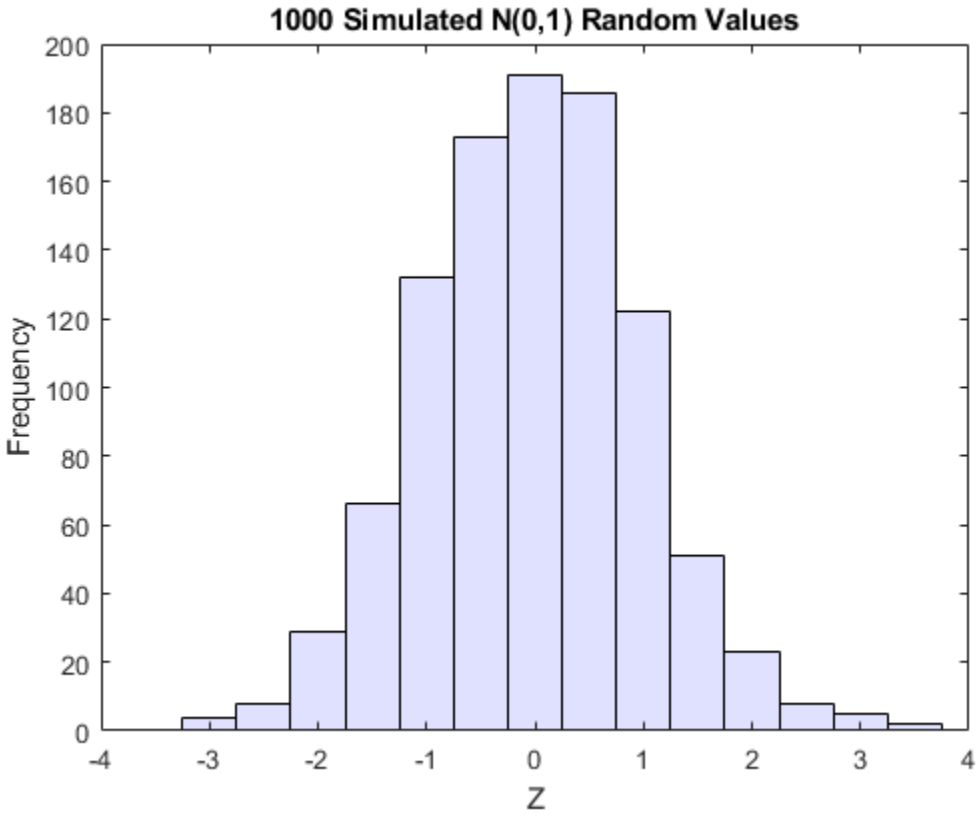
By definition, applying the normal cumulative distribution function (cdf), denoted here by Φ, to a standard normal random variable results in a random variable that is uniform on the interval [0,1]. To see this, if Z has a standard normal distribution, then the cdf of $U = \Phi(Z)$ is

$$\Pr\{U \le u\} = \Pr\{\Phi(Z) \le u\} = \Pr\left\{Z \le \Phi^{-1}(u)\right\} = u$$

and that is the cdf of a Unif(0,1) random variable. Histograms of some simulated normal and transformed values demonstrate that fact:

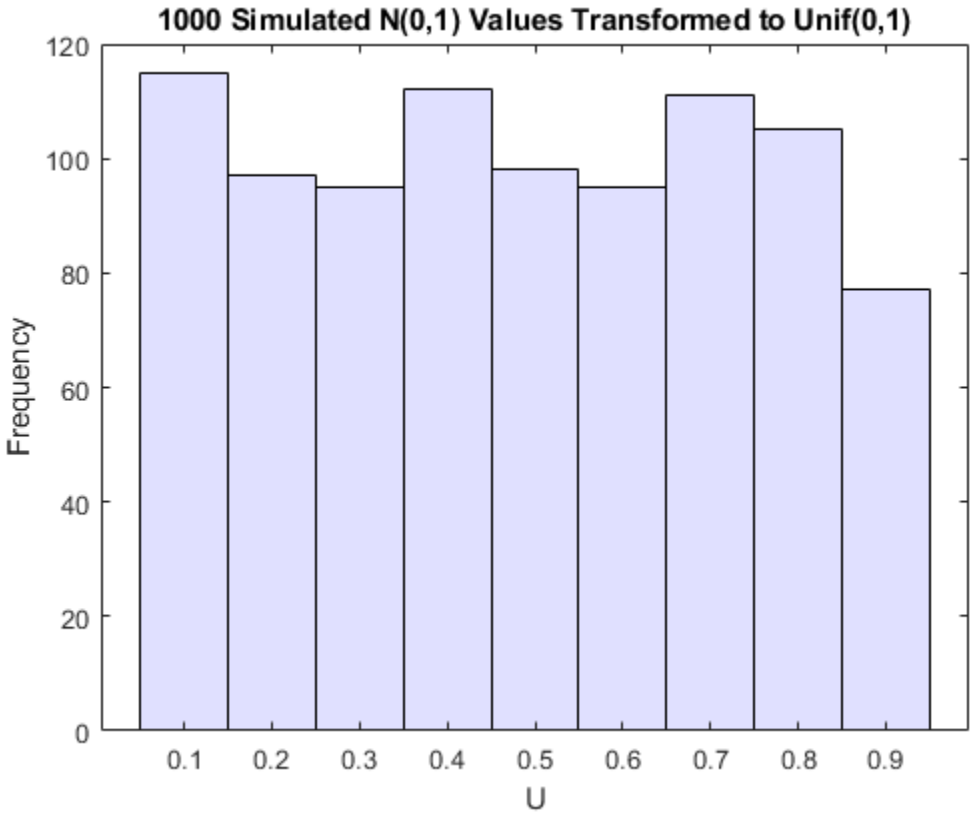
```
n = 1000;
rng default % for reproducibility
z = normrnd(0,1,n,1); % generate standard normal data

histogram(z,-3.75:.5:3.75,'FaceColor',[.8 .8 1]) % plot the histogram of data
xlim([-4 4])
title('1000 Simulated N(0,1) Random Values')
xlabel('Z')
ylabel('Frequency')
```



```
u = normcdf(z);  % compute the cdf values of the sample data

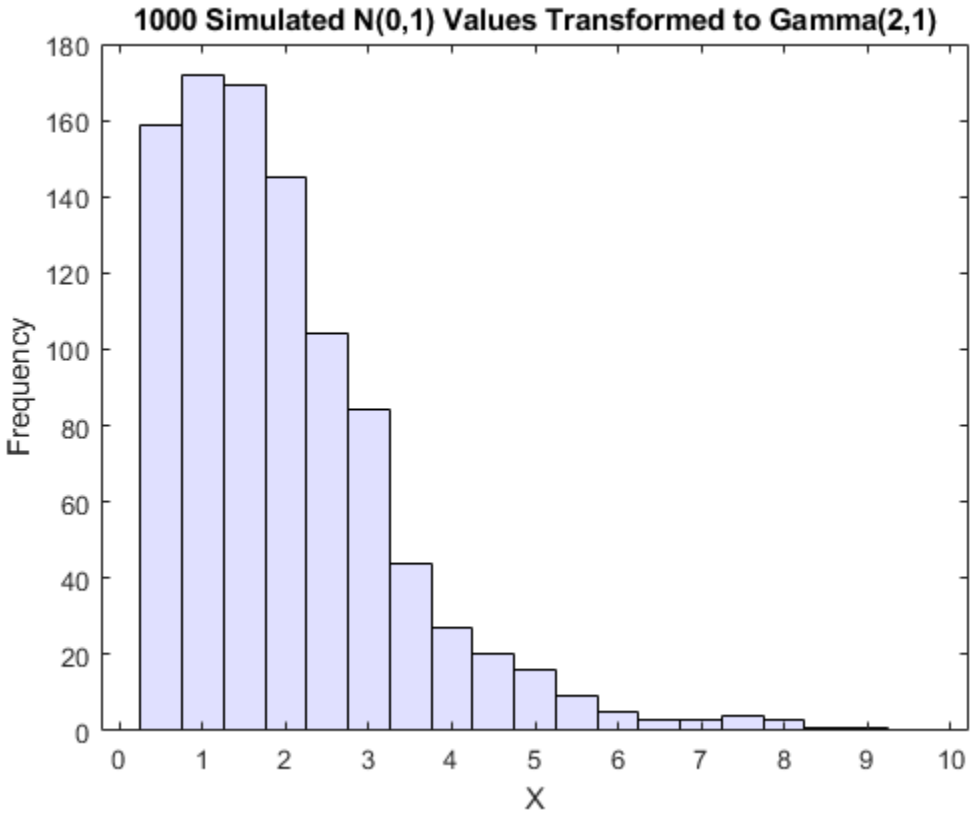
figure
histogram(u,.05:.1:.95,'FaceColor',[.8 .8 1]) % plot the histogram of the cdf values
title('1000 Simulated N(0,1) Values Transformed to Unif(0,1)')
xlabel('U')
ylabel('Frequency')
```



Borrowing from the theory of univariate random number generation, applying the inverse cdf of any distribution, *F*, to a Unif(0,1) random variable results in a random variable whose distribution is exactly *F* (see “Inversion Methods” on page 7-3). The proof is essentially the opposite of the preceding proof for the forward case. Another histogram illustrates the transformation to a gamma distribution:

```
x = gaminv(u,2,1); % transform to gamma values

figure
histogram(x,.25:.5:9.75,'FaceColor',[.8 .8 1]) % plot the histogram of gamma values
title('1000 Simulated N(0,1) Values Transformed to Gamma(2,1)')
xlabel('X')
ylabel('Frequency')
```



You can apply this two-step transformation to each variable of a standard bivariate normal, creating dependent random variables with arbitrary marginal distributions. Because the transformation works on each component separately, the two resulting random variables need not even have the same marginal distributions. The transformation is defined as:

$$Z = [Z_1, Z_2] \sim N\left([0,0], \begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix}\right)$$

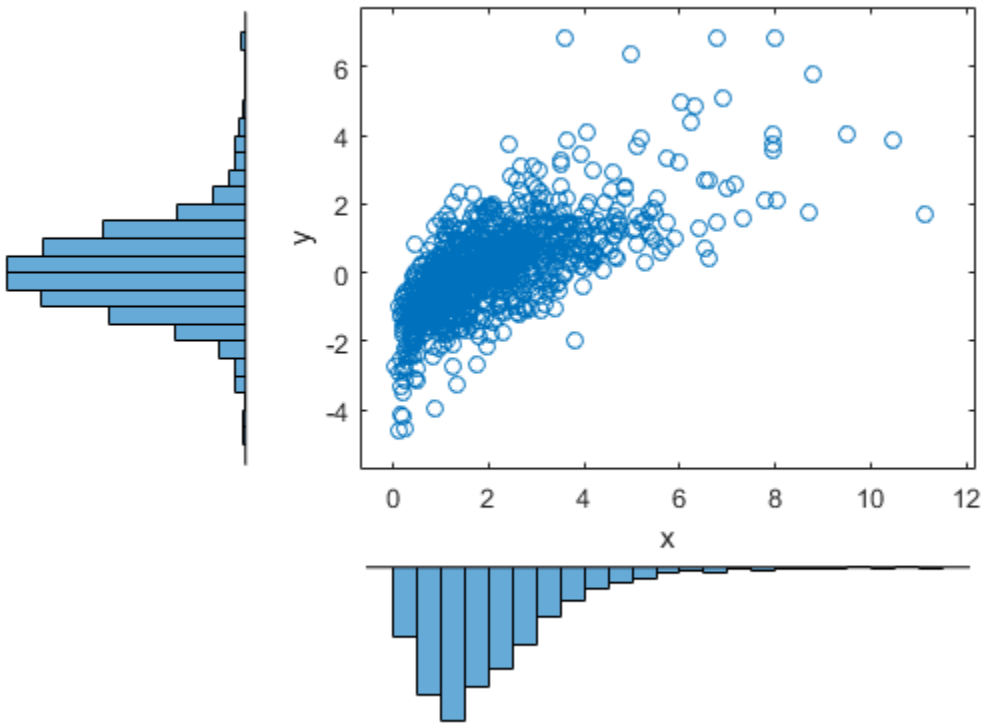
$$U = [\Phi(Z_1), \Phi(Z_2)]$$

$$X = [G_1(U_1), G_2(U_2)]$$

where G_1 and G_2 are inverse cdfs of two possibly different distributions. For example, the following generates random vectors from a bivariate distribution with t_5 and Gamma(2,1) marginals:

```
n = 1000; rho = .7;
Z = mvnrnd([0 0],[1 rho; rho 1],n);
U = normcdf(Z);
X = [gaminv(U(:,1),2,1) tinv(U(:,2),5)];

% draw the scatter plot of data with histograms
figure
scatterhist(X(:,1),X(:,2),'Direction','out')
```



This plot has histograms alongside a scatter plot to show both the marginal distributions, and the dependence.

Using Rank Correlation Coefficients

The correlation parameter, ρ, of the underlying bivariate normal determines the dependence between X1 and X2 in this construction. However, the linear correlation of X1 and X2 is not ρ. For example, in the original lognormal case, a closed form for that correlation is:

$$\mathrm{cor}(X1, X2) = \frac{e^{\rho\sigma^2} - 1}{e^{\sigma^2} - 1}$$

which is strictly less than ρ, unless ρ is exactly 1. In more general cases such as the Gamma/t construction, the linear correlation between X1 and X2 is difficult or impossible to express in terms of ρ, but simulations show that the same effect happens.

That is because the linear correlation coefficient expresses the linear dependence between random variables, and when nonlinear transformations are applied to those random variables, linear correlation is not preserved. Instead, a rank correlation coefficient, such as Kendall's τ or Spearman's ρ, is more appropriate.

Roughly speaking, these rank correlations measure the degree to which large or small values of one random variable associate with large or small values of another. However, unlike the linear

correlation coefficient, they measure the association only in terms of ranks. As a consequence, the rank correlation is preserved under any monotonic transformation. In particular, the transformation method just described preserves the rank correlation. Therefore, knowing the rank correlation of the bivariate normal Z exactly determines the rank correlation of the final transformed random variables, X. While the linear correlation coefficient, ρ, is still needed to parameterize the underlying bivariate normal, Kendall's τ or Spearman's ρ are more useful in describing the dependence between random variables, because they are invariant to the choice of marginal distribution.

For the bivariate normal, there is a simple one-to-one mapping between Kendall's τ or Spearman's ρ, and the linear correlation coefficient ρ:

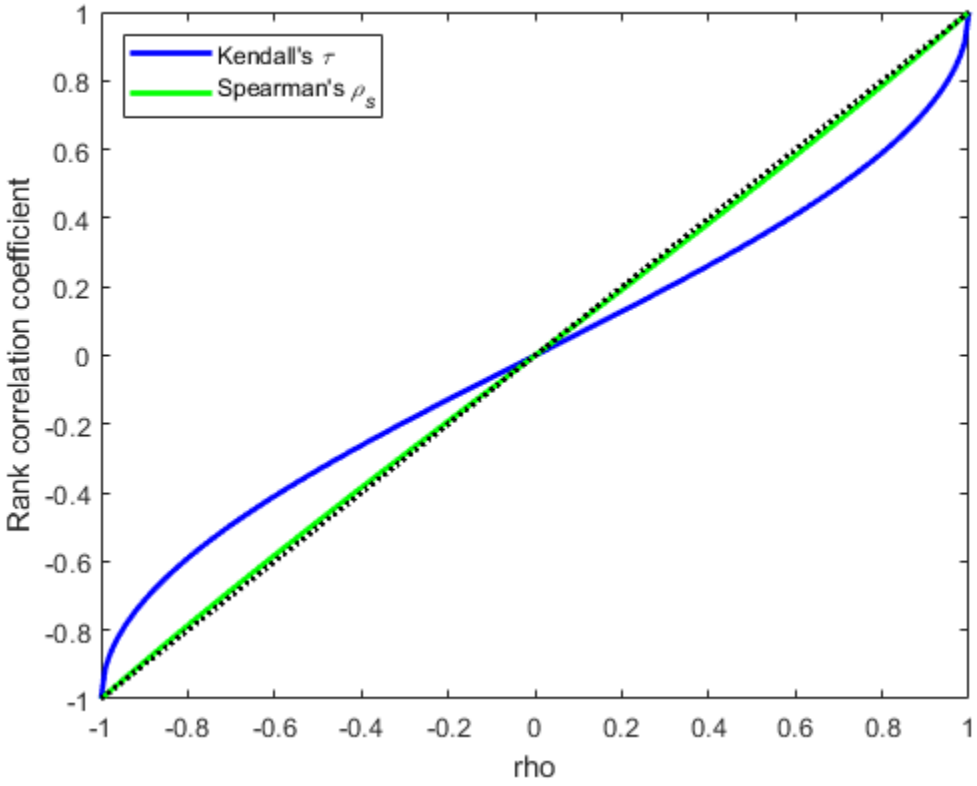
$$\tau = \frac{2}{\pi}\arcsin(\rho) \text{ or } \rho = \sin\left(\tau\frac{\pi}{2}\right)$$

$$\rho_S = \frac{6}{\pi}\arcsin\left(\frac{\rho}{2}\right) \text{ or } \rho = 2\sin\left(\rho_S\frac{\pi}{6}\right)$$

The following plot shows the relationship.

```
rho = -1:.01:1;
tau = 2.*asin(rho)./pi;
rho_s = 6.*asin(rho./2)./pi;

plot(rho,tau,'b-','LineWidth',2)
hold on
plot(rho,rho_s,'g-','LineWidth',2)
plot([-1 1],[-1 1],'k:','LineWidth',2)
axis([-1 1 -1 1])
xlabel('rho')
ylabel('Rank correlation coefficient')
legend('Kendall''s {\it\tau}', ...
       'Spearman''s {\it\rho_s}', ...
       'location','NW')
```



Thus, it is easy to create the desired rank correlation between `X1` and `X2`, regardless of their marginal distributions, by choosing the correct ρ parameter value for the linear correlation between `Z1` and `Z2`.

For the multivariate normal distribution, Spearman's rank correlation is almost identical to the linear correlation. However, this is not true once you transform to the final random variables.

Using Bivariate Copulas

The first step of the construction described in the previous section defines what is known as a bivariate Gaussian copula. A copula is a multivariate probability distribution, where each random variable has a uniform marginal distribution on the unit interval `[0,1]`. These variables may be completely independent, deterministically related (e.g., `U2 = U1`), or anything in between. Because of the possibility for dependence among variables, you can use a copula to construct a new multivariate distribution for dependent variables. By transforming each of the variables in the copula separately using the inversion method, possibly using different cdfs, the resulting distribution can have arbitrary marginal distributions. Such multivariate distributions are often useful in simulations, when you know that the different random inputs are not independent of each other.

Statistics and Machine Learning Toolbox functions compute:

- Probability density functions (`copulapdf`) and the cumulative distribution functions (`copulacdf`) for Gaussian copulas

- Rank correlations from linear correlations (`copulastat`) and vice versa (`copulaparam`)
- Random vectors (`copularnd`)
- Parameters for copulas fit to data (`copulafit`)

For example, use the `copularnd` function to create scatter plots of random values from a bivariate Gaussian copula for various levels of ρ, to illustrate the range of different dependence structures. The family of bivariate Gaussian copulas is parameterized by the linear correlation matrix:

$$P = \begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix}$$

`U1` and `U2` approach linear dependence as ρ approaches ± 1, and approach complete independence as ρ approaches zero:

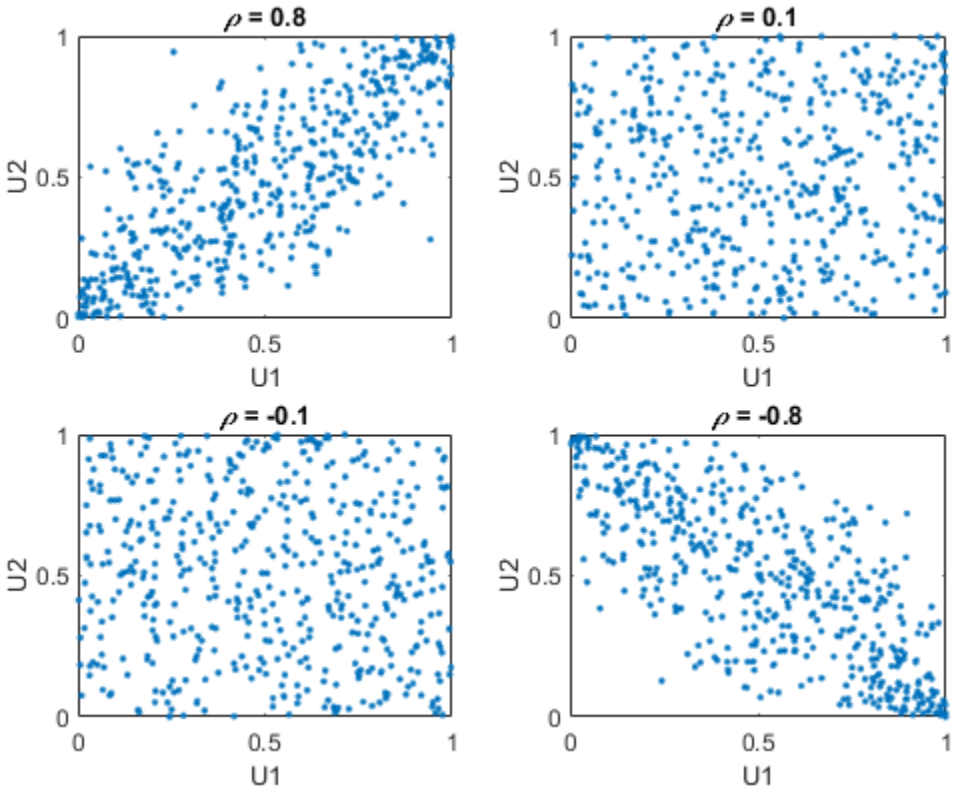
```
n = 500;

rng('default') % for reproducibility
U = copularnd('Gaussian',[1 .8; .8 1],n);
subplot(2,2,1)
plot(U(:,1),U(:,2),'.')
title('{\it\rho} = 0.8')
xlabel('U1')
ylabel('U2')

U = copularnd('Gaussian',[1 .1; .1 1],n);
subplot(2,2,2)
plot(U(:,1),U(:,2),'.')
title('{\it\rho} = 0.1')
xlabel('U1')
ylabel('U2')

U = copularnd('Gaussian',[1 -.1; -.1 1],n);
subplot(2,2,3)
plot(U(:,1),U(:,2),'.')
title('{\it\rho} = -0.1')
xlabel('U1')
ylabel('U2')

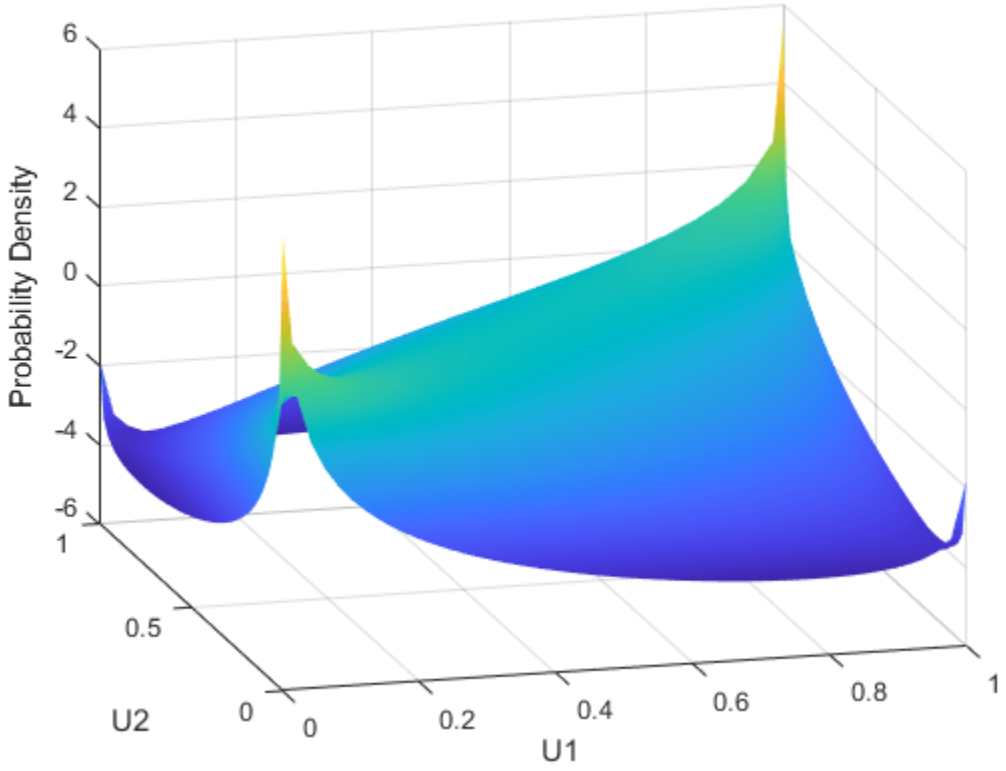
U = copularnd('Gaussian',[1 -.8; -.8 1],n);
subplot(2,2,4)
plot(U(:,1),U(:,2),'.')
title('{\it\rho} = -0.8')
xlabel('U1')
ylabel('U2')
```



The dependence between `U1` and `U2` is completely separate from the marginal distributions of `X1 = G(U1)` and `X2 = G(U2)`. `X1` and `X2` can be given any marginal distributions, and still have the same rank correlation. This is one of the main appeals of copulas—they allow this separate specification of dependence and marginal distribution. You can also compute the pdf (`copulapdf`) and the cdf (`copulacdf`) for a copula. For example, these plots show the pdf and cdf for $\rho = .8$:

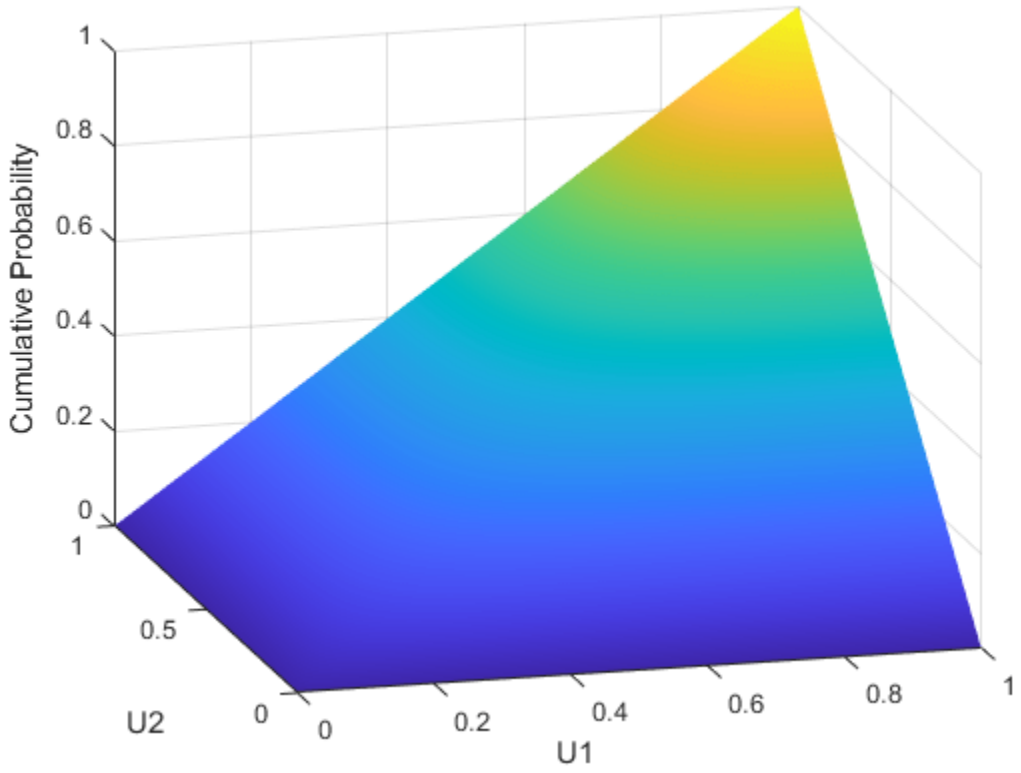
```
u1 = linspace(1e-3,1-1e-3,50);
u2 = linspace(1e-3,1-1e-3,50);
[U1,U2] = meshgrid(u1,u2);
Rho = [1 .8; .8 1];
f = copulapdf('t',[U1(:) U2(:)],Rho,5);
f = reshape(f,size(U1));

figure
surf(u1,u2,log(f),'FaceColor','interp','EdgeColor','none')
view([-15,20])
xlabel('U1')
ylabel('U2')
zlabel('Probability Density')
```



```
u1 = linspace(1e-3,1-1e-3,50);
u2 = linspace(1e-3,1-1e-3,50);
[U1,U2] = meshgrid(u1,u2);
F = copulacdf('t',[U1(:) U2(:)],Rho,5);
F = reshape(F,size(U1));

figure()
surf(u1,u2,F,'FaceColor','interp','EdgeColor','none')
view([-15,20])
xlabel('U1')
ylabel('U2')
zlabel('Cumulative Probability')
```



A different family of copulas can be constructed by starting from a bivariate t distribution and transforming using the corresponding t cdf. The bivariate t distribution is parameterized with P, the linear correlation matrix, and ν, the degrees of freedom. Thus, for example, you can speak of a t_1 or a t_5 copula, based on the multivariate t with one and five degrees of freedom, respectively.

Just as for Gaussian copulas, Statistics and Machine Learning Toolbox functions for t copulas compute:

- Probability density functions (`copulapdf`) and the cumulative distribution functions (`copulacdf`) for t copulas
- Rank correlations from linear correlations (`copulastat`) and vice versa (`copulaparam`)
- Random vectors (`copularnd`)
- Parameters for copulas fit to data (`copulafit`)

For example, use the `copularnd` function to create scatter plots of random values from a bivariate t_1 copula for various levels of ρ, to illustrate the range of different dependence structures:

```
n = 500;
nu = 1;

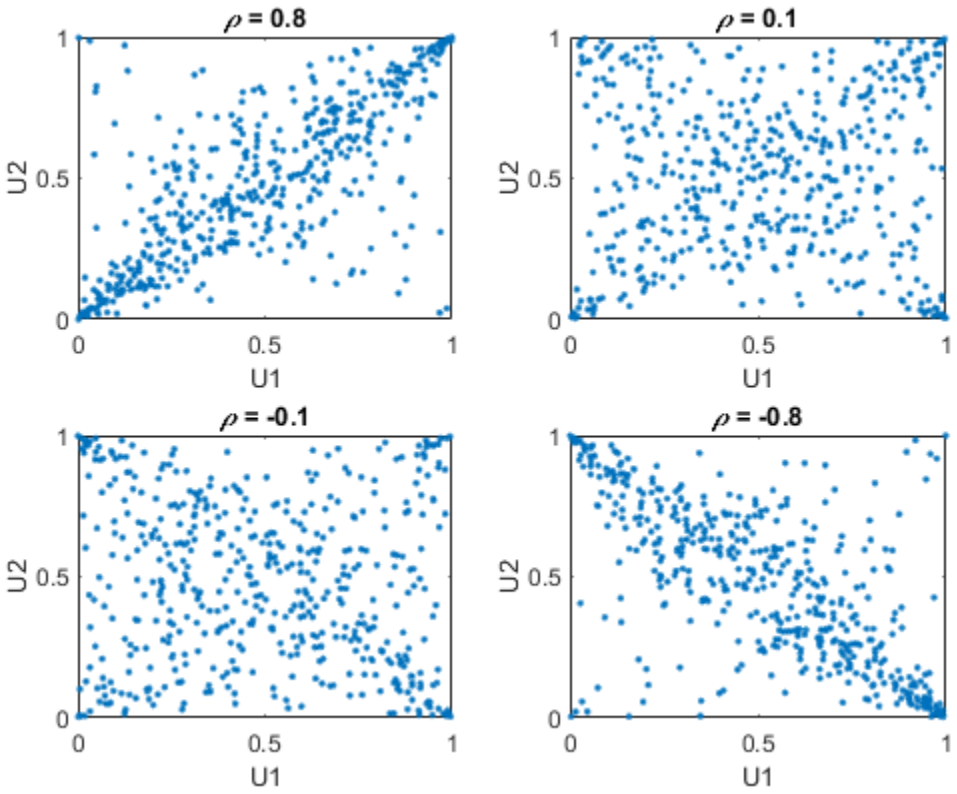
rng('default') % for reproducibility
U = copularnd('t',[1 .8; .8 1],nu,n);
subplot(2,2,1)
plot(U(:,1),U(:,2),'.')
title('{\it\rho} = 0.8')
```

```
xlabel('U1')
ylabel('U2')

U = copularnd('t',[1 .1; .1 1],nu,n);
subplot(2,2,2)
plot(U(:,1),U(:,2),'.')
title('{\it\rho} = 0.1')
xlabel('U1')
ylabel('U2')

U = copularnd('t',[1 -.1; -.1 1],nu,n);
subplot(2,2,3)
plot(U(:,1),U(:,2),'.')
title('{\it\rho} = -0.1')
xlabel('U1')
ylabel('U2')

U = copularnd('t',[1 -.8; -.8 1],nu, n);
subplot(2,2,4)
plot(U(:,1),U(:,2),'.')
title('{\it\rho} = -0.8')
xlabel('U1')
ylabel('U2')
```



A t copula has uniform marginal distributions for `U1` and `U2`, just as a Gaussian copula does. The rank correlation τ or ρ_s between components in a t copula is also the same function of ρ as for a Gaussian. However, as these plots demonstrate, a t_1 copula differs quite a bit from a Gaussian copula, even

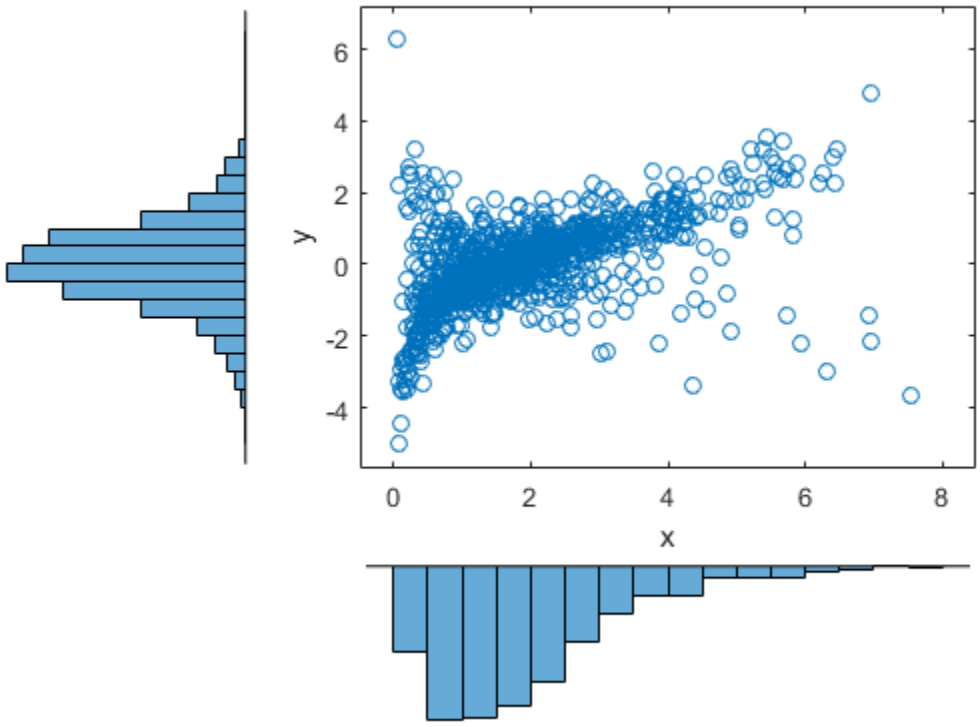
when their components have the same rank correlation. The difference is in their dependence structure. Not surprisingly, as the degrees of freedom parameter ν is made larger, a t_ν copula approaches the corresponding Gaussian copula.

As with a Gaussian copula, any marginal distributions can be imposed over a t copula. For example, using a t copula with 1 degree of freedom, you can again generate random vectors from a bivariate distribution with Gamma(2,1) and t_5 marginals using `copularnd`:

```
n = 1000;
rho = .7;
nu = 1;

rng('default') % for reproducibility
U = copularnd('t',[1 rho; rho 1],nu,n);
X = [gaminv(U(:,1),2,1) tinv(U(:,2),5)];

figure
scatterhist(X(:,1),X(:,2),'Direction','out')
```



Compared to the bivariate Gamma/t distribution constructed earlier, which was based on a Gaussian copula, the distribution constructed here, based on a t_1 copula, has the same marginal distributions and the same rank correlation between variables but a very different dependence structure. This illustrates the fact that multivariate distributions are not uniquely defined by their marginal distributions, or by their correlations. The choice of a particular copula in an application may be based on actual observed data, or different copulas may be used as a way of determining the sensitivity of simulation results to the input distribution.

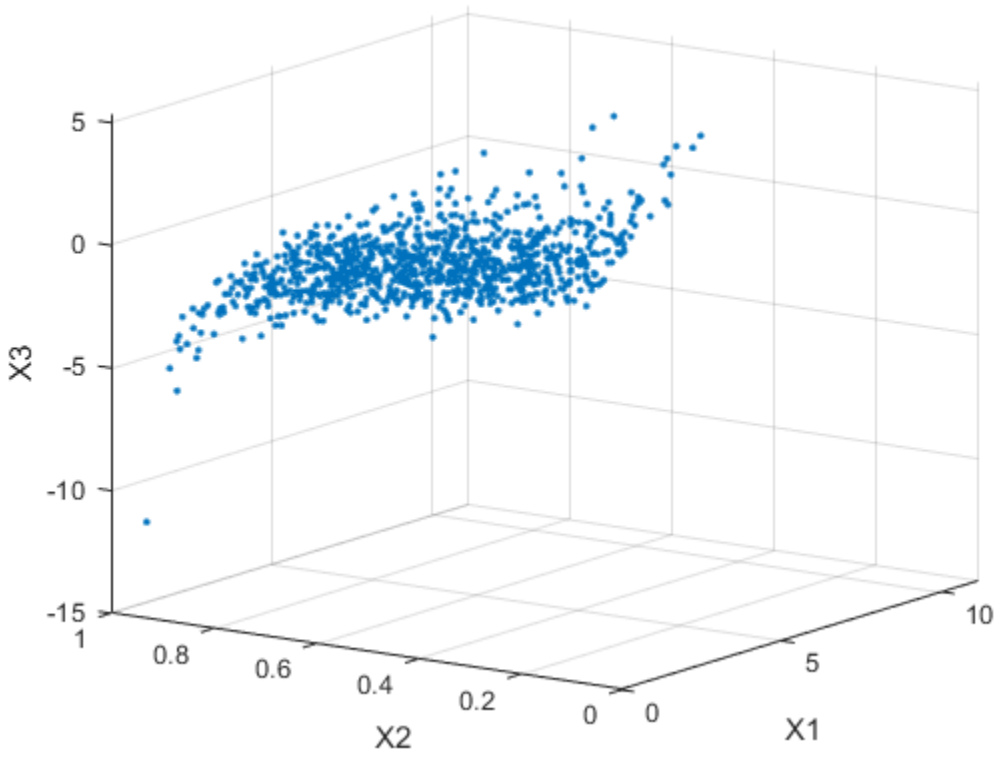
Higher Dimension Copulas

The Gaussian and t copulas are known as elliptical copulas. It is easy to generalize elliptical copulas to a higher number of dimensions. For example, simulate data from a trivariate distribution with Gamma(2,1), Beta(2,2), and t_5 marginals using a Gaussian copula and `copularnd`, as follows:

```
n = 1000;
Rho = [1 .4 .2; .4 1 -.8; .2 -.8 1];
rng('default') % for reproducibility
U = copularnd('Gaussian',Rho,n);
X = [gaminv(U(:,1),2,1) betainv(U(:,2),2,2) tinv(U(:,3),5)];
```

Plot the data.

```
subplot(1,1,1)
plot3(X(:,1),X(:,2),X(:,3),'.')
grid on
view([-55, 15])
xlabel('X1')
ylabel('X2')
zlabel('X3')
```



Notice that the relationship between the linear correlation parameter ρ and, for example, Kendall's τ, holds for each entry in the correlation matrix P used here. You can verify that the sample rank correlations of the data are approximately equal to the theoretical values:

```
tauTheoretical = 2.*asin(Rho)./pi
```

```
tauTheoretical = 3×3

    1.0000    0.2620    0.1282
    0.2620    1.0000   -0.5903
    0.1282   -0.5903    1.0000
```

```
tauSample = corr(X,'type','Kendall')
```

```
tauSample = 3×3

    1.0000    0.2581    0.1414
    0.2581    1.0000   -0.5790
    0.1414   -0.5790    1.0000
```

Archimedean Copulas

Statistics and Machine Learning Toolbox functions are available for three bivariate Archimedean copula families:

- Clayton copulas
- Frank copulas
- Gumbel copulas

These are one-parameter families that are defined directly in terms of their cdfs, rather than being defined constructively using a standard multivariate distribution.

To compare these three Archimedean copulas to the Gaussian and *t* bivariate copulas, first use the `copulastat` function to find the rank correlation for a Gaussian or *t* copula with linear correlation parameter of 0.8, and then use the `copulaparam` function to find the Clayton copula parameter that corresponds to that rank correlation:

```
tau = copulastat('Gaussian',.8 ,'type','kendall')
```

```
tau = 0.5903
```

```
alpha = copulaparam('Clayton',tau,'type','kendall')
```

```
alpha = 2.8820
```

Finally, plot a random sample from the Clayton copula with `copularnd`. Repeat the same procedure for the Frank and Gumbel copulas:

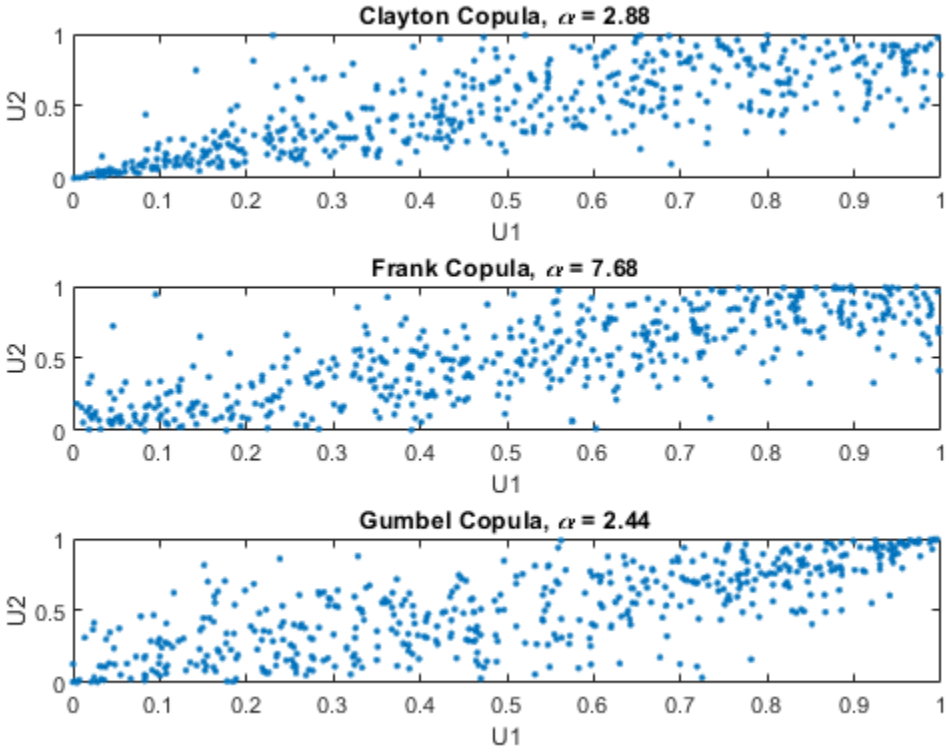
```
n = 500;

U = copularnd('Clayton',alpha,n);
subplot(3,1,1)
plot(U(:,1),U(:,2),'.');
title(['Clayton Copula, {\it\alpha} = ',sprintf('%0.2f',alpha)])
xlabel('U1')
ylabel('U2')

alpha = copulaparam('Frank',tau,'type','kendall');
```

```
U = copularnd('Frank',alpha,n);
subplot(3,1,2)
plot(U(:,1),U(:,2),'.')
title(['Frank Copula, {\it\alpha} = ',sprintf('%0.2f',alpha)])
xlabel('U1')
ylabel('U2')

alpha = copulaparam('Gumbel',tau,'type','kendall');
U = copularnd('Gumbel',alpha,n);
subplot(3,1,3)
plot(U(:,1),U(:,2),'.')
title(['Gumbel Copula, {\it\alpha} = ',sprintf('%0.2f',alpha)])
xlabel('U1')
ylabel('U2')
```



Simulating Dependent Multivariate Data Using Copulas

To simulate dependent multivariate data using a copula, you must specify each of the following:

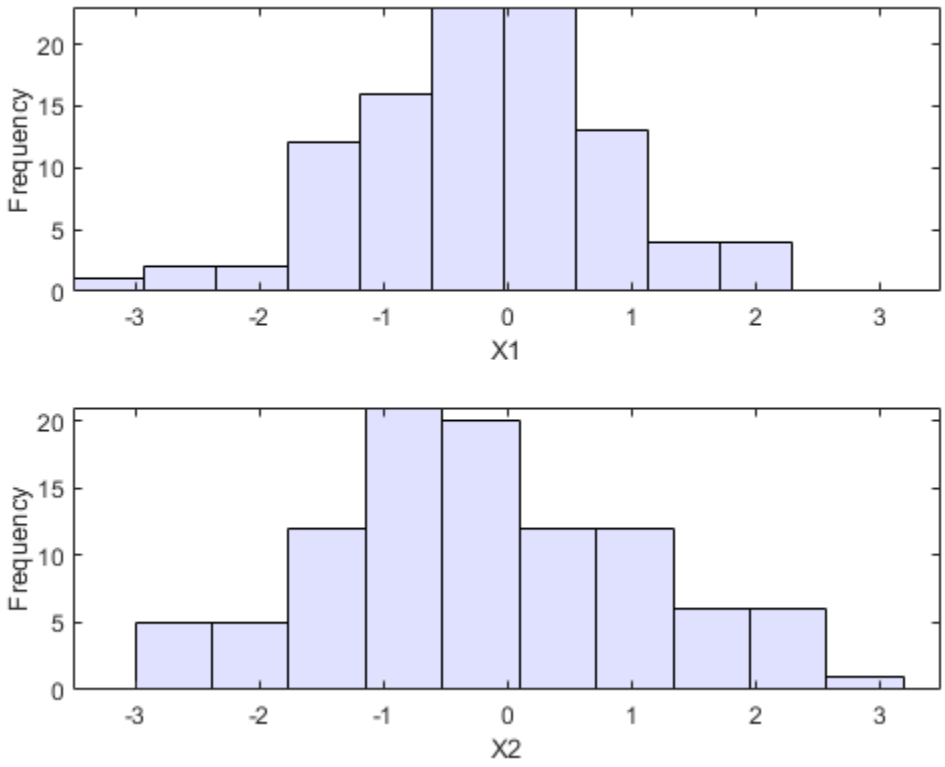
- The copula family (and any shape parameters)
- The rank correlations among variables
- Marginal distributions for each variable

Suppose you have return data for two stocks and want to run a Monte Carlo simulation with inputs that follow the same distributions as the data:

```
load stockreturns
nobs = size(stocks,1);

subplot(2,1,1)
histogram(stocks(:,1),10,'FaceColor',[.8 .8 1])
xlim([-3.5 3.5])
xlabel('X1')
ylabel('Frequency')

subplot(2,1,2)
histogram(stocks(:,2),10,'FaceColor',[.8 .8 1])
xlim([-3.5 3.5])
xlabel('X2')
ylabel('Frequency')
```



You could fit a parametric model separately to each dataset, and use those estimates as the marginal distributions. However, a parametric model may not be sufficiently flexible. Instead, you can use a nonparametric model to transform to the marginal distributions. All that is needed is a way to compute the inverse cdf for the nonparametric model.

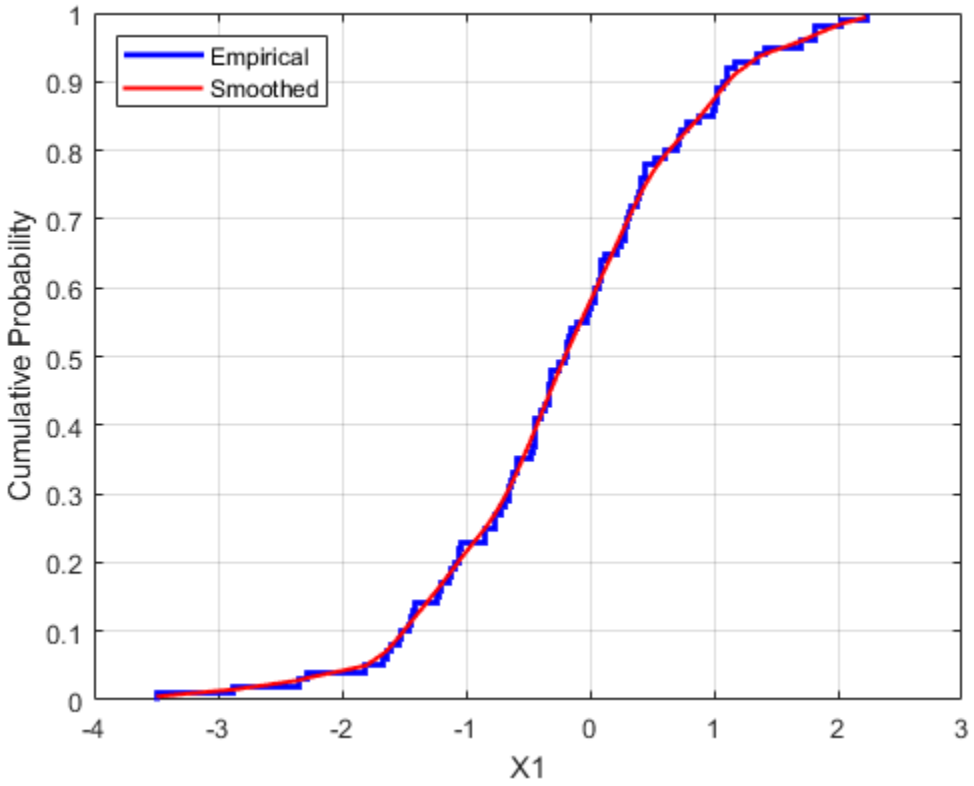
The simplest nonparametric model is the empirical cdf, as computed by the `ecdf` function. For a discrete marginal distribution, this is appropriate. However, for a continuous distribution, use a model that is smoother than the step function computed by `ecdf`. One way to do that is to estimate the empirical cdf and interpolate between the midpoints of the steps with a piecewise linear function. Another way is to use kernel smoothing with `ksdensity`. For example, compare the empirical cdf to a kernel smoothed cdf estimate for the first variable:

```
[Fi,xi] = ecdf(stocks(:,1));

figure()
stairs(xi,Fi,'b','LineWidth',2)
hold on

Fi_sm = ksdensity(stocks(:,1),xi,'function','cdf','width',.15);

plot(xi,Fi_sm,'r-','LineWidth',1.5)
xlabel('X1')
ylabel('Cumulative Probability')
legend('Empirical','Smoothed','Location','NW')
grid on
```



For the simulation, experiment with different copulas and correlations. Here, you will use a bivariate *t* copula with a fairly small degrees of freedom parameter. For the correlation parameter, you can compute the rank correlation of the data.

```
nu = 5;
tau = corr(stocks(:,1),stocks(:,2),'type','kendall')
```

```
tau = 0.5180
```

Find the corresponding linear correlation parameter for the *t* copula using `copulaparam`.

```
rho = copulaparam('t', tau, nu, 'type','kendall')
```

```
rho = 0.7268
```

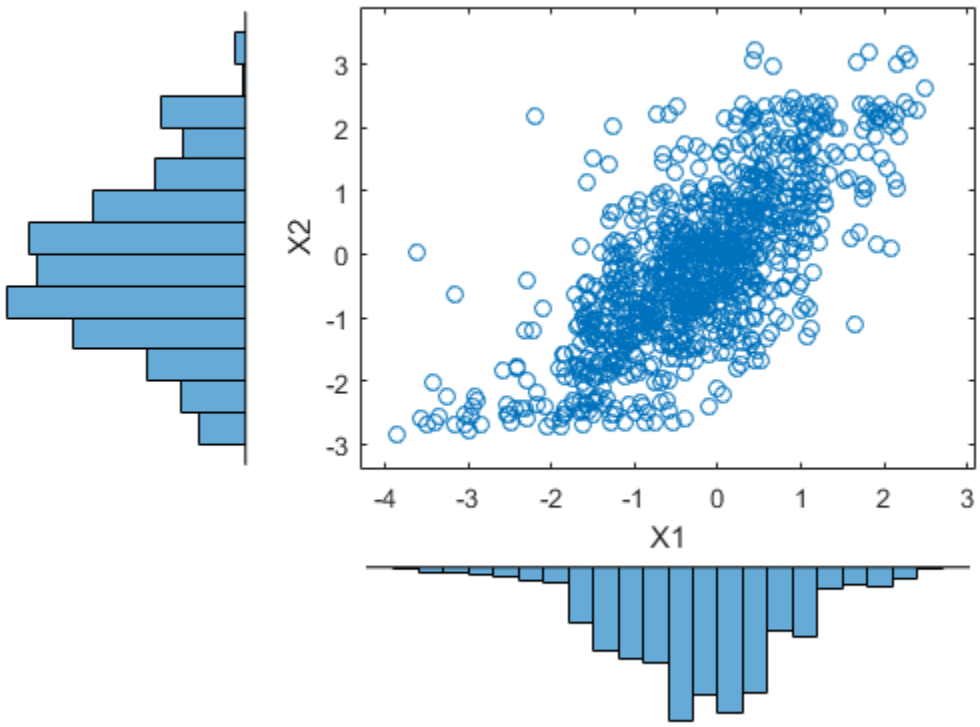
Next, use `copularnd` to generate random values from the *t* copula and transform using the nonparametric inverse cdfs. The `ksdensity` function allows you to make a kernel estimate of distribution and evaluate the inverse cdf at the copula points all in one step:

```
n = 1000;
U = copularnd('t',[1 rho; rho 1],nu,n);
X1 = ksdensity(stocks(:,1),U(:,1),...
               'function','icdf','width',.15);
X2 = ksdensity(stocks(:,2),U(:,2),...
               'function','icdf','width',.15);
```

Alternatively, when you have a large amount of data or need to simulate more than one set of values, it may be more efficient to compute the inverse cdf over a grid of values in the interval `(0,1)` and use interpolation to evaluate it at the copula points:

```
p = linspace(0.00001,0.99999,1000);
G1 = ksdensity(stocks(:,1),p,'function','icdf','width',0.15);
X1 = interp1(p,G1,U(:,1),'spline');
G2 = ksdensity(stocks(:,2),p,'function','icdf','width',0.15);
X2 = interp1(p,G2,U(:,2),'spline');

scatterhist(X1,X2,'Direction','out')
```



The marginal histograms of the simulated data are a smoothed version of the histograms for the original data. The amount of smoothing is controlled by the bandwidth input to `ksdensity`.

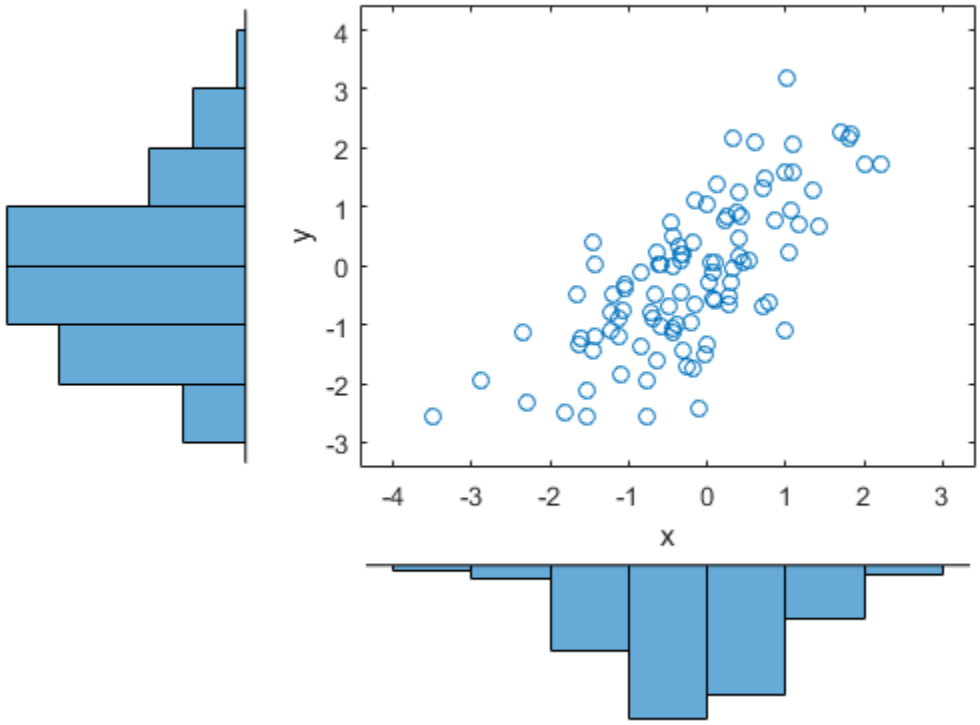
Fitting Copulas to Data

This example shows how to use `copulafit` to calibrate copulas with data. To generate data `Xsim` with a distribution "just like" (in terms of marginal distributions and correlations) the distribution of data in the matrix `X`, you need to fit marginal distributions to the columns of `X`, use appropriate cdf functions to transform `X` to `U`, so that `U` has values between 0 and 1, use `copulafit` to fit a copula to `U`, generate new data `Usim` from the copula, and use appropriate inverse cdf functions to transform `Usim` to `Xsim` .

Load and plot the simulated stock return data.

```
load stockreturns
x = stocks(:,1);
y = stocks(:,2);

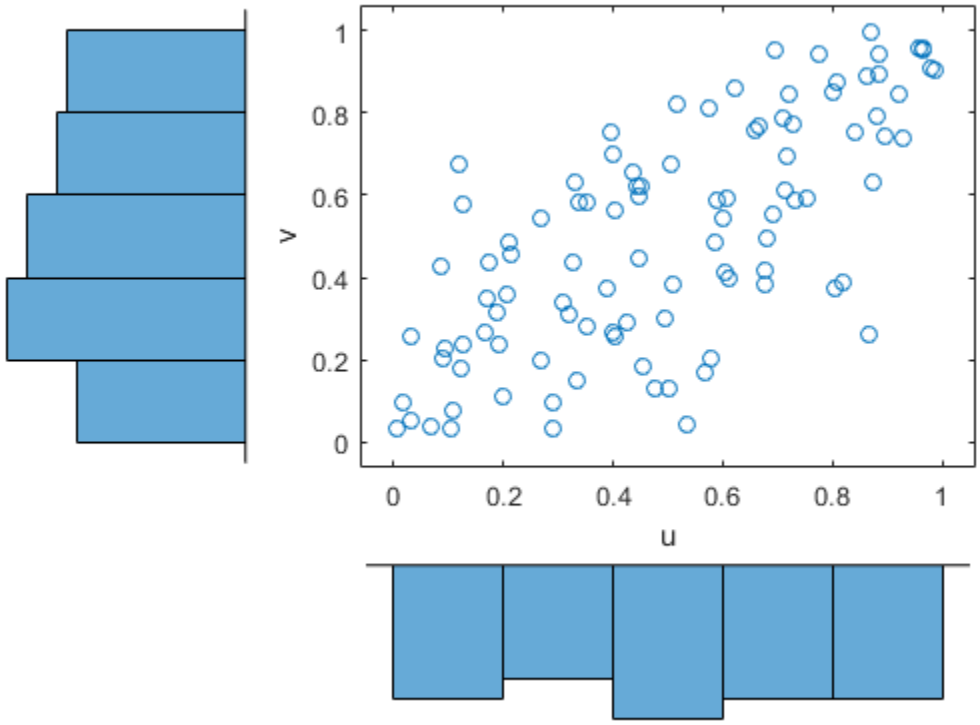
scatterhist(x,y,'Direction','out')
```



Transform the data to the copula scale (unit square) using a kernel estimator of the cumulative distribution function.

```
u = ksdensity(x,x,'function','cdf');
v = ksdensity(y,y,'function','cdf');

scatterhist(u,v,'Direction','out')
xlabel('u')
ylabel('v')
```



Fit a *t* copula.

```
[Rho,nu] = copulafit('t',[u v],'Method','ApproximateML')
```

```
Rho = 2×2

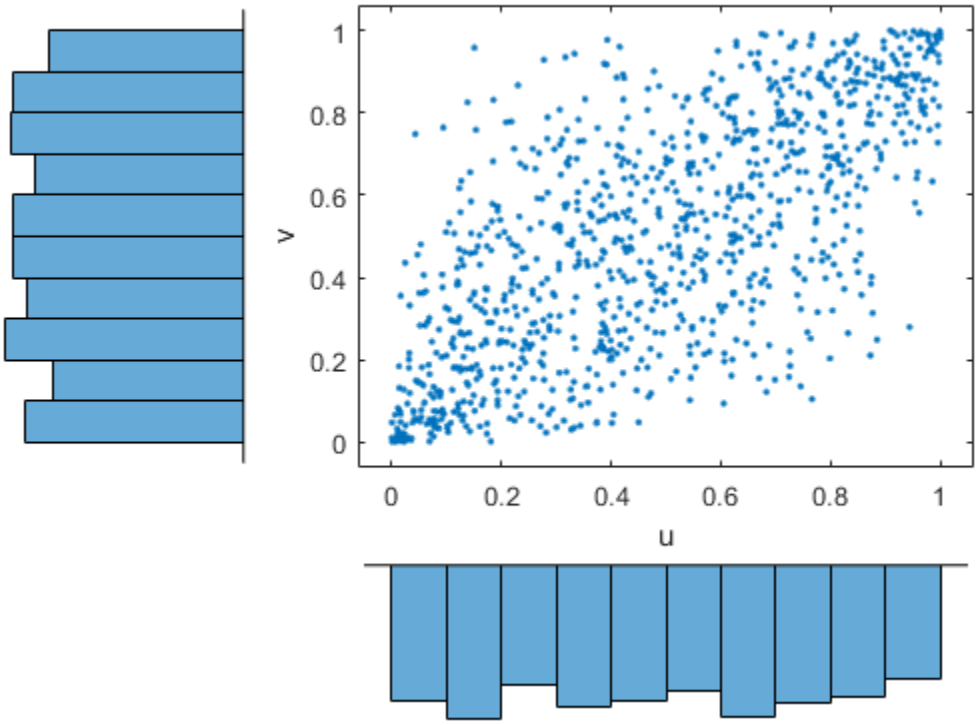
    1.0000    0.7220
    0.7220    1.0000

nu = 3.4516e+06
```

Generate a random sample from the *t* copula.

```
r = copularnd('t',Rho,nu,1000);
u1 = r(:,1);
v1 = r(:,2);

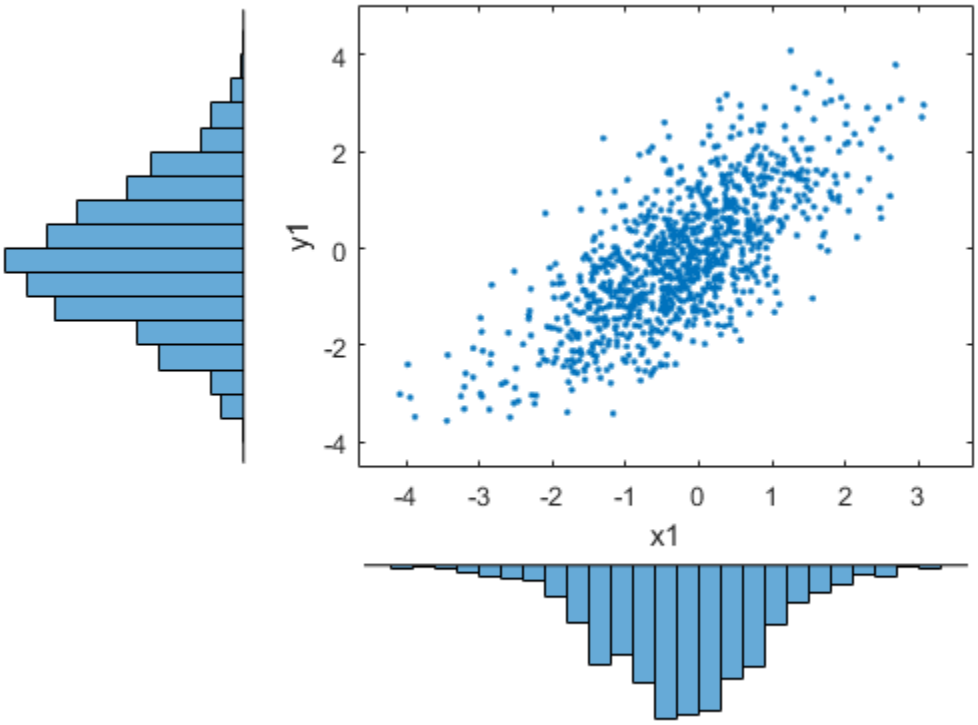
scatterhist(u1,v1,'Direction','out')
xlabel('u')
ylabel('v')
set(get(gca,'children'),'marker','.')
```



Transform the random sample back to the original scale of the data.

```
x1 = ksdensity(x,u1,'function','icdf');
y1 = ksdensity(y,v1,'function','icdf');

scatterhist(x1,y1,'Direction','out')
set(get(gca,'children'),'marker','.')
```



As the example illustrates, copulas integrate naturally with other distribution fitting functions.

Simulating Dependent Random Variables Using Copulas

This example shows how to use copulas to generate data from multivariate distributions when there are complicated relationships among the variables, or when the individual variables are from different distributions.

MATLAB® is an ideal tool for running simulations that incorporate random inputs or noise. Statistics and Machine Learning Toolbox™ provides functions to create sequences of random data according to many common univariate distributions. The Toolbox also includes a few functions to generate random data from multivariate distributions, such as the multivariate normal and multivariate t. However, there is no built-in way to generate multivariate distributions for all marginal distributions, or in cases where the individual variables are from different distributions.

Recently, copulas have become popular in simulation models. Copulas are functions that describe dependencies among variables, and provide a way to create distributions to model correlated multivariate data. Using a copula, a data analyst can construct a multivariate distribution by specifying marginal univariate distributions, and choosing a particular copula to provide a correlation structure between variables. Bivariate distributions, as well as distributions in higher dimensions, are possible. In this example, we discuss how to use copulas to generate dependent multivariate random data in MATLAB, using Statistics and Machine Learning Toolbox.

Dependence Between Simulation Inputs

One of the design decisions for a Monte-Carlo simulation is a choice of probability distributions for the random inputs. Selecting a distribution for each individual variable is often straightforward, but deciding what dependencies should exist between the inputs may not be. Ideally, input data to a simulation should reflect what is known about dependence among the real quantities being modelled. However, there may be little or no information on which to base any dependence in the simulation, and in such cases, it is a good idea to experiment with different possibilities, in order to determine the model's sensitivity.

However, it can be difficult to actually generate random inputs with dependence when they have distributions that are not from a standard multivariate distribution. Further, some of the standard multivariate distributions can model only very limited types of dependence. It's always possible to make the inputs independent, and while that is a simple choice, it's not always sensible and can lead to the wrong conclusions.

For example, a Monte-Carlo simulation of financial risk might have random inputs that represent different sources of insurance losses. These inputs might be modeled as lognormal random variables. A reasonable question to ask is how dependence between these two inputs affects the results of the simulation. Indeed, it might be known from real data that the same random conditions affect both sources, and ignoring that in the simulation could lead to the wrong conclusions.

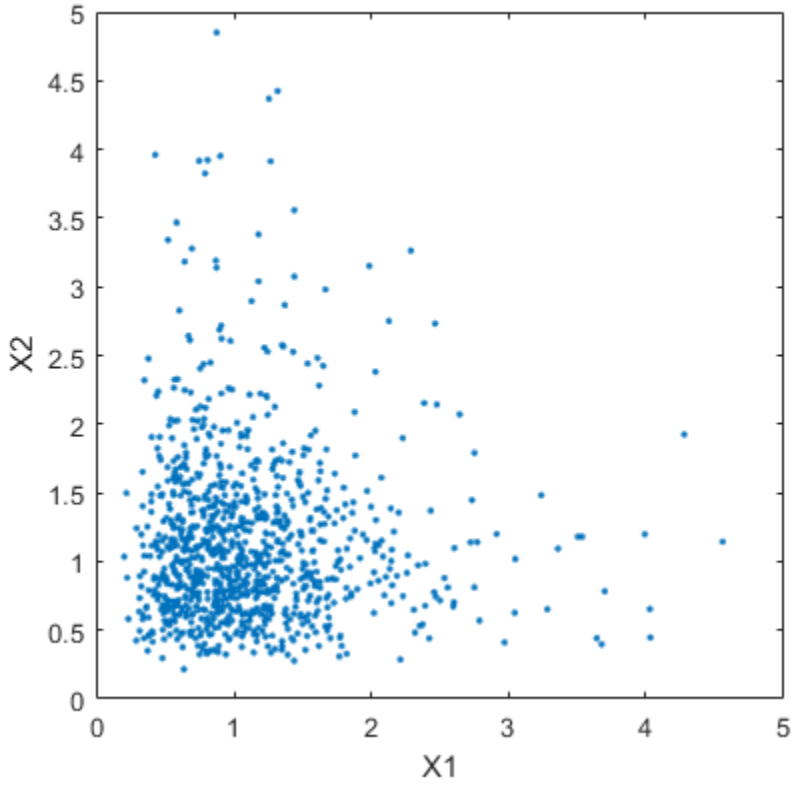
Simulation of independent lognormal random variables is trivial. The simplest way would be to use the `lognrnd` function. Here, we'll use the `mvnrnd` function to generate n pairs of independent normal random variables, and then exponentiate them. Notice that the covariance matrix used here is diagonal, i.e., independence between the columns of Z.

```
n = 1000;
sigma = .5;
SigmaInd = sigma.^2 .* [1 0; 0 1]
```

```
SigmaInd =
```

```
    0.2500         0
         0    0.2500
```

```
ZInd = mvnrnd([0 0], SigmaInd, n);
XInd = exp(ZInd);
plot(XInd(:,1),XInd(:,2),'.');
axis equal;
axis([0 5 0 5]);
xlabel('X1');
ylabel('X2');
```



Dependent bivariate lognormal r.v.'s are also easy to generate, using a covariance matrix with non-zero off-diagonal terms.

```
rho = .7;
SigmaDep = sigma.^2 .* [1 rho; rho 1]
```

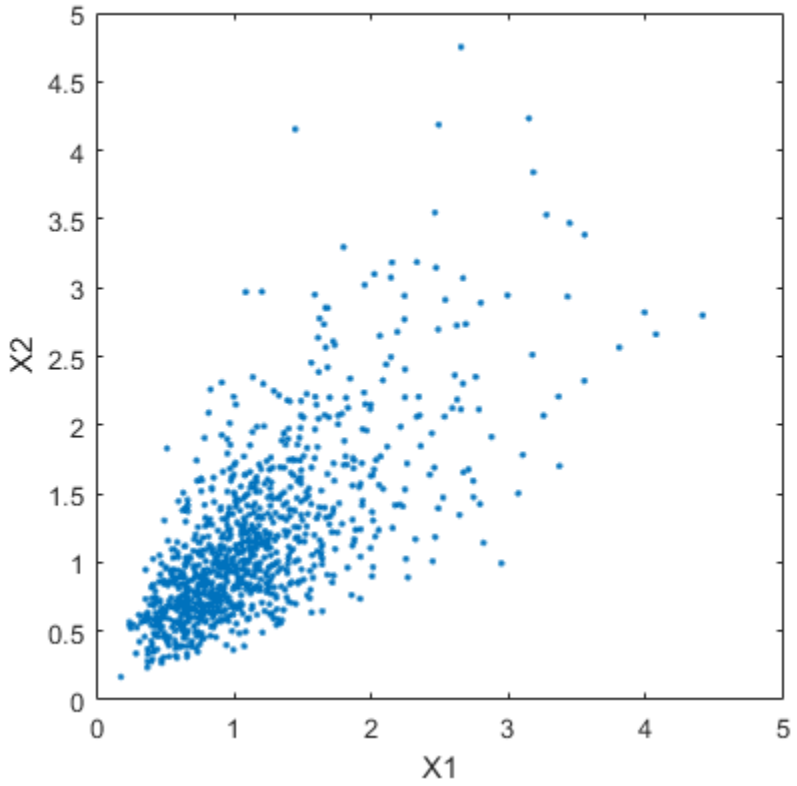
```
SigmaDep =

    0.2500    0.1750
    0.1750    0.2500
```

```
ZDep = mvnrnd([0 0], SigmaDep, n);
XDep = exp(ZDep);
```

A second scatter plot illustrates the difference between these two bivariate distributions.

```
plot(XDep(:,1),XDep(:,2),'.');
axis equal;
axis([0 5 0 5]);
xlabel('X1');
ylabel('X2');
```



It's clear that there is more of a tendency in the second dataset for large values of X1 to be associated with large values of X2, and similarly for small values. This dependence is determined by the correlation parameter, rho, of the underlying bivariate normal. The conclusions drawn from the simulation could well depend on whether or not X1 and X2 were generated with dependence or not.

The bivariate lognormal distribution is a simple solution in this case, and of course easily generalizes to higher dimensions and cases where the marginal distributions are *different* lognormals. Other multivariate distributions also exist, for example, the multivariate t and the Dirichlet distributions are used to simulate dependent t and beta random variables, respectively. But the list of simple multivariate distributions is not long, and they only apply in cases where the marginals are all in the same family (or even the exact same distributions). This can be a real limitation in many situations.

A More General Method for Constructing Dependent Bivariate Distributions

Although the above construction that creates a bivariate lognormal is simple, it serves to illustrate a method which is more generally applicable. First, we generate pairs of values from a bivariate normal distribution. There is statistical dependence between these two variables, and each has a normal marginal distribution. Next, a transformation (the exponential function) is applied separately to each

variable, changing the marginal distributions into lognormals. The transformed variables still have a statistical dependence.

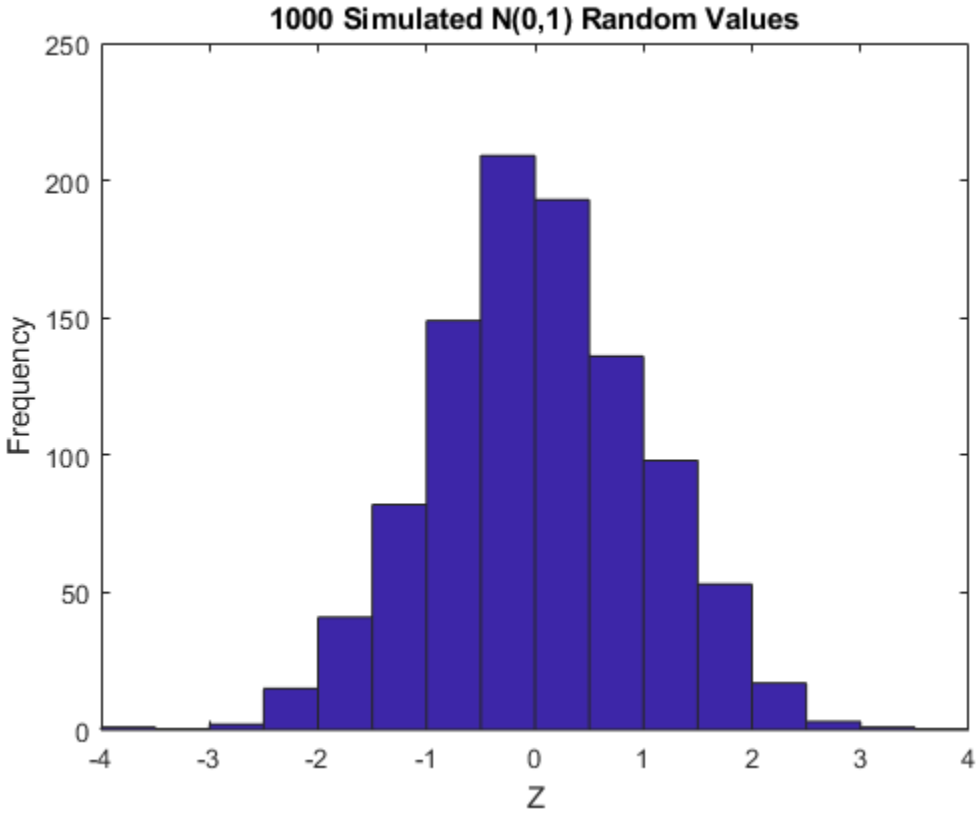
If a suitable transformation could be found, this method could be generalized to create dependent bivariate random vectors with other marginal distributions. In fact, a general method of constructing such a transformation does exist, although not as simple as just exponentiation.

By definition, applying the normal CDF (denoted here by PHI) to a standard normal random variable results in a r.v. that is uniform on the interval [0, 1]. To see this, if Z has a standard normal distribution, then the CDF of U = PHI(Z) is

```
  Pr{U <= u0} = Pr{PHI(Z) <= u0} = Pr{Z <= PHI^(-1)(u0)} = u0,
```

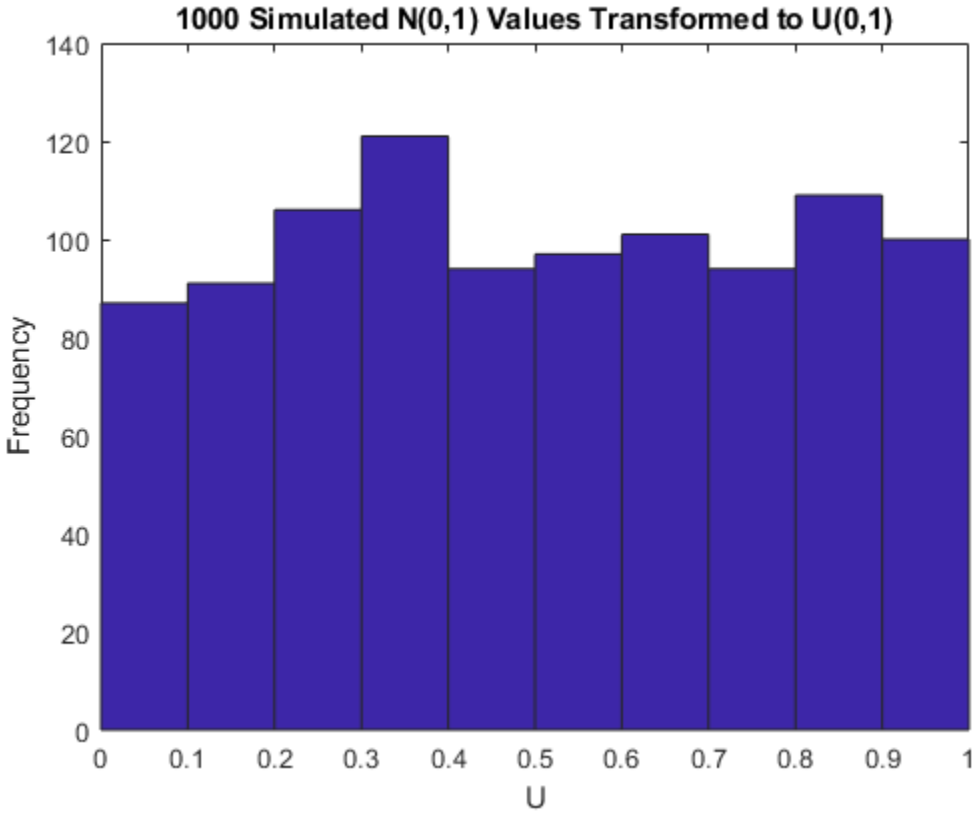
and that is the CDF of a U(0,1) r.v. Histograms of some simulated normal and transformed values demonstrate that fact.

```
n = 1000;
z = normrnd(0,1,n,1);
hist(z,-3.75:.5:3.75);
xlim([-4 4]);
title('1000 Simulated N(0,1) Random Values');
xlabel('Z');
ylabel('Frequency');
```



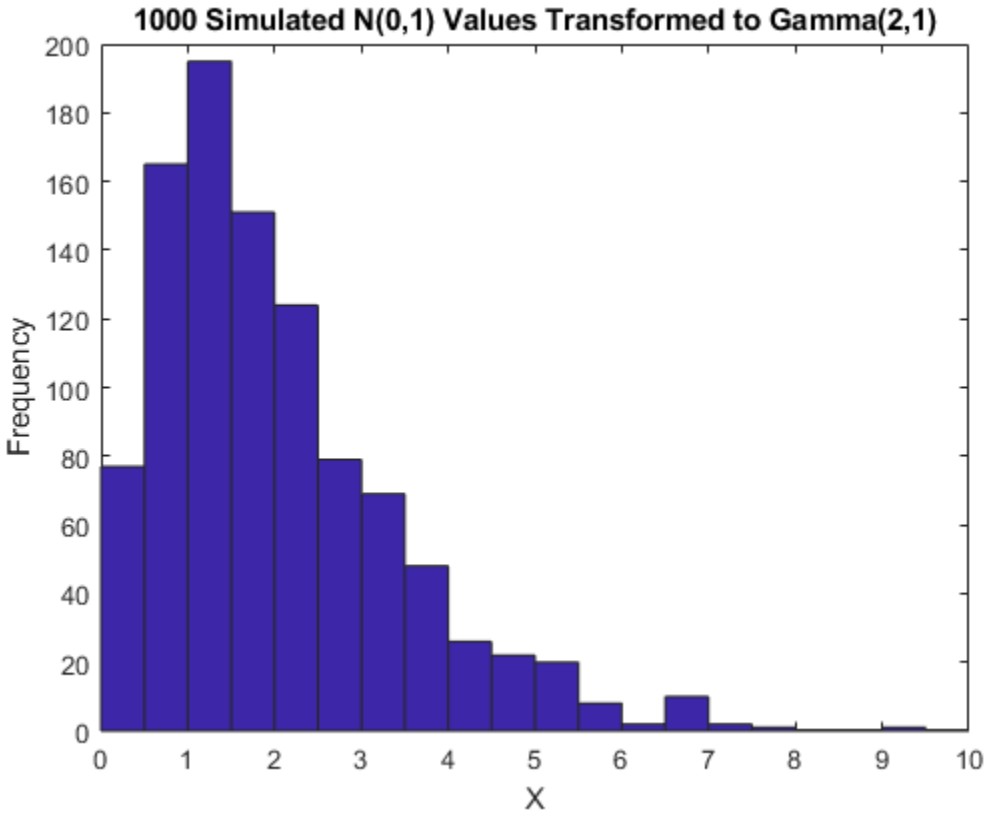
```
u = normcdf(z);
hist(u,.05:.1:.95);
title('1000 Simulated N(0,1) Values Transformed to U(0,1)');
```

```
xlabel('U');
ylabel('Frequency');
```



Now, borrowing from the theory of univariate random number generation, applying the inverse CDF of any distribution F to a U(0,1) random variable results in a r.v. whose distribution is exactly F. This is known as the Inversion Method. The proof is essentially the opposite of the above proof for the forward case. Another histogram illustrates the transformation to a gamma distribution.

```
x = gaminv(u,2,1);
hist(x,.25:.5:9.75);
title('1000 Simulated N(0,1) Values Transformed to Gamma(2,1)');
xlabel('X');
ylabel('Frequency');
```



This two-step transformation can be applied to each variable of a standard bivariate normal, creating dependent r.v.'s with arbitrary marginal distributions. Because the transformation works on each component separately, the two resulting r.v.'s need not even have the same marginal distributions. The transformation is defined as

```
Z = [Z1 Z2] ~ N([0 0],[1 rho; rho 1])
U = [PHI(Z1) PHI(Z2)]
X = [G1(U1) G2(U2)]
```

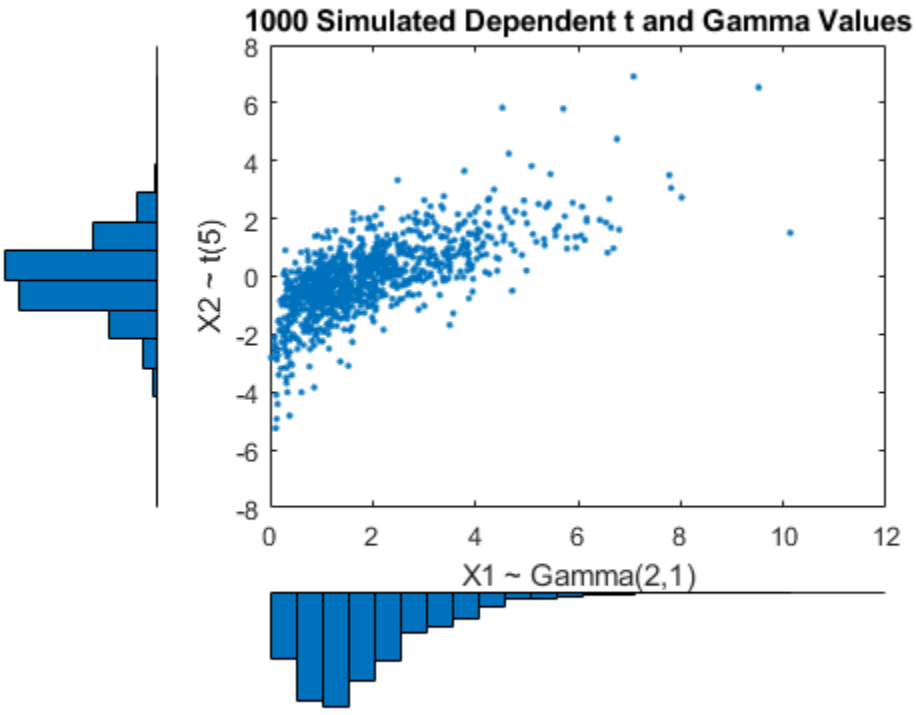
where G1 and G2 are inverse CDFs of two possibly different distributions. For example, we can generate random vectors from a bivariate distribution with t(5) and Gamma(2,1) marginals.

```
n = 1000;
rho = .7;
Z = mvnrnd([0 0], [1 rho; rho 1], n);
U = normcdf(Z);
X = [gaminv(U(:,1),2,1) tinv(U(:,2),5)];
```

This plot has histograms alongside a scatter plot to show both the marginal distributions, and the dependence.

```
[n1,ctr1] = hist(X(:,1),20);
[n2,ctr2] = hist(X(:,2),20);
subplot(2,2,2);
plot(X(:,1),X(:,2),'.');
axis([0 12 -8 8]);
h1 = gca;
```

```
title('1000 Simulated Dependent t and Gamma Values');
xlabel('X1 ~ Gamma(2,1)');
ylabel('X2 ~ t(5)');
subplot(2,2,4);
bar(ctr1,-n1,1);
axis([0 12 -max(n1)*1.1 0]);
axis('off');
h2 = gca;
subplot(2,2,1);
barh(ctr2,-n2,1);
axis([-max(n2)*1.1 0 -8 8]);
axis('off');
h3 = gca;
h1.Position = [0.35 0.35 0.55 0.55];
h2.Position = [.35 .1 .55 .15];
h3.Position = [.1 .35 .15 .55];
colormap([.8 .8 1]);
```



Rank Correlation Coefficients

Dependence between X1 and X2 in this construction is determined by the correlation parameter, rho, of the underlying bivariate normal. However, it is *not* true that the linear correlation of X1 and X2 is rho. For example, in the original lognormal case, there is a closed form for that correlation:

```
cor(X1,X2) = (exp(rho.*sigma.^2) - 1) ./ (exp(sigma.^2) - 1)
```

which is strictly less than rho unless rho is exactly one. In more general cases, though, such as the Gamma/t construction above, the linear correlation between X1 and X2 is difficult or impossible to express in terms of rho, but simulations can be used to show that the same effect happens.

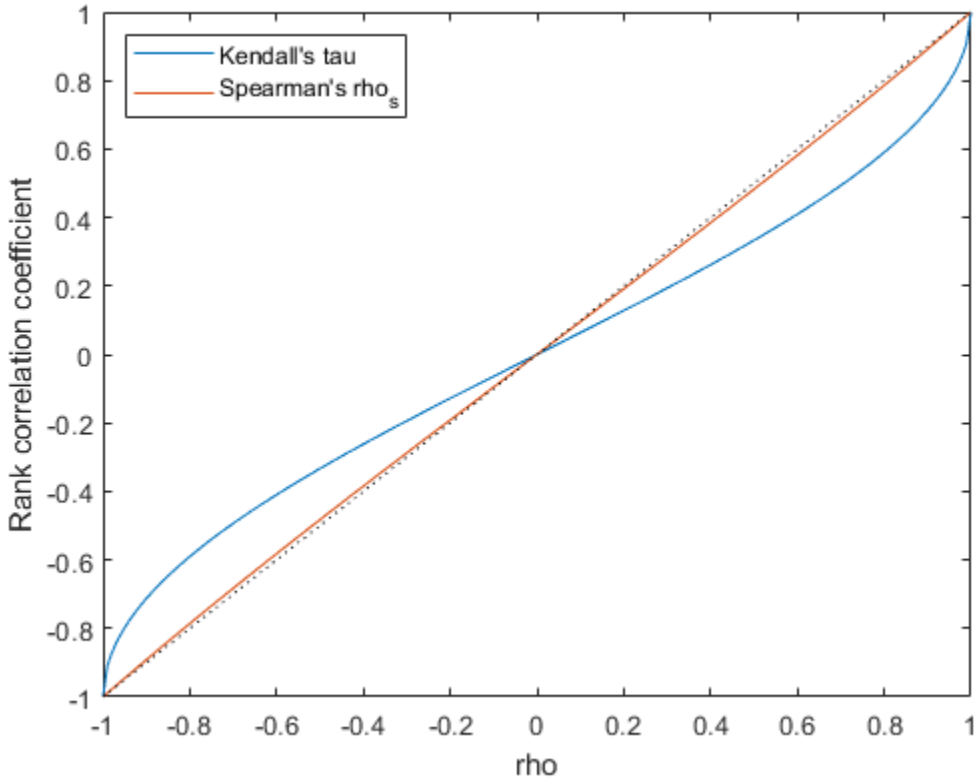
That's because the linear correlation coefficient expresses the *linear* dependence between r.v.'s, and when nonlinear transformations are applied to those r.v.'s, linear correlation is not preserved. Instead, a rank correlation coefficient, such as Kendall's tau or Spearman's rho, is more appropriate.

Roughly speaking, these rank correlations measure the degree to which large or small values of one r.v. associate with large or small values of another. However, unlike the linear correlation coefficient, they measure the association only in terms of ranks. As a consequence, the rank correlation is preserved under any monotonic transformation. In particular, the transformation method just described preserves the rank correlation. Therefore, knowing the rank correlation of the bivariate normal Z exactly determines the rank correlation of the final transformed r.v.'s X. While rho is still needed to parameterize the underlying bivariate normal, Kendall's tau or Spearman's rho are more useful in describing the dependence between r.v.'s, because they are invariant to the choice of marginal distribution.

It turns out that for the bivariate normal, there is a simple 1-1 mapping between Kendall's tau or Spearman's rho, and the linear correlation coefficient rho:

```
  tau   = (2/pi)*arcsin(rho)     or   rho = sin(tau*pi/2)
  rho_s = (6/pi)*arcsin(rho/2)   or   rho = 2*sin(rho_s*pi/6)

subplot(1,1,1);
rho = -1:.01:1;
tau = 2.*asin(rho)./pi;
rho_s = 6.*asin(rho./2)./pi;
plot(rho,tau,'-', rho,rho_s,'-', [-1 1],[-1 1],'k:');
axis([-1 1 -1 1]);
xlabel('rho');
ylabel('Rank correlation coefficient');
legend('Kendall''s tau', 'Spearman''s rho_s', 'location','northwest');
```



Thus, it's easy to create the desired rank correlation between X1 and X2, regardless of their marginal distributions, by choosing the correct rho parameter value for the linear correlation between Z1 and Z2.

Notice that for the multivariate normal distribution, Spearman's rank correlation is almost identical to the linear correlation. However, this is not true once we transform to the final random variables.

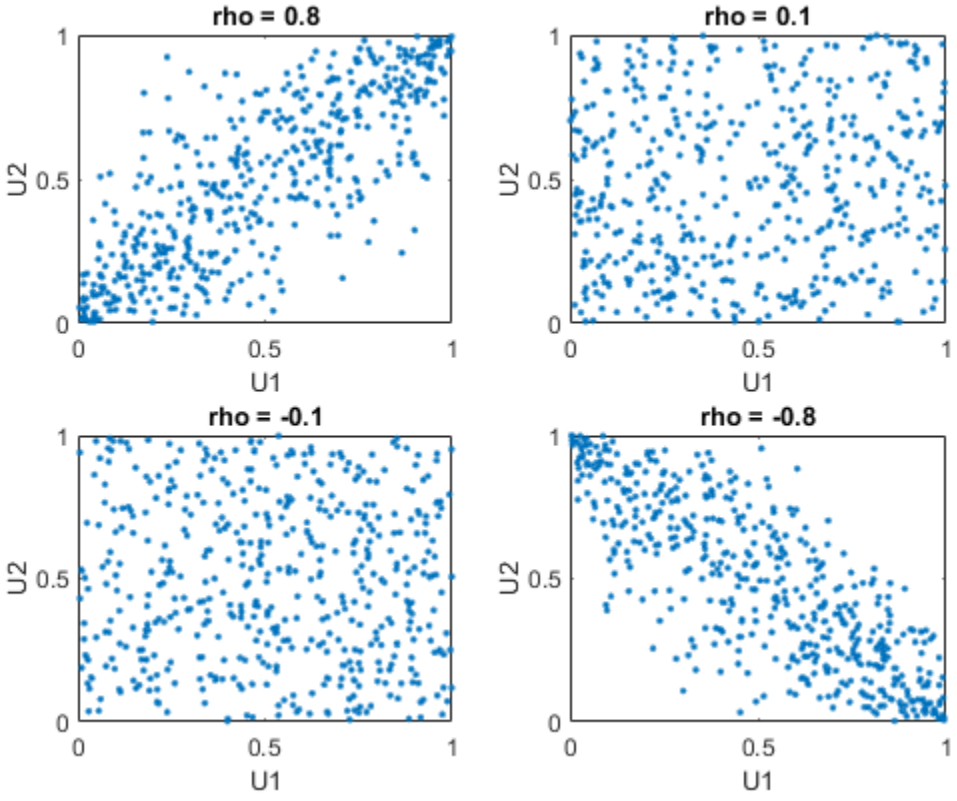
Copulas

The first step of the construction described above defines what is known as a copula, specifically, a Gaussian copula. A bivariate copula is simply a probability distribution on two random variables, each of whose marginal distributions is uniform. These two variables may be completely independent, deterministically related (e.g., U2 = U1), or anything in between. The family of bivariate Gaussian copulas is parameterized by Rho = [1 rho; rho 1], the linear correlation matrix. U1 and U2 approach linear dependence as rho approaches +/- 1, and approach complete independence as rho approaches zero.

Scatter plots of some simulated random values for various levels of rho illustrate the range of different possibilities for Gaussian copulas:

```
n = 500;
Z = mvnrnd([0 0], [1 .8; .8 1], n);
U = normcdf(Z,0,1);
subplot(2,2,1);
plot(U(:,1),U(:,2),'.');
title('rho = 0.8');
```

```
xlabel('U1');
ylabel('U2');
Z = mvnrnd([0 0], [1 .1; .1 1], n);
U = normcdf(Z,0,1);
subplot(2,2,2);
plot(U(:,1),U(:,2),'.');
title('rho = 0.1');
xlabel('U1');
ylabel('U2');
Z = mvnrnd([0 0], [1 -.1; -.1 1], n);
U = normcdf(Z,0,1);
subplot(2,2,3);
plot(U(:,1),U(:,2),'.');
title('rho = -0.1');
xlabel('U1');
ylabel('U2');
Z = mvnrnd([0 0], [1 -.8; -.8 1], n);
U = normcdf(Z,0,1);
subplot(2,2,4);
plot(U(:,1),U(:,2),'.');
title('rho = -0.8');
xlabel('U1');
ylabel('U2');
```



The dependence between U1 and U2 is completely separate from the marginal distributions of X1 = G(U1) and X2 = G(U2). X1 and X2 can be given *any* marginal distributions, and still have the same

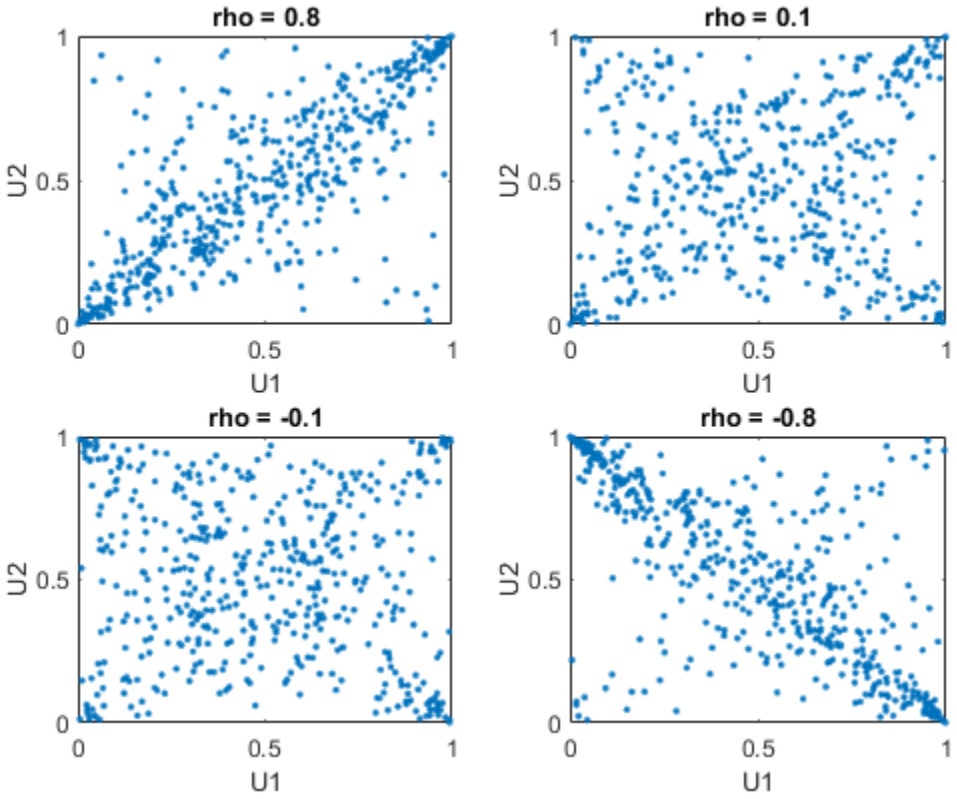
rank correlation. This is one of the main appeals of copulas -- they allow this separate specification of dependence and marginal distribution.

t Copulas

A different family of copulas can be constructed by starting from a bivariate t distribution, and transforming using the corresponding t CDF. The bivariate t distribution is parameterized with Rho, the linear correlation matrix, and nu, the degrees of freedom. Thus, for example, we can speak of a t(1) or a t(5) copula, based on the multivariate t with one and five degrees of freedom, respectively.

Scatter plots of some simulated random values for various levels of rho illustrate the range of different possibilities for t(1) copulas:

```
n = 500;
nu = 1;
T = mvtrnd([1 .8; .8 1], nu, n);
U = tcdf(T,nu);
subplot(2,2,1);
plot(U(:,1),U(:,2),'.');
title('rho = 0.8');
xlabel('U1');
ylabel('U2');
T = mvtrnd([1 .1; .1 1], nu, n);
U = tcdf(T,nu);
subplot(2,2,2);
plot(U(:,1),U(:,2),'.');
title('rho = 0.1');
xlabel('U1');
ylabel('U2');
T = mvtrnd([1 -.1; -.1 1], nu, n);
U = tcdf(T,nu);
subplot(2,2,3);
plot(U(:,1),U(:,2),'.');
title('rho = -0.1');
xlabel('U1');
ylabel('U2');
T = mvtrnd([1 -.8; -.8 1], nu, n);
U = tcdf(T,nu);
subplot(2,2,4);
plot(U(:,1),U(:,2),'.');
title('rho = -0.8');
xlabel('U1');
ylabel('U2');
```



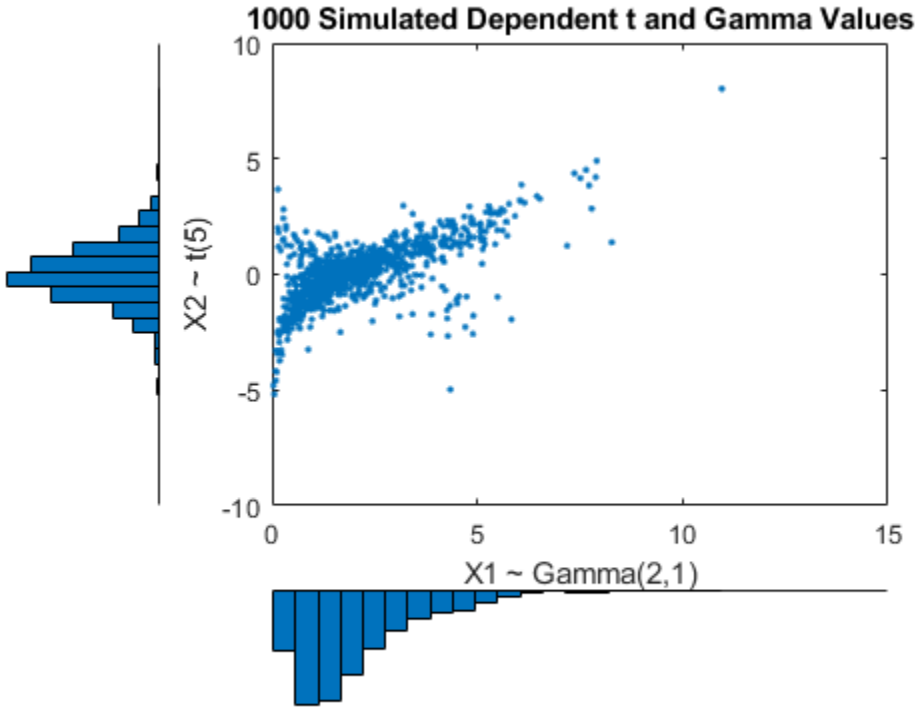
A t copula has uniform marginal distributions for U1 and U2, just as a Gaussian copula does. The rank correlation tau or rho_s between components in a t copula is also the same function of rho as for a Gaussian. However, as these plots demonstrate, a t(1) copula differs quite a bit from a Gaussian copula, even when their components have the same rank correlation. The difference is in their dependence structure. Not surprisingly, as the degrees of freedom parameter nu is made larger, a t(nu) copula approaches the corresponding Gaussian copula.

As with a Gaussian copula, any marginal distributions can be imposed over a t copula. For example, using a t copula with 1 degree of freedom, we can again generate random vectors from a bivariate distribution with Gam(2,1) and t(5) marginals:

```
subplot(1,1,1);
n = 1000;
rho = .7;
nu = 1;
T = mvtrnd([1 rho; rho 1], nu, n);
U = tcdf(T,nu);
X = [gaminv(U(:,1),2,1) tinv(U(:,2),5)];

[n1,ctr1] = hist(X(:,1),20);
[n2,ctr2] = hist(X(:,2),20);
subplot(2,2,2);
plot(X(:,1),X(:,2),'.');
axis([0 15 -10 10]);
h1 = gca;
title('1000 Simulated Dependent t and Gamma Values');
xlabel('X1 ~ Gamma(2,1)');
```

```
ylabel('X2 ~ t(5)');
subplot(2,2,4);
bar(ctr1,-n1,1);
axis([0 15 -max(n1)*1.1 0]);
axis('off');
h2 = gca;
subplot(2,2,1);
barh(ctr2,-n2,1);
axis([-max(n2)*1.1 0 -10 10]);
axis('off');
h3 = gca;
h1.Position = [0.35 0.35 0.55 0.55];
h2.Position = [.35 .1 .55 .15];
h3.Position = [.1 .35 .15 .55];
colormap([.8 .8 1]);
```

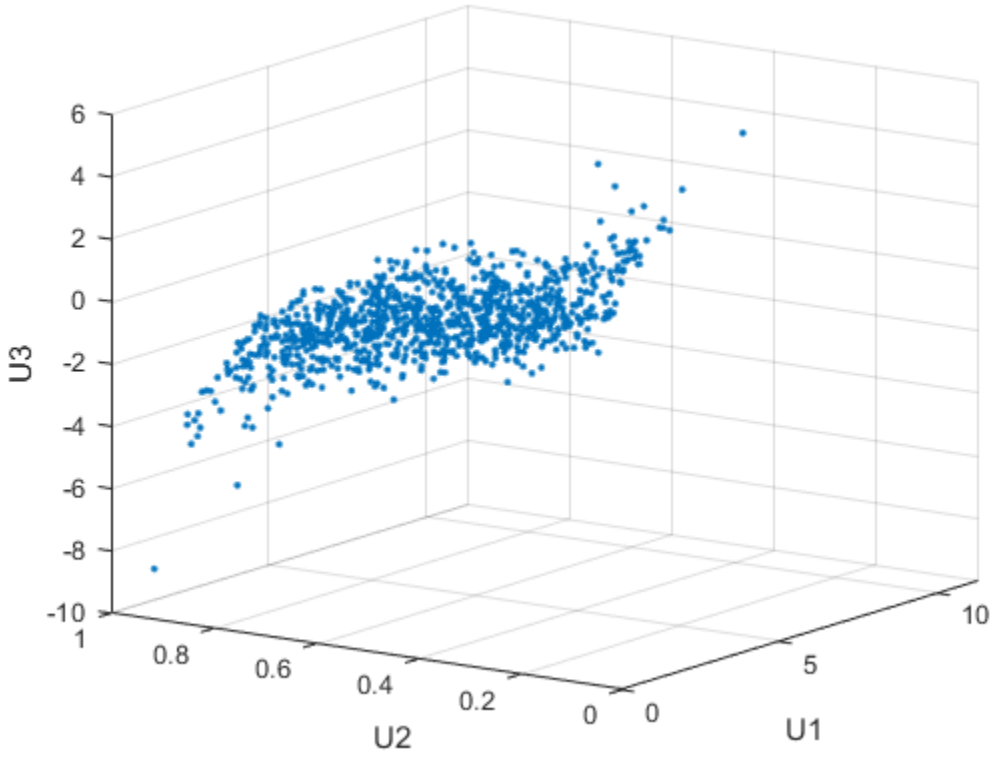


Compared to the bivariate Gamma/t distribution constructed earlier, which was based on a Gaussian copula, the distribution constructed here, based on a t(1) copula, has the same marginal distributions and the same rank correlation between variables, but a very different dependence structure. This illustrates the fact that multivariate distributions are not uniquely defined by their marginal distributions, or by their correlations. The choice of a particular copula in an application may be based on actual observed data, or different copulas may be used as a way of determining the sensitivity of simulation results to the input distribution.

Higher-Order Copulas

The Gaussian and t copulas are known as elliptical copulas. It's easy to generalize elliptical copulas to a higher number of dimensions. For example, we can simulate data from a trivariate distribution with Gamma(2,1), Beta(2,2), and t(5) marginals using a Gaussian copula as follows.

```
subplot(1,1,1);
n = 1000;
Rho = [1 .4 .2; .4 1 -.8; .2 -.8 1];
Z = mvnrnd([0 0 0], Rho, n);
U = normcdf(Z,0,1);
X = [gaminv(U(:,1),2,1) betainv(U(:,2),2,2) tinv(U(:,3),5)];
plot3(X(:,1),X(:,2),X(:,3),'.');
grid on;
view([-55, 15]);
xlabel('U1');
ylabel('U2');
zlabel('U3');
```



Notice that the relationship between the linear correlation parameter rho and, for example, Kendall's tau, holds for each entry in the correlation matrix Rho used here. We can verify that the sample rank correlations of the data are approximately equal to the theoretical values.

```
tauTheoretical = 2.*asin(Rho)./pi
```

```
tauTheoretical =
```

```
    1.0000    0.2620    0.1282
    0.2620    1.0000   -0.5903
    0.1282   -0.5903    1.0000
```

```
tauSample = corr(X, 'type','Kendall')
```

```
tauSample =

    1.0000    0.2655    0.1060
    0.2655    1.0000   -0.6076
    0.1060   -0.6076    1.0000
```

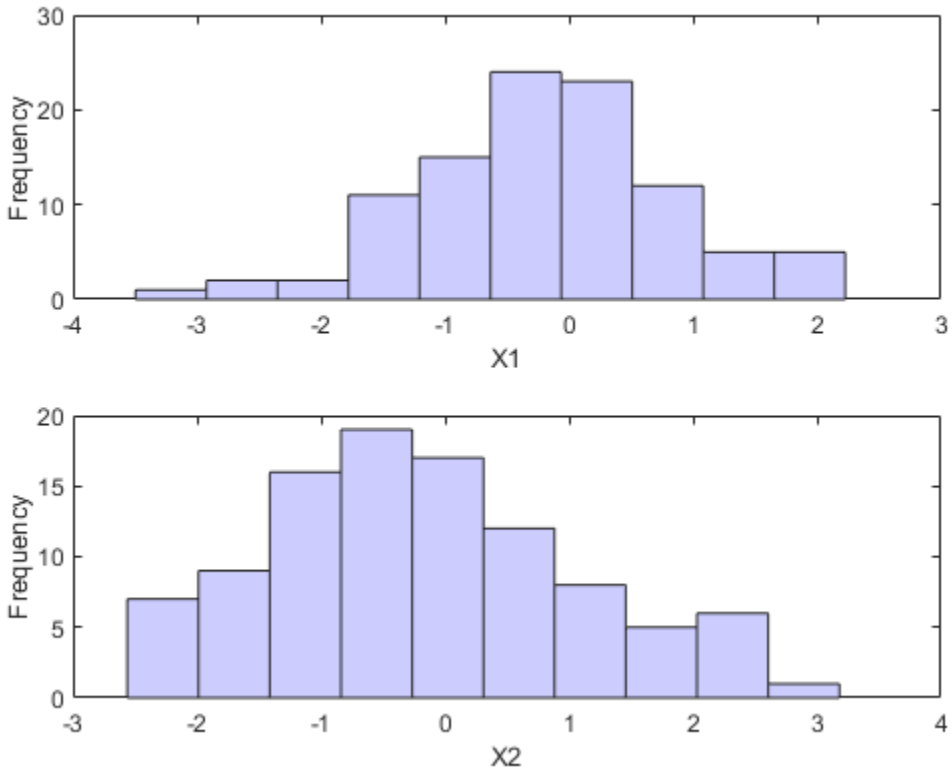
Copulas and Empirical Marginal Distributions

To simulate dependent multivariate data using a copula, we have seen that we need to specify

```
  1) the copula family (and any shape parameters),
  2) the rank correlations among variables, and
  3) the marginal distributions for each variable
```

Suppose we have two sets of stock return data, and we would like to run a Monte Carlo simulation with inputs that follow the same distributions as our data.

```
load stockreturns
nobs = size(stocks,1);
subplot(2,1,1);
hist(stocks(:,1),10);
xlabel('X1');
ylabel('Frequency');
subplot(2,1,2);
hist(stocks(:,2),10);
xlabel('X2');
ylabel('Frequency');
```

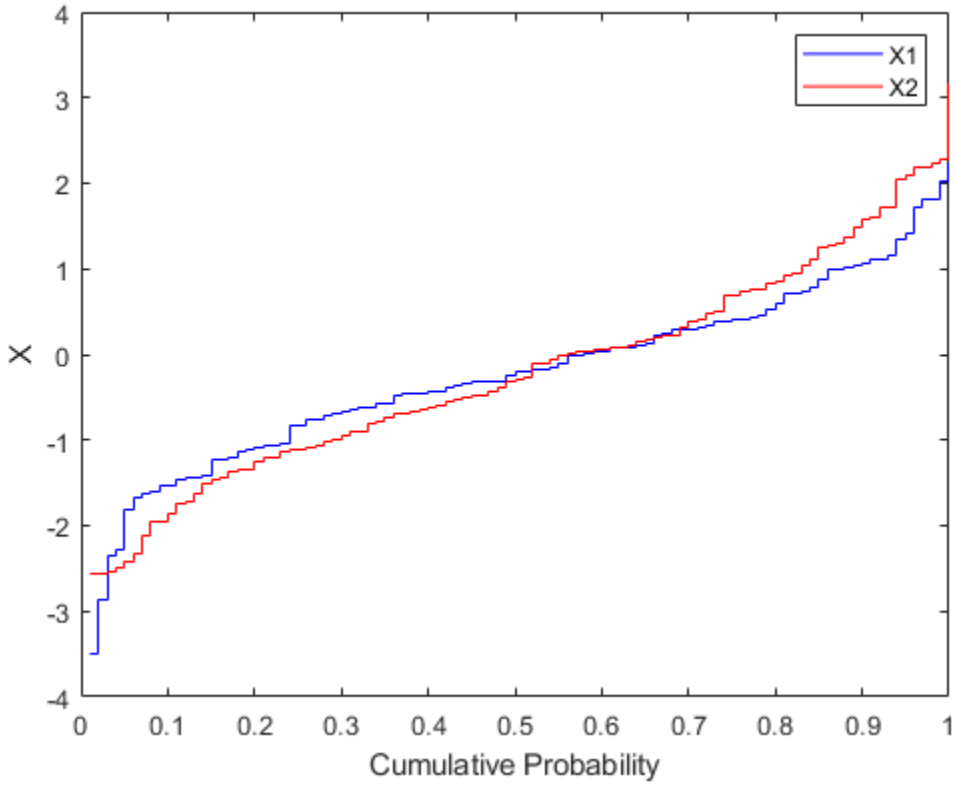


(These two data vectors have the same length, but that is not crucial.)

We could fit a parametric model separately to each dataset, and use those estimates as our marginal distributions. However, a parametric model may not be sufficiently flexible. Instead, we can use an empirical model for the marginal distributions. We only need a way to compute the inverse CDF.

The empirical inverse CDF for these datasets is just a stair function, with steps at the values 1/nobs, 2/nobs, ... 1. The step heights are simply the sorted data.

```
invCDF1 = sort(stocks(:,1));
n1 = length(stocks(:,1));
invCDF2 = sort(stocks(:,2));
n2 = length(stocks(:,2));
subplot(1,1,1);
stairs((1:nobs)/nobs, invCDF1,'b');
hold on;
stairs((1:nobs)/nobs, invCDF2,'r');
hold off;
legend('X1','X2');
xlabel('Cumulative Probability');
ylabel('X');
```

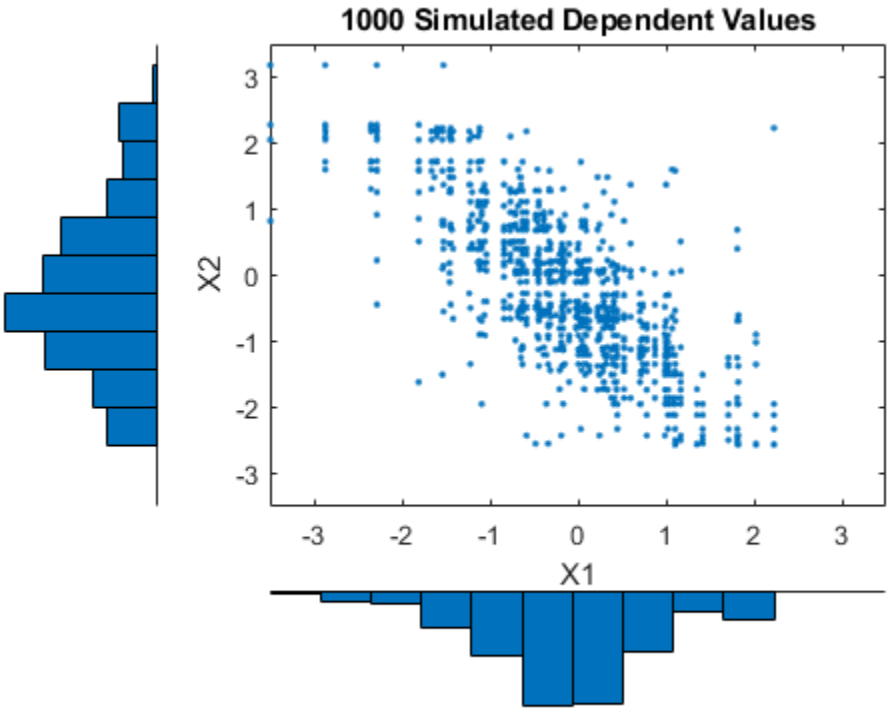


For the simulation, we might want to experiment with different copulas and correlations. Here, we'll use a bivariate t(5) copula with a fairly large negative correlation parameter.

```
n = 1000;
rho = -.8;
nu = 5;
T = mvtrnd([1 rho; rho 1], nu, n);
U = tcdf(T,nu);
X = [invCDF1(ceil(n1*U(:,1))) invCDF2(ceil(n2*U(:,2)))];

[n1,ctr1] = hist(X(:,1),10);
[n2,ctr2] = hist(X(:,2),10);
subplot(2,2,2);
plot(X(:,1),X(:,2),'.');
axis([-3.5 3.5 -3.5 3.5]);
h1 = gca;
title('1000 Simulated Dependent Values');
xlabel('X1');
ylabel('X2');
subplot(2,2,4);
bar(ctr1,-n1,1);
axis([-3.5 3.5 -max(n1)*1.1 0]);
axis('off');
h2 = gca;
subplot(2,2,1);
barh(ctr2,-n2,1);
axis([-max(n2)*1.1 0 -3.5 3.5]);
```

```
axis('off');
h3 = gca;
h1.Position = [0.35 0.35 0.55 0.55];
h2.Position = [.35 .1 .55 .15];
h3.Position = [.1 .35 .15 .55];
colormap([.8 .8 1]);
```



The marginal histograms of the simulated data closely match those of the original data, and would become identical as we simulate more pairs of values. Notice that the values are drawn from the original data, and because there are only 100 observations in each dataset, the simulated data are somewhat "discrete". One way to overcome this would be to add a small amount of random variation, possibly normally distributed, to the final simulated values. This is equivalent to using a smoothed version of the empirical inverse CDF.

Fitting Custom Univariate Distributions

This example shows how to use the Statistics and Machine Learning Toolbox™ function `mle` to fit custom distributions to univariate data.

Using `mle`, you can compute maximum likelihood parameter estimates, and estimate their precision, for many kinds of distributions beyond those for which the Toolbox provides specific fitting functions.

To do this, you need to define the distribution using one or more M functions. In the simplest cases, you can write code to compute the probability density function (PDF) for the distribution that you want to fit, and `mle` will do most of the remaining work for you. This example covers those cases. In problems with censored data, you must also write code to compute the cumulative distribution function (CDF) or the survival function (SF). In some other problems, it may be advantageous to define the log-likelihood function (LLF) itself. The second part of this example, “Fitting Custom Univariate Distributions, Part 2” on page 5-176, covers both of those latter cases.

Fitting Custom Distributions: A Zero-Truncated Poisson Example

Count data are often modelled using a Poisson distribution, and you can use the Statistics and Machine Learning Toolbox function `poissfit` to fit a Poisson model. However, in some situations, counts that are zero do not get recorded in the data, and so fitting a Poisson distribution is not straight-forward because of those "missing zeros". This example will show how to fit a Poisson distribution to zero-truncated data, using the function `mle`.

For this example, we'll use simulated data from a zero-truncated Poisson distribution. First, we generate some random Poisson data.

```
rng(18,'twister');
n = 75;
lambda = 1.75;
x = poissrnd(lambda,n,1);
```

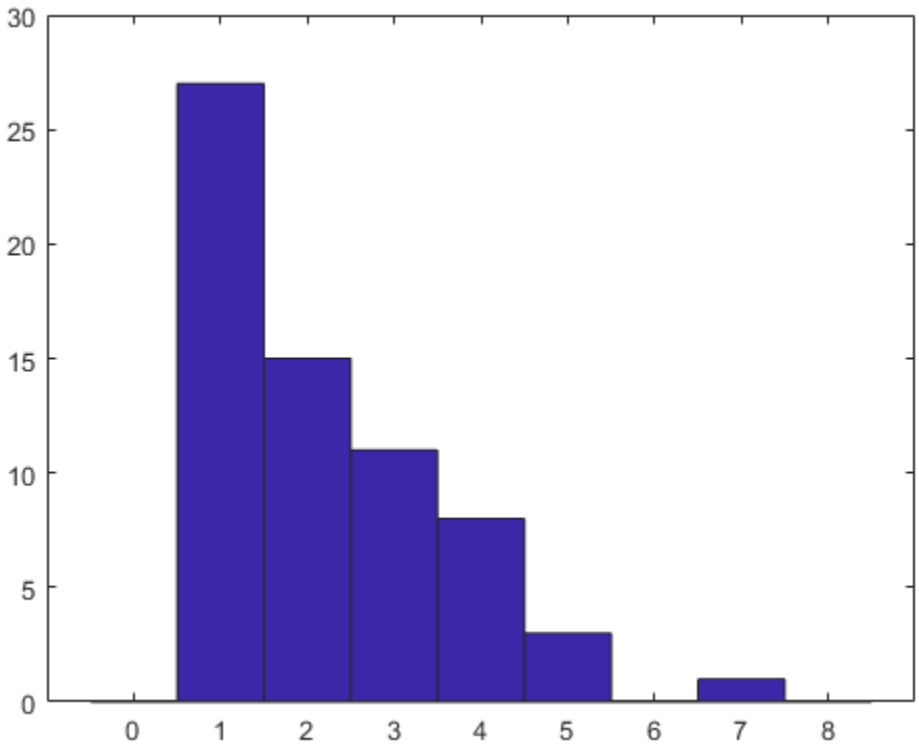
Next, we remove all the zeros from the data to simulate the truncation.

```
x = x(x > 0);
length(x)
```

```
ans = 65
```

Here's a histogram of these simulated data. Notice that the data look reasonably like a Poisson distribution, except that there are no zeros. We will fit them with a distribution that is identical to a Poisson on the positive integers, but that has no probability at zero. In this way, we can estimate the Poisson parameter lambda while accounting for the "missing zeros".

```
hist(x,[0:1:max(x)+1]);
```



The first step is to define the zero-truncated Poisson distribution by its probability function (PF). We will create a function to compute the probability for each point in x, given a value for the Poisson distribution's mean parameter lambda. The PF for a zero-truncated Poisson is just the usual Poisson PF, renormalized so that it sums to one. With zero truncation, the renormalization is just 1-Pr{0}. The easiest way to create a function for the PF is to use an anonymous function.

```
pf_truncpoiss = @(x,lambda) poisspdf(x,lambda) ./ (1-poisscdf(0,lambda));
```

For simplicity, we have assumed that all the x values given to this function will be positive integers, with no checks. Error checking, or a more complicated distribution, would probably take more than a single line of code, suggesting that the function should be defined in a separate file.

The next step is to provide a reasonable rough first guess for the parameter lambda. In this case, we'll just use the sample mean.

```
start = mean(x)
```

```
start = 2.2154
```

We provide `mle` with the data, and with the anonymous function, using the 'pdf' parameter. (The Poisson is discrete, so this is really a probability function, not a PDF.) Because the mean parameter of the Poisson distribution must be positive, we also specify a lower bound for lambda. `mle` returns the maximum likelihood estimate of lambda, and, optionally, approximate 95% confidence intervals for the parameters.

```
[lambdaHat,lambdaCI] = mle(x, 'pdf',pf_truncpoiss, 'start',start, 'lower',0)
```

```
lambdaHat = 1.8760

lambdaCI = 2×1

    1.4990
    2.2530
```

Notice that the parameter estimate is smaller than the sample mean. That's just as it should be, because the maximum likelihood estimate accounts for the missing zeros not present in the data.

We can also compute a standard error estimate for lambda, using the large-sample variance approximation returned by `mlecov`.

```
avar = mlecov(lambdaHat, x, 'pdf',pf_truncpoiss);
stderr = sqrt(avar)

stderr = 0.1923
```

Supplying Additional Values to the Distribution Function: A Truncated Normal Example

It sometimes also happens that continuous data are truncated. For example, observations larger than some fixed value might not be recorded because of limitations in the way the data are collected. This example will show how to fit a normal distribution to truncated data, using the function `mle`.

For this example, we simulate data from a truncated normal distribution. First, we generate some random normal data.

```
n = 75;
mu = 1;
sigma = 3;
x = normrnd(mu,sigma,n,1);
```

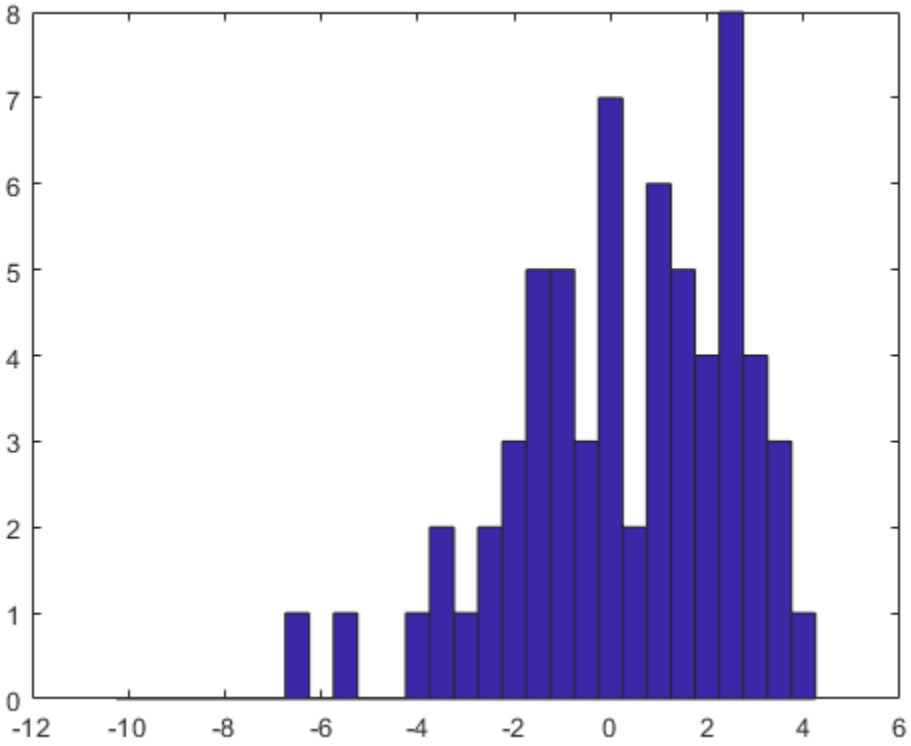
Next, we remove any observations that fall beyond the truncation point, xTrunc. Throughout this example, we'll assume that xTrunc is known, and does not need to be estimated.

```
xTrunc = 4;
x = x(x < xTrunc);
length(x)

ans = 64
```

Here's a histogram of these simulated data. We will fit them with a distribution that is identical to a normal for x < xTrunc, but that has zero probability above xTrunc. In this way, we can estimate the normal parameters mu and sigma while accounting for the "missing tail".

```
hist(x,(-10:.5:4));
```



As in the previous example, we will define the truncated normal distribution by its PDF, and create a function to compute the probability density for each point in x, given values for the parameters mu and sigma. With the truncation point fixed and known, the PDF for a truncated normal is just the usual normal PDF, truncated, and then renormalized so that it integrates to one. The renormalization is just the CDF evaluated at xTrunc. For simplicity, we'll assume that all x values are less than xTrunc, without checking. We'll use an anonymous function to define the PDF.

```
pdf_truncnorm = @(x,mu,sigma) normpdf(x,mu,sigma) ./ normcdf(xTrunc,mu,sigma);
```

The truncation point, xTrunc, is not being estimated, and so it is not among the distribution parameters in the PDF function's input argument list. xTrunc is also not part of the data vector input argument. With an anonymous function, we can simply refer to the variable xTrunc that has already been defined in the workspace, and there is no need to worry about passing it in as an additional argument.

We also need to provide a rough starting guess for the parameter estimates. In this case, because the truncation is not too extreme, the sample mean and standard deviation will probably work well.

```
start = [mean(x),std(x)]
```

```
start = 1×2

    0.2735    2.2660
```

We provide `mle` with the data, and with the anonymous function, using the 'pdf' parameter. Because sigma must be positive, we also specify lower parameter bounds. `mle` returns the maximum likelihood

estimates of mu and sigma as a single vector, as well as a matrix of approximate 95% confidence intervals for the two parameters.

```
[paramEsts,paramCIs] = mle(x, 'pdf',pdf_truncnorm, 'start',start, 'lower',[-Inf 0])
```

```
paramEsts = 1×2

    0.9911    2.7800

paramCIs = 2×2

   -0.1605    1.9680
    2.1427    3.5921
```

Notice that the estimates of mu and sigma are quite a bit larger than the sample mean and standard deviation. This is because the model fit has accounted for the "missing" upper tail of the distribution.

We can compute an approximate covariance matrix for the parameter estimates using `mlecov`. The approximation is usually reasonable in large samples, and the standard errors of the estimates can be approximated by the square roots of the diagonal elements.

```
acov = mlecov(paramEsts, x, 'pdf',pdf_truncnorm)
```

```
acov = 2×2

    0.3452    0.1660
    0.1660    0.1717

stderr = sqrt(diag(acov))
```

```
stderr = 2×1

    0.5876
    0.4143
```

Fitting a More Complicated Distribution: A Mixture of Two Normals

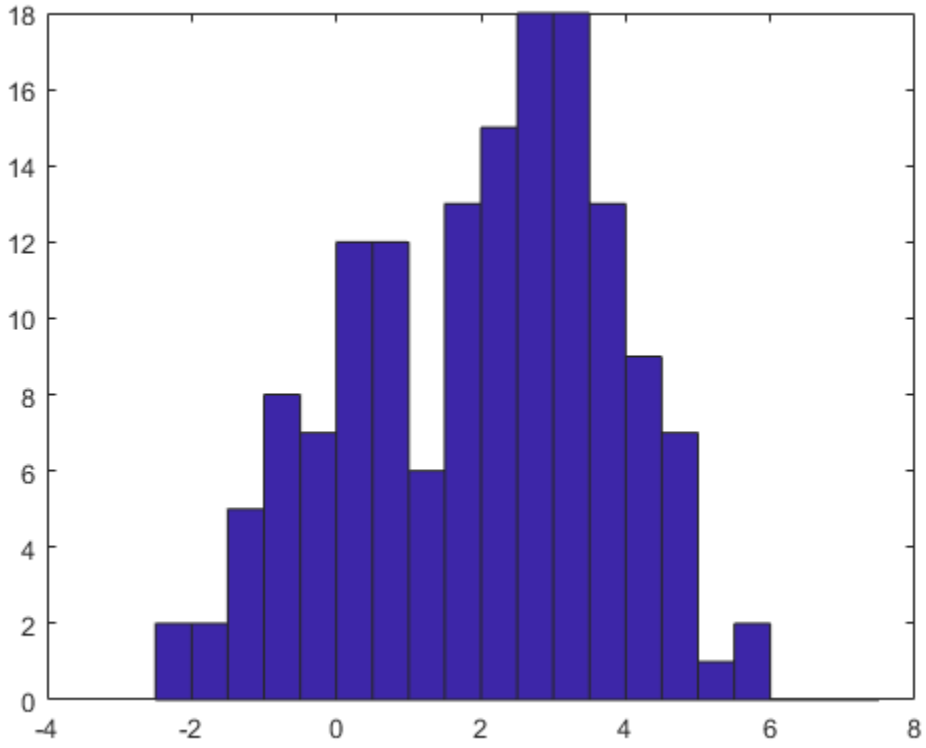
Some datasets exhibit bimodality, or even multimodality, and fitting a standard distribution to such data is usually not appropriate. However, a mixture of simple unimodal distributions can often model such data very well. In fact, it may even be possible to give an interpretation to the source of each component in the mixture, based on application-specific knowledge.

In this example, we will fit a mixture of two normal distributions to some simulated data. This mixture might be described with the following constructive definition for generating a random value:

```
First, flip a biased coin.  If it lands heads, pick a value at random
from a normal distribution with mean mu_1 and standard deviation
sigma_1. If the coin lands tails, pick a value at random from a normal
distribution with mean mu_2 and standard deviation sigma_2.
```

For this example, we'll generate data from a mixture of Student's t distributions rather than using the same model as we are fitting. This is the sort of thing you might do in a Monte-Carlo simulation to test how robust a fitting method is to departures from the assumptions of the model being fit. Here, however, we'll fit just one simulated data set.

```
x = [trnd(20,1,50) trnd(4,1,100)+3];
hist(x,-2.25:.5:7.25);
```



As in the previous examples, we'll define the model to fit by creating a function that computes the probability density. The PDF for a mixture of two normals is just a weighted sum of the PDFs of the two normal components, weighted by the mixture probability. This PDF is simple enough to create using an anonymous function. The function takes six inputs: a vector of data at which to evaluate the PDF, and the distribution's five parameters. Each component has parameters for its mean and standard deviation; the mixture probability makes a total of five.

```
pdf_normmixture = @(x,p,mu1,mu2,sigma1,sigma2) ...
                        p*normpdf(x,mu1,sigma1) + (1-p)*normpdf(x,mu2,sigma2);
```

We'll also need an initial guess for the parameters. The more parameters a model has, the more a reasonable starting point matters. For this example, we'll start with an equal mixture (p = 0.5) of normals, centered at the two quartiles of the data, with equal standard deviations. The starting value for standard deviation comes from the formula for the variance of a mixture in terms of the mean and variance of each component.

```
pStart = .5;
muStart = quantile(x,[.25 .75])
```

```
muStart = 1×2

    0.5970    3.2456
```

```
sigmaStart = sqrt(var(x) - .25*diff(muStart).^2)
```

```
sigmaStart = 1.2153

start = [pStart muStart sigmaStart sigmaStart];
```

Finally, we need to specify bounds of zero and one for the mixing probability, and lower bounds of zero for the standard deviations. The remaining elements of the bounds vectors are set to +Inf or -Inf, to indicate no restrictions.

```
lb = [0 -Inf -Inf 0 0];
ub = [1 Inf Inf Inf Inf];
paramEsts = mle(x, 'pdf',pdf_normmixture, 'start',start, ...
                           'lower',lb, 'upper',ub)

Warning: Maximum likelihood estimation did not converge.  Iteration limit exceeded.

paramEsts = 1×5

    0.3523    0.0257    3.0489    1.0546    1.0629
```

The default for custom distributions is 200 iterations.

```
statset('mlecustom')

ans = struct with fields:
          Display: 'off'
      MaxFunEvals: 400
          MaxIter: 200
           TolBnd: 1.0000e-06
           TolFun: 1.0000e-06
        TolTypeFun: []
             TolX: 1.0000e-06
         TolTypeX: []
          GradObj: 'off'
         Jacobian: []
        DerivStep: 6.0555e-06
      FunValCheck: 'on'
           Robust: []
     RobustWgtFun: []
           WgtFun: []
             Tune: []
      UseParallel: []
    UseSubstreams: []
          Streams: {}
        OutputFcn: []
```

Override that default, using an options structure created with the `statset` function. Also increase the function evaluation limit.

```
options = statset('MaxIter',300, 'MaxFunEvals',600);
paramEsts = mle(x, 'pdf',pdf_normmixture, 'start',start, ...
                           'lower',lb, 'upper',ub, 'options',options)

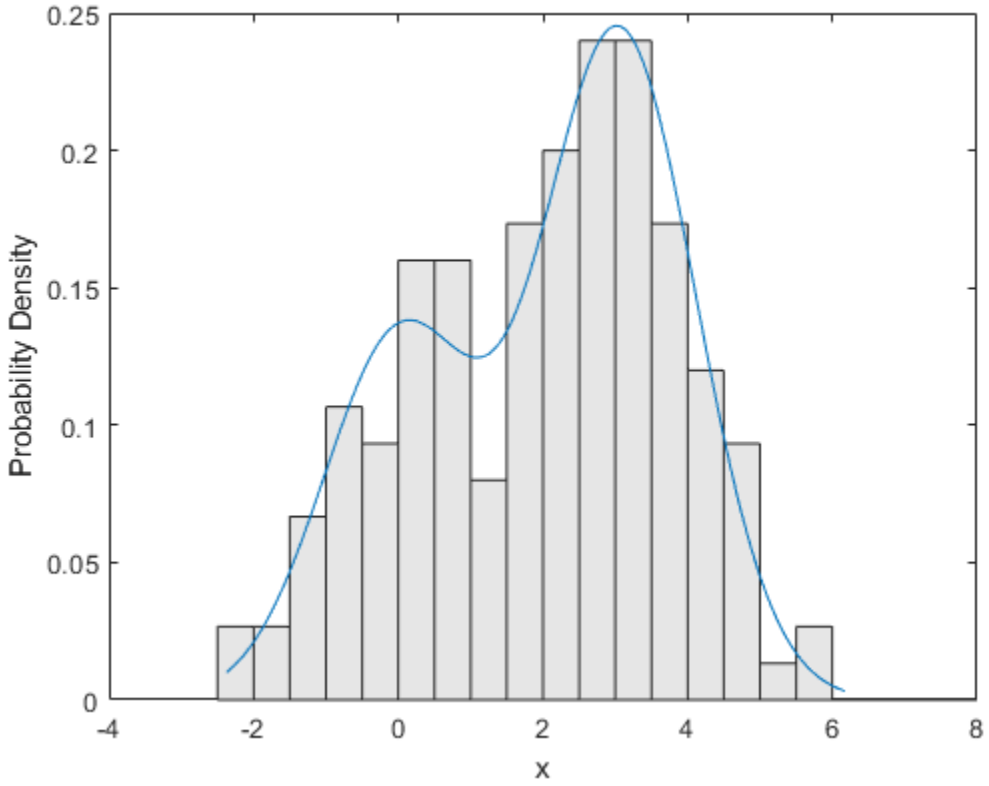
paramEsts = 1×5

    0.3523    0.0257    3.0489    1.0546    1.0629
```

It appears that the final iterations to convergence mattered only in the last few digits of the result. Nonetheless, it is always a good idea to make sure that convergence has been reached.

Finally, we can plot the fitted density against a probability histogram of the raw data, to check the fit visually.

```
bins = -2.5:.5:7.5;
h = bar(bins,histc(x,bins)/(length(x)*.5),'histc');
h.FaceColor = [.9 .9 .9];
xgrid = linspace(1.1*min(x),1.1*max(x),200);
pdfgrid = pdf_normmixture(xgrid,paramEsts(1),paramEsts(2),paramEsts(3),paramEsts(4),paramEsts(5))
hold on
plot(xgrid,pdfgrid,'-')
hold off
xlabel('x')
ylabel('Probability Density')
```



Using Nested Functions: A Normal Example with Unequal Precisions

It sometimes happens when data are collected that each observation was made with a different precision or reliability. For example, if several experimenters each make a number of independent measurements of the same quantity, but each reports only the average of their measurements, the reliability of each reported data point will depend on the number of raw observations that went into it. If the original raw data are not available, an estimate of their distribution must account for the fact that the data that are available, the averages, each have different variances. This model actually has an explicit solution for maximum likelihood parameter estimates. However, for the purposes of illustration, we will use `mle` to estimate the parameters.

Assume that we have 10 data points, where each one is actually the average of anywhere from 1 to 8 observations. Those original observations are not available, but we know how many there were for each of our data points. We need to estimate the mean and standard deviation of the raw data.

```
x = [0.25 -1.24 1.38 1.39 -1.43 2.79 3.52 0.92 1.44 1.26];
m = [   8     2    1    3     8    4    2    5    2    4];
```

The variance of each data point is inversely proportional to the number of observations that went into it, so we will use 1/m to weight the variance of each data point in a maximum likelihood fit.

```
w = 1 ./ m
```

```
w = 1×10

    0.1250    0.5000    1.0000    0.3333    0.1250    0.2500    0.5000    0.2000    0.5000    0.2
```

In the model we're fitting here, we could define the distribution by its PDF, but using a log PDF is somewhat more natural, because the normal PDF is of the form

```
  c .* exp(-0.5 .* z.^2),
```

and `mle` would have to take the log of the PDF anyway, to compute the log-likelihood. So instead, we will create a function that computes the log PDF directly.

The log PDF function has to compute the log of the probability density for each point in x, given values for mu and sigma. It will also need to account for the different variance weights. Unlike the previous examples, this distribution function is a little more complicated than a one-liner, and is most clearly written as a separate function in its own file. Because the log PDF function needs the observation counts as additional data, the most straight-forward way to accomplish this fit is to use nested functions.

We've created a separate file for a function called `wgtnormfit.m`. This function contains data initialization, a nested function for the log PDF in the weighted normal model, and a call to the `mle` function to actually fit the model. Because sigma must be positive, we must specify lower parameter bounds. The call to `mle` returns the maximum likelihood estimates of mu and sigma in a single vector.

```
type wgtnormfit.m
```

```
function paramEsts = wgtnormfit
%WGTNORMFIT Fitting example for a weighted normal distribution.

%   Copyright 1984-2012 The MathWorks, Inc.

x = [0.25 -1.24 1.38 1.39 -1.43 2.79 3.52 0.92 1.44 1.26]';
m = [   8     2    1    3     8    4    2    5    2    4]';

    function logy = logpdf_wn(x,mu,sigma)
        v = sigma.^2 ./ m;
        logy = -(x-mu).^2 ./ (2.*v) - .5.*log(2.*pi.*v);
    end

paramEsts = mle(x, 'logpdf',@logpdf_wn, 'start',[mean(x),std(x)], 'lower',[-Inf,0]);

end
```

In `wgtnormfit.m`, we pass `mle` a handle to the nested function `logpdf_wn`, using the 'logpdf' parameter. That nested function refers to the observation counts, m, in the computation of the weighted log PDF. Because the vector m is defined in its parent function, `logpdf_wn` has access to it, and there is no need to worry about passing m in as an explicit input argument.

We need to provide a rough first guess for the parameter estimates. In this case, the unweighted sample mean and standard deviation should be ok, and that's what `wgtnormfit.m` uses.

```
start = [mean(x),std(x)]
```

```
start = 1×2

    1.0280    1.5490
```

To fit the model, we run the fitting function.

```
paramEsts = wgtnormfit
```

```
paramEsts = 1×2

    0.6244    2.8823
```

Notice that the estimate of mu is less than two-thirds that of the sample mean. That's just as it should be: the estimate is be influenced most by the most reliable data points, i.e., the ones that were based on the largest number of raw observations. In this dataset, those points tend to pull the estimate down from the unweighted sample mean.

Using a Parameter Transformation: The Normal Example (continued)

In maximum likelihood estimation, confidence intervals for the parameters are usually computed using a large-sample normal approximation for the distribution of the estimators. This is often a reasonable assumption, but with small sample sizes, it is sometimes advantageous to improve that normal approximation by transforming one or more parameters. In this example, we have a location parameter and a scale parameter. Scale parameters are often transformed to their log, and we will do that here with sigma. First, we'll create a new log PDF function, and then recompute the estimates using that parameterization.

The new log PDF function is created as a nested function within the function `wgtnormfit2.m`. As in the first fit, this file contains data initialization, a nested function for the log PDF in the weighted normal model, and a call to the `mle` function to actually fit the model. Because sigma can be any positive value, log(sigma) is unbounded, and we no longer need to specify lower or upper bounds. Also, the call to `mle` in this case returns both the parameter estimates and confidence intervals.

```
type wgtnormfit2.m
```

```
function [paramEsts,paramCIs] = wgtnormfit2
%WGTNORMFIT2 Fitting example for a weighted normal distribution (log(sigma) parameterization).

%   Copyright 1984-2012 The MathWorks, Inc.

x = [0.25 -1.24 1.38 1.39 -1.43 2.79 3.52 0.92 1.44 1.26]';
m = [   8     2    1    3     8    4    2    5    2    4]';

    function logy = logpdf_wn2(x,mu,logsigma)
```

```
        v = exp(logsigma).^2 ./ m;
        logy = -(x-mu).^2 ./ (2.*v) - .5.*log(2.*pi.*v);
    end

[paramEsts,paramCIs] = mle(x, 'logpdf',@logpdf_wn2, 'start',[mean(x),log(std(x))]);

end
```

Notice that `wgtnormfit2.m` uses the same starting point, transformed to the new parameterization, i.e., the log of the sample standard deviation.

```
start = [mean(x),log(std(x))]
```

```
start = 1×2

    1.0280    0.4376
```

```
[paramEsts,paramCIs] = wgtnormfit2
```

```
paramEsts = 1×2

    0.6244    1.0586

paramCIs = 2×2

   -0.2802    0.6203
    1.5290    1.4969
```

Since the parameterization uses log(sigma), we have to transform back to the original scale to get an estimate and confidence interval for sigma. Notice that the estimates for both mu and sigma are the same as in the first fit, because maximum likelihood estimates are invariant to parameterization.

```
muHat = paramEsts(1)
```

```
muHat = 0.6244
```

```
sigmaHat = exp(paramEsts(2))
```

```
sigmaHat = 2.8823
```

```
muCI = paramCIs(:,1)
```

```
muCI = 2×1

   -0.2802
    1.5290
```

```
sigmaCI = exp(paramCIs(:,2))
```

```
sigmaCI = 2×1

    1.8596
    4.4677
```

Fitting Custom Univariate Distributions, Part 2

This example shows how to use some more advanced techniques with the Statistics and Machine Learning Toolbox™ function `mle` to fit custom distributions to univariate data. The techniques include fitting models to censored data, and illustration of some of the numerical details of fitting with custom distributions.

See “Fitting Custom Univariate Distributions” on page 5-165 for additional examples of fitting custom distributions to univariate data.

Fitting Custom Distributions with Censored Data

The extreme value distribution is often used to model failure times of mechanical parts, and experiments in such cases are sometimes only run for a fixed length of time. If not all of the experimental units have failed within that time, then the data are right-censored, that is, the value of some failure times are not known exactly, but only known to be larger than a certain value.

The Statistics and Machine Learning Toolbox includes the function `evfit`, which fits an extreme value distribution to data, including data with censoring. However, for the purposes of this example, we will ignore `evfit`, and show how to use `mle` and custom distributions to fit a model to censored data, using the extreme value distribution.

Because the values for the censored data are not known exactly, maximum likelihood estimation becomes more difficult. In particular, both the PDF and the CDF are needed to compute the log-likelihood. Therefore, you must provide `mle` with functions for both of those in order to fit censored data. The Statistics and Machine Learning Toolbox includes the functions `evpdf` and `evcdf`, so for this example, the work of writing the code has already been done.

We'll fit the model to simulated data. The first step is to generate some uncensored extreme value data.

```
rng(0,'twister');
n = 50;
mu = 5;
sigma = 2.5;
x = evrnd(mu,sigma,n,1);
```

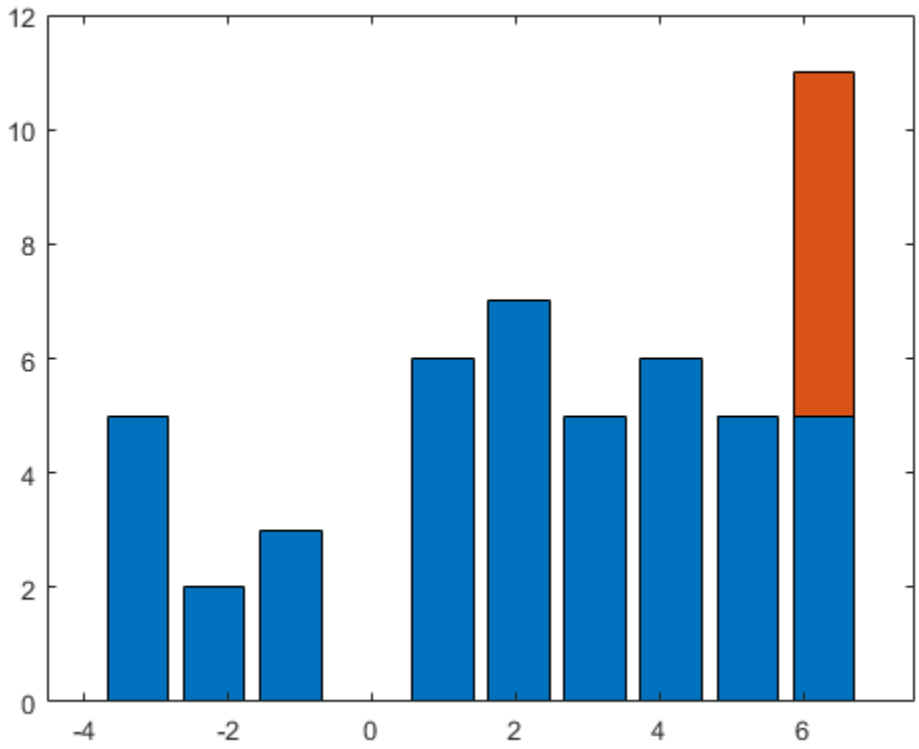
Next, we censor any values that are larger than a predetermined cutoff, by replacing those values with the cutoff value. This is known as Type II censoring, and with the cutoff at 7, about 12% of the original data end up being censored.

```
c = (x > 7);
x(c) = 7;
sum(c)/length(c)
```

```
ans = 0.1200
```

We can plot a histogram of these data, including a stacked bar to represent the censored observations.

```
[uncensCnts,binCtrs] = hist(x(~c));
censCnts = hist(x(c),binCtrs);
bar(binCtrs,[uncensCnts' censCnts'],'stacked');
```



Although there is censoring, the fraction of censored observations is relatively small, and so the method of moments can provide a reasonable starting point for the parameter estimates. We compute the values of mu and sigma that correspond to the observed mean and standard deviation of the uncensored data.

```
sigma0 = sqrt(6)*std(x(~c))./pi
```

```
sigma0 = 2.3495
```

```
mu0 = mean(x(~c))-psi(1).*sigma0
```

```
mu0 = 3.5629
```

In addition to passing the data, x, and handles to the PDF and CDF functions into `mle`, we also use the 'censoring' parameter to pass in the censoring vector, c. Because the scale parameter, sigma, must be positive, we specify lower parameter bounds. `mle` returns the maximum likelihood estimates of the two extreme value distribution parameters, mu and sigma, as well as approximate 95% confidence intervals.

```
[paramEsts,paramCIs] = mle(x, 'censoring',c, 'pdf',@evpdf, 'cdf',@evcdf, ...
                           'start',[mu0 sigma0], 'lower',[-Inf,0])
```

```
paramEsts = 1×2

    4.5530    3.0215

paramCIs = 2×2
```

```
    3.6455    2.2937
    5.4605    3.7494
```

Some Numerical Issues in Fitting Custom Distributions

Fitting a custom distribution requires an initial guess for the parameters, and it's often difficult to know how good or bad a starting point is a priori. In the previous example, if we had picked a starting point that was farther away from the maximum likelihood estimates, some of the observations could have been very far out in the tails of the extreme value distribution corresponding to the starting point. One of two things might then have happened.

First, one of the PDF values might have become so small that it underflowed to zero in double precision arithmetic. Second, one of the CDF values might have become so close to 1 that it rounded up in double precision. (It's also possible that a CDF value might have become so small as to underflow, but that turns out not to be a problem.)

Either of these conditions causes problems when `mle` computes the log-likelihood, because they lead to log-likelihood values of -Inf, and the optimization algorithm in `mle` cannot normally be expected to step out of such regions.

Knowing what the maximum likelihood estimates are, let's see what happens with a different starting point.

```
start = [1 1];
try
    [paramEsts,paramCIs] = mle(x, 'censoring',c, 'pdf',@evpdf, 'cdf',@evcdf, ...
                               'start',start, 'lower',[-Inf,0])
catch ME
    disp(ME.message)
end
```

```
The CDF function returned values greater than or equal to 1.
```

In this case, the second problem has occurred: Some of the CDF values at the initial parameter guess are computed as exactly 1, and so the log-likelihood is infinite. We could try setting `mle`'s 'FunValCheck' control parameter to 'off', which would disable checking for non-finite likelihood values, and then hope for the best. But the right way to solve this numerical problem is at its root, and in this case it's not hard to do.

Notice that the extreme value CDF is of the form

```
  p = 1 - exp( -exp((x-mu)./sigma) )
```

The contribution of the censored observations to the log-likelihood is the log of their survival function (SF) values, i.e., log(1-CDF). For the extreme value distribution, the log of the SF is just -exp((x-mu)./sigma). If we could compute the log-likelihood using the log SF directly, (instead of, in effect, computing log(1 - (1-exp(logSF)))) we would avoid the rounding issues with the CDF. That's because observations whose CDF values are not distinguishable from 1 in double precision have log SF values that are still easily representable as non-zero values. For example, a CDF value of (1 - 1e-20) rounds to 1 in double precision, because double precision `eps` is about 2e-16.

```
SFval = 1e-20;
CDFval = 1 - SFval
```

```
CDFval = 1
```

However, the log of the corresponding SF value, i.e. log(1-CDF), is easily represented.

```
log(SFval)
```

```
ans = -46.0517
```

A similar observation can be made about using the log PDF rather than the PDF itself -- the contribution of uncensored observations to the log-likelihood is the log of their PDF values. Using the log PDF directly (instead of, in effect, computing log(exp(logPDF))) avoids underflow problems where the PDF is not distinguishable from zero in double precision, but the log PDF is still easily representable as a finite negative number. For example, a PDF value of 1e-400 underflows in double precision, because double precision `realmin` is about 2e-308.

```
logPDFval = -921;
PDFval = exp(logPDFval)
```

```
PDFval = 0
```

`mle` provides a syntax for specifying a custom distribution using the log PDF and the log SF (rather than the PDF and CDF), via the 'logpdf' and 'logsf' parameters. Unlike the PDF and CDF functions, there are no existing functions, so we'll create anonymous functions that compute these values:

```
evlogpdf = @(x,mu,sigma) ((x - mu) ./ sigma - exp((x - mu) ./ sigma)) - log(sigma);
evlogsf = @(x,mu,sigma) -exp((x-mu)./sigma);
```

Using the same starting point, the alternate logPDF/logSF specification of the extreme value distribution makes the problem solvable:

```
start = [1 1];
[paramEsts,paramCIs] = mle(x, 'censoring',c, 'logpdf',evlogpdf, 'logsf',evlogsf, ...
                           'start',start, 'lower',[-Inf,0])
```

```
paramEsts = 1×2

    4.5530    3.0215

paramCIs = 2×2

    3.6455    2.2937
    5.4605    3.7494
```

However, this strategy cannot always mitigate a poor starting point, and a careful choice of starting point is always recommended.

Supplying a Gradient

By default, `mle` uses the function `fminsearch` to find parameter values that maximize the log-likelihood for the data. `fminsearch` uses an optimization algorithm that is derivative-free, and is often a good choice.

However, for some problems, choosing an optimization algorithm that uses the derivatives of the log-likelihood function can make the difference between converging to the maximum likelihood estimates or not, especially when the starting point is far away from the final answer. Providing the derivatives can also sometimes speed up the convergence.

If your MATLAB® installation includes the Optimization Toolbox™, `mle` allows you to use the function `fmincon`, which includes optimization algorithms that can use derivative information. To take best advantage of the algorithms in `fmincon`, you can specify a custom distribution using a log-likelihood function, written to return not only the log-likelihood itself, but its gradient as well. The gradient of the log-likelihood function is simply the vector of its partial derivatives with respect to its parameters.

This strategy requires extra preparation, to write code that computes both the log-likelihood and its gradient. For this example, we've the created code to do that for the extreme value distribution as a separate file `evnegloglike.m`.

```
type evnegloglike.m
```

```
function [nll,ngrad] = evnegloglike(params,x,cens,freq)
%EVNEGLOGLIKE Negative log-likelihood for the extreme value distribution.

%   Copyright 1984-2004 The MathWorks, Inc.

if numel(params)~=2
    error(message('stats:probdists:WrongParameterLength',2));
end
mu = params(1);
sigma = params(2);
nunc = sum(1-cens);
z = (x - mu) ./ sigma;
expz = exp(z);
nll = sum(expz) - sum(z(~cens)) + nunc.*log(sigma);
if nargout > 1
    ngrad = [-sum(expz)./sigma + nunc./sigma, ...
             -sum(z.*expz)./sigma + sum(z(~cens))./sigma + nunc./sigma];
end
```

Notice that the function `evnegloglike` returns the *negative* of both the log-likelihood values and of the gradient values, because MLE *minimizes* that negative log-likelihood.

To compute the maximum likelihood estimates using a gradient-based optimization algorithm, we use the `'nloglf'` parameter, specifying that we are providing a handle to a function that computes the negative log-likelihood, and the `'optimfun'` parameter, specifying `fmincon` as the optimization function. `mle` will automatically detect that `evnegloglike` can return both the negative log-likelihood and its gradient.

```
start = [1 1];
[paramEsts,paramCIs] = mle(x, 'censoring',c, 'nloglf',@evnegloglike, ...
                           'start',start, 'lower',[-Inf,0], 'optimfun','fmincon')
```

```
paramEsts = 1×2

    4.5530    3.0215

paramCIs = 2×2

    3.6455    2.2937
    5.4605    3.7493
```

Nonparametric Estimates of Cumulative Distribution Functions and Their Inverses

This example shows how to estimate the cumulative distribution function (CDF) from data in a nonparametric or semiparametric way. It also illustrates the inversion method for generating random numbers from the estimated CDF. The Statistics and Machine Learning Toolbox™ includes more than two dozen random number generator functions for parametric univariate probability distributions. These functions allow you to generate random inputs for a wide variety of simulations, however, there are situations where it is necessary to generate random values to simulate data that are not described by a simple parametric family.

The toolbox also includes the functions `pearsrnd` and `johnsrnd`, for generating random values without having to specify a parametric distribution from which to draw--those functions allow you to specify a distribution in terms of its moments or quantiles, respectively.

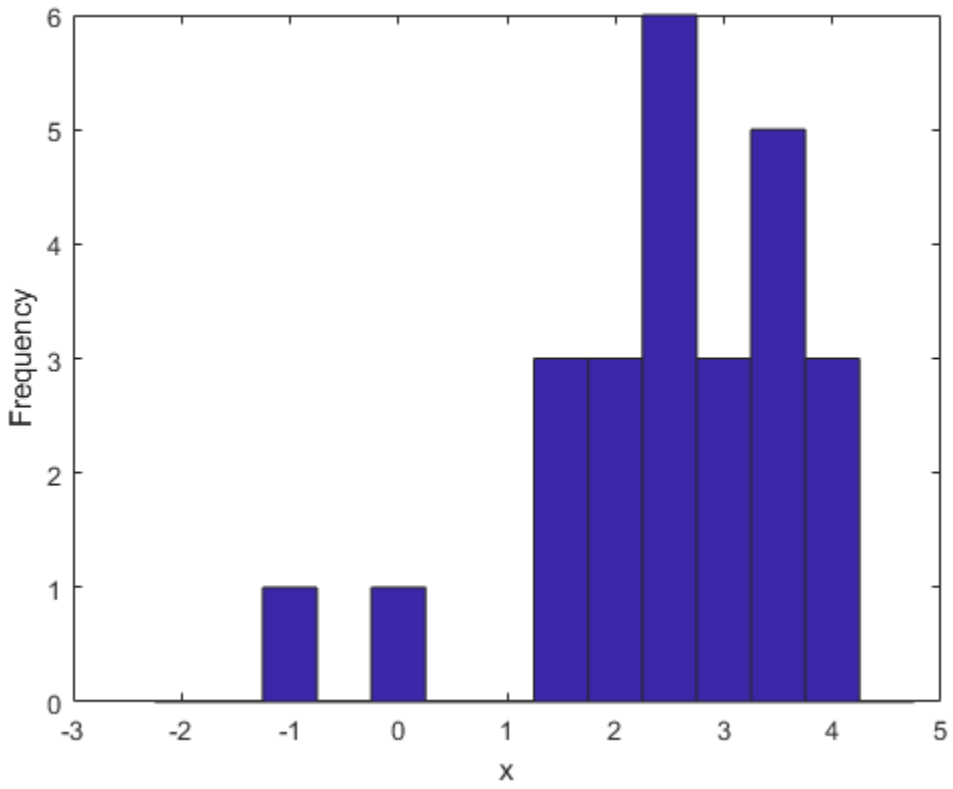
However, there are still situations where even more flexibility is needed, to generate random values that "imitate" data that you have collected even more closely. In this case, you might use a nonparametric estimate of the CDF of those data, and use the inversion method to generate random values. The inversion method involves generating uniform random values on the unit interval, and transforming them to a desired distribution using the inverse CDF for that distribution.

From the opposite perspective, it is sometimes desirable to use a nonparametric estimate of the CDF to transform observed data onto the unit interval, giving them an approximate uniform distribution.

The `ecdf` function computes one type of nonparametric CDF estimate, the empirical CDF, which is a stairstep function. This example illustrates some smoother alternatives, which may be more suitable for simulating or transforming data from a continuous distribution.

For the purpose of illustration, here are some simple simulated data. There are only 25 observations, a small number chosen to make the plots in the example easier to read. The data are also sorted to simplify plotting.

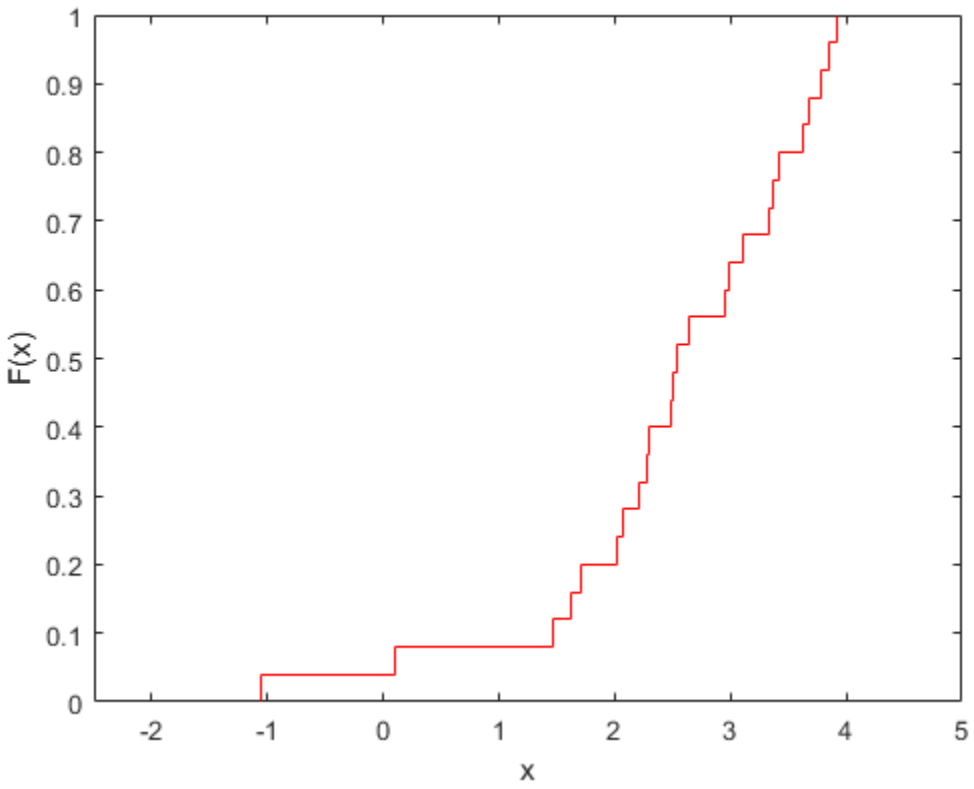
```
rng(19,'twister');
n = 25;
x = evrnd(3,1,n,1); x = sort(x);
hist(x,-2:.5:4.5);
xlabel('x'); ylabel('Frequency');
```



A Piecewise Linear Nonparametric CDF Estimate

The `ecdf` function provides a simple way to compute and plot a "stairstep" empirical CDF for data. In the simplest cases, this estimate makes discrete jumps of 1/n at each data point.

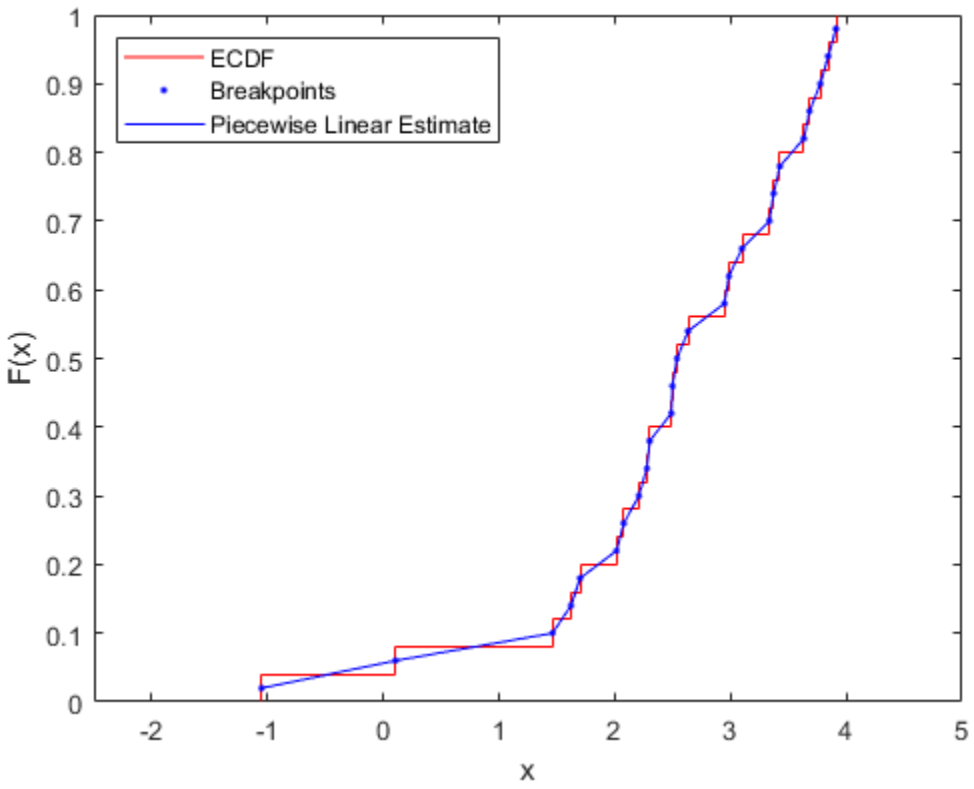
```
[Fi,xi] = ecdf(x);
stairs(xi,Fi,'r');
xlim([-2.5 5]); xlabel('x'); ylabel('F(x)');
```



This estimate is useful for many purposes, including investigating the goodness of fit of a parametric model to data. Its discreteness, however, may make it unsuitable for use in empirically transforming continuous data to or from the unit interval.

It is simple to modify the empirical CDF to address that problems. Instead of taking discrete jumps of 1/n at each data point, define a function that is piecewise linear, with breakpoints at the midpoints of those jumps. The height at each of the data points is then [1/2n, 3/2n, ..., (n-1/2)/n], instead of [(1/n), (2/n), ..., 1]. Use the output of `ecdf` to compute those breakpoints, and then "connect the dots" to define the piecewise linear function.

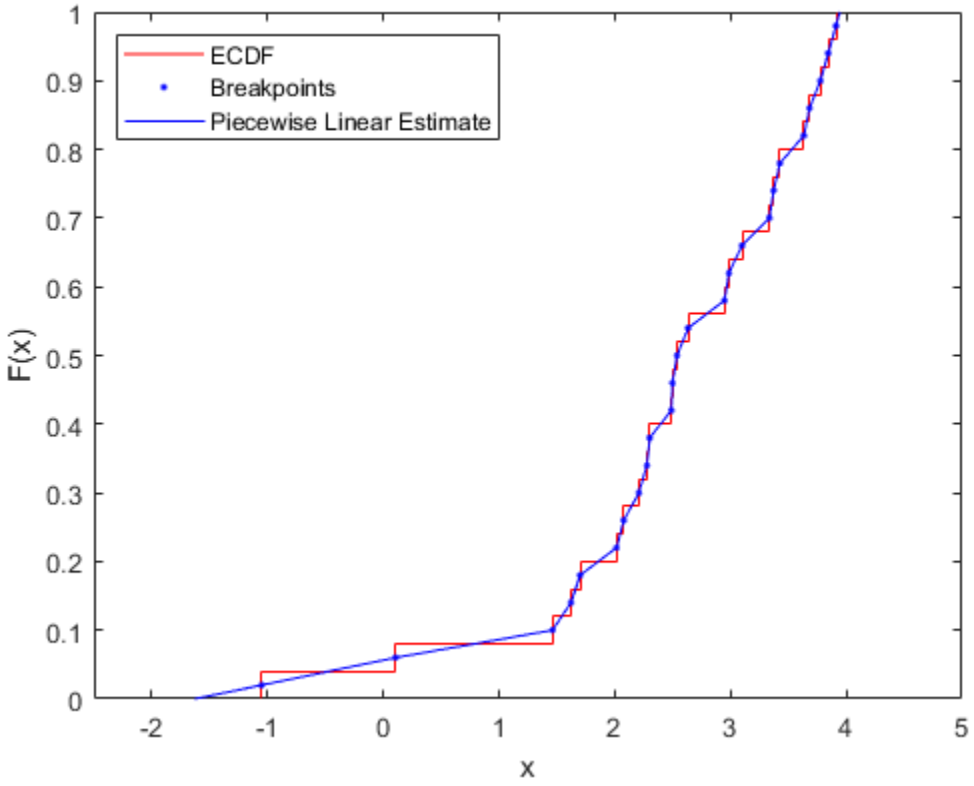
```
xj = xi(2:end);
Fj = (Fi(1:end-1)+Fi(2:end))/2;
hold on
plot(xj,Fj,'b.', xj,Fj,'b-');
hold off
legend({'ECDF' 'Breakpoints' 'Piecewise Linear Estimate'},'location','NW');
```



Because `ecdf` deals appropriately with repeated values and censoring, this calculation works even in cases with more complicated data than in this example.

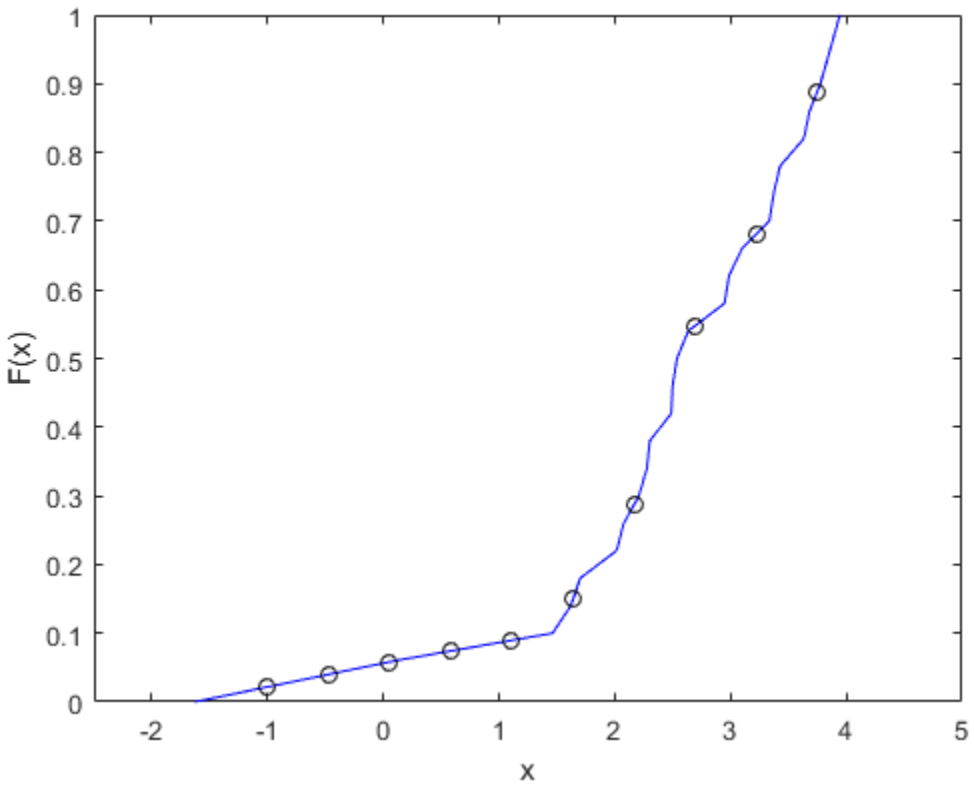
Since the smallest data point corresponds to a height of 1/2n, and the largest to 1-1/2n, the first and last linear segments must be extended beyond the data, to make the function reach 0 and 1.

```
xj = [xj(1)-Fj(1)*(xj(2)-xj(1))/((Fj(2)-Fj(1)));
      xj;
      xj(n)+(1-Fj(n))*((xj(n)-xj(n-1))/(Fj(n)-Fj(n-1)))];
Fj = [0; Fj; 1];
hold on
plot(xj,Fj,'b-','HandleVisibility','off');
hold off
```



This piecewise linear function provides a nonparametric estimate of the CDF that is continuous and symmetric. Evaluating it at points other than the original data is just a matter of linear interpolation, and it can be convenient to define an anonymous function to do that.

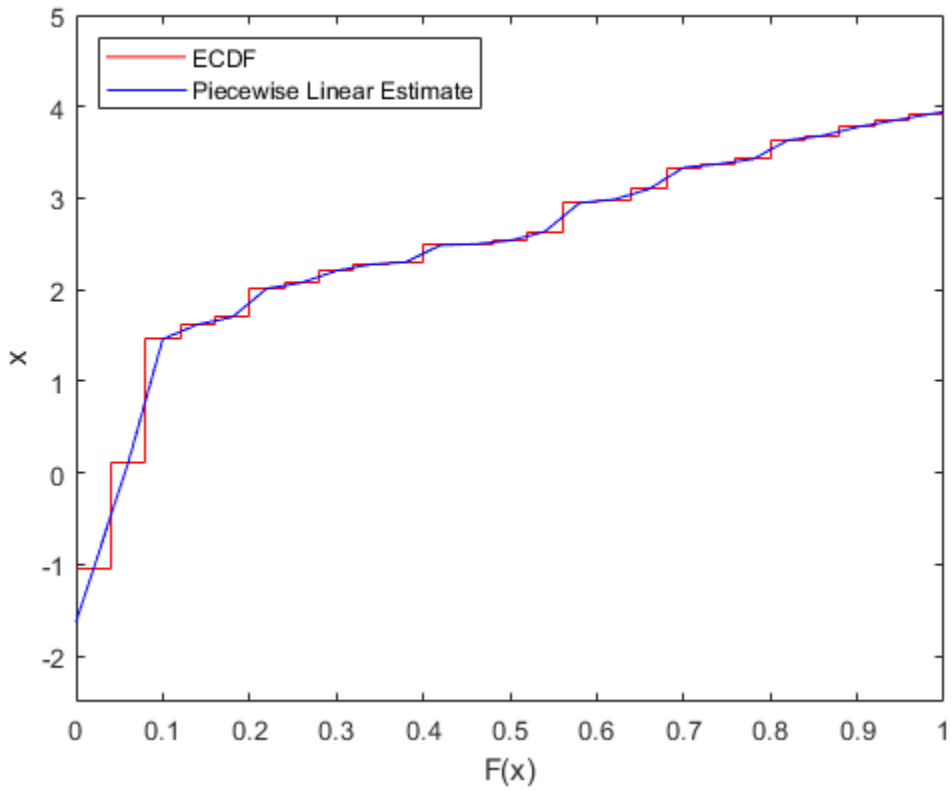
```
F = @(y) interp1(xj,Fj,y,'linear','extrap');
y = linspace(-1,3.75,10);
plot(xj,Fj,'b-',y,F(y),'ko');
xlim([-2.5 5]); xlabel('x'); ylabel('F(x)');
```



A Piecewise Linear Nonparametric Inverse CDF Estimate

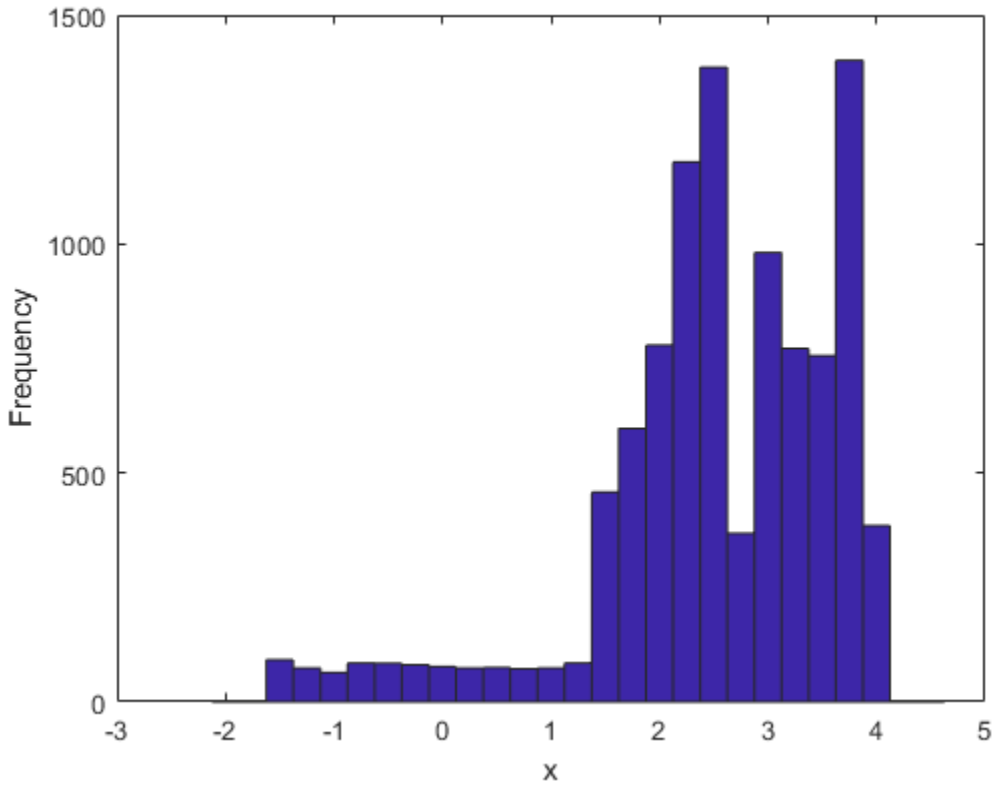
You can use the same calculations to compute a nonparametric estimate of the inverse CDF. In fact, the inverse CDF estimate is just the CDF estimate with the axes swapped.

```
stairs(Fi,[xi(2:end); xi(end)],'r');
hold on
plot(Fj,xj,'b-');
hold off
ylim([-2.5 5]); ylabel('x'); xlabel('F(x)');
legend({'ECDF' 'Piecewise Linear Estimate'},'location','NW');
```



Evaluating this nonparametric inverse CDF at points other than the original breakpoints is again just a matter of linear interpolation. For example, generate uniform random values and use the CDF estimate to transform them back to the scale of your original observed data. This is the inversion method.

```
Finv = @(u) interp1(Fj,xj,u,'linear','extrap');
u = rand(10000,1);
hist(Finv(u),-2:.25:4.5);
xlabel('x'); ylabel('Frequency');
```



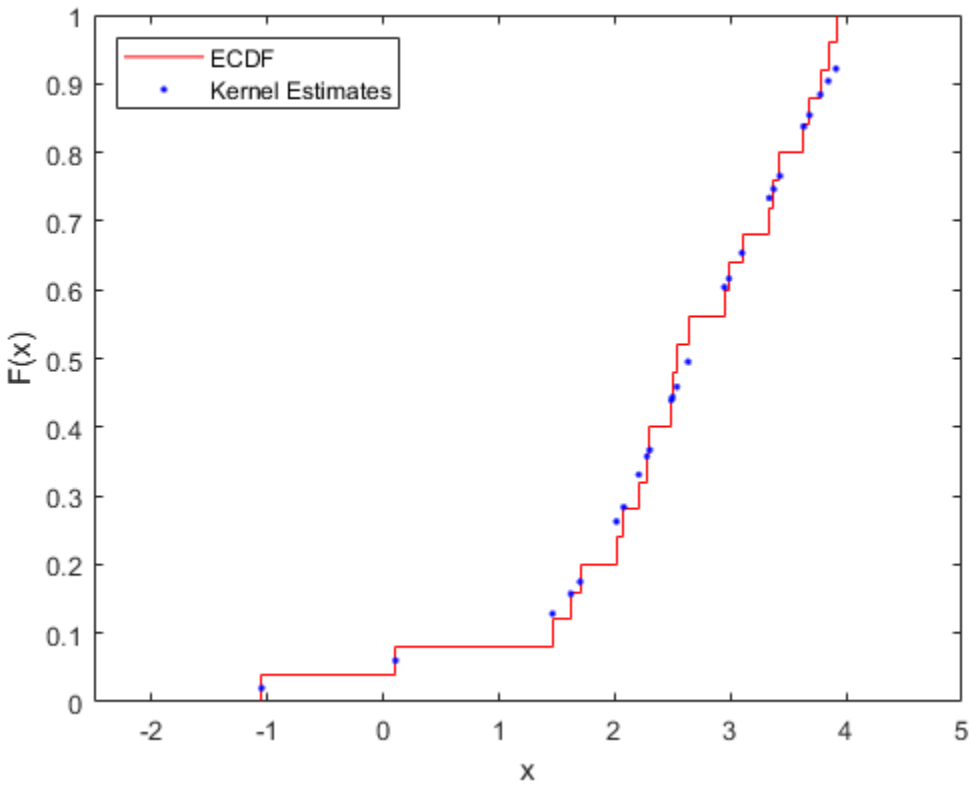
Notice that this histogram of simulated data is more spread out than the histogram of the original data. This is due, in part, to the much larger sample size--the original data consist of only 25 values. But it is also because the piecewise linear CDF estimate, in effect, "spreads out" each of the original observations over an interval, and more so in regions where the individual observations are well-separated.

For example, the two individual observations to the left of zero correspond to a wide, flat region of low density in the simulated data. In contrast, in regions where the data are closely spaced, towards the right tail, for example, the piecewise linear CDF estimate "spreads out" the observations to a lesser extent. In that sense, the method performs a simple version of what is known as variable bandwidth smoothing. However, despite the smoothing, the simulated data retain most of the idiosyncrasies of the original data, i.e., the regions of high and low density.

Kernel Estimators for the CDF and Inverse CDF

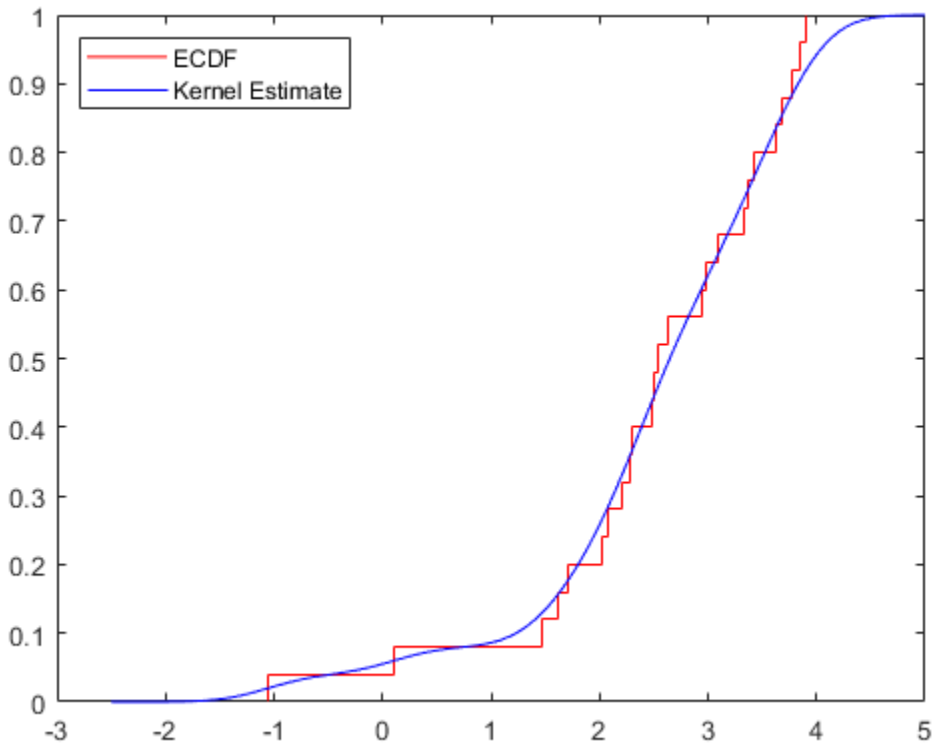
Instead of estimating the CDF using a piecewise linear function, you can perform kernel estimation using the `ksdensity` function to make a smooth nonparametric estimate. Though it is often used to make a nonparametric *density* estimate, `ksdensity` can also estimate other functions. For example, to transform your original data to the unit interval, use it to estimate the CDF.

```
F = ksdensity(x, x, 'function','cdf', 'width',.35);
stairs(xi,Fi,'r');
hold on
plot(x,F,'b.');
hold off
xlim([-2.5 5]); xlabel('x'); ylabel('F(x)');
legend({'ECDF' 'Kernel Estimates'},'location','NW');
```



`ksdensity` also provides a convenient way to evaluate the kernel CDF estimate at points other than the original data. For example, plot the estimate as a smooth curve.

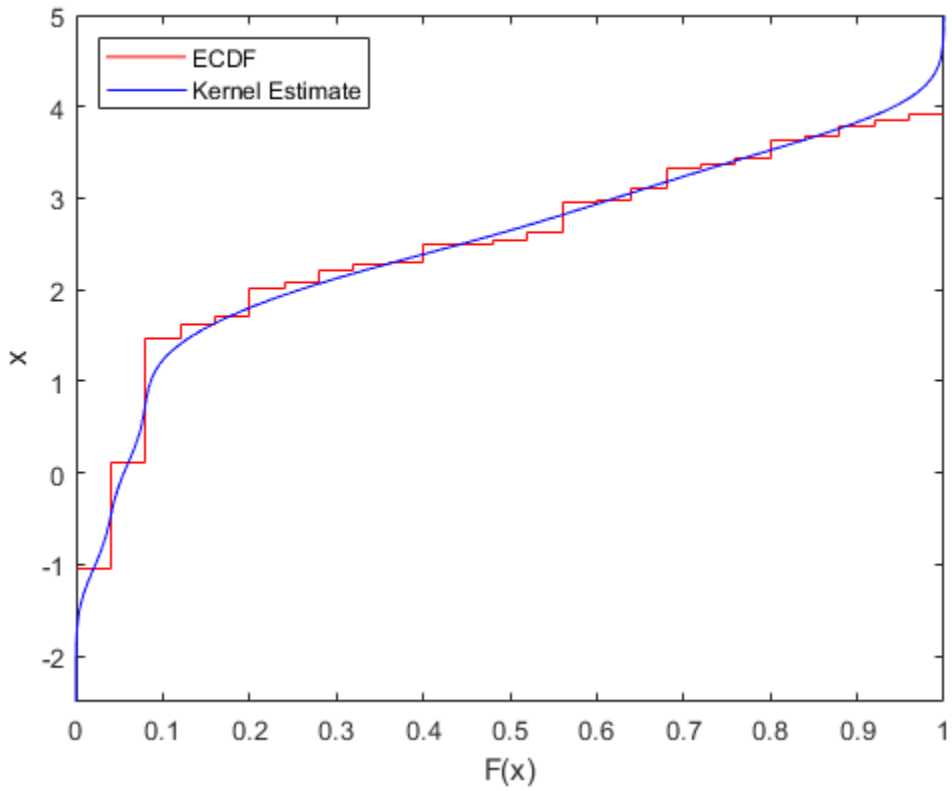
```
y = linspace(-2.5,5,1000);
Fy = ksdensity(x, y, 'function','cdf', 'width',.35);
stairs(xi,Fi,'r');
hold on
plot(y,Fy,'b-');
hold off
legend({'ECDF' 'Kernel Estimate'},'location','NW');
```



`ksdensity` uses a bandwidth parameter to control the amount of smoothing in the estimates it computes, and it is possible to let `ksdensity` choose a default value. The examples here use a fairly small bandwidth to limit the amount of smoothing. Even so, the kernel estimate does not follow the ECDF as closely as the piecewise linear estimate does.

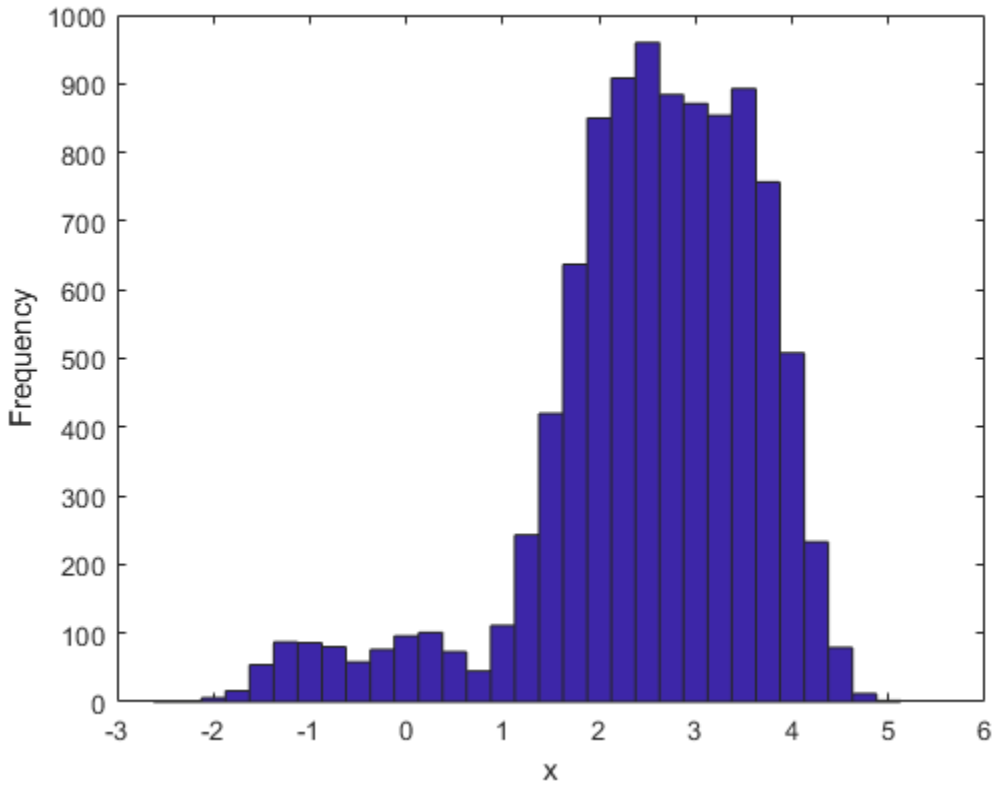
One way to estimate the inverse CDF using kernel estimation is to compute the kernel CDF estimate on a grid of points spanning the range of the original data, and then use the same procedure as for the piecewise linear estimate. For example, to plot the inverse CDF kernel estimate as a smooth curve, simply swap the axes.

```
stairs(Fi,[xi(2:end); xi(end)],'r');
hold on
plot(Fy,y,'b-');
hold off
ylim([-2.5 5]); ylabel('x'); xlabel('F(x)');
legend({'ECDF' 'Kernel Estimate'},'location','NW');
```



To transform uniform random values back to the scale of the original data, interpolate using the grid of CDF estimates.

```
Finv = @(u) interp1(Fy,y,u,'linear','extrap');
hist(Finv(u),-2.5:.25:5);
xlabel('x'); ylabel('Frequency');
```



Notice that the simulated data using the kernel CDF estimate has not completely "smoothed over" the two individual observations to the left of zero present in the original data. The kernel estimate uses a fixed bandwidth. With the particular bandwidth value used in this example, those two observations contribute to two localized areas of density, rather than a wide flat region as was the case with the piecewise linear estimate. In contrast, the kernel estimate has smoothed the data *more* in the right tail than the piecewise linear estimate.

Another way to generate simulated data using kernel estimation is to use `ksdensity` to compute an estimate of the inverse CDF directly, again using the `'function'` parameter. For example, transform those same uniform values.

```
r = ksdensity(x, u, 'function','icdf', 'width',.35);
```

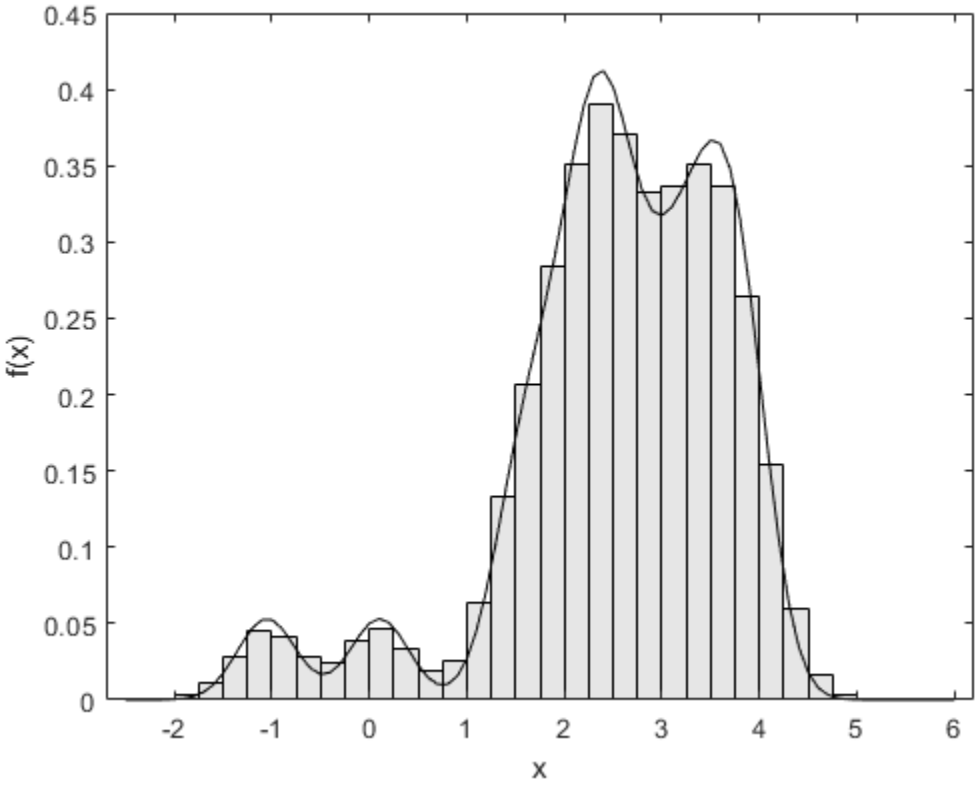
However, using the latter method can be time-consuming for large amounts of data. A simpler, but equivalent, method is to resample with replacement from the original data and add some appropriate random noise.

```
r = datasample(x,100000,'replace',true) + normrnd(0,.35,100000,1);
```

If you generate enough random values, a histogram of the result follows the kernel density estimate of the original data very closely.

```
binwidth = .25;
edges = -2.5:binwidth:6;
ctrs = edges(1:end-1) + binwidth./2;
counts = histc(r,edges); counts = counts(1:end-1);
bar(ctrs,counts./(sum(counts).*binwidth),1,'FaceColor',[.9 .9 .9]);
```

```
hold on
xgrid = edges(1):.1:edges(end);
fgrid = ksdensity(x, xgrid, 'function','pdf', 'width',.3);
plot(xgrid,fgrid,'k-');
hold off
xlabel('x'); ylabel('f(x)');
```



A Semiparametric CDF Estimate

A nonparametric CDF estimate requires a good deal of data to achieve reasonable precision. In addition, data only affect the estimate "locally." That is, in regions where there is a high density of data, the estimate is based on more observations than in regions where there is a low density of data. In particular, nonparametric estimates do not perform well in the tails of a distribution, where data are sparse by definition.

Fitting a semiparametric model to your data using the `paretotails` function allows the best of both the nonparametric and parametric worlds. In the "center" of the distribution, the model uses the piecewise linear nonparametric estimate for the CDF. In each tail, it uses a generalized Pareto distribution. The generalized Pareto is often used as a model for the tail(s) of a dataset, and while it is flexible enough to fit a wide variety of distribution tails, it is sufficiently constrained so that it requires few data to provide a plausible and smooth fit to tail data.

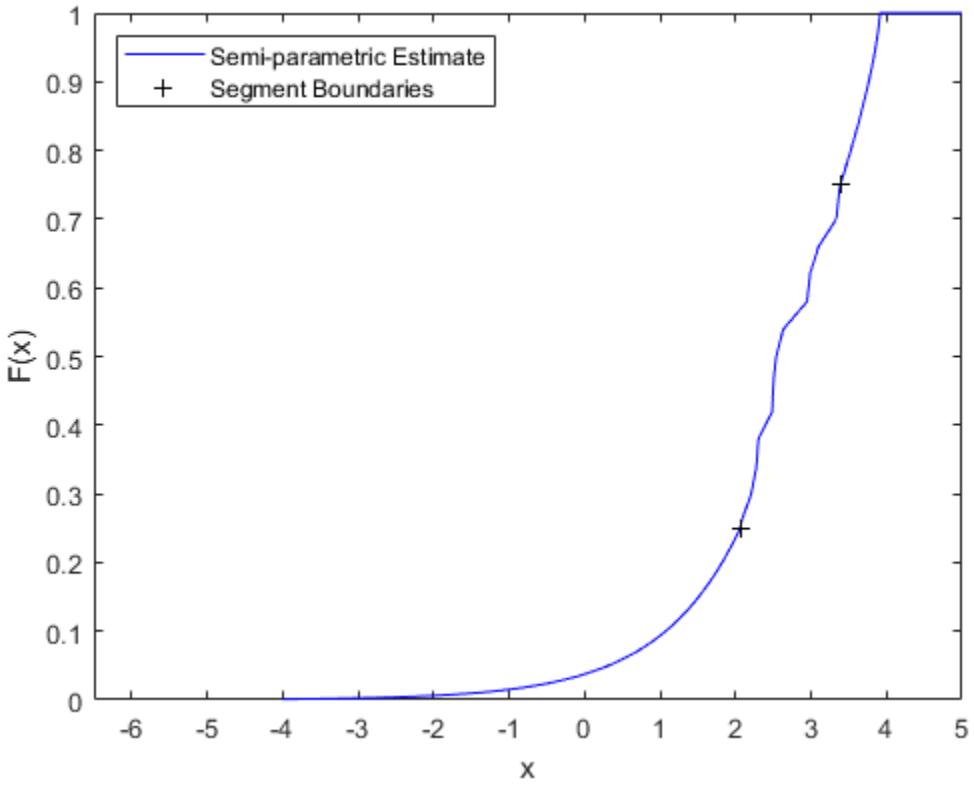
For example, you might define the "center" of the data as the middle 50%, and specify that the transitions between the nonparametric estimate and the Pareto fits take place at the .25 and .75 quantiles of your data. To evaluate the CDF of the semiparametric model fit, use the fit's `cdf` method.

```
semipFit = paretotails(x,.25,.75);
```

```
Warning: Problem fitting generalized Pareto distribution to upper tail. Maximum
likelihood has converged to a boundary point of the parameter space.
```

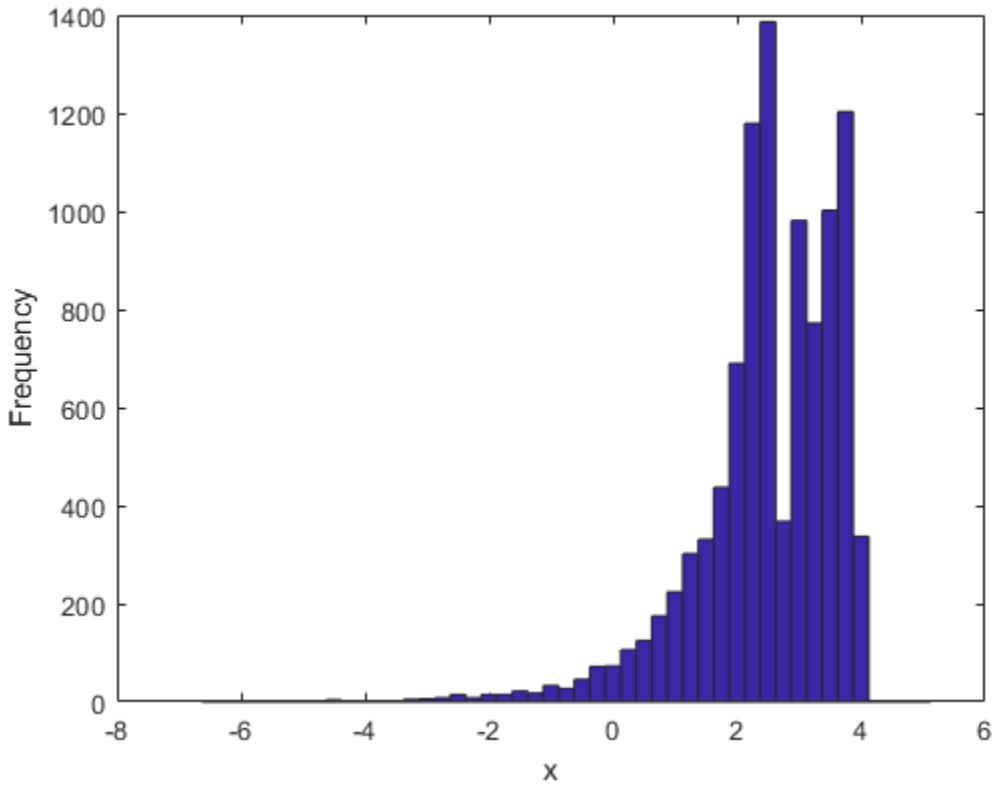
The warning is due to using so few data -- 6 points in each tail in this case -- and indicates that the fitted generalized Pareto distribution in the upper tail extends exactly to the smallest observation, and no further. You can see that in the histogram shown below. In a real application, you would usually have more data, and the warning would typically not occur.

```
[p,q] = boundary(semipFit);
y = linspace(-4,6,1000);
Fy = cdf(semipFit,y);
plot(y,Fy,'b-', q,p,'k+');
xlim([-6.5 5]); xlabel('x'); ylabel('F(x)');
legend({'Semi-parametric Estimate' 'Segment Boundaries'},'location','NW');
```



To transform uniform random values back to the scale of your original data, use the fit's `icdf` method.

```
r = icdf(semipFit,u);
hist(r,-6.5:.25:5);
xlabel('x'); ylabel('Frequency');
```



This semiparametric estimate has smoothed the tails of the data more than the center, because of the parametric model used in the tails. In that sense, the estimate is more similar to the piecewise linear estimate than to the kernel estimate. However, it is also possible to use `paretotails` to create a semiparametric fit that uses kernel estimation in the center of the data.

Conclusions

This example illustrates three methods for computing a nonparametric or semiparametric CDF or inverse CDF estimate from data. The three methods impose different amounts and types of smoothing on the data. Which method you choose depends on how each method captures or fails to capture what you consider the important features of your data.

Modelling Tail Data with the Generalized Pareto Distribution

This example shows how to fit tail data to the Generalized Pareto distribution by maximum likelihood estimation.

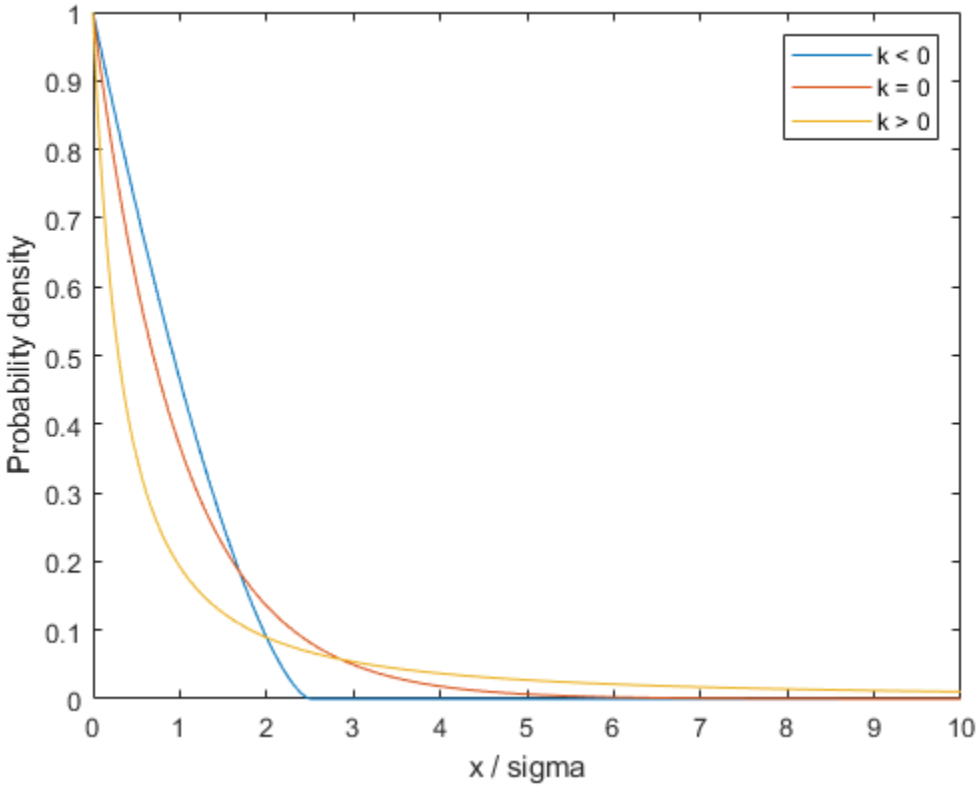
Fitting a parametric distribution to data sometimes results in a model that agrees well with the data in high density regions, but poorly in areas of low density. For unimodal distributions, such as the normal or Student's t, these low density regions are known as the "tails" of the distribution. One reason why a model might fit poorly in the tails is that by definition, there are fewer data in the tails on which to base a choice of model, and so models are often chosen based on their ability to fit data near the mode. Another reason might be that the distribution of real data is often more complicated than the usual parametric models.

However, in many applications, fitting the data in the tail is the main concern. The Generalized Pareto distribution (GP) was developed as a distribution that can model tails of a wide variety of distributions, based on theoretical arguments. One approach to distribution fitting that involves the GP is to use a non-parametric fit (the empirical cumulative distribution function, for example) in regions where there are many observations, and to fit the GP to the tail(s) of the data.

The Generalized Pareto Distribution

The Generalized Pareto (GP) is a right-skewed distribution, parameterized with a shape parameter, k, and a scale parameter, sigma. k is also known as the "tail index" parameter, and can be positive, zero, or negative.

```
x = linspace(0,10,1000);
plot(x,gppdf(x,-.4,1),'-', x,gppdf(x,0,1),'-', x,gppdf(x,2,1),'-');
xlabel('x / sigma');
ylabel('Probability density');
legend({'k < 0' 'k = 0' 'k > 0'});
```



Notice that for k < 0, the GP has zero probability above an upper limit of -(1/k). For k >= 0, the GP has no upper limit. Also, the GP is often used in conjunction with a third, threshold parameter that shifts the lower limit away from zero. We will not need that generality here.

The GP distribution is a generalization of both the exponential distribution (k = 0) and the Pareto distribution (k > 0). The GP includes those two distributions in a larger family so that a continuous range of shapes is possible.

Simulating Exceedance Data

The GP distribution can be defined constructively in terms of exceedances. Starting with a probability distribution whose right tail drops off to zero, such as the normal, we can sample random values independently from that distribution. If we fix a threshold value, throw out all the values that are below the threshold, and subtract the threshold off of the values that are not thrown out, the result is known as exceedances. The distribution of the exceedances is approximately a GP. Similarly, we can set a threshold in the left tail of a distribution, and ignore all values above that threshold. The threshold must be far enough out in the tail of the original distribution for the approximation to be reasonable.

The original distribution determines the shape parameter, k, of the resulting GP distribution. Distributions whose tails fall off as a polynomial, such as Student's t, lead to a positive shape parameter. Distributions whose tails decrease exponentially, such as the normal, correspond to a zero shape parameter. Distributions with finite tails, such as the beta, correspond to a negative shape parameter.

Real-world applications for the GP distribution include modelling extremes of stock market returns, and modelling extreme floods. For this example, we'll use simulated data, generated from a Student's t distribution with 5 degrees of freedom. We'll take the largest 5% of 2000 observations from the t distribution, and then subtract off the 95% quantile to get exceedances.

```
rng(3,'twister');
x = trnd(5,2000,1);
q = quantile(x,.95);
y = x(x>q) - q;
n = numel(y)
```

```
n =

   100
```

Fitting the Distribution Using Maximum Likelihood

The GP distribution is defined for 0 < sigma, and -Inf < k < Inf. However, interpretation of the results of maximum likelihood estimation is problematic when k < -1/2. Fortunately, those cases correspond to fitting tails from distributions like the beta or triangular, and so will not present a problem here.

```
paramEsts = gpfit(y);
kHat      = paramEsts(1)   % Tail index parameter
sigmaHat  = paramEsts(2)   % Scale parameter
```

```
kHat =

    0.0987

sigmaHat =

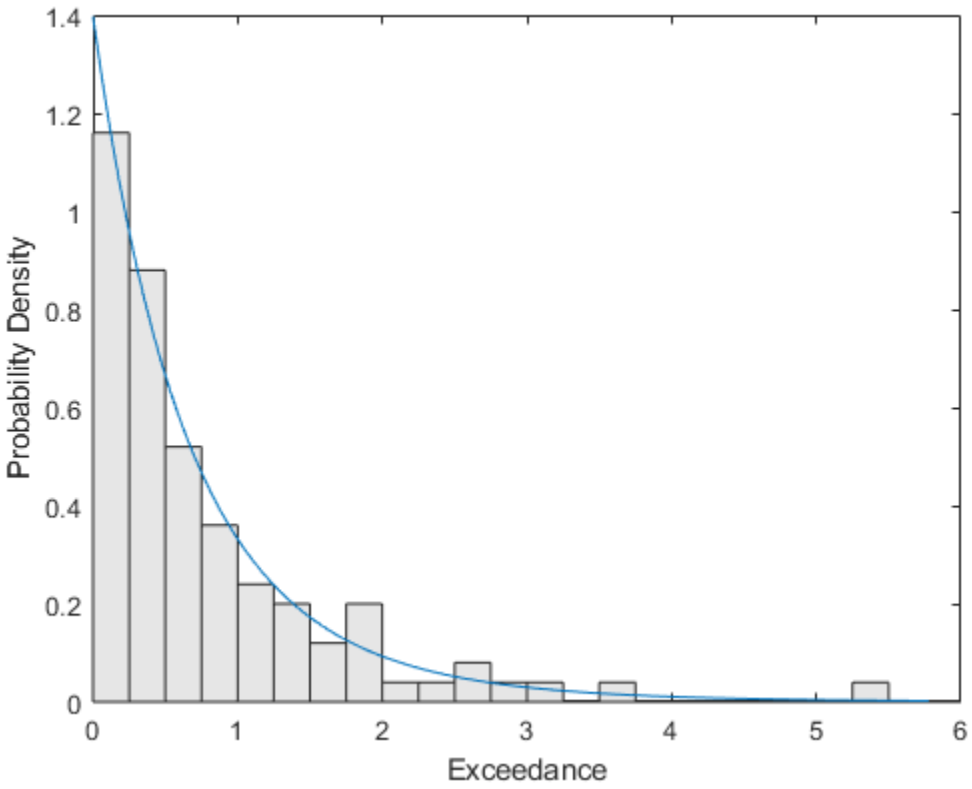
    0.7156
```

As might be expected, since the simulated data were generated using a t distribution, the estimate of k is positive.

Checking the Fit Visually

To visually assess how good the fit is, we'll plot a scaled histogram of the tail data, overlaid with the density function of the GP that we've estimated. The histogram is scaled so that the bar heights times their width sum to 1.

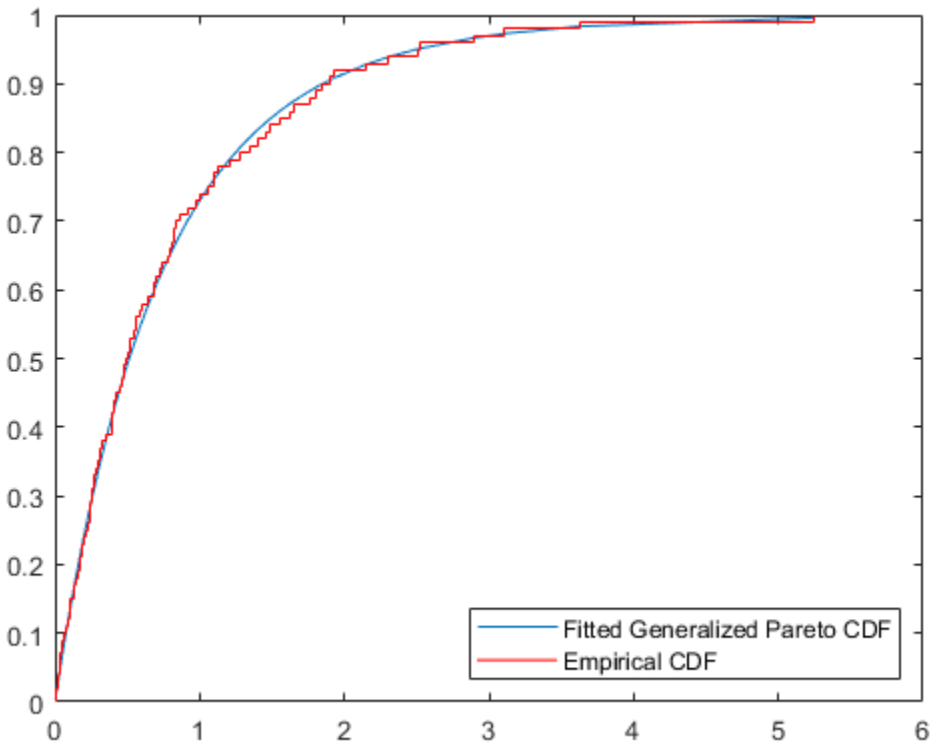
```
bins = 0:.25:7;
h = bar(bins,histc(y,bins)/(length(y)*.25),'histc');
h.FaceColor = [.9 .9 .9];
ygrid = linspace(0,1.1*max(y),100);
line(ygrid,gppdf(ygrid,kHat,sigmaHat));
xlim([0,6]);
xlabel('Exceedance');
ylabel('Probability Density');
```



We've used a fairly small bin width, so there is a good deal of noise in the histogram. Even so, the fitted density follows the shape of the data, and so the GP model seems to be a good choice.

We can also compare the empirical CDF to the fitted CDF.

```
[F,yi] = ecdf(y);
plot(yi,gpcdf(yi,kHat,sigmaHat),'-');
hold on;
stairs(yi,F,'r');
hold off;
legend('Fitted Generalized Pareto CDF','Empirical CDF','location','southeast');
```



Computing Standard Errors for the Parameter Estimates

To quantify the precision of the estimates, we'll use standard errors computed from the asymptotic covariance matrix of the maximum likelihood estimators. The function `gplike` computes, as its second output, a numerical approximation to that covariance matrix. Alternatively, we could have called `gpfit` with two output arguments, and it would have returned confidence intervals for the parameters.

```
[nll,acov] = gplike(paramEsts, y);
stdErr = sqrt(diag(acov))
```

```
stdErr =

    0.1158
    0.1093
```

These standard errors indicate that the relative precision of the estimate for k is quite a bit lower than that for sigma -- its standard error is on the order of the estimate itself. Shape parameters are often difficult to estimate. It's important to keep in mind that computation of these standard errors assumed that the GP model is correct, and that we have enough data for the asymptotic approximation to the covariance matrix to hold.

Checking the Asymptotic Normality Assumption

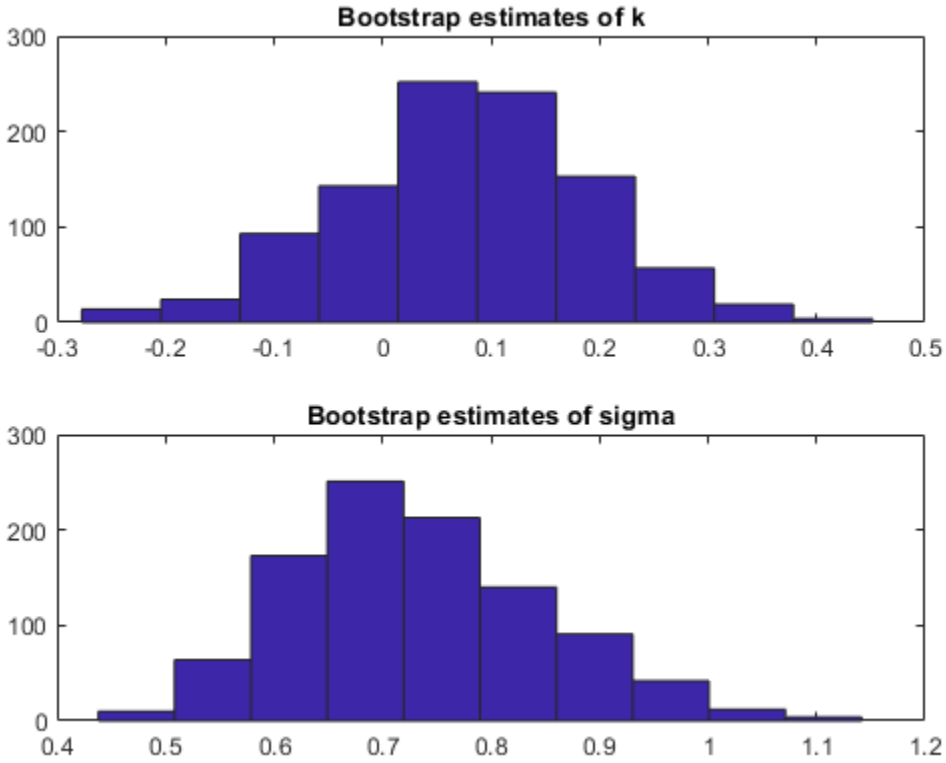
Interpretation of the standard errors usually involves assuming that, if the same fit could be repeated many times on data that came from the same source, the maximum likelihood estimates of the parameters would approximately follow a normal distribution. For example, confidence intervals are often based this assumption.

However, that normal approximation may or may not be a good one. To assess how good it is in this example, we can use a bootstrap simulation. We will generate 1000 replicate datasets by resampling from the data, fit a GP distribution to each one, and save all the replicate estimates.

```
replEsts = bootstrp(1000,@gpfit,y);
```

As a rough check on the sampling distribution of the parameter estimators, we can look at histograms of the bootstrap replicates.

```
subplot(2,1,1);
hist(replEsts(:,1));
title('Bootstrap estimates of k');
subplot(2,1,2);
hist(replEsts(:,2));
title('Bootstrap estimates of sigma');
```

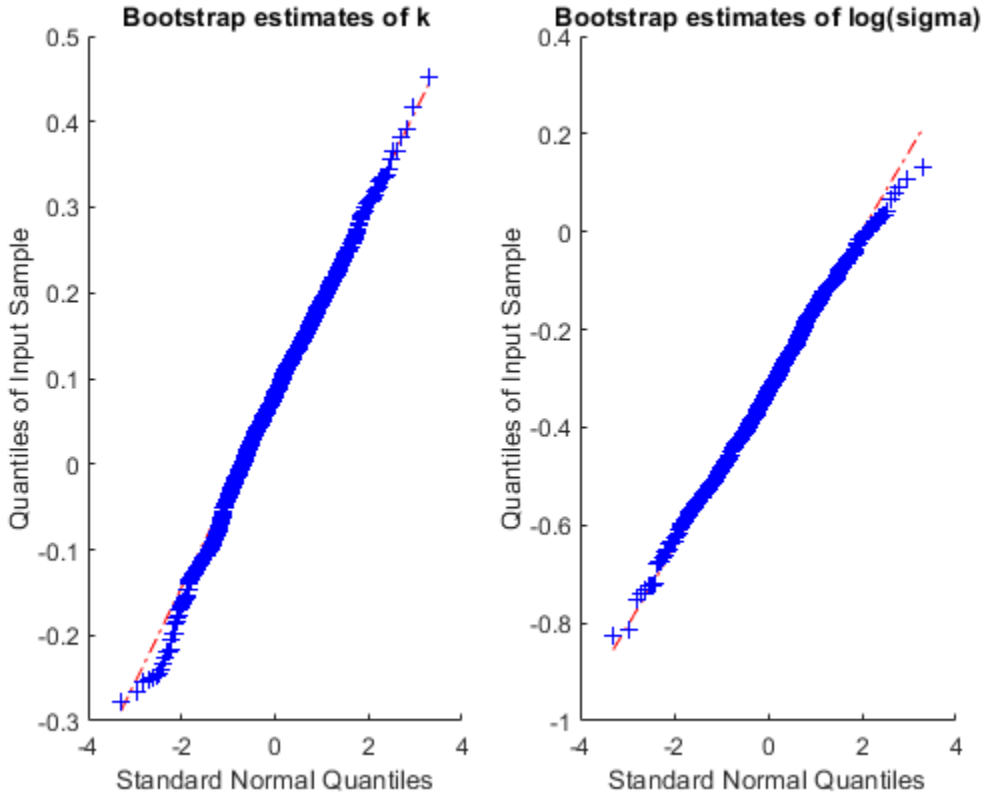


Using a Parameter Transformation

The histogram of the bootstrap estimates for k appears to be only a little asymmetric, while that for the estimates of sigma definitely appears skewed to the right. A common remedy for that skewness is

to estimate the parameter and its standard error on the log scale, where a normal approximation may be more reasonable. A Q-Q plot is a better way to assess normality than a histogram, because non-normality shows up as points that do not approximately follow a straight line. Let's check that to see if the log transform for sigma is appropriate.

```
subplot(1,2,1);
qqplot(replEsts(:,1));
title('Bootstrap estimates of k');
subplot(1,2,2);
qqplot(log(replEsts(:,2)));
title('Bootstrap estimates of log(sigma)');
```



The bootstrap estimates for k and log(sigma) appear acceptably close to normality. A Q-Q plot for the estimates of sigma, on the unlogged scale, would confirm the skewness that we've already seen in the histogram. Thus, it would be more reasonable to construct a confidence interval for sigma by first computing one for log(sigma) under the assumption of normality, and then exponentiating to transform that interval back to the original scale for sigma.

In fact, that's exactly what the function `gpfit` does behind the scenes.

```
[paramEsts,paramCI] = gpfit(y);

kHat
kCI  = paramCI(:,1)
```

```
kHat =
```

```
    0.0987

kCI =

   -0.1283
    0.3258

sigmaHat
sigmaCI  = paramCI(:,2)

sigmaHat =

    0.7156

sigmaCI =

    0.5305
    0.9654
```

Notice that while the 95% confidence interval for k is symmetric about the maximum likelihood estimate, the confidence interval for sigma is not. That's because it was created by transforming a symmetric CI for log(sigma).

Modelling Data with the Generalized Extreme Value Distribution

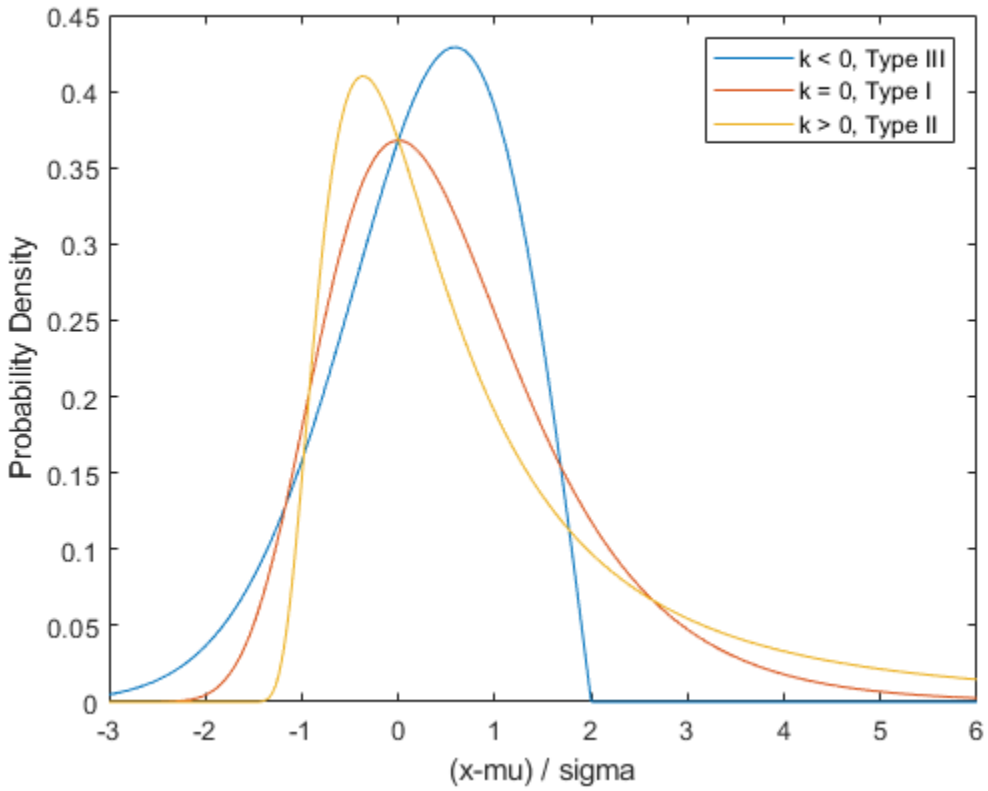
This example shows how to fit the generalized extreme value distribution using maximum likelihood estimation. The extreme value distribution is used to model the largest or smallest value from a group or block of data.

Three types of extreme value distributions are common, each as the limiting case for different types of underlying distributions. For example, the type I extreme value is the limit distribution of the maximum (or minimum) of a block of normally distributed data, as the block size becomes large. In this example, we will illustrate how to fit such data using a single distribution that includes all three types of extreme value distributions as special case, and investigate likelihood-based confidence intervals for quantiles of the fitted distribution.

The Generalized Extreme Value Distribution

The Generalized Extreme Value (GEV) distribution unites the type I, type II, and type III extreme value distributions into a single family, to allow a continuous range of possible shapes. It is parameterized with location and scale parameters, mu and sigma, and a shape parameter, k. When k < 0, the GEV is equivalent to the type III extreme value. When k > 0, the GEV is equivalent to the type II. In the limit as k approaches 0, the GEV becomes the type I.

```
x = linspace(-3,6,1000);
plot(x,gevpdf(x,-.5,1,0),'-', x,gevpdf(x,0,1,0),'-', x,gevpdf(x,.5,1,0),'-');
xlabel('(x-mu) / sigma');
ylabel('Probability Density');
legend({'k < 0, Type III' 'k = 0, Type I' 'k > 0, Type II'});
```



Notice that for k < 0 or k > 0, the density has zero probability above or below, respectively, the upper or lower bound -(1/k). In the limit as k approaches 0, the GEV is unbounded. This can be summarized as the constraint that 1+k*(y-mu)/sigma must be positive.

Simulating Block Maximum Data

The GEV can be defined constructively as the limiting distribution of block maxima (or minima). That is, if you generate a large number of independent random values from a single probability distribution, and take their maximum value, the distribution of that maximum is approximately a GEV.

The original distribution determines the shape parameter, k, of the resulting GEV distribution. Distributions whose tails fall off as a polynomial, such as Student's t, lead to a positive shape parameter. Distributions whose tails decrease exponentially, such as the normal, correspond to a zero shape parameter. Distributions with finite tails, such as the beta, correspond to a negative shape parameter.

Real applications for the GEV might include modelling the largest return for a stock during each month. Here, we will simulate data by taking the maximum of 25 values from a Student's t distribution with two degrees of freedom. The simulated data will include 75 random block maximum values.

```
rng(0,'twister');
y = max(trnd(2,25,75),[],1);
```

Fitting the Distribution by Maximum Likelihood

The function `gevfit` returns both maximum likelihood parameter estimates, and (by default) 95% confidence intervals.

```
[paramEsts,paramCIs] = gevfit(y);

kMLE = paramEsts(1)        % Shape parameter
sigmaMLE = paramEsts(2)    % Scale parameter
muMLE = paramEsts(3)       % Location parameter
```

```
kMLE =

    0.4901

sigmaMLE =

    1.4856

muMLE =

    2.9710
```

```
kCI = paramCIs(:,1)
sigmaCI = paramCIs(:,2)
muCI = paramCIs(:,3)
```

```
kCI =

    0.2020
    0.7782

sigmaCI =

    1.1431
    1.9307

muCI =

    2.5599
    3.3821
```

Notice that the 95% confidence interval for k does not include the value zero. The type I extreme value distribution is apparently not a good model for these data. That makes sense, because the underlying distribution for the simulation had much heavier tails than a normal, and the type II extreme value distribution is theoretically the correct one as the block size becomes large.

As an alternative to confidence intervals, we can also compute an approximation to the asymptotic covariance matrix of the parameter estimates, and from that extract the parameter standard errors.

```
[nll,acov] = gevlike(paramEsts,y);
paramSEs = sqrt(diag(acov))
```

```
paramSEs =

    0.1470
    0.1986
    0.2097
```

Checking the Fit Visually

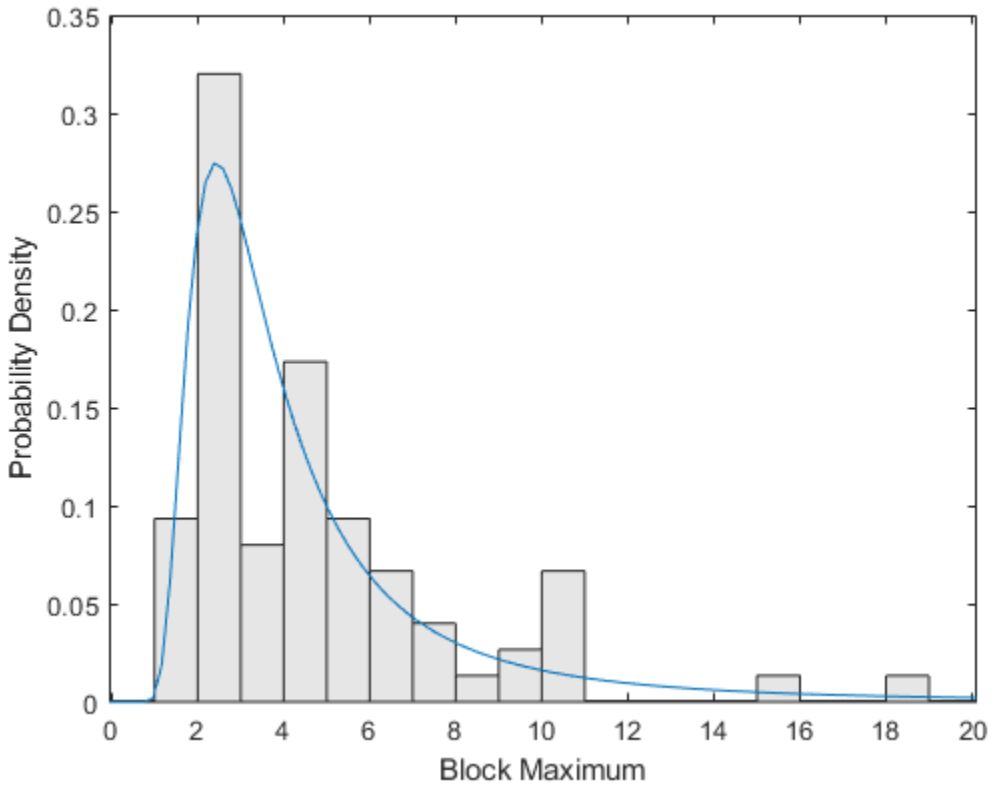
To visually assess how good the fit is, we'll look at plots of the fitted probability density function (PDF) and cumulative distribution function (CDF).

The support of the GEV depends on the parameter values. In this case, the estimate for k is positive, so the fitted distribution has zero probability below a lower bound.

```
lowerBnd = muMLE-sigmaMLE./kMLE;
```

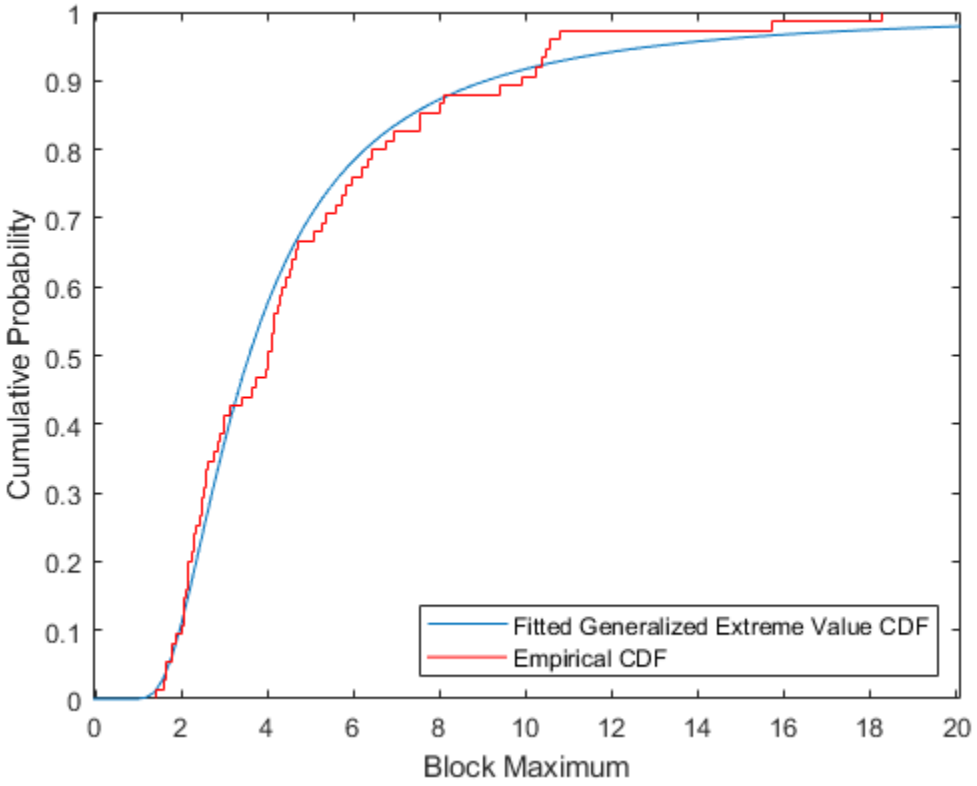
First, we'll plot a scaled histogram of the data, overlaid with the PDF for the fitted GEV model. This histogram is scaled so that the bar heights times their width sum to 1, to make it comparable to the PDF.

```
ymax = 1.1*max(y);
bins = floor(lowerBnd):ceil(ymax);
h = bar(bins,histc(y,bins)/length(y),'histc');
h.FaceColor = [.9 .9 .9];
ygrid = linspace(lowerBnd,ymax,100);
line(ygrid,gevpdf(ygrid,kMLE,sigmaMLE,muMLE));
xlabel('Block Maximum');
ylabel('Probability Density');
xlim([lowerBnd ymax]);
```



We can also compare the fit to the data in terms of cumulative probability, by overlaying the empirical CDF and the fitted CDF.

```
[F,yi] = ecdf(y);
plot(ygrid,gevcdf(ygrid,kMLE,sigmaMLE,muMLE),'-');
hold on;
stairs(yi,F,'r');
hold off;
xlabel('Block Maximum');
ylabel('Cumulative Probability');
legend('Fitted Generalized Extreme Value CDF','Empirical CDF','location','southeast');
xlim([lowerBnd ymax]);
```



Estimating Quantiles of the Model

While the parameter estimates may be important by themselves, a quantile of the fitted GEV model is often the quantity of interest in analyzing block maxima data.

For example, the return level Rm is defined as the block maximum value expected to be exceeded only once in m blocks. That is just the (1-1/m)'th quantile. We can plug the maximum likelihood parameter estimates into the inverse CDF to estimate Rm for m=10.

```
R10MLE = gevinv(1-1./10,kMLE,sigmaMLE,muMLE)
```

```
R10MLE =

    9.0724
```

We could compute confidence limits for R10 using asymptotic approximations, but those may not be valid. Instead, we will use a likelihood-based method to compute confidence limits. This method often produces more accurate results than one based on the estimated covariance matrix of the parameter estimates.

Given any set of values for the parameters mu, sigma, and k, we can compute a log-likelihood -- for example, the MLEs are the parameter values that maximize the GEV log-likelihood. As the parameter values move away from the MLEs, their log-likelihood typically becomes significantly less than the maximum. If we look at the set of parameter values that produce a log-likelihood larger than a specified critical value, this is a complicated region in the parameter space. However, for a suitable

critical value, it is a confidence region for the model parameters. The region contains parameter values that are "compatible with the data". The critical value that determines the region is based on a chi-square approximation, and we'll use 95% as our confidence level. (Note that we will actually work with the negative of the log-likelihood.)

```
nllCritVal = gevlike([kMLE,sigmaMLE,muMLE],y) + .5*chi2inv(.95,1)
```

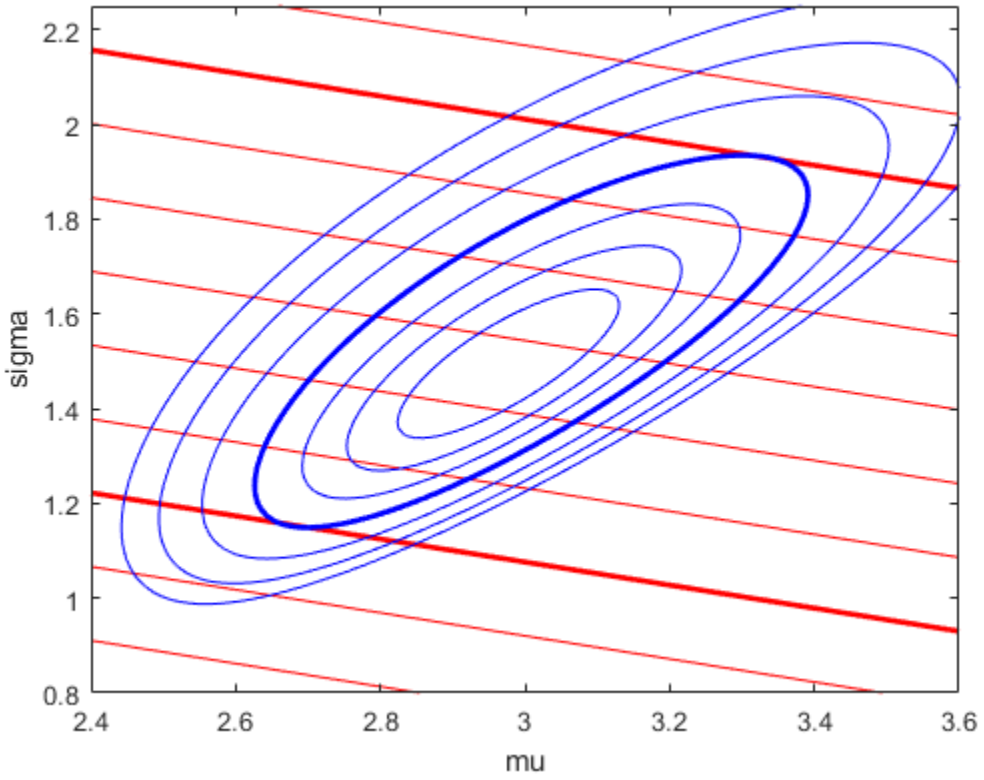
```
nllCritVal =

  170.3044
```

For any set of parameter values mu, sigma, and k, we can compute R10. Therefore, we can find the smallest R10 value achieved within the critical region of the parameter space where the negative log-likelihood is larger than the critical value. That smallest value is the lower likelihood-based confidence limit for R10.

This is difficult to visualize in all three parameter dimensions, but as a thought experiment, we can fix the shape parameter, k, we can see how the procedure would work over the two remaining parameters, sigma and mu.

```
sigmaGrid = linspace(.8, 2.25, 110);
muGrid = linspace(2.4, 3.6);
nllGrid = zeros(length(sigmaGrid),length(muGrid));
R10Grid = zeros(length(sigmaGrid),length(muGrid));
for i = 1:size(nllGrid,1)
    for j = 1:size(nllGrid,2)
        nllGrid(i,j) = gevlike([kMLE,sigmaGrid(i),muGrid(j)],y);
        R10Grid(i,j) = gevinv(1-1./10,kMLE,sigmaGrid(i),muGrid(j));
    end
end
nllGrid(nllGrid>gevlike([kMLE,sigmaMLE,muMLE],y)+6) = NaN;
contour(muGrid,sigmaGrid,R10Grid,6.14:.64:12.14,'LineColor','r');
hold on
contour(muGrid,sigmaGrid,R10Grid,[7.42 11.26],'LineWidth',2,'LineColor','r');
contour(muGrid,sigmaGrid,nllGrid,[168.7 169.1 169.6 170.3:1:173.3],'LineColor','b');
contour(muGrid,sigmaGrid,nllGrid,[nllCritVal nllCritVal],'LineWidth',2,'LineColor','b');
hold off
axis([2.4 3.6 .8 2.25]);
xlabel('mu');
ylabel('sigma');
```



The blue contours represent the log-likelihood surface, and the bold blue contour is the boundary of the critical region. The red contours represent the surface for R10 -- larger values are to the top right, lower to the bottom left. The contours are straight lines because for fixed k, Rm is a linear function of sigma and mu. The bold red contours are the lowest and highest values of R10 that fall within the critical region. In the full three dimensional parameter space, the log-likelihood contours would be ellipsoidal, and the R10 contours would be surfaces.

Finding the lower confidence limit for R10 is an optimization problem with nonlinear inequality constraints, and so we will use the function `fmincon` from the Optimization Toolbox™. We need to find the smallest R10 value, and therefore the objective to be minimized is R10 itself, equal to the inverse CDF evaluated for p=1-1/m. We'll create a wrapper function that computes Rm specifically for m=10.

```
CIobjfun = @(params) gevinv(1-1./10,params(1),params(2),params(3));
```

To perform the constrained optimization, we'll also need a function that defines the constraint, that is, that the negative log-likelihood be less than the critical value. The constraint function should return positive values when the constraint is violated. We'll create an anonymous function, using the simulated data and the critical log-likelihood value. It also returns an empty value because we're not using any equality constraints here.

```
CIconfun = @(params) deal(gevlike(params,y) - nllCritVal, []);
```

Finally, we call `fmincon`, using the active-set algorithm to perform the constrained optimization.

```
opts = optimset('Algorithm','active-set', 'Display','notify', 'MaxFunEvals',500, ...
                'RelLineSrchBnd',.1, 'RelLineSrchBndDuration',Inf);
```

```
[params,R10Lower,flag,output] = ...
    fmincon(CIobjfun,paramEsts,[],[],[],[],[],[],CIconfun,opts);
```

```
Feasible point with lower objective function value found.
```

To find the upper likelihood confidence limit for R10, we simply reverse the sign on the objective function to find the *largest* R10 value in the critical region, and call `fmincon` a second time.

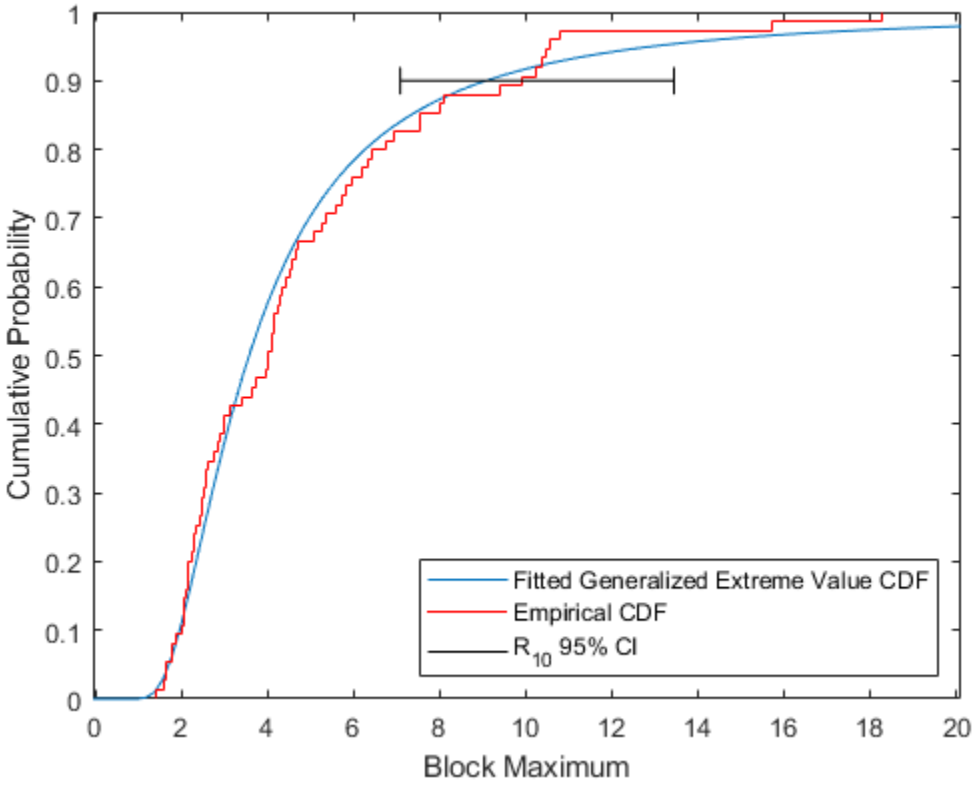
```
CIobjfun = @(params) -gevinv(1-1./10,params(1),params(2),params(3));
[params,R10Upper,flag,output] = ...
    fmincon(CIobjfun,paramEsts,[],[],[],[],[],[],CIconfun,opts);
R10Upper = -R10Upper;

R10CI = [R10Lower, R10Upper]
```

```
R10CI =

    7.0841   13.4452
```

```
plot(ygrid,gevcdf(ygrid,kMLE,sigmaMLE,muMLE),'-');
hold on;
stairs(yi,F,'r');
plot(R10CI([1 1 1 1 2 2 2 2]), [.88 .92 NaN .9 .9 NaN .88 .92],'k-')
hold off;
xlabel('Block Maximum');
ylabel('Cumulative Probability');
legend('Fitted Generalized Extreme Value CDF','Empirical CDF', ...
       'R_{10} 95% CI','location','southeast');
xlim([lowerBnd ymax]);
```



Likelihood Profile for a Quantile

Sometimes just an interval does not give enough information about the quantity being estimated, and a profile likelihood is needed instead. To find the log-likelihood profile for R10, we will fix a possible value for R10, and then maximize the GEV log-likelihood, with the parameters constrained so that they are consistent with that current value of R10. This is a nonlinear equality constraint. If we do that over a range of R10 values, we get a likelihood profile.

As with the likelihood-based confidence interval, we can think about what this procedure would be if we fixed k and worked over the two remaining parameters, sigma and mu. Each red contour line in the contour plot shown earlier represents a fixed value of R10; the profile likelihood optimization consists of stepping along a single R10 contour line to find the highest log-likelihood (blue) contour.

For this example, we'll compute a profile likelihood for R10 over the values that were included in the likelihood confidence interval.

```
R10grid = linspace(R10CI(1)-.05*diff(R10CI), R10CI(2)+.05*diff(R10CI), 51);
```

The objective function for the profile likelihood optimization is simply the log-likelihood, using the simulated data.

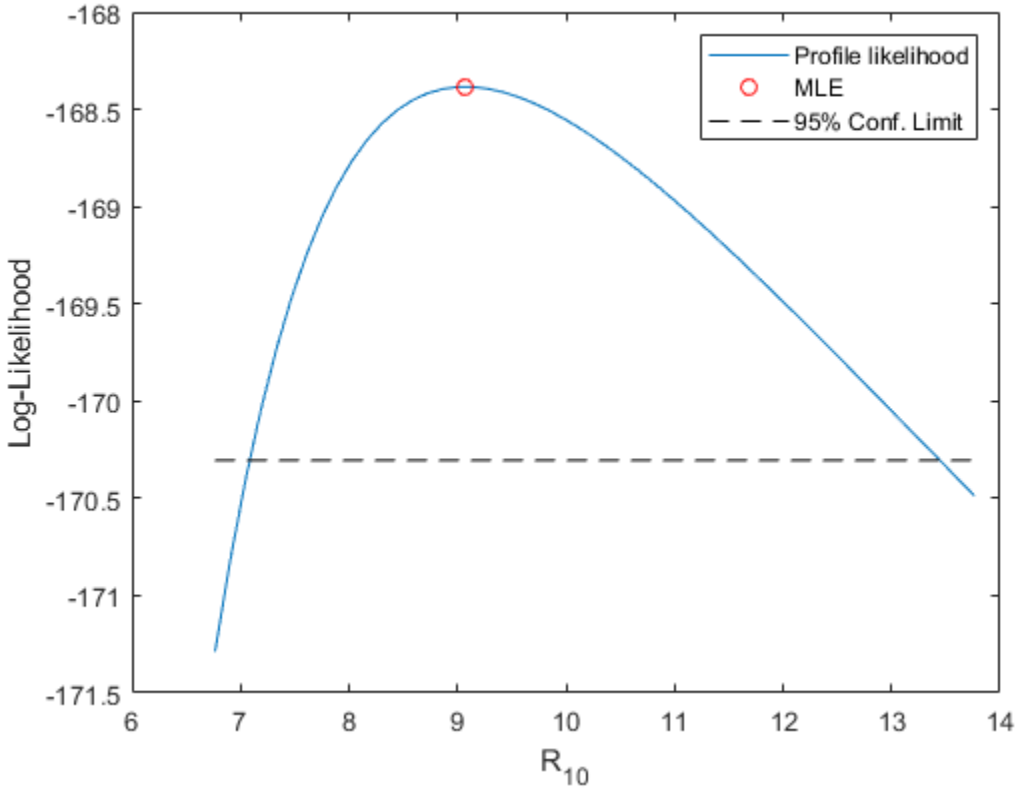
```
PLobjfun = @(params) gevlike(params,y);
```

To use `fmincon`, we'll need a function that returns non-zero values when the constraint is violated, that is, when the parameters are not consistent with the current value of R10. For each value of R10, we'll create an anonymous function for the particular value of R10 under consideration. It also returns an empty value because we're not using any inequality constraints here.

Finally, we'll call `fmincon` at each value of R10, to find the corresponding constrained maximum of the log-likelihood. We'll start near the maximum likelihood estimate of R10, and work out in both directions.

```
Lprof = nan(size(R10grid));
params = paramEsts;
[dum,peak] = min(abs(R10grid-R10MLE));
for i = peak:1:length(R10grid)
    PLconfun = ...
        @(params) deal([], gevinv(1-1./10,params(1),params(2),params(3)) - R10grid(i));
    [params,Lprof(i),flag,output] = ...
        fmincon(PLobjfun,params,[],[],[],[],[],[],PLconfun,opts);
end
params = paramEsts;
for i = peak-1:-1:1
    PLconfun = ...
        @(params) deal([], gevinv(1-1./10,params(1),params(2),params(3)) - R10grid(i));
    [params,Lprof(i),flag,output] = ...
        fmincon(PLobjfun,params,[],[],[],[],[],[],PLconfun,opts);
end

plot(R10grid,-Lprof,'-', R10MLE,-gevlike(paramEsts,y),'ro', ...
     [R10grid(1), R10grid(end)],[-nllCritVal,-nllCritVal],'k--');
xlabel('R_{10}');
ylabel('Log-Likelihood');
legend('Profile likelihood','MLE','95% Conf. Limit');
```



Curve Fitting and Distribution Fitting

This example shows how to perform curve fitting and distribution fitting, and discusses when each method is appropriate.

Choose Between Curve Fitting and Distribution Fitting

Curve fitting and distribution fitting are different types of data analysis.

- Use curve fitting when you want to model a response variable as a function of a predictor variable.
- Use distribution fitting when you want to model the probability distribution of a single variable.

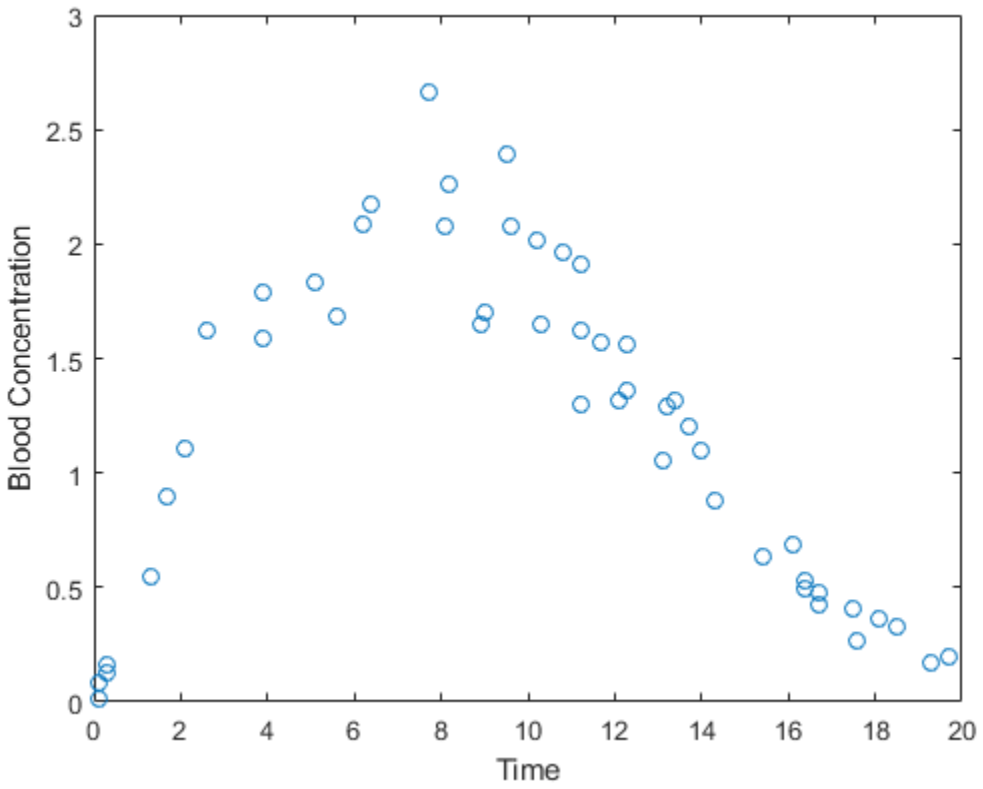
Curve Fitting

In the following experimental data, the predictor variable is `time`, the time after the ingestion of a drug. The response variable is `conc`, the concentration of the drug in the bloodstream. Assume that only the response data `conc` is affected by experimental error.

```
time = [ 0.1   0.1   0.3   0.3   1.3   1.7   2.1   2.6   3.9   3.9 ...
         5.1   5.6   6.2   6.4   7.7   8.1   8.2   8.9   9.0   9.5 ...
         9.6  10.2  10.3  10.8  11.2  11.2  11.2  11.7  12.1  12.3 ...
        12.3  13.1  13.2  13.4  13.7  14.0  14.3  15.4  16.1  16.1 ...
        16.4  16.4  16.7  16.7  17.5  17.6  18.1  18.5  19.3  19.7]';
conc = [0.01  0.08  0.13  0.16  0.55  0.90  1.11  1.62  1.79  1.59 ...
        1.83  1.68  2.09  2.17  2.66  2.08  2.26  1.65  1.70  2.39 ...
        2.08  2.02  1.65  1.96  1.91  1.30  1.62  1.57  1.32  1.56 ...
        1.36  1.05  1.29  1.32  1.20  1.10  0.88  0.63  0.69  0.69 ...
        0.49  0.53  0.42  0.48  0.41  0.27  0.36  0.33  0.17  0.20]';
```

Suppose you want to model blood concentration as a function of time. Plot `conc` against `time`.

```
plot(time,conc,'o');
xlabel('Time');
ylabel('Blood Concentration');
```



Assume that `conc` follows a two-parameter Weibull curve as a function of `time`. A Weibull curve has the form and parameters

$$y = c(x/a)^{(b-1)}e^{-(x/a)^b},$$

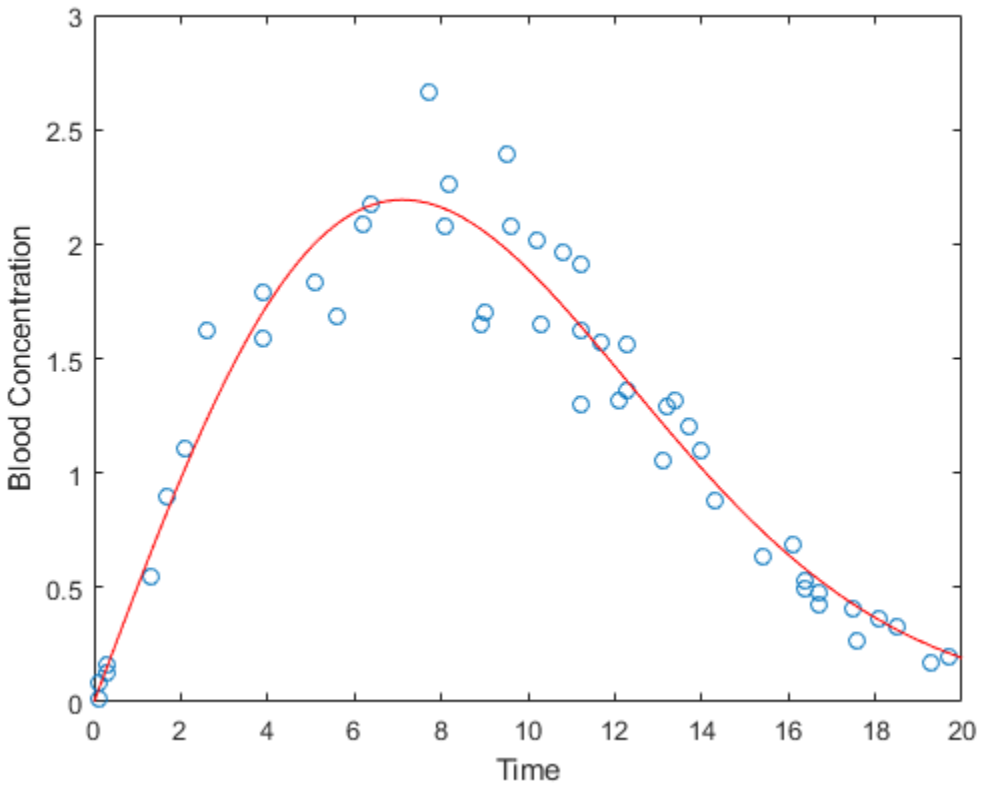
where a is a horizontal scaling, b is a shape parameter, and c is a vertical scaling.

Fit the Weibull model using nonlinear least squares.

```
modelFun =  @(p,x) p(3) .* (x./p(1)).^(p(2)-1) .* exp(-(x./p(1)).^p(2));
startingVals = [10 2 5];
nlModel = fitnlm(time,conc,modelFun,startingVals);
```

Plot the Weibull curve onto the data.

```
xgrid = linspace(0,20,100)';
line(xgrid,predict(nlModel,xgrid),'Color','r');
```



The fitted Weibull model is problematic. `fitnlm` assumes the experimental errors are additive and come from a symmetric distribution with constant variance. However, the scatter plot shows that the error variance is proportional to the height of the curve. Furthermore, the additive, symmetric errors imply that a negative blood concentration measurement is possible.

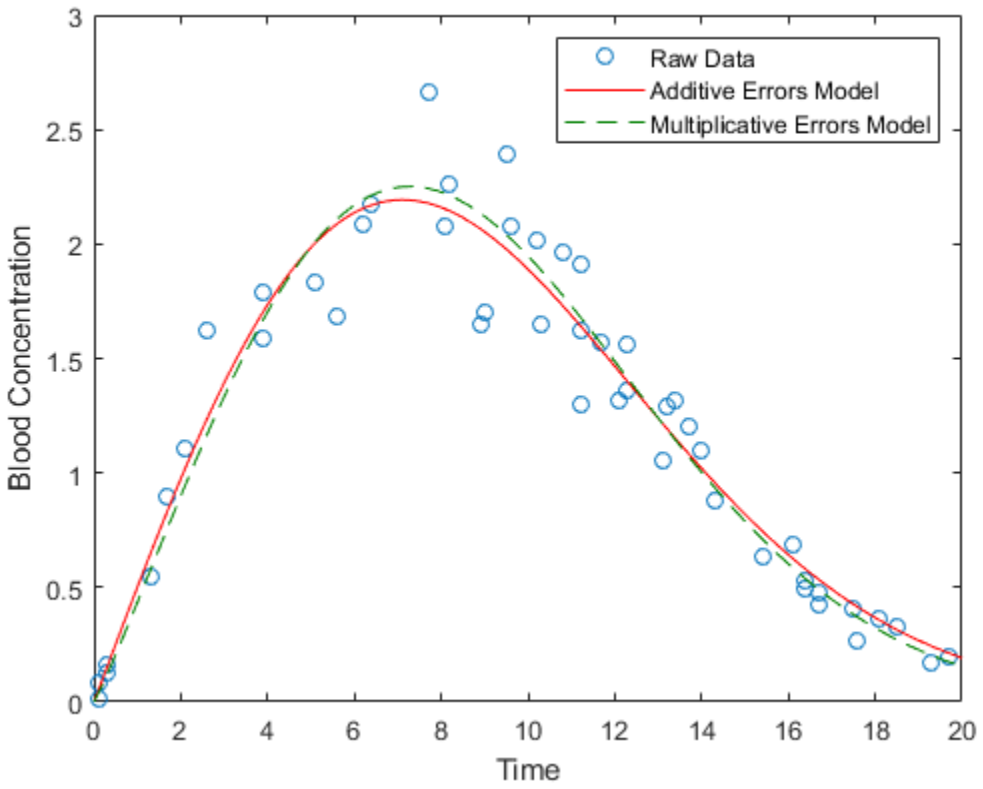
A more realistic assumption is that multiplicative errors are symmetric on the log scale. Under that assumption, fit a Weibull curve to the data by taking the log of both sides. Use nonlinear least squares to fit the curve:

$$\log(y) = \log(c) + (b-1)\log(x/a) - (x/a)^b .$$

```
nlModel2 = fitnlm(time,log(conc),@(p,x) log(modelFun(p,x)),startingVals);
```

Add the new curve to the existing plot.

```
line(xgrid,exp(predict(nlModel2,xgrid)),'Color',[0 .5 0],'LineStyle','--');
legend({'Raw Data','Additive Errors Model','Multiplicative Errors Model'});
```



The model object `nlModel2` contains estimates of precision. A best practice is to check the model's goodness of fit. For example, make residual plots on the log scale to check the assumption of constant variance for the multiplicative errors.

In this example, using the multiplicative errors model has little effect on the model predictions. For an example where the type of model has more of an impact, see “Pitfalls in Fitting Nonlinear Models by Transforming to Linearity” on page 13-53.

Functions for Curve Fitting

- Statistics and Machine Learning Toolbox™ includes these functions for fitting models: `fitnlm` for nonlinear least-squares models, `fitglm` for generalized linear models, `fitrgp` for Gaussian process regression models, and `fitrsvm` for support vector machine regression models.
- Curve Fitting Toolbox™ provides command line and graphical tools that simplify tasks in curve fitting. For example, the toolbox provides automatic choice of starting coefficient values for various models, as well as robust and nonparametric fitting methods.
- Optimization Toolbox™ has functions for performing complicated types of curve fitting analyses, such as analyzing models with constraints on the coefficients.
- The MATLAB® function `polyfit` fits polynomial models, and the MATLAB function `fminsearch` is useful in other kinds of curve fitting.

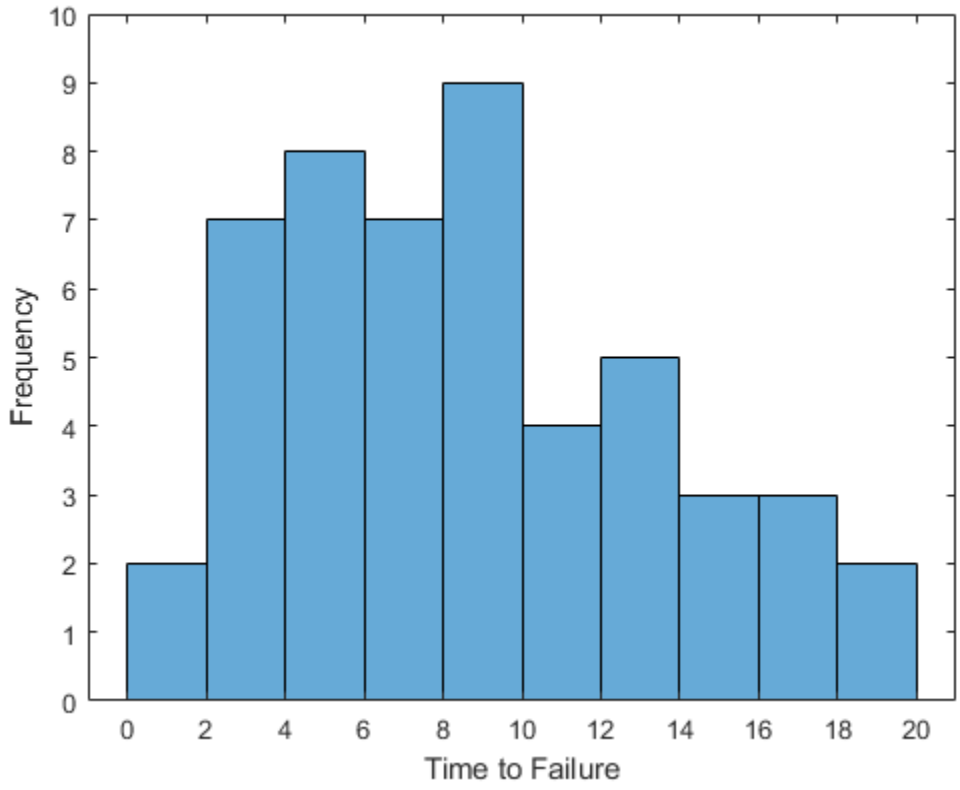
Distribution Fitting

Suppose you want to model the distribution of electrical component lifetimes. The variable `life` measures the time to failure for 50 identical electrical components.

```
life = [ 6.2 16.1 16.3 19.0 12.2  8.1  8.8  5.9  7.3  8.2 ...
        16.1 12.8  9.8 11.3  5.1 10.8  6.7  1.2  8.3  2.3 ...
         4.3  2.9 14.8  4.6  3.1 13.6 14.5  5.2  5.7  6.5 ...
         5.3  6.4  3.5 11.4  9.3 12.4 18.3 15.9  4.0 10.4 ...
         8.7  3.0 12.1  3.9  6.5  3.4  8.5  0.9  9.9  7.9]';
```

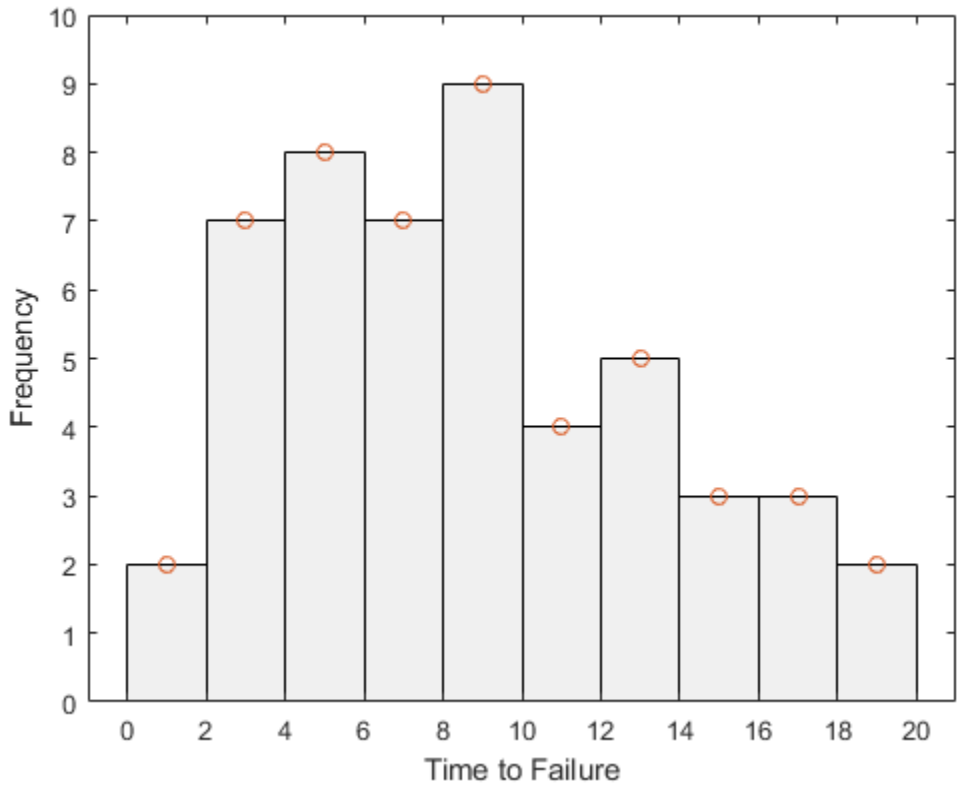
Visualize the data with a histogram.

```
binWidth = 2;
lastVal = ceil(max(life));
binEdges = 0:binWidth:lastVal+1;
h = histogram(life,binEdges);
xlabel('Time to Failure');
ylabel('Frequency');
ylim([0 10]);
```



Because lifetime data often follows a Weibull distribution, one approach might be to use the Weibull curve from the previous curve fitting example to fit the histogram. To try this approach, convert the histogram to a set of points (x,y), where x is a bin center and y is a bin height, and then fit a curve to those points.

```
counts = histcounts(life,binEdges);
binCtrs = binEdges(1:end-1) + binWidth/2;
h.FaceColor = [.9 .9 .9];
hold on
plot(binCtrs,counts,'o');
hold off
```



Fitting a curve to a histogram, however, is problematic and usually not recommended.

1. The process violates basic assumptions of least-squares fitting. The bin counts are nonnegative, implying that measurement errors cannot be symmetric. Also, the bin counts have different variability in the tails than in the center of the distribution. Finally, the bin counts have a fixed sum, implying that they are not independent measurements.
2. If you fit a Weibull curve to the bar heights, you have to constrain the curve because the histogram is a scaled version of an empirical probability density function (pdf).
3. For continuous data, fitting a curve to a histogram rather than data discards information.
4. The bar heights in the histogram are dependent on the choice of bin edges and bin widths.

For many parametric distributions, maximum likelihood is a better way to estimate parameters because it avoids these problems. The Weibull pdf has almost the same form as the Weibull curve:

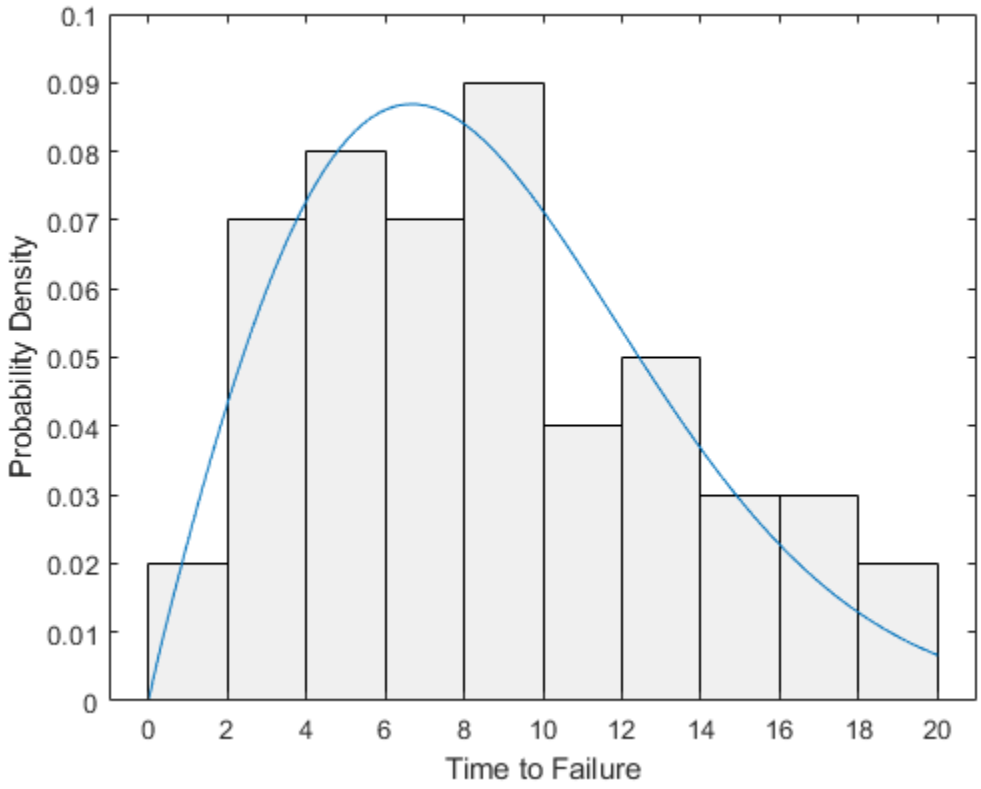
$$y = (b/a)(x/a)^{(b-1)}e^{-(x/a)^b}.$$

However, b/a replaces the scale parameter c because the function must integrate to 1. To fit a Weibull distribution to the data using maximum likelihood, use `fitdist` and specify `'Weibull'` as the distribution name. Unlike least squares, maximum likelihood finds a Weibull pdf that best matches the scaled histogram without minimizing the sum of the squared differences between the pdf and the bar heights.

```
pd = fitdist(life,'Weibull');
```

Plot a scaled histogram of the data and superimpose the fitted pdf.

```
h = histogram(life,binEdges,'Normalization','pdf','FaceColor',[.9 .9 .9]);
xlabel('Time to Failure');
ylabel('Probability Density');
ylim([0 0.1]);
xgrid = linspace(0,20,100)';
pdfEst = pdf(pd,xgrid);
line(xgrid,pdfEst)
```



A best practice is to check the model's goodness of fit.

Although fitting a curve to a histogram is usually not recommended, the process is appropriate in some cases. For an example, see “Fitting Custom Univariate Distributions” on page 5-165.

Functions for Distribution Fitting

- Statistics and Machine Learning Toolbox™ includes the function `fitdist` for fitting probability distribution objects to data. It also includes dedicated fitting functions (such as `wblfit`) for fitting parametric distributions using maximum likelihood, the function `mle` for fitting custom distributions without dedicated fitting functions, and the function `ksdensity` for fitting nonparametric distribution models to data.
- Statistics and Machine Learning Toolbox additionally provides the Distribution Fitter app, which simplifies many tasks in distribution fitting, such as generating visualizations and diagnostic plots.
- Functions in Optimization Toolbox™ enable you to fit complicated distributions, including those with constraints on the parameters.

- The MATLAB® function `fminsearch` provides maximum likelihood distribution fitting.

More About

- “Supported Distributions” on page 5-14

Fitting a Univariate Distribution Using Cumulative Probabilities

This example shows how to fit univariate distributions using least squares estimates of the cumulative distribution functions. This is a generally-applicable method that can be useful in cases when maximum likelihood fails, for instance some models that include a threshold parameter.

The most common method for fitting a univariate distribution to data is maximum likelihood. But maximum likelihood does not work in all cases, and other estimation methods, such as the Method of Moments, are sometimes needed. When applicable, maximum likelihood is probably the better choice of methods, because it is often more efficient. But the method described here provides another tool that can be used when needed.

Fitting an Exponential Distribution Using Least Squares

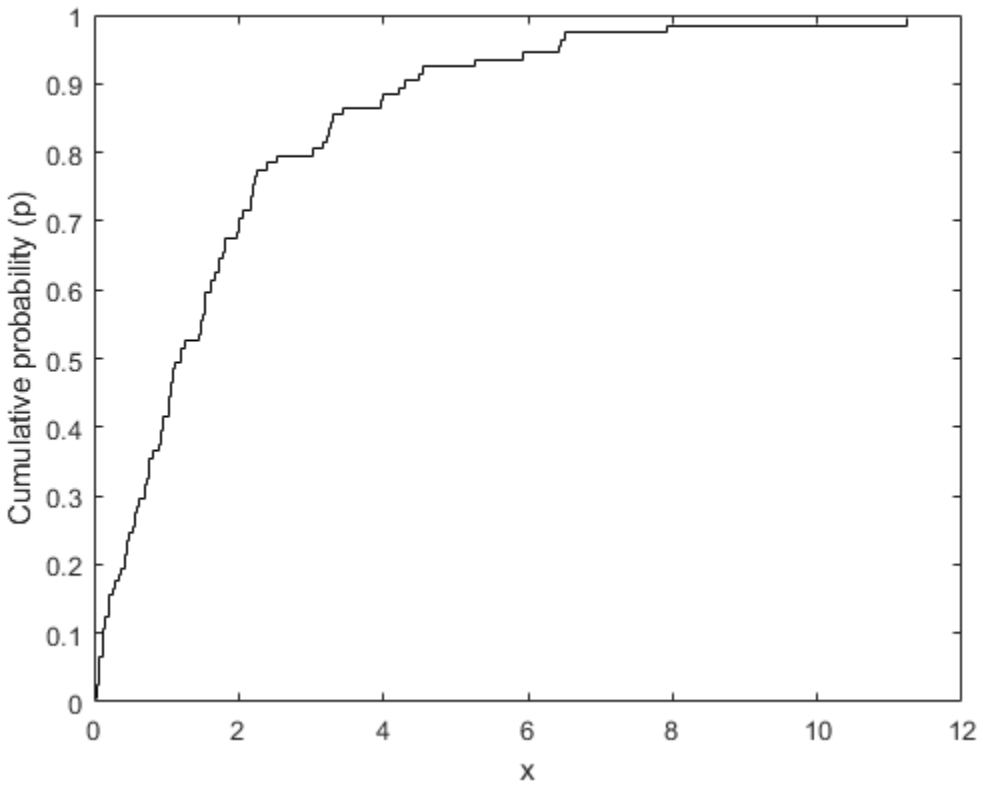
The term "least squares" is most commonly used in the context of fitting a regression line or surface to model a response variable as a function of one or more predictor variables. The method described here is a very different application of least squares: univariate distribution fitting, with only a single variable.

To begin, first simulate some sample data. We'll use an exponential distribution to generate the data. For the purposes of this example, as in practice, we'll assume that the data are not known to have come from a particular model.

```
rng(37,'twister');
n = 100;
x = exprnd(2,n,1);
```

Next, compute the empirical cumulative distribution function (ECDF) of the data. This is simply a step function with a jump in cumulative probability, p, of 1/n at each data point, x.

```
x = sort(x);
p = ((1:n)-0.5)' ./ n;
stairs(x,p,'k-');
xlabel('x');
ylabel('Cumulative probability (p)');
```



We'll fit an exponential distribution to these data. One way to do that is to find the exponential distribution whose cumulative distribution function (CDF) best approximates (in a sense to be explained below) the ECDF of the data. The exponential CDF is p = Pr{X <= x} = 1 - exp(-x/mu). Transforming that to -log(1-p)*mu = x gives a linear relationship between -log(1-p) and x. If the data do come from an exponential, we ought to see, at least approximately, a linear relationship if we plug the computed x and p values from the ECDF into that equation. If we use least squares to fit a straight line through the origin to x vs. -log(1-p), then that fitted line represents the exponential distribution that is "closest" to the data. The slope of the line is an estimate of the parameter mu.

Equivalently, we can think of y = -log(1-p) as an "idealized sample" from a standard (mean 1) exponential distribution. These idealized values are exactly equally spaced on the probability scale. A Q-Q plot of x and y ought to be approximately linear if the data come from an exponential distribution, and we'll fit the least squares line through the origin to x vs. y.

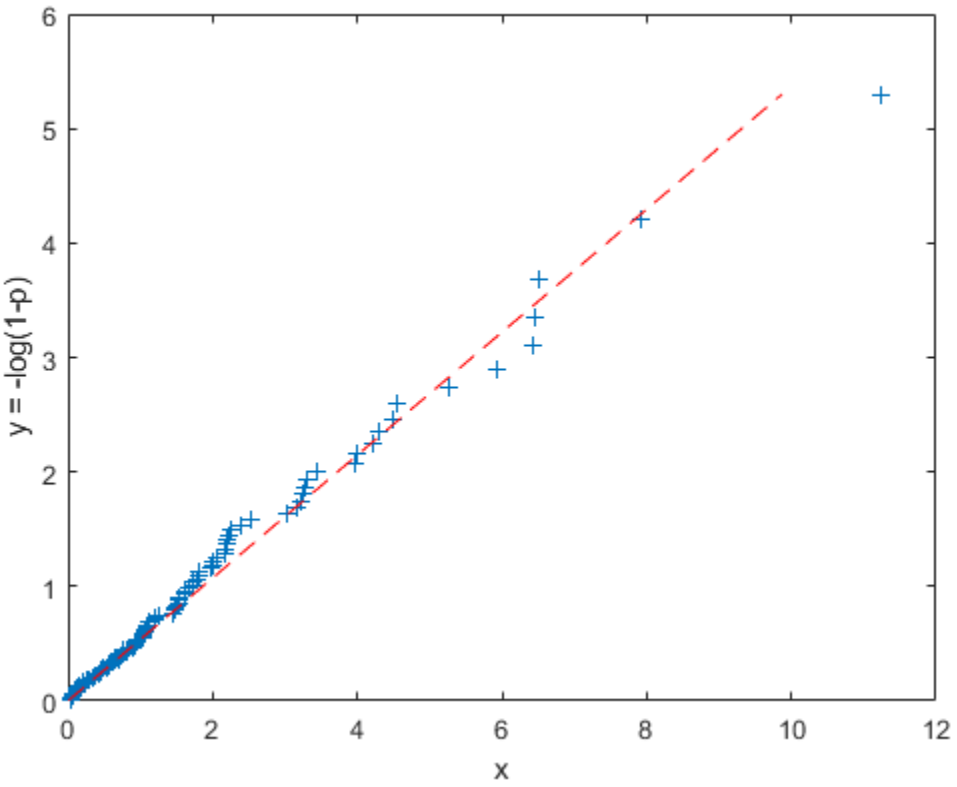
```
y = -log(1 - p);
muHat = y \ x
```

```
muHat =

    1.8627
```

Plot the data and the fitted line.

```
plot(x,y,'+', y*muHat,y,'r--');
xlabel('x');
ylabel('y = -log(1-p)');
```



Notice that the linear fit we've made minimizes the sum of squared errors in the horizontal, or "x", direction. That's because the values for y = -log(1-p) are deterministic, and it's the x values that are random. It's also possible to regress y vs. x, or to use other types of linear fits, for example, weighted regression, orthogonal regression, or even robust regression. We will not explore those possibilities here.

For comparison, fit the data by maximum likelihood.

```
muMLE = expfit(x)
```

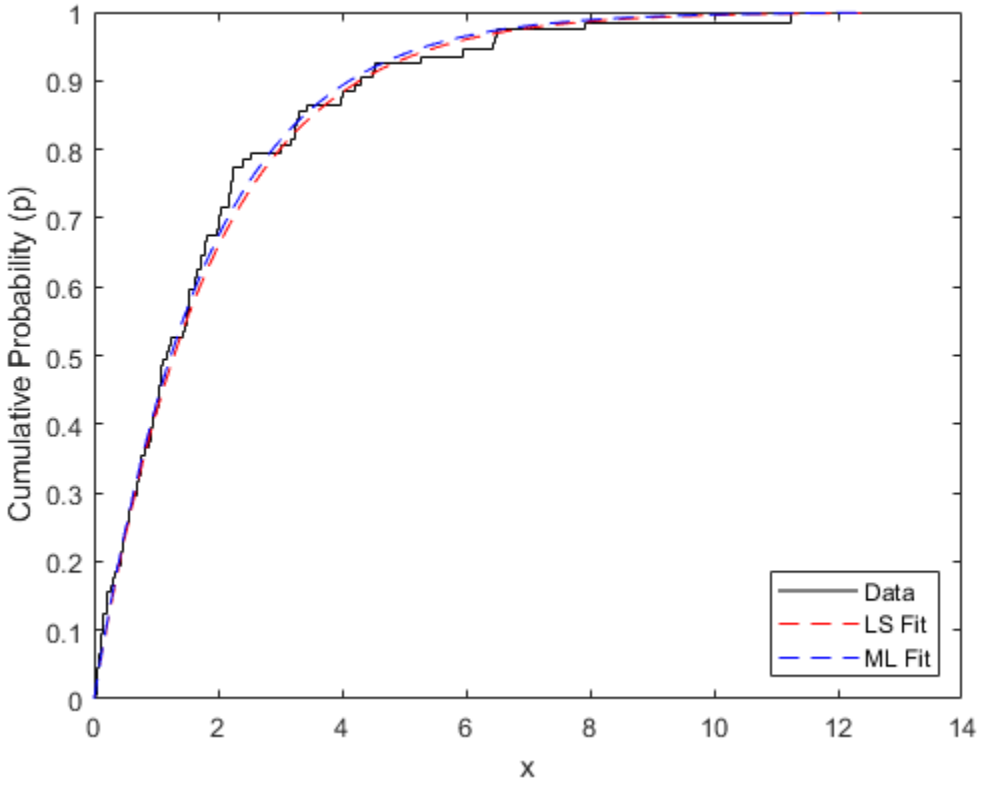
```
muMLE =

    1.7894
```

Now plot the two estimated distributions on the untransformed cumulative probability scale.

```
stairs(x,p,'k-');
hold on
xgrid = linspace(0,1.1*max(x),100)';
plot(xgrid,expcdf(xgrid,muHat),'r--', xgrid,expcdf(xgrid,muMLE),'b--');
hold off
```

```
xlabel('x'); ylabel('Cumulative Probability (p)');
legend({'Data','LS Fit','ML Fit'},'location','southeast');
```



The two methods give very similar fitted distributions, although the LS fit has been influenced more by observations in the tail of the distribution.

Fitting a Weibull Distribution

For a slightly more complex example, simulate some sample data from a Weibull distribution, and compute the ECDF of x.

```
n = 100;
x = wblrnd(2,1,n,1);
x = sort(x);
p = ((1:n)-0.5)' ./ n;
```

To fit a Weibull distribution to these data, notice that the CDF for the Weibull is p = Pr{X <= x} = 1 - exp(-(x/a)^b). Transforming that to log(a) + log(-log(1-p))*(1/b) = log(x) again gives a linear relationship, this time between log(-log(1-p)) and log(x). We can use least squares to fit a straight line on the transformed scale using p and x from the ECDF, and the slope and intercept of that line lead to estimates of a and b.

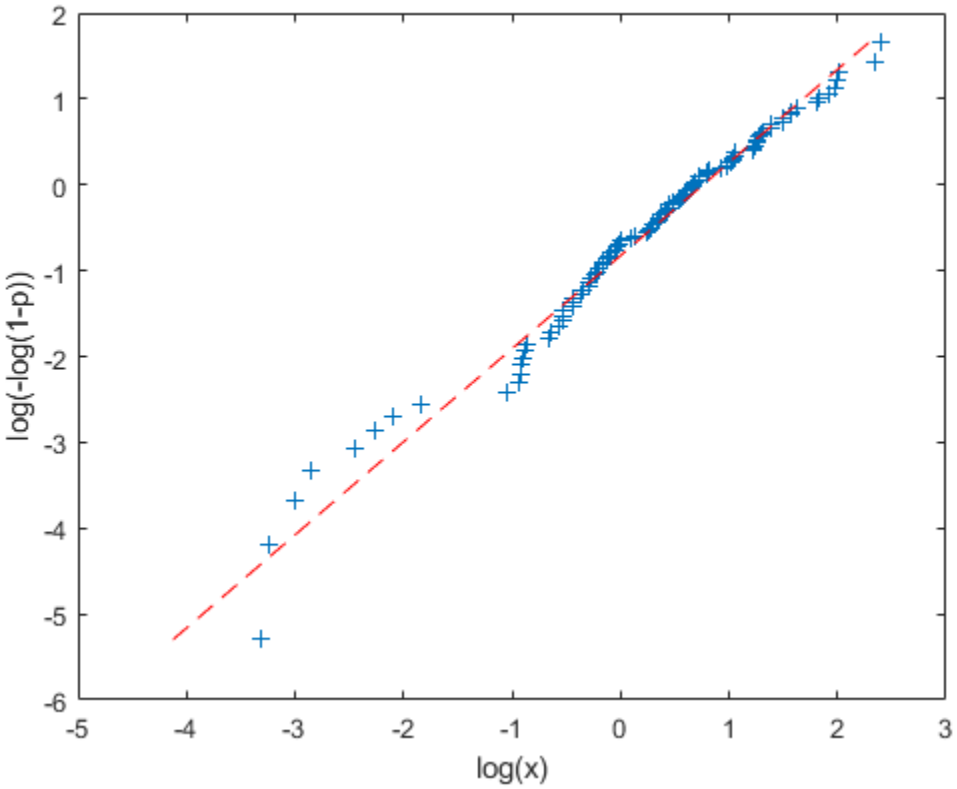
```
logx = log(x);
logy = log(-log(1 - p));
poly = polyfit(logy,logx,1);
paramHat = [exp(poly(2)) 1/poly(1)]
```

```
paramHat =

    2.1420    1.0843
```

Plot the data and the fitted line on the transformed scale.

```
plot(logx,logy,'+', log(paramHat(1)) + logy/paramHat(2),logy,'r--');
xlabel('log(x)');
ylabel('log(-log(1-p))');
```

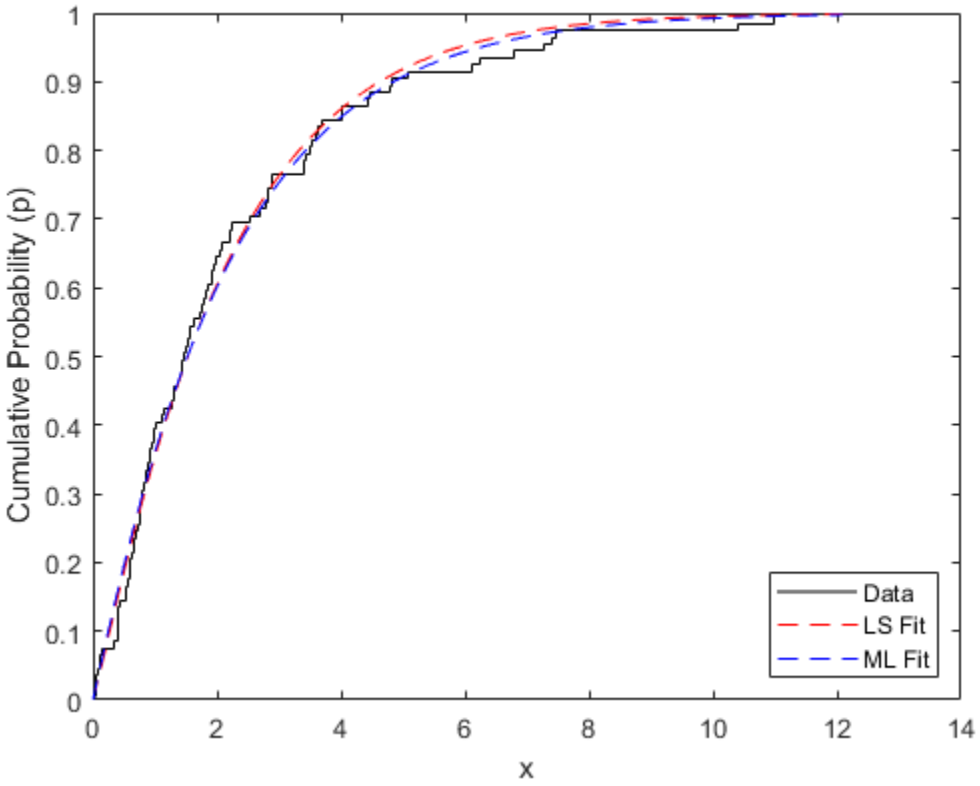


For comparison, fit the data by maximum likelihood, and plot the two estimated distributions on the untransformed scale.

```
paramMLE = wblfit(x)
stairs(x,p,'k');
hold on
xgrid = linspace(0,1.1*max(x),100)';
plot(xgrid,wblcdf(xgrid,paramHat(1),paramHat(2)),'r--', ...
     xgrid,wblcdf(xgrid,paramMLE(1),paramMLE(2)),'b--');
hold off
xlabel('x'); ylabel('Cumulative Probability (p)');
legend({'Data','LS Fit','ML Fit'},'location','southeast');
```

```
paramMLE =
```

```
    2.1685    1.0372
```

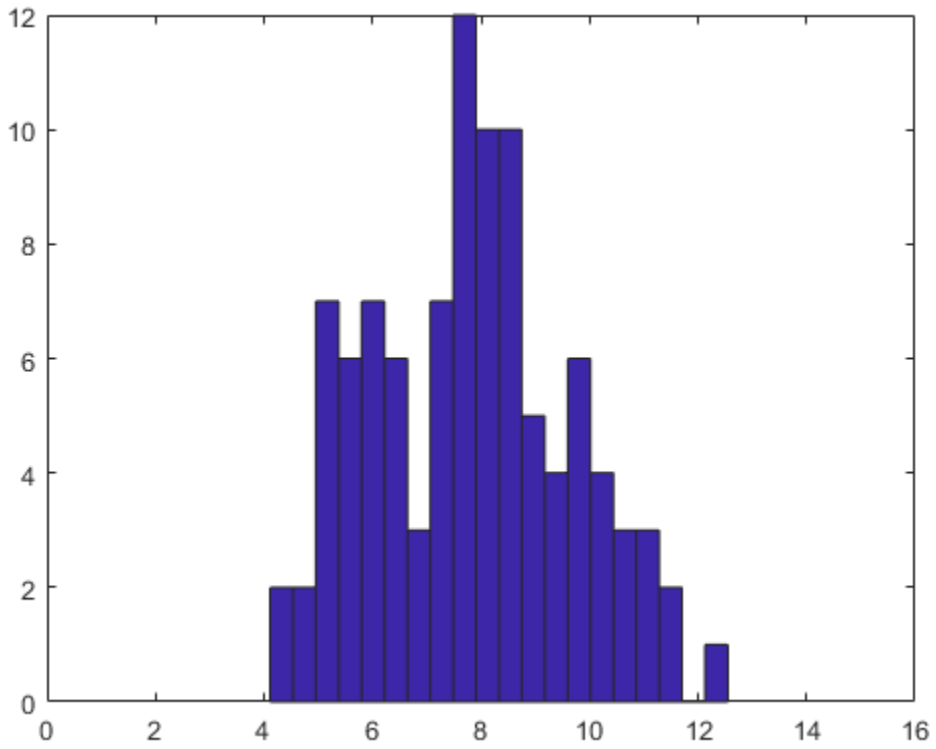


A Threshold Parameter Example

It's sometimes necessary to fit positive distributions like the Weibull or lognormal with a threshold parameter. For example, a Weibull random variable takes values over (0,Inf), and a threshold parameter, c, shifts that range to (c,Inf). If the threshold parameter is known, then there is no difficulty. But if the threshold parameter is not known, it must instead be estimated. These models are difficult to fit with maximum likelihood -- the likelihood can have multiple modes, or even become infinite for parameter values that are not reasonable for the data, and so maximum likelihood is often not a good method. But with a small addition to the least squares procedure, we can get stable estimates.

To illustrate, we'll simulate some data from a three-parameter Weibull distribution, with a threshold value. As above, we'll assume for the purposes of the example that the data are not known to have come from a particular model, and that the threshold is not known.

```
n = 100;
x = wblrnd(4,2,n,1) + 4;
hist(x,20); xlim([0 16]);
```

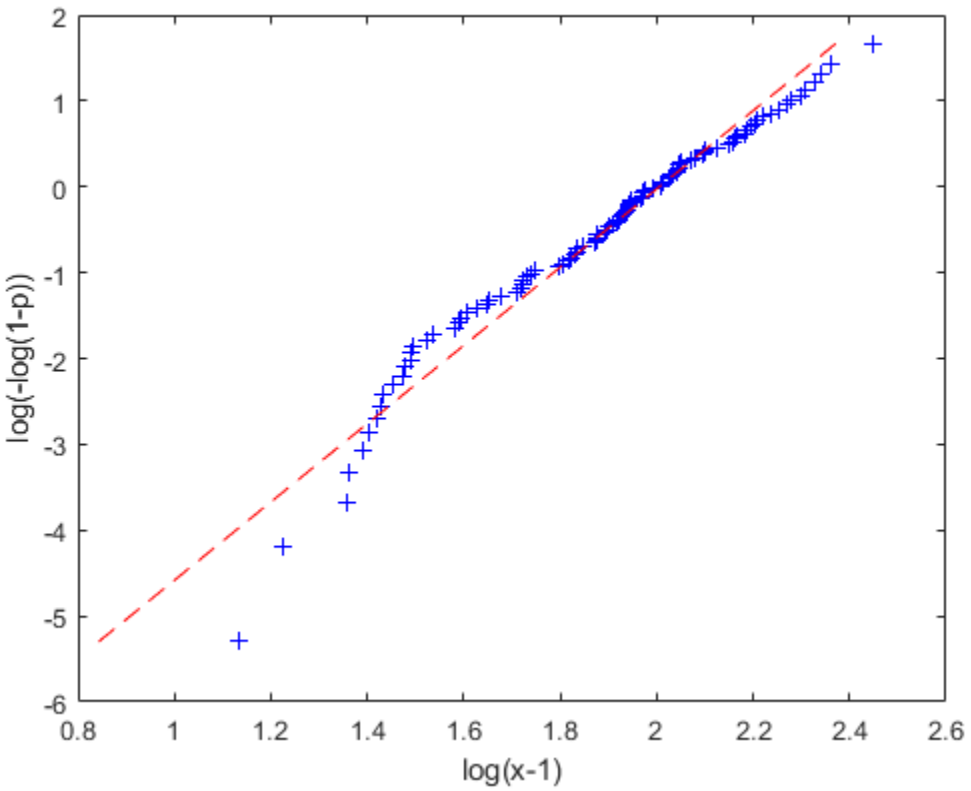


How can we fit a three-parameter Weibull distribution to these data? If we knew what the threshold value was, 1 for example, we could subtract that value from the data and then use the least squares procedure to estimate the Weibull shape and scale parameters.

```
x = sort(x);
p = ((1:n)-0.5)' ./ n;
logy = log(-log(1-p));
logxm1 = log(x-1);
poly1 = polyfit(log(-log(1-p)),log(x-1),1);
paramHat1 = [exp(poly1(2)) 1/poly1(1)]
plot(logxm1,logy,'b+', log(paramHat1(1)) + logy/paramHat1(2),logy,'r--');
xlabel('log(x-1)');
ylabel('log(-log(1-p))');
```

```
paramHat1 =

    7.4305    4.5574
```



That's not a very good fit -- log(x-1) and log(-log(1-p)) do not have a linear relationship. Of course, that's because we don't know the correct threshold value. If we try subtracting different threshold values, we get different plots and different parameter estimates.

```
logxm2 = log(x-2);
poly2 = polyfit(log(-log(1-p)),log(x-2),1);
paramHat2 = [exp(poly2(2)) 1/poly2(1)]
```

```
paramHat2 =

    6.4046    3.7690
```

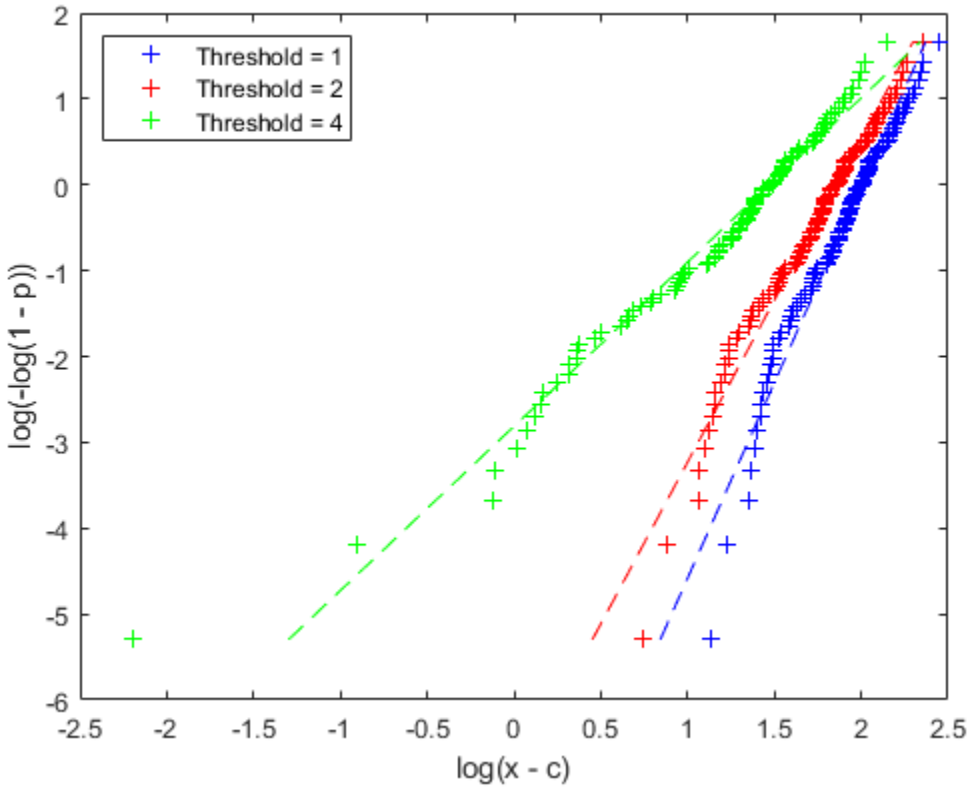
```
logxm4 = log(x-4);
poly4 = polyfit(log(-log(1-p)),log(x-4),1);
paramHat4 = [exp(poly4(2)) 1/poly4(1)]
```

```
paramHat4 =

    4.3530    1.9130
```

```
plot(logxm1,logy,'b+', logxm2,logy,'r+', logxm4,logy,'g+', ...
     log(paramHat1(1)) + logy/paramHat1(2),logy,'b--', ...
     log(paramHat2(1)) + logy/paramHat2(2),logy,'r--', ...
     log(paramHat4(1)) + logy/paramHat4(2),logy,'g--');
```

```
xlabel('log(x - c)');
ylabel('log(-log(1 - p))');
legend({'Threshold = 1' 'Threshold = 2' 'Threshold = 4'}, 'location','northwest');
```



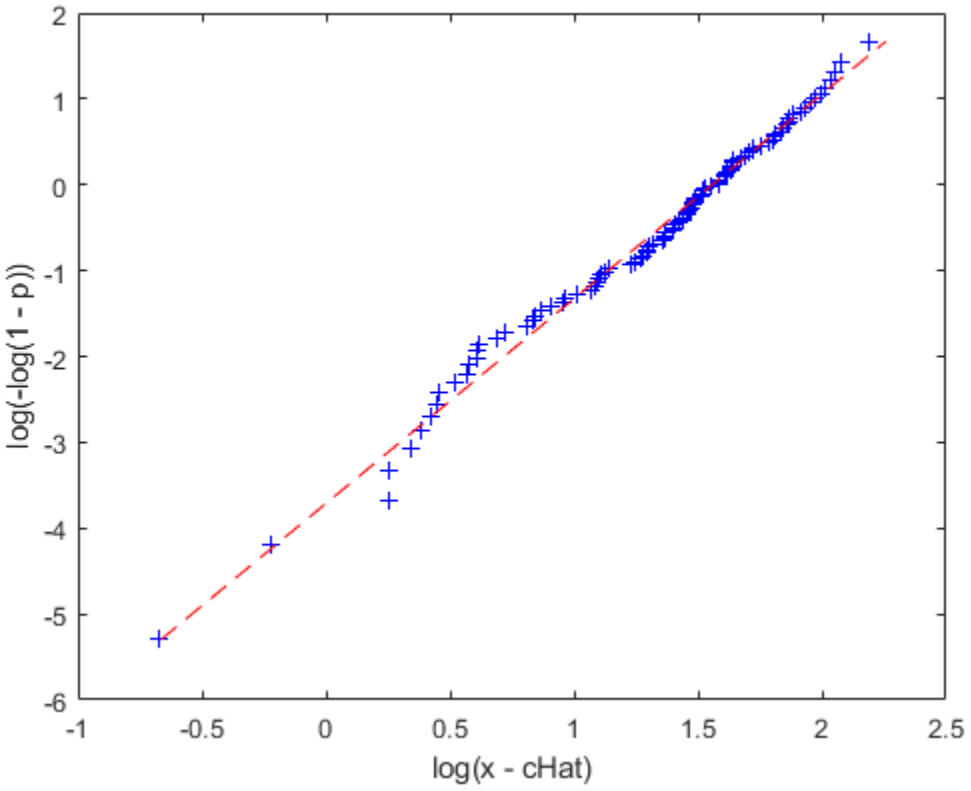
The relationship between log(x-4) and log(-log(1-p)) appears approximately linear. Since we'd expect to see an approximately linear plot if we subtracted the true threshold parameter, this is evidence that 4 might be a reasonable value for the threshold. On the other hand, the plots for 2 and 3 differ more systematically from linear, which is evidence that those values are not consistent with the data.

This argument can be formalized. For each provisional value of the threshold parameter, the corresponding provisional Weibull fit can be characterized as the parameter values that maximize the R^2 value of a linear regression on the transformed variables log(x-c) and log(-log(1-p)). To estimate the threshold parameter, we can carry that one step further, and maximize the R^2 value over all possible threshold values.

```
r2 = @(x,y) 1 - norm(y - polyval(polyfit(x,y,1),x)).^2 / norm(y - mean(y)).^2;
threshObj = @(c) -r2(log(-log(1-p)),log(x-c));
cHat = fminbnd(threshObj,.75*min(x), .9999*min(x));
poly = polyfit(log(-log(1-p)),log(x-cHat),1);
paramHat = [exp(poly(2)) 1/poly(1) cHat]
logx = log(x-cHat);
logy = log(-log(1-p));
plot(logx,logy,'b+', log(paramHat(1)) + logy/paramHat(2),logy,'r--');
xlabel('log(x - cHat)');
ylabel('log(-log(1 - p))');
```

```
paramHat =

    4.7448    2.3839    3.6029
```



Non-Location-Scale Families

The exponential distribution is a scale family, and on the log scale, the Weibull distribution is a location-scale family, so this least squares method was straightforward in those two cases. The general procedure to fit a location-scale distribution is

- Compute the ECDF of the observed data.
- Transform the distribution's CDF to get a linear relationship between some function of the data and some function of the cumulative probability. These two functions do not involve the distribution parameters, but the slope and intercept of the line do.
- Plug the values of x and p from the ECDF into that transformed CDF, and fit a straight line using least squares.
- Solve for the distribution parameters in terms of the slope and intercept of the line.

We also saw that fitting a distribution that is a location-scale family with an additional a threshold parameter is only slightly more difficult.

But other distributions that are not location-scale families, like the gamma, are a bit trickier. There's no transformation of the CDF that will give a relationship that is linear. However, we can use a similar

idea, only this time working on the untransformed cumulative probability scale. A P-P plot is the appropriate way to visualize that fitting procedure.

If the empirical probabilities from the ECDF are plotted against fitted probabilities from a parametric model, a tight scatter along the 1:1 line from zero to one indicates that the parameter values define a distribution that explains the observed data well, because the fitted CDF approximates the empirical CDF well. The idea is to find parameter values that make the probability plot as close to the 1:1 line as possible. That may not even be possible, if the distribution is not a good model for the data. If the P-P plot shows a systematic departure from the 1:1 line, then the model may be questionable. However, it's important to remember that since the points in these plots are not independent, interpretation is not exactly the same as a regression residual plot.

For example, we'll simulate some data and fit a gamma distribution.

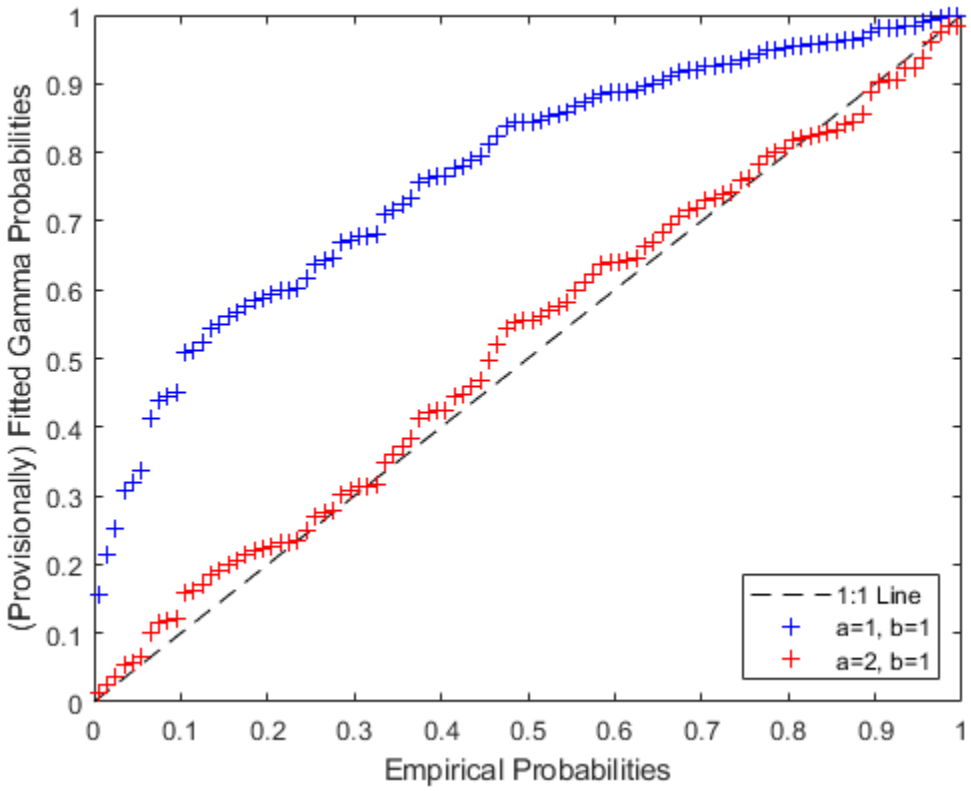
```
n = 100;
x = gamrnd(2,1,n,1);
```

Compute the ECDF of x.

```
x = sort(x);
pEmp = ((1:n)-0.5)' ./ n;
```

We can make a probability plot using any initial guess for the gamma distribution's parameters, a=1 and b=1, say. That guess is not very good -- the probabilities from the parametric CDF are not close to the probabilities from the ECDF. If we tried a different a and b, we'd get a different scatter on the P-P plot, with a different discrepancy from the 1:1 line. Since we know the true a and b in this example, we'll try those values.

```
a0 = 1; b0 = 1;
p0Fit = gamcdf(x,a0,b0);
a1 = 2; b1 = 1;
p1Fit = gamcdf(x,a1,b1);
plot([0 1],[0 1],'k--', pEmp,p0Fit,'b+', pEmp,p1Fit,'r+');
xlabel('Empirical Probabilities');
ylabel('(Provisionally) Fitted Gamma Probabilities');
legend({'1:1 Line','a=1, b=1', 'a=2, b=1'}, 'location','southeast');
```



The second set of values for a and b make for a much better plot, and thus are more compatible with the data, if you are measuring "compatible" by how straight you can make the P-P plot.

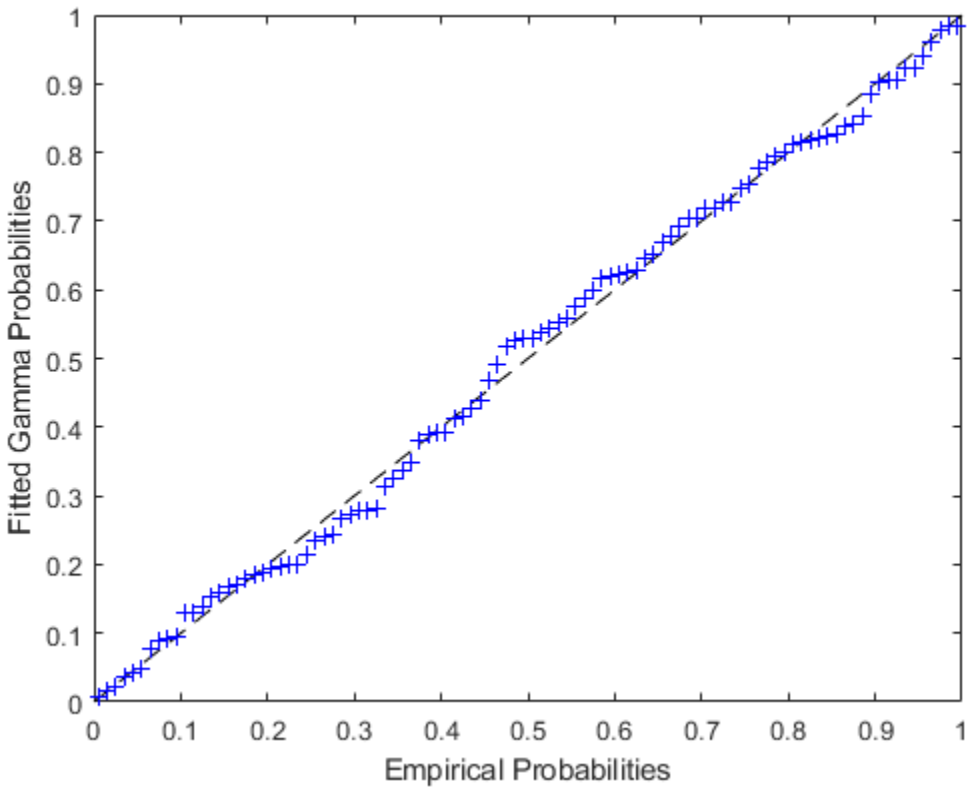
To make the scatter match the 1:1 line as closely possible, we can find the values of a and b that minimize a weighted sum of the squared distances to the 1:1 line. The weights are defined in terms of the empirical probabilities, and are lowest in the center of the plot and highest at the extremes. These weights compensate for the variance of the fitted probabilities, which is highest near the median and lowest in the tails. This weighted least squares procedure defines the estimator for a and b.

```
wgt = 1 ./ sqrt(pEmp.*(1-pEmp));
gammaObj = @(params) sum(wgt.*(gamcdf(x,exp(params(1)),exp(params(2)))-pEmp).^2);
paramHat = fminsearch(gammaObj,[log(a1),log(b1)]);
paramHat = exp(paramHat)
```

```
paramHat =

    2.2759    0.9059
```

```
pFit = gamcdf(x,paramHat(1),paramHat(2));
plot([0 1],[0 1],'k--', pEmp,pFit,'b+');
xlabel('Empirical Probabilities');
ylabel('Fitted Gamma Probabilities');
```



Notice that in the location-scale cases considered earlier, we could fit the distribution with a single straight line fit. Here, as with the threshold parameter example, we had to iteratively find the best-fit parameter values.

Model Misspecification

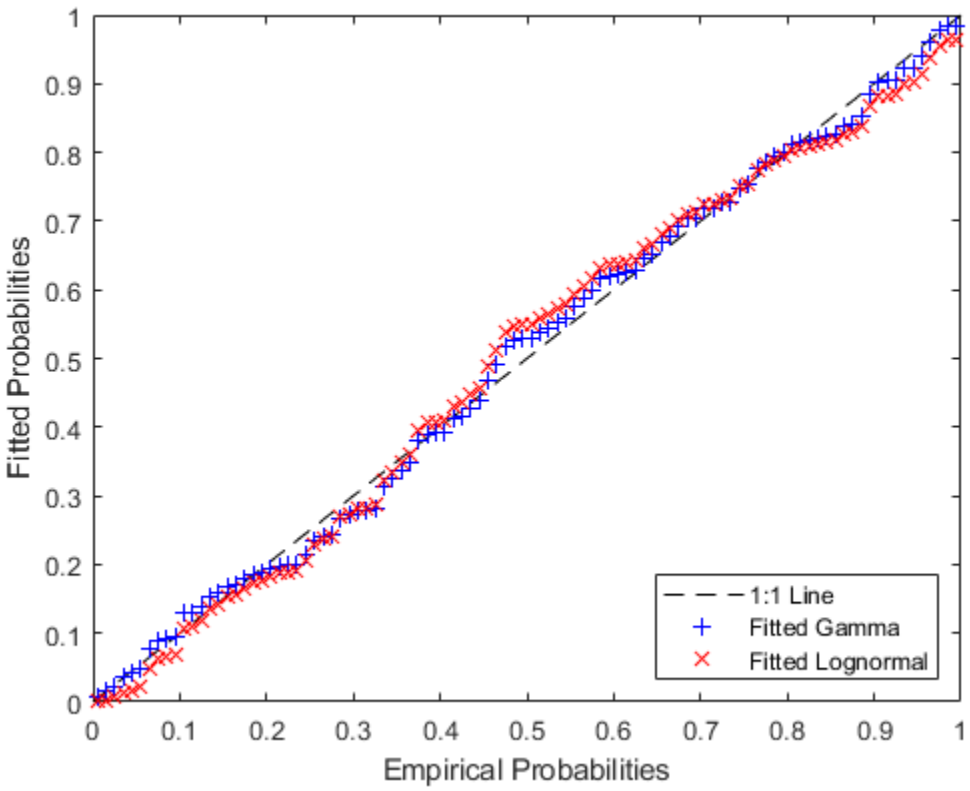
The P-P plot can also be useful for comparing fits from different distribution families. What happens if we try to fit a lognormal distribution to these data?

```
wgt = 1 ./ sqrt(pEmp.*(1-pEmp));
LNobj = @(params) sum(wgt.*(logncdf(x,params(1),exp(params(2)))-pEmp).^2);
mu0 = mean(log(x)); sigma0 = std(log(x));
paramHatLN = fminsearch(LNobj,[mu0,log(sigma0)]);
paramHatLN(2) = exp(paramHatLN(2))
```

```
paramHatLN =

    0.5331    0.7038
```

```
pFitLN = logncdf(x,paramHatLN(1),paramHatLN(2));
hold on
plot(pEmp,pFitLN,'rx');
hold off
ylabel('Fitted Probabilities');
legend({'1:1 Line', 'Fitted Gamma', 'Fitted Lognormal'},'location','southeast');
```



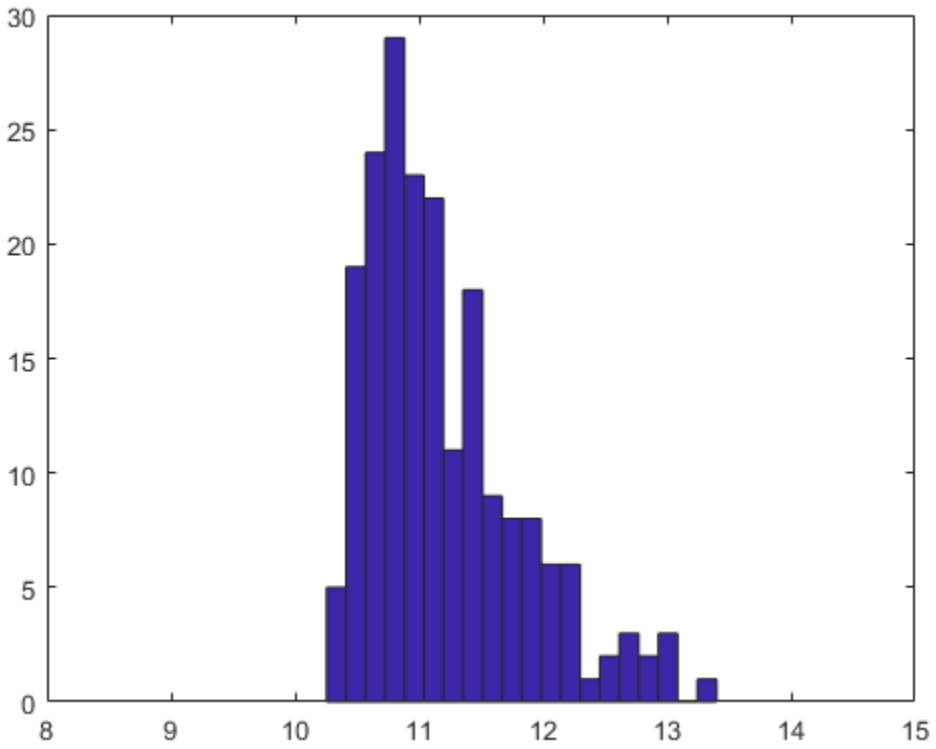
Notice how the lognormal fit differs systematically from the gamma fit in the tails. It grows more slowly in the left tail, and dies more slowly in the right tail. The gamma seems to be a slightly better fit to the data.

A Lognormal Threshold Parameter Example

The lognormal distribution is simple to fit by maximum likelihood, because once the log transformation is applied to the data, maximum likelihood is identical to fitting a normal. But it is sometimes necessary to estimate a threshold parameter in a lognormal model. The likelihood for such a model is unbounded, and so maximum likelihood does not work. However, the least squares method provides a way to make estimates. Since the two-parameter lognormal distribution can be log-transformed to a location-scale family, we could follow the same steps as in the earlier example that showed fitting a Weibull distribution with threshold parameter. Here, however, we'll do the estimation on the cumulative probability scale, as in the previous example showing a fit with the gamma distribution.

To illustrate, we'll simulate some data from a three-parameter lognormal distribution, with a threshold.

```
n = 200;
x = lognrnd(0,.5,n,1) + 10;
hist(x,20); xlim([8 15]);
```



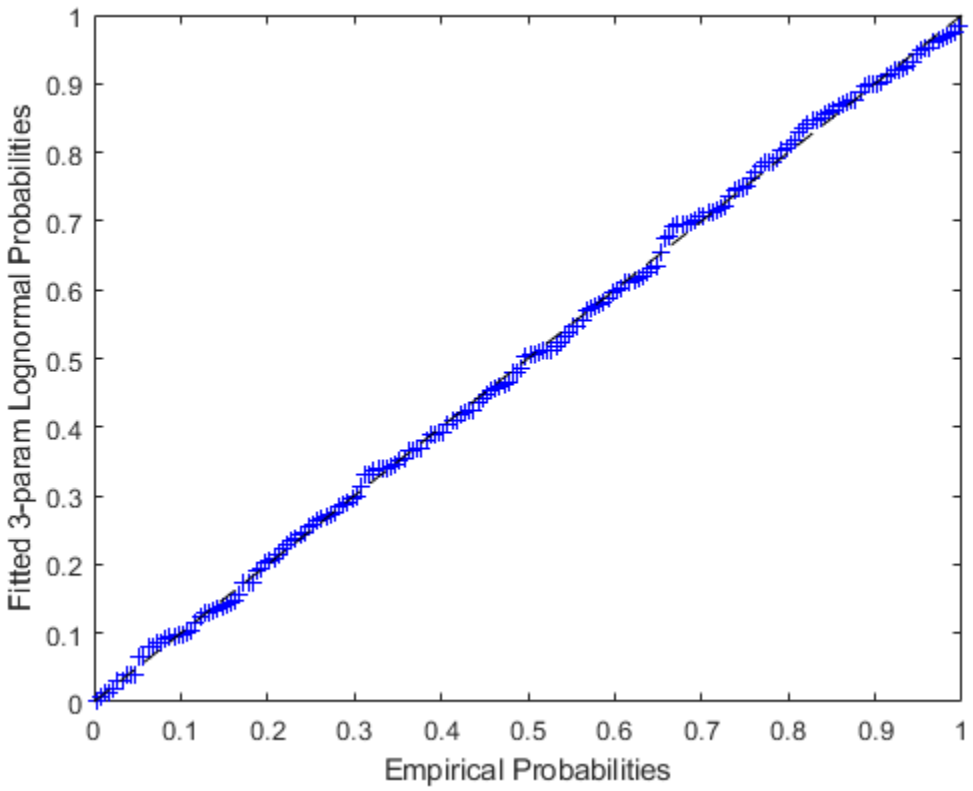
Compute the ECDF of x, and find the parameters for the best-fit three-parameter lognormal distribution.

```
x = sort(x);
pEmp = ((1:n)-0.5)' ./ n;
wgt = 1 ./ sqrt(pEmp.*(1-pEmp));
LN3obj = @(params) sum(wgt.*(logncdf(x-params(3),params(1),exp(params(2)))-pEmp).^2);
c0 = .99*min(x);
mu0 = mean(log(x-c0)); sigma0 = std(log(x-c0));
paramHat = fminsearch(LN3obj,[mu0,log(sigma0),c0]);
paramHat(2) = exp(paramHat(2))
```

```
paramHat =

   -0.0698    0.5930   10.1045
```

```
pFit = logncdf(x-paramHat(3),paramHat(1),paramHat(2));
plot(pEmp,pFit,'b+', [0 1],[0 1],'k--');
xlabel('Empirical Probabilities');
ylabel('Fitted 3-param Lognormal Probabilities');
```



Measures of Precision

Parameter estimates are only part of the story -- a model fit also needs some measure of how precise the estimates are, typically standard errors. With maximum likelihood, the usual method is to use the information matrix and a large-sample asymptotic argument to approximate the covariance matrix of the estimator over repeated sampling. No such theory exists for these least squares estimators.

However, Monte-Carlo simulation provides another way to estimate standard errors. If we use the fitted model to generate a large number of datasets, we can approximate the standard error of the estimators with the Monte-Carlo standard deviation. For simplicity, we've defined a fitting function in a separate file, `logn3fit.m`.

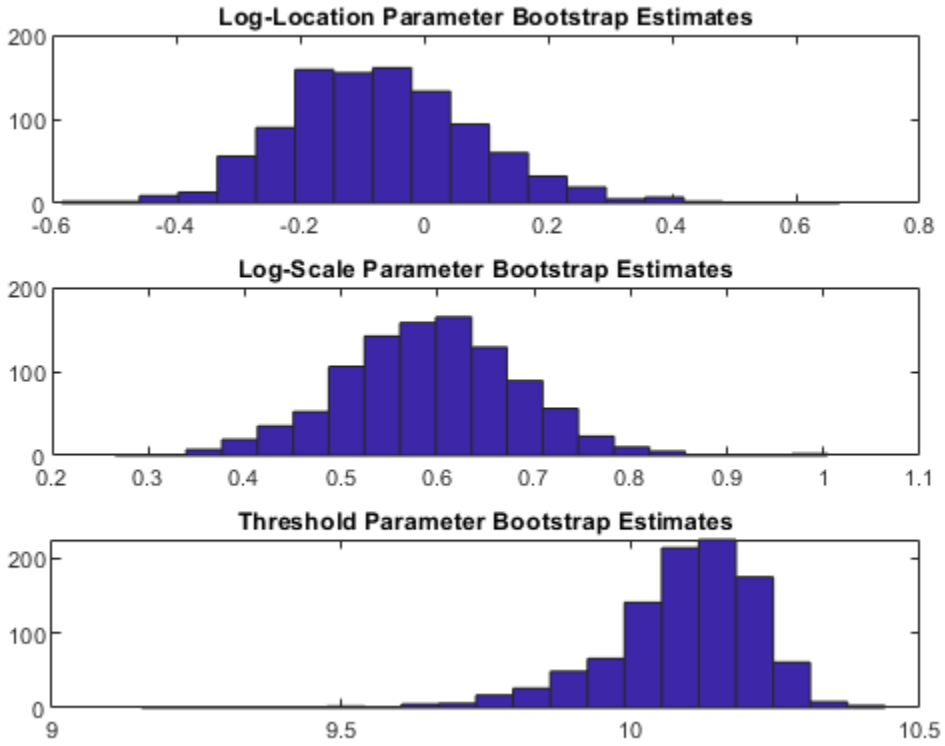
```
estsSim = zeros(1000,3);
for i = 1:size(estsSim,1)
    xSim = lognrnd(paramHat(1),paramHat(2),n,1) + paramHat(3);
    estsSim(i,:) = logn3fit(xSim);
end
std(estsSim)

ans =

    0.1542    0.0908    0.1303
```

It might also be useful to look at the distribution of the estimates, to check if the assumption of approximate normality is reasonable for this sample size, or to check for bias.

```
subplot(3,1,1), hist(estsSim(:,1),20);
title('Log-Location Parameter Bootstrap Estimates');
subplot(3,1,2), hist(estsSim(:,2),20);
title('Log-Scale Parameter Bootstrap Estimates');
subplot(3,1,3), hist(estsSim(:,3),20);
title('Threshold Parameter Bootstrap Estimates');
```



Clearly, the estimator for the threshold parameter is skewed. This is to be expected, since it is bounded above by the minimum data value. The other two histograms indicate that approximate normality might be a questionable assumption for the log-location parameter (the first histogram) as well. The standard errors computed above must be interpreted with that in mind, and the usual construction for confidence intervals might not be appropriate for the log-location and threshold parameters.

The means of the simulated estimates are close to the parameter values used to generate simulated data, indicating that the procedure is approximately unbiased at this sample size, at least for parameter values near the estimates.

```
[paramHat; mean(estsSim)]
```

```
ans =

   -0.0698    0.5930   10.1045
   -0.0690    0.5926   10.0905
```

Finally, we could also have used the function `bootstrp` to compute bootstrap standard error estimates. These do not make any parametric assumptions about the data.

```
estsBoot = bootstrp(1000,@logn3fit,x);
std(estsBoot)
```

```
ans =

    0.1490    0.0785    0.1180
```

The bootstrap standard errors are not far off from the Monte-Carlo calculations. That's not surprising, since the fitted model is the same one from which the example data were generated.

Summary

The fitting method described here is an alternative to maximum likelihood that can be used to fit univariate distributions when maximum likelihood fails to provide useful parameter estimates. One important application is in fitting distributions involving a threshold parameter, such as the three-parameter lognormal. Standard errors are more difficult to compute than for maximum likelihood estimates, because analytic approximations do not exist, but simulation provides a feasible alternative.

The P-P plots used here to illustrate the fitting method are useful in their own right, as a visual indication of lack of fit when fitting a univariate distribution.

Gaussian Processes

Gaussian Process Regression Models

Gaussian process regression (GPR) models are nonparametric kernel-based probabilistic models. You can train a GPR model using the `fitrgp` function.

Consider the training set $\{(x_i, y_i); i = 1, 2, ..., n\}$, where $x_i \in \mathbb{R}^d$ and $y_i \in \mathbb{R}$, drawn from an unknown distribution. A GPR model addresses the question of predicting the value of a response variable y_{new}, given the new input vector x_{new}, and the training data. A linear regression model is of the form

$$y = x^T\beta + \varepsilon,$$

where $\varepsilon \sim N(0, \sigma^2)$. The error variance σ^2 and the coefficients β are estimated from the data. A GPR model explains the response by introducing latent variables, $f(x_i)$, $i = 1, 2, ..., n$, from a Gaussian process (GP), and explicit basis functions, h. The covariance function of the latent variables captures the smoothness of the response and basis functions project the inputs x into a p-dimensional feature space.

A GP is a set of random variables, such that any finite number of them have a joint Gaussian distribution. If $\left\{f(x), x \in \mathbb{R}^d\right\}$ is a GP, then given n observations $x_1, x_2, ..., x_n$, the joint distribution of the random variables $f(x_1), f(x_2), ..., f(x_n)$ is Gaussian. A GP is defined by its mean function $m(x)$ and covariance function, $k(x, x')$. That is, if $\left\{f(x), x \in \mathbb{R}^d\right\}$ is a Gaussian process, then $E(f(x)) = m(x)$ and $Cov[f(x), f(x')] = E[\{f(x) - m(x)\}\{f(x') - m(x')\}] = k(x, x')$.

Now consider the following model.

$$h(x)^T\beta + f(x),$$

where $f(x) \sim GP(0, k(x, x'))$, that is $f(x)$ are from a zero mean GP with covariance function, $k(x, x')$. $h(x)$ are a set of basis functions that transform the original feature vector x in R^d into a new feature vector $h(x)$ in R^p. β is a p-by-1 vector of basis function coefficients. This model represents a GPR model. An instance of response y can be modeled as

$$P(y_i|f(x_i), x_i) \sim N\left(y_i \middle| h(x_i)^T\beta + f(x_i), \sigma^2\right)$$

Hence, a GPR model is a probabilistic model. There is a latent variable $f(x_i)$ introduced for each observation x_i, which makes the GPR model nonparametric. In vector form, this model is equivalent to

$$P(y \mid f, X) \sim N(y \mid H\beta + f, \sigma^2 I),$$

where

$$X = \begin{pmatrix} x_1^T \\ x_2^T \\ \vdots \\ x_n^T \end{pmatrix}, \quad y = \begin{pmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{pmatrix}, \quad H = \begin{pmatrix} h\left(x_1^T\right) \\ h\left(x_2^T\right) \\ \vdots \\ h\left(x_n^T\right) \end{pmatrix}, \quad f = \begin{pmatrix} f(x_1) \\ f(x_2) \\ \vdots \\ f(x_n) \end{pmatrix}.$$

The joint distribution of latent variables $f(x_1)$, $f(x_2)$, ..., $f(x_n)$ in the GPR model is as follows:

$$P(f \mid X) \sim N(f \mid 0, K(X, X)),$$

close to a linear regression model, where $K(X,X)$ looks as follows:

$$K(X,X) = \begin{pmatrix} k(x_1,x_1) & k(x_1,x_2) & \cdots & k(x_1,x_n) \\ k(x_2,x_1) & k(x_2,x_2) & \cdots & k(x_2,x_n) \\ \vdots & \vdots & \vdots & \vdots \\ k(x_n,x_1) & k(x_n,x_2) & \cdots & k(x_n,x_n) \end{pmatrix}.$$

The covariance function $k(x,x')$ is usually parameterized by a set of kernel parameters or hyperparameters, θ. Often $k(x,x')$ is written as $k(x,x'|\theta)$ to explicitly indicate the dependence on θ.

`fitrgp` estimates the basis function coefficients, β, the noise variance, σ^2, and the hyperparameters, θ, of the kernel function from the data while training the GPR model. You can specify the basis function, the kernel (covariance) function, and the initial values for the parameters.

Because a GPR model is probabilistic, it is possible to compute the prediction intervals using the trained model (see `predict` and `resubPredict`).

You can also compute the regression error using the trained GPR model (see `loss` and `resubLoss`).

Compare Prediction Intervals of GPR Models

This example fits GPR models to a noise-free data set and a noisy data set. The example compares the predicted responses and prediction intervals of the two fitted GPR models.

Generate two observation data sets from the function $g(x) = x \cdot \sin(x)$.

```
rng('default') % For reproducibility
x_observed = linspace(0,10,21)';
y_observed1 = x_observed.*sin(x_observed);
y_observed2 = y_observed1 + 0.5*randn(size(x_observed));
```

The values in `y_observed1` are noise free, and the values in `y_observed2` include some random noise.

Fit GPR models to the observed data sets.

```
gprMdl1 = fitrgp(x_observed,y_observed1);
gprMdl2 = fitrgp(x_observed,y_observed2);
```

Compute the predicted responses and 95% prediction intervals using the fitted models.

```
x = linspace(0,10)';
[ypred1,~,yint1] = predict(gprMdl1,x);
[ypred2,~,yint2] = predict(gprMdl2,x);
```

Resize a figure to display two plots in one figure.

```
fig = figure;
fig.Position(3) = fig.Position(3)*2;
```

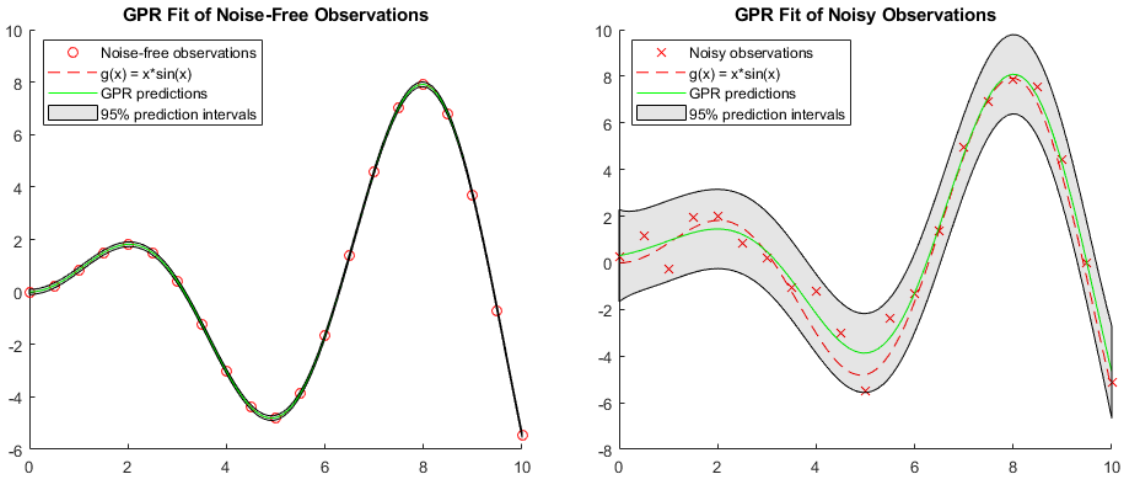
Create a 1-by-2 tiled chart layout.

```
tiledlayout(1,2,'TileSpacing','compact')
```

For each tile, draw a scatter plot of observed data points and a function plot of $x \cdot \sin(x)$. Then add a plot of GP predicted responses and a patch of prediction intervals.

```
nexttile
hold on
scatter(x_observed,y_observed1,'r') % Observed data points
fplot(@(x) x.*sin(x),[0,10],'--r')  % Function plot of x*sin(x)
plot(x,ypred1,'g')                  % GPR predictions
patch([x;flipud(x)],[yint1(:,1);flipud(yint1(:,2))],'k','FaceAlpha',0.1); % Prediction intervals
hold off
title('GPR Fit of Noise-Free Observations')
legend({'Noise-free observations','g(x) = x*sin(x)','GPR predictions','95% prediction intervals'}

nexttile
hold on
scatter(x_observed,y_observed2,'xr') % Observed data points
fplot(@(x) x.*sin(x),[0,10],'--r')   % Function plot of x*sin(x)
plot(x,ypred2,'g')                   % GPR predictions
patch([x;flipud(x)],[yint2(:,1);flipud(yint2(:,2))],'k','FaceAlpha',0.1); % Prediction intervals
hold off
title('GPR Fit of Noisy Observations')
legend({'Noisy observations','g(x) = x*sin(x)','GPR predictions','95% prediction intervals'},'Lo
```



When the observations are noise free, the predicted responses of the GPR fit cross the observations. The standard deviation of the predicted response is almost zero. Therefore, the prediction intervals are very narrow. When observations include noise, the predicted responses do not cross the observations, and the prediction intervals become wide.

Kernel (Covariance) Function Options

In supervised learning, it is expected that the points with similar predictor values x_i, naturally have close response (target) values y_i. In Gaussian processes, the covariance function expresses this similarity [1]. It specifies the covariance between the two latent variables $f(x_i)$ and $f(x_j)$, where both x_i and x_j are d-by-1 vectors. In other words, it determines how the response at one point x_i is affected by responses at other points x_j, $i \neq j$, $i = 1, 2, \ldots, n$. The covariance function $k(x_i, x_j)$ can be defined by various kernel functions. It can be parameterized in terms of the kernel parameters in vector θ. Hence, it is possible to express the covariance function as $k(x_i, x_j|\theta)$.

For many standard kernel functions, the kernel parameters are based on the signal standard deviation σ_f and the characteristic length scale σ_l. The characteristic length scales briefly define how far apart the input values x_i can be for the response values to become uncorrelated. Both σ_l and σ_f need to be greater than 0, and this can be enforced by the unconstrained parametrization vector θ, such that

$$\theta_1 = \log\sigma_l, \quad \theta_2 = \log\sigma_f .$$

The built-in kernel (covariance) functions *with same length scale for each predictor* are:

- **Squared Exponential Kernel**

  This is one of the most commonly used covariance functions and is the default option for `fitrgp`. The squared exponential kernel function is defined as

  $$k(x_i, x_j|\theta) = \sigma_f^2 \exp\left[-\frac{1}{2}\frac{(x_i - x_j)^T(x_i - x_j)}{\sigma_l^2}\right].$$

  where σ_l is the characteristic length scale, and σ_f is the signal standard deviation.

- **Exponential Kernel**

  You can specify the exponential kernel function using the `'KernelFunction','exponential'` name-value pair argument. This covariance function is defined by

  $$k(x_i, x_j|\theta) = \sigma_f^2 \exp\left(-\frac{r}{\sigma_l}\right),$$

  where σ_l is the characteristic length scale and

  $$r = \sqrt{(x_i - x_j)^T(x_i - x_j)}$$

  is the Euclidean distance between x_i and x_j.

- **Matern 3/2**

  You can specify the Matern 3/2 kernel function using the `'KernelFunction','matern32'` name-value pair argument. This covariance function is defined by

  $$k(x_i, x_j|\theta) = \sigma_f^2\left(1 + \frac{\sqrt{3}r}{\sigma_l}\right)\exp\left(-\frac{\sqrt{3}r}{\sigma_l}\right),$$

  where

$$r = \sqrt{(x_i - x_j)^T (x_i - x_j)}$$

is the Euclidean distance between x_i and x_j.

- **Matern 5/2**

  You can specify the Matern 5/2 kernel function using the `'KernelFunction','matern52'` name-value pair argument. The Matern 5/2 covariance function is defined as

  $$k(x_i, x_j) = \sigma_f^2 \left(1 + \frac{\sqrt{5}r}{\sigma_l} + \frac{5r^2}{3\sigma_l^2}\right) \exp\left(-\frac{\sqrt{5}r}{\sigma_l}\right),$$

  where

  $$r = \sqrt{(x_i - x_j)^T (x_i - x_j)}$$

  is the Euclidean distance between x_i and x_j.

- **Rational Quadratic Kernel**

  You can specify the rational quadratic kernel function using the `'KernelFunction','rationalquadratic'` name-value pair argument. This covariance function is defined by

  $$k(x_i, x_j \mid \theta) = \sigma_f^2 \left(1 + \frac{r^2}{2\alpha\sigma_l^2}\right)^{-\alpha},$$

  where σ_l is the characteristic length scale, α is a positive-valued scale-mixture parameter, and

  $$r = \sqrt{(x_i - x_j)^T (x_i - x_j)}$$

  is the Euclidean distance between x_i and x_j.

It is possible to use a separate length scale σ_m for each predictor m, $m = 1, 2, \ldots, d$. The built-in kernel (covariance) functions with a separate length scale for each predictor implement automatic relevance determination (ARD) [2]. The unconstrained parametrization θ in this case is

$$\theta_m = \log \sigma_m, \quad \text{for } m = 1, 2, \ldots, d$$
$$\theta_{d+1} = \log \sigma_f .$$

The built-in kernel (covariance) functions *with separate length scale for each predictor* are:

- **ARD Squared Exponential Kernel**

  You can specify this kernel function using the `'KernelFunction','ardsquaredexponential'` name-value pair argument. This covariance function is the squared exponential kernel function, with a separate length scale for each predictor. It is defined as

  $$k(x_i, x_j \mid \theta) = \sigma_f^2 \exp\left[-\frac{1}{2} \sum_{m=1}^{d} \frac{(x_{im} - x_{jm})^2}{\sigma_m^2}\right].$$

- **ARD Exponential Kernel**

You can specify this kernel function using the `'KernelFunction','ardexponential'` name-value pair argument. This covariance function is the exponential kernel function, with a separate length scale for each predictor. It is defined as

$$k(x_i, x_j \mid \theta) = \sigma_f^2 \exp(-r),$$

where

$$r = \sqrt{\sum_{m=1}^{d} \frac{(x_{im} - x_{jm})^2}{\sigma_m^2}}.$$

- **ARD Matern 3/2**

  You can specify this kernel function using the `'KernelFunction','ardmatern32'` name-value pair argument. This covariance function is the Matern 3/2 kernel function, with a different length scale for each predictor. It is defined as

  $$k(x_i, x_j \mid \theta) = \sigma_f^2 (1 + \sqrt{3}\, r) \exp(-\sqrt{3}\, r),$$

  where

  $$r = \sqrt{\sum_{m=1}^{d} \frac{(x_{im} - x_{jm})^2}{\sigma_m^2}}.$$

- **ARD Matern 5/2**

  You can specify this kernel function using the `'KernelFunction','ardmatern52'` name-value pair argument. This covariance function is the Matern 5/2 kernel function, with a different length scale for each predictor. It is defined as

  $$k(x_i, x_j \mid \theta) = \sigma_f^2 \left(1 + \sqrt{5}\, r + \frac{5}{3} r^2\right) \exp(-\sqrt{5}\, r),$$

  where

  $$r = \sqrt{\sum_{m=1}^{d} \frac{(x_{im} - x_{jm})^2}{\sigma_m^2}}.$$

- **ARD Rational Quadratic Kernel**

  You can specify this kernel function using the `'KernelFunction','ardrationalquadratic'` name-value pair argument. This covariance function is the rational quadratic kernel function, with a separate length scale for each predictor. It is defined as

  $$k(x_i, x_j \mid \theta) = \sigma_f^2 \left(1 + \frac{1}{2\alpha} \sum_{m=1}^{d} \frac{(x_{im} - x_{jm})^2}{\sigma_m^2}\right)^{-\alpha}.$$

You can specify the kernel function using the `KernelFunction` name-value pair argument in a call to `fitrgp`. You can either specify one of the built-in kernel parameter options, or specify a custom function. When providing the initial kernel parameter values for a built-in kernel function, input the initial values for signal standard deviation and the characteristic length scale(s) as a numeric vector. When providing the initial kernel parameter values for a custom kernel function, input the initial values the unconstrained parametrization vector θ. `fitrgp` uses analytical derivatives to estimate

parameters when using a built-in kernel function, whereas when using a custom kernel function it uses numerical derivatives.

Exact GPR Method

In this section...

An instance of response y from a Gaussian process regression (GPR) model on page 6-2 can be modeled as

$$P(y_i|f(x_i),x_i) \sim N\left(y_i\middle|h(x_i)^T\beta + f(x_i),\sigma^2\right)$$

Hence, making predictions for new data from a GPR model requires:

- Knowledge of the coefficient vector, β, of fixed basis functions
- Ability to evaluate the covariance function $k(x,x'|\theta)$ for arbitrary x and x', given the kernel parameters or hyperparameters, θ.
- Knowledge of the noise variance σ^2 that appears in the density $P(y_i|f(x_i),x_i)$

That is, one needs first to estimate β, θ, and σ^2 from the data (X, y).

Parameter Estimation

One approach for estimating the parameters β, θ, and σ^2 of a GPR model is by maximizing the likelihood $P(y\,|\,X)$ as a function of β, θ, and σ^2[1]. That is, if $\widehat{\beta}$, $\widehat{\theta}$, and $\widehat{\sigma}^2$ are the estimates of β, θ, and σ^2, respectively, then:

$$\widehat{\beta},\widehat{\theta},\widehat{\sigma}^2 = \underset{\beta,\theta,\sigma^2}{\arg\max}\log P\left(y\middle|X,\beta,\theta,\sigma^2\right).$$

Because

$$P(y|X) = P\left(y\middle|X,\beta,\theta,\sigma^2\right) = \mathrm{N}\left(y\middle|H\beta,K(X,X|\theta)+\sigma^2 I_n\right),$$

the marginal log likelihood function is as follows:

$$\log P\left(y\middle|X,\beta,\theta,\sigma^2\right) = -\frac{1}{2}(y-H\beta)^T\left[K(X,X|\theta)+\sigma^2 I_n\right]^{-1}(y-H\beta) - \frac{n}{2}\log 2\pi - \frac{1}{2}\log\left|K(X,X|\theta)+\sigma^2 I_n\right|.$$

where H is the vector of explicit basis functions, and $K(X,X|\theta)$ is the covariance function matrix (for more information, see “Gaussian Process Regression Models” on page 6-2).

To estimate the parameters, the software first computes $\widehat{\beta}\left(\theta,\sigma^2\right)$, which maximizes the log likelihood function with respect to β for given θ and σ^2. It then uses this estimate to compute the β-profiled likelihood:

$$\log\left\{P\left(y\middle|X,\widehat{\beta}\left(\theta,\sigma^2\right),\theta,\sigma^2\right)\right\}.$$

The estimate of β for given θ, and σ^2 is

$$\widehat{\beta}\left(\theta,\sigma^2\right)=\left[\,H^T\left[K(X,X\,|\,\theta)+\sigma^2I_n\right]^{-1}H\right]^{-1}H^T\left[K(X,X\,|\,\theta)+\sigma^2I_n\right]^{-1}y\,.$$

Then, the β-profiled log likelihood is given by

$$\begin{aligned}\log P\left(y\middle|X,\widehat{\beta}\,(\theta,\sigma^2),\theta,\sigma^2\right)=&-\frac{1}{2}\left(y-H\widehat{\beta}\left(\theta,\sigma^2\right)\right)^T\left[K(X,X\,|\,\theta)+\sigma^2I_n\right]^{-1}\left(y-H\widehat{\beta}\left(\theta,\sigma^2\right)\right)\\&-\frac{n}{2}\log 2\pi-\frac{1}{2}\log\left|K(X,X\,|\,\theta)+\sigma^2I_n\right|\end{aligned}$$

The software then maximizes the β-profiled log-likelihood over θ, and σ^2 to find their estimates.

Prediction

Making probabilistic predictions from a GPR model with known parameters requires the density $P(y_{new}\,|\,y,X,x_{new})$. Using the definition of conditional probabilities, one can write:

$$P(y_{new}\,|\,y,X,x_{new})=\frac{P(y_{new},y\,|\,X,x_{new})}{P(y\,|\,X,x_{new})}\,.$$

To find the joint density in the numerator, it is necessary to introduce the latent variables f_{new} and f corresponding to y_{new}, and y, respectively. Then, it is possible to use the joint distribution for y_{new}, y, f_{new}, and f to compute $P(y_{new},y|X,x_{new})$:

$$\begin{aligned}P(y_{new},y|X,x_{new})&=\int\int P(y_{new},y,f_{new},f|X,x_{new})dfdf_{new}\\&=\int\int P(y_{new},y|f_{new},f,X,x_{new})P(f_{new},f|X,x_{new})dfdf_{new}\,.\end{aligned}$$

Gaussian process models assume that each response y_i only depends on the corresponding latent variable f_i and the feature vector x_i. Writing $P(y_{new},y|f_{new},f,X,x_{new})$ as a product of conditional densities and based on this assumption produces:

$$P(y_{new},y|f_{new},f,X,x_{new})=P(y_{new}|f_{new},x_{new})\prod_{i=1}^{n}P(y_i|f(x_i),x_i)\,.$$

After integrating with respect to y_{new}, the result only depends on f and X:

$$P(y|f,X)=\prod_{i=1}^{n}P(y_i|f_i,x_i)=\prod_{i=1}^{n}\mathrm{N}\left(y_i|h(x_i)^T\beta+f_i,\sigma^2\right).$$

Hence,

$$P(y_{new},\ y|f_{new},\ f,\ X,\ x_{new})=P(y_{new}|f_{new},\ x_{new})P(y|f,X)\,.$$

Again using the definition of conditional probabilities,

$$P(f_{new},f|X,x_{new})=P(f_{new}|f,X,x_{new})*P(f|X,x_{new}),$$

it is possible to write $P(y_{new}, y|X, x_{new})$ as follows:

$$P(y_{new}, y|X, x_{new}) = \int\int P(y_{new}|f_{new},\ x_{new})P(y|f, X)P(f_{new}|f, X, x_{new})P(f|X, x_{new})dfdf_{new}\,.$$

Using the facts that

$$P(f|X, x_{new}) = P(f|X)$$

and

$$P(y|f, X)P(f|X) = P(y, f|X) = P(f|y, X)P(y|X),$$

one can rewrite $P(y_{new}, y|X, x_{new})$ as follows:

$$P(y_{new}, y|X, x_{new}) = P(y|X)\int\int P(y_{new}|f_{new},\ x_{new})P(f|y, X)P(f_{new}|f, X, x_{new})dfdf_{new}\,.$$

It is also possible to show that

$$P(y|X, x_{new}) = P(y|X)\,.$$

Hence, the required density $P(y_{new}\,|\,y, X, x_{new})$ is:

$$\begin{aligned} P(y_{new}|y, X, x_{new}) &= \frac{P(y_{new}, y\,|\,X, x_{new})}{P(y\,|\,X, x_{new})} = \frac{P(y_{new}, y\,|\,X, x_{new})}{P(y\,|\,X)} \\ &= \int\int \underbrace{P(y_{new}|f_{new},\ x_{new})}_{(1)}\underbrace{P(f|y, X)}_{(2)}\underbrace{P(f_{new}|f, X, x_{new})}_{(3)}dfdf_{new}\,. \end{aligned}$$

It can be shown that

(1) $P(y_{new}|f_{new}, x_{new}) = \mathrm{N}\left(y_{new}\middle|h(x_{new})^T\beta + f_{new}, \sigma^2_{new}\right)$

(2) $P(f|y, X) = \mathrm{N}\left(f\middle|\frac{1}{\sigma^2}\left(\frac{I_n}{\sigma^2} + K(X, X)^{-1}\right)^{-1}(y - H\beta), \left(\frac{I_n}{\sigma^2} + K(X, X)^{-1}\right)^{-1}\right)$

(3) $P(f_{new}|f, X, x_{new}) = \mathrm{N}\left(f_{new}\middle|K\left(x^T_{new}, X\right)K(X, X)^{-1}f, \Delta\right)$,

where $\Delta = k(x_{new}, x_{new}) - K\left(x^T_{new}, X\right)K(X, X)^{-1}K\left(X, x^T_{new}\right)$.

After the integration and required algebra, the density of the new response y_{new} at a new point x_{new}, given y, X is found as

$$P(y_{new}|y, X, x_{new}) = \mathrm{N}\left(y_{new}\middle|h(x_{new})^T\beta + \mu, \sigma^2_{new} + \Sigma\right),$$

where

$$\mu = K\left(x^T_{new}, X\right)\underbrace{\left(K(X, X) + \sigma^2 I_n\right)^{-1}}_{\alpha}(y - H\beta)$$

and

$$\Sigma = k(x_{new}, x_{new}) - K\left(x^T_{new}, X\right)\left(K(X, X) + \sigma^2 I_n\right)^{-1}K\left(X, x^T_{new}\right).$$

The expected value of prediction y_{new} at a new point x_{new} given y, X, and parameters β, θ, and σ^2 is

$$\begin{aligned} E\left(y_{new}|y,\ X, x_{new}, \beta, \theta, \sigma^2\right) &= h(x_{new})^T\beta + K\left(x_{new}^T, X\middle|\theta\right)\alpha \\ &= h(x_{new})^T\beta + \sum_{i=1}^{n} \alpha_i k(x_{new}, x_i|\theta), \end{aligned}$$

where

$$\alpha = \left(K(X,X|\theta) + \sigma^2 I_n\right)^{-1}(y - H\beta)\,.$$

Computational Complexity of Exact Parameter Estimation and Prediction

Training a GPR model with the exact method (when `FitMethod` is `'Exact'`) requires the inversion of an n-by-n kernel matrix $K(X,X)$. The memory requirement for this step scales as $O(n^2)$ since $K(X,X)$ must be stored in memory. One evaluation of $\log P(y|X)$ scales as $O(n^3)$. Therefore, the computational complexity is $O(kn^3)$, where k is the number of function evaluations needed for maximization and n is the number of observations.

Making predictions on new data involves the computation of $\widehat{\alpha}$. If prediction intervals are desired, this step could also involve the computation and storage of the Cholesky factor of $\left(K(X,X) + \sigma^2 I_n\right)$ for later use. The computational complexity of this step using the direct computation of $\widehat{\alpha}$ is $O(n^3)$ and the memory requirement is $O(n^2)$.

Hence, for large n, estimation of parameters or computing predictions can be very expensive. The approximation methods usually involve rearranging the computation so as to avoid the inversion of an n-by-n matrix. For the available approximation methods, please see the related links at the bottom of the page.

Subset of Data Approximation for GPR Models

Training a GPR model with the exact method (when `FitMethod` is `'Exact'`) requires the inversion of an n-by-n matrix. Therefore, the computational complexity is $O(kn^3)$, where k is the number of function evaluations required for estimating β, θ, and σ^2, and n is the number of observations. For large n, estimation of parameters or computing predictions can be very expensive.

One simple way to solve the computational complexity problem with large data sets is to select $m < n$ observations out of n and then apply exact GPR model on page 6-10 to these m points to estimate β, θ, and σ^2 while ignoring the other $(n – m)$ points. This smaller subset is known as the *active set*. And this approximation method is called the Subset of Data (SD) method.

The computational complexity when using SD method is $O(km^3)$, where k is the number of function evaluations and m is the active set size. The storage requirements are $O(m^2)$ since only a part of the full kernel matrix $K(X, X|\theta)$ needs to be stored in memory.

You can specify the SD method for parameter estimation by using the `'FitMethod','sd'` name-value pair argument in the call to `fitrgp`. To specify the SD method for prediction, use the `'PredictMethod','sd'` name-value pair argument.

For estimating parameters using the exact GPR model, see parameter estimation using the exact GPR method on page 6-10. For making predictions using the exact GPR model, see prediction using the exact GPR method on page 6-11.

Subset of Regressors Approximation for GPR Models

In this section...

The subset of regressors (SR) approximation method consists of replacing the kernel function $k(x, x_r|\theta)$ in the exact GPR method on page 6-10 by its approximation $\widehat{k}_{SR}(x, x_r|\theta, \mathrm{A})$, given the active set $\mathrm{A} \subset \mathrm{N} = \{1, 2, ..., n\}$. You can specify the SR method for parameter estimation by using the `'FitMethod','sr'` name-value pair argument in the call to `fitrgp`. For prediction using SR, you can use the `'PredictMethod','sr'` name-value pair argument in the call to `fitrgp`.

Approximating the Kernel Function

For the exact GPR model on page 6-11, the expected prediction in GPR depends on the set of N functions $\mathrm{S_N} = \{k(x, x_i|\theta), i = 1, 2, ..., n\}$, where $\mathrm{N} = \{1, 2, ..., n\}$ is the set of indices of all observations, and n is the total number of observations. The idea is to approximate the span of these functions by a smaller set of functions, $\mathrm{S_A}$, where $\mathrm{A} \subset \mathrm{N} = \{1, 2, ..., n\}$ is the subset of indices of points selected to be in the active set. Consider $\mathrm{S_A} = \left\{k\left(x, x_j\middle|\theta\right), j \in \mathrm{A}\right\}$. The aim is to approximate the elements of $\mathrm{S_N}$ as linear combinations of the elements of $\mathrm{S_A}$.

Suppose the approximation to $k(x, x_r|\theta)$ using the functions in $\mathrm{S_A}$ is as follows:

$$\widehat{k}\,(x, x_r|\theta) = \sum_{j \in \mathrm{A}} c_{jr} k\left(x, x_j\middle|\theta\right),$$

where $c_{jr} \in \mathbb{R}$ are the coefficients of the linear combination for approximating $k(x, x_r|\theta)$. Suppose C is the matrix that contains all the coefficients c_{jr}. Then, C, is a $|\mathrm{A}| \times n$ matrix such that $C(j, r) = c_{jr}$. The software finds the best approximation to the elements of $\mathrm{S_N}$ using the active set $\mathrm{A} \subset \mathrm{N} = \{1, 2, ..., n\}$ by minimizing the error function

$$E(\mathrm{A}, C) = \sum_{r=1}^{n} \left\| k(x, x_r|\theta) - \widehat{k}\,(x, x_r|\theta) \right\|^2_{\mathscr{H}},$$

where $\mathscr{H}$ is the Reproducing Kernel Hilbert Spaces (RKHS) associated with the kernel function k [1], [2].

The coefficient matrix that minimizes $E(\mathrm{A}, C)$ is

$$\widehat{C}_{\mathrm{A}} = K(X_{\mathrm{A}}, X_{\mathrm{A}}|\theta)^{-1} K(X_{\mathrm{A}}, X|\theta),$$

and an approximation to the kernel function using the elements in the active set $\mathrm{A} \subset \mathrm{N} = \{1, 2, ..., n\}$ is

$$\widehat{k}\,(x, x_r|\theta) = \sum_{j \in \mathrm{A}} c_{jr} k\left(x, x_j\middle|\theta\right) = K\left(x^T, X_{\mathrm{A}}\middle|\theta\right) C(:, r)\,.$$

The SR approximation to the kernel function using the active set $A \subset N = \{1, 2, ..., n\}$ is defined as:

$$\widehat{k}_{SR}(x, x_r|\theta, A) = K\left(x^T, X_A\middle|\theta\right)\widehat{C}_A(:, r) = K\left(x^T, X_A\middle|\theta\right)K(X_A, X_A|\theta)^{-1}K\left(X_A, x_r^T\middle|\theta\right)$$

and the SR approximation to $K(X, X|\theta)$ is:

$$\widehat{K}_{SR}(X, X|\theta, A) = \ K(X, X_A|\theta)\, K(X_A, X_A|\theta)^{-1}\, K(X_A, X|\theta)\,.$$

Parameter Estimation

Replacing $K(X, X|\theta)$ by $\widehat{K}_{SR}(X, X|\theta, A)$ in the marginal log likelihood function produces its SR approximation:

$$\log P_{SR}\left(y\middle|X, \beta, \theta, \sigma^2, A\right) = -\frac{1}{2}(y - H\beta)^T\left[\widehat{K}_{SR}(X, X|\theta, A) + \sigma^2 I_n\right]^{-1}(y - H\beta)$$
$$-\frac{N}{2}\log 2\pi - \frac{1}{2}\log\left|\widehat{K}_{SR}(X, X|\theta, A) + \sigma^2 I_n\right|$$

As in the exact method on page 6-10, the software estimates the parameters by first computing $\widehat{\beta}\left(\theta, \sigma^2\right)$, the optimal estimate of β, given θ and σ^2. Then it estimates θ, and σ^2 using the β-profiled marginal log likelihood. The SR estimate to β for given θ, and σ^2 is:

$$\widehat{\beta}_{SR}\left(\theta, \sigma^2, A\right) = \left[H^T\left[\widehat{K}_{SR}(X, X|\theta, A) + \sigma^2 I_n\right]^{-1}H\right]^{-1}_{*} H^T\left[\widehat{K}_{SR}(X, X|\theta, A) + \sigma^2 I_n\right]^{-1}y,$$

where

$$\left[\widehat{K}_{SR}(X, X|\theta, A) + \sigma^2 I_n\right]^{-1} = \frac{I_N}{\sigma^2} - \frac{K(X, X_A|\theta)}{\sigma^2}A_A^{-1}\frac{K(X_A, X|\theta)}{\sigma^2},$$

$$A_A = K(X_A, X_A|\theta) + \frac{K(X_A, X|\theta)K(X, X_A|\theta)}{\sigma^2},$$

$$* = \frac{H^T H}{\sigma^2} - \frac{H^T K(X, X_A|\theta)}{\sigma^2}A_A^{-1}\frac{K(X_A, X|\theta)H}{\sigma^2},$$

$$** = \frac{H^T y}{\sigma^2} - \frac{H^T K(X, X_A|\theta)}{\sigma^2}A_A^{-1}\frac{K(X_A, X|\theta)y}{\sigma^2}.$$

And the SR approximation to the β-profiled marginal log likelihood is:

$$\log P_{SR}\left(y\middle|X, \widehat{\beta}_{SR}\left(\theta, \sigma^2, A\right), \theta, \sigma^2, A\right) =$$
$$-\frac{1}{2}\left(y - H\widehat{\beta}_{SR}\left(\theta, \sigma^2, A\right)\right)^T\left[\widehat{K}_{SR}(X, X|\theta, A) + \sigma^2 I_n\right]^{-1}\left(y - H\widehat{\beta}_{SR}\left(\theta, \sigma^2, A\right)\right)$$
$$-\frac{N}{2}\log 2\pi - \frac{1}{2}\log\left|\widehat{K}_{SR}(X, X|\theta, A) + \sigma^2 I_n\right|.$$

Prediction

The SR approximation to the distribution of y_{new} given y, X, x_{new} is

$$P(y_{new}|y, X, x_{new}) = \mathrm{N}\left(y_{new}\middle|h(x_{new})^T\beta + \mu_{SR}, \sigma^2_{new} + \Sigma_{SR}\right),$$

where μ_{SR} and Σ_{SR} are the SR approximations to μ and Σ shown in prediction using the exact GPR method on page 6-11.

μ_{SR} and Σ_{SR} are obtained by replacing $k(x, x_r|\theta)$ by its SR approximation $\widehat{k}_{SR}(x, x_r|\theta, \mathrm{A})$ in μ and Σ, respectively.

That is,

$$\mu_{SR} = \underbrace{\widehat{K}_{SR}\left(x^T_{new}, X\middle|\theta, \mathrm{A}\right)}_{(1)}\underbrace{\left(\widehat{K}_{SR}(X, X|\theta, \mathrm{A}) + \sigma^2 I_N\right)^{-1}}_{(2)}(y - H\beta).$$

Since

$$(1) = K\left(x^T_{new}, X_\mathrm{A}\middle|\theta\right) K(X_\mathrm{A}, X_\mathrm{A}|\theta)^{-1}K(X_\mathrm{A}, X|\theta),$$

$$(2) = \frac{I_N}{\sigma^2} - \frac{K(X, X_\mathrm{A}|\theta)}{\sigma^2}\left[K(X_\mathrm{A}, X_\mathrm{A}|\theta) + \frac{K(X_\mathrm{A}, X|\theta)\,K(X, X_\mathrm{A}|\theta)}{\sigma^2}\right]^{-1}\frac{K(X_\mathrm{A}, X|\theta)}{\sigma^2},$$

and from the fact that $I_N - B(A + B)^{-1} = A(A + B)^{-1}$, μ_{SR} can be written as

$$\mu_{SR} = K\left(x^T_{new}, X_\mathrm{A}\middle|\theta\right)\left[K(X_\mathrm{A}, X_\mathrm{A}|\theta) + \frac{K(X_\mathrm{A}, X|\theta)K(X, X_\mathrm{A}|\theta)}{\sigma^2}\right]^{-1}\frac{K(X_\mathrm{A}, X|\theta)}{\sigma^2}(y - H\beta).$$

Similarly, Σ_{SR} is derived as follows:

$$\Sigma_{SR} = \underbrace{\widehat{k}_{SR}(x_{new}, x_{new}|\theta, \mathrm{A})}_{*} - \underbrace{\widehat{K}_{SR}\left(x^T_{new}, X\middle|\theta, \mathrm{A}\right)}_{**}\underbrace{\left(\widehat{K}_{SR}(X, X|\theta, \mathrm{A}) + \sigma^2 I_N\right)^{-1}}_{***}\underbrace{\widehat{K}_{SR}\left(X, x^T_{new}\middle|\theta, \mathrm{A}\right)}_{****}.$$

Because

$$* = K\left(x^T_{new}, X_\mathrm{A}\middle|\theta\right)K(X_\mathrm{A}, X_\mathrm{A}|\theta)^{-1}K\left(X_\mathrm{A}, x^T_{new}\middle|\theta\right),$$

$$** = K\left(x^T_{new}, X_\mathrm{A}\middle|\theta\right)K(X_\mathrm{A}, X_\mathrm{A}|\theta)^{-1}K(X_\mathrm{A}, X|\theta),$$

$*** = (2)$ in the equation of μ_{SR},

$$**** = K(X, X_\mathrm{A}|\theta)K(X_\mathrm{A}, X_\mathrm{A}|\theta)^{-1}K\left(X_\mathrm{A}, x^T_{new}\middle|\theta\right),$$

Σ_{SR} is found as follows:

$$\sum_{SR} = K\left(x^T_{new}, X_\mathrm{A}\middle|\theta\right)\left[K(X_\mathrm{A}, X_\mathrm{A}|\theta) + \frac{K(X_\mathrm{A}, X|\theta)\,K(X, X_\mathrm{A}|\theta))}{\sigma^2}\right]^{-1}K\left(X_\mathrm{A}, x^T_{new}\middle|\theta\right).$$

Predictive Variance Problem

One of the disadvantages of the SR method is that it can give unreasonably small predictive variances when making predictions in a region far away from the chosen active set $\mathrm{A} \subset \mathrm{N} = \{1, 2, ..., n\}$.

Consider making a prediction at a new point x_{new} that is far away from the training set X. In other words, assume that $K\left(x_{new}^T, X\middle|\theta\right) \approx 0$.

For exact GPR, the posterior distribution of f_{new} given y, X and x_{new} would be Normal with mean $\mu = 0$ and variance $\Sigma = k(x_{new}, x_{new}|\theta)$. This value is correct in the sense that, if x_{new} is far from X, then the data (X, y) does not supply any new information about f_{new} and so the posterior distribution of f_{new} given y, X, and x_{new} should reduce to the prior distribution f_{new} given x_{new}, which is a Normal distribution with mean 0 and variance $k(x_{new}, x_{new}|\theta)$.

For the SR approximation, if x_{new} is far away from X (and hence also far away from X_A), then $\mu_{SR} = 0$ and $\Sigma_{SR} = 0$. Thus in this extreme case, μ_{SR} agrees with μ from exact GPR, but Σ_{SR} is unreasonably small compared to Σ from exact GPR.

The fully independent conditional approximation method on page 6-19 can help avoid this problem.

Fully Independent Conditional Approximation for GPR Models

In this section...

The fully independent conditional (FIC) approximation[1] is a way of systematically approximating the true GPR kernel function in a way that avoids the predictive variance problem of the SR approximation on page 6-17 while still maintaining a valid Gaussian process. You can specify the FIC method for parameter estimation by using the `'FitMethod','fic'` name-value pair argument in the call to `fitrgp`. For prediction using FIC, you can use the `'PredictMethod','fic'` name-value pair argument in the call to `fitrgp`.

Approximating the Kernel Function

The FIC approximation to $k\left(x_i, x_j|\theta\right)$ for active set $\mathrm{A} \subset \mathrm{N} = \{1, 2, \ldots, n\}$ is given by:

$$\widehat{k}_{FIC}\left(x_i, x_j|\theta, \mathrm{A}\right) = \widehat{k}_{SR}\left(x_i, x_j|\theta, \mathrm{A}\right) + \delta_{ij}\left(k\left(x_i, x_j|\theta\right) - \widehat{k}_{SR}\left(x_i, x_j|\theta, \mathrm{A}\right)\right),$$

$$\delta_{ij} = \begin{cases} 1, & \text{if } i = j, \\ 0 & \text{if } i \neq j. \end{cases}$$

That is, the FIC approximation is equal to the SR approximation if $i \neq j$. For $i = j$, the software uses the exact kernel value rather than an approximation. Define an n-by-n diagonal matrix $\Omega(X|\theta, \mathrm{A})$ as follows:

$$\begin{aligned} \left[\Omega(X|\theta, \mathrm{A})\right]_{ij} &= \delta_{ij}\left(k\left(x_i, x_j|\theta\right) - \widehat{k}_{SR}\left(x_i, x_j|\theta, \mathrm{A}\right)\right) \\ &= \begin{cases} k\left(x_i, x_j|\theta\right) - \widehat{k}_{SR}\left(x_i, x_j|\theta, \mathrm{A}\right) & \text{if } i = j, \\ 0 & \text{if } i \neq j. \end{cases} \end{aligned}$$

The FIC approximation to $K(X, X|\theta)$ is then given by:

$$\begin{aligned} \widehat{K}_{FIC}(X, X|\theta, \mathrm{A}) &= \widehat{K}_{SR}(X, X|\theta, \mathrm{A}) + \Omega(X|\theta, \mathrm{A}) \\ &= K(X, X_{\mathrm{A}}|\theta)K(X_{\mathrm{A}}, X_{\mathrm{A}}|\theta)^{-1}K(X_{\mathrm{A}}, X|\theta) + \Omega(X|\theta, \mathrm{A}). \end{aligned}$$

Parameter Estimation

Replacing $K(X, X|\theta)$ by $\widehat{K}_{FIC}(X, X|\theta, \mathrm{A})$ in the marginal log likelihood function produces its FIC approximation:

$$\begin{aligned} \log P_{FIC}\left(y\middle|X, \beta, \theta, \sigma^2, \mathrm{A}\right) = &-\frac{1}{2}(y - H\beta)^T\left[\widehat{K}_{FIC}(X, X|\theta, \mathrm{A}) + \sigma^2 I_n\right]^{-1}(y - H\beta) \\ &-\frac{N}{2}\log 2\pi - \frac{1}{2}\log\left|\widehat{K}_{FIC}(X, X|\theta, \mathrm{A}) + \sigma^2 I_n\right|. \end{aligned}$$

As in the exact method on page 6-10, the software estimates the parameters by first computing $\widehat{\beta}\left(\theta,\sigma^2\right)$, the optimal estimate of β, given θ and σ^2. Then it estimates θ, and σ^2 using the β-profiled marginal log likelihood. The FIC estimate to β for given θ, and σ^2 is

$$\widehat{\beta}_{FIC}\left(\theta,\sigma^2,\mathrm{A}\right)=\left[H^T\left(\widehat{K}_{FIC}(X,X|\theta,\mathrm{A})+\sigma^2 I_N\right)^{-1}H\right]^{-1}H^T\left(\widehat{K}_{FIC}(X,X|\theta,\mathrm{A})+\sigma^2 I_N\right)^{-1}y,$$

$$*=H^T\Lambda\left(\theta,\sigma^2,\mathrm{A}\right)^{-1}H-H^T\Lambda\left(\theta,\sigma^2,\mathrm{A}\right)^{-1}K(X,X_\mathrm{A}|\theta)B_\mathrm{A}^{-1}K(X_\mathrm{A},X|\theta)\Lambda\left(\theta,\sigma^2,\mathrm{A}\right)^{-1}H,$$

$$**=H^T\Lambda\left(\theta,\sigma^2,\mathrm{A}\right)^{-1}y-H^T\Lambda\left(\theta,\sigma^2,\mathrm{A}\right)^{-1}K(X,X_\mathrm{A}|\theta)B_\mathrm{A}^{-1}K(X_\mathrm{A},X|\theta)\Lambda\left(\theta,\sigma^2,\mathrm{A}\right)^{-1}y,$$

$$B_\mathrm{A}=K(X_\mathrm{A},X_\mathrm{A}|\theta)+K(X_\mathrm{A},X|\theta)\Lambda\left(\theta,\sigma^2,\mathrm{A}\right)^{-1}K(X,X_\mathrm{A}|\theta),$$

$$\Lambda\left(\theta,\sigma^2,\mathrm{A}\right)=\Omega(X|\theta,\mathrm{A})+\sigma^2 I_n\,.$$

Using $\widehat{\beta}_{FIC}\left(\theta,\sigma^2,\mathrm{A}\right)$, the β-profiled marginal log likelihood for FIC approximation is:

$$\log P_{FIC}\left(y\middle|X,\widehat{\beta}_{FIC}\left(\theta,\sigma^2,\mathrm{A}\right),\theta,\sigma^2,\mathrm{A}\right)=$$
$$-\frac{1}{2}\left(y-H\widehat{\beta}_{FIC}\left(\theta,\sigma^2,\mathrm{A}\right)\right)^T\left(\widehat{K}_{FIC}(X,X|\theta,\mathrm{A})+\sigma^2 I_N\right)^{-1}\left(y-H\widehat{\beta}_{FIC}\left(\theta,\sigma^2,\mathrm{A}\right)\right)$$
$$-\frac{N}{2}\log 2\pi-\frac{1}{2}\log\left|\widehat{K}_{FIC}(X,X|\theta,\mathrm{A})+\sigma^2 I_N\right|,$$

where

$$\left(\widehat{K}_{FIC}(X,X|\theta,\mathrm{A})+\sigma^2 I_N\right)^{-1}$$
$$=\Lambda\left(\theta,\sigma^2,\mathrm{A}\right)^{-1}-\Lambda\left(\theta,\sigma^2,\mathrm{A}\right)^{-1}K(X,X_\mathrm{A}|\theta)B_\mathrm{A}^{-1}K(X_\mathrm{A},X|\theta)\Lambda\left(\theta,\sigma^2,\mathrm{A}\right)^{-1},$$
$$\log\left|\widehat{K}_{FIC}(X,X|\theta,\mathrm{A})+\sigma^2 I_N\right|=\log\left|\Lambda\left(\theta,\sigma^2,\mathrm{A}\right)\right|+\log|B_\mathrm{A}|-\log|K(X_\mathrm{A},X_\mathrm{A}|\theta)|\,.$$

Prediction

The FIC approximation to the distribution of y_{new} given y, X, x_{new} is

$$P(y_{new}\,|\,y,X,x_{new})=\mathrm{N}\left(y_{new}\middle|h(x_{new})^T\beta+\mu_{FIC},\sigma_{new}^2+\Sigma_{FIC}\right),$$

where μ_{FIC} and Σ_{FIC} are the FIC approximations to μ and Σ given in prediction using exact GPR method on page 6-11. As in the SR case, μ_{FIC} and Σ_{FIC} are obtained by replacing all occurrences of the true kernel with its FIC approximation. The final forms of μ_{FIC} and Σ_{FIC} are as follows:

$$\mu_{FIC}=K\left(x_{new}^T,X_\mathrm{A}\middle|\theta\right)B_\mathrm{A}^{-1}K(X_\mathrm{A},X|\theta)\,\Lambda\left(\theta,\sigma^2,\mathrm{A}\right)^{-1}(y-H\beta),$$

$$\Sigma_{FIC}=k(x_{new},x_{new}|\theta)-K\left(x_{new}^T,X_\mathrm{A}\middle|\theta\right)K(X_\mathrm{A},X_\mathrm{A}|\theta)^{-1}K\left(X_\mathrm{A},x_{new}^T\middle|\theta\right)$$
$$+K\left(x_{new}^T,X_\mathrm{A}\middle|\theta\right)B_\mathrm{A}^{-1}K\left(X_\mathrm{A},x_{new}^T\middle|\theta\right),$$

where

$$B_{\mathrm{A}} = K(X_{\mathrm{A}}, X_{\mathrm{A}}|\theta) + K(X_{\mathrm{A}}, X|\theta)\Lambda\left(\theta, \sigma^2, \mathrm{A}\right)^{-1}K(X, X_{\mathrm{A}}|\theta),$$

$$\Lambda\left(\theta, \sigma^2, \mathrm{A}\right) = \Omega(X|\theta, \mathrm{A}) + \sigma^2 I_n\,.$$

Block Coordinate Descent Approximation for GPR Models

For a large number of observations, using the exact method for parameter estimation and making predictions on new data can be expensive (see “Exact GPR Method” on page 6-10). One of the approximation methods that help deal with this issue for prediction is the Block Coordinate Descent (BCD) method. You can make predictions using the BCD method by first specifying the predict method using the `'PredictMethod','bcd'` name-value pair argument in the call to `fitrgp`, and then using the `predict` function.

The idea of the BCD method is to compute

$$\widehat{\alpha} = \left(K(X,X) + \sigma^2 I_N\right)^{-1}(y - H\beta)$$

in a different way than the exact method. BCD estimates $\widehat{\alpha}$ by solving the following optimization problem:

$$\widehat{\alpha} = \arg\min_{\alpha} f(\alpha)$$

where

$$f(\alpha) = \frac{1}{2}\alpha^T\left[K(X,X) + \sigma^2 I_N\right]\alpha - \alpha^T(y - H\beta).$$

`fitrgp` uses block coordinate descent (BCD) to solve the above optimization problem. For users familiar with support vector machines (SVMs), sequential minimal optimization (SMO) and ISDA (iterative single data algorithm) used to fit SVMs are special cases of BCD. `fitrgp` performs two steps for each BCD update - block selection and block update. In the block selection phase, `fitrgp` uses a combination of random and greedy strategies for selecting the set of α coefficients to optimize next. In the block update phase, the selected α coefficients are optimized while keeping the other α coefficients fixed to their previous values. These two steps are repeated until convergence. BCD does not store the $n*n$ matrix $K(X,X)$ in memory but it just computes chunks of the $K(X,X)$ matrix as needed. As a result BCD is more memory efficient compared to `'PredictMethod','exact'`.

Practical experience indicates that it is not necessary to solve the optimization problem for computing α to very high precision. For example, it is reasonable to stop the iterations when $||\nabla f(\alpha)||$ drops below $\eta||\nabla f(\alpha_0)||$, where α_0 is the initial value of α and η is a small constant (say $\eta = 10^{-3}$). The results from `'PredictMethod','exact'` and `'PredictMethod','bcd'` are equivalent except BCD computes α in a different way. Hence, `'PredictMethod','bcd'` can be thought of as a memory efficient way of doing `'PredictMethod','exact'`. BCD is often faster than `'PredictMethod','exact'` for large n. However, you cannot compute the prediction intervals using the `'PredictMethod','bcd'` option. This is because computing prediction intervals requires solving a problem like the one solved for computing α for every test point, which again is expensive.

Fit GPR Models Using BCD Approximation

This example shows fitting a Gaussian Process Regression (GPR) model to data with a large number of observations, using the Block Coordinate Descent (BCD) Approximation.

Small n - `PredictMethod 'exact' and 'bcd'` Produce the Same Results

Generate a small sample dataset.

```
rng(0,'twister');
n = 1000;
X = linspace(0,1,n)';
X = [X,X.^2];
y = 1 + X*[1;2] + sin(20*X*[1;-2])./(X(:,1)+1) + 0.2*randn(n,1);
```

Create a GPR model using `'FitMethod','exact'` and `'PredictMethod','exact'`.

```
gpr = fitrgp(X,y,'KernelFunction','squaredexponential',...
    'FitMethod','exact','PredictMethod','exact');
```

Create another GPR model using `'FitMethod','exact'` and `'PredictMethod','bcd'`.

```
gprbcd = fitrgp(X,y,'KernelFunction','squaredexponential',...
    'FitMethod','exact','PredictMethod','bcd','BlockSize',200);
```

`'PredictMethod','exact'` and `'PredictMethod','bcd'` should be equivalent. They compute the same $\hat{\alpha}$ but just in different ways. You can also see the iterations by using the `'Verbose',1` name-value pair argument in the call to `fitrgp` .

Compute the fitted values using the two methods and compare them:

```
ypred    = resubPredict(gpr);
ypredbcd = resubPredict(gprbcd);

max(abs(ypred-ypredbcd))
```

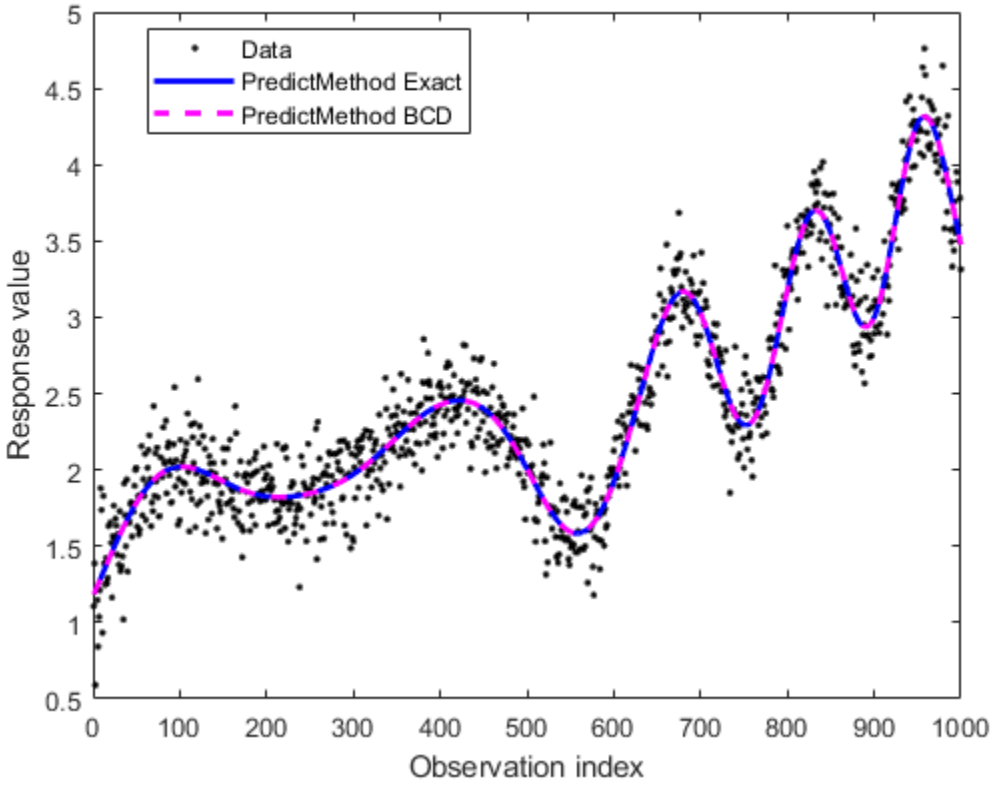
```
ans =

   5.8853e-04
```

The fitted values are close to each other.

Now, plot the data along with fitted values for `'PredictMethod','exact'` and `'PredictMethod','bcd'`.

```
figure;
plot(y,'k.');
hold on;
plot(ypred,'b-','LineWidth',2);
plot(ypredbcd,'m--','LineWidth',2);
legend('Data','PredictMethod Exact','PredictMethod BCD','Location','Best');
xlabel('Observation index');
ylabel('Response value');
```



It can be seen that `'PredictMethod','exact'` and `'PredictMethod','bcd'` produce nearly identical fits.

Large n - Use `'FitMethod','sd'` and `'PredictMethod','bcd'`

Generate a bigger dataset similar to the previous one.

```
rng(0,'twister');
n = 50000;
X = linspace(0,1,n)';
X = [X,X.^2];
y = 1 + X*[1;2] + sin(20*X*[1;-2])./(X(:,1)+1) + 0.2*randn(n,1);
```

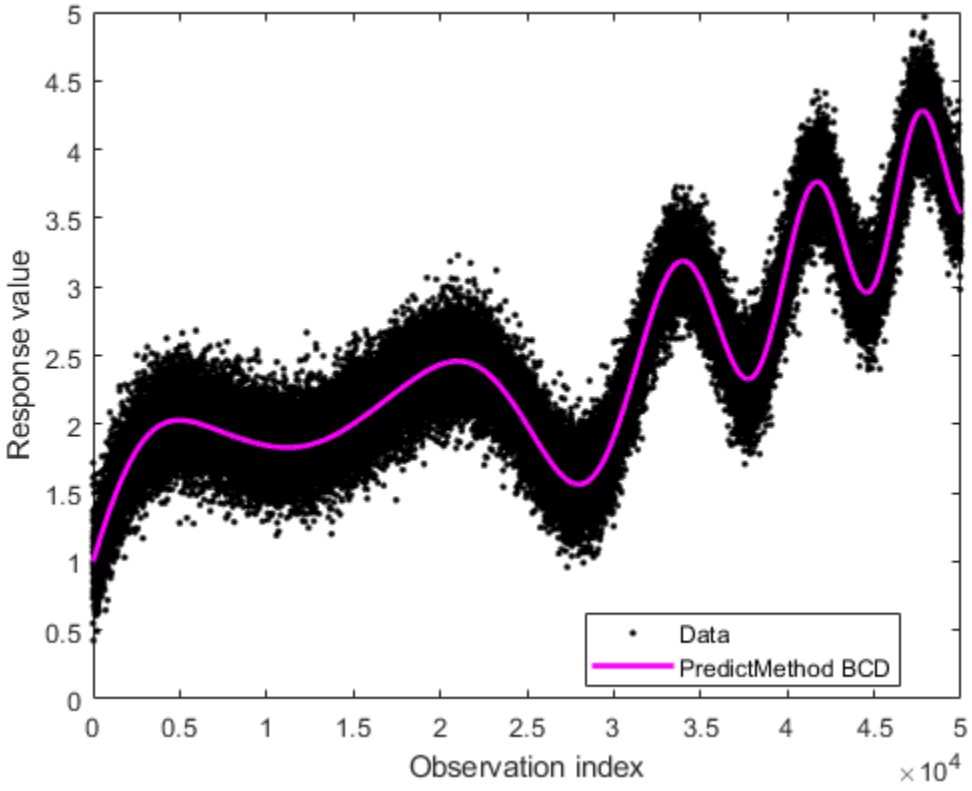
For $n = 50000$, the matrix $K(X, X)$ would be 50000-by-50000. Storing $K(X, X)$ in memory would require around 20 GB of RAM. To fit a GPR model to this dataset, use `'FitMethod','sd'` with a random subset of $m = 2000$ points. The `'ActiveSetSize'` name-value pair argument in the call to `fitrgp` specifies the active set size m. For computing α use `'PredictMethod','bcd'` with a `'BlockSize'` of 5000. The `'BlockSize'` name-value pair argument in `fitrgp` specifies the number of elements of the α vector that the software optimizes at each iteration. A `'BlockSize'` of 5000 assumes that the computer you use can store a 5000-by-5000 matrix in memory.

```
gprbcd = fitrgp(X,y,'KernelFunction','squaredexponential',...,
     'FitMethod','sd','ActiveSetSize',2000,'PredictMethod','bcd','BlockSize',5000);
```

Plot the data and the fitted values.

```
figure;
plot(y,'k.');
```

```
hold on;
plot(resubPredict(gprbcd),'m-','LineWidth',2);
legend('Data','PredictMethod BCD','Location','Best');
xlabel('Observation index');
ylabel('Response value');
```



The plot is similar to the one for smaller n .

Random Number Generation

Generating Pseudorandom Numbers

Pseudorandom numbers are generated by deterministic algorithms. They are "random" in the sense that, on average, they pass statistical tests regarding their distribution and correlation. They differ from true random numbers in that they are generated by an algorithm, rather than a truly random process.

Random number generators (RNGs) like those in MATLAB are algorithms for generating pseudorandom numbers with a specified distribution.

For more information on the GUI for generating random numbers from supported distributions, see “Explore the Random Number Generation UI” on page 5-85.

Common Pseudorandom Number Generation Methods

Methods for generating pseudorandom numbers usually start with uniform random numbers, like the MATLAB `rand` function produces. The methods described in this section detail how to produce random numbers from other distributions.

Direct Methods

Direct methods directly use the definition of the distribution.

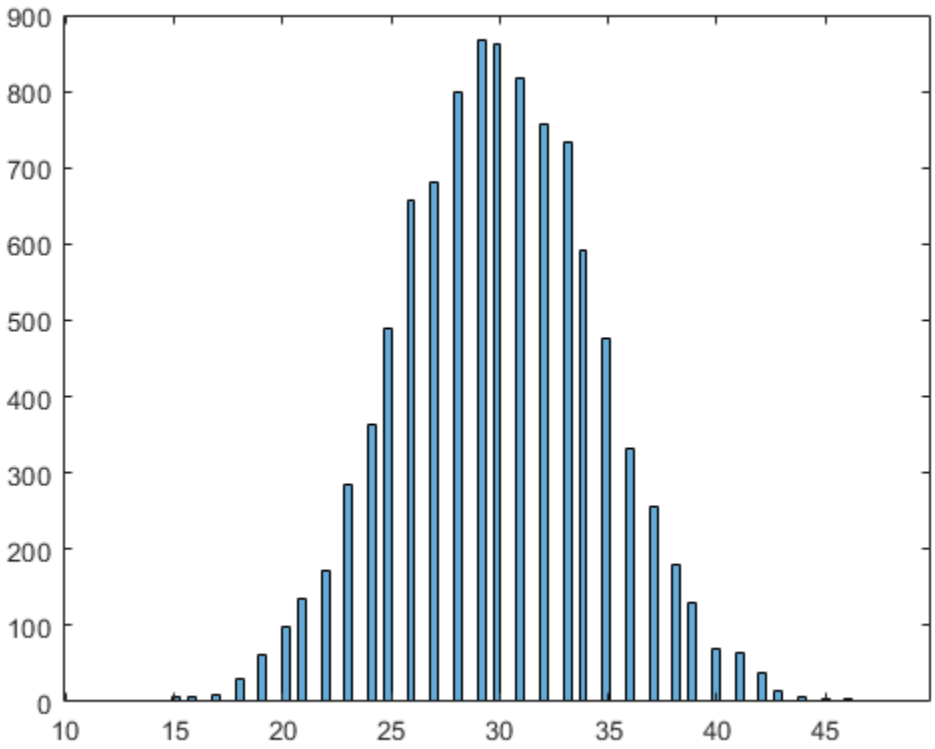
For example, consider binomial random numbers. A binomial random number is the number of heads in N tosses of a coin with probability p of a heads on any single toss. If you generate N uniform random numbers on the interval `(0,1)` and count the number less than p, then the count is a binomial random number with parameters N and p.

This function is a simple implementation of a binomial RNG using the direct approach:

```
function X = directbinornd(N,p,m,n)
    X = zeros(m,n); % Preallocate memory
    for i = 1:m*n
        u = rand(N,1);
        X(i) = sum(u < p);
    end
end
```

For example:

```
rng('default') % For reproducibility
X = directbinornd(100,0.3,1e4,1);
histogram(X,101)
```



The `binornd` function uses a modified direct method, based on the definition of a binomial random variable as the sum of Bernoulli random variables.

You can easily convert the previous method to a random number generator for the Poisson distribution with parameter λ. The "Poisson Distribution" on page B-131 is the limiting case of the binomial distribution as N approaches infinity, p approaches zero, and Np is held fixed at λ. To generate Poisson random numbers, create a version of the previous generator that inputs λ rather than N and p, and internally sets N to some large number and p to λ/N.

The `poissrnd` function actually uses two direct methods:

- A waiting time method for small values of λ
- A method due to Ahrens and Dieter for larger values of λ

Inversion Methods

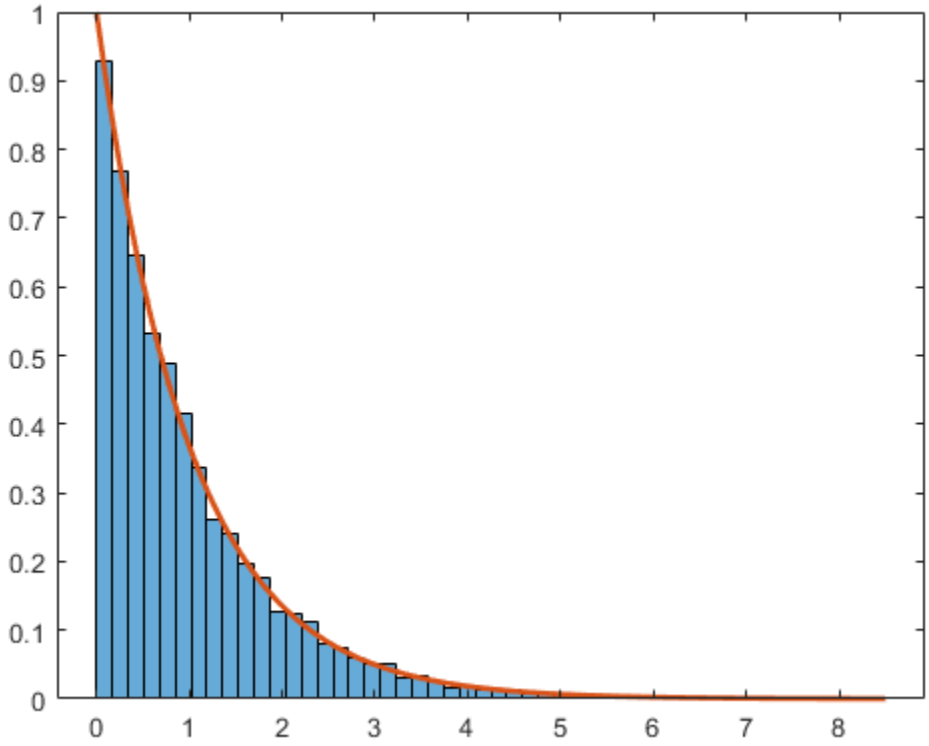
Inversion methods are based on the observation that continuous cumulative distribution functions (cdfs) range uniformly over the interval `(0,1)`. If u is a uniform random number on `(0,1)`, then using $X = F^{-1}(U)$ generates a random number X from a continuous distribution with specified cdf F.

For example, the following code generates random numbers from a specific "Exponential Distribution" on page B-33 using the inverse cdf and the MATLAB® uniform random number generator `rand`:

```
rng('default') % For reproducibility
mu = 1;
X = expinv(rand(1e4,1),mu);
```

Compare the distribution of the generated random numbers to the pdf of the specified exponential.

```
numbins = 50;
h = histogram(X,numbins,'Normalization','pdf');
hold on
x = linspace(h.BinEdges(1),h.BinEdges(end));
y = exppdf(x,mu);
plot(x,y,'LineWidth',2)
hold off
```



Inversion methods also work for discrete distributions. To generate a random number X from a discrete distribution with probability mass vector $P(X = x_i) = p_i$ where $x_0 < x_1 < x_2 < \ldots$, generate a uniform random number u on `(0,1)` and then set $X = x_i$ if $F(x_{i-1}) < u < F(x_i)$.

For example, the following function implements an inversion method for a discrete distribution with probability mass vector p:

```
function X = discreteinvrnd(p,m,n)
    X = zeros(m,n); % Preallocate memory
    for i = 1:m*n
        u = rand;
        I = find(u < cumsum(p));
        X(i) = min(I);
```

```
    end
end
```

Use the function to generate random numbers from any discrete distribution.

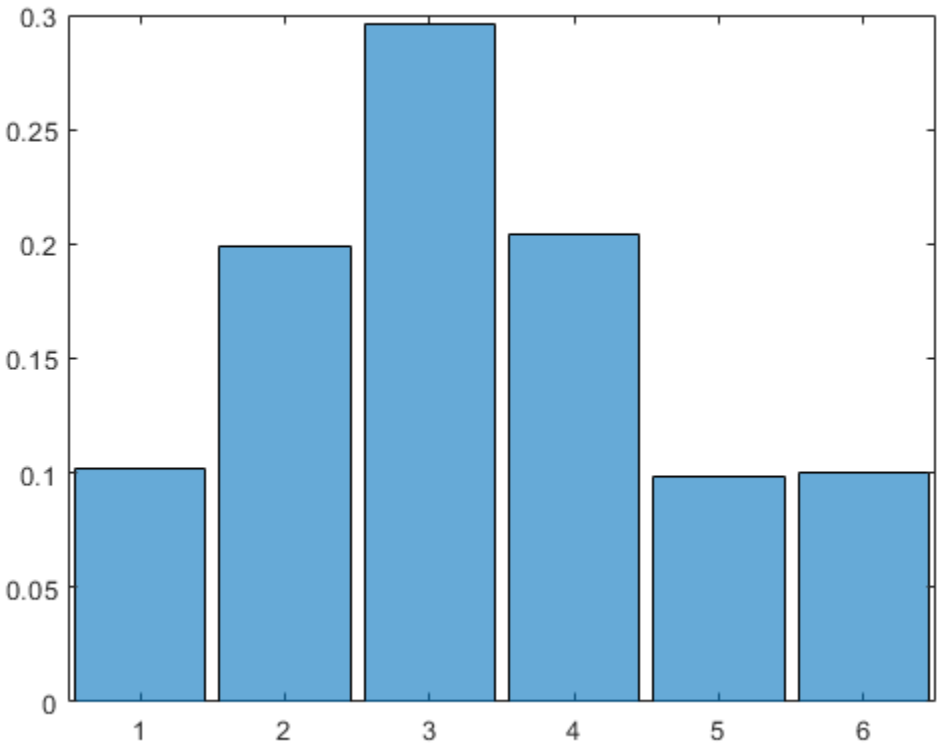
```
p = [0.1 0.2 0.3 0.2 0.1 0.1]; % Probability mass function (pmf) values
X = discreteinvrnd(p,1e4,1);
```

Alternatively, you can use the `discretize` function to generate discrete random numbers.

```
X = discretize(rand(1e4,1),[0 cusmsum(p)]);
```

Plot the histogram of the generated random numbers, and confirm then the distribution follows the specified pmf values.

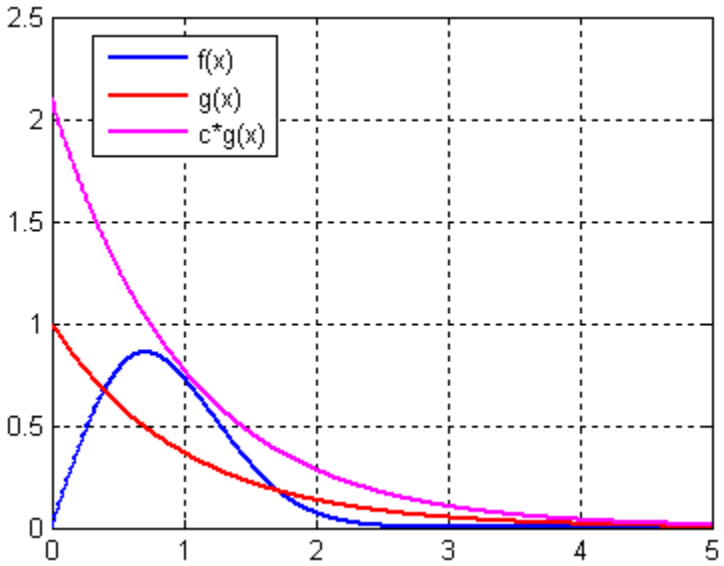
```
histogram(categorical(X),'Normalization','probability')
```



Acceptance-Rejection Methods

The functional form of some distributions makes it difficult or time-consuming to generate random numbers using direct or inversion methods. Acceptance-rejection methods provide an alternative in these cases.

Acceptance-rejection methods begin with uniform random numbers, but require an additional random number generator. If your goal is to generate a random number from a continuous distribution with pdf f, acceptance-rejection methods first generate a random number from a continuous distribution with pdf g satisfying $f(x) \le cg(x)$ for some c and all x.



A continuous acceptance-rejection RNG proceeds as follows:

1. Chooses a density g.
2. Finds a constant c such that $f(x)/g(x) \le c$ for all x.
3. Generates a uniform random number u.
4. Generates a random number v from g.
5. If $cu \le f(v)/g(v)$, accepts and returns v. Otherwise, rejects v and goes to step 3.

For efficiency, a "cheap" method is necessary for generating random numbers from g, and the scalar c should be small. The expected number of iterations to produce a single random number is c.

The following function implements an acceptance-rejection method for generating random numbers from pdf f given f, g, the RNG `grnd` for g, and the constant c:

```
function X = accrejrnd(f,g,grnd,c,m,n)
    X = zeros(m,n); % Preallocate memory
    for i = 1:m*n
        accept = false;
        while accept == false
            u = rand();
            v = grnd();
            if c*u <= f(v)/g(v)
               X(i) = v;
               accept = true;
            end
        end
    end
end
```

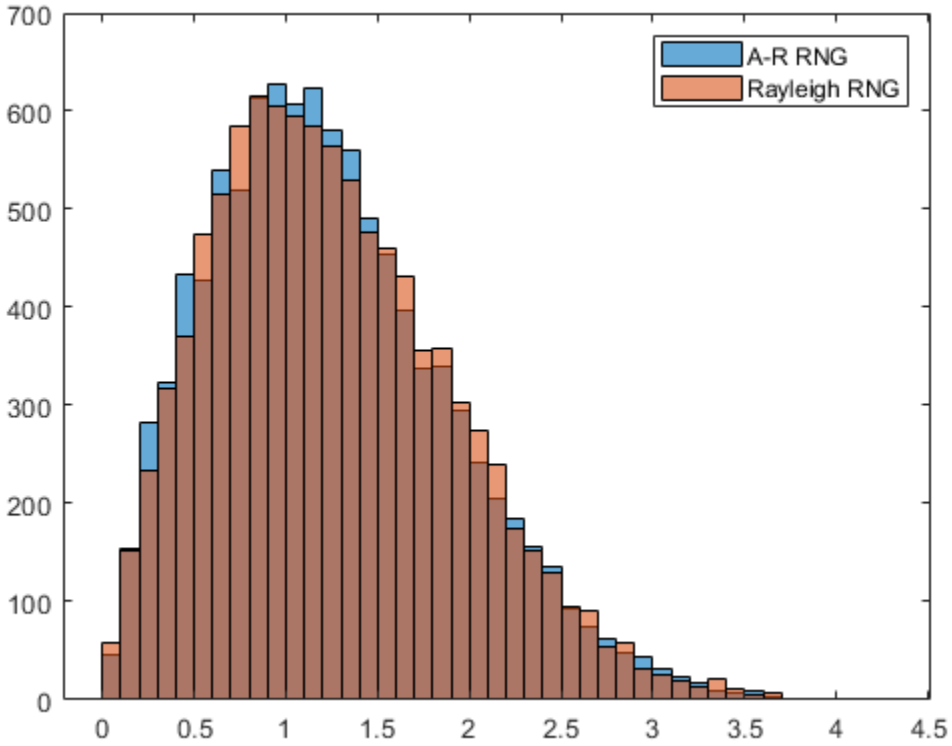
For example, the function $f(x) = xe^{-x^2/2}$ satisfies the conditions for a pdf on $[0, \infty)$ (nonnegative and integrates to 1). The exponential pdf with mean 1, $f(x) = e^{-x}$, dominates g for c greater than about 2.2. Thus, you can use `rand` and `exprnd` to generate random numbers from f:

```
f = @(x)x.*exp(-(x.^2)/2);
g = @(x)exp(-x);
```

```
grnd = @()exprnd(1);
rng('default') % For reproducibility
X = accrejrnd(f,g,grnd,2.2,1e4,1);
```

The pdf f is actually a “Rayleigh Distribution” on page B-137 with shape parameter 1. This example compares the distribution of random numbers generated by the acceptance-rejection method with those generated by `raylrnd`:

```
Y = raylrnd(1,1e4,1);
histogram(X)
hold on
histogram(Y)
legend('A-R RNG','Rayleigh RNG')
```



The `raylrnd` function uses a transformation method, expressing a Rayleigh random variable in terms of a chi-square random variable, which you compute using `randn`.

Acceptance-rejection methods also work for discrete distributions. In this case, the goal is to generate random numbers from a distribution with probability mass $P_p(X = i) = p_i$, assuming that you have a method for generating random numbers from a distribution with probability mass $P_q(X = i) = q_i$. The RNG proceeds as follows:

1. Chooses a density P_q.
2. Finds a constant c such that $p_i/q_i \le c$ for all i.
3. Generates a uniform random number u.

4 Generates a random number v from P_q.

5 If $cu \le p_v/q_v$, accepts and returns v. Otherwise, rejects v and goes to step 3.

Representing Sampling Distributions Using Markov Chain Samplers

In this section...

For more complex probability distributions, you might need more advanced methods for generating samples than the methods described in “Common Pseudorandom Number Generation Methods” on page 7-2. Such distributions arise, for example, in Bayesian data analysis and in the large combinatorial problems of Markov chain Monte Carlo (MCMC) simulations. An alternative is to construct a Markov chain with a stationary distribution equal to the target sampling distribution, using the states of the chain to generate random numbers after an initial burn-in period in which the state distribution converges to the target.

Using the Metropolis-Hastings Algorithm

The Metropolis-Hastings algorithm draws samples from a distribution that is only known up to a constant. Random numbers are generated from a distribution with a probability density function that is equal to or proportional to a proposal function.

To generate random numbers:

1. Assume an initial value $x(t)$.
2. Draw a sample, $y(t)$, from a proposal distribution $q(y|x(t))$.
3. Accept $y(t)$ as the next sample $x(t + 1)$ with probability $r(x(t),y(t))$, and keep $x(t)$ as the next sample $x(t + 1)$ with probability $1 – r(x(t),y(t))$, where:

   $$r(x, y) = min\left\{\frac{f(y)}{f(x)}\frac{q(x|y)}{q(y|x)}, 1\right\}$$

4. Increment $t \rightarrow t + 1$, and repeat steps 2 and 3 until you get the desired number of samples.

Generate random numbers using the Metropolis-Hastings method with the `mhsample` function. To produce quality samples efficiently with the Metropolis-Hastings algorithm, it is crucial to select a good proposal distribution. If it is difficult to find an efficient proposal distribution, use slice sampling (`slicesample`) or Hamiltonian Monte Carlo (`hmcSampler`) instead.

Using Slice Sampling

In instances where it is difficult to find an efficient Metropolis-Hastings proposal distribution, the slice sampling algorithm does not require an explicit specification. The slice sampling algorithm draws samples from the region under the density function using a sequence of vertical and horizontal steps. First, it selects a height at random from 0 to the density function $f(x)$. Then, it selects a new x value at random by sampling from the horizontal “slice” of the density above the selected height. A similar slice sampling algorithm is used for a multivariate distribution.

If a function $f(x)$ proportional to the density function is given, then do the following to generate random numbers:

1. Assume an initial value $x(t)$ within the domain of $f(x)$.
2. Draw a real value y uniformly from $(0, f(x(t)))$, thereby defining a horizontal "slice" as $S = \{x: y < f(x)\}$.
3. Find an interval $I = (L, R)$ around $x(t)$ that contains all, or much of the "slice" S.
4. Draw the new point $x(t + 1)$ within this interval.
5. Increment $t \rightarrow t + 1$ and repeat steps 2 through 4 until you get the desired number of samples.

Slice sampling can generate random numbers from a distribution with an arbitrary form of the density function, provided that an efficient numerical procedure is available to find the interval $I = (L,R)$, which is the "slice" of the density.

Generate random numbers using the slice sampling method with the `slicesample` function.

Using Hamiltonian Monte Carlo

Metropolis-Hastings and slice sampling can produce MCMC chains that mix slowly and take a long time to converge to the stationary distribution, especially in medium-dimensional and high-dimensional problems. Use the gradient-based Hamiltonian Monte Carlo (HMC) sampler to speed up sampling in these situations.

To use HMC sampling, you must specify log $f(x)$ (up to an additive constant) and its gradient. You can use a numerical gradient, but this leads to slower sampling. All sampling variables must be unconstrained, meaning that log $f(x)$ and its gradient are well-defined for all real x. To sample constrained variables, transform these variables into unconstrained ones before using the HMC sampler.

The HMC sampling algorithm introduces a random "momentum vector" z and defines a joint density of z and the "position vector" x as $P(x,z) = f(x)g(z)$. The goal is to sample from this joint distribution and then to ignore the values of z — the marginal distribution of x has the desired density $f(x)$.

The HMC algorithm assigns a Gaussian density with covariance matrix M (the "mass matrix") to z:

$$g(z) \propto \exp\left(-\frac{1}{2}z^T M^{-1} z\right)$$

Then, it defines an "energy function" as

$$E(x, z) = -\log f(x) + \frac{1}{2}z^T M^{-1} z = U(x) + K(z)$$

with $U(x) = -\log f(x)$ the "potential energy" and $K(z) = z^T M^{-1} z/2$ the "kinetic energy". The joint density is given by $P(x,z) \propto \exp\{-E(x,z)\}$.

To generate random samples, the HMC algorithm:

1. Assumes an initial value x of the position vector.
2. Generates a sample of the momentum vector: $z \sim g(z)$.
3. Evolves the state (x, z) for some amount of fictitious time τ to a new state (x', z') using the "equations of motion":

$$\frac{dz}{d\tau} = -\frac{\partial U}{\partial x}$$

$$\frac{dx}{d\tau} = \frac{\partial K}{\partial z}$$

If the equations of motion could be solved exactly, the energy (and hence the density) would remain constant: $E(x,z) = E(x',z')$. In practice, the equations of motions must be solved numerically (usually using so-called leapfrog integration) and the energy is not conserved.

4. Accepts x' as the next sample with probability $p_{acc} = \min(1, \exp\{E(x,z) - E(x',z')\})$, and keeps x as the next sample with probability $1 - p_{acc}$.
5. Repeats steps 2 through 4 until it has generated the desired number of samples.

To use HMC sampling, create a sampler using the `hmcSampler` function. After creating a sampler, you can compute MAP (maximum-a-posteriori) point estimates, tune the sampler, draw samples, and check convergence diagnostics. For an example of this workflow, see “Bayesian Linear Regression Using Hamiltonian Monte Carlo” on page 7-26.

Generating Quasi-Random Numbers

In this section...

Quasi-Random Sequences

Quasi-random number generators (QRNGs) produce highly uniform samples of the unit hypercube. QRNGs minimize the discrepancy between the distribution of generated points and a distribution with equal proportions of points in each sub-cube of a uniform partition of the hypercube. As a result, QRNGs systematically fill the “holes” in any initial segment of the generated quasi-random sequence.

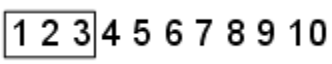
Unlike the pseudorandom sequences described in “Common Pseudorandom Number Generation Methods” on page 7-2, quasi-random sequences fail many statistical tests for randomness. Approximating true randomness, however, is not their goal. Quasi-random sequences seek to fill space uniformly, and to do so in such a way that initial segments approximate this behavior up to a specified density.

QRNG applications include:

- **Quasi-Monte Carlo (QMC) integration.** Monte Carlo techniques are often used to evaluate difficult, multi-dimensional integrals without a closed-form solution. QMC uses quasi-random sequences to improve the convergence properties of these techniques.
- **Space-filling experimental designs.** In many experimental settings, taking measurements at every factor setting is expensive or infeasible. Quasi-random sequences provide efficient, uniform sampling of the design space.
- **Global optimization.** Optimization algorithms typically find a local optimum in the neighborhood of an initial value. By using a quasi-random sequence of initial values, searches for global optima uniformly sample the basins of attraction of all local minima.

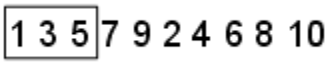
Example: Using Scramble, Leap, and Skip

Imagine a simple 1-D sequence that produces the integers from 1 to 10. This is the basic sequence and the first three points are `[1,2,3]`:

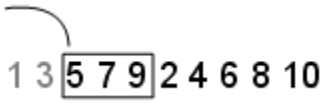


Now look at how `Scramble`, `Skip`, and `Leap` work together:

- `Scramble` — Scrambling shuffles the points in one of several different ways. In this example, assume a scramble turns the sequence into `1,3,5,7,9,2,4,6,8,10`. The first three points are now `[1,3,5]`:



- `Skip` — A `Skip` value specifies the number of initial points to ignore. In this example, set the `Skip` value to 2. The sequence is now `5,7,9,2,4,6,8,10` and the first three points are `[5,7,9]`:



- `Leap` — A `Leap` value specifies the number of points to ignore for each one you take. Continuing the example with the `Skip` set to 2, if you set the `Leap` to 1, the sequence uses every other point. In this example, the sequence is now `5,9,4,8` and the first three points are `[5,9,4]`:

Quasi-Random Point Sets

Statistics and Machine Learning Toolbox functions support these quasi-random sequences:

- **Halton sequences.** Produced by the `haltonset` function. These sequences use different prime bases to form successively finer uniform partitions of the unit interval in each dimension.
- **Sobol sequences.** Produced by the `sobolset` function. These sequences use a base of 2 to form successively finer uniform partitions of the unit interval, and then reorder the coordinates in each dimension.
- **Latin hypercube sequences.** Produced by the `lhsdesign` function. Though not quasi-random in the sense of minimizing discrepancy, these sequences nevertheless produce sparse uniform samples useful in experimental designs.

Quasi-random sequences are functions from the positive integers to the unit hypercube. To be useful in application, an initial point set of a sequence must be generated. Point sets are matrices of size *n*-by-*d*, where *n* is the number of points and *d* is the dimension of the hypercube being sampled. The functions `haltonset` and `sobolset` construct point sets with properties of a specified quasi-random sequence. Initial segments of the point sets are generated by the `net` method of the `haltonset` and `sobolset` classes, but points can be generated and accessed more generally using parenthesis indexing.

Because of the way in which quasi-random sequences are generated, they may contain undesirable correlations, especially in their initial segments, and especially in higher dimensions. To address this issue, quasi-random point sets often skip, leap over, or scramble values in a sequence. The `haltonset` and `sobolset` functions allow you to specify both a `Skip` and a `Leap` property of a quasi-random sequence, and the `scramble` method of the `haltonset` and `sobolset` classes allows you apply a variety of scrambling techniques. Scrambling reduces correlations while also improving uniformity.

Generate a Quasi-Random Point Set

This example shows how to use `haltonset` to construct a 2-D Halton quasi-random point set.

Create a `haltonset` object `p`, that skips the first 1000 values of the sequence and then retains every 101st point.

```
rng default  % For reproducibility
p = haltonset(2,'Skip',1e3,'Leap',1e2)

p =
Halton point set in 2 dimensions (89180190640991 points)

Properties:
               Skip : 1000
               Leap : 100
    ScrambleMethod : none
```

The object `p` encapsulates properties of the specified quasi-random sequence. The point set is finite, with a length determined by the `Skip` and `Leap` properties and by limits on the size of point set indices.

Use `scramble` to apply reverse-radix scrambling.

```
p = scramble(p,'RR2')

p =
Halton point set in 2 dimensions (89180190640991 points)

Properties:
               Skip : 1000
               Leap : 100
    ScrambleMethod : RR2
```

Use `net` to generate the first 500 points.

```
X0 = net(p,500);
```

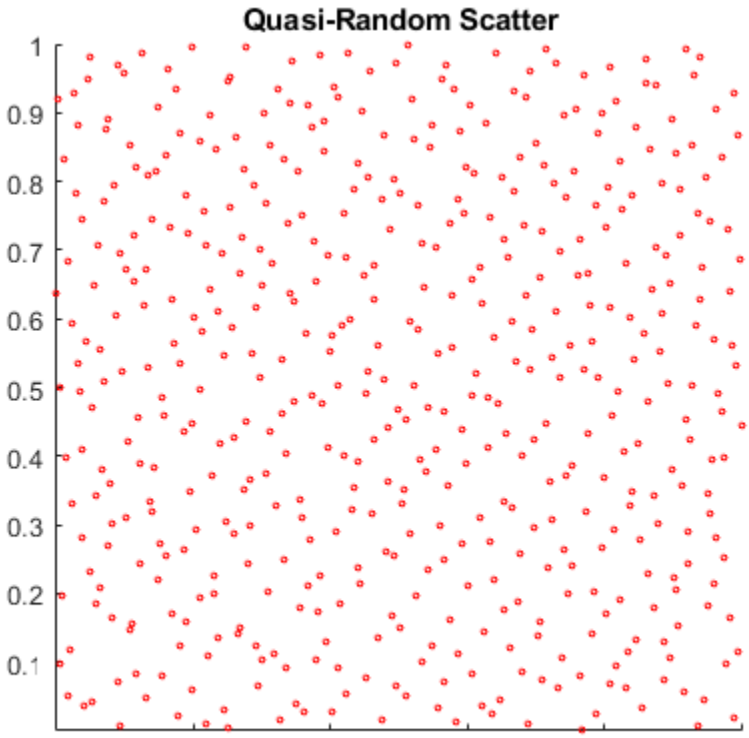
This is equivalent to

```
X0 = p(1:500,:);
```

Values of the point set `X0` are not generated and stored in memory until you access `p` using `net` or parenthesis indexing.

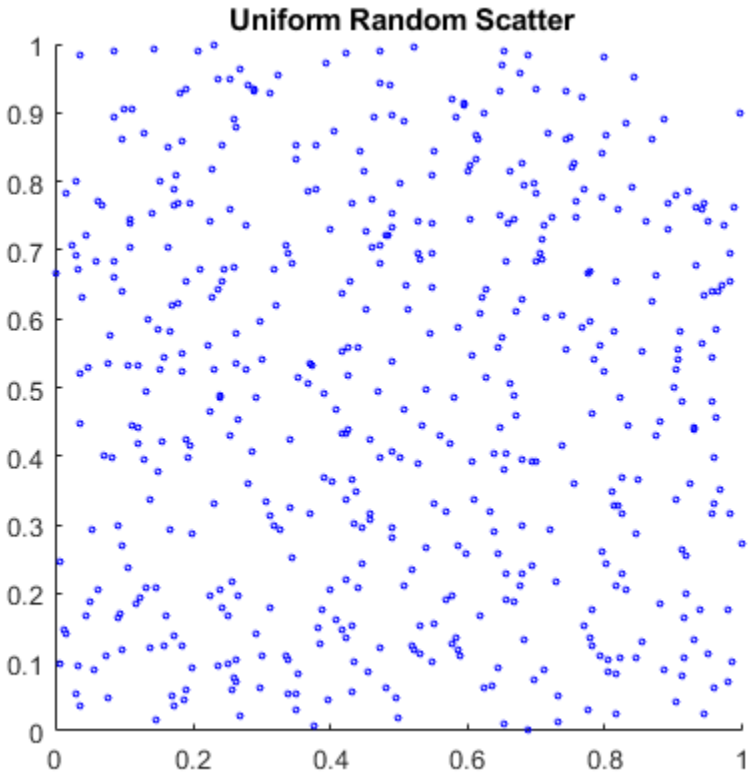
To appreciate the nature of quasi-random numbers, create a scatter plot of the two dimensions in `X0`.

```
scatter(X0(:,1),X0(:,2),5,'r')
axis square
title('{\bf Quasi-Random Scatter}')
```



Compare this to a scatter of uniform pseudorandom numbers generated by the `rand` function.

```
X = rand(500,2);
scatter(X(:,1),X(:,2),5,'b')
axis square
title('{\bf Uniform Random Scatter}')
```

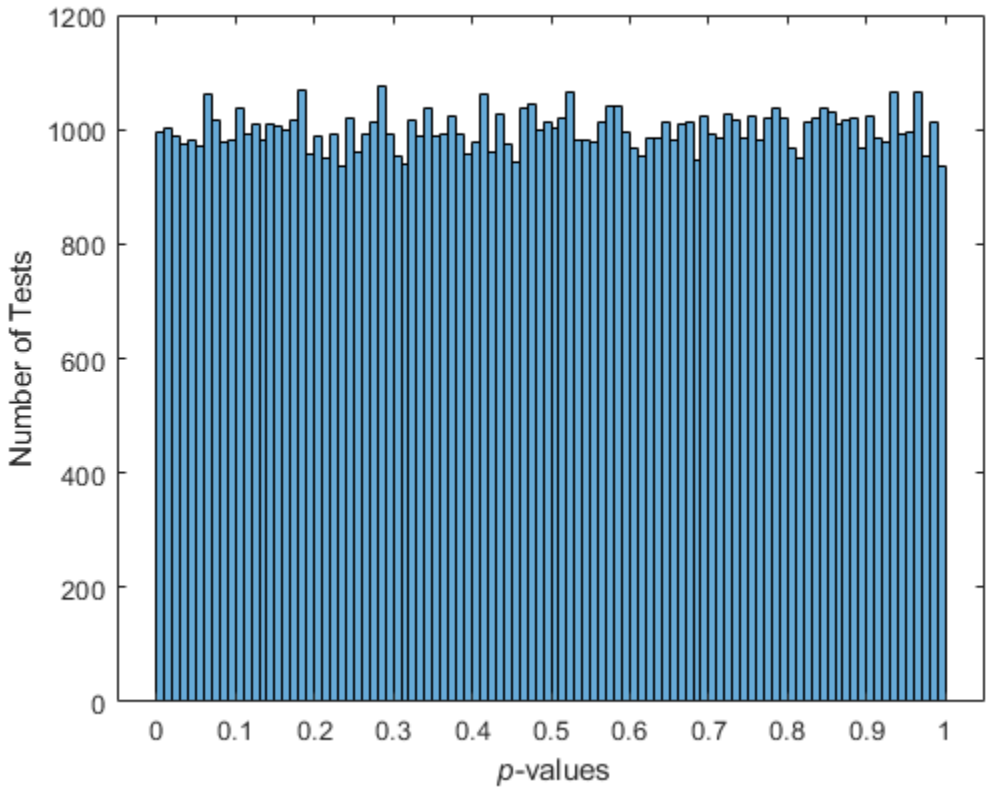


The quasi-random scatter appears more uniform, avoiding the clumping in the pseudorandom scatter.

In a statistical sense, quasi-random numbers are too uniform to pass traditional tests of randomness. For example, a Kolmogorov-Smirnov test, performed by `kstest`, is used to assess whether or not a point set has a uniform random distribution. When performed repeatedly on uniform pseudorandom samples, such as those generated by `rand`, the test produces a uniform distribution of *p*-values.

```
nTests = 1e5;
sampSize = 50;
PVALS = zeros(nTests,1);
for test = 1:nTests
    x = rand(sampSize,1);
    [h,pval] = kstest(x,[x,x]);
    PVALS(test) = pval;
end

histogram(PVALS,100)
h = findobj(gca,'Type','patch');
xlabel('{\it p}-values')
ylabel('Number of Tests')
```

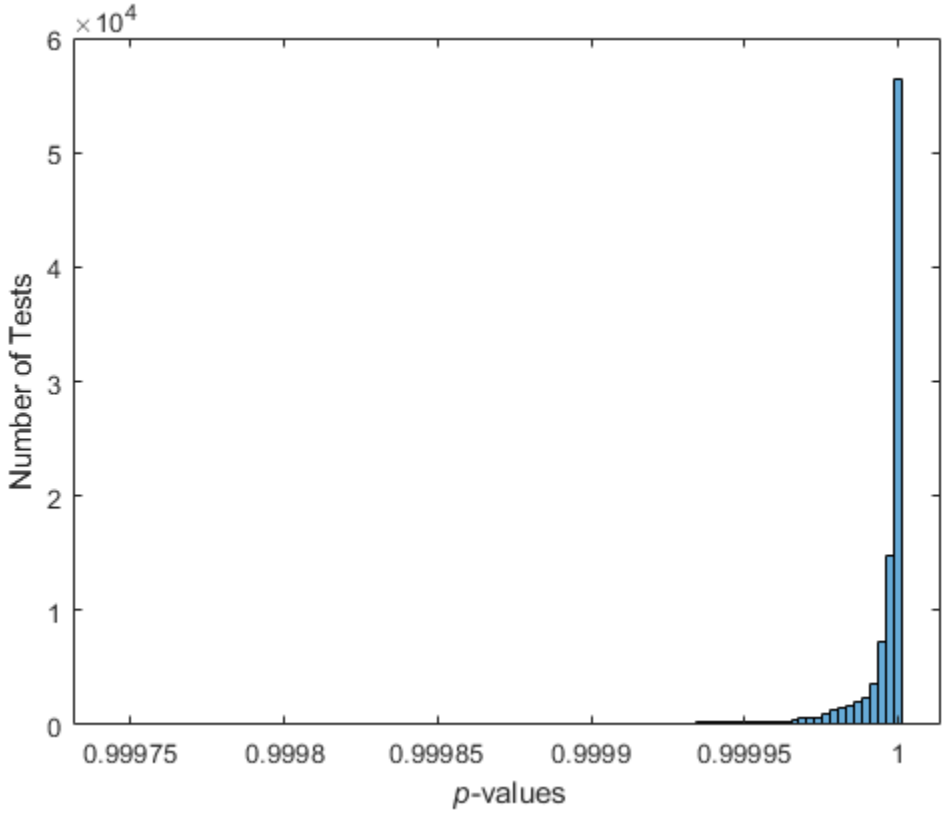


The results are quite different when the test is performed repeatedly on uniform quasi-random samples.

```
p = haltonset(1,'Skip',1e3,'Leap',1e2);
p = scramble(p,'RR2');

nTests = 1e5;
sampSize = 50;
PVALS = zeros(nTests,1);
for test = 1:nTests
    x = p(test:test+(sampSize-1),:);
    [h,pval] = kstest(x,[x,x]);
    PVALS(test) = pval;
end

histogram(PVALS,100)
xlabel('{\it p}-values')
ylabel('Number of Tests')
```



Small *p*-values call into question the null hypothesis that the data are uniformly distributed. If the hypothesis is true, about 5% of the *p*-values are expected to fall below 0.05. The results are remarkably consistent in their failure to challenge the hypothesis.

Quasi-Random Streams

Quasi-random streams, produced by the `qrandstream` function, are used to generate sequential quasi-random outputs, rather than point sets of a specific size. Streams are used like pseudoRNGS, such as `rand`, when client applications require a source of quasi-random numbers of indefinite size that can be accessed intermittently. Properties of a quasi-random stream, such as its type (Halton or Sobol), dimension, skip, leap, and scramble, are set when the stream is constructed.

In implementation, quasi-random streams are essentially very large quasi-random point sets, though they are accessed differently. The state of a quasi-random stream is the scalar index of the next point to be taken from the stream. Use the `qrand` method of the `qrandstream` on page 33-5078 class to generate points from the stream, starting from the current state. Use the `reset` method to reset the state to `1`. Unlike point sets, streams do not support parenthesis indexing.

Generate a Quasi-Random Stream

This example shows how to generate samples from a quasi-random point set.

Use `haltonset` to create a quasi-random point set `p`, then repeatedly increment the index into the point set `test` to generate different samples.

```
p = haltonset(1,'Skip',1e3,'Leap',1e2);
p = scramble(p,'RR2');

nTests = 1e5;
sampSize = 50;
PVALS = zeros(nTests,1);
for test = 1:nTests
    x = p(test:test+(sampSize-1),:);
    [h,pval] = kstest(x,[x,x]);
    PVALS(test) = pval;
end
```

The same results are obtained by using `qrandstream` to construct a quasi-random stream `q` based on the point set `p` and letting the stream take care of increments to the index.

```
p = haltonset(1,'Skip',1e3,'Leap',1e2);
p = scramble(p,'RR2');
q = qrandstream(p);

nTests = 1e5;
sampSize = 50;
PVALS = zeros(nTests,1);
for test = 1:nTests
    X = qrand(q,sampSize);
    [h,pval] = kstest(X,[X,X]);
    PVALS(test) = pval;
end
```

Generating Data Using Flexible Families of Distributions

This example shows how to generate data using the Pearson and Johnson systems of distributions.

Pearson and Johnson Systems

As described in “Working with Probability Distributions” on page 5-3, choosing an appropriate parametric family of distributions to model your data can be based on *a priori* or *a posteriori* knowledge of the data-producing process, but the choice is often difficult. The *Pearson and Johnson systems* can make such a choice unnecessary. Each system is a flexible parametric family of distributions that includes a wide range of distribution shapes, and it is often possible to find a distribution within one of these two systems that provides a good match to your data.

Data Input

The following parameters define each member of the Pearson and Johnson systems.

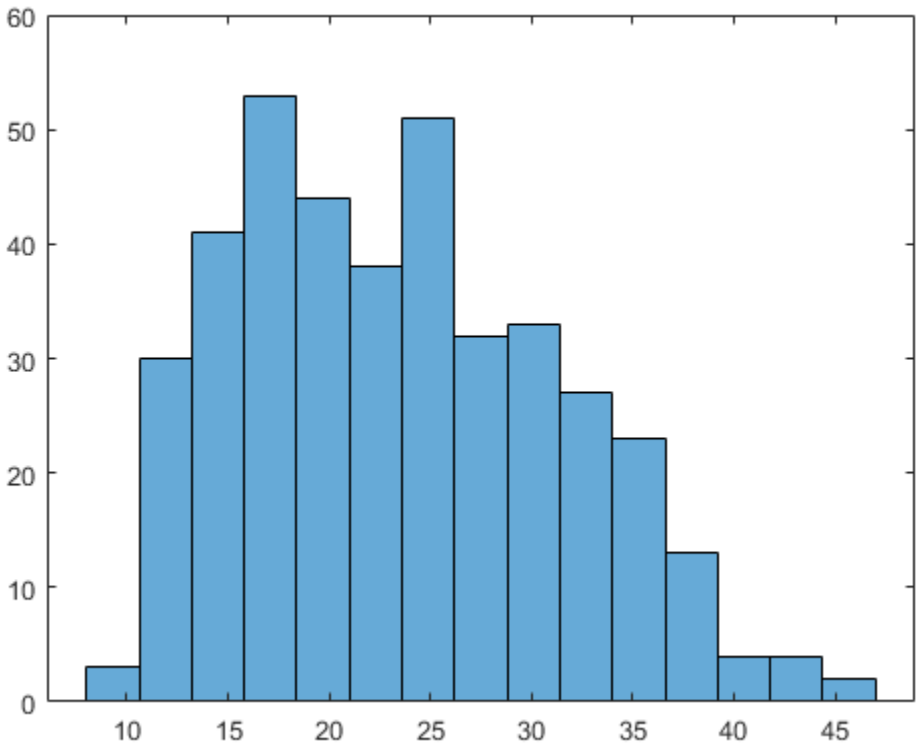
- Mean — Estimated by `mean`
- Standard deviation — Estimated by `std`
- Skewness — Estimated by `skewness`
- Kurtosis — Estimated by `kurtosis`

These statistics can also be computed with the `moment` function. The Johnson system, while based on these four parameters, is more naturally described using quantiles, estimated by the `quantile` function.

The `pearsrnd` and `johnsrnd` functions take input arguments defining a distribution (parameters or quantiles, respectively) and return the type and the coefficients of the distribution in the corresponding system. Both functions also generate random numbers from the specified distribution.

As an example, load the data in `carbig.mat`, which includes a variable `MPG` containing measurements of the gas mileage for each car.

```
load carbig
MPG = MPG(~isnan(MPG));
histogram(MPG,15)
```



The following two sections model the distribution with members of the Pearson and Johnson systems, respectively.

Generating Data Using the Pearson System

The statistician Karl Pearson devised a system, or family, of distributions that includes a unique distribution corresponding to every valid combination of mean, standard deviation, skewness, and kurtosis. If you compute sample values for each of these moments from data, it is easy to find the distribution in the Pearson system that matches these four moments and to generate a random sample.

The Pearson system embeds seven basic types of distribution together in a single parametric framework. It includes common distributions such as the normal and *t* distributions, simple transformations of standard distributions such as a shifted and scaled beta distribution and the inverse gamma distribution, and one distribution—the Type IV—that is not a simple transformation of any standard distribution.

For a given set of moments, there are distributions that are not in the system that also have those same first four moments, and the distribution in the Pearson system may not be a good match to your data, particularly if the data are multimodal. But the system does cover a wide range of distribution shapes, including both symmetric and skewed distributions.

To generate a sample from the Pearson distribution that closely matches the `MPG` data, simply compute the four sample moments and treat those as distribution parameters.

```
moments = {mean(MPG),std(MPG),skewness(MPG),kurtosis(MPG)};
rng('default')  % For reproducibility
[r,type] = pearsrnd(moments{:},10000,1);
```

The optional second output from `pearsrnd` indicates which type of distribution within the Pearson system matches the combination of moments.

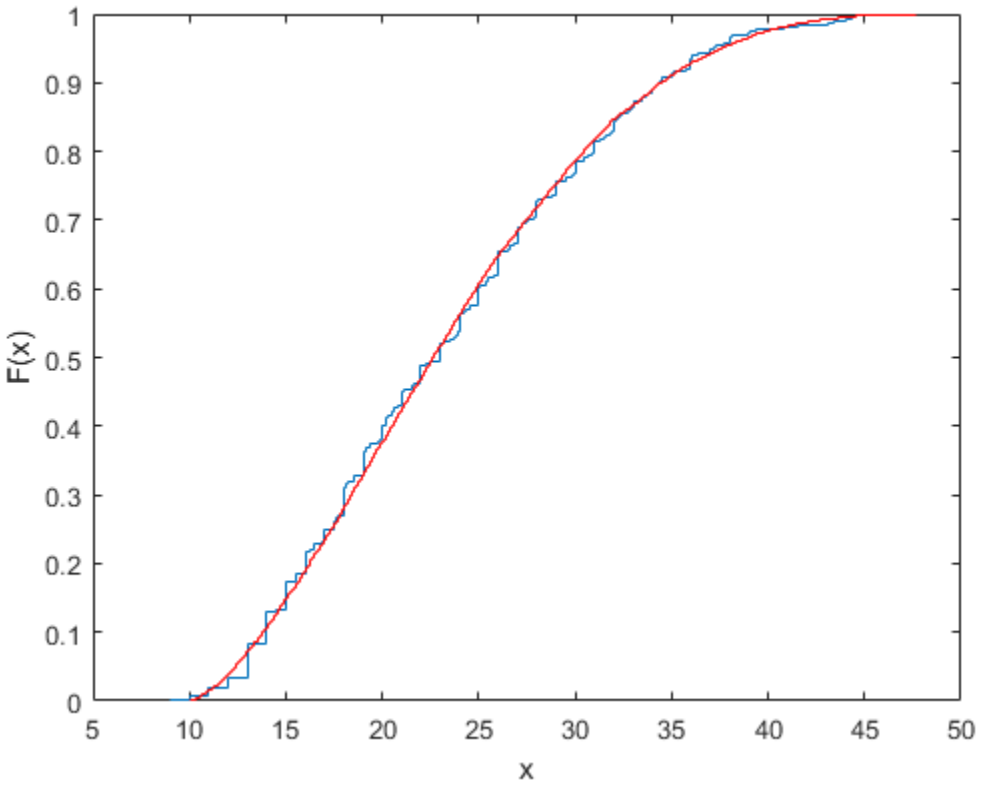
```
type
```

```
type = 1
```

In this case, `pearsrnd` has determined that the data are best described with a Type I Pearson distribution, which is a shifted, scaled beta distribution.

Verify that the sample resembles the original data by overlaying the empirical cumulative distribution functions.

```
ecdf(MPG);
[Fi,xi] = ecdf(r);
hold on;
stairs(xi,Fi,'r');
hold off
```



Generating Data Using the Johnson System

Statistician Norman Johnson devised a different system of distributions that also includes a unique distribution for every valid combination of mean, standard deviation, skewness, and kurtosis.

However, since it is more natural to describe distributions in the Johnson system using quantiles, working with this system is different than working with the Pearson system.

The Johnson system is based on three possible transformations of a normal random variable, plus the identity transformation. The three nontrivial cases are known as `SL` , `SU` , and `SB` , corresponding to exponential, logistic, and hyperbolic sine transformations. All three can be written as

$$X = \gamma + \delta \cdot \Gamma\left(\frac{Z - \xi}{\lambda}\right)$$

where Z is a standard normal random variable, Γ is the transformation, and γ, δ, ξ, and λ are scale and location parameters. The fourth case, `SN` , is the identity transformation.

To generate a sample from the Johnson distribution that matches the `MPG` data, first define the four quantiles to which the four evenly spaced standard normal quantiles of -1.5, -0.5, 0.5, and 1.5 should be transformed. That is, you compute the sample quantiles of the data for the cumulative probabilities of 0.067, 0.309, 0.691, and 0.933.

```
probs = normcdf([-1.5 -0.5 0.5 1.5])
```

```
probs = 1×4

    0.0668    0.3085    0.6915    0.9332
```

```
quantiles = quantile(MPG,probs)
```

```
quantiles = 1×4

   13.0000   18.0000   27.2000   36.0000
```

Then treat those quantiles as distribution parameters.

```
[r1,type] = johnsrnd(quantiles,10000,1);
```

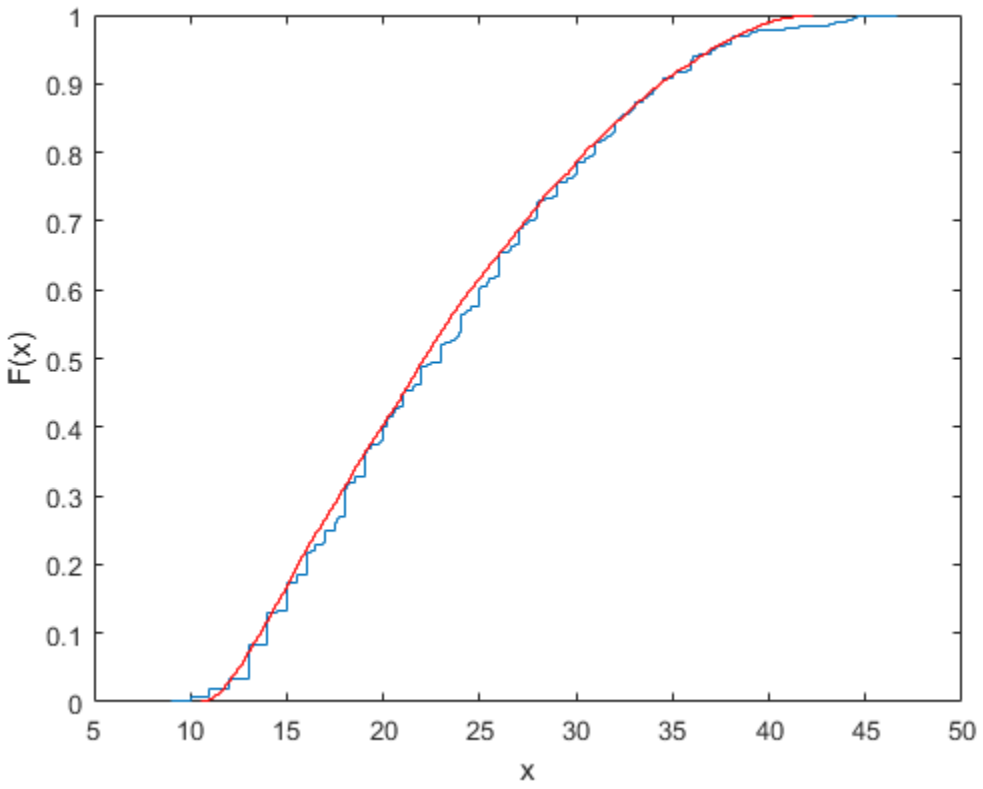
The optional second output from `johnsrnd` indicates which type of distribution within the Johnson system matches the quantiles.

```
type
```

```
type =
'SB'
```

You can verify that the sample resembles the original data by overlaying the empirical cumulative distribution functions.

```
ecdf(MPG);
[Fi,xi] = ecdf(r1);
hold on;
stairs(xi,Fi,'r');
hold off
```



In some applications, it may be important to match the quantiles better in some regions of the data than in others. To do that, specify four evenly spaced standard normal quantiles at which you want to match the data, instead of the default -1.5, -0.5, 0.5, and 1.5. For example, you might care more about matching the data in the right tail than in the left, and so you specify standard normal quantiles that emphasizes the right tail.

```
qnorm = [-.5 .25 1 1.75];
probs = normcdf(qnorm);
qemp = quantile(MPG,probs);
r2 = johnsrnd([qnorm; qemp],10000,1);
```

However, while the new sample matches the original data better in the right tail, it matches much worse in the left tail.

```
[Fj,xj] = ecdf(r2);
hold on;
stairs(xj,Fj,'g');
hold off
```

Bayesian Linear Regression Using Hamiltonian Monte Carlo

This example shows how to perform Bayesian inference on a linear regression model using a Hamiltonian Monte Carlo (HMC) sampler.

In Bayesian parameter inference, the goal is to analyze statistical models with the incorporation of prior knowledge of model parameters. The posterior distribution of the free parameters θ combines the likelihood function $P(y|\theta)$ with the prior distribution $P(\theta)$, using Bayes' theorem:

$$P(\theta|y) = \frac{P(y|\theta)P(\theta)}{P(y)}.$$

Usually, the best way to summarize the posterior distribution is to obtain samples from that distribution using Monte Carlo methods. Using these samples, you can estimate marginal posterior distributions and derived statistics such as the posterior mean, median, and standard deviation. HMC is a gradient-based Markov Chain Monte Carlo sampler that can be more efficient than standard samplers, especially for medium-dimensional and high-dimensional problems.

Linear Regression Model

Analyze a linear regression model with the intercept α, the linear coefficients β (a column vector), and the noise variance σ^2 of the data distribution as free parameters. Assume that each data point has an independent Gaussian distribution:

$$y_i|\theta \sim \mathcal{N}(\mu_i(\theta), \sigma^2).$$

Model the mean μ_i of the Gaussian distribution as a function of the predictors x_i and model parameters as

$$\mu_i = \alpha + x_i^T\beta.$$

In a Bayesian analysis, you also must assign prior distributions to all free parameters. Assign independent Gaussian priors on the intercept and linear coefficients:

$\alpha \sim \mathcal{N}(\alpha_0, \sigma_\alpha^2)$,

$\beta_i \sim \mathcal{N}(\beta_0, \sigma_\beta^2)$.

To use HMC, all sampling variables must be unconstrained, meaning that the posterior density and its gradient must be well-defined for all real parameter values. If you have a parameter that is constrained to an interval, then you must transform this parameter into an unbounded one. To conserve probability, you must multiply the prior distribution by the corresponding Jacobian factor. Also, take this factor into account when calculating the gradient of the posterior.

The noise variance is a (squared) scale parameter that can only be positive. It then can be easier and more natural to consider its logarithm as the free parameter, which is unbounded. Assign a normal prior to the logarithm of the noise variance:

$\log\sigma^2 \sim \mathcal{N}(\kappa, \omega^2)$.

Write the logarithm of the posterior density of the free parameters $\theta = (\alpha; \beta; \log\sigma^2)$ as

$$\log P(\theta|y) = \text{const.} + \log P(y|\theta) + \log P(\theta).$$

Ignore the constant term and call the sum of the last two terms $g(\theta)$. To use HMC, create a function handle that evaluates $g(\theta)$ and its gradient $\partial g/\partial\theta$ for any value of θ. The functions used to calculate $g(\theta)$ are located at the end of the script.

Create Data Set

Define true parameter values for the intercept, the linear coefficients `Beta`, and the noise standard deviation. Knowing the true parameter values makes it possible to compare with the output of the HMC sampler. Only the first predictor affects the response.

```
NumPredictors = 2;

trueIntercept = 2;
trueBeta = [3;0];
trueNoiseSigma = 1;
```

Use these parameter values to create a normally distributed sample data set at random values of the two predictors.

```
NumData = 100;
rng('default') %For reproducibility
X = rand(NumData,NumPredictors);
mu = X*trueBeta + trueIntercept;
y = normrnd(mu,trueNoiseSigma);
```

Define Posterior Probability Density

Choose the means and standard deviations of the Gaussian priors.

```
InterceptPriorMean = 0;
InterceptPriorSigma = 10;
BetaPriorMean = 0;
BetaPriorSigma = 10;
LogNoiseVarianceMean = 0;
LogNoiseVarianceSigma = 2;
```

Save a function `logPosterior` on the MATLAB® path that returns the logarithm of the product of the prior and likelihood, and the gradient of this logarithm. The `logPosterior` function is defined at the end of this example. Then, call the function with arguments to define the `logpdf` input argument to the `hmcSampler` function.

```
logpdf = @(Parameters)logPosterior(Parameters,X,y, ...
    InterceptPriorMean,InterceptPriorSigma, ...
    BetaPriorMean,BetaPriorSigma, ...
    LogNoiseVarianceMean,LogNoiseVarianceSigma);
```

Create HMC Sampler

Define the initial point to start sampling from, and then call the `hmcSampler` function to create the Hamiltonian sampler as a `HamiltonianSampler` object. Display the sampler properties.

```
Intercept = randn;
Beta = randn(NumPredictors,1);
LogNoiseVariance = randn;
```

```
startpoint = [Intercept;Beta;LogNoiseVariance];
smp = hmcSampler(logpdf,startpoint,'NumSteps',50);

smp
```

```
smp =

  HamiltonianSampler with properties:

                StepSize: 0.1000
                NumSteps: 50
              MassVector: [4x1 double]
            JitterMethod: 'jitter-both'
      StepSizeTuningMethod: 'dual-averaging'
    MassVectorTuningMethod: 'iterative-sampling'
                   LogPDF: [function_handle]
             VariableNames: {4x1 cell}
                StartPoint: [4x1 double]
```

Estimate MAP Point

Estimate the MAP (maximum-a-posteriori) point of the posterior density. You can start sampling from any point, but it is often more efficient to estimate the MAP point, and then use it as a starting point for tuning the sampler and drawing samples. Estimate and display the MAP point. You can show more information during optimization by setting the `'VerbosityLevel'` value to 1.

```
[MAPpars,fitInfo] = estimateMAP(smp,'VerbosityLevel',0);
MAPIntercept = MAPpars(1)
MAPBeta = MAPpars(2:end-1)
MAPLogNoiseVariance = MAPpars(end)
```

```
MAPIntercept =

    2.3857

MAPBeta =

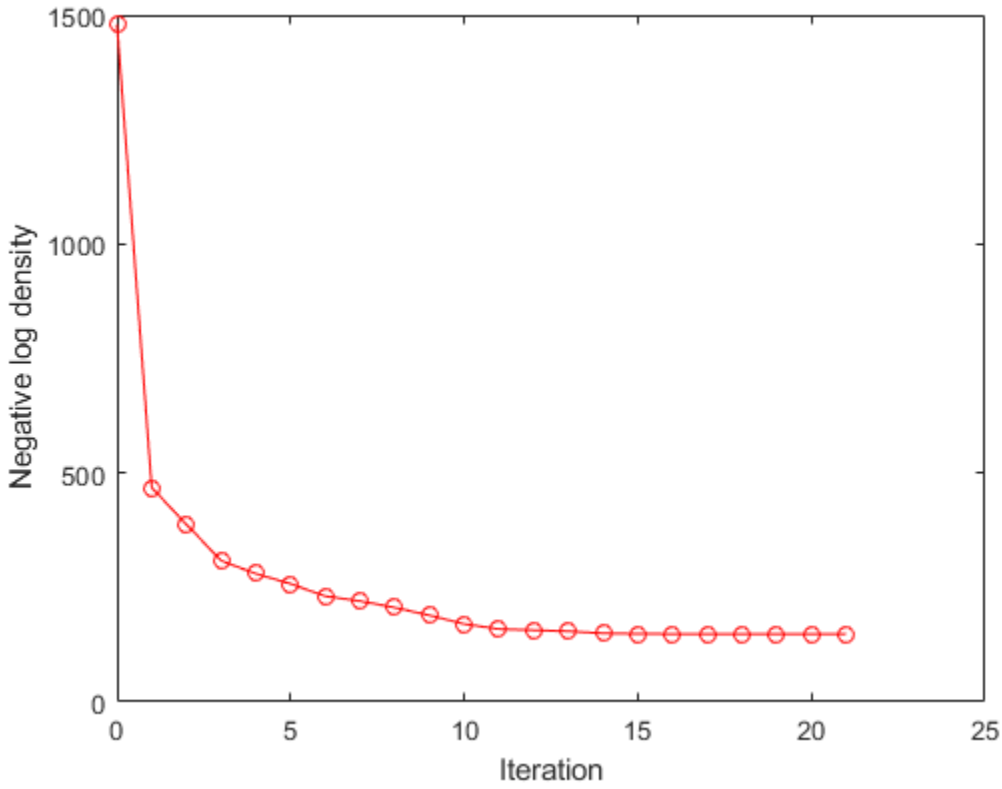
    2.5495
   -0.4508

MAPLogNoiseVariance =

   -0.1007
```

To check that the optimization has converged to a local optimum, plot the `fitInfo.Objective` field. This field contains the values of the negative log density at each iteration of the function optimization. The final values are all similar, so the optimization has converged.

```
plot(fitInfo.Iteration,fitInfo.Objective,'ro-');
xlabel('Iteration');
ylabel('Negative log density');
```



Tune Sampler

It is important to select good values for the sampler parameters to get efficient sampling. The best way to find good values is to automatically tune the `MassVector`, `StepSize`, and `NumSteps` parameters using the `tuneSampler` method. Use the method to:

1. Tune the `MassVector` of the sampler.

2. Tune `StepSize` and `NumSteps` for a fixed simulation length to achieve a certain acceptance ratio. The default target acceptance ratio of 0.65 is good in most cases.

Start tuning at the estimated MAP point for more efficient tuning.

```
[smp,tuneinfo] = tuneSampler(smp,'Start',MAPpars);
```

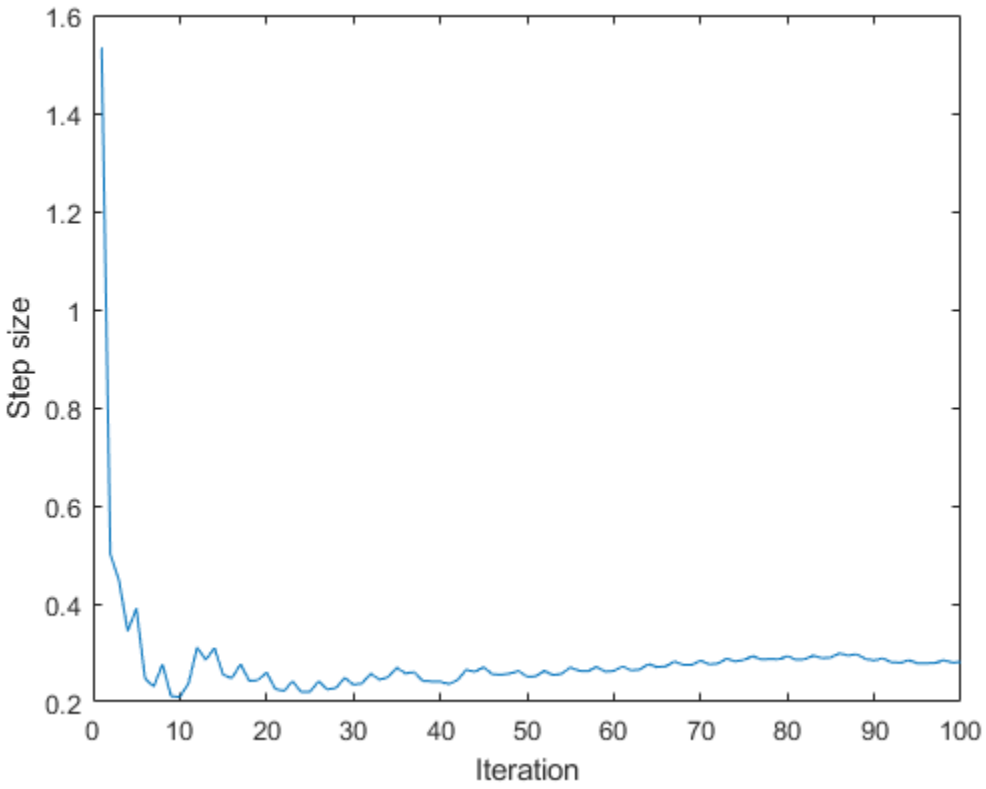
Plot the evolution of the step size during tuning to ensure that the step size tuning has converged. Display the achieved acceptance ratio.

```
figure;
plot(tuneinfo.StepSizeTuningInfo.StepSizeProfile);
xlabel('Iteration');
ylabel('Step size');

accratio = tuneinfo.StepSizeTuningInfo.AcceptanceRatio
```

```
accratio =
```

```
    0.6400
```



Draw Samples

Draw samples from the posterior density, using a few independent chains. Choose different initial points for the chains, randomly distributed around the estimated MAP point. Specify the number of burn-in samples to discard from the beginning of the Markov chain and the number of samples to generate after the burn-in.

Set the `'VerbosityLevel'` value to print details during sampling for the first chain.

```
NumChains = 4;
chains = cell(NumChains,1);
Burnin = 500;
NumSamples = 1000;
for c = 1:NumChains
    if (c == 1)
        level = 1;
    else
        level = 0;
    end
    chains{c} = drawSamples(smp,'Start',MAPpars + randn(size(MAPpars)), ...
        'Burnin',Burnin,'NumSamples',NumSamples, ...
        'VerbosityLevel',level,'NumPrint',300);
end
```

```
|=====================================================================================|
|   ITER   |    LOG PDF    |  STEP SIZE  |  NUM STEPS  |  ACC RATIO  |  DIVERGENT  |
|=====================================================================================|
|      300 | -1.484164e+02 |   2.532e-01 |          12 |   9.500e-01 |           0 |
|      600 | -1.492436e+02 |   2.128e-02 |           4 |   9.450e-01 |           0 |
|      900 | -1.509753e+02 |   2.171e-01 |           5 |   9.444e-01 |           0 |
|     1200 | -1.493455e+02 |   1.128e-01 |          16 |   9.358e-01 |           0 |
|     1500 | -1.489602e+02 |   2.532e-01 |          12 |   9.373e-01 |           0 |
```

Examine Convergence Diagnostics

Use the `diagnostics` method to compute standard MCMC diagnostics. For each sampling parameter, the method uses all the chains to compute these statistics:

- Posterior mean estimate (`Mean`)
- Estimate of the Monte Carlo standard error (`MCSE`), which is the standard deviation of the posterior mean estimate
- Estimate of the posterior standard deviation (`SD`)
- Estimates of the 5th and 95th quantiles of the marginal posterior distribution (`Q5` and `Q95`)
- Effective sample size for the posterior mean estimate (`ESS`)
- Gelman-Rubin convergence statistic (`RHat`). As a rule of thumb, values of `RHat` less than `1.1` are interpreted as a sign that the chain has converged to the desired distribution. If `RHat` for any variable is larger than `1.1`, then try drawing more samples using the `drawSamples` method.

Display the diagnostics table and the true values of the sampling parameters defined in the beginning of the example. Since the prior distribution is noninformative for this data set, the true values are between (or near) the 5th and 95th quantiles.

```
diags = diagnostics(smp,chains)
truePars = [trueIntercept;trueBeta;log(trueNoiseSigma^2)]
```

```
diags =

  4x8 table

    Name       Mean         MCSE         SD          Q5          Q95        ESS       RHat
    ______    _________    _________    _______    ________    _______    ______    ______

    {'x1'}      2.3805    0.0053354    0.28028      1.8966     2.8335    2759.7    1.0005
    {'x2'}      2.5544    0.0062264    0.33478      1.9989     3.1026    2890.9    1.0004
    {'x3'}    -0.44516    0.0064468     0.3415     -1.0247    0.10198      2806         1
    {'x4'}    -0.062826    0.0028183    0.14112    -0.28345    0.17997    2507.5    1.0004

truePars =

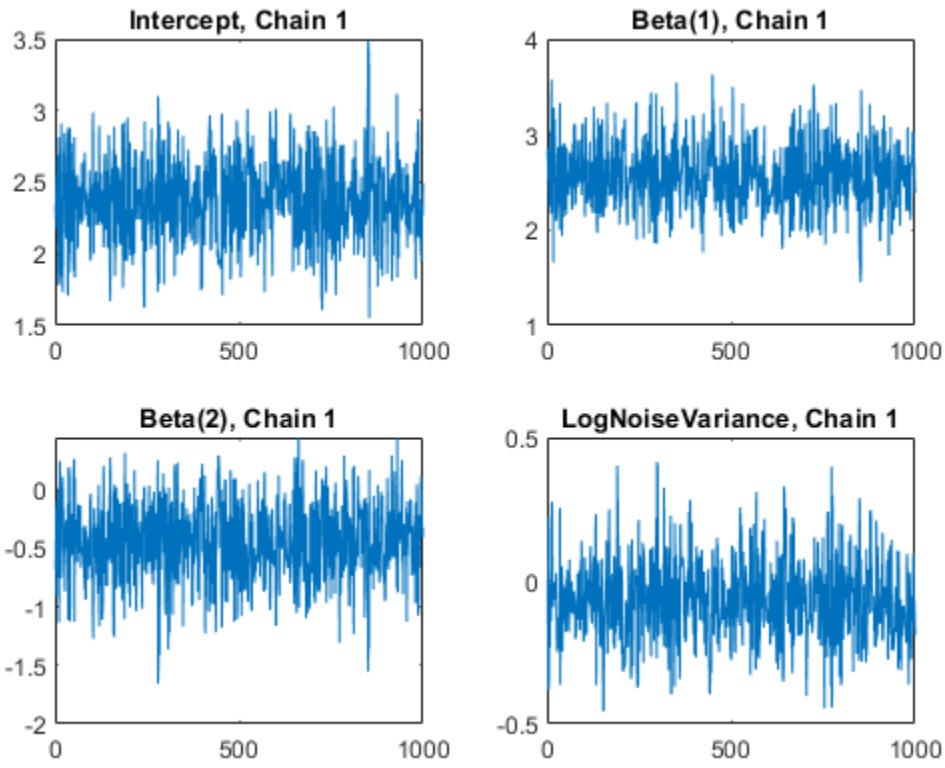
     2
     3
     0
     0
```

Visualize Samples

Investigate issues such as convergence and mixing to determine whether the drawn samples represent a reasonable set of random realizations from the target distribution. To examine the output, plot the trace plots of the samples using the first chain.

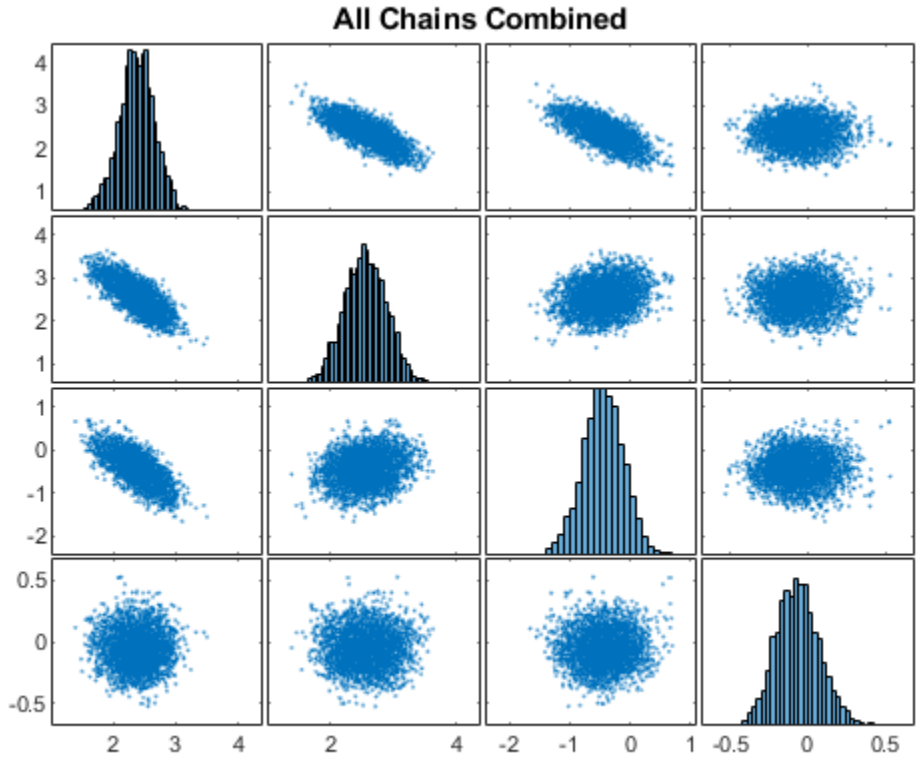
The `drawSamples` method discards burn-in samples from the beginning of the Markov chain to reduce the effect of the sampling starting point. Furthermore, the trace plots look like high-frequency noise, without any visible long-range correlation between the samples. This behavior indicates that the chain is mixed well.

```
figure;
subplot(2,2,1);
plot(chains{1}(:,1));
title(sprintf('Intercept, Chain 1'));
for p = 2:1+NumPredictors
    subplot(2,2,p);
    plot(chains{1}(:,p));
    title(sprintf('Beta(%d), Chain 1',p-1));
end
subplot(2,2,4);
plot(chains{1}(:,end));
title(sprintf('LogNoiseVariance, Chain 1'));
```



Combine the chains into one matrix and create scatter plots and histograms to visualize the 1-D and 2-D marginal posterior distributions.

```
concatenatedSamples = vertcat(chains{:});
figure;
plotmatrix(concatenatedSamples);
title('All Chains Combined');
```



Functions for Computing Posterior Distribution

The `logPosterior` function returns the logarithm of the product of a normal likelihood and a normal prior for the linear model. The input argument `Parameter` has the format `[Intercept;Beta;LogNoiseVariance]`. `X` and `Y` contain the values of the predictors and response, respectively.

The `normalPrior` function returns the logarithm of the multivariate normal probability density with means `Mu` and standard deviations `Sigma`, specified as scalars or columns vectors the same length as `P`. The second output argument is the corresponding gradient.

```
function [logpdf, gradlogpdf] = logPosterior(Parameters,X,Y, ...
    InterceptPriorMean,InterceptPriorSigma, ...
    BetaPriorMean,BetaPriorSigma, ...
    LogNoiseVarianceMean,LogNoiseVarianceSigma)

% Unpack the parameter vector
Intercept        = Parameters(1);
Beta             = Parameters(2:end-1);
LogNoiseVariance = Parameters(end);
% Compute the log likelihood and its gradient
```

```
Sigma                   = sqrt(exp(LogNoiseVariance));
Mu                      = X*Beta + Intercept;
Z                       = (Y - Mu)/Sigma;
loglik                  = sum(-log(Sigma) - .5*log(2*pi) - .5*Z.^2);
gradIntercept1          = sum(Z/Sigma);
gradBeta1               = X'*Z/Sigma;
gradLogNoiseVariance1    = sum(-.5 + .5*(Z.^2));
% Compute log priors and gradients
[LPIntercept, gradIntercept2]           = normalPrior(Intercept,InterceptPriorMean,InterceptPrior
[LPBeta, gradBeta2]                     = normalPrior(Beta,BetaPriorMean,BetaPriorSigma);
[LPLogNoiseVar, gradLogNoiseVariance2]  = normalPrior(LogNoiseVariance,LogNoiseVarianceMean,LogNo
logprior                                = LPIntercept + LPBeta + LPLogNoiseVar;
% Return the log posterior and its gradient
logpdf               = loglik + logprior;
gradIntercept        = gradIntercept1 + gradIntercept2;
gradBeta             = gradBeta1 + gradBeta2;
gradLogNoiseVariance = gradLogNoiseVariance1 + gradLogNoiseVariance2;
gradlogpdf           = [gradIntercept;gradBeta;gradLogNoiseVariance];
end

function [logpdf,gradlogpdf] = normalPrior(P,Mu,Sigma)
Z          = (P - Mu)./Sigma;
logpdf     = sum(-log(Sigma) - .5*log(2*pi) - .5*(Z.^2));
gradlogpdf = -Z./Sigma;
end
```

Bayesian Analysis for a Logistic Regression Model

This example shows how to make Bayesian inferences for a logistic regression model using `slicesample`.

Statistical inferences are usually based on maximum likelihood estimation (MLE). MLE chooses the parameters that maximize the likelihood of the data, and is intuitively appealing. In MLE, parameters are assumed to be unknown but fixed, and are estimated with some confidence. In Bayesian statistics, the uncertainty about the unknown parameters is quantified using probability so that the unknown parameters are regarded as random variables.

Bayesian Inference

Bayesian inference is the process of analyzing statistical models with the incorporation of prior knowledge about the model or model parameters. The root of such inference is Bayes' theorem:

$$P(\text{parameters}|\text{data}) = \frac{P(\text{data}|\text{parameters}) \times P(\text{parameters})}{P(\text{data})} \propto \text{likelihood} \times \text{prior}$$

For example, suppose we have normal observations

$$X|\theta \sim N(\theta, \sigma^2)$$

where sigma is known and the prior distribution for theta is

$$\theta \sim N(\mu, \tau^2)$$

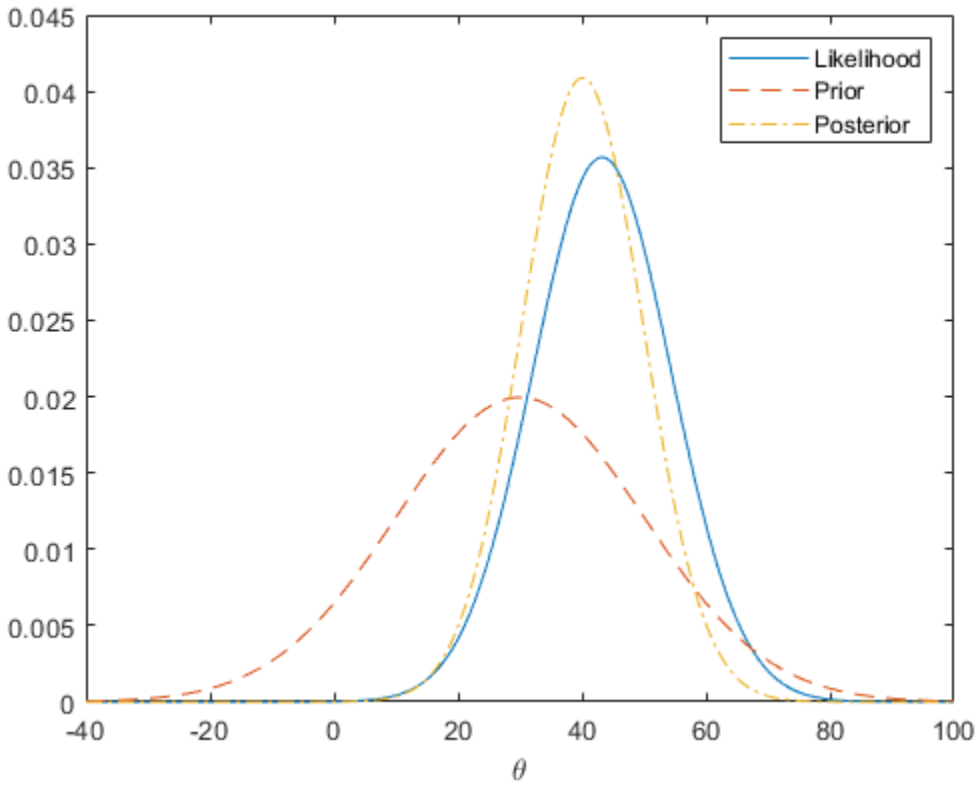
In this formula mu and tau, sometimes known as hyperparameters, are also known. If we observe n samples of X, we can obtain the posterior distribution for theta as

$$\theta|X \sim N\left(\frac{\tau^2}{\sigma^2/n + \tau^2}\bar{X} + \frac{\sigma^2/n}{\sigma^2/n + \tau^2}\mu, \frac{(\sigma^2/n) \times \tau^2}{\sigma^2/n + \tau^2}\right)$$

The following graph shows the prior, likelihood, and posterior for theta.

```
rng(0,'twister');

n = 20;
sigma = 50;
x = normrnd(10,sigma,n,1);
mu = 30;
tau = 20;
theta = linspace(-40, 100, 500);
y1 = normpdf(mean(x),theta,sigma/sqrt(n));
y2 = normpdf(theta,mu,tau);
postMean = tau^2*mean(x)/(tau^2+sigma^2/n) + sigma^2*mu/n/(tau^2+sigma^2/n);
postSD = sqrt(tau^2*sigma^2/n/(tau^2+sigma^2/n));
y3 = normpdf(theta, postMean,postSD);
plot(theta,y1,'-', theta,y2,'--', theta,y3,'-.')
legend('Likelihood','Prior','Posterior')
xlabel('\theta')
```



Car Experiment Data

In some simple problems such as the previous normal mean inference example, it is easy to figure out the posterior distribution in a closed form. But in general problems that involve non-conjugate priors, the posterior distributions are difficult or impossible to compute analytically. We will consider logistic regression as an example. This example involves an experiment to help model the proportion of cars of various weights that fail a mileage test. The data include observations of weight, number of cars tested, and number failed. We will work with a transformed version of the weights to reduce the correlation in our estimates of the regression parameters.

```
% A set of car weights
weight = [2100 2300 2500 2700 2900 3100 3300 3500 3700 3900 4100 4300]';
weight = (weight-2800)/1000;     % recenter and rescale
% The number of cars tested at each weight
total = [48 42 31 34 31 21 23 23 21 16 17 21]';
% The number of cars that have poor mpg performances at each weight
poor = [1 2 0 3 8 8 14 17 19 15 17 21]';
```

Logistic Regression Model

Logistic regression, a special case of a generalized linear model, is appropriate for these data since the response variable is binomial. The logistic regression model can be written as:

$$P(\text{failure}) = \frac{e^{Xb}}{1 + e^{Xb}}$$

where X is the design matrix and b is the vector containing the model parameters. In MATLAB®, we can write this equation as:

```
logitp = @(b,x) exp(b(1)+b(2).*x)./(1+exp(b(1)+b(2).*x));
```

If you have some prior knowledge or some non-informative priors are available, you could specify the prior probability distributions for the model parameters. For instance, in this example, we use normal priors for the intercept `b1` and slope `b2`, i.e.

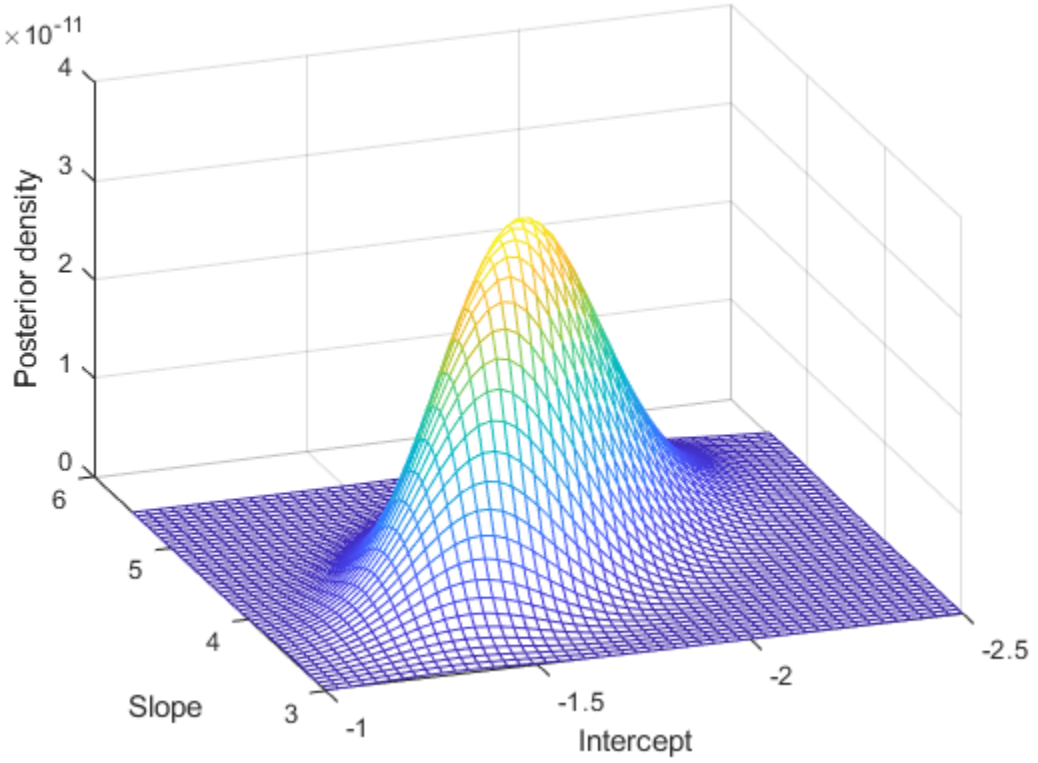
```
prior1 = @(b1) normpdf(b1,0,20);    % prior for intercept
prior2 = @(b2) normpdf(b2,0,20);    % prior for slope
```

By Bayes' theorem, the joint posterior distribution of the model parameters is proportional to the product of the likelihood and priors.

```
post = @(b) prod(binopdf(poor,total,logitp(b,weight))) ...  % likelihood
            * prior1(b(1)) * prior2(b(2));                  % priors
```

Note that the normalizing constant for the posterior in this model is analytically intractable. However, even without knowing the normalizing constant, you can visualize the posterior distribution, if you know the approximate range of the model parameters.

```
b1 = linspace(-2.5, -1, 50);
b2 = linspace(3, 5.5, 50);
simpost = zeros(50,50);
for i = 1:length(b1)
    for j = 1:length(b2)
        simpost(i,j) = post([b1(i), b2(j)]);
    end;
end;
mesh(b2,b1,simpost)
xlabel('Slope')
ylabel('Intercept')
zlabel('Posterior density')
view(-110,30)
```



This posterior is elongated along a diagonal in the parameter space, indicating that, after we look at the data, we believe that the parameters are correlated. This is interesting, since before we collected any data we assumed they were independent. The correlation comes from combining our prior distribution with the likelihood function.

Slice Sampling

Monte Carlo methods are often used in Bayesian data analysis to summarize the posterior distribution. The idea is that, even if you cannot compute the posterior distribution analytically, you can generate a random sample from the distribution and use these random values to estimate the posterior distribution or derived statistics such as the posterior mean, median, standard deviation, etc. Slice sampling is an algorithm designed to sample from a distribution with an arbitrary density function, known only up to a constant of proportionality -- exactly what is needed for sampling from a complicated posterior distribution whose normalization constant is unknown. The algorithm does not generate independent samples, but rather a Markovian sequence whose stationary distribution is the target distribution. Thus, the slice sampler is a Markov Chain Monte Carlo (MCMC) algorithm. However, it differs from other well-known MCMC algorithms because only the scaled posterior need be specified -- no proposal or marginal distributions are needed.

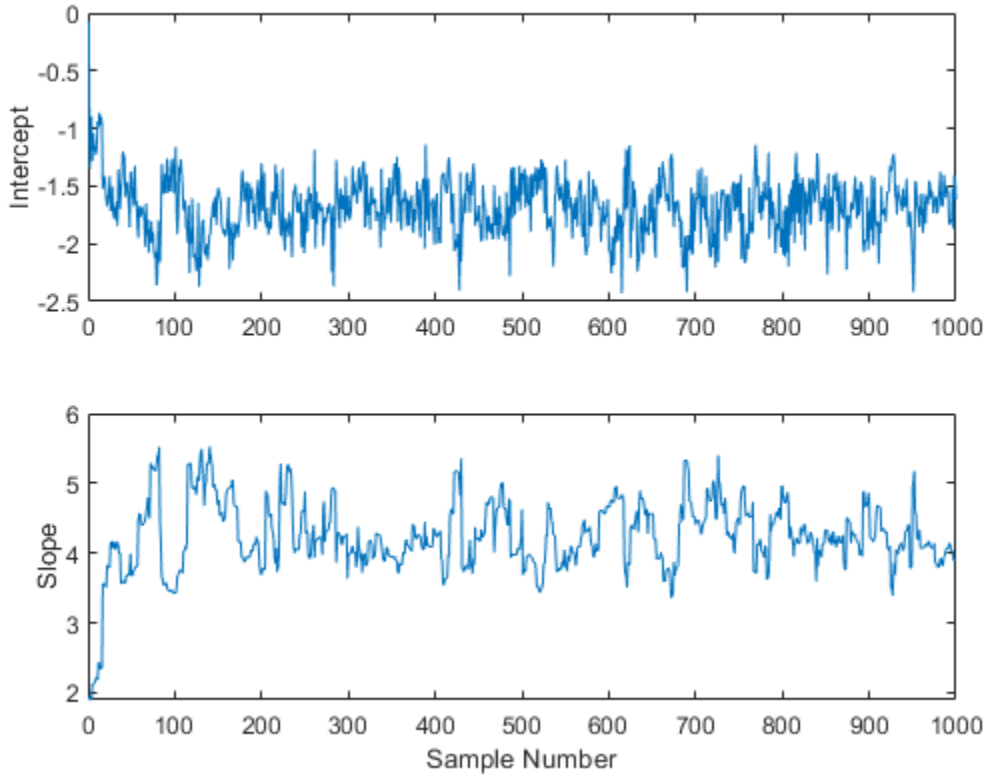
This example shows how to use the slice sampler as part of a Bayesian analysis of the mileage test logistic regression model, including generating a random sample from the posterior distribution for the model parameters, analyzing the output of the sampler, and making inferences about the model parameters. The first step is to generate a random sample.

```
initial = [1 1];
nsamples = 1000;
trace = slicesample(initial,nsamples,'pdf',post,'width',[20 2]);
```

Analysis of Sampler Output

After obtaining a random sample from the slice sampler, it is important to investigate issues such as convergence and mixing, to determine whether the sample can reasonably be treated as a set of random realizations from the target posterior distribution. Looking at marginal trace plots is the simplest way to examine the output.

```
subplot(2,1,1)
plot(trace(:,1))
ylabel('Intercept');
subplot(2,1,2)
plot(trace(:,2))
ylabel('Slope');
xlabel('Sample Number');
```

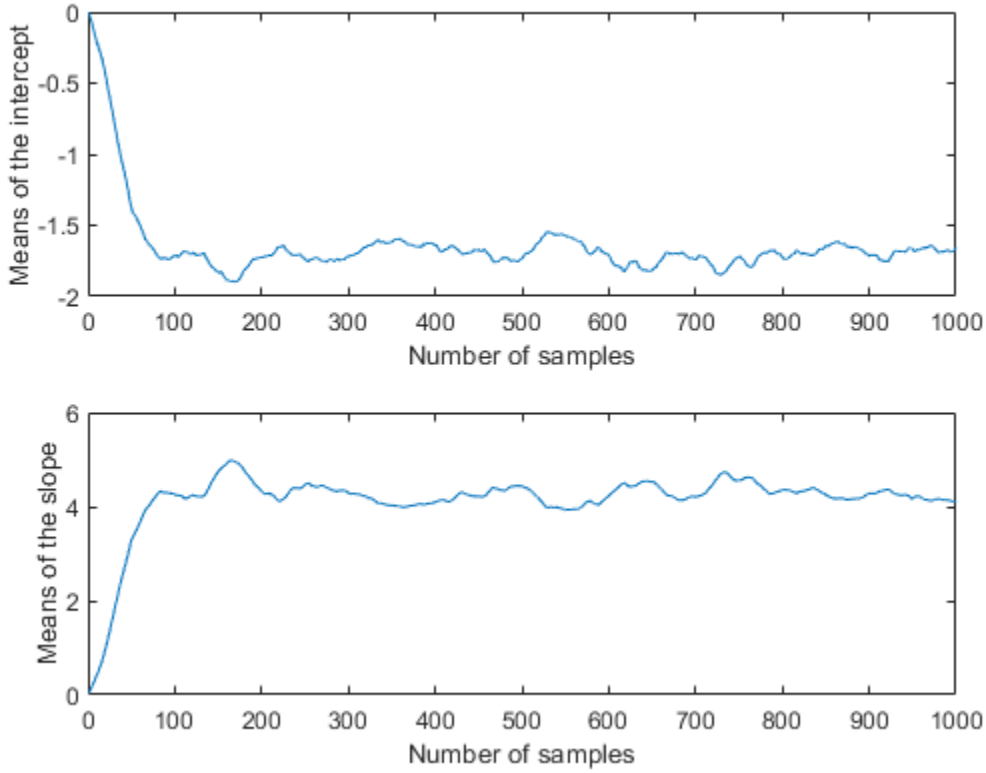


It is apparent from these plots is that the effects of the parameter starting values take a while to disappear (perhaps fifty or so samples) before the process begins to look stationary.

It is also be helpful in checking for convergence to use a moving window to compute statistics such as the sample mean, median, or standard deviation for the sample. This produces a smoother plot than the raw sample traces, and can make it easier to identify and understand any non-stationarity.

```
movavg = filter( (1/50)*ones(50,1), 1, trace);
subplot(2,1,1)
```

```
plot(movavg(:,1))
xlabel('Number of samples')
ylabel('Means of the intercept');
subplot(2,1,2)
plot(movavg(:,2))
xlabel('Number of samples')
ylabel('Means of the slope');
```

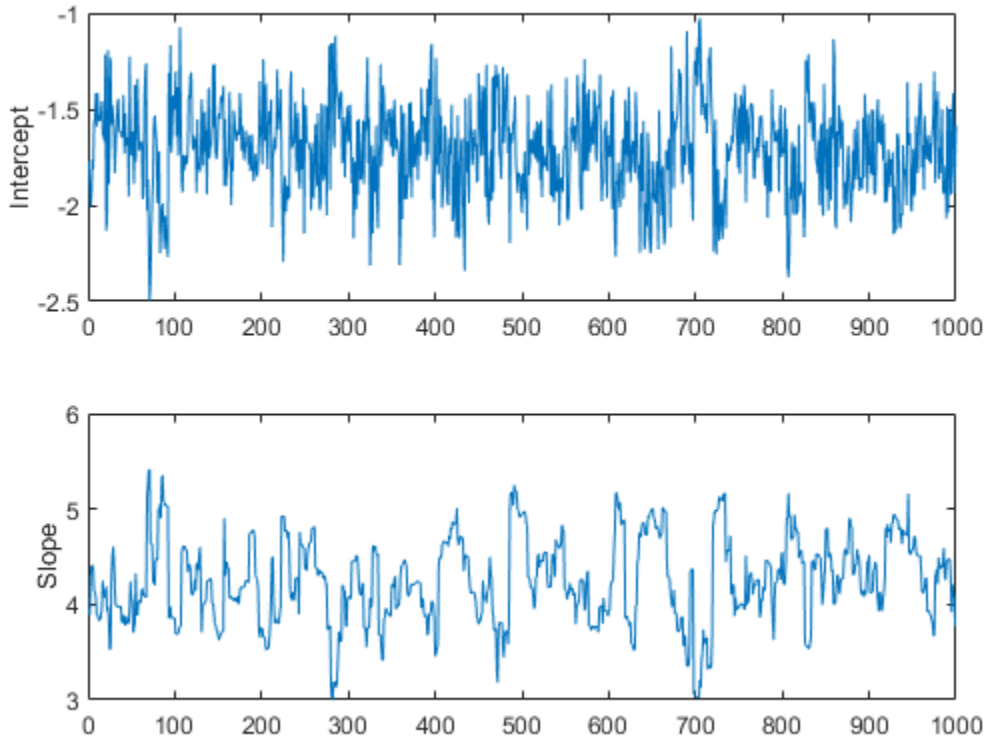


Because these are moving averages over a window of 50 iterations, the first 50 values are not comparable to the rest of the plot. However, the remainder of each plot seems to confirm that the parameter posterior means have converged to stationarity after 100 or so iterations. It is also apparent that the two parameters are correlated with each other, in agreement with the earlier plot of the posterior density.

Since the settling-in period represents samples that cannot reasonably be treated as random realizations from the target distribution, it's probably advisable not to use the first 50 or so values at the beginning of the slice sampler's output. You could just delete those rows of the output, however, it's also possible to specify a "burn-in" period. This is convenient when a suitable burn-in length is already known, perhaps from previous runs.

```
trace = slicesample(initial,nsamples,'pdf',post, ...
                                     'width',[20 2],'burnin',50);
subplot(2,1,1)
plot(trace(:,1))
ylabel('Intercept');
subplot(2,1,2)
```

```
plot(trace(:,2))
ylabel('Slope');
```



These trace plots do not seem to show any non-stationarity, indicating that the burn-in period has done its job.

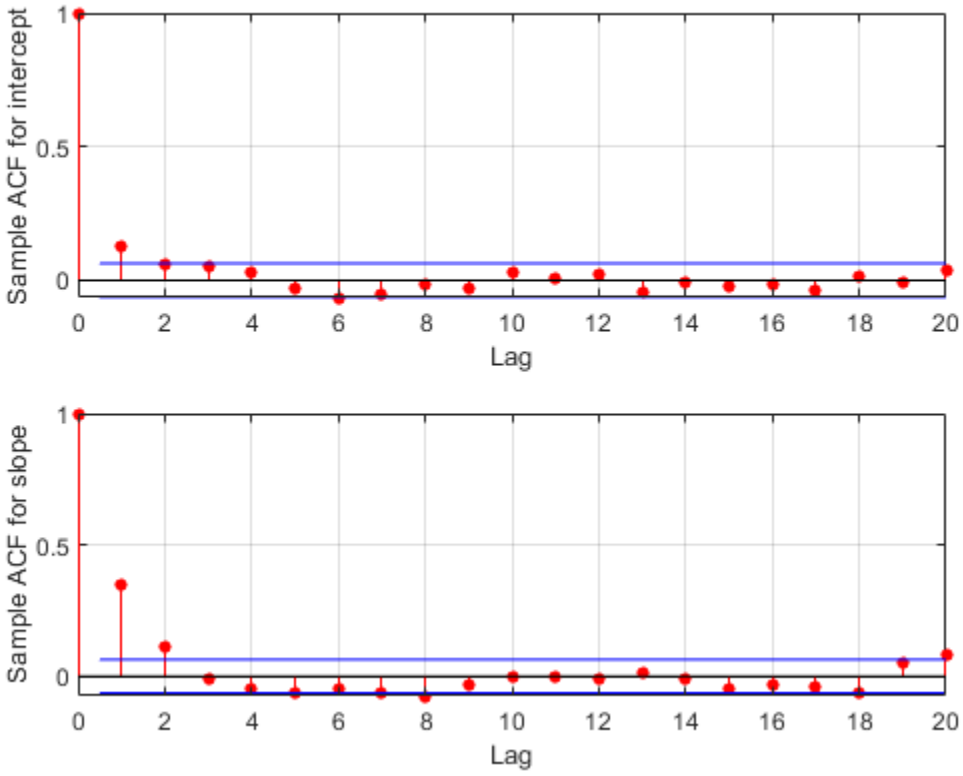
However, there is a second aspect of the trace plots that should also be explored. While the trace for the intercept looks like high frequency noise, the trace for the slope appears to have a lower frequency component, indicating there autocorrelation between values at adjacent iterations. We could still compute the mean from this autocorrelated sample, but it is often convenient to reduce the storage requirements by removing redundancy in the sample. If this eliminated the autocorrelation, it would also allow us to treat this as a sample of independent values. For example, you can thin out the sample by keeping only every 10th value.

```
trace = slicesample(initial,nsamples,'pdf',post,'width',[20 2], ...
                                                 'burnin',50,'thin',10);
```

To check the effect of this thinning, it is useful to estimate the sample autocorrelation functions from the traces and use them to check if the samples mix rapidly.

```
F    =  fft(detrend(trace,'constant'));
F    =  F .* conj(F);
ACF  =  ifft(F);
ACF  =  ACF(1:21,:);                          % Retain lags up to 20.
ACF  =  real([ACF(1:21,1) ./ ACF(1,1) ...
             ACF(1:21,2) ./ ACF(1,2)]);       % Normalize.
bounds  =  sqrt(1/nsamples) * [2 ; -2];       % 95% CI for iid normal
```

```
labs = {'Sample ACF for intercept','Sample ACF for slope' };
for i = 1:2
    subplot(2,1,i)
    lineHandles  =  stem(0:20, ACF(:,i) , 'filled' , 'r-o');
    lineHandles.MarkerSize = 4;
    grid('on')
    xlabel('Lag')
    ylabel(labs{i})
    hold on
    plot([0.5 0.5 ; 20 20] , [bounds([1 1]) bounds([2 2])] , '-b');
    plot([0 20] , [0 0] , '-k');
    hold off
    a  =  axis;
    axis([a(1:3) 1]);
end
```



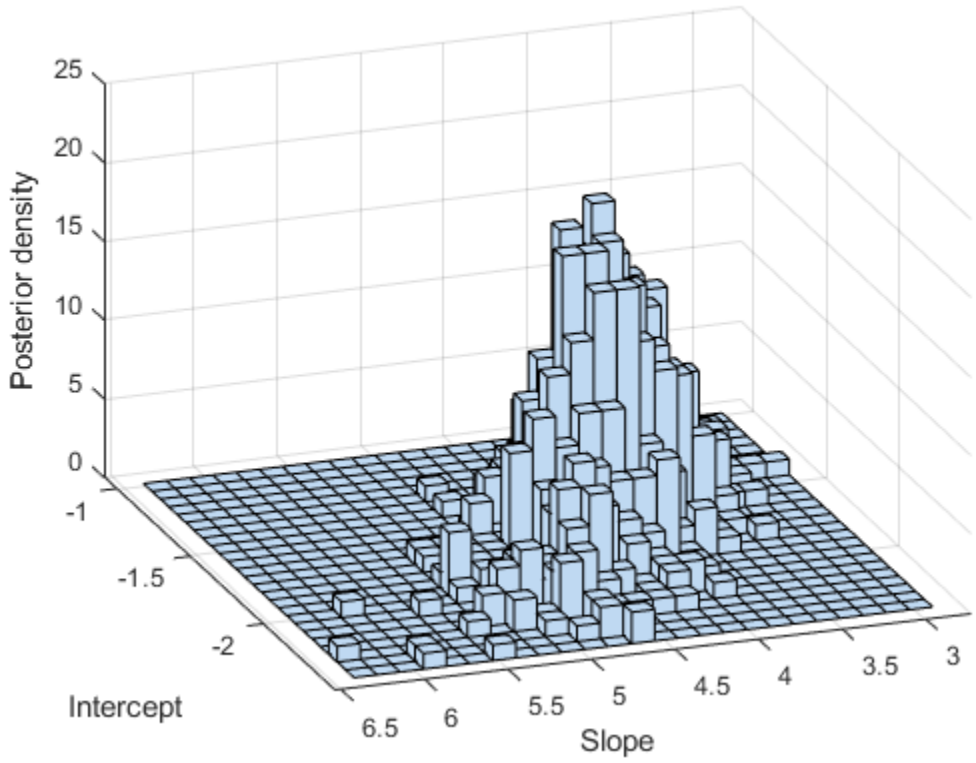
The autocorrelation values at the first lag are significant for the intercept parameter, and even more so for the slope parameter. We could repeat the sampling using a larger thinning parameter in order to reduce the correlation further. For the purposes of this example, however, we'll continue to use the current sample.

Inference for the Model Parameters

As expected, a histogram of the sample mimics the plot of the posterior density.

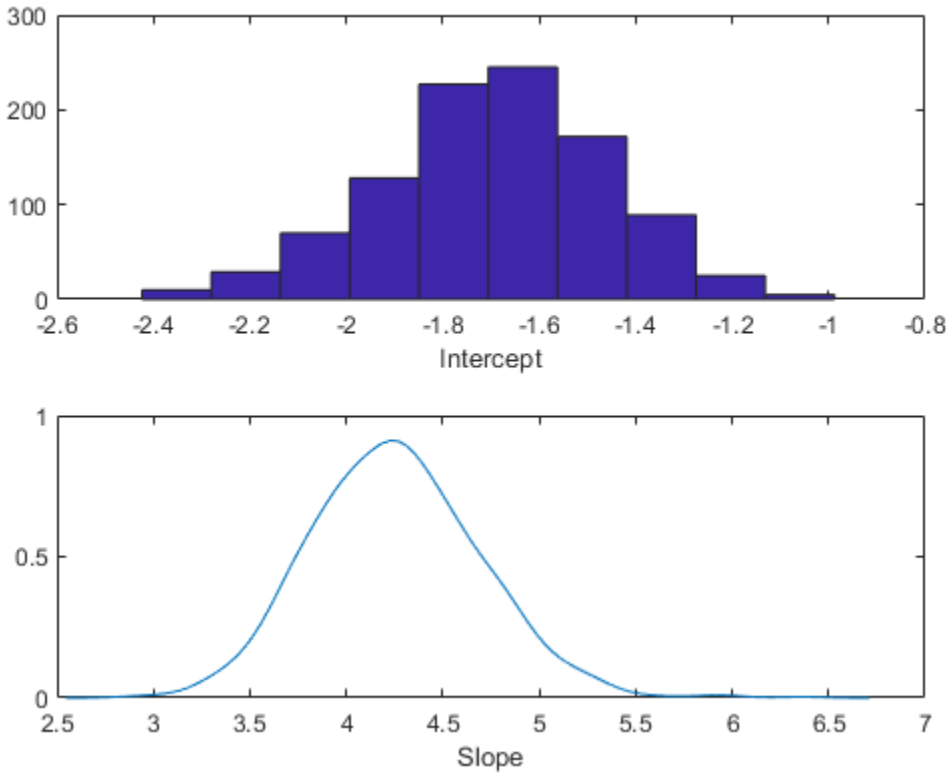
```
subplot(1,1,1)
hist3(trace,[25,25]);
```

```
xlabel('Intercept')
ylabel('Slope')
zlabel('Posterior density')
view(-110,30)
```



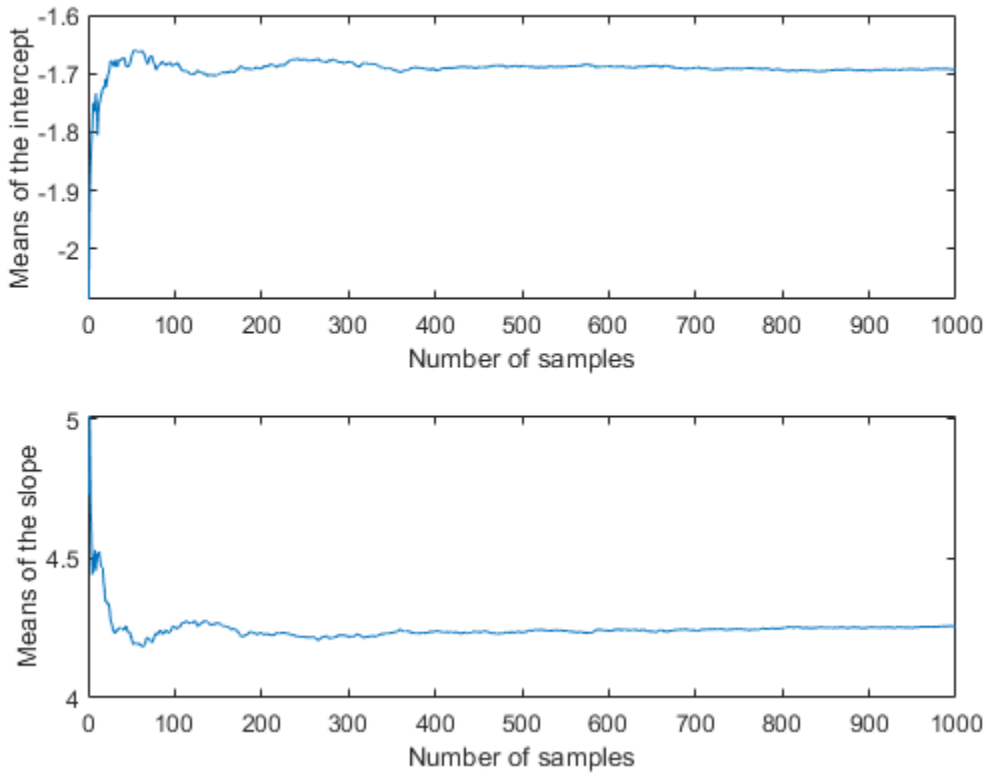
You can use a histogram or a kernel smoothing density estimate to summarize the marginal distribution properties of the posterior samples.

```
subplot(2,1,1)
hist(trace(:,1))
xlabel('Intercept');
subplot(2,1,2)
ksdensity(trace(:,2))
xlabel('Slope');
```



You could also compute descriptive statistics such as the posterior mean or percentiles from the random samples. To determine if the sample size is large enough to achieve a desired precision, it is helpful to monitor the desired statistic of the traces as a function of the number of samples.

```
csum = cumsum(trace);
subplot(2,1,1)
plot(csum(:,1)'./(1:nsamples))
xlabel('Number of samples')
ylabel('Means of the intercept');
subplot(2,1,2)
plot(csum(:,2)'./(1:nsamples))
xlabel('Number of samples')
ylabel('Means of the slope');
```



In this case, it appears that the sample size of 1000 is more than sufficient to give good precision for the posterior mean estimate.

```
bHat = mean(trace)
```

```
bHat =

   -1.6931    4.2569
```

Summary

The Statistics and Machine Learning Toolbox™ offers a variety of functions that allow you to specify likelihoods and priors easily. They can be combined to derive a posterior distribution. The `slicesample` function enables you to carry out Bayesian analysis in MATLAB using Markov Chain Monte Carlo simulation. It can be used even in problems with posterior distributions that are difficult to sample from using standard random number generators.

Hypothesis Tests

Hypothesis Test Terminology

All hypothesis tests share the same basic terminology and structure.

- A *null hypothesis* is an assertion about a population that you would like to test. It is "null" in the sense that it often represents a status quo belief, such as the absence of a characteristic or the lack of an effect. It may be formalized by asserting that a population parameter, or a combination of population parameters, has a certain value. In the example given in the "Hypothesis Testing" on page 8-5, the null hypothesis would be that the average price of gas across the state was $1.15. This is written H_0: $\mu = 1.15$.
- An *alternative hypothesis* is a contrasting assertion about the population that can be tested against the null hypothesis. In the example given in the "Hypothesis Testing" on page 8-5, possible alternative hypotheses are:

  H_1: $\mu \neq 1.15$ — State average was different from $1.15 (two-tailed test)

  H_1: $\mu > 1.15$ — State average was greater than $1.15 (right-tail test)

  H_1: $\mu < 1.15$ — State average was less than $1.15 (left-tail test)
- To conduct a hypothesis test, a random sample from the population is collected and a relevant *test statistic* is computed to summarize the sample. This statistic varies with the type of test, but its distribution under the null hypothesis must be known (or assumed).
- The *p value* of a test is the probability, under the null hypothesis, of obtaining a value of the test statistic as extreme or more extreme than the value computed from the sample.
- The *significance level* of a test is a threshold of probability α agreed to before the test is conducted. A typical value of α is 0.05. If the p value of a test is less than α, the test rejects the null hypothesis. If the p value is greater than α, there is insufficient evidence to reject the null hypothesis. Note that lack of evidence for rejecting the null hypothesis is not evidence for accepting the null hypothesis. Also note that substantive "significance" of an alternative cannot be inferred from the statistical significance of a test.
- The significance level α can be interpreted as the probability of rejecting the null hypothesis when it is actually true—a *type I error*. The distribution of the test statistic under the null hypothesis determines the probability α of a type I error. Even if the null hypothesis is not rejected, it may still be false—a *type II error*. The distribution of the test statistic under the alternative hypothesis determines the probability β of a type II error. Type II errors are often due to small sample sizes. The *power* of a test, $1 - \beta$, is the probability of correctly rejecting a false null hypothesis.
- Results of hypothesis tests are often communicated with a *confidence interval*. A confidence interval is an estimated range of values with a specified probability of containing the true population value of a parameter. Upper and lower bounds for confidence intervals are computed from the sample estimate of the parameter and the known (or assumed) sampling distribution of the estimator. A typical assumption is that estimates will be normally distributed with repeated sampling (as dictated by the Central Limit Theorem). Wider confidence intervals correspond to poor estimates (smaller samples); narrow intervals correspond to better estimates (larger samples). If the null hypothesis asserts the value of a population parameter, the test rejects the null hypothesis when the hypothesized value lies outside the computed confidence interval for the parameter.

Hypothesis Test Assumptions

Different hypothesis tests make different assumptions about the distribution of the random variable being sampled in the data. These assumptions must be considered when choosing a test and when interpreting the results.

For example, the *z*-test (`ztest`) and the *t*-test (`ttest`) both assume that the data are independently sampled from a normal distribution. Statistics and Machine Learning Toolbox functions are available for testing this assumption, such as `chi2gof`, `jbtest`, `lillietest`, and `normplot`.

Both the *z*-test and the *t*-test are relatively robust with respect to departures from this assumption, so long as the sample size n is large enough. Both tests compute a sample mean $\bar{x}$, which, by the Central Limit Theorem, has an approximately normal sampling distribution with mean equal to the population mean μ, regardless of the population distribution being sampled.

The difference between the *z*-test and the *t*-test is in the assumption of the standard deviation σ of the underlying normal distribution. A *z*-test assumes that σ is known; a *t*-test does not. As a result, a *t*-test must compute an estimate s of the standard deviation from the sample.

Test statistics for the *z*-test and the *t*-test are, respectively,

$$z = \frac{\bar{x} - \mu}{\sigma/\sqrt{n}}$$

$$t = \frac{\bar{x} - \mu}{s/\sqrt{n}}$$

Under the null hypothesis that the population is distributed with mean μ, the *z*-statistic has a standard normal distribution, $N(0,1)$. Under the same null hypothesis, the *t*-statistic has Student's *t* distribution with $n - 1$ degrees of freedom. For small sample sizes, Student's *t* distribution is flatter and wider than $N(0,1)$, compensating for the decreased confidence in the estimate s. As sample size increases, however, Student's *t* distribution approaches the standard normal distribution, and the two tests become essentially equivalent.

Knowing the distribution of the test statistic under the null hypothesis allows for accurate calculation of *p*-values. Interpreting *p*-values in the context of the test assumptions allows for critical analysis of test results.

Assumptions underlying Statistics and Machine Learning Toolbox hypothesis tests are given in the reference pages for implementing functions.

Hypothesis Testing

Hypothesis testing is a common method of drawing inferences about a population based on statistical evidence from a sample.

As an example, suppose someone says that at a certain time in the state of Massachusetts the average price of a gallon of regular unleaded gas was $1.15. How could you determine the truth of the statement? You could try to find prices at every gas station in the state at the time. That approach would be definitive, but it could be time-consuming, costly, or even impossible.

A simpler approach would be to find prices at a small number of randomly selected gas stations around the state, and then compute the sample average.

Sample averages differ from one another due to chance variability in the selection process. Suppose your sample average comes out to be $1.18. Is the $0.03 difference an artifact of random sampling or significant evidence that the average price of a gallon of gas was in fact greater than $1.15? Hypothesis testing is a statistical method for making such decisions.

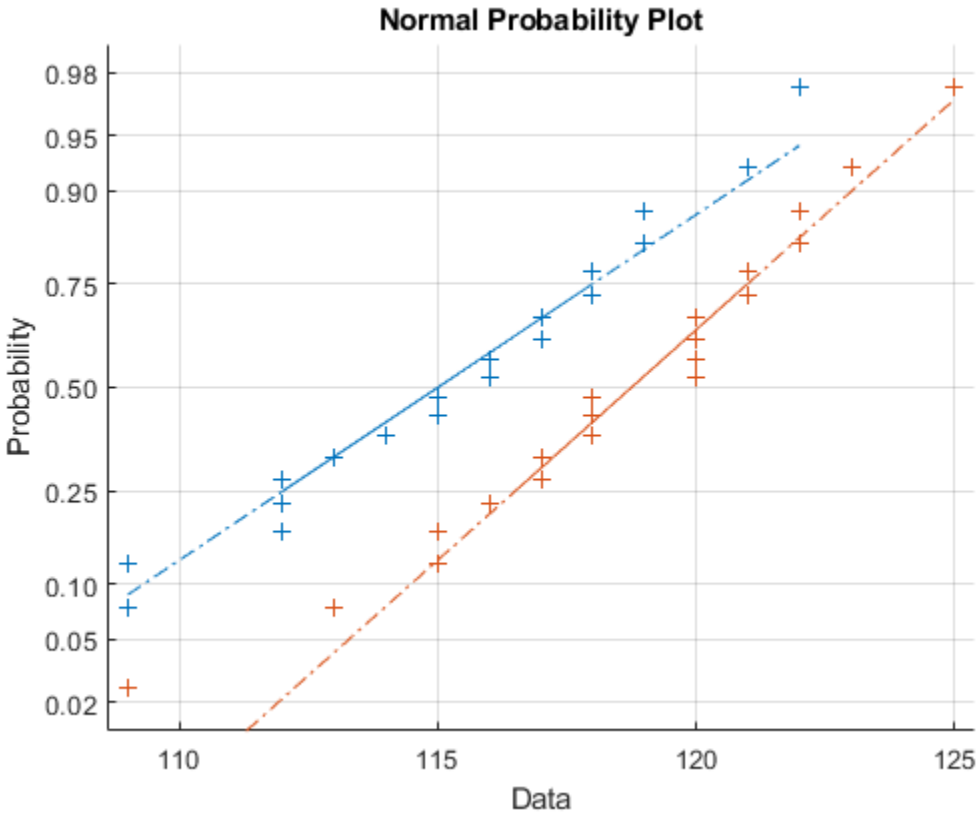
This example shows how to use hypothesis testing to analyze gas prices measured across the state of Massachusetts during two separate months.

This example uses the gas price data in the file `gas.mat`. The file contains two random samples of prices for a gallon of gas around the state of Massachusetts in 1993. The first sample, `price1`, contains 20 random observations around the state on a single day in January. The second sample, `price2`, contains 20 random observations around the state one month later.

```
load gas
prices = [price1 price2];
```

As a first step, you might want to test the assumption that the samples come from normal distributions. A normal probability plot gives a quick idea.

```
normplot(prices)
```



Both scatters approximately follow straight lines through the first and third quartiles of the samples, indicating approximate normal distributions. The February sample (the right-hand line) shows a slight departure from normality in the lower tail. A shift in the mean from January to February is evident. A hypothesis test is used to quantify the test of normality. Since each sample is relatively small, a Lilliefors test is recommended.

```
lillietest(price1)
```

```
ans = 0
```

```
lillietest(price2)
```

```
ans = 0
```

The default significance level of `lillietest` is 5%. The logical 0 returned by each test indicates a failure to reject the null hypothesis that the samples are normally distributed. This failure may reflect normality in the population or it may reflect a lack of strong evidence against the null hypothesis due to the small sample size.

Now compute the sample means.

```
sample_means = mean(prices)
```

```
sample_means = 1×2

  115.1500  118.5000
```

You might want to test the null hypothesis that the mean price across the state on the day of the January sample was $1.15. If you know that the standard deviation in prices across the state has historically, and consistently, been $0.04, then a *z*-test is appropriate.

```
[h,pvalue,ci] = ztest(price1/100,1.15,0.04)
```

```
h = 0

pvalue = 0.8668

ci = 2×1

    1.1340
    1.1690
```

The logical output `h = 0` indicates a failure to reject the null hypothesis at the default significance level of 5%. This is a consequence of the high probability under the null hypothesis, indicated by the *p* value, of observing a value as extreme or more extreme of the *z*-statistic computed from the sample. The 95% confidence interval on the mean [1.1340 1.1690] includes the hypothesized population mean of $1.15.

Does the later sample offer stronger evidence for rejecting a null hypothesis of a state-wide average price of $1.15 in February? The shift shown in the probability plot and the difference in the computed sample means suggest this. The shift might indicate a significant fluctuation in the market, raising questions about the validity of using the historical standard deviation. If a known standard deviation cannot be assumed, a *t*-test is more appropriate.

```
[h,pvalue,ci] = ttest(price2/100,1.15)
```

```
h = 1

pvalue = 4.9517e-04

ci = 2×1

    1.1675
    1.2025
```

The logical output `h = 1` indicates a rejection of the null hypothesis at the default significance level of 5%. In this case, the 95% confidence interval on the mean does not include the hypothesized population mean of $1.15.

You might want to investigate the shift in prices a little more closely. The function `ttest2` tests if two independent samples come from normal distributions with equal but unknown standard deviations and the same mean, against the alternative that the means are unequal.

```
[h,sig,ci] = ttest2(price1,price2)
```

```
h = 1

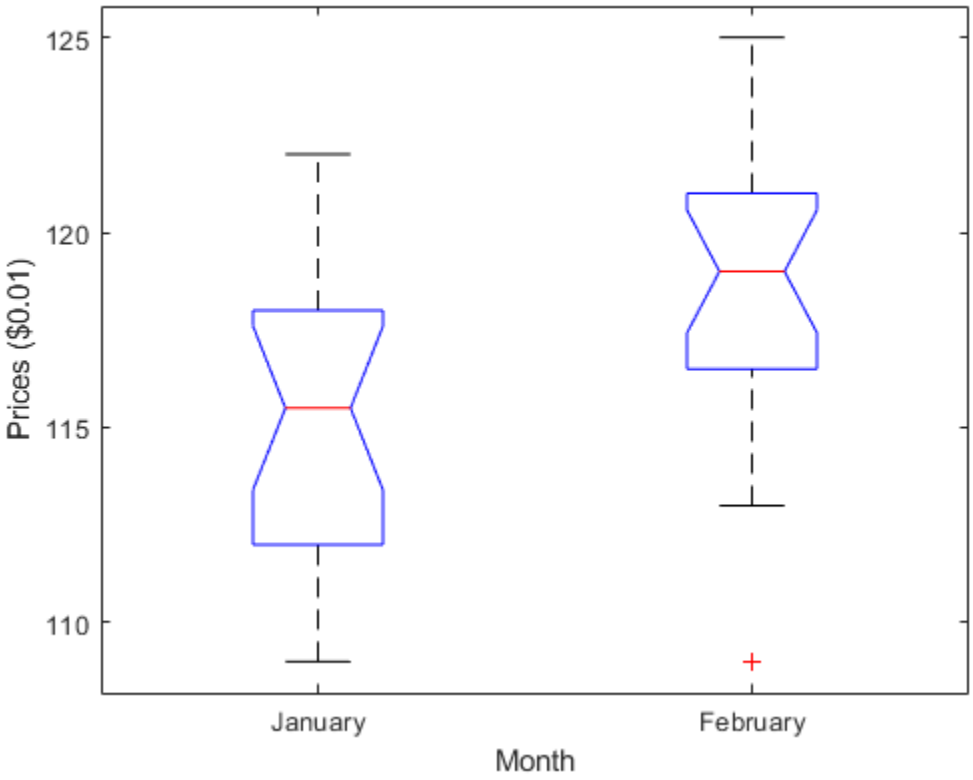
sig = 0.0083

ci = 2×1

   -5.7845
   -0.9155
```

The null hypothesis is rejected at the default 5% significance level, and the confidence interval on the difference of means does not include the hypothesized value of 0. A notched box plot is another way to visualize the shift.

```
boxplot(prices,1)
h = gca;
h.XTick = [1 2];
h.XTickLabel = {'January','February'};
xlabel('Month')
ylabel('Prices ($0.01)')
```



The plot displays the distribution of the samples around their medians. The heights of the notches in each box are computed so that the side-by-side boxes have nonoverlapping notches when their medians are different at a default 5% significance level. The computation is based on an assumption of normality in the data, but the comparison is reasonably robust for other distributions. The side-by-side plots provide a kind of visual hypothesis test, comparing medians rather than means. The plot above appears to barely reject the null hypothesis of equal medians.

The nonparametric Wilcoxon rank sum test, implemented by the function `ranksum`, can be used to quantify the test of equal medians. It tests if two independent samples come from identical continuous (not necessarily normal) distributions with equal medians, against the alternative that they do not have equal medians.

```
[p,h] = ranksum(price1,price2)
```

```
p = 0.0095
```

```
h = logical
   1
```

The test rejects the null hypothesis of equal medians at the default 5% significance level.

Available Hypothesis Tests

Function	Description
`ansaribradley`	Ansari-Bradley test. Tests if two independent samples come from the same distribution, against the alternative that they come from distributions that have the same median and shape but different variances.
`barttest`	Bartlett's test. Tests if the variances of the data values along each principal component are equal, against the alternative that the variances are not all equal.
`chi2gof`	Chi-square goodness-of-fit test. Tests if a sample comes from a specified distribution, against the alternative that it does not come from that distribution.
`dwtest`	Durbin-Watson test. Tests if the residuals from a linear regression are uncorrelated, against the alternative that there is autocorrelation among them.
`friedman`	Friedman's test. Tests if the column effects in a two-way layout are all the same, against the alternative that the column effects are not all the same.
`jbtest`	Jarque-Bera test. Tests if a sample comes from a normal distribution with unknown mean and variance, against the alternative that it does not come from a normal distribution.
`kruskalwallis`	Kruskal-Wallis test. Tests if multiple samples are all drawn from the same populations (or equivalently, from different populations with the same distribution), against the alternative that they are not all drawn from the same population.
`kstest`	One-sample Kolmogorov-Smirnov test. Tests if a sample comes from a continuous distribution with specified parameters, against the alternative that it does not come from that distribution.
`kstest2`	Two-sample Kolmogorov-Smirnov test. Tests if two samples come from the same continuous distribution, against the alternative that they do not come from the same distribution.
`lillietest`	Lilliefors test. Tests if a sample comes from a distribution in the normal family, against the alternative that it does not come from a normal distribution.
`linhyptest`	Linear hypothesis test. Tests if `H*b = c` for parameter estimates `b` with estimated covariance `H` and specified `c`, against the alternative that `H*b ≠ c`.
`ranksum`	Wilcoxon rank sum test. Tests if two independent samples come from identical continuous distributions with equal medians, against the alternative that they do not have equal medians.
`runstest`	Runs test. Tests if a sequence of values comes in random order, against the alternative that the ordering is not random.
`signrank`	One-sample or paired-sample Wilcoxon signed rank test. Tests if a sample comes from a continuous distribution symmetric about a specified median, against the alternative that it does not have that median.

Function	Description
`signtest`	One-sample or paired-sample sign test. Tests if a sample comes from an arbitrary continuous distribution with a specified median, against the alternative that it does not have that median.
`ttest`	One-sample or paired-sample *t*-test. Tests if a sample comes from a normal distribution with unknown variance and a specified mean, against the alternative that it does not have that mean.
`ttest2`	Two-sample *t*-test. Tests if two independent samples come from normal distributions with unknown but equal (or, optionally, unequal) variances and the same mean, against the alternative that the means are unequal.
`vartest`	One-sample chi-square variance test. Tests if a sample comes from a normal distribution with specified variance, against the alternative that it comes from a normal distribution with a different variance.
`vartest2`	Two-sample *F*-test for equal variances. Tests if two independent samples come from normal distributions with the same variance, against the alternative that they come from normal distributions with different variances.
`vartestn`	Bartlett multiple-sample test for equal variances. Tests if multiple samples come from normal distributions with the same variance, against the alternative that they come from normal distributions with different variances.
`ztest`	One-sample *z*-test. Tests if a sample comes from a normal distribution with known variance and specified mean, against the alternative that it does not have that mean.

Note In addition to the previous functions, Statistics and Machine Learning Toolbox functions are available for analysis of variance (ANOVA), which perform hypothesis tests in the context of linear modeling.

Selecting a Sample Size

This example shows how to determine the number of samples or observations needed to carry out a statistical test. It illustrates sample size calculations for a simple problem, then shows how to use the `sampsizepwr` function to compute power and sample size for two more realistic problems. Finally, it illustrates the use of Statistics and Machine Learning Toolbox™ functions to compute the required sample size for a test that the `sampsizepwr` function does not support.

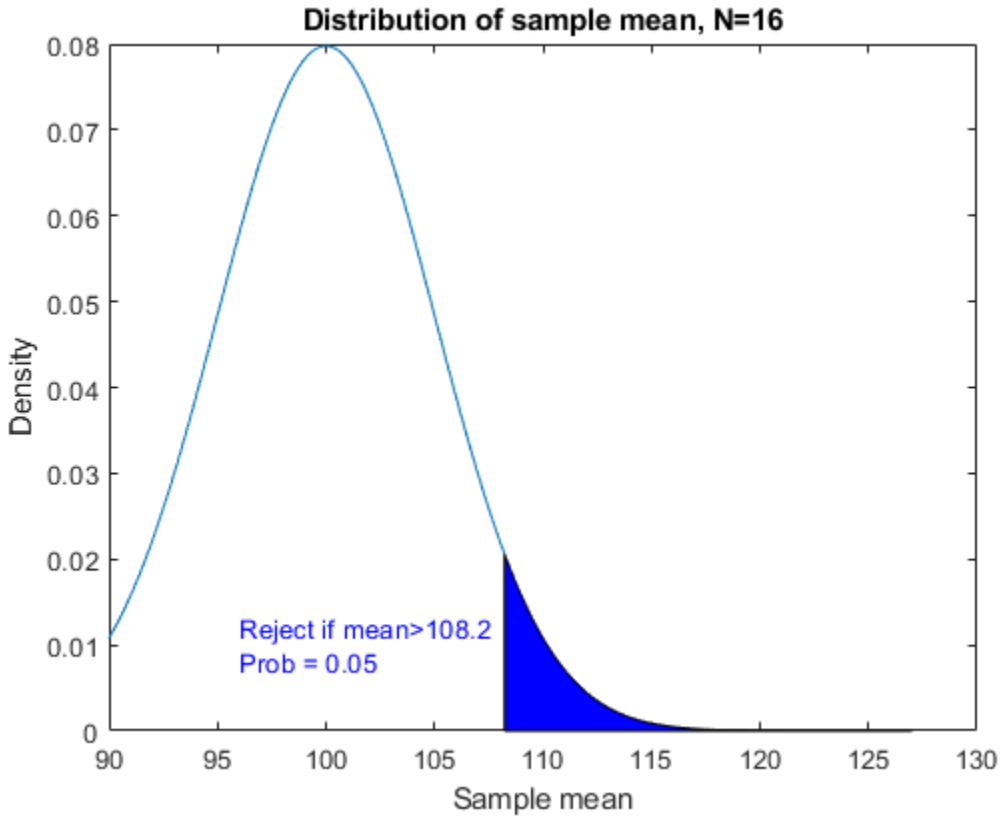
Testing a Normal Mean with Known Standard Deviation, One-Sided

Just to introduce some concepts, let's consider an unrealistically simple example where we want to test a mean and we know the standard deviation. Our data are continuous, and can be modeled with the normal distribution. We need to determine a sample size N so that we can distinguish between a mean of 100 and a mean of 110. We know the standard deviation is 20.

When we carry out a statistical test, we generally test a **null hypothesis** against an **alternative hypothesis**. We find a test statistic T, and look at its distribution under the null hypothesis. If we observe an unusual value, say one that has less than 5% chance of happening if the null hypothesis is true, then we reject the null hypothesis in favor of the alternative. (The 5% probability is known as the **significance level** of the test.) If the value is not unusual, we do not reject the null hypothesis.

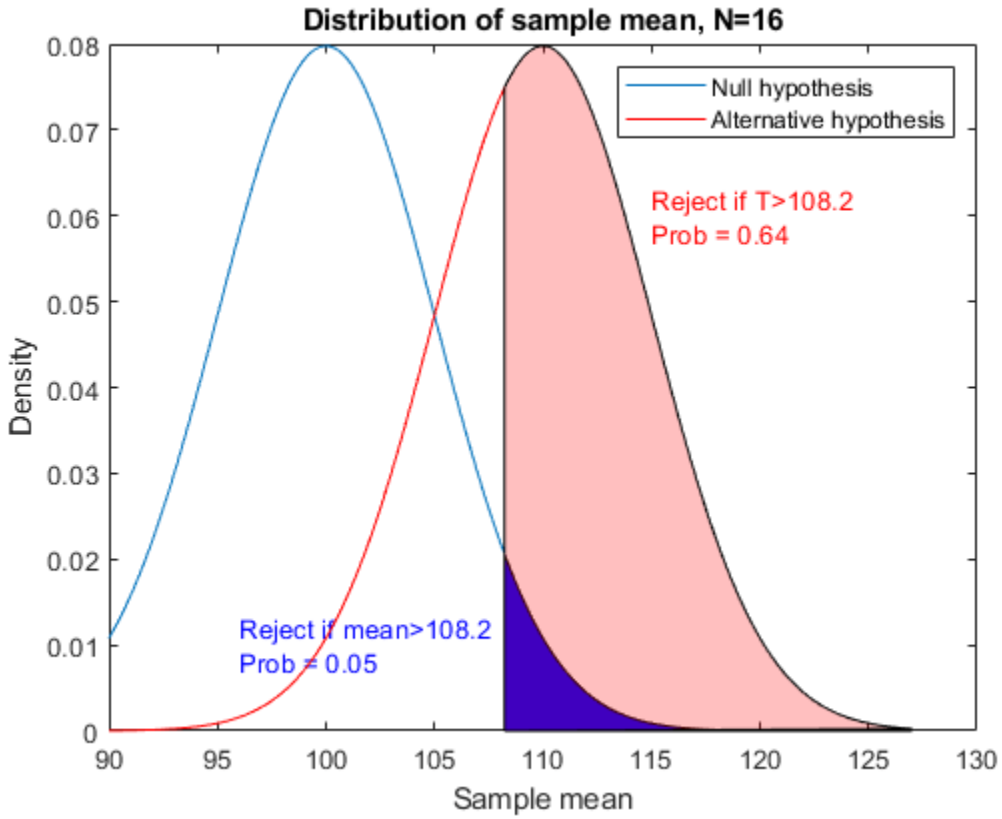
In this case the test statistic T is the sample mean. Under the null hypothesis it has a mean of 100 and a standard deviation of 20/sqrt(N). First let's look at a fixed sample size, say N=16. We will reject the null hypothesis if T is in the shaded region, which is the upper tail of its distribution. That makes this a one-sided test, since we will not reject if T is in the lower tail. The cutoff for this shaded region is 1.6 standard deviations above the mean.

```
rng(0,'twister');
mu0 = 100;
sig = 20;
N = 16;
alpha = 0.05;
conf = 1-alpha;
cutoff = norminv(conf, mu0, sig/sqrt(N));
x = [linspace(90,cutoff), linspace(cutoff,127)];
y = normpdf(x,mu0,sig/sqrt(N));
h1 = plot(x,y);
xhi = [cutoff, x(x>=cutoff)];
yhi = [0, y(x>=cutoff)];
patch(xhi,yhi,'b');
title('Distribution of sample mean, N=16');
xlabel('Sample mean');
ylabel('Density');
text(96,.01,sprintf('Reject if mean>%.4g\nProb = 0.05',cutoff),'Color','b');
```



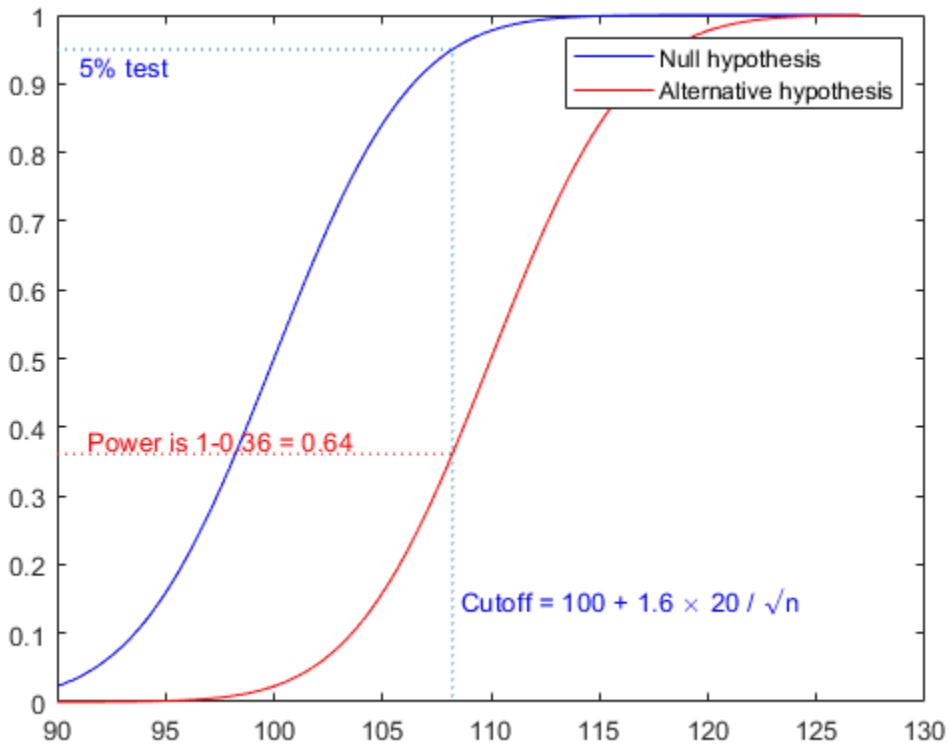
This is how T behaves under the null hypothesis, but what about under an alternative? Our alternative distribution has a mean of 110, as represented by the red curve.

```
mu1 = 110;
y2 = normpdf(x,mu1,sig/sqrt(N));
h2 = line(x,y2,'Color','r');
yhi = [0, y2(x>=cutoff)];
patch(xhi,yhi,'r','FaceAlpha',0.25);
P = 1 - normcdf(cutoff,mu1,sig/sqrt(N));
text(115,.06,sprintf('Reject if T>%.4g\nProb = %.2g',cutoff,P),'Color',[1 0 0]);
legend([h1 h2],'Null hypothesis','Alternative hypothesis');
```



There is a larger chance of rejecting the null hypothesis if the alternative is true. This is just what we want. It's easier to visualize if we look at the cumulative distribution function (cdf) instead of the density (pdf). We can read probabilities directly from this graph, instead of having to compute areas.

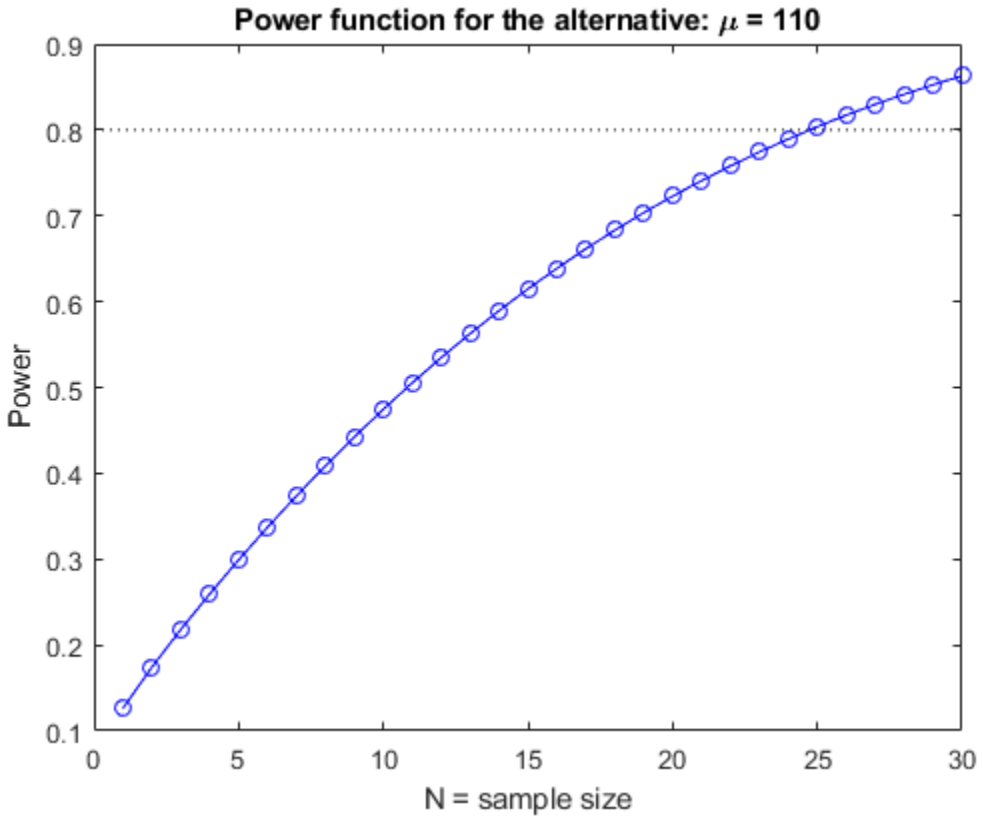
```
ynull = normcdf(x,mu0,sig/sqrt(N));
yalt = normcdf(x,mu1,sig/sqrt(N));
h12 = plot(x,ynull,'b-',x,yalt,'r-');
zval = norminv(conf);
cutoff = mu0 + zval * sig / sqrt(N);
line([90,cutoff,cutoff],[conf, conf, 0],'LineStyle',':');
msg = sprintf(' Cutoff = 100 + %.2g \\times 20 / \\surd{n}',zval);
text(cutoff,.15,msg,'Color','b');
text(min(x),conf,sprintf('   %g%% test',100*alpha),'Color','b',...
                        'verticalalignment','top')
palt = normcdf(cutoff,mu1,sig/sqrt(N));
line([90,cutoff],[palt,palt],'Color','r','LineStyle',':');
text(91,palt+.02,sprintf(' Power is 1-%.2g = %.2g',palt,1-palt),'Color',[1 0 0]);
legend(h12,'Null hypothesis','Alternative hypothesis');
```



This graph shows the probability of getting a significant statistic (rejecting the null hypothesis) for two different mu values when N=16.

The **power function** is defined as the probability of rejecting the null hypothesis when the alternative is true. It depends on the value of the alternative and on the sample size. We'll graph the power (which is one minus the cdf) as a function of N, fixing the alternative at 110. We'll select N to achieve a power of 80%. The graph shows that we need about N=25.

```
DesiredPower = 0.80;
Nvec = 1:30;
cutoff = mu0 + norminv(conf)*sig./sqrt(Nvec);
power = 1 - normcdf(cutoff, mu1, sig./sqrt(Nvec));
plot(Nvec,power,'bo-',[0 30],[DesiredPower DesiredPower],'k:');
xlabel('N = sample size')
ylabel('Power')
title('Power function for the alternative: \mu = 110')
```



In this overly simple example there is a formula to compute the required value directly to get a power of 80%:

```
mudiff = (mu1 - mu0) / sig;
N80 = ceil(((norminv(1-DesiredPower)-norminv(conf)) / mudiff)^2)
```

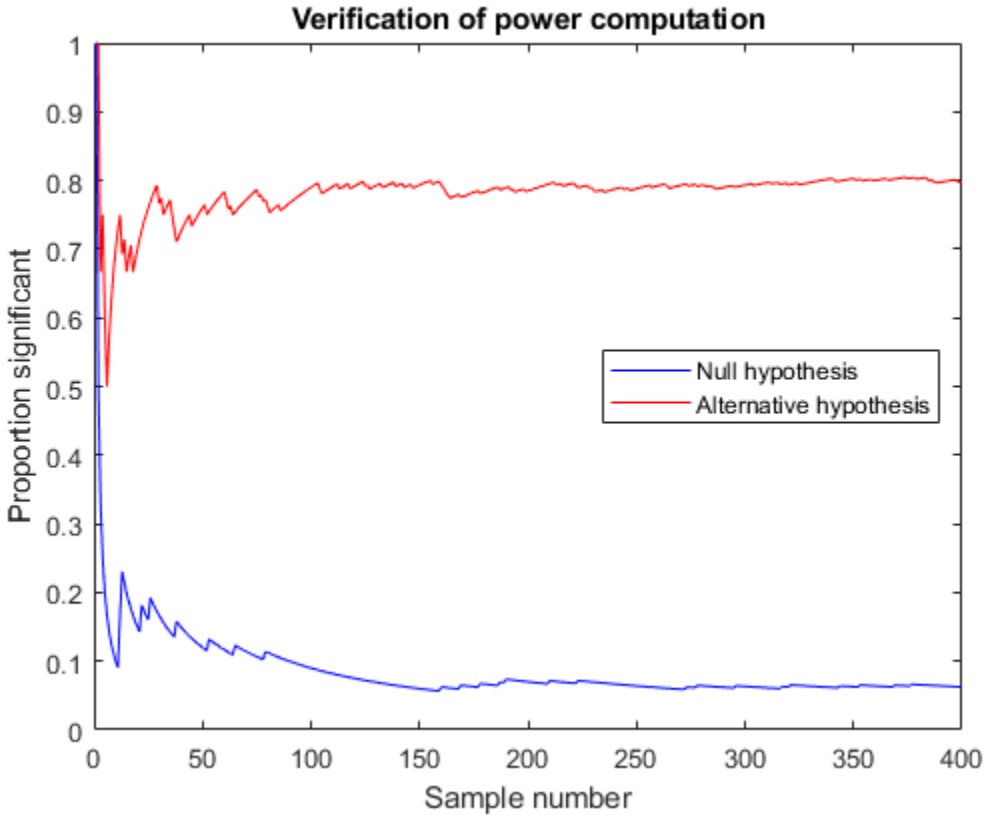
```
N80 =

    25
```

To verify that this works, let's do a Monte Carlo simulation and generate 400 samples of size 25 both under the null hypothesis with mean 100, and under the alternative hypothesis with mean 110. If we test each sample to see if its mean is 100, we should expect about 5% of the first group and 80% of the second group to be significant.

```
nsamples = 400;
samplenum = 1:nsamples;
N = 25;
h0 = zeros(1,nsamples);
h1 = h0;
for j = 1:nsamples
    Z0 = normrnd(mu0,sig,N,1);
    h0(j) = ztest(Z0,mu0,sig,alpha,'right');
    Z1 = normrnd(mu1,sig,N,1);
    h1(j) = ztest(Z1,mu0,sig,alpha,'right');
```

```
end
p0 = cumsum(h0) ./ samplenum;
p1 = cumsum(h1) ./ samplenum;
plot(samplenum,p0,'b-',samplenum,p1,'r-')
xlabel('Sample number')
ylabel('Proportion significant')
title('Verification of power computation')
legend('Null hypothesis','Alternative hypothesis','Location','East')
```



Testing a Normal Mean with Unknown Standard Deviation, Two-Sided

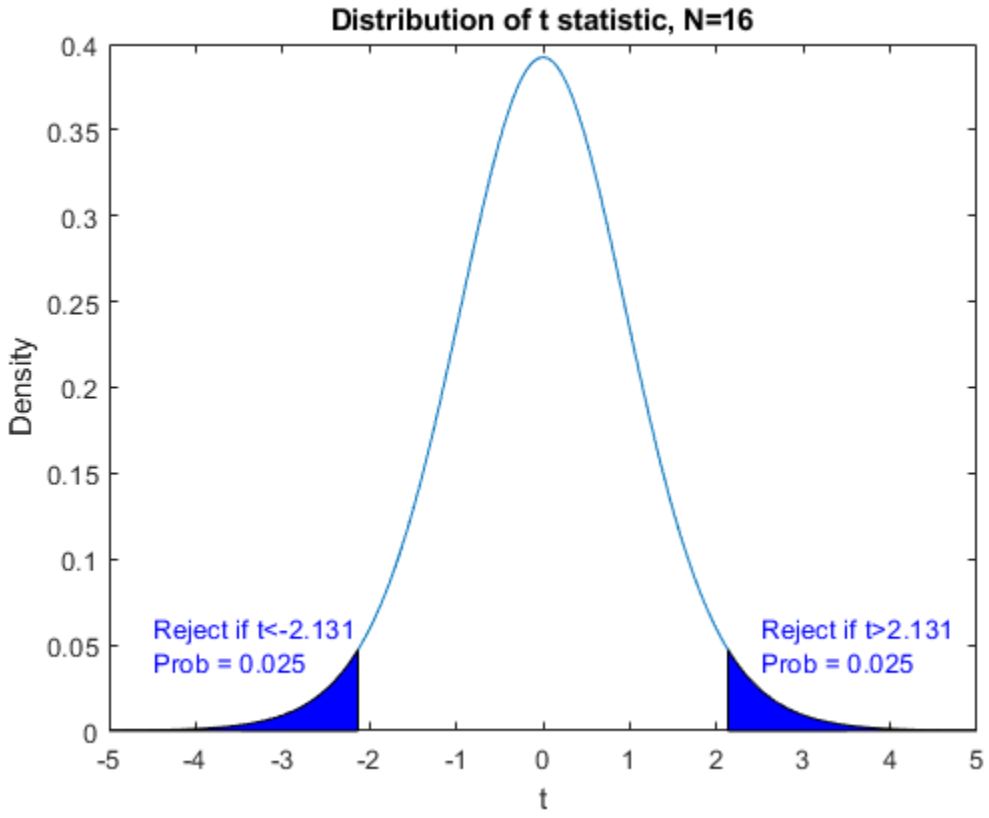
Now let's suppose we don't know the standard deviation, and we want to perform a two-sided test, that is, one that rejects the null hypothesis whether the sample mean is too high or too low.

The test statistic is a t statistic, which is the difference between the sample mean and the mean being tested, divided by the standard error of the mean. Under the null hypothesis, this has Student's t distribution with N-1 degrees of freedom. Under the alternative hypothesis, the distribution is a noncentral t distribution with a noncentrality parameter equal to the normalized difference between the true mean and the mean being tested.

For this two-sided test we have to allocate the 5% chance of an error under the null hypothesis equally to both tails, and reject if the test statistic is too extreme in either direction. We also have to consider both tails under any alternative.

```
N = 16;
df = N-1;
alpha = 0.05;
```

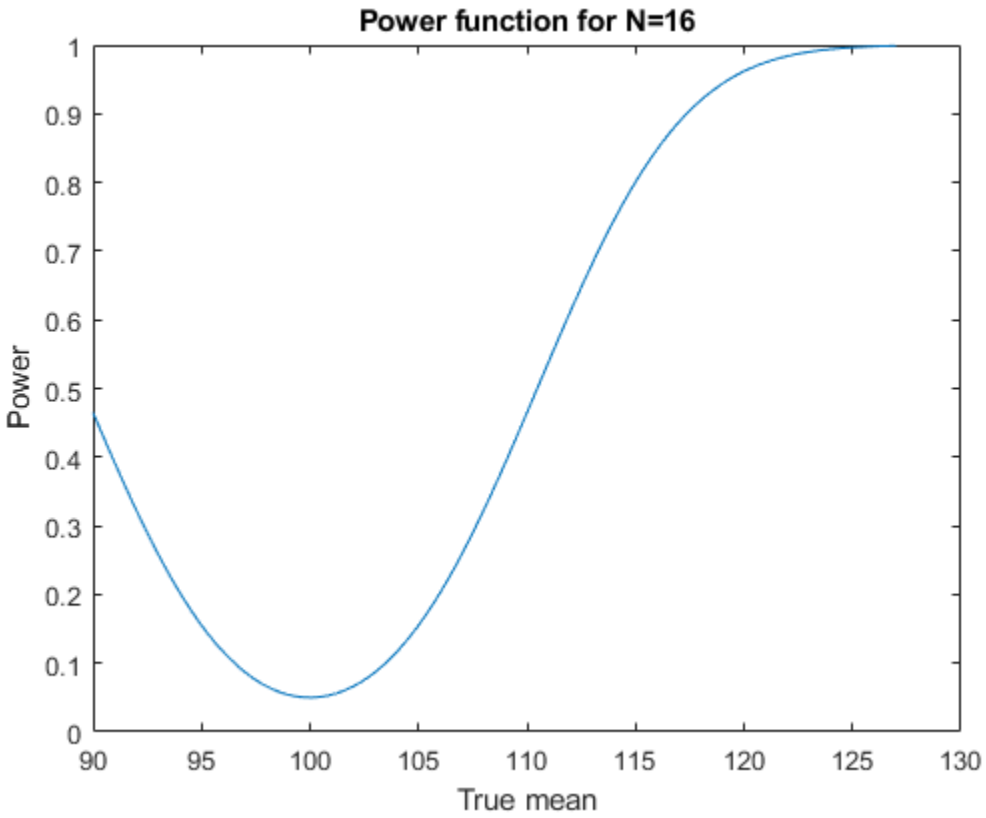
```
conf = 1-alpha;
cutoff1 = tinv(alpha/2,df);
cutoff2 = tinv(1-alpha/2,df);
x = [linspace(-5,cutoff1), linspace(cutoff1,cutoff2),linspace(cutoff2,5)];
y = tpdf(x,df);
h1 = plot(x,y);
xlo = [x(x<=cutoff1),cutoff1];
ylo = [y(x<=cutoff1),0];
xhi = [cutoff2,x(x>=cutoff2)];
yhi = [0, y(x>=cutoff2)];
patch(xlo,ylo,'b');
patch(xhi,yhi,'b');
title('Distribution of t statistic, N=16');
xlabel('t');
ylabel('Density');
text(2.5,.05,sprintf('Reject if t>%.4g\nProb = 0.025',cutoff2),'Color','b');
text(-4.5,.05,sprintf('Reject if t<%.4g\nProb = 0.025',cutoff1),'Color','b');
```



Instead of examining the power function just under the null hypothesis and a single alternative value of mu, we can look at it as a function of mu. The power increases as mu moves away from the null hypothesis value in either direction. We can use the `sampsizepwr` function to compute the power. For a power calculation we need to specify a value for the standard deviation, which we suspect will be roughly 20. Here's a picture of the power function for a sample size N=16.

```
N = 16;
x = linspace(90,127);
power = sampsizepwr('t',[100 20],x,[],N);
```

```
plot(x,power);
xlabel('True mean')
ylabel('Power')
title('Power function for N=16')
```



We want a power of 80% when the mean is 110. According to this graph, our power is less than 50% with a sample size of N=16. What sample size will give the power we want?

```
N = sampsizepwr('t',[100 20],110,0.8)
```

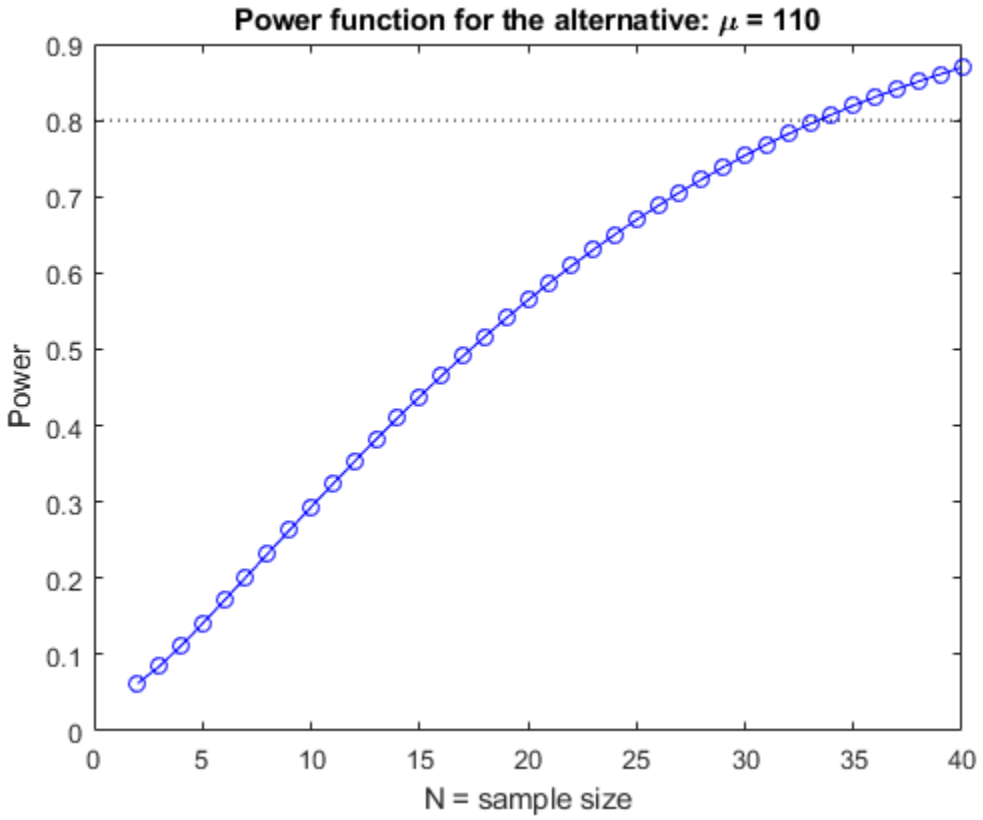
```
N =

    34
```

We need a sample size of about 34. Compared with the previous example, we need to take nine additional observations to allow a two-sided test and to make up for not knowing the true standard deviation.

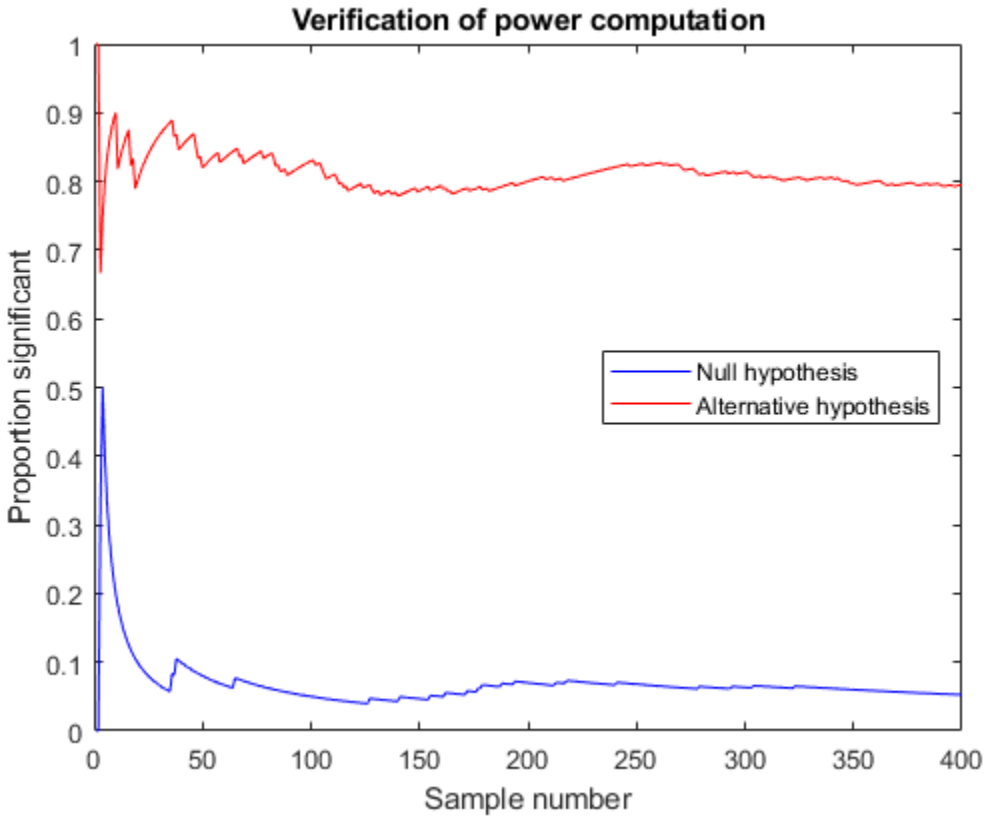
We can make a plot of the power function for various values of N.

```
Nvec = 2:40;
power = sampsizepwr('t',[100 20],110,[],Nvec);
plot(Nvec,power,'bo-',[0 40],[DesiredPower DesiredPower],'k:');
xlabel('N = sample size')
ylabel('Power')
title('Power function for the alternative: \mu = 110')
```



And we can do a simulation similar to the earlier one to verify that we get the power we need.

```
nsamples = 400;
samplenum = 1:nsamples;
N = 34;
h0 = zeros(1,nsamples);
h1 = h0;
for j = 1:nsamples
    Z0 = normrnd(mu0,sig,N,1);
    h0(j) = ttest(Z0,mu0,alpha);
    Z1 = normrnd(mu1,sig,N,1);
    h1(j) = ttest(Z1,mu0,alpha);
end
p0 = cumsum(h0) ./ samplenum;
p1 = cumsum(h1) ./ samplenum;
plot(samplenum,p0,'b-',samplenum,p1,'r-')
xlabel('Sample number')
ylabel('Proportion significant')
title('Verification of power computation')
legend('Null hypothesis','Alternative hypothesis','Location','East')
```



Suppose we could afford to take a sample size of 50. Presumably our power for detecting the alternative value mu=110 would be larger than 80%. If we maintain the power at 80%, what alternative could we detect?

```
mu1 = sampsizepwr('t',[100 20],[],.8,50)
```

```
mu1 =

  108.0837
```

Testing a Proportion

Now let's turn to the problem of determining the sample size needed to distinguish between two proportions. Suppose that we are sampling a population in which about 30% favor some candidate, and we want to sample enough people so we can distinguish this value from 33%.

The idea here is the same as before. Here we can use the sample count as our test statistic. This count has a binomial distribution. For any sample size N we can compute the cutoff for rejecting the null hypothesis P=0.30. For N=100, for instance, we would reject the null hypothesis if the sample count is larger than a cutoff value computed as follows:

```
N = 100;
alpha = 0.05;
p0 = 0.30;
p1 = 0.33;
cutoff = binoinv(1-alpha, N, p0)
```

```
cutoff =

    38
```

A complication with the binomial distribution comes because it is discrete. The probability of exceeding the cutoff value is not exactly 5%:

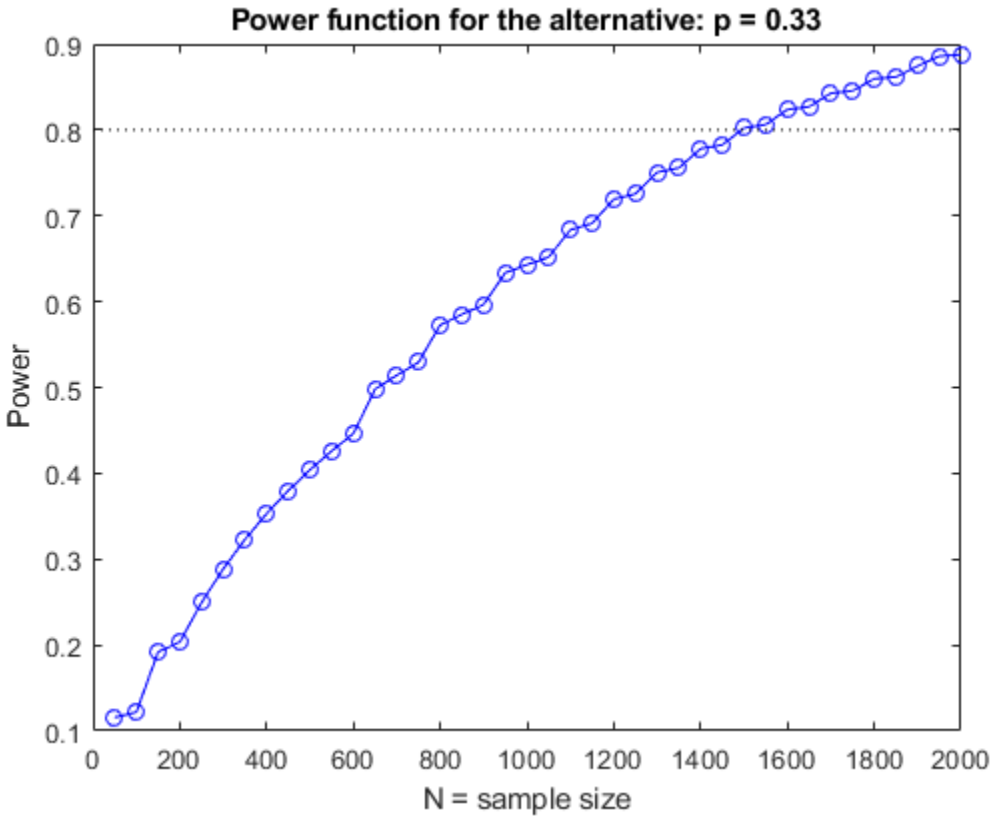
```
1 - binocdf(cutoff, N, p0)
```

```
ans =

    0.0340
```

Once again, let's compute the power against the alternative P=0.33 for a range of sample sizes. We'll use a one-sided (right-tailed) test because we're interested only in alternative values greater than 30%.

```
Nvec = 50:50:2000;
power = sampsizepwr('p',p0,p1,[],Nvec,'tail','right');
plot(Nvec,power,'bo-',[0 2000],[DesiredPower DesiredPower],'k:');
xlabel('N = sample size')
ylabel('Power')
title('Power function for the alternative: p = 0.33')
```



We can use the `sampsizepwr` function to request the sample size required for a power of 80%.

```
approxN = sampsizepwr('p',p0,p1,0.80,[],'tail','right')
```

```
Warning: Values N>200 are approximate.  Plotting the power as a function
of N may reveal lower N values that have the required power.

approxN =

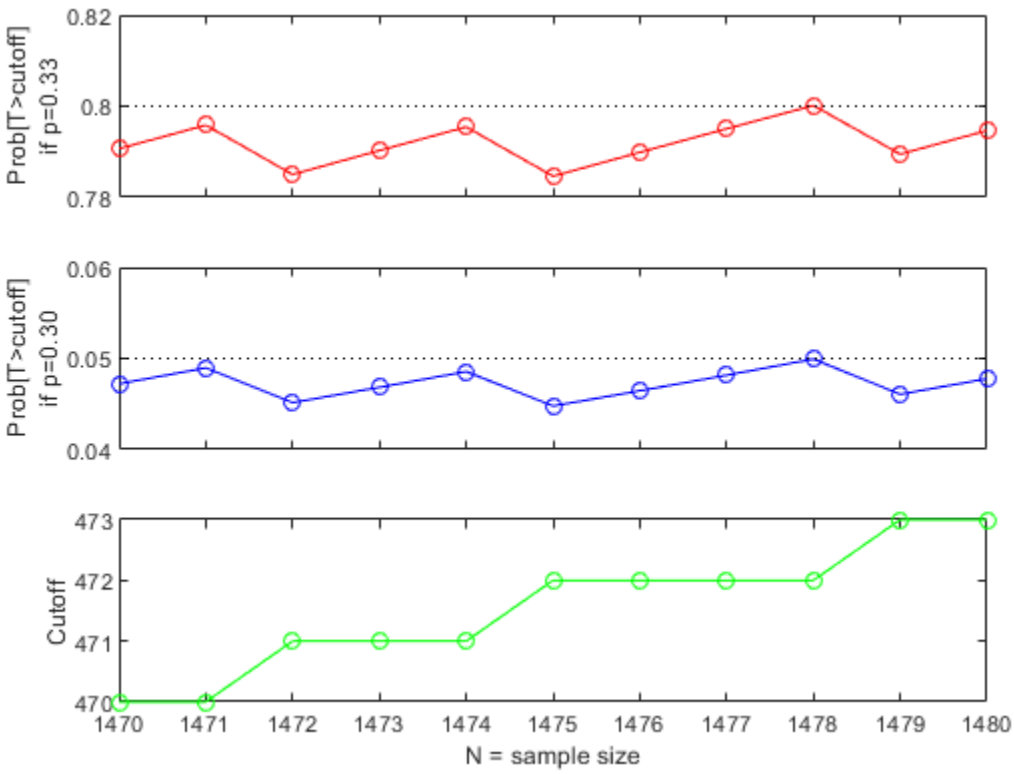
        1500
```

A warning message informs us that the answer is just approximate. If we look at the power function for different sample sizes, we can see that the function is generally increasing, but irregular because the binomial distribution is discrete. Let's look at the probability of rejecting the null hypothesis for both p=0.30 and p=0.33 in the range of samples sizes from 1470 to 1480.

```
subplot(3,1,1);
Nvec = 1470:1480;
power = sampsizepwr('p',p0,p1,[],Nvec,'tail','right');
plot(Nvec,power,'ro-',[min(Nvec),max(Nvec)],[DesiredPower DesiredPower],'k:');
ylabel(sprintf('Prob[T>cutoff]\nif p=0.33'))
h_gca = gca;
h_gca.XTickLabel = '';
ylim([.78, .82]);

subplot(3,1,2);
alf = sampsizepwr('p',p0,p0,[],Nvec,'tail','right');
plot(Nvec,alf,'bo-',[min(Nvec),max(Nvec)],[alpha alpha],'k:');
ylabel(sprintf('Prob[T>cutoff]\nif p=0.30'))
h_gca = gca;
h_gca.XTickLabel = '';
ylim([.04, .06]);

subplot(3,1,3);
cutoff = binoinv(1-alpha, Nvec, p0);
plot(Nvec,cutoff,'go-');
xlabel('N = sample size')
ylabel('Cutoff')
```



This plot reveals that the power function curve (top plot) is not only irregular, but also decreases at some sample sizes. These are the sample sizes for which it is necessary to increase the cutoff value (bottom plot) in order to keep the significance level (middle plot) no larger than 5%. We can find a smaller sample size within this range that gives the desired power of 80%:

```
min(Nvec(power>=0.80))
```

```
ans =

        1478
```

Testing a Correlation

In the examples we've considered so far, we were able to figure out the cutoff for a test statistic to achieve a certain significance level, and to calculate the probability of exceeding that cutoff under an alternative hypothesis. For our final example, let's consider a problem where that is not so easy.

Imagine we can take samples from two variables X and Y, and we want to know what sample size we would need to test whether they are uncorrelated versus the alternative that their correlation is as high as 0.4. Although it is possible to work out the distribution of the sample correlation by transforming it to a t distribution, let's use a method that we can use even in problems where we can't work out the distribution of the test statistic.

For a given sample size, we can use Monte Carlo simulation to determine an approximate cutoff value for a test of the correlation. Let's do a large simulation run so we can get this value accurately. We'll start with a sample size of 25.

```
nsamples = 10000;
N = 25;
alpha = 0.05;
conf = 1-alpha;
r = zeros(1,nsamples);
for j = 1:nsamples
    xy = normrnd(0,1,N,2);
    r(j) = corr(xy(:,1),xy(:,2));
end
cutoff = quantile(r,conf)
```

```
cutoff =

    0.3372
```

Then we can generate samples under the alternative hypothesis, and estimate the power of the test.

```
nsamples = 1000;
mu = [0; 0];
sig = [1 0.4; 0.4 1];
r = zeros(1,nsamples);
for j = 1:nsamples
    xy = mvnrnd(mu,sig,N);
    r(j) = corr(xy(:,1),xy(:,2));
end
[power,powerci] = binofit(sum(r>cutoff),nsamples)
```

```
power =

    0.6470

powerci =

    0.6165    0.6767
```

We estimate the power to be 65%, and we have 95% confidence that the true value is between 62% and 68%. To get a power of 80%, we need a larger sample size. We might try increasing N to 50, estimating the cutoff value for this sample size, and repeating the power simulation.

```
nsamples = 10000;
N = 50;
alpha = 0.05;
conf = 1-alpha;
r = zeros(1,nsamples);
for j = 1:nsamples
    xy = normrnd(0,1,N,2);
    r(j) = corr(xy(:,1),xy(:,2));
end
cutoff = quantile(r,conf)
```

```
nsamples = 1000;
mu = [0; 0];
sig = [1 0.4; 0.4 1];
r = zeros(1,nsamples);
for j = 1:nsamples
    xy = mvnrnd(mu,sig,N);
    r(j) = corr(xy(:,1),xy(:,2));
end
[power,powerci] = binofit(sum(r>cutoff),nsamples)

cutoff =

    0.2315

power =

    0.8990

powerci =

    0.8786    0.9170
```

This sample size gives a power better than our target of 80%. We could continue experimenting this way, trying to find a sample size less than 50 that would meet our requirements.

Conclusion

The probability functions in the Statistics and Machine Learning Toolbox can be used to determine the sample size required to achieve a desired level of power in a hypothesis test. In some problems the sample size can be compute directly; in others it is necessary to search over a range of sample sizes until the right value is found. Random number generators can help verify that the desired power is met, and can also be used to study the power of a specific test under alternative conditions.

Analysis of Variance

Introduction to Analysis of Variance

Analysis of variance (ANOVA) is a procedure for assigning sample variance to different sources and deciding whether the variation arises within or among different population groups. Samples are described in terms of variation around group means and variation of group means around an overall mean. If variations within groups are small relative to variations between groups, a difference in group means may be inferred. Hypothesis tests are used to quantify decisions.

One-Way ANOVA

In this section...

Introduction to One-Way ANOVA

You can use the function `anova1` to perform one-way analysis of variance (ANOVA). The purpose of one-way ANOVA is to determine whether data from several groups (levels) of a factor have a common mean. That is, one-way ANOVA enables you to find out whether different groups of an independent variable have different effects on the response variable *y*. Suppose, a hospital wants to determine if the two new proposed scheduling methods reduce patient wait times more than the old way of scheduling appointments. In this case, the independent variable is the scheduling method, and the response variable is the waiting time of the patients.

One-way ANOVA is a simple special case of the linear model on page 11-6. The one-way ANOVA form of the model is

$$y_{ij} = \alpha_j + \varepsilon_{ij}$$

with the following assumptions:

- y_{ij} is an observation, in which i represents the observation number, and j represents a different group (level) of the variable y. All y_{ij} are independent.
- α_j represents the population mean for the jth group (level or treatment).
- ε_{ij} is the random error, independent and normally distributed, with zero mean and constant variance, i.e., $\varepsilon_{ij} \sim N(0,\sigma^2)$.

This model is also called the *means model*. The model assumes that the columns of y are the constant α_j plus the error component ε_{ij}. ANOVA helps determine if the constants are all the same.

ANOVA tests the hypothesis that all group means are equal ($H_0: \alpha_1 = \alpha_2 = ... = \alpha_k$) against the alternative hypothesis that at least one group is different from the others ($H_1: \alpha_i \neq \alpha_j$ for at least one i and j). `anova1(y)` tests the equality of column means for the data in matrix `y`, where each column is a different group and has the same number of observations (i.e., a balanced design). `anova1(y,group)` tests the equality of group means, specified in `group`, for the data in vector or matrix `y`. In this case, each group or column can have a different number of observations (i.e., an unbalanced design).

ANOVA is based on the assumption that all sample populations are normally distributed. It is known to be robust to modest violations of this assumption. You can check the normality assumption visually by using a normality plot (`normplot`). Alternatively, you can use one of the Statistics and Machine Learning Toolbox functions that checks for normality: the Anderson-Darling test (`adtest`), the chi-squared goodness of fit test (`chi2gof`), the Jarque-Bera test (`jbtest`), or the Lilliefors test (`lillietest`).

Prepare Data for One-Way ANOVA

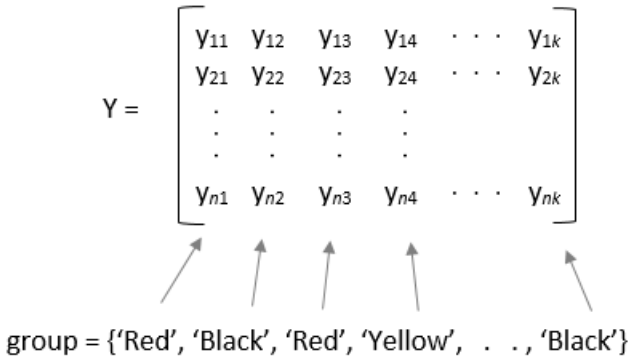
You can provide sample data as a vector or a matrix.

- If the sample data is in a vector, `y`, then you must provide grouping information using the `group` input variable: `anova1(y,group)`.

  `group` must be a numeric vector, logical vector, categorical vector, character array, string array, or cell array of character vectors, with one name for each element of `y`. The `anova1` function treats the `y` values corresponding to the same value of `group` as part of the same group. For example,

  
  Use this design when groups have different numbers of elements (unbalanced ANOVA).
- If the sample data is in a matrix, `y`, providing the group information is optional.
  - If you do not specify the input variable `group`, then `anova1` treats each column of `y` as a separate group, and evaluates whether the population means of the columns are equal. For example,

    
    Use this form of design when each group has the same number of elements (balanced ANOVA).
  - If you specify the input variable `group`, then each element in `group` represents a group name for the corresponding column in `y`. The `anova1` function treats the columns with the same group name as part of the same group. For example,



`anova1` ignores any `NaN` values in `y`. Also, if `group` contains empty or `NaN` values, `anova1` ignores the corresponding observations in `y`. The `anova1` function performs balanced ANOVA if each group has the same number of observations after the function disregards empty or `NaN` values. Otherwise, `anova1` performs unbalanced ANOVA.

Perform One-Way ANOVA

This example shows how to perform one-way ANOVA to determine whether data from several groups have a common mean.

Load and display the sample data.

```
load hogg
hogg
```

```
hogg = 6×5

    24    14    11     7    19
    15     7     9     7    24
    21    12     7     4    19
    27    17    13     7    15
    33    14    12    12    10
    23    16    18    18    20
```

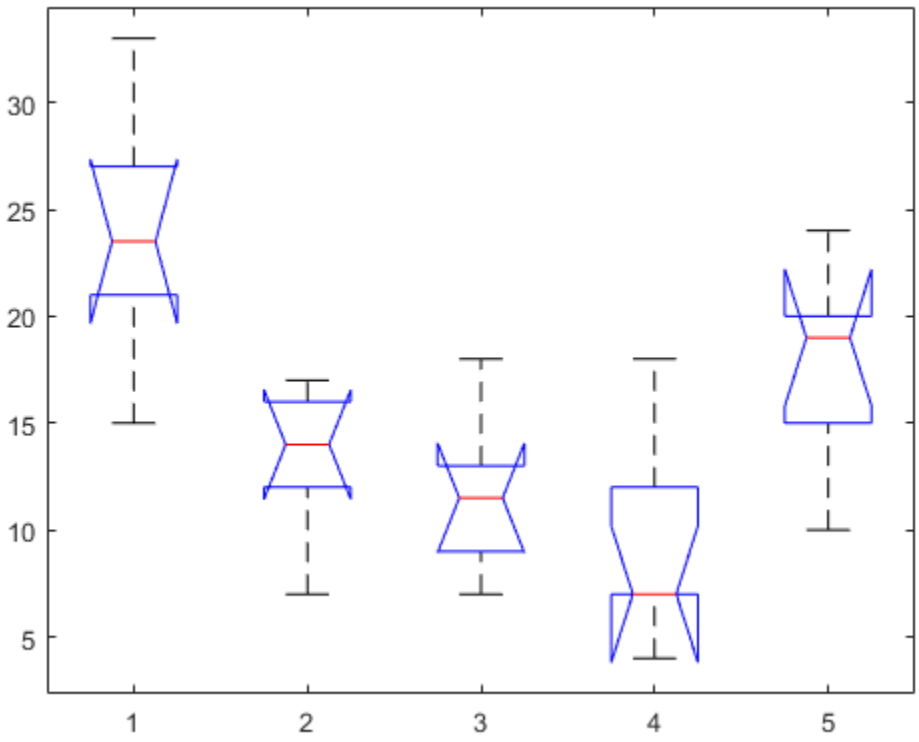
The data comes from a Hogg and Ledolter (1987) study on bacteria counts in shipments of milk. The columns of the matrix `hogg` represent different shipments. The rows are bacteria counts from cartons of milk chosen randomly from each shipment.

Test if some shipments have higher counts than others. By default, `anova1` returns two figures. One is the standard ANOVA table, and the other one is the box plots of data by group.

```
[p,tbl,stats] = anova1(hogg);
```

ANOVA Table

Source	SS	df	MS	F	Prob>F
Columns	803	4	200.75	9.01	0.0001
Error	557.17	25	22.287		
Total	1360.17	29			



```
p
```

```
p = 1.1971e-04
```

The small *p*-value of about 0.0001 indicates that the bacteria counts from the different shipments are not the same.

You can get some graphical assurance that the means are different by looking at the box plots. The notches, however, compare the medians, not the means. For more information on this display, see `boxplot`.

View the standard ANOVA table. `anova1` saves the standard ANOVA table as a cell array in the output argument `tbl`.

```
tbl
```

```
tbl=4×6 cell array
  Columns 1 through 5
```

```
    {'Source' }    {'SS'        }    {'df'}    {'MS'      }    {'F'       }
    {'Columns'}    {[  803.0000]}    {[ 4]}    {[200.7500]}    {[  9.0076]}
    {'Error'  }    {[  557.1667]}    {[25]}    {[ 22.2867]}    {0x0 double}
    {'Total'  }    {[1.3602e+03]}    {[29]}    {0x0 double}    {0x0 double}

  Column 6

    {'Prob>F'    }
    {[1.1971e-04]}
    {0x0 double  }
    {0x0 double  }
```

Save the *F*-statistic value in the variable `Fstat`.

```
Fstat = tbl{2,5}
```

```
Fstat = 9.0076
```

View the statistics necessary to make a multiple pairwise comparison of group means. `anova1` saves these statistics in the structure `stats`.

```
stats
```

```
stats = struct with fields:
    gnames: [5x1 char]
         n: [6 6 6 6 6]
    source: 'anova1'
     means: [23.8333 13.3333 11.6667 9.1667 17.8333]
        df: 25
         s: 4.7209
```

ANOVA rejects the null hypothesis that all group means are equal, so you can use the multiple comparisons to determine which group means are different from others. To conduct multiple comparison tests, use the function `multcompare`, which accepts `stats` as an input argument. In this example, `anova1` rejects the null hypothesis that the mean bacteria counts from all four shipments are equal to each other, i.e., $H_0: \mu_1 = \mu_2 = \mu_3 = \mu_4$.

Perform a multiple comparison test to determine which shipments are different than the others in terms of mean bacteria counts.

```
multcompare(stats)
```

```
ans = 10×6

    1.0000    2.0000    2.4953   10.5000   18.5047    0.0059
    1.0000    3.0000    4.1619   12.1667   20.1714    0.0013
    1.0000    4.0000    6.6619   14.6667   22.6714    0.0001
    1.0000    5.0000   -2.0047    6.0000   14.0047    0.2119
    2.0000    3.0000   -6.3381    1.6667    9.6714    0.9719
    2.0000    4.0000   -3.8381    4.1667   12.1714    0.5544
    2.0000    5.0000  -12.5047   -4.5000    3.5047    0.4806
    3.0000    4.0000   -5.5047    2.5000   10.5047    0.8876
    3.0000    5.0000  -14.1714   -6.1667    1.8381    0.1905
    4.0000    5.0000  -16.6714   -8.6667   -0.6619    0.0292
```

The first two columns show which group means are compared with each other. For example, the first row compares the means for groups 1 and 2. The last column shows the *p*-values for the tests. The *p*-values 0.0059, 0.0013, and 0.0001 indicate that the mean bacteria counts in the milk from the first shipment is different from the ones from the second, third, and fourth shipments. The *p*-value of 0.0292 indicates that the mean bacteria counts in the milk from the fourth shipment is different from the ones from the fifth. The procedure fails to reject the hypotheses that the other group means are different from each other.

The figure also illustrates the same result. The blue bar shows the comparison interval for the first group mean, which does not overlap with the comparison intervals for the second, third, and fourth group means, shown in red. The comparison interval for the mean of fifth group, shown in gray,

overlaps with the comparison interval for the first group mean. Hence, the group means for the first and fifth groups are not significantly different from each other.

Mathematical Details

ANOVA tests for the difference in the group means by partitioning the total variation in the data into two components:

- Variation of group means from the overall mean, i.e., $\bar{y}_{\cdot j} - \bar{y}_{\cdot\cdot}$ (variation between groups), where $\bar{y}_{\cdot j}$ is the sample mean of group j, and $\bar{y}_{\cdot\cdot}$ is the overall sample mean.
- Variation of observations in each group from their group mean estimates, $y_{ij} - \bar{y}_{\cdot j}$ (variation within group).

In other words, ANOVA partitions the total sum of squares (SST) into sum of squares due to between-groups effect (SSR) and sum of squared errors(SSE).

$$\underbrace{\sum_i \sum_j \left(y_{ij} - \bar{y}_{\cdot\cdot}\right)^2}_{SST} = \underbrace{\sum_j n_j \left(\bar{y}_{\cdot j} - \bar{y}_{\cdot\cdot}\right)^2}_{SSR} + \underbrace{\sum_i \sum_j \left(y_{ij} - \bar{y}_{\cdot j}\right)^2}_{SSE},$$

where n_j is the sample size for the jth group, $j = 1, 2, \ldots, k$.

Then ANOVA compares the variation between groups to the variation within groups. If the ratio of between-group variation to within-group variation is significantly high, then you can conclude that the group means are significantly different from each other. You can measure this using a test statistic that has an F-distribution with (k – 1, N – k) degrees of freedom:

$$F = \frac{SSR/k-1}{SSE/N-k} = \frac{MSR}{MSE} \sim F_{k-1,\,N-k},$$

where MSR is the mean squared treatment, MSE is the mean squared error, k is the number of groups, and N is the total number of observations. If the p-value for the F-statistic is smaller than the significance level, then the test rejects the null hypothesis that all group means are equal and concludes that at least one of the group means is different from the others. The most common significance levels are 0.05 and 0.01.

ANOVA Table

The ANOVA table captures the variability in the model by source, the F-statistic for testing the significance of this variability, and the p-value for deciding on the significance of this variability. The p-value returned by `anova1` depends on assumptions about the random disturbances ε_{ij} in the model equation. For the p-value to be correct, these disturbances need to be independent, normally distributed, and have constant variance. The standard ANOVA table has this form:

Source	SS	df	MS	F	p-value
Group (Between)	SSR	$k-1$	MSR = SSR/($k-1$)	MSR/MSE	$P(F_{k-1,N-k}) > F$
Error (Within)	SSE	$N-k$	MSE = SSE/($N-k$)		
Total	SST	$N-1$			

`anova1` returns the standard ANOVA table as a cell array with six columns.

Column	Definition
`Source`	Source of the variability.
`SS`	Sum of squares due to each source.
`df`	Degrees of freedom associated with each source. Suppose N is the total number of observations and k is the number of groups. Then, $N – k$ is the within-groups degrees of freedom (`Error`), $k – 1$ is the between-groups degrees of freedom (`Columns`), and $N – 1$ is the total degrees of freedom: $N – 1 = (N – k) + (k – 1)$.
`MS`	Mean squares for each source, which is the ratio `SS/df`.
`F`	F-statistic, which is the ratio of the mean squares.
`Prob>F`	p-value, which is the probability that the F-statistic can take a value larger than the computed test-statistic value. `anova1` derives this probability from the cdf of the F-distribution.

The rows of the ANOVA table show the variability in the data, divided by the source.

Row (Source)	Definition
`Groups` or `Columns`	Variability due to the differences among the group means (variability *between* groups)
`Error`	Variability due to the differences between the data in each group and the group mean (variability *within* groups)
`Total`	Total variability

Two-Way ANOVA

In this section...

Introduction to Two-Way ANOVA

You can use the function `anova2` to perform a balanced two-way analysis of variance (ANOVA). To perform two-way ANOVA for an unbalanced design, use `anovan`. For an example, see “Two-Way ANOVA for Unbalanced Design” on page 33-82.

As in one-way ANOVA, the data for a two-way ANOVA study can be experimental or observational. The difference between one-way and two-way ANOVA is that in two-way ANOVA, the effects of two factors on a response variable are of interest. These two factors can be independent, and have no interaction effect, or the impact of one factor on the response variable can depend on the group (level) of the other factor. If the two factors have no interactions, the model is called an *additive* model.

Suppose an automobile company has two factories, and each factory makes the same three car models. The gas mileage in the cars can vary from factory to factory and from model to model. These two factors, factory and model, explain the differences in mileage, that is, the response. One measure of interest is the difference in mileage due to the production methods between factories. Another measure of interest is the difference in the mileage of the models (irrespective of the factory) due to different design specifications. The effects of these measures of interest are *additive*. In addition, suppose only one model has different gas mileage between factories, while the mileage of the other two models is the same between factories. This is called an *interaction* effect. To measure an interaction effect, there must be multiple observations for some combination of factory and car model. These multiple observations are called *replications*.

Two-way ANOVA is a special case of the linear model on page 11-6. The two-way ANOVA form of the model is

$$y_{ijr} = \mu + \alpha_i + \beta_j + (\alpha\beta)_{ij} + \varepsilon_{ijr}$$

where,

- y_{ijr} is an observation of the response variable.
  - i represents group i of row factor A, $i = 1, 2, \ldots, I$.
  - j represents group j of column factor B, $j = 1, 2, \ldots, J$.
  - r represents the replication number, $r = 1, 2, \ldots, R$.

  There are a total of $N = I*J*R$ observations.
- μ is the overall mean.
- α_i are the deviations of groups defined by row factor A from the overall mean μ. The values of α_i sum to 0.

$$\sum_{i=1}^{I}\alpha_i = 0.$$

- β_j are the deviations of groups defined by column factor B from the overall mean μ. The values of β_j sum to 0.

$$\sum_{j=1}^{J}\beta_j = 0.$$

- $\alpha\beta_{ij}$ are the interactions. The values in each row and in each column of $\alpha\beta_{ij}$ sum to 0.

$$\sum_{i=1}^{I}(\alpha\beta)_{ij} = \sum_{j=1}^{J}(\alpha\beta)_{ij} = 0.$$

- ε_{ijr} are the random disturbances. They are assumed to be independent, normally distributed, and have constant variance.

In the mileage example:

- y_{ijr} are the gas mileage observations, μ is the overall mean gas mileage.
- α_i are the deviations of each car's gas mileage from the mean gas mileage μ due to the car's *model*.
- β_j are the deviations of each car's gas mileage from the mean gas mileage μ due to the car's *factory*.

`anova2` requires that data be balanced, so each combination of model and factory must have the same number of cars.

Two-way ANOVA tests hypotheses about the effects of factors A and B, and their interaction on the response variable y. The hypotheses about the equality of the mean response for groups of row factor A are

$$H_0: \alpha_1 = \alpha_2 \cdots = \alpha_I$$
$$H_1: \text{ at least one } \alpha_i \text{ is different, } i = 1,\ 2,\ \ldots,\ I.$$

The hypotheses about the equality of the mean response for groups of column factor B are

$$H_0: \beta_1 = \beta_2 = \cdots = \beta_J$$
$$H_1: \text{ at least one } \beta_j \text{ is different, } j = 1,\ 2,\ \ldots,\ J.$$

The hypotheses about the interaction of the column and row factors are

$$H_0: (\alpha\beta)_{ij} = 0$$
$$H_1: \text{at least one } (\alpha\beta)_{ij} \neq 0$$

Prepare Data for Balanced Two-Way ANOVA

To perform balanced two-way ANOVA using `anova2`, you must arrange data in a specific matrix form. The columns of the matrix must correspond to groups of the column factor, B. The rows must correspond to the groups of the row factor, A, with the same number of replications for each combination of the groups of factors A and B.

Suppose that row factor A has three groups, and column factor B has two groups (levels). Also suppose that each combination of factors A and B has two measurements or observations (`reps = 2`). Then, each group of factor A has six observations and each group of factor B four observations.

$$\begin{array}{cc} B=1 & B=2 \\ \left[\begin{array}{cc} y_{111} & y_{121} \\ y_{112} & y_{122} \\ y_{211} & y_{221} \\ y_{212} & y_{222} \\ y_{311} & y_{321} \\ y_{312} & y_{322} \end{array}\right] & \begin{array}{l} \} A=1 \\ \} A=2 \\ \} A=3 \end{array} \end{array}$$

The subscripts indicate row, column, and replication, respectively. For example, y_{221} corresponds to the measurement for the second group of factor A, the second group of factor B, and the first replication for this combination.

Perform Two-Way ANOVA

This example shows how to perform two-way ANOVA to determine the effect of car model and factory on the mileage rating of cars.

Load and display the sample data.

```
load mileage
mileage
```

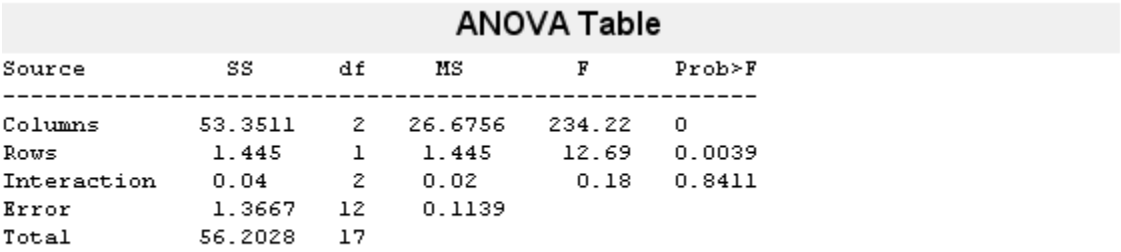
```
mileage = 6×3

   33.3000   34.5000   37.4000
   33.4000   34.8000   36.8000
   32.9000   33.8000   37.6000
   32.6000   33.4000   36.6000
   32.5000   33.7000   37.0000
   33.0000   33.9000   36.7000
```

There are three car models (columns) and two factories (rows). The data has six mileage rows because each factory provided three cars of each model for the study (i.e., the replication number is three). The data from the first factory is in the first three rows, and the data from the second factory is in the last three rows.

Perform two-way ANOVA. Return the structure of statistics, `stats`, to use in multiple comparisons.

```
nmbcars = 3; % Number of cars from each model, i.e., number of replications
[~,~,stats] = anova2(mileage,nmbcars);
```



You can use the *F*-statistics to do hypotheses tests to find out if the mileage is the same across models, factories, and model - factory pairs. Before performing these tests, you must adjust for the additive effects. `anova2` returns the *p*-value from these tests.

The *p*-value for the model effect (`Columns`) is zero to four decimal places. This result is a strong indication that the mileage varies from one model to another.

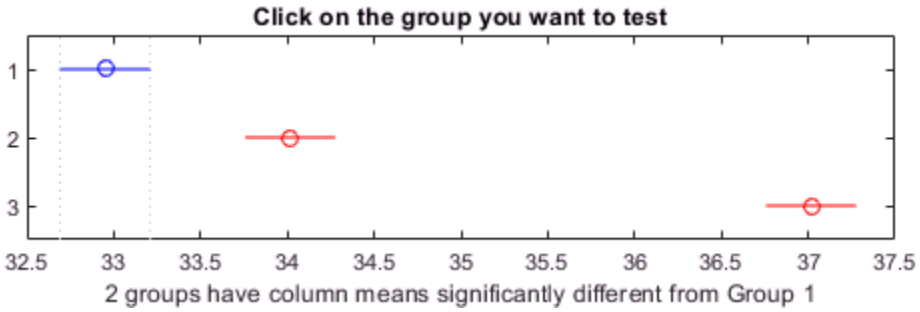
The *p*-value for the factory effect (`Rows`) is 0.0039, which is also highly significant. This value indicates that one factory is out-performing the other in the gas mileage of the cars it produces. The observed *p*-value indicates that an *F*-statistic as extreme as the observed *F* occurs by chance about four out of 1000 times, if the gas mileage were truly equal from factory to factory.

The factories and models appear to have no interaction. The *p*-value, 0.8411, means that the observed result is likely (84 out of 100 times), given that there is no interaction.

Perform “Multiple Comparisons” on page 9-18 to find out which pair of the three car models is significantly different.

```
c = multcompare(stats)
```

```
Note: Your model includes an interaction term.  A test of main effects can be
difficult to interpret when the model includes interactions.
```



```
c = 3×6

    1.0000    2.0000   -1.5865   -1.0667   -0.5469    0.0004
    1.0000    3.0000   -4.5865   -4.0667   -3.5469    0.0000
    2.0000    3.0000   -3.5198   -3.0000   -2.4802    0.0000
```

In the matrix `c`, the first two columns show the pairs of car models that are compared. The last column shows the *p*-values for the test. All *p*-values are small (0.0004, 0, and 0), which indicates that the mean mileage of all car models are significantly different from each other.

In the figure, the blue bar is the comparison interval for the mean mileage of the first car model. The red bars are the comparison intervals for the mean mileage of the second and third car models. None of the second and third comparison intervals overlap with the first comparison interval, indicating that the mean mileage of the first car model is different from the mean mileage of the second and the third car models. If you click on one of the other bars, you can test for the other car models. None of the comparison intervals overlap, indicating that the mean mileage of each car model is significantly different from the other two.

Mathematical Details

The two-factor ANOVA partitions the total variation into the following components:

- Variation of row factor group means from the overall mean, $\bar{y}_{i..} - \bar{y}_{...}$
- Variation of column factor group means from the overall mean, $\bar{y}_{.j.} - \bar{y}_{...}$
- Variation of overall mean plus the replication mean from the column factor group mean plus row factor group mean, $\bar{y}_{ij.} - \bar{y}_{i..} - \bar{y}_{.j.} + \bar{y}_{...}$
- Variation of observations from the replication means, $y_{ijk} - \bar{y}_{ij.}$

ANOVA partitions the total sum of squares (SST) into the sum of squares due to row factor A (SS_A), the sum of squares due to column factor B (SS_B), the sum of squares due to interaction between A and B (SS_{AB}), and the sum of squares error (SSE).

$$\underbrace{\sum_{i=1}^{m}\sum_{j=1}^{k}\sum_{r=1}^{R}\left(y_{ijk}-\bar{y}_{...}\right)^2}_{SST} = \underbrace{kR\sum_{i=1}^{m}\left(\bar{y}_{i..}-\bar{y}_{...}\right)^2}_{SS_B} + \underbrace{mR\sum_{j=1}^{k}\left(\bar{y}_{.j.}-\bar{y}_{...}\right)^2}_{SS_A}$$
$$+\underbrace{R\sum_{i=1}^{m}\sum_{j=1}^{k}\left(\bar{y}_{ij.}-\bar{y}_{i..}-\bar{y}_{.j.}+\bar{y}_{...}\right)^2}_{SS_{AB}} + \underbrace{\sum_{i=1}^{m}\sum_{j=1}^{k}\sum_{r=1}^{R}\left(y_{ijk}-\bar{y}_{ij.}\right)^2}_{SSE}$$

ANOVA takes the variation due to the factor or interaction and compares it to the variation due to error. If the ratio of the two variations is high, then the effect of the factor or the interaction effect is statistically significant. You can measure the statistical significance using a test statistic that has an F-distribution.

For the null hypothesis that the mean response for groups of the row factor A are equal, the test statistic is

$$F = \frac{SS_B/(m-1)}{SSE/mk(R-1)} \sim F_{m-1,\,mk(R-1)}.$$

For the null hypothesis that the mean response for groups of the column factor B are equal, the test statistic is

$$F = \frac{SS_A/(k-1)}{SSE/mk(R-1)} \sim F_{k-1,\,mk(R-1)}.$$

For the null hypothesis that the interaction of the column and row factors are equal to zero, the test statistic is

$$F = \frac{SS_{AB}/(m-1)(k-1)}{SSE/mk(R-1)} \sim F_{(m-1)(k-1),\,mk(R-1)}.$$

If the p-value for the F-statistic is smaller than the significance level, then ANOVA rejects the null hypothesis. The most common significance levels are 0.01 and 0.05.

ANOVA Table

The ANOVA table captures the variability in the model by the source, the F-statistic for testing the significance of this variability, and the p-value for deciding on the significance of this variability. The

p-value returned by `anova2` depends on assumptions about the random disturbances, ε_{ij}, in the model equation. For the *p*-value to be correct, these disturbances need to be independent, normally distributed, and have constant variance. The standard ANOVA table has this form:

Source	SS	df	MS	F	*p*-value
Columns	SS_A	$k - 1$	MS_A	MS_A/MSE	$P(F_{k-1,mk(R-1)}) > F$
Rows	SS_B	$m - 1$	MS_B	MS_B/MSE	$P(F_{m-1,mk(R-1)}) > F$
Interaction	SS_{AB}	$(m-1)(k-1)$	MS_{AB}	MS_{AB}/MSE	$P(F_{(m-1)(k-1),mk(R-1)}) > F$
Error	SSE	$mk(R-1)$	MSE		
Total	SST	$mkR - 1$			

`anova2` returns the standard ANOVA table as a cell array with six columns.

Column	Definition
`Source`	The source of the variability.
`SS`	The sum of squares due to each source.
`df`	The degrees of freedom associated with each source. Suppose *J* is the number of groups in the column factor, *I* is the number of groups in the row factor, and *R* is the number of replications. Then, the total number of observations is *IJR* and the total degrees of freedom is *IJR* – 1. *I* – 1 is the degrees of freedom for the row factor,*J* – 1 is the degrees of freedom for the column factor, (*I* – 1)(*J* – 1) is the interaction degrees of freedom, and *IJ*(*R* – 1) is the error degrees of freedom.
`MS`	The mean squares for each source, which is the ratio `SS/df`.
`F`	*F*-statistic, which is the ratio of the mean squares.
`Prob>F`	The *p*-value, which is the probability that the *F*-statistic can take a value larger than the computed test-statistic value. `anova2` derives this probability from the cdf of the *F*-distribution.

The rows of the ANOVA table show the variability in the data that is divided by the source.

Row (Source)	Definition
`Columns`	Variability due to the column factor
`Rows`	Variability due to the row factor
`Interaction`	Variability due to the interaction of the row and column factors
`Error`	Variability due to the differences between the data in each group and the group mean (variability *within* groups)

Row (Source)	Definition
`Total`	Total variability

Multiple Comparisons

In this section...

Introduction

Analysis of variance (ANOVA) techniques test whether a set of group means (treatment effects) are equal or not. Rejection of the null hypothesis leads to the conclusion that not all group means are the same. This result, however, does not provide further information on which group means are different.

Performing a series of *t*-tests to determine which pairs of means are significantly different is not recommended. When you perform multiple *t*-tests, the probability that the means appear significant, and significant difference results might be due to large number of tests. These *t*-tests use the data from the same sample, hence they are not independent. This fact makes it more difficult to quantify the level of significance for multiple tests.

Suppose that in a single *t*-test, the probability that the null hypothesis (H_0) is rejected when it is actually true is a small value, say 0.05. Suppose also that you conduct six independent *t*-tests. If the significance level for each test is 0.05, then the probability that the tests correctly fail to reject H_0, when H_0 is true for each case, is $(0.95)^6 = 0.735$. And the probability that one of the tests incorrectly rejects the null hypothesis is 1 – 0.735 = 0.265, which is much higher than 0.05.

To compensate for multiple tests, you can use multiple comparison procedures. The Statistics and Machine Learning Toolbox function `multcompare` performs multiple pairwise comparison of the group means, or treatment effects. The options are Tukey’s honestly significant difference criterion (default option), the Bonferroni method, Scheffe’s procedure, Fisher’s least significant differences (lsd) method, and Dunn & Sidák’s approach to *t*-test.

To perform multiple comparisons of group means, provide the structure `stats` as an input for `multcompare`. You can obtain `stats` from one of the following functions :

- `anova1` — One-way ANOVA on page 9-3
- `anova2` — Two-way ANOVA on page 9-11
- `anovan` — *N*-way ANOVA on page 9-25
- `aoctool` — Interactive ANCOVA on page 9-39
- `kruskalwallis` — Nonparametric method on page 9-47 for one-way layout
- `friedman` — Nonparametric method on page 9-47 for two-way layout

For multiple comparison procedure options for repeated measures, see `multcompare` (`RepeatedMeasuresModel`).

Multiple Comparisons Using One-Way ANOVA

Load the sample data.

```
load carsmall
```

`MPG` represents the miles per gallon for each car, and `Cylinders` represents the number of cylinders in each car, either 4, 6, or 8 cylinders.

Test if the mean miles per gallon (mpg) is different across cars that have different numbers of cylinders. Also compute the statistics needed for multiple comparison tests.

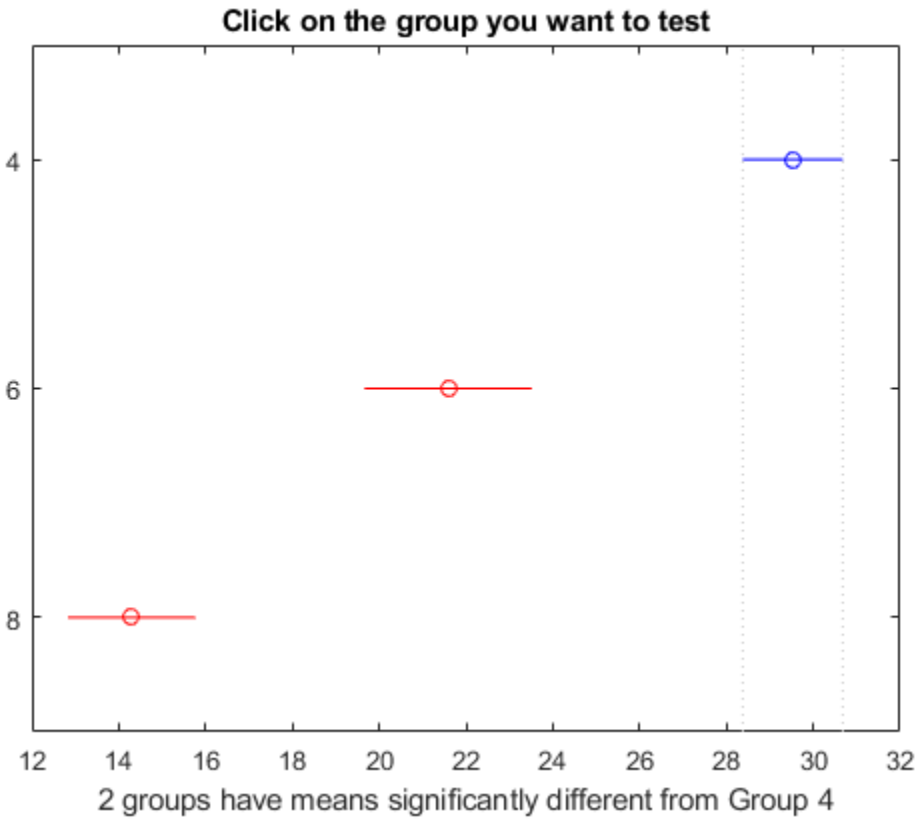
```
[p,~,stats] = anova1(MPG,Cylinders,'off');
p
```

```
p = 4.4902e-24
```

The small *p*-value of about 0 is a strong indication that mean miles per gallon is significantly different across cars with different numbers of cylinders.

Perform a multiple comparison test, using the Bonferroni method, to determine which numbers of cylinders make a difference in the performance of the cars.

```
[results,means] = multcompare(stats,'CType','bonferroni')
```



```
results = 3×6

    1.0000    2.0000    4.8605    7.9418   11.0230    0.0000
    1.0000    3.0000   12.6127   15.2337   17.8548    0.0000
    2.0000    3.0000    3.8940    7.2919   10.6899    0.0000
```

```
means = 3×2

   29.5300    0.6363
   21.5882    1.0913
   14.2963    0.8660
```

In the `results` matrix, 1, 2, and 3 correspond to cars with 4, 6, and 8 cylinders, respectively. The first two columns show which groups are compared. For example, the first row compares the cars with 4 and 6 cylinders. The fourth column shows the mean mpg difference for the compared groups. The third and fifth columns show the lower and upper limits for a 95% confidence interval for the difference in the group means. The last column shows the *p*-values for the tests. All *p*-values are zero, which indicates that the mean mpg for all groups differ across all groups.

In the figure the blue bar represents the group of cars with 4 cylinders. The red bars represent the other groups. None of the red comparison intervals for the mean mpg of cars overlap, which means that the mean mpg is significantly different for cars having 4, 6, or 8 cylinders.

The first column of the `means` matrix has the mean mpg estimates for each group of cars. The second column contains the standard errors of the estimates.

Multiple Comparisons for Three-Way ANOVA

Load the sample data.

```
y = [52.7 57.5 45.9 44.5 53.0 57.0 45.9 44.0]';
g1 = [1 2 1 2 1 2 1 2];
g2 = {'hi';'hi';'lo';'lo';'hi';'hi';'lo';'lo'};
g3 = {'may';'may';'may';'may';'june';'june';'june';'june'};
```

`y` is the response vector and `g1`, `g2`, and `g3` are the grouping variables (factors). Each factor has two levels, and every observation in `y` is identified by a combination of factor levels. For example, observation `y(1)` is associated with level 1 of factor `g1`, level `'hi'` of factor `g2`, and level `'may'` of factor `g3`. Similarly, observation `y(6)` is associated with level 2 of factor `g1`, level `'hi'` of factor `g2`, and level `'june'` of factor `g3`.

Test if the response is the same for all factor levels. Also compute the statistics required for multiple comparison tests.

```
[~,~,stats] = anovan(y,{g1 g2 g3},'model','interaction',...
    'varnames',{'g1','g2','g3'});
```

Analysis of Variance

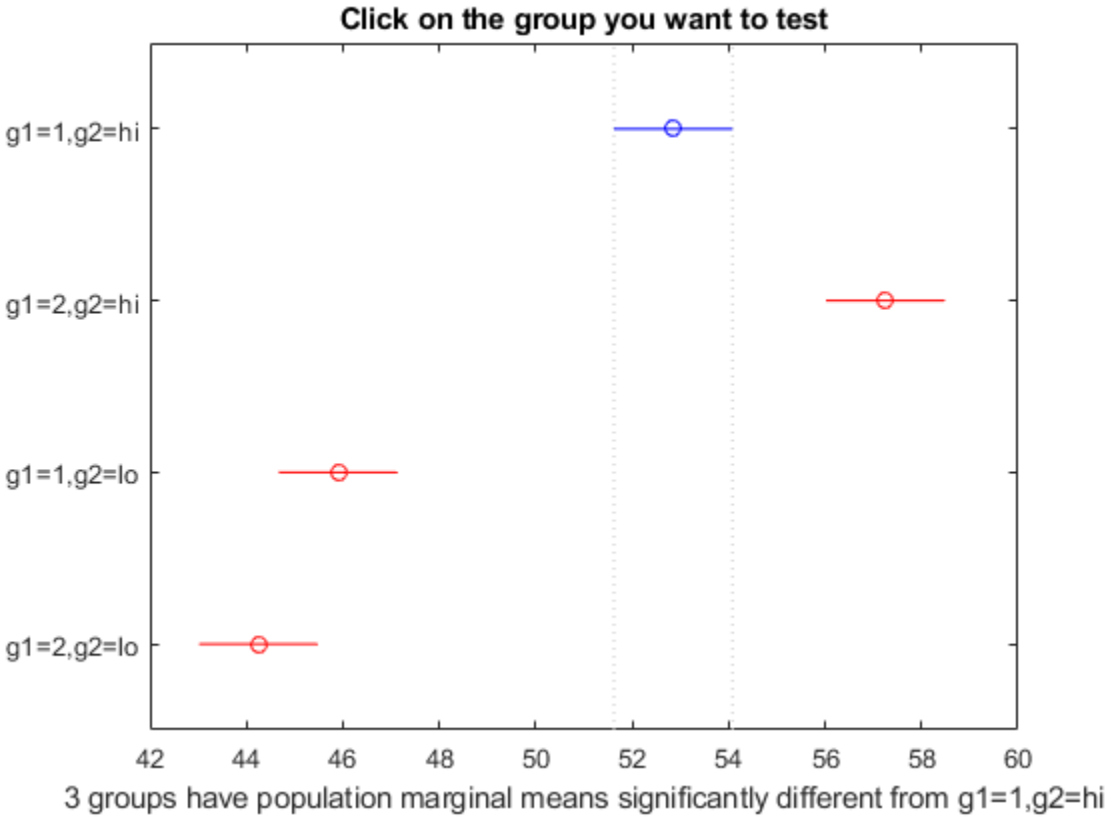
Source	Sum Sq.	d.f.	Mean Sq.	F	Prob>F
g1	3.781	1	3.781	336.11	0.0347
g2	199.001	1	199.001	17689	0.0048
g3	0.061	1	0.061	5.44	0.2578
g1*g2	18.301	1	18.301	1626.78	0.0158
g1*g3	0.211	1	0.211	18.78	0.1444
g2*g3	0.011	1	0.011	1	0.5
Error	0.011	1	0.011		
Total	221.379	7			

Constrained (Type III) sums of squares.

The *p*-value of 0.2578 indicates that the mean responses for levels `'may'` and `'june'` of factor `g3` are not significantly different. The *p*-value of 0.0347 indicates that the mean responses for levels `1` and `2` of factor `g1` are significantly different. Similarly, the *p*-value of 0.0048 indicates that the mean responses for levels `'hi'` and `'lo'` of factor `g2` are significantly different.

Perform multiple comparison tests to find out which groups of the factors `g1` and `g2` are significantly different.

```
results = multcompare(stats,'Dimension',[1 2])
```



```
results = 6×6

    1.0000    2.0000   -6.8604   -4.4000   -1.9396    0.0272
    1.0000    3.0000    4.4896    6.9500    9.4104    0.0170
    1.0000    4.0000    6.1396    8.6000   11.0604    0.0136
    2.0000    3.0000    8.8896   11.3500   13.8104    0.0101
    2.0000    4.0000   10.5396   13.0000   15.4604    0.0087
    3.0000    4.0000   -0.8104    1.6500    4.1104    0.0737
```

`multcompare` compares the combinations of groups (levels) of the two grouping variables, `g1` and `g2`. In the `results` matrix, the number 1 corresponds to the combination of level `1` of `g1` and level `hi` of `g2`, the number 2 corresponds to the combination of level `2` of `g1` and level `hi` of `g2`. Similarly, the number 3 corresponds to the combination of level `1` of `g1` and level `lo` of `g2`, and the number 4 corresponds to the combination of level `2` of `g1` and level `lo` of `g2`. The last column of the matrix contains the *p*-values.

For example, the first row of the matrix shows that the combination of level `1` of `g1` and level `hi` of `g2` has the same mean response values as the combination of level `2` of `g1` and level `hi` of `g2`. The *p*-value corresponding to this test is 0.0280, which indicates that the mean responses are significantly different. You can also see this result in the figure. The blue bar shows the comparison interval for the mean response for the combination of level `1` of `g1` and level `hi` of `g2`. The red bars are the comparison intervals for the mean response for other group combinations. None of the red bars overlap with the blue bar, which means the mean response for the combination of level `1` of `g1` and level `hi` of `g2` is significantly different from the mean response for other group combinations.

You can test the other groups by clicking on the corresponding comparison interval for the group. The bar you click on turns to blue. The bars for the groups that are significantly different are red. The bars for the groups that are not significantly different are gray. For example, if you click on the comparison interval for the combination of level `1` of `g1` and level `lo` of `g2`, the comparison interval for the combination of level `2` of `g1` and level `lo` of `g2` overlaps, and is therefore gray. Conversely, the other comparison intervals are red, indicating significant difference.

Multiple Comparison Procedures

To specify the multiple comparison procedure you want `multcompare` to conduct use the `'CType'` name-value pair argument. `multcompare` provides the following procedures:

- “Tukey’s Honestly Significant Difference Procedure” on page 9-22
- “Bonferroni Method” on page 9-23
- “Dunn & Sidák’s Approach” on page 9-23
- “Least Significant Difference” on page 9-23
- “Scheffe’s Procedure” on page 9-24

Tukey’s Honestly Significant Difference Procedure

You can specify Tukey’s honestly significant difference procedure using the `'CType','Tukey-Kramer'` or `'CType','hsd'` name-value pair argument. The test is based on studentized range distribution. Reject $H_0{:}\alpha_i = \alpha_j$ if

$$|t| = \frac{\left|\bar{y}_i - \bar{y}_j\right|}{\sqrt{MSE\left(\frac{1}{n_i} + \frac{1}{n_j}\right)}} > \frac{1}{\sqrt{2}} q_{\alpha, k, N-k,}$$

where $q_{\alpha, k, N-k}$ is the upper 100*(1 – α)th percentile of the studentized range distribution with parameter k and N – k degrees of freedom. k is the number of groups (treatments or marginal means) and N is the total number of observations.

Tukey's honestly significant difference procedure is optimal for balanced one-way ANOVA and similar procedures with equal sample sizes. It has been proven to be conservative for one-way ANOVA with different sample sizes. According to the unproven Tukey-Kramer conjecture, it is also accurate for problems where the quantities being compared are correlated, as in analysis of covariance with unbalanced covariate values.

Bonferroni Method

You can specify the Bonferroni method using the `'CType','bonferroni'` name-value pair. This method uses critical values from Student's t-distribution after an adjustment to compensate for multiple comparisons. The test rejects H_0:$\alpha_i = \alpha_j$ at the $\alpha/2\binom{k}{2}$ significance level, where k is the number of groups if

$$|t| = \frac{|\bar{y}_i - \bar{y}_j|}{\sqrt{MSE\left(\frac{1}{n_i} + \frac{1}{n_j}\right)}} > t_{\alpha/2\binom{k}{2}, N-k,}$$

where N is the total number of observations and k is the number of groups (marginal means). This procedure is conservative, but usually less so than the Scheffé procedure.

Dunn & Sidák's Approach

You can specify Dunn & Sidák's approach using the `'CType','dunn-sidak'` name-value pair argument. It uses critical values from the t-distribution, after an adjustment for multiple comparisons that was proposed by Dunn and proved accurate by Sidák. This test rejects H_0:$\alpha_i = \alpha_j$ if

$$|t| = \frac{|\bar{y}_i - \bar{y}_j|}{\sqrt{MSE\left(\frac{1}{n_i} + \frac{1}{n_j}\right)}} > t_{1-\eta/2, \nu,}$$

where

$$\eta = 1 - (1-\alpha)^{1/\binom{k}{2}}$$

and k is the number of groups. This procedure is similar to, but less conservative than, the Bonferroni procedure.

Least Significant Difference

You can specify the least significance difference procedure using the `'CType','lsd'` name-value pair argument. This test uses the test statistic

$$t = \frac{\bar{y}_i - \bar{y}_j}{\sqrt{MSE\left(\frac{1}{n_i} + \frac{1}{n_j}\right)}}.$$

It rejects H_0:$\alpha_i = \alpha_j$ if

$$|\bar{y}_i - \bar{y}_j| > t_{\alpha/2, N-k} \sqrt{MSE\left(\frac{1}{n_i} + \frac{1}{n_j}\right)}.$$
$$\text{LSD}$$

Fisher suggests a protection against multiple comparisons by performing LSD only when the null hypothesis H_0: $\alpha_1 = \alpha_2 = \ldots = \alpha_k$ is rejected by ANOVA *F*-test. Even in this case, LSD might not reject any of the individual hypotheses. It is also possible that ANOVA does not reject H_0, even when there are differences between some group means. This behavior occurs because the equality of the remaining group means can cause the *F*-test statistic to be nonsignificant. Without any condition, LSD does not provide any protection against the multiple comparison problem.

Scheffe's Procedure

You can specify Scheffe's procedure using the `'CType','scheffe'` name-value pair argument. The critical values are derived from the *F* distribution. The test rejects H_0:$\alpha_i = \alpha_j$ if

$$\frac{|\bar{y}_i - \bar{y}_j|}{\sqrt{MSE\left(\frac{1}{n_i} + \frac{1}{n_j}\right)}} > \sqrt{(k-1)F_{k-1, N-k, \alpha}}$$

This procedure provides a simultaneous confidence level for comparisons of all linear combinations of the means. It is conservative for comparisons of simple differences of pairs.

N-Way ANOVA

In this section...

Introduction to N-Way ANOVA

You can use the function `anovan` to perform *N*-way ANOVA. Use *N*-way ANOVA to determine if the means in a set of data differ with respect to groups (levels) of multiple factors. By default, `anovan` treats all grouping variables as fixed effects. For an example of ANOVA with random effects, see “ANOVA with Random Effects” on page 9-33. For repeated measures, see `fitrm` and `ranova`.

N-way ANOVA is a generalization of two-way ANOVA. For three factors, for example, the model can be written as

$$y_{ijkr} = \mu + \alpha_i + \beta_j + \gamma_k + (\alpha\beta)_{ij} + (\alpha\gamma)_{ik} + (\beta\gamma)_{jk} + (\alpha\beta\gamma)_{ijk} + \varepsilon_{ijkr},$$

where

- y_{ijkr} is an observation of the response variable. i represents group i of factor A, $i = 1, 2, \ldots, I$, j represents group j of factor B, $j = 1, 2, \ldots, J$, k represents group k of factor C, and r represents the replication number, $r = 1, 2, \ldots, R$. For constant R, there are a total of $N = I*J*K*R$ observations, but the number of observations does not have to be the same for each combination of groups of factors.
- μ is the overall mean.
- α_i are the deviations of groups of factor A from the overall mean μ due to factor A. The values of α_i sum to 0.

  $$\sum_{i=1}^{I} \alpha_i = 0.$$
- β_j are the deviations of groups in factor B from the overall mean μ due to factor B. The values of β_j sum to 0.

  $$\sum_{j=1}^{J} \beta_j = 0.$$
- γ_k are the deviations of groups in factor C from the overall mean μ due to factor C. The values of γ_k sum to 0.

  $$\sum_{k=1}^{K} \gamma_k = 0.$$
- $(\alpha\beta)_{ij}$ is the interaction term between factors A and B. $(\alpha\beta)_{ij}$ sum to 0 over either index.

  $$\sum_{i=1}^{I} (\alpha\beta)_{ij} = \sum_{j=1}^{J} (\alpha\beta)_{ij} = 0.$$
- $(\alpha\gamma)_{ik}$ is the interaction term between factors A and C. The values of $(\alpha\gamma)_{ik}$ sum to 0 over either index.

  $$\sum_{i=1}^{I} (\alpha\gamma)_{ik} = \sum_{k=1}^{K} (\alpha\gamma)_{ik} = 0.$$

- $(\beta\gamma)_{jk}$ is the interaction term between factors B and C. The values of $(\beta\gamma)_{jk}$ sum to 0 over either index.

  $$\sum_{j=1}^{J}(\beta\gamma)_{jk} = \sum_{k=1}^{K}(\beta\gamma)_{jk} = 0.$$

- $(\alpha\beta\gamma)_{ijk}$ is the three-way interaction term between factors A, B, and C. The values of $(\alpha\beta\gamma)_{ijk}$ sum to 0 over any index.

  $$\sum_{i=1}^{I}(\alpha\beta\gamma)_{ijk} = \sum_{j=1}^{J}(\alpha\beta\gamma)_{ijk} = \sum_{k=1}^{K}(\alpha\beta\gamma)_{ijk} = 0.$$

- ε_{ijkr} are the random disturbances. They are assumed to be independent, normally distributed, and have constant variance.

Three-way ANOVA tests hypotheses about the effects of factors A, B, C, and their interactions on the response variable y. The hypotheses about the equality of the mean responses for groups of factor A are

$$H_0: \alpha_1 = \alpha_2 \cdots = \alpha_I$$
$$H_1: \text{ at least one } \alpha_i \text{ is different, } i = 1, 2, \ldots, I.$$

The hypotheses about the equality of the mean response for groups of factor B are

$$H_0: \beta_1 = \beta_2 = \cdots = \beta_J$$
$$H_1: \text{ at least one } \beta_j \text{ is different, } j = 1, 2, \ldots, J.$$

The hypotheses about the equality of the mean response for groups of factor C are

$$H_0: \gamma_1 = \gamma_2 = \cdots = \gamma_K$$
$$H_1: \text{ at least one } \gamma_k \text{ is different, } k = 1, 2, \ldots, K.$$

The hypotheses about the interaction of the factors are

$$H_0: (\alpha\beta)_{ij} = 0$$
$$H_1: \text{at least one } (\alpha\beta)_{ij} \neq 0$$

$$H_0: (\alpha\gamma)_{ik} = 0$$
$$H_1: \text{at least one } (\alpha\gamma)_{ik} \neq 0$$

$$H_0: (\beta\gamma)_{jk} = 0$$
$$H_1: \text{at least one } (\beta\gamma)_{jk} \neq 0$$

$$H_0: (\alpha\beta\gamma)_{ijk} = 0$$
$$H_1: \text{at least one } (\alpha\beta\gamma)_{ijk} \neq 0$$

In this notation parameters with two subscripts, such as $(\alpha\beta)_{ij}$, represent the interaction effect of two factors. The parameter $(\alpha\beta\gamma)_{ijk}$ represents the three-way interaction. An ANOVA model can have the full set of parameters or any subset, but conventionally it does not include complex interaction terms unless it also includes all simpler terms for those factors. For example, one would generally not include the three-way interaction without also including all two-way interactions.

Prepare Data for N-Way ANOVA

Unlike `anova1` and `anova2`, `anovan` does not expect data in a tabular form. Instead, it expects a vector of response measurements and a separate vector (or text array) containing the values corresponding to each factor. This input data format is more convenient than matrices when there are more than two factors or when the number of measurements per factor combination is not constant.

$$
\begin{array}{rcccccccccc}
y & = & [& y_1, & y_2, & y_3, & y_4, & y_5, & \cdots, & y_N &]' \\
 & & & \uparrow & \uparrow & \uparrow & \uparrow & \uparrow & & \uparrow & \\
g1 & = & \{ & 'A', & 'A', & 'C', & 'B', & 'B', & \cdots, & 'D' & \} \\
g2 & = & [& 1 & 2 & 1 & 3 & 1 & \cdots, & 2 &] \\
g3 & = & \{ & \text{'hi'}, & \text{'mid'}, & \text{'low'}, & \text{'mid'}, & \text{'hi'}, & \cdots, & \text{'low'} & \}
\end{array}
$$

Perform N-Way ANOVA

This example shows how to perform N-way ANOVA on car data with mileage and other information on 406 cars made between 1970 and 1982.

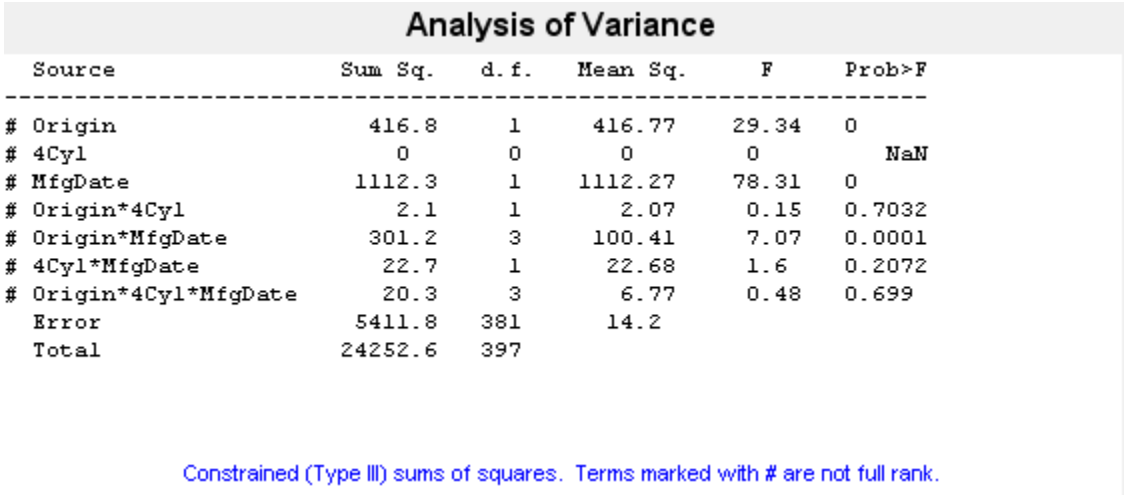
Load the sample data.

```
load carbig
```

The example focusses on four variables. `MPG` is the number of miles per gallon for each of 406 cars (though some have missing values coded as `NaN`). The other three variables are factors: `cyl4` (four-cylinder car or not), `org` (car originated in Europe, Japan, or the USA), and `when` (car was built early in the period, in the middle of the period, or late in the period).

Fit the full model, requesting up to three-way interactions and Type 3 sums-of-squares.

```
varnames = {'Origin';'4Cyl';'MfgDate'};
anovan(MPG,{org cyl4 when},3,3,varnames)
```



```
ans = 7×1

    0.0000
       NaN
```

```
    0.0000
    0.7032
    0.0001
    0.2072
    0.6990
```

Note that many terms are marked by a # symbol as not having full rank, and one of them has zero degrees of freedom and is missing a *p*-value. This can happen when there are missing factor combinations and the model has higher-order terms. In this case, the cross-tabulation below shows that there are no cars made in Europe during the early part of the period with other than four cylinders, as indicated by the 0 in `tbl(2,1,1)`.

```
[tbl,chi2,p,factorvals] = crosstab(org,when,cyl4)
```

```
tbl =
tbl(:,:,1) =

    82    75    25
     0     4     3
     3     3     4

tbl(:,:,2) =

    12    22    38
    23    26    17
    12    25    32

chi2 = 207.7689

p = 8.0973e-38

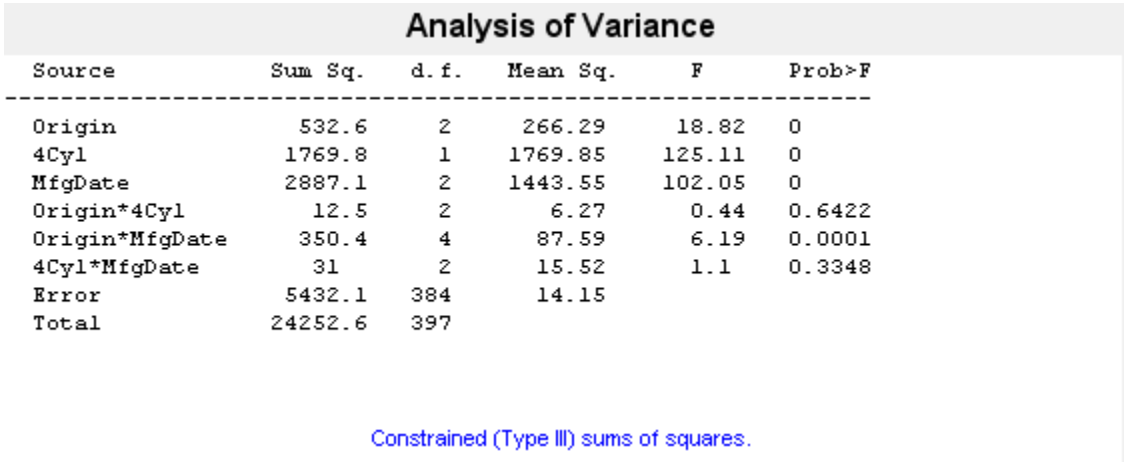
factorvals=3×3 cell array
    {'USA'   }    {'Early'}    {'Other'   }
    {'Europe'}    {'Mid'  }    {'Four'    }
    {'Japan' }    {'Late' }    {0x0 double}
```

Consequently it is impossible to estimate the three-way interaction effects, and including the three-way interaction term in the model makes the fit singular.

Using even the limited information available in the ANOVA table, you can see that the three-way interaction has a *p*-value of 0.699, so it is not significant.

Examine only two-way interactions.

```
[p,tbl2,stats,terms] = anovan(MPG,{org cyl4 when},2,3,varnames);
```



```
terms
```

```
terms = 6×3

     1     0     0
     0     1     0
     0     0     1
     1     1     0
     1     0     1
     0     1     1
```

Now all terms are estimable. The *p*-values for interaction term 4 (`Origin*4Cyl`) and interaction term 6 (`4Cyl*MfgDate`) are much larger than a typical cutoff value of 0.05, indicating these terms are not significant. You could choose to omit these terms and pool their effects into the error term. The output `terms` variable returns a matrix of codes, each of which is a bit pattern representing a term.

Omit terms from the model by deleting their entries from `terms`.

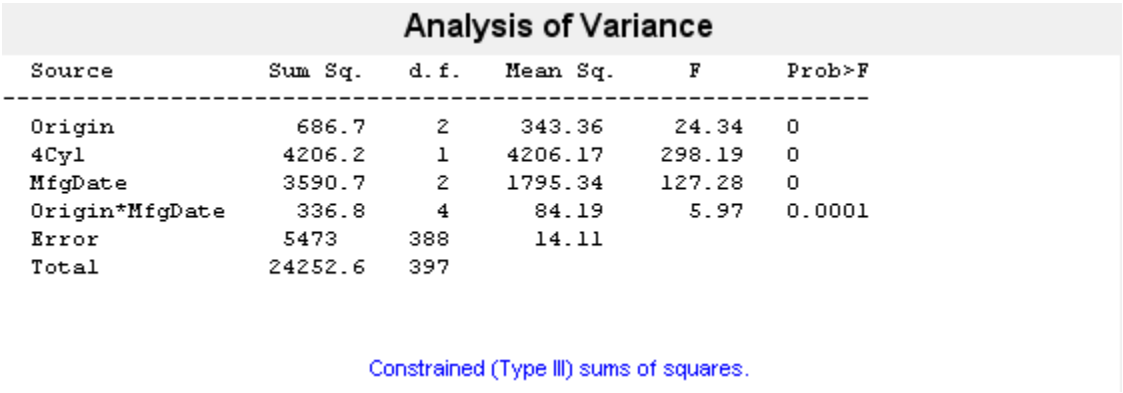
```
terms([4 6],:) = []
```

```
terms = 4×3

     1     0     0
     0     1     0
     0     0     1
     1     0     1
```

Run `anovan` again, this time supplying the resulting vector as the model argument. Also return the statistics required for multiple comparisons of factors.

```
[~,~,stats] = anovan(MPG,{org cyl4 when},terms,3,varnames)
```

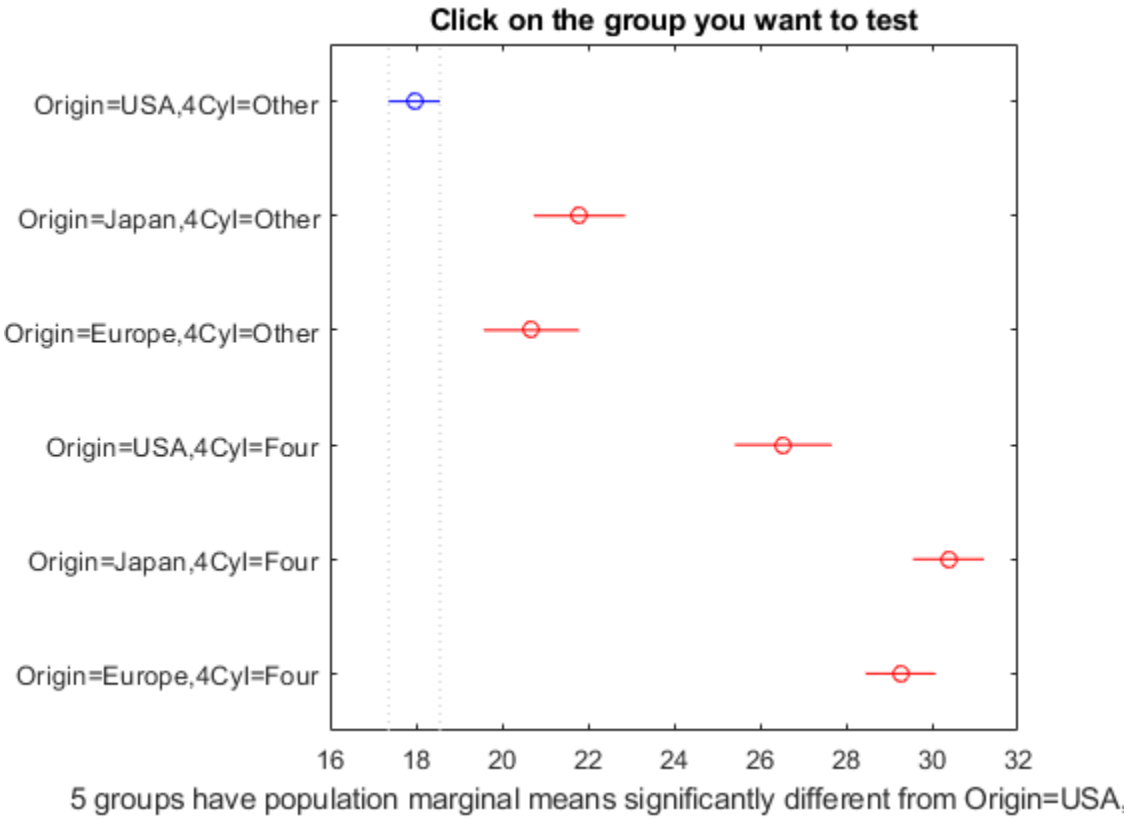


```
stats = struct with fields:
          source: 'anovan'
           resid: [1x406 double]
          coeffs: [18x1 double]
             Rtr: [10x10 double]
        rowbasis: [10x18 double]
             dfe: 388
             mse: 14.1056
     nullproject: [18x10 double]
           terms: [4x3 double]
         nlevels: [3x1 double]
      continuous: [0 0 0]
           vmeans: [3x1 double]
         termcols: [5x1 double]
      coeffnames: {18x1 cell}
            vars: [18x3 double]
        varnames: {3x1 cell}
        grpnames: {3x1 cell}
         vnested: []
             ems: []
           denom: []
         dfdenom: []
         msdenom: []
          varest: []
           varci: []
         txtdenom: []
           txtems: []
          rtnames: []
```

Now you have a more parsimonious model indicating that the mileage of these cars seems to be related to all three factors, and that the effect of the manufacturing date depends on where the car was made.

Perform multiple comparisons for Origin and Cylinder.

```
results = multcompare(stats,'Dimension',[1,2])
```



```
results = 15×6

    1.0000    2.0000   -5.4891   -3.8412   -2.1932    0.0000
    1.0000    3.0000   -4.4146   -2.7251   -1.0356    0.0001
    1.0000    4.0000   -9.9992   -8.5828   -7.1664         0

ANOVA with Random Effects

This example shows how to use `anovan` to fit models where a factor's levels represent a random selection from a larger (infinite) set of possible levels.

In an ordinary ANOVA model, each grouping variable represents a fixed factor. The levels of that factor are a fixed set of values. The goal is to determine whether different factor levels lead to different response values.

Set Up the Model

Load the sample data.

```
load mileage
```

The `anova2` function works only with balanced data, and it infers the values of the grouping variables from the row and column numbers of the input matrix. The `anovan` function, on the other hand, requires you to explicitly create vectors of grouping variable values. Create these vectors in the following way.

Create an array indicating the factory for each value in mileage. This array is 1 for the first column, 2 for the second, and 3 for the third.

```
factory  = repmat(1:3,6,1);
```

Create an array indicating the car model for each mileage value. This array is 1 for the first three rows of mileage, and 2 for the remaining three rows.

```
carmod = [ones(3,3); 2*ones(3,3)];
```

Turn these matrices into vectors and display them.

```
mileage = mileage(:);
factory = factory(:);
carmod = carmod(:);
[mileage factory carmod]
```

```
ans = 18×3

   33.3000    1.0000    1.0000
   33.4000    1.0000    1.0000
   32.9000    1.0000    1.0000
   32.6000    1.0000    2.0000
   32.5000    1.0000    2.0000
   33.0000    1.0000    2.0000
   34.5000    2.0000    1.0000
   34.8000    2.0000    1.0000
   33.8000    2.0000    1.0000
   33.4000    2.0000    2.0000
      ⋮
```

Fit a Random Effects Model

Suppose you are studying a few factories but you want information about what would happen if you build these same car models in a different factory, either one that you already have or another that

you might construct. To get this information, fit the analysis of variance model, specifying a model that includes an interaction term and that the factory factor is random.

```
[pvals,tbl,stats] = anovan(mileage, {factory carmod}, ...
'model',2, 'random',1,'varnames',{'Factory' 'Car Model'});
```

Analysis of Variance

Source	Sum Sq.	d.f.	Mean Sq.	F	Prob>F
Factory	53.3511	2	26.6756	1333.78	0.0007
Car Model	1.445	1	1.445	72.25	0.0136
Factory*Car Model	0.04	2	0.02	0.18	0.8411
Error	1.3667	12	0.1139		
Total	56.2028	17			

Constrained (Type III) sums of squares.

In the fixed effects version of this fit, which you get by omitting the inputs `'random',1` in the preceding code, the effect of car model is significant, with a *p*-value of 0.0039. But in this example, which takes into account the random variation of the effect of the variable `'Car Model'` from one factory to another, the effect is still significant, but with a higher *p*-value of 0.0136.

F-Statistics for Models with Random Effects

The *F*-statistic in a model having random effects is defined differently than in a model having all fixed effects. In the fixed effects model, you compute the *F*-statistic for any term by taking the ratio of the mean square for that term with the mean square for error. In a random effects model, however, some *F*-statistics use a different mean square in the denominator.

In the example described in **Set Up the Model**, the effect of the variable `'Factory'` could vary across car models. In this case, the interaction mean square takes the place of the error mean square in the *F*-statistic.

Find the *F*-statistic.

```
F = 26.6756 / 0.02
```

```
F = 1.3338e+03
```

The degrees of freedom for the statistic are the degrees of freedom for the numerator (2) and denominator (2) mean squares.

Find the *p*-value.

```
pval = 1 - fcdf(F,2,2)
```

```
pval = 7.4919e-04
```

With random effects, the expected value of each mean square depends not only on the variance of the error term, but also on the variances contributed by the random effects. You can see these dependencies by writing the expected values as linear combinations of contributions from the various model terms.

Find the coefficients of these linear combinations.

```
stats.ems

ans = 4×4

    6.0000    0.0000    3.0000    1.0000
    0.0000    9.0000    3.0000    1.0000
    0.0000    0.0000    3.0000    1.0000
         0         0         0    1.0000
```

This returns the `ems` field of the `stats` structure.

Display text representations of the linear combinations.

```
stats.txtems

ans = 4x1 cell
    {'6*V(Factory)+3*V(Factory*Car Model)+V(Error)'  }
    {'9*Q(Car Model)+3*V(Factory*Car Model)+V(Error)'}
    {'3*V(Factory*Car Model)+V(Error)'               }
    {'V(Error)'                                      }
```

The expected value for the mean square due to car model (second term) includes contributions from a quadratic function of the car model effects, plus three times the variance of the interaction term's effect, plus the variance of the error term. Notice that if the car model effects were all zero, the expression would reduce to the expected mean square for the third term (the interaction term). That is why the *F*-statistic for the car model effect uses the interaction mean square in the denominator.

In some cases there is no single term whose expected value matches the one required for the denominator of the *F*-statistic. In that case, the denominator is a linear combination of mean squares. The stats structure contains fields giving the definitions of the denominators for each *F*-statistic. The `txtdenom` field, `stats.txtdenom`, contains a text representation, and the `denom` field contains a matrix that defines a linear combination of the variances of terms in the model. For balanced models like this one, the `denom` matrix, `stats.denom`, contains zeros and ones, because the denominator is just a single term's mean square.

Display the `txtdenom` field.

```
stats.txtdenom

ans = 3x1 cell
    {'MS(Factory*Car Model)'}
    {'MS(Factory*Car Model)'}
    {'MS(Error)'            }
```

Display the `denom` field.

```
stats.denom

ans = 3×3

    0.0000    1.0000         0
    0.0000    1.0000   -0.0000
   -0.0000    0.0000    1.0000
```

Variance Components

For the model described in **Set Up the Model**, consider the mileage for a particular car of a particular model made at a random factory. The variance of that car is the sum of components, or contributions, one from each of the random terms.

Display the names of the random terms.

```
stats.rtnames
```

```
ans = 3x1 cell
    {'Factory'          }
    {'Factory*Car Model'}
    {'Error'            }
```

You do not know the variances, but you can estimate them from the data. Recall that the `ems` field of the `stats` structure expresses the expected value of each term's mean square as a linear combination of unknown variances for random terms, and unknown quadratic forms for fixed terms. If you take the expected mean square expressions for the random terms, and equate those expected values to the computed mean squares, you get a system of equations that you can solve for the unknown variances. These solutions are the variance component estimates.

Display the variance component estimate for each term.

```
stats.varest
```

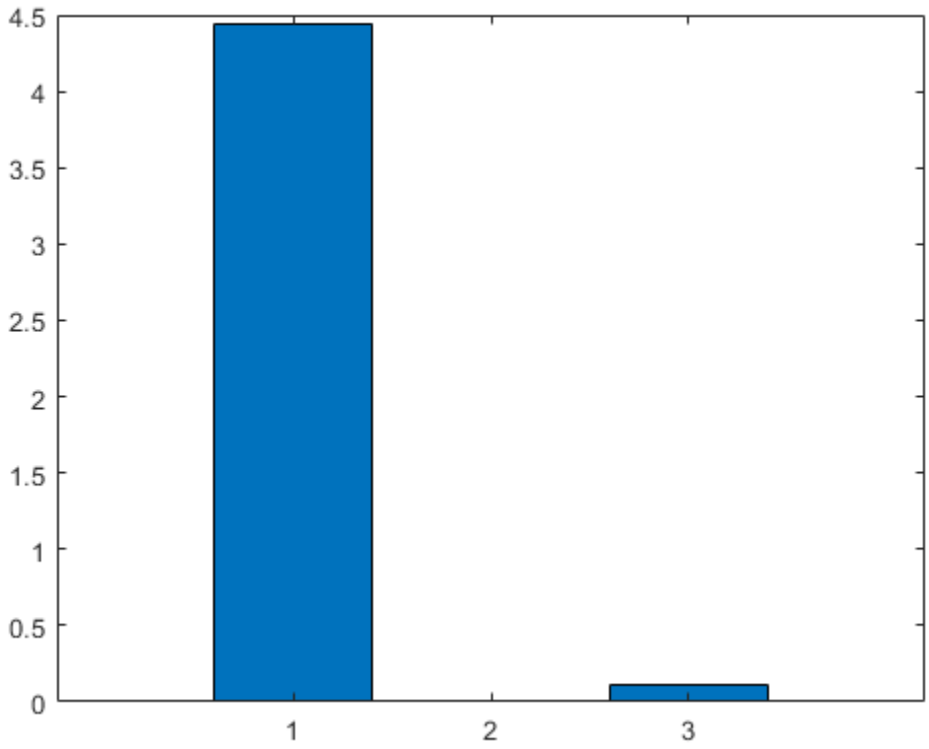
```
ans = 3×1

    4.4426
   -0.0313
    0.1139
```

Under some conditions, the variability attributed to a term is unusually low, and that term's variance component estimate is negative. In those cases it is common to set the estimate to zero, which you might do, for example, to create a bar graph of the components.

Create a bar graph of the components.

```
bar(max(0,stats.varest))
```



```
gca.xtick = 1:3;
gca.xticklabel = stats.rtnames;
```

You can also compute confidence bounds for the variance estimate. The `anovan` function does this by computing confidence bounds for the variance expected mean squares, and finding lower and upper limits on each variance component containing all of these bounds. This procedure leads to a set of bounds that is conservative for balanced data. (That is, 95% confidence bounds will have a probability of at least 95% of containing the true variances if the number of observations for each combination of grouping variables is the same.) For unbalanced data, these are approximations that are not guaranteed to be conservative.

Display the variance estimates and the confidence limits for the variance estimates of each component.

```
[{'Term' 'Estimate' 'Lower' 'Upper'};
 stats.rtnames, num2cell([stats.varest stats.varci])]
```

```
ans=4×4 cell array
    {'Term'             }    {'Estimate'}    {'Lower' }    {'Upper'   }
    {'Factory'          }    {[  4.4426]}    {[1.0736]}    {[175.6038]}
    {'Factory*Car Model'}    {[ -0.0313]}    {[   NaN]}    {[     NaN]}
    {'Error'            }    {[  0.1139]}    {[0.0586]}    {[  0.3103]}
```

Other ANOVA Models

The `anovan` function also has arguments that enable you to specify two other types of model terms:

- `'nested'` argument specifies a matrix that indicates which factors are nested within other factors. A nested factor is one that takes different values within each level its nested factor.

  Suppose an automobile company has three factories, and each factory makes two car models. The gas mileage in the cars can vary from factory to factory and from model to model. These two factors, factory and model, explain the differences in mileage, that is, the response. One measure of interest is the difference in mileage due to the production methods between factories. Another measure of interest is the difference in the mileage of the models (irrespective of the factory) due to different design specifications. Suppose also that, each factory produces distinct car models for a total of six car models. Then, the car model is nested in factory.

Factory	Car Model
1	1
1	2
2	3
2	4
3	5
3	6

  It is also common with nested models to number the nested factor the same way in each nested factor.
- `'continuous'` argument specifies that some factors are to be treated as continuous variables. The remaining factors are categorical variables. Although the `anovan` function can fit models with multiple continuous and categorical predictors, the simplest model that combines one predictor of each type is known as an *analysis of covariance* model. “Analysis of Covariance” on page 9-39 describes a specialized tool for fitting this model.

Analysis of Covariance

In this section...

Introduction to Analysis of Covariance

Analysis of covariance is a technique for analyzing grouped data having a response (y, the variable to be predicted) and a predictor (x, the variable used to do the prediction). Using analysis of covariance, you can model y as a linear function of x, with the coefficients of the line possibly varying from group to group.

Analysis of Covariance Tool

The `aoctool` function opens an interactive graphical environment for fitting and prediction with analysis of covariance (ANOCOVA) models. It fits the following models for the ith group:

Same mean	$y = \alpha + \varepsilon$
Separate means	$y = (\alpha + \alpha_i) + \varepsilon$
Same line	$y = \alpha + \beta x + \varepsilon$
Parallel lines	$y = (\alpha + \alpha_i) + \beta x + \varepsilon$
Separate lines	$y = (\alpha + \alpha_i) + (\beta + \beta_i)x + \varepsilon$

For example, in the parallel lines model the intercept varies from one group to the next, but the slope is the same for each group. In the same mean model, there is a common intercept and no slope. In order to make the group coefficients well determined, the tool imposes the constraints

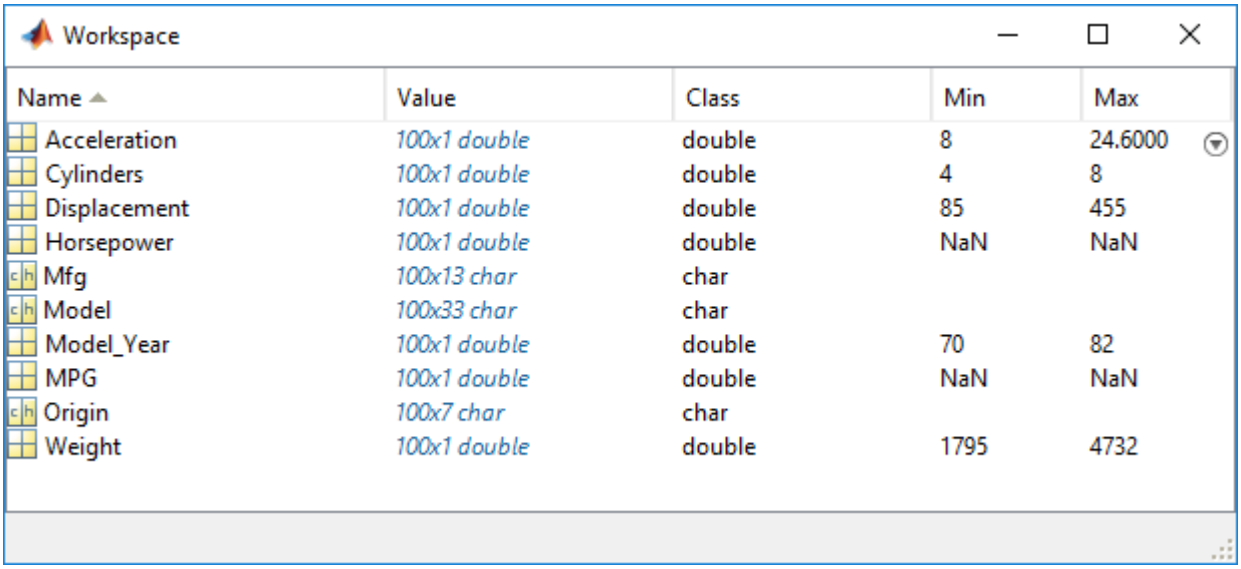
$$\sum \alpha_j = \sum \beta_j = 0$$

The following steps describe the use of `aoctool`.

1. **Load the data.** The Statistics and Machine Learning Toolbox data set `carsmall.mat` contains information on cars from the years 1970, 1976, and 1982. This example studies the relationship between the weight of a car and its mileage, and whether this relationship has changed over the years. To start the demonstration, load the data set.

   ```
   load carsmall
   ```

   The Workspace Browser shows the variables in the data set.



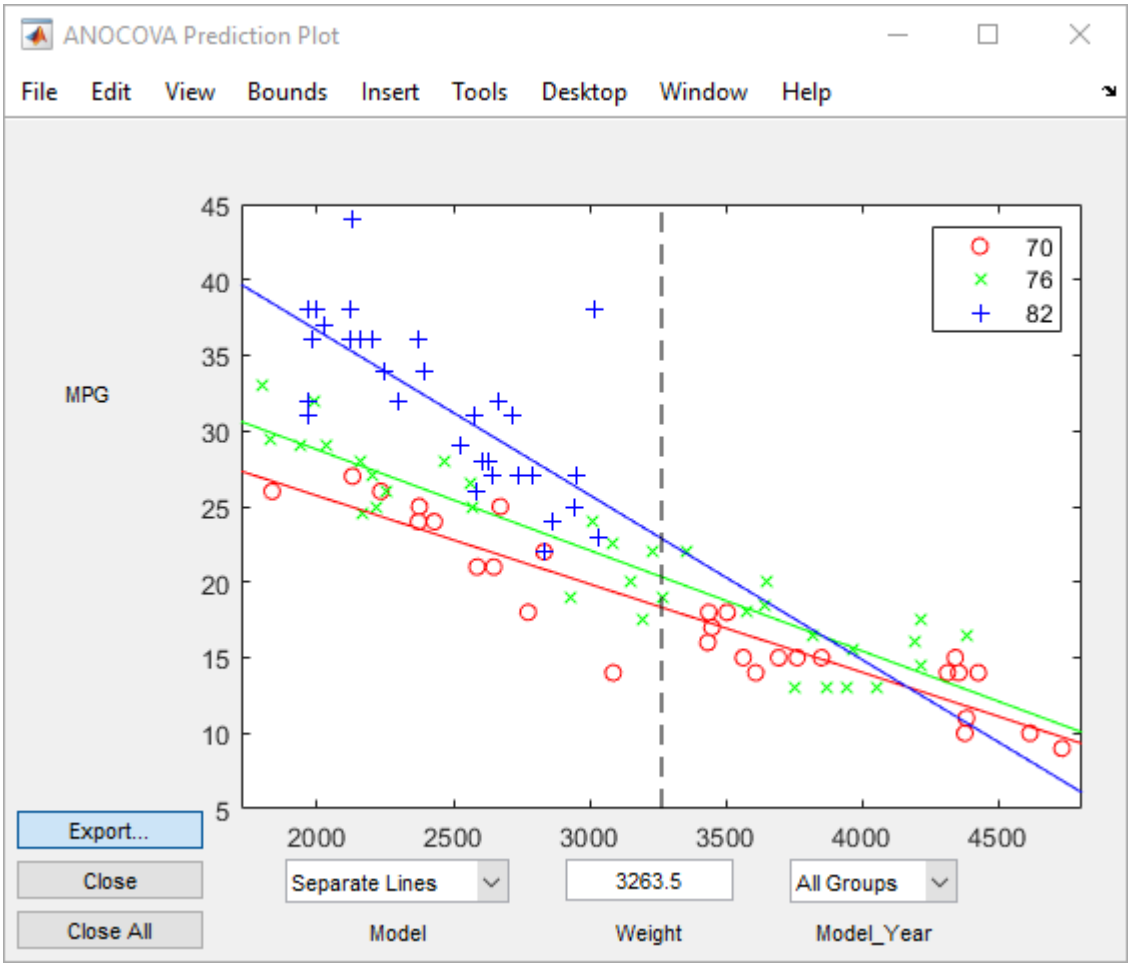
You can also use `aoctool` with your own data.

2 **Start the tool.** The following command calls `aoctool` to fit a separate line to the column vectors `Weight` and `MPG` for each of the three model group defined in `Model_Year`. The initial fit models the *y* variable, `MPG`, as a linear function of the *x* variable, `Weight`.

```
[h,atab,ctab,stats] = aoctool(Weight,MPG,Model_Year);
```

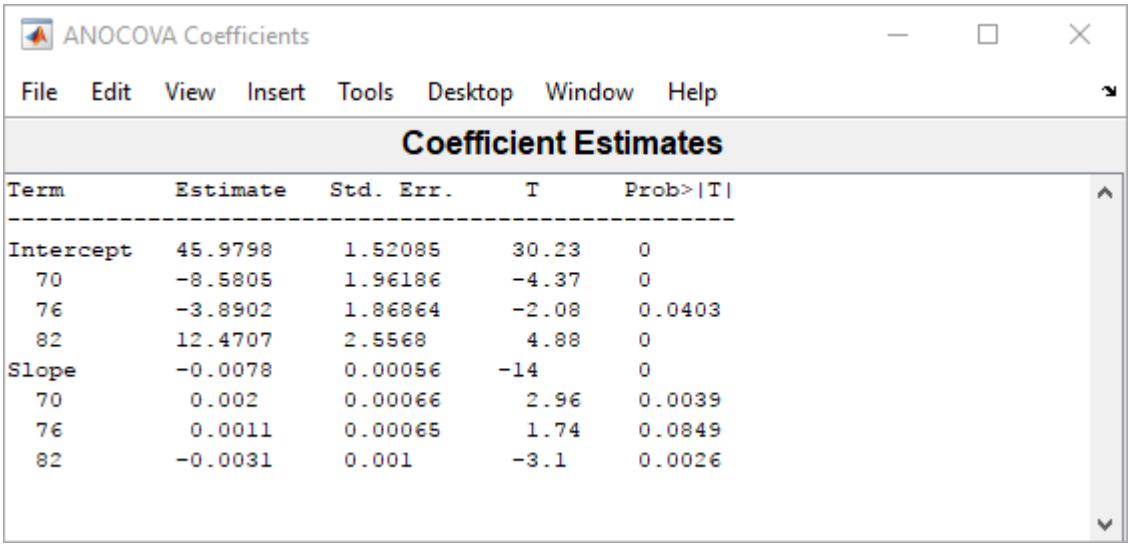
See the `aoctool` function reference page for detailed information about calling `aoctool`.

3 **Examine the output.** The graphical output consists of a main window with a plot, a table of coefficient estimates, and an analysis of variance table. In the plot, each `Model_Year` group has a separate line. The data points for each group are coded with the same color and symbol, and the fit for each group has the same color as the data points.



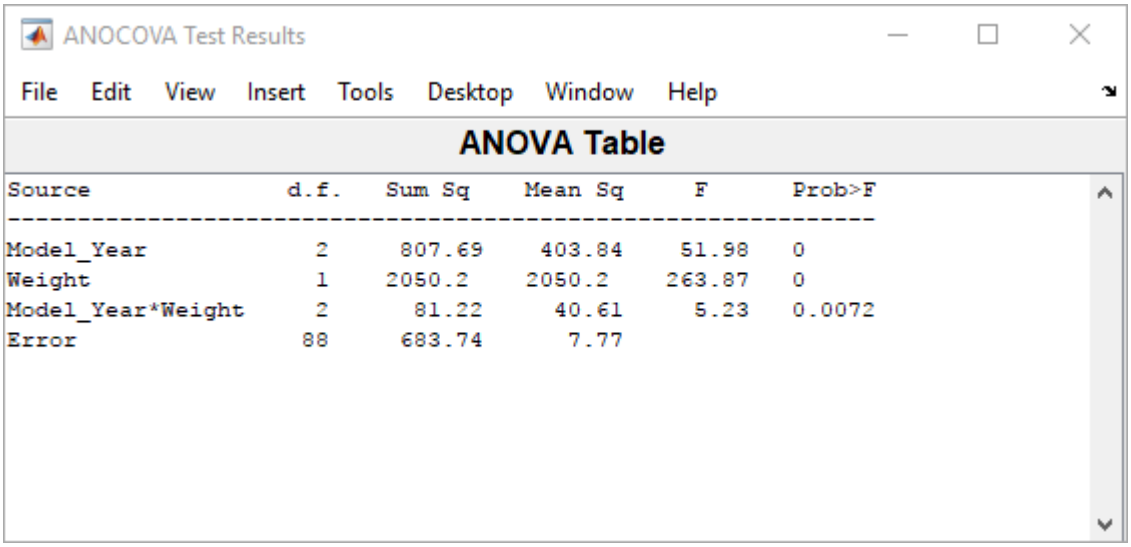
The coefficients of the three lines appear in the figure titled ANOCOVA Coefficients. You can see that the slopes are roughly –0.0078, with a small deviation for each group:

- Model year 1970: $y = (45.9798 - 8.5805) + (-0.0078 + 0.002)x + \varepsilon$
- Model year 1976: $y = (45.9798 - 3.8902) + (-0.0078 + 0.0011)x + \varepsilon$
- Model year 1982: $y = (45.9798 + 12.4707) + (-0.0078 - 0.0031)x + \varepsilon$



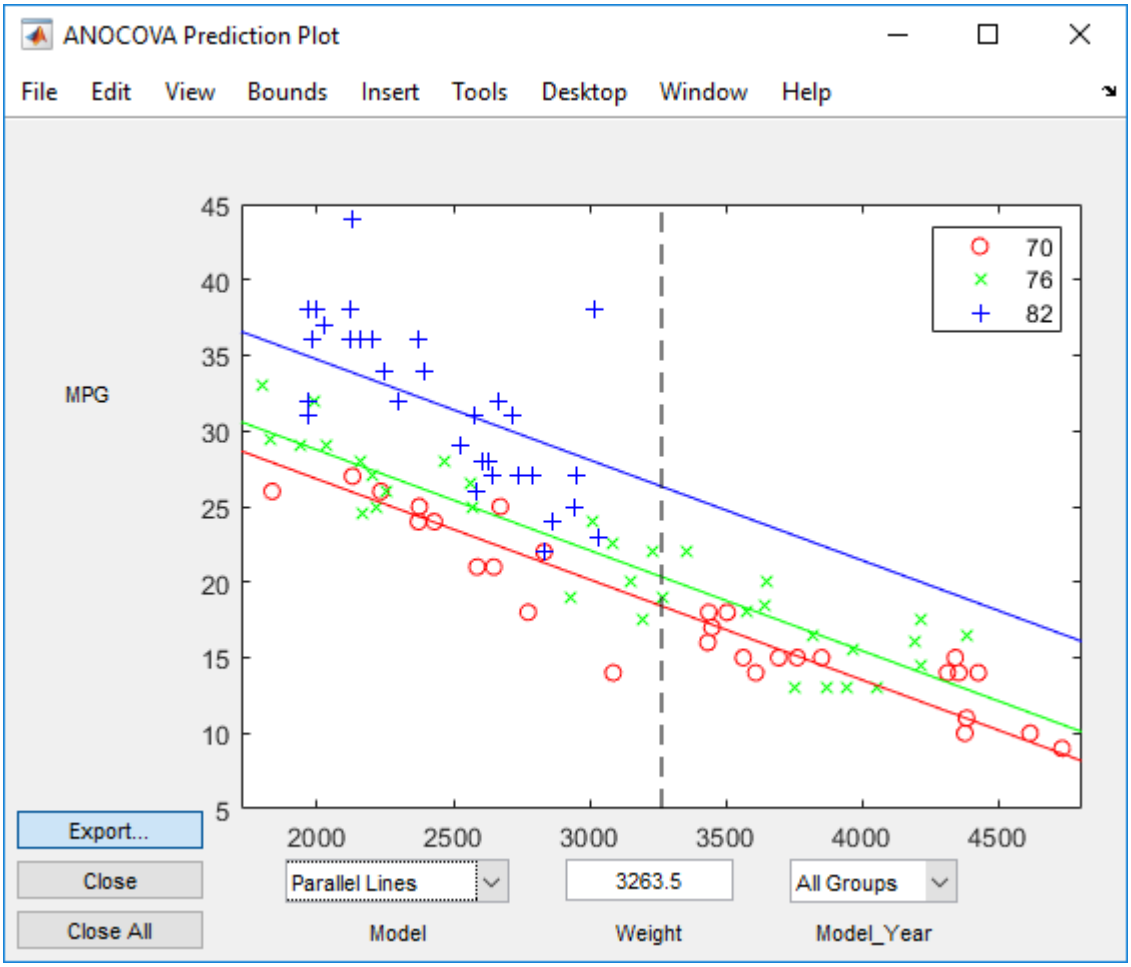
Term	Estimate	Std. Err.	T	Prob>|T|
Intercept	45.9798	1.52085	30.23	0
70	-8.5805	1.96186	-4.37	0
76	-3.8902	1.86864	-2.08	0.0403
82	12.4707	2.5568	4.88	0
Slope	-0.0078	0.00056	-14	0
70	0.002	0.00066	2.96	0.0039
76	0.0011	0.00065	1.74	0.0849
82	-0.0031	0.001	-3.1	0.0026

Because the three fitted lines have slopes that are roughly similar, you may wonder if they really are the same. The `Model_Year*Weight` interaction expresses the difference in slopes, and the ANOVA table shows a test for the significance of this term. With an F statistic of 5.23 and a p value of 0.0072, the slopes are significantly different.



Source	d.f.	Sum Sq	Mean Sq	F	Prob>F
Model_Year	2	807.69	403.84	51.98	0
Weight	1	2050.2	2050.2	263.87	0
Model_Year*Weight	2	81.22	40.61	5.23	0.0072
Error	88	683.74	7.77		

4 **Constrain the slopes to be the same.** To examine the fits when the slopes are constrained to be the same, return to the ANOCOVA Prediction Plot window and use the **Model** pop-up menu to select a `Parallel Lines` model. The window updates to show the following graph.

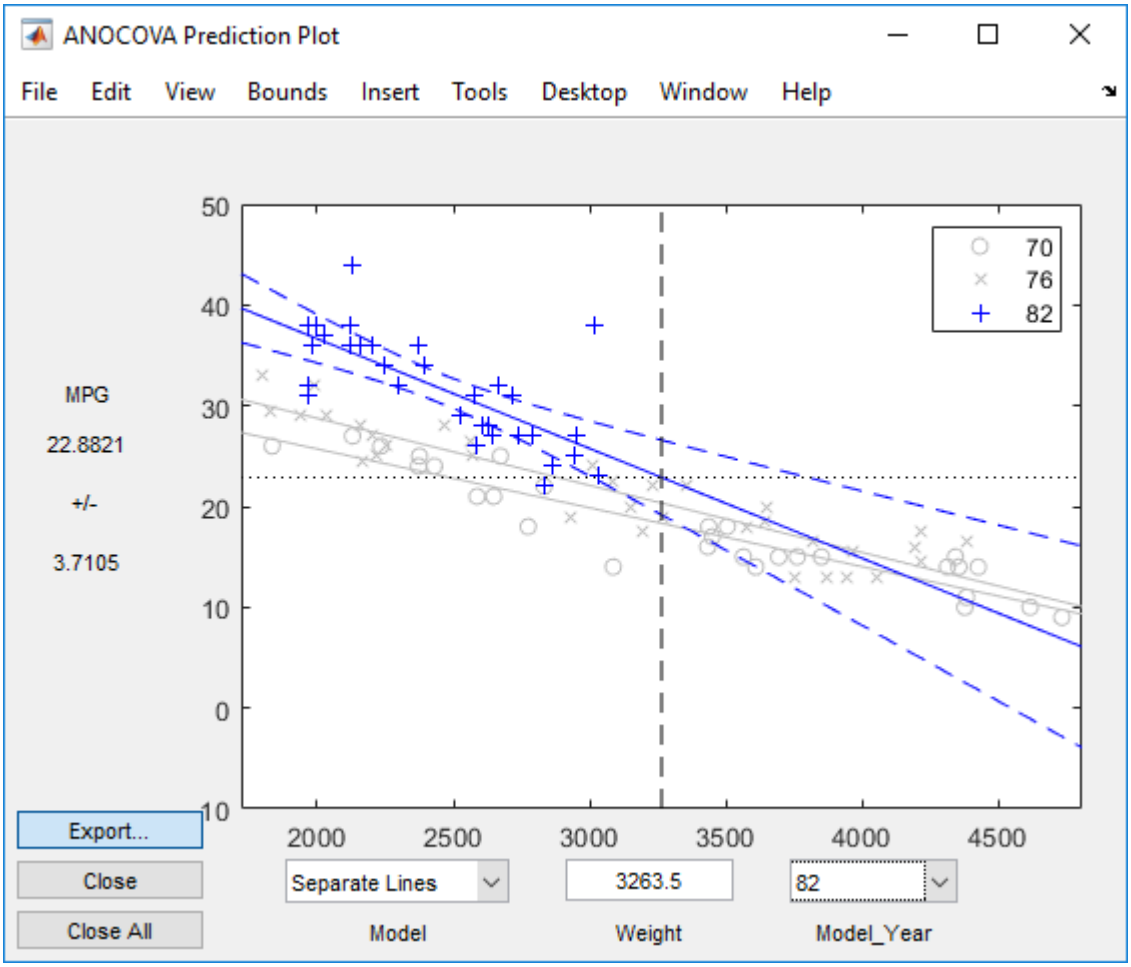


Though this fit looks reasonable, it is significantly worse than the `Separate Lines` model. Use the **Model** pop-up menu again to return to the original model.

Confidence Bounds

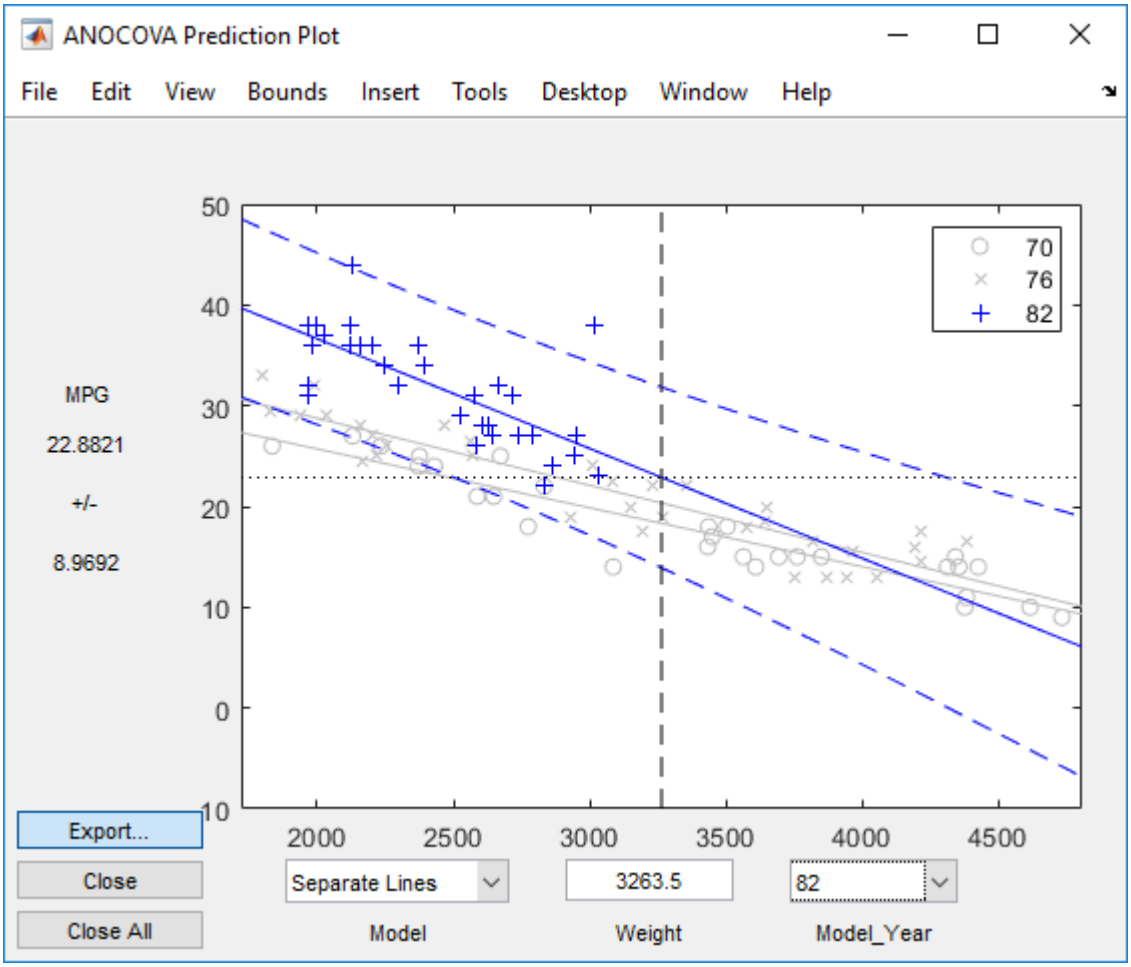
The example in “Analysis of Covariance Tool” on page 9-39 provides estimates of the relationship between `MPG` and `Weight` for each `Model_Year`, but how accurate are these estimates? To find out, you can superimpose confidence bounds on the fits by examining them one group at a time.

1. In the **Model_Year** menu at the lower right of the figure, change the setting from `All Groups` to 82. The data and fits for the other groups are dimmed, and confidence bounds appear around the 82 fit.



The dashed lines form an envelope around the fitted line for model year 82. Under the assumption that the true relationship is linear, these bounds provide a 95% confidence region for the true line. Note that the fits for the other model years are well outside these confidence bounds for `Weight` values between `2000` and `3000`.

2 Sometimes it is more valuable to be able to predict the response value for a new observation, not just estimate the average response value. Use the `aoctool` function **Bounds** menu to change the definition of the confidence bounds from `Line` to `Observation`. The resulting wider intervals reflect the uncertainty in the parameter estimates as well as the randomness of a new observation.



Like the `polytool` function, the `aoctool` function has cross hairs that you can use to manipulate the `Weight` and watch the estimate and confidence bounds along the *y*-axis update. These values appear only when a single group is selected, not when `All Groups` is selected.

Multiple Comparisons

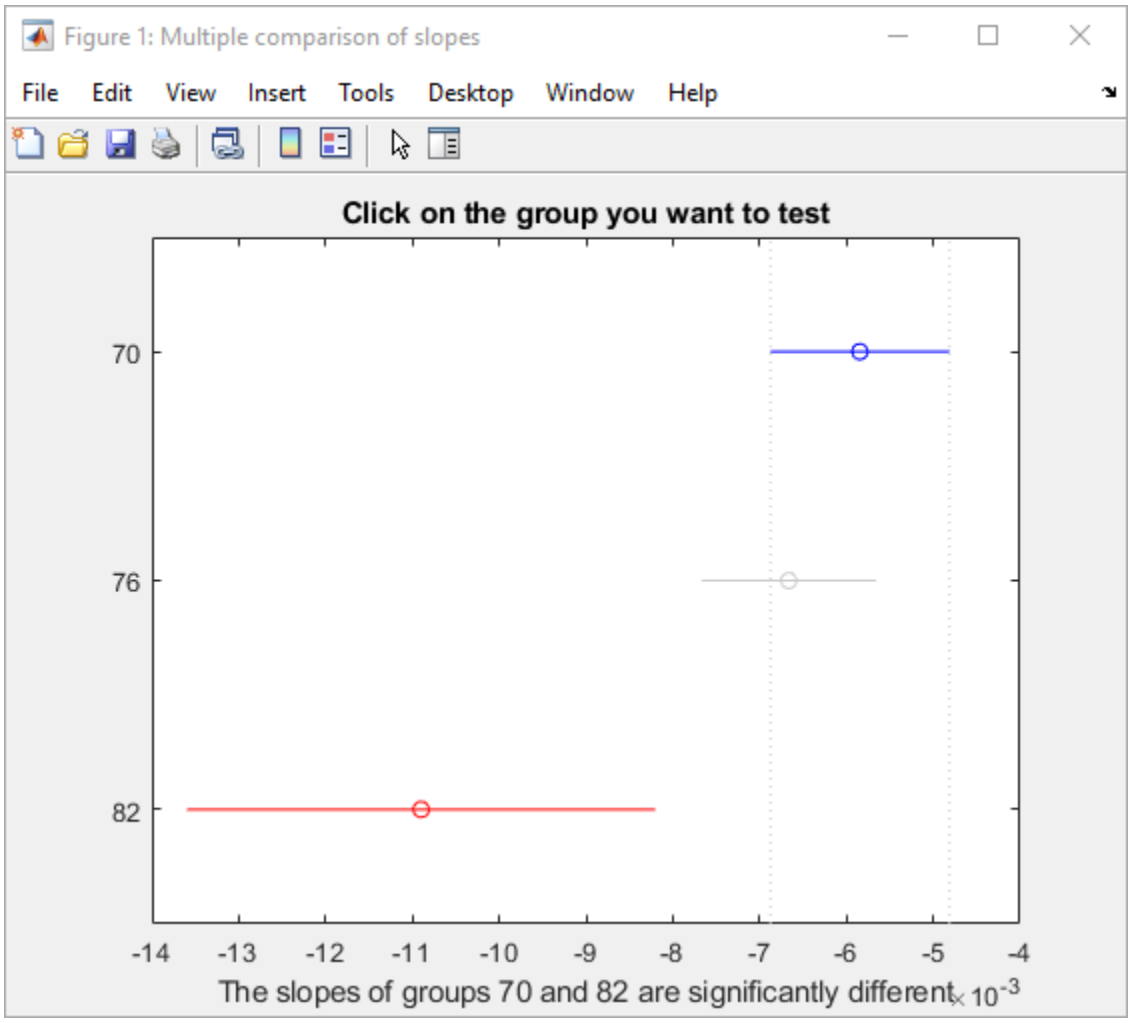
You can perform a multiple comparison test by using the `stats` output structure from `aoctool` as input to the `multcompare` function. The `multcompare` function can test either slopes, intercepts, or population marginal means (the predicted MPG of the mean weight for each group). The example in “Analysis of Covariance Tool” on page 9-39 shows that the slopes are not all the same, but could it be that two are the same and only the other one is different? You can test that hypothesis.

```
multcompare(stats,0.05,'on','','s')

ans =
    1.0000    2.0000   -0.0012    0.0008    0.0029
    1.0000    3.0000    0.0013    0.0051    0.0088
    2.0000    3.0000    0.0005    0.0042    0.0079
```

This matrix shows that the estimated difference between the intercepts of groups 1 and 2 (1970 and 1976) is 0.0008, and a confidence interval for the difference is [–0.0012, 0.0029]. There is no

significant difference between the two. There are significant differences, however, between the intercept for 1982 and each of the other two. The graph shows the same information.



Note that the `stats` structure was created in the initial call to the `aoctool` function, so it is based on the initial model fit (typically a separate-lines model). If you change the model interactively and want to base your multiple comparisons on the new model, you need to run `aoctool` again to get another `stats` structure, this time specifying your new model as the initial model.

Nonparametric Methods

In this section...

Introduction to Nonparametric Methods

Statistics and Machine Learning Toolbox functions include nonparametric versions of one-way and two-way analysis of variance. Unlike classical tests, nonparametric tests make only mild assumptions about the data, and are appropriate when the distribution of the data is non-normal. On the other hand, they are less powerful than classical methods for normally distributed data.

Both of the nonparametric functions described here will return a `stats` structure that can be used as an input to the `multcompare` function for multiple comparisons.

Kruskal-Wallis Test

The example “Perform One-Way ANOVA” on page 9-5 uses one-way analysis of variance to determine if the bacteria counts of milk varied from shipment to shipment. The one-way analysis rests on the assumption that the measurements are independent, and that each has a normal distribution with a common variance and with a mean that was constant in each column. You can conclude that the column means were not all the same. The following example repeats that analysis using a nonparametric procedure.

The Kruskal-Wallis test is a nonparametric version of one-way analysis of variance. The assumption behind this test is that the measurements come from a continuous distribution, but not necessarily a normal distribution. The test is based on an analysis of variance using the ranks of the data values, not the data values themselves. Output includes a table similar to an ANOVA table, and a box plot.

You can run this test as follows:

```
load hogg

p = kruskalwallis(hogg)
p =
    0.0020
```

The low *p* value means the Kruskal-Wallis test results agree with the one-way analysis of variance results.

Friedman's Test

“Perform Two-Way ANOVA” on page 9-13 uses two-way analysis of variance to study the effect of car model and factory on car mileage. The example tests whether either of these factors has a significant effect on mileage, and whether there is an interaction between these factors. The conclusion of the example is there is no interaction, but that each individual factor has a significant effect. The next example examines whether a nonparametric analysis leads to the same conclusion.

Friedman's test is a nonparametric test for data having a two-way layout (data grouped by two categorical factors). Unlike two-way analysis of variance, Friedman's test does not treat the two factors symmetrically and it does not test for an interaction between them. Instead, it is a test for whether the columns are different after adjusting for possible row differences. The test is based on an analysis of variance using the ranks of the data across categories of the row factor. Output includes a table similar to an ANOVA table.

You can run Friedman's test as follows.

```
load mileage
p = friedman(mileage,3)
p =
  7.4659e-004
```

Recall the classical analysis of variance gave a p value to test column effects, row effects, and interaction effects. This p value is for column effects. Using either this p value or the p value from ANOVA ($p < 0.0001$), you conclude that there are significant column effects.

In order to test for row effects, you need to rearrange the data to swap the roles of the rows in columns. For a data matrix `x` with no replications, you could simply transpose the data and type

```
p = friedman(x')
```

With replicated data it is slightly more complicated. A simple way is to transform the matrix into a three-dimensional array with the first dimension representing the replicates, swapping the other two dimensions, and restoring the two-dimensional shape.

```
x = reshape(mileage, [3 2 3]);
x = permute(x,[1 3 2]);
x = reshape(x,[9 2])
x =
   33.3000   32.6000
   33.4000   32.5000
   32.9000   33.0000
   34.5000   33.4000
   34.8000   33.7000
   33.8000   33.9000
   37.4000   36.6000
   36.8000   37.0000
   37.6000   36.7000

friedman(x,3)
ans =
    0.0082
```

Again, the conclusion is similar to that of the classical analysis of variance. Both this p value and the one from ANOVA ($p = 0.0039$) lead you to conclude that there are significant row effects.

You cannot use Friedman's test to test for interactions between the row and column factors.

MANOVA

In this section...

Introduction to MANOVA

The analysis of variance technique in “Perform One-Way ANOVA” on page 9-5 takes a set of grouped data and determine whether the mean of a variable differs significantly among groups. Often there are multiple response variables, and you are interested in determining whether the entire set of means is different from one group to the next. There is a multivariate version of analysis of variance that can address the problem.

ANOVA with Multiple Responses

The `carsmall` data set has measurements on a variety of car models from the years 1970, 1976, and 1982. Suppose you are interested in whether the characteristics of the cars have changed over time.

```
load carsmall
whos
```

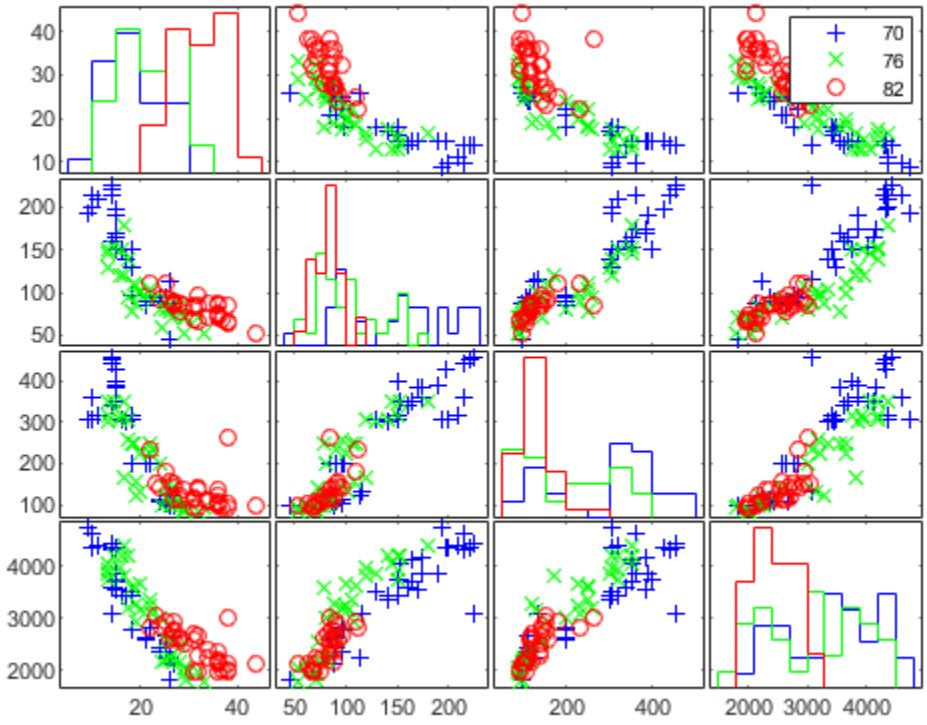
```
  Name                Size            Bytes  Class     Attributes

  Acceleration      100x1               800  double
  Cylinders         100x1               800  double
  Displacement      100x1               800  double
  Horsepower        100x1               800  double
  MPG               100x1               800  double
  Mfg               100x13             2600  char
  Model             100x33             6600  char
  Model_Year        100x1               800  double
  Origin            100x7              1400  char
  Weight            100x1               800  double
```

Four of these variables (`Acceleration`, `Displacement`, `Horsepower`, and `MPG`) are continuous measurements on individual car models. The variable `Model_Year` indicates the year in which the car was made. You can create a grouped plot matrix of these variables using the `gplotmatrix` function.

Create a grouped plot matrix of these variables using the `gplotmatrix` function.

```
x = [MPG Horsepower Displacement Weight];
gplotmatrix(x,[],Model_Year,[],'+xo')
```



(When the second argument of `gplotmatrix` is empty, the function graphs the columns of the `x` argument against each other, and places histograms along the diagonals. The empty fourth argument produces a graph with the default colors. The fifth argument controls the symbols used to distinguish between groups.)

It appears the cars do differ from year to year. The upper right plot, for example, is a graph of `MPG` versus `Weight`. The 1982 cars appear to have higher mileage than the older cars, and they appear to weigh less on average. But as a group, are the three years significantly different from one another? The `manova1` function can answer that question.

```
[d,p,stats] = manova1(x,Model_Year)
```

```
d = 2

p = 2×1
10^-6 ×

    0.0000
    0.1141

stats = struct with fields:
           W: [4x4 double]
           B: [4x4 double]
           T: [4x4 double]
         dfW: 90
         dfB: 2
```

```
       dfT: 92
    lambda: [2x1 double]
     chisq: [2x1 double]
   chisqdf: [2x1 double]
  eigenval: [4x1 double]
  eigenvec: [4x4 double]
     canon: [100x4 double]
     mdist: [1x100 double]
    gmdist: [3x3 double]
    gnames: {3x1 cell}
```

The `manova1` function produces three outputs:

- The first output `d` is an estimate of the dimension of the group means. If the means were all the same, the dimension would be 0, indicating that the means are at the same point. If the means differed but fell along a line, the dimension would be 1. In the example the dimension is 2, indicating that the group means fall in a plane but not along a line. This is the largest possible dimension for the means of three groups.
- The second output `p` is a vector of *p*-values for a sequence of tests. The first *p*-value tests whether the dimension is 0, the next whether the dimension is 1, and so on. In this case both *p*-values are small. That's why the estimated dimension is 2.
- The third output `stats` is a structure containing several fields, described in the following section.

Fields of the `stats` Structure

The `W`, `B`, and `T` fields are matrix analogs to the within, between, and total sums of squares in ordinary one-way analysis of variance. The next three fields are the degrees of freedom for these matrices. Fields `lambda`, `chisq`, and `chisqdf` are the ingredients of the test for the dimensionality of the group means. (The *p*-values for these tests are the first output argument of `manova1`.)

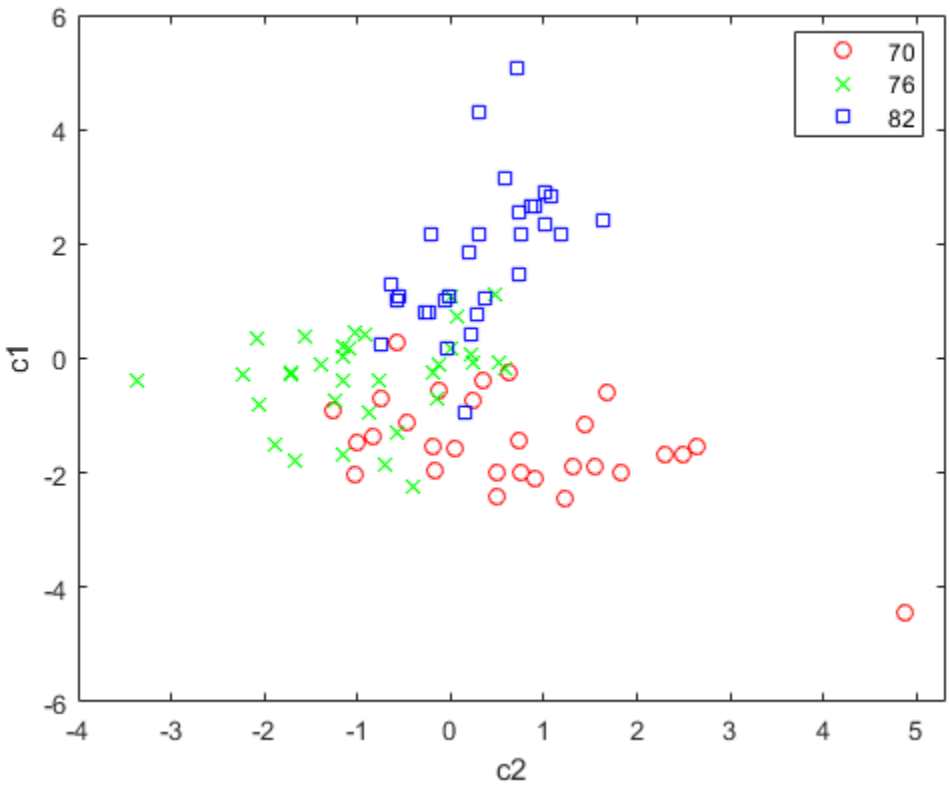
The next three fields are used to do a canonical analysis. Recall that in “Principal Component Analysis (PCA)” on page 15-68 you look for the combination of the original variables that has the largest possible variation. In multivariate analysis of variance, you instead look for the linear combination of the original variables that has the largest separation between groups. It is the single variable that would give the most significant result in a univariate one-way analysis of variance. Having found that combination, you next look for the combination with the second highest separation, and so on.

The `eigenvec` field is a matrix that defines the coefficients of the linear combinations of the original variables. The `eigenval` field is a vector measuring the ratio of the between-group variance to the within-group variance for the corresponding linear combination. The `canon` field is a matrix of the canonical variable values. Each column is a linear combination of the mean-centered original variables, using coefficients from the `eigenvec` matrix.

```
c1 = stats.canon(:,1);
c2 = stats.canon(:,2);
```

Plot the grouped scatter plot of the first two canonical variables.

```
figure
gscatter(c2,c1,Model_Year,[],'oxs')
```



A grouped scatter plot of the first two canonical variables shows more separation between groups then a grouped scatter plot of any pair of original variables. In this example, it shows three clouds of points, overlapping but with distinct centers. One point in the bottom right sits apart from the others. You can mark this point on the plot using the `gname` function.

Roughly speaking, the first canonical variable, `c1`, separates the 1982 cars (which have high values of `c1`) from the older cars. The second canonical variable, `c2`, reveals some separation between the 1970 and 1976 cars.

The final two fields of the `stats` structure are Mahalanobis distances. The `mdist` field measures the distance from each point to its group mean. Points with large values may be outliers. In this data set, the largest outlier is the one in the scatter plot, the Buick Estate station wagon. (Note that you could have supplied the model name to the `gname` function above if you wanted to label the point with its model name rather than its row number.)

Find the largest distance from the group mean.

```
max(stats.mdist)
```

```
ans = 31.5273
```

Find the point that has the largest distance from the group mean.

```
find(stats.mdist == ans)
```

```
ans = 20
```

Find the car model that corresponds to the largest distance from the group mean.

```
Model(20,:)
```

```
ans =
'buick estate wagon (sw)          '
```

The `gmdist` field measures the distances between each pair of group means. Examine the group means using `grpstats`.

```
grpstats(x, Model_Year)
```

```
ans = 3×4
10^3 ×

    0.0177    0.1489    0.2869    3.4413
    0.0216    0.1011    0.1978    3.0787
    0.0317    0.0815    0.1289    2.4535
```

Find the distances between the each pair of group means.

```
stats.gmdist
```

```
ans = 3×3

         0    3.8277   11.1106
    3.8277         0    6.1374
   11.1106    6.1374         0
```

As might be expected, the multivariate distance between the extreme years 1970 and 1982 (11.1) is larger than the difference between more closely spaced years (3.8 and 6.1). This is consistent with the scatter plots, where the points seem to follow a progression as the year changes from 1970 through 1976 to 1982. If you had more groups, you might find it instructive to use the `manovacluster` function to draw a diagram that presents clusters of the groups, formed using the distances between their means.

Model Specification for Repeated Measures Models

Model specification for a repeated measures model is a character vector or string scalar representing a formula in the form

```
'y1-yk ~ terms',
```

where the responses and terms are in Wilkinson notation.

For example, if you have five repeated measures $y1$, $y2$, $y3$, $y4$, and $y5$, and you include the terms $X1$, $X2$, $X3$, $X4$, and $X3$:$X4$ in your linear model, then you can specify `modelspec` as follows:

```
'y1-y5 ~ X1 + X2 + X3*X4'.
```

Wilkinson Notation

Wilkinson notation describes the factors present in models. It does not describe the multipliers (coefficients) of those factors.

Use these rules to specify the responses in `modelspec`.

Wilkinson Notation	Description
`Y1,Y2,Y3`	Specific list of variables
`Y1-Y5`	All table variables from `Y1` through `Y5`

The following rules are for specifying terms in `modelspec`.

Wilkinson Notation	Factors in Standard Notation
`1`	Constant (intercept) term
`X^k`, where `k` is a positive integer	X, X^2, ..., X^k
`X1 + X2`	X1, X2
`X1*X2`	X1, X2, X1*X2
`X1:X2`	X1*X2 only
`-X2`	Do not include X2
`X1*X2 + X3`	X1, X2, X3, X1*X2
`X1 + X2 + X3 + X1:X2`	X1, X2, X3, X1*X2
`X1*X2*X3 - X1:X2:X3`	X1, X2, X3, X1*X2, X1*X3, X2*X3
`X1*(X2 + X3)`	X1, X2, X3, X1*X2, X1*X3

Statistics and Machine Learning Toolbox notation always includes a constant term unless you explicitly remove the term using `-1`.

Compound Symmetry Assumption and Epsilon Corrections

The regular *p*-value calculations in the repeated measures anova (`ranova`) are accurate if the theoretical distribution of the response variables has compound symmetry. This means that all response variables have the same variance, and each pair of response variables share a common correlation. That is,

$$\Sigma = \sigma^2 \begin{pmatrix} 1 & \rho & \cdots & \rho \\ \rho & 1 & \cdots & \rho \\ \vdots & \vdots & \ddots & \vdots \\ \rho & \rho & \cdots & 1 \end{pmatrix}.$$

Under the compound symmetry assumption, the *F*-statistics in the repeated measures anova table have an *F*-distribution with degrees of freedom (v_1, v_2). Here, v_1 is the rank of the contrast being tested, and v_2 is the degrees of freedom for error. If the compound symmetry assumption is not true, the *F*-statistic has an approximate *F*-distribution with degrees of freedom (εv_1, εv_2), where ε is the correction factor. Then, the *p*-value must be computed using the adjusted values. The three different correction factor computations are as follows:

- **Greenhouse-Geisser approximation**

  $$\varepsilon_{GG} = \frac{\left(\sum_{i=1}^{p} \lambda_i\right)^2}{d \sum_{i=1}^{p} \lambda_i^2},$$

  where λ_i i = 1, 2, .., p are the eigenvalues of the covariance matrix. p is the number of variables, and d is equal to p-1.

- **Huynh-Feldt approximation**

  $$\varepsilon_{HF} = \min\left(1, \frac{nd\varepsilon_{GG} - 2}{d(n - rx) - d^2\varepsilon_{GG}}\right),$$

  where n is the number of rows in the design matrix and r is the rank of the design matrix.

- **Lower bound on the true *p*-value**

  $$\varepsilon_{LB} = \frac{1}{d}.$$

More About

- “Mauchly’s Test of Sphericity” on page 9-57

Mauchly’s Test of Sphericity

The regular *p*-value calculations in the repeated measures anova (`ranova`) are accurate if the theoretical distribution of the response variables have compound symmetry. This means that all response variables have the same variance, and each pair of response variables share a common correlation. That is,

$$\Sigma = \sigma^2 \begin{pmatrix} 1 & \rho & \cdots & \rho \\ \rho & 1 & \cdots & \rho \\ \vdots & \vdots & \ddots & \vdots \\ \rho & \rho & \cdots & 1 \end{pmatrix}.$$

If the compound symmetry assumption is false, then the degrees of freedom for the repeated measures anova test must be adjusted by a factor ε, and the *p*-value must be computed using the adjusted values.

Compound symmetry implies sphericity.

For a repeated measures model with responses $y1$, $y2$, ..., sphericity means that all pair-wise differences $y1 - y2$, $y1 - y3$, ... have the same theoretical variance. Mauchly’s test is the most accepted test for sphericity.

Mauchly’s W statistic is

$$W = \frac{|T|}{(trace(T)/p)^d},$$

where

$$T = M'\widehat{\sum}M.$$

M is a p-by-d orthogonal contrast matrix, Σ is the covariance matrix, p is the number of variables, and $d = p - 1$.

A chi-square test statistic assesses the significance of W. If n is the number of rows in the design matrix, and r is the rank of the design matrix, then the chi-square statistic is

$$C = -(n - r)\log(W)D,$$

where

$$D = 1 - \frac{2d^2 + d + 2}{6d(n - r)}.$$

The C test statistic has a chi-square distribution with $(p(p - 1)/2) - 1$ degrees of freedom. A small *p*-value for the Mauchly’s test indicates that the sphericity assumption does not hold.

The `rmanova` method computes the *p*-values for the repeated measures anova based on the results of the Mauchly’s test and each epsilon value.

- “Compound Symmetry Assumption and Epsilon Corrections” on page 9-55

Multivariate Analysis of Variance for Repeated Measures

Multivariate analysis of variance analysis is a test of the form `A*B*C = D`, where `B` is the *p*-by-*r* matrix of coefficients. *p* is the number of terms, such as the constant, linear predictors, dummy variables for categorical predictors, and products and powers, *r* is the number of repeated measures, and *n* is the number of subjects. `A` is an *a*-by-*p* matrix, with rank $a \le p$, defining hypotheses based on the between-subjects model. `C` is an *r*-by-*c* matrix, with rank $c \le r \le n - p$, defining hypotheses based on the within-subjects model, and `D` is an *a*-by-*c* matrix, containing the hypothesized value.

`manova` tests if the model terms are significant in their effect on the response by measuring how they contribute to the overall covariance. It includes all terms in the between-subjects model. `manova` always takes `D` as zero. The multivariate response for each observation (subject) is the vector of repeated measures.

`manova` uses four different methods to measure these contributions: Wilks' lambda, Pillai's trace, Hotelling-Lawley trace, Roy's maximum root statistic. Define

$$T = A\widehat{B}C - D,$$
$$Z = A(X'X)^{-1}A'.$$

Then, the hypotheses sum of squares and products matrix is

$$Q_h = T'Z^{-1}T,$$

and the residuals sum of squares and products matrix is

$$Q_e = C'(R'R)C,$$

where

$$R = Y - X\widehat{B}.$$

The matrix Q_h is analogous to the numerator of a univariate *F*-test, and Q_e is analogous to the error sum of squares. Hence, the four statistics `manova` uses are:

- **Wilks' lambda**

  $$\Lambda = \frac{|Q_e|}{|Q_h + Q_e|} = \prod \frac{1}{1 + \lambda_i},$$

Bayesian Optimization

Bayesian Optimization Algorithm

In this section...

Algorithm Outline

The Bayesian optimization algorithm attempts to minimize a scalar objective function $f(x)$ for x in a bounded domain. The function can be deterministic or stochastic, meaning it can return different results when evaluated at the same point x. The components of x can be continuous reals, integers, or categorical, meaning a discrete set of names.

Note Throughout this discussion, D represents the number of components of x.

The key elements in the minimization are:

- A Gaussian process model of $f(x)$.
- A Bayesian update procedure for modifying the Gaussian process model at each new evaluation of $f(x)$.
- An acquisition function $a(x)$ (based on the Gaussian process model of f) that you maximize to determine the next point x for evaluation. For details, see “Acquisition Function Types” on page 10-3 and “Acquisition Function Maximization” on page 10-5.

Algorithm outline:

- Evaluate $y_i = f(x_i)$ for `NumSeedPoints` points x_i, taken at random within the variable bounds. `NumSeedPoints` is a `bayesopt` setting. If there are evaluation errors, take more random points until there are `NumSeedPoints` successful evaluations. The probability distribution of each component is either uniform or log-scaled, depending on the `Transform` value in `optimizableVariable`.

Then repeat the following steps:

1. Update the Gaussian process model of $f(x)$ to obtain a posterior distribution over functions $Q(f|x_i, y_i \text{ for } i = 1,\ldots,t)$. (Internally, `bayesopt` uses `fitrgp` to fit a Gaussian process model to the data.)
2. Find the new point x that maximizes the acquisition function $a(x)$.

The algorithm stops after reaching any of the following:

- A fixed number of iterations (default 30).
- A fixed time (default is no time limit).
- A stopping criterion that you supply in “Bayesian Optimization Output Functions” on page 10-19 or “Bayesian Optimization Plot Functions” on page 10-11.

For the algorithmic differences in parallel, see “Parallel Bayesian Algorithm” on page 10-7.

Gaussian Process Regression for Fitting the Model

The underlying probabilistic model for the objective function f is a Gaussian process prior with added Gaussian noise in the observations. So the prior distribution on $f(x)$ is a Gaussian process with mean $\mu(x;\theta)$ and covariance kernel function $k(x,x';\theta)$. Here, θ is a vector of kernel parameters. For the particular kernel function `bayesopt` uses, see “Kernel Function” on page 10-3.

In a bit more detail, denote a set of points $X = x_i$ with associated objective function values $F = f_i$. The prior’s joint distribution of the function values F is multivariate normal, with mean $\mu(X)$ and covariance matrix $K(X,X)$, where $K_{ij} = k(x_i,x_j)$.

Without loss of generality, the prior mean is given as `0`.

Also, the observations are assumed to have added Gaussian noise with variance σ^2. So the prior distribution has covariance $K(X,X;\theta) + \sigma^2 I$.

Fitting a Gaussian process regression model to observations consists of finding values for the noise variance σ^2 and kernel parameters θ. This fitting is a computationally intensive process performed by `fitrgp`.

For details on fitting a Gaussian process to observations, see “Gaussian Process Regression”.

Kernel Function

The kernel function $k(x,x';\theta)$ can significantly affect the quality of a Gaussian process regression. `bayesopt` uses the ARD Matérn 5/2 kernel defined in “Kernel (Covariance) Function Options” on page 6-6.

See Snoek, Larochelle, and Adams [3].

Acquisition Function Types

Six choices of acquisition functions are available for `bayesopt`. There are three basic types, with `expected-improvement` also modified by `per-second` or `plus`:

- `'expected-improvement-per-second-plus'` (default)
- `'expected-improvement'`
- `'expected-improvement-plus'`
- `'expected-improvement-per-second'`
- `'lower-confidence-bound'`
- `'probability-of-improvement'`

The acquisition functions evaluate the “goodness” of a point x based on the posterior distribution function Q. When there are coupled constraints, including the Error constraint (see “Objective Function Errors” on page 10-36), all acquisition functions modify their estimate of “goodness” following a suggestion of Gelbart, Snoek, and Adams [2]. Multiply the “goodness” by an estimate of the probability that the constraints are satisfied, to arrive at the acquisition function.

- “Expected Improvement” on page 10-4
- “Probability of Improvement” on page 10-4
- “Lower Confidence Bound” on page 10-4

Expected Improvement

The `'expected-improvement'` family of acquisition functions evaluates the expected amount of improvement in the objective function, ignoring values that cause an increase in the objective. In other words, define

- x_{best} as the location of the lowest posterior mean.
- $\mu_Q(x_{\text{best}})$ as the lowest value of the posterior mean.

Then the expected improvement

$$EI(x,Q) = E_Q\left[\max\left(0, \mu_Q(x_{\text{best}}) - f(x)\right)\right].$$

Probability of Improvement

The `'probability-of-improvement'` acquisition function makes a similar, but simpler, calculation as `'expected-improvement'`. In both cases, `bayesopt` first calculates x_{best} and $\mu_Q(x_{\text{best}})$. Then for `'probability-of-improvement'`, `bayesopt` calculates the probability PI that a new point x leads to a better objective function value, modified by a “margin” parameter m:

$$PI(x,Q) = P_Q\left(f(x) < \mu_Q(x_{\text{best}}) - m\right).$$

`bayesopt` takes m as the estimated noise standard deviation. `bayesopt` evaluates this probability as

$$PI = \Phi\left(\nu_Q(x)\right),$$

where

$$\nu_Q(x) = \frac{\mu_Q(x_{\text{best}}) - m - \mu_Q(x)}{\sigma_Q(x)}.$$

Here $\Phi(\cdot)$ is the unit normal CDF, and σ_Q is the posterior standard deviation of the Gaussian process at x.

Lower Confidence Bound

The `'lower-confidence-bound'` acquisition function looks at the curve G two standard deviations below the posterior mean at each point:

$$G(x) = \mu_Q(x) - 2\sigma_Q(x).$$

$G(x)$ is the $2\sigma_Q$ lower confidence envelope of the objective function model. `bayesopt` then maximizes the negative of G:

$$LCB = 2\sigma_Q(x) - \mu_Q(x).$$

Per Second

Sometimes, the time to evaluate the objective function can depend on the region. For example, many Support Vector Machine calculations vary in timing a good deal over certain ranges of points. If so, `bayesopt` can obtain better improvement per second by using time-weighting in its acquisition function. The cost-weighted acquisition functions have the phrase `per-second` in their names.

These acquisition functions work as follows. During the objective function evaluations, `bayesopt` maintains another Bayesian model of objective function evaluation time as a function of position x. The expected improvement per second that the acquisition function uses is

$$EIpS(x) = \frac{EI_Q(x)}{\mu_S(x)},$$

where $\mu_S(x)$ is the posterior mean of the timing Gaussian process model.

Plus

To escape a local objective function minimum, the acquisition functions with `plus` in their names modify their behavior when they estimate that they are overexploiting an area. To understand overexploiting, let $\sigma_F(x)$ be the standard deviation of the posterior objective function at x. Let σ be the posterior standard deviation of the additive noise, so that

$$\sigma_Q^2(x) = \sigma_F^2(x) + \sigma^2.$$

Define t_σ to be the value of the `ExplorationRatio` option, a positive number. The `bayesopt` `plus` acquisition functions, after each iteration, evaluate whether the next point x satisfies

$$\sigma_F(x) < t_\sigma\sigma.$$

If so, the algorithm declares that x is overexploiting. Then the acquisition function modifies its “Kernel Function” on page 10-3 by multiplying θ by the number of iterations, as suggested by Bull [1]. This modification raises the variance σ_Q for points in between observations. It then generates a new point based on the new fitted kernel function. If the new point x is again overexploiting, the acquisition function multiplies θ by an additional factor of 10 and tries again. It continues in this way up to five times, trying to generate a point x that is not overexploiting. The algorithm accepts the new x as the next point.

`ExplorationRatio` therefore controls a tradeoff between exploring new points for a better global solution, versus concentrating near points that have already been examined.

Acquisition Function Maximization

Internally, `bayesopt` maximizes an acquisition function using the following general steps:

1. For algorithms starting with `'expected-improvement'` and for `'probability-of-improvement'`, `bayesopt` estimates the smallest feasible mean of the posterior distribution $\mu_Q(x_{\text{best}})$ by sampling several thousand points within the variable bounds, taking several of the best (low mean value) feasible points, and improving them using local search, to find the ostensible best feasible point. Feasible means that the point satisfies constraints (see “Constraints in Bayesian Optimization” on page 10-38).
2. For all algorithms, `bayesopt` samples several thousand points within the variable bounds, takes several of the best (high acquisition function) feasible points, and improves them using local search, to find the ostensible best feasible point. The acquisition function value depends on the modeled posterior distribution, not a sample of the objective function, and so it can be calculated quickly.

Parallel Bayesian Optimization

In this section...

Optimize in Parallel

Running Bayesian optimization in parallel can save time. Running in parallel requires Parallel Computing Toolbox. `bayesopt` performs parallel objective function evaluations concurrently on parallel workers.

To optimize in parallel:

- `bayesopt` — Set the `UseParallel` name-value pair to `true`. For example,

  ```
  results = bayesopt(fun,vars,'UseParallel',true);
  ```

- Fit functions — Set the `UseParallel` field of the `HyperparameterOptimizationOptions` structure to `true`. For example,

  ```
  Mdl = fitcsvm(X,Y,'OptimizeHyperparameters','auto',...
      'HyperparameterOptimizationOptions',struct('UseParallel',true))
  ```

Parallel Bayesian Algorithm

The parallel Bayesian optimization algorithm is similar to the serial algorithm, which is described in “Bayesian Optimization Algorithm” on page 10-2. The differences are:

- `bayesopt` assigns points to evaluate to the parallel workers, generally one point at a time. `bayesopt` calculates on the client to determine which point to assign.
- After `bayesopt` evaluates the initial random points, it chooses points to evaluate by fitting a Gaussian process (GP) model. To fit a GP model while some workers are still evaluating points, `bayesopt` imputes a value to each point that is still on a worker. The imputed value is the mean of the GP model value at the points it is evaluating, or some other value as specified by the `bayesopt 'ParallelMethod'` name-value pair. For parallel optimization of fit functions, `bayesopt` uses the default `ParallelMethod` imputed value.
- After `bayesopt` assigns a point to evaluate, and before it computes a new point to assign, it checks whether too many workers are idle. The threshold for active workers is determined by the `MinWorkerUtilization` name-value pair. If too many workers are idle, then `bayesopt` assigns random points, chosen uniformly within bounds, to all idle workers. This step causes the workers to be active more quickly, but the workers have random points rather than fitted points. If the number of idle workers does not exceed the threshold, then `bayesopt` chooses a point to evaluate as usual, by fitting a GP model and maximizing the acquisition function.

Note Due to the nonreproducibility of parallel timing, parallel Bayesian optimization does not necessarily yield reproducible results.

Settings for Best Parallel Performance

Fit functions have no special settings for better parallel performance. In contrast, several `bayesopt` settings can help to speed an optimization.

Solver Options

Setting the `GPActiveSetSize` option to a smaller value than the default (`300`) can speed the solution. The cost is potential inaccuracy in the points that `bayesopt` chooses to evaluate, because the GP model of the objective function can be less accurate than with a larger value. Setting the option to a larger value can result in a more accurate GP model, but requires more time to create the model.

Setting the `ParallelMethod` option to `'max-observed'` can lead `bayesopt` to search more widely for a global optimum. This choice can lead to a better solution in less time. However, the default value of `'clipped-model-prediction'` is often best.

Setting the `MinWorkerUtilization` option to a large value can result in higher parallel utilization. However, this setting causes more completely random points to be evaluated, which can lead to less accurate solutions. A large value, in this context, depends on how many workers you have. The default is `floor(0.8*N)`, where `N` is the number of parallel workers. Setting the option to a lower value can give lower parallel utilization, but with the benefit of higher quality points.

Placing the Objective Function on Workers

You can place an objective function on the parallel workers in one of three ways. Some have better performance, but require a more complex setup.

1. Automatic If you give a function handle as the objective function, `bayesopt` sends the handle to all the parallel workers at the beginning of its run. For example,

```
load ionosphere
splits = optimizableVariable('splits',[1,100],'Type','integer');
minleaf = optimizableVariable('minleaf',[1,100],'Type','integer');
fun = @(params)kfoldLoss(fitctree(X,Y,'Kfold',5,...
    'MaxNumSplits',params.splits,'MinLeaf',params.minleaf));

results = bayesopt(fun,[splits,minleaf],'UseParallel',true);
```

This method is effective if the handle is small, or if you run the optimization only once. However, if you plan to run the optimization several times, you can save time by using one of the other two techniques.

2. Parallel constant If you plan to run an optimization several times, save time by transferring the objective function to the workers only once. This technique is especially effective when the function handle incorporates a large amount of data. Transfer the objective once by setting the function handle to a `parallel.pool.Constant` construct, as in this example.

```
load ionosphere
splits = optimizableVariable('splits',[1,100],'Type','integer');
minleaf = optimizableVariable('minleaf',[1,100],'Type','integer');
fun = @(params)kfoldLoss(fitctree(X,Y,'Kfold',5,...
    'MaxNumSplits',params.splits,'MinLeaf',params.minleaf));

C = copyFunctionHandleToWorkers(fun);
```

```
results1 = bayesopt(C,[splits,minleaf],'UseParallel',true);
results2 = bayesopt(C,[splits,minleaf],'UseParallel',true,...
    'MaxObjectiveEvaluations',50);
results3 = bayesopt(C,[splits,minleaf],'UseParallel',true,...
    'AcquisitionFunction','expected-improvement');
```

In this example, `copyFunctionHandleToWorkers` sends the function handle to the workers only once.

3. Create objective function on workers If you have a great deal of data to send to the workers, you can avoid loading the data in the client by using `spmd` to load the data on the workers. Use a `Composite` with `parallel.pool.Constant` to access the distributed objective functions.

```
% makeFun is at the end of this script
spmd
    fun = makeFun();
end

% ObjectiveFunction is now a Composite. Get a parallel.pool.Constant
% that refers to it, without copying it to the client:
C = parallel.pool.Constant(fun);

% You could also use the line
% C = parallel.pool.Constant(@MakeFun);
% In this case, you do not use spmd

% Call bayesopt, passing the Constant
splits = optimizableVariable('splits', [1 100]);
minleaf = optimizableVariable('minleaf', [1 100]);
bo = bayesopt(C,[splits minleaf],'UseParallel',true);

function f = makeFun()
load('ionosphere','X','Y');
f = @fun;
    function L = fun(Params)
        L = kfoldLoss(fitctree(X,Y, ...
            'KFold', 5,...
            'MaxNumSplits',Params.splits, ...
            'MinLeaf', Params.minleaf));
    end
end
```

In this example, the function handle exists only on the workers. The handle never appears on the client.

Differences in Parallel Bayesian Optimization Output

When `bayesopt` runs in parallel, the Bayesian optimization output includes these differences.

- **Iterative Display** — Iterative display includes a column showing the number of active workers. This is the number after `bayesopt` assigns a job to the next worker.
- **Plot Functions**
  - Objective Function Model plot (`@plotObjectiveModel`) shows the pending points (those points executing on parallel workers). The height of the points depends on the `ParallelMethod` name-value pair.

- Elapsed Time plot (`@plotElapsedTime`) shows the total elapsed time with the label **Real time** and the total objective function evaluation time, summed over all workers, with the label **Objective evaluation time (all workers)**. Objective evaluation time includes the time to start a worker on a job.

Bayesian Optimization Plot Functions

In this section...

Built-In Plot Functions

There are two sets of built-in plot functions.

Model Plots — Apply When D ≤ 2	Description
`@plotAcquisitionFunction`	Plot the acquisition function surface.
`@plotConstraintModels`	Plot each constraint model surface. Negative values indicate feasible points. Also plot a *P*(feasible) surface. Also plot the error model, if it exists, which ranges from –1 to 1. Negative values mean that the model probably does not error, positive values mean that it probably does error. The model is: Plotted error = 2*Probability(error) – 1.
`@plotObjectiveEvaluationTimeModel`	Plot the objective function evaluation time model surface.
`@plotObjectiveModel`	Plot the `fun` model surface, the estimated location of the minimum, and the location of the next proposed point to evaluate. For one-dimensional problems, plot envelopes one credible interval above and below the mean function, and envelopes one noise standard deviation above and below the mean.

Trace Plots — Apply to All D	Description
`@plotObjective`	Plot each observed function value versus the number of function evaluations.
`@plotObjectiveEvaluationTime`	Plot each observed function evaluation run time versus the number of function evaluations.
`@plotMinObjective`	Plot the minimum observed and estimated function values versus the number of function evaluations.
`@plotElapsedTime`	Plot three curves: the total elapsed time of the optimization, the total function evaluation time, and the total modeling and point selection time, all versus the number of function evaluations.

Note When there are coupled constraints, iterative display and plot functions can give counterintuitive results such as:

- A *minimum objective* plot can increase.
- The optimization can declare a problem infeasible even when it showed an earlier feasible point.

The reason for this behavior is that the decision about whether a point is feasible can change as the optimization progresses. `bayesopt` determines feasibility with respect to its constraint model, and this model changes as `bayesopt` evaluates points. So a "minimum objective" plot can increase when the minimal point is later deemed infeasible, and the iterative display can show a feasible point that is later deemed infeasible.

Custom Plot Function Syntax

A custom plot function has the same syntax as a custom output function (see "Bayesian Optimization Output Functions" on page 10-19):

```
stop = plotfun(results,state)
```

`bayesopt` passes the `results` and `state` variables to your function. Your function returns `stop`, which you set to `true` to halt the iterations, or to `false` to continue the iterations.

`results` is an object of class `BayesianOptimization` that contains the available information on the computations.

`state` has these possible values:

- `'initial'` — `bayesopt` is about to start iterating. Use this state to set up a plot or to perform other initializations.
- `'iteration'` — `bayesopt` just finished an iteration. Generally, you perform most of the plotting or other calculations in this state.
- `'done'` — `bayesopt` just finished its final iteration. Clean up plots or otherwise prepare for the plot function to shut down.

Create a Custom Plot Function

This example shows how to create a custom plot function for `bayesopt`. It further shows how to use information in the `UserData` property of a `BayesianOptimization` object.

Problem Statement

The problem is to find parameters of a Support Vector Machine (SVM) classification to minimize the cross-validated loss. The specific model is the same as in "Optimize a Cross-Validated SVM Classifier Using bayesopt" on page 10-45. Therefore, the objective function is essentially the same, except it also computes `UserData`, in this case the number of support vectors in an SVM model fitted to the current parameters.

Create a custom plot function that plots the number of support vectors in the SVM model as the optimization progresses. To give the plot function access to the number of support vectors, create a third output, `UserData`, to return the number of support vectors.

Objective Function

Create an objective function that computes the cross-validation loss for a fixed cross-validation partition, and that returns the number of support vectors in the resulting model.

```
function [f,viol,nsupp] = mysvmminfn(x,cdata,grp,c)
SVMModel = fitcsvm(cdata,grp,'KernelFunction','rbf',...
    'KernelScale',x.sigma,'BoxConstraint',x.box);
f = kfoldLoss(crossval(SVMModel,'CVPartition',c));
viol = [];
nsupp = sum(SVMModel.IsSupportVector);
end
```

Custom Plot Function

Create a custom plot function that uses the information computed in `UserData`. Have the function plot both the current number of constraints and the number of constraints for the model with the best objective function found.

```
function stop = svmsuppvec(results,state)
persistent hs nbest besthist nsupptrace
stop = false;
switch state
    case 'initial'
        hs = figure;
        besthist = [];
        nbest = 0;
        nsupptrace = [];
    case 'iteration'
        figure(hs)
        nsupp = results.UserDataTrace{end};   % get nsupp from UserDataTrace property.
        nsupptrace(end+1) = nsupp; % accumulate nsupp values in a vector.
        if (results.ObjectiveTrace(end) == min(results.ObjectiveTrace)) || (length(results.Objec
            nbest = nsupp;
        end
        besthist = [besthist,nbest];
        plot(1:length(nsupptrace),nsupptrace,'b',1:length(besthist),besthist,'r--')
        xlabel 'Iteration number'
        ylabel 'Number of support vectors'
        title 'Number of support vectors at each iteration'
        legend('Current iteration','Best objective','Location','best')
        drawnow
end
```

Set Up the Model

Generate ten base points for each class.

```
rng default
grnpop = mvnrnd([1,0],eye(2),10);
redpop = mvnrnd([0,1],eye(2),10);
```

Generate 100 data points of each class.

```
redpts = zeros(100,2);grnpts = redpts;
for i = 1:100
    grnpts(i,:) = mvnrnd(grnpop(randi(10),:),eye(2)*0.02);
    redpts(i,:) = mvnrnd(redpop(randi(10),:),eye(2)*0.02);
end
```

Put the data into one matrix, and make a vector `grp` that labels the class of each point.

```
cdata = [grnpts;redpts];
grp = ones(200,1);
% Green label 1, red label -1
grp(101:200) = -1;
```

Check the basic classification of all the data using the default SVM parameters.

```
SVMModel = fitcsvm(cdata,grp,'KernelFunction','rbf','ClassNames',[-1 1]);
```

Set up a partition to fix the cross validation. Without this step, the cross validation is random, so the objective function is not deterministic.

```
c = cvpartition(200,'KFold',10);
```

Check the cross-validation accuracy of the original fitted model.

```
loss = kfoldLoss(fitcsvm(cdata,grp,'CVPartition',c,...
    'KernelFunction','rbf','BoxConstraint',SVMModel.BoxConstraints(1),...
    'KernelScale',SVMModel.KernelParameters.Scale))
```

```
loss =

    0.1350
```

Prepare Variables for Optimization

The objective function takes an input `z = [rbf_sigma,boxconstraint]` and returns the cross-validation loss value of `z`. Take the components of `z` as positive, log-transformed variables between `1e-5` and `1e5`. Choose a wide range because you do not know which values are likely to be good.

```
sigma = optimizableVariable('sigma',[1e-5,1e5],'Transform','log');
box = optimizableVariable('box',[1e-5,1e5],'Transform','log');
```

Set Plot Function and Call the Optimizer

Search for the best parameters `[sigma,box]` using `bayesopt`. For reproducibility, choose the `'expected-improvement-plus'` acquisition function. The default acquisition function depends on run time, so it can give varying results.

Plot the number of support vectors as a function of the iteration number, and plot the number of support vectors for the best parameters found.

```
obj = @(x)mysvmminfn(x,cdata,grp,c);
results = bayesopt(obj,[sigma,box],...
    'IsObjectiveDeterministic',true,'Verbose',0,...
    'AcquisitionFunctionName','expected-improvement-plus',...
    'PlotFcn',{@svmsuppvec,@plotObjectiveModel,@plotMinObjective})
```

```
results =

  BayesianOptimization with properties:

                      ObjectiveFcn: @(x)mysvmminfn(x,cdata,grp,c)
```

```

Bayesian Optimization Output Functions

In this section...

What Is a Bayesian Optimization Output Function?

An output function is a function that is called at the end of every iteration of `bayesopt`. An output function can halt iterations. It can also create plots, save information to your workspace or to a file, or perform any other calculation you like.

Other than halting the iterations, output functions cannot change the course of a Bayesian optimization. They simply monitor the progress of the optimization.

Built-In Output Functions

These built-in output functions save your optimization results to a file or to the workspace.

- `@assignInBase` — Saves your results after each iteration to a variable named `'BayesoptResults'` in your workspace. To choose a different name, pass the `SaveVariableName` name-value pair.
- `@saveToFile` — Saves your results after each iteration to a file named `'BayesoptResults.mat'` in your current folder. To choose a different name or folder, pass the `SaveFileName` name-value pair.

For example, to save the results after each iteration to a workspace variable named `'BayesIterations'`,

```
results = bayesopt(fun,vars,'OutputFcn',@assignInBase, ...
    'SaveVariableName','BayesIterations')
```

Custom Output Functions

Write a custom output function with signature

```
stop = outputfun(results,state)
```

`bayesopt` passes the `results` and `state` variables to your function. Your function returns `stop`, which you set to `true` to halt the iterations, or to `false` to allow the iterations to continue.

`results` is an object of class `BayesianOptimization`. `results` contains the available information on the computations so far.

`state` has possible values:

- `'initial'` — `bayesopt` is about to start iterating.
- `'iteration'` — `bayesopt` just finished an iteration.

- `'done'` — `bayesopt` just finished its final iteration.

For an example, see “Bayesian Optimization Output Function” on page 10-20.

Bayesian Optimization Output Function

This example shows how to use a custom output function with Bayesian optimization. The output function halts the optimization when the objective function, which is the cross-validation error rate, drops below 13%. The output function also plots the time for each iteration.

```
function stop = outputfun(results,state)
persistent h
stop = false;
switch state
    case 'initial'
        h = figure;
    case 'iteration'
        if results.MinObjective < 0.13
            stop = true;
        end
        figure(h)
        tms = results.IterationTimeTrace;
        plot(1:numel(tms),tms')
        xlabel('Iteration Number')
        ylabel('Time for Iteration')
        title('Time for Each Iteration')
        drawnow
end
```

The objective function is the cross validation loss of the KNN classification of the `ionosphere` data. Load the data and, for reproducibility, set the default random stream.

```
load ionosphere
rng default
```

Optimize over neighborhood size from 1 through 30, and for three distance metrics.

```
num = optimizableVariable('n',[1,30],'Type','integer');
dst = optimizableVariable('dst',{'chebychev','euclidean','minkowski'},'Type','categorical');
vars = [num,dst];
```

Set the cross-validation partition and objective function. For reproducibility, set the `AcquisitionFunctionName` to `'expected-improvement-plus'`. Run the optimization.

```
c = cvpartition(351,'Kfold',5);
fun = @(x)kfoldLoss(fitcknn(X,Y,'CVPartition',c,'NumNeighbors',x.n,...
    'Distance',char(x.dst),'NSMethod','exhaustive'));
results = bayesopt(fun,vars,'OutputFcn',@outputfun,...
    'AcquisitionFunctionName','expected-improvement-plus');
```

```

Bayesian Optimization Workflow

In this section...

What Is Bayesian Optimization?

Optimization, in its most general form, is the process of locating a point that minimizes a real-valued function called the objective function. Bayesian optimization is the name of one such process. Bayesian optimization internally maintains a Gaussian process model of the objective function, and uses objective function evaluations to train the model. One innovation in Bayesian optimization is the use of an acquisition function, which the algorithm uses to determine the next point to evaluate. The acquisition function can balance sampling at points that have low modeled objective functions, and exploring areas that have not yet been modeled well. For details, see “Bayesian Optimization Algorithm” on page 10-2.

Bayesian optimization is part of Statistics and Machine Learning Toolbox because it is well-suited to optimizing hyperparameters of classification and regression algorithms. A hyperparameter is an internal parameter of a classifier or regression function, such as the box constraint of a support vector machine, or the learning rate of a robust classification ensemble. These parameters can strongly affect the performance of a classifier or regressor, and yet it is typically difficult or time-consuming to optimize them. See “Bayesian Optimization Characteristics” on page 10-27.

Typically, optimizing the hyperparameters means that you try to minimize the cross-validation loss of a classifier or regression.

Ways to Perform Bayesian Optimization

You can perform a Bayesian optimization in several ways:

- `fitcauto` and `fitrauto` — Pass predictor and response data to the `fitcauto` or `fitrauto` function to optimize across a selection of model types and hyperparameter values. Unlike other approaches, using `fitcauto` or `fitrauto` does not require you to specify a single model before the optimization; model selection is part of the optimization process. The optimization minimizes cross-validation loss, which is modeled using a multi-`TreeBagger` model in `fitcauto` and a multi-`RegressionGP` model in `fitrauto`, rather than a single Gaussian process regression model as used in other approaches. See “Bayesian Optimization” on page 33-1571 for `fitcauto` and “Bayesian Optimization” on page 33-2113 for `fitrauto`.
- Classification Learner and Regression Learner apps — Choose **Optimizable** models in the machine learning apps and automatically tune their hyperparameter values by using Bayesian optimization. The optimization minimizes the model loss based on the selected validation options. This approach has fewer tuning options than using a fit function, but allows you to perform

Bayesian optimization directly in the apps. See “Hyperparameter Optimization in Classification Learner App” on page 23-54 and “Hyperparameter Optimization in Regression Learner App” on page 24-30.

- Fit function — Include the `OptimizeHyperparameters` name-value pair in many fitting functions to apply Bayesian optimization automatically. The optimization minimizes cross-validation loss. This approach gives you fewer tuning options than using `bayesopt`, but enables you to perform Bayesian optimization more easily. See “Bayesian Optimization Using a Fit Function” on page 10-26.
- `bayesopt` — Exert the most control over your optimization by calling `bayesopt` directly. This approach requires you to write an objective function, which does not have to represent cross-validation loss. See “Bayesian Optimization Using bayesopt” on page 10-26.

Bayesian Optimization Using a Fit Function

To minimize the error in a cross-validated response via Bayesian optimization, follow these steps.

1. Choose your classification or regression solver among `fitcdiscr`, `fitcecoc`, `fitcensemble`, `fitckernel`, `fitcknn`, `fitclinear`, `fitcnb`, `fitcsvm`, `fitctree`, `fitrensemble`, `fitrgp`, `fitrkernel`, `fitrlinear`, `fitrsvm`, or `fitrtree`.
2. Decide on the hyperparameters to optimize, and pass them in the `OptimizeHyperparameters` name-value pair. For each fit function, you can choose from a set of hyperparameters. See Eligible Hyperparameters for Fit Functions, or use the `hyperparameters` function, or consult the fit function reference page.

   You can pass a cell array of parameter names. You can also set `'auto'` as the `OptimizeHyperparameters` value, which chooses a typical set of hyperparameters to optimize, or `'all'` to optimize all available parameters.
3. For ensemble fit functions `fitcecoc`, `fitcensemble`, and `fitrensemble`, also include parameters of the weak learners in the `OptimizeHyperparameters` cell array.
4. Optionally, create an options structure for the `HyperparameterOptimizationOptions` name-value pair. See “Hyperparameter Optimization Options for Fit Functions” on page 10-29.
5. Call the fit function with the appropriate name-value pairs.

For examples, see “Optimize an SVM Classifier Fit Using Bayesian Optimization” on page 10-55 and “Optimize a Boosted Regression Ensemble” on page 10-63. Also, every fit function reference page contains a Bayesian optimization example.

Bayesian Optimization Using bayesopt

To perform a Bayesian optimization using `bayesopt`, follow these steps.

1. Prepare your variables. See “Variables for a Bayesian Optimization” on page 10-33.
2. Create your objective function. See “Bayesian Optimization Objective Functions” on page 10-36. If necessary, create constraints, too. See “Constraints in Bayesian Optimization” on page 10-38. To include extra parameters in an objective function, see “Parameterizing Functions”.
3. Decide on options, meaning the `bayseopt` `Name,Value` on page 33-133 pairs. You are not required to pass any options to `bayesopt` but you typically do, especially when trying to improve a solution.
4. Call `bayesopt`.

5 Examine the solution. You can decide to resume the optimization by using `resume`, or restart the optimization, usually with modified options.

For an example, see “Optimize a Cross-Validated SVM Classifier Using bayesopt” on page 10-45.

Bayesian Optimization Characteristics

Bayesian optimization algorithms are best suited to these problem types.

Characteristic	Details
Low dimension	Bayesian optimization works best in a low number of dimensions, typically 10 or fewer. While Bayesian optimization can solve some problems with a few dozen variables, it is not recommended for dimensions higher than about 50.
Expensive objective	Bayesian optimization is designed for objective functions that are slow to evaluate. It has considerable overhead, typically several seconds for each iteration.
Low accuracy	Bayesian optimization does not necessarily give very accurate results. If you have a deterministic objective function, you can sometimes improve the accuracy by starting a standard optimization algorithm from the `bayesopt` solution.
Global solution	Bayesian optimization is a global technique. Unlike many other algorithms, to search for a global solution you do not have to start the algorithm from various initial points.
Hyperparameters	Bayesian optimization is well-suited to optimizing hyperparameters of another function. A hyperparameter is a parameter that controls the behavior of a function. For example, the `fitcsvm` function fits an SVM model to data. It has hyperparameters `BoxConstraint` and `KernelScale` for its `'rbf'` `KernelFunction`. For an example of Bayesian optimization applied to hyperparameters, see “Optimize a Cross-Validated SVM Classifier Using bayesopt” on page 10-45.

Parameters Available for Fit Functions

Eligible Hyperparameters for Fit Functions

Function Name	Eligible Parameters

`fitcdiscr`	`Delta`
	`Gamma`
	`DiscrimType`

`fitcecoc`	`Coding` eligible `fitcdiscr` parameters for `'Learners','discriminant'` eligible `fitckernel` parameters for `'Learners','kernel'` eligible `fitcknn` parameters for `'Learners','knn'` eligible `fitclinear` parameters for `'Learners','linear'` eligible `fitcsvm` parameters for `'Learners','svm'` eligible `fitctree` parameters for `'Learners','tree'`

Hyperparameter Optimization Options for Fit Functions

When optimizing using a fit function, you have these options available in the `HyperparameterOptimizationOptions` name-value pair. Give the value as a structure. All fields in the structure are optional.

Field Name	Values	Default
`Optimizer`	• `'bayesopt'` — Use Bayesian optimization. Internally, this setting calls `bayesopt`. • `'gridsearch'` — Use grid search with `NumGridDivisions` values per dimension. • `'randomsearch'` — Search at random among `MaxObjectiveEvaluations` points. `'gridsearch'` searches in a random order, using uniform sampling without replacement from the grid. After optimization, you can get a table in grid order by using the command `sortrows(Mdl.HyperparameterOptimizationResults)`.	`'bayesopt'`
`AcquisitionFunctionName`	• `'expected-improvement-per-second-plus'` • `'expected-improvement'` • `'expected-improvement-plus'` • `'expected-improvement-per-second'` • `'lower-confidence-bound'` • `'probability-of-improvement'` Acquisition functions whose names include `per-second` do not yield reproducible results because the optimization depends on the runtime of the objective function. Acquisition functions whose names include `plus` modify their behavior when they are overexploiting an area. For more details, see “Acquisition Function Types” on page 10-3.	`'expected-improvement-per-second-plus'`
`MaxObjectiveEvaluations`	Maximum number of objective function evaluations.	`30` for `'bayesopt'` or `'randomsearch'`, and the entire grid for `'gridsearch'`
`MaxTime`	Time limit, specified as a positive real. The time limit is in seconds, as measured by `tic` and `toc`. Run time can exceed `MaxTime` because `MaxTime` does not interrupt function evaluations.	`Inf`
`NumGridDivisions`	For `'gridsearch'`, the number of values in each dimension. The value can be a vector of positive integers giving the number of values for each dimension, or a scalar that applies to all dimensions. This field is ignored for categorical variables.	`10`

Field Name	Values	Default
`ShowPlots`	Logical value indicating whether to show plots. If `true`, this field plots the best objective function value against the iteration number. If there are one or two optimization parameters, and if `Optimizer` is `'bayesopt'`, then `ShowPlots` also plots a model of the objective function against the parameters.	`true`
`SaveIntermediateResults`	Logical value indicating whether to save results when `Optimizer` is `'bayesopt'`. If `true`, this field overwrites a workspace variable named `'BayesoptResults'` at each iteration. The variable is a `BayesianOptimization` object.	`false`
`Verbose`	Display to the command line. • `0` — No iterative display • `1` — Iterative display • `2` — Iterative display with extra information For details, see the `bayesopt` `Verbose` name-value pair argument.	`1`
`UseParallel`	Logical value indicating whether to run Bayesian optimization in parallel, which requires Parallel Computing Toolbox. Due to the nonreproducibility of parallel timing, parallel Bayesian optimization does not necessarily yield reproducible results. For details, see “Parallel Bayesian Optimization” on page 10-7.	`false`
`Repartition`	Logical value indicating whether to repartition the cross-validation at every iteration. If `false`, the optimizer uses a single partition for the optimization. `true` usually gives the most robust results because this setting takes partitioning noise into account. However, for good results, `true` requires at least twice as many function evaluations.	`false`
Use no more than one of the following three field names.		
`CVPartition`	A `cvpartition` object, as created by `cvpartition`.	`'Kfold',5` if you do not specify any cross-validation field
`Holdout`	A scalar in the range `(0,1)` representing the holdout fraction.	
`Kfold`	An integer greater than 1.

Variables for a Bayesian Optimization

In this section...

Syntax for Creating Optimization Variables

For each variable in your objective function, create a variable description object using `optimizableVariable`. Each variable has a unique name and a range of values. The minimal syntax for variable creation is

```
variable = optimizableVariable(Name,Range)
```

This function creates a real variable that ranges from the lower bound `Range(1)` to the upper bound `Range(2)`.

You can specify three types of variables in the `Type` name-value pair:

- `'real'` — Continuous real values between finite bounds. Give `Range` as the two-element vector `[lower upper]`, which represent the lower and upper bounds.
- `'integer'` — Integer values between finite bounds, similar to `'real'`.
- `'categorical'` — Cell array of names of possible values, such as `{'red','green','blue'}`, that you specify in the `Range` argument.

For `'real'` or `'integer'` variables, you can specify that `bayesopt` searches in a log-scaled space by setting the `Transform` name-value pair to `'log'`. For this transformation, ensure that the lower bound in the `Range` is strictly positive.

Include variables for `bayesopt` as a vector in the second argument.

```
results = bayesopt(fun,[xvar,ivar,rvar])
```

To exclude a variable from an optimization, set `Optimize` to `false`, either in the name-value pair of `optimizableVariable`, or by dot notation:

```
xvar.Optimize = false;
```

Tip

- There are two names associated with an `optimizableVariable`:
  - The MATLAB workspace variable name
  - The name of the variable in the optimization

  For example,

  ```
  xvar = optimizableVariable('spacevar',[1,100]);
  ```

  `xvar` is the MATLAB workspace variable, and `'spacevar'` is the variable in the optimization.

  Use these names as follows:

- Use `xvar` as an element in the vector of variables you pass to `bayesopt`. For example,

  ```
  results = bayesopt(fun,[xvar,tvar])
  ```

- Use `'spacevar'` as the name of the variable in the optimization. For example, in an objective function,

  ```
  function objective = mysvmfun(x,cdata,grp)
  SVMModel = fitcsvm(cdata,grp,'KernelFunction','rbf',...
      'BoxConstraint',x.spacevar,...
      'KernelScale',x.tvar);
  objective = kfoldLoss(crossval(SVMModel));
  ```

Variables for Optimization Examples

Real variable from 0 to 1:

```
var1 = optimizableVariable('xvar',[0 1])
```

```
var1 =
  optimizableVariable with properties:

         Name: 'xvar'
        Range: [0 1]
         Type: 'real'
    Transform: 'none'
     Optimize: 1
```

Integer variable from 1 to 1000 on a log scale:

```
var2 = optimizableVariable('ivar',[1 1000],'Type','integer','Transform','log')
```

```
var2 =
  optimizableVariable with properties:

         Name: 'ivar'
        Range: [1 1000]
         Type: 'integer'
    Transform: 'log'
     Optimize: 1
```

Categorical variable of rainbow colors:

```
var3 = optimizableVariable('rvar',{'r' 'o' 'y' 'g' 'b' 'i' 'v'},'Type','categorical')
```

```
var3 =
  optimizableVariable with properties:

         Name: 'rvar'
        Range: {'r'  'o'  'y'  'g'  'b'  'i'  'v'}
         Type: 'categorical'
    Transform: 'none'
     Optimize: 1
```

Bayesian Optimization Objective Functions

In this section...

Objective Function Syntax

`bayesopt` attempts to minimize an objective function. If, instead, you want to maximize a function, set the objective function to the negative of the function you want to maximize. See “Maximizing Functions”. To include extra parameters in an objective function, see “Parameterizing Functions”.

`bayesopt` passes a table of variables to the objective function. The variables have the names and types that you declare; see “Variables for a Bayesian Optimization” on page 10-33.

The objective function has the following signature:

```
[objective,coupledconstraints,userdata] = fun(x)
```

1. `objective` — The objective function value at `x`, a real scalar.
2. `coupledconstraints` — Value of coupled constraints, if any (optional output), a vector of real values. A negative value indicates that a constraint is satisfied, a positive value indicates that it is not satisfied. For details, see “Coupled Constraints” on page 10-40.
3. `userdata` — Optional data that your function can return for further uses, such as plotting or logging (optional output). For an example, see “Bayesian Optimization Plot Functions” on page 10-11.

Objective Function Example

This objective function returns the loss in a cross-validated fit of an SVM model with parameters `box` and `sigma`. The objective also returns a coupled constraint function that is positive (infeasible) when the number of support vectors exceeds 100 (100 is feasible, 101 is not).

```
function [objective,constraint] = mysvmfun(x,cdata,grp)
SVMModel = fitcsvm(cdata,grp,'KernelFunction','rbf',...
    'BoxConstraint',x.box,...
    'KernelScale',x.sigma);
objective = kfoldLoss(crossval(SVMModel));
constraint = sum(SVMModel.SupportVectors) - 100.5;
```

To use the objective function, assuming that `cdata` and `grp` exist in the workspace, create an anonymous function that incorporates the data, as described in “Parameterizing Functions”.

```
fun = @(x)mysvmfun(x,cdata,grp);
results = bayesopt(fun,vars) % Assumes vars exists
```

Objective Function Errors

`bayesopt` deems your objective function to return an error when the objective function returns anything other than a finite real scalar. For example, if your objective function returns a complex

value, `NaN`, `Inf`, or matrix with more than one entry, then `bayesopt` deems that your objective function errors. If `bayesopt` encounters an error, it continues to optimize, and automatically updates a Bayesian model of points that lead to errors. This Bayesian model is the Error model. `bayesopt` incorporates the Error model as a coupled constraint. See “Coupled Constraints” on page 10-40.

When errors exist, you can plot the Error model by setting the `bayesopt` `PlotFcn` name-value pair `@plotConstraintModels`. Or you can retrospectively call `plot` on the results of a Bayesian optimization, and include `@plotConstraintModels`.

Constraints in Bayesian Optimization

In this section...

Bounds

`bayesopt` requires finite bounds on all variables. (`categorical` variables are, by nature, bounded in their possible values.) Pass the lower and upper bounds for real and integer-valued variables in `optimizableVariable`.

`bayesopt` uses these bounds to sample points, either uniformly or log-scaled. You set the scaling for sampling in `optimizableVariable`.

For example, to constrain a variable `X1` to values between `1e-6` and `1e3`, scaled logarithmically,

```
xvar = optimizableVariable('X1',[1e-6,1e3],'Transform','log')
```

`bayesopt` includes the endpoints in its range. Therefore, you cannot use 0 as a lower bound for a log-transformed variable.

Tip To use a zero lower bound in a log-transformed variable, set the lower bound to `1`, then inside the objective function use `x-1`.

Deterministic Constraints — XConstraintFcn

Sometimes your problem is valid or well-defined only for points in a certain region, called the feasible region. A deterministic constraint is a deterministic function that returns `true` when a point is feasible, and `false` when a point is infeasible. So deterministic constraints are not stochastic, and they are not functions of a group of points, but of individual points.

Tip It is more efficient to use `optimizableVariable` bounds, instead of deterministic constraints, to confine the optimization to a rectangular region.

Write a deterministic constraint function using the signature

```
tf = xconstraint(X)
```

- `X` is a width-D table of arbitrary height.
- `tf` is a logical column vector, where `tf(i) = true` exactly when `X(i,:)` is feasible.

Pass the deterministic constraint function in the `bayesopt` `XConstraintFcn` name-value pair. For example,

```
results = bayesopt(fun,vars,'XConstraintFcn',@xconstraint)
```

`bayesopt` evaluates deterministic constraints on thousands of points, and so runs faster when your constraint function is vectorized. See “Vectorization”.

For example, suppose that the variables named `'x1'` and `'x2'` are feasible when the norm of the vector `[x1 x2]` is less than `6`, and when `x1 <= x2`. The following constraint function evaluates these constraints.

```
function tf = xconstraint(X)
tf1 = sqrt(X.x1.^2 + X.x2.^2) < 6;
tf2 = X.x1 <= X.x2;
tf = tf1 & tf2;
```

Conditional Constraints — ConditionalVariableFcn

Conditional constraints are functions that enforce one of the following two conditions:

- When some variables have certain values, other variables are set to given values.
- When some variables have certain values, other variables have `NaN` or, for categorical variables, `<undefined>` values.

Specify a conditional constraint by setting the `bayesopt` `ConditionalVariableFcn` name-value pair to a function handle, say `@condvariablefcn`. The `@condvariablefcn` function must have the signature

```
Xnew = condvariablefcn(X)
```

- `X` is a width-`D` table of arbitrary height.
- `Xnew` is a table the same type and size as `X`.

`condvariablefcn` sets `Xnew` to be equal to `X`, except it also sets the relevant variables in each row of `Xnew` to the correct values for the constraint.

Note If you have both conditional constraints and deterministic constraints, `bayesopt` applies the conditional constraints first. Therefore, if your conditional constraint function can set variables to `NaN` or `<undefined>`, ensure that your deterministic constraint function can process these values correctly.

Conditional constraints ensure that variable values are sensible. Therefore, `bayesopt` applies conditional constraints first so that all passed values are sensible.

Conditional Constraint That Sets a Variable Value

Suppose that you are optimizing a classification using `fitcdiscr`, and you optimize over both the `'DiscrimType'` and `'Gamma'` name-value pair arguments. When `'DiscrimType'` is one of the quadratic types, `'Gamma'` must be `0` or the solver errors. In that case, use this conditional constraint function:

```
function XTable = fitcdiscrCVF(XTable)
% Gamma must be 0 if discrim type is a quadratic
XTable.Gamma(ismember(XTable.DiscrimType, {'quadratic',...
```

```
        'diagQuadratic','pseudoQuadratic'})) = 0;
end
```

Conditional Constraint That Sets a Variable to NaN

Suppose that you are optimizing a classification using `fitcsvm`, and you optimize over both the `'KernelFunction'` and `'PolynomialOrder'` name-value pair arguments. When `'KernelFunction'` is not `'polynomial'`, the `'PolynomialOrder'` setting does not apply. The following function enforces this conditional constraint.

```
function Xnew = condvariablefcn(X)
Xnew = X;
Xnew.PolynomialOrder(Xnew.KernelFunction ~= 'polynomial') = NaN;
```

You can save a line of code as follows:

```
function X = condvariablefcn(X)
X.PolynomialOrder(Xnew.KernelFunction ~= 'polynomial') = NaN;
```

In addition, define an objective function that does not pass the `'PolynomialOrder'` name-value pair argument to `fitcsvm` when the value of `'PolynomialOrder'` is `NaN`.

```
fun = @(X)mysvmfun(X,predictors,responce,c)

function objective = mysvmfun(X,predictors,response,c)
    args = {predictors,response, ...
        'CVPartition',c, ...
        'KernelFunction',X.KernelFunction};
    if ~isnan(X.PolynomialOrder)
        args = [args,{'PolynomialOrder',X.PolynomialOrder}];
    end
    objective = kfoldLoss(fitcsvm(args{:}));
end
```

Coupled Constraints

Coupled constraints are constraints that you can evaluate only by calling the objective function. These constraints can be stochastic or deterministic. Return these constraint values from your objective function in the second argument. See “Bayesian Optimization Objective Functions” on page 10-36.

The objective function returns a numeric vector for the coupled constraints, one entry for each coupled constraint. For each entry, a negative value indicates that the constraint is satisfied (also called feasible). A positive value indicates that the constraint is not satisfied (infeasible).

`bayesopt` automatically creates a coupled constraint, called the Error constraint, for every run. This constraint enables `bayesopt` to model points that cause errors in objective function evaluation. For details, see “Objective Function Errors” on page 10-36 and `predictError`.

If you have coupled constraints in addition to the Error constraint:

- Include the `NumCoupledConstraints` name-value pair in your `bayesopt` call (required). Do not include the Error constraint in this number.
- If any of your coupled constraints are stochastic, include the `AreCoupledConstraintsDeterministic` name-value pair and pass `false` for any stochastic constraint.

Observe the coupled constraint values in each iteration by setting the `bayesopt` `Verbose` name-value pair to `1` or `2`.

Note When there are coupled constraints, iterative display and plot functions can give counterintuitive results such as:

- A *minimum objective* plot can increase.
- The optimization can declare a problem infeasible even when it showed an earlier feasible point.

The reason for this behavior is that the decision about whether a point is feasible can change as the optimization progresses. `bayesopt` determines feasibility with respect to its constraint model, and this model changes as `bayesopt` evaluates points. So a "minimum objective" plot can increase when the minimal point is later deemed infeasible, and the iterative display can show a feasible point that is later deemed infeasible.

For an example, see "Bayesian Optimization with Coupled Constraints" on page 10-41.

Bayesian Optimization with Coupled Constraints

A coupled constraint is one that can be evaluated only by evaluating the objective function. In this case, the objective function is the cross-validated loss of an SVM model. The coupled constraint is that the number of support vectors is no more than 100. The model details are in "Optimize a Cross-Validated SVM Classifier Using bayesopt" on page 10-45.

Create the data for classification.

```
rng default
grnpop = mvnrnd([1,0],eye(2),10);
redpop = mvnrnd([0,1],eye(2),10);
redpts = zeros(100,2);
grnpts = redpts;
for i = 1:100
    grnpts(i,:) = mvnrnd(grnpop(randi(10),:),eye(2)*0.02);
    redpts(i,:) = mvnrnd(redpop(randi(10),:),eye(2)*0.02);
end
cdata = [grnpts;redpts];
grp = ones(200,1);
grp(101:200) = -1;
c = cvpartition(200,'KFold',10);
sigma = optimizableVariable('sigma',[1e-5,1e5],'Transform','log');
box = optimizableVariable('box',[1e-5,1e5],'Transform','log');
```

The objective function is the cross-validation loss of the SVM model for partition `c`. The coupled constraint is the number of support vectors minus 100.5. This ensures that 100 support vectors give a negative constraint value, but 101 support vectors give a positive value. The model has 200 data points, so the coupled constraint values range from -99.5 (there is always at least one support vector) to 99.5. Positive values mean the constraint is not satisfied.

```
function [objective,constraint] = mysvmfun(x,cdata,grp,c)
SVMModel = fitcsvm(cdata,grp,'KernelFunction','rbf',...
    'BoxConstraint',x.box,...
    'KernelScale',x.sigma);
```

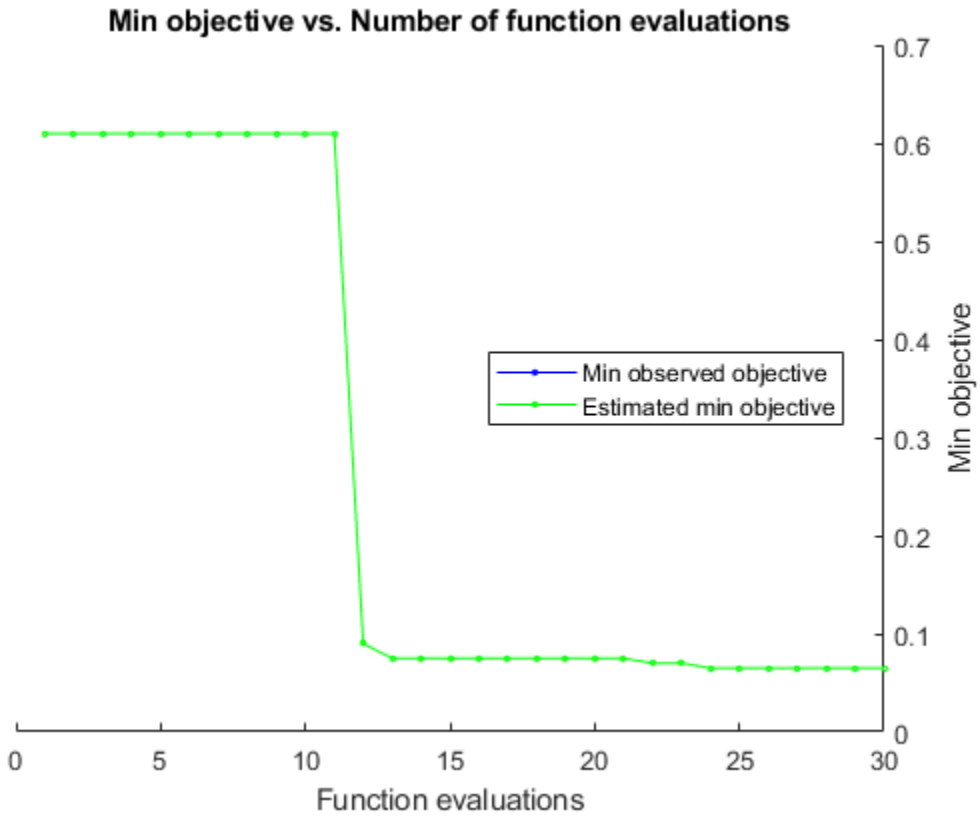
```
cvModel = crossval(SVMModel,'CVPartition',c);
objective = kfoldLoss(cvModel);
constraint = sum(SVMModel.IsSupportVector)-100.5;
```

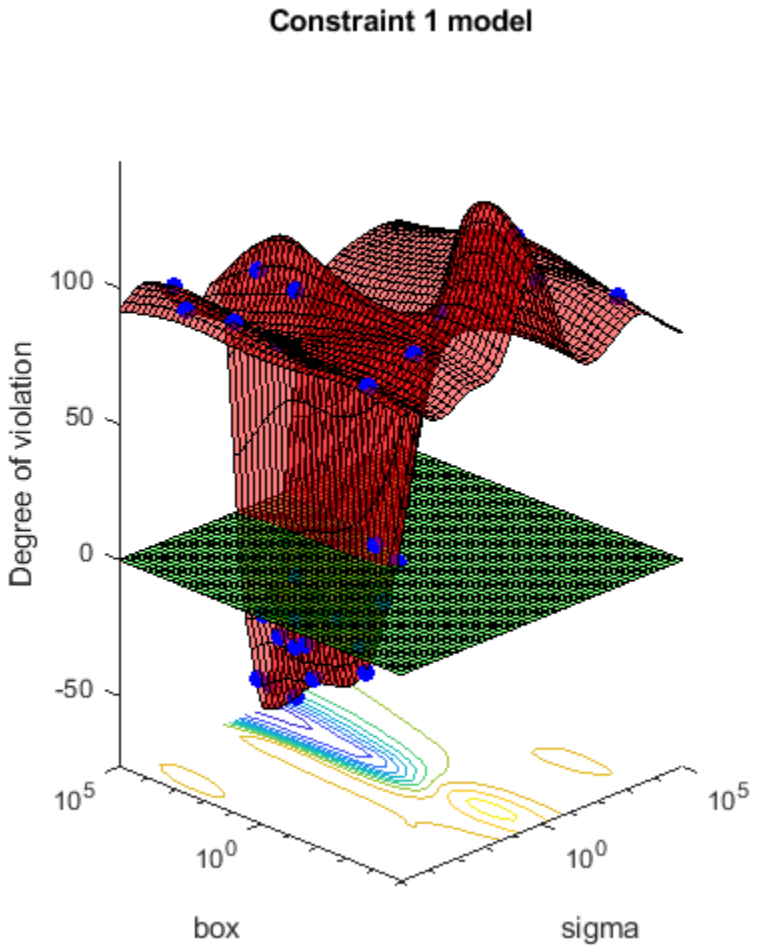
Pass the partition `c` and fitting data `cdata` and `grp` to the objective function `fun` by creating `fun` as an anonymous function that incorporates this data. See “Parameterizing Functions”.

```
fun = @(x)mysvmfun(x,cdata,grp,c);
```

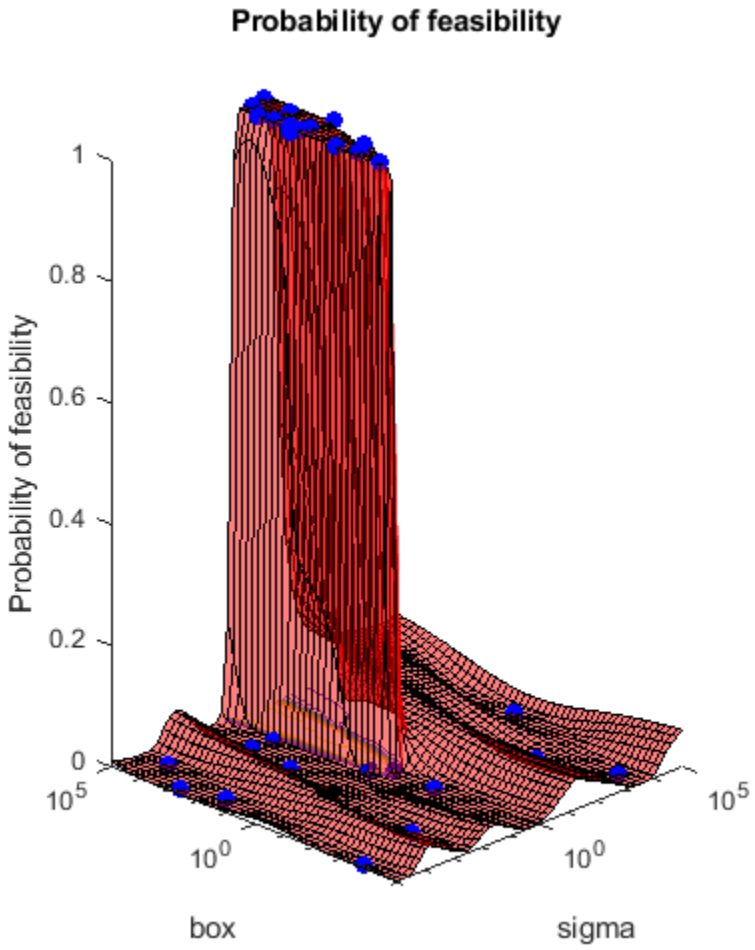
Set the `NumCoupledConstraints` to `1` so the optimizer knows that there is a coupled constraint. Set options to plot the constraint model.

```
results = bayesopt(fun,[sigma,box],'IsObjectiveDeterministic',true,...
    'NumCoupledConstraints',1,'PlotFcn',...
    {@plotMinObjective,@plotConstraintModels},...
    'AcquisitionFunctionName','expected-improvement-plus','Verbose',0);
```





Constraint 1 model
Degree of violation
100
50
0
-50
10^5
10^0
box
10^5
10^0
sigma



Most points lead to an infeasible number of support vectors.

Optimize a Cross-Validated SVM Classifier Using bayesopt

This example shows how to optimize an SVM classification using the `bayesopt` function. The classification works on locations of points from a Gaussian mixture model. In *The Elements of Statistical Learning*, Hastie, Tibshirani, and Friedman (2009), page 17 describes the model. The model begins with generating 10 base points for a "green" class, distributed as 2-D independent normals with mean (1,0) and unit variance. It also generates 10 base points for a "red" class, distributed as 2-D independent normals with mean (0,1) and unit variance. For each class (green and red), generate 100 random points as follows:

1. Choose a base point *m* of the appropriate color uniformly at random.
2. Generate an independent random point with 2-D normal distribution with mean *m* and variance I/5, where I is the 2-by-2 identity matrix. In this example, use a variance I/50 to show the advantage of optimization more clearly.

After generating 100 green and 100 red points, classify them using `fitcsvm`. Then use `bayesopt` to optimize the parameters of the resulting SVM model with respect to cross validation.

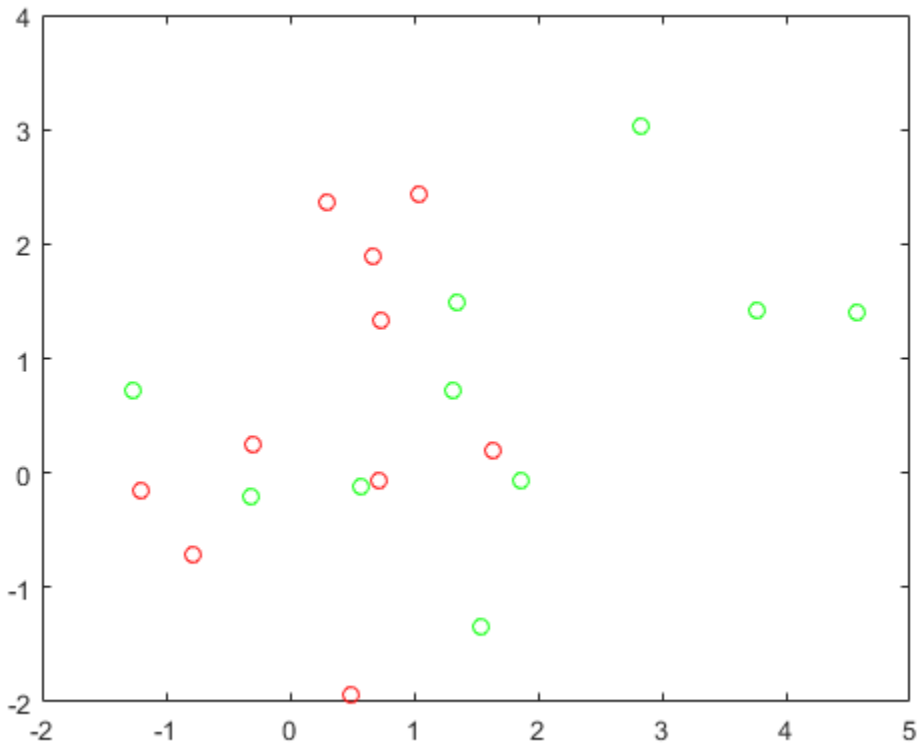
Generate the Points and Classifier

Generate the 10 base points for each class.

```
rng default
grnpop = mvnrnd([1,0],eye(2),10);
redpop = mvnrnd([0,1],eye(2),10);
```

View the base points.

```
plot(grnpop(:,1),grnpop(:,2),'go')
hold on
plot(redpop(:,1),redpop(:,2),'ro')
hold off
```



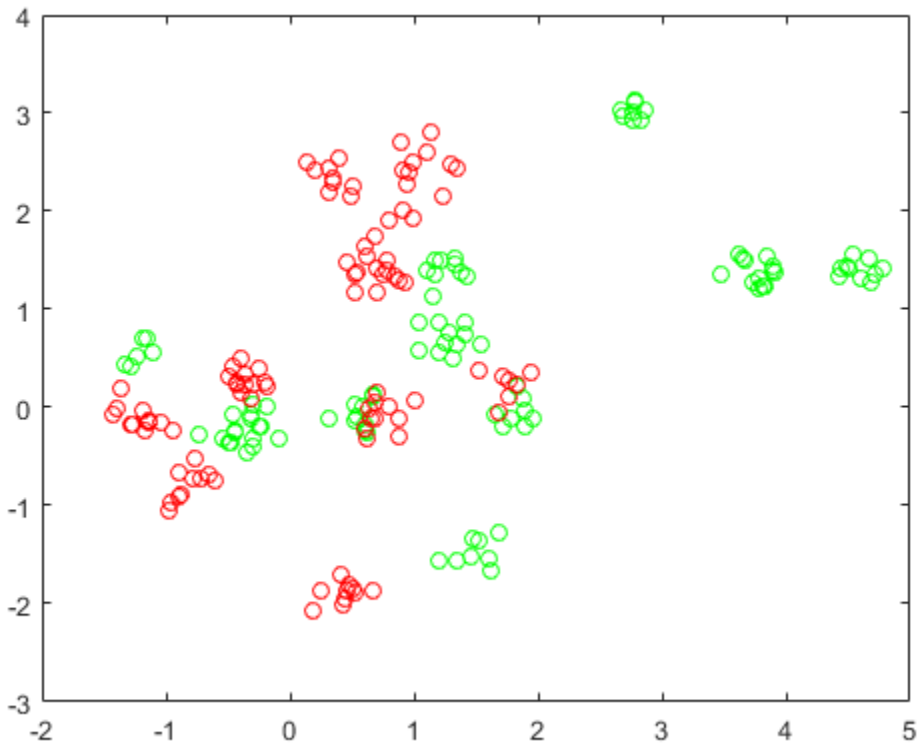
Since some red base points are close to green base points, it can be difficult to classify the data points based on location alone.

Generate the 100 data points of each class.

```
redpts = zeros(100,2);grnpts = redpts;
for i = 1:100
    grnpts(i,:) = mvnrnd(grnpop(randi(10),:),eye(2)*0.02);
    redpts(i,:) = mvnrnd(redpop(randi(10),:),eye(2)*0.02);
end
```

View the data points.

```
figure
plot(grnpts(:,1),grnpts(:,2),'go')
hold on
plot(redpts(:,1),redpts(:,2),'ro')
hold off
```



Prepare Data For Classification

Put the data into one matrix, and make a vector `grp` that labels the class of each point.

```
cdata = [grnpts;redpts];
grp = ones(200,1);
% Green label 1, red label -1
grp(101:200) = -1;
```

Prepare Cross-Validation

Set up a partition for cross-validation. This step fixes the train and test sets that the optimization uses at each step.

```
c = cvpartition(200,'KFold',10);
```

Prepare Variables for Bayesian Optimization

Set up a function that takes an input `z = [rbf_sigma,boxconstraint]` and returns the cross-validation loss value of `z`. Take the components of `z` as positive, log-transformed variables between `1e-5` and `1e5`. Choose a wide range, because you don't know which values are likely to be good.

```
sigma = optimizableVariable('sigma',[1e-5,1e5],'Transform','log');
box = optimizableVariable('box',[1e-5,1e5],'Transform','log');
```

Objective Function

This function handle computes the cross-validation loss at parameters `[sigma,box]`. For details, see `kfoldLoss`.

`bayesopt` passes the variable `z` to the objective function as a one-row table.

```
minfn = @(z)kfoldLoss(fitcsvm(cdata,grp,'CVPartition',c,...
    'KernelFunction','rbf','BoxConstraint',z.box,...
    'KernelScale',z.sigma));
```

Optimize Classifier

Search for the best parameters `[sigma,box]` using `bayesopt`. For reproducibility, choose the `'expected-improvement-plus'` acquisition function. The default acquisition function depends on run time, and so can give varying results.

```
results = bayesopt(minfn,[sigma,box],'IsObjectiveDeterministic',true,...
    'AcquisitionFunctionName','expected-improvement-plus')
```

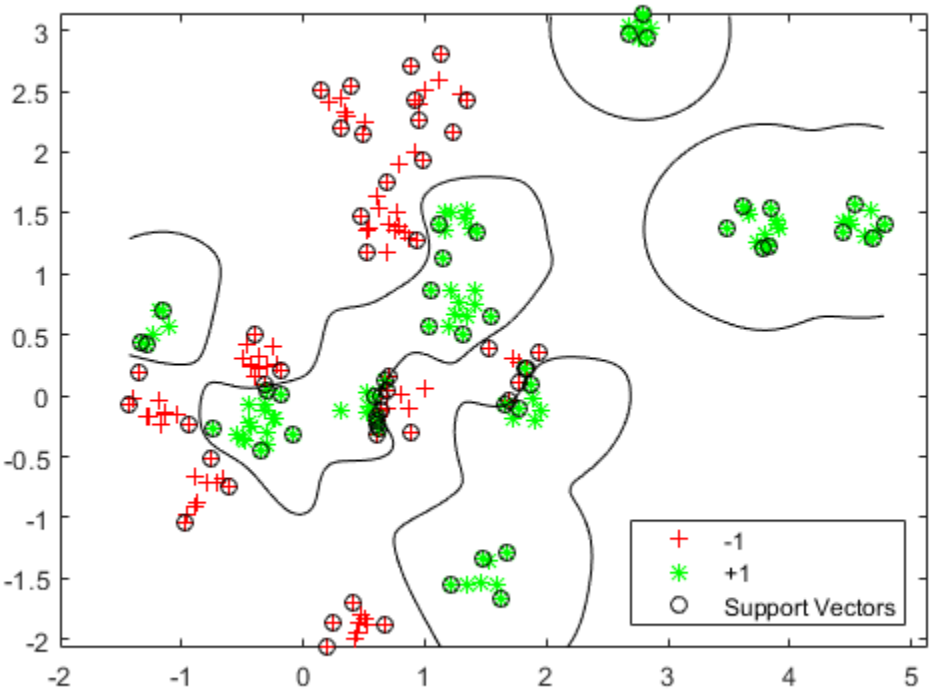
Use the results to train a new, optimized SVM classifier.

```
z(1) = results.XAtMinObjective.sigma;
z(2) = results.XAtMinObjective.box;
SVMModel = fitcsvm(cdata,grp,'KernelFunction','rbf',...
    'KernelScale',z(1),'BoxConstraint',z(2));
```

Plot the classification boundaries. To visualize the support vector classifier, predict scores over a grid.

```
d = 0.02;
[x1Grid,x2Grid] = meshgrid(min(cdata(:,1)):d:max(cdata(:,1)),...
    min(cdata(:,2)):d:max(cdata(:,2)));
xGrid = [x1Grid(:),x2Grid(:)];
[~,scores] = predict(SVMModel,xGrid);

h = nan(3,1); % Preallocation
figure;
h(1:2) = gscatter(cdata(:,1),cdata(:,2),grp,'rg','+*');
hold on
h(3) = plot(cdata(SVMModel.IsSupportVector,1),...
    cdata(SVMModel.IsSupportVector,2),'ko');
contour(x1Grid,x2Grid,reshape(scores(:,2),size(x1Grid)),[0 0],'k');
legend(h,{'-1','+1','Support Vectors'},'Location','Southeast');
axis equal
hold off
```



Evaluate Accuracy on New Data

Generate and classify some new data points.

```
grnobj = gmdistribution(grnpop,.2*eye(2));
redobj = gmdistribution(redpop,.2*eye(2));

newData = random(grnobj,10);
newData = [newData;random(redobj,10)];
grpData = ones(20,1);
grpData(11:20) = -1; % red = -1

v = predict(SVMModel,newData);

g = nan(7,1);
figure;
h(1:2) = gscatter(cdata(:,1),cdata(:,2),grp,'rg','+*');
hold on
h(3:4) = gscatter(newData(:,1),newData(:,2),v,'mc','**');
h(5) = plot(cdata(SVMModel.IsSupportVector,1),...
    cdata(SVMModel.IsSupportVector,2),'ko');

Optimize an SVM Classifier Fit Using Bayesian Optimization

This example shows how to optimize an SVM classification using the `fitcsvm` function and `OptimizeHyperparameters` name-value pair. The classification works on locations of points from a Gaussian mixture model. In *The Elements of Statistical Learning*, Hastie, Tibshirani, and Friedman (2009), page 17 describes the model. The model begins with generating 10 base points for a "green" class, distributed as 2-D independent normals with mean (1,0) and unit variance. It also generates 10 base points for a "red" class, distributed as 2-D independent normals with mean (0,1) and unit variance. For each class (green and red), generate 100 random points as follows:

1. Choose a base point *m* of the appropriate color uniformly at random.
2. Generate an independent random point with 2-D normal distribution with mean *m* and variance I/5, where I is the 2-by-2 identity matrix. In this example, use a variance I/50 to show the advantage of optimization more clearly.

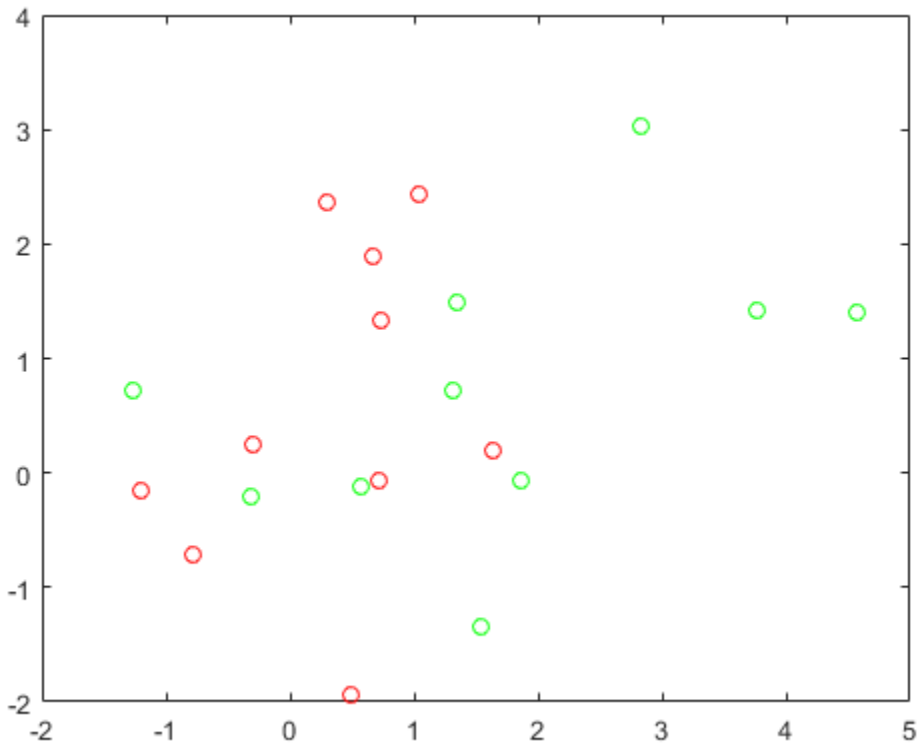
Generate the Points and Classifier

Generate the 10 base points for each class.

```
rng default % For reproducibility
grnpop = mvnrnd([1,0],eye(2),10);
redpop = mvnrnd([0,1],eye(2),10);
```

View the base points.

```
plot(grnpop(:,1),grnpop(:,2),'go')
hold on
plot(redpop(:,1),redpop(:,2),'ro')
hold off
```



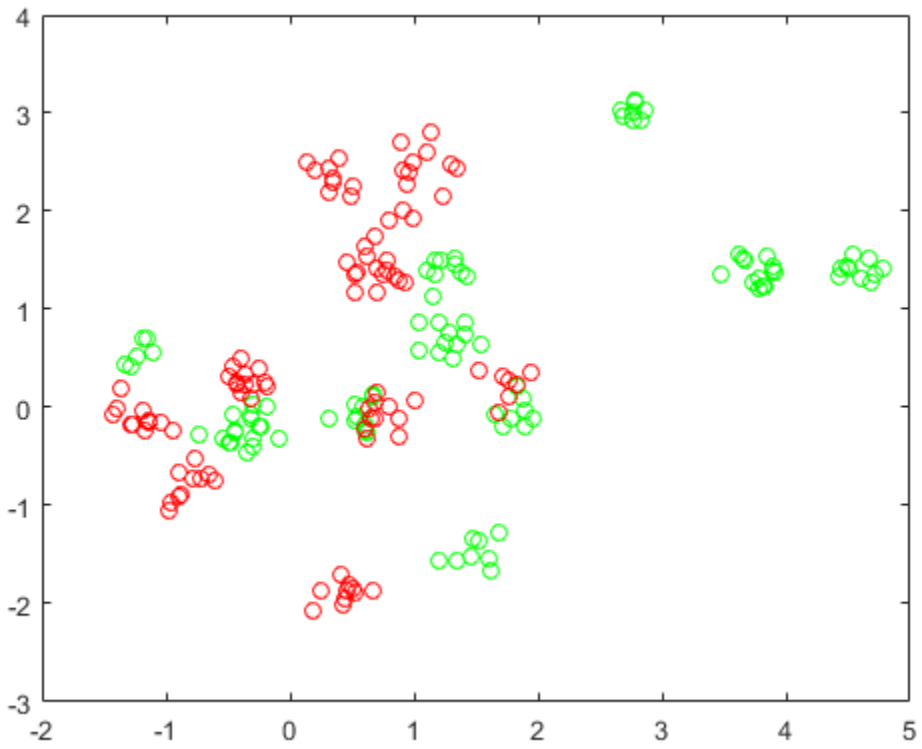
Since some red base points are close to green base points, it can be difficult to classify the data points based on location alone.

Generate the 100 data points of each class.

```
redpts = zeros(100,2);grnpts = redpts;
for i = 1:100
    grnpts(i,:) = mvnrnd(grnpop(randi(10),:),eye(2)*0.02);
    redpts(i,:) = mvnrnd(redpop(randi(10),:),eye(2)*0.02);
end
```

View the data points.

```
figure
plot(grnpts(:,1),grnpts(:,2),'go')
hold on
plot(redpts(:,1),redpts(:,2),'ro')
hold off
```



Prepare Data For Classification

Put the data into one matrix, and make a vector `grp` that labels the class of each point.

```
cdata = [grnpts;redpts];
grp = ones(200,1);
% Green label 1, red label -1
grp(101:200) = -1;
```

Prepare Cross-Validation

Set up a partition for cross-validation. This step fixes the train and test sets that the optimization uses at each step.

```
c = cvpartition(200,'KFold',10);
```

Optimize the Fit

To find a good fit, meaning one with a low cross-validation loss, set options to use Bayesian optimization. Use the same cross-validation partition `c` in all optimizations.

For reproducibility, use the `'expected-improvement-plus'` acquisition function.

```
opts = struct('Optimizer','bayesopt','ShowPlots',true,'CVPartition',c,...
    'AcquisitionFunctionName','expected-improvement-plus');
svmmod = fitcsvm(cdata,grp,'KernelFunction','rbf',...
    'OptimizeHyperparameters','auto','HyperparameterOptimizationOptions',opts)
```

Optimize a Boosted Regression Ensemble

This example shows how to optimize hyperparameters of a boosted regression ensemble. The optimization minimizes the cross-validation loss of the model.

The problem is to model the efficiency in miles per gallon of an automobile, based on its acceleration, engine displacement, horsepower, and weight. Load the `carsmall` data, which contains these and other predictors.

```
load carsmall
X = [Acceleration Displacement Horsepower Weight];
Y = MPG;
```

Fit a regression ensemble to the data using the `LSBoost` algorithm, and using surrogate splits. Optimize the resulting model by varying the number of learning cycles, the maximum number of surrogate splits, and the learn rate. Furthermore, allow the optimization to repartition the cross-validation between every iteration.

For reproducibility, set the random seed and use the `'expected-improvement-plus'` acquisition function.

```
rng('default')
Mdl = fitrensemble(X,Y, ...
    'Method','LSBoost', ...
    'Learner',templateTree('Surrogate','on'), ...
    'OptimizeHyperparameters',{'NumLearningCycles','MaxNumSplits','LearnRate'}, ...
    'HyperparameterOptimizationOptions',struct('Repartition',true, ...
    'AcquisitionFunctionName','expected-improvement-plus'))
```

For a different way of optimizing this ensemble, see “Optimize Regression Ensemble Using Cross-Validation” on page 33-2317.

Parametric Regression Analysis

Choose a Regression Function

Regression is the process of fitting models to data. The models must have numerical responses. For models with categorical responses, see “Parametric Classification” on page 17-2 or “Supervised Learning Workflow and Algorithms” on page 18-3. The regression process depends on the model. If a model is parametric, regression estimates the parameters from the data. If a model is linear in the parameters, estimation is based on methods from linear algebra that minimize the norm of a residual vector. If a model is nonlinear in the parameters, estimation is based on search methods from optimization that minimize the norm of a residual vector.

This table describes which function to use depending on the type of regression problem.

Model Components	Result of Regression	Function to Use
Continuous or categorical predictors, continuous response, linear model	Fitted model coefficients	`fitlm`. See “Linear Regression” on page 11-9.
Continuous or categorical predictors, continuous response, linear model of unknown complexity	Fitted model and fitted coefficients	`stepwiselm`. See “Stepwise Regression” on page 11-99.
Continuous or categorical predictors, response possibly with restrictions such as nonnegative or integer-valued, generalized linear model	Fitted generalized linear model coefficients	`fitglm` or `stepwiseglm`. See “Generalized Linear Models” on page 12-9.
Continuous predictors with a continuous nonlinear response, parametrized nonlinear model	Fitted nonlinear model coefficients	`fitnlm`. See “Nonlinear Regression” on page 13-2.
Continuous predictors, continuous response, linear model	Set of models from ridge, lasso, or elastic net regression	`lasso` or `ridge`. See “Lasso and Elastic Net” on page 11-112 or “Ridge Regression” on page 11-109.
Correlated continuous predictors, continuous response, linear model	Fitted model and fitted coefficients	`plsregress`. See “Partial Least Squares” on page 11-126.
Continuous or categorical predictors, continuous response, unknown model	Nonparametric model	`fitrtree` or `fitrensemble`.
Categorical predictors only	ANOVA	`anova`, `anova1`, `anova2`, `anovan`.
Continuous predictors, multivariable response, linear model	Fitted multivariate regression model coefficients	`mvregress`
Continuous predictors, continuous response, mixed-effects model	Fitted mixed-effects model coefficients	`nlmefit` or `nlmefitsa`. See “Mixed-Effects Models” on page 13-17.

Update Legacy Code with New Fitting Methods

There are several Statistics and Machine Learning Toolbox functions for performing regression. The following sections describe how to replace calls to older functions to new versions:

regress into fitlm

Previous Syntax:

```
[b,bint,r,rint,stats] = regress(y,X)
```

where X contains a column of ones.

Current Syntax:

```
mdl = fitlm(X,y)
```

where you do not add a column of ones to X.

Equivalent values of the previous outputs:

- `b` — `mdl.Coefficients.Estimate`
- `bint` — `coefCI(mdl)`
- `r` — `mdl.Residuals.Raw`
- `rint` — There is no exact equivalent. Try examining `mdl.Residuals.Studentized` to find outliers.
- `stats` — `mdl` contains various properties that replace components of `stats`.

regstats into fitlm

Previous Syntax:

```
stats = regstats(y,X,model,whichstats)
```

Current Syntax:

```
mdl = fitlm(X,y,model)
```

Obtain statistics from the properties and methods of the `LinearModel` object (`mdl`). For example, see the `mdl.Diagnostics` and `mdl.Residuals` properties.

robustfit into fitlm

Previous Syntax:

```
[b,stats] = robustfit(X,y,wfun,tune,const)
```

Current Syntax:

```
mdl = fitlm(X,y,'robust','on') % bisquare
```

Or to use the *`wfun`* weight and the *`tune`* tuning parameter:

```
opt.RobustWgtFun = 'wfun';
opt.Tune = tune; % optional
mdl = fitlm(X,y,'robust',opt)
```

Obtain statistics from the properties and methods of the `LinearModel` object (`mdl`). For example, see the `mdl.Diagnostics` and `mdl.Residuals` properties.

stepwisefit into stepwiselm

Previous Syntax:

```
[b,se,pval,inmodel,stats,nextstep,history] = stepwisefit(X,y,Name,Value)
```

Current Syntax:

```
mdl = stepwiselm(ds,modelspec,Name,Value)
```

or

```
mdl = stepwiselm(X,y,modelspec,Name,Value)
```

Obtain statistics from the properties and methods of the `LinearModel` object (`mdl`). For example, see the `mdl.Diagnostics` and `mdl.Residuals` properties.

glmfit into fitglm

Previous Syntax:

```
[b,dev,stats] = glmfit(X,y,distr,param1,val1,...)
```

Current Syntax:

```
mdl = fitglm(X,y,distr,...)
```

Obtain statistics from the properties and methods of the `GeneralizedLinearModel` object (`mdl`). For example, the deviance is `mdl.Deviance`, and to compare `mdl` against a constant model, use `devianceTest(mdl)`.

nlinfit into fitnlm

Previous Syntax:

```
[beta,r,J,COVB,mse] = nlinfit(X,y,fun,beta0,options)
```

Current Syntax:

```
mdl = fitnlm(X,y,fun,beta0,'Options',options)
```

Equivalent values of the previous outputs:

- `beta` — `mdl.Coefficients.Estimate`
- `r` — `mdl.Residuals.Raw`
- `covb` — `mdl.CoefficientCovariance`
- `mse` — `mdl.mse`

`mdl` does not provide the Jacobian (`J`) output. The primary purpose of `J` was to pass it into `nlparci` or `nlpredci` to obtain confidence intervals for the estimated coefficients (parameters) or predictions. Obtain those confidence intervals as:

```
parci = coefCI(mdl)
[pred,predci] = predict(mdl)
```

What Is a Linear Regression Model?

A linear regression model describes the relationship between a *dependent variable*, y, and one or more *independent variables*, X. The dependent variable is also called the *response variable*. Independent variables are also called *explanatory* or *predictor variables*. Continuous predictor variables are also called *covariates*, and categorical predictor variables are also called *factors*. The matrix X of observations on predictor variables is usually called the *design matrix*.

A multiple linear regression model is

$$y_i = \beta_0 + \beta_1 X_{i1} + \beta_2 X_{i2} + \cdots + \beta_p X_{ip} + \varepsilon_i, \quad i = 1, \cdots, n,$$

where

- y_i is the ith response.
- β_k is the kth coefficient, where β_0 is the constant term in the model. Sometimes, design matrices might include information about the constant term. However, `fitlm` or `stepwiselm` by default includes a constant term in the model, so you must not enter a column of 1s into your design matrix X.
- X_{ij} is the ith observation on the jth predictor variable, $j = 1, \ldots, p$.
- ε_i is the ith noise term, that is, random error.

If a model includes only one predictor variable ($p = 1$), then the model is called a simple linear regression model.

In general, a linear regression model can be a model of the form

$$y_i = \beta_0 + \sum_{k=1}^{K} \beta_k f_k\left(X_{i1}, X_{i2}, \cdots, X_{ip}\right) + \varepsilon_i, \quad i = 1, \cdots, n,$$

where $f(.)$ is a scalar-valued function of the independent variables, X_{ij}s. The functions, $f(X)$, might be in any form including nonlinear functions or polynomials. The linearity, in the linear regression models, refers to the linearity of the coefficients β_k. That is, the response variable, y, is a linear function of the coefficients, β_k.

Some examples of linear models are:

$$y_i = \beta_0 + \beta_1 X_{1i} + \beta_2 X_{2i} + \beta_3 X_{3i} + \varepsilon_i$$
$$y_i = \beta_0 + \beta_1 X_{1i} + \beta_2 X_{2i} + \beta_3 X_{1i}^3 + \beta_4 X_{2i}^2 + \varepsilon_i$$
$$y_i = \beta_0 + \beta_1 X_{1i} + \beta_2 X_{2i} + \beta_3 X_{1i} X_{2i} + \beta_4 \log X_{3i} + \varepsilon_i$$

The following, however, are not linear models since they are not linear in the unknown coefficients, β_k.

$$\log y_i = \beta_0 + \beta_1 X_{1i} + \beta_2 X_{2i} + \varepsilon_i$$
$$y_i = \beta_0 + \beta_1 X_{1i} + \frac{1}{\beta_2 X_{2i}} + e^{\beta_3 X_{1i} X_{2i}} + \varepsilon_i$$

The usual assumptions for linear regression models are:

- The noise terms, ε_i, are uncorrelated.

- The noise terms, ε_i, have independent and identical normal distributions with mean zero and constant variance, σ^2. Thus,

$$\begin{aligned} E(y_i) &= E\left(\sum_{k=0}^{K} \beta_k f_k(X_{i1}, X_{i2}, \cdots, X_{ip}) + \varepsilon_i\right) \\ &= \sum_{k=0}^{K} \beta_k f_k(X_{i1}, X_{i2}, \cdots, X_{ip}) + E(\varepsilon_i) \\ &= \sum_{k=0}^{K} \beta_k f_k(X_{i1}, X_{i2}, \cdots, X_{ip}) \end{aligned}$$

  and

$$V(y_i) = V\left(\sum_{k=0}^{K} \beta_k f_k(X_{i1}, X_{i2}, \cdots, X_{ip}) + \varepsilon_i\right) = V(\varepsilon_i) = \sigma^2$$

  So the variance of y_i is the same for all levels of X_{ij}.
- The responses y_i are uncorrelated.

The fitted linear function is

$$\widehat{y}_i = \sum_{k=0}^{K} b_k f_k(X_{i1}, X_{i2}, \cdots, X_{ip}), \quad i = 1, \cdots, n,$$

where $\widehat{y}_i$ is the estimated response and b_ks are the fitted coefficients. The coefficients are estimated so as to minimize the mean squared difference between the prediction vector $\widehat{y}$ and the true response vector y, that is $\widehat{y} - y$. This method is called the *method of least squares*. Under the assumptions on the noise terms, these coefficients also maximize the likelihood of the prediction vector.

In a linear regression model of the form $y = \beta_1 X_1 + \beta_2 X_2 + \ldots + \beta_p X_p$, the coefficient β_k expresses the impact of a one-unit change in predictor variable, X_j, on the mean of the response E(y), provided that all other variables are held constant. The sign of the coefficient gives the direction of the effect. For example, if the linear model is E(y) = 1.8 – 2.35X_1 + X_2, then –2.35 indicates a 2.35 unit decrease in the mean response with a one-unit increase in X_1, given X_2 is held constant. If the model is E(y) = 1.1 + 1.5X_1^2 + X_2, the coefficient of X_1^2 indicates a 1.5 unit increase in the mean of Y with a one-unit increase in X_1^2 given all else held constant. However, in the case of E(y) = 1.1 + 2.1X_1 + 1.5X_1^2, it is difficult to interpret the coefficients similarly, since it is not possible to hold X_1 constant when X_1^2 changes or vice versa.

Linear Regression

In this section...

Prepare Data

To begin fitting a regression, put your data into a form that fitting functions expect. All regression techniques begin with input data in an array `X` and response data in a separate vector `y`, or input data in a table or dataset array `tbl` and response data as a column in `tbl`. Each row of the input data represents one observation. Each column represents one predictor (variable).

For a table or dataset array `tbl`, indicate the response variable with the `'ResponseVar'` name-value pair:

```
mdl = fitlm(tbl,'ResponseVar','BloodPressure');
```

The response variable is the last column by default.

You can use numeric categorical predictors. A categorical predictor is one that takes values from a fixed set of possibilities.

- For a numeric array `X`, indicate the categorical predictors using the `'Categorical'` name-value pair. For example, to indicate that predictors `2` and `3` out of six are categorical:

  ```
  mdl = fitlm(X,y,'Categorical',[2,3]);
  % or equivalently
  mdl = fitlm(X,y,'Categorical',logical([0 1 1 0 0 0]));
  ```
- For a table or dataset array `tbl`, fitting functions assume that these data types are categorical:

  - Logical vector
  - Categorical vector
  - Character array
  - String array

  If you want to indicate that a numeric predictor is categorical, use the `'Categorical'` name-value pair.

Represent missing numeric data as `NaN`. To represent missing data for other data types, see “Missing Group Values” on page 2-46.

Dataset Array for Input and Response Data

To create a dataset array from an Excel spreadsheet:

```
ds = dataset('XLSFile','hospital.xls', ...
    'ReadObsNames',true);
```

To create a dataset array from workspace variables:

```
load carsmall
ds = dataset(MPG,Weight);
ds.Year = categorical(Model_Year);
```

Table for Input and Response Data

To create a table from an Excel spreadsheet:

```
tbl = readtable('hospital.xls', ...
    'ReadRowNames',true);
```

To create a table from workspace variables:

```
load carsmall
tbl = table(MPG,Weight);
tbl.Year = categorical(Model_Year);
```

Numeric Matrix for Input Data, Numeric Vector for Response

For example, to create numeric arrays from workspace variables:

```
load carsmall
X = [Weight Horsepower Cylinders Model_Year];
y = MPG;
```

To create numeric arrays from an Excel spreadsheet:

```
[X, Xnames] = xlsread('hospital.xls');
y = X(:,4); % response y is systolic pressure
X(:,4) = []; % remove y from the X matrix
```

Notice that the nonnumeric entries, such as `sex`, do not appear in `X`.

Choose a Fitting Method

There are three ways to fit a model to data:

- “Least-Squares Fit” on page 11-10
- “Robust Fit” on page 11-10
- “Stepwise Fit” on page 11-11

Least-Squares Fit

Use `fitlm` to construct a least-squares fit of a model to the data. This method is best when you are reasonably certain of the model’s form, and mainly need to find its parameters. This method is also useful when you want to explore a few models. The method requires you to examine the data manually to discard outliers, though there are techniques to help (see “Examine Quality and Adjust Fitted Model” on page 11-14).

Robust Fit

Use `fitlm` with the `RobustOpts` name-value pair to create a model that is little affected by outliers. Robust fitting saves you the trouble of manually discarding outliers. However, `step` does not work

with robust fitting. This means that when you use robust fitting, you cannot search stepwise for a good model.

Stepwise Fit

Use `stepwiselm` to find a model, and fit parameters to the model. `stepwiselm` starts from one model, such as a constant, and adds or subtracts terms one at a time, choosing an optimal term each time in a greedy fashion, until it cannot improve further. Use stepwise fitting to find a good model, which is one that has only relevant terms.

The result depends on the starting model. Usually, starting with a constant model leads to a small model. Starting with more terms can lead to a more complex model, but one that has lower mean squared error. See “Compare large and small stepwise models” on page 11-99.

You cannot use robust options along with stepwise fitting. So after a stepwise fit, examine your model for outliers (see “Examine Quality and Adjust Fitted Model” on page 11-14).

Choose a Model or Range of Models

There are several ways of specifying a model for linear regression. Use whichever you find most convenient.

- “Brief Name” on page 11-11
- “Terms Matrix” on page 11-12
- “Formula” on page 11-12

For `fitlm`, the model specification you give is the model that is fit. If you do not give a model specification, the default is `'linear'`.

For `stepwiselm`, the model specification you give is the starting model, which the stepwise procedure tries to improve. If you do not give a model specification, the default starting model is `'constant'`, and the default upper bounding model is `'interactions'`. Change the upper bounding model using the `Upper` name-value pair.

Note There are other ways of selecting models, such as using `lasso`, `lassoglm`, `sequentialfs`, or `plsregress`.

Brief Name

Name	Model Type
`'constant'`	Model contains only a constant (intercept) term.
`'linear'`	Model contains an intercept and linear terms for each predictor.
`'interactions'`	Model contains an intercept, linear terms, and all products of pairs of distinct predictors (no squared terms).
`'purequadratic'`	Model contains an intercept, linear terms, and squared terms.
`'quadratic'`	Model contains an intercept, linear terms, interactions, and squared terms.

Name	Model Type
`'poly`*`ijk`*`'`	Model is a polynomial with all terms up to degree *`i`* in the first predictor, degree *`j`* in the second predictor, etc. Use numerals `0` through `9`. For example, `'poly2111'` has a constant plus all linear and product terms, and also contains terms with predictor 1 squared.

For example, to specify an interaction model using `fitlm` with matrix predictors:

```
mdl = fitlm(X,y,'interactions');
```

To specify a model using `stepwiselm` and a table or dataset array `tbl` of predictors, suppose you want to start from a constant and have a linear model upper bound. Assume the response variable in `tbl` is in the third column.

```
mdl2 = stepwiselm(tbl,'constant', ...
    'Upper','linear','ResponseVar',3);
```

Terms Matrix

A terms matrix `T` is a *t*-by-(*p* + 1) matrix specifying terms in a model, where *t* is the number of terms, *p* is the number of predictor variables, and +1 accounts for the response variable. The value of `T(i,j)` is the exponent of variable `j` in term `i`.

For example, suppose that an input includes three predictor variables `x1`, `x2`, and `x3` and the response variable `y` in the order `x1`, `x2`, `x3`, and `y`. Each row of `T` represents one term:

- `[0 0 0 0]` — Constant term or intercept
- `[0 1 0 0]` — `x2`; equivalently, `x1^0 * x2^1 * x3^0`
- `[1 0 1 0]` — `x1*x3`
- `[2 0 0 0]` — `x1^2`
- `[0 1 2 0]` — `x2*(x3^2)`

The `0` at the end of each term represents the response variable. In general, a column vector of zeros in a terms matrix represents the position of the response variable. If you have the predictor and response variables in a matrix and column vector, then you must include `0` for the response variable in the last column of each row.

Formula

A formula for a model specification is a character vector or string scalar of the form

`'`*`y ~ terms`*`'`,

- *`y`* is the response name.
- *`terms`* contains
  - Variable names
  - `+` to include the next variable
  - `-` to exclude the next variable
  - `:` to define an interaction, a product of terms

- * to define an interaction and all lower-order terms
- ^ to raise the predictor to a power, exactly as in * repeated, so ^ includes lower order terms as well
- ( ) to group terms

Tip Formulas include a constant (intercept) term by default. To exclude a constant term from the model, include `-1` in the formula.

Examples:

`'y ~ x1 + x2 + x3'` is a three-variable linear model with intercept.
`'y ~ x1 + x2 + x3 - 1'` is a three-variable linear model without intercept.
`'y ~ x1 + x2 + x3 + x2^2'` is a three-variable model with intercept and a `x2^2` term.
`'y ~ x1 + x2^2 + x3'` is the same as the previous example, since `x2^2` includes a `x2` term.
`'y ~ x1 + x2 + x3 + x1:x2'` includes an `x1*x2` term.
`'y ~ x1*x2 + x3'` is the same as the previous example, since `x1*x2 = x1 + x2 + x1:x2`.
`'y ~ x1*x2*x3 - x1:x2:x3'` has all interactions among `x1`, `x2`, and `x3`, except the three-way interaction.
`'y ~ x1*(x2 + x3 + x4)'` has all linear terms, plus products of `x1` with each of the other variables.

For example, to specify an interaction model using `fitlm` with matrix predictors:

```
mdl = fitlm(X,y,'y ~ x1*x2*x3 - x1:x2:x3');
```

To specify a model using `stepwiselm` and a table or dataset array `tbl` of predictors, suppose you want to start from a constant and have a linear model upper bound. Assume the response variable in `tbl` is named `'y'`, and the predictor variables are named `'x1'`, `'x2'`, and `'x3'`.

```
mdl2 = stepwiselm(tbl,'y ~ 1','Upper','y ~ x1 + x2 + x3');
```

Fit Model to Data

The most common optional arguments for fitting:

- For robust regression in `fitlm`, set the `'RobustOpts'` name-value pair to `'on'`.
- Specify an appropriate upper bound model in `stepwiselm`, such as set `'Upper'` to `'linear'`.
- Indicate which variables are categorical using the `'CategoricalVars'` name-value pair. Provide a vector with column numbers, such as `[1 6]` to specify that predictors `1` and `6` are categorical. Alternatively, give a logical vector the same length as the data columns, with a `1` entry indicating that variable is categorical. If there are seven predictors, and predictors `1` and `6` are categorical, specify `logical([1,0,0,0,0,1,0])`.
- For a table or dataset array, specify the response variable using the `'ResponseVar'` name-value pair. The default is the last column in the array.

For example,

```
mdl = fitlm(X,y,'linear', ...
    'RobustOpts','on','CategoricalVars',3);
mdl2 = stepwiselm(tbl,'constant', ...
    'ResponseVar','MPG','Upper','quadratic');
```

Examine Quality and Adjust Fitted Model

After fitting a model, examine the result and make adjustments.

Model Display

A linear regression model shows several diagnostics when you enter its name or enter `disp(mdl)`. This display gives some of the basic information to check whether the fitted model represents the data adequately.

For example, fit a linear model to data constructed with two out of five predictors not present and with no intercept term:

```
X = randn(100,5);
y = X*[1;0;3;0;-1] + randn(100,1);
mdl = fitlm(X,y)
```

```
mdl =
Linear regression model:
    y ~ 1 + x1 + x2 + x3 + x4 + x5

Estimated Coefficients:
                   Estimate        SE        tStat        pValue
                   ________    ________    ________    __________

    (Intercept)     0.038164    0.099458     0.38372       0.70205
    x1               0.92794    0.087307      10.628    8.5494e-18
    x2              -0.075593     0.10044    -0.75264       0.45355
    x3                 2.8965    0.099879          29    1.1117e-48
    x4              0.045311     0.10832     0.41831       0.67667
    x5              -0.99708     0.11799     -8.4504     3.593e-13

Number of observations: 100, Error degrees of freedom: 94
Root Mean Squared Error: 0.972
R-squared: 0.93,  Adjusted R-Squared: 0.926
F-statistic vs. constant model: 248, p-value = 1.5e-52
```

Notice that:

- The display contains the estimated values of each coefficient in the `Estimate` column. These values are reasonably near the true values `[0;1;0;3;0;-1]`.
- There is a standard error column for the coefficient estimates.
- The reported `pValue` (which are derived from the *t* statistics (`tStat`) under the assumption of normal errors) for predictors 1, 3, and 5 are extremely small. These are the three predictors that were used to create the response data `y`.
- The `pValue` for `(Intercept)`, `x2` and `x4` are much larger than 0.01. These three predictors were not used to create the response data `y`.
- The display contains R^2, adjusted R^2, and F statistics.

ANOVA

To examine the quality of the fitted model, consult an ANOVA table. For example, use `anova` on a linear model with five predictors:

```
tbl = anova(mdl)
```

```
tbl=6×5 table
              SumSq     DF    MeanSq        F         pValue
             _______    __    _______    _______    __________

    x1        106.62     1     106.62     112.96    8.5494e-18
    x2       0.53464     1    0.53464    0.56646       0.45355
    x3        793.74     1     793.74     840.98    1.1117e-48
    x4       0.16515     1    0.16515    0.17498       0.67667
    x5        67.398     1     67.398      71.41     3.593e-13
    Error     88.719    94    0.94382
```

This table gives somewhat different results than the model display. The table clearly shows that the effects of `x2` and `x4` are not significant. Depending on your goals, consider removing `x2` and `x4` from the model.

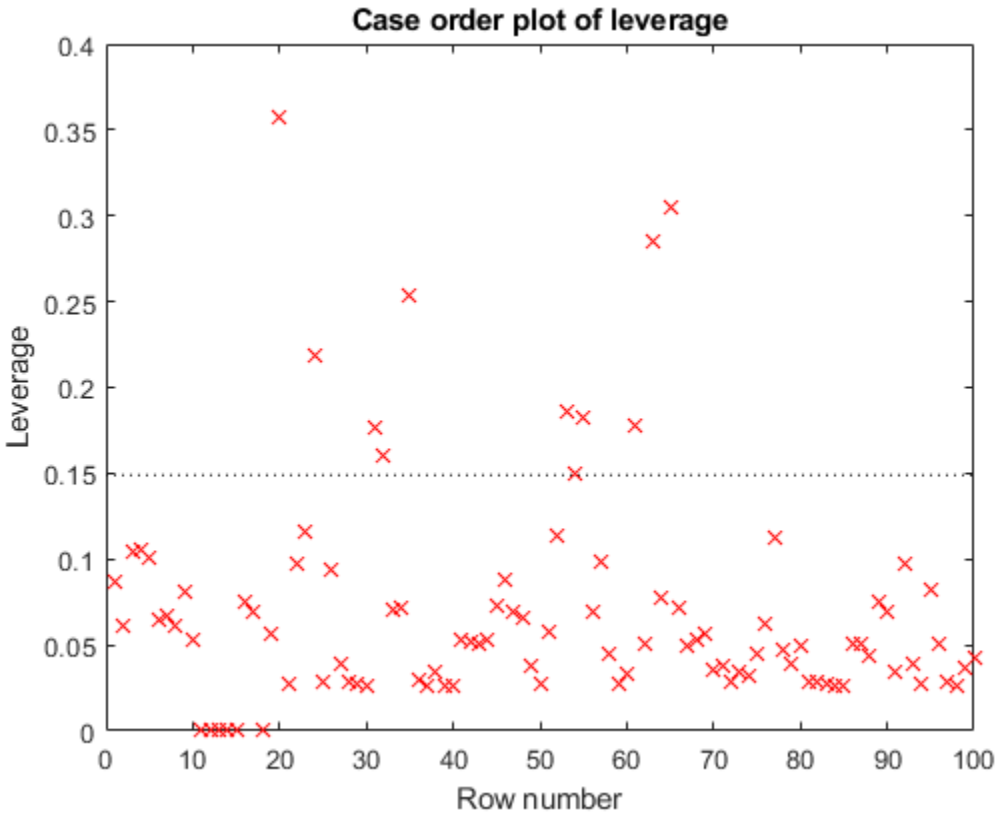
Diagnostic Plots

Diagnostic plots help you identify outliers, and see other problems in your model or fit. For example, load the `carsmall` data, and make a model of `MPG` as a function of `Cylinders` (categorical) and `Weight`:

```
load carsmall
tbl = table(Weight,MPG,Cylinders);
tbl.Cylinders = categorical(tbl.Cylinders);
mdl = fitlm(tbl,'MPG ~ Cylinders*Weight + Weight^2');
```

Make a leverage plot of the data and model.

```
plotDiagnostics(mdl)
```



There are a few points with high leverage. But this plot does not reveal whether the high-leverage points are outliers.

Look for points with large Cook's distance.

```
plotDiagnostics(mdl,'cookd')
```

There is one point with large Cook’s distance. Identify it and remove it from the model. You can use the Data Cursor to click the outlier and identify it, or identify it programmatically:

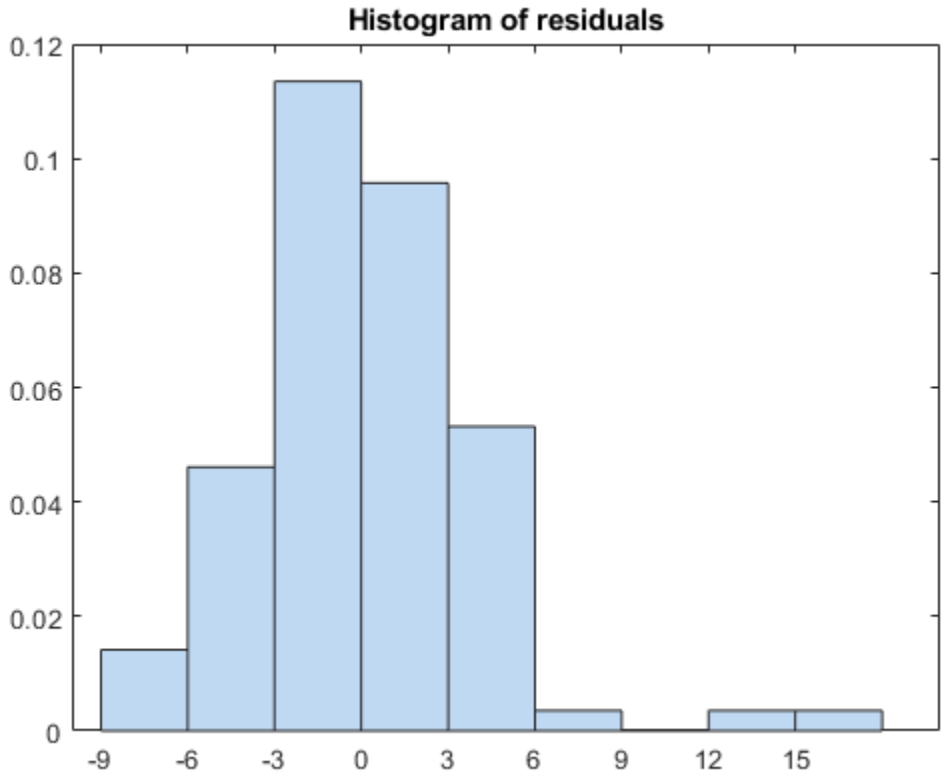
```
[~,larg] = max(mdl.Diagnostics.CooksDistance);
mdl2 = fitlm(tbl,'MPG ~ Cylinders*Weight + Weight^2','Exclude',larg);
```

Residuals — Model Quality for Training Data

There are several residual plots to help you discover errors, outliers, or correlations in the model or data. The simplest residual plots are the default histogram plot, which shows the range of the residuals and their frequencies, and the probability plot, which shows how the distribution of the residuals compares to a normal distribution with matched variance.

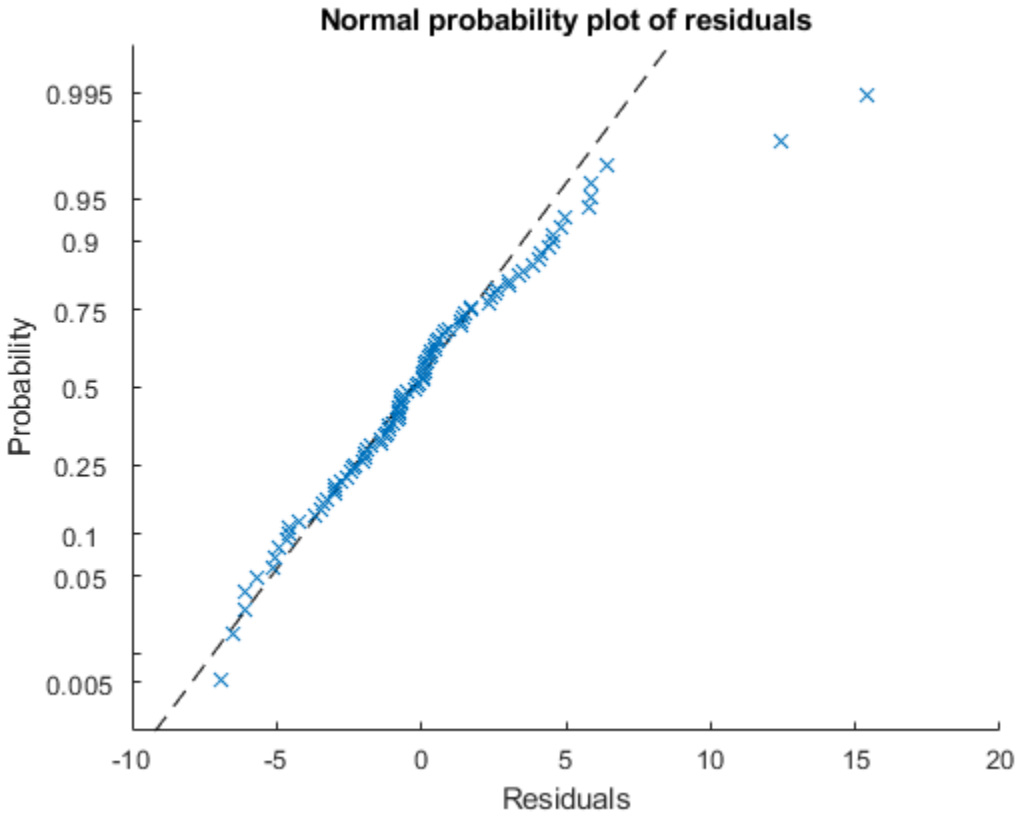
Examine the residuals:

```
plotResiduals(mdl)
```



The observations above 12 are potential outliers.

```
plotResiduals(mdl,'probability')
```



The two potential outliers appear on this plot as well. Otherwise, the probability plot seems reasonably straight, meaning a reasonable fit to normally distributed residuals.

You can identify the two outliers and remove them from the data:

```
outl = find(mdl.Residuals.Raw > 12)
```

```
outl = 2×1

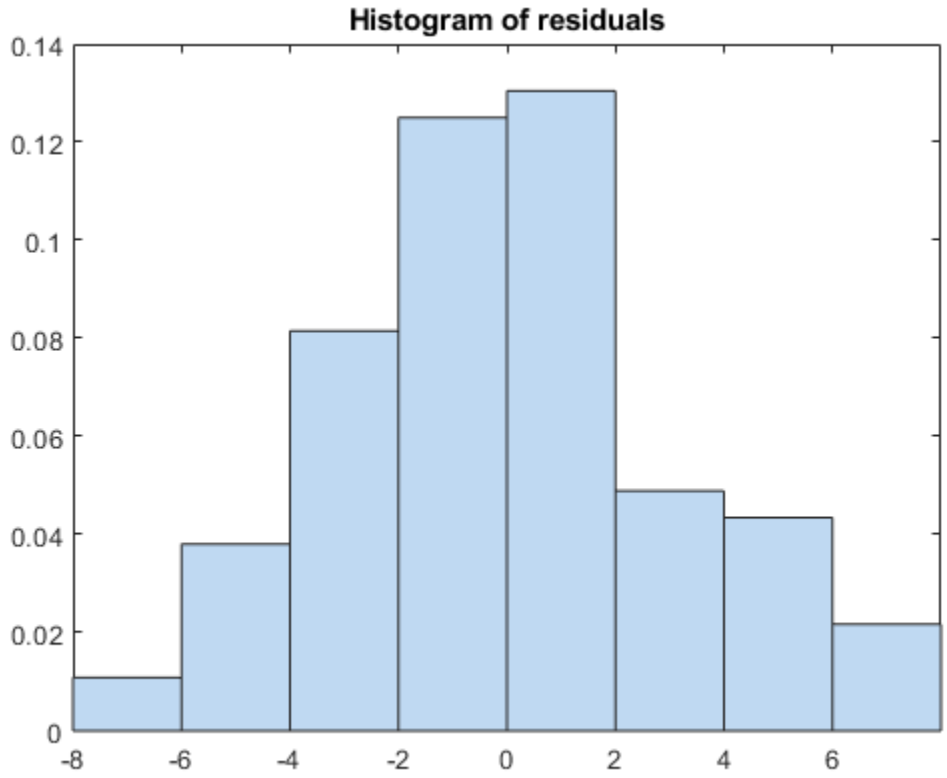
    90
    97
```

To remove the outliers, use the `Exclude` name-value pair:

```
mdl3 = fitlm(tbl,'MPG ~ Cylinders*Weight + Weight^2','Exclude',outl);
```

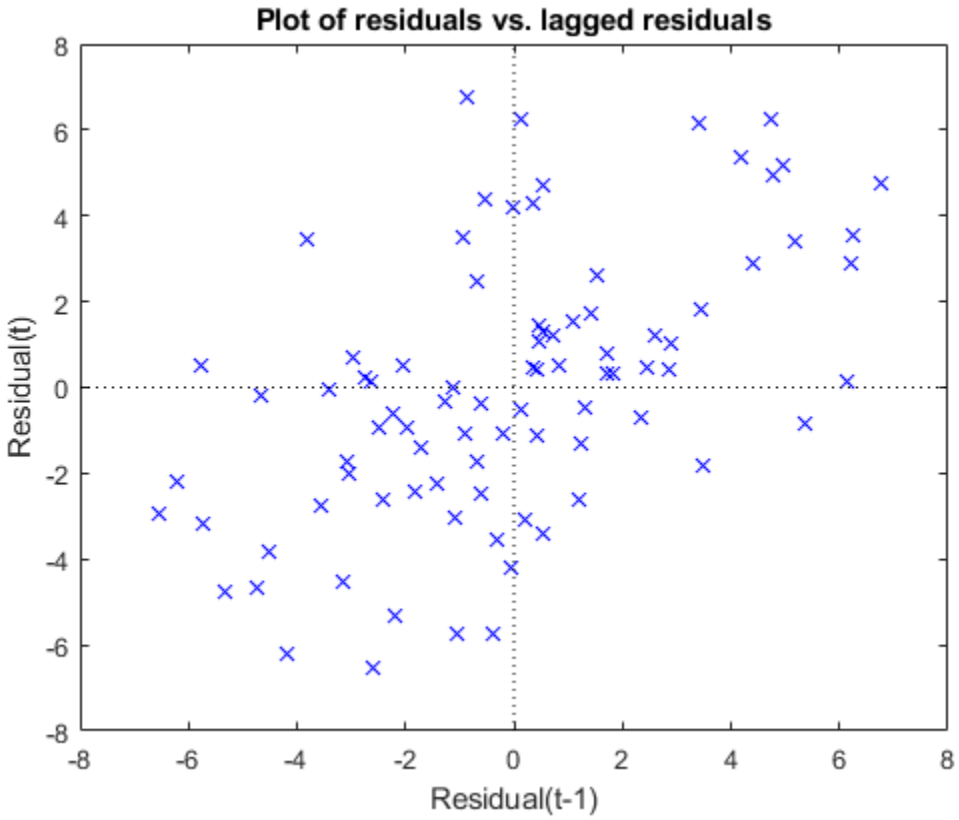
Examine a residuals plot of mdl2:

```
plotResiduals(mdl3)
```



The new residuals plot looks fairly symmetric, without obvious problems. However, there might be some serial correlation among the residuals. Create a new plot to see if such an effect exists.

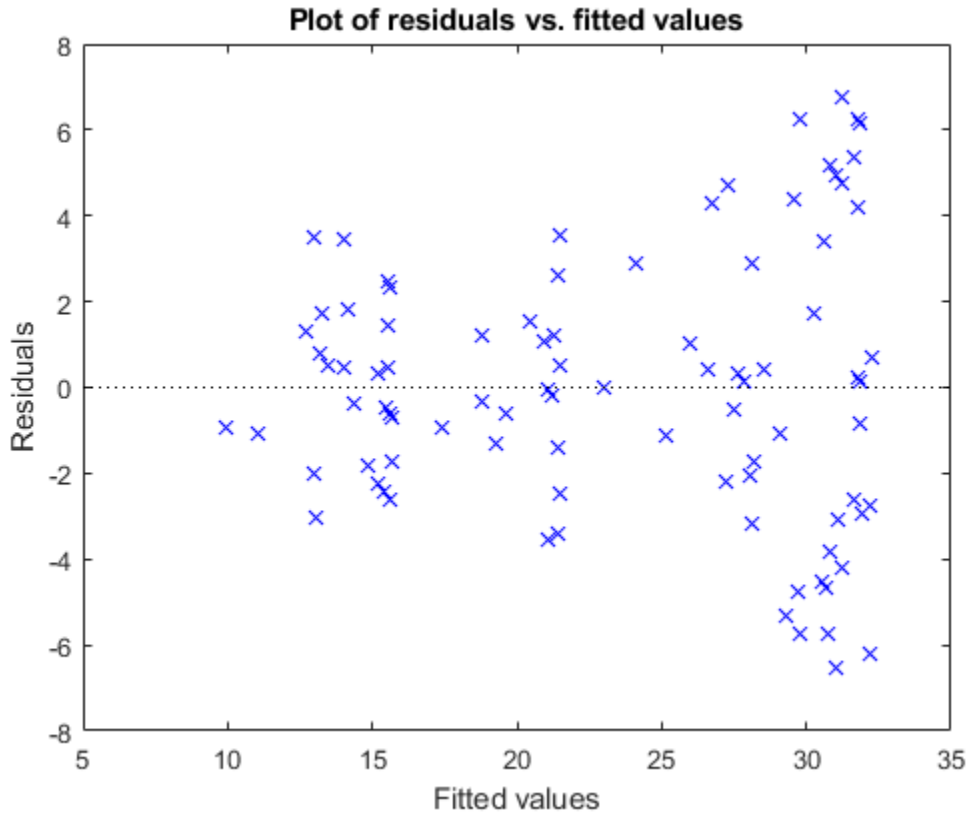
```
plotResiduals(mdl3,'lagged')
```



The scatter plot shows many more crosses in the upper-right and lower-left quadrants than in the other two quadrants, indicating positive serial correlation among the residuals.

Another potential issue is when residuals are large for large observations. See if the current model has this issue.

```
plotResiduals(mdl3,'fitted')
```



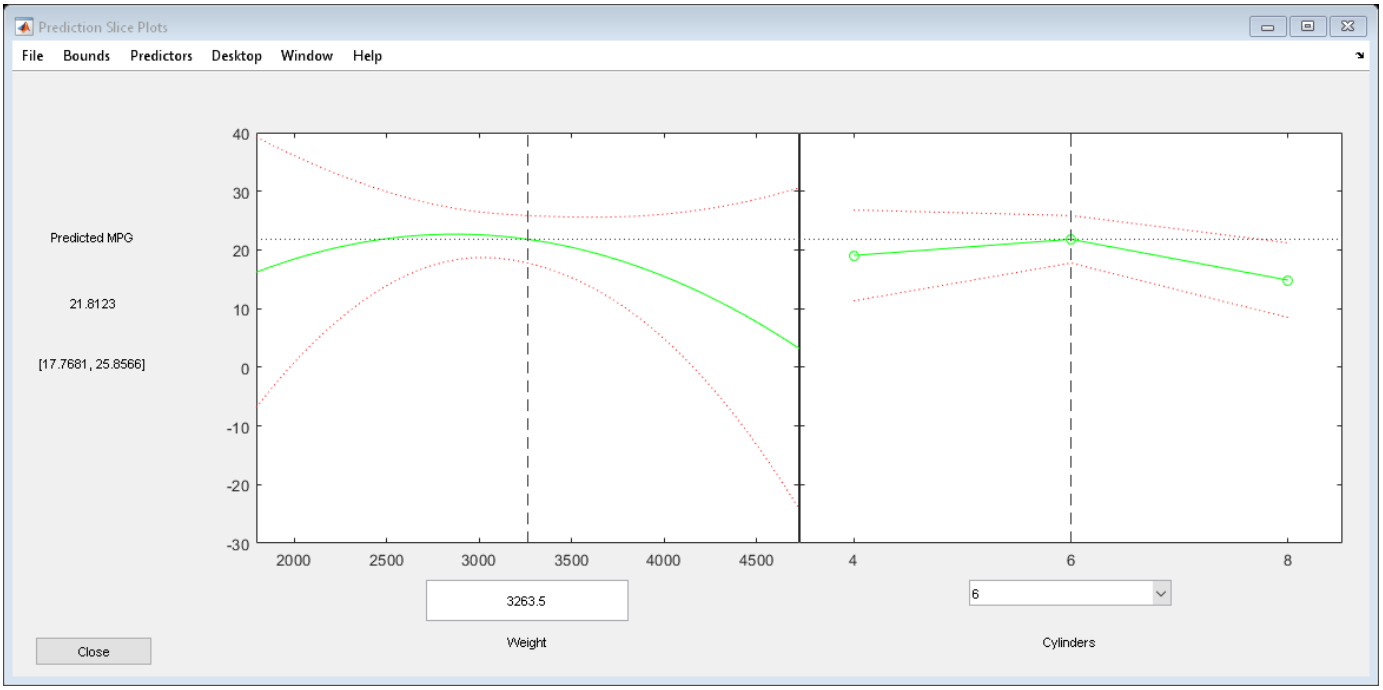
There is some tendency for larger fitted values to have larger residuals. Perhaps the model errors are proportional to the measured values.

Plots to Understand Predictor Effects

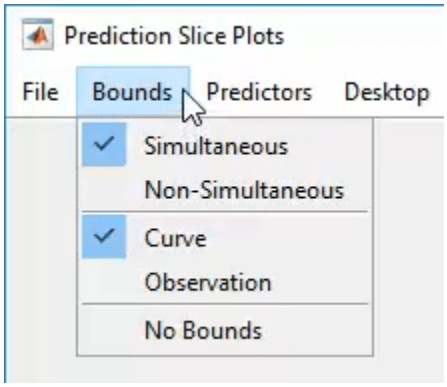
This example shows how to understand the effect each predictor has on a regression model using a variety of available plots.

Examine a slice plot of the responses. This displays the effect of each predictor separately.

```
plotSlice(mdl)
```

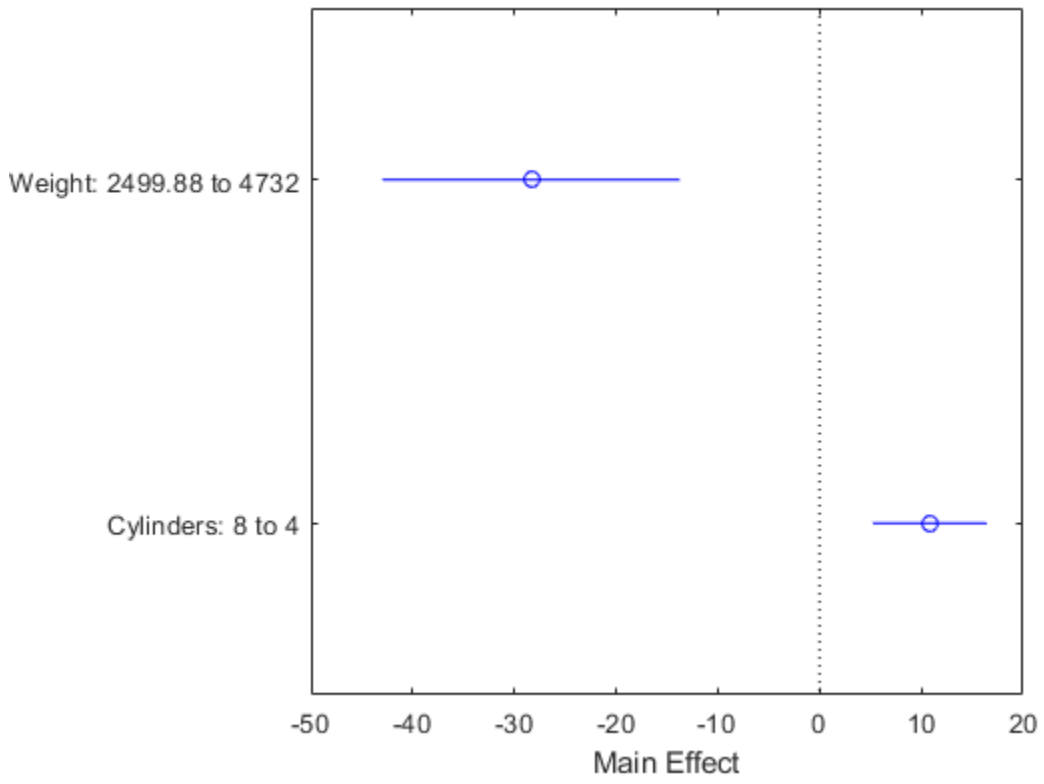


You can drag the individual predictor values, which are represented by dashed blue vertical lines. You can also choose between simultaneous and non-simultaneous confidence bounds, which are represented by dashed red curves.



Use an effects plot to show another view of the effect of predictors on the response.

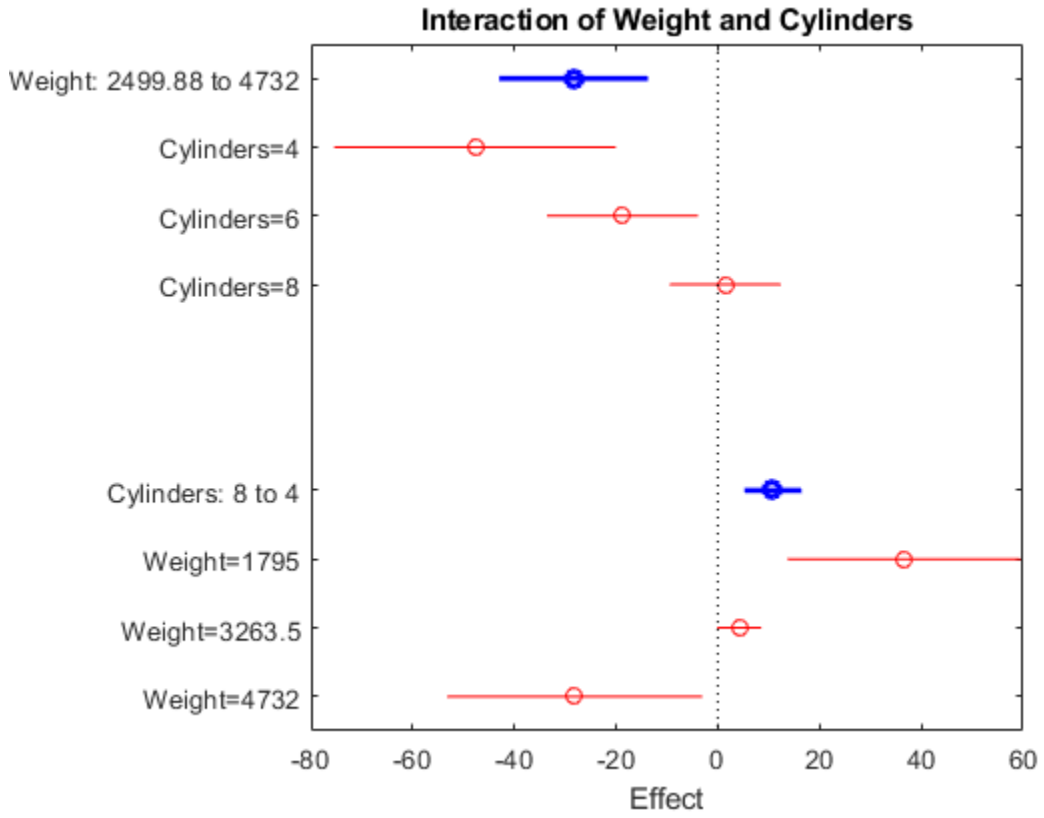
```
plotEffects(mdl)
```



This plot shows that changing `Weight` from about 2500 to 4732 lowers `MPG` by about 30 (the location of the upper blue circle). It also shows that changing the number of cylinders from 8 to 4 raises `MPG` by about 10 (the lower blue circle). The horizontal blue lines represent confidence intervals for these predictions. The predictions come from averaging over one predictor as the other is changed. In cases such as this, where the two predictors are correlated, be careful when interpreting the results.

Instead of viewing the effect of averaging over a predictor as the other is changed, examine the joint interaction in an interaction plot.

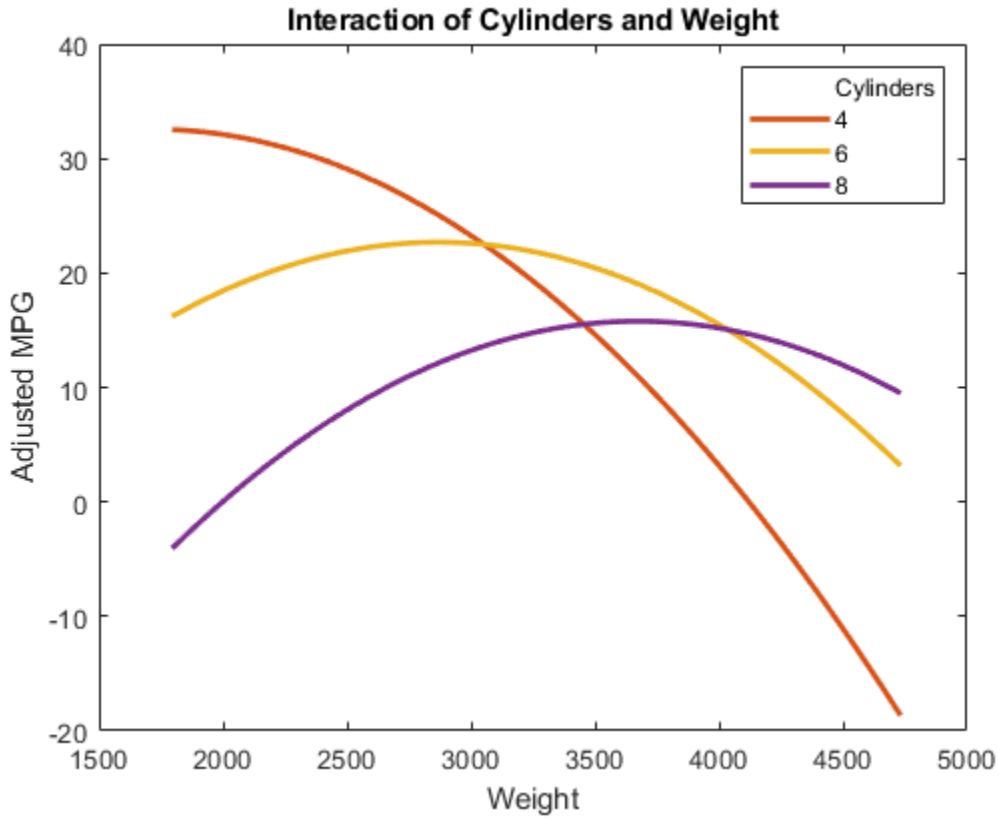
```
plotInteraction(mdl,'Weight','Cylinders')
```



The interaction plot shows the effect of changing one predictor with the other held fixed. In this case, the plot is much more informative. It shows, for example, that lowering the number of cylinders in a relatively light car (`Weight` = 1795) leads to an increase in mileage, but lowering the number of cylinders in a relatively heavy car (`Weight` = 4732) leads to a decrease in mileage.

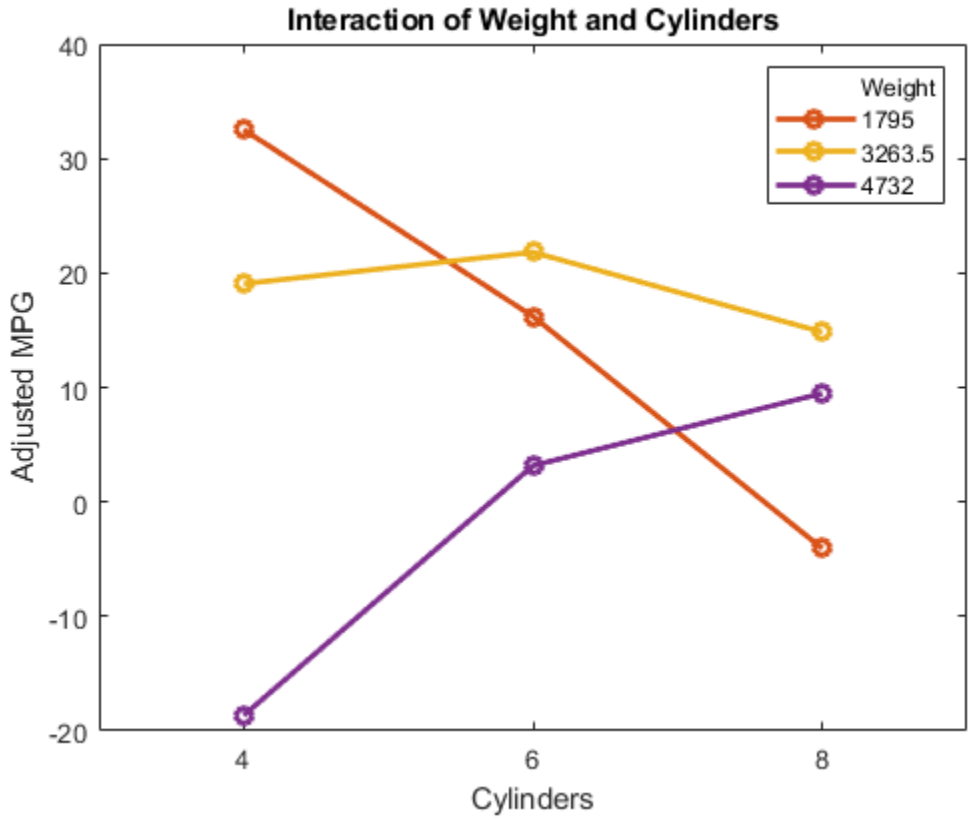
For an even more detailed look at the interactions, look at an interaction plot with predictions. This plot holds one predictor fixed while varying the other, and plots the effect as a curve. Look at the interactions for various fixed numbers of cylinders.

```
plotInteraction(mdl,'Cylinders','Weight','predictions')
```



Now look at the interactions with various fixed levels of weight.

```
plotInteraction(mdl,'Weight','Cylinders','predictions')
```

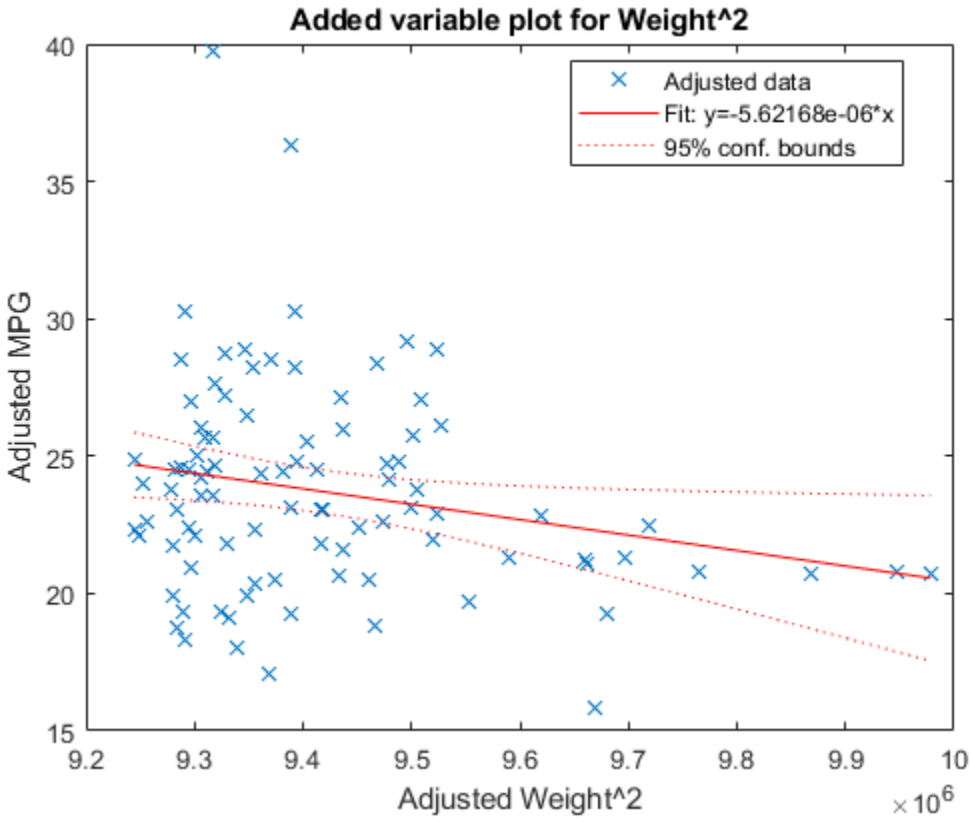


Plots to Understand Terms Effects

This example shows how to understand the effect of each term in a regression model using a variety of available plots.

Create an added variable plot with `Weight^2` as the added variable.

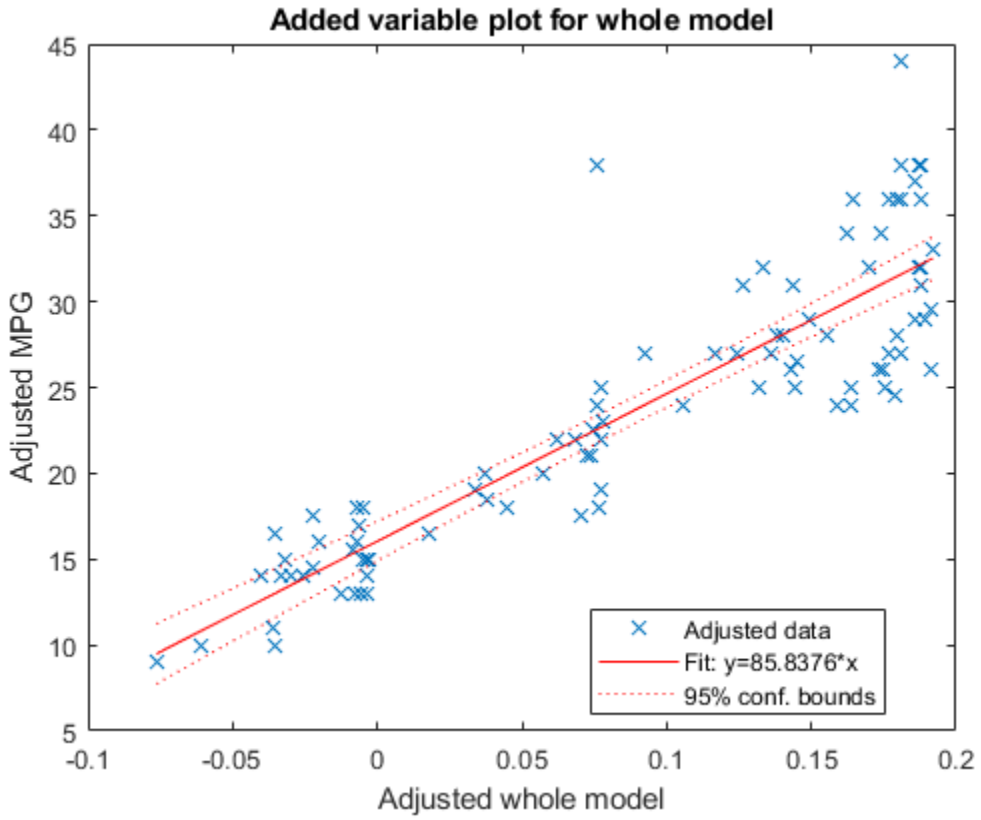
```
plotAdded(mdl,'Weight^2')
```



This plot shows the results of fitting both `Weight^2` and `MPG` to the terms other than `Weight^2`. The reason to use `plotAdded` is to understand what additional improvement in the model you get by adding `Weight^2`. The coefficient of a line fit to these points is the coefficient of `Weight^2` in the full model. The `Weight^2` predictor is just over the edge of significance (`pValue` < 0.05) as you can see in the coefficients table display. You can see that in the plot as well. The confidence bounds look like they could not contain a horizontal line (constant `y`), so a zero-slope model is not consistent with the data.

Create an added variable plot for the model as a whole.

```
plotAdded(mdl)
```



The model as a whole is very significant, so the bounds don't come close to containing a horizontal line. The slope of the line is the slope of a fit to the predictors projected onto their best-fitting direction, or in other words, the norm of the coefficient vector.

Change Models

There are two ways to change a model:

- `step` — Add or subtract terms one at a time, where `step` chooses the most important term to add or remove.
- `addTerms` and `removeTerms` — Add or remove specified terms. Give the terms in any of the forms described in “Choose a Model or Range of Models” on page 11-11.

If you created a model using `stepwiselm`, then `step` can have an effect only if you give different upper or lower models. `step` does not work when you fit a model using `RobustOpts`.

For example, start with a linear model of mileage from the `carbig` data:

```
load carbig
tbl = table(Acceleration,Displacement,Horsepower,Weight,MPG);
mdl = fitlm(tbl,'linear','ResponseVar','MPG')
```

```
mdl =
Linear regression model:
    MPG ~ 1 + Acceleration + Displacement + Horsepower + Weight

Estimated Coefficients:
```

```
                     Estimate         SE         tStat        pValue
                    ___________    __________    ________    __________

    (Intercept)         45.251         2.456      18.424    7.0721e-55
    Acceleration     -0.023148        0.1256     -0.1843       0.85388
    Displacement    -0.0060009     0.0067093    -0.89441       0.37166
    Horsepower       -0.043608      0.016573     -2.6312      0.008849
    Weight          -0.0052805    0.00081085     -6.5123    2.3025e-10

Number of observations: 392, Error degrees of freedom: 387
Root Mean Squared Error: 4.25
R-squared: 0.707,  Adjusted R-Squared: 0.704
F-statistic vs. constant model: 233, p-value = 9.63e-102
```

Try to improve the model using step for up to 10 steps:

```
mdl1 = step(mdl,'NSteps',10)
```

```
1. Adding Displacement:Horsepower, FStat = 87.4802, pValue = 7.05273e-19

mdl1 =
Linear regression model:
    MPG ~ 1 + Acceleration + Weight + Displacement*Horsepower

Estimated Coefficients:
                                Estimate         SE         tStat       pValue
                               ___________    __________    _______    __________

    (Intercept)                   61.285         2.8052     21.847    1.8593e-69
    Acceleration                 -0.34401        0.11862      -2.9     0.0039445
    Displacement                 -0.081198      0.010071    -8.0623    9.5014e-15
    Horsepower                    -0.24313      0.026068    -9.3265    8.6556e-19
    Weight                      -0.0014367    0.00084041    -1.7095      0.088166
    Displacement:Horsepower    0.00054236    5.7987e-05     9.3531    7.0527e-19

Number of observations: 392, Error degrees of freedom: 386
Root Mean Squared Error: 3.84
R-squared: 0.761,  Adjusted R-Squared: 0.758
F-statistic vs. constant model: 246, p-value = 1.32e-117
```

`step` stopped after just one change.

To try to simplify the model, remove the `Acceleration` and `Weight` terms from `mdl1`:

```
mdl2 = removeTerms(mdl1,'Acceleration + Weight')
```

```
mdl2 =
Linear regression model:
    MPG ~ 1 + Displacement*Horsepower

Estimated Coefficients:
                                Estimate         SE         tStat       pValue
                               ___________    __________    _______    __________

    (Intercept)                   53.051         1.526      34.765    3.0201e-121
    Displacement                 -0.098046    0.0066817    -14.674     4.3203e-39
    Horsepower                    -0.23434     0.019593     -11.96     2.8024e-28
```

```
    Displacement:Horsepower    0.00058278    5.193e-05     11.222     1.6816e-25

Number of observations: 392, Error degrees of freedom: 388
Root Mean Squared Error: 3.94
R-squared: 0.747,  Adjusted R-Squared: 0.745
F-statistic vs. constant model: 381, p-value = 3e-115
```

`mdl2` uses just `Displacement` and `Horsepower`, and has nearly as good a fit to the data as `mdl1` in the `Adjusted R-Squared` metric.

Predict or Simulate Responses to New Data

A `LinearModel` object offers three functions to predict or simulate the response to new data: `predict`, `feval`, and `random`.

`predict`

Use the `predict` function to predict and obtain confidence intervals on the predictions.

Load the `carbig` data and create a default linear model of the response `MPG` to the `Acceleration`, `Displacement`, `Horsepower`, and `Weight` predictors.

```
load carbig
X = [Acceleration,Displacement,Horsepower,Weight];
mdl = fitlm(X,MPG);
```

Create a three-row array of predictors from the minimal, mean, and maximal values. `X` contains some `NaN` values, so specify the `'omitnan'` option for the `mean` function. The `min` and `max` functions omit `NaN` values in the calculation by default.

```
Xnew = [min(X);mean(X,'omitnan');max(X)];
```

Find the predicted model responses and confidence intervals on the predictions.

```
[NewMPG, NewMPGCI] = predict(mdl,Xnew)
```

```
NewMPG = 3×1

   34.1345
   23.4078
    4.7751

NewMPGCI = 3×2

   31.6115   36.6575
   22.9859   23.8298
    0.6134    8.9367
```

The confidence bound on the mean response is narrower than those for the minimum or maximum responses.

`feval`

Use the `feval` function to predict responses. When you create a model from a table or dataset array, `feval` is often more convenient than `predict` for predicting responses. When you have new

predictor data, you can pass it to `feval` without creating a table or matrix. However, `feval` does not provide confidence bounds.

Load the `carbig` data set and create a default linear model of the response `MPG` to the predictors `Acceleration`, `Displacement`, `Horsepower`, and `Weight`.

```
load carbig
tbl = table(Acceleration,Displacement,Horsepower,Weight,MPG);
mdl = fitlm(tbl,'linear','ResponseVar','MPG');
```

Predict the model response for the mean values of the predictors.

```
NewMPG = feval(mdl,mean(Acceleration,'omitnan'),mean(Displacement,'omitnan'),mean(Horsepower,'om
```

```
NewMPG = 23.4078
```

`random`

Use the `random` function to simulate responses. The `random` function simulates new random response values, equal to the mean prediction plus a random disturbance with the same variance as the training data.

Load the `carbig` data and create a default linear model of the response `MPG` to the `Acceleration`, `Displacement`, `Horsepower`, and `Weight` predictors.

```
load carbig
X = [Acceleration,Displacement,Horsepower,Weight];
mdl = fitlm(X,MPG);
```

Create a three-row array of predictors from the minimal, mean, and maximal values.

```
Xnew = [min(X);mean(X,'omitnan');max(X)];
```

Generate new predicted model responses including some randomness.

```
rng('default') % for reproducibility
NewMPG = random(mdl,Xnew)
```

```
NewMPG = 3×1

   36.4178
   31.1958
   -4.8176
```

Because a negative value of `MPG` does not seem sensible, try predicting two more times.

```
NewMPG = random(mdl,Xnew)
```

```
NewMPG = 3×1

   37.7959
   24.7615
   -0.7783
```

```
NewMPG = random(mdl,Xnew)
```

```
NewMPG = 3×1
```

```
   32.2931
   24.8628
   19.9715
```

Clearly, the predictions for the third (maximal) row of `Xnew` are not reliable.

Share Fitted Models

Suppose you have a linear regression model, such as `mdl` from the following commands.

```
load carbig
tbl = table(Acceleration,Displacement,Horsepower,Weight,MPG);
mdl = fitlm(tbl,'linear','ResponseVar','MPG');
```

To share the model with other people, you can:

- Provide the model display.

```
mdl
```

```
mdl =
Linear regression model:
    MPG ~ 1 + Acceleration + Displacement + Horsepower + Weight

Estimated Coefficients:
                    Estimate         SE         tStat        pValue
                   __________    __________    ________    __________

    (Intercept)         45.251         2.456      18.424    7.0721e-55
    Acceleration     -0.023148        0.1256     -0.1843       0.85388
    Displacement    -0.0060009     0.0067093    -0.89441       0.37166
    Horsepower       -0.043608      0.016573     -2.6312      0.008849
    Weight          -0.0052805    0.00081085     -6.5123    2.3025e-10

Number of observations: 392, Error degrees of freedom: 387
Root Mean Squared Error: 4.25
R-squared: 0.707,  Adjusted R-Squared: 0.704
F-statistic vs. constant model: 233, p-value = 9.63e-102
```

- Provide the model definition and coefficients.

```
mdl.Formula
```

```
ans =
MPG ~ 1 + Acceleration + Displacement + Horsepower + Weight
```

```
mdl.CoefficientNames
```

```
ans = 1x5 cell
  Columns 1 through 4

    {'(Intercept)'}    {'Acceleration'}    {'Displacement'}    {'Horsepower'}

  Column 5

    {'Weight'}
```

```
mdl.Coefficients.Estimate

ans = 5×1

   45.2511
   -0.0231
   -0.0060
   -0.0436
   -0.0053
```

Linear Regression Workflow

This example shows how to fit a linear regression model. A typical workflow involves the following: import data, fit a regression, test its quality, modify it to improve the quality, and share it.

Step 1. Import the data into a table.

`hospital.xls` is an Excel® spreadsheet containing patient names, sex, age, weight, blood pressure, and dates of treatment in an experimental protocol. First read the data into a table.

```
patients = readtable('hospital.xls','ReadRowNames',true);
```

Examine the five rows of data.

```
patients(1:5,:)
```

```
ans=5×11 table
                 name          sex      age    wgt    smoke    sys    dia    trial1    trial2
              _____________    _____    ___    ___    _____    ___    ___    ______    ______

    YPL-320    {'SMITH'   }    {'m'}    38     176      1      124    93       18       -99
    GLI-532    {'JOHNSON' }    {'m'}    43     163      0      109    77       11        13
    PNI-258    {'WILLIAMS'}    {'f'}    38     131      0      125    83      -99       -99
    MIJ-579    {'JONES'   }    {'f'}    40     133      0      117    75        6        12
    XLK-030    {'BROWN'   }    {'f'}    49     119      0      122    80       14        23
```

The `sex` and `smoke` fields seem to have two choices each. So change these fields to categorical.

```
patients.smoke = categorical(patients.smoke,0:1,{'No','Yes'});
patients.sex = categorical(patients.sex);
```

Step 2. Create a fitted model.

Your goal is to model the systolic pressure as a function of a patient's age, weight, sex, and smoking status. Create a linear formula for `'sys'` as a function of `'age'`, `'wgt'`, `'sex'`, and `'smoke'` .

```
modelspec = 'sys ~ age + wgt + sex + smoke';
mdl = fitlm(patients,modelspec)
```

```
mdl =
Linear regression model:
    sys ~ 1 + sex + age + wgt + smoke

Estimated Coefficients:
                   Estimate        SE        tStat        pValue
                   ________    ________    ________    __________

    (Intercept)      118.28      7.6291      15.504    9.1557e-28
    sex_m           0.88162      2.9473     0.29913       0.76549
    age             0.08602     0.06731       1.278       0.20438
    wgt            -0.016685    0.055714    -0.29947       0.76524
    smoke_Yes          9.884      1.0406       9.498    1.9546e-15

Number of observations: 100, Error degrees of freedom: 95
Root Mean Squared Error: 4.81
```

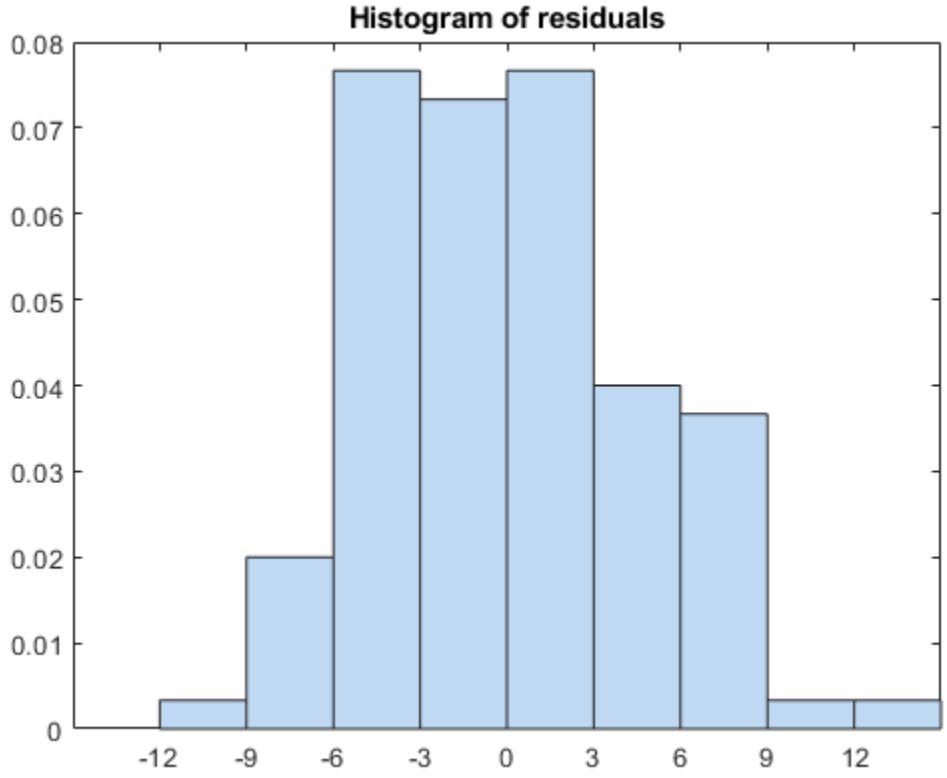
```
R-squared: 0.508,  Adjusted R-Squared: 0.487
F-statistic vs. constant model: 24.5, p-value = 5.99e-14
```

The sex, age, and weight predictors have rather high *p*-values, indicating that some of these predictors might be unnecessary.

Step 3. Locate and remove outliers.

See if there are outliers in the data that should be excluded from the fit. Plot the residuals.

```
plotResiduals(mdl)
```



There is one possible outlier, with a value greater than 12. This is probably not truly an outlier. For demonstration, here is how to find and remove it.

Find the outlier.

```
outlier = mdl.Residuals.Raw > 12;
find(outlier)
```

```
ans = 84
```

Remove the outlier.

```
mdl = fitlm(patients,modelspec,...
    'Exclude',84);

mdl.ObservationInfo(84,:)
```

```
ans=1×4 table
               Weights    Excluded    Missing    Subset
               _______    ________    _______    ______

    WXM-486       1        true        false     false
```

Observation 84 is no longer in the model.

Step 4. Simplify the model.

Try to obtain a simpler model, one with fewer predictors but the same predictive accuracy. `step` looks for a better model by adding or removing one term at a time. Allow `step` take up to 10 steps.

```
mdl1 = step(mdl,'NSteps',10)
```

```
1. Removing wgt, FStat = 4.6001e-05, pValue = 0.9946
2. Removing sex, FStat = 0.063241, pValue = 0.80199

mdl1 =
Linear regression model:
    sys ~ 1 + age + smoke

Estimated Coefficients:
                   Estimate       SE       tStat       pValue
                   ________    ________    ______    __________

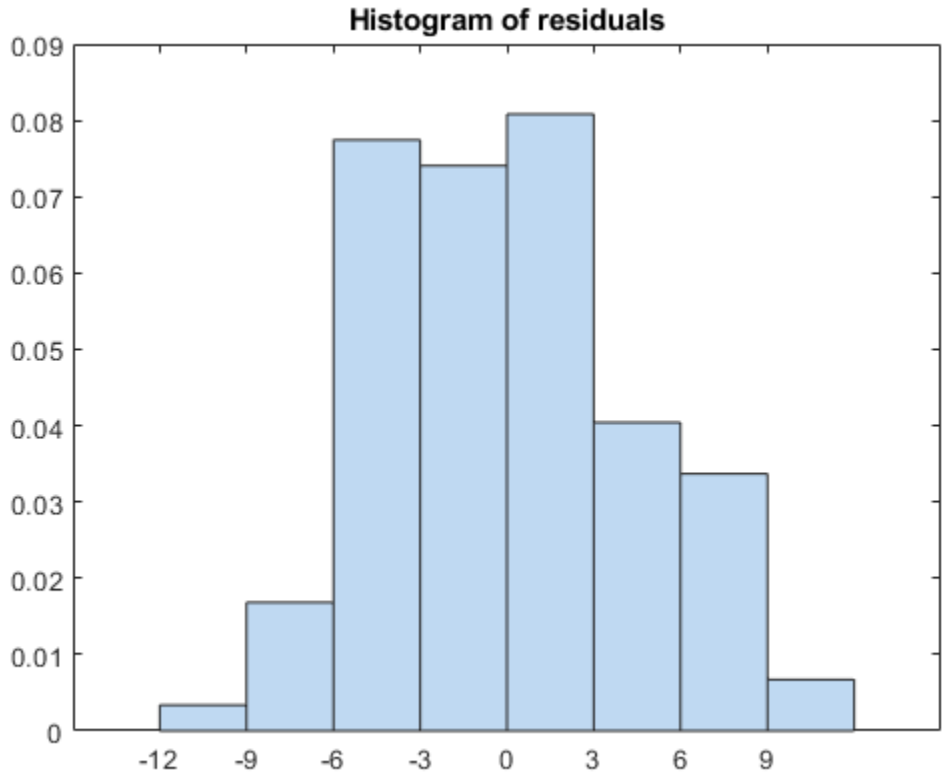
    (Intercept)     115.11       2.5364    45.383    1.1407e-66
    age            0.10782     0.064844    1.6628       0.09962
    smoke_Yes       10.054      0.97696    10.291    3.5276e-17

Number of observations: 99, Error degrees of freedom: 96
Root Mean Squared Error: 4.61
R-squared: 0.536,  Adjusted R-Squared: 0.526
F-statistic vs. constant model: 55.4, p-value = 1.02e-16
```

`step` took two steps. This means it could not improve the model further by adding or subtracting a single term.

Plot the effectiveness of the simpler model on the training data.

```
plotResiduals(mdl1)
```



The residuals look about as small as those of the original model.

Step 5. Predict responses to new data.

Suppose you have four new people, aged 25, 30, 40, and 65, and the first and third smoke. Predict their systolic pressure using `mdl1`.

```
ages = [25;30;40;65];
smoker = {'Yes';'No';'Yes';'No'};
systolicnew = feval(mdl1,ages,smoker)
```

```
systolicnew = 4×1

  127.8561
  118.3412
  129.4734
  122.1149
```

To make predictions, you need only the variables that `mdl1` uses.

Step 6. Share the model.

You might want others to be able to use your model for prediction. Access the terms in the linear model.

```
coefnames = mdl1.CoefficientNames
```

```
coefnames = 1x3 cell
    {'(Intercept)'}    {'age'}    {'smoke_Yes'}
```

View the model formula.

```
mdl1.Formula
```

```
ans =
sys ~ 1 + age + smoke
```

Access the coefficients of the terms.

```
coefvals = mdl1.Coefficients(:,1).Estimate
```

```
coefvals = 3×1

  115.1066
    0.1078
   10.0540
```

The model is `sys = 115.1066 + 0.1078*age + 10.0540*smoke`, where `smoke` is `1` for a smoker, and `0` otherwise.

Regression Using Dataset Arrays

This example shows how to perform linear and stepwise regression analyses using dataset arrays.

Load sample data.

```
load imports-85
```

Store predictor and response variables in dataset array.

```
ds = dataset(X(:,7),X(:,8),X(:,9),X(:,15),'Varnames',...
{'curb_weight','engine_size','bore','price'});
```

Fit linear regression model.

Fit a linear regression model that explains the price of a car in terms of its curb weight, engine size, and bore.

```
fitlm(ds,'price~curb_weight+engine_size+bore')
```

```
ans =
Linear regression model:
    price ~ 1 + curb_weight + engine_size + bore

Estimated Coefficients:
                    Estimate        SE         tStat       pValue
                   __________    _________    _______    __________

    (Intercept)        64.095        3.703     17.309    2.0481e-41
    curb_weight    -0.0086681    0.0011025    -7.8623      2.42e-13
    engine_size     -0.015806     0.013255    -1.1925       0.23452
    bore              -2.6998       1.3489    -2.0015      0.046711

Number of observations: 201, Error degrees of freedom: 197
Root Mean Squared Error: 3.95
R-squared: 0.674,  Adjusted R-Squared: 0.669
F-statistic vs. constant model: 136, p-value = 1.14e-47
```

The command `fitlm(ds)` also returns the same result because `fitlm`, by default, assumes the predictor variable is in the last column of the dataset array `ds`.

Recreate dataset array and repeat analysis.

This time, put the response variable in the first column of the dataset array.

```
 ds = dataset(X(:,15),X(:,7),X(:,8),X(:,9),'Varnames',...
{'price','curb_weight','engine_size','bore'});
```

When the response variable is in the first column of `ds`, define its location. For example, `fitlm`, by default, assumes that `bore` is the response variable. You can define the response variable in the model using either:

```
fitlm(ds,'ResponseVar','price');
```

or

```
fitlm(ds,'ResponseVar',logical([1 0 0 0]));
```

Perform stepwise regression.

```
stepwiselm(ds,'quadratic','lower','price~1',...
'ResponseVar','price')

1. Removing bore^2, FStat = 0.01282, pValue = 0.90997
2. Removing engine_size^2, FStat = 0.078043, pValue = 0.78027
3. Removing curb_weight:bore, FStat = 0.70558, pValue = 0.40195

ans =
Linear regression model:
    price ~ 1 + curb_weight*engine_size + engine_size*bore + curb_weight^2

Estimated Coefficients:

                             __________    __________    _______    __________

    (Intercept)                 131.13        14.273     9.1873    6.2319e-17
    curb_weight               -0.043315     0.0085114    -5.0891    8.4682e-07
    engine_size                -0.17102       0.13844    -1.2354       0.21819
    bore                        -12.244         4.999    -2.4493      0.015202
    curb_weight:engine_size   -6.3411e-05    2.6577e-05     -2.386      0.017996
    engine_size:bore            0.092554      0.037263     2.4838      0.013847
    curb_weight^2              8.0836e-06    1.9983e-06     4.0451    7.5432e-05

Number of observations: 201, Error degrees of freedom: 194
Root Mean Squared Error: 3.59
R-squared: 0.735,  Adjusted R-Squared: 0.726
F-statistic vs. constant model: 89.5, p-value = 3.58e-53
```

The initial model is a quadratic formula, and the lowest model considered is the constant. Here, `stepwiselm` performs a backward elimination technique to determine the terms in the model. The final model is `price ~ 1 + curb_weight*engine_size + engine_size*bore + curb_weight^2`, which corresponds to

$$P = \beta_0 + \beta_C C + \beta_E E + \beta_B B + \beta_{CE} CE + \beta_{EB} EB + \beta_{C^2} C^2 + \epsilon$$

where P is price, C is curb weight, E is engine size, B is bore, β_i is the coefficient for the corresponding term in the model, and ϵ is the error term. The final model includes all three main effects, the interaction effects for curb weight and engine size and engine size and bore, and the second-order term for curb weight.

Linear Regression Using Tables

This example shows how to perform linear and stepwise regression analyses using tables.

Load sample data.

```
load imports-85
```

Store predictor and response variables in a table.

```
tbl = table(X(:,7),X(:,8),X(:,9),X(:,15),'VariableNames',...
{'curb_weight','engine_size','bore','price'});
```

Fit linear regression model.

Fit a linear regression model that explains the price of a car in terms of its curb weight, engine size, and bore.

```
fitlm(tbl,'price~curb_weight+engine_size+bore')
```

```
ans =
Linear regression model:
    price ~ 1 + curb_weight + engine_size + bore

Estimated Coefficients:
                    Estimate        SE         tStat       pValue
                   __________    _________    _______    __________

    (Intercept)        64.095        3.703     17.309    2.0481e-41
    curb_weight    -0.0086681    0.0011025    -7.8623      2.42e-13
    engine_size     -0.015806     0.013255    -1.1925       0.23452

Linear Regression with Interaction Effects

Construct and analyze a linear regression model with interaction effects and interpret the results.

Load sample data.

```
load hospital
```

To retain only the first column of blood pressure, store data in a table.

```
tbl = table(hospital.Sex,hospital.Age,hospital.Weight,hospital.Smoker,hospital.BloodPressure(:,1
    'VariableNames',{'Sex','Age','Weight','Smoker','BloodPressure'});
```

Perform stepwise linear regression.

For the initial model, use the full model with all terms and their pairwise interactions.

```
mdl = stepwiselm(tbl,'interactions')
```

```
1. Removing Sex:Smoker, FStat = 0.050738, pValue = 0.8223
2. Removing Weight:Smoker, FStat = 0.07758, pValue = 0.78124
3. Removing Age:Weight, FStat = 1.9717, pValue = 0.16367
4. Removing Sex:Age, FStat = 0.32389, pValue = 0.57067
5. Removing Age:Smoker, FStat = 2.4939, pValue = 0.11768

mdl =
Linear regression model:
    BloodPressure ~ 1 + Age + Smoker + Sex*Weight

Estimated Coefficients:
                       Estimate       SE        tStat       pValue
                       ________    _________    _______    __________

    (Intercept)         133.17       10.337     12.883      1.76e-22
    Sex_Male           -35.269       17.524    -2.0126      0.047015
    Age                0.11584     0.067664      1.712      0.090198
    Weight             -0.1393     0.080211    -1.7367      0.085722
    Smoker_1            9.8307       1.0229     9.6102    1.2391e-15
    Sex_Male:Weight     0.2341      0.11192     2.0917      0.039162

Number of observations: 100, Error degrees of freedom: 94
Root Mean Squared Error: 4.72
R-squared: 0.53,  Adjusted R-Squared: 0.505
F-statistic vs. constant model: 21.2, p-value = 4e-14
```

The final model in formula form is `BloodPressure ~ 1 + Age + Smoker + Sex*Weight`. This model includes all four main effects (Age, Smoker, Sex, Weight) and the two-way interaction between `Sex` and `Weight`. This model corresponds to

$$BP = \beta_0 + \beta_A X_A + \beta_{Sm} I_{Sm} + \beta_S I_S + \beta_W X_W + \beta_{SW} X_W I_S + \epsilon,$$

where

- BP is the blood pressure
- β_i are the coefficients

- I_{Sm} is the indicator variable for smoking; $I_{Sm} = 1$ indicates a smoking patient whereas $I_{Sm} = 0$ indicates a nonsmoking patient
- I_S is the indicator variable for sex; $I_S = 1$ indicates a male patient whereas $I_S = 0$ indicates a female patient
- X_A is the `Age` variable
- X_W is the `Weight` variable
- ϵ is the error term

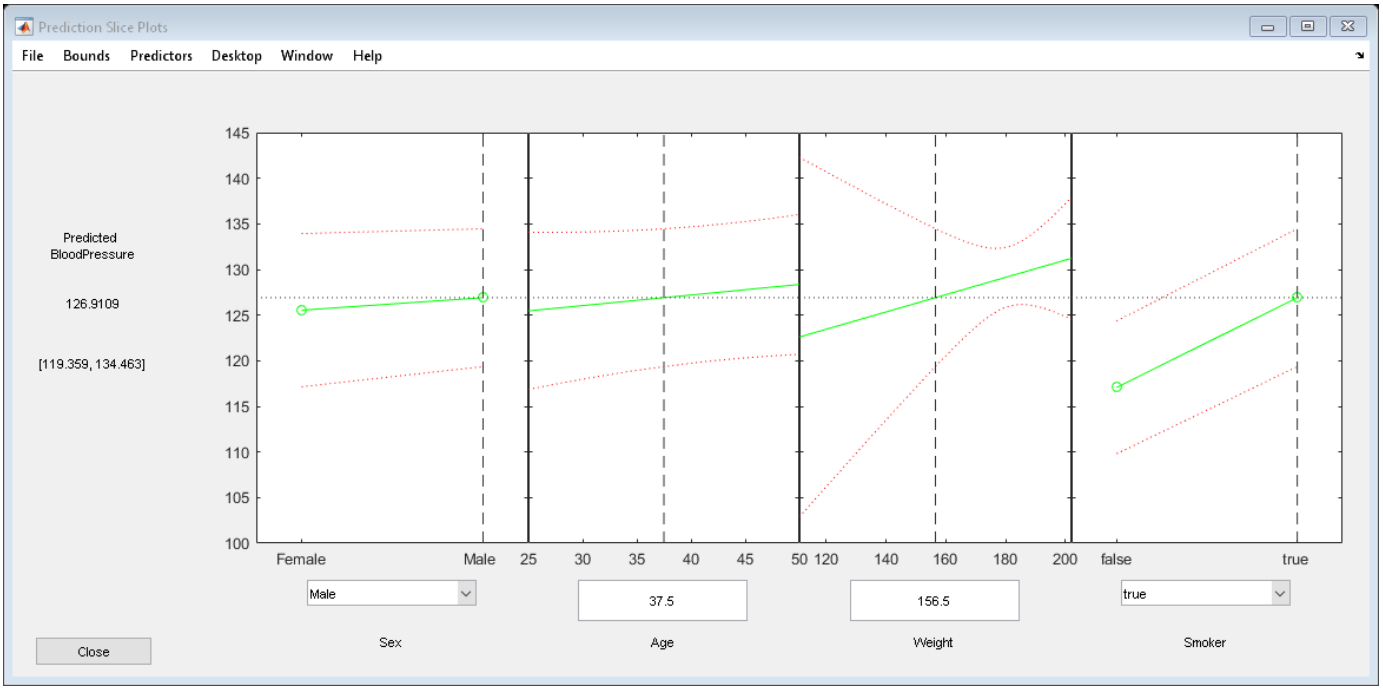
The following table shows the fitted linear model for each gender and smoking combination.

I_{Sm}	I_S	Linear Model
1(Smoker)	1(Male)	$BP = (\beta_0 + \beta_{Sm} + \beta_S) + \beta_A X_A + (\beta_W + \beta_{SW}) X_W$ $\widehat{BP} = 107.5617 + 0.11584 X_A + 0.11826 X_W$
1(Smoker)	0(Female)	$BP = (\beta_0 + \beta_{Sm}) + \beta_A X_A + \beta_W X_W$ $\widehat{BP} = 143.0007 + 0.11584 X_A - 0.1393 X_W$
0(Nonsmoker)	1(Male)	$BP = (\beta_0 + \beta_S) + \beta_A X_A + (\beta_W + \beta_{SW}) X_W$ $\widehat{BP} = 97.901 + 0.11584 X_A + 0.11826 X_W$
0(Nonsmoker)	0(Female)	$BP = \beta_0 + \beta_A X_A + \beta_W X_W$ $\widehat{BP} = 133.17 + 0.11584 X_A - 0.1393 X_W$

As seen from these models, β_{Sm} and β_S show how much the intercept of the response function changes when the indicator variable takes the value 1 compared to when it takes the value 0. β_{SW}, however, shows the effect of the Weight variable on the response variable when the indicator variable for sex takes the value 1 compared to when it takes the value 0. You can explore the main and interaction effects in the final model using the methods of the `LinearModel` class as follows.

Plot prediction slice plots.

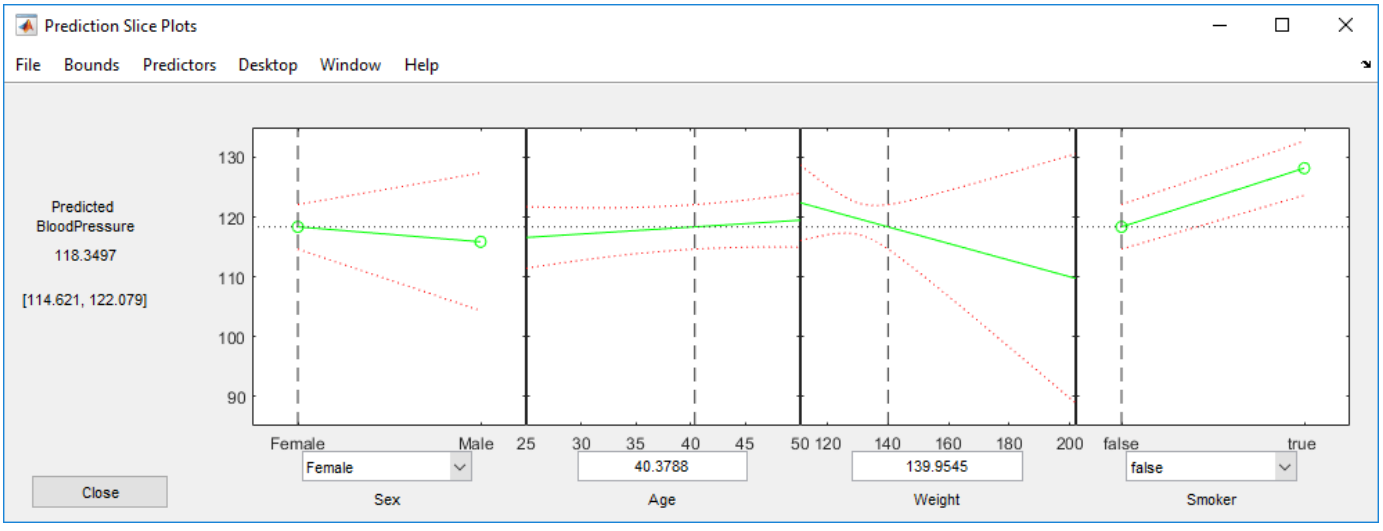
```
figure
plotSlice(mdl)
```



This plot shows the main effects for all predictor variables. The green line in each panel shows the change in the response variable as a function of the predictor variable when all other predictor variables are held constant. For example, for a smoking male patient aged 37.5, the expected blood pressure increases as the weight of the patient increases, given all else the same.

The dashed red curves in each panel show the 95% confidence bounds for the predicted response values.

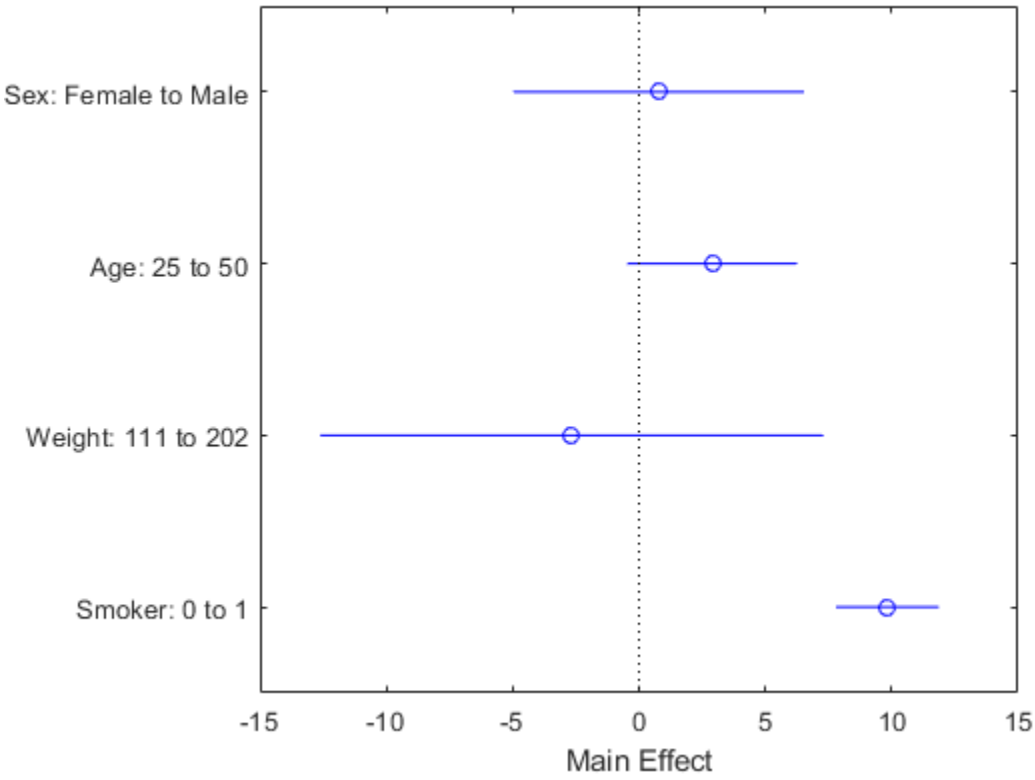
The horizontal dashed line in each panel shows the predicted response for the specific value of the predictor variable corresponding to the vertical dashed line. You can drag these lines to get the predicted response values at other predictor values, as shown next.



For example, the predicted value of the response variable is 118.3497 when a patient is female, nonsmoking, age 40.3788, and weighs 139.9545 pounds. The values in the square brackets, [114.621, 122.079], show the lower and upper limits of a 95% confidence interval for the estimated response. Note that, for a nonsmoking female patient, the expected blood pressure decreases as the weight increases, given all else is held constant.

Plot main effects.

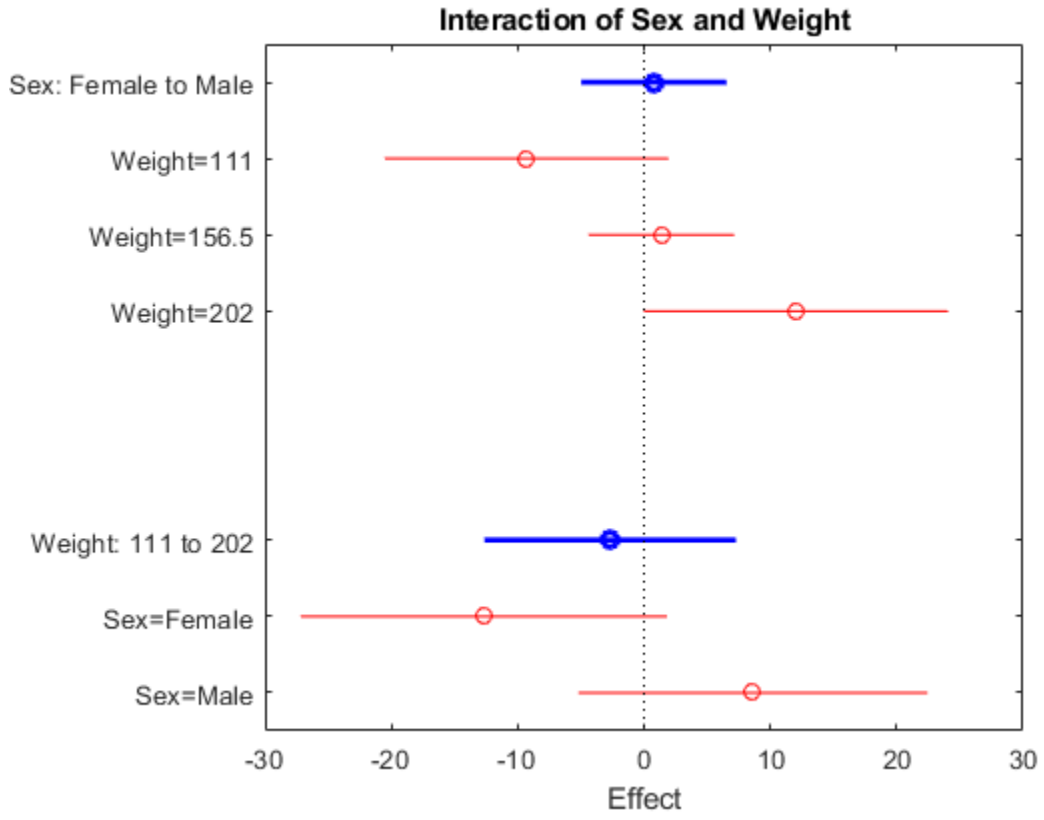
```
plotEffects(mdl)
```



This plot displays the main effects. The circles show the magnitude of the effect and the blue lines show the upper and lower confidence limits for the main effect. For example, being a smoker increases the expected blood pressure by 10 units, compared to being a nonsmoker, given all else is held constant. Expected blood pressure increases about two units for males compared to females, again, given other predictors held constant. An increase in age from 25 to 50 causes an expected increase of 4 units, whereas a change in weight from 111 to 202 causes about a 4-unit decrease in the expected blood pressure, given all else held constant.

Plot interaction effects.

```
figure
plotInteraction(mdl,'Sex','Weight')
```



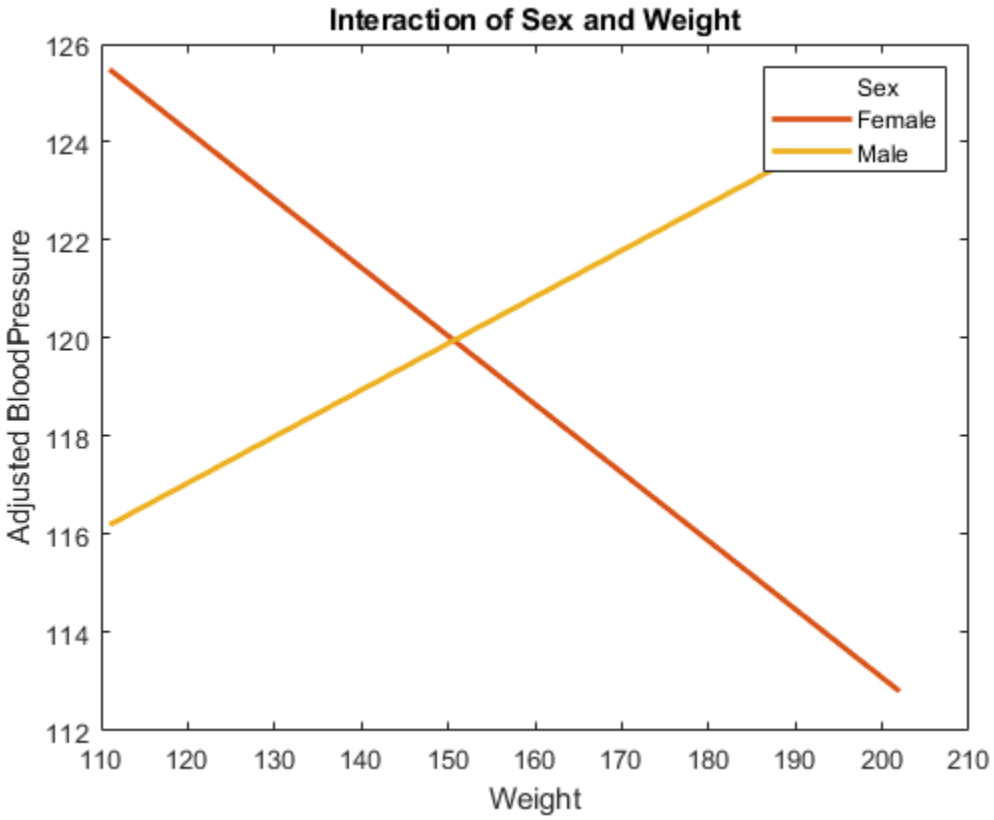
This plot displays the impact of a change in one factor given the other factor is fixed at a value.

Be cautious while interpreting the interaction effects. When there is not enough data on all factor combinations or the data is highly correlated, it might be difficult to determine the interaction effect of changing one factor while keeping the other fixed. In such cases, the estimated interaction effect is an extrapolation from the data.

The blue circles show the main effect of a specific term, as in the main effects plot. The red circles show the impact of a change in one term for fixed values of the other term. For example, in the bottom half of this plot, the red circles show the impact of a weight change in female and male patients, separately. You can see that an increase in a female's weight from 111 to 202 pounds causes about a 14-unit decrease in the expected blood pressure, while an increase of the same amount in the weight of a male patient causes about a 5-unit increase in the expected blood pressure, again given other predictors are held constant.

Plot prediction effects.

```
figure
plotInteraction(mdl,'Sex','Weight','predictions')
```



This plot shows the effect of changing one variable as the other predictor variable is held constant. In this example, the last figure shows the response variable, blood pressure, as a function of weight, when the variable sex is fixed at males and females. The lines for males and females are crossing which indicates a strong interaction between weight and sex. You can see that the expected blood pressure increases as the weight of a male patient increases, but decreases as the weight of a female patient increases.

Interpret Linear Regression Results

This example shows how to display and interpret linear regression output statistics.

Fit Linear Regression Model

Load the `carsmall` data set, a matrix input data set.

```
load carsmall
X = [Weight,Horsepower,Acceleration];
```

Fit a linear regression model by using `fitlm`.

```
lm = fitlm(X,MPG)
```

```
lm =
Linear regression model:
    y ~ 1 + x1 + x2 + x3

Estimated Coefficients:
                   Estimate        SE          tStat        pValue
                  __________    _________    _________    __________

    (Intercept)        47.977       3.8785        12.37    4.8957e-21
    x1             -0.0065416    0.0011274      -5.8023    9.8742e-08
    x2              -0.042943     0.024313      -1.7663       0.08078
    x3              -0.011583      0.19333    -0.059913       0.95236

Number of observations: 93, Error degrees of freedom: 89
Root Mean Squared Error: 4.09
R-squared: 0.752,  Adjusted R-Squared: 0.744
F-statistic vs. constant model: 90, p-value = 7.38e-27
```

The model display includes the model formula, estimated coefficients, and model summary statistics.

The model formula in the display, `y ~ 1 + x1 + x2 + x3`, corresponds to $y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \epsilon$.

The model display shows the estimated coefficient information, which is stored in the `Coefficients` property. Display the `Coefficients` property.

```
lm.Coefficients
```

```
ans=4×4 table
                   Estimate        SE          tStat        pValue
                  __________    _________    _________    __________

    (Intercept)        47.977       3.8785        12.37    4.8957e-21
    x1             -0.0065416    0.0011274      -5.8023    9.8742e-08
    x2              -0.042943     0.024313      -1.7663       0.08078
    x3              -0.011583      0.19333    -0.059913       0.95236
```

The `Coefficient` property includes these columns:

- `Estimate` — Coefficient estimates for each corresponding term in the model. For example, the estimate for the constant term (`intercept`) is 47.977.

- `SE` — Standard error of the coefficients.
- `tStat` — *t*-statistic for each coefficient to test the null hypothesis that the corresponding coefficient is zero against the alternative that it is different from zero, given the other predictors in the model. Note that `tStat = Estimate/SE`. For example, the *t*-statistic for the intercept is 47.977/3.8785 = 12.37.
- `pValue` — *p*-value for the *t*-statistic of the hypothesis test that the corresponding coefficient is equal to zero or not. For example, the *p*-value of the *t*-statistic for `x2` is greater than 0.05, so this term is not significant at the 5% significance level given the other terms in the model.

The summary statistics of the model are:

- `Number of observations` — Number of rows without any `NaN` values. For example, `Number of observations` is 93 because the `MPG` data vector has six `NaN` values and the `Horsepower` data vector has one `NaN` value for a different observation, where the number of rows in `X` and `MPG` is 100.
- `Error degrees of freedom` — $n - p$, where n is the number of observations, and p is the number of coefficients in the model, including the intercept. For example, the model has four predictors, so the `Error degrees of freedom` is 93 – 4 = 89.
- `Root mean squared error` — Square root of the mean squared error, which estimates the standard deviation of the error distribution.
- `R-squared` and `Adjusted R-squared` — Coefficient of determination and adjusted coefficient of determination, respectively. For example, the `R-squared` value suggests that the model explains approximately 75% of the variability in the response variable `MPG`.
- `F-statistic vs. constant model` — Test statistic for the *F*-test on the regression model, which tests whether the model fits significantly better than a degenerate model consisting of only a constant term.
- `p-value` — *p*-value for the *F*-test on the model. For example, the model is significant with a *p*-value of 7.3816e-27.

ANOVA

Perform analysis of variance (ANOVA) for the model.

```
anova(lm,'summary')
```

```

                SumSq     DF    MeanSq      F         pValue
                ______    __    ______    ______    __________

    Total       6004.8    92    65.269
    Model         4516     3    1505.3    89.987    7.3816e-27
    Residual    1488.8    89    16.728
```

This `anova` display shows the following.

- `SumSq` — Sum of squares for the regression model, `Model`, the error term, `Residual`, and the total, `Total`.
- `DF` — Degrees of freedom for each term. Degrees of freedom is $n - 1$ for the total, $p - 1$ for the model, and $n - p$ for the error term, where n is the number of observations, and p is the number of coefficients in the model, including the intercept. For example, `MPG` data vector has six `NaN` values and one of the data vectors, `Horsepower`, has one `NaN` value for a different observation, so the

total degrees of freedom is 93 – 1 = 92. There are four coefficients in the model, so the model `DF` is 4 – 1 = 3, and the `DF` for error term is 93 – 4 = 89.

- `MeanSq` — Mean squared error for each term. Note that `MeanSq = SumSq/DF`. For example, the mean squared error for the error term is 1488.8/89 = 16.728. The square root of this value is the `root mean squared error` in the linear regression display, or 4.09.
- `F` — *F*-statistic value, which is the same as `F-statistic vs. constant model` in the linear regression display. In this example, it is 89.987, and in the linear regression display this *F*-statistic value is rounded up to 90.
- `pValue` — *p*-value for the *F*-test on the model. In this example, it is 7.3816e-27.

If there are higher-order terms in the regression model, `anova` partitions the model `SumSq` into the part explained by the higher-order terms and the rest. The corresponding *F*-statistics are for testing the significance of the linear terms and higher-order terms as separate groups.

If the data includes replicates, or multiple measurements at the same predictor values, then the `anova` partitions the error `SumSq` into the part for the replicates and the rest. The corresponding *F*-statistic is for testing the lack-of-fit by comparing the model residuals with the model-free variance estimate computed on the replicates.

Decompose ANOVA table for model terms.

```
anova(lm)
```

```
ans=4×5 table
              SumSq      DF     MeanSq          F          pValue
            ________    __    ________    _________    __________

    x1         563.18     1      563.18       33.667    9.8742e-08
    x2         52.187     1      52.187       3.1197       0.08078
    x3       0.060046     1    0.060046    0.0035895       0.95236
    Error      1488.8    89      16.728
```

This `anova` display shows the following:

- First column — Terms included in the model.
- `SumSq` — Sum of squared error for each term except for the constant.
- `DF` — Degrees of freedom. In this example, `DF` is 1 for each term in the model and $n - p$ for the error term, where n is the number of observations, and p is the number of coefficients in the model, including the intercept. For example, the `DF` for the error term in this model is 93 – 4 = 89. If any of the variables in the model is a categorical variable, the `DF` for that variable is the number of indicator variables created for its categories (number of categories – 1).
- `MeanSq` — Mean squared error for each term. Note that `MeanSq = SumSq/DF`. For example, the mean squared error for the error term is 1488.8/89 = 16.728.
- `F` — *F*-values for each coefficient. The *F*-value is the ratio of the mean squared of each term and mean squared error, that is, `F = MeanSq(xi)/MeanSq(Error)`. Each *F*-statistic has an *F* distribution, with the numerator degrees of freedom, `DF` value for the corresponding term, and the denominator degrees of freedom, $n - p$. n is the number of observations, and p is the number of coefficients in the model. In this example, each *F*-statistic has an $F_{(1,89)}$ distribution.
- `pValue` — *p*-value for each hypothesis test on the coefficient of the corresponding term in the linear model. For example, the *p*-value for the *F*-statistic coefficient of `x2` is 0.08078, and is not significant at the 5% significance level given the other terms in the model.

Coefficient Confidence Intervals

Display coefficient confidence intervals.

```
coefCI(lm)
```

```
ans = 4×2

   40.2702   55.6833
   -0.0088   -0.0043
   -0.0913    0.0054
   -0.3957    0.3726
```

The values in each row are the lower and upper confidence limits, respectively, for the default 95% confidence intervals for the coefficients. For example, the first row shows the lower and upper limits, 40.2702 and 55.6833, for the intercept, β_0. Likewise, the second row shows the limits for β_1 and so on. Confidence intervals provide a measure of precision for linear regression coefficient estimates. A $100(1-\alpha)\,\%$ confidence interval gives the range the corresponding regression coefficient will be in with $100(1-\alpha)\,\%$ confidence.

You can also change the confidence level. Find the 99% confidence intervals for the coefficients.

```
coefCI(lm,0.01)
```

```
ans = 4×2

   37.7677   58.1858
   -0.0095   -0.0036
   -0.1069    0.0211
   -0.5205    0.4973
```

Hypothesis Test on Coefficients

Test the null hypothesis that all predictor variable coefficients are equal to zero versus the alternate hypothesis that at least one of them is different from zero.

```
[p,F,d] = coefTest(lm)
```

```
p = 7.3816e-27

F = 89.9874

d = 3
```

Here, `coefTest` performs an *F*-test for the hypothesis that all regression coefficients (except for the intercept) are zero versus at least one differs from zero, which essentially is the hypothesis on the model. It returns *p*, the *p*-value, `F`, the *F*-statistic, and `d`, the numerator degrees of freedom. The *F*-statistic and *p*-value are the same as the ones in the linear regression display and `anova` for the model. The degrees of freedom is 4 – 1 = 3 because there are four predictors (including the intercept) in the model.

Now, perform a hypothesis test on the coefficients of the first and second predictor variables.

```
H = [0 1 0 0; 0 0 1 0];
[p,F,d] = coefTest(lm,H)
```

```
p = 5.1702e-23

F = 96.4873

d = 2
```

The numerator degrees of freedom is the number of coefficients tested, which is 2 in this example. The results indicate that at least one of β_2 and β_3 differs from zero.

Cook’s Distance

Purpose

Cook’s distance is the scaled change in fitted values, which is useful for identifying outliers in the X values (observations for predictor variables). Cook’s distance shows the influence of each observation on the fitted response values. An observation with Cook’s distance larger than three times the mean Cook’s distance might be an outlier.

Definition

Each element in the Cook's distance D is the normalized change in the fitted response values due to the deletion of an observation. The Cook’s distance of observation i is

$$D_i = \frac{\sum_{j=1}^{n} \left(\widehat{y}_j - \widehat{y}_{j(i)}\right)^2}{p\,MSE},$$

where

- $\widehat{y}_j$ is the jth fitted response value.
- $\widehat{y}_{j(i)}$ is the jth fitted response value, where the fit does not include observation i.
- MSE is the mean squared error.
- p is the number of coefficients in the regression model.

Cook’s distance is algebraically equivalent to the following expression:

$$D_i = \frac{r_i^2}{p\,MSE}\left(\frac{h_{ii}}{(1-h_{ii})^2}\right),$$

where r_i is the ith residual, and h_{ii} is the ith leverage value.

How To

After fitting the model `mdl`, for example, you can use `fitlm` or `stepwiselm` to:

- Display the Cook’s distance values by indexing into the property using dot notation.

  ```
  mdl.Diagnostics.CooksDistance
  ```

  `CooksDistance` is an n-by-1 column vector in the `Diagnostics` table of the `LinearModel` object.
- Plot the Cook’s distance values.

  ```
  plotDiagnostics(mdl,'cookd')
  ```

  For details, see the `plotDiagnostics` function of the `LinearModel` object.

Determine Outliers Using Cook's Distance

This example shows how to use Cook's Distance to determine the outliers in the data.

Load the sample data and define the independent and response variables.

```
load hospital
X = double(hospital(:,2:5));
y = hospital.BloodPressure(:,1);
```

Fit the linear regression model.

```
mdl = fitlm(X,y);
```

Plot the Cook's distance values.

```
plotDiagnostics(mdl,'cookd')
```

The dashed line in the figure corresponds to the recommended threshold value, `3*mean(mdl.Diagnostics.CooksDistance)`. The plot has some observations with Cook's distance values greater than the threshold value, which for this example is 3*(0.0108) = 0.0324. In particular, there are two Cook's distance values that are relatively higher than the others, which exceed the threshold value. You might want to find and omit these from your data and rebuild your model.

Find the observations with Cook's distance values that exceed the threshold value.

```
find((mdl.Diagnostics.CooksDistance)>3*mean(mdl.Diagnostics.CooksDistance))
```

```
ans = 10×1

     2
    13
    28
    44
    58
    70
    71
    84
    93
    95
```

Find the observations with Cook's distance values that are relatively larger than the other observations with Cook's distances exceeding the threshold value.

```
find((mdl.Diagnostics.CooksDistance)>5*mean(mdl.Diagnostics.CooksDistance))
```

```
ans = 2×1

     2
    84
```

Coefficient Standard Errors and Confidence Intervals

In this section...

Coefficient Covariance and Standard Errors

Purpose

Estimated coefficient variances and covariances capture the precision of regression coefficient estimates. The coefficient variances and their square root, the standard errors, are useful in testing hypotheses for coefficients.

Definition

The estimated covariance matrix is

$$\sum = MSE(X'X)^{-1},$$

where MSE is the mean squared error, and X is the matrix of observations on the predictor variables. `CoefficientCovariance`, a property of the fitted model, is a p-by-p covariance matrix of regression coefficient estimates. p is the number of coefficients in the regression model. The diagonal elements are the variances of the individual coefficients.

How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can display the coefficient covariances using

```
mdl.CoefficientCovariance
```

Compute Coefficient Covariance and Standard Errors

This example shows how to compute the covariance matrix and standard errors of the coefficients.

Load the sample data and define the predictor and response variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = fitlm(X,y);
```

Display the coefficient covariance matrix.

```
CM = mdl.CoefficientCovariance
```

```
CM = 5×5

   27.5113   11.0027   -0.1542   -0.2444    0.2702

```

Coefficient Confidence Intervals

Purpose

The coefficient confidence intervals provide a measure of precision for linear regression coefficient estimates. A 100(1–α)% confidence interval gives the range that the corresponding regression coefficient will be in with 100(1–α)% confidence.

Definition

The software finds confidence intervals using the Wald method. The 100*(1 – α)% confidence intervals for regression coefficients are

$$b_i \pm t_{(1-\alpha/2,\, n-p)} SE(b_i),$$

where b_i is the coefficient estimate, $SE(b_i)$ is the standard error of the coefficient estimate, and $t_{(1-\alpha/2,n-p)}$ is the 100(1 – α/2) percentile of t-distribution with n – p degrees of freedom. n is the number of observations and p is the number of regression coefficients.

How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can obtain the default 95% confidence intervals for coefficients using

```
coefCI(mdl)
```

You can also change the confidence level using

```
coefCI(mdl,alpha)
```

For details, see the `coefCI` function of `LinearModel` object.

Compute Coefficient Confidence Intervals

This example shows how to compute coefficient confidence intervals.

Load the sample data and fit a linear regression model.

```
load hald
mdl = fitlm(ingredients,heat);
```

Display the 95% coefficient confidence intervals.

```
coefCI(mdl)
```

```
ans = 5×2

  -99.1786  223.9893
   -0.1663    3.2685
   -1.1589    2.1792
   -1.6385    1.8423
   -1.7791    1.4910
```

The values in each row are the lower and upper confidence limits, respectively, for the default 95% confidence intervals for the coefficients. For example, the first row shows the lower and upper limits, -99.1786 and 223.9893, for the intercept, β_0 . Likewise, the second row shows the limits for β_1 and so on.

Display the 90% confidence intervals for the coefficients ($\alpha = 0.1$).

```
coefCI(mdl,0.1)
```

```
ans = 5×2

  -67.8949  192.7057
    0.1662    2.9360
   -0.8358    1.8561
   -1.3015    1.5053
   -1.4626    1.1745
```

The confidence interval limits become narrower as the confidence level decreases.

Coefficient of Determination (R-Squared)

Purpose

Coefficient of determination (R-squared) indicates the proportionate amount of variation in the response variable y explained by the independent variables X in the linear regression model. The larger the R-squared is, the more variability is explained by the linear regression model.

Definition

R-squared is the proportion of the total sum of squares explained by the model. `Rsquared`, a property of the fitted model, is a structure with two fields:

- `Ordinary` — Ordinary (unadjusted) R-squared

  $$R^2 = \frac{SSR}{SST} = 1 - \frac{SSE}{SST}.$$

- `Adjusted` — R-squared adjusted for the number of coefficients

  $$R^2_{adj} = 1 - \left(\frac{n-1}{n-p}\right)\frac{SSE}{SST}.$$

  SSE is the sum of squared error, SSR is the sum of squared regression, SST is the sum of squared total, n is the number of observations, and p is the number of regression coefficients. Note that p includes the intercept, so for example, p is 2 for a linear fit. Because R-squared increases with added predictor variables in the regression model, the adjusted R-squared adjusts for the number of predictor variables in the model. This makes it more useful for comparing models with a different number of predictors.

How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can obtain either R-squared value as a scalar by indexing into the property using dot notation, for example,

```
mdl.Rsquared.Ordinary
mdl.Rsquared.Adjusted
```

You can also obtain the SSE, SSR, and SST using the properties with the same name.

```
mdl.SSE
mdl.SSR
mdl.SST
```

Display Coefficient of Determination

This example shows how to display R-squared (coefficient of determination) and adjusted R-squared. Load the sample data and define the response and independent variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = fitlm(X,y)

mdl =
Linear regression model:
    y ~ 1 + x1 + x2 + x3 + x4

Estimated Coefficients:
                   Estimate        SE        tStat        pValue
                   ________    ________    ________    __________

    (Intercept)        117.4      5.2451      22.383    1.1667e-39
    x1               0.88162      2.9473     0.29913       0.76549
    x2               0.08602     0.06731       1.278       0.20438
    x3             -0.016685    0.055714    -0.29947       0.76524
    x4                 9.884      1.0406       9.498    1.9546e-15

Number of observations: 100, Error degrees of freedom: 95
Root Mean Squared Error: 4.81
R-squared: 0.508,  Adjusted R-Squared: 0.487
F-statistic vs. constant model: 24.5, p-value = 5.99e-14
```

The R-squared and adjusted R-squared values are 0.508 and 0.487, respectively. Model explains about 50% of the variability in the response variable.

Access the R-squared and adjusted R-squared values using the property of the fitted `LinearModel` object.

```
mdl.Rsquared.Ordinary

ans = 0.5078

mdl.Rsquared.Adjusted

ans = 0.4871
```

The adjusted R-squared value is smaller than the ordinary R-squared value.

Delete-1 Statistics

In this section...

Delete-1 Change in Covariance (CovRatio)

Purpose

Delete-1 change in covariance (`CovRatio`) identifies the observations that are influential in the regression fit. An influential observation is one where its exclusion from the model might significantly alter the regression function. Values of `CovRatio` larger than 1 + 3*p/n or smaller than 1 – 3*p/n indicate influential points, where p is the number of regression coefficients, and n is the number of observations.

Definition

The `CovRatio` statistic is the ratio of the determinant of the coefficient covariance matrix with observation i deleted to the determinant of the covariance matrix for the full model:

$$\text{CovRatio} = \frac{\det\left\{MSE(i)[X'(i)X(i)]^{-1}\right\}}{\det\left[MSE(X'X)^{-1}\right]}.$$

`CovRatio` is an n-by-1 vector in the `Diagnostics` table of the fitted `LinearModel` object. Each element is the ratio of the generalized variance of the estimated coefficients when the corresponding element is deleted to the generalized variance of the coefficients using all the data.

How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Display the `CovRatio` by indexing into the property using dot notation

  ```
  mdl.Diagnostics.CovRatio
  ```

- Plot the delete-1 change in covariance using

  ```
  plotDiagnostics(mdl,'CovRatio')
  ```

  For details, see the `plotDiagnostics` method of the `LinearModel` class.

Determine Influential Observations Using CovRatio

This example shows how to use the `CovRatio` statistics to determine the influential points in data. Load the sample data and define the response and predictor variables.

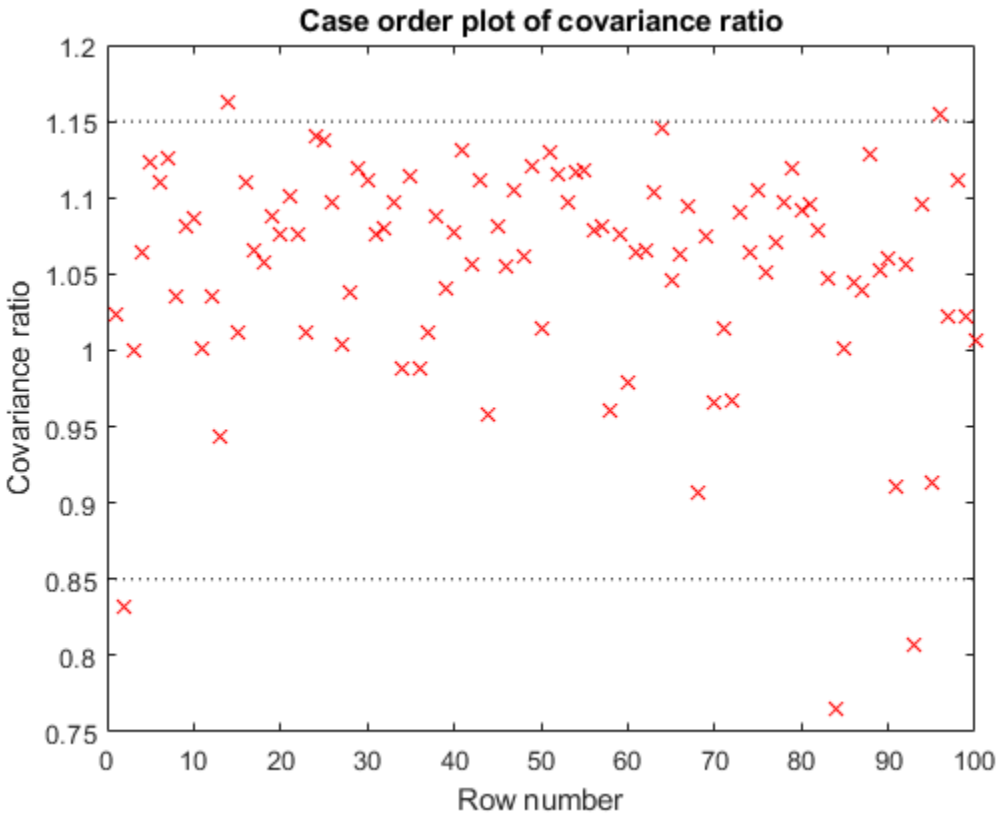
```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = fitlm(X,y);
```

Plot the `CovRatio` statistics.

```
plotDiagnostics(mdl,'CovRatio')
```



For this example, the threshold limits are 1 + 3*5/100 = 1.15 and 1 - 3*5/100 = 0.85. There are a few points beyond the limits, which might be influential points.

Find the observations that are beyond the limits.

```
find((mdl.Diagnostics.CovRatio)>1.15|(mdl.Diagnostics.CovRatio)<0.85)
```

```
ans = 5×1

     2
    14
    84
    93
    96
```

Delete-1 Scaled Difference in Coefficient Estimates (Dfbetas)

Purpose

The sign of a delete-1 scaled difference in coefficient estimate (`Dfbetas`) for coefficient j and observation i indicates whether that observation causes an increase or decrease in the estimate of the regression coefficient. The absolute value of a `Dfbetas` indicates the magnitude of the difference relative to the estimated standard deviation of the regression coefficient. A `Dfbetas` value larger than 3/sqrt(n) in absolute value indicates that the observation has a large influence on the corresponding coefficient.

Definition

`Dfbetas` for coefficient j and observation i is the ratio of the difference in the estimate of coefficient j using all observations and the one obtained by removing observation i, and the standard error of the coefficient estimate obtained by removing observation i. The `Dfbetas` for coefficient j and observation i is

$$Dfbetas_{ij} = \frac{b_j - b_{j(i)}}{\sqrt{MSE_{(i)}}(1 - h_{ii})},$$

where b_j is the estimate for coefficient j, $b_{j(i)}$ is the estimate for coefficient j by removing observation i, $MSE_{(i)}$ is the mean squared error of the regression fit by removing observation i, and h_{ii} is the leverage value for observation i. `Dfbetas` is an n-by-p matrix in the `Diagnostics` table of the fitted `LinearModel` object. Each cell of `Dfbetas` corresponds to the `Dfbetas` value for the corresponding coefficient obtained by removing the corresponding observation.

How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can obtain the `Dfbetas` values as an n-by-p matrix by indexing into the property using dot notation,

```
mdl.Diagnostics.Dfbetas
```

Determine Observations Influential on Coefficients Using Dfbetas

This example shows how to determine the observations that have large influence on coefficients using `Dfbetas`. Load the sample data and define the response and independent variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = fitlm(X,y);
```

Find the `Dfbetas` values that are high in absolute value.

```
[row,col] = find(abs(mdl.Diagnostics.Dfbetas)>3/sqrt(100));
disp([row col])
```

```
     2     1
    28     1
    84     1
    93     1
```

```
     2     2
    13     3
    84     3
     2     4
    84     4
```

Delete-1 Scaled Change in Fitted Values (Dffits)

Purpose

The delete-1 scaled change in fitted values (`Dffits`) show the influence of each observation on the fitted response values. `Dffits` values with an absolute value larger than 2*sqrt(*p*/*n*) might be influential.

Definition

`Dffits` for observation *i* is

$$\text{Dffits}_i = sr_i\sqrt{\frac{h_{ii}}{1-h_{ii}}},$$

where sr_i is the studentized residual, and h_{ii} is the leverage value of the fitted `LinearModel` object. `Dffits` is an *n*-by-1 column vector in the `Diagnostics` table of the fitted `LinearModel` object. Each element in `Dffits` is the change in the fitted value caused by deleting the corresponding observation and scaling by the standard error.

How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Display the `Dffits` values by indexing into the property using dot notation

  ```
  mdl.Diagnostics.Dffits
  ```

- Plot the delete-1 scaled change in fitted values using

  ```
  plotDiagnostics(mdl,'Dffits')
  ```

  For details, see the `plotDiagnostics` method of the `LinearModel` class for details.

Determine Observations Influential on Fitted Response Using Dffits

This example shows how to determine the observations that are influential on the fitted response values using `Dffits` values. Load the sample data and define the response and independent variables.

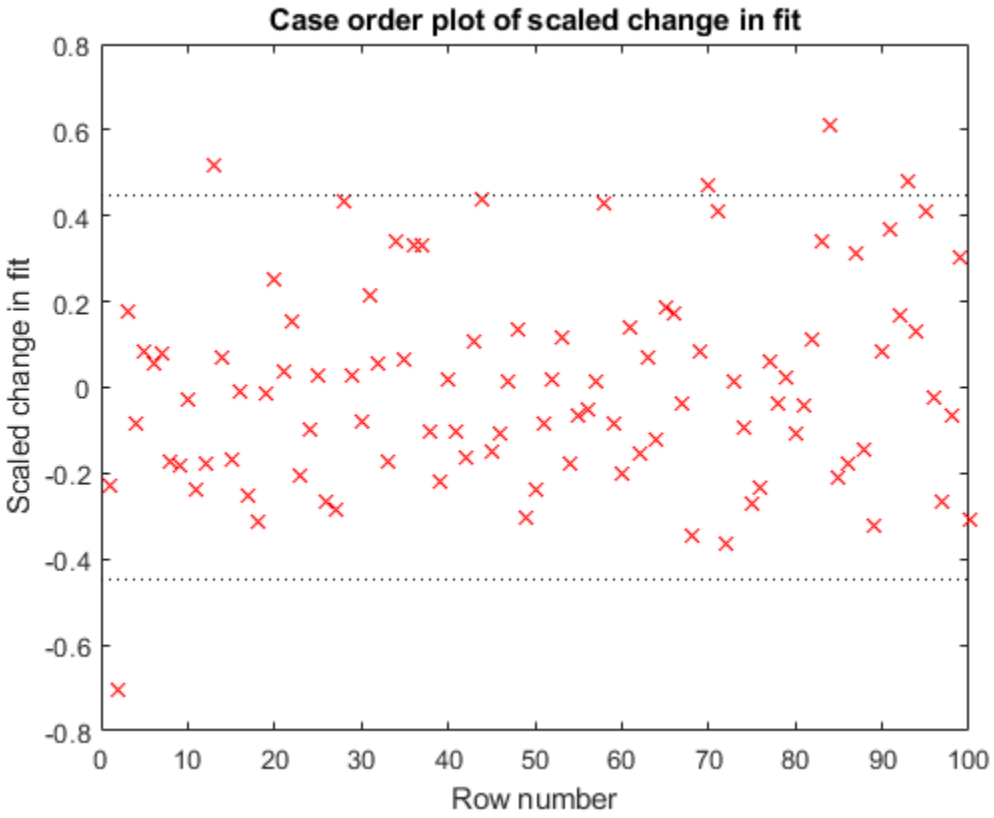
```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = fitlm(X,y);
```

Plot the `Dffits` values.

```
plotDiagnostics(mdl,'Dffits')
```



The influential threshold limit for the absolute value of `Dffits` in this example is 2*sqrt(5/100) = 0.45. Again, there are some observations with `Dffits` values beyond the recommended limits.

Find the `Dffits` values that are large in absolute value.

```
find(abs(mdl.Diagnostics.Dffits)>2*sqrt(4/100))
```

```
ans = 10×1

     2
    13
    28
    44
    58
    70
    71
    84
    93
    95
```

Delete-1 Variance (S2_i)

Purpose

The delete-1 variance (`S2_i`) shows how the mean squared error changes when an observation is removed from the data set. You can compare the `S2_i` values with the value of the mean squared error.

Definition

`S2_i` is a set of residual variance estimates obtained by deleting each observation in turn. The `S2_i` value for observation i is

$$S2\_i = MSE_{(i)} = \frac{\sum_{j \neq i}^{n} \left[y_j - \hat{y}_{j(i)} \right]^2}{n - p - 1},$$

where y_j is the jth observed response value. `S2_i` is an n-by-1 vector in the `Diagnostics` table of the fitted `LinearModel` object. Each element in `S2_i` is the mean squared error of the regression obtained by deleting that observation.

How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Display the `S2_i` vector by indexing into the property using dot notation

  ```
  mdl.Diagnostics.S2_i
  ```

- Plot the delete-1 variance values using

  ```
  plotDiagnostics(mdl,'S2_i')
  ```

  For details, see the `plotDiagnostics` method of the `LinearModel` class.

Compute and Examine Delete-1 Variance Values

This example shows how to compute and plot S2_i values to examine the change in the mean squared error when an observation is removed from the data. Load the sample data and define the response and independent variables.

```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = fitlm(X,y);
```

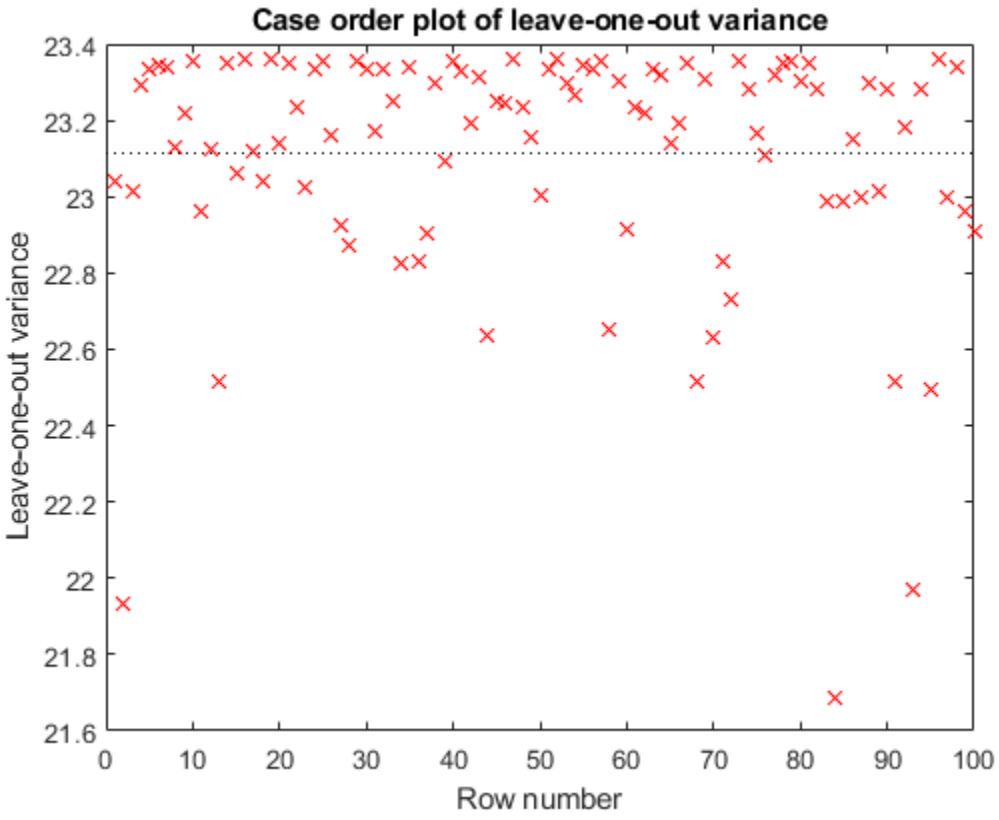
Display the MSE value for the model.

```
mdl.MSE
```

```
ans = 23.1140
```

Plot the S2_i values.

```
plotDiagnostics(mdl,'S2_i')
```



This plot makes it easy to compare the S2_i values to the MSE value of 23.114, indicated by the horizontal dashed lines. You can see how deleting one observation changes the error variance.

Durbin-Watson Test

Purpose

The Durbin-Watson test assesses whether or not there is autocorrelation among the residuals of time series data.

Definition

The Durbin-Watson test statistic, `DW`, is

$$DW = \frac{\sum_{i=1}^{n-1} (r_{i+1} - r_i)^2}{\sum_{i=1}^{n} r_i^2},$$

where r_i is the ith raw residual, and n is the number of observations.

How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can perform the Durbin-Watson test using

```
dwtest(mdl)
```

For details, see the `dwtest` method of the `LinearModel` class.

Test for Autocorrelation Among Residuals

This example shows how to test for autocorrelation among the residuals of a linear regression model.

Load the sample data and fit a linear regression model.

```
load hald
mdl = fitlm(ingredients,heat);
```

Perform a two-sided Durbin-Watson test to determine if there is any autocorrelation among the residuals of the linear model, `mdl`.

```
[p,DW] = dwtest(mdl,'exact','both')
```

```
p = 0.8421
```

```
DW = 2.0526
```

The value of the Durbin-Watson test statistic is 2.0526. The p-value of 0.8421 suggests that the residuals are not autocorrelated.

F-statistic and t-statistic

In this section...

F-statistic

Purpose

In linear regression, the F-statistic is the test statistic for the analysis of variance (ANOVA) approach to test the significance of the model or the components in the model.

Definition

The F-statistic in the linear model output display is the test statistic for testing the statistical significance of the model. The F-statistic values in the `anova` display are for assessing the significance of the terms or components in the model.

How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Find the `F-statistic vs. constant model` in the output display or by using

  ```
  disp(mdl)
  ```
- Display the ANOVA for the model using

  ```
  anova(mdl,'summary')
  ```
- Obtain the F-statistic values for the components, except for the constant term using

  ```
  anova(mdl)
  ```

  For details, see the `anova` method of the `LinearModel` class.

Assess Fit of Model Using F-statistic

This example shows how to assess the fit of the model and the significance of the regression coefficients using the F-statistic.

Load the sample data.

```
load hospital
tbl = table(hospital.Age,hospital.Weight,hospital.Smoker,hospital.BloodPressure(:,1), ...
      'VariableNames',{'Age','Weight','Smoker','BloodPressure'});
tbl.Smoker = categorical(tbl.Smoker);
```

Fit a linear regression model.

```
mdl = fitlm(tbl,'BloodPressure ~ Age*Weight + Smoker + Weight^2')
```

```
mdl =
Linear regression model:
    BloodPressure ~ 1 + Smoker + Age*Weight + Weight^2

Estimated Coefficients:
                    Estimate        SE         tStat        pValue
                   __________    _________    ________    __________

    (Intercept)        168.02       27.694       6.067    2.7149e-08
    Age              0.079569      0.39861     0.19962       0.84221
    Weight            -0.69041       0.3435     -2.0099      0.047305
    Smoker_true         9.8027       1.0256      9.5584    1.5969e-15
    Age:Weight     0.00021796    0.0025258    0.086294       0.93142
    Weight^2        0.0021877    0.0011037      1.9822      0.050375

Number of observations: 100, Error degrees of freedom: 94
Root Mean Squared Error: 4.73
R-squared: 0.528,  Adjusted R-Squared: 0.503
F-statistic vs. constant model: 21, p-value = 4.81e-14
```

The F-statistic of the linear fit versus the constant model is 21, with a *p*-value of 4.81e-14. The model is significant at the 5% significance level. The R-squared value of 0.528 means the model explains about 53% of the variability in the response. There might be other predictor (explanatory) variables that are not included in the current model.

Display the ANOVA table for the fitted model.

```
anova(mdl,'summary')
```

```
ans=5×5 table
                    SumSq     DF    MeanSq      F         pValue
                    ______    __    ______    ______    __________

    Total           4461.2    99    45.062
    Model           2354.5     5     470.9    21.012    4.8099e-14
    . Linear        2263.3     3    754.42    33.663    7.2417e-15
    . Nonlinear     91.248     2    45.624    2.0358        0.1363
    Residual        2106.6    94    22.411
```

This display separates the variability in the model into linear and nonlinear terms. Since there are two non-linear terms (`Weight^2` and the interaction between `Weight` and `Age`), the nonlinear degrees of freedom in the `DF` column is 2. There are three linear terms in the model (one `Smoker` indicator variable, `Weight`, and `Age`). The corresponding F-statistics in the `F` column are for testing the significance of the linear and nonlinear terms as separate groups.

When there are replicated observations, the residual term is also separated into two parts; first is the error due to the lack of fit, and second is the pure error independent from the model, obtained from the replicated observations. In that case, the F-statistic is for testing the lack of fit, that is, whether the fit is adequate or not. But, in this example, there are no replicated observations.

Display the ANOVA table for the model terms.

```
anova(mdl)
```

```
ans=6×5 table
                    SumSq      DF     MeanSq         F          pValue
```

```
                ________    __    ________    _________    __________

Age               62.991     1      62.991       2.8107      0.096959
Weight          0.064104     1    0.064104    0.0028604       0.95746
Smoker            2047.5     1      2047.5       91.363    1.5969e-15
Age:Weight       0.16689     1     0.16689    0.0074466       0.93142
Weight^2          88.057     1      88.057       3.9292      0.050375
Error             2106.6    94      22.411
```

This display decomposes the ANOVA table into the model terms. The corresponding F-statistics in the `F` column assess the statistical significance of each term. For example, the F-test for `Smoker` tests whether the coefficient of the indicator variable for `Smoker` is different from zero. That is, the F-test determines whether being a smoker has a significant effect on `BloodPressure`. The degrees of freedom for each model term is the numerator degrees of freedom for the corresponding F-test. All the terms have one degree of freedom. In the case of a categorical variable, the degrees of freedom is the number of indicator variables. `Smoker` has only one indicator variable, so it also has one degree of freedom.

t-statistic

Purpose

In linear regression, the *t*-statistic is useful for making inferences about the regression coefficients. The hypothesis test on coefficient *i* tests the null hypothesis that it is equal to zero – meaning the corresponding term is not significant – versus the alternate hypothesis that the coefficient is different from zero.

Definition

For a hypotheses test on coefficient *i*, with

$H_0 : \beta_i = 0$

$H_1 : \beta_i \neq 0$,

the *t*-statistic is:

$$t = \frac{b_i}{SE(b_i)},$$

where $SE(b_i)$ is the standard error of the estimated coefficient b_i.

How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Find the coefficient estimates, the standard errors of the estimates (`SE`), and the *t*-statistic values of hypothesis tests for the corresponding coefficients (`tStat`) in the output display.
- Call for the display using

  ```
  display(mdl)
  ```

Assess Significance of Regression Coefficients Using t-statistic

This example shows how to test for the significance of the regression coefficients using t-statistic.

Load the sample data and fit the linear regression model.

```
load hald
mdl = fitlm(ingredients,heat)
```

```
mdl =
Linear regression model:
    y ~ 1 + x1 + x2 + x3 + x4

Estimated Coefficients:
                   Estimate      SE        tStat       pValue
                   ________    _______    ________    ________

    (Intercept)      62.405     70.071      0.8906     0.39913
    x1               1.5511    0.74477      2.0827    0.070822
    x2              0.51017    0.72379     0.70486      0.5009
    x3              0.10191    0.75471     0.13503     0.89592
    x4             -0.14406    0.70905    -0.20317     0.84407

Number of observations: 13, Error degrees of freedom: 8
Root Mean Squared Error: 2.45
R-squared: 0.982,  Adjusted R-Squared: 0.974
F-statistic vs. constant model: 111, p-value = 4.76e-07
```

You can see that for each coefficient, `tStat = Estimate/SE`. The *p*-values for the hypotheses tests are in the `pValue` column. Each *t*-statistic tests for the significance of each term given other terms in the model. According to these results, none of the coefficients seem significant at the 5% significance level, although the R-squared value for the model is really high at 0.97. This often indicates possible multicollinearity among the predictor variables.

Use stepwise regression to decide which variables to include in the model.

```
load hald
mdl = stepwiselm(ingredients,heat)
```

```
1. Adding x4, FStat = 22.7985, pValue = 0.000576232
2. Adding x1, FStat = 108.2239, pValue = 1.105281e-06

mdl =
Linear regression model:
    y ~ 1 + x1 + x4

Estimated Coefficients:
                   Estimate       SE        tStat       pValue
                   ________    ________    _______    __________

    (Intercept)      103.1        2.124      48.54    3.3243e-13
    x1                1.44      0.13842     10.403    1.1053e-06
    x4              -0.61395    0.048645    -12.621    1.8149e-07

Number of observations: 13, Error degrees of freedom: 10
Root Mean Squared Error: 2.73
```

```
R-squared: 0.972,  Adjusted R-Squared: 0.967
F-statistic vs. constant model: 177, p-value = 1.58e-08
```

In this example, `stepwiselm` starts with the constant model (default) and uses forward selection to incrementally add `x4` and `x1`. Each predictor variable in the final model is significant given the other one is in the model. The algorithm stops when adding none of the other predictor variables significantly improves in the model. For details on stepwise regression, see `stepwiselm`.

Hat Matrix and Leverage

In this section...

Hat Matrix

Purpose

The hat matrix provides a measure of leverage. It is useful for investigating whether one or more observations are outlying with regard to their X values, and therefore might be excessively influencing the regression results.

Definition

The hat matrix is also known as the *projection matrix* because it projects the vector of observations, y, onto the vector of predictions, $\widehat{y}$, thus putting the "hat" on y. The hat matrix H is defined in terms of the data matrix X:

$$H = X(X^TX)^{-1}X^T$$

and determines the fitted or predicted values since

$$\widehat{y} = Hy = Xb\,.$$

The diagonal elements of H, h_{ii}, are called leverages and satisfy

$$0 \le h_{ii} \le 1$$

$$\sum_{i=1}^{n} h_{ii} = p,$$

where p is the number of coefficients, and n is the number of observations (rows of X) in the regression model. `HatMatrix` is an n-by-n matrix in the `Diagnostics` table.

How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Display the `HatMatrix` by indexing into the property using dot notation

  ```
  mdl.Diagnostics.HatMatrix
  ```

  When n is large, `HatMatrix` might be computationally expensive. In those cases, you can obtain the diagonal values directly, using

  ```
  mdl.Diagnostics.Leverage
  ```

Leverage

Purpose

Leverage is a measure of the effect of a particular observation on the regression predictions due to the position of that observation in the space of the inputs. In general, the farther a point is from the center of the input space, the more leverage it has. Because the sum of the leverage values is p, an observation i can be considered as an outlier if its leverage substantially exceeds the mean leverage value, p/n, for example, a value larger than $2*p/n$.

Definition

The leverage of observation i is the value of the ith diagonal term, h_{ii}, of the hat matrix, H, where

$H = X(X^TX)^{-1}X^T$.

The diagonal terms satisfy

$$0 \le h_{ii} \le 1$$

$$\sum_{i=1}^{n} h_{ii} = p,$$

where p is the number of coefficients in the regression model, and n is the number of observations. The minimum value of h_{ii} is $1/n$ for a model with a constant term. If the fitted model goes through the origin, then the minimum leverage value is 0 for an observation at $x = 0$.

It is possible to express the fitted values, $\widehat{y}$, by the observed values, y, since

$$\widehat{y} = Hy = Xb\,.$$

Hence, h_{ii} expresses how much the observation y_i has impact on $\widehat{y}_i$. A large value of h_{ii} indicates that the ith case is distant from the center of all X values for all n cases and has more leverage. `Leverage` is an n-by-1 column vector in the `Diagnostics` table.

How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Display the `Leverage` vector by indexing into the property using dot notation

  ```
  mdl.Diagnostics.Leverage
  ```

- Plot the leverage for the values fitted by your model using

  ```
  plotDiagnostics(mdl)
  ```

  See the `plotDiagnostics` method of the `LinearModel` class for details.

Determine High Leverage Observations

This example shows how to compute `Leverage` values and assess high leverage observations. Load the sample data and define the response and independent variables.

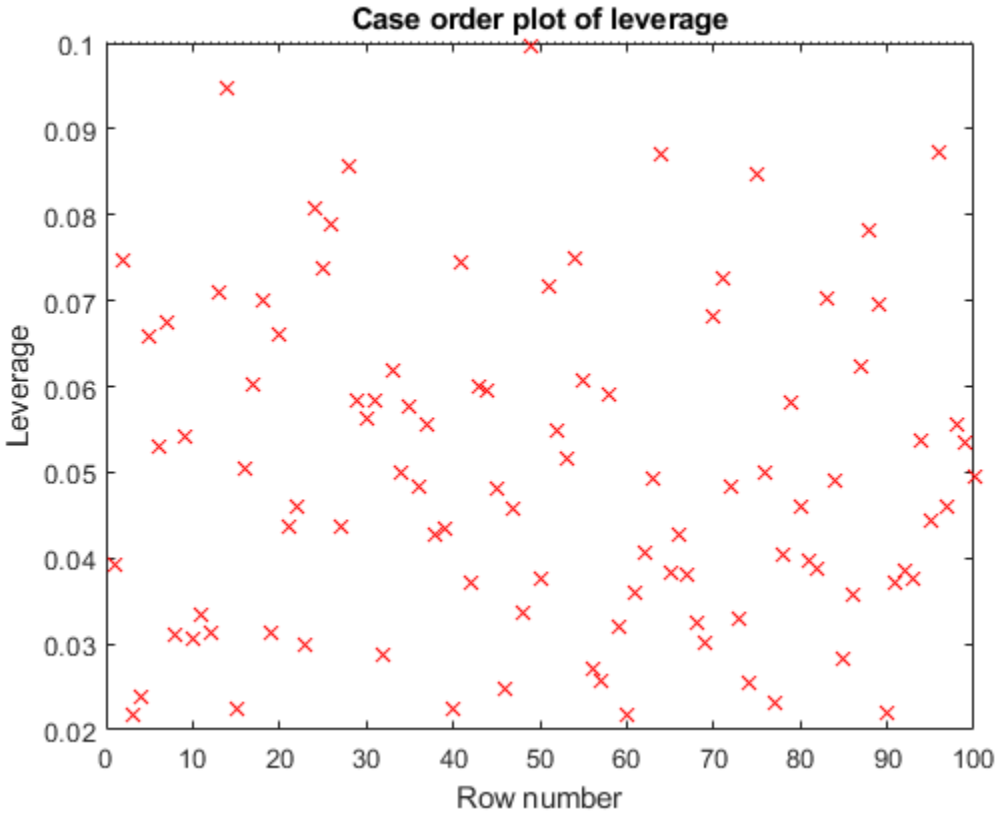
```
load hospital
y = hospital.BloodPressure(:,1);
X = double(hospital(:,2:5));
```

Fit a linear regression model.

```
mdl = fitlm(X,y);
```

Plot the leverage values.

```
plotDiagnostics(mdl)
```



For this example, the recommended threshold value is 2*5/100 = 0.1. There is no indication of high leverage observations.

Residuals

Purpose

Residuals are useful for detecting outlying y values and checking the linear regression assumptions with respect to the error term in the regression model. High-leverage observations have smaller residuals because they often shift the regression line or surface closer to them. You can also use residuals to detect some forms of heteroscedasticity and autocorrelation.

Definition

The `Residuals` matrix is an n-by-4 table containing four types of residuals, with one row for each observation.

Raw Residuals

Observed minus fitted values, that is,

$$r_i = y_i - \widehat{y}_i.$$

Pearson Residuals

Raw residuals divided by the root mean squared error, that is,

$$pr_i = \frac{r_i}{\sqrt{MSE}},$$

where r_i is the raw residual and MSE is the mean squared error.

Standardized Residuals

Standardized residuals are raw residuals divided by their estimated standard deviation. The standardized residual for observation i is

$$st_i = \frac{r_i}{\sqrt{MSE(1-h_{ii})}},$$

where MSE is the mean squared error and h_{ii} is the leverage value for observation i.

Studentized Residuals

Studentized residuals are the raw residuals divided by an independent estimate of the residual standard deviation. The residual for observation i is divided by an estimate of the error standard deviation based on all observations except for observation i.

$$sr_i = \frac{r_i}{\sqrt{MSE_{(i)}(1-h_{ii})}},$$

where $MSE_{(i)}$ is the mean squared error of the regression fit calculated by removing observation i, and h_{ii} is the leverage value for observation i. The studentized residual sr_i has a t-distribution with $n - p - 1$ degrees of freedom.

How To

After obtaining a fitted model, say, `mdl`, using `fitlm` or `stepwiselm`, you can:

- Find the `Residuals` table under `mdl` object.
- Obtain any of these columns as a vector by indexing into the property using dot notation, for example,

  ```
  mdl.Residuals.Raw
  ```

- Plot any of the residuals for the values fitted by your model using

  ```
  plotResiduals(mdl)
  ```

  For details, see the `plotResiduals` method of the `LinearModel` class.

Assess Model Assumptions Using Residuals

This example shows how to assess the model assumptions by examining the residuals of a fitted linear regression model.

Load the sample data and store the independent and response variables in a table.

```
 load imports-85
 tbl = table(X(:,7),X(:,8),X(:,9),X(:,15),'VariableNames',...
{'curb_weight','engine_size','bore','price'});
```

Fit a linear regression model.

```
mdl = fitlm(tbl)
```

```
mdl =
Linear regression model:
    price ~ 1 + curb_weight + engine_size + bore

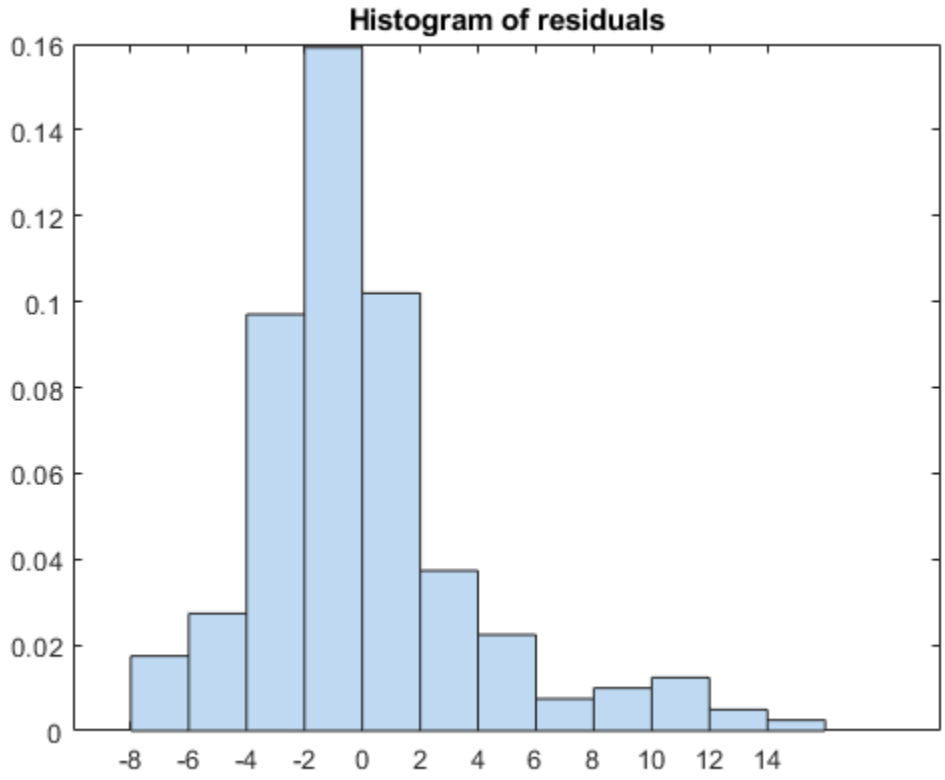
Estimated Coefficients:
                    Estimate        SE         tStat       pValue
                   __________    _________    _______    __________

    (Intercept)        64.095        3.703     17.309    2.0481e-41
    curb_weight    -0.0086681    0.0011025    -7.8623      2.42e-13
    engine_size     -0.015806     0.013255    -1.1925       0.23452
    bore              -2.6998       1.3489    -2.0015      0.046711

Number of observations: 201, Error degrees of freedom: 197
Root Mean Squared Error: 3.95
R-squared: 0.674,  Adjusted R-Squared: 0.669
F-statistic vs. constant model: 136, p-value = 1.14e-47
```

Plot the histogram of raw residuals.

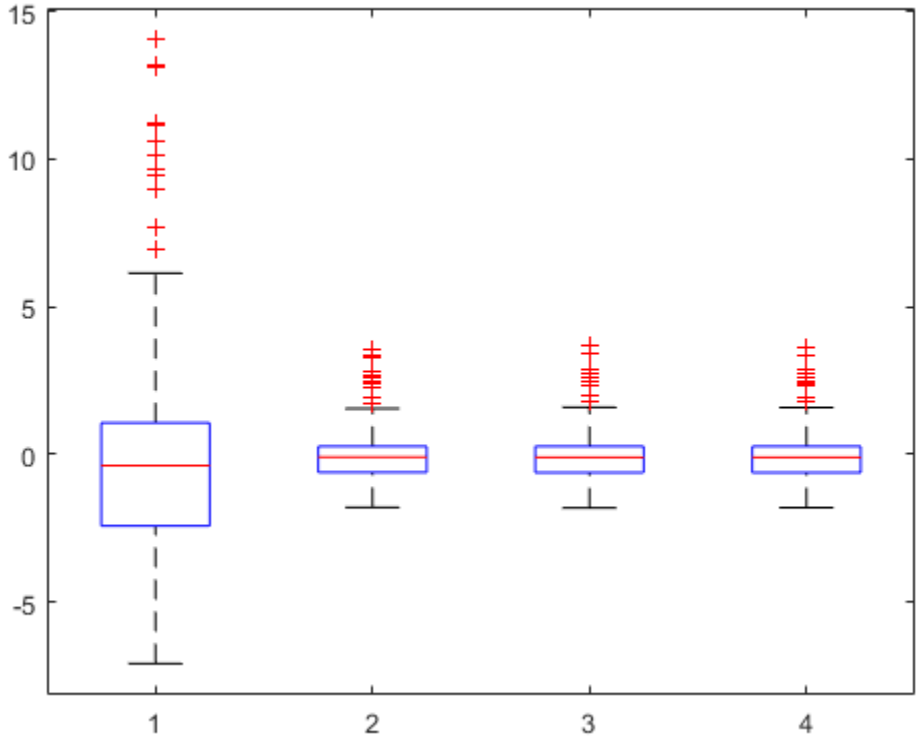
```
plotResiduals(mdl)
```



The histogram shows that the residuals are slightly right skewed.

Plot the box plot of all four types of residuals.

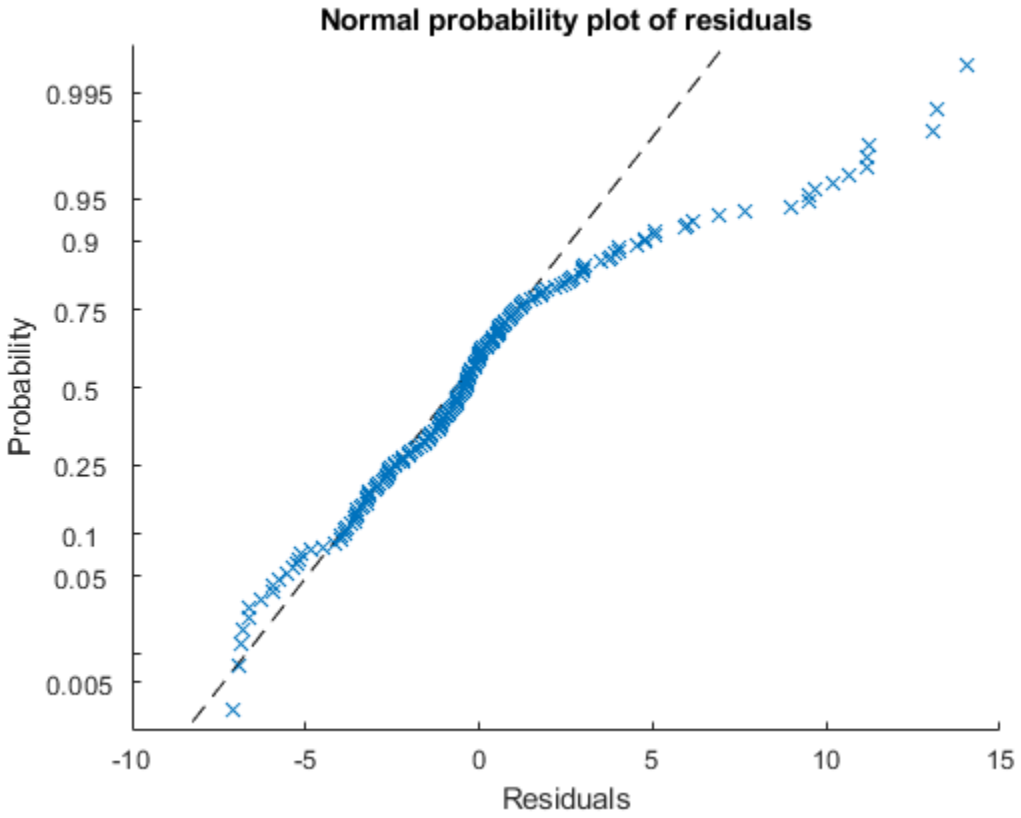
```
Res = table2array(mdl.Residuals);
boxplot(Res)
```



You can see the right-skewed structure of the residuals in the box plot as well.

Plot the normal probability plot of the raw residuals.

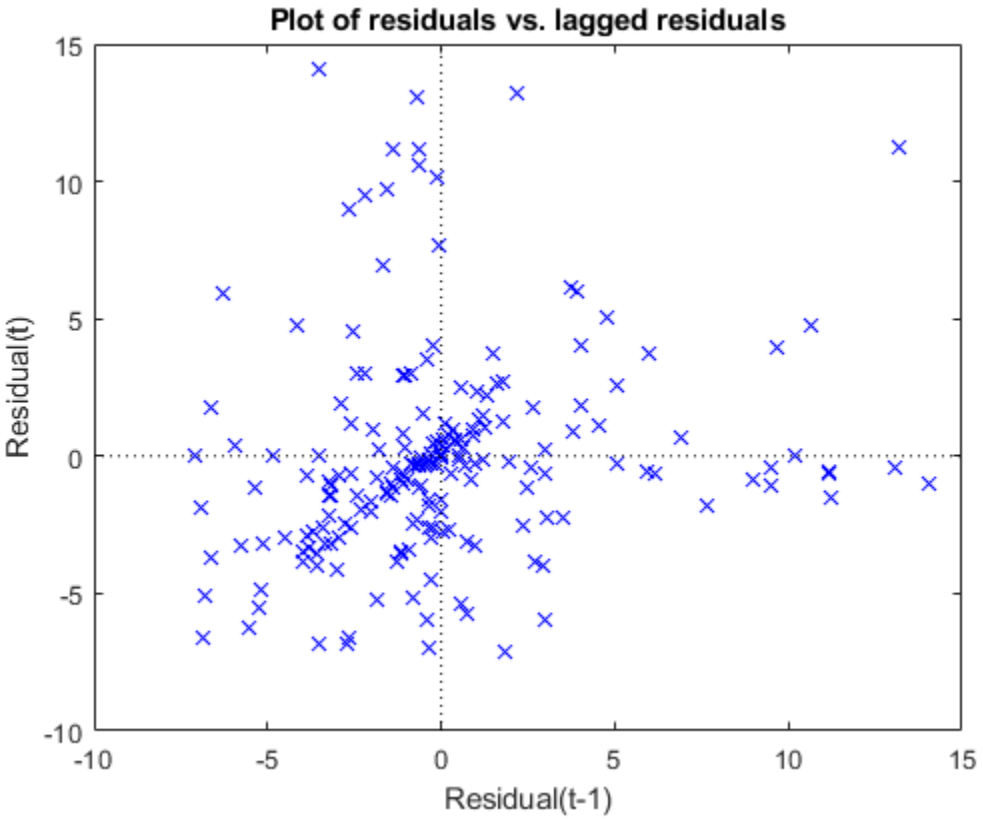
```
plotResiduals(mdl,'probability')
```



This normal probability plot also shows the deviation from normality and the skewness on the right tail of the distribution of residuals.

Plot the residuals versus lagged residuals.

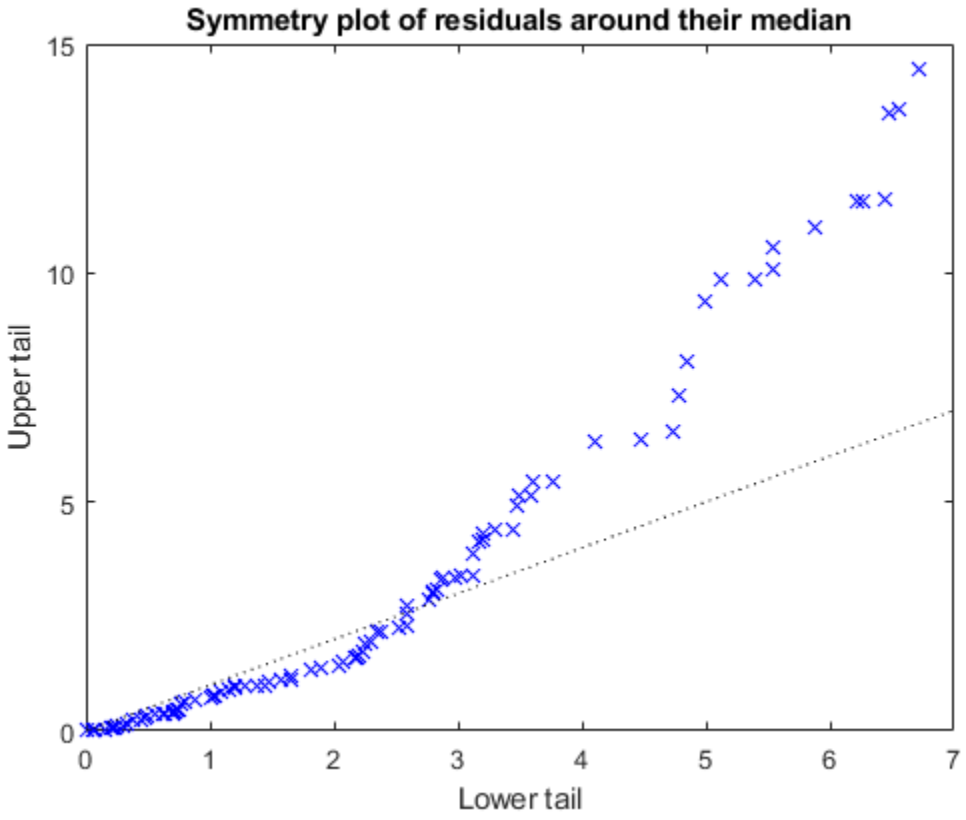
```
plotResiduals(mdl,'lagged')
```



This graph shows a trend, which indicates a possible correlation among the residuals. You can further check this using `dwtest(mdl)`. Serial correlation among residuals usually means that the model can be improved.

Plot the symmetry plot of residuals.

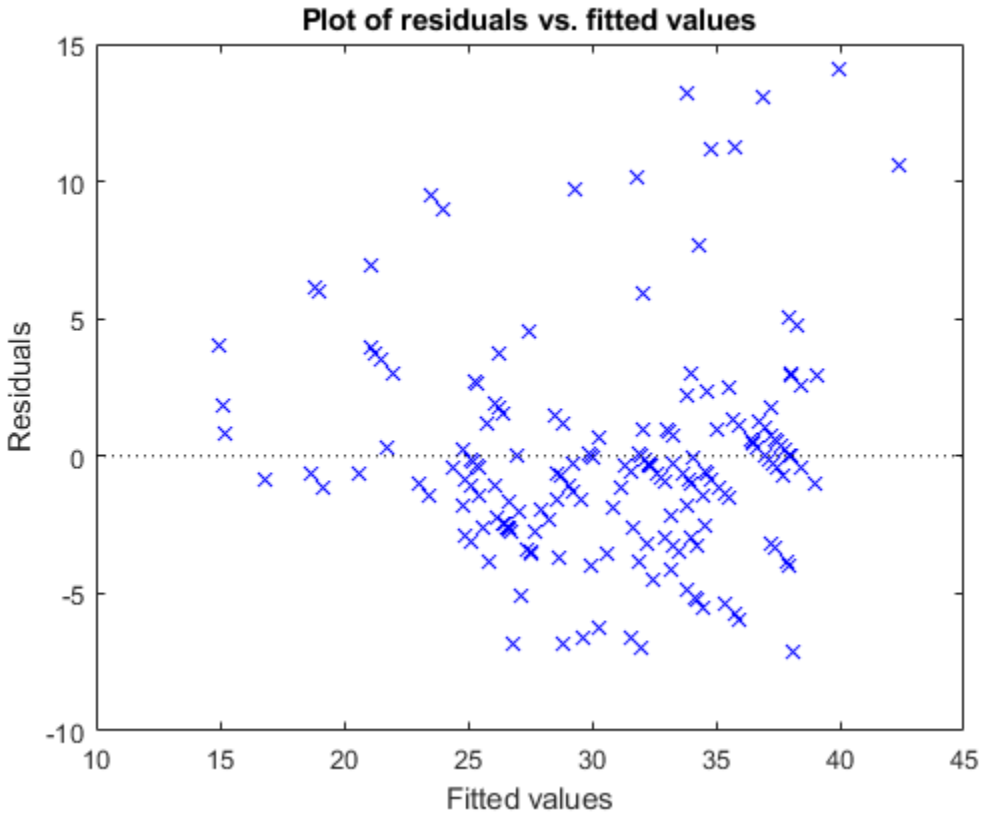
```
plotResiduals(mdl,'symmetry')
```



This plot also suggests that the residuals are not distributed equally around their median, as would be expected for normal distribution.

Plot the residuals versus the fitted values.

```
plotResiduals(mdl,'fitted')
```



The increase in the variance as the fitted values increase suggests possible heteroscedasticity.

Wilkinson Notation

In this section...

Overview

Wilkinson notation provides a way to describe regression and repeated measures models without specifying coefficient values. This specialized notation identifies the response variable and which predictor variables to include or exclude from the model. You can also include squared and higher-order terms, interaction terms, and grouping variables in the model formula.

Specifying a model using Wilkinson notation provides several advantages:

- You can include or exclude individual predictors and interaction terms from the model. For example, using the `'Interactions'` name-value pair available in each model fitting functions includes interaction terms for all pairs of variables. Using Wilkinson notation instead allows you to include only the interaction terms of interest.
- You can change the model formula without changing the design matrix, if your input data uses the `table` data type. For example, if you fit an initial model using all the available predictor variables, but decide to remove a variable that is not statistically significant, then you can re-write the model formula to include only the variables of interest. You do not need to make any changes to the input data itself.

Statistics and Machine Learning Toolbox offers several model fitting functions that use Wilkinson notation, including:

- Linear models (using `fitlm` and `stepwiselm`)
- Generalized linear models (using `fitglm`)
- Linear mixed-effects models (using `fitlme` and `fitlmematrix`)
- Generalized linear mixed-effects models (using `fitglme`)
- Repeated measures models (using `fitrm`)
- Cox proportional hazards model (using `fitcox`)

Formula Specification

A formula for model specification is a character vector or string scalar of the form `y ~ terms`, where `y` is the name of the response variable, and `terms` defines the model using the predictor variable names and the following operators.

Predictor Variables

Predictor Terms in Model	Wilkinson Notation
intercept	`1`
no intercept	`-1`
x_1	`x1`
x_1, x_2	`x1 + x2`
x_1, x_2, x_1x_2	`x1*x2` or `x1 + x2 + x1:x2`
x_1x_2	`x1:x2`
x_1, x_1^2	`x1^2`
x_1^2	`x1^2 - x1`

Wilkinson notation includes an intercept term in the model by default, even if you do not add 1 to the model formula. To exclude the intercept from the model, use -1 in the formula.

The * operator (for interactions) and the ^ operator (for power and exponents) automatically include all lower-order terms. For example, if you specify `x^3`, the model will automatically include x^3, x^2, and x. If you want to exclude certain variables from the model, use the − operator to remove the unwanted terms.

Random-Effects and Mixed-Effects Models

For random-effects and mixed-effects models, the formula specification includes the names of the predictor variables and the grouping variables. For example, if the predictor variable x_1 is a random effect grouped by the variable g, then represent this in Wilkinson notation as follows:

```
(x1 | g)
```

Repeated Measures Models

For repeated measures models, the formula specification includes all of the repeated measures as responses, and the factors as predictor variables. Specify the response variables for repeated measures models as described in the following table.

Response Terms in Model	Wilkinson Notation
y_1	`y1`
y_1, y_2, y_3	`y1,y2,y3`
y_1, y_2, y_3, y_4, y_5	`y1-y5`

For example, if you have three repeated measures as responses and the factors x_1, x_2, and x_3 as the predictor variables, then you can define the repeated measures model using Wilkinson notation as follows:

```
y1,y2,y3 ~ x1 + x2 + x3
```

or

```
y1-y3 ~ x1 + x2 + x3
```

Variable Names

If the input data (response and predictor variables) is stored in a table or dataset array, you can specify the formula using the variable names. For example, load the `carsmall` sample data. Create a table containing `Weight`, `Acceleration`, and `MPG`. Name each variable using the `'VariableNames'` name-value pair argument of the fitting function `fitlm`. Then fit the following model to the data:

$$MPG = \beta_0 + \beta_1 Weight + \beta_2 Acceleration$$

```
load carsmall
tbl = table(Weight,Acceleration,MPG, ...
    'VariableNames',{'Weight','Acceleration','MPG'});
mdl = fitlm(tbl,'MPG ~ Weight + Acceleration')
```

```
mdl =

Linear regression model:
    MPG ~ 1 + Weight + Acceleration

Estimated Coefficients:
                    Estimate         SE         tStat       pValue
                   __________    __________    _______    __________

    (Intercept)         45.155        3.4659     13.028    1.6266e-22
    Weight          -0.0082475    0.00059836    -13.783    5.3165e-24
    Acceleration       0.19694       0.14743     1.3359       0.18493

Number of observations: 94, Error degrees of freedom: 91
Root Mean Squared Error: 4.12
R-squared: 0.743,  Adjusted R-Squared: 0.738
F-statistic vs. constant model: 132, p-value = 1.38e-27
```

The model object display uses the variable names provided in the input table.

If the input data is stored as a matrix, you can specify the formula using default variable names such as `y`, `x1`, and `x2`. For example, load the `carsmall` sample data. Create a matrix containing the predictor variables `Weight` and `Acceleration`. Then fit the following model to the data:

$$MPG = \beta_0 + \beta_1 Weight + \beta_2 Acceleration$$

```
load carsmall
X = [Weight,Acceleration];
y = MPG;
mdl = fitlm(X,y,'y ~ x1 + x2')
```

```
mdl =

Linear regression model:
    y ~ 1 + x1 + x2

Estimated Coefficients:
                    Estimate         SE         tStat       pValue
                   __________    __________    _______    __________
```

```
    (Intercept)        45.155        3.4659     13.028    1.6266e-22
    x1             -0.0082475    0.00059836    -13.783    5.3165e-24
    x2                0.19694       0.14743     1.3359       0.18493

Number of observations: 94, Error degrees of freedom: 91
Root Mean Squared Error: 4.12
R-squared: 0.743,  Adjusted R-Squared: 0.738
F-statistic vs. constant model: 132, p-value = 1.38e-27
```

The term `x1` in the model specification formula corresponds to the first column of the predictor variable matrix `X`. The term `x2` corresponds to the second column of the input matrix. The term `y` corresponds to the response variable.

Linear Model Examples

Use `fitlm` and `stepwiselm` to fit linear models.

Intercept and Two Predictors

For a linear regression model with an intercept and two fixed-effects predictors, such as

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \varepsilon_i,$$

specify the model formula using Wilkinson notation as follows:

```
'y ~ x1 + x2'
```

No Intercept and Two Predictors

For a linear regression model with no intercept and two fixed-effects predictors, such as

$$y_i = \beta_1 x_{i1} + \beta_2 x_{i2} + \varepsilon_i\,,$$

specify the model formula using Wilkinson notation as follows:

```
'y ~ -1 + x1 + x2'
```

Intercept, Two Predictors, and an Interaction Term

For a linear regression model with an intercept, two fixed-effects predictors, and an interaction term, such as

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i1} x_{i2} + \varepsilon_i\,,$$

specify the model formula using Wilkinson notation as follows:

```
'y ~ x1*x2'
```

or

```
'y ~ x1 + x2 + x1:x2'
```

Intercept, Three Predictors, and All Interaction Effects

For a linear regression model with an intercept, three fixed-effects predictors, and interaction effects between all three predictors plus all lower-order terms, such as

$$y_i = \beta_0 + \beta_1 xi_1 + \beta_2 x_{i2} + \beta_3 x_{i3} + \beta_4 x_1 x_{i2} + \beta_5 x_1 x_{i3} + \beta_6 x_2 x_{i3} + \beta_7 x_{i1} x_{i2} x_{i3} + \varepsilon_i ,$$

specify the model formula using Wilkinson notation as follows:

```
'y ~ x1*x2*x3'
```

Intercept, Three Predictors, and Selected Interaction Effects

For a linear regression model with an intercept, three fixed-effects predictors, and interaction effects between two of the predictors, such as

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i3} + \beta_4 x_1 x_{i2} + \varepsilon_i ,$$

specify the model formula using Wilkinson notation as follows:

```
'y ~ x1*x2 + x3'
```

or

```
'y ~ x1 + x2 + x3 + x1:x2'
```

Intercept, Three Predictors, and Lower-Order Interaction Effects Only

For a linear regression model with an intercept, three fixed-effects predictors, and pairwise interaction effects between all three predictors, but excluding an interaction effect between all three predictors simultaneously, such as

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i3} + \beta_4 x_1 x_{i2} + \beta_5 x_{i1} x_{i3} + \beta_6 x_{i2} x_{i3} + \varepsilon_i ,$$

specify the model formula using Wilkinson notation as follows:

```
'y ~ x1*x2*x3 - x1:x2:x3'
```

Linear Mixed-Effects Model Examples

Use `fitlme` and `fitlmematrix` to fit linear mixed-effects models.

Random Effect Intercept, No Predictors

For a linear mixed-effects model that contains a random intercept but no predictor terms, such as

$$y_{im} = \beta_{0m} ,$$

where

$$\beta_{0m} = \beta_{00} + b_{0m} ,\ b_{0m} \sim N\left(0, \sigma_0^2\right)$$

and g is the grouping variable with m levels, specify the model formula using Wilkinson notation as follows:

```
'y ~ (1 | g)'
```

Random Intercept and Fixed Slope for One Predictor

For a linear mixed-effects model that contains a fixed intercept, random intercept, and fixed slope for the continuous predictor variable, such as

$$y_{im} = \beta_{0m} + \beta_1 x_{im},$$

where

$$\beta_{0m} = \beta_{00} + b_{0m},\ b_{0m} \sim N\left(0, \sigma_0^2\right)$$

and g is the grouping variable with m levels, specify the model formula using Wilkinson notation as follows:

```
'y ~ x1 + (1 | g)'
```

Random Intercept and Random Slope for One Predictor

For a linear mixed-effects model that contains a fixed intercept, plus a random intercept and a random slope that have a possible correlation between them, such as

$$y_{im} = \beta_{0m} + \beta_{1m} x_{im},$$

where

$$\beta_{0m} = \beta_{00} + b_{0m}$$

$$\beta_{1m} = \beta_{10} + b_{1m}$$

$$\begin{bmatrix} b_{0m} \\ b_{1m} \end{bmatrix} \sim N\left\{0, \sigma^2 D(\theta)\right\}$$

and D is a 2-by-2 symmetric and positive semidefinite covariance matrix, parameterized by a variance component vector θ, specify the model formula using Wilkinson notation as follows:

```
'y ~ x1 + (x1 | g)'
```

The pattern of the random effects covariance matrix is determined by the model fitting function. To specify the covariance matrix pattern, use the name-value pairs available through `fitlme` when fitting the model. For example, you can specify the assumption that the random intercept and random slope are independent of one another using the `'CovariancePattern'` name-value pair argument in `fitlme`.

Generalized Linear Model Examples

Use `fitglm` and `stepwiseglm` to fit generalized linear models.

In a generalized linear model, the y response variable has a distribution other than normal, but you can represent the model as an equation that is linear in the regression coefficients. Specifying a generalized linear model requires three parts:

- Distribution of the response variable
- Link function
- Linear predictor

The distribution of the response variable and the link function are specified using name-value pair arguments in the fit function `fitglm` or `stepwiseglm`.

The linear predictor portion of the equation, which appears on the right side of the ~ symbol in the model specification formula, uses Wilkinson notation in the same way as for the linear model examples.

A generalized linear model models the link function, rather than the actual response, as y. This is reflected in the output display for the model object.

Intercept and Two Predictors

For a generalized linear regression model with an intercept and two predictors, such as

$$\log(y_i) = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2},$$

specify the model formula using Wilkinson notation as follows:

```
'y ~ x1 + x2'
```

Generalized Linear Mixed-Effects Model Examples

Use `fitglme` to fit generalized linear mixed-effects models.

In a generalized linear mixed-effects model, the y response variable has a distribution other than normal, but you can represent the model as an equation that is linear in the regression coefficients. Specifying a generalized linear model requires three parts:

- Distribution of the response variable
- Link function
- Linear predictor

The distribution of the response variable and the link function are specified using name-value pair arguments in the fit function `fitglme`.

The linear predictor portion of the equation, which appears on the right side of the ~ symbol in the model specification formula, uses Wilkinson notation in the same way as for the linear mixed-effects model examples.

A generalized linear model models the link function as y, not the response itself. This is reflected in the output display for the model object.

The pattern of the random effects covariance matrix is determined by the model fitting function. To specify the covariance matrix pattern, use the name-value pairs available through `fitglme` when fitting the model. For example, you can specify the assumption that the random intercept and random slope are independent of one another using the `'CovariancePattern'` name-value pair argument in `fitglme`.

Random Intercept and Fixed Slope for One Predictor

For a generalized linear mixed-effects model that contains a fixed intercept, random intercept, and fixed slope for the continuous predictor variable, where the response can be modeled using a Poisson distribution, such as

$$\log(y_{im}) = \beta_0 + \beta_1 x_{im} + b_i ,$$

where

$$b_i \sim N\left(0, \sigma_b^2\right)$$

and g is the grouping variable with m levels, specify the model formula using Wilkinson notation as follows:

```
'y ~ x1 + (1 | g)'
```

Repeated Measures Model Examples

Use `fitrm` to fit repeated measures models.

One Predictor

For a repeated measures model with five response measurements and one predictor variable, specify the model formula using Wilkinson notation as follows:

```
'y1-y5 ~ x1'
```

Three Predictors and an Interaction Term

For a repeated measures model with five response measurements and three predictor variables, plus an interaction between two of the predictor variables, specify the model formula using Wilkinson notation as follows:

```
'y1-y5 ~ x1*x2 + x3'
```

Stepwise Regression

In this section...

Stepwise Regression to Select Appropriate Models

`stepwiselm` creates a linear model and automatically adds to or trims the model. To create a small model, start from a constant model. To create a large model, start with a model containing many terms. A large model usually has lower error as measured by the fit to the original data, but might not have any advantage in predicting new data.

`stepwiselm` can use all the name-value options from `fitlm`, with additional options relating to the starting and bounding models. In particular:

- For a small model, start with the default lower bounding model: `'constant'` (a model that has no predictor terms).
- The default upper bounding model has linear terms and interaction terms (products of pairs of predictors). For an upper bounding model that also includes squared terms, set the `Upper` name-value pair to `'quadratic'`.

Compare large and small stepwise models

This example shows how to compare models that `stepwiselm` returns starting from a constant model and starting from a full interaction model.

Load the `carbig` data and create a table from some of the data.

```
load carbig
tbl = table(Acceleration,Displacement,Horsepower,Weight,MPG);
```

Create a mileage model stepwise starting from the constant model.

```
mdl1 = stepwiselm(tbl,'constant','ResponseVar','MPG')
```

```
1. Adding Weight, FStat = 888.8507, pValue = 2.9728e-103
2. Adding Horsepower, FStat = 3.8217, pValue = 0.00049608
3. Adding Horsepower:Weight, FStat = 64.8709, pValue = 9.93362e-15

mdl1 =
Linear regression model:
    MPG ~ 1 + Horsepower*Weight

Estimated Coefficients:
                        Estimate         SE         tStat       pValue
                       __________    __________    _______    __________

    (Intercept)           63.558        2.3429      27.127    1.2343e-91
    Horsepower           -0.25084      0.027279    -9.1952    2.3226e-18
    Weight               -0.010772    0.00077381    -13.921    5.1372e-36
    Horsepower:Weight    5.3554e-05    6.6491e-06     8.0542    9.9336e-15
```

```
Number of observations: 392, Error degrees of freedom: 388
Root Mean Squared Error: 3.93
R-squared: 0.748,  Adjusted R-Squared: 0.746
F-statistic vs. constant model: 385, p-value = 7.26e-116
```

Create a mileage model stepwise starting from the full interaction model.

```
mdl2 = stepwiselm(tbl,'interactions','ResponseVar','MPG')
```

```
1. Removing Acceleration:Displacement, FStat = 0.024186, pValue = 0.8765
2. Removing Displacement:Weight, FStat = 0.33103, pValue = 0.56539
3. Removing Acceleration:Horsepower, FStat = 1.7334, pValue = 0.18876
4. Removing Acceleration:Weight, FStat = 0.93269, pValue = 0.33477
5. Removing Horsepower:Weight, FStat = 0.64486, pValue = 0.42245

mdl2 =
Linear regression model:
    MPG ~ 1 + Acceleration + Weight + Displacement*Horsepower

Estimated Coefficients:
                              Estimate         SE         tStat       pValue
                             __________    __________    _______    __________

    (Intercept)                 61.285        2.8052     21.847    1.8593e-69
    Acceleration               -0.34401       0.11862      -2.9     0.0039445
    Displacement               -0.081198      0.010071    -8.0623    9.5014e-15
    Horsepower                 -0.24313       0.026068    -9.3265    8.6556e-19
    Weight                     -0.0014367     0.00084041  -1.7095      0.088166
    Displacement:Horsepower    0.00054236     5.7987e-05   9.3531    7.0527e-19

Number of observations: 392, Error degrees of freedom: 386
Root Mean Squared Error: 3.84
R-squared: 0.761,  Adjusted R-Squared: 0.758
F-statistic vs. constant model: 246, p-value = 1.32e-117
```

Notice that:

- `mdl1` has four coefficients (the `Estimate` column), and `mdl2` has six coefficients.
- The adjusted R-squared of `mdl1` is `0.746`, which is slightly less (worse) than that of `mdl2`, `0.758`.

Create a mileage model stepwise with a full quadratic model as the upper bound, starting from the full quadratic model:

```
mdl3 = stepwiselm(tbl,'quadratic','ResponseVar','MPG','Upper','quadratic');
```

```
1. Removing Acceleration:Horsepower, FStat = 0.075209, pValue = 0.78405
2. Removing Acceleration:Weight, FStat = 0.072756, pValue = 0.78751
3. Removing Horsepower:Weight, FStat = 0.12569, pValue = 0.72314
4. Removing Weight^2, FStat = 1.194, pValue = 0.27521
5. Removing Displacement:Weight, FStat = 1.2839, pValue = 0.25789
6. Removing Displacement^2, FStat = 2.069, pValue = 0.15114
7. Removing Horsepower^2, FStat = 0.74063, pValue = 0.39
```

Compare the three model complexities by examining their formulas.

```
mdl1.Formula
```

```
ans =
MPG ~ 1 + Horsepower*Weight
```

```
mdl2.Formula
```

```
ans =
MPG ~ 1 + Acceleration + Weight + Displacement*Horsepower
```

```
mdl3.Formula
```

```
ans =
MPG ~ 1 + Weight + Acceleration*Displacement + Displacement*Horsepower
        + Acceleration^2
```

The adjusted R^2 values improve slightly as the models become more complex:

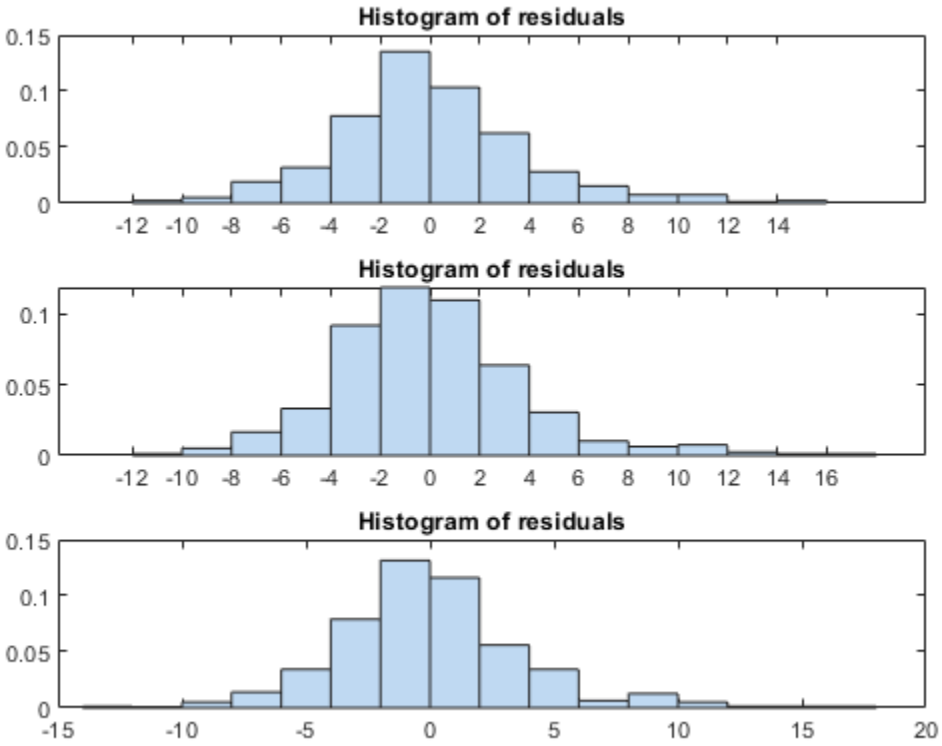
```
RSquared = [mdl1.Rsquared.Adjusted, ...
    mdl2.Rsquared.Adjusted, mdl3.Rsquared.Adjusted]
```

```
RSquared = 1×3

    0.7465    0.7580    0.7599
```

Compare residual plots of the three models.

```
subplot(3,1,1)
plotResiduals(mdl1)
subplot(3,1,2)
plotResiduals(mdl2)
subplot(3,1,3)
plotResiduals(mdl3)
```



The models have similar residuals. It is not clear which fits the data better.

Interestingly, the more complex models have larger maximum deviations of the residuals:

```
Rrange1 = [min(mdl1.Residuals.Raw),max(mdl1.Residuals.Raw)];
Rrange2 = [min(mdl2.Residuals.Raw),max(mdl2.Residuals.Raw)];
Rrange3 = [min(mdl3.Residuals.Raw),max(mdl3.Residuals.Raw)];
Rranges = [Rrange1;Rrange2;Rrange3]
```

```
Rranges = 3×2

Reduce Outlier Effects Using Robust Regression

In this section...

You can reduce outlier effects in linear regression models by using robust linear regression. This topic defines robust regression, shows how to use it to fit a linear model, and compares the results to a standard fit. You can use `fitlm` with the `'RobustOpts'` name-value pair argument to fit a robust regression model. Or you can use `robustfit` to simply compute the robust regression coefficient parameters.

Why Use Robust Regression?

Robust linear regression is less sensitive to outliers than standard linear regression. Standard linear regression uses ordinary least-squares fitting to compute the model parameters that relate the response data to the predictor data with one or more coefficients. (See “Estimation of Multivariate Regression Models” on page 15-5 for more details.) As a result, outliers have a large influence on the fit, because squaring the residuals magnifies the effects of these extreme data points. Models that use standard linear regression, described in “What Is a Linear Regression Model?” on page 11-6, are based on certain assumptions, such as a normal distribution of errors in the observed responses. If the distribution of errors is asymmetric or prone to outliers, model assumptions are invalidated, and parameter estimates, confidence intervals, and other computed statistics become unreliable.

Robust regression uses a method called iteratively reweighted least squares to assign a weight to each data point. This method is less sensitive to large changes in small parts of the data. As a result, robust linear regression is less sensitive to outliers than standard linear regression.

Iteratively Reweighted Least Squares

In weighted least squares, the fitting process includes the weight as an additional scale factor, which improves the fit. The weights determine how much each response value influences the final parameter estimates. A low-quality data point (for example, an outlier) should have less influence on the fit. To compute the weights w_i, you can use predefined weight functions, such as Tukey's bisquare function (see the name-value pair argument `'RobustOpts'` in `fitlm` for more options).

The *iteratively reweighted least-squares* algorithm automatically and iteratively calculates the weights. At initialization, the algorithm assigns equal weight to each data point, and estimates the model coefficients using ordinary least squares. At each iteration, the algorithm computes the weights w_i, giving lower weight to points farther from model predictions in the previous iteration. The algorithm then computes model coefficients b using weighted least squares. Iteration stops when the values of the coefficient estimates converge within a specified tolerance. This algorithm simultaneously seeks to find the curve that fits the bulk of the data using the least-squares approach, and to minimize the effects of outliers.

For more details, see “Steps for Iteratively Reweighted Least Squares” on page 11-107.

Compare Results of Standard and Robust Least-Squares Fit

This example shows how to use robust regression with the `fitlm` function, and compares the results of a robust fit to a standard least-squares fit.

Load the `moore` data. The predictor data is in the first five columns, and the response data is in the sixth.

```
load moore
X = moore(:,1:5);
y = moore(:,6);
```

Fit the least-squares linear model to the data.

```
mdl = fitlm(X,y)
```

```
mdl =
Linear regression model:
    y ~ 1 + x1 + x2 + x3 + x4 + x5

Estimated Coefficients:
                    Estimate          SE          tStat       pValue
                   ___________    __________    _________    ________

    (Intercept)        -2.1561       0.91349      -2.3603      0.0333
    x1             -9.0116e-06    0.00051835    -0.017385     0.98637
    x2                0.0013159     0.0012635       1.0415     0.31531
    x3                0.0001278    7.6902e-05       1.6618     0.11876
    x4                0.0078989         0.014      0.56421     0.58154
    x5               0.00014165    7.3749e-05       1.9208    0.075365

Number of observations: 20, Error degrees of freedom: 14
Root Mean Squared Error: 0.262
R-squared: 0.811,  Adjusted R-Squared: 0.743
F-statistic vs. constant model: 12, p-value = 0.000118
```

Fit the robust linear model to the data by using the `'RobustOps'` name-value pair argument.

```
mdlr = fitlm(X,y,'RobustOpts','on')
```

```
mdlr =
Linear regression model (robust fit):
    y ~ 1 + x1 + x2 + x3 + x4 + x5

Estimated Coefficients:
                    Estimate          SE          tStat       pValue
                   ___________    __________    _________    ________

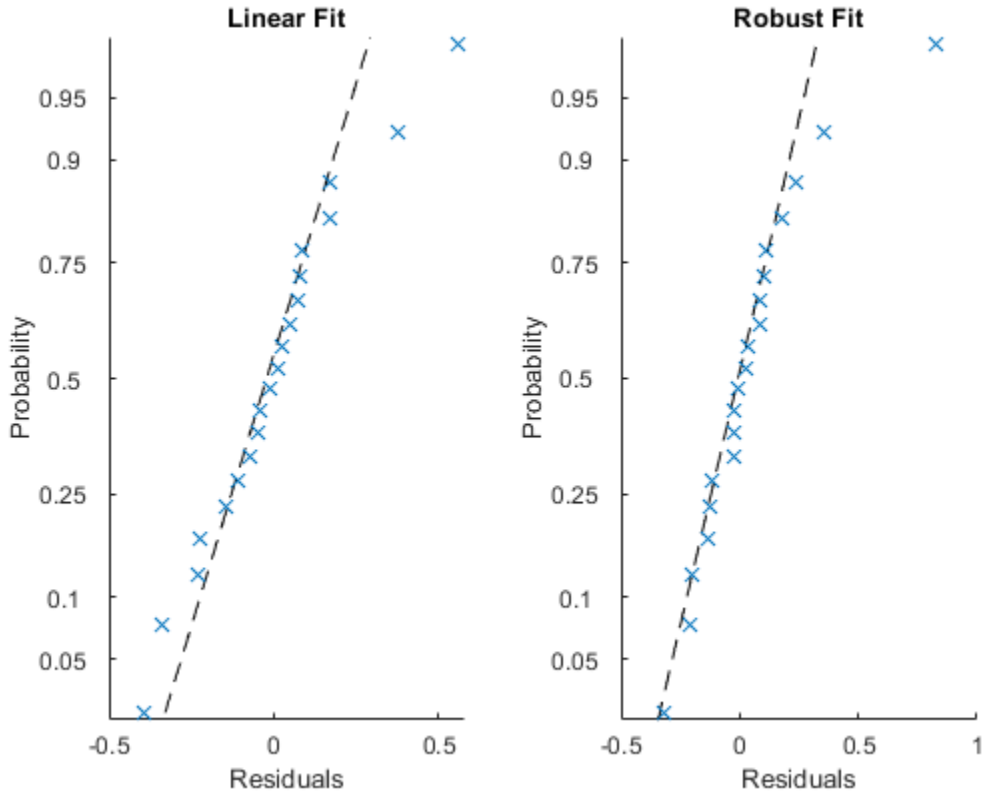
    (Intercept)        -1.7516       0.86953      -2.0144     0.063595
    x1              1.7006e-05    0.00049341     0.034467      0.97299
    x2              0.00088843     0.0012027       0.7387      0.47229
    x3              0.00015729    7.3202e-05       2.1487     0.049639
    x4               0.0060468      0.013326      0.45375      0.65696
    x5              6.8807e-05    7.0201e-05      0.98015      0.34365

Number of observations: 20, Error degrees of freedom: 14
```

```
Root Mean Squared Error: 0.249
R-squared: 0.775,  Adjusted R-Squared: 0.694
F-statistic vs. constant model: 9.64, p-value = 0.000376
```

Visually examine the residuals of the two models.

```
tiledlayout(1,2)
nexttile
plotResiduals(mdl,'probability')
title('Linear Fit')
nexttile
plotResiduals(mdlr,'probability')
title('Robust Fit')
```



The residuals from the robust fit (right half of the plot) are closer to the straight line, except for the one obvious outlier.

Find the index of the outlier.

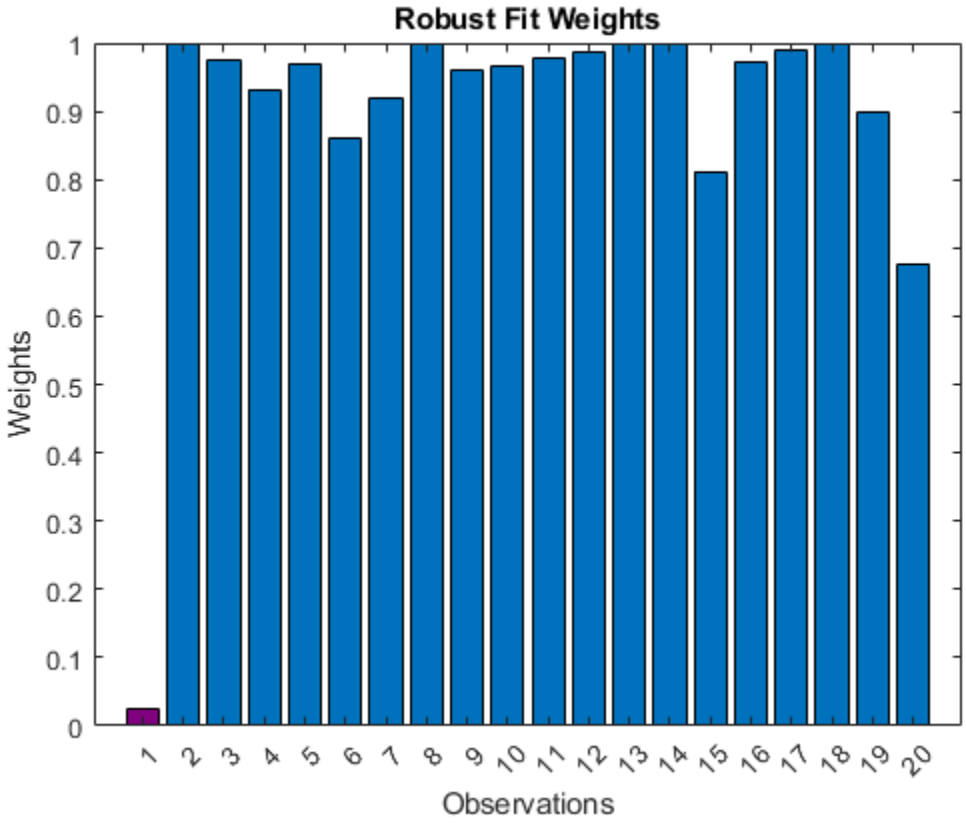
```
outlier = find(isoutlier(mdlr.Residuals.Raw))
```

```
outlier = 1
```

Plot the weights of the observations in the robust fit.

```
figure
b = bar(mdlr.Robust.Weights);
b.FaceColor = 'flat';
```

```
b.CData(outlier,:) = [.5 0 .5];
xticks(1:length(mdlr.Residuals.Raw))
xlabel('Observations')
ylabel('Weights')
title('Robust Fit Weights')
```



The weight of the outlier in the robust fit (purple bar) is much less than the weights of the other observations.

Steps for Iteratively Reweighted Least Squares

The iteratively reweighted least-squares algorithm follows this procedure:

1. Start with an initial estimate of the weights and fit the model by weighted least squares.
2. Compute the adjusted residuals. The adjusted residuals are given by

   $$r_{\text{adj}} = \frac{r_i}{\sqrt{1 - h_i}}$$

   where r_i are the ordinary least-squares residuals, and h_i are the least-squares fit leverage values. Leverages adjust the residuals by reducing the weight of high-leverage data points, which have a large effect on the least-squares fit (see “Hat Matrix and Leverage” on page 11-77).
3. Standardize the residuals. The standardized adjusted residuals are given by

$$u = \frac{r_{\text{adj}}}{Ks} = \frac{r_i}{Ks\sqrt{1-h_i}}$$

where K is a tuning constant, and s is an estimate of the standard deviation of the error term given by `s = MAD/0.6745`.

`MAD` is the median absolute deviation of the residuals from their median. The constant 0.6745 makes the estimate unbiased for the normal distribution. If the predictor data matrix `X` has p columns, the software excludes the smallest p absolute deviations when computing the median.

4 Compute the robust weights w_i as a function of u. For example, the bisquare weights are given by

$$w_i = \begin{cases} (1-u_i 2)^2 & , |u_i| < 1 \\ 0 & , |u_i| \geq 1 \end{cases}$$

5 Estimate the robust regression coefficients b. The weights modify the expression for the parameter estimates b as follows

$$b = \widehat{\beta} = (X^T WT)^{-1} X^T W y$$

where W is the diagonal weight matrix, X is the predictor data matrix, and y is the response vector.

6 Estimate the weighted least-squares error

$$e = \sum_1^n w_i (y_i - \widehat{y}_i)^2 = \sum_1^n w_i r_i^2$$

where w_i are the weights, y_i are the observed responses, $\hat{y}_i$ are the fitted responses, and r_i are the residuals.

7 Iteration stops if the fit converges or the maximum number of iterations is reached. Otherwise, perform the next iteration of the least-squares fitting by returning to the second step.

Ridge Regression

In this section...

Introduction to Ridge Regression

Coefficient estimates for the models described in “Linear Regression” on page 11-9 rely on the independence of the model terms. When terms are correlated and the columns of the design matrix X have an approximate linear dependence, the matrix $(X^TX)^{-1}$ becomes close to singular. As a result, the least-squares estimate

$$\widehat{\beta} = (X^TX)^{-1}X^Ty$$

becomes highly sensitive to random errors in the observed response y, producing a large variance. This situation of multicollinearity can arise, for example, when data are collected without an experimental design.

Ridge regression addresses the problem by estimating regression coefficients using

$$\widehat{\beta} = (X^TX + kI)^{-1}X^Ty$$

where k is the ridge parameter and I is the identity matrix. Small positive values of k improve the conditioning of the problem and reduce the variance of the estimates. While biased, the reduced variance of ridge estimates often result in a smaller mean square error when compared to least-squares estimates.

The Statistics and Machine Learning Toolbox function `ridge` carries out ridge regression.

Ridge Regression

This example shows how to perform ridge regression.

Load the data in `acetylene.mat`, with observations of the predictor variables `x1`, `x2`, `x3`, and the response variable `y`.

```
load acetylene
```

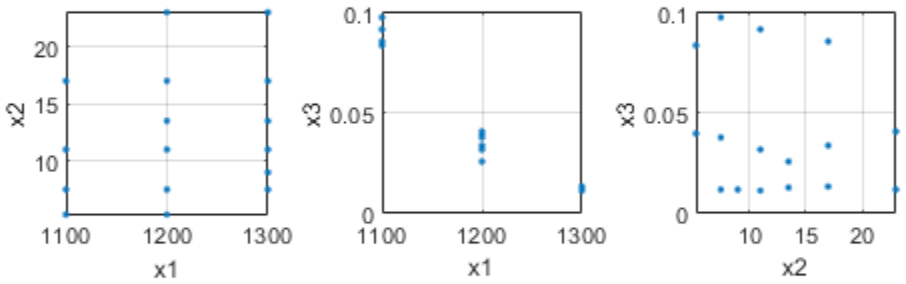
Plot the predictor variables against each other.

```
subplot(1,3,1)
plot(x1,x2,'.')
xlabel('x1')
ylabel('x2')
grid on
axis square

subplot(1,3,2)
plot(x1,x3,'.')
xlabel('x1')
ylabel('x3')
```

```
grid on
axis square

subplot(1,3,3)
plot(x2,x3,'.')
xlabel('x2')
ylabel('x3')
grid on
axis square
```



Note the correlation between `x1` and the other two predictor variables.

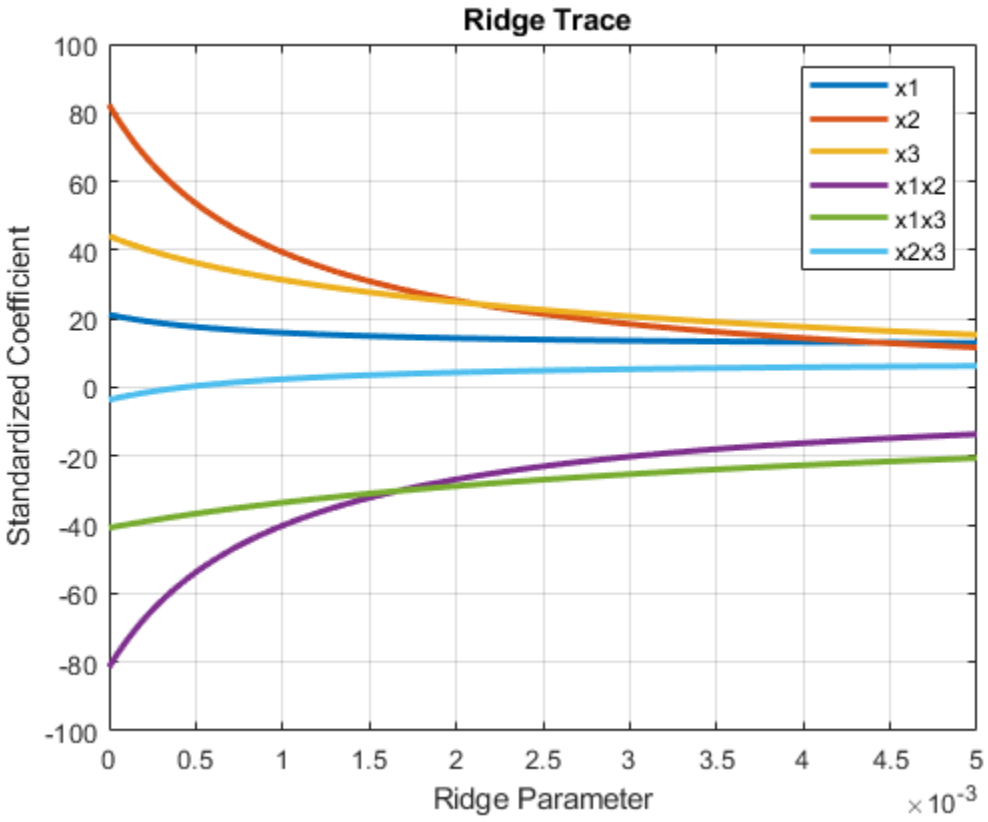
Use `ridge` and `x2fx` to compute coefficient estimates for a multilinear model with interaction terms, for a range of ridge parameters.

```
X = [x1 x2 x3];
D = x2fx(X,'interaction');
D(:,1) = []; % No constant term
k = 0:1e-5:5e-3;
betahat = ridge(y,D,k);
```

Plot the ridge trace.

```
figure
plot(k,betahat,'LineWidth',2)
ylim([-100 100])
grid on
xlabel('Ridge Parameter')
```

```
ylabel('Standardized Coefficient')
title('{\bf Ridge Trace}')
legend('x1','x2','x3','x1x2','x1x3','x2x3')
```



The estimates stabilize to the right of the plot. Note that the coefficient of the `x2x3` interaction term changes sign at a value of the ridge parameter $\approx 5 \times 10^{-4}$.

Lasso and Elastic Net

In this section...

What Are Lasso and Elastic Net?

Lasso is a regularization technique. Use `lasso` to:

- Reduce the number of predictors in a regression model.
- Identify important predictors.
- Select among redundant predictors.
- Produce shrinkage estimates with potentially lower predictive errors than ordinary least squares.

Elastic net is a related technique. Use elastic net when you have several highly correlated variables. `lasso` provides elastic net regularization when you set the `Alpha` name-value pair to a number strictly between `0` and `1`.

See “Lasso and Elastic Net Details” on page 11-112.

For lasso regularization of regression ensembles, see `regularize`.

Lasso and Elastic Net Details

Overview of Lasso and Elastic Net

Lasso is a regularization technique for performing linear regression. Lasso includes a penalty term that constrains the size of the estimated coefficients. Therefore, it resembles ridge regression on page 11-109. Lasso is a shrinkage estimator: it generates coefficient estimates that are biased to be small. Nevertheless, a lasso estimator can have smaller mean squared error than an ordinary least-squares estimator when you apply it to new data.

Unlike ridge regression, as the penalty term increases, lasso sets more coefficients to zero. This means that the lasso estimator is a smaller model, with fewer predictors. As such, lasso is an alternative to stepwise regression on page 11-99 and other model selection and dimensionality reduction techniques.

Elastic net is a related technique. Elastic net is a hybrid of ridge regression and lasso regularization. Like lasso, elastic net can generate reduced models by generating zero-valued coefficients. Empirical studies have suggested that the elastic net technique can outperform lasso on data with highly correlated predictors.

Definition of Lasso

The lasso technique solves this regularization problem. For a given value of λ, a nonnegative parameter, `lasso` solves the problem

$$\min_{\beta_0,\beta}\left(\frac{1}{2N}\sum_{i=1}^{N}\left(y_i-\beta_0-x_i^T\beta\right)^2+\lambda\sum_{j=1}^{p}\left|\beta_j\right|\right).$$

- N is the number of observations.
- y_i is the response at observation i.
- x_i is data, a vector of p values at observation i.
- λ is a positive regularization parameter corresponding to one value of `Lambda`.
- The parameters β_0 and β are scalar and p-vector respectively.

As λ increases, the number of nonzero components of β decreases.

The lasso problem involves the L^1 norm of β, as contrasted with the elastic net algorithm.

Definition of Elastic Net

The elastic net technique solves this regularization problem. For an α strictly between 0 and 1, and a nonnegative λ, elastic net solves the problem

$$\min_{\beta_0,\beta}\left(\frac{1}{2N}\sum_{i=1}^{N}\left(y_i-\beta_0-x_i^T\beta\right)^2+\lambda P_\alpha(\beta)\right),$$

where

$$P_\alpha(\beta)=\frac{(1-\alpha)}{2}\|\beta\|_2^2+\alpha\|\beta\|_1=\sum_{j=1}^{p}\left(\frac{(1-\alpha)}{2}\beta_j^2+\alpha\left|\beta_j\right|\right).$$

Elastic net is the same as lasso when $\alpha = 1$. As α shrinks toward 0, elastic net approaches `ridge` regression. For other values of α, the penalty term $P_\alpha(\beta)$ interpolates between the L^1 norm of β and the squared L^2 norm of β.

```

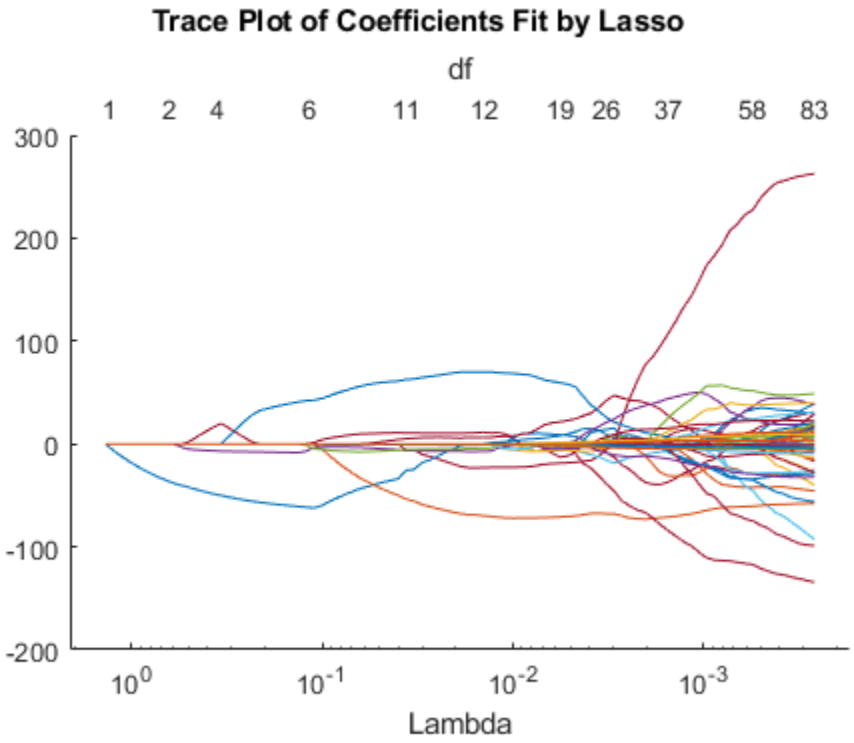
Lasso and elastic net are especially well suited for wide data, that is, data with more predictors than observations with lasso and elastic net. There are redundant predictors in this type of data. You can use `lasso` along with cross validation to identify important predictors.

Compute the default `lasso` fit.

```
[b fitinfo] = lasso(NIR,octane);
```

Plot the number of predictors in the fitted lasso regularization as a function of `Lambda` , using a logarithmic *x* -axis.

```
lassoPlot(b,fitinfo,'PlotType','Lambda','XScale','log');
```



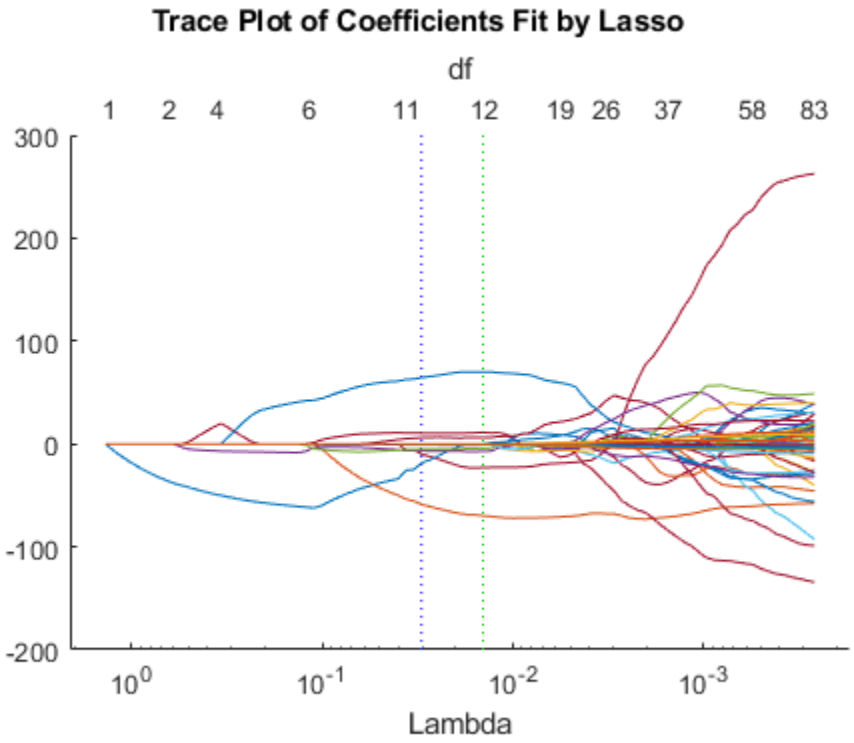
It is difficult to tell which value of `Lambda` is appropriate. To determine a good value, try fitting with cross validation.

```
tic
[b fitinfo] = lasso(NIR,octane,'CV',10);
toc
```

```
Elapsed time is 7.353767 seconds.
```

Plot the result.

```
lassoPlot(b,fitinfo,'PlotType','Lambda','XScale','log');
```



Display the suggested value of `Lambda` .

```
fitinfo.Lambda1SE
```

```
ans =

    0.0302
```

Display the `Lambda` with minimal MSE.

```
fitinfo.LambdaMinMSE
```

```
ans =

    0.0144
```

Examine the quality of the fit for the suggested value of `Lambda` .

```
lambdaindex = fitinfo.Index1SE;
mse = fitinfo.MSE(lambdaindex)
df = fitinfo.DF(lambdaindex)
```

```
mse =
```

```
    0.0528

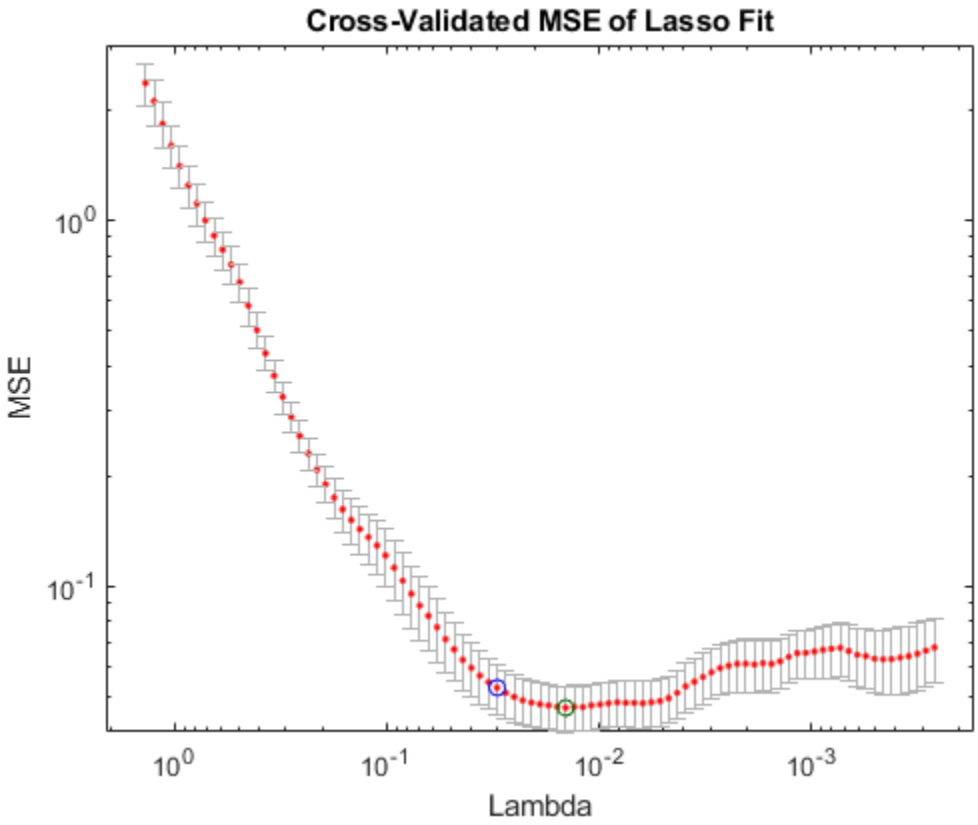
df =

    11
```

The fit uses just 11 of the 401 predictors and achieves a small cross-validated MSE.

Examine the plot of cross-validated MSE.

```
lassoPlot(b,fitinfo,'PlotType','CV');
% Use a log scale for MSE to see small MSE values better
set(gca,'YScale','log');
```



As `Lambda` increases (toward the left), MSE increases rapidly. The coefficients are reduced too much and they do not adequately fit the responses. As `Lambda` decreases, the models are larger (have more nonzero coefficients). The increasing MSE suggests that the models are overfitted.

The default set of `Lambda` values does not include values small enough to include all predictors. In this case, there does not appear to be a reason to look at smaller values. However, if you want smaller values than the default, use the `LambdaRatio` parameter, or supply a sequence of `Lambda` values using the `Lambda` parameter. For details, see the `lasso` reference page.

Cross validation can be slow. If you have a Parallel Computing Toolbox license, speed the computation of cross-validated lasso estimate using parallel computing. Start a parallel pool.

```
mypool = parpool()
```

```
Starting parallel pool (parpool) using the 'local' profile ...
connected to 6 workers.

mypool =

 Pool with properties:

            Connected: true
           NumWorkers: 6
              Cluster: local
        AttachedFiles: {}
    AutoAddClientPath: true
          IdleTimeout: 30 minutes (30 minutes remaining)
          SpmdEnabled: true
```

Set the parallel computing option and compute the lasso estimate.

```
opts = statset('UseParallel',true);
tic;
[b fitinfo] = lasso(NIR,octane,'CV',10,'Options',opts);
toc
```

```
Elapsed time is 3.799009 seconds.
```

Computing in parallel using two workers is faster on this problem.

Stop parallel pool.

```
delete(mypool)
```

```
Parallel pool using the 'local' profile is shutting down.
```

Lasso Regularization

This example shows how `lasso` identifies and discards unnecessary predictors.

Generate 200 samples of five-dimensional artificial data X from exponential distributions with various means.

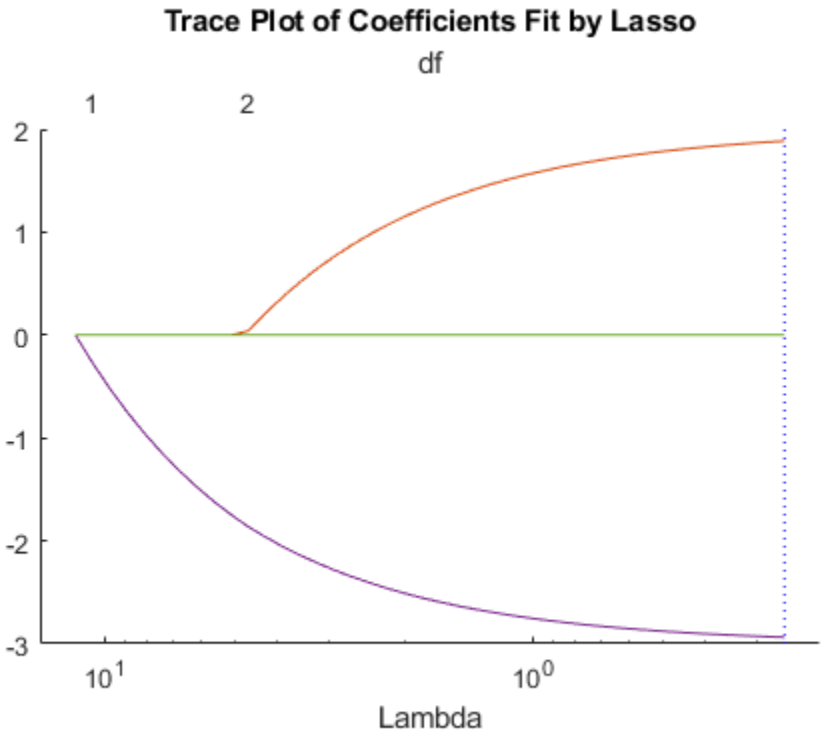
```
rng(3,'twister') % For reproducibility
X = zeros(200,5);
for ii = 1:5
    X(:,ii) = exprnd(ii,200,1);
end
```

Generate response data `Y = X*r + eps` , where `r` has just two nonzero components, and the noise `eps` is normal with standard deviation 0.1.

```
r = [0;2;0;-3;0];
Y = X*r + randn(200,1)*.1;
```

Fit a cross-validated sequence of models with `lasso` , and plot the result.

```
[b,fitinfo] = lasso(X,Y,'CV',10);
lassoPlot(b,fitinfo,'PlotType','Lambda','XScale','log');
```



The plot shows the nonzero coefficients in the regression for various values of the `Lambda` regularization parameter. Larger values of `Lambda` appear on the left side of the graph, meaning more regularization, resulting in fewer nonzero regression coefficients.

The dashed vertical lines represent the `Lambda` value with minimal mean squared error (on the right), and the `Lambda` value with minimal mean squared error plus one standard deviation. This latter value is a recommended setting for `Lambda` . These lines appear only when you perform cross validation. Cross validate by setting the `'CV'` name-value pair argument. This example uses 10-fold cross validation.

The upper part of the plot shows the degrees of freedom (df), meaning the number of nonzero coefficients in the regression, as a function of Lambda. On the left, the large value of Lambda causes all but one coefficient to be 0. On the right all five coefficients are nonzero, though the plot shows only two clearly. The other three coefficients are so small that you cannot visually distinguish them from 0.

For small values of Lambda (toward the right in the plot), the coefficient values are close to the least-squares estimate.

Find the `Lambda` value of the minimal cross-validated mean squared error plus one standard deviation. Examine the MSE and coefficients of the fit at that `Lambda` .

```
lam = fitinfo.Index1SE;
fitinfo.MSE(lam)
```

```
ans = 0.1398
```

```
b(:,lam)
```

```
ans = 5×1

         0
    1.8855
         0
   -2.9367
         0
```

`lasso` did a good job finding the coefficient vector `r` .

For comparison, find the least-squares estimate of `r` .

```
rhat = X\Y
```

```
rhat = 5×1

   -0.0038
    1.9952
    0.0014
   -2.9993
    0.0031
```

The estimate `b(:,lam)` has slightly more mean squared error than the mean squared error of `rhat` .

```
res = X*rhat - Y;     % Calculate residuals
MSEmin = res'*res/200 % b(:,lam) value is 0.1398
```

```
MSEmin = 0.0088
```

But `b(:,lam)` has only two nonzero components, and therefore can provide better predictive estimates on new data.

Lasso and Elastic Net with Cross Validation

This example shows how to predict the mileage (MPG) of a car based on its weight, displacement, horsepower, and acceleration, using the lasso and elastic net methods.

Load the `carbig` data set.

```
load carbig
```

Extract the continuous (noncategorical) predictors (lasso does not handle categorical predictors).

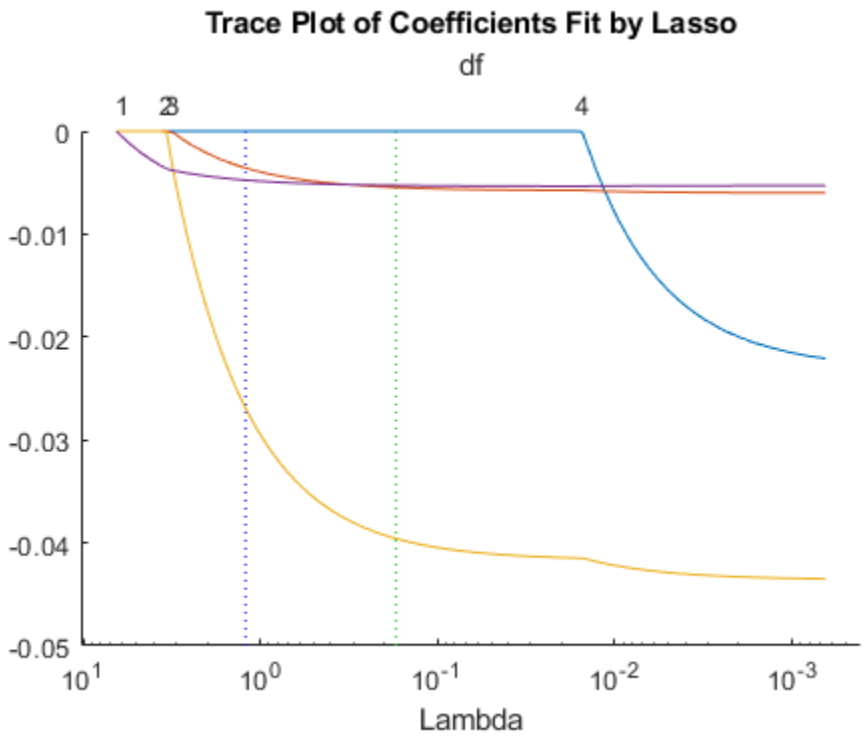
```
X = [Acceleration Displacement Horsepower Weight];
```

Perform a lasso fit with 10-fold cross validation.

```
[b,fitinfo] = lasso(X,MPG,'CV',10);
```

Plot the result.

```
lassoPlot(b,fitinfo,'PlotType','Lambda','XScale','log');
```



Calculate the correlation of the predictors. Eliminate NaNs first.

```
nonan = ~any(isnan([X MPG]),2);
Xnonan = X(nonan,:);
MPGnonan = MPG(nonan,:);
corr(Xnonan)
```

```
ans = 4×4

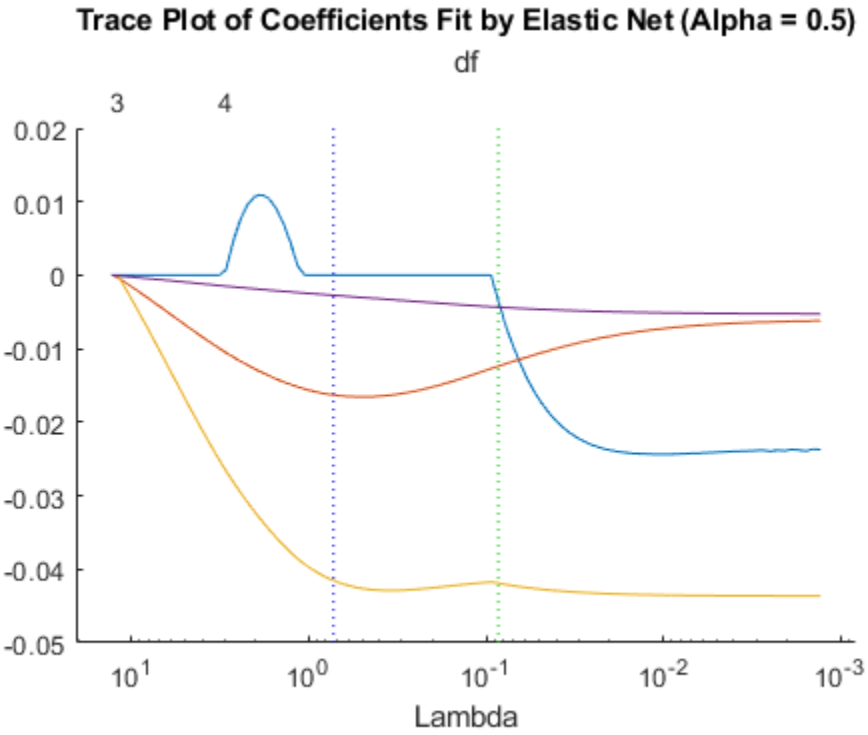
    1.0000   -0.5438   -0.6892   -0.4168
   -0.5438    1.0000    0.8973    0.9330
   -0.6892    0.8973    1.0000    0.8645
   -0.4168    0.9330    0.8645    1.0000
```

Because some predictors are highly correlated, perform elastic net fitting. Use `Alpha` = 0.5.

```
[ba,fitinfoa] = lasso(X,MPG,'CV',10,'Alpha',.5);
```

Plot the result. Name each predictor so you can tell which curve is which.

```
pnames = {'Acceleration','Displacement','Horsepower','Weight'};
lassoPlot(ba,fitinfoa,'PlotType','Lambda','XScale','log',...
    'PredictorNames',pnames);
```



When you activate the data cursor and click the plot, you see the name of the predictor, the coefficient, the value of `Lambda`, and the index of that point, meaning the column in `b` associated with that fit.

Here, the elastic net and lasso results are not very similar. Also, the elastic net plot reflects a notable qualitative property of the elastic net technique. The elastic net retains three nonzero coefficients as `Lambda` increases (toward the left of the plot), and these three coefficients reach 0 at about the same `Lambda` value. In contrast, the lasso plot shows two of the three coefficients becoming 0 at the same value of `Lambda`, while another coefficient remains nonzero for higher values of `Lambda`.

This behavior exemplifies a general pattern. In general, elastic net tends to retain or drop groups of highly correlated predictors as `Lambda` increases. In contrast, lasso tends to drop smaller groups, or even individual predictors.

Partial Least Squares

In this section...

Introduction to Partial Least Squares

Partial least-squares (PLS) regression is a technique used with data that contain correlated predictor variables. This technique constructs new predictor variables, known as components, as linear combinations of the original predictor variables. PLS constructs these components while considering the observed response values, leading to a parsimonious model with reliable predictive power.

The technique is something of a cross between multiple linear regression on page 11-9 and principal component analysis on page 15-68:

- Multiple linear regression finds a combination of the predictors that best fit a response.
- Principal component analysis finds combinations of the predictors with large variance, reducing correlations. The technique makes no use of response values.
- PLS finds combinations of the predictors that have a large covariance with the response values.

PLS therefore combines information about the variances of both the predictors and the responses, while also considering the correlations among them.

PLS shares characteristics with other regression and feature transformation techniques. It is similar to ridge regression on page 11-109 in that it is used in situations with correlated predictors. It is similar to stepwise regression on page 11-99 (or more general feature selection on page 15-49 techniques) in that it can be used to select a smaller set of model terms. PLS differs from these methods, however, by transforming the original predictor space into the new component space.

The function `plsregress` carries out PLS regression.

Partial Least Squares

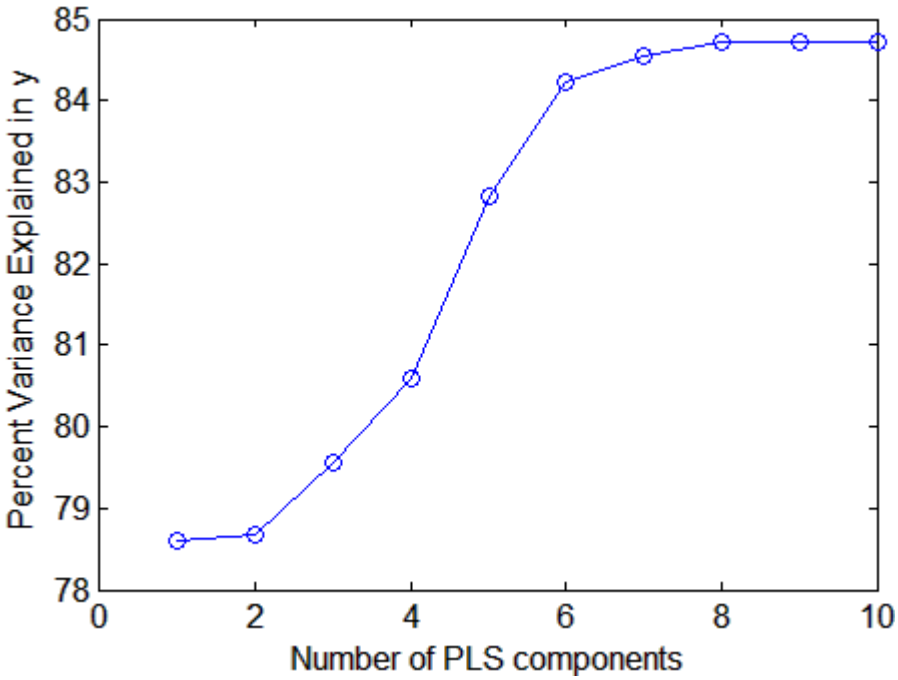
For example, consider the data on biochemical oxygen demand in `moore.mat`, padded with noisy versions of the predictors to introduce correlations:

```
load moore
y = moore(:,6);              % Response
X0 = moore(:,1:5);           % Original predictors
X1 = X0+10*randn(size(X0));  % Correlated predictors
X = [X0,X1];
```

Use `plsregress` to perform PLS regression with the same number of components as predictors, then plot the percentage variance explained in the response as a function of the number of components:

```
[XL,yl,XS,YS,beta,PCTVAR] = plsregress(X,y,10);

plot(1:10,cumsum(100*PCTVAR(2,:)),'-bo');
xlabel('Number of PLS components');
ylabel('Percent Variance Explained in y');
```

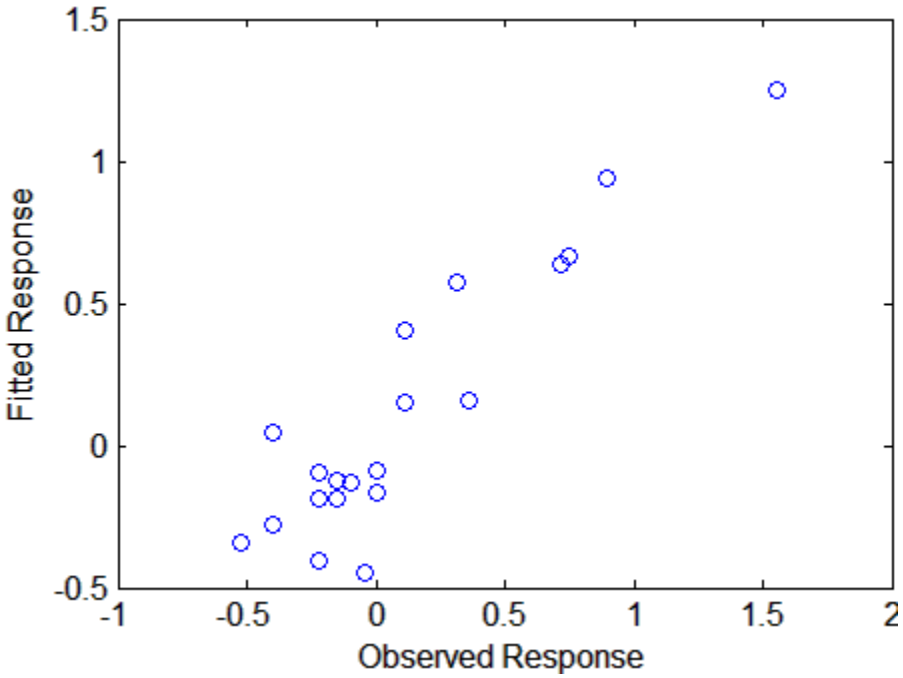


Choosing the number of components in a PLS model is a critical step. The plot gives a rough indication, showing nearly 80% of the variance in y explained by the first component, with as many as five additional components making significant contributions.

The following computes the six-component model:

```
[XL,yl,XS,YS,beta,PCTVAR,MSE,stats] = plsregress(X,y,6);
yfit = [ones(size(X,1),1) X]*beta;

plot(y,yfit,'o')
```

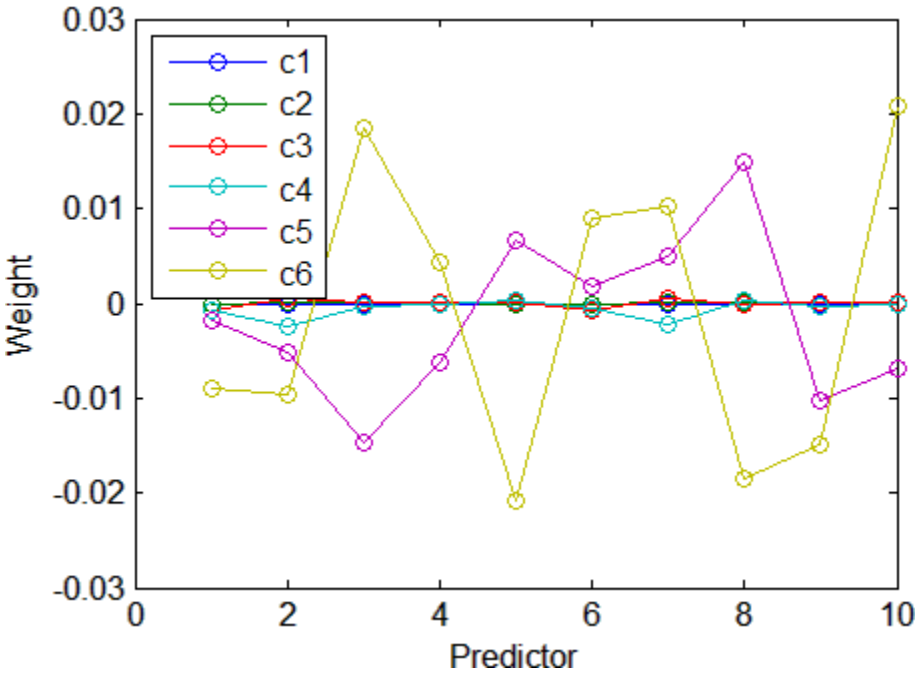


The scatter shows a reasonable correlation between fitted and observed responses, and this is confirmed by the R^2 statistic:

```
TSS = sum((y-mean(y)).^2);
RSS = sum((y-yfit).^2);
Rsquared = 1 - RSS/TSS
Rsquared =
    0.8421
```

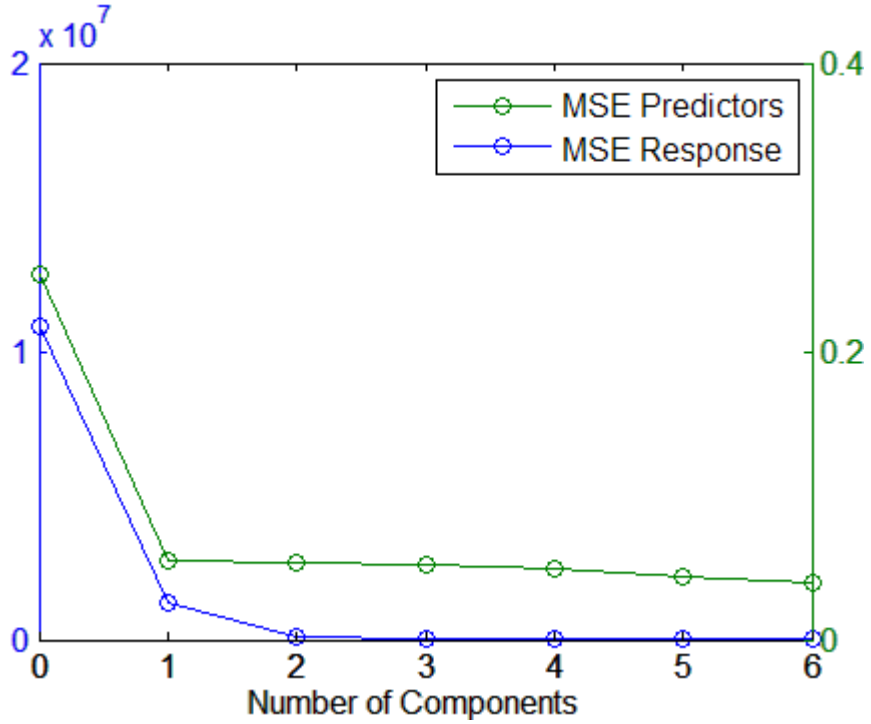
A plot of the weights of the ten predictors in each of the six components shows that two of the components (the last two computed) explain the majority of the variance in X:

```
plot(1:10,stats.W,'o-');
legend({'c1','c2','c3','c4','c5','c6'},'Location','NW')
xlabel('Predictor');
ylabel('Weight');
```



A plot of the mean-squared errors suggests that as few as two components may provide an adequate model:

```
[axes,h1,h2] = plotyy(0:6,MSE(1,:),0:6,MSE(2,:));
set(h1,'Marker','o')
set(h2,'Marker','o')
legend('MSE Predictors','MSE Response')
xlabel('Number of Components')
```



The calculation of mean-squared errors by `plsregress` is controlled by optional parameter name/value pairs specifying cross-validation type and the number of Monte Carlo repetitions.

Linear Mixed-Effects Models

Linear mixed-effects models are extensions of linear regression models for data that are collected and summarized in groups. These models describe the relationship between a response variable and independent variables, with coefficients that can vary with respect to one or more grouping variables. A mixed-effects model consists of two parts, fixed effects and random effects. Fixed-effects terms are usually the conventional linear regression part, and the random effects are associated with individual experimental units drawn at random from a population. The random effects have prior distributions whereas fixed effects do not. Mixed-effects models can represent the covariance structure related to the grouping of data by associating the common random effects to observations that have the same level of a grouping variable. The standard form of a linear mixed-effects model is

$$y = \underbrace{X\beta}_{fixed} + \underbrace{Zb}_{random} + \underbrace{\varepsilon}_{error},$$

where

- y is the n-by-1 response vector, and n is the number of observations.
- X is an n-by-p fixed-effects design matrix.
- β is a p-by-1 fixed-effects vector.
- Z is an n-by-q random-effects design matrix.
- b is a q-by-1 random-effects vector.
- ε is the n-by-1 observation error vector.

The assumptions for the linear mixed-effects model are:

- Random-effects vector, b, and the error vector, ε, have the following prior distributions:

  $$b \sim N\left(0, \sigma^2 D(\theta)\right),$$
  $$\varepsilon \sim N\left(0, \sigma^2 I\right),$$

  where D is a symmetric and positive semidefinite matrix, parameterized by a variance component vector θ, I is an n-by-n identity matrix, and σ^2 is the error variance.
- Random-effects vector, b, and the error vector, ε, are independent from each other.

Mixed-effects models are also called *multilevel models* or *hierarchical models* depending on the context. Mixed-effects models is a more general term than the latter two. Mixed-effects models might include factors that are not necessarily multilevel or hierarchical, for example crossed factors. That is why mixed-effects is the terminology preferred here. Sometimes mixed-effects models are expressed as multilevel regression models (first level and grouping level models) that are fit simultaneously. For example, a varying or random intercept model, with one continuous predictor variable x and one grouping variable with M levels, can be expressed as

$$y_{im} = \beta_{0m} + \beta_1 x_{im} + \varepsilon_{im}, \quad i = 1, 2, .., n, \quad m = 1, 2, ..., M, \quad \varepsilon_{im} \sim N\left(0, \sigma^2\right),$$
$$\beta_{0m} = \beta_{00} + b_{0m}, \quad b_{0m} \sim N\left(0, \sigma_0^2\right),$$

where y_{im} corresponds to data for observation i and group m, n is the total number of observations, and b_{0m} and ε_{im} are independent of each other. After substituting the group-level parameters in the first-level model, the model for the response vector becomes

$$y_{im} = \underbrace{\beta_{00} + \beta_1 x_{im}}_{fixed\ effects} + \underbrace{b_{0m}}_{random\ effects} + \varepsilon_{im}.$$

A random intercept and slope model with one continuous predictor variable x, where both the intercept and slope vary independently by a grouping variable with M levels is

$$y_{im} = \beta_{0m} + \beta_{1m} x_{im} + \varepsilon_{im}, \quad i = 1, 2, \ldots, n, \quad m = 1, 2, \ldots, M, \quad \varepsilon_{im} \sim N\left(0, \sigma^2\right),$$
$$\beta_{0m} = \beta_{00} + b_{0m}, \quad b_{0m} \sim N\left(0, \sigma_0^2\right),$$
$$\beta_{1m} = \beta_{10} + b_{1m}, \quad b_{1m} \sim N\left(0, \sigma_1^2\right),$$

or

$$b_m = \begin{pmatrix} b_{0m} \\ b_{1m} \end{pmatrix} \sim N\left(0, \begin{pmatrix} \sigma_0^2 & 0 \\ 0 & \sigma_1^2 \end{pmatrix}\right).$$

You might also have correlated random effects. In general, for a model with a random intercept and slope, the distribution of the random effects is

$$b_m = \begin{pmatrix} b_{0m} \\ b_{1m} \end{pmatrix} \sim N\left(0, \sigma^2 D(\theta)\right),$$

where D is a 2-by-2 symmetric and positive semidefinite matrix, parameterized by a variance component vector θ.

After substituting the group-level parameters in the first-level model, the model for the response vector is

$$y_{im} = \underbrace{\beta_{00} + \beta_{10} x_{im}}_{fixed\ effects} + \underbrace{b_{0m} + b_{1m} x_{im}}_{random\ effects} + \varepsilon_{im}, \quad i = 1, 2, \ldots, n, \quad m = 1, 2, \ldots, M.$$

If you express the group-level variable, x_{im}, in the random-effects term by z_{im}, this model is

$$y_{im} = \underbrace{\beta_{00} + \beta_{10} x_{im}}_{fixed\ effects} + \underbrace{b_{0m} + b_{1m} z_{im}}_{random\ effects} + \varepsilon_{im}, \quad i = 1, 2, \ldots, n, \quad m = 1, 2, \ldots, M.$$

In this case, the same terms appear in both the fixed-effects design matrix and random-effects design matrix. Each z_{im} and x_{im} correspond to the level m of the grouping variable.

It is also possible to explain more of the group-level variations by adding more group-level predictor variables. A random-intercept and random-slope model with one continuous predictor variable x, where both the intercept and slope vary independently by a grouping variable with M levels, and one group-level predictor variable v_m is

$$y_{im} = \beta_{0im} + \beta_{1im} x_{im} + \varepsilon_{im}, \quad i = 1, 2, \ldots, n, \quad m = 1, 2, \ldots, M, \quad \varepsilon_{im} \sim N\left(0, \sigma^2\right),$$
$$\beta_{0im} = \beta_{00} + \beta_{01} v_{im} + b_{0m}, \quad b_{0m} \sim N\left(0, \sigma_0^2\right),$$
$$\beta_{1im} = \beta_{10} + \beta_{11} v_{im} + b_{1m}, \quad b_{1m} \sim N\left(0, \sigma_1^2\right).$$

This model results in main effects of the group-level predictor and an interaction term between the first-level and group-level predictor variables in the model for the response variable as

$$y_{im} = \beta_{00} + \beta_{01}v_{im} + b_{0m} + (\beta_{10} + \beta_{11}v_{im} + b_{1m})x_{im} + \varepsilon_{im}, \quad i = 1, 2, ..., n, \quad m = 1, 2, ..., M,$$
$$= \underbrace{\beta_{00} + \beta_{10}x_{im} + \beta_{01}v_{im} + \beta_{11}v_{im}x_{im}}_{fixed\ effects} + \underbrace{b_{0m} + b_{1m}x_{im}}_{random\ effects} + \varepsilon_{im}.$$

The term $\beta_{11}v_m x_{im}$ is often called a cross-level interaction in many textbooks on multilevel models. The model for the response variable y can be expressed as

$$y_{im} = \begin{bmatrix}1 & x_{1im} & v_{im} & v_{im}x_{1im}\end{bmatrix}\begin{bmatrix}\beta_{00}\\ \beta_{10}\\ \beta_{01}\\ \beta_{11}\end{bmatrix} + \begin{bmatrix}1 & x_{1im}\end{bmatrix}\begin{bmatrix}b_{0m}\\ b_{1m}\end{bmatrix} + \varepsilon_{im}, \quad i = 1, 2, ..., n, \quad m = 1, 2, ..., M,$$

which corresponds to the standard form given earlier,

$$y = X\beta + Zb + \varepsilon.$$

In general, if there are R grouping variables, and $m(r,i)$ shows the level of grouping variable r, for observation i, then the model for the response variable for observation i is

$$y_i = x_i^T\beta + \sum_{r=1}^{R} z_{ir}b^{(r)}_{m(r,i)} + \varepsilon_i, \quad i = 1, 2, ..., n,$$

where β is a p-by-1 fixed-effects vector, $b^{(r)}_{m(r,i)}$ is a $q(r)$-by-1 random-effects vector for the rth grouping variable and level $m(r,i)$, and ε_i is a 1-by-1 error term for observation i.

Prepare Data for Linear Mixed-Effects Models

In this section...

Tables and Dataset Arrays

To fit a linear-mixed effects model, you must store your data in a table or dataset array. In your table or dataset array, you must have a column for each variable including the response variable. More specifically, the table or dataset array, say `tbl`, must contain the following:

- A response variable y
- Predictive variables X_j which can be continuous or grouping variables
- Grouping variables g_1, g_2, ..., g_R,

where the grouping variables in X_j and g_r can be categorical, logical, a character array, a string array, or a cell array of character vectors, $r = 1, 2, ..., R$.

You must organize your data so that each row represents an observation. And each row should contain the value of variables and the levels of grouping variables corresponding to that observation. For example, if you have data from an experiment with four treatment options, on five different types of individuals chosen randomly from a population of individuals (blocks), the table or dataset array must look like this.

Block	Treatment	Response
1	1	y11
1	2	y12
1	3	y13
1	4	y14
...	...	...
5	1	y51
5	2	y52
5	3	y53
5	4	y54

Now, consider a split-plot experiment, where the effect of four different types of fertilizers on the yield of tomato plants is studied. The soil where the tomato plants are planted is divided into three blocks based on the soil type: sandy, silty, and loamy. Each block is divided into five plots, where five types of tomato plants, (cherry, heirloom, grape, vine, and plum) are randomly assigned to these plots. Then, the tomato plants in the plots are divided into subplots, where each subplot is treated by one of the four fertilizers. The data from this experiment looks like:

Soil	Tomato	Fertilizer	Yield
'Sandy'	'Plum'	1	104

Soil	Tomato	Fertilizer	Yield
'Sandy'	'Plum'	2	136
'Sandy'	'Plum'	3	158
'Sandy'	'Plum'	4	174
'Sandy'	'Cherry'	1	57
'Sandy'	'Cherry'	2	86
...	...	...	...
'Sandy'	'Vine'	3	99
'Sandy'	'Vine'	4	117
'Silty'	'Plum'	1	120
'Silty'	'Plum'	2	115
...	...	...	...
'Loamy'	'Vine'	3	111
'Loamy'	'Vine'	4	105

You must specify the model you want to fit using the `formula` input argument to `fitlme`.

In general, a formula for model specification is a character vector or string scalar of the form `'y ~ terms'`. For linear mixed-effects models, this formula is in the form `'y ~ fixed + (random1|grouping1) + ... + (randomR|groupingR)'`, where `fixed` contains the fixed-effects terms and `random1, ..., randomR` contain the random-effects terms. For example, for the previous fertilizer experiment, consider the following mixed-effects model

$$y_{imjk} = \beta_0 + \sum_{m=2}^{4} \beta_{1m} I[F]_{im} + \sum_{j=2}^{5} \beta_{2j} I[T]_{ij} + b_{0k} S_k + b_{0jk} (S*T)_{jk} + \varepsilon_{imjk},$$

where $i = 1, 2, ..., 60$, the index m corresponds to the fertilizer types, j corresponds to the tomato types, and $k = 1, 2, 3$ corresponds to the blocks (soil). S_k represents the kth soil type, and $I[F]_{im}$ is the dummy variable representing level m of the fertilizer. Similarly, $I[T]_{ij}$ is the dummy variable representing the level j of the tomato type.

You can fit this model using the formula `'Yield ~ 1 + Fertilizer + Tomato + (1|Soil)+(1|Soil:Tomato)'`.

For detailed information on how to specify your model using formula, see “Relationship Between Formula and Design Matrices” on page 11-138.

Design Matrices

If you cannot easily describe your model using a formula, you can create design matrices to define the fixed and random effects, and fit the model using `fitlmematrix(X,y,Z,G)`. You must create your design matrices as follows.

Fixed-effects and random-effects design matrices `X` and `Z`:

- Enter a column of 1s for the intercept using `ones(n,1)`, where n is the total number of observations.

- If `X1` is a continuous variable, then enter `X1` as it is in a separate column.
- If `X1` is a categorical variable with *m* levels, then there must be *m* – 1 dummy variables for *m* – 1 levels of `X1` in `X`.

  For example, consider an experiment where you want to study the impact of quality of raw materials from four different providers on the productivity of a production line. If you fit a linear mixed-effects model with intercept and provider as the fixed-effects terms, intercept is the random-effects term, and you use reference contrasts coding, then you must construct your fixed- and random-effects design matrices as follows.

  ```
  D = dummyvar(provider); % Create dummy variables
  X = [ones(n,1) D(:,2) D(:,3) D(:,4)];
  Z = [ones(n,1)];
  ```

  Because reference contrast coding uses the first provider as the reference, and the model has an intercept, you must use the dummy variables for only the last three providers.
- If there is an interaction term of predictor variables `X1` and `X2`, then you must enter a column that you form by elementwise product of the vectors `X1` and `X2`.

  For example, if you want to fit a model, where there is an intercept, a continuous treatment factor, a continuous time factor, and their interaction as the fixed-effects in a longitudinal study, and time is the random-effects term, then your fixed- and random-effects design matrices should look like

  ```
  X = [ones(n,1),treatment,time,treatment.*time];
  y = response;
  Z = [time];
  ```

Grouping variables `G`:

There is one column for each grouping variable and a column of elementwise product of the grouping variables in case of a nesting.

For example, if you want to group plots (`plot`) within blocks (`block`), then you must add a column of elementwise product of `plot` by `block`. More specifically, if you want to fit a model where there is intercept and a continuous treatment factor as the fixed-effects in a split-block experiment, and the intercept and treatment are grouped by the plots nested within blocks, then the design matrices should look like this.

```
X = [ones(n,1),treatment];
y = response;
Z = [ones(n,1),treatment];
G = [block.*plot];
```

Suppose in the earlier quality of raw materials example, the raw materials arrive in bulks, and the bulks are nested within providers. If you want to fit a linear mixed-effects model, where intercept is grouped by the bulks within providers, then your design matrices should look like this.

```
D = dummyvar(provider);
X = [ones(n,1) D(:,2) D(:,3) D(:,4)];
y = response;
Z = ones(n,1);
G = [provider.*bulks];
```

In the earlier longitudinal study example, if you want to add random effects for intercept and time grouped by subjects that participated in the study, then your design matrices should look like

```
X = [ones(n,1),treatment,time, treatment.*time];
y = response;
Z = [ones(n,1),time];
G = subject;
```

Relation of Matrix Form to Tables and Dataset Arrays

`fitlme(tbl,formula)` and `fitlmematrix(X,y,Z,G)` are equivalent in functionality, such that

- `y` is the *n*-by-1 response vector.
- `X` is an *n*-by-*p* fixed-effects design matrix. `fitlme` constructs this from the expression `fixed` in `formula`.
- `Z` is an *R*-by-1 cell array with `Z{r}` being an *n*-by-*q*(*r*) random-effects design matrix constructed from the *r*th expression in `random` in `formula`, *r* = 1, 2, ..., *R*.
- `G` is an *R*-by-1 cell array with `G{r}` being an *n*-by-1 grouping variable, g_r, in `formula` with *M*(*r*) levels or groups.

For example, if `tbl` is a table or dataset array containing the response variable `y`, the continuous variables `X1` and `X2`, and the grouping variable `g`, then to fit a linear mixed-effects model that corresponds to the formula expression `'y ~ X1+ X2+ (X1*X2|g)'` using `fitlmematrix(X,y,Z,G)` the input arguments must correspond to the following:

```
y = tbl.y
X = [ones(n,1), tbl.X1, tbl.X2]
Z = [ones(n,1), tbl.X1, tbl.X2, tbl.X1.*tbl.X2]
G = tbl.g
```

Relationship Between Formula and Design Matrices

In this section...

Formula

In general, a formula for model specification is a character vector or string scalar of the form `'y ~ terms'`. For the linear mixed-effects models, this formula is in the form `'y ~ fixed + (random1|grouping1) + ... + (randomR|groupingR)'`, where `fixed` and `random` contain the fixed-effects and the random-effects terms.

Suppose a table `tbl` contains the following:

- A response variable, `y`
- Predictor variables, X_j, which can be continuous or grouping variables
- Grouping variables, g_1, g_2, ..., g_R,

where the grouping variables in X_j and g_r can be categorical, logical, character arrays, string arrays, or cell arrays of character vectors.

Then, in a formula of the form, `'y ~ fixed + (random`$_1$`|g`$_1$`) + ... + (random`$_R$`|g`$_R$`)'`, the term `fixed` corresponds to a specification of the fixed-effects design matrix `X`, `random`$_1$ is a specification of the random-effects design matrix Z_1 corresponding to grouping variable g_1, and similarly `random`$_R$ is a specification of the random-effects design matrix Z_R corresponding to grouping variable g_R. You can express the `fixed` and `random` terms using Wilkinson notation.

Wilkinson notation describes the factors present in models. The notation relates to factors present in models, not to the multipliers (coefficients) of those factors.

Wilkinson Notation	Factors in Standard Notation
`1`	Constant (intercept) term
`X^k`, where `k` is a positive integer	`X`, X^2, ..., X^k
`X1 + X2`	`X1`, `X2`
`X1*X2`	`X1`, `X2`, `X1.*X2 (elementwise multiplication of X1 and X2)`
`X1:X2`	`X1.*X2` only
`- X2`	Do not include `X2`
`X1*X2 + X3`	`X1`, `X2`, `X3`, `X1*X2`
`X1 + X2 + X3 + X1:X2`	`X1`, `X2`, `X3`, `X1*X2`
`X1*X2*X3 - X1:X2:X3`	`X1`, `X2`, `X3`, `X1*X2`, `X1*X3`, `X2*X3`
`X1*(X2 + X3)`	`X1`, `X2`, `X3`, `X1*X2`, `X1*X3`

Statistics and Machine Learning Toolbox notation always includes a constant term unless you explicitly remove the term using `-1`. Here are some examples for linear mixed-effects model specification.

Examples:

Formula	Description
`'y ~ X1 + X2'`	Fixed effects for the intercept, `X1` and `X2`. This is equivalent to `'y ~ 1 + X1 + X2'`.
`'y ~ -1 + X1 + X2'`	No intercept and fixed effects for `X1` and `X2`. The implicit intercept term is suppressed by including `-1`.
`'y ~ 1 + (1 | g1)'`	Fixed effects for the intercept plus random effect for the intercept for each level of the grouping variable `g1`.
`'y ~ X1 + (1 | g1)'`	Random intercept model with a fixed slope.
`'y ~ X1 + (X1 | g1)'`	Random intercept and slope, with possible correlation between them. This is equivalent to `'y ~ 1 + X1 + (1 + X1|g1)'`.
`'y ~ X1 + (1 | g1) + (-1 + X1 | g1)'`	Independent random effects terms for intercept and slope.
`'y ~ 1 + (1 | g1) + (1 | g2) + (1 | g1:g2)'`	Random intercept model with independent main effects for `g1` and `g2`, plus an independent interaction effect.

Design Matrices for Fixed and Random Effects

`fitlme` converts the expressions in the `fixed` and `random` parts (not grouping variables) of a formula into design matrices as follows:

- Each term in a formula adds one or more columns to the corresponding design matrix.
- A term containing a single continuous variable adds one column to the design matrix.
- A fixed term containing a categorical variable `X` with k levels adds (k – 1) dummy variables to the design matrix.

  For example, if the variable `Supplier` represents three different suppliers a manufacturer receives parts from, i.e. a categorical variable with three levels, and out of six batches of parts, the first two batches come from supplier 1 (level 1), the second two batches come from supplier 2 (level 2), and the last two batches come from supplier 3 (level 3), such as

```
Supplier =

     1
     1
     2
     2
     3
     3
```

Then, adding `Supplier` to the formula as a fixed-effects or random-effects term adds the following two dummy variables to the corresponding design matrix, using the `'reference'` contrast:

```
 0     0
 0     0
 1     0
 1     0
 0     1
 0     1
```

For more details on dummy variables, see “Dummy Variables” on page 2-48. For other contrast options, see the `'DummyVarCoding'` name-value pair argument of `fitlme`.

- If `X1` and `X2` are continuous variables, the product term `X1:X2` adds one column obtained by elementwise multiplication of `X1` and `X2` to the design matrix.
- If `X1` is continuous and `X2` is categorical with *k* levels, the product term `X1:X2` multiplies elementwise `X1` with the (*k* – 1) dummy variables representing `X2`, and adds these (*k* – 1) columns to the design matrix.

  For example, if `Drug` is the amount of a drug given to patients, a continuous treatment, and `Time` is three distinct points in time when the health measures are taken, a categorical variable with three levels, and out of nine observations, the first three are observed at time point 1, the second three are observed at time point 2, and the last three are observed at time point 3 so that

```
[Drug Time] =

    0.1000    1.0000
    0.2000    1.0000
    0.5000    2.0000
    0.6000    2.0000
    0.3000    3.0000
    0.8000    3.0000
```

  Then, the product term `Drug:Time` adds the following two variables to the design matrix:

```
     0         0
     0         0
0.5000         0
0.6000         0
     0    0.3000
     0    0.8000
```

- If `X1` and `X2` are categorical variables with *k* and *m* levels respectively, the product term `X1:X2` adds (*k* – 1)*(*m* – 1) dummy variables to the design matrix formed by taking the elementwise product of each dummy variable representing `X1` with each dummy variable representing `X2`.

  For example, in an experiment to determine the impact of the type of corn and the popping method on the yield, suppose there are three types of `Corn` and two types of `Method` as follows:

```
    1    oil
    1    oil
    1    air
    1    air
    2    oil
    2    oil
    2    air
    2    air
```

```
3    oil
3    oil
3    air
3    air
```

Then, the interaction term `Corn:Method` adds the following to the design matrix:

```
0     0
0     0
0     0
0     0
1     0
1     0
0     0
0     0
0     1
0     1
0     0
0     0
```

- The term `X1*X2` adds the necessary number of columns for `X1`, `X2`, and `X1:X2` to the design matrix.
- The term `X1^2` adds the necessary number of columns for `X1` and `X1:X1` to the design matrix.
- The symbol `1` (one) in the formula stands for a column of all 1s. By default a column of 1s is included in the design matrix. To exclude a column of ones from the design matrix, you must explicitly specify `−1` as a term in the expression.

Grouping Variables

`fitlme` handles the grouping variables in the `(.|group)` part of a formula as follows:

- If a grouping variable has k levels, then k dummy variables represent this grouping.

  For example, suppose `District` is a categorical grouping variable with three levels, showing the three types of districts, and out of six schools, the first two are in district 1, the second two are in district 2, and the last two are in district 3, so that

```
District =

     1
     1
     2
     2
     3
     3
```

  Then, the dummy variables that represent this grouping are:

```
  1     0     0
  1     0     0
  0     1     0
  0     1     0
  0     0     1
  0     0     1
```

- If `X1` is a continuous random-effects variable and `X2` is a grouping variable with k levels, then the random term `(X1 − 1|X2)` multiplies elementwise `X1` with the k dummy variables representing `X2` and adds these k columns to the random-effects design matrix.

For example, suppose `Score` is a continuous variable showing the scores of students from a math exam in a school, and `Class` is a categorical variable with three levels, showing the three different classes in a school. Also, suppose out of nine observations first three correspond to the scores of students in the first class, the second three correspond to scores of students in the second class, and the last three correspond to the scores of students in the third class, such as

```
[Score Class] =

    78.0000    1.0000
    68.0000    1.0000
    81.0000    2.0000
    53.0000    2.0000
    85.0000    3.0000
    72.0000    3.0000
```

Then, the random term `(Score – 1|Class)` adds the following three columns to the random-effects design matrix:

```
 78.0000          0          0
 68.0000          0          0
       0    81.0000          0
       0    53.0000          0
       0          0    85.0000
       0          0    72.0000
```

- If `X1` is a continuous predictor variable and `X2` and `X3` are grouping variables with k and m levels respectively, the term `(X1|X2:X3)` represents this grouping of `X1` with $k*m$ dummy variables formed by taking the elementwise product of each dummy variable representing `X2` with each dummy variable representing `X3`.

  For example, suppose `Treatment` is a continuous predictor variable, and there are three levels of `Block` and two levels of `Plot` nested within the block as follows:

```
   0.1000    1    a
   0.2000    1    b
   0.5000    2    a
   0.6000    2    b
   0.3000    3    a
   0.8000    3    b
```

  Then, the random term `(Treatment – 1|Block:Plot)` adds the following to the random-effects design matrix:

```
 0.1000         0         0         0         0         0
      0    0.2000         0         0         0         0
      0         0    0.5000         0         0         0
      0         0         0    0.6000         0         0
      0         0         0         0    0.3000         0
      0         0         0         0         0    0.8000
```

Estimating Parameters in Linear Mixed-Effects Models

In this section...

A linear mixed-effects model is of the form

$$y = \underbrace{X\beta}_{fixed} + \underbrace{Zb}_{random} + \underbrace{\varepsilon}_{error},$$

where

- y is the n-by-1 response vector, and n is the number of observations.
- X is an n-by-p fixed-effects design matrix.
- β is a p-by-1 fixed-effects vector.
- Z is an n-by-q random-effects design matrix.
- b is a q-by-1 random-effects vector.
- ε is the n-by-1 observation error vector.

The random-effects vector, b, and the error vector, ε, are assumed to have the following independent prior distributions:

$$b \sim N\left(0, \sigma^2 D(\theta)\right),$$
$$\varepsilon \sim N\left(0, \sigma^2 I\right),$$

where D is a symmetric and positive semidefinite matrix, parameterized by a variance component vector θ, I is an n-by-n identity matrix, and σ^2 is the error variance.

In this model, the parameters to estimate are the fixed-effects coefficients β, and the variance components θ and σ^2. The two most commonly used approaches to parameter estimation in linear mixed-effects models are maximum likelihood and restricted maximum likelihood methods.

Maximum Likelihood (ML)

The maximum likelihood estimation includes both regression coefficients and the variance components, that is, both fixed-effects and random-effects terms in the likelihood function.

For a linear mixed-effects model defined above, the conditional response of the response variable y given β, b, θ, and σ^2 is

$$y \left| b, \beta, \theta, \sigma^2 \sim N\left(X\beta + Zb, \sigma^2 I_n\right)\right. .$$

The likelihood of y given β, θ, and σ^2 is

$$P\left(y \left| \beta, \theta, \sigma^2\right.\right) = \int P\left(y \left| b, \beta, \theta, \sigma^2\right.\right) P\left(b \left| \theta, \sigma^2\right.\right) db,$$

where

$$P\left(b\left|\theta,\sigma^2\right.\right)=\frac{1}{\left(2\pi\sigma^2\right)^{q/2}}\frac{1}{\left|D(\theta)\right|^{1/2}}\exp\left\{-\frac{1}{2\sigma^2}b^TD^{-1}b\right\}\quad\text{and}$$

$$P\left(y\left|b,\beta,\theta,\sigma^2\right.\right)=\frac{1}{\left(2\pi\sigma^2\right)^{n/2}}\exp\left\{-\frac{1}{2\sigma^2}(y-X\beta-Zb)^T(y-X\beta-Zb)\right\}.$$

Suppose $\Lambda(\theta)$ is the lower triangular Cholesky factor of $D(\theta)$ and $\Delta(\theta)$ is the inverse of $\Lambda(\theta)$. Then,

$$D(\theta)^{-1}=\Delta(\theta)^T\Delta(\theta).$$

Define

$$r^2(\beta,b,\theta)=b^T\Delta(\theta)^T\Delta(\theta)b+(y-X\beta-Zb)^T(y-X\beta-Zb),$$

and suppose b^* is the value of b that satisfies

$$\left.\frac{\partial r^2(\beta,b,\theta)}{\partial b}\right|_{b^*}=0$$

for given β and θ. Then, the likelihood function is

$$P\left(y\left|\beta,\theta,\sigma^2\right.\right)=\left(2\pi\sigma^2\right)^{-n/2}\left|D(\theta)\right|^{-1/2}\exp\left\{-\frac{1}{2\sigma^2}r^2(\beta,b^*(\beta),\theta)\right\}\frac{1}{\left|\Delta^T\Delta+Z^TZ\right|^{1/2}}.$$

$P(y|\beta,\theta,\sigma^2)$ is first maximized with respect to β and σ^2 for a given θ. Thus the optimized solutions $\widehat{\beta}(\theta)$ and $\widehat{\sigma}^2(\theta)$are obtained as functions of θ. Substituting these solutions into the likelihood function produces $P\left(y\left|\widehat{\beta}(\theta),\theta,\widehat{\sigma}^2(\theta)\right.\right)$. This expression is called a profiled likelihood where β and σ^2 have been profiled out. $P\left(y\left|\widehat{\beta}(\theta),\theta,\widehat{\sigma}^2(\theta)\right.\right)$ is a function of θ, and the algorithm then optimizes it with respect to θ. Once it finds the optimal estimate of θ, the estimates of β and σ^2 are given by $\widehat{\beta}(\theta)$ and $\widehat{\sigma}^2(\theta)$.

The ML method treats β as fixed but unknown quantities when the variance components are estimated, but does not take into account the degrees of freedom lost by estimating the fixed effects. This causes ML estimates to be biased with smaller variances. However, one advantage of ML over REML is that it is possible to compare two models in terms of their fixed- and random-effects terms. On the other hand, if you use REML to estimate the parameters, you can only compare two models, that are nested in their random-effects terms, with the same fixed-effects design.

Restricted Maximum Likelihood (REML)

Restricted maximum likelihood estimation includes only the variance components, that is, the parameters that parameterize the random-effects terms in the linear mixed-effects model. β is estimated in a second step. Assuming a uniform improper prior distribution for β and integrating the likelihood $P(y|\beta,\theta,\sigma^2)$ with respect to β results in the restricted likelihood $P(y|\theta,\sigma^2)$. That is,

$$P\left(y\left|\theta,\sigma^2\right.\right)=\int P\left(y\left|\beta,\theta,\sigma^2\right.\right)P(\beta)d\beta=\int P\left(y\left|\beta,\theta,\sigma^2\right.\right)d\beta.$$

The algorithm first profiles out $\widehat{\sigma}_R^2$ and maximizes remaining objective function with respect to θ to find $\widehat{\theta}_R$. The restricted likelihood is then maximized with respect to σ^2 to find $\widehat{\sigma}_R^2$. Then, it estimates β by finding its expected value with respect to the posterior distribution

$$P\left(\beta \middle| y, \widehat{\theta}_R, \widehat{\sigma}_R^2\right).$$

REML accounts for the degrees of freedom lost by estimating the fixed effects, and makes a less biased estimation of random effects variances. The estimates of θ and σ^2 are invariant to the value of β and less sensitive to outliers in the data compared to ML estimates. However, if you use REML to estimate the parameters, you can only compare two models that have the identical fixed-effects design matrices and are nested in their random-effects terms.

Linear Mixed-Effects Model Workflow

This example shows how to fit and analyze a linear mixed-effects model (LME).

Load the sample data.

```
load flu
```

The `flu` dataset array has a `Date` variable, and 10 variables containing estimated influenza rates (in 9 different regions, estimated from Google® searches, plus a nationwide estimate from the CDC).

Reorganize and plot the data.

To fit a linear-mixed effects model, your data must be in a properly formatted dataset array. To fit a linear mixed-effects model with the influenza rates as the responses, combine the nine columns corresponding to the regions into an array. The new dataset array, `flu2`, must have the response variable `FluRate`, the nominal variable `Region` that shows which region each estimate is from, the nationwide estimate `WtdILI`, and the grouping variable `Date`.

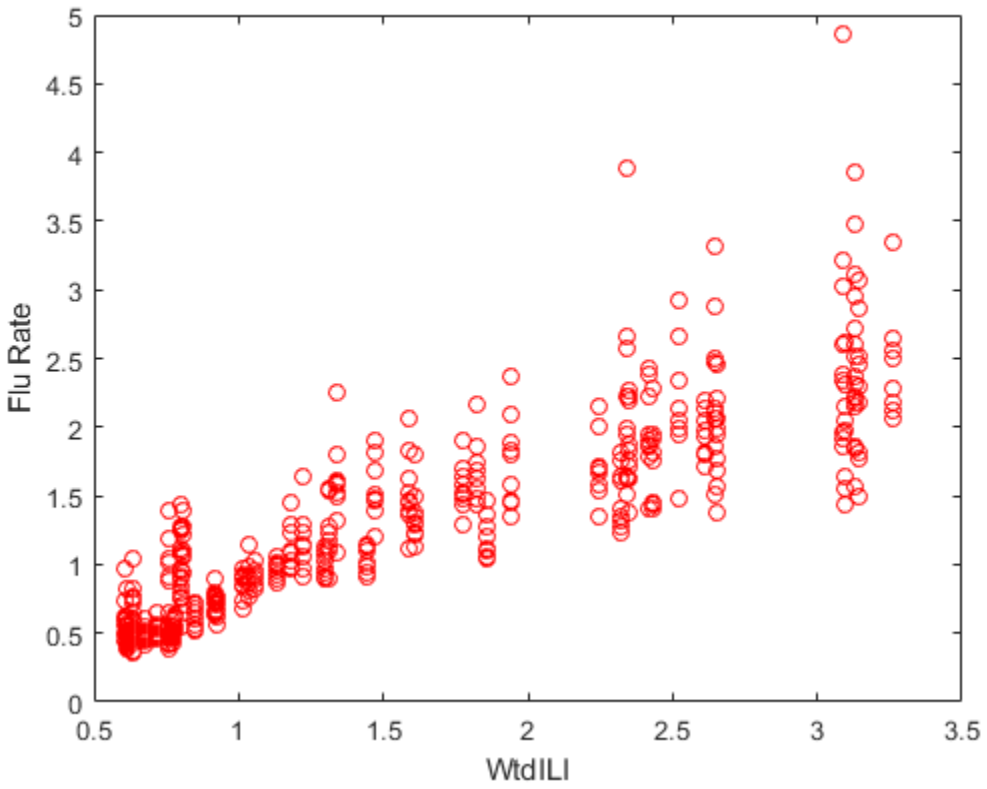
```
flu2 = stack(flu,2:10,'NewDataVarName','FluRate',...
    'IndVarName','Region');
flu2.Date = nominal(flu2.Date);
```

Define `flu2` as a `table`.

```
flu2 = dataset2table(flu2);
```

Plot flu rates versus the nationwide estimate.

```
plot(flu2.WtdILI,flu2.FluRate,'ro')
xlabel('WtdILI')
ylabel('Flu Rate')
```



You can see that the flu rates in regions have a direct relationship with the nationwide estimate.

Fit an LME model and interpret the results.

Fit a linear mixed-effects model with the nationwide estimate as the predictor variable and a random intercept that varies by `Date`.

```
lme = fitlme(flu2,'FluRate ~ 1 + WtdILI + (1|Date)')
```

```
lme =

Linear mixed-effects model fit by ML

Model information:
    Number of observations             468
    Fixed effects coefficients           2
    Random effects coefficients         52
    Covariance parameters                2

Formula:
    FluRate ~ 1 + WtdILI + (1 | Date)

Model fit statistics:
    AIC       BIC       LogLikelihood    Deviance
    286.24    302.83    -139.12          278.24
```

```
Fixed effects coefficients (95% CIs):
    Name                  Estimate    SE          tStat     DF     pValue
    {'(Intercept)'}       0.16385     0.057525    2.8484    466     0.0045885
    {'WtdILI'     }        0.7236     0.032219    22.459    466    3.0502e-76

    Lower       Upper
    0.050813    0.27689
     0.66028    0.78691

Random effects covariance parameters (95% CIs):
Group: Date (52 Levels)
    Name1                 Name2                 Type          Estimate
    {'(Intercept)'}       {'(Intercept)'}       {'std'}       0.17146

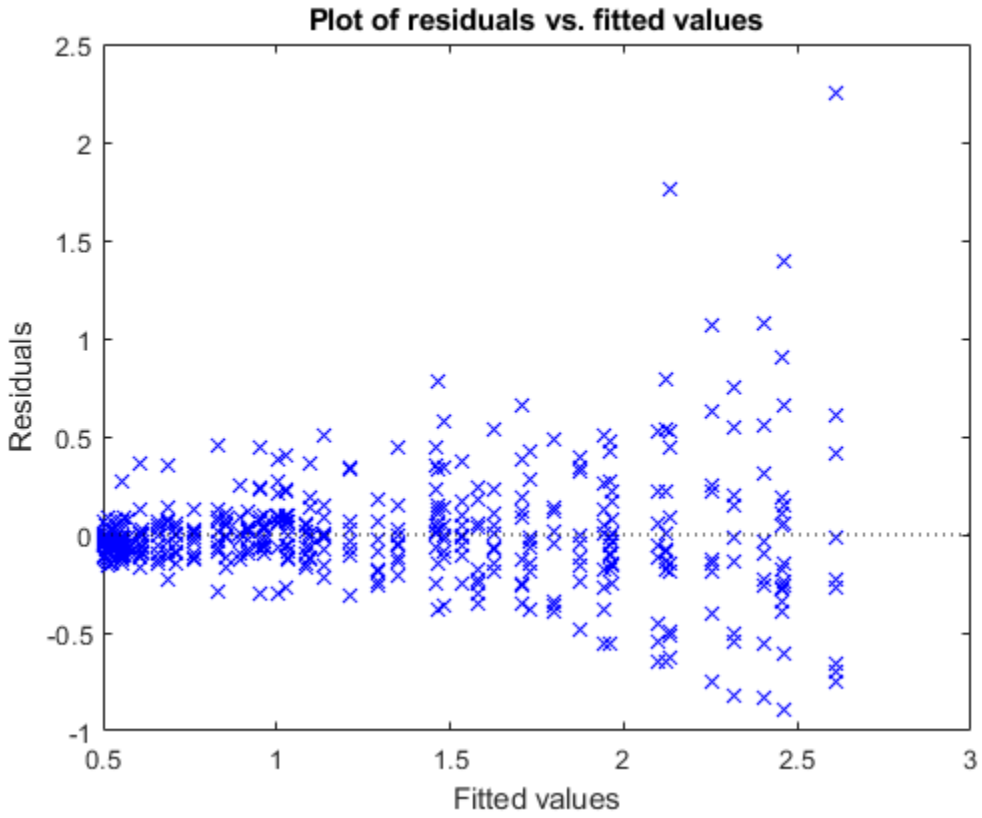
    Lower      Upper
    0.13227    0.22226

Group: Error
    Name              Estimate    Lower      Upper
    {'Res Std'}       0.30201     0.28217    0.32324
```

The small p-values of 0.0045885 and 3.0502e-76 indicate that both the intercept and nationwide estimate are significant. Also, the confidence limits for the standard deviation of the random-effects term, σ_b, do not include 0 (0.13227, 0.22226), which indicates that the random-effects term is significant.

Plot the raw residuals versus the fitted values.

```
figure();
plotResiduals(lme,'fitted')
```



The variance of residuals increases with increasing fitted response values, which is known as heteroscedasticity.

Find the two observations on the top right that appear like outliers.

```
find(residuals(lme) > 1.5)
```

```
ans =

    98
   107
```

Refit the model by removing these observations.

```
lme = fitlme(flu2,'FluRate ~ 1 + WtdILI + (1|Date)','Exclude',[98,107]);
```

Improve the model.

Determine if including an independent random term for the nationwide estimate grouped by `Date` improves the model.

```
altlme = fitlme(flu2,'FluRate ~ 1 + WtdILI + (1|Date) + (WtdILI-1|Date)',...
'Exclude',[98,107])
```

```
altlme =
```

```
Linear mixed-effects model fit by ML

Model information:
    Number of observations             466
    Fixed effects coefficients           2
    Random effects coefficients        104
    Covariance parameters                3

Formula:
    FluRate ~ 1 + WtdILI + (1 | Date) + (WtdILI | Date)

Model fit statistics:
    AIC       BIC       LogLikelihood    Deviance
    179.39    200.11    -84.694          169.39

Fixed effects coefficients (95% CIs):
    Name                   Estimate    SE          tStat     DF     pValue
    {'(Intercept)'}        0.17837     0.054585    3.2676    464     0.001165
    {'WtdILI'     }        0.70836     0.030594    23.153    464    2.123e-79

    Lower      Upper
     0.0711    0.28563
    0.64824    0.76849

Random effects covariance parameters (95% CIs):
Group: Date (52 Levels)
    Name1                  Name2                  Type           Estimate
    {'(Intercept)'}        {'(Intercept)'}        {'std'}        0.16631

    Lower      Upper
    0.12977    0.21313

Group: Date (52 Levels)
    Name1             Name2             Type           Estimate      Lower
    {'WtdILI'}        {'WtdILI'}        {'std'}        4.6939e-08    NaN

    Upper
    NaN

Group: Error
    Name               Estimate    Lower      Upper
    {'Res Std'}        0.26691     0.24934    0.28572
```

The estimated standard deviation of `WtdILI` term is nearly 0 and its confidence interval cannot be computed. This is an indication that the model is overparameterized and the `(WtdILI-1|Date)` term is not significant. You can formally test this using the `compare` method as follows: `compare(lme,altlme,'CheckNesting',true)`.

Add a random effects-term for intercept grouped by Region to the initial model `lme`.

```
lme2 = fitlme(flu2,'FluRate ~ 1 + WtdILI + (1|Date) + (1|Region)',...
'Exclude',[98,107]);
```

Compare the models `lme` and `lme2`.

```
compare(lme,lme2,'CheckNesting',true)
```

```
ans =

    THEORETICAL LIKELIHOOD RATIO TEST

    Model    DF    AIC       BIC       LogLik     LRStat    deltaDF    pValue
    lme      4     177.39    193.97    -84.694
    lme2     5     62.265    82.986    -26.133    117.12    1          0
```

The p-value of 0 indicates that `lme2` is a better fit than `lme`.

Now, check if adding a potentially correlated random-effects term for the intercept and national average improves the model `lme2`.

```
lme3 = fitlme(flu2,'FluRate ~ 1 + WtdILI + (1|Date) + (1 + WtdILI|Region)',...
'Exclude',[98,107])
```

```
lme3 =

    {'Res Std'}        0.20976     0.19568    0.22486
```

The estimate for the standard deviation of the random-effects term for intercept grouped by Region is 0.0077037, its confidence interval is very large and includes zero. This indicates that the random-effects for intercept grouped by Region is insignificant. The correlation between the random-effects for intercept and `WtdILI` is -0.059604. Its confidence interval is also very large and includes zero. This is an indication that the correlation is not significant.

Refit the model by eliminating the intercept from the `(1 + WtdILI | Region)` random-effects term.

```
lme3 = fitlme(flu2,'FluRate ~ 1 + WtdILI + (1|Date) + (WtdILI - 1|Region)',...
'Exclude',[98,107])

    {'Res Std'}        0.20979     0.19585    0.22473
```

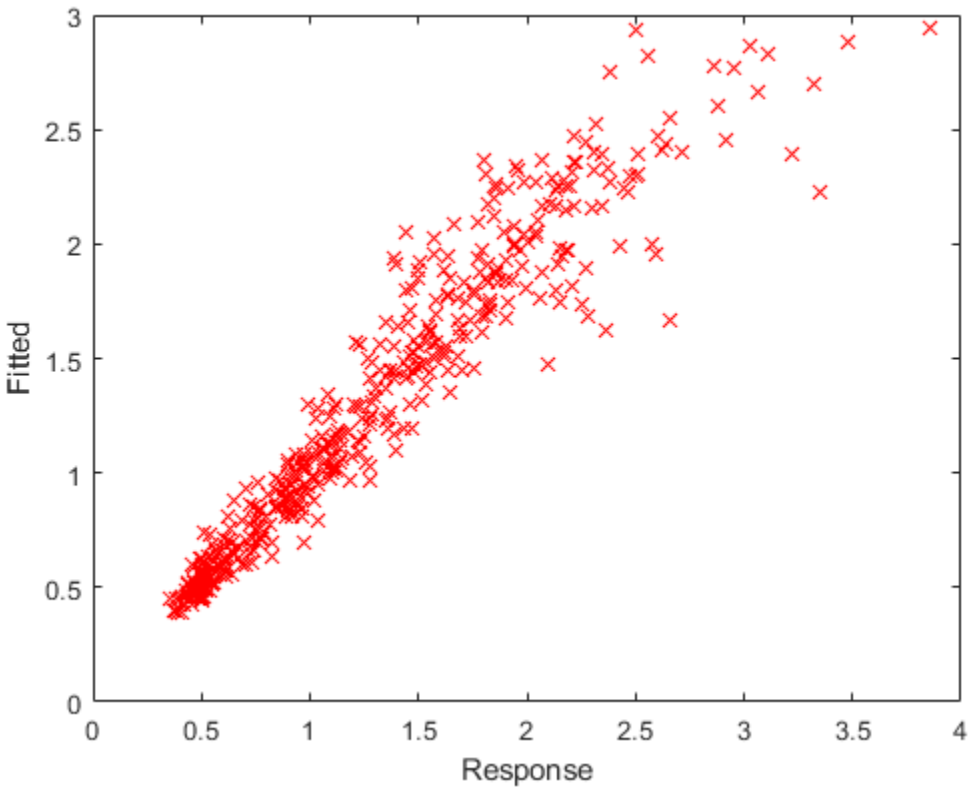
The p-value of 0.028463 indicates that the coefficient of the quadratic term `WtdILI^2` is significant.

Plot the fitted response versus the observed response and residuals.

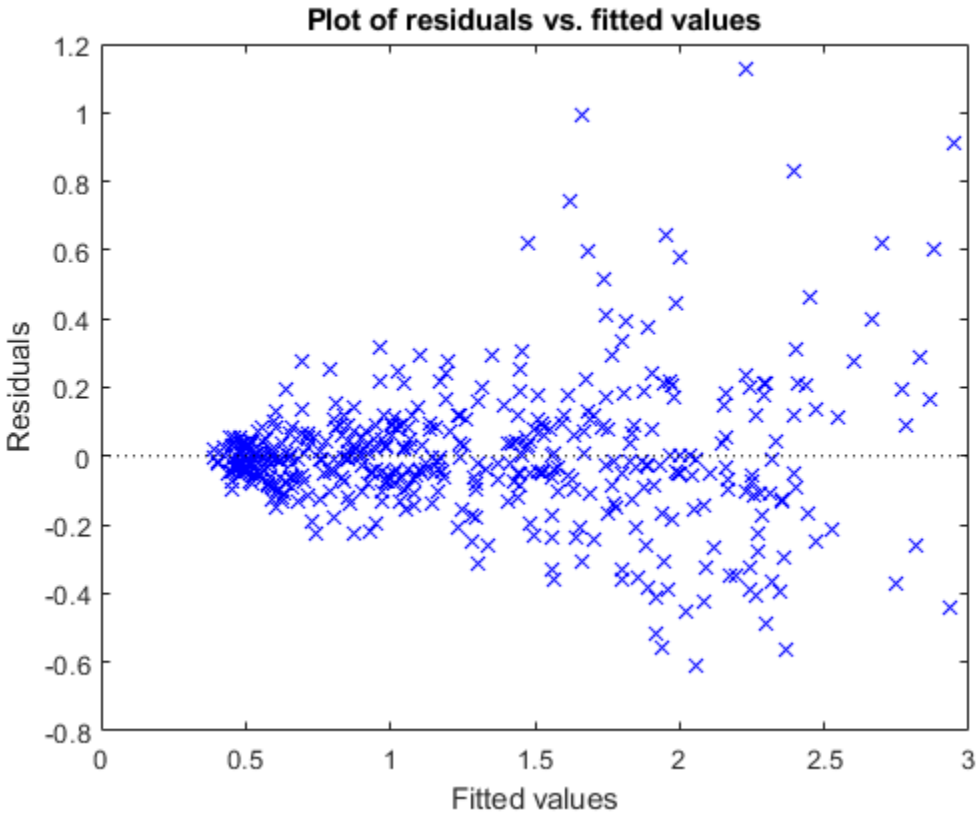
```
F = fitted(lme4);
R = response(lme4);
figure();
plot(R,F,'rx')
xlabel('Response')
ylabel('Fitted')
```



The fitted versus observed response values form almost 45-degree angle indicating a good fit.

Plot the residuals versus the fitted values.

```
figure();
plotResiduals(lme4,'fitted')
```



Although it has improved, you can still see some heteroscedasticity in the model. This might be due to another predictor that does not exist in the data set, hence not in the model.

Find the fitted flu rate value for region ENCentral, date 11/6/2005.

```
F(flu2.Region == 'ENCentral' & flu2.Date == '11/6/2005')
```

```
ans =

    1.4860
```

Randomly generate response values.

Randomly generate response values for a national estimate of 1.625, region MidAtl, and date 4/23/2006. First, define the new table. Because Date and Region are nominal in the original table, you must define them similarly in the new table.

```
tblnew.Date = nominal('4/23/2006');
tblnew.WtdILI = 1.625;
tblnew.Region = nominal('MidAtl');
tblnew = struct2table(tblnew);
```

Now, generate the response value.

```
random(lme4,tblnew)
```

```
ans =

    1.2679
```

Fit Mixed-Effects Spline Regression

This example shows how to fit a mixed-effects linear spline model.

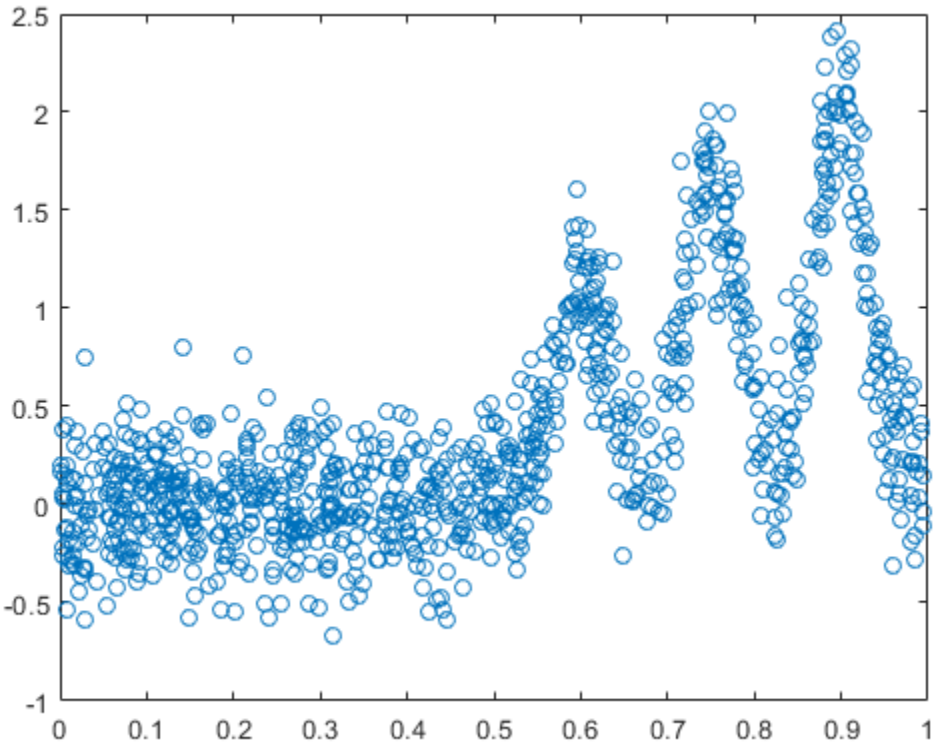
Load the sample data.

```
load('mespline.mat');
```

This is simulated data.

Plot y versus sorted x.

```
[x_sorted,I] = sort(x,'ascend');
plot(x_sorted,y(I),'o')
```



Fit the following mixed-effects linear spline regression model

$$y_i = \beta_1 + \beta_2 x_i + \sum_{j=1}^{K} b_j (x_i - k_j)_+ + \epsilon_i$$

where k_j is the j th knot, and K is the total number of knots. Assume that $b_j \sim N(0, \sigma_b^2)$ and $\epsilon \sim N(0, \sigma^2)$.

Define the knots.

```
k = linspace(0.05,0.95,100);
```

Define the design matrices.

```
X = [ones(1000,1),x];
Z = zeros(length(x),length(k));
for j = 1:length(k)
      Z(:,j) = max(X(:,2) - k(j),0);
end
```

Fit the model with an isotropic covariance structure for the random effects.

```
lme = fitlmematrix(X,y,Z,[],'CovariancePattern','Isotropic');
```

Fit a fixed-effects only model.

```
X = [X Z];
lme_fixed = fitlmematrix(X,y,[],[]);
```

Compare `lme_fixed` and `lme` via a simulated likelihood ratio test.

```
compare(lme,lme_fixed,'NSim',500,'CheckNesting',true)
```

```
ans =
    Simulated Likelihood Ratio Test: Nsim = 500, Alpha = 0.05

    Model        DF     AIC       BIC       LogLik     LRStat    pValue
    lme            4    170.62    190.25    -81.309
    lme_fixed    103    113.38    618.88     46.309    255.24    0.68064

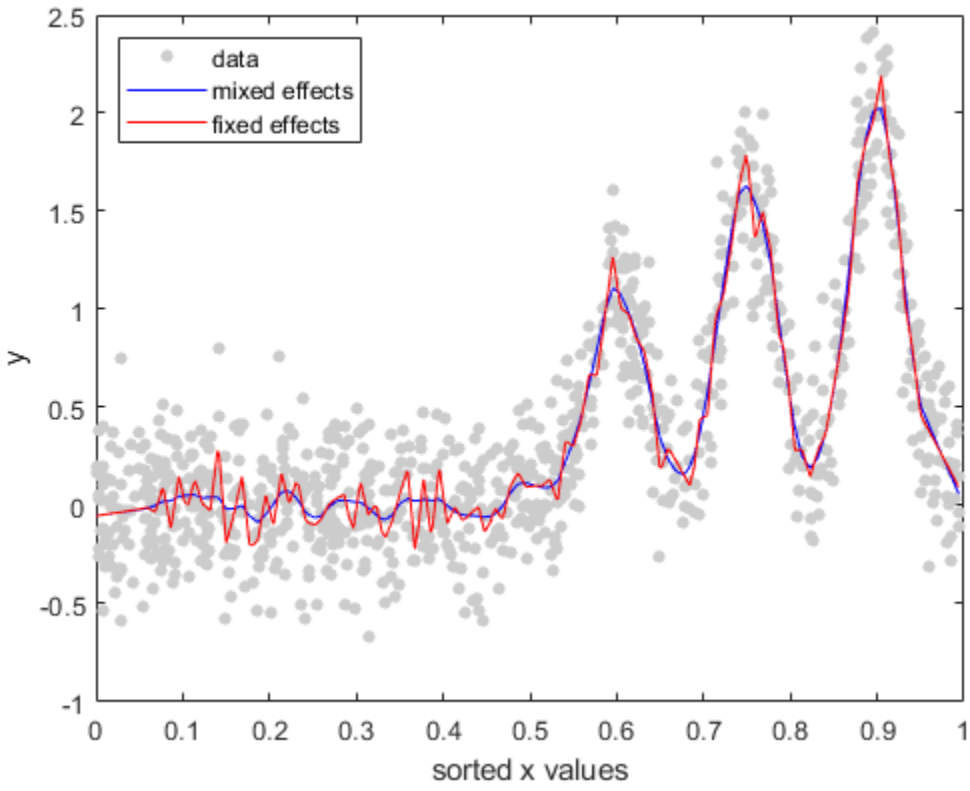
    Lower      Upper

    0.63784    0.72129
```

The *p*-value indicates that the fixed-effects only model is not a better fit than the mixed-effects spline regression model.

Plot the fitted values from both models on top of the original response data.

```
R = response(lme);
figure();
plot(x_sorted,R(I),'o', 'MarkerFaceColor',[0.8,0.8,0.8],...
    'MarkerEdgeColor',[0.8,0.8,0.8],'MarkerSize',4);
hold on
F = fitted(lme);
F_fixed = fitted(lme_fixed);
plot(x_sorted,F(I),'b');
plot(x_sorted,F_fixed(I),'r');
legend('data','mixed effects','fixed effects','Location','NorthWest')
xlabel('sorted x values');
ylabel('y');
hold off
```



You can also see from the figure that the mixed-effects model provides a better fit to data than the fixed-effects only model.

Train Linear Regression Model

Statistics and Machine Learning Toolbox™ provides several features for training a linear regression model.

- For greater accuracy on low-dimensional through medium-dimensional data sets, use `fitlm`. After fitting the model, you can use the object functions to improve, evaluate, and visualize the fitted model. To regularize a regression, use `lasso` or `ridge`.
- For reduced computation time on high-dimensional data sets, use `fitrlinear`. This function offers useful options for cross-validation, regularization, and hyperparameter optimization.

This example shows the typical workflow for linear regression analysis using `fitlm`. The workflow includes preparing a data set, fitting a linear regression model, evaluating and improving the fitted model, and predicting response values for new predictor data. The example also describes how to fit and evaluate a linear regression model for tall arrays.

Prepare Data

Load the sample data set `NYCHousing2015`.

```
load NYCHousing2015
```

The data set includes 10 variables with information on the sales of properties in New York City in 2015. This example uses some of these variables to analyze the sale prices.

Instead of loading the sample data set `NYCHousing2015`, you can download the data from the NYC Open Data website and import the data as follows.

```
folder = 'Annualized_Rolling_Sales_Update';
ds = spreadsheetDatastore(folder,"TextType","string","NumHeaderLines",4);
ds.Files = ds.Files(contains(ds.Files,"2015"));
ds.SelectedVariableNames = ["BOROUGH","NEIGHBORHOOD","BUILDINGCLASSCATEGORY","RESIDENTIALUNITS",
    "COMMERCIALUNITS","LANDSQUAREFEET","GROSSSQUAREFEET","YEARBUILT","SALEPRICE","SALEDATE"];
NYCHousing2015 = readall(ds);
```

Preprocess the data set to choose the predictor variables of interest. First, change the variable names to lowercase for readability.

```
NYCHousing2015.Properties.VariableNames = lower(NYCHousing2015.Properties.VariableNames);
```

Next, convert the `saledate` variable, specified as a `datetime` array, into two numeric columns `MM` (month) and `DD` (day), and remove the `saledate` variable. Ignore the year values because all samples are for the year 2015.

```
[~,NYCHousing2015.MM,NYCHousing2015.DD] = ymd(NYCHousing2015.saledate);
NYCHousing2015.saledate = [];
```

The numeric values in the `borough` variable indicate the names of the boroughs. Change the variable to a categorical variable using the names.

```
NYCHousing2015.borough = categorical(NYCHousing2015.borough,1:5, ...
    ["Manhattan","Bronx","Brooklyn","Queens","Staten Island"]);
```

The `neighborhood` variable has 254 categories. Remove this variable for simplicity.

```
NYCHousing2015.neighborhood = [];
```

Convert the `buildingclasscategory` variable to a categorical variable, and explore the variable by using the `wordcloud` function.

```
NYCHousing2015.buildingclasscategory = categorical(NYCHousing2015.buildingclasscategory);
wordcloud(NYCHousing2015.buildingclasscategory);
```

Assume that you are interested only in one-, two-, and three-family dwellings. Find the sample indices for these dwellings and delete the other samples. Then, change the data type of the `buildingclasscategory` variable to `double`.

```
idx = ismember(string(NYCHousing2015.buildingclasscategory), ...
    ["01  ONE FAMILY DWELLINGS","02  TWO FAMILY DWELLINGS","03  THREE FAMILY DWELLINGS"]);
NYCHousing2015 = NYCHousing2015(idx,:);
NYCHousing2015.buildingclasscategory = renamecats(NYCHousing2015.buildingclasscategory, ...
    ["01  ONE FAMILY DWELLINGS","02  TWO FAMILY DWELLINGS","03  THREE FAMILY DWELLINGS"], ...
    ["1","2","3"]);
NYCHousing2015.buildingclasscategory = double(NYCHousing2015.buildingclasscategory);
```

The `buildingclasscategory` variable now indicates the number of families in one dwelling.

Explore the response variable `saleprice` using the `summary` function.

```
s = summary(NYCHousing2015);
s.saleprice
```

```
ans = struct with fields:
           Size: [37881 1]
           Type: 'double'
```

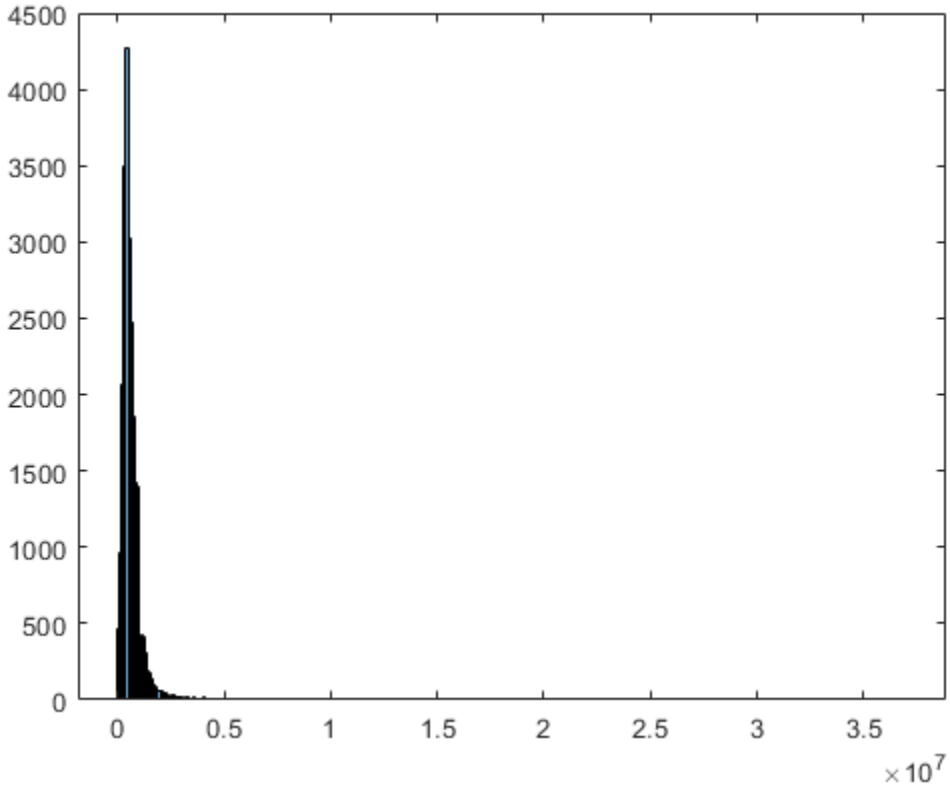
```
    Description: ''
          Units: ''
     Continuity: []
            Min: 0
         Median: 352000
            Max: 37000000
     NumMissing: 0
```

Assume that a `saleprice` less than or equal to $1000 indicates ownership transfer without a cash consideration. Remove the samples that have this `saleprice`.

```
idx0 = NYCHousing2015.saleprice <= 1000;
NYCHousing2015(idx0,:) = [];
```

Create a histogram of the `saleprice` variable.

```
histogram(NYCHousing2015.saleprice)
```

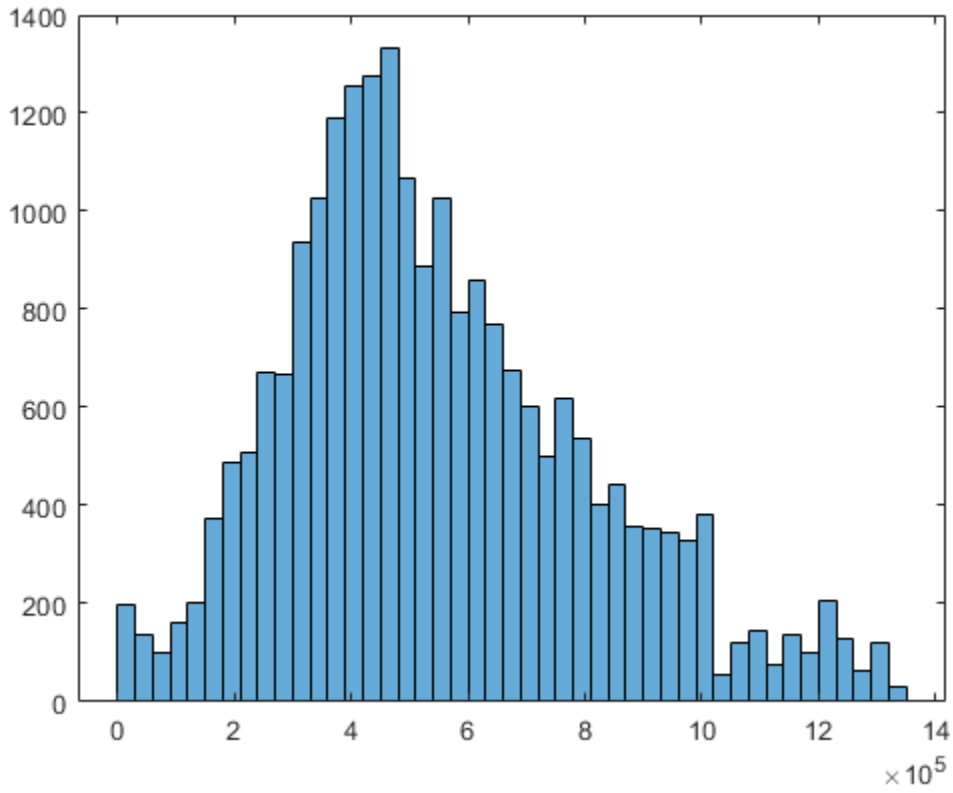


The maximum value of `saleprice` is 3.7×10^7, but most values are smaller than 0.5×10^7. You can identify the outliers of `saleprice` by using the `isoutlier` function.

```
idx = isoutlier(NYCHousing2015.saleprice);
```

Remove the identified outliers and create the histogram again.

```
NYCHousing2015(idx,:) = [];
histogram(NYCHousing2015.saleprice)
```



Partition the data set into a training set and test set by using `cvpartition`.

```
rng('default') % For reproducibility
c = cvpartition(height(NYCHousing2015),"holdout",0.3);
trainData = NYCHousing2015(training(c),:);
testData = NYCHousing2015(test(c),:);
```

Train Model

Fit a linear regression model by using the `fitlm` function.

```
mdl = fitlm(trainData,"PredictorVars",["borough","grosssquarefeet", ...
    "landsquarefeet","buildingclasscategory","yearbuilt","MM","DD"], ...
    "ResponseVar","saleprice")
```

```
mdl =
Linear regression model:
    saleprice ~ 1 + borough + buildingclasscategory + landsquarefeet + grosssquarefeet + yearbui

Estimated Coefficients:
                            Estimate          SE         tStat        pValue

```

`mdl` is a `LinearModel` object. The model display includes the model formula, estimated coefficients, and summary statistics.

`borough` is a categorical variable that has five categories: `Manhattan`, `Bronx`, `Brooklyn`, `Queens`, and `Staten Island`. The fitted model `mdl` has four indicator variables. The `fitlm` function uses the first category `Manhattan` as a reference level, so the model does not include the indicator variable for the reference level. `fitlm` fixes the coefficient of the indicator variable for the reference level as zero. The coefficient values of the four indicator variables are relative to `Manhattan`. For more details on how the function treats a categorical predictor, see “Algorithms” on page 33-1997 of `fitlm`.

To learn how to interpret the values in the model display, see “Interpret Linear Regression Results” on page 11-50.

You can use the properties of a `LinearModel` object to investigate a fitted linear regression model. The object properties include information about coefficient estimates, summary statistics, fitting method, and input data. For example, you can find the R-squared and adjusted R-squared values in the `Rsquared` property. You can access the property values through the Workspace browser or using dot notation.

```
mdl.Rsquared
```

```
ans = struct with fields:
    Ordinary: 0.2352
    Adjusted: 0.2348
```

The model display also shows these values. The R-squared value indicates that the model explains approximately 24% of the variability in the response variable. See “Properties” on page 33-3508 of a `LinearModel` object for details about other properties.

Evaluate Model

The model display shows the *p*-value of each coefficient. The *p*-values indicate which variables are significant to the model. For the categorical predictor `borough`, the model uses four indicator variables and displays four *p*-values. To examine the categorical variable as a group of indicator variables, use the object function `anova`. This function returns analysis of variance (ANOVA) statistics of the model.

```
anova(mdl)
```

```
ans=8×5 table
                              SumSq        DF        MeanSq         F         pValue
```

```

The *p*-values for the indicator variables `borough_Brooklyn` and `borough_Queens` are large, but the *p*-value of the `borough` variable as a group of four indicator variables is almost zero, which indicates that the `borough` variable is statistically significant.

The *p*-values of `buildingclasscategory` and `DD` are larger than 0.05, which indicates that these variables are not significant at the 5% significance level. Therefore, you can consider removing these variables.

You can also use `coeffCI`, `coeefTest`, and `dwTest` to further evaluate the fitted model.

- `coefCI` returns confidence intervals of the coefficient estimates.
- `coefTest` performs a linear hypothesis test on the model coefficients.
- `dwtest` performs the Durbin-Watson test. (This test is used for time series data, so `dwtest` is not appropriate for the housing data in this example.)

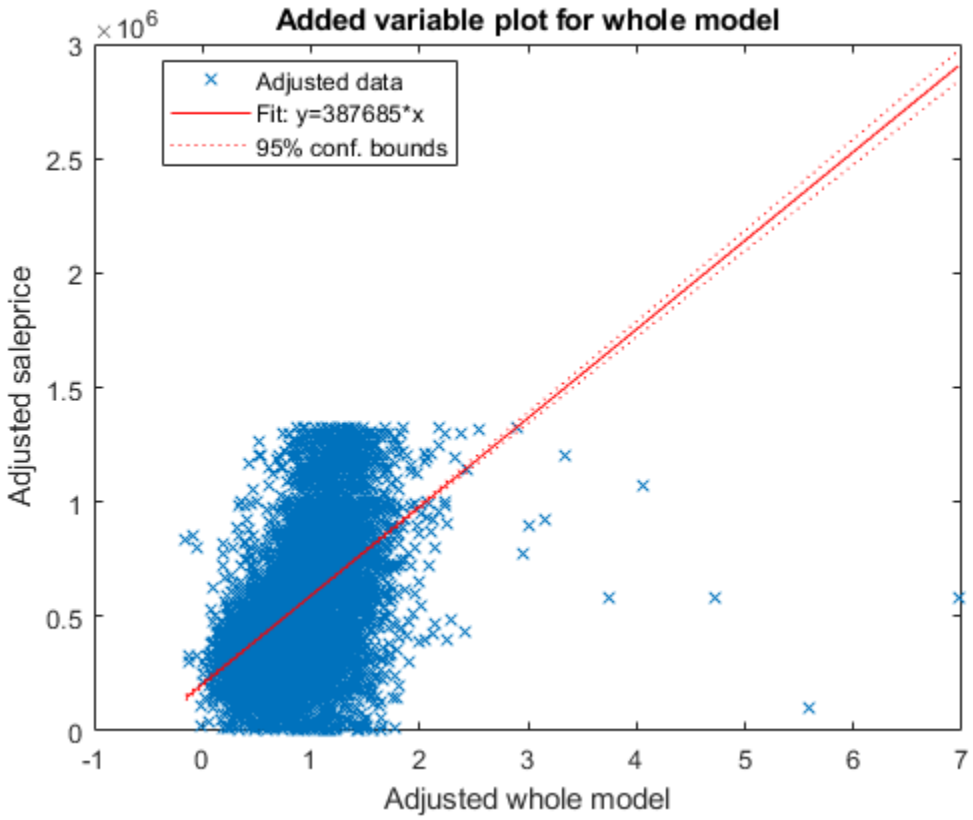
Visualize Model and Summary Statistics

A `LinearModel` object provides multiple plotting functions.

- When creating a model, use `plotAdded` to understand the effect of adding or removing a predictor variable.
- When verifying a model, use `plotDiagnostics` to find questionable data and to understand the effect of each observation. Also, use `plotResiduals` to analyze the residuals of the model.
- After fitting a model, use `plotAdjustedResponse`, `plotPartialDependence`, and `plotEffects` to understand the effect of a particular predictor. Use `plotInteraction` to examine the interaction effect between two predictors. Also, use `plotSlice` to plot slices through the prediction surface.

In addition, `plot` creates an added variable plot for the whole model, except the intercept term, if `mdl` includes multiple predictor variables.

```
plot(mdl)
```



This plot is equivalent to `plotAdded(mdl)`. The fitted line represents how the model, as a group of variables, can explain the response variable. The slope of the fitted line is not close to zero, and the confidence bound does not include a horizontal line, indicating that the model fits better than a degenerate model consisting of only a constant term. The test statistic value shown in the model display (`F-statistic vs. constant model`) also indicates that the model fits better than the degenerate model.

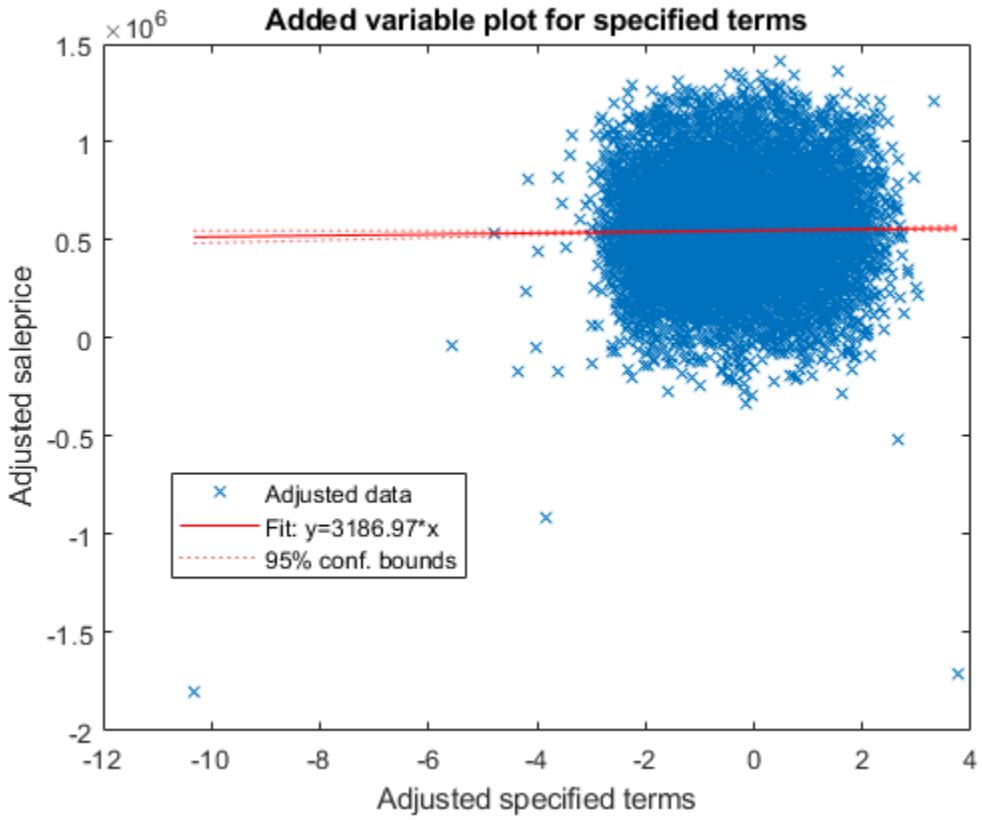
Create an added variable plot for the insignificant variables `buildingclasscategory` and `DD`. The *p*-values of these variables are larger than 0.05. First, find the indices of these coefficients in `mdl.CoefficientNames`.

```
mdl.CoefficientNames
```

```
ans = 1×11 cell
    {'(Intercept)'}    {'borough_Bronx'}    {'borough_Brooklyn'}    {'borough_Queens'}    {'borou
```

`buildingclasscategory` and `DD` are the 6th and 11th coefficients, respectively. Create an added plot for these two variables.

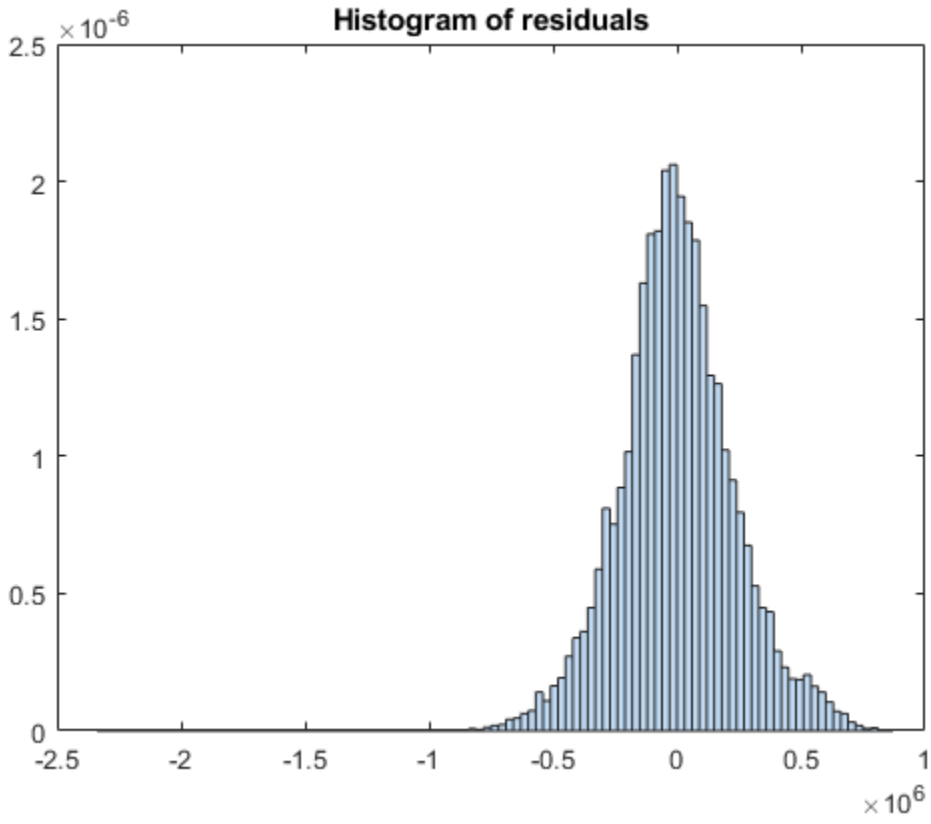
```
plotAdded(mdl,[6,11])
```



The slope of the fitted line is close to zero, indicating that the information from the two variables does not explain the part of the response values not explained by the other predictors. For more details about an added variable plot, see “Added Variable Plot” on page 33-4579.

Create a histogram of the model residuals. `plotResiduals` plots a histogram of the raw residuals using probability density function scaling.

```
plotResiduals(mdl)
```



The histogram shows that a few residuals are smaller than -1×10^6. Identify these outliers.

```
find(mdl.Residuals.Raw < -1*10^6)
```

```
ans = 4×1

        1327
        4136
        4997
       13894
```

Alternatively, you can find the outliers by using `isoutlier`. Specify the `'grubbs'` option to apply Grubb's test. This option is suitable for a normally distributed data set.

```
find(isoutlier(mdl.Residuals.Raw,'grubbs'))
```

```
ans = 3×1

        1327
        4136
        4997
```

The `isoutlier` function does not identify residual `13894` as an outlier. This residual is close to -1×10^6. Display the residual value.

```
mdl.Residuals.Raw(13894)
```

```
ans = -1.0720e+06
```

You can exclude outliers when fitting a linear regression model by using the "'Exclude'" on page 33-0 name-value pair argument. In this case, the example adjusts the fitted model and checks whether the improved model can also explain the outliers.

Adjust Model

Remove the `DD` and `buildingclasscategory` variables using `removeTerms`.

```
newMdl1 = removeTerms(mdl,"DD + buildingclasscategory")
```

```
newMdl1 =
Linear regression model:
    saleprice ~ 1 + borough + landsquarefeet + grosssquarefeet + yearbuilt + MM

Estimated Coefficients:
                            Estimate          SE         tStat        pValue
                          ____________    ____________    ________    __________

    (Intercept)              2.0529e+05    1.0274e+05      1.9981      0.045726
    borough_Bronx           -3.0038e+05         56675        -5.3    1.1739e-07
    borough_Brooklyn             -39704         56488    -0.70286       0.48215
    borough_Queens               -90231         56537      -1.596       0.11052
    borough_Staten Island   -2.2149e+05         56720     -3.9049    9.4652e-05
    landsquarefeet                13.04       0.83912       15.54    4.6278e-54
    grosssquarefeet              113.85        2.5078      45.396             0
    yearbuilt                    96.649        45.395      2.1291      0.033265
    MM                           3875.6        543.49       7.131    1.0396e-12

Number of observations: 15848, Error degrees of freedom: 15839
Root Mean Squared Error: 2.32e+05
R-squared: 0.235,  Adjusted R-Squared: 0.235
F-statistic vs. constant model: 608, p-value = 0
```

Because the two variables are not significant in explaining the response variable, the R-squared and adjusted R-squared values of `newMdl1` are close to the values of `mdl`.

Improve the model by adding or removing variables using `step`. The default upper bound of the model is a model containing an intercept term, the linear term for each predictor, and all products of pairs of distinct predictors (no squared terms), and the default lower bound is a model containing an intercept term. Specify the maximum number of steps to take as 30. The function stops when no single step improves the model.

```
newMdl2 = step(newMdl1,'NSteps',30)
```

```

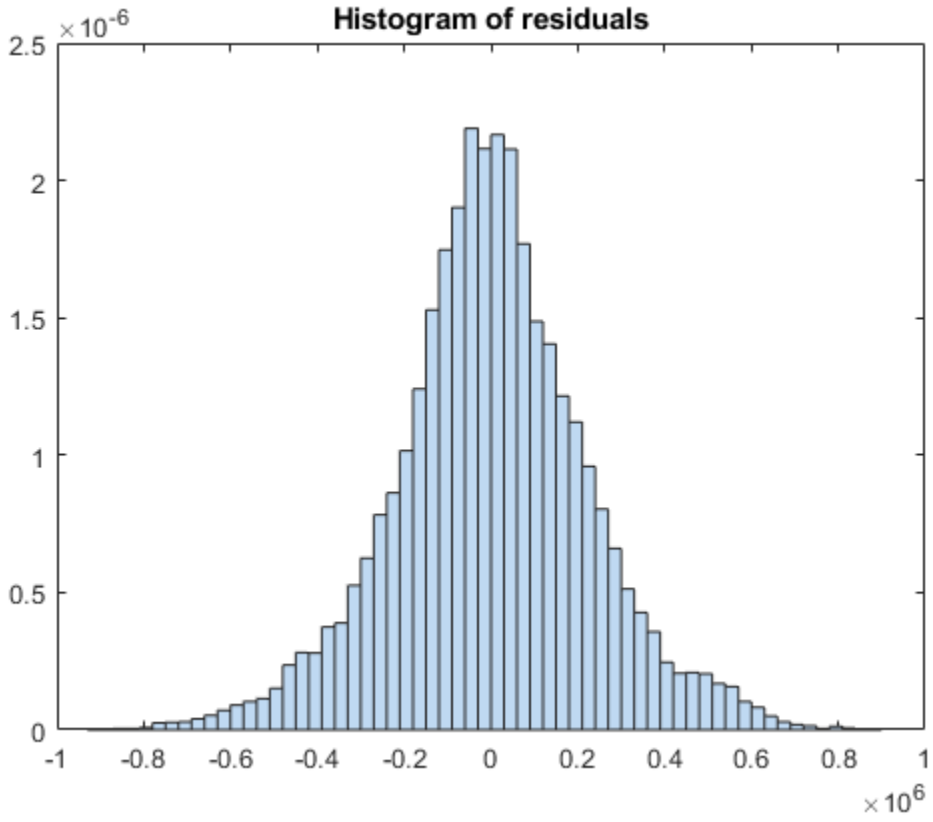
Number of observations: 15848, Error degrees of freedom: 15804
Root Mean Squared Error: 2.25e+05
R-squared: 0.285,  Adjusted R-Squared: 0.283
F-statistic vs. constant model: 146, p-value = 0
```

The R-squared and adjusted R-squared values of `newMdl2` are larger than the values of `newMdl1`.

Create a histogram of the model residuals by using `plotResiduals`.

```
plotResiduals(newMdl2)
```



The residual histogram of `newMdl2` is symmetric, without outliers.

You can also use `addTerms` to add specific terms. Alternatively, you can use `stepwiselm` to specify terms in a starting model and continue improving the model by using stepwise regression.

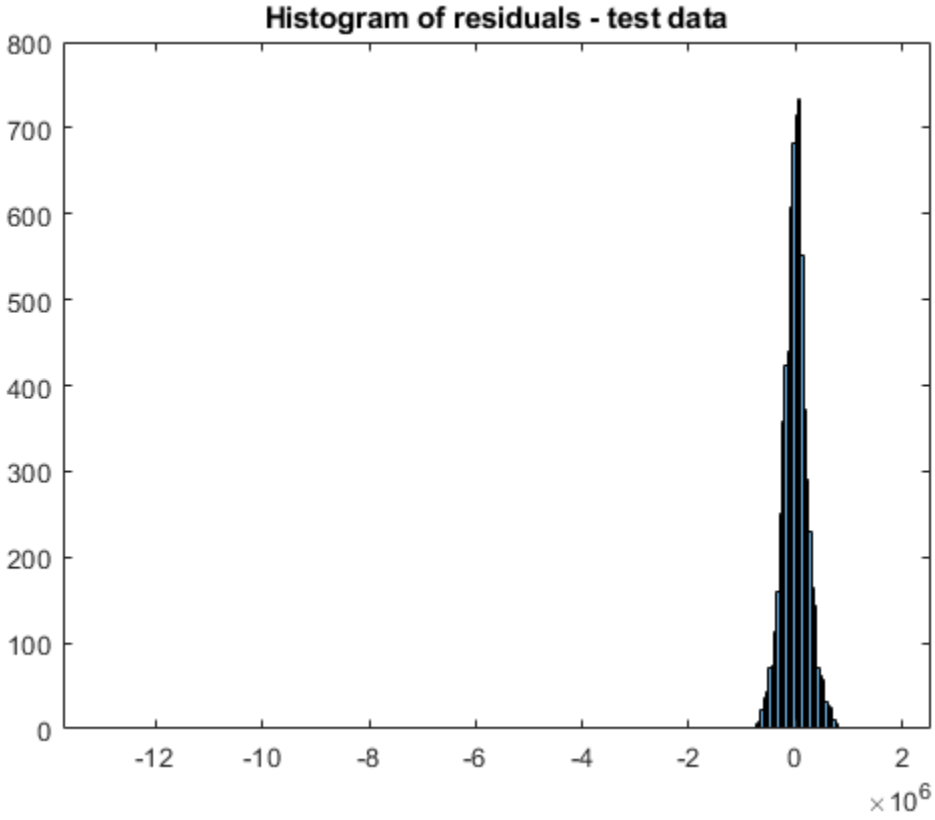
Predict Responses to New Data

Predict responses to the test data set `testData` by using the fitted model `newMdl2` and the object function `predict` to

```
ypred = predict(newMdl2,testData);
```

Plot the residual histogram of the test data set.

```
errs = ypred - testData.saleprice;
histogram(errs)
title("Histogram of residuals - test data")
```



The residual values have a few outliers.

```
errs(isoutlier(errs,'grubbs'))
```

```
ans = 6×1
10^7 ×

   -1.2981
    0.1019
    0.1122
    0.1331
```

Analyze Using Tall Arrays

The `fitlm` function supports tall arrays for out-of-memory data, with some limitations. For tall data, `fitlm` returns a `CompactLinearModel` object that contains most of the same properties as a `LinearModel` object. The main difference is that the compact object is sensitive to memory

requirements. The compact object does not have properties that include the data, or that include an array of the same size as the data. Therefore, some `LinearModel` object functions that require data do not work with a compact model. See “Object Functions” on page 33-823 for the list of supported object functions. Also, see “Tall Arrays” on page 33-1998 for the usage notes and limitations of `fitlm` for tall arrays.

When you perform calculations on tall arrays, MATLAB® uses either a parallel pool (default if you have Parallel Computing Toolbox™) or the local MATLAB session. If you want to run the example using the local MATLAB session when you have Parallel Computing Toolbox, you can change the global execution environment by using the `mapreducer` function.

Assume that all the data in the datastore `ds` does not fit in memory. You can use `tall` instead of `readall` to read `ds`.

```
NYCHousing2015 = tall(ds);
```

For this example, convert the in-memory table `NYCHousing2015` to a tall table by using the `tall` function.

```
NYCHousing2015_t = tall(NYCHousing2015);
```

```
Starting parallel pool (parpool) using the 'local' profile ...
Connected to the parallel pool (number of workers: 6).
```

Partition the data set into a training set and test set. When you use `cvpartition` with tall arrays, the function partitions the data set based on the variable supplied as the first input argument. For classification problems, you typically use the response variable (a grouping variable) and create a random stratified partition to get even distribution between training and test sets for all groups. For regression problems, this stratification is not adequate, and you can use the `'Stratify'` name-value pair argument to turn off the option.

In this example, specify the predictor variable `NYCHousing2015_t.borough` as the first input argument to make the distribution of boroughs roughly the same across the training and tests sets. For reproducibility, set the seed of the random number generator using `tallrng`. The results can vary depending on the number of workers and the execution environment for the tall arrays. For details, see “Control Where Your Code Runs”.

```
tallrng('default') % For reproducibility
c = cvpartition(NYCHousing2015_t.borough,"holdout",0.3);
trainData_t = NYCHousing2015_t(training(c),:);
testData_t = NYCHousing2015_t(test(c),:);
```

Because `fitlm` returns a compact model object for tall arrays, you cannot improve the model using the `step` function. Instead, you can explore the model parameters by using the object functions and then adjust the model as needed. You can also gather a subset of the data into the workspace, use `stepwiselm` to iteratively develop the model in memory, and then scale up to use tall arrays. For details, see Model Development of “Statistics and Machine Learning with Big Data Using Tall Arrays” on page 30-24.

In this example, fit a linear regression model using the model formula of `newMdl2`.

```
mdl_t = fitlm(trainData_t,newMdl2.Formula)
```

```
Evaluating tall expression using the Parallel Pool 'local':
- Pass 1 of 1: Completed in 7.4 sec
Evaluation completed in 9.2 sec
```

```
mdl_t =

```

`mdl_t` is a `CompactLinearModel` object. `mdl_t` is not exactly the same as `newMdl2` because the partitioned training data set obtained from the tall table is not the same as the one from the in-memory data set.

You cannot use the `plotResiduals` function to create a histogram of the model residuals because `mdl_t` is a compact object. Instead, compute the residuals directly from the compact object and create the histogram using `histogram`.

```
mdl_t_Residual = trainData_t.saleprice - predict(mdl_t,trainData_t);
histogram(mdl_t_Residual)
```

```
Evaluating tall expression using the Parallel Pool 'local':
- Pass 1 of 2: Completed in 2.5 sec
- Pass 2 of 2: Completed in 0.63 sec
Evaluation completed in 3.8 sec
```

```
title("Histogram of residuals - train data")
```

Predict responses to the test data set `testData_t` by using `predict`.

```
ypred_t = predict(mdl_t,testData_t);
```

Plot the residual histogram of the test data set.

```
errs_t = ypred_t - testData_t.saleprice;
histogram(errs_t)
```

```
Evaluating tall expression using the Parallel Pool 'local':
- Pass 1 of 2: 0% complete
Evaluation 0% complete

- Pass 1 of 2: 6% complete

Analyze Time Series Data

This example shows how to visualize and analyze time series data using a `timeseries` object and the `regress` function.

Air Passenger Data

First we create an array of monthly counts of airline passengers, measured in thousands, for the period January 1949 through December 1960.

```
%   1949 1950 1951 1952 1953 1954 1955 1956 1957 1958 1959 1960
y = [112  115  145  171  196  204  242  284  315  340  360  417    % Jan
     118  126  150  180  196  188  233  277  301  318  342  391    % Feb
     132  141  178  193  236  235  267  317  356  362  406  419    % Mar
     129  135  163  181  235  227  269  313  348  348  396  461    % Apr
     121  125  172  183  229  234  270  318  355  363  420  472    % May
     135  149  178  218  243  264  315  374  422  435  472  535    % Jun
     148  170  199  230  264  302  364  413  465  491  548  622    % Jul
     148  170  199  242  272  293  347  405  467  505  559  606    % Aug
     136  158  184  209  237  259  312  355  404  404  463  508    % Sep
     119  133  162  191  211  229  274  306  347  359  407  461    % Oct
     104  114  146  172  180  203  237  271  305  310  362  390    % Nov
     118  140  166  194  201  229  278  306  336  337  405  432 ]; % Dec

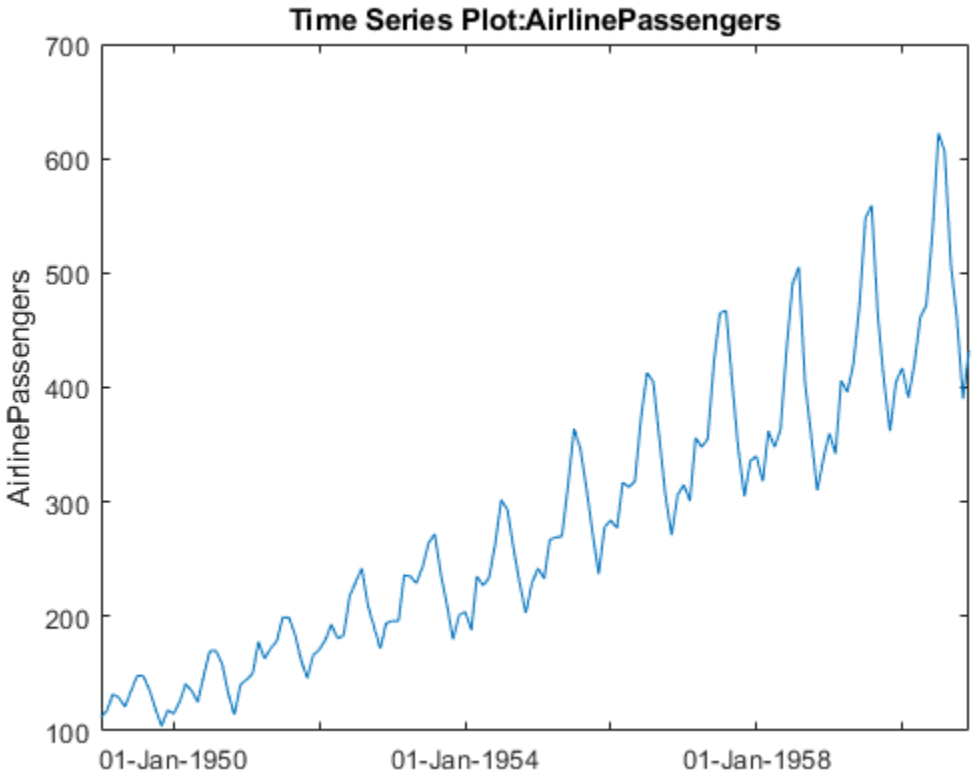
```

Create Time Series Object

When we create a time series object, we can keep the time information along with the data values. We have monthly data, so we create an array of dates and use it along with the Y data to create the time series object.

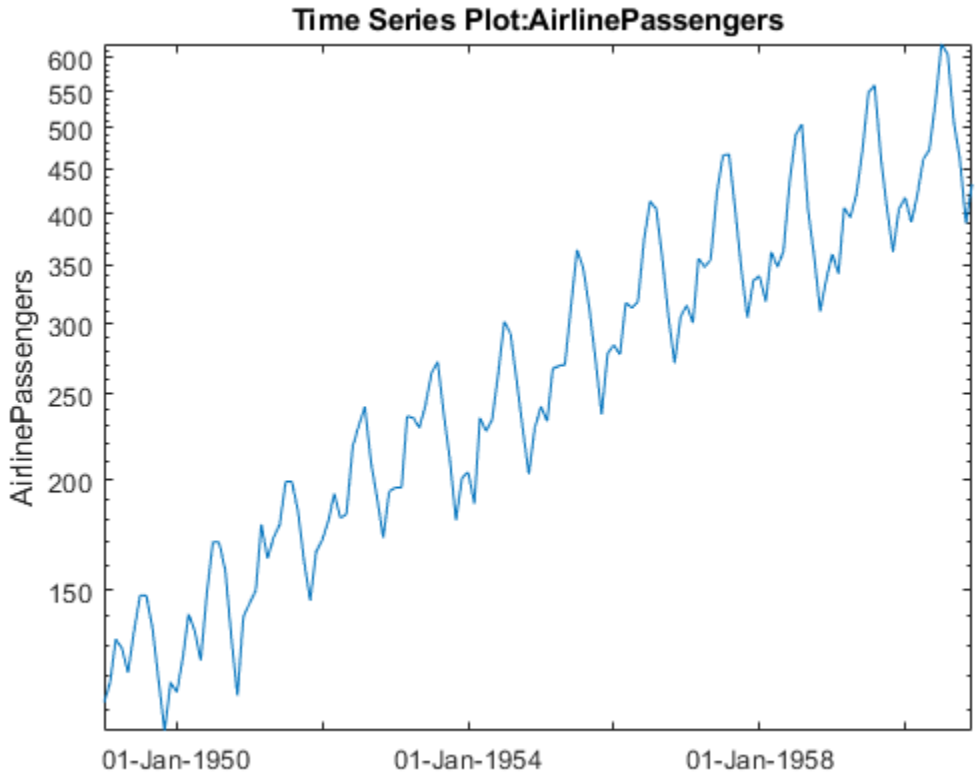
```
yr = repmat((1949:1960),12,1);
mo = repmat((1:12)',1,12);
time = datestr(datenum(yr(:),mo(:),1));
ts = timeseries(y(:),time,'name','AirlinePassengers');
ts.TimeInfo.Format = 'dd-mmm-yyyy';
tscol = tscollection(ts);
plot(ts)
```



Examine Trend and Seasonality

This series seems to have a strong seasonal component, with a trend that may be linear or quadratic. Furthermore, the magnitude of the seasonal variation increases as the general level increases. Perhaps a log transformation would make the seasonal variation be more constant. First we'll change the axis scale.

```
h_gca = gca;
h_gca.YScale = 'log';
```

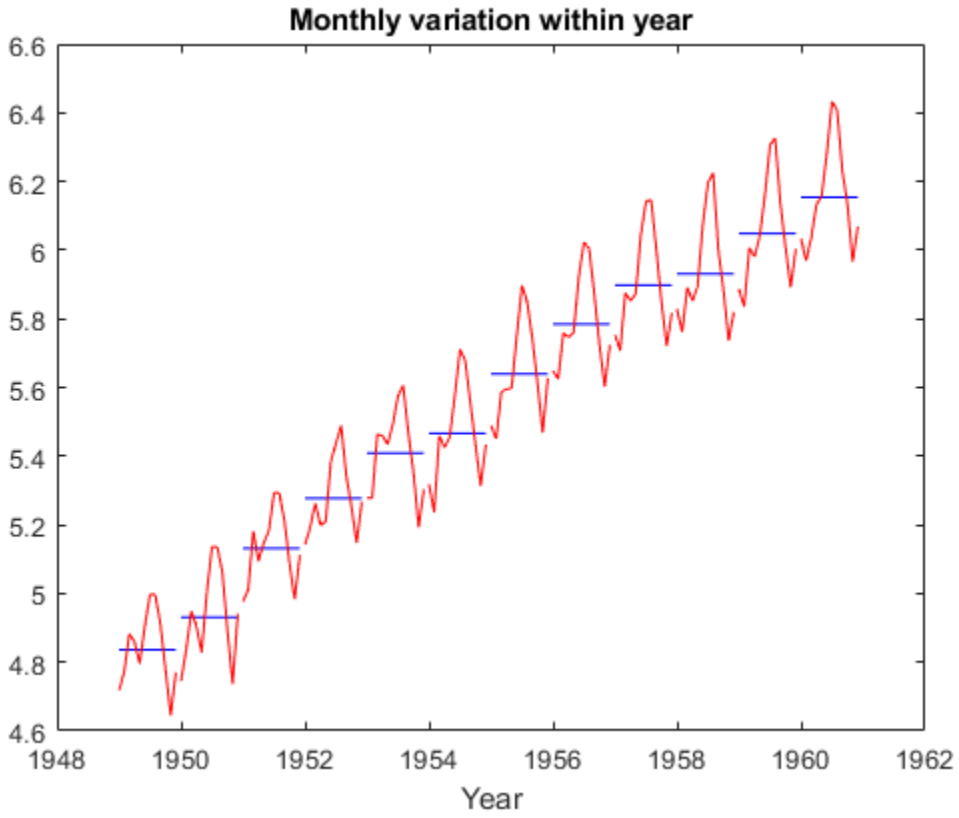


It appears that it would be easier to model the seasonal component on the log scale. We'll create a new time series with a log transformation.

```
tscol = addts(tscol,log(ts.data),'logAirlinePassengers');
logts = tscol.logAirlinePassengers;
```

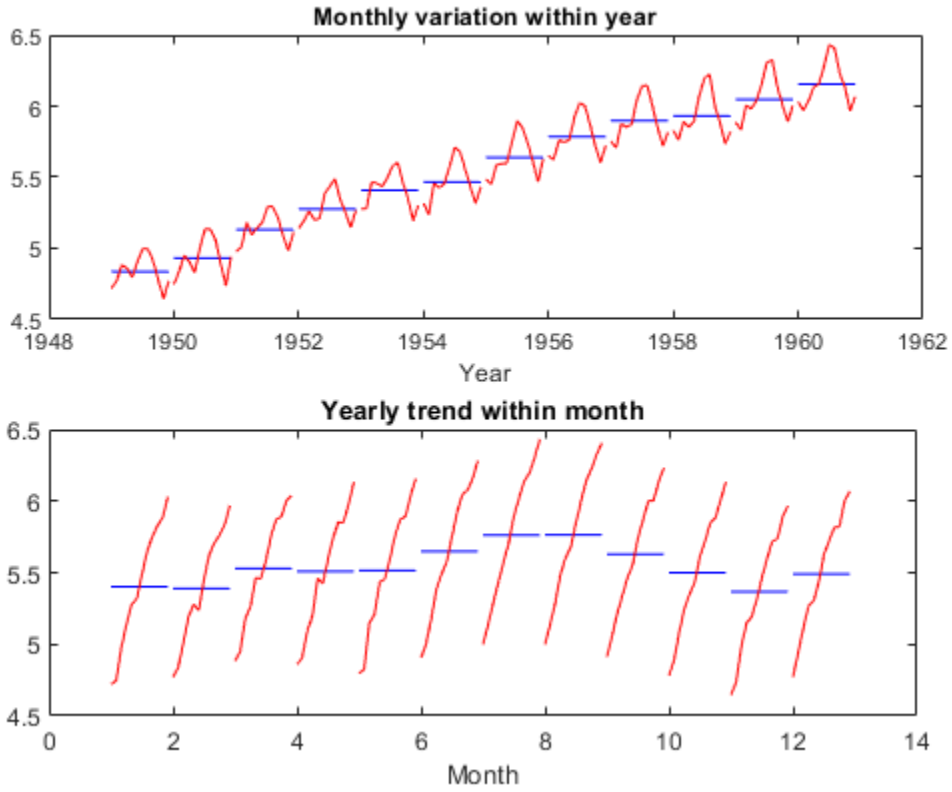
Now let's plot the yearly averages, with monthly deviations superimposed. We want to see if the month-to-month variation within years appears constant. For these manipulations treating the data as a matrix in a month-by-year format, it's more convenient to operate on the original data matrix.

```
t = reshape(datenum(time),12,12);
logy = log(y);
ymean = repmat(mean(logy),12,1);
ydiff = logy - ymean;
x = yr + (mo-1)/12;
plot(x,ymean,'b-',x,ymean+ydiff,'r-')
title('Monthly variation within year')
xlabel('Year')
```



Now let's reverse the years and months, and try to see if the year-to-year trend is constant for each month.

```
h_gca = gca;
h_gca.Position = [0.13 0.58 0.78 0.34];
subplot(2,1,2);
t = reshape(datenum(time),12,12);
mmean = repmat(mean(logy,2),1,12);
mdiff = logy - mmean;
x = mo + (yr-min(yr(:)))/12;
plot(x',mmean','b-',x',(mmean+mdiff)','r-')
title('Yearly trend within month')
xlabel('Month')
```



Model Trend and Seasonality

Let's attempt to model this series as a linear trend plus a seasonal component.

```
subplot(1,1,1);
X = [dummyvar(mo(:)) logts.time];
[b,bint,resid] = regress(logts.data,X);
tscol = addts(tscol,X*b,'Fit1')

Time Series Collection Object: unnamed

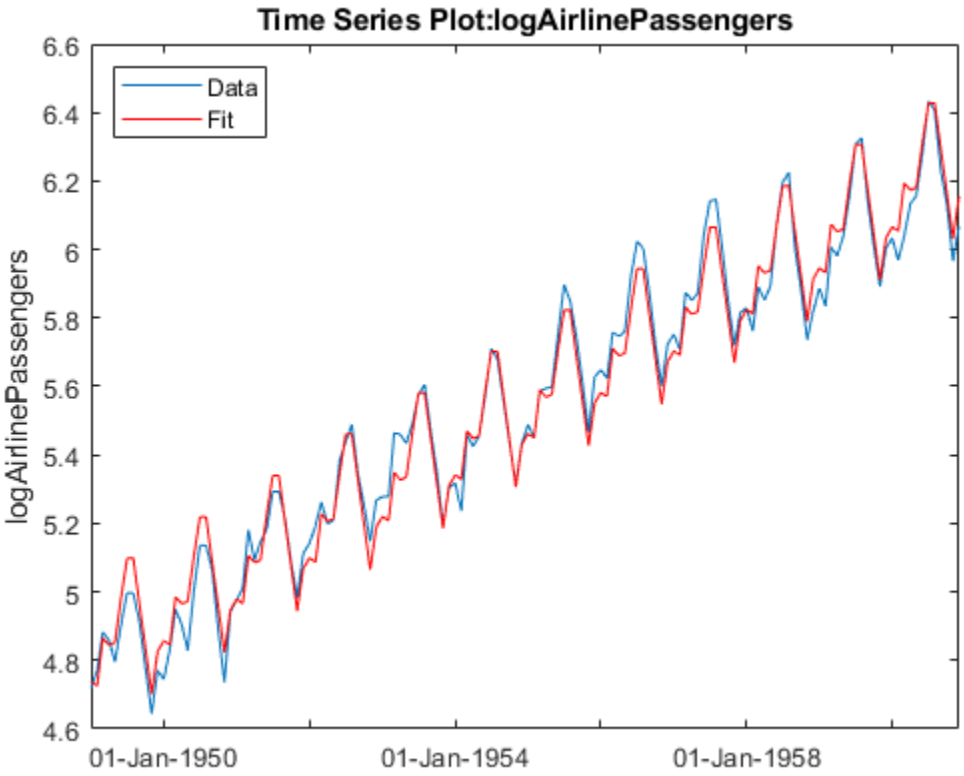
Time vector characteristics

      Start date            01-Jan-1949
      End date              01-Dec-1960

Member Time Series Objects:

      AirlinePassengers
      logAirlinePassengers
      Fit1

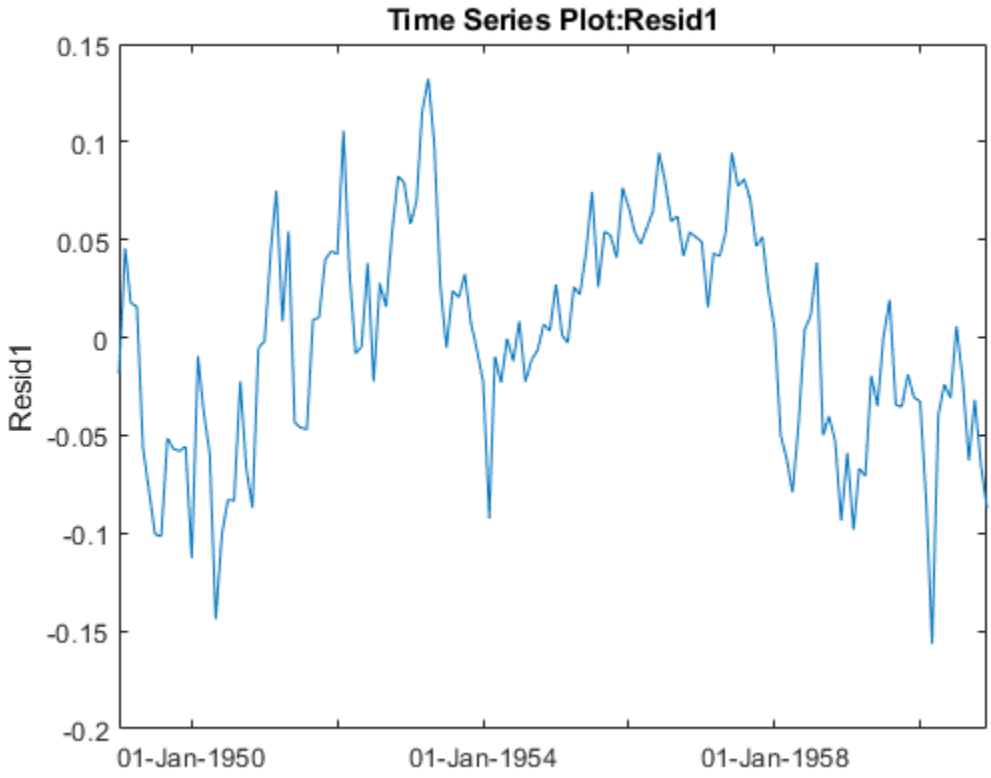
plot(logts)
hold on
plot(tscol.Fit1,'Color','r')
hold off
legend('Data','Fit','location','NW')
```



Based on this graph, the fit appears to be good. The differences between the actual data and the fitted values may well be small enough for our purposes.

But let's try to investigate this some more. We would like the residuals to look independent. If there is autocorrelation (correlation between adjacent residuals), then there may be an opportunity to model that and make our fit better. Let's create a time series from the residuals and plot it.

```
tscol = addts(tscol,resid,'Resid1');
plot(tscol.Resid1)
```



The residuals do not look independent. In fact, the correlation between adjacent residuals looks quite strong. We can test this formally using a Durbin-Watson test.

```
[p,dw] = dwtest(tscol.Resid1.data,X)
```

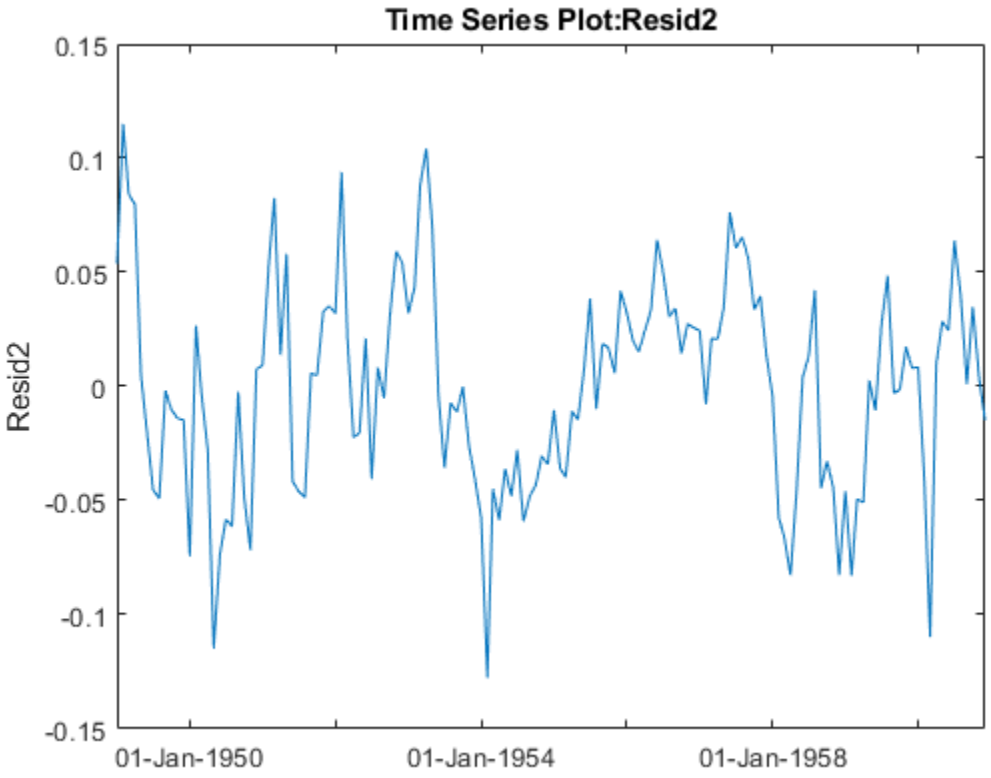
```
p = 7.7787e-30
```

```
dw = 0.4256
```

A low p-value for the Durbin-Watson statistic is an indication that the residuals are correlated across time. A typical cutoff for hypothesis tests is to decide that $p<0.05$ is significant. Here the very small p-value gives strong evidence that the residuals are correlated.

We can attempt to change the model to remove the autocorrelation. The general shape of the curve is high in the middle and low at the ends. This suggests that we should allow for a quadratic trend term. However, it also appears that autocorrelation will remain after we add this term. Let's try it.

```
X = [dummyvar(mo(:)) logts.time logts.time.^2];
[b2,bint,resid2] = regress(logts.data,X);
tscol = addts(tscol,resid2,'Resid2');
plot(tscol.Resid2)
```



```
[p,dw] = dwtest(tscol.Resid2.data,X)
```

```
p = 8.7866e-20
```

```
dw = 0.6487
```

Adding the squared term did remove the pronounced curvature in the original residual plot, but both the plot and the new Durbin-Watson test show that there is still significant correlation in the residuals.

Autocorrelation like this could be the result of other causes that are not captured in our X variable. Perhaps we could collect other data that would help us improve our model and reduce the correlation. In the absence of other data, we might simply add another parameter to the model to represent the autocorrelation. Let's do that, removing the squared term, and using an autoregressive model for the error.

In an autoregressive process, we have two stages:

```
Y(t) = X(t,:)*b + r(t)       % regression model for original data
r(t) = rho * r(t-1) + u(t)   % autoregressive model for residuals
```

Unlike in the usual regression model when we would like the residual series `r(t)` to be a set of independent values, this model allows the residuals to follow an autoregressive model with its own error term `u(t)` that consists of independent values.

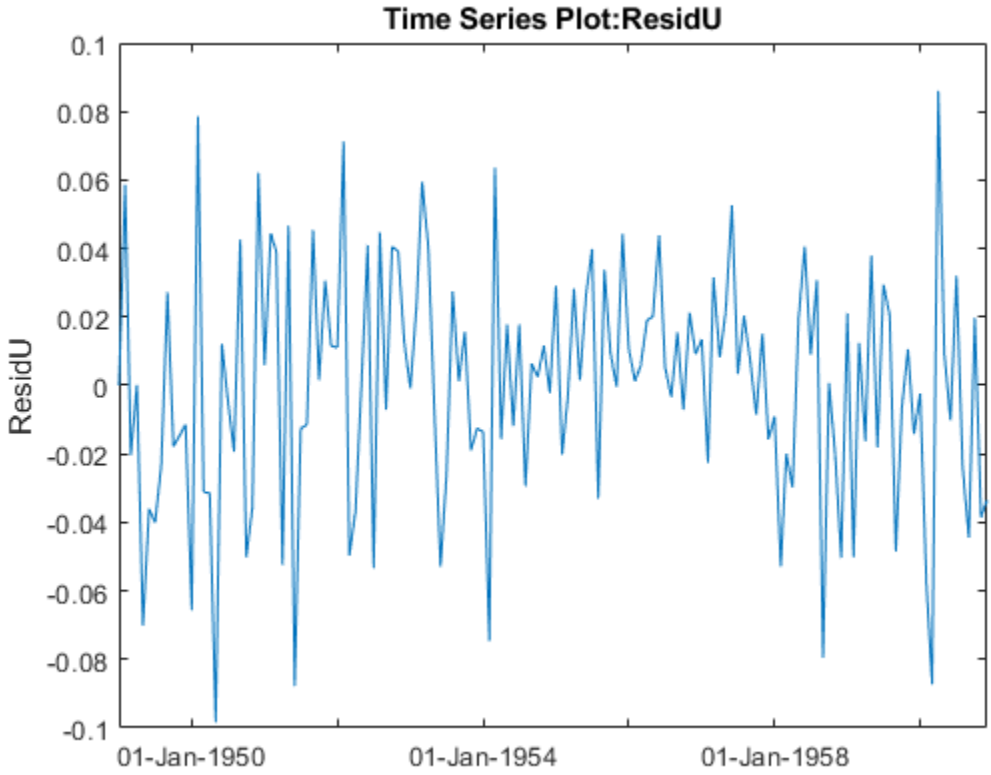
To create this model, we want to write an anonymous function `f` to compute fitted values `Yfit`, so that `Y-Yfit` gives the u values:

```
   Yfit(t) = rho*Y(t-1) + (X(t,:) - rho*X(t-1,:))*b
```

In this anonymous function we combine `[rho; b]` into a single parameter vector `c`. The resulting residuals look much closer to an uncorrelated series.

```
r = corr(resid(1:end-1),resid(2:end));  % initial guess for rho
X = [dummyvar(mo(:)) logts.time];
Y = logts.data;
f = @(c,x) [Y(1); c(1)*Y(1:end-1) + (x(2:end,:)- c(1)*x(1:end-1,:))*c(2:end)];
c = nlinfit(X,Y,f,[r; b]);

u = Y - f(c,X);
tscol = addts(tscol,u,'ResidU');
plot(tscol.ResidU);
```



Summary

This example provides an illustration of how to use the MATLAB® time series object along with features from the Statistics and Machine Learning Toolbox. It is simple to use the `ts.data` notation to extract the data and supply it as input to any function. The `controlchart` function also accepts time series objects directly.

More elaborate analyses are possible by using features specifically designed for time series, such as those in Econometrics Toolbox™ and System Identification Toolbox™.

Partial Least Squares Regression and Principal Components Regression

This example shows how to apply Partial Least Squares Regression (PLSR) and Principal Components Regression (PCR), and discusses the effectiveness of the two methods. PLSR and PCR are both methods to model a response variable when there are a large number of predictor variables, and those predictors are highly correlated or even collinear. Both methods construct new predictor variables, known as components, as linear combinations of the original predictor variables, but they construct those components in different ways. PCR creates components to explain the observed variability in the predictor variables, without considering the response variable at all. On the other hand, PLSR does take the response variable into account, and therefore often leads to models that are able to fit the response variable with fewer components. Whether or not that ultimately translates into a more parsimonious model, in terms of its practical use, depends on the context.

Loading the Data

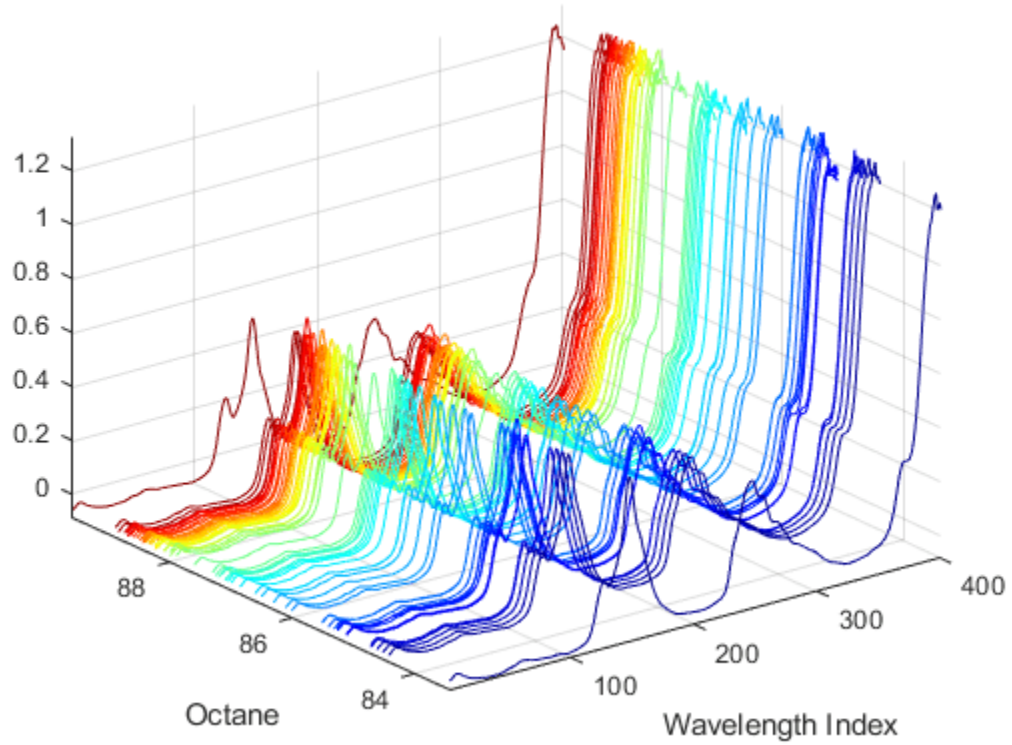
Load a data set comprising spectral intensities of 60 samples of gasoline at 401 wavelengths, and their octane ratings. These data are described in Kalivas, John H., "Two Data Sets of Near Infrared Spectra," Chemometrics and Intelligent Laboratory Systems, v.37 (1997) pp.255-259.

```
load spectra
whos NIR octane
```

```
  Name         Size              Bytes  Class     Attributes

  NIR         60x401            192480  double
  octane      60x1                 480  double
```

```
[dummy,h] = sort(octane);
oldorder = get(gcf,'DefaultAxesColorOrder');
set(gcf,'DefaultAxesColorOrder',jet(60));
plot3(repmat(1:401,60,1)',repmat(octane(h),1,401)',NIR(h,:)');
set(gcf,'DefaultAxesColorOrder',oldorder);
xlabel('Wavelength Index'); ylabel('Octane'); axis('tight');
grid on
```



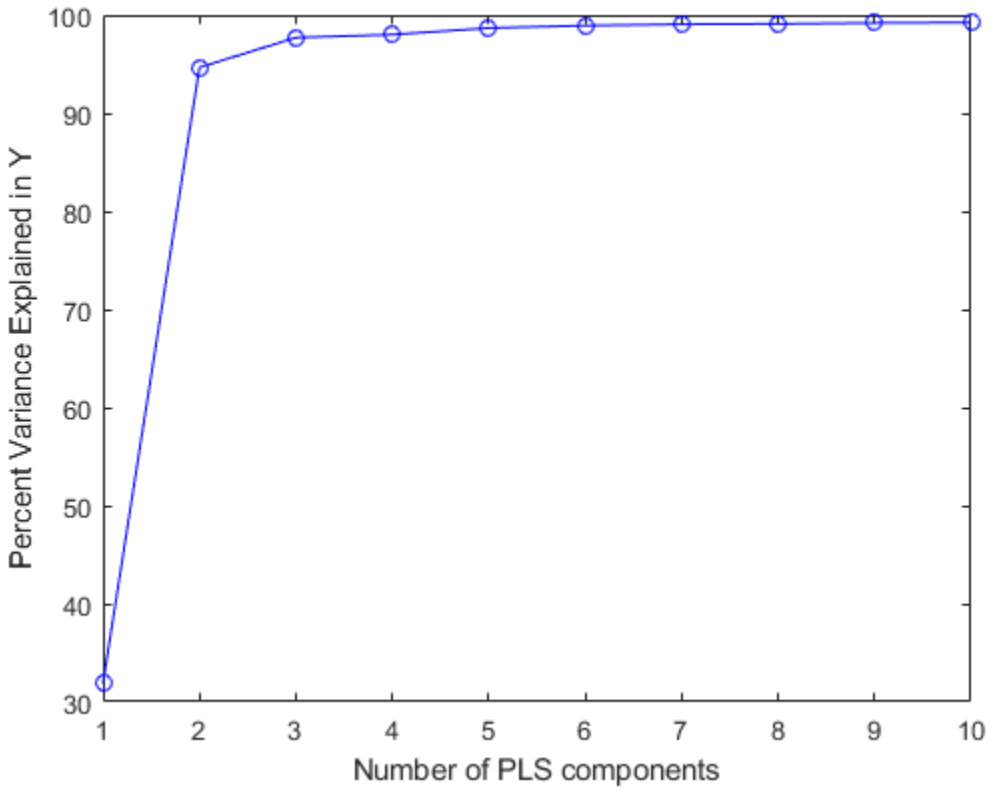
Fitting the Data with Two Components

Use the `plsregress` function to fit a PLSR model with ten PLS components and one response.

```
X = NIR;
y = octane;
[n,p] = size(X);
[Xloadings,Yloadings,Xscores,Yscores,betaPLS10,PLSPctVar] = plsregress(...
    X,y,10);
```

Ten components may be more than will be needed to adequately fit the data, but diagnostics from this fit can be used to make a choice of a simpler model with fewer components. For example, one quick way to choose the number of components is to plot the percent of variance explained in the response variable as a function of the number of components.

```
plot(1:10,cumsum(100*PLSPctVar(2,:)),'-bo');
xlabel('Number of PLS components');
ylabel('Percent Variance Explained in Y');
```



In practice, more care would probably be advisable in choosing the number of components. Cross-validation, for instance, is a widely-used method that will be illustrated later in this example. For now, the above plot suggests that PLSR with two components explains most of the variance in the observed `y`. Compute the fitted response values for the two-component model.

```
[Xloadings,Yloadings,Xscores,Yscores,betaPLS] = plsregress(X,y,2);
yfitPLS = [ones(n,1) X]*betaPLS;
```

Next, fit a PCR model with two principal components. The first step is to perform Principal Components Analysis on `X`, using the `pca` function, and retaining two principal components. PCR is then just a linear regression of the response variable on those two components. It often makes sense to normalize each variable first by its standard deviation when the variables have very different amounts of variability, however, that is not done here.

```
[PCALoadings,PCAScores,PCAVar] = pca(X,'Economy',false);
betaPCR = regress(y-mean(y), PCAScores(:,1:2));
```

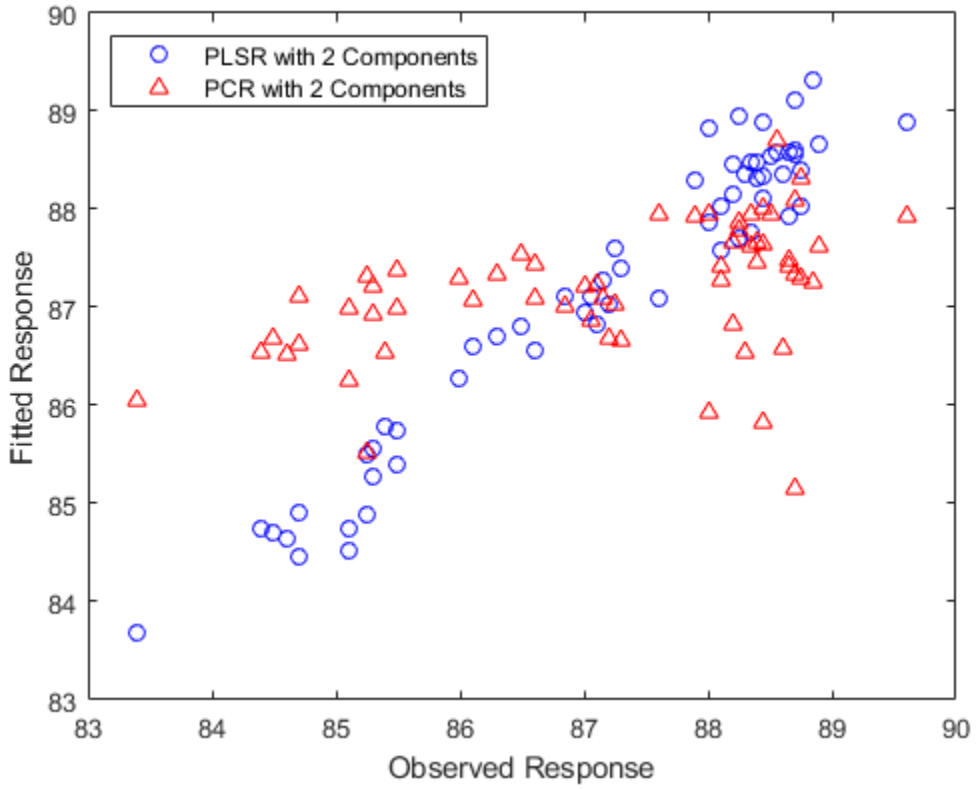
To make the PCR results easier to interpret in terms of the original spectral data, transform to regression coefficients for the original, uncentered variables.

```
betaPCR = PCALoadings(:,1:2)*betaPCR;
betaPCR = [mean(y) - mean(X)*betaPCR; betaPCR];
yfitPCR = [ones(n,1) X]*betaPCR;
```

Plot fitted vs. observed response for the PLSR and PCR fits.

```
plot(y,yfitPLS,'bo',y,yfitPCR,'r^');
xlabel('Observed Response');
```

```
ylabel('Fitted Response');
legend({'PLSR with 2 Components' 'PCR with 2 Components'},  ...
    'location','NW');
```



In a sense, the comparison in the plot above is not a fair one -- the number of components (two) was chosen by looking at how well a two-component PLSR model predicted the response, and there's no reason why the PCR model should be restricted to that same number of components. With the same number of components, however, PLSR does a much better job at fitting `y`. In fact, looking at the horizontal scatter of fitted values in the plot above, PCR with two components is hardly better than using a constant model. The r-squared values from the two regressions confirm that.

```
TSS = sum((y-mean(y)).^2);
RSS_PLS = sum((y-yfitPLS).^2);
rsquaredPLS = 1 - RSS_PLS/TSS
```

```
rsquaredPLS =

    0.9466
```

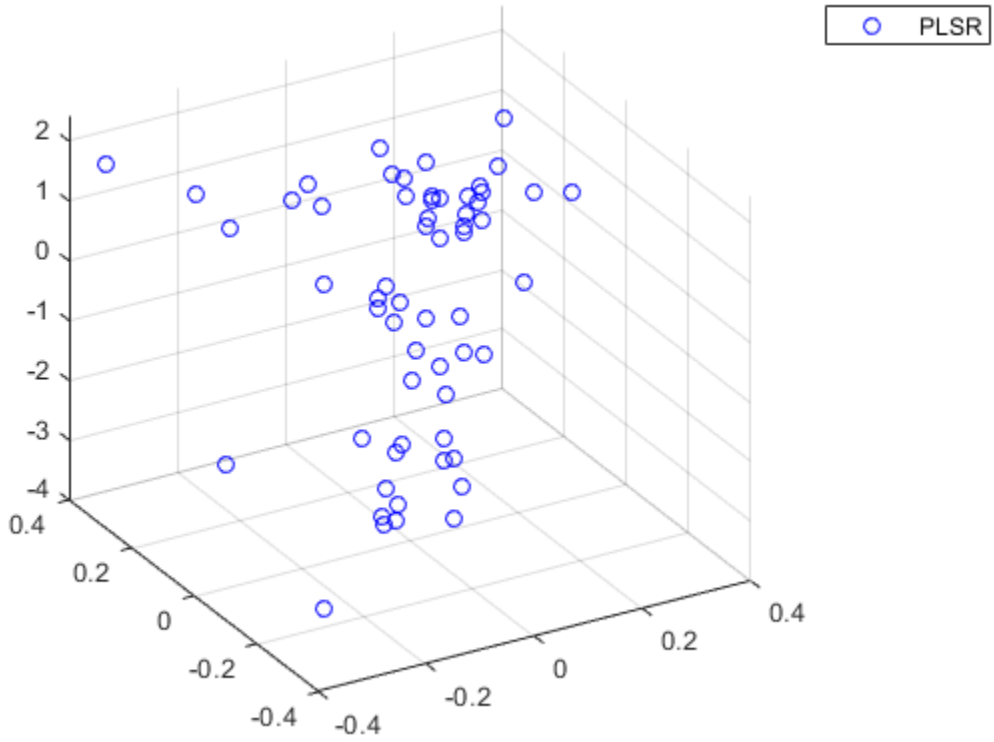
```
RSS_PCR = sum((y-yfitPCR).^2);
rsquaredPCR = 1 - RSS_PCR/TSS
```

```
rsquaredPCR =
```

```
    0.1962
```

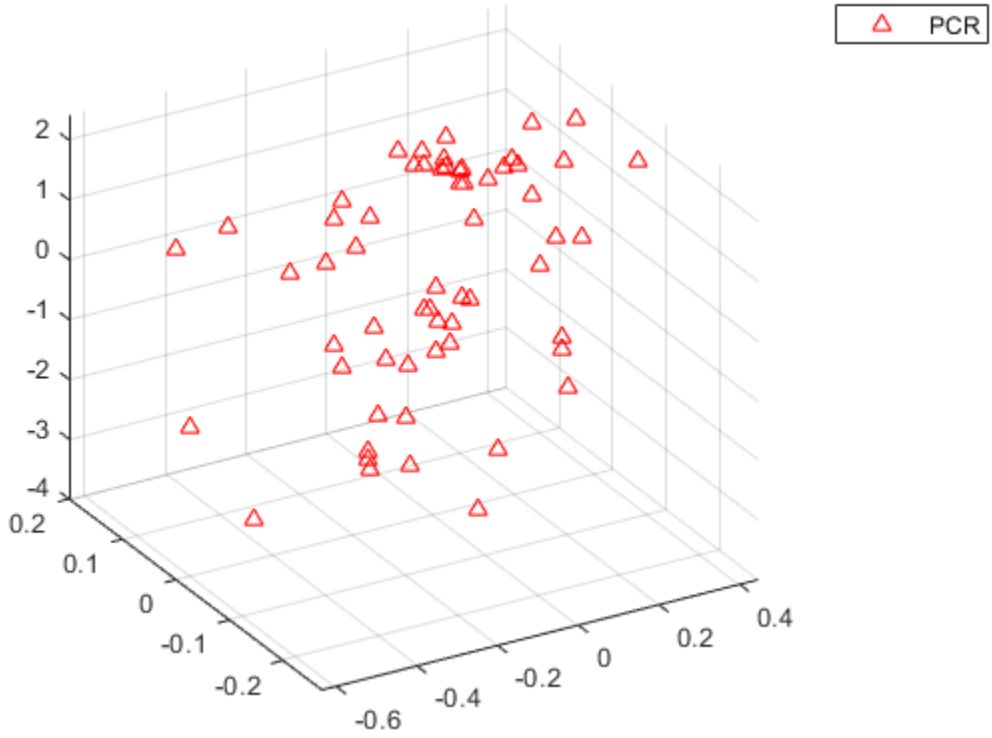
Another way to compare the predictive power of the two models is to plot the response variable against the two predictors in both cases.

```
plot3(Xscores(:,1),Xscores(:,2),y-mean(y),'bo');
legend('PLSR');
grid on; view(-30,30);
```



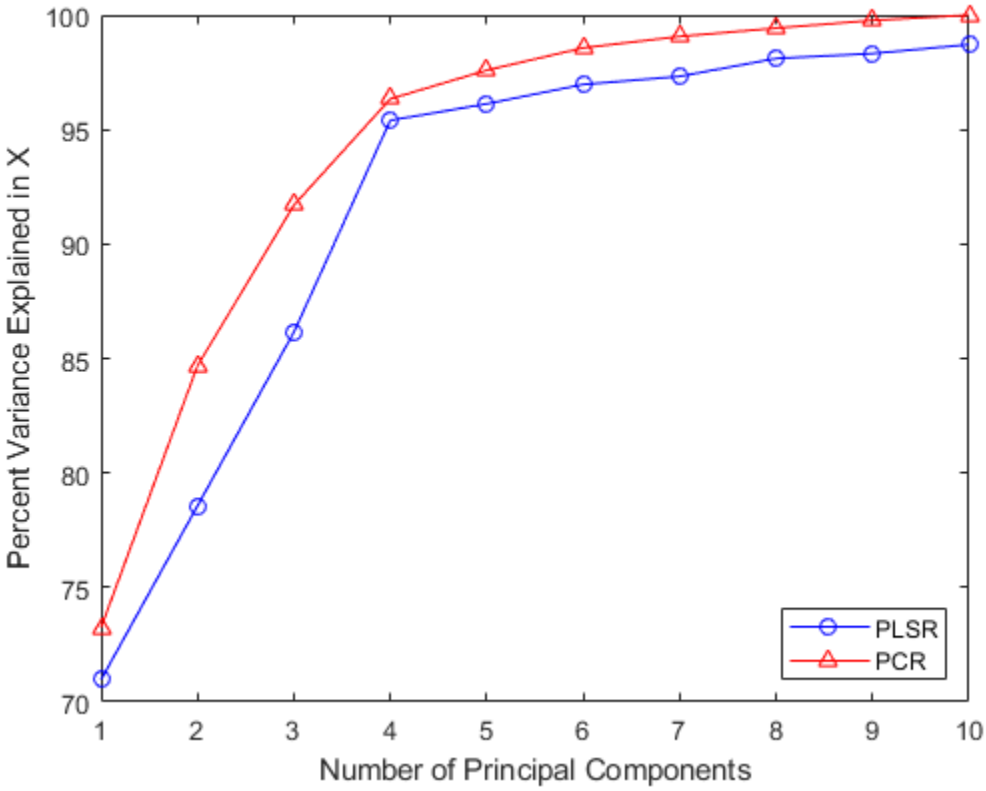
It's a little hard to see without being able to interactively rotate the figure, but the PLSR plot above shows points closely scattered about a plane. On the other hand, the PCR plot below shows a cloud of points with little indication of a linear relationship.

```
plot3(PCAScores(:,1),PCAScores(:,2),y-mean(y),'r^');
legend('PCR');
grid on; view(-30,30);
```



Notice that while the two PLS components are much better predictors of the observed y, the following figure shows that they explain somewhat less variance in the observed X than the first two principal components used in the PCR.

```
plot(1:10,100*cumsum(PLSPctVar(1,:)),'b-o',1:10,  ...
    100*cumsum(PCAVar(1:10))/sum(PCAVar(1:10)),'r-^');
xlabel('Number of Principal Components');
ylabel('Percent Variance Explained in X');
legend({'PLSR' 'PCR'},'location','SE');
```

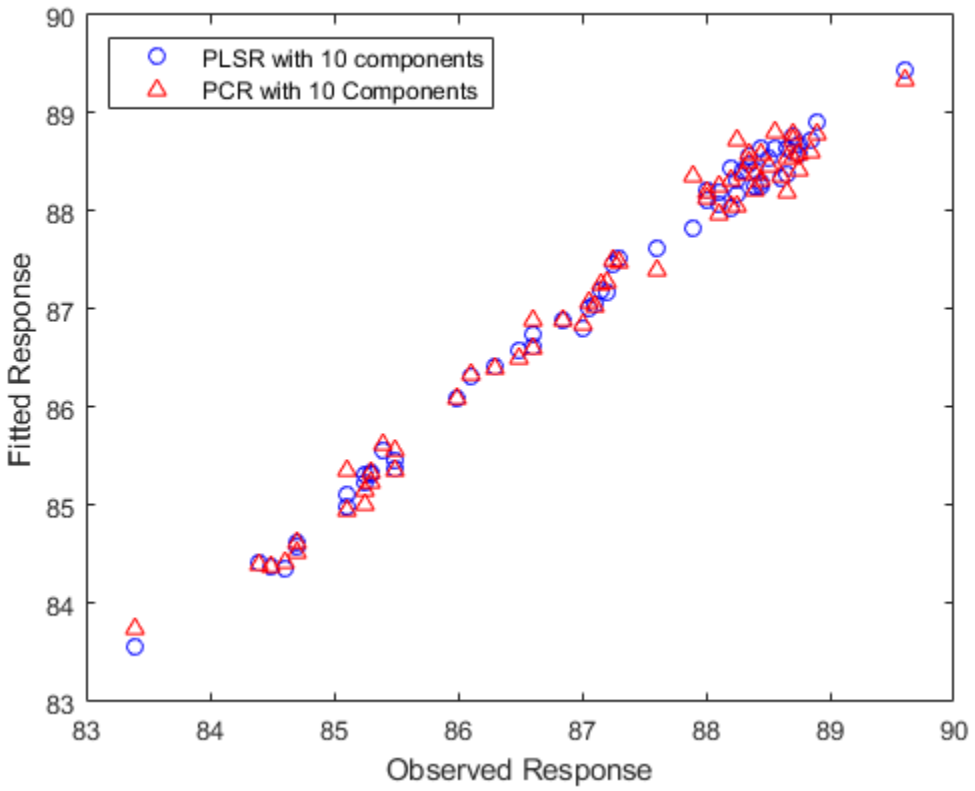


The fact that the PCR curve is uniformly higher suggests why PCR with two components does such a poor job, relative to PLSR, in fitting y. PCR constructs components to best explain X, and as a result, those first two components ignore the information in the data that is important in fitting the observed y.

Fitting with More Components

As more components are added in PCR, it will necessarily do a better job of fitting the original data y, simply because at some point most of the important predictive information in X will be present in the principal components. For example, the following figure shows that the difference in residuals for the two methods is much less dramatic when using ten components than it was for two components.

```
yfitPLS10 = [ones(n,1) X]*betaPLS10;
betaPCR10 = regress(y-mean(y), PCAScores(:,1:10));
betaPCR10 = PCALoadings(:,1:10)*betaPCR10;
betaPCR10 = [mean(y) - mean(X)*betaPCR10; betaPCR10];
yfitPCR10 = [ones(n,1) X]*betaPCR10;
plot(y,yfitPLS10,'bo',y,yfitPCR10,'r^');
xlabel('Observed Response');
ylabel('Fitted Response');
legend({'PLSR with 10 components' 'PCR with 10 Components'},  ...
    'location','NW');
```



Both models fit `y` fairly accurately, although PLSR still makes a slightly more accurate fit. However, ten components is still an arbitrarily-chosen number for either model.

Choosing the Number of Components with Cross-Validation

It's often useful to choose the number of components to minimize the expected error when predicting the response from future observations on the predictor variables. Simply using a large number of components will do a good job in fitting the current observed data, but is a strategy that leads to overfitting. Fitting the current data too well results in a model that does not generalize well to other data, and gives an overly-optimistic estimate of the expected error.

Cross-validation is a more statistically sound method for choosing the number of components in either PLSR or PCR. It avoids overfitting data by not reusing the same data to both fit a model and to estimate prediction error. Thus, the estimate of prediction error is not optimistically biased downwards.

`plsregress` has an option to estimate the mean squared prediction error (MSEP) by cross-validation, in this case using 10-fold C-V.

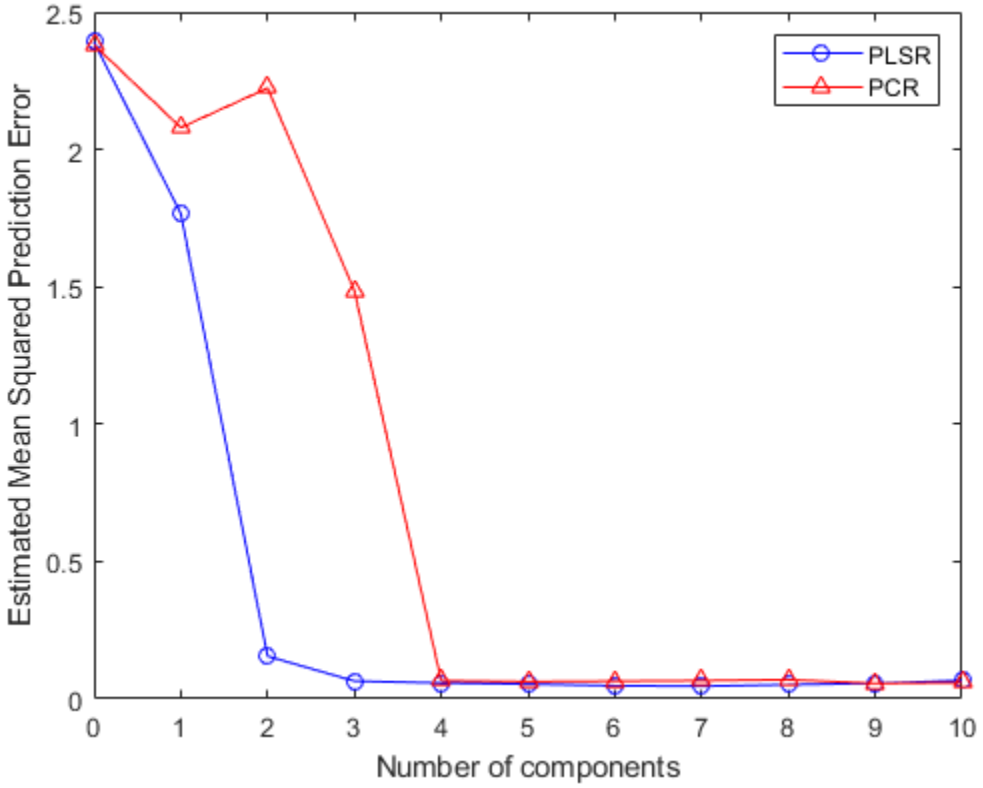
```
[Xl,Yl,Xs,Ys,beta,pctVar,PLSmsep] = plsregress(X,y,10,'CV',10);
```

For PCR, `crossval` combined with a simple function to compute the sum of squared errors for PCR, can estimate the MSEP, again using 10-fold cross-validation.

```
PCRmsep = sum(crossval(@pcrsse,X,y,'KFold',10),1) / n;
```

The MSEP curve for PLSR indicates that two or three components does about as good a job as possible. On the other hand, PCR needs four components to get the same prediction accuracy.

```
plot(0:10,PLSmsep(2,:),'b-o',0:10,PCRmsep,'r-^');
xlabel('Number of components');
ylabel('Estimated Mean Squared Prediction Error');
legend({'PLSR' 'PCR'},'location','NE');
```



In fact, the second component in PCR *increases* the prediction error of the model, suggesting that the combination of predictor variables contained in that component is not strongly correlated with `y`. Again, that's because PCR constructs components to explain variation in `X`, not `y`.

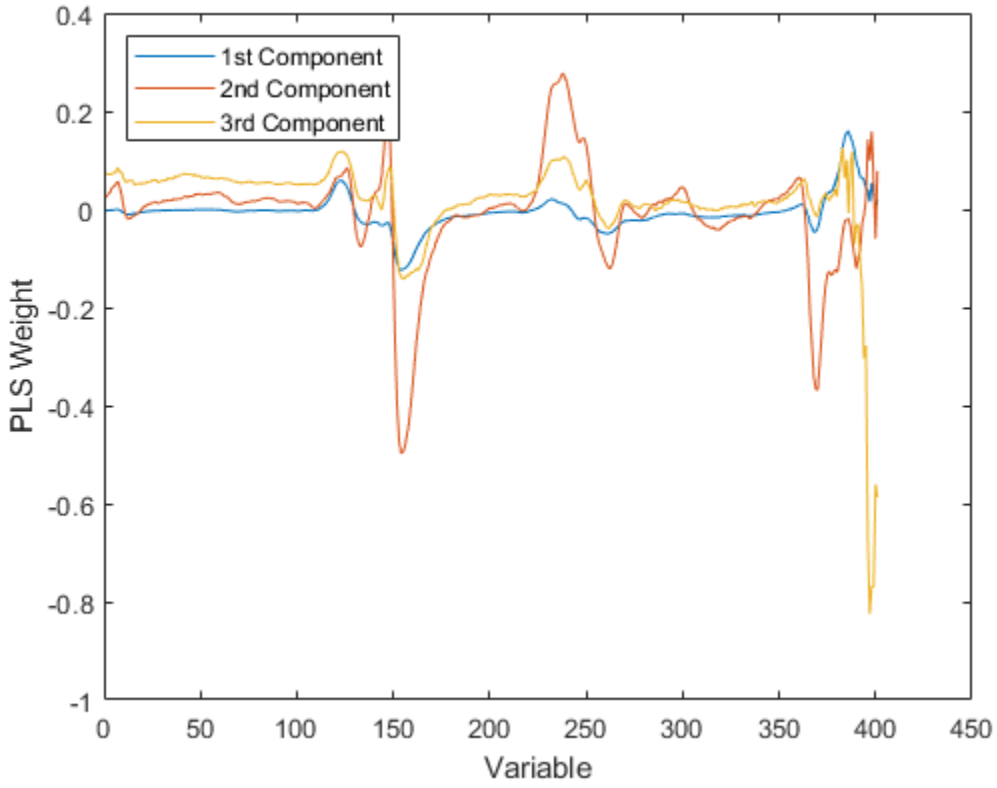
Model Parsimony

So if PCR requires four components to get the same prediction accuracy as PLSR with three components, is the PLSR model more parsimonious? That depends on what aspect of the model you consider.

The PLS weights are the linear combinations of the original variables that define the PLS components, i.e., they describe how strongly each component in the PLSR depends on the original variables, and in what direction.

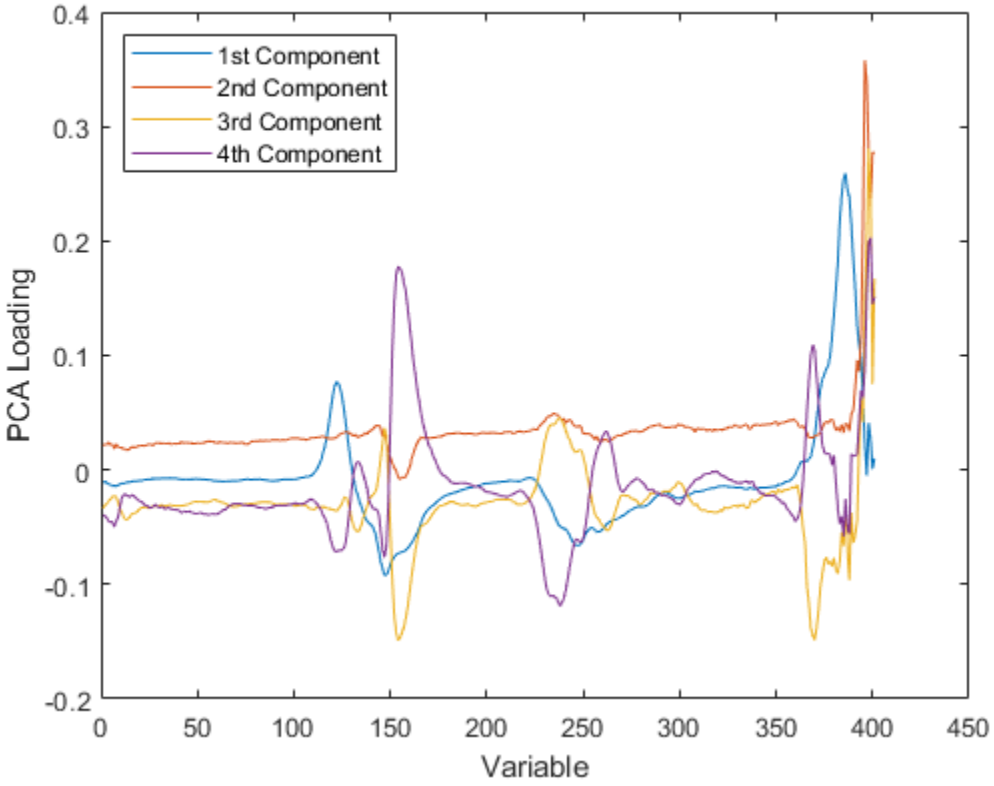
```
[Xl,Yl,Xs,Ys,beta,pctVar,mse,stats] = plsregress(X,y,3);
plot(1:401,stats.W,'-');
xlabel('Variable');
ylabel('PLS Weight');
```

```
legend({'1st Component' '2nd Component' '3rd Component'},  ...
    'location','NW');
```



Similarly, the PCA loadings describe how strongly each component in the PCR depends on the original variables.

```
plot(1:401,PCALoadings(:,1:4),'-');
xlabel('Variable');
ylabel('PCA Loading');
legend({'1st Component' '2nd Component' '3rd Component'  ...
    '4th Component'},'location','NW');
```



For either PLSR or PCR, it may be that each component can be given a physically meaningful interpretation by inspecting which variables it weights most heavily. For instance, with these spectral data it may be possible to interpret intensity peaks in terms of compounds present in the gasoline, and then to observe that weights for a particular component pick out a small number of those compounds. From that perspective, fewer components are simpler to interpret, and because PLSR often requires fewer components to predict the response adequately, it leads to more parsimonious models.

On the other hand, both PLSR and PCR result in one regression coefficient for each of the original predictor variables, plus an intercept. In that sense, neither is more parsimonious, because regardless of how many components are used, both models depend on all predictors. More concretely, for these data, both models need 401 spectral intensity values in order to make a prediction.

However, the ultimate goal may to reduce the original set of variables to a smaller subset still able to predict the response accurately. For example, it may be possible to use the PLS weights or the PCA loadings to select only those variables that contribute most to each component. As shown earlier, some components from a PCR model fit may serve primarily to describe the variation in the predictor variables, and may include large weights for variables that are not strongly correlated with the response. Thus, PCR can lead to retaining variables that are unnecessary for prediction.

For the data used in this example, the difference in the number of components needed by PLSR and PCR for accurate prediction is not great, and the PLS weights and PCA loadings seem to pick out the same variables. That may not be true for other data.

Generalized Linear Models

Multinomial Models for Nominal Responses

The outcome of a response variable might be one of a restricted set of possible values. If there are only two possible outcomes, such as a yes or no answer to a question, these responses are called binary responses. If there are multiple outcomes, then they are called polytomous responses. Some examples include the degree of a disease (mild, medium, severe), preferred districts to live in a city, and so on. When the response variable is *nominal*, there is no natural order among the response variable categories. Nominal response models explain and predict the probability that an observation is in each category of a categorical response variable.

A nominal response model is one of several natural extensions of the binary logit model and is also called a *multinomial logit* model. The multinomial logit model explains the relative risk of being in one category versus being in the reference category, k, using a linear combination of predictor variables. Consequently, the probability of each outcome is expressed as a nonlinear function of p predictor variables. The `'interactions','on'` name-value pair argument in `mnrfit` corresponds to this multinomial model with separate intercept and slopes among categories. `mnrfit` uses the default logit link function for multinomial models. You cannot specify a different link function for multinomial responses.

The multinomial logit model is

$$\ln\left(\frac{\pi_1}{\pi_k}\right) = \alpha_1 + \beta_{11}X_1 + \beta_{12}X_2 + \cdots + \beta_{1p}X_p,$$

$$\ln\left(\frac{\pi_2}{\pi_k}\right) = \alpha_2 + \beta_{21}X_1 + \beta_{22}X_2 + \cdots + \beta_{2p}X_p,$$

$$\vdots$$

$$\ln\left(\frac{\pi_{k-1}}{\pi_k}\right) = \alpha_{(k-1)} + \beta_{(k-1)1}X_1 + \beta_{(k-1)2}X_2 + \cdots + \beta_{(k-1)p}X_p,$$

where $\pi_j = \mathrm{P}(y = j)$ is the probability of an outcome being in category j, k is the number of response categories, and p is the number of predictor variables. Theoretically, any category can be the reference category, but `mnrfit` chooses the last one, k, as the reference category. Thus, `mnrfit` assumes the coefficients of the kth category are zero. The total of j – 1 equations are solved simultaneously to estimate the coefficients. `mnrfit` uses the iteratively weighted least squares algorithm to find the maximum likelihood estimates.

The coefficients in the model express the effects of the predictor variables on the relative risk or the log odds of being in category j versus the reference category, here k. For example, the coefficient β_{23} indicates that the probability of the response variable being in category 2 compared to the probability of being in category k increases $\exp(\beta_{23})$ times for each unit increase in X_3, given all else is held constant. Or it indicates that the relative log odds of the response variable being category 2 versus in category k increases β_{23} times with a one-unit increase in X_3, given all else equal.

Based on the nominal response model, and the assumption that the coefficients for the last category are zero, the probability of being in each category is

$$\pi_j = P(y = j) = \frac{e^{\alpha_j + \sum_{l=1}^{p} \beta_{jl}x_l}}{1 + \sum_{j=1}^{k-1} e^{\alpha_j + \sum_{l=1}^{p} \beta_{jl}x_l}}, \quad j = 1, \cdots, k-1.$$

The probability of the kth category becomes

$$\pi_k = P(y = k) = \frac{1}{1 + \sum_{j=1}^{k-1} e^{\alpha_j + \sum_{l=1}^{p} \beta_{jl} x_l}},$$

which is simply equal to $1 - \pi_1 - \pi_2 - \ldots - \pi_{k-1}$.

After estimating the model coefficients using `mnrfit`, you can estimate the category probabilities or the number in each category using `mnrval` (the default name-value pair is `'type','category'`). This function accepts the coefficient estimates and the model statistics `mnrfit` returns and estimates the categorical probabilities or the number in each category and their confidence bounds. You can also specify the cumulative or conditional probabilities or numbers to estimate using the `'type'` name-value pair argument in `mnrval`.

Multinomial Models for Ordinal Responses

The outcome of a response variable might be one of a restricted set of possible values. If there are only two possible outcomes, such as male and female for gender, these responses are called binary responses. If there are multiple outcomes, then they are called polytomous responses. Some examples of polytomous responses include levels of a disease (mild, medium, severe), preferred districts to live in a city, the species for a certain flower type, and so on. Sometimes there might be a natural order among the response categories. These responses are called *ordinal responses*.

The ordering might be inherent in the category choices, such as an individual being not satisfied, satisfied, or very satisfied with an online customer service. The ordering might also be introduced by categorization of a latent (continuous) variable, such as in the case of an individual being in the low risk, medium risk, or high risk group for developing a certain disease, based on a quantitative medical measure such as blood pressure.

You can specify a multinomial regression model that uses the natural ordering among the response categories. This ordinal model describes the relationship between the cumulative probabilities of the categories and predictor variables.

Different link functions can describe this relationship with logit and probit being the most used.

- **Logit:** The default link function `mnrfit` uses for ordinal categories is the *logit* link function. This models the *log cumulative odds*. The `'link','logit'` name-value pair specifies this in `mnrfit`. Log cumulative odds is the logarithm of the ratio of the probability that a response belongs to a category with a value less than or equal to category j, $P(y \le c_j)$, and the probability that a response belongs to a category with a value greater than category j, $P(y > c_j)$.

  Ordinal models are usually based on the assumption that the effects of predictor variables are the same for all categories on the logarithmic scale. That is, the model has different intercepts but common slopes (coefficients) among categories. This model is called *parallel regression* or the *proportional odds* model. It is the default for ordinal responses, and the `'interactions','off'` name-value pair specifies this model in `mnrfit`.

  The proportional odds model is

$$\ln\left(\frac{P(y \le c_1)}{P(y > c_1)}\right) = \ln\left(\frac{\pi_1}{\pi_2 + \cdots + \pi_k}\right) = \alpha_1 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_p X_p,$$

$$\ln\left(\frac{P(y \le c_2)}{P(y > c_2)}\right) = \ln\left(\frac{\pi_1 + \pi_2}{\pi_3 + \cdots + \pi_k}\right) = \alpha_2 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_p X_p,$$

$$\vdots$$

$$\ln\left(\frac{P(y \le c_{k-1})}{P(y > c_{k-1})}\right) = \ln\left(\frac{\pi_1 + \pi_2 + \cdots + \pi_{k-1}}{\pi_k}\right) = \alpha_{k-1} + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_p X_p,$$

  where π_j, $j = 1, 2, \ldots, k$, are the category probabilities.

  For example, for a response variable with three categories, there are $3 - 1 = 2$ equations as follows:

$$\ln\left(\frac{\pi_1}{\pi_2 + \pi_3}\right) = \alpha_1 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_p X_p,$$

$$\ln\left(\frac{\pi_1 + \pi_2}{\pi_3}\right) = \alpha_2 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_p X_p.$$

Under the proportional odds assumption, the partial effect of a predictor variable X is invariant to the choice of the response variable category, j. For example, if there are three categories, then the coefficients express the impact of a predictor variable on the relative risk or log odds of the response value being in category 1 versus categories 2 or 3, or in category 1 or 2 versus category 3.

Thus, a unit change in variable X_2 would mean a change in the cumulative odds of the response value being in category 1 versus categories 2 or 3, or category 1 or 2 versus category 3 by a factor of $\exp(\beta_2)$, given all else equal.

You can alternatively fit a model with different intercept and slopes among the categories by using the `'interactions','on'` name-value pair argument. However, using this option for ordinal models when the equal slopes model is true causes a loss of efficiency (you lose the advantage of estimating fewer parameters).

- **Probit:** The `'link','probit'` name-value pair argument uses the *probit* link function which is based on a normally distributed latent variable assumption. For ordinal response variables this is also called an *ordered probit* model. Consider the regression model that describes the relationship of a latent variable y^* of an ordinal process and a vector of predictor variables, X,

  $$y^* = \beta X + \varepsilon,$$

  where the error term ε has a standard normal distribution. Suppose there is the following relationship between the latent variable y^* and the observed variable y:

  $$\begin{aligned} y &= c_1 \quad if \quad \alpha_0 < y^* \le \alpha_1, \\ y &= c_2 \quad if \quad \alpha_1 < y^* \le \alpha_2, \\ &\vdots \qquad\qquad \vdots \\ y &= c_k \quad if \quad \alpha_{k-1} < y^* \le \alpha_k, \end{aligned}$$

  where $\alpha_0 = -\infty$ and $\alpha_k = \infty$. Then, the cumulative probability of y being in category j or one of earlier categories, $P(y \le c_j)$, is equal to

  $$P\left(y \le c_j\right) = P\left(y^* < \alpha_j\right) = P\left(\beta X + \varepsilon < \alpha_j\right) = P\left(\varepsilon < \alpha_j - \beta X\right) = \Phi\left(\alpha_j - \beta X\right),$$

  where Φ is standard normal cumulative distribution function. Thus,

  $$\Phi^{-1}\left(P\left(y \le c_j\right)\right) = \alpha_j - \beta X,$$

  where α_j corresponds to the cut points of the latent variable and the intercept in the regression model. This only holds under the assumptions of a normal latent variable and parallel regression. More generally, for a response variable with k categories and multiple predictors, the ordered probit model is

  $$\begin{aligned} \Phi^{-1}(P(y \le c_1)) &= \alpha_1 + \beta_1 X_1 + \cdots + \beta_p X_p, \\ \Phi^{-1}(P(y \le c_2)) &= \alpha_2 + \beta_1 X_1 + \cdots + \beta_p X_p, \\ &\vdots \qquad\qquad\qquad \vdots \\ \Phi^{-1}(P(y \le c_{k-1})) &= \alpha_{k-1} + \beta_1 X_1 + \cdots + \beta_p X_p, \end{aligned}$$

  where $P(y \le c_j) = \pi_1 + \pi_2 + \ldots + \pi_j$.

  The coefficients indicate the impact of a unit change in the predictor variable on the likelihood of a state. A positive coefficient, β_1, for example, indicates an increase in the underlying latent

variable with an increase in the corresponding predictor variable, X_1. Hence, it causes a decrease in $P(y \le c_1)$ and an increase in $P(y \le c_k)$.

After estimating the model coefficients using `mnrfit`, you can estimate the cumulative probabilities or the cumulative number in each category using `mnrval` with the `'type','cumulative'` name-value pair option. `mnrval` accepts the coefficient estimates and the model statistics `mnrfit` returns, and estimates the categorical probabilities or the number in each category and their confidence intervals. You can specify which category or conditional probabilities or numbers to estimate by changing the value of the `'type'` name-value pair argument.

More About

- “Multinomial Models for Nominal Responses” on page 12-2
- “Hierarchical Multinomial Models” on page 12-7

Hierarchical Multinomial Models

The outcome of a response variable might sometimes be one of a restricted set of possible values. If there are only two possible outcomes, such as male and female for gender, these responses are called binary responses. If there are multiple outcomes, then they are called polytomous responses. These responses are usually qualitative rather than quantitative, such as preferred districts to live in a city, the severity level of a disease, the species for a certain flower type, and so on. Polytomous responses might also have categories which are not independent of each other. Instead the response happens in a sequential manner, or one category is nested in the previous one. These types of responses are called *hierarchical*, *or sequential*, or *nested multinomial responses*.

For example, if the response is the number of cigarettes a person smokes in a given day, the first level is whether the person is a smoker or not. Given that he or she is a smoker, the number of cigarettes he or she smokes can be from one to five or more than five a day. Given that it is more than 5, this person might be smoking from 6 to 10 or more than 10 cigarettes a day, and so on. The risk group at each level changes accordingly. At level one, the risk group is all of the individuals of interest (smoker or not), say m. If out of m individuals, y_1 of them are not smokers, then at level two, the risk group is the number of all smoking individuals, $m - y_1$. If y_2 of these $m - y_1$ individuals smoke from one to five cigarettes a day, then at level three, the risk group is $m - y_1 - y_2$. So, at each level, the number of people in that category becomes a conditional binomial observation.

The hierarchical multinomial regression models are extensions of binary regression models based on conditional binary observations. The default is a model with different intercept and slopes (coefficients) among categories, in which case `mnrfit` fits a sequence of conditional binomial models. The `'interactions','on'` name-value pair specifies this in `mnrfit`. The default link function is logit and the `'link','logit'` name-value pair specifies this model in `mnrfit`.

Suppose the probability that an individual is in category j given that he or she is not in the previous categories is π_j, and the cumulative probability that a response belongs to a category j or a previous category is $P(y \le c_j)$. Then the hierarchical model with a logit link function and different slopes assumption is

$$\ln\left(\frac{\pi_1}{1-P(y\le c_1)}\right) = \ln\left(\frac{\pi_1}{1-\pi_1}\right) = \alpha_1 + \beta_{11}X_1 + \beta_{12}X_2 + \cdots + \beta_{1p}X_p,$$

$$\ln\left(\frac{\pi_2}{1-P(y\le c_2)}\right) = \ln\left(\frac{\pi_2}{1-(\pi_1+\pi_2)}\right) = \alpha_2 + \beta_{21}X_2 + \beta_{22}X_2 + \cdots + \beta_{2p}X_p,$$

$$\vdots$$

$$\ln\left(\frac{\pi_{k-1}}{1-P(y\le c_{k-1})}\right) = \ln\left(\frac{\pi_{k-1}}{1-(\pi_1+\cdots+\pi_{k-1})}\right) = \alpha_{k-1} + \beta_{(k-1)1}X_1 + \beta_{(k-1)2}X_2 + \cdots + \beta_{(k-1)p}X_p\,.$$

For example, for a response variable with four sequential categories, there are $4 - 1 = 3$ equations as follows:

$$\ln\left(\frac{\pi_1}{\pi_2+\pi_3+\pi_4}\right) = \alpha_1 + \beta_{11}X_1 + \beta_{12}X_2 + \cdots + \beta_{1p}X_p,$$

$$\ln\left(\frac{\pi_2}{\pi_3+\pi_4}\right) = \alpha_2 + \beta_{21}X_1 + \beta_{22}X_2 + \cdots + \beta_{2p}X_p,$$

$$\ln\left(\frac{\pi_3}{\pi_4}\right) = \alpha_3 + \beta_{31}X_1 + \beta_{32}X_2 + \cdots + \beta_{3p}X_p\,.$$

The coefficients β_{ij} are interpreted within each level. For example, for the previous smoking example, β_{12} shows the impact of X_2 on the log odds of a person being a smoker versus a nonsmoker, provided that everything else is held constant. Alternatively, β_{22} shows the impact of X_2 on the log odds of a person smoking one to five cigarettes versus more than five cigarettes a day, given that he or she is a smoker, provided that everything else is held constant. Similarly, β_{23}, shows the effect of X_2 on the log odds of a person smoking 6 to 10 cigarettes versus more than 10 cigarettes a day, given that he or she smokes more than 5 cigarettes a day, provided that everything else is held constant.

You can specify other link functions for hierarchical models. The `'link','probit'` name-value pair argument uses the probit link function. With the separate slopes assumption, the model becomes

$$\begin{aligned}
\Phi^{-1}(\pi_1) &= \alpha_1 + \beta_{11}X_1 + \cdots + \beta_{1p}X_p, \\
\Phi^{-1}(\pi_2) &= \alpha_2 + \beta_{21}X_1 + \cdots + \beta_{2p}X_p, \\
&\vdots \qquad\qquad\qquad \vdots \\
\Phi^{-1}(\pi_k) &= \alpha_k + \beta_{k1}X_1 + \cdots + \beta_{kp}X_p,
\end{aligned}$$

where π_j is the conditional probability of being in category j, given that it is not in categories previous to category j. And $\Phi^{-1}(.)$ is the inverse of the standard normal cumulative distribution function.

After estimating the model coefficients using `mnrfit`, you can estimate the cumulative probabilities or the cumulative number in each category using `mnrval` with the `'type','conditional'` name-value pair argument. The function `mnrval` accepts the coefficient estimates and the model statistics `mnrfit` returns, and estimates the categorical probabilities or the number in each category and their confidence bounds. You can specify which category or cumulative probabilities or numbers to estimate by changing the value of the `'type'` name-value pair argument in `mnrval`.

Generalized Linear Models

In this section...

What Are Generalized Linear Models?

Linear regression models describe a linear relationship between a response and one or more predictive terms. Many times, however, a nonlinear relationship exists. “Nonlinear Regression” on page 13-2 describes general nonlinear models. A special class of nonlinear models, called *generalized linear models*, uses linear methods.

Recall that linear models have these characteristics:

- At each set of values for the predictors, the response has a normal distribution with mean μ.
- A coefficient vector b defines a linear combination Xb of the predictors X.
- The model is $\mu = Xb$.

In generalized linear models, these characteristics are generalized as follows:

- At each set of values for the predictors, the response has a distribution that can be normal on page B-119, binomial on page B-10, Poisson on page B-131, gamma on page B-47, or inverse Gaussian on page B-75, with parameters including a mean μ.
- A coefficient vector b defines a linear combination Xb of the predictors X.
- A link function f defines the model as $f(\mu) = Xb$.

Prepare Data

To begin fitting a regression, put your data into a form that fitting functions expect. All regression techniques begin with input data in an array `X` and response data in a separate vector `y`, or input data in a table or dataset array `tbl` and response data as a column in `tbl`. Each row of the input data represents one observation. Each column represents one predictor (variable).

For a table or dataset array `tbl`, indicate the response variable with the `'ResponseVar'` name-value pair:

```
mdl = fitglm(tbl,'ResponseVar','BloodPressure');
```

The response variable is the last column by default.

You can use numeric categorical predictors. A categorical predictor is one that takes values from a fixed set of possibilities.

- For a numeric array `X`, indicate the categorical predictors using the `'Categorical'` name-value pair. For example, to indicate that predictors 2 and 3 out of six are categorical:

  ```
  mdl = fitglm(X,y,'Categorical',[2,3]);
  % or equivalently
  mdl = fitglm(X,y,'Categorical',logical([0 1 1 0 0 0]));
  ```

- For a table or dataset array `tbl`, fitting functions assume that these data types are categorical:

  - Logical vector
  - Categorical vector
  - Character array
  - String array

  If you want to indicate that a numeric predictor is categorical, use the `'Categorical'` name-value pair.

Represent missing numeric data as `NaN`. To represent missing data for other data types, see “Missing Group Values” on page 2-46.

- For a `'binomial'` model with data matrix `X`, the response `y` can be:

  - Binary column vector — Each entry represents success (`1`) or failure (`0`).
  - Two-column matrix of integers — The first column is the number of successes in each observation, the second column is the number of trials in that observation.

- For a `'binomial'` model with table or dataset `tbl`:

  - Use the `ResponseVar` name-value pair to specify the column of `tbl` that gives the number of successes in each observation.
  - Use the `BinomialSize` name-value pair to specify the column of `tbl` that gives the number of trials in each observation.

Dataset Array for Input and Response Data

For example, to create a dataset array from an Excel spreadsheet:

```
ds = dataset('XLSFile','hospital.xls',...
     'ReadObsNames',true);
```

To create a dataset array from workspace variables:

```
load carsmall
ds = dataset(MPG,Weight);
ds.Year = ordinal(Model_Year);
```

Table for Input and Response Data

To create a table from workspace variables:

```
load carsmall
tbl = table(MPG,Weight);
tbl.Year = ordinal(Model_Year);
```

Numeric Matrix for Input Data, Numeric Vector for Response

For example, to create numeric arrays from workspace variables:

```
load carsmall
X = [Weight Horsepower Cylinders Model_Year];
y = MPG;
```

To create numeric arrays from an Excel spreadsheet:

```
[X, Xnames] = xlsread('hospital.xls');
y = X(:,4); % response y is systolic pressure
X(:,4) = []; % remove y from the X matrix
```

Notice that the nonnumeric entries, such as `sex`, do not appear in `X`.

Choose Generalized Linear Model and Link Function

Often, your data suggests the distribution type of the generalized linear model.

Response Data Type	Suggested Model Distribution Type
Any real number	`'normal'`
Any positive number	`'gamma'` or `'inverse gaussian'`
Any nonnegative integer	`'poisson'`
Integer from 0 to `n`, where `n` is a fixed positive value	`'binomial'`

Set the model distribution type with the `Distribution` name-value pair. After selecting your model type, choose a link function to map between the mean μ and the linear predictor Xb.

Value	Description
`'comploglog'`	$\log(-\log((1 - \mu))) = Xb$
`'identity'`, default for the distribution `'normal'`	$\mu = Xb$
`'log'`, default for the distribution `'poisson'`	$\log(\mu) = Xb$
`'logit'`, default for the distribution `'binomial'`	$\log(\mu/(1 - \mu)) = Xb$
`'loglog'`	$\log(-\log(\mu)) = Xb$
`'probit'`	$\Phi^{-1}(\mu) = Xb$, where Φ is the normal (Gaussian) cumulative distribution function
`'reciprocal'`, default for the distribution `'gamma'`	$\mu^{-1} = Xb$
`p` (a number), default for the distribution `'inverse gaussian'` (with $p = -2$)	$\mu^p = Xb$

Value	Description
A cell array of the form `{FL FD FI}`, containing three function handles created using `@`, which define the link (`FL`), the derivative of the link (`FD`), and the inverse link (`FI`). Or, a structure of function handles with the field `Link` containing `FL`, the field `Derivative` containing `FD`, and the field `Inverse` containing `FI`.	User-specified link function (see “Custom Link Function” on page 12-12)

The nondefault link functions are mainly useful for binomial models. These nondefault link functions are `'comploglog'`, `'loglog'`, and `'probit'`.

Custom Link Function

The link function defines the relationship $f(\mu) = Xb$ between the mean response μ and the linear combination $Xb = X*b$ of the predictors. You can choose one of the built-in link functions or define your own by specifying the link function `FL`, its derivative `FD`, and its inverse `FI`:

- The link function `FL` calculates $f(\mu)$.
- The derivative of the link function `FD` calculates $df(\mu)/d\mu$.
- The inverse function `FI` calculates $g(Xb) = \mu$.

You can specify a custom link function in either of two equivalent ways. Each way contains function handles that accept a single array of values representing μ or Xb, and returns an array the same size. The function handles are either in a cell array or a structure:

- Cell array of the form `{FL FD FI}`, containing three function handles, created using `@`, that define the link (`FL`), the derivative of the link (`FD`), and the inverse link (`FI`).
- Structure `s` with three fields, each containing a function handle created using `@`:
  - `s.Link` — Link function
  - `s.Derivative` — Derivative of the link function
  - `s.Inverse` — Inverse of the link function

For example, to fit a model using the `'probit'` link function:

```
x = [2100 2300 2500 2700 2900 ...
     3100 3300 3500 3700 3900 4100 4300]';
n = [48 42 31 34 31 21 23 23 21 16 17 21]';
y = [1 2 0 3 8 8 14 17 19 15 17 21]';
g = fitglm(x,[y n],...
    'linear','distr','binomial','link','probit')

g =

Generalized Linear regression model:
    probit(y) ~ 1 + x1
    Distribution = Binomial

Estimated Coefficients:
                   Estimate     SE            tStat     pValue
    (Intercept)      -7.3628       0.66815    -11.02    3.0701e-28
```

```
    x1             0.0023039    0.00021352     10.79    3.8274e-27

12 observations, 10 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 241, p-value = 2.25e-54
```

You can perform the same fit using a custom link function that performs identically to the `'probit'` link function:

```
s = {@norminv,@(x)1./normpdf(norminv(x)),@normcdf};
g = fitglm(x,[y n],...
    'linear','distr','binomial','link',s)

g =

Generalized Linear regression model:
    link(y) ~ 1 + x1
    Distribution = Binomial

Estimated Coefficients:
                   Estimate     SE            tStat     pValue
    (Intercept)      -7.3628       0.66815    -11.02    3.0701e-28
    x1             0.0023039    0.00021352     10.79    3.8274e-27

12 observations, 10 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 241, p-value = 2.25e-54
```

The two models are the same.

Equivalently, you can write `s` as a structure instead of a cell array of function handles:

```
s.Link = @norminv;
s.Derivative = @(x) 1./normpdf(norminv(x));
s.Inverse = @normcdf;
g = fitglm(x,[y n],...
    'linear','distr','binomial','link',s)

g =

Generalized Linear regression model:
    link(y) ~ 1 + x1
    Distribution = Binomial

Estimated Coefficients:
                   Estimate     SE            tStat     pValue
    (Intercept)      -7.3628       0.66815    -11.02    3.0701e-28
    x1             0.0023039    0.00021352     10.79    3.8274e-27

12 observations, 10 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 241, p-value = 2.25e-54
```

Choose Fitting Method and Model

There are two ways to create a fitted model.

- Use `fitglm` when you have a good idea of your generalized linear model, or when you want to adjust your model later to include or exclude certain terms.
- Use `stepwiseglm` when you want to fit your model using stepwise regression. `stepwiseglm` starts from one model, such as a constant, and adds or subtracts terms one at a time, choosing an optimal term each time in a greedy fashion, until it cannot improve further. Use stepwise fitting to find a good model, one that has only relevant terms.

  The result depends on the starting model. Usually, starting with a constant model leads to a small model. Starting with more terms can lead to a more complex model, but one that has lower mean squared error.

In either case, provide a model to the fitting function (which is the starting model for `stepwiseglm`).

Specify a model using one of these methods.

- "Brief Model Name" on page 12-14
- "Terms Matrix" on page 12-14
- "Formula" on page 12-15

Brief Model Name

Name	Model Type
`'constant'`	Model contains only a constant (intercept) term.
`'linear'`	Model contains an intercept and linear terms for each predictor.
`'interactions'`	Model contains an intercept, linear terms, and all products of pairs of distinct predictors (no squared terms).
`'purequadratic'`	Model contains an intercept, linear terms, and squared terms.
`'quadratic'`	Model contains an intercept, linear terms, interactions, and squared terms.
`'poly`*`ijk`*`'`	Model is a polynomial with all terms up to degree *`i`* in the first predictor, degree *`j`* in the second predictor, etc. Use numerals `0` through `9`. For example, `'poly2111'` has a constant plus all linear and product terms, and also contains terms with predictor 1 squared.

Terms Matrix

A terms matrix `T` is a *t*-by-(*p* + 1) matrix specifying terms in a model, where *t* is the number of terms, *p* is the number of predictor variables, and +1 accounts for the response variable. The value of `T(i,j)` is the exponent of variable `j` in term `i`.

For example, suppose that an input includes three predictor variables `x1`, `x2`, and `x3` and the response variable `y` in the order `x1`, `x2`, `x3`, and `y`. Each row of `T` represents one term:

- `[0 0 0 0]` — Constant term or intercept
- `[0 1 0 0]` — `x2`; equivalently, `x1^0 * x2^1 * x3^0`
- `[1 0 1 0]` — `x1*x3`
- `[2 0 0 0]` — `x1^2`
- `[0 1 2 0]` — `x2*(x3^2)`

The `0` at the end of each term represents the response variable. In general, a column vector of zeros in a terms matrix represents the position of the response variable. If you have the predictor and response variables in a matrix and column vector, then you must include `0` for the response variable in the last column of each row.

Formula

A formula for a model specification is a character vector or string scalar of the form

`'y ~ terms'`,

- *`y`* is the response name.
- *`terms`* contains
  - Variable names
  - `+` to include the next variable
  - `-` to exclude the next variable
  - `:` to define an interaction, a product of terms
  - `*` to define an interaction and all lower-order terms
  - `^` to raise the predictor to a power, exactly as in `*` repeated, so `^` includes lower order terms as well
  - `()` to group terms

Tip Formulas include a constant (intercept) term by default. To exclude a constant term from the model, include `-1` in the formula.

Examples:

`'y ~ x1 + x2 + x3'` is a three-variable linear model with intercept.
`'y ~ x1 + x2 + x3 - 1'` is a three-variable linear model without intercept.
`'y ~ x1 + x2 + x3 + x2^2'` is a three-variable model with intercept and a `x2^2` term.
`'y ~ x1 + x2^2 + x3'` is the same as the previous example, since `x2^2` includes a `x2` term.
`'y ~ x1 + x2 + x3 + x1:x2'` includes an `x1*x2` term.
`'y ~ x1*x2 + x3'` is the same as the previous example, since `x1*x2 = x1 + x2 + x1:x2`.
`'y ~ x1*x2*x3 - x1:x2:x3'` has all interactions among `x1`, `x2`, and `x3`, except the three-way interaction.
`'y ~ x1*(x2 + x3 + x4)'` has all linear terms, plus products of `x1` with each of the other variables.

Fit Model to Data

Create a fitted model using `fitglm` or `stepwiseglm`. Choose between them as in “Choose Fitting Method and Model” on page 12-13. For generalized linear models other than those with a normal distribution, give a `Distribution` name-value pair as in “Choose Generalized Linear Model and Link Function” on page 12-11. For example,

```
mdl = fitglm(X,y,'linear','Distribution','poisson')
% or
mdl = fitglm(X,y,'quadratic',...
         'Distribution','binomial')
```

Examine Quality and Adjust the Fitted Model

After fitting a model, examine the result.

Model Display

A linear regression model shows several diagnostics when you enter its name or enter `disp(mdl)`. This display gives some of the basic information to check whether the fitted model represents the data adequately.

For example, fit a Poisson model to data constructed with two out of five predictors not affecting the response, and with no intercept term:

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[.4;.2;.3]);
y = poissrnd(mu);
mdl = fitglm(X,y,...
    'linear','Distribution','poisson')

mdl =

Generalized Linear regression model:
    log(y) ~ 1 + x1 + x2 + x3 + x4 + x5
    Distribution = Poisson

Estimated Coefficients:
                   Estimate     SE          tStat       pValue
    (Intercept)     0.039829     0.10793     0.36901       0.71212
    x1               0.38551    0.076116      5.0647    4.0895e-07
    x2             -0.034905    0.086685    -0.40266        0.6872
    x3              -0.17826    0.093552     -1.9054      0.056722
    x4               0.21929     0.09357      2.3436      0.019097
    x5               0.28918      0.1094      2.6432     0.0082126

100 observations, 94 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 44.9, p-value = 1.55e-08
```

Notice that:

- The display contains the estimated values of each coefficient in the `Estimate` column. These values are reasonably near the true values `[0;.4;0;0;.2;.3]`, except possibly the coefficient of `x3` is not terribly near `0`.
- There is a standard error column for the coefficient estimates.
- The reported `pValue` (which are derived from the *t* statistics under the assumption of normal errors) for predictors 1, 4, and 5 are small. These are the three predictors that were used to create the response data `y`.

- The `pValue` for `(Intercept)`, `x2` and `x3` are larger than 0.01. These three predictors were not used to create the response data `y`. The `pValue` for `x3` is just over `.05`, so might be regarded as possibly significant.
- The display contains the Chi-square statistic.

Diagnostic Plots

Diagnostic plots help you identify outliers, and see other problems in your model or fit. To illustrate these plots, consider binomial regression with a logistic link function.

The logistic model is useful for proportion data. It defines the relationship between the proportion p and the weight w by:

$\log[p/(1 - p)] = b_1 + b_2 w$

This example fits a binomial model to data. The data are derived from `carbig.mat`, which contains measurements of large cars of various weights. Each weight in `w` has a corresponding number of cars in `total` and a corresponding number of poor-mileage cars in `poor`.

It is reasonable to assume that the values of `poor` follow binomial on page B-10 distributions, with the number of trials given by `total` and the percentage of successes depending on `w`. This distribution can be accounted for in the context of a logistic model by using a generalized linear model with link function $\log(\mu/(1 - \mu)) = Xb$. This link function is called `'logit'`.

```
w = [2100 2300 2500 2700 2900 3100 ...
     3300 3500 3700 3900 4100 4300]';
total = [48 42 31 34 31 21 23 23 21 16 17 21]';
poor = [1 2 0 3 8 8 14 17 19 15 17 21]';
mdl = fitglm(w,[poor total],...
    'linear','Distribution','binomial','link','logit')
```

```
mdl =

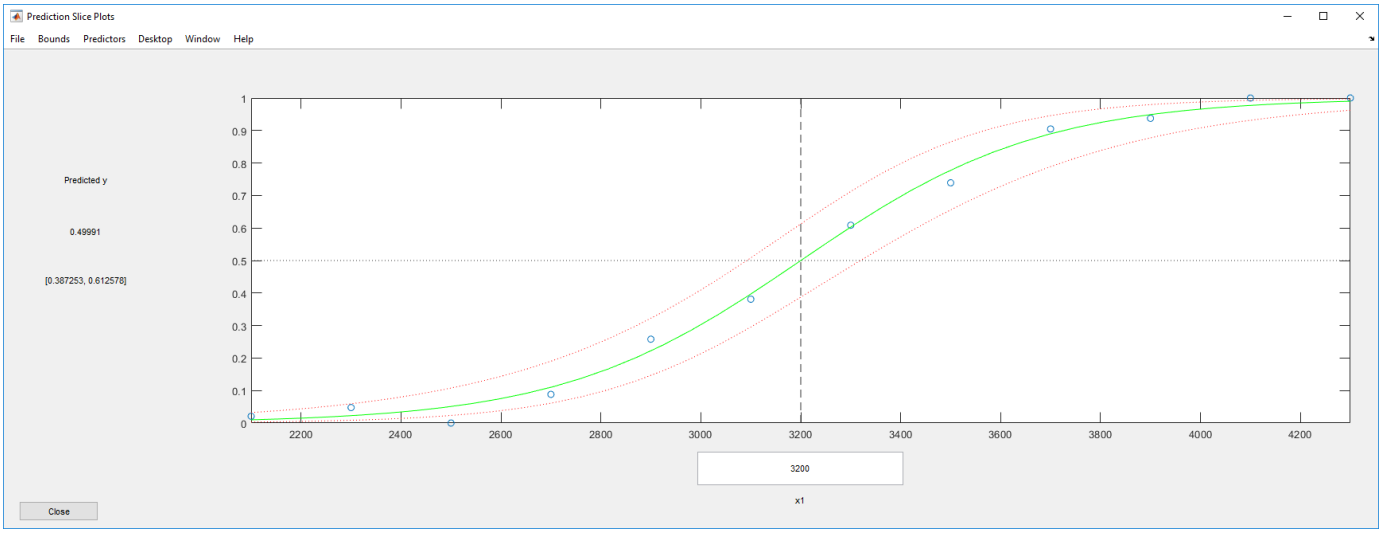
Generalized Linear regression model:
    logit(y) ~ 1 + x1
    Distribution = Binomial

Estimated Coefficients:
                   Estimate     SE            tStat      pValue
    (Intercept)       -13.38         1.394    -9.5986    8.1019e-22
    x1             0.0041812    0.00044258     9.4474    3.4739e-21

12 observations, 10 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 242, p-value = 1.3e-54
```

See how well the model fits the data.

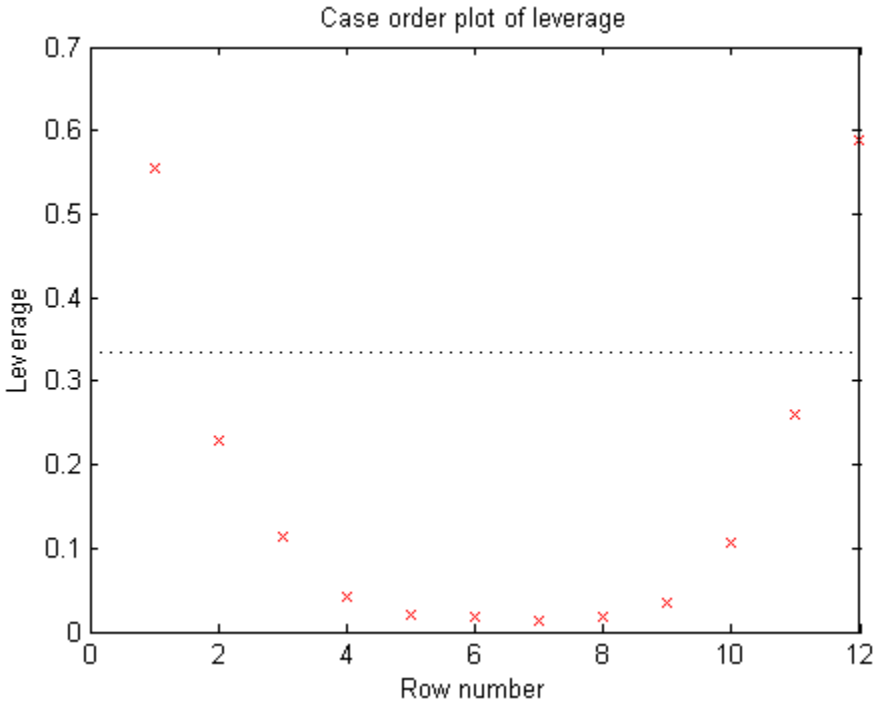
```
plotSlice(mdl)
```



The fit looks reasonably good, with fairly wide confidence bounds.

To examine further details, create a leverage plot.

```
plotDiagnostics(mdl)
```



This is typical of a regression with points ordered by the predictor variable. The leverage of each point on the fit is higher for points with relatively extreme predictor values (in either direction) and low for points with average predictor values. In examples with multiple predictors and with points not ordered by predictor value, this plot can help you identify which observations have high leverage because they are outliers as measured by their predictor values.

Residuals — Model Quality for Training Data

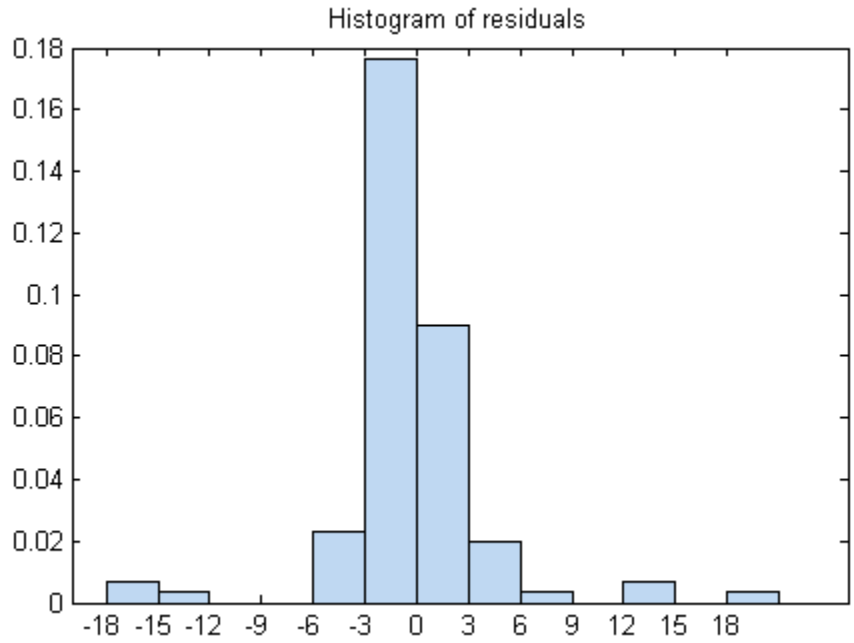
There are several residual plots to help you discover errors, outliers, or correlations in the model or data. The simplest residual plots are the default histogram plot, which shows the range of the residuals and their frequencies, and the probability plot, which shows how the distribution of the residuals compares to a normal distribution with matched variance.

This example shows residual plots for a fitted Poisson model. The data construction has two out of five predictors not affecting the response, and no intercept term:

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = fitglm(X,y,...
    'linear','Distribution','poisson');
```

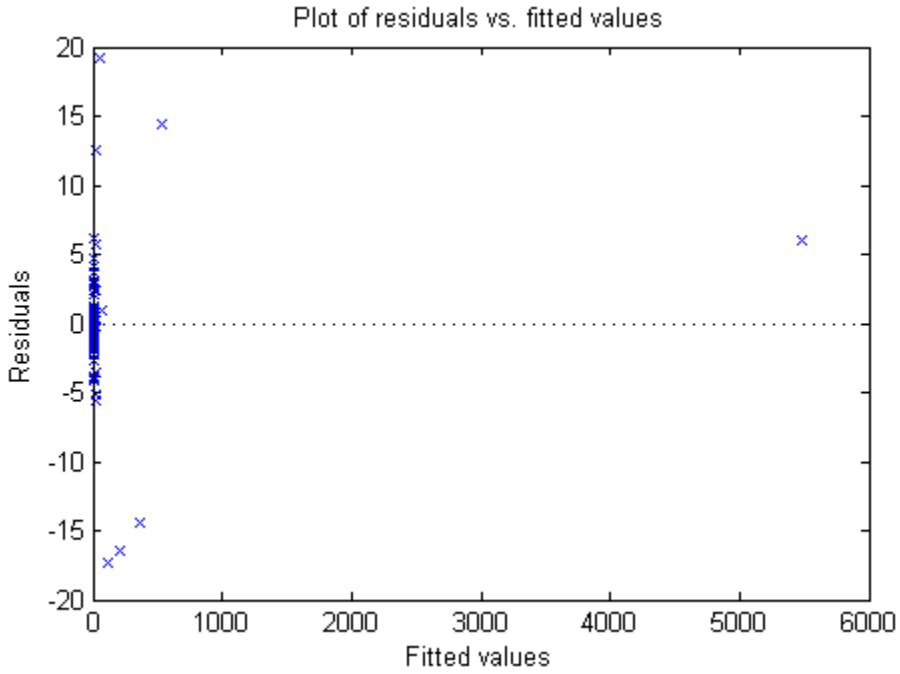
Examine the residuals:

```
plotResiduals(mdl)
```



While most residuals cluster near 0, there are several near ±18. So examine a different residuals plot.

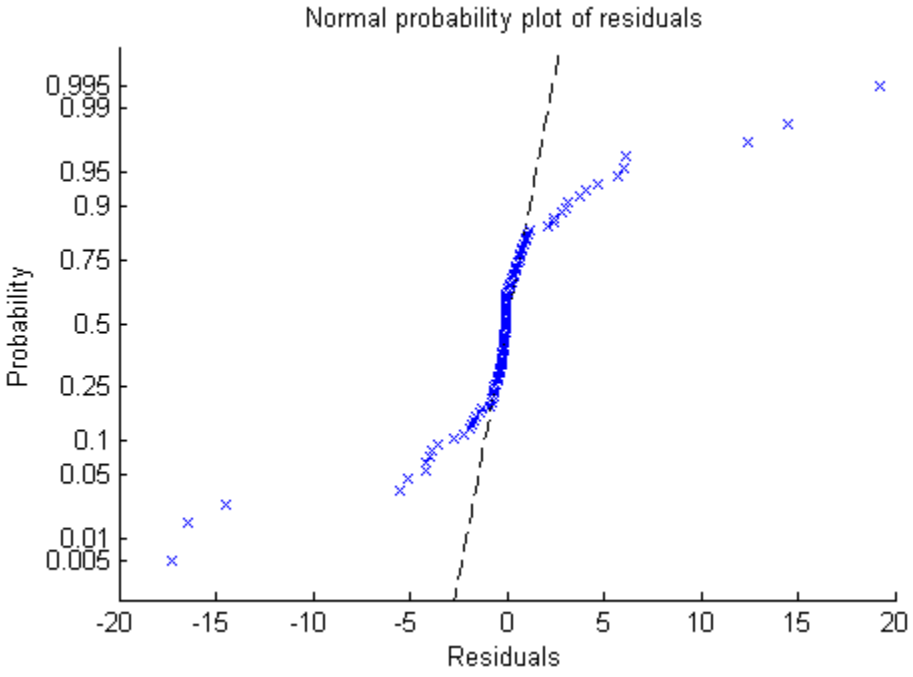
```
plotResiduals(mdl,'fitted')
```



The large residuals don’t seem to have much to do with the sizes of the fitted values.

Perhaps a probability plot is more informative.

```
plotResiduals(mdl,'probability')
```



Now it is clear. The residuals do not follow a normal distribution. Instead, they have fatter tails, much as an underlying Poisson distribution.

Plots to Understand Predictor Effects and How to Modify a Model

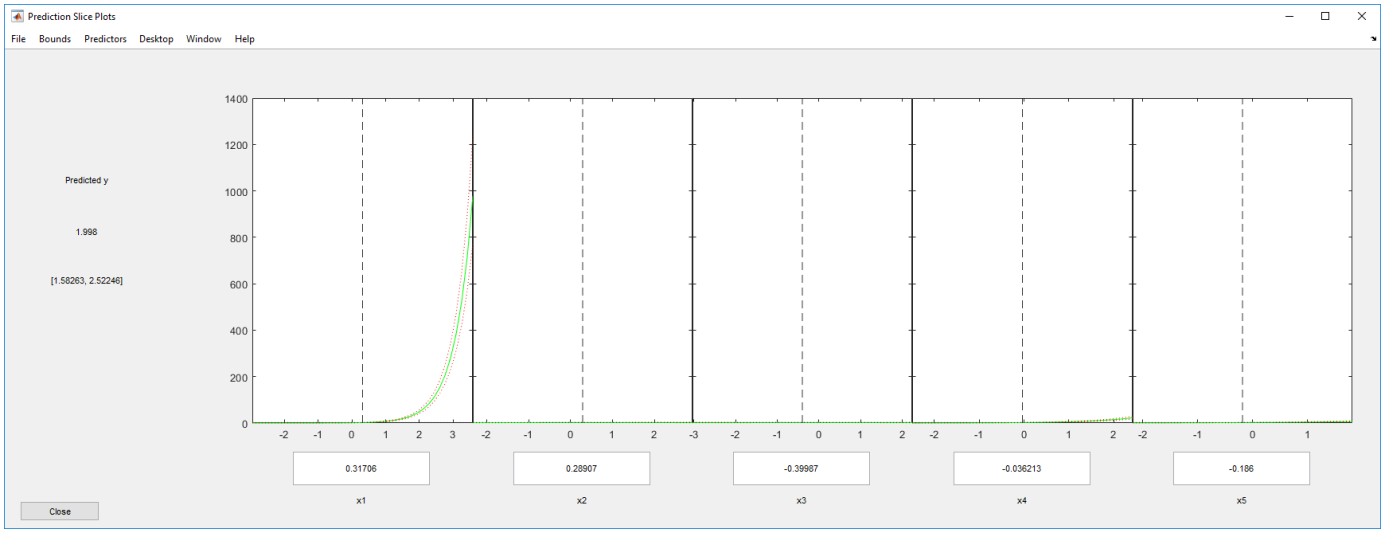
This example shows how to understand the effect each predictor has on a regression model, and how to modify the model to remove unnecessary terms.

1 Create a model from some predictors in artificial data. The data do not use the second and third columns in X. So you expect the model not to show much dependence on those predictors.

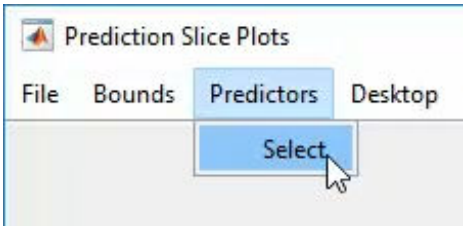
```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = fitglm(X,y,...
    'linear','Distribution','poisson');
```

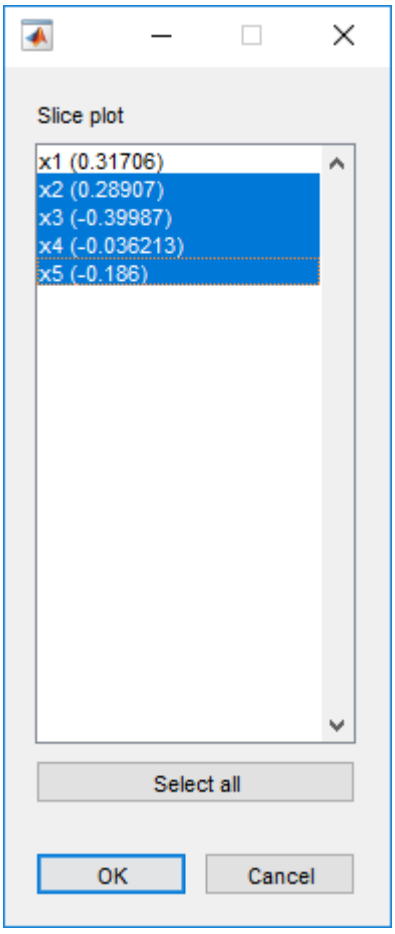
2 Examine a slice plot of the responses. This displays the effect of each predictor separately.

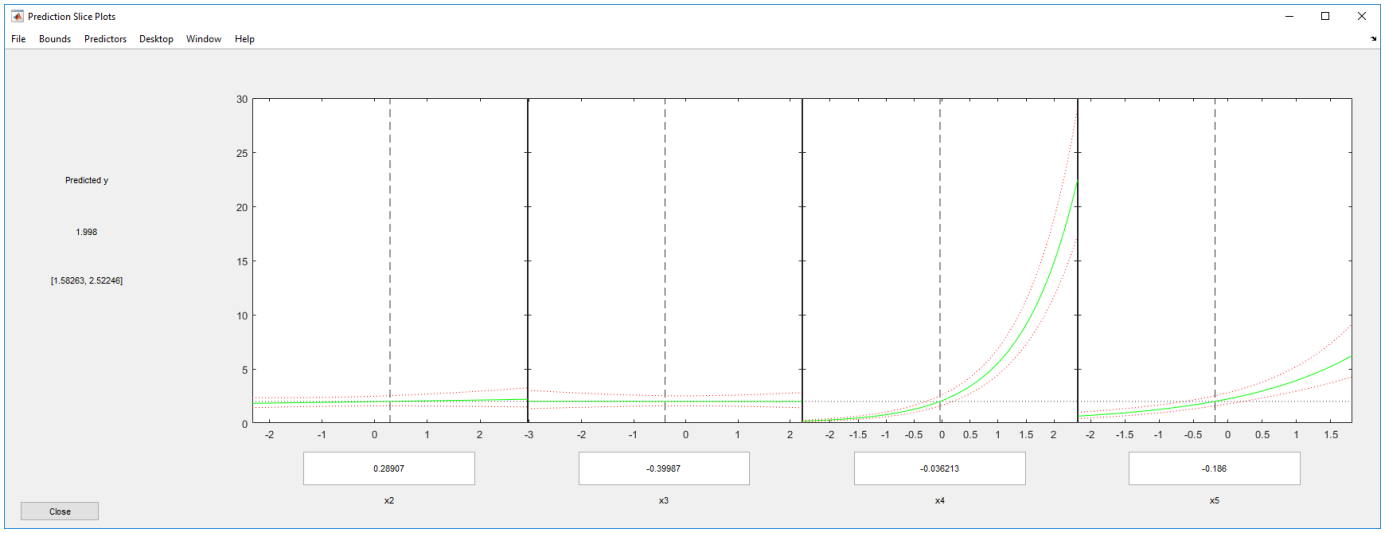
```
plotSlice(mdl)
```



The scale of the first predictor is overwhelming the plot. Disable it using the **Predictors** menu.







Now it is clear that predictors 2 and 3 have little to no effect.

You can drag the individual predictor values, which are represented by dashed blue vertical lines. You can also choose between simultaneous and non-simultaneous confidence bounds, which are

represented by dashed red curves. Dragging the predictor lines confirms that predictors 2 and 3 have little to no effect.

3 Remove the unnecessary predictors using either `removeTerms` or `step`. Using `step` can be safer, in case there is an unexpected importance to a term that becomes apparent after removing another term. However, sometimes `removeTerms` can be effective when `step` does not proceed. In this case, the two give identical results.

```
mdl1 = removeTerms(mdl,'x2 + x3')
```

```
mdl1 =

Generalized Linear regression model:
    log(y) ~ 1 + x1 + x4 + x5
    Distribution = Poisson

Estimated Coefficients:
                   Estimate    SE          tStat     pValue
    (Intercept)    0.17604     0.062215    2.8295       0.004662
    x1              1.9122     0.024638    77.614              0
    x4             0.98521     0.026393    37.328    5.6696e-305
    x5             0.61321     0.038435    15.955     2.6473e-57

100 observations, 96 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 4.97e+04, p-value = 0
```

```
mdl1 = step(mdl,'NSteps',5,'Upper','linear')
```

```
1. Removing x3, Deviance = 93.856, Chi2Stat = 0.00075551, PValue = 0.97807
2. Removing x2, Deviance = 96.333, Chi2Stat = 2.4769, PValue = 0.11553

mdl1 =

Generalized Linear regression model:
    log(y) ~ 1 + x1 + x4 + x5
    Distribution = Poisson

Estimated Coefficients:
                   Estimate    SE          tStat     pValue
    (Intercept)    0.17604     0.062215    2.8295       0.004662
    x1              1.9122     0.024638    77.614              0
    x4             0.98521     0.026393    37.328    5.6696e-305
    x5             0.61321     0.038435    15.955     2.6473e-57

100 observations, 96 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 4.97e+04, p-value = 0
```

Predict or Simulate Responses to New Data

There are three ways to use a linear model to predict the response to new data:

- “predict” on page 12-24
- “feval” on page 12-24
- “random” on page 12-25

predict

The `predict` method gives a prediction of the mean responses and, if requested, confidence bounds.

This example shows how to predict and obtain confidence intervals on the predictions using the `predict` method.

1. Create a model from some predictors in artificial data. The data do not use the second and third columns in X. So you expect the model not to show much dependence on these predictors. Construct the model stepwise to include the relevant predictors automatically.

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = stepwiseglm(X,y,...
    'constant','upper','linear','Distribution','poisson');
```

```
1. Adding x1, Deviance = 2515.02869, Chi2Stat = 47242.9622, PValue = 0
2. Adding x4, Deviance = 328.39679, Chi2Stat = 2186.6319, PValue = 0
3. Adding x5, Deviance = 96.3326, Chi2Stat = 232.0642, PValue = 2.114384e-52
```

2. Generate some new data, and evaluate the predictions from the data.

```
Xnew = randn(3,5) + repmat([1 2 3 4 5],[3,1]); % new data
[ynew,ynewci] = predict(mdl,Xnew)
```

```
ynew =

   1.0e+04 *

    0.1130
    1.7375
    3.7471

ynewci =

   1.0e+04 *

    0.0821    0.1555
    1.2167    2.4811
    2.8419    4.9407
```

feval

When you construct a model from a table or dataset array, `feval` is often more convenient for predicting mean responses than `predict`. However, `feval` does not provide confidence bounds.

This example shows how to predict mean responses using the `feval` method.

1. Create a model from some predictors in artificial data. The data do not use the second and third columns in X. So you expect the model not to show much dependence on these predictors. Construct the model stepwise to include the relevant predictors automatically.

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[2;1;.5]);
y = poissrnd(mu);
```

```
X = array2table(X); % create data table
y = array2table(y);
tbl = [X y];

mdl = stepwiseglm(tbl,...
    'constant','upper','linear','Distribution','poisson');
```

```
1. Adding x1, Deviance = 2515.02869, Chi2Stat = 47242.9622, PValue = 0
2. Adding x4, Deviance = 328.39679, Chi2Stat = 2186.6319, PValue = 0
3. Adding x5, Deviance = 96.3326, Chi2Stat = 232.0642, PValue = 2.114384e-52
```

2 Generate some new data, and evaluate the predictions from the data.

```
Xnew = randn(3,5) + repmat([1 2 3 4 5],[3,1]); % new data
ynew = feval(mdl,Xnew(:,1),Xnew(:,4),Xnew(:,5)) % only need predictors 1,4,5
```

```
ynew =

   1.0e+04 *

    0.1130
    1.7375
    3.7471
```

Equivalently,

```
ynew = feval(mdl,Xnew(:,[1 4 5])) % only need predictors 1,4,5
```

```
ynew =

   1.0e+04 *

    0.1130
    1.7375
    3.7471
```

random

The `random` method generates new random response values for specified predictor values. The distribution of the response values is the distribution used in the model. `random` calculates the mean of the distribution from the predictors, estimated coefficients, and link function. For distributions such as normal, the model also provides an estimate of the variance of the response. For the binomial and Poisson distributions, the variance of the response is determined by the mean; `random` does not use a separate “dispersion” estimate.

This example shows how to simulate responses using the `random` method.

1 Create a model from some predictors in artificial data. The data do not use the second and third columns in `X`. So you expect the model not to show much dependence on these predictors. Construct the model stepwise to include the relevant predictors automatically.

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = stepwiseglm(X,y,...
    'constant','upper','linear','Distribution','poisson');
```

```
1. Adding x1, Deviance = 2515.02869, Chi2Stat = 47242.9622, PValue = 0
2. Adding x4, Deviance = 328.39679, Chi2Stat = 2186.6319, PValue = 0
3. Adding x5, Deviance = 96.3326, Chi2Stat = 232.0642, PValue = 2.114384e-52
```

2 Generate some new data, and evaluate the predictions from the data.

```
Xnew = randn(3,5) + repmat([1 2 3 4 5],[3,1]); % new data
ysim = random(mdl,Xnew)

ysim =

         1111
        17121
        37457
```

The predictions from `random` are Poisson samples, so are integers.

3 Evaluate the `random` method again, the result changes.

```
ysim = random(mdl,Xnew)

ysim =

         1175
        17320
        37126
```

Share Fitted Models

The model display contains enough information to enable someone else to recreate the model in a theoretical sense. For example,

```
rng('default') % for reproducibility
X = randn(100,5);
mu = exp(X(:,[1 4 5])*[2;1;.5]);
y = poissrnd(mu);
mdl = stepwiseglm(X,y,...
    'constant','upper','linear','Distribution','poisson')

1. Adding x1, Deviance = 2515.02869, Chi2Stat = 47242.9622, PValue = 0
2. Adding x4, Deviance = 328.39679, Chi2Stat = 2186.6319, PValue = 0
3. Adding x5, Deviance = 96.3326, Chi2Stat = 232.0642, PValue = 2.114384e-52

mdl =

Generalized Linear regression model:
    log(y) ~ 1 + x1 + x4 + x5
    Distribution = Poisson

Estimated Coefficients:
                   Estimate    SE          tStat     pValue
    (Intercept)    0.17604     0.062215    2.8295       0.004662
    x1              1.9122     0.024638    77.614             0
    x4             0.98521     0.026393    37.328    5.6696e-305
    x5             0.61321     0.038435    15.955     2.6473e-57

100 observations, 96 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 4.97e+04, p-value = 0
```

You can access the model description programmatically, too. For example,

```
mdl.Coefficients.Estimate
```

```
ans =

    0.1760
    1.9122
    0.9852
    0.6132
```

```
mdl.Formula
```

```
ans =

log(y) ~ 1 + x1 + x4 + x5
```

Generalized Linear Model Workflow

This example shows how to fit a generalized linear model and analyze the results. A typical workflow involves these steps: import data, fit a generalized linear model, test its quality, modify the model to improve its quality, and make predictions based on the model. In this example, you use the Fisher iris data to compute the probability that a flower is in one of two classes.

Load Data

Load the Fisher iris data.

```
load fisheriris
```

Extract rows 51 to 150, which have the classification versicolor or virginica.

```
X = meas(51:end,:);
```

Create logical response variables that are `true` for versicolor and `false` for virginica.

```
y = strcmp('versicolor',species(51:end));
```

Fit Generalized Linear Model

Fit a binomial generalized linear model to the data.

```
mdl = fitglm(X,y,'linear','Distribution','binomial')
```

```
mdl =
Generalized linear regression model:
    logit(y) ~ 1 + x1 + x2 + x3 + x4
    Distribution = Binomial

Estimated Coefficients:
                   Estimate      SE       tStat      pValue
                   ________    ______    _______    ________

    (Intercept)     42.638     25.708     1.6586    0.097204
    x1              2.4652     2.3943     1.0296     0.30319
    x2              6.6809     4.4796     1.4914     0.13585
    x3             -9.4294     4.7372    -1.9905    0.046537
    x4             -18.286     9.7426    -1.8769    0.060529

100 observations, 95 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 127, p-value = 1.95e-26
```

According to the model display, some *p*-values in the `pValue` column are not small, which implies that you can simplify the model.

Examine and Improve Model

Determine if 95% confidence intervals for the coefficients include 0. If so, you can remove the model terms with those intervals.

```
confint = coefCI(mdl)
```

```
confint = 5×2
```

```
   -8.3984   93.6740
   -2.2881    7.2185
   -2.2122   15.5739
  -18.8339   -0.0248
  -37.6277    1.0554
```

Only the fourth predictor x3 has a coefficient whose confidence interval does not include 0.

The coefficients of x1 and x2 have large *p*-values and their 95% confidence intervals include 0. Test whether both coefficients can be zero. Specify a hypothesis matrix to select the coefficients of x1 and x2.

```
M = [0 1 0 0 0
     0 0 1 0 0];
p = coefTest(mdl,M)
```

```
p = 0.1442
```

The *p*-value is approximately 0.14, which is not small. Remove x1 and x2 from the model.

```
mdl1 = removeTerms(mdl,'x1 + x2')
```

```
mdl1 =
Generalized linear regression model:
    logit(y) ~ 1 + x3 + x4
    Distribution = Binomial

Estimated Coefficients:
                   Estimate      SE       tStat       pValue
                   ________    ______    _______    __________

    (Intercept)     45.272     13.612      3.326    0.00088103
    x3             -5.7545     2.3059    -2.4956      0.012576
    x4             -10.447     3.7557    -2.7816     0.0054092

100 observations, 97 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 118, p-value = 2.3e-26
```

Alternatively, you can identify important predictors using stepwiseglm.

```
mdl2 = stepwiseglm(X,y,'constant','Distribution','binomial','Upper','linear')
```

```
1. Adding x4, Deviance = 33.4208, Chi2Stat = 105.2086, PValue = 1.099298e-24
2. Adding x3, Deviance = 20.5635, Chi2Stat = 12.8573, PValue = 0.000336166
3. Adding x2, Deviance = 13.2658, Chi2Stat = 7.29767, PValue = 0.00690441

mdl2 =
Generalized linear regression model:
    logit(y) ~ 1 + x2 + x3 + x4
    Distribution = Binomial

Estimated Coefficients:
                   Estimate      SE       tStat      pValue
                   ________    ______    _______    ________

    (Intercept)     50.527     23.995     2.1057    0.035227
```

```
    x2              8.3761     4.7612     1.7592    0.078536
    x3             -7.8745     3.8407    -2.0503    0.040334
    x4              -21.43     10.707    -2.0014     0.04535

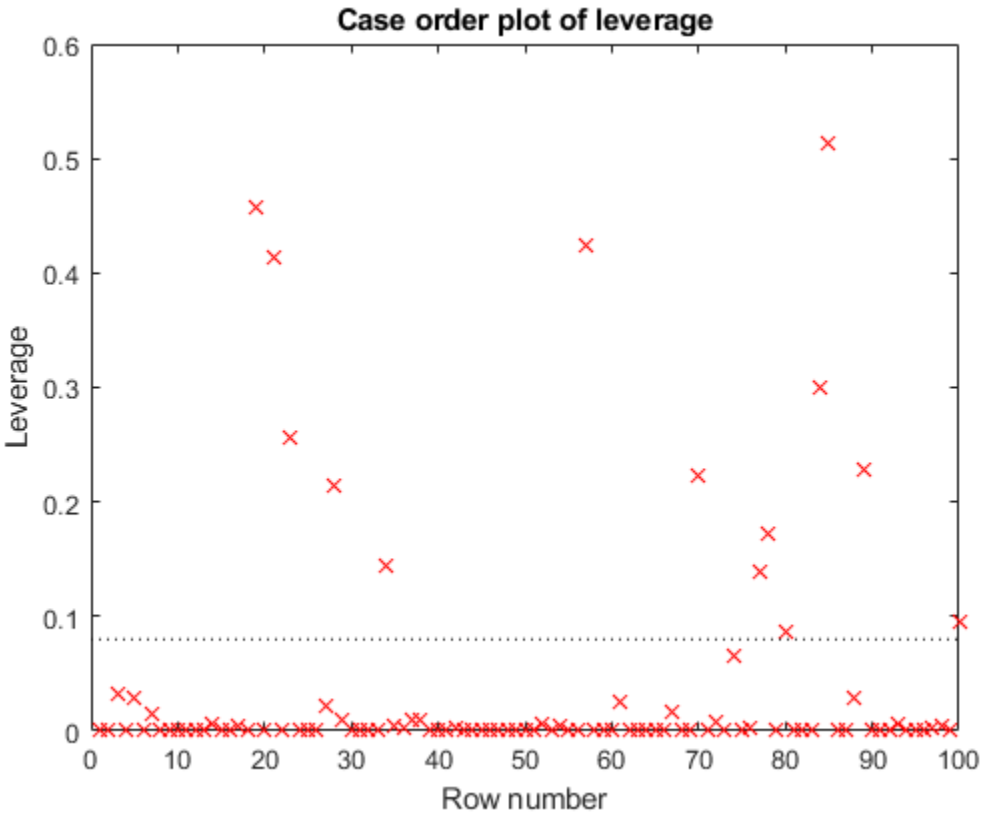
100 observations, 96 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 125, p-value = 5.4e-27
```

The *p*-value (`pValue`) for `x2` in the coefficient table is greater than 0.05, but `stepwiseglm` includes `x2` in the model because the *p*-value (`PValue`) for adding `x2` is smaller than 0.05. The `stepwiseglm` function computes `PValue` using the fits with and without `x2`, whereas the function computes `pValue` based on an approximate standard error computed only from the final model. Therefore, `PValue` is more reliable than `pValue`.

Identify Outliers

Examine a leverage plot to look for influential outliers.

```
plotDiagnostics(mdl2,'leverage')
```



An observation can be considered an outlier if its leverage substantially exceeds `p/n`, where `p` is the number of coefficients and `n` is the number of observations. The dotted reference line is a recommended threshold, computed by `2*p/n`, which corresponds to 0.08 in this plot. Some observations have leverage values larger than `10*p/n` (that is, 0.40). Identify these observation points.

```
idxOutliers = find(mdl2.Diagnostics.Leverage > 10*mdl2.NumCoefficients/mdl2.NumObservations)
```

```
idxOutliers = 4×1

    19
    21
    57
    85
```

See if the model coefficients change when you fit a model excluding these points.

```
oldCoeffs = mdl2.Coefficients.Estimate;
mdl3 = fitglm(X,y,'linear','Distribution','binomial', ...
    'PredictorVars',2:4,'Exclude',idxOutliers);
newCoeffs = mdl3.Coefficients.Estimate;
disp([oldCoeffs newCoeffs])
```

```
   50.5268   44.0085
    8.3761    5.6361
   -7.8745   -6.1145
  -21.4296  -18.1236
```

The model coefficients in `mdl3` are different from those in mdl2. This result implies that the responses at the high-leverage points are not consistent with the predicted values from the reduced model.

Predict Probability of Being Versicolor

Use `mdl3` to predict the probability that a flower with average measurements is versicolor. Generate confidence intervals for the prediction.

```
[newf,newc] = predict(mdl3,mean(X))
```

```
newf = 0.4558
```

```
newc = 1×2

    0.1234    0.8329
```

The model gives almost a 46% probability that the average flower is versicolor, with a wide confidence interval.

Lasso Regularization of Generalized Linear Models

In this section...

What is Generalized Linear Model Lasso Regularization?

Lasso is a regularization technique. Use `lassoglm` to:

- Reduce the number of predictors in a generalized linear model.
- Identify important predictors.
- Select among redundant predictors.
- Produce shrinkage estimates with potentially lower predictive errors than ordinary least squares.

Elastic net is a related technique. Use it when you have several highly correlated variables. `lassoglm` provides elastic net regularization when you set the `Alpha` name-value pair to a number strictly between `0` and `1`.

For details about lasso and elastic net computations and algorithms, see “Generalized Linear Model Lasso and Elastic Net” on page 12-32. For a discussion of generalized linear models, see “What Are Generalized Linear Models?” on page 12-9.

Generalized Linear Model Lasso and Elastic Net

Overview of Lasso and Elastic Net

Lasso is a regularization technique for estimating generalized linear models. Lasso includes a penalty term that constrains the size of the estimated coefficients. Therefore, it resembles “Ridge Regression” on page 11-109. Lasso is a shrinkage estimator: it generates coefficient estimates that are biased to be small. Nevertheless, a lasso estimator can have smaller error than an ordinary maximum likelihood estimator when you apply it to new data.

Unlike ridge regression, as the penalty term increases, the lasso technique sets more coefficients to zero. This means that the lasso estimator is a smaller model, with fewer predictors. As such, lasso is an alternative to stepwise regression on page 11-99 and other model selection and dimensionality reduction techniques.

Elastic net is a related technique. Elastic net is akin to a hybrid of ridge regression and lasso regularization. Like lasso, elastic net can generate reduced models by generating zero-valued coefficients. Empirical studies suggest that the elastic net technique can outperform lasso on data with highly correlated predictors.

Definition of Lasso for Generalized Linear Models

For a nonnegative value of λ, `lassoglm` solves the problem

$$\min_{\beta_0,\beta}\left(\frac{1}{N}\text{Deviance}(\beta_0,\beta)+\lambda\sum_{j=1}^{p}\left|\beta_j\right|\right).$$

- The function Deviance in this equation is the deviance of the model fit to the responses using the intercept β_0 and the predictor coefficients β. The formula for Deviance depends on the `distr` parameter you supply to `lassoglm`. Minimizing the λ-penalized deviance is equivalent to maximizing the λ-penalized loglikelihood.
- N is the number of observations.
- λ is a nonnegative regularization parameter corresponding to one value of `Lambda`.
- The parameters β_0 and β are a scalar and a vector of length p, respectively.

As λ increases, the number of nonzero components of β decreases.

The lasso problem involves the L^1 norm of β, as contrasted with the elastic net algorithm.

Definition of Elastic Net for Generalized Linear Models

For α strictly between 0 and 1, and nonnegative λ, elastic net solves the problem

$$\min_{\beta_0,\beta}\left(\frac{1}{N}\text{Deviance}(\beta_0,\beta)+\lambda P_\alpha(\beta)\right),$$

where

$$P_\alpha(\beta)=\frac{(1-\alpha)}{2}\|\beta\|_2^2+\alpha\|\beta\|_1=\sum_{j=1}^{p}\left(\frac{(1-\alpha)}{2}\beta_j^2+\alpha\left|\beta_j\right|\right).$$

Elastic net is the same as lasso when $\alpha = 1$. For other values of α, the penalty term $P_\alpha(\beta)$ interpolates between the L^1 norm of β and the squared L^2 norm of β. As α shrinks toward 0, elastic net approaches `ridge` regression.

Regularize Poisson Regression

This example shows how to identify and remove redundant predictors from a generalized linear model.

Create data with 20 predictors, and Poisson responses using just three of the predictors, plus a constant.

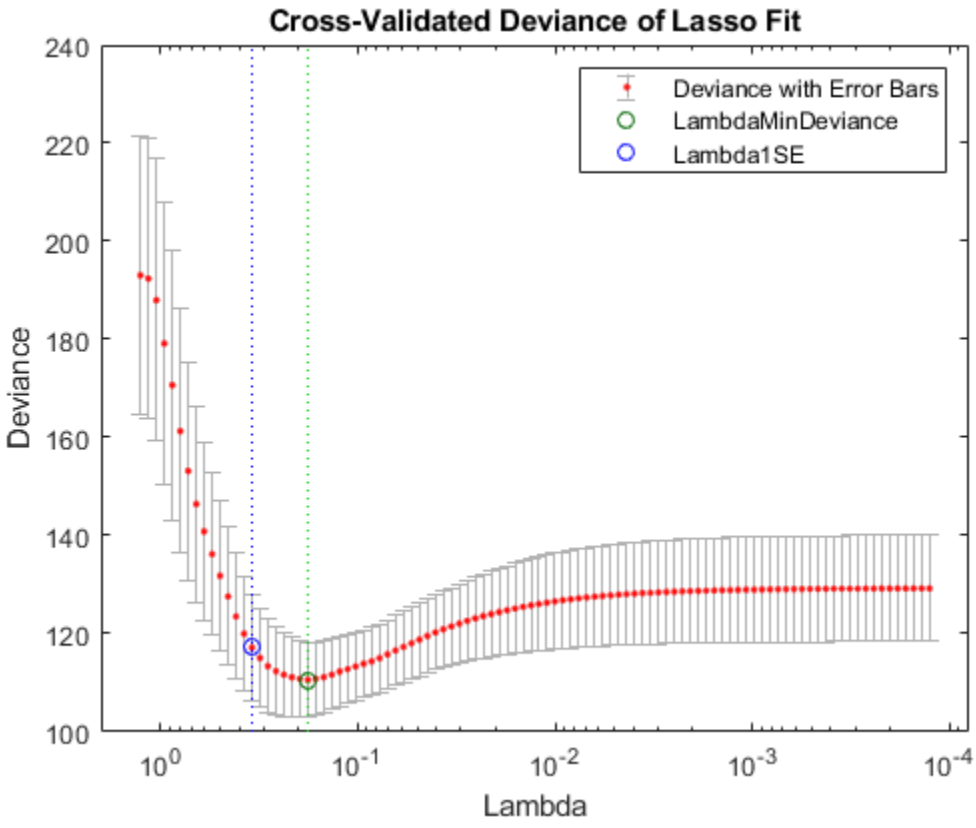
```
rng('default') % for reproducibility
X = randn(100,20);
mu = exp(X(:,[5 10 15])*[.4;.2;.3] + 1);
y = poissrnd(mu);
```

Construct a cross-validated lasso regularization of a Poisson regression model of the data.

```
[B,FitInfo] = lassoglm(X,y,'poisson','CV',10);
```

Examine the cross-validation plot to see the effect of the `Lambda` regularization parameter.

```
lassoPlot(B,FitInfo,'plottype','CV');
legend('show') % show legend
```



The green circle and dashed line locate the `Lambda` with minimal cross-validation error. The blue circle and dashed line locate the point with minimal cross-validation error plus one standard deviation.

Find the nonzero model coefficients corresponding to the two identified points.

```
minpts = find(B(:,FitInfo.IndexMinDeviance))
```

```
minpts = 7×1

     3
     5
     6
    10
    11
    15
    16
```

```
min1pts = find(B(:,FitInfo.Index1SE))
```

```
min1pts = 3×1

     5
    10
    15
```

The coefficients from the minimal plus one standard error point are exactly those coefficients used to create the data.

Find the values of the model coefficients at the minimal plus one standard error point.

```
B(min1pts,FitInfo.Index1SE)
```

```
ans = 3×1

    0.2903
    0.0789
    0.2081
```

The values of the coefficients are, as expected, smaller than the original `[0.4,0.2,0.3]`. Lasso works by "shrinkage," which biases predictor coefficients toward zero.

The constant term is in the `FitInfo.Intercept` vector.

```
FitInfo.Intercept(FitInfo.Index1SE)
```

```
ans = 1.0879
```

The constant term is near 1, which is the value used to generate the data.

Regularize Logistic Regression

This example shows how to regularize binomial regression. The default (canonical) link function for binomial regression is the logistic function.

Step 1. Prepare the data.

Load the `ionosphere` data. The response `Y` is a cell array of `'g'` or `'b'` characters. Convert the cells to logical values, with `true` representing `'g'`. Remove the first two columns of `X` because they have some awkward statistical properties, which are beyond the scope of this discussion.

```
load ionosphere
Ybool = strcmp(Y,'g');
X = X(:,3:end);
```

Step 2. Create a cross-validated fit.

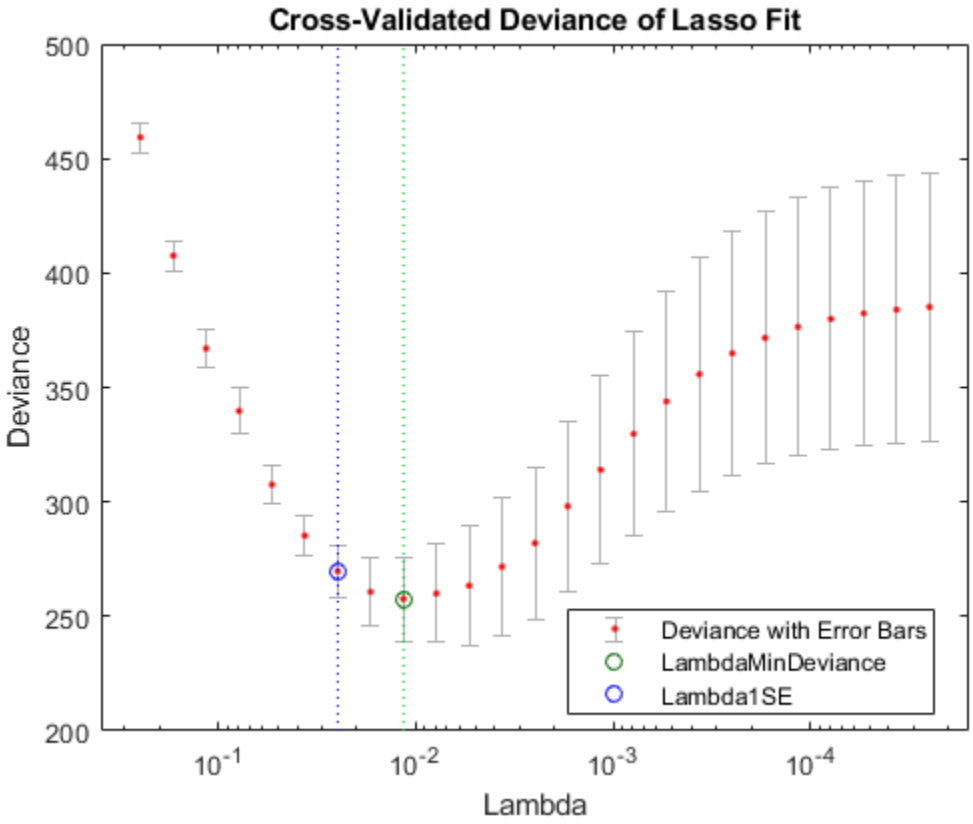
Construct a regularized binomial regression using 25 `Lambda` values and 10-fold cross validation. This process can take a few minutes.

```
rng('default') % for reproducibility
[B,FitInfo] = lassoglm(X,Ybool,'binomial',...
    'NumLambda',25,'CV',10);
```

Step 3. Examine plots to find appropriate regularization.

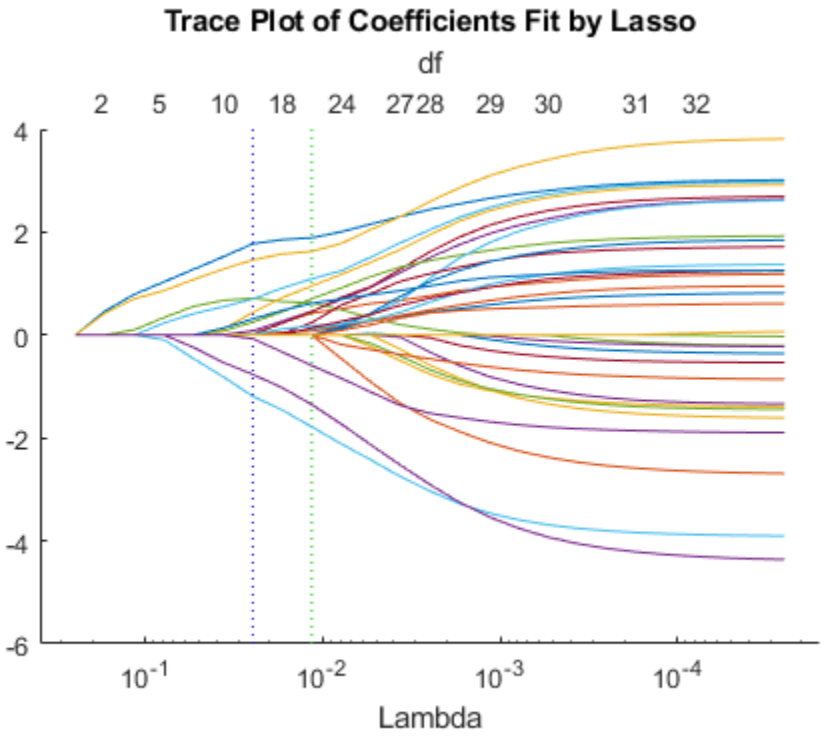
`lassoPlot` can give both a standard trace plot and a cross-validated deviance plot. Examine both plots.

```
lassoPlot(B,FitInfo,'PlotType','CV');
legend('show','Location','best') % show legend
```



The plot identifies the minimum-deviance point with a green circle and dashed line as a function of the regularization parameter `Lambda`. The blue circled point has minimum deviance plus no more than one standard deviation.

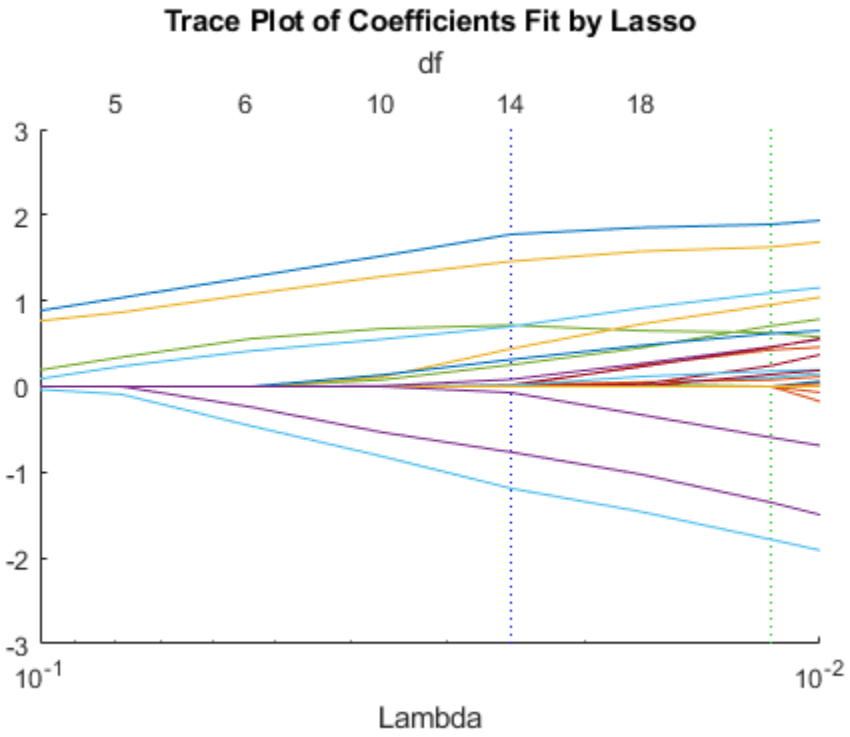
```
lassoPlot(B,FitInfo,'PlotType','Lambda','XScale','log');
```



The trace plot shows nonzero model coefficients as a function of the regularization parameter `Lambda`. Because there are 32 predictors and a linear model, there are 32 curves. As `Lambda` increases to the left, `lassoglm` sets various coefficients to zero, removing them from the model.

The trace plot is somewhat compressed. Zoom in to see more detail.

```
xlim([.01 .1])
ylim([-3 3])
```



As `Lambda` increases toward the left side of the plot, fewer nonzero coefficients remain.

Find the number of nonzero model coefficients at the `Lambda` value with minimum deviance plus one standard deviation point. The regularized model coefficients are in column `FitInfo.Index1SE` of the `B` matrix.

```
indx = FitInfo.Index1SE;
B0 = B(:,indx);
nonzeros = sum(B0 ~= 0)
```

```
nonzeros =

    14
```

When you set `Lambda` to `FitInfo.Index1SE`, `lassoglm` removes over half of the 32 original predictors.

Step 4. Create a regularized model.

The constant term is in the `FitInfo.Index1SE` entry of the `FitInfo.Intercept` vector. Call that value `cnst`.

The model is logit(mu) = log(mu/(1 - mu)) = `X*B0 + cnst` . Therefore, for predictions, mu = `exp(X*B0 + cnst)/(1+exp(x*B0 + cnst))`.

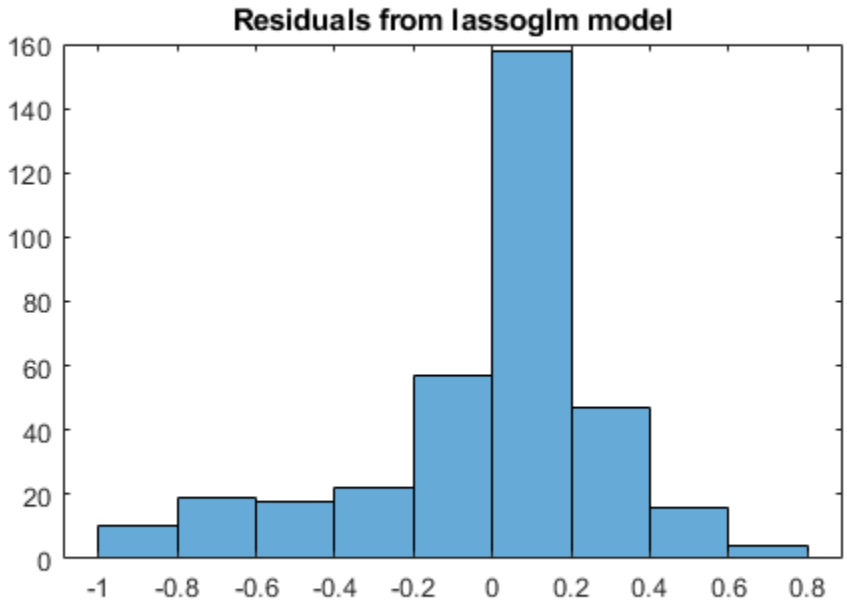
The `glmval` function evaluates model predictions. It assumes that the first model coefficient relates to the constant term. Therefore, create a coefficient vector with the constant term first.

```
cnst = FitInfo.Intercept(indx);
B1 = [cnst;B0];
```

Step 5. Examine residuals.

Plot the training data against the model predictions for the regularized `lassoglm` model.

```
preds = glmval(B1,X,'logit');
histogram(Ybool - preds) % plot residuals
title('Residuals from lassoglm model')
```



Step 6. Alternative: Use identified predictors in a least-squares generalized linear model.

Instead of using the biased predictions from the model, you can make an unbiased model using just the identified predictors.

```
predictors = find(B0); % indices of nonzero predictors
mdl = fitglm(X,Ybool,'linear',...
    'Distribution','binomial','PredictorVars',predictors)
```

```
mdl =

Generalized linear regression model:
```

```
    y ~ [Linear formula with 15 terms in 14 predictors]
    Distribution = Binomial

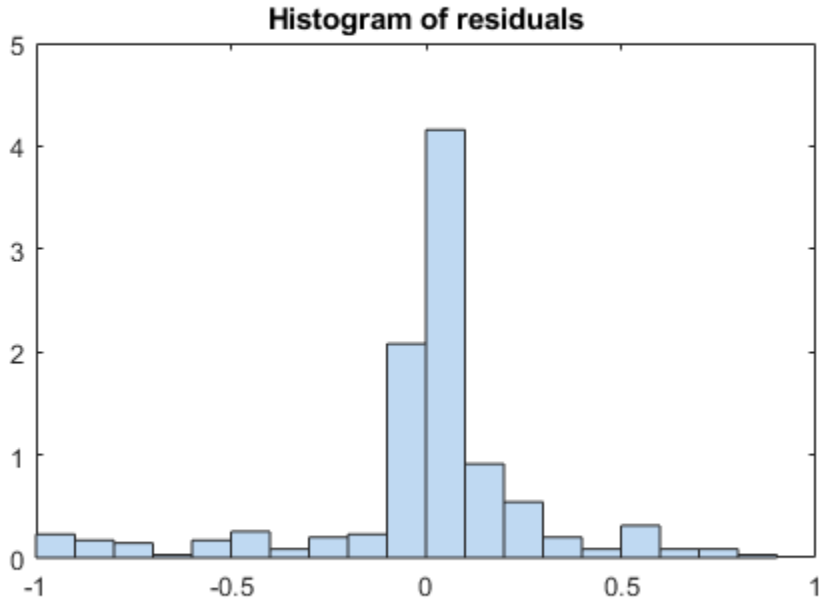
Estimated Coefficients:
                   Estimate       SE        tStat        pValue
                   ________    _______    ________    __________

    (Intercept)      -2.9367    0.50926     -5.7666    8.0893e-09
    x1                 2.492    0.60795       4.099    4.1502e-05
    x3                2.5501    0.63304      4.0284     5.616e-05
    x4               0.48816    0.50336      0.9698       0.33215
    x5                0.6158    0.62192     0.99015        0.3221
    x6                 2.294     0.5421      4.2317    2.3198e-05
    x7               0.77842    0.57765      1.3476        0.1778
    x12               1.7808    0.54316      3.2786     0.0010432
    x16            -0.070993    0.50515    -0.14054       0.88823
    x20              -2.7767    0.55131     -5.0365    4.7402e-07
    x24               2.0212    0.57639      3.5067    0.00045372
    x25              -2.3796    0.58274     -4.0835    4.4363e-05
    x27              0.79564    0.55904      1.4232       0.15467
    x29               1.2689    0.55468      2.2876      0.022162
    x32              -1.5681    0.54336     -2.8859     0.0039035

351 observations, 336 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 262, p-value = 1e-47
```

Plot the residuals of the model.

```
plotResiduals(mdl)
```



As expected, residuals from the least-squares model are slightly smaller than those of the regularized model. However, this does not mean that `mdl` is a better predictor for new data.

Regularize Wide Data in Parallel

This example shows how to regularize a model with many more predictors than observations. *Wide data* is data with more predictors than observations. Typically, with wide data you want to identify important predictors. Use `lassoglm` as an exploratory or screening tool to select a smaller set of variables to prioritize your modeling and research. Use parallel computing to speed up cross validation.

Load the `ovariancancer` data. This data has 216 observations and 4000 predictors in the `obs` workspace variable. The responses are binary, either `'Cancer'` or `'Normal'`, in the `grp` workspace variable. Convert the responses to binary for use in `lassoglm`.

```
load ovariancancer
y = strcmp(grp,'Cancer');
```

Set options to use parallel computing. Prepare to compute in parallel using `parpool`.

```
opt = statset('UseParallel',true);
parpool()
```

```
Starting parallel pool (parpool) using the 'local' profile ...
Connected to the parallel pool (number of workers: 6).

ans =

 ProcessPool with properties:

            Connected: true
           NumWorkers: 6
              Cluster: local
        AttachedFiles: {}
    AutoAddClientPath: true
          IdleTimeout: 30 minutes (30 minutes remaining)
          SpmdEnabled: true
```

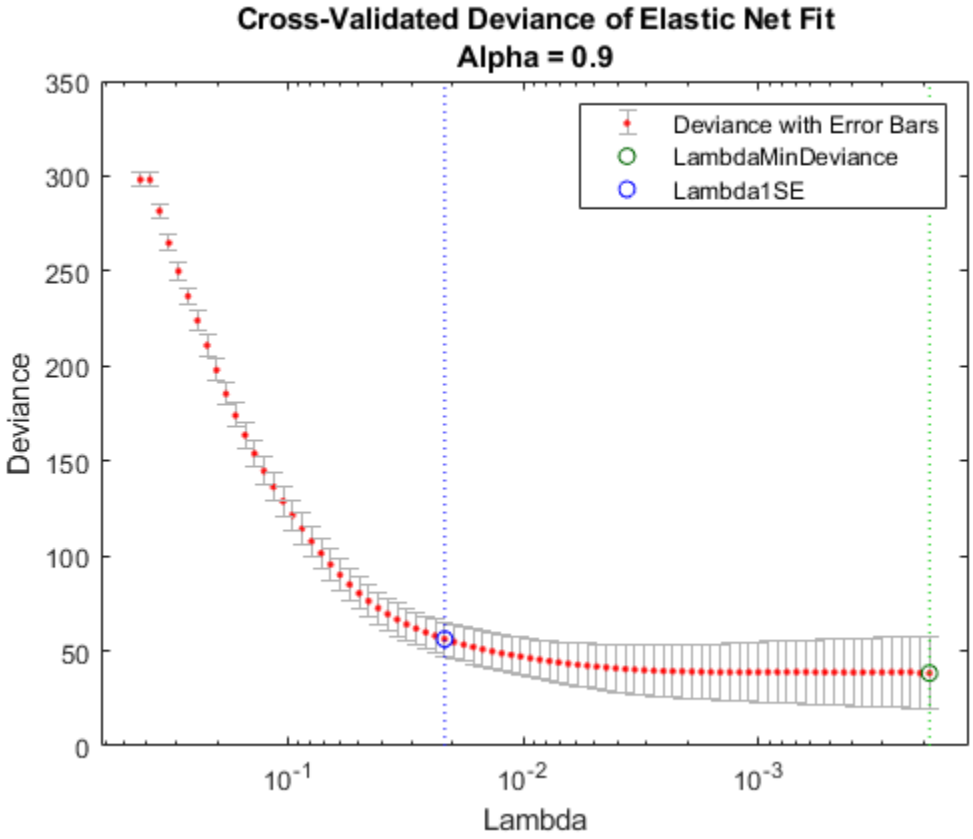
Fit a cross-validated set of regularized models. Use the `Alpha` parameter to favor retaining groups of highly correlated predictors, as opposed to eliminating all but one member of the group. Commonly, you use a relatively large value of `Alpha`.

```
rng('default') % For reproducibility
tic
[B,S] = lassoglm(obs,y,'binomial','NumLambda',100, ...
  'Alpha',0.9,'LambdaRatio',1e-4,'CV',10,'Options',opt);
toc
```

```
Elapsed time is 90.892114 seconds.
```

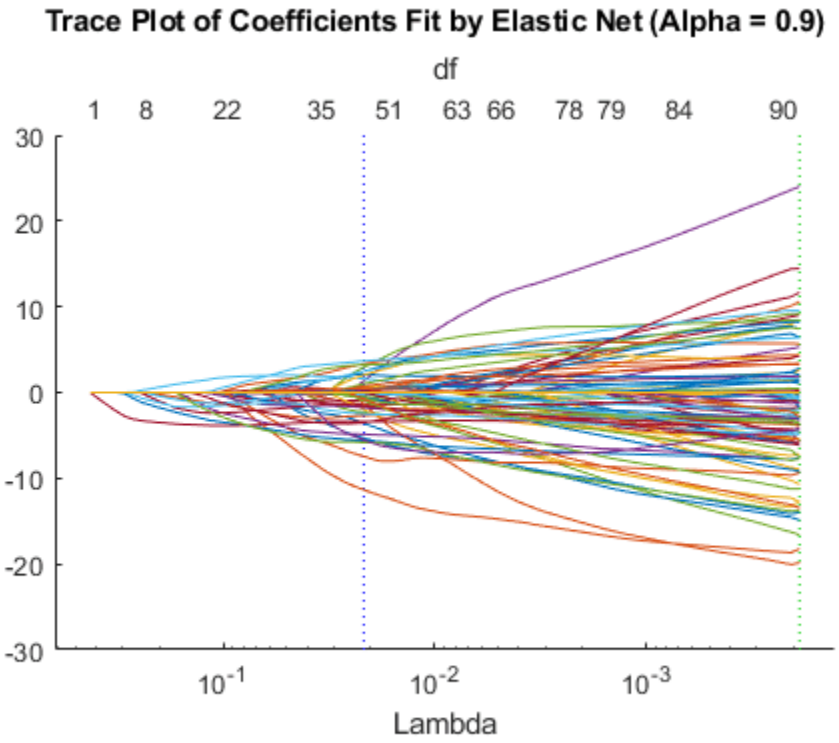
Examine cross-validation plot.

```
lassoPlot(B,S,'PlotType','CV');
legend('show') % Show legend
```



Examine trace plot.

```
lassoPlot(B,S,'PlotType','Lambda','XScale','log')
```



The right (green) vertical dashed line represents the `Lambda` providing the smallest cross-validated deviance. The left (blue) dashed line has the minimal deviance plus no more than one standard deviation. This blue line has many fewer predictors:

```
[S.DF(S.Index1SE) S.DF(S.IndexMinDeviance)]
```

```
ans = 1×2

    50    89
```

You asked `lassoglm` to fit using 100 different `Lambda` values. How many did it use?

```
size(B)
```

```
ans = 1×2

        4000          84
```

`lassoglm` stopped after 84 values because the deviance was too small for small `Lambda` values. To avoid overfitting, `lassoglm` halts when the deviance of the fitted model is too small compared to the deviance in the binary responses, ignoring the predictor variables.

You can force `lassoglm` to include more terms by using the `'Lambda'` name-value pair argument. For example, define a set of `Lambda` values that additionally includes three values smaller than the values in `S.Lambda`.

```
minLambda = min(S.Lambda);
explicitLambda = [minLambda*[.1 .01 .001] S.Lambda];
```

Specify `'Lambda',explicitLambda` when you call the `lassoglm` function. `lassoglm` halts when the deviance of the fitted model is too small, even though you explicitly provide a set of `Lambda` values.

To save time, you can use:

- Fewer `Lambda`, meaning fewer fits
- Fewer cross-validation folds
- A larger value for `LambdaRatio`

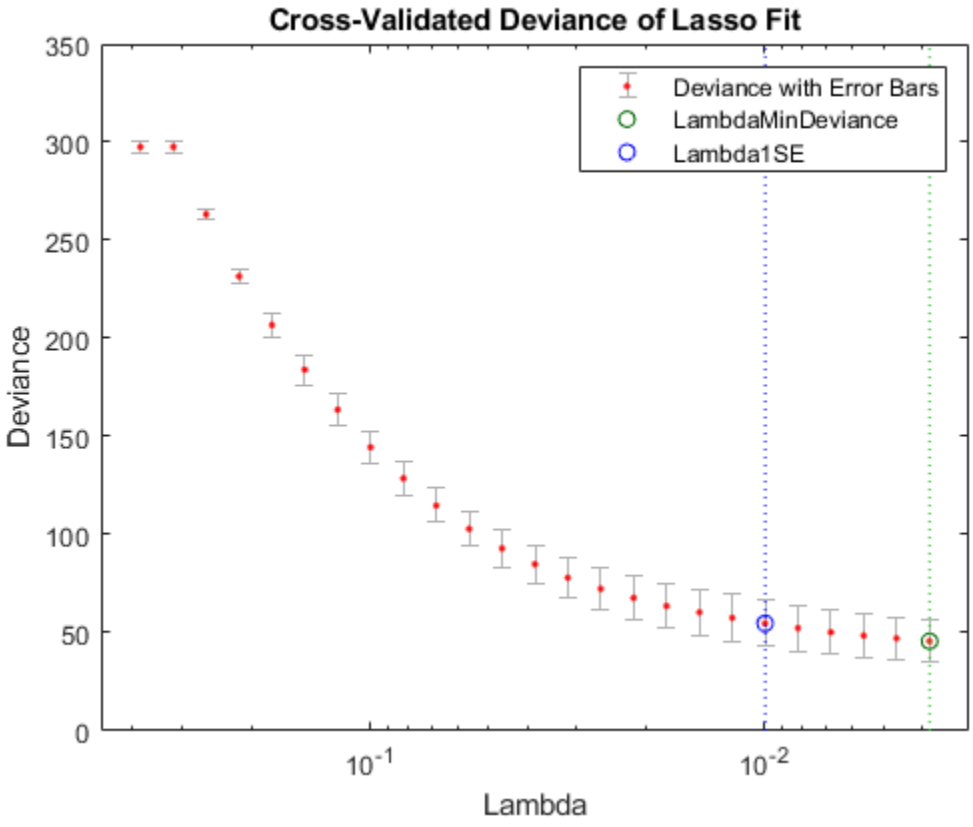
Use serial computation and all three of these time-saving methods:

```
tic
[Bquick,Squick] = lassoglm(obs,y,'binomial','NumLambda',25,...
    'LambdaRatio',1e-2,'CV',5);
toc
```

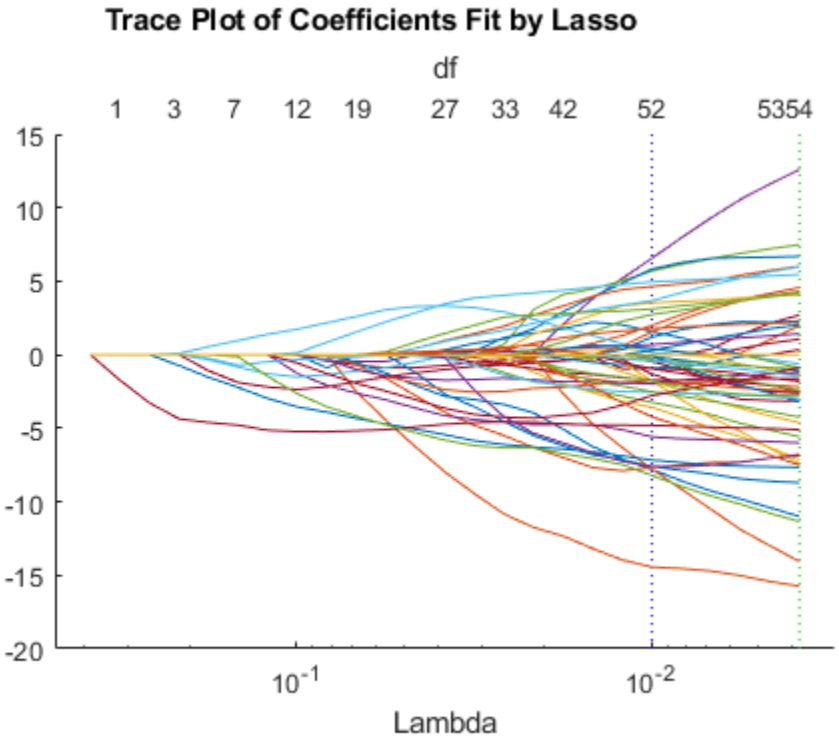
```
Elapsed time is 16.517331 seconds.
```

Graphically compare the new results to the first results.

```
lassoPlot(Bquick,Squick,'PlotType','CV');
legend('show') % Show legend
```



```
lassoPlot(Bquick,Squick,'PlotType','Lambda','XScale','log')
```



The number of nonzero coefficients in the lowest plus one standard deviation model is around 50, similar to the first computation.

Generalized Linear Mixed-Effects Models

In this section...

What Are Generalized Linear Mixed-Effects Models?

Generalized linear mixed-effects (GLME) models describe the relationship between a response variable and independent variables using coefficients that can vary with respect to one or more grouping variables, for data with a response variable distribution other than normal. You can think of GLME models as extensions of generalized linear models on page 12-9 (GLM) for data that are collected and summarized in groups. Alternatively, you can think of GLME models as a generalization of linear mixed-effects models on page 11-131 (LME) for data where the response variable is not normally distributed.

A mixed-effects model consists of fixed-effects and random-effects terms. Fixed-effects terms are usually the conventional linear regression part of the model. Random-effects terms are associated with individual experimental units drawn at random from a population, and account for variations between groups that might affect the response. The random effects have prior distributions, whereas the fixed effects do not.

GLME Model Equations

The standard form of a generalized linear mixed-effects model is

$$y_i | b \sim Distr\left(\mu_i, \frac{\sigma^2}{w_i}\right)$$

$$g(\mu) = X\beta + Zb + \delta\,,$$

where

- y is an n-by-1 response vector, and y_i is its ith element.
- b is the random-effects vector.
- $Distr$ is a specified conditional distribution of y given b.
- μ is the conditional mean of y given b, and μ_i is its ith element.
- σ^2 is the dispersion parameter.
- w is the effective observation weight vector, and w_i is the weight for observation i.

  - For a binomial distribution, the effective observation weight is equal to the prior weight specified using the `'Weights'` name-value pair argument in `fitglme`, multiplied by the binomial size specified using the `'BinomialSize'` name-value pair argument.
  - For all other distributions, the effective observation weight is equal to the prior weight specified using the `'Weights'` name-value pair argument in `fitglme`.
- $g(\mu)$ is a link function that defines the relationship between the mean response μ and the linear combination of the predictors.
- X is an n-by-p fixed-effects design matrix.
- β is a p-by-1 fixed-effects vector.
- Z is an n-by-q random-effects design matrix.
- b is a q-by-1 random-effects vector.
- δ is a model offset vector.

The model for the mean response μ is

$$\mu = g^{-1}(\eta),$$

where g^{-1} is inverse of the link function $g(\mu)$, and $\widehat{\eta}_{ME}$ is the linear predictor of the fixed and random effects of the generalized linear mixed-effects model

$$\eta = X\beta + Zb + \delta .$$

A GLME model is parameterized by β, θ, and σ^2.

The assumptions for generalized linear mixed-effects models are:

- The random effects vector b has the prior distribution:

  $$b \left| \sigma^2, \theta \sim N\left(0, \sigma^2 D(\theta)\right), \right.$$

  where σ^2 is the dispersion parameter, and D is a symmetric and positive semidefinite matrix parameterized by an unconstrained parameter vector θ.
- The observations y_i are conditionally independent given b.

Prepare Data for Model Fitting

To fit a GLME model to your data, use `fitglme`. Format your input data using the `table` data type. Each row of the table represents one observation, and each column represents one predictor variable. For more information on creating and using `table`, see “Create and Work with Tables”.

Input data can include continuous and grouping variables. `fitglme` assumes that predictors using the following data types are categorical:

- Logical
- Categorical
- Character vector or character array
- String array
- Cell array of character vectors

If the input data table contains any `NaN` values, then `fitglme` excludes that entire row of data from the fit. To exclude additional rows of data, you can use the `'Exclude'` name-value pair argument of `fitglme` when fitting the model.

Choose a Distribution Type for the Model

GLME models are used when the response data does not follow a normal distribution. Therefore, when fitting a model using `fitglme`, you must specify the response distribution type using the `'Distribution'` name-value pair argument. Often, the type of response data suggests the appropriate distribution type for the model.

Type of Response Data	Suggested Response Distribution Type
Any real number	`'Normal'`
Any positive number	`'Gamma'` or `'InverseGaussian'`
Any nonnegative integer	`'Poisson'`
Integer from 0 to *n*, where *n* is a fixed positive value	`'Binomial'`

Choose a Link Function for the Model

GLME models use a link function, *g*, to map the relationship between the mean response and the linear combination of the predictors. By default, `fitglme` uses a predefined, commonly accepted link function based on the specified distribution of the response data, as shown in the following table. However, you can specify a different link function from the list of predefined functions, or define your own, using the `'Link'` name-value pair argument of `fitglme`.

Value	Description
`'comploglog'`	`g(mu) = log(-log(1-mu))`
`'identity'`	`g(mu) = mu` Canonical link for the normal distribution.
`'log'`	`g(mu) = log(mu)` Canonical link for the Poisson distribution.
`'logit'`	`g(mu) = log(mu/(1-mu))` Canonical link for the binomial distribution.
`'loglog'`	`g(mu) = log(-log(mu))`
`'probit'`	`g(mu) = norminv(mu)`
`'reciprocal'`	`g(mu) = mu.^(-1)`
Scalar value `P`	`g(mu) = mu.^P`

Value	Description
Structure `S`	A structure containing four fields whose values are function handles: • `S.Link` — Link function • `S.Derivative` — Derivative • `S.SecondDerivative` — Second derivative • `S.Inverse` — Inverse of link If `'FitMethod'` is `'MPL'` or `'REMPL'`, or if `S` represents a canonical link for the specified distribution, you can omit the specification of `S.SecondDerivative`.

When fitting a model to data, `fitglme` uses the canonical link function by default.

Distribution	Default Link Function
`'Normal'`	`'identity'`
`'Binomial'`	`'logit'`
`'Poisson'`	`'log'`
`'Gamma'`	`-1`
`'InverseGaussian'`	`-2`

The link functions `'comploglog'`, `'loglog'`, and `'probit'` are mainly useful for binomial models.

Specify the Model Formula

Model specification for `fitglme` uses Wilkinson notation, which is a character vector or string scalar of the form `'y ~ terms'`, where `y` is the response variable name, and `terms` is written in the following notation.

Wilkinson Notation	Factors in Standard Notation
`1`	Constant (intercept) term
`X^k`, where `k` is a positive integer	$X, X^2, ..., X^k$
`X1 + X2`	`X1`, `X2`
`X1*X2`	`X1`, `X2`, `X1.*X2 (element-wise multiplication of X1 and X2)`
`X1:X2`	`X1.*X2` only
`- X2`	Do not include `X2`
`X1*X2 + X3`	`X1`, `X2`, `X3`, `X1*X2`
`X1 + X2 + X3 + X1:X2`	`X1`, `X2`, `X3`, `X1*X2`
`X1*X2*X3 - X1:X2:X3`	`X1`, `X2`, `X3`, `X1*X2`, `X1*X3`, `X2*X3`
`X1*(X2 + X3)`	`X1`, `X2`, `X3`, `X1*X2`, `X1*X3`

Formulas include a constant (intercept) term by default. To exclude a constant term from the model, include –1 in the formula.

For generalized linear mixed-effects models, the formula specification is of the form `'y ~ fixed + (random1|grouping1) + ... + (randomR|groupingR)'`, where `fixed` and `random` contain the fixed-effects and the random-effects terms, respectively.

Suppose the input data table contains the following:

- A response variable, `y`
- Predictor variables, `X1`, `X2`, ..., `XJ`, where *J* is the total number of predictor variables (including continuous and grouping variables).
- Grouping variables, `g1`, `g2`, ..., `gR`, where *R* is the number of grouping variables.

The grouping variables in `XJ` and `gR` can be categorical, logical, character arrays, string arrays, or cell arrays of character vectors.

Then, in a formula of the form `'y ~ fixed + (random1|g1) + ... + (randomR|gR)'`, the term `fixed` corresponds to a specification of the fixed-effects design matrix `X`, `random1` is a specification of the random-effects design matrix `Z1` corresponding to grouping variable `g1`, and similarly `randomR` is a specification of the random-effects design matrix `ZR` corresponding to grouping variable `gR`. You can express the `fixed` and `random` terms using Wilkinson notation as follows.

Formula	Description
`'y ~ X1 + X2'`	Fixed effects for the intercept, `X1`, and `X2`. This formula is equivalent to `'y ~ 1 + X1 + X2'`.
`'y ~ -1 + X1 + X2'`	No intercept, with fixed effects for `X1` and `X2`. The implicit intercept term is suppressed by including `-1`.
`'y ~ 1 + (1 | g1)'`	A fixed effect for the intercept, plus a random effect for the intercept for each level of the grouping variable `g1`.
`'y ~ X1 + (1 | g1)'`	Random intercept model with a fixed slope.
`'y ~ X1 + (X1 | g1)'`	Random intercept and slope, with possible correlation between them. This formula is equivalent to `'y ~ 1 + X1 + (1 + X1|g1)'`.
`'y ~ X1 + (1 | g1) + (-1 + X1 | g1)'`	Independent random-effects terms for intercept and slope.
`'y ~ 1 + (1 | g1) + (1 | g2) + (1 | g1:g2)'`	Random intercept model with independent main effects for `g1` and `g2`, plus an independent interaction effect.

For example, the sample data `mfr` contains simulated data from a manufacturing company that operates 50 factories across the world. Each factory runs a batch process to create a finished product. The company wants to decrease the number of defects in each batch, so it developed a new manufacturing process. To test the effectiveness of the new process, the company selected 20 of its factories at random to participate in an experiment: Ten factories implemented the new process, while the other ten continued to run the old process. In each of the 20 factories, the company ran five batches (for a total of 100 batches), and recorded data on processing time (`time_dev`), temperature (`temp_dev`), number of defects (`defects`), and a categorical variable indicating the raw materials supplier (`supplier`) for each batch.

To determine whether the new process (represented by the predictor variable `newprocess`) significantly reduces the number of defects, fit a GLME model using `newprocess`, `time_dev`, `temp_dev`, and `supplier` as fixed-effects predictors. Include a random-effects intercept grouped by `factory`, to account for quality differences that might exist due to factory-specific variations. The response variable `defects` has a Poisson distribution.

The number of defects can be modeled using a Poisson distribution

$$defects_{ij} \sim Poisson(\mu_{ij})$$

This corresponds to the generalized linear mixed-effects model

$$\log(\mu_{ij}) = \beta_0 + \beta_1 newprocess_{ij} + \beta_2 time\_dev_{ij} + \beta_3 temp\_dev_{ij} + \beta_4 supplier\_C_{ij} + \beta_5 supplier\_B_{ij} + b_i,$$

where

- $defects_{ij}$ is the number of defects observed in the batch produced by factory i (where i = 1, 2, ..., 20) during batch j (where j = 1, 2, ..., 5).
- μ_{ij} is the mean number of defects corresponding to factory i during batch j.
- $supplier\_C_{ij}$ and $supplier\_B_{ij}$ are dummy variables that indicate whether company `C` or `B`, respectively, supplied the process chemicals for the batch produced by factory i during batch j.
- $b_i \sim N(0,\sigma_b^2)$ is a random-effects intercept for each factory i that accounts for factory-specific variation in quality.

Using Wilkinson notation, specify this model as:

```
'defects ~ 1 + newprocess + time_dev + temp_dev + supplier + (1|factory)'
```

To account for the Poisson distribution of the response variable, when fitting the model using `fitglme`, specify the `'Distribution'` name-value pair argument as `'Poisson'`. By default, `fitglme` uses a log link function for response variables with a Poisson distribution.

Display the Model

The output of the fitting function `fitglme` provides information about generalized linear mixed-effects model.

Using the `mfr` manufacturing experiment data, fit a model using `newprocess`, `time_dev`, `temp_dev`, and `supplier` as fixed-effects predictors. Specify the response distribution as Poisson, the link function as log, and the fit method as Laplace.

```
load mfr

glme = fitglme(mfr,...
        'defects ~ 1 + newprocess + time_dev + temp_dev + supplier + (1|factory)',...
        'Distribution','Poisson','Link','log','FitMethod','Laplace',...
        'DummyVarCoding','effects')
```

```
glme =

Generalized linear mixed-effects model fit by ML

Model information:
```

```
    Number of observations             100
    Fixed effects coefficients           6
    Random effects coefficients         20
    Covariance parameters                1
    Distribution                   Poisson
    Link                           Log
    FitMethod                      Laplace

Formula:
    defects ~ 1 + newprocess + time_dev + temp_dev + supplier + (1 | factory)

Random effects covariance parameters:
Group: factory (20 Levels)
    Name1               Name2               Type         Estimate
    '(Intercept)'       '(Intercept)'       'std'        0.31381

Group: Error
    Name                    Estimate
    'sqrt(Dispersion)'      1
```

The `Model information` table displays the total number of observations in the sample data (100), the number of fixed- and random-effects coefficients (6 and 20, respectively), and the number of covariance parameters (1). It also indicates that the response variable has a `Poisson` distribution, the link function is `Log`, and the fit method is `Laplace`.

`Formula` indicates the model specification using Wilkinson's notation.

The `Model fit statistics` table displays statistics used to assess the goodness of fit of the model. This includes the Akaike information criterion (`AIC`), Bayesian information criterion (`BIC`) values, log likelihood (`LogLikelihood`), and deviance (`Deviance`) values.

The `Fixed effects coefficients` table indicates that `fitglme` returned 95% confidence intervals. It contains one row for each fixed-effects predictor, and each column contains statistics corresponding to that predictor. Column 1 (`Name`) contains the name of each fixed-effects coefficient, column 2 (`Estimate`) contains its estimated value, and column 3 (`SE`) contains the standard error of the coefficient. Column 4 (`tStat`) contains the *t*-statistic for a hypothesis test that the coefficient is equal to 0. Column 5 (`DF`) and column 6 (`pValue`) contain the degrees of freedom and *p*-value that correspond to the *t*-statistic, respectively. The last two columns (`Lower` and `Upper`) display the lower and upper limits, respectively, of the 95% confidence interval for each fixed-effects coefficient.

`Random effects covariance parameters` displays a table for each grouping variable (here, only `factory`), including its total number of levels (20), and the type and estimate of the covariance parameter. Here, `std` indicates that `fitglme` returns the standard deviation of the random effect associated with the factory predictor, which has an estimated value of 0.31381. It also displays a table containing the error parameter type (here, the square root of the dispersion parameter), and its estimated value of 1.

The standard display generated by `fitglme` does not provide confidence intervals for the random-effects parameters. To compute and display these values, use `covarianceParameters`.

Work with the Model

After you create a GLME model using `fitglme`, you can use additional functions to work with the model.

Inspect and Test Coefficients and Confidence Intervals

To extract estimates of the fixed- and random-effects coefficients, covariance parameters, design matrices, and related statistics:

- `fixedEffects` extracts estimated fixed-effects coefficients and related statistics from a fitted model. Related statistics include the standard error; the *t*-statistic, degrees of freedom, and *p*-value for a hypothesis test of whether each parameter is equal to 0; and the confidence intervals.
- `randomEffects` extracts estimated random-effects coefficients and related statistics from a fitted GLME model. Related statistics include the estimated empirical Bayes predictor (EBP) of each random effect, the square root of the conditional mean squared error of prediction (CMSEP) given the covariance parameters and the response; the *t*-statistic, estimated degrees of freedom, and *p*-value for a hypothesis test of whether each random effect is equal to 0; and the confidence intervals.
- `covarianceParameters` extracts estimated covariance parameters and related statistics from a fitted GLME model. Related statistics include estimate of the covariance parameter, and the confidence intervals.
- `designMatrix` extracts the fixed- and random-effects design matrices, or a specified subset thereof, from the fitted GLME model.

To conduct customized hypothesis tests for the significance of fixed- and random-effects coefficients, and to compute custom confidence intervals:

- `anova` performs a marginal *F*-test (hypothesis test) on fixed-effects terms, to determine if all coefficients representing the fixed-effects terms are equal to 0. You can use `anova` to test the combined significance of the coefficients of categorical predictors.
- `coefCI` computes confidence intervals for fixed- and random-effects parameters from a fitted GLME model. By default, `fitglme` computes 95% confidence intervals. Use `coefCI` to compute the boundaries at a different confidence level.
- `coefTest` performs custom hypothesis tests on fixed-effects or random-effects vectors of a fitted generalized linear mixed-effects model. For example, you can specify contrast matrices.

Generate New Response Values and Refit Model

To generate new response values, including fitted, predicted, and random responses, based on the fitted GLME model:

- `fitted` computes fitted response values using the original predictor values, and the estimated coefficient and parameter values from the fitted model.
- `predict` computes the predicted conditional or marginal mean of the response using either the original predictor values or new predictor values, and the estimated coefficient and parameter values from the fitted model.
- `random` generates random responses from a fitted model.

- `refit` creates a new fitted GLME model, based on the original model and a new response vector.

Inspect and Visualize Residuals

To extract and visualize residuals from the fitted GLME model:

- `residuals` extracts the raw or Pearson residuals from the fitted model. You can also specify whether to compute the conditional or marginal residuals.
- `plotResiduals` creates plots using the raw or Pearson residuals from the fitted model, including:
  - A histogram of the residuals
  - A scatterplot of the residuals versus fitted values
  - A scatterplot of residuals versus lagged residuals

Fit a Generalized Linear Mixed-Effects Model

This example shows how to fit a generalized linear mixed-effects model (GLME) to sample data.

Load the sample data.

Load the sample data.

```
load mfr
```

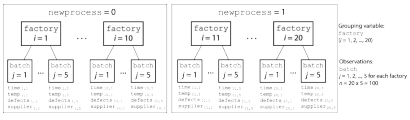
A manufacturing company operates 50 factories across the world, and each runs a batch process to create a finished product. The company wants to decrease the number of defects in each batch, so it developed a new manufacturing process. However, the company wants to test the new process in select factories to ensure that it is effective before rolling it out to all 50 locations.

To test whether the new process significantly reduces the number of defects in each batch, the company selected 20 of its factories at random to participate in an experiment. Ten factories implemented the new process, while the other ten used the old process.

In each of the 20 factories (i = 1, 2, ..., 20), the company ran five batches (j = 1, 2, ..., 5) and recorded the following data in the table `mfr`:

- Flag to indicate use of the new process:
  - If the batch used the new process, then `newprocess = 1`
  - If the batch used the old process, then `newprocess = 0`
- Processing time for the batch, in hours (`time`)
- Temperature of the batch, in degrees Celsius (`temp`)
- Supplier of the chemical used in the batch (`supplier`)
  - `supplier` is a categorical variable with levels `A`, `B`, and `C`, where each level represents one of the three suppliers
- Number of defects in the batch (defects)

The data also includes `time_dev` and `temp_dev`, which represent the absolute deviation of time and temperature, respectively, from the process standard of 3 hours and 20 degrees Celsius. The response variable `defects` has a Poisson distribution. This is simulated data.



The company wants to determine whether the new process significantly reduces the number of defects in each batch, while accounting for quality differences that might exist due to factory-specific variations in time, temperature, and supplier. The number of defects per batch can be modeled using a Poison distribution:

$$defects_{ij} \sim Poisson(\mu_{ij})$$

Use a generalized linear mixed-effects model to model the number of defects per batch:

$$\log(\mu_{ij}) = \beta_0 + \beta_1 newprocess_{ij} + \beta_2 time\_dev_{ij} + \beta_3 temp\_dev_{ij} + \beta_4 supplier\_C_{ij} + \beta_5 supplier\_B_{ij} + b_i,$$

where

- $defects_{ij}$ is the number of defects observed in the batch produced by factory i during batch j.
- μ_{ij} is the mean number of defects corresponding to factory i (where i = 1, 2, ..., 20) during batch j (where j = 1, 2, ..., 5).
- $newprocess_{ij}$, $time\_dev_{ij}$, and $temp\_dev_{ij}$ are the measurements for each variable that correspond to factory i during batch j. For example, $newprocess_{ij}$ indicates whether the batch produced by factory i during batch j used the new process.
- $supplier\_C_{ij}$ and $supplier\_B_{ij}$ are dummy variables that use effects (sum-to-zero) coding to indicate whether company `C` or `B`, respectively, supplied the process chemicals for the batch produced by factory i during batch j.
- $b_i \sim N(0,\sigma_b^2)$ is a random-effects intercept for each factory i that accounts for factory-specific variation in quality.

Fit a GLME model and interpret the results.

Fit a generalized linear mixed-effects model using `newprocess`, `time_dev`, `temp_dev`, and `supplier` as fixed-effects predictors. Include a random-effects term for intercept grouped by `factory`, to account for quality differences that might exist due to factory-specific variations. The response variable `defects` has a Poisson distribution, and the appropriate link function for this model is log. Use the Laplace fit method to estimate the coefficients. Specify the dummy variable encoding as `'effects'`, so the dummy variable coefficients sum to 0.

```
glme = fitglme(mfr,...
'defects ~ 1 + newprocess + time_dev + temp_dev + supplier + (1|factory)',...
'Distribution','Poisson','Link','log','FitMethod','Laplace',...
'DummyVarCoding','effects')
```

```
glme =

    '(Intercept)'       '(Intercept)'       'std'        0.31381

Group: Error
    Name                      Estimate
    'sqrt(Dispersion)'        1
```

The `Model information` table displays the total number of observations in the sample data (100), the number of fixed- and random-effects coefficients (6 and 20, respectively), and the number of covariance parameters (1). It also indicates that the response variable has a `Poisson` distribution, the link function is `Log`, and the fit method is `Laplace`.

`Formula` indicates the model specification using Wilkinson's notation.

The `Model fit statistics` table displays statistics used to assess the goodness of fit of the model. This includes the Akaike information criterion (`AIC`), Bayesian information criterion (`BIC`) values, log likelihood (`LogLikelihood`), and deviance (`Deviance`) values.

The `Fixed effects coefficients` table indicates that `fitglme` returned 95% confidence intervals. It contains one row for each fixed-effects predictor, and each column contains statistics corresponding to that predictor. Column 1 (`Name`) contains the name of each fixed-effects coefficient, column 2 (`Estimate`) contains its estimated value, and column 3 (`SE`) contains the standard error of the coefficient. Column 4 (`tStat`) contains the *t*-statistic for a hypothesis test that the coefficient is equal to 0. Column 5 (`DF`) and column 6 (`pValue`) contain the degrees of freedom and *p*-value that correspond to the *t*-statistic, respectively. The last two columns (`Lower` and `Upper`) display the lower and upper limits, respectively, of the 95% confidence interval for each fixed-effects coefficient.

`Random effects covariance parameters` displays a table for each grouping variable (here, only `factory`), including its total number of levels (20), and the type and estimate of the covariance parameter. Here, `std` indicates that `fitglme` returns the standard deviation of the random effect associated with the factory predictor, which has an estimated value of 0.31381. It also displays a table containing the error parameter type (here, the square root of the dispersion parameter), and its estimated value of 1.

The standard display generated by `fitglme` does not provide confidence intervals for the random-effects parameters. To compute and display these values, use `covarianceParameters`.

Check significance of random effect.

To determine whether the random-effects intercept grouped by `factory` is statistically significant, compute the confidence intervals for the estimated covariance parameter.

```
[psi,dispersion,stats] = covarianceParameters(glme);
```

`covarianceParameters` returns the estimated covariance parameter in `psi`, the estimated dispersion parameter `dispersion`, and a cell array of related statistics `stats`. The first cell of `stats` contains statistics for `factory`, while the second cell contains statistics for the dispersion parameter.

Display the first cell of `stats` to see the confidence intervals for the estimated covariance parameter for `factory`.

```
stats{1}
```

```
ans =
```

```
    Covariance Type: Isotropic

    Group      Name1               Name2               Type
    factory    '(Intercept)'       '(Intercept)'       'std'

    Estimate    Lower      Upper
    0.31381     0.19253    0.51148
```

The columns `Lower` and `Upper` display the default 95% confidence interval for the estimated covariance parameter for `factory`. Because the interval [0.19253,0.51148] does not contain 0, the random-effects intercept is significant at the 5% significance level. Therefore, the random effect due to factory-specific variation must be considered before drawing any conclusions about the effectiveness of the new manufacturing process.

Compare two models.

Compare the mixed-effects model that includes a random-effects intercept grouped by `factory` with a model that does not include the random effect, to determine which model is a better fit for the data. Fit the first model, `FEglme`, using only the fixed-effects predictors `newprocess`, `time_dev`, `temp_dev`, and `supplier`. Fit the second model, `glme`, using these same fixed-effects predictors, but also including a random-effects intercept grouped by `factory`.

```
FEglme = fitglme(mfr,...
'defects ~ 1 + newprocess + time_dev + temp_dev + supplier',...
'Distribution','Poisson','Link','log','FitMethod','Laplace');

glme = fitglme(mfr,...
'defects ~ 1 + newprocess + time_dev + temp_dev + supplier + (1|factory)',...
'Distribution','Poisson','Link','log','FitMethod','Laplace');
```

Compare the two models using a likelihood ratio test. Specify `'CheckNesting'` as `true`, so `compare` returns a warning if the nesting requirements are not satisfied.

```
results = compare(FEglme,glme,'CheckNesting',true)

results =

    Theoretical Likelihood Ratio Test

    Model     DF    AIC       BIC       LogLik     LRStat    deltaDF
    FEglme    6     431.02    446.65    -209.51
    glme      7     416.35    434.58    -201.17    16.672    1

    pValue

    4.4435e-05
```

`compare` returns the degrees of freedom (`DF`), the Akaike information criterion (`AIC`), Bayesian information criterion (`BIC`), and log likelihood values for each model. `glme` has smaller AIC, BIC, and log likelihood values than `FEglme`, which indicates that `glme` (the model containing the random-effects term for intercept grouped by factory) is the better-fitting model for this data. Additionally, the small *p*-value indicates that `compare` rejects the null hypothesis that the response vector was

generated by the fixed-effects-only model `FEglme`, in favor of the alternative that the response vector was generated by the mixed-effects model `glme`.

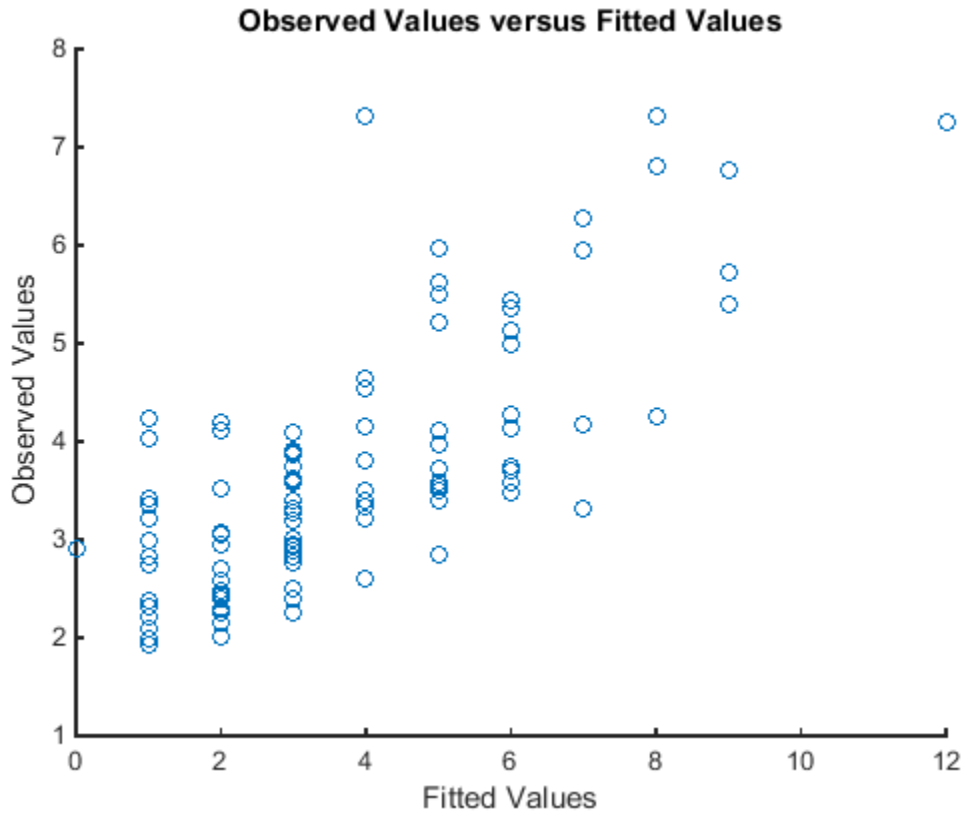
Plot the results.

Generate the fitted conditional mean values for the model.

```
mufit = fitted(glme);
```

Plot the observed response values versus the fitted response values.

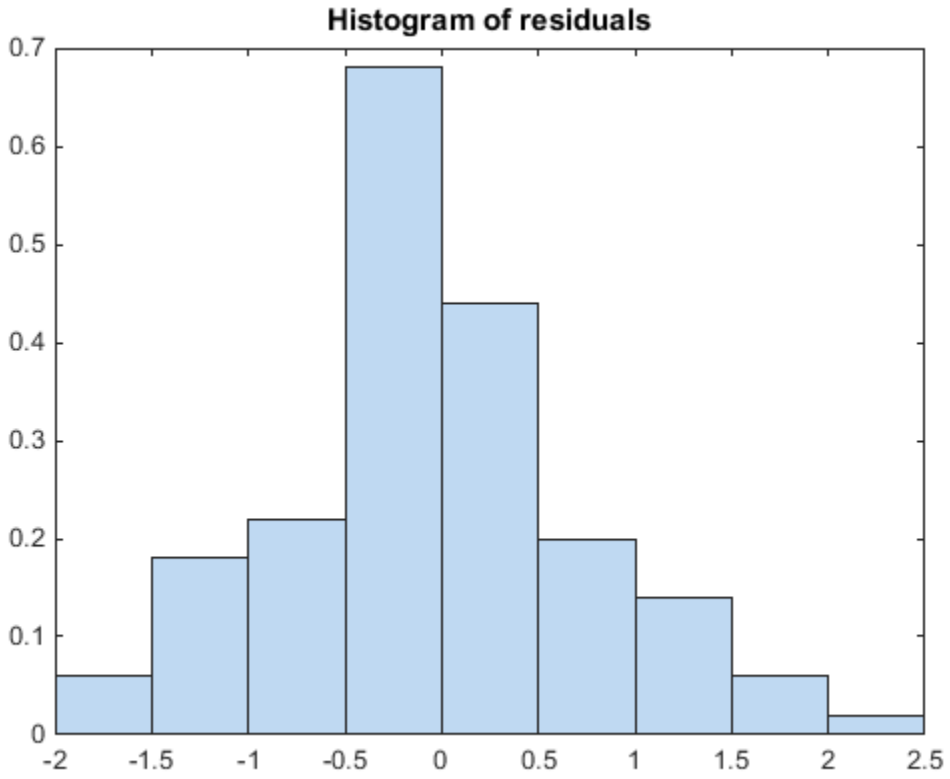
```
figure
scatter(mfr.defects,mufit)
title('Observed Values versus Fitted Values')
xlabel('Fitted Values')
ylabel('Observed Values')
```



Create diagnostic plots using conditional Pearson residuals to test model assumptions. Since raw residuals for generalized linear mixed-effects models do not have a constant variance across observations, use the conditional Pearson residuals instead.

Plot a histogram to visually confirm that the mean of the Pearson residuals is equal to 0. If the model is correct, we expect the Pearson residuals to be centered at 0.

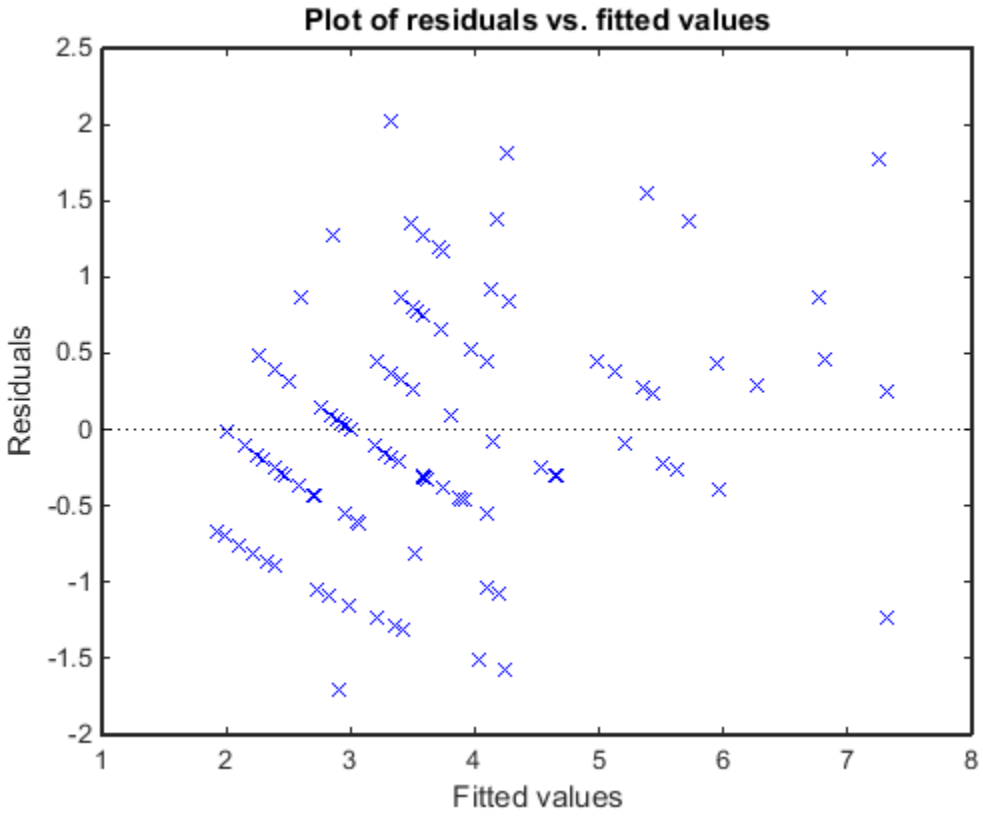
```
plotResiduals(glme,'histogram','ResidualType','Pearson')
```



The histogram shows that the Pearson residuals are centered at 0.

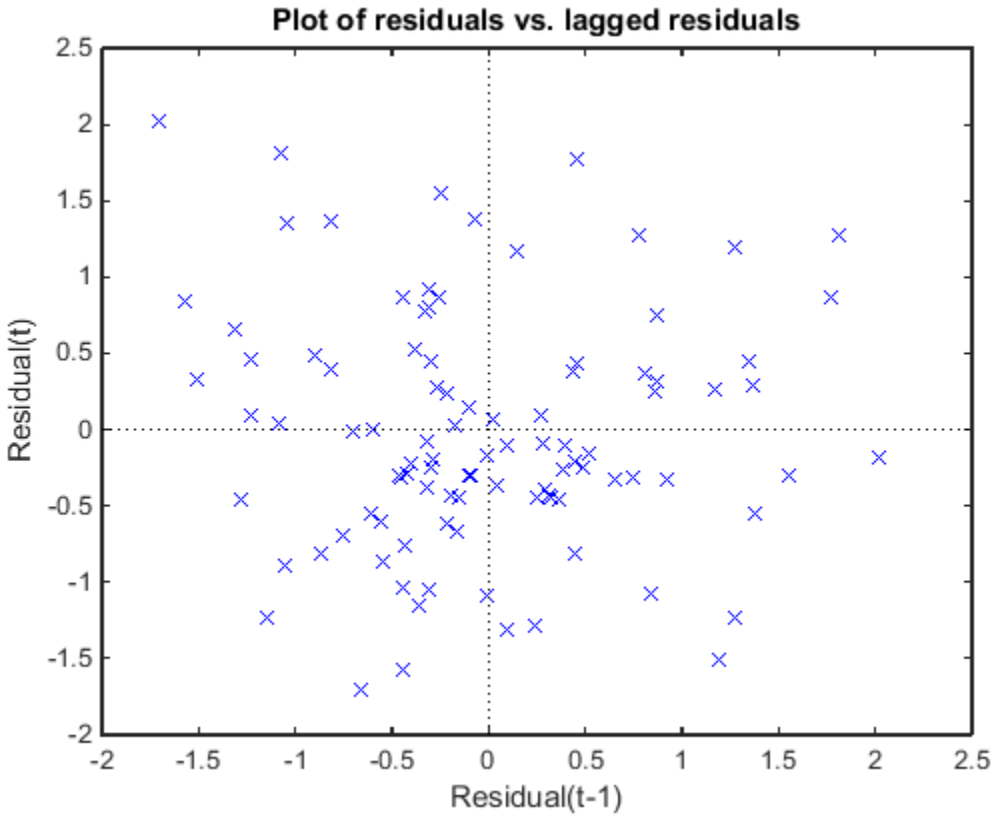
Plot the Pearson residuals versus the fitted values, to check for signs of nonconstant variance among the residuals (heteroscedasticity). We expect the conditional Pearson residuals to have a constant variance. Therefore, a plot of conditional Pearson residuals versus conditional fitted values should not reveal any systematic dependence on the conditional fitted values.

```
plotResiduals(glme,'fitted','ResidualType','Pearson')
```



The plot does not show a systematic dependence on the fitted values, so there are no signs of nonconstant variance among the residuals.

Plot the Pearson residuals versus lagged residuals, to check for correlation among the residuals. The conditional independence assumption in GLME implies that the conditional Pearson residuals are approximately uncorrelated.



There is no pattern to the plot, so there are no signs of correlation among the residuals.

- “Generalized Linear Models” on page 12-9

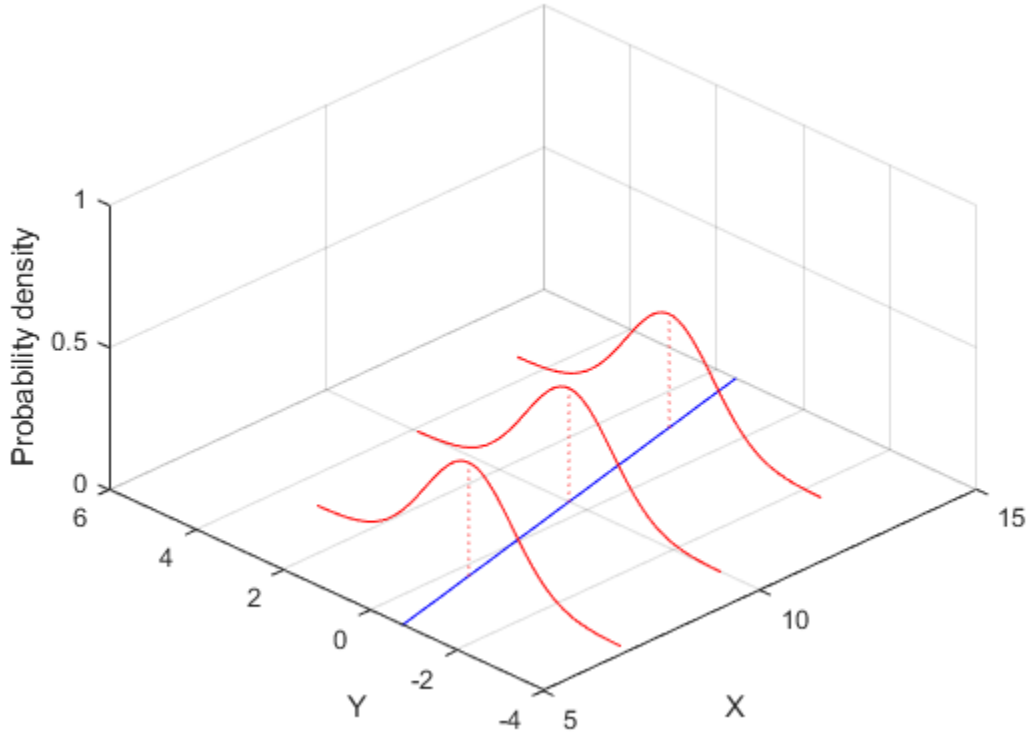
Fitting Data with Generalized Linear Models

This example shows how to fit and evaluate generalized linear models using `glmfit` and `glmval`. Ordinary linear regression can be used to fit a straight line, or any function that is linear in its parameters, to data with normally distributed errors. This is the most commonly used regression model; however, it is not always a realistic one. Generalized linear models extend the linear model in two ways. First, assumption of linearity in the parameters is relaxed, by introducing the link function. Second, error distributions other than the normal can be modeled

Generalized Linear Models

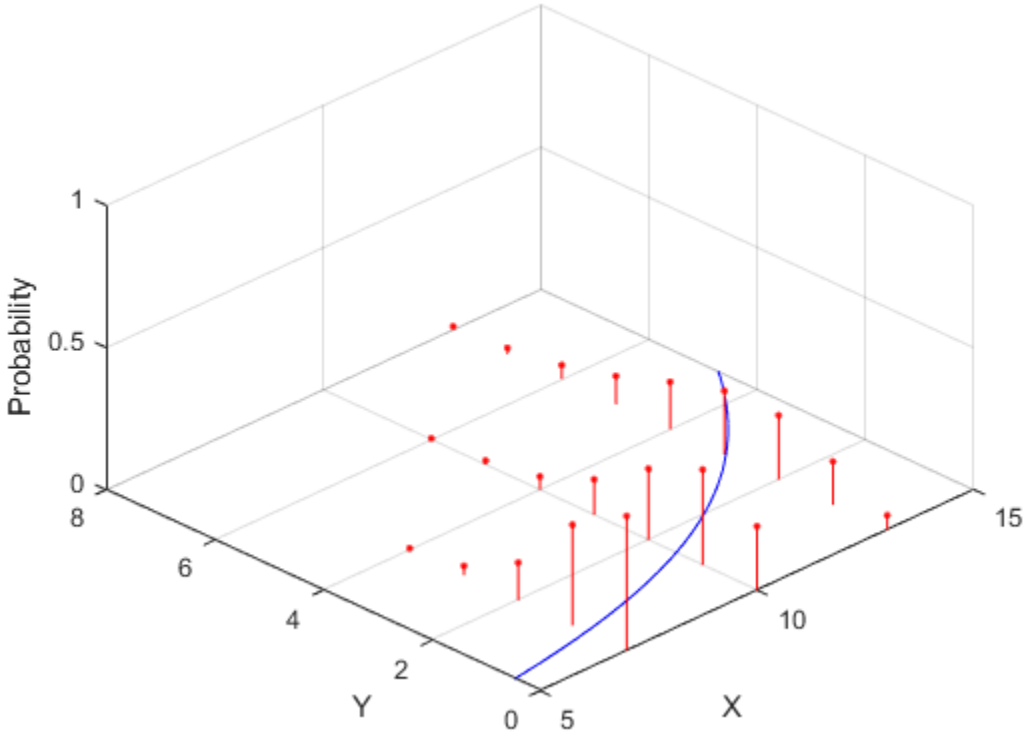
A regression model defines the distribution of a response variable (often generically denoted as y) in terms of one or more predictor variables (often denoted x1, x2, etc.). The most commonly used regression model, the ordinary linear regression, models y as a normal random variable, whose mean is linear function of the predictors, b0 + b1*x1 + ... , and whose variance is constant. In the simplest case of a single predictor x, the model can be represented as a straight line with Gaussian distributions about each point.

```
mu = @(x) -1.9+.23*x;
x = 5:.1:15;
yhat = mu(x);
dy = -3.5:.1:3.5; sz = size(dy); k = (length(dy)+1)/2;
x1 =  7*ones(sz); y1 = mu(x1)+dy; z1 = normpdf(y1,mu(x1),1);
x2 = 10*ones(sz); y2 = mu(x2)+dy; z2 = normpdf(y2,mu(x2),1);
x3 = 13*ones(sz); y3 = mu(x3)+dy; z3 = normpdf(y3,mu(x3),1);
plot3(x,yhat,zeros(size(x)),'b-', ...
      x1,y1,z1,'r-', x1([k k]),y1([k k]),[0 z1(k)],'r:', ...
      x2,y2,z2,'r-', x2([k k]),y2([k k]),[0 z2(k)],'r:', ...
      x3,y3,z3,'r-', x3([k k]),y3([k k]),[0 z3(k)],'r:');
zlim([0 1]);
xlabel('X'); ylabel('Y'); zlabel('Probability density');
grid on; view([-45 45]);
```



In a generalized linear model, the mean of the response is modeled as a monotonic nonlinear transformation of a linear function of the predictors, g(b0 + b1*x1 + ...) . The inverse of the transformation g is known as the "link" function. Examples include the logit (sigmoid) link and the log link. Also, y may have a non-normal distribution, such as the binomial or Poisson. For example, a Poisson regression with log link and a single predictor x can be represented as an exponential curve with Poisson distributions about each point.

```
mu = @(x) exp(-1.9+.23*x);
x = 5:.1:15;
yhat = mu(x);
x1 =  7*ones(1,5);  y1 = 0:4; z1 = poisspdf(y1,mu(x1));
x2 = 10*ones(1,7); y2 = 0:6; z2 = poisspdf(y2,mu(x2));
x3 = 13*ones(1,9); y3 = 0:8; z3 = poisspdf(y3,mu(x3));
plot3(x,yhat,zeros(size(x)),'b-', ...
      [x1; x1],[y1; y1],[z1; zeros(size(y1))],'r-', x1,y1,z1,'r.', ...
      [x2; x2],[y2; y2],[z2; zeros(size(y2))],'r-', x2,y2,z2,'r.', ...
      [x3; x3],[y3; y3],[z3; zeros(size(y3))],'r-', x3,y3,z3,'r.');
zlim([0 1]);
xlabel('X'); ylabel('Y'); zlabel('Probability');
grid on; view([-45 45]);
```

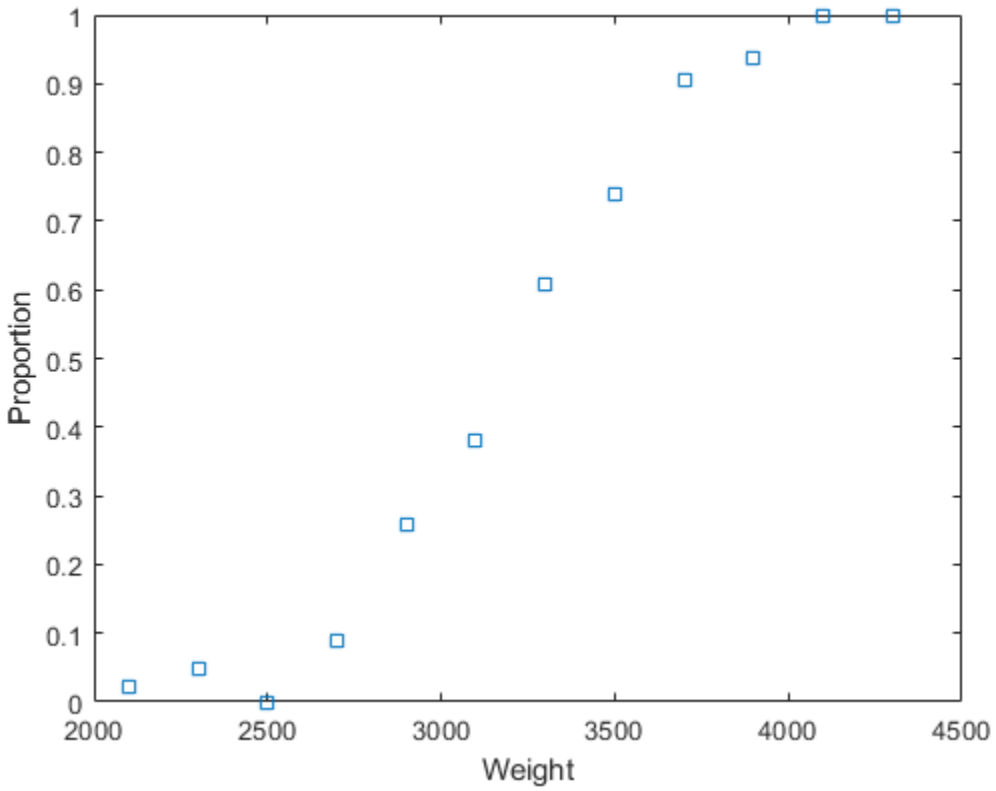


Fitting a Logistic Regression

This example involves an experiment to help model the proportion of cars of various weights that fail a mileage test. The data include observations of weight, number of cars tested, and number failed.

```
% A set of car weights
weight = [2100 2300 2500 2700 2900 3100 3300 3500 3700 3900 4100 4300]';
% The number of cars tested at each weight
tested = [48 42 31 34 31 21 23 23 21 16 17 21]';
% The number of cars failing the test at each weight
failed = [1 2 0 3 8 8 14 17 19 15 17 21]';
% The proportion of cars failing for each weight
proportion = failed ./ tested;

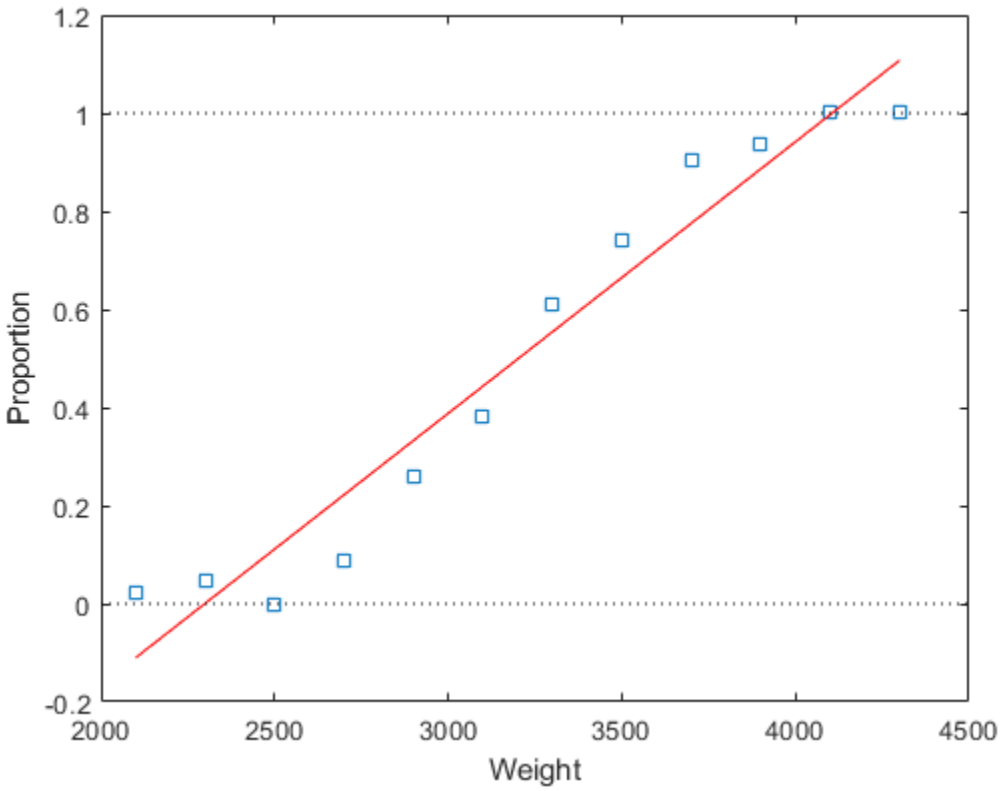
plot(weight,proportion,'s')
xlabel('Weight'); ylabel('Proportion');
```



This graph is a plot of the proportion of cars failing, as a function of weight. It's reasonable to assume that the failure counts came from a binomial distribution, with a probability parameter P that increases with weight. But how exactly should P depend on weight?

We can try fitting a straight line to these data.

```
linearCoef = polyfit(weight,proportion,1);
linearFit = polyval(linearCoef,weight);
plot(weight,proportion,'s', weight,linearFit,'r-', [2000 4500],[0 0],'k:', [2000 4500],[1 1],'k:
xlabel('Weight'); ylabel('Proportion');
```



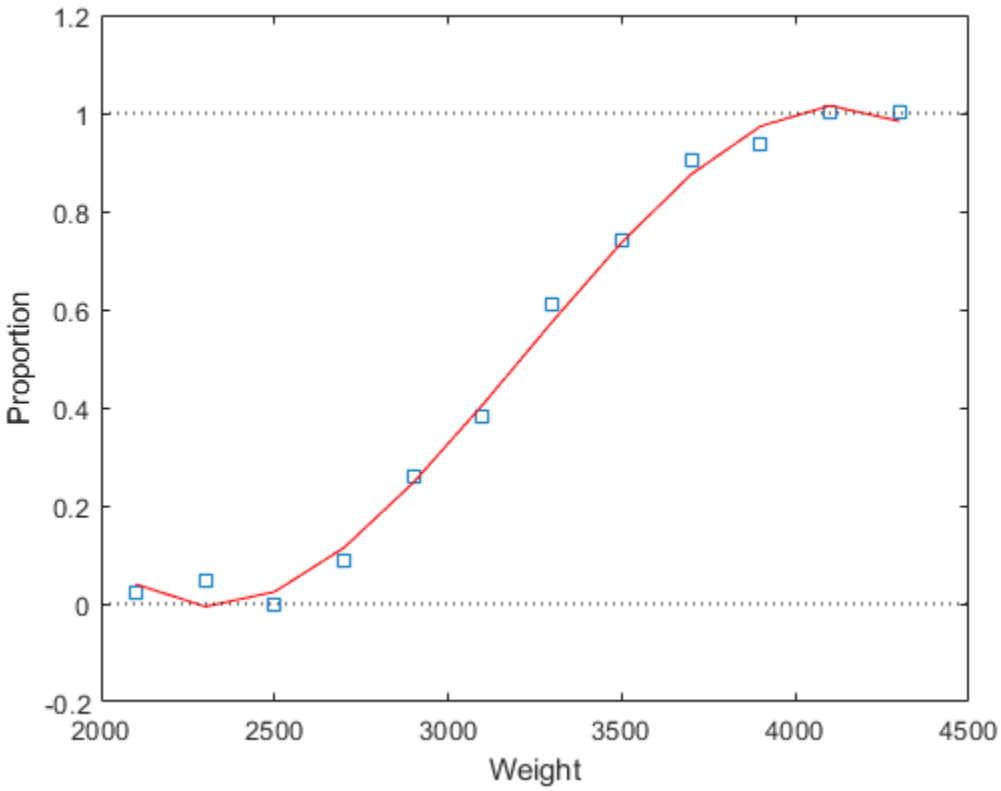
There are two problems with this linear fit:

1) The line predicts proportions less than 0 and greater than 1.

2) The proportions are not normally distributed, since they are necessarily bounded. This violates one of the assumptions required for fitting a simple linear regression model.

Using a higher-order polynomial may appear to help.

```
[cubicCoef,stats,ctr] = polyfit(weight,proportion,3);
cubicFit = polyval(cubicCoef,weight,[],ctr);
plot(weight,proportion,'s', weight,cubicFit,'r-', [2000 4500],[0 0],'k:', [2000 4500],[1 1],'k:'
xlabel('Weight'); ylabel('Proportion');
```

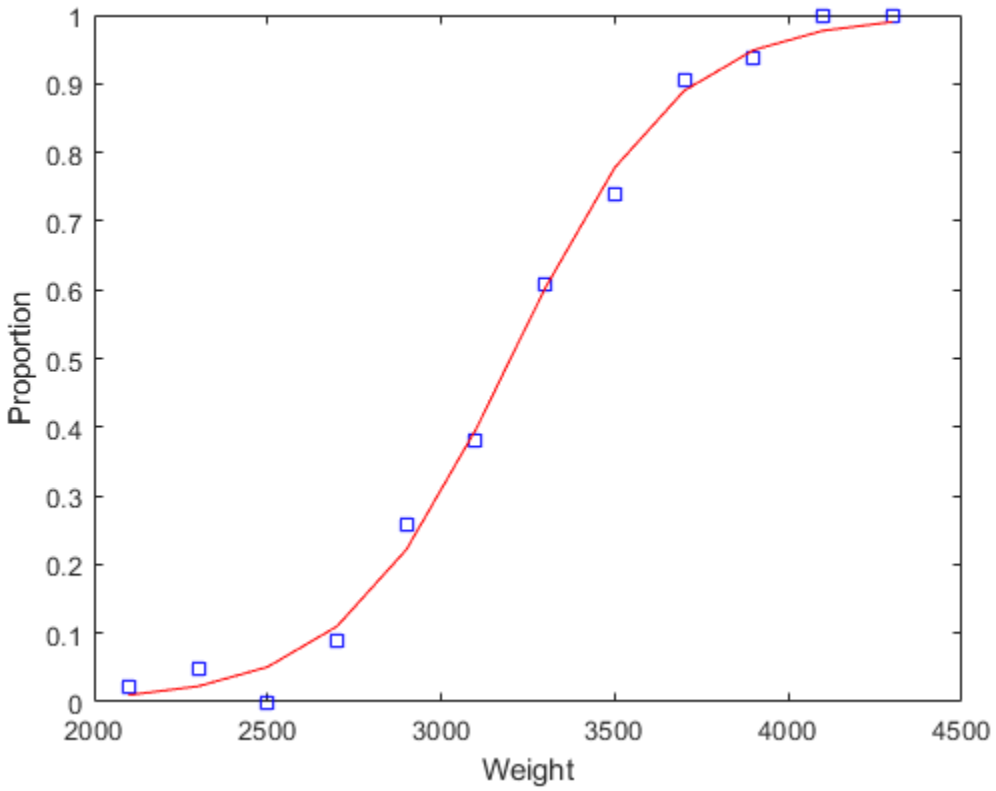


However, this fit still has similar problems. The graph shows that the fitted proportion starts to decrease as weight goes above 4000; in fact it will become negative for larger weight values. And of course, the assumption of a normal distribution is still violated.

Instead, a better approach is to use `glmfit` to fit a logistic regression model. Logistic regression is a special case of a generalized linear model, and is more appropriate than a linear regression for these data, for two reasons. First, it uses a fitting method that is appropriate for the binomial distribution. Second, the logistic link limits the predicted proportions to the range [0,1].

For logistic regression, we specify the predictor matrix, and a matrix with one column containing the failure counts, and one column containing the number tested. We also specify the binomial distribution and the logit link.

```
[logitCoef,dev] = glmfit(weight,[failed tested],'binomial','logit');
logitFit = glmval(logitCoef,weight,'logit');
plot(weight,proportion,'bs', weight,logitFit,'r-');
xlabel('Weight'); ylabel('Proportion');
```



As this plot indicates, the fitted proportions asymptote to zero and one as weight becomes small or large.

Model Diagnostics

The `glmfit` function provides a number of outputs for examining the fit and testing the model. For example, we can compare the deviance values for two models to determine if a squared term would improve the fit significantly.

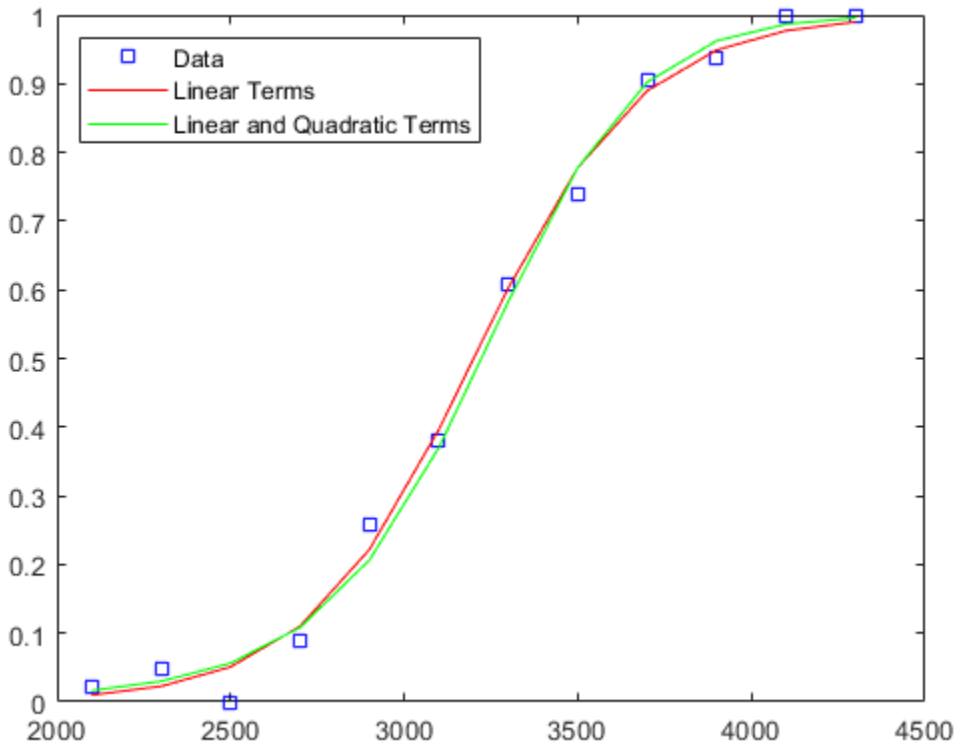
```
[logitCoef2,dev2] = glmfit([weight weight.^2],[failed tested],'binomial','logit');
pval = 1 - chi2cdf(dev-dev2,1)
```

```
pval =

    0.4019
```

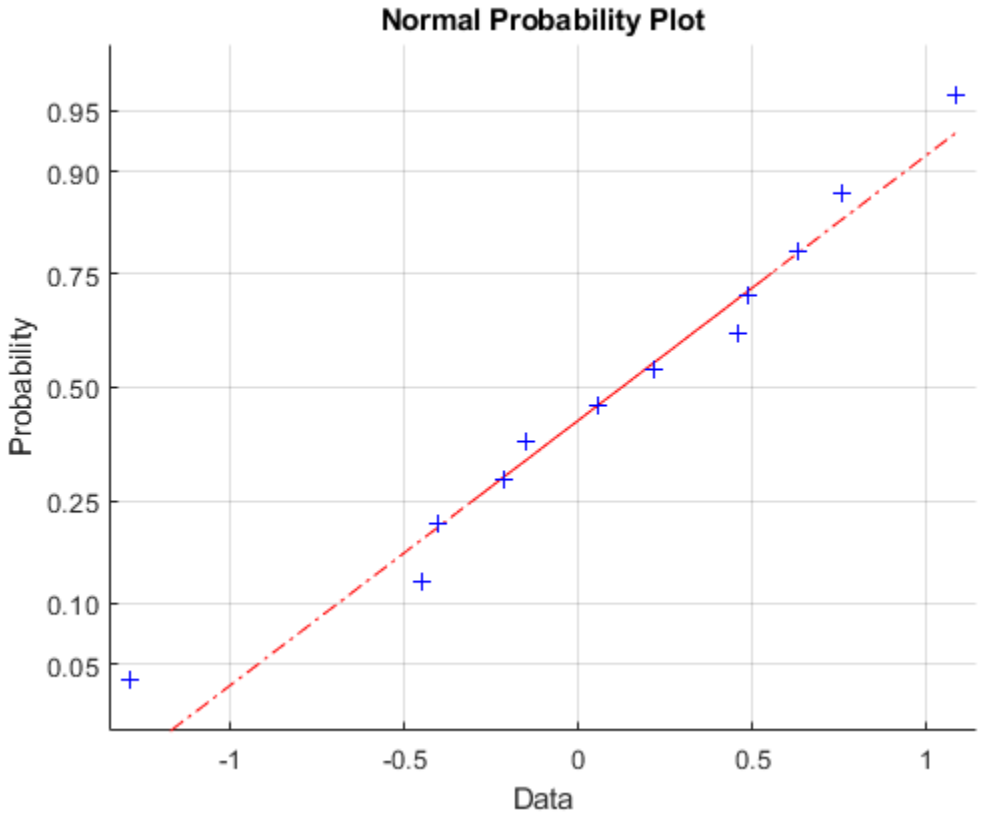
The large p-value indicates that, for these data, a quadratic term does not improve the fit significantly. A plot of the two fits shows there is little difference in the fits.

```
logitFit2 = glmval(logitCoef2,[weight weight.^2],'logit');
plot(weight,proportion,'bs', weight,logitFit,'r-', weight,logitFit2,'g-');
legend('Data','Linear Terms','Linear and Quadratic Terms','Location','northwest');
```



To check the goodness of fit, we can also look at a probability plot of the Pearson residuals. These are normalized so that when the model is a reasonable fit to the data, they have roughly a standard normal distribution. (Without this standardization, the residuals would have different variances.)

```
[logitCoef,dev,stats] = glmfit(weight,[failed tested],'binomial','logit');
normplot(stats.residp);
```

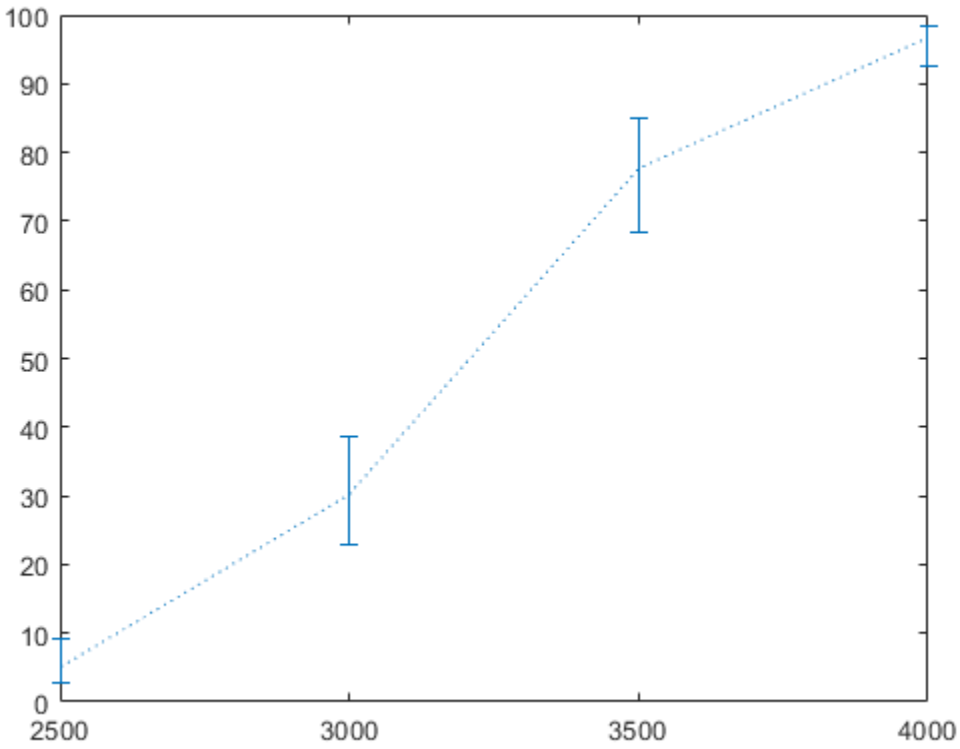


The residual plot shows a nice agreement with the normal distribution.

Evaluating the Model Predictions

Once we are satisfied with the model, we can use it to make predictions, including computing confidence bounds. Here we predict the expected number of cars, out of 100 tested, that would fail the mileage test at each of four weights.

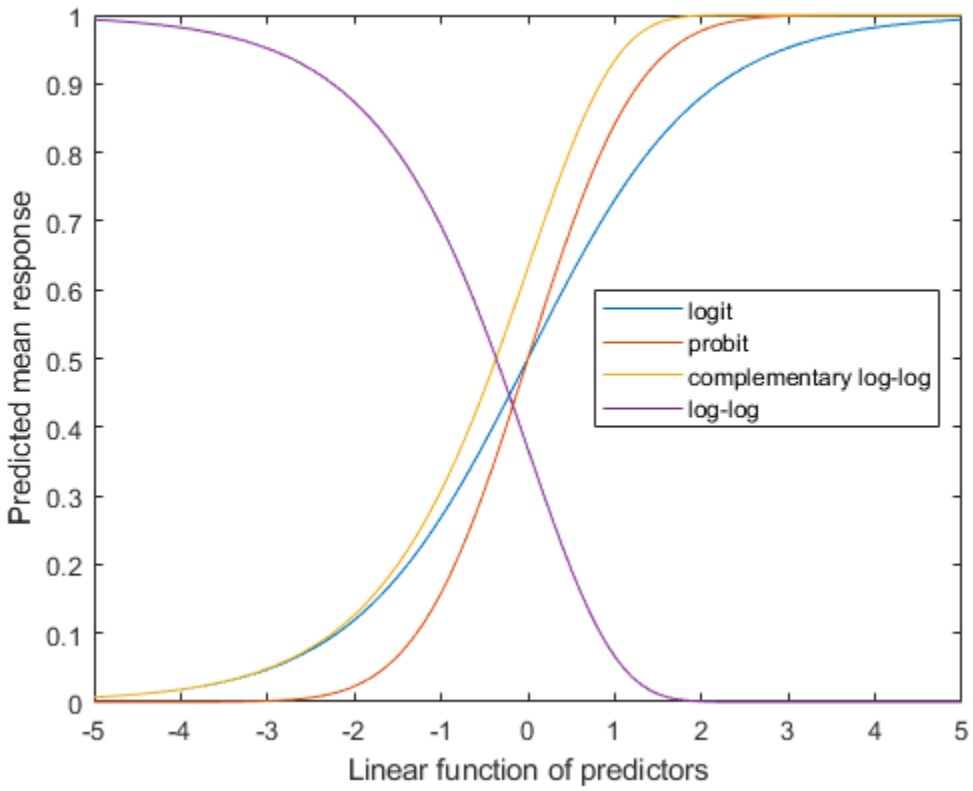
```
weightPred = 2500:500:4000;
[failedPred,dlo,dhi] = glmval(logitCoef,weightPred,'logit',stats,.95,100);
errorbar(weightPred,failedPred,dlo,dhi,':');
```



Link Functions for Binomial Models

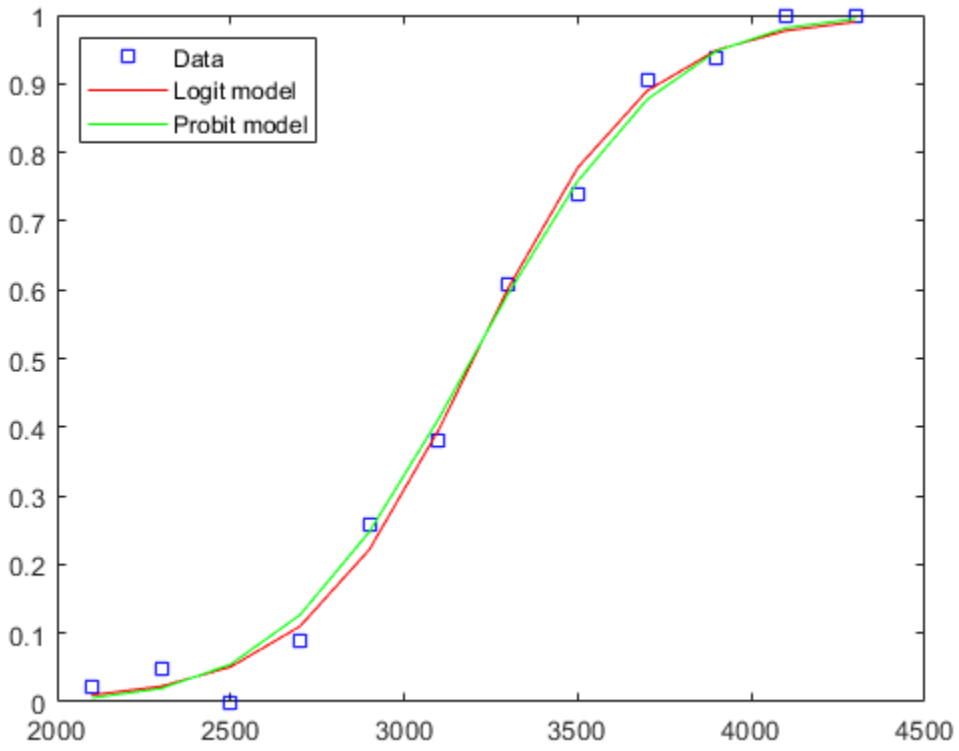
For each of the five distributions that `glmfit` supports, there is a canonical (default) link function. For the binomial distribution, the canonical link is the logit. However, there are also three other links that are sensible for binomial models. All four maintain the mean response in the interval [0, 1].

```
eta = -5:.1:5;
plot(eta,1 ./ (1 + exp(-eta)),'-', eta,normcdf(eta), '-', ...
     eta,1 - exp(-exp(eta)),'-', eta,exp(-exp(eta)),'-');
xlabel('Linear function of predictors'); ylabel('Predicted mean response');
legend('logit','probit','complementary log-log','log-log','location','east');
```



For example, we can compare a fit with the probit link to one with the logit link.

```
probitCoef = glmfit(weight,[failed tested],'binomial','probit');
probitFit = glmval(probitCoef,weight,'probit');
plot(weight,proportion,'bs', weight,logitFit,'r-', weight,probitFit,'g-');
legend('Data','Logit model','Probit model','Location','northwest');
```



It's often difficult for the data to distinguish between these four link functions, and a choice is often made on theoretical grounds.

Train Generalized Additive Model for Binary Classification

This example shows how to train a generalized additive model (GAM) with optimal parameters and how to assess the predictive performance of the trained model. The example first finds the optimal parameter values for a univariate GAM (parameters for linear terms) and then finds the values for a bivariate GAM (parameters for interaction terms). Also, the example explains how to interpret the trained model by examining local effects of terms on a specific prediction and by computing the partial dependence of the predictions on predictors.

Load Sample Data

Load the 1994 census data stored in `census1994.mat`. The data set consists of demographic data from the US Census Bureau to predict whether an individual makes over $50,000 per year. The classification task is to fit a model that predicts the salary category of people given their age, working class, education level, marital status, race, and so on.

```
load census1994
```

`census1994` contains the training data set `adultdata` and the test data set `adulttest`. To reduce the running time for this example, subsample 500 training observations and 500 test observations by using the `datasample` function.

```
rng('default')
NumSamples = 5e2;
adultdata = datasample(adultdata,NumSamples,'Replace',false);
adulttest = datasample(adulttest,NumSamples,'Replace',false);
```

Find Optimal Parameters for Univariate GAM

Optimize the parameters for a univariate GAM with respect to cross-validation by using the `bayesopt` function.

Prepare `optimizableVariable` objects for the name-value arguments of a univariate GAM: `MaxNumSplitsPerPredictor`, `NumTreesPerPredictor`, and `InitialLearnRateForPredictors`.

```
maxNumSplitsPerPredictor = optimizableVariable('maxNumSplitsPerPredictor',[1,10],'Type','integer
numTreesPerPredictor = optimizableVariable('numTreesPerPredictor',[1,500],'Type','integer');
initialLearnRateForPredictors = optimizableVariable('initialLearnRateForPredictors',[1e-3,1],'Ty
```

Create an objective function that takes an input `z = [maxNumSplitsPerPredictor,numTreesPerPredictor,initialLearnRateForPredictors]` and returns the cross-validated loss value at the parameters in `z`.

```
minfun1 = @(z)kfoldLoss(fitcgam(adultdata,'salary','Weights','fnlwgt', ...
    'CrossVal','on', ...
    'InitialLearnRateForPredictors',z.initialLearnRateForPredictors, ...
    'MaxNumSplitsPerPredictor',z.maxNumSplitsPerPredictor, ...
    'NumTreesPerPredictor',z.numTreesPerPredictor));
```

If you specify the cross-validation option `'CrossVal','on'`, then the `fitcgam` function returns a cross-validated model object `ClassificationPartitionedGAM`. The `kfoldLoss` function returns the classification loss obtained by the cross-validated model. Therefore, the function handle `minfun` computes the cross-validation loss at the parameters in `z`.

Search for the best parameters using `bayesopt`. For reproducibility, choose the `'expected-improvement-plus'` acquisition function. The default acquisition function depends on run time and, therefore, can give varying results.

```
results1 = bayesopt(minfun1, ...
    [initialLearnRateForPredictors,maxNumSplitsPerPredictor,numTreesPerPredictor], ...
    'IsObjectiveDeterministic',true, ...
    'AcquisitionFunctionName','expected-improvement-plus');
```

```

Train Univariate GAM with Optimal Parameters

Train an optimized GAM using the `zbest1` values. A recommended practice is to specify the class names.

```
Mdl1 = fitcgam(adultdata,'salary','Weights','fnlwgt', ...
    'ClassNames',categorical({'<=50K','>50K'}), ...
    'InitialLearnRateForPredictors',zbest1.initialLearnRateForPredictors, ...
    'MaxNumSplitsPerPredictor',zbest1.maxNumSplitsPerPredictor, ...
    'NumTreesPerPredictor',zbest1.numTreesPerPredictor)

Mdl1 =
  ClassificationGAM
           PredictorNames: {'age'  'workClass'  'education'  'education_num'  'marital_status'
             ResponseName: 'salary'
    CategoricalPredictors: [2 3 5 6 7 8 9 13]
               ClassNames: [<=50K    >50K]
           ScoreTransform: 'logit'
                Intercept: -1.7383
          NumObservations: 500

  Properties, Methods
```

`Mdl1` is a `ClassificationGAM` model object. The model display shows a partial list of the model properties. To view the full list of the model properties, double-click the variable name `Mdl1` in the Workspace. The Variables editor opens for `Mdl1`. Alternatively, you can display the properties in the Command Window by using dot notation. For example, display the `ReasonForTermination` property.

```
Mdl1.ReasonForTermination

ans = struct with fields:
      PredictorTrees: 'Terminated after training the requested number of trees.'
    InteractionTrees: ''
```

The `PredictorTrees` field of the property value indicates that `Mdl1` includes the specified number of trees. `NumTreesPerPredictor` of `fitcgam` specifies the maximum number of trees per predictor, and the function can stop before training the requested number of trees. You can use the `ReasonForTermination` property to determine whether the trained model contains the specified number of trees.

If you specify to include interaction terms so that `fitcgam` trains trees for them, then the `InteractionTrees` field contains a nonempty value.

Find Optimal Parameters for Bivariate GAM

Find the parameters for interaction terms of a bivariate GAM by using the `bayesopt` function.

Prepare `optimizableVariable` objects for the name-value arguments for the interaction terms: `InitialLearnRateForInteractions`, `MaxNumSplitsPerInteraction`, `NumTreesPerInteraction`, and `InitialLearnRateForInteractions`.

```
initialLearnRateForInteractions = optimizableVariable('initialLearnRateForInteractions',[1e-3,1]
maxNumSplitsPerInteraction = optimizableVariable('maxNumSplitsPerInteraction',[1,10],'Type','inte
numTreesPerInteraction = optimizableVariable('numTreesPerInteraction',[1,500],'Type','integer');
numInteractions = optimizableVariable('numInteractions',[1,28],'Type','integer');
```

Create an objective function for the optimization. Use the optimal parameter values in `zbest1` so that the software finds optimal parameter values for interaction terms based on the `zbest1` values.

```
minfun2 = @(z)kfoldLoss(fitcgam(adultdata,'salary','Weights','fnlwgt', ...
    'CrossVal','on', ...
    'InitialLearnRateForPredictors',zbest1.initialLearnRateForPredictors, ...
    'MaxNumSplitsPerPredictor',zbest1.maxNumSplitsPerPredictor, ...
    'NumTreesPerPredictor',zbest1.numTreesPerPredictor, ...
    'InitialLearnRateForInteractions',z.initialLearnRateForInteractions, ...
    'MaxNumSplitsPerInteraction',z.maxNumSplitsPerInteraction, ...
    'NumTreesPerInteraction',z.numTreesPerInteraction, ...
    'Interactions',z.numInteractions));
```

Search for the best parameters using `bayesopt`. The optimization process trains multiple models and displays warning messages if the models include no interaction terms. Disable all warnings before calling `bayesopt` and restore the warning state after running `bayesopt`. You can leave the warning state unchanged to view the warning messages.

```
orig_state = warning('query');
warning('off')
results2 = bayesopt(minfun2, ...
    [initialLearnRateForInteractions,maxNumSplitsPerInteraction,numTreesPerInteraction,numInterac
    'IsObjectiveDeterministic',true, ...
    'AcquisitionFunctionName','expected-improvement-plus');
```

```

             ResponseName: 'salary'
    CategoricalPredictors: [2 3 5 6 7 8 9 13]
               ClassNames: [<=50K    >50K]
          ScoreTransform: 'logit'
               Intercept: -1.7755
             Interactions: [4×2 double]
         NumObservations: 500

  Properties, Methods
```

Alternatively, you can add interaction terms to the univariate GAM by using the `addInteractions` function.

```
Mdl2 = addInteractions(Mdl1,zbest2.numInteractions, ...
    'InitialLearnRateForInteractions',zbest2.initialLearnRateForInteractions, ...
    'MaxNumSplitsPerInteraction',zbest2.maxNumSplitsPerInteraction, ...
    'NumTreesPerInteraction',zbest2.numTreesPerInteraction);
```

The second input argument specifies the maximum number of interaction terms, and the `NumTreesPerInteraction` name-value argument specifies the maximum number of trees per interaction term. The `addInteractions` function can include fewer interaction terms and stop before training the requested number of trees. You can use the `Interactions` and `ReasonForTermination` properties to check the actual number of interaction terms and number of trees in the trained model.

Display the interaction terms in `Mdl`.

```
Mdl.Interactions
```

```
ans = 4×2

     7    10
     4     7
     7     9
     5    10
```

Each row of `Interactions` represents one interaction term and contains the column indexes of the predictor variables for the interaction term. You can use the `Interactions` property to check the interaction terms in the model and the order in which `fitcgam` adds them to the model.

Display the interaction terms in `Mdl` using the predictor names.

```
Mdl.PredictorNames(Mdl.Interactions)
```

```
ans = 4×2 cell
    {'relationship'  }    {'capital_gain'}
    {'education_num' }    {'relationship'}
    {'relationship'  }    {'sex'         }
    {'marital_status'}    {'capital_gain'}
```

Display the reason for termination to determine whether the model contains the specified number of trees for each linear term and each interaction term.

```
Mdl.ReasonForTermination
```

```
ans = struct with fields:
      PredictorTrees: 'Terminated after training the requested number of trees.'
    InteractionTrees: 'Terminated after training the requested number of trees.'
```

Assess Predictive Performance on New Observations

Assess the performance of the trained model by using the test sample `adulttest` and the object functions `predict`, `loss`, `edge`, and `margin`. You can use a full or compact model with these functions.

- `predict` — Classify observations
- `loss` — Compute classification loss (misclassification rate in decimal, by default)
- `margin` — Compute classification margins
- `edge` — Compute classification edge (average of classification margins)

If you want to assess the performance of the training data set, use the resubstitution object functions: `resubPredict`, `resubLoss`, `resubMargin`, and `resubEdge`. To use these functions, you must use the full model that contains the training data.

Create a compact model to reduce the size of the trained model.

```
CMdl = compact(Mdl);
whos('Mdl','CMdl')
```

```
  Name      Size              Bytes  Class                                                 Attri

  CMdl      1x1             3272176  classreg.learning.classif.CompactClassificationGAM
  Mdl       1x1             3389515  ClassificationGAM
```

Predict labels and scores for the test data set (`adulttest`), and compute model statistics (loss, margin, and edge) using the test data set.

```
[labels,scores] = predict(CMdl,adulttest);
L = loss(CMdl,adulttest,'Weights',adulttest.fnlwgt);
M = margin(CMdl,adulttest);
E = edge(CMdl,adulttest,'Weights',adulttest.fnlwgt);
```

Predict labels and scores and compute the statistics without including interaction terms in the trained model.

```
[labels_nointeraction,scores_nointeraction] = predict(CMdl,adulttest,'IncludeInteractions',false)
L_nointeractions = loss(CMdl,adulttest,'Weights',adulttest.fnlwgt,'IncludeInteractions',false);
M_nointeractions = margin(CMdl,adulttest,'IncludeInteractions',false);
E_nointeractions = edge(CMdl,adulttest,'Weights',adulttest.fnlwgt,'IncludeInteractions',false);
```

Compare the results obtained by including both linear and interaction terms to the results obtained by including only linear terms.

Create a table containing the observed labels, predicted labels, and scores. Display the first eight rows of the table.

```
t = table(adulttest.salary,labels,scores,labels_nointeraction,scores_nointeraction, ...
    'VariableNames',{'True Labels','Predicted Labels','Scores' ...
    'Predicted Labels without interactions','Scores without interactions'});
head(t)
```

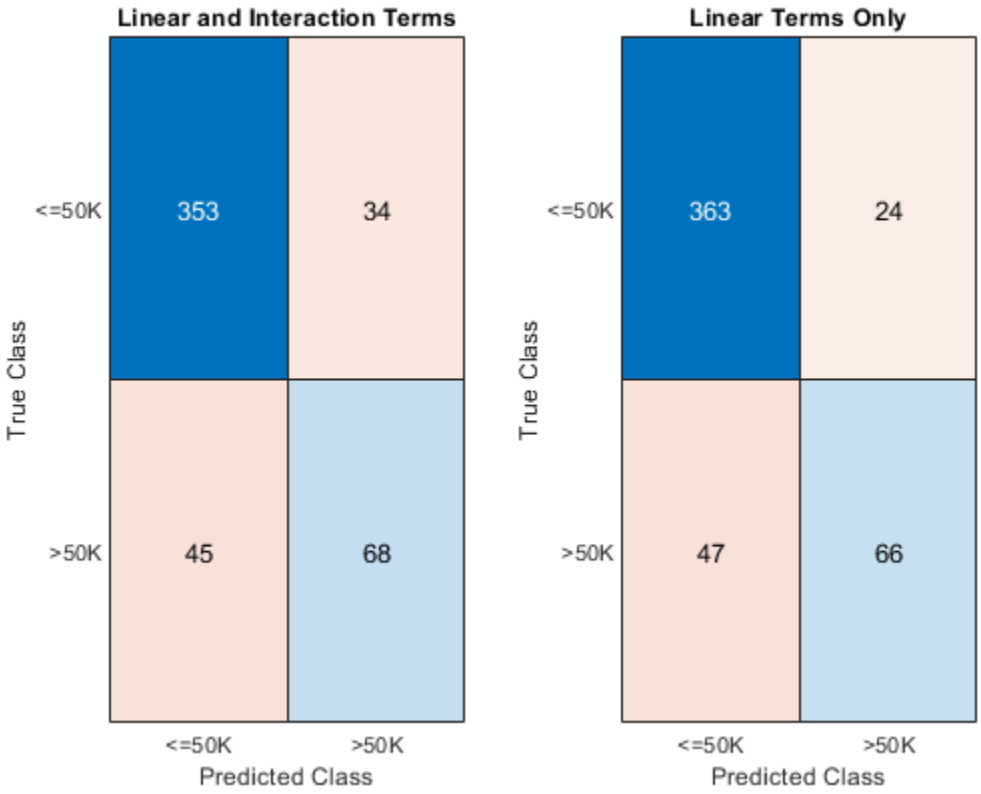
```
ans=8×5 table
    True Labels    Predicted Labels          Scores          Predicted Labels without interac
    ___________    ________________    ____________________    ____________________________

       <=50K           <=50K          0.97921      0.020787                 <=50K
       <=50K           <=50K                1     8.258e-17                 <=50K
       <=50K           <=50K                1    1.8297e-19                 <=50K
       <=50K           <=50K          0.87422       0.12578                 <=50K
       <=50K           <=50K                1    3.5643e-07                 <=50K
       <=50K           <=50K          0.60371       0.39629                 <=50K
       <=50K           >50K           0.49917       0.50083                 >50K
```

```
    >50K            >50K            0.3109        0.6891                    <=50K
```

Create a confusion chart from the true labels `adulttest.salary` and the predicted labels.

```
tiledlayout(1,2);
nexttile
confusionchart(adulttest.salary,labels)
title('Linear and Interaction Terms')
nexttile
confusionchart(adulttest.salary,labels_nointeraction)
title('Linear Terms Only')
```



Display the computed loss and edge values.

```
table([L; E], [L_nointeractions; E_nointeractions], ...
    'VariableNames',{'Linear and Interaction Terms','Only Linear Terms'}, ...
    'RowNames',{'Loss','Edge'})
```

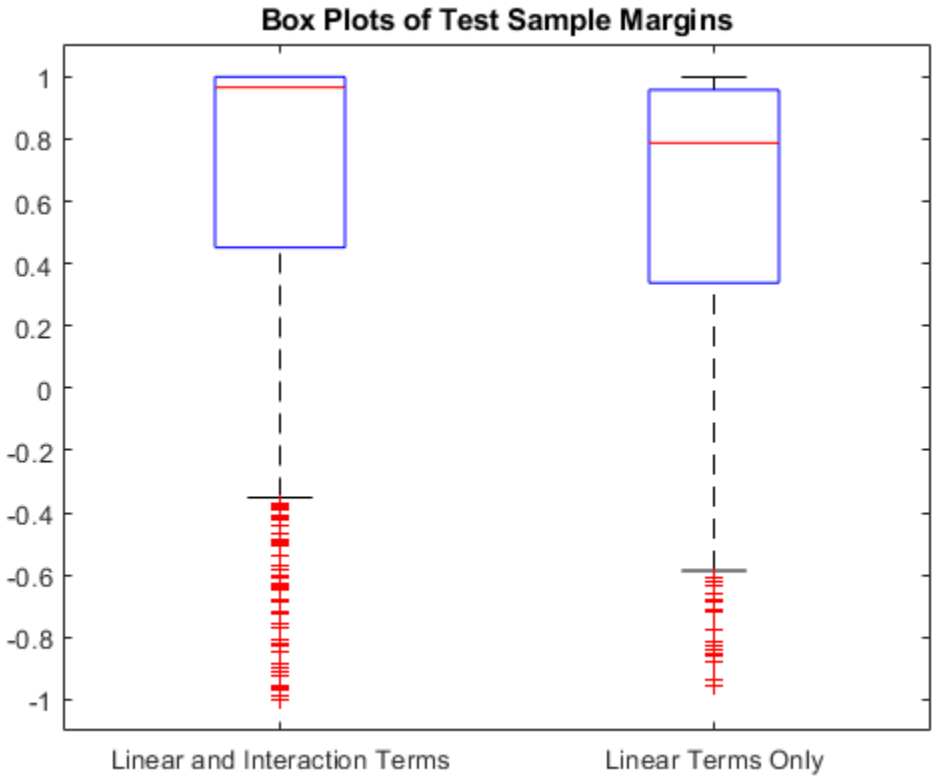
```
ans=2×2 table
           Linear and Interaction Terms    Only Linear Terms
           ____________________________    _________________

    Loss              0.14868                  0.13852
    Edge              0.63926                  0.58405
```

The model achieves a smaller loss when only linear terms are included, but achieves a higher edge value when both linear and interaction terms are included.

Display the distributions of the margins using box plots.

```
figure
boxplot([M M_nointeractions],'Labels',{'Linear and Interaction Terms','Linear Terms Only'})
title('Box Plots of Test Sample Margins')
```



Interpret Prediction

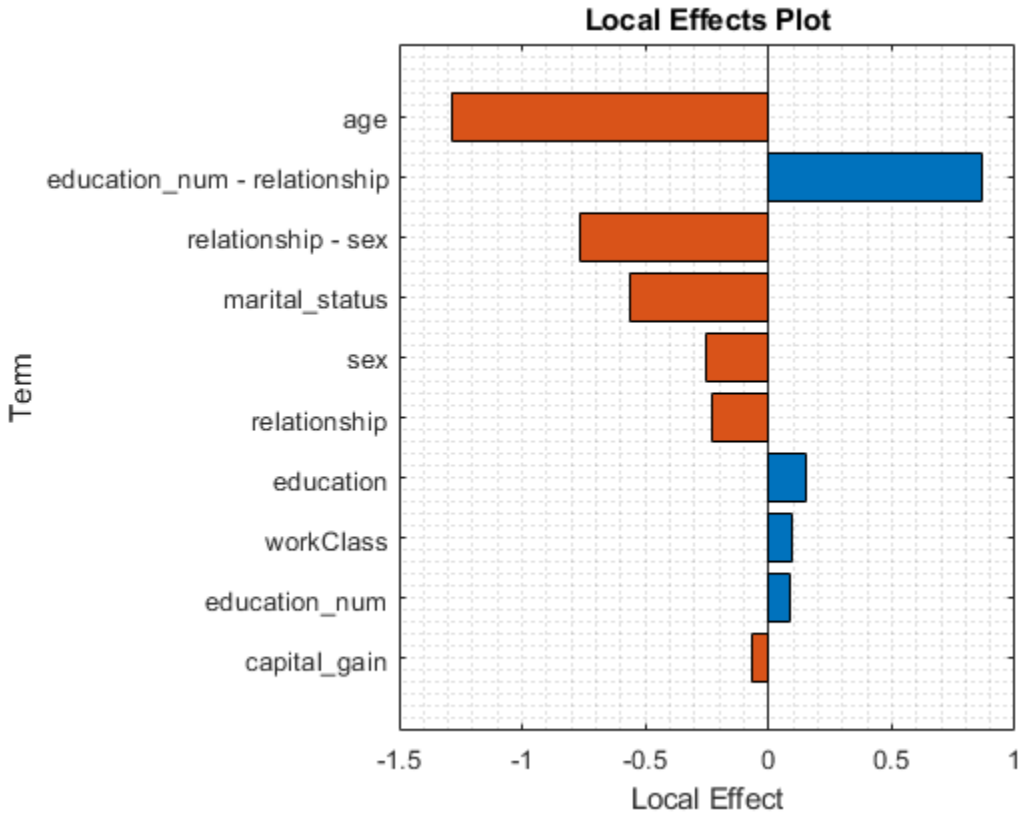
Interpret the prediction for the first test observation by using the `plotLocalEffects` function. Also, create partial dependence plots for some important terms in the model by using the `plotPartialDependence` function.

Classify the first observation of the test data, and plot the local effects of the terms in `CMdl` on the prediction. To display an existing underscore in any predictor name, change the `TickLabelInterpreter` value of the axes to `'none'`.

```
label = predict(CMdl,adulttest(1,:))
```

```
label = categorical
     <=50K
```

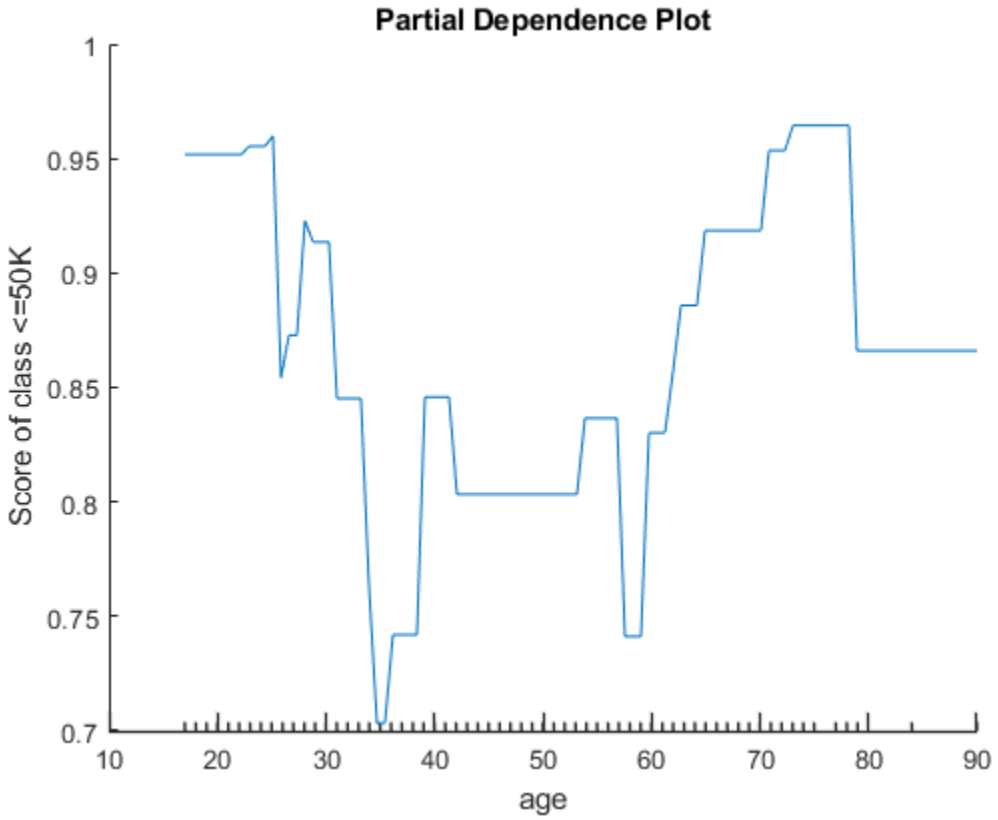
```
f1 = figure;
plotLocalEffects(CMdl,adulttest(1,:))
f1.CurrentAxes.TickLabelInterpreter = 'none';
```



The `predict` function classifies the first observation `adulttest(1,:)` as `'<=50K'`. The `plotLocalEffects` function creates a horizontal bar graph that shows the local effects of the 10 most important terms on the prediction. Each local effect value shows the contribution of each term to the classification score for `'<=50K'`, which is the logit of the posterior probability that the classification is `'<=50K'` for the observation.

Create a partial dependence plot for the term `age`. Specify both the training and test data sets to compute the partial dependence values using both sets.

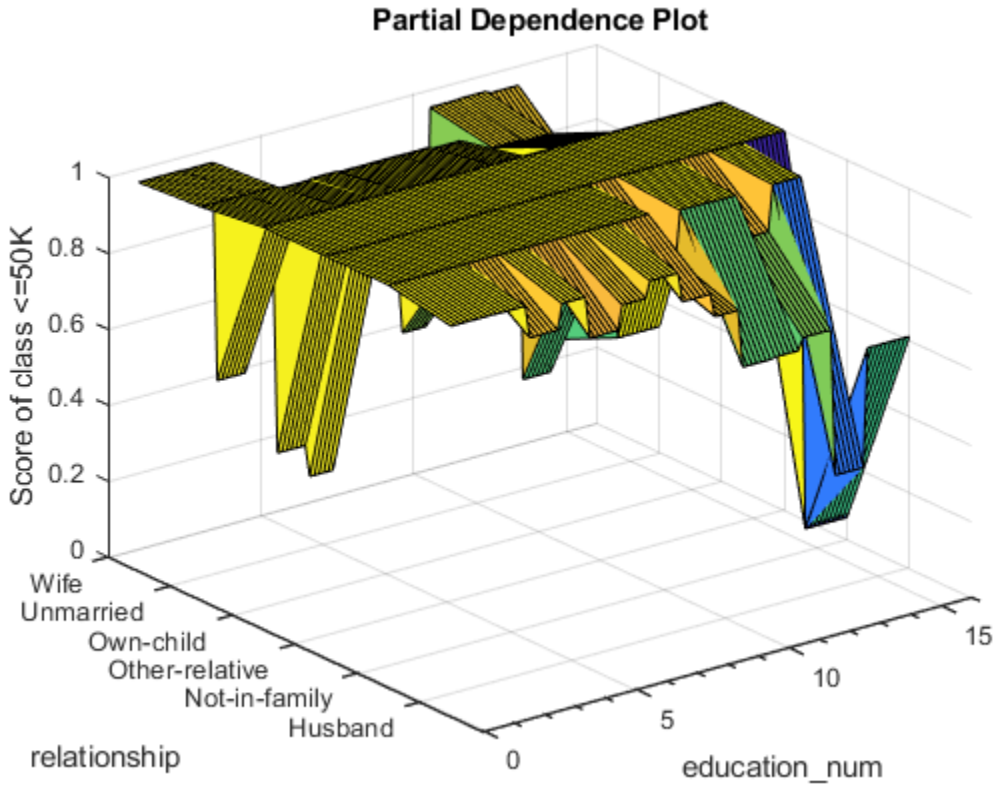
```
figure
plotPartialDependence(CMdl,'age',label,[adultdata; adulttest])
```



The plotted line represents the averaged partial relationships between the predictor `age` and the score of the class `<=50K` in the trained model. The *x*-axis minor ticks represent the unique values in the predictor `age`.

Create partial dependence plots for the terms `education_num` and `relationship`.

```
f2 = figure;
plotPartialDependence(CMdl,["education_num","relationship"],label,[adultdata; adulttest])
f2.CurrentAxes.TickLabelInterpreter = 'none';
```



The plot shows the partial dependence on `education_num`, which has a different trend depending on the `relationship` value.

- “Train Generalized Additive Model for Regression” on page 12-91

Train Generalized Additive Model for Regression

This example shows how to train a generalized additive model (GAM) with optimal parameters and how to assess the predictive performance of the trained model. The example first finds the optimal parameter values for a univariate GAM (parameters for linear terms) and then finds the values for a bivariate GAM (parameters for interaction terms). Also, The example explains how to interpret the trained model by examining local effects of terms on a specific prediction and by computing the partial dependence of the predictions on predictors.

Load Sample Data

Load the sample data set `NYCHousing2015`.

```
load NYCHousing2015
```

The data set includes 10 variables with information on the sales of properties in New York City in 2015. This example uses these variables to analyze the sale prices (`SALEPRICE`).

Preprocess the data set. Assume that a `SALEPRICE` less than or equal to $1000 indicates ownership transfer without a cash consideration. Remove the samples that have this `SALEPRICE`. Also, remove the outliers identified by the `isoutlier` function. Then, convert the `datetime` array (`SALEDATE`) to the month numbers and move the response variable (`SALEPRICE`) to the last column. Change zeros in `LANDSQUAREFEET`, `GROSSSQUAREFEET`, and `YEARBUILT` to `NaN`s.

```
idx1 = NYCHousing2015.SALEPRICE <= 1000;
idx2 = isoutlier(NYCHousing2015.SALEPRICE);
NYCHousing2015(idx1|idx2,:) = [];
NYCHousing2015.SALEDATE = month(NYCHousing2015.SALEDATE);
NYCHousing2015 = movevars(NYCHousing2015,'SALEPRICE','After','SALEDATE');
NYCHousing2015.LANDSQUAREFEET(NYCHousing2015.LANDSQUAREFEET == 0) = NaN;
NYCHousing2015.GROSSSQUAREFEET(NYCHousing2015.GROSSSQUAREFEET == 0) = NaN;
NYCHousing2015.YEARBUILT(NYCHousing2015.YEARBUILT == 0) = NaN;
```

Display the first three rows of the table.

```
head(NYCHousing2015,3)
```

```

       2       {'BATHGATE'}    {'01  ONE FAMILY DWELLINGS'}          1                   1
       2       {'BATHGATE'}    {'01  ONE FAMILY DWELLINGS'}          1                   2
```

Randomly select 1000 samples by using the `datasample` function, and partition observations into a training set and a test set by using the `cvpartition` function. Specify a 10% holdout sample for testing.

```
rng('default') % For reproducibility
NumSamples = 1e3;
NYCHousing2015 = datasample(NYCHousing2015,NumSamples,'Replace',false);
cv = cvpartition(size(NYCHousing2015,1),'HoldOut',0.10);
```

Extract the training and test indices, and create tables for training and test data sets.

```
tbl_training = NYCHousing2015(training(cv),:);
tbl_test = NYCHousing2015(test(cv),:);
```

Find Optimal Parameters for Univariate GAM

Optimize the parameters for a univariate GAM with respect to cross-validation by using the `bayesopt` function.

Prepare `optimizableVariable` objects for the name-value arguments of a univariate GAM: `MaxNumSplitsPerPredictor`, `NumTreesPerPredictor`, and `InitialLearnRateForPredictors`.

```
maxNumSplitsPerPredictor = optimizableVariable('maxNumSplitsPerPredictor',[1,10],'Type','integer
numTreesPerPredictor = optimizableVariable('numTreesPerPredictor',[1,500],'Type','integer');
initialLearnRateForPredictors = optimizableVariable('initialLearnRateForPredictors',[1e-3,1],'Ty
```

Create an objective function that takes an input `z = [maxNumSplitsPerPredictor,numTreesPerPredictor,initialLearnRateForPredictors]` and returns the cross-validated loss value at the parameters in `z`.

```
minfun1 = @(z)kfoldLoss(fitrgam(tbl_training,'SALEPRICE', ...
    'CrossVal','on', ...
    'InitialLearnRateForPredictors',z.initialLearnRateForPredictors, ...
    'MaxNumSplitsPerPredictor',z.maxNumSplitsPerPredictor, ...
    'NumTreesPerPredictor',z.numTreesPerPredictor));
```

If you specify the cross-validation option `'CrossVal','on'`, then the `fitrgam` function returns a cross-validated model object `RegressionPartitionedGAM`. The `kfoldLoss` function returns the regression loss (mean squared error) obtained by the cross-validated model. Therefore, the function handle `minfun1` computes the cross-validation loss at the parameters in `z`.

Search for the best parameters using `bayesopt`. For reproducibility, choose the `'expected-improvement-plus'` acquisition function. The default acquisition function depends on run time and, therefore, can give varying results.

```
results1 = bayesopt(minfun1, ...
    [initialLearnRateForPredictors,maxNumSplitsPerPredictor,numTreesPerPredictor], ...
    'IsObjectiveDeterministic',true, ...
    'AcquisitionFunctionName','expected-improvement-plus');
```

```

  Properties, Methods
```

`Mdl1` is a `RegressionGAM` model object. The model display shows a partial list of the model properties. To view the full list of properties, double-click the variable name `Mdl1` in the Workspace. The Variables editor opens for `Mdl1`. Alternatively, you can display the properties in the Command Window by using dot notation. For example, display the `ReasonForTermination` property.

```
Mdl1.ReasonForTermination

ans = struct with fields:
      PredictorTrees: 'Terminated after training the requested number of trees.'
    InteractionTrees: ''
```

The `PredictorTrees` field of the property value indicates that `Mdl1` includes the specified number of trees. `NumTreesPerPredictor` of `fitrgam` specifies the maximum number of trees per predictor, and the function can stop before training the requested number of trees. You can use the `ReasonForTermination` property to determine whether the trained model contains the specified number of trees.

If you specify to include interaction terms so that `fitrgam` trains trees for them. the `InteractionTrees` field contains a nonempty value.

Find Optimal Parameters for Bivariate GAM

Find the parameters for interaction terms of a bivariate GAM by using the `bayesopt` function.

Prepare `optimizableVariable` for the name-value arguments for the interaction terms: `InitialLearnRateForInteractions`, `MaxNumSplitsPerInteraction`, `NumTreesPerInteraction`, and `InitialLearnRateForInteractions`.

```
initialLearnRateForInteractions = optimizableVariable('initialLearnRateForInteractions',[1e-3,1]
maxNumSplitsPerInteraction = optimizableVariable('maxNumSplitsPerInteraction',[1,10],'Type','inte
numTreesPerInteraction = optimizableVariable('numTreesPerInteraction',[1,500],'Type','integer');
numInteractions = optimizableVariable('numInteractions',[1,28],'Type','integer');
```

Create an objective function for the optimization. Use the optimal parameter values in `zbest1` so that the software finds optimal parameter values for interaction terms based on the `zbest1` values.

```
minfun2 = @(z)kfoldLoss(fitrgam(tbl_training,'SALEPRICE', ...
    'CrossVal','on', ...
    'InitialLearnRateForPredictors',zbest1.initialLearnRateForPredictors, ...
    'MaxNumSplitsPerPredictor',zbest1.maxNumSplitsPerPredictor, ...
    'NumTreesPerPredictor',zbest1.numTreesPerPredictor, ...
    'InitialLearnRateForInteractions',z.initialLearnRateForInteractions, ...
    'MaxNumSplitsPerInteraction',z.maxNumSplitsPerInteraction, ...
    'NumTreesPerInteraction',z.numTreesPerInteraction, ...
    'Interactions',z.numInteractions));
```

Search for the best parameters using `bayesopt`. The optimization process trains multiple models and displays warning messages if the models include no interaction terms. Disable all warnings before calling `bayesopt` and restore the warning state after running `bayesopt`. You can leave the warning state unchanged to view the warning messages.

```
orig_state = warning('query');
warning('off')
results2 = bayesopt(minfun2, ...
    [initialLearnRateForInteractions,maxNumSplitsPerInteraction,numTreesPerInteraction,numInterac
    'IsObjectiveDeterministic',true, ...
    'AcquisitionFunctionName','expected-improvement-plus');

    _______________________________    __________________________    ______________________    __

                0.99848                             6                          1
```

Train Bivariate GAM with Optimal Parameters

Train an optimized GAM using the `zbest1` and `zbest2` values.

```
Mdl = fitrgam(tbl_training,'SALEPRICE', ...
    'InitialLearnRateForPredictors',zbest1.initialLearnRateForPredictors, ...
    'MaxNumSplitsPerPredictor',zbest1.maxNumSplitsPerPredictor, ...
    'NumTreesPerPredictor',zbest1.numTreesPerPredictor, ...
    'InitialLearnRateForInteractions',zbest2.initialLearnRateForInteractions, ...
    'MaxNumSplitsPerInteraction',zbest2.maxNumSplitsPerInteraction, ...
    'NumTreesPerInteraction',zbest2.numTreesPerInteraction, ...
    'Interactions',zbest2.numInteractions)
```

```
Mdl =
  RegressionGAM
             PredictorNames: {'BOROUGH'  'NEIGHBORHOOD'  'BUILDINGCLASSCATEGORY'  'RESIDENTIALUNITS
               ResponseName: 'SALEPRICE'
    CategoricalPredictors: [2 3]
        ResponseTransform: 'none'
                Intercept: 4.9741e+05
             Interactions: [3×2 double]
          NumObservations: 900

  Properties, Methods
```

Alternatively, you can add interaction terms to the univariate GAM by using the `addInteractions` function.

```
Mdl2 = addInteractions(Mdl1,zbest2.numInteractions, ...
    'InitialLearnRateForInteractions',zbest2.initialLearnRateForInteractions, ...
    'MaxNumSplitsPerInteraction',zbest2.maxNumSplitsPerInteraction, ...
    'NumTreesPerInteraction',zbest2.numTreesPerInteraction);
```

The second input argument specifies the maximum number of interaction terms, and the `NumTreesPerInteraction` name-value argument specifies the maximum number of trees per interaction term. The `addInteractions` function can include fewer interaction terms and stop before training the requested number of trees. You can use the `Interactions` and `ReasonForTermination` properties to check the actual number of interaction terms and number of trees in the trained model.

Display the interaction terms in `Mdl`.

```
Mdl.Interactions
```

```
ans = 3×2
```

```
     3     6
     4     6
     6     8
```

Each row of `Interactions` represents one interaction term and contains the column indexes of the predictor variables for the interaction term. You can use the `Interactions` property to check the interaction terms in the model and the order in which `fitrgam` adds them to the model.

Display the interaction terms in `Mdl` using the predictor names.

```
Mdl.PredictorNames(Mdl.Interactions)
```

```
ans = 3×2 cell
    {'BUILDINGCLASSCATEGORY'}    {'LANDSQUAREFEET'}
    {'RESIDENTIALUNITS'     }    {'LANDSQUAREFEET'}
    {'LANDSQUAREFEET'       }    {'YEARBUILT'     }
```

Display the reason for termination to determine whether the model contains the specified number of trees for each linear term and each interaction term.

```
Mdl.ReasonForTermination
```

```
ans = struct with fields:
      PredictorTrees: 'Terminated after training the requested number of trees.'
    InteractionTrees: 'Terminated after training the requested number of trees.'
```

Assess Predictive Performance on New Observations

Assess the performance of the trained model by using the test sample `tbl_test` and the object functions `predict` and `loss`. You can use a full or compact model with these functions.

- `predict` — Predict responses
- `loss` — Compute regression loss (mean squared error, by default)

If you want to assess the performance of the training data set, use the resubstitution object functions: `resubPredict` and `resubLoss`. To use these functions, you must use the full model that contains the training data.

Create a compact model to reduce the size of the trained model.

```
CMdl = compact(Mdl);
whos('Mdl','CMdl')
```

```
  Name      Size             Bytes  Class                                          Attributes

  CMdl      1x1             370211  classreg.learning.regr.CompactRegressionGAM
  Mdl       1x1             528102  RegressionGAM
```

Predict responses and compute mean squared errors for the test data set `tbl_test`.

```
yFit = predict(CMdl,tbl_test);
L = loss(CMdl,tbl_test)
```

```
L = 1.2855e+11
```

Find predicted responses and errors without including interaction terms in the trained model.

```
yFit_nointeraction = predict(CMdl,tbl_test,'IncludeInteractions',false);
L_nointeractions = loss(CMdl,tbl_test,'IncludeInteractions',false)
```

```
L_nointeractions = 1.3031e+11
```

The model achieves a smaller error for the test data set when both linear and interaction terms are included.

Compare the results obtained by including both linear to interaction terms and the results obtained by including only linear terms. Create a table containing the observed responses and predicted responses. Display the first eight rows of the table.

```
t = table(tbl_test.SALEPRICE,yFit,yFit_nointeraction, ...
    'VariableNames',{'Observed Value','Predicted Response','Predicted Response Without Interactio
head(t)
```

```
ans=8×3 table
    Observed Value    Predicted Response    Predicted Response Without Interactions
    ______________    __________________    ______________________________________

         3.6e+05          4.9812e+05                    5.2712e+05
         1.8e+05          2.7349e+05                    2.7415e+05
         1.9e+05          3.3682e+05                    3.3748e+05
        4.26e+05            6.15e+05                    5.6542e+05
        3.91e+05          3.1262e+05                    3.1328e+05
         2.3e+05          1.0606e+05                    1.0672e+05
      4.7333e+05          1.0773e+06                    1.1399e+06
           2e+05          2.9506e+05                     3.305e+05
```

Interpret Prediction

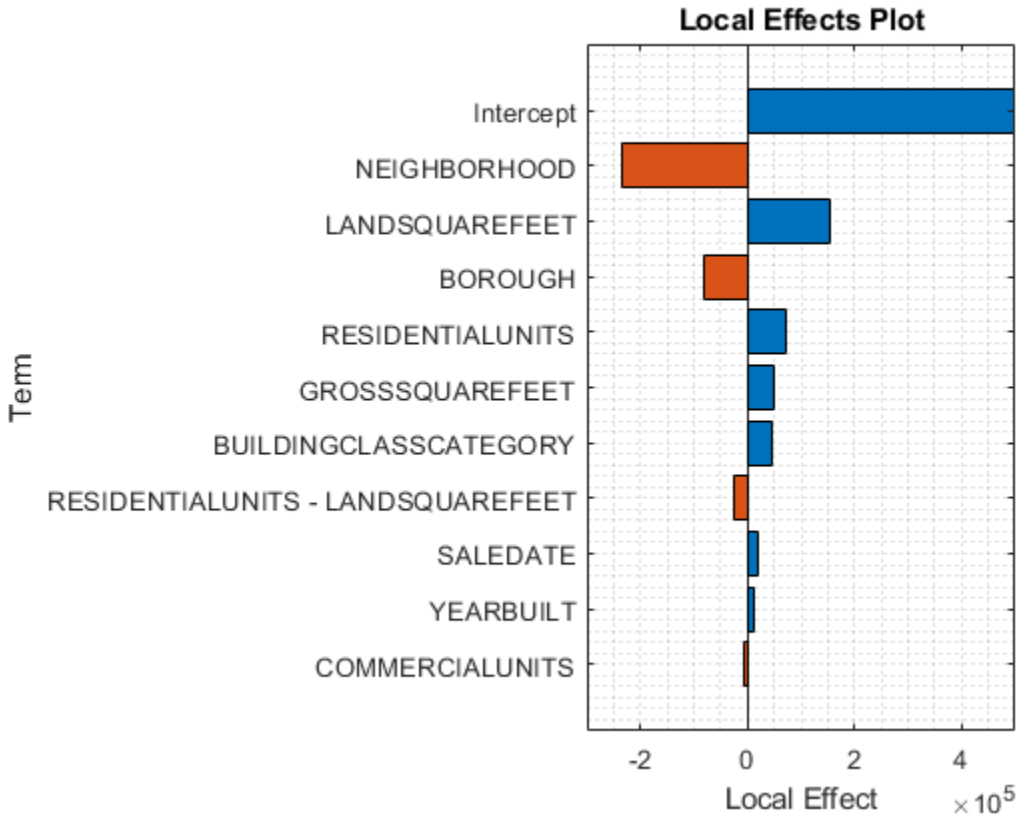
Interpret the prediction for the first test observation by using the `plotLocalEffects` function. Also, create partial dependence plots for some important terms in the model by using the `plotPartialDependence` function.

Predict a response value for the first observation of the test data, and plot the local effects of the terms in `CMdl` on the prediction. Specify `'IncludeIntercept',true` to include the intercept term in the plot.

```
yFit = predict(CMdl,tbl_test(1,:))
```

```
yFit = 4.9812e+05
```

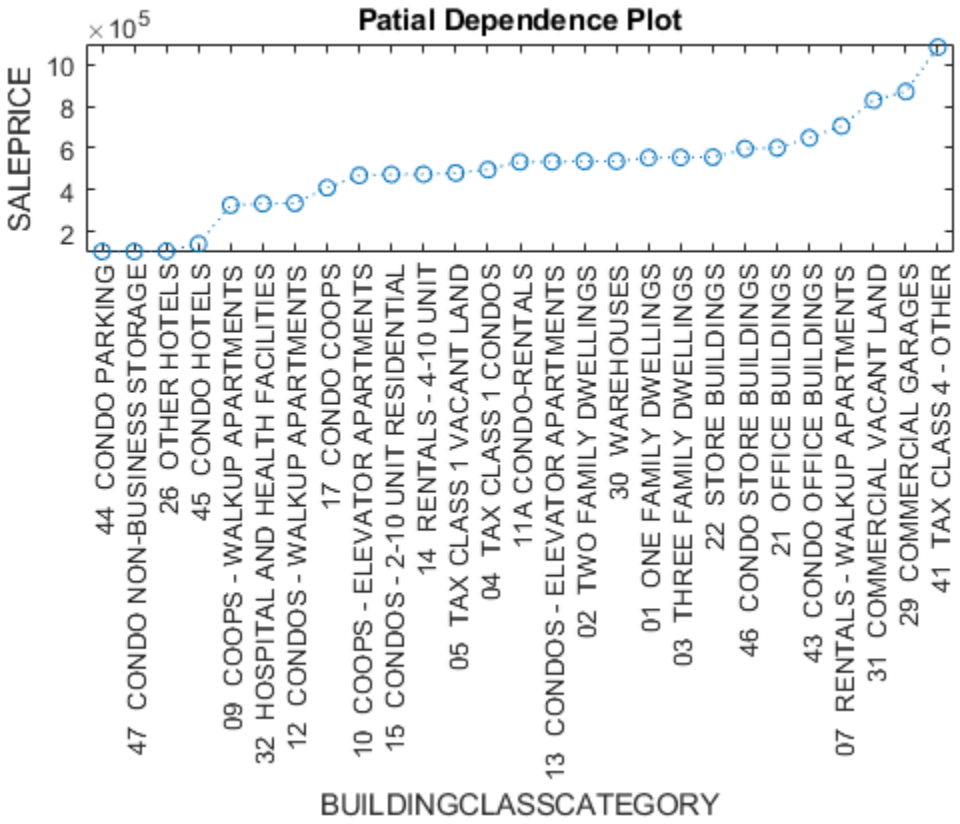
```
plotLocalEffects(CMdl,tbl_test(1,:),'IncludeIntercept',true)
```



The `predict` function returns the sale price for the first observation `tbl_test(1,:)`. The `plotLocalEffects` function creates a horizontal bar graph that shows the local effects of the terms in `CMdl` on the prediction. Each local effect value shows the contribution of each term to the predicted sale price for `tbl_test(1,:)`.

Compute the partial dependence values for `BUILDINGCLASSCATEGORY` and plot the sorted values. Specify both the training and test data sets to compute the partial dependence values using both sets.

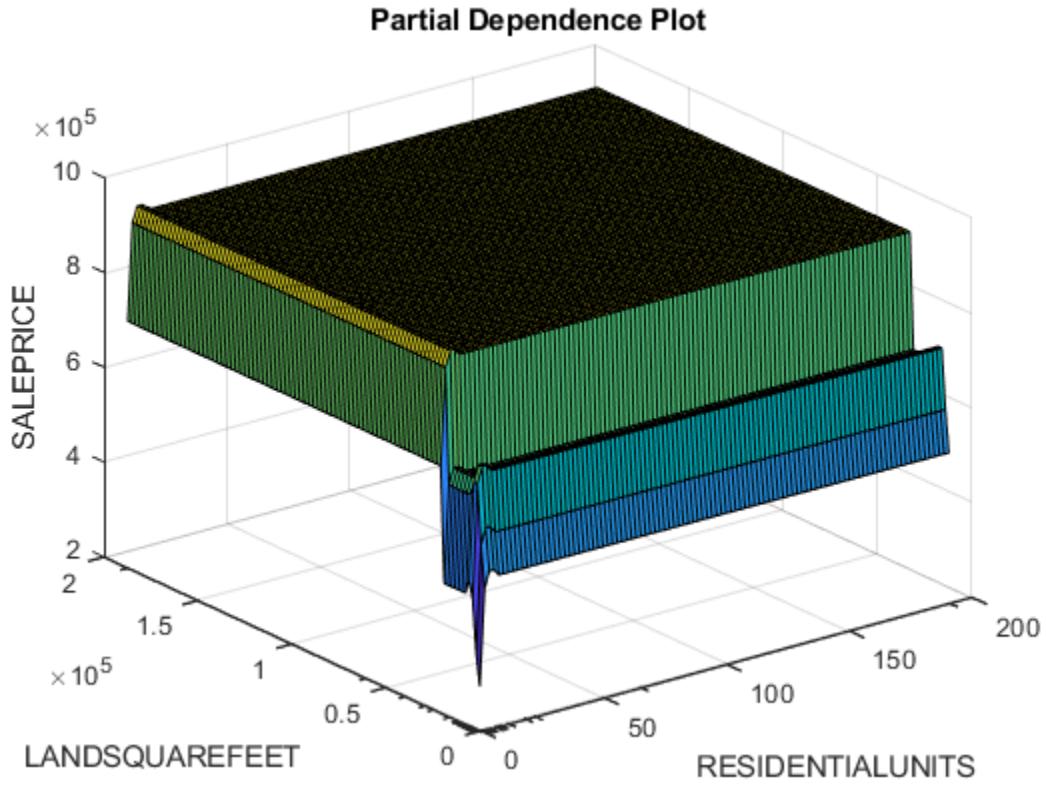
```
[pd,x,y] = partialDependence(CMdl,'BUILDINGCLASSCATEGORY',[tbl_training; tbl_test]);
[pd_sorted,I] = sort(pd);
x_sorted = x(I);
x_sorted = reordercats(x_sorted,I);
figure
plot(x_sorted,pd_sorted,'o:')
xlabel('BUILDINGCLASSCATEGORY')
ylabel('SALEPRICE')
title('Patial Dependence Plot')
```



The plotted line represents the averaged partial relationships between the predictor `BUILDINGCLASSCATEGORY` and the response `SALEPRICE` in the trained model.

Create a partial dependence plot for the terms `RESIDENTIALUNITS` and `LANDSQUAREFEET`.

```
figure
plotPartialDependence(CMdl,["RESIDENTIALUNITS","LANDSQUAREFEET"],[tbl_training; tbl_test])
```



The minor ticks in the *x*-axis (`RESIDENTIALUNITS`) and *y*-axis (`LANDSQUAREFEET`) represent the unique values of the predictors in the specified data. The predictor values include a few outliers, and most of the `RESIDENTIALUNITS` and `LANDSQUAREFEET` values are less than 10 and 50,000, respectively. The plot shows that the `SALEPRICE` values do not vary significantly when the `RESIDENTIALUNITS` and `LANDSQUAREFEET` values are greater than 10 and 50,000.

Nonlinear Regression

Nonlinear Regression

In this section...

What Are Parametric Nonlinear Regression Models?

Parametric nonlinear models represent the relationship between a continuous response variable and one or more continuous predictor variables in the form

$y = f(X,\beta) + \varepsilon,$

where

- y is an n-by-1 vector of observations of the response variable.
- f is any function of X and β that evaluates each row of X along with the vector β to compute the prediction for the corresponding row of y.
- X is an n-by-p matrix of predictors, with one row for each observation, and one column for each predictor.
- β is a p-by-1 vector of unknown parameters to be estimated.
- ε is an n-by-1 vector of independent, identically distributed random disturbances.

In contrast, nonparametric models do not attempt to characterize the relationship between predictors and response with model parameters. Descriptions are often graphical, as in the case of “Decision Trees” on page 19-2.

`fitnlm` attempts to find values of the parameters β that minimize the mean squared differences between the observed responses y and the predictions of the model $f(X,\beta)$. To do so, it needs a starting value `beta0` before iteratively modifying the vector β to a vector with minimal mean squared error.

Prepare Data

To begin fitting a regression, put your data into a form that fitting functions expect. All regression techniques begin with input data in an array `X` and response data in a separate vector `y`, or input data in a table or dataset array `tbl` and response data as a column in `tbl`. Each row of the input data represents one observation. Each column represents one predictor (variable).

For a table or dataset array `tbl`, indicate the response variable with the `'ResponseVar'` name-value pair:

```
mdl = fitlm(tbl,'ResponseVar','BloodPressure');
```

The response variable is the last column by default.

You cannot use categorical predictors for nonlinear regression. A categorical predictor is one that takes values from a fixed set of possibilities.

Represent missing data as `NaN` for both input data and response data.

Dataset Array for Input and Response Data

For example, to create a dataset array from an Excel spreadsheet:

```
ds = dataset('XLSFile','hospital.xls',...
     'ReadObsNames',true);
```

To create a dataset array from workspace variables:

```
load carsmall
ds = dataset(Weight,Model_Year,MPG);
```

Table for Input and Response Data

To create a table from an Excel spreadsheet:

```
tbl = readtable('hospital.xls',...
     'ReadRowNames',true);
```

To create a table from workspace variables:

```
load carsmall
tbl = table(Weight,Model_Year,MPG);
```

Numeric Matrix for Input Data and Numeric Vector for Response

For example, to create numeric arrays from workspace variables:

```
load carsmall
X = [Weight Horsepower Cylinders Model_Year];
y = MPG;
```

To create numeric arrays from an Excel spreadsheet:

```
[X, Xnames] = xlsread('hospital.xls');
y = X(:,4); % response y is systolic pressure
X(:,4) = []; % remove y from the X matrix
```

Notice that the nonnumeric entries, such as `sex`, do not appear in `X`.

Represent the Nonlinear Model

There are several ways to represent a nonlinear model. Use whichever is most convenient.

The nonlinear model is a required input to `fitnlm`, in the `modelfun` input.

`fitnlm` assumes that the response function $f(X,\beta)$ is smooth in the parameters β. If your function is not smooth, `fitnlm` can fail to provide optimal parameter estimates.

- “Function Handle to Anonymous Function or Function File” on page 13-4

• “Text Representation of Formula” on page 13-4

Function Handle to Anonymous Function or Function File

The function handle @*modelfun*(b,x) accepts a vector b and matrix, table, or dataset array x. The function handle should return a vector f with the same number of rows as x. For example, the function file hougen.m computes

$$\text{hougen}(b,x) = \frac{b(1)x(2) - x(3)/b(5)}{1 + b(2)x(1) + b(3)x(2) + b(4)x(3)}.$$

Examine the function by entering type hougen at the MATLAB command line.

```
function yhat = hougen(beta,x)
%HOUGEN Hougen-Watson model for reaction kinetics.
%   YHAT = HOUGEN(BETA,X) gives the predicted values of the
%   reaction rate, YHAT, as a function of the vector of
%   parameters, BETA, and the matrix of data, X.
%   BETA must have 5 elements and X must have three
%   columns.
%
%   The model form is:
%   y = (b1*x2 - x3/b5)./(1+b2*x1+b3*x2+b4*x3)
%
%   Reference:
%      [1]  Bates, Douglas, and Watts, Donald, "Nonlinear
%      Regression Analysis and Its Applications", Wiley
%      1988 p. 271-272.

%   Copyright 1993-2004 The MathWorks, Inc.
%   B.A. Jones 1-06-95.

b1 = beta(1);
b2 = beta(2);
b3 = beta(3);
b4 = beta(4);
b5 = beta(5);

x1 = x(:,1);
x2 = x(:,2);
x3 = x(:,3);

yhat = (b1*x2 - x3/b5)./(1+b2*x1+b3*x2+b4*x3);
```

You can write an anonymous function that performs the same calculation as hougen.m.

```
modelfun = @(b,x)(b(1)*x(:,2) - x(:,3)/b(5))./...
(1 + b(2)*x(:,1) + b(3)*x(:,2) + b(4)*x(:,3));
```

Text Representation of Formula

For data in a matrix X and response in a vector y:

- Represent the formula using 'x1' as the first predictor (column) in X, 'x2' as the second predictor, etc.
- Represent the vector of parameters to optimize as 'b1', 'b2', etc.

- Write the formula as `'y ~ (mathematical expressions)'`.

For example, to represent the response to the reaction data:

```
modelfun = 'y ~ (b1*x2 - x3/b5)/(1 + b2*x1 + b3*x2 + b4*x3)';
```

For data in a table or dataset array, you can use formulas represented as the variable names from the table or dataset array. Put the response variable name at the left of the formula, followed by a `~`, followed by a character vector representing the response formula.

This example shows how to create a character vector to represent the response to the `reaction` data that is in a dataset array.

1. Load the `reaction` data.

   ```
   load reaction
   ```

2. Put the data into a dataset array, where each variable has a name given in `xn` or `yn`.

   ```
   ds = dataset({reactants,xn(1,:),xn(2,:),xn(3,:)},...
       {rate,yn});
   ```

3. Examine the first row of the dataset array.

   ```
   ds(1,:)

   ans =

       Hydrogen    n_Pentane    Isopentane    ReactionRate
       470         300          10            8.55
   ```

4. Write the `hougen` formula using names in the dataset array.

   ```
   modelfun = ['ReactionRate ~ (b1*n_Pentane - Isopentane/b5) /'...
   ' (1 + Hydrogen*b2 + n_Pentane*b3 + Isopentane*b4)']

   modelfun =
   ReactionRate ~ (b1*n_Pentane - Isopentane/b5) / ...
        (1 + Hydrogen*b2 + n_Pentane*b3 + Isopentane*b4)
   ```

Choose Initial Vector beta0

The initial vector for the fitting iterations, `beta0`, can greatly influence the quality of the resulting fitted model. `beta0` gives the dimensionality of the problem, meaning it needs the correct length. A good choice of `beta0` leads to a quick, reliable model, while a poor choice can lead to a long computation, or to an inadequate model.

It is difficult to give advice on choosing a good `beta0`. If you believe certain components of the vector should be positive or negative, set your `beta0` to have those characteristics. If you know the approximate value of other components, include them in `beta0`. However, if you don’t know good values, try a random vector, such as

```
beta0 = randn(nVars,1);
% or
beta0 = 10*rand(nVars,1);
```

Fit Nonlinear Model to Data

The syntax for fitting a nonlinear regression model using a table or dataset array `tbl` is

```
mdl = fitnlm(tbl,modelfun,beta0)
```

The syntax for fitting a nonlinear regression model using a numeric array `X` and numeric response vector `y` is

```
mdl = fitnlm(X,y,modelfun,beta0)
```

For information on representing the input parameters, see “Prepare Data” on page 13-2, “Represent the Nonlinear Model” on page 13-3, and “Choose Initial Vector beta0” on page 13-5.

`fitnlm` assumes that the response variable in a table or dataset array `tbl` is the last column. To change this, use the `ResponseVar` name-value pair to name the response column.

Examine Quality and Adjust the Fitted Nonlinear Model

There are diagnostic plots to help you examine the quality of a model. `plotDiagnostics(mdl)` gives a variety of plots, including leverage and Cook's distance plots. `plotResiduals(mdl)` gives the difference between the fitted model and the data.

There are also properties of `mdl` that relate to the model quality. `mdl.RMSE` gives the root mean square error between the data and the fitted model. `mdl.Residuals.Raw` gives the raw residuals. `mdl.Diagnostics` contains several fields, such as `Leverage` and `CooksDistance`, that can help you identify particularly interesting observations.

This example shows how to examine a fitted nonlinear model using diagnostic, residual, and slice plots.

Load the sample data.

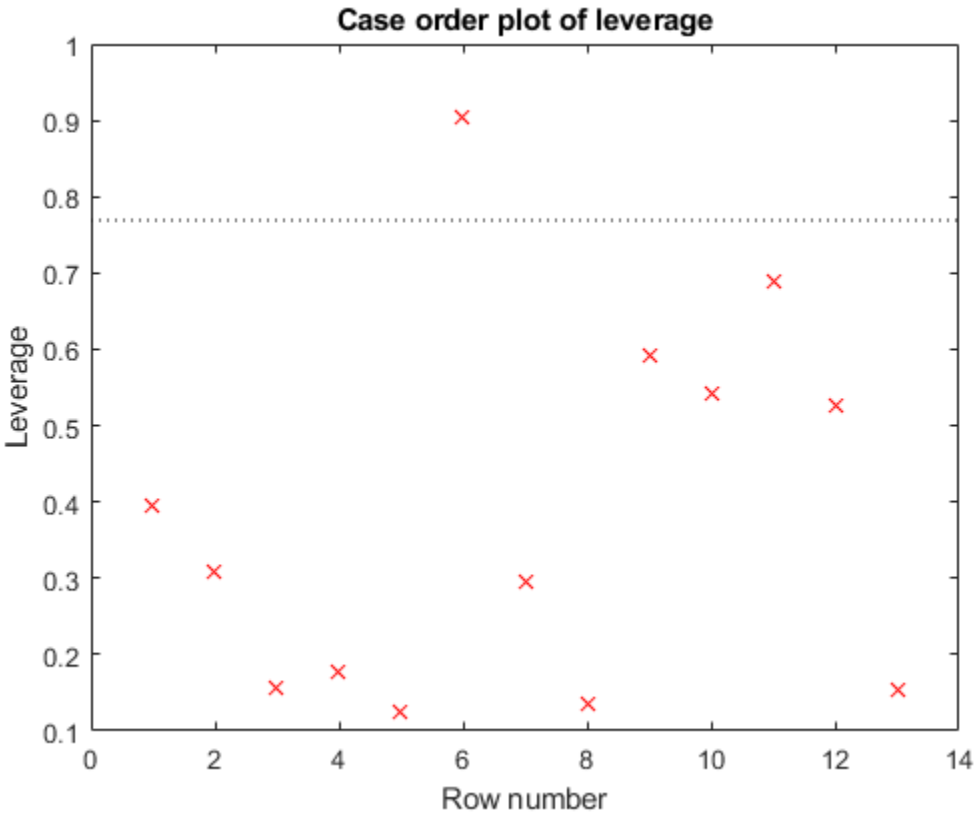
```
load reaction
```

Create a nonlinear model of rate as a function of `reactants` using the `hougen.m` function.

```
beta0 = ones(5,1);
mdl = fitnlm(reactants,...
    rate,@hougen,beta0);
```

Make a leverage plot of the data and model.

```
plotDiagnostics(mdl)
```



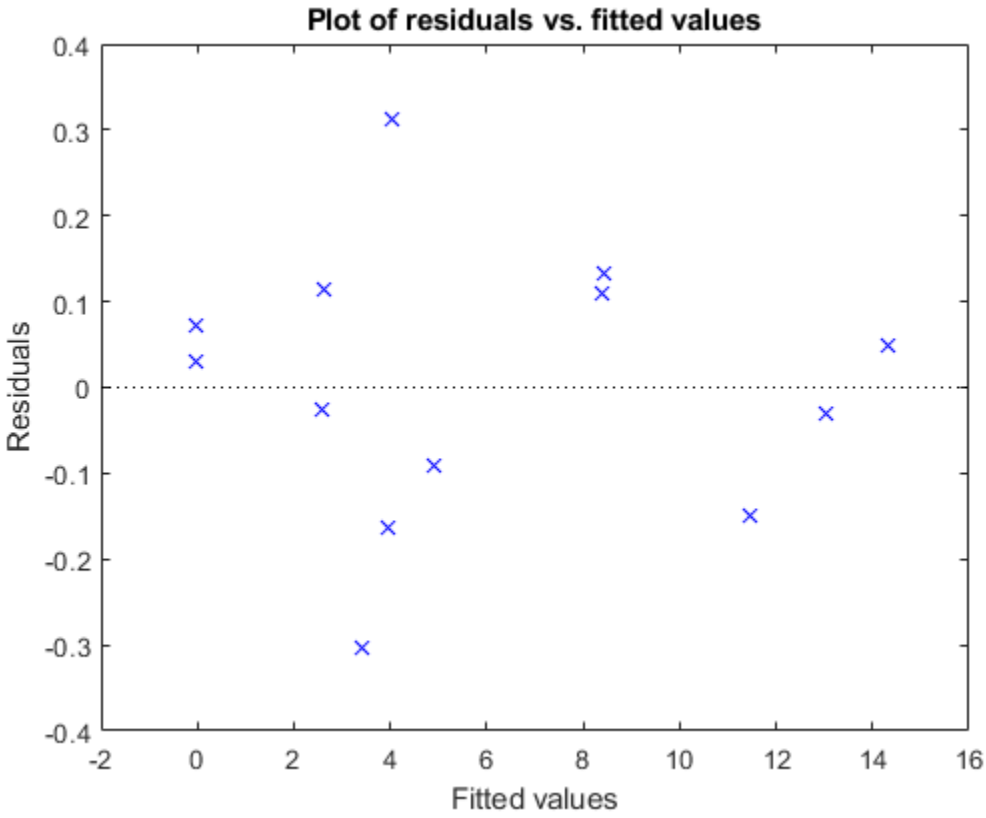
There is one point that has high leverage. Locate the point.

```
[~,maxl] = max(mdl.Diagnostics.Leverage)
```

```
maxl = 6
```

Examine a residuals plot.

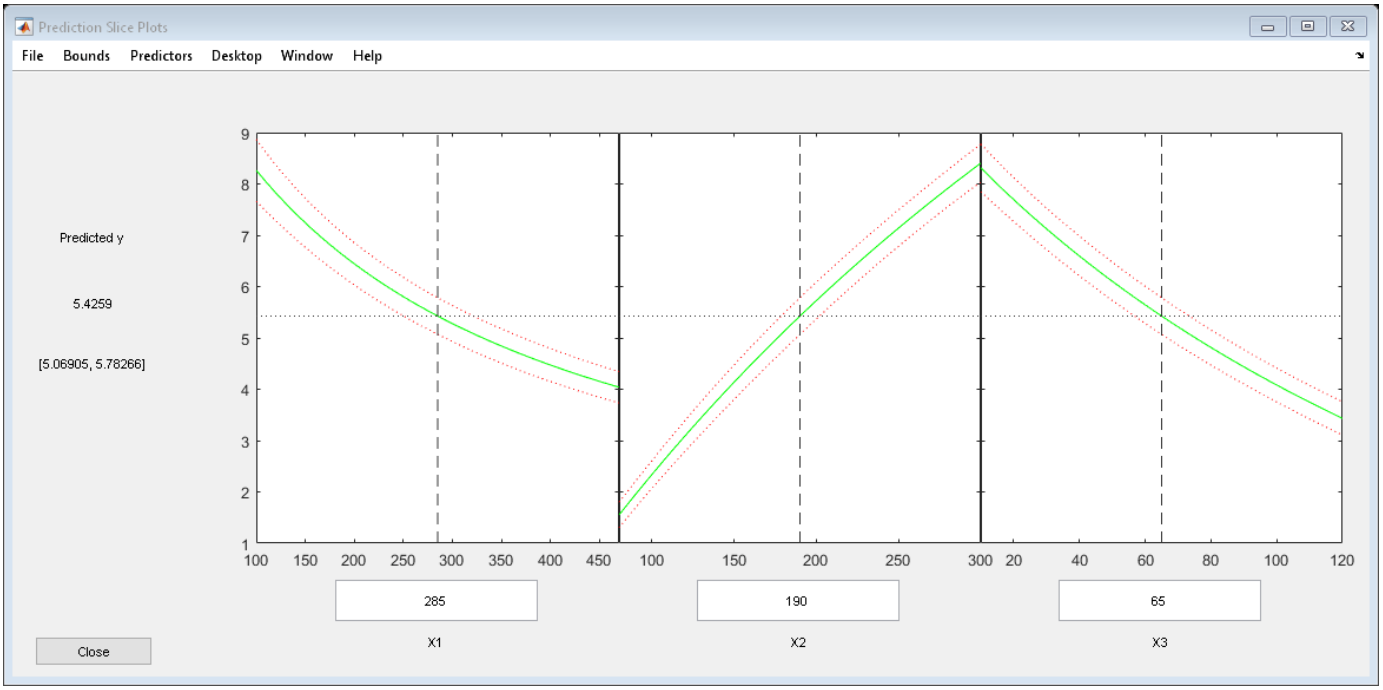
```
plotResiduals(mdl,'fitted')
```



Nothing stands out as an outlier.

Use a slice plot to show the effect of each predictor on the model.

```
plotSlice(mdl)
```



You can drag the vertical dashed blue lines to see the effect of a change in one predictor on the response. For example, drag the X2 line to the right, and notice that the slope of the X3 line changes.

Predict or Simulate Responses Using a Nonlinear Model

This example shows how to use the methods `predict`, `feval`, and `random` to predict and simulate responses to new data.

Randomly generate a sample from a Cauchy distribution.

```
rng('default')
X = rand(100,1);
X = tan(pi*X - pi/2);
```

Generate the response according to the model `y = b1*(pi /2 + atan((x - b2) / b3))` and add noise to the response.

```
modelfun = @(b,x) b(1) * ...
    (pi/2 + atan((x - b(2))/b(3)));
y = modelfun([12 5 10],X) + randn(100,1);
```

Fit a model starting from the arbitrary parameters b = [1,1,1].

```
beta0 = [1 1 1]; % An arbitrary guess
mdl = fitnlm(X,y,modelfun,beta0)
```

```
mdl =
Nonlinear regression model:
    y ~ b1*(pi/2 + atan((x - b2)/b3))

Estimated Coefficients:
```

```
          Estimate      SE       tStat       pValue
          ________    ________    _______    __________

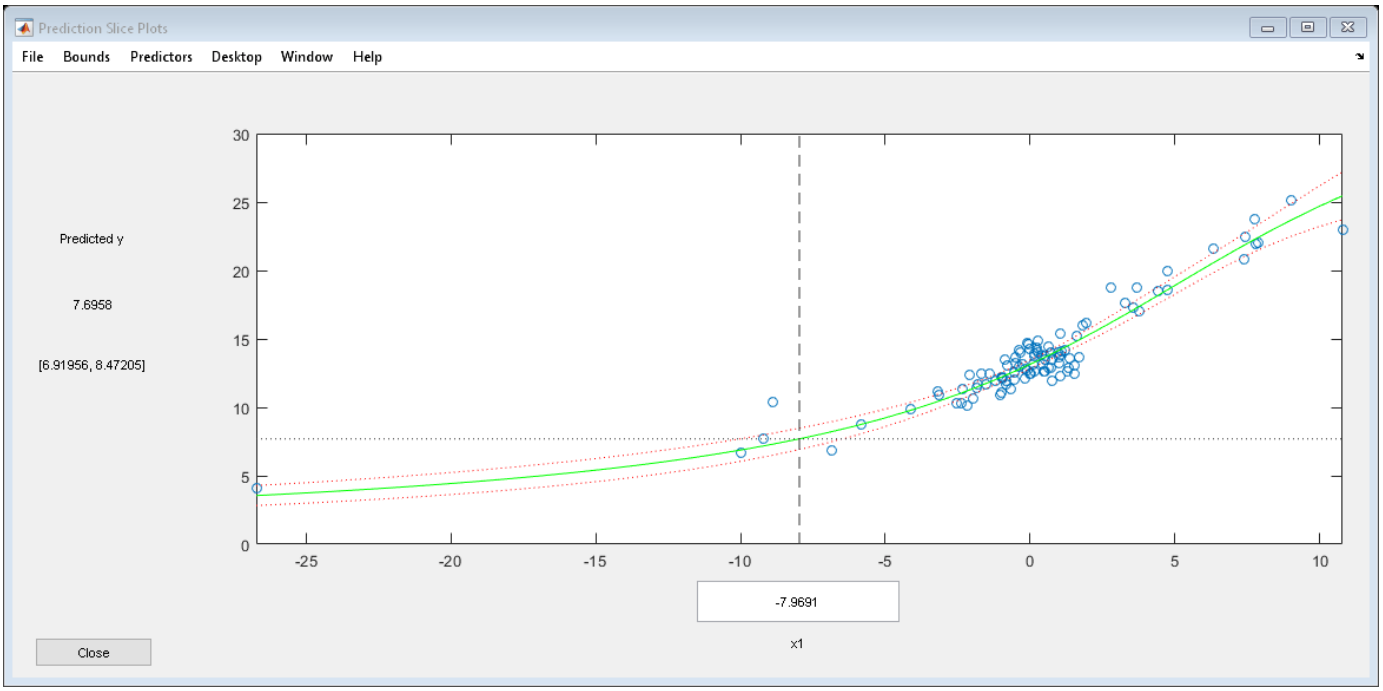
    b1      12.082     0.80028    15.097    3.3151e-27
    b2      5.0603      1.0825    4.6747    9.5063e-06
    b3        9.64     0.46499    20.732    2.0382e-37

Number of observations: 100, Error degrees of freedom: 97
Root Mean Squared Error: 1.02
R-Squared: 0.92,  Adjusted R-Squared 0.918
F-statistic vs. zero model: 6.45e+03, p-value = 1.72e-111
```

The fitted values are within a few percent of the parameters [12,5,10].

Examine the fit.

```
plotSlice(mdl)
```



predict

The `predict` method predicts the mean responses and, if requested, gives confidence bounds. Find the predicted response values and predicted confidence intervals about the response at X values [-15;5;12].

```
Xnew = [-15;5;12];
[ynew,ynewci] = predict(mdl,Xnew)
```

```
ynew = 3×1

    5.4122
   18.9022
   26.5161
```

```
ynewci = 3×2

    4.8233    6.0010
   18.4555   19.3490
   25.0170   28.0151
```

The confidence intervals are reflected in the slice plot.

`feval`

The `feval` method predicts the mean responses. `feval` is often more convenient to use than predict when you construct a model from a dataset array.

Create the nonlinear model from a dataset array.

```
ds = dataset({X,'X'},{y,'y'});
mdl2 = fitnlm(ds,modelfun,beta0);
```

Find the predicted model responses (CDF) at X values [-15;5;12].

```
Xnew = [-15;5;12];
ynew = feval(mdl2,Xnew)
```

```
ynew = 3×1

    5.4122
   18.9022
   26.5161
```

`random`

The `random` method simulates new random response values, equal to the mean prediction plus a random disturbance with the same variance as the training data.

```
Xnew = [-15;5;12];
ysim = random(mdl,Xnew)
```

```
ysim = 3×1

    6.0505
   19.0893
   25.4647
```

Rerun the random method. The results change.

```
ysim = random(mdl,Xnew)
```

```
ysim = 3×1

    6.3813
   19.2157
   26.6541
```

Nonlinear Regression Workflow

This example shows how to do a typical nonlinear regression workflow: import data, fit a nonlinear regression, test its quality, modify it to improve the quality, and make predictions based on the model.

Step 1. Prepare the data.

Load the `reaction` data.

```
load reaction
```

Examine the data in the workspace. `reactants` is a matrix with 13 rows and 3 columns. Each row corresponds to one observation, and each column corresponds to one variable. The variable names are in `xn`:

```
xn
```

```
xn = 3x10 char array
    'Hydrogen  '
    'n-Pentane '
    'Isopentane'
```

Similarly, `rate` is a vector of 13 responses, with the variable name in `yn`:

```
yn
```

```
yn =
'Reaction Rate'
```

The `hougen.m` file contains a nonlinear model of reaction rate as a function of the three predictor variables. For a 5-D vector b and 3-D vector x,

$$hougen(b,x) = \frac{b(1)x(2) - x(3)/b(5)}{1 + b(2)x(1) + b(3)x(2) + b(4)x(3)}$$

As a start point for the solution, take `b` as a vector of ones.

```
beta0 = ones(5,1);
```

Step 2. Fit a nonlinear model to the data.

```
mdl = fitnlm(reactants,...
    rate,@hougen,beta0)
```

```
mdl =
Nonlinear regression model:
    y ~ hougen(b,X)

Estimated Coefficients:
          Estimate       SE       tStat     pValue
          ________    ________    ______    _______

    b1      1.2526     0.86702    1.4447    0.18654
    b2    0.062776    0.043562    1.4411    0.18753
    b3    0.040048    0.030885    1.2967    0.23089
    b4     0.11242    0.075158    1.4957    0.17309
    b5      1.1914     0.83671    1.4239     0.1923
```

```
Number of observations: 13, Error degrees of freedom: 8
Root Mean Squared Error: 0.193
R-Squared: 0.999,  Adjusted R-Squared 0.998
F-statistic vs. zero model: 3.91e+03, p-value = 2.54e-13
```

Step 3. Examine the quality of the model.

The root mean squared error is fairly low compared to the range of observed values.

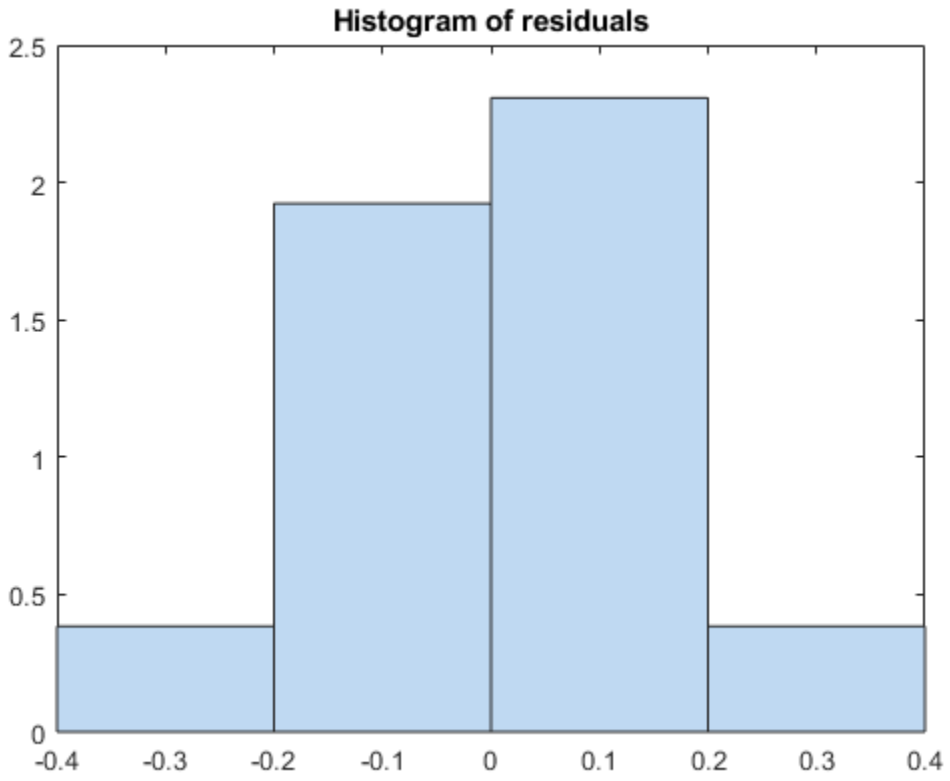
```
[mdl.RMSE min(rate) max(rate)]
```

```
ans = 1×3

    0.1933    0.0200   14.3900
```

Examine a residuals plot.

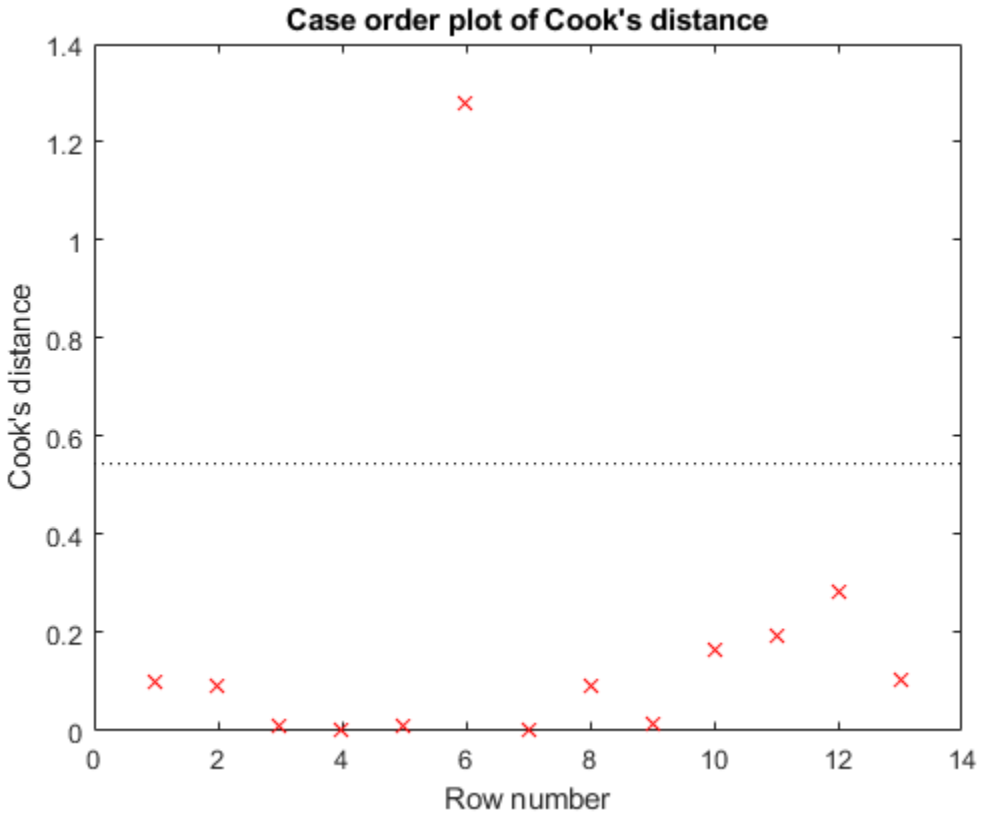
```
plotResiduals(mdl)
```



The model seems adequate for the data.

Examine a diagnostic plot to look for outliers.

```
plotDiagnostics(mdl,'cookd')
```



Observation 6 seems out of line.

Step 4. Remove the outlier.

Remove the outlier from the fit using the `Exclude` name-value pair.

```
mdl1 = fitnlm(reactants,...
    rate,@hougen,ones(5,1),'Exclude',6)
```

```
mdl1 =
Nonlinear regression model:
    y ~ hougen(b,X)

Estimated Coefficients:
          Estimate       SE       tStat     pValue
          ________    ________    ______    _______

    b1       0.619      0.4552    1.3598    0.21605
    b2    0.030377    0.023061    1.3172    0.22924
    b3    0.018927     0.01574    1.2024    0.26828
    b4    0.053411    0.041084       1.3    0.23476
    b5      2.4125      1.7903    1.3475     0.2198

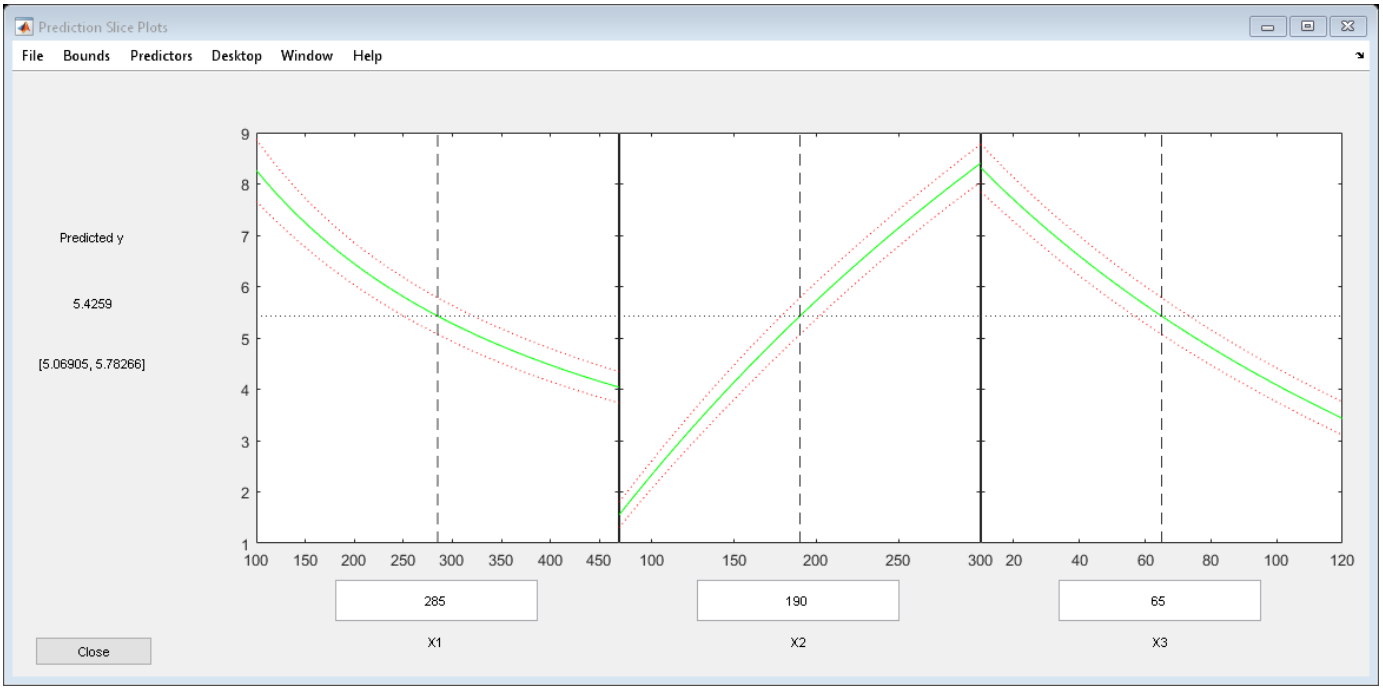
Number of observations: 12, Error degrees of freedom: 7
Root Mean Squared Error: 0.198
R-Squared: 0.999,  Adjusted R-Squared 0.998
F-statistic vs. zero model: 2.67e+03, p-value = 2.54e-11
```

The model coefficients changed quite a bit from those in `mdl`.

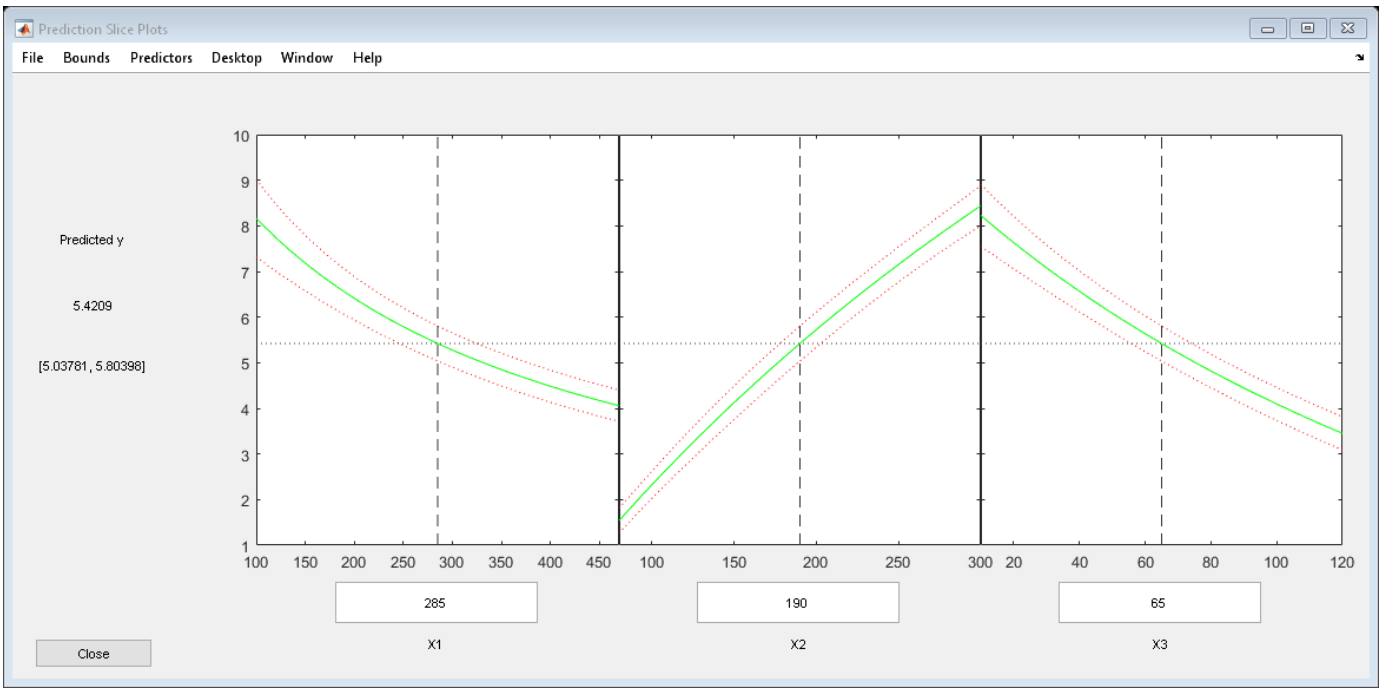
Step 5. Examine slice plots of both models.

To see the effect of each predictor on the response, make a slice plot using `plotSlice(mdl)`.

```
plotSlice(mdl)
```



```
plotSlice(mdl1)
```



The plots look very similar, with slightly wider confidence bounds for `mdl1`. This difference is understandable, since there is one less data point in the fit, representing over 7% fewer observations.

Step 6. Predict for new data.

Create some new data and predict the response from both models.

```
Xnew =  [200,200,200;100,200,100;500,50,5];
[ypred yci] = predict(mdl,Xnew)
```

```
ypred = 3×1

    1.8762
    6.2793
    1.6718

yci = 3×2

    1.6283    2.1242
    5.9789    6.5797
    1.5589    1.7846
```

```
[ypred1 yci1] = predict(mdl1,Xnew)
```

```
ypred1 = 3×1

    1.8984
    6.2555
    1.6594

yci1 = 3×2

    1.6260    2.1708
    5.9323    6.5787
    1.5345    1.7843
```

Even though the model coefficients are dissimilar, the predictions are nearly identical.

Mixed-Effects Models

In this section...

Introduction to Mixed-Effects Models

In statistics, an effect is anything that influences the value of a response variable at a particular setting of the predictor variables. Effects are translated into model parameters. In linear models, effects become coefficients, representing the proportional contributions of model terms. In nonlinear models, effects often have specific physical interpretations, and appear in more general nonlinear combinations.

Fixed effects represent population parameters, assumed to be the same each time data is collected. Estimating fixed effects is the traditional domain of regression modeling. Random effects, by comparison, are sample-dependent random variables. In modeling, random effects act like additional error terms, and their distributions and covariances must be specified.

For example, consider a model of the elimination of a drug from the bloodstream. The model uses time t as a predictor and the concentration of the drug C as the response. The nonlinear model term C_0e^{-rt} combines parameters C_0 and r, representing, respectively, an initial concentration and an elimination rate. If data is collected across multiple individuals, it is reasonable to assume that the elimination rate is a random variable r_i depending on individual i, varying around a population mean $\bar{r}$. The term C_0e^{-rt} becomes

$$C_0e^{-[\bar{r}+(r_i-\bar{r})]t} = C_0e^{-(\beta+b_i)t},$$

where $\beta = \bar{r}$ is a fixed effect and $b_i = r_i - \bar{r}$ is a random effect.

Random effects are useful when data falls into natural groups. In the drug elimination model, the groups are simply the individuals under study. More sophisticated models might group data by an individual's age, weight, diet, etc. Although the groups are not the focus of the study, adding random effects to a model extends the reliability of inferences beyond the specific sample of individuals.

Mixed-effects models account for both fixed and random effects. As with all regression models, their purpose is to describe a response variable as a function of the predictor variables. Mixed-effects models, however, recognize correlations within sample subgroups. In this way, they provide a compromise between ignoring data groups entirely and fitting each group with a separate model.

Mixed-Effects Model Hierarchy

Suppose data for a nonlinear regression model falls into one of m distinct groups $i = 1, \ldots, m$. To account for the groups in a model, write response j in group i as:

$$y_{ij} = f(\varphi, x_{ij}) + \varepsilon_{ij}$$

y_{ij} is the response, x_{ij} is a vector of predictors, φ is a vector of model parameters, and ε_{ij} is the measurement or process error. The index j ranges from 1 to n_i, where n_i is the number of observations in group i. The function f specifies the form of the model. Often, x_{ij} is simply an observation time t_{ij}. The errors are usually assumed to be independent and identically, normally distributed, with constant variance.

Estimates of the parameters in φ describe the population, assuming those estimates are the same for all groups. If, however, the estimates vary by group, the model becomes

$$y_{ij} = f(\varphi_i, x_{ij}) + \varepsilon_{ij}$$

In a mixed-effects model, φ_i may be a combination of a fixed and a random effect:

$$\varphi_i = \beta + b_i$$

The random effects b_i are usually described as multivariate normally distributed, with mean zero and covariance Ψ. Estimating the fixed effects β and the covariance of the random effects Ψ provides a description of the population that does not assume the parameters φ_i are the same across groups. Estimating the random effects b_i also gives a description of specific groups within the data.

Model parameters do not have to be identified with individual effects. In general, design matrices A and B are used to identify parameters with linear combinations of fixed and random effects:

$$\varphi_i = A\beta + Bb_i$$

If the design matrices differ among groups, the model becomes

$$\varphi_i = A_i\beta + B_ib_i$$

If the design matrices also differ among observations, the model becomes

$$\varphi_{ij} = A_{ij}\beta + B_{ij}b_i$$
$$y_{ij} = f(\varphi_{ij}, x_{ij}) + \varepsilon_{ij}$$

Some of the group-specific predictors in x_{ij} may not change with observation j. Calling those v_i, the model becomes

$$y_{ij} = f(\varphi_{ij}, x_{ij}, v_i) + \varepsilon_{ij}$$

Specifying Mixed-Effects Models

Suppose data for a nonlinear regression model falls into one of m distinct groups $i = 1, \ldots, m$. (Specifically, suppose that the groups are not nested.) To specify a general nonlinear mixed-effects model for this data:

1. Define group-specific model parameters φ_i as linear combinations of fixed effects β and random effects b_i.
2. Define response values y_i as a nonlinear function f of the parameters and group-specific predictor variables X_i.

The model is:

$$\varphi_i = A_i\beta + B_i b_i$$
$$y_i = f(\varphi_i, X_i) + \varepsilon_i$$
$$b_i \sim N(0, \Psi)$$
$$\varepsilon_i \sim N(0, \sigma^2)$$

This formulation of the nonlinear mixed-effects model uses the following notation:

φ_i	A vector of group-specific model parameters
β	A vector of fixed effects, modeling population parameters
b_i	A vector of multivariate normally distributed group-specific random effects
A_i	A group-specific design matrix for combining fixed effects
B_i	A group-specific design matrix for combining random effects
X_i	A data matrix of group-specific predictor values
y_i	A data vector of group-specific response values
f	A general, real-valued function of φ_i and X_i
ε_i	A vector of group-specific errors, assumed to be independent, identically, normally distributed, and independent of b_i
Ψ	A covariance matrix for the random effects
σ^2	The error variance, assumed to be constant across observations

For example, consider a model of the elimination of a drug from the bloodstream. The model incorporates two overlapping phases:

- An initial phase p during which drug concentrations reach equilibrium with surrounding tissues
- A second phase q during which the drug is eliminated from the bloodstream

For data on multiple individuals i, the model is

$$y_{ij} = C_{pi}e^{-r_{pi}t_{ij}} + C_{qi}e^{-r_{qi}t_{ij}} + \varepsilon_{ij},$$

where y_{ij} is the observed concentration in individual i at time t_{ij}. The model allows for different sampling times and different numbers of observations for different individuals.

The elimination rates r_{pi} and r_{qi} must be positive to be physically meaningful. Enforce this by introducing the log rates $R_{pi} = \log(r_{pi})$ and $R_{qi} = \log(r_{qi})$ and reparameterizing the model:

$$y_{ij} = C_{pi}e^{-\exp(R_{pi})t_{ij}} + C_{qi}e^{-\exp(R_{qi})t_{ij}} + \varepsilon_{ij}$$

Choosing which parameters to model with random effects is an important consideration when building a mixed-effects model. One technique is to add random effects to all parameters, and use estimates of their variances to determine their significance in the model. An alternative is to fit the model separately to each group, without random effects, and look at the variation of the parameter estimates. If an estimate varies widely across groups, or if confidence intervals for each group have minimal overlap, the parameter is a good candidate for a random effect.

To introduce fixed effects β and random effects b_i for all model parameters, reexpress the model as follows:

$$\begin{aligned} y_{ij} &= [\bar{C}_p + (C_{pi} - \bar{C}_p)]e^{-\exp[\bar{R}_p + (R_{pi} - \bar{R}_p)]t_{ij}} + \\ &\quad [\bar{C}_q + (C_{qi} - \bar{C}_q)]e^{-\exp[\bar{R}_q + (R_{qi} - \bar{R}_q)]t_{ij}} + \varepsilon_{ij} \\ &= (\beta_1 + b_{1i})e^{-\exp(\beta_2 + b_{2i})t_{ij}} + \\ &\quad (\beta_3 + b_{3i})e^{-\exp(\beta_4 + b_{4i})t_{ij}} + \varepsilon_{ij} \end{aligned}$$

In the notation of the general model:

$$\beta = \begin{pmatrix} \beta_1 \\ \vdots \\ \beta_4 \end{pmatrix}, b_i = \begin{pmatrix} b_{i1} \\ \vdots \\ b_{i4} \end{pmatrix}, y_i = \begin{pmatrix} y_{i1} \\ \vdots \\ y_{in_i} \end{pmatrix}, X_i = \begin{pmatrix} t_{i1} \\ \vdots \\ t_{in_i} \end{pmatrix},$$

where n_i is the number of observations of individual i. In this case, the design matrices A_i and B_i are, at least initially, 4-by-4 identity matrices. Design matrices may be altered, as necessary, to introduce weighting of individual effects, or time dependency.

Fitting the model and estimating the covariance matrix Ψ often leads to further refinements. A relatively small estimate for the variance of a random effect suggests that it can be removed from the model. Likewise, relatively small estimates for covariances among certain random effects suggests that a full covariance matrix is unnecessary. Since random effects are unobserved, Ψ must be estimated indirectly. Specifying a diagonal or block-diagonal covariance pattern for Ψ can improve convergence and efficiency of the fitting algorithm.

Statistics and Machine Learning Toolbox functions `nlmefit` and `nlmefitsa` fit the general nonlinear mixed-effects model to data, estimating the fixed and random effects. The functions also estimate the covariance matrix Ψ for the random effects. Additional diagnostic outputs allow you to assess tradeoffs between the number of model parameters and the goodness of fit.

Specifying Covariate Models

If the model in “Specifying Mixed-Effects Models” on page 13-18 assumes a group-dependent covariate such as weight (w) the model becomes:

$$\begin{pmatrix} \varphi_1 \\ \varphi_2 \\ \varphi_3 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & wi \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} \beta_1 \\ \beta_2 \\ \beta_3 \\ \beta_4 \end{pmatrix} + \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} b_1 \\ b_2 \\ b_3 \end{pmatrix}$$

Thus, the parameter φ_i for any individual in the `i`th group is:

$$\begin{pmatrix} \varphi_{1_i} \\ \varphi_{2_i} \\ \varphi_{3_i} \end{pmatrix} = \begin{pmatrix} \beta_1 + \beta_4 * w_i \\ \beta_2 \\ \beta_3 \end{pmatrix} + \begin{pmatrix} b_{1_i} \\ b_{2_i} \\ b_{3_i} \end{pmatrix}$$

To specify a covariate model, use the `'FEGroupDesign'` option.

`'FEGroupDesign'` is a `p-by-q-by-m` array specifying a different `p-by-q` fixed-effects design matrix for each of the `m` groups. Using the previous example, the array resembles the following:

1. Create the array.

```
% Number of parameters in the model (Phi)
num_params = 3;
% Number of covariates
num_cov = 1;
% Assuming number of groups in the data set is 7
num_groups = 7;
% Array of covariate values
covariates = [75; 52; 66; 55; 70; 58; 62 ];
A = repmat(eye(num_params, num_params+num_cov),...
[1,1,num_groups]);
A(1,num_params+1,1:num_groups) = covariates(:,1)
```

2. Create a `struct` with the specified design matrix.

```
options.FEGroupDesign = A;
```

3. Specify the arguments for `nlmefit` (or `nlmefitsa`) as shown in “Mixed-Effects Models Using nlmefit and nlmefitsa” on page 13-33.

Choosing nlmefit or nlmefitsa

Statistics and Machine Learning Toolbox provides two functions, `nlmefit` and `nlmefitsa` for fitting nonlinear mixed-effects models. Each function provides different capabilities, which may help you decide which to use.

Approximation Methods

`nlmefit` provides the following four approximation methods for fitting nonlinear mixed-effects models:

- `'LME'` — Use the likelihood for the linear mixed-effects model at the current conditional estimates of `beta` and `B`. This is the default.
- `'RELME'` — Use the restricted likelihood for the linear mixed-effects model at the current conditional estimates of `beta` and `B`.

- `'FO'` — First-order Laplacian approximation without random effects.
- `'FOCE'` — First-order Laplacian approximation at the conditional estimates of `B`.

`nlmefitsa` provides an additional approximation method, Stochastic Approximation Expectation-Maximization (SAEM) [25] with three steps :

1. Simulation: Generate simulated values of the random effects b from the posterior density $p(b|\Sigma)$ given the current parameter estimates.
2. Stochastic approximation: Update the expected value of the log likelihood function by taking its value from the previous step, and moving part way toward the average value of the log likelihood calculated from the simulated random effects.
3. Maximization step: Choose new parameter estimates to maximize the log likelihood function given the simulated values of the random effects.

Both `nlmefit` and `nlmefitsa` attempt to find parameter estimates to maximize a likelihood function, which is difficult to compute. `nlmefit` deals with the problem by approximating the likelihood function in various ways, and maximizing the approximate function. It uses traditional optimization techniques that depend on things like convergence criteria and iteration limits.

`nlmefitsa`, on the other hand, simulates random values of the parameters in such a way that in the long run they converge to the values that maximize the exact likelihood function. The results are random, and traditional convergence tests don't apply. Therefore `nlmefitsa` provides options to plot the results as the simulation progresses, and to restart the simulation multiple times. You can use these features to judge whether the results have converged to the accuracy you desire.

Parameters Specific to nlmefitsa

The following parameters are specific to `nlmefitsa`. Most control the stochastic algorithm.

- `Cov0` — Initial value for the covariance matrix `PSI`. Must be an r-by-r positive definite matrix. If empty, the default value depends on the values of `BETA0`.
- `ComputeStdErrors` — `true` to compute standard errors for the coefficient estimates and store them in the output `STATS` structure, or `false` (default) to omit this computation.
- `LogLikMethod` — Specifies the method for approximating the log likelihood.
- `NBurnIn` — Number of initial burn-in iterations during which the parameter estimates are not recomputed. Default is 5.
- `NIterations` — Controls how many iterations are performed for each of three phases of the algorithm.
- `NMCMCIterations` — Number of Markov Chain Monte Carlo (MCMC) iterations.

Model and Data Requirements

There are some differences in the capabilities of `nlmefit` and `nlmefitsa`. Therefore some data and models are usable with either function, but some may require you to choose just one of them.

- **Error models** — `nlmefitsa` supports a variety of error models. For example, the standard deviation of the response can be constant, proportional to the function value, or a combination of the two. `nlmefit` fits models under the assumption that the standard deviation of the response is constant. One of the error models, `'exponential'`, specifies that the log of the response has a constant standard deviation. You can fit such models using `nlmefit` by providing the log response as input, and by rewriting the model function to produce the log of the nonlinear function value.

- **Random effects** — Both functions fit data to a nonlinear function with parameters, and the parameters may be simple scalar values or linear functions of covariates. `nlmefit` allows any coefficients of the linear functions to have both fixed and random effects. `nlmefitsa` supports random effects only for the constant (intercept) coefficient of the linear functions, but not for slope coefficients. So in the example in “Specifying Covariate Models” on page 13-20, `nlmefitsa` can treat only the first three beta values as random effects.
- **Model form** — `nlmefit` supports a very general model specification, with few restrictions on the design matrices that relate the fixed coefficients and the random effects to the model parameters. `nlmefitsa` is more restrictive:
  - The fixed effect design must be constant in every group (for every individual), so an observation-dependent design is not supported.
  - The random effect design must be constant for the entire data set, so neither an observation-dependent design nor a group-dependent design is supported.
  - As mentioned under **Random Effects**, the random effect design must not specify random effects for slope coefficients. This implies that the design must consist of zeros and ones.
  - The random effect design must not use the same random effect for multiple coefficients, and cannot use more than one random effect for any single coefficient.
  - The fixed effect design must not use the same coefficient for multiple parameters. This implies that it can have at most one nonzero value in each column.

  If you want to use `nlmefitsa` for data in which the covariate effects are random, include the covariates directly in the nonlinear model expression. Don't include the covariates in the fixed or random effect design matrices.
- **Convergence** — As described in the **Model form**, `nlmefit` and `nlmefitsa` have different approaches to measuring convergence. `nlmefit` uses traditional optimization measures, and `nlmefitsa` provides diagnostics to help you judge the convergence of a random simulation.

In practice, `nlmefitsa` tends to be more robust, and less likely to fail on difficult problems. However, `nlmefit` may converge faster on problems where it converges at all. Some problems may benefit from a combined strategy, for example by running `nlmefitsa` for a while to get reasonable parameter estimates, and using those as a starting point for additional iterations using `nlmefit`.

Using Output Functions with Mixed-Effects Models

The `Outputfcn` field of the `options` structure specifies one or more functions that the solver calls after each iteration. Typically, you might use an output function to plot points at each iteration or to display optimization quantities from the algorithm. To set up an output function:

1. Write the output function as a MATLAB file function or local function.
2. Use `statset` to set the value of `Outputfcn` to be a function handle, that is, the name of the function preceded by the `@` sign. For example, if the output function is `outfun.m`, the command

   ```
   options = statset('OutputFcn', @outfun);
   ```

   specifies `OutputFcn` to be the handle to `outfun`. To specify multiple output functions, use the syntax:

   ```
   options = statset('OutputFcn',{@outfun, @outfun2});
   ```
3. Call the optimization function with `options` as an input argument.

For an example of an output function, see “Sample Output Function” on page 13-27.

Structure of the Output Function

The function definition line of the output function has the following form:

```
stop = outfun(beta,status,state)
```

where

- *beta* is the current fixed effects.
- *status* is a structure containing data from the current iteration. “Fields in status” on page 13-24 describes the structure in detail.
- *state* is the current state of the algorithm. “States of the Algorithm” on page 13-25 lists the possible values.
- *stop* is a flag that is `true` or `false` depending on whether the optimization routine should quit or continue. See “Stop Flag” on page 13-26 for more information.

The solver passes the values of the input arguments to `outfun` at each iteration.

Fields in status

The following table lists the fields of the `status` structure:

Field	Description
`procedure`	• `'ALT'` — alternating algorithm for the optimization of the linear mixed effects or restricted linear mixed effects approximations • `'LAP'` — optimization of the Laplacian approximation for first order or first order conditional estimation
`iteration`	An integer starting from 0.

Field	Description

`inner`	A structure describing the status of the inner iterations within the `ALT` and `LAP` procedures, with the fields:
	• `procedure` — When `procedure` is `'ALT'`:
	  • `'PNLS'` (penalized nonlinear least squares)
	  • `'LME'` (linear mixed-effects estimation)
	  • `'none'`
	  When `procedure` is `'LAP'`,
	  • `'PNLS'` (penalized nonlinear least squares)
	  • `'PLM'` (profiled likelihood maximization)
	  • `'none'`
	• `state` — one of the following:
	  • `'init'`
	  • `'iter'`
	  • `'done'`
	  • `'none'`
	• `iteration` — an integer starting from 0, or `NaN`. For `nlmefitsa` with burn-in iterations, the output function is called after each of those iterations with a negative value for `STATUS.iteration`.

`fval`	The current log likelihood
`Psi`	The current random-effects covariance matrix
`theta`	The current parameterization of `Psi`
`mse`	The current error variance

States of the Algorithm

The following table lists the possible values for `state`:

state	Description
`'init'`	The algorithm is in the initial state before the first iteration.
`'iter'`	The algorithm is at the end of an iteration.
`'done'`	The algorithm is in the final state after the last iteration.

The following code illustrates how the output function might use the value of `state` to decide which tasks to perform at the current iteration:

```
switch state
    case 'iter'
          % Make updates to plot or guis as needed
    case 'init'
          % Setup for plots or guis
    case 'done'
          % Cleanup of plots, guis, or final plot
```

```
otherwise
end
```

Stop Flag

The output argument `stop` is a flag that is `true` or `false`. The flag tells the solver whether it should quit or continue. The following examples show typical ways to use the `stop` flag.

Stopping an Optimization Based on Intermediate Results

The output function can stop the estimation at any iteration based on the values of arguments passed into it. For example, the following code sets stop to true based on the value of the log likelihood stored in the `'fval'`field of the status structure:

```
stop = outfun(beta,status,state)
stop = false;
% Check if loglikelihood is more than 132.
if status.fval > -132
    stop = true;
end
```

Stopping an Iteration Based on GUI Input

If you design a GUI to perform `nlmefit` iterations, you can make the output function stop when a user clicks a **Stop** button on the GUI. For example, the following code implements a dialog to cancel calculations:

```
function retval = stop_outfcn(beta,str,status)
persistent h stop;
if isequal(str.inner.state,'none')
    switch(status)
        case 'init'
            % Initialize dialog
            stop = false;
            h = msgbox('Press STOP to cancel calculations.',...
                'NLMEFIT: Iteration 0 ');
            button = findobj(h,'type','uicontrol');
            set(button,'String','STOP','Callback',@stopper)
            pos = get(h,'Position');
            pos(3) = 1.1 * pos(3);
            set(h,'Position',pos)
            drawnow
        case 'iter'
            % Display iteration number in the dialog title
            set(h,'Name',sprintf('NLMEFIT: Iteration %d',...
                str.iteration))
            drawnow;
        case 'done'
            % Delete dialog
            delete(h);
    end
end
if stop
    % Stop if the dialog button has been pressed
    delete(h)
end
retval = stop;
```

```
    function stopper(varargin)
        % Set flag to stop when button is pressed
        stop = true;
        disp('Calculation stopped.')
    end
end
```

Sample Output Function

`nmlefitoutputfcn` is the sample Statistics and Machine Learning Toolbox output function for `nlmefit` and `nlmefitsa`. It initializes or updates a plot with the fixed-effects (`BETA`) and variance of the random effects (`diag(STATUS.Psi)`). For `nlmefit`, the plot also includes the log-likelihood (`STATUS.fval`).

`nlmefitoutputfcn` is the default output function for `nlmefitsa`. To use it with `nlmefit`, specify a function handle for it in the options structure:

```
opt = statset('OutputFcn', @nlmefitoutputfcn, …)
beta = nlmefit(…, 'Options', opt, …)
```

To prevent `nlmefitsa` from using of this function, specify an empty value for the output function:

```
opt = statset('OutputFcn', [], …)
beta = nlmefitsa(…, 'Options', opt, …)
```

`nlmefitoutputfcn` stops `nlmefit` or `nlmefitsa` if you close the figure that it produces.

Examining Residuals for Model Verification

You can examine the `stats` structure, which is returned by both `nlmefit` and `nlmefitsa`, to determine the quality of your model. The `stats` structure contains fields with conditional weighted residuals (`cwres` field) and individual weighted residuals (`iwres` field). Since the model assumes that residuals are normally distributed, you can examine the residuals to see how well this assumption holds.

This example generates synthetic data using normal distributions. It shows how the fit statistics look:

- Good when testing against the same type of model as generates the data
- Poor when tested against incorrect data models

1 Initialize a 2-D model with 100 individuals:

```
nGroups = 100; % 100 Individuals
nlmefun = @(PHI,t)(PHI(:,1)*5 + PHI(:,2)^2.*t); % Regression fcn
REParamsSelect = [1  2]; % Both Parameters have random effect
errorParam = .03;
beta0 = [ 1.5  5]; % Parameter means
psi = [ 0.35  0; ...  % Covariance Matrix
       0   0.51 ];
time =[0.25;0.5;0.75;1;1.25;2;3;4;5;6];
nParameters = 2;
rng(0,'twister') % for reproducibility
```

2 Generate the data for fitting with a proportional error model:

```
b_i = mvnrnd(zeros(1, numel(REParamsSelect)), psi, nGroups);
individualParameters = zeros(nGroups,nParameters);
individualParameters(:, REParamsSelect) = ...
     bsxfun(@plus,beta0(REParamsSelect), b_i);

groups = repmat(1:nGroups,numel(time),1);
groups = vertcat(groups(:));

y = zeros(numel(time)*nGroups,1);
x = zeros(numel(time)*nGroups,1);
for i = 1:nGroups
    idx = groups == i;
    f = nlmefun(individualParameters(i,:), time);
    % Make a proportional error model for y:
    y(idx) = f + errorParam*f.*randn(numel(f),1);
    x(idx) = time;
end

P = [ 1 0 ; 0 1 ];
```

3 Fit the data using the same regression function and error model as the model generator:

```
[~,~,stats] = nlmefit(x,y,groups, ...
    [],nlmefun,[1 1],'REParamsSelect',REParamsSelect,...
    'ErrorModel','Proportional','CovPattern',P);
```

4 Create a plotting routine by copying the following function definition, and creating a file `plotResiduals.m` on your MATLAB path:

```
function plotResiduals(stats)
pwres = stats.pwres;
iwres = stats.iwres;
```

```
cwres = stats.cwres;
figure
subplot(2,3,1);
normplot(pwres); title('PWRES')
subplot(2,3,4);
createhistplot(pwres);

subplot(2,3,2);
normplot(cwres); title('CWRES')
subplot(2,3,5);
createhistplot(cwres);

subplot(2,3,3);
normplot(iwres); title('IWRES')
subplot(2,3,6);
createhistplot(iwres); title('IWRES')

function createhistplot(pwres)
h = histogram(pwres);

% x is the probability/height for each bin
x = h.Values/sum(h.Values*h.BinWidth)

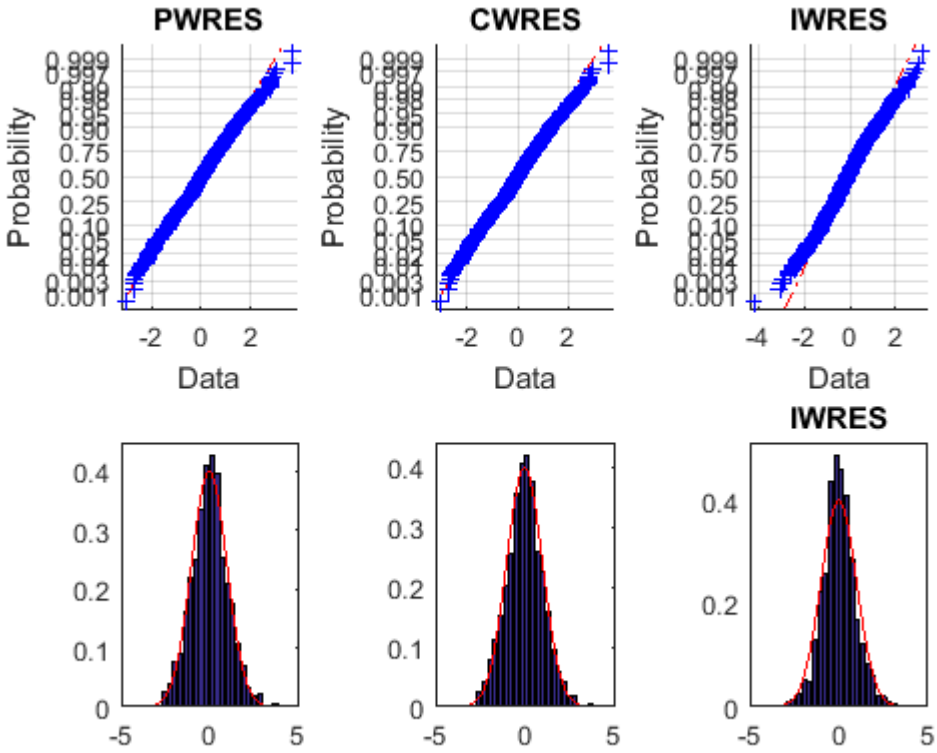
% n is the center of each bin
n = h.BinEdges + (0.5*h.BinWidth)
n(end) = [];

bar(n,x);
ylim([0 max(x)*1.05]);
hold on;
x2 = -4:0.1:4;
f2 = normpdf(x2,0,1);
plot(x2,f2,'r');
end

end
```

5 Plot the residuals using the `plotResiduals` function:

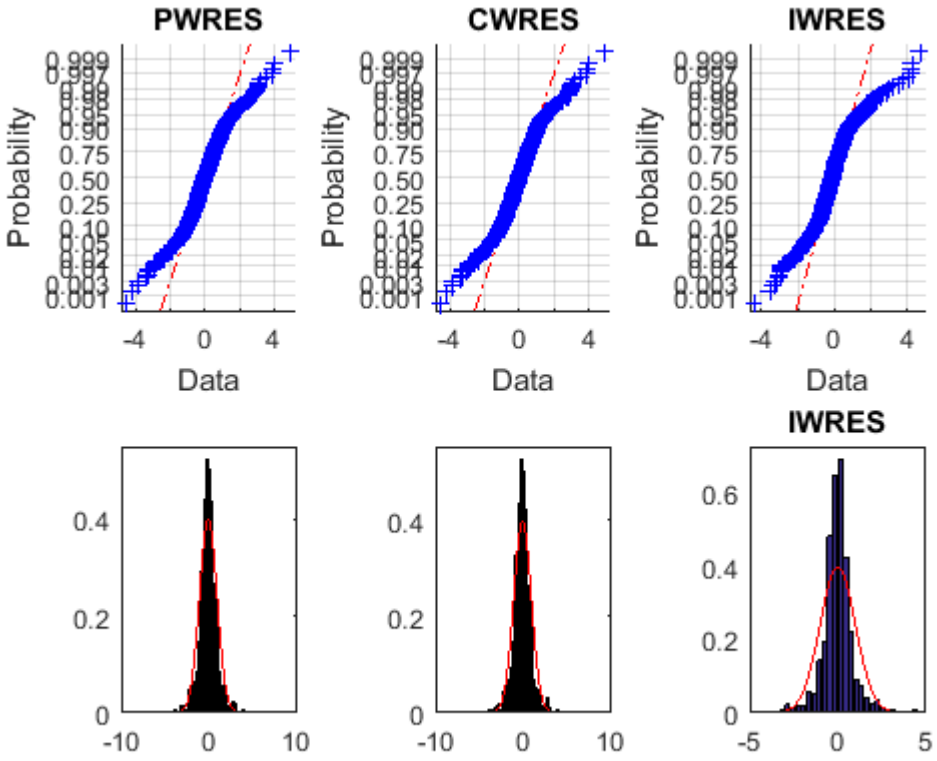
```
plotResiduals(stats);
```



The upper probability plots look straight, meaning the residuals are normally distributed. The bottom histogram plots match the superimposed normal density plot. So you can conclude that the error model matches the data.

6 For comparison, fit the data using a constant error model, instead of the proportional model that created the data:

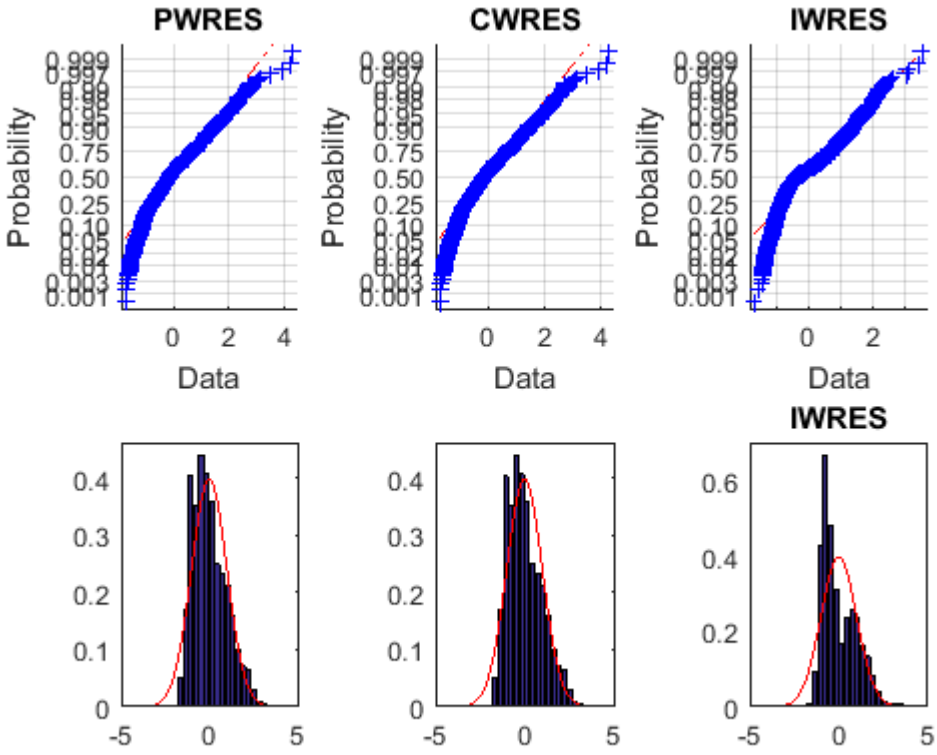
```
[~,~,stats] = nlmefit(x,y,groups, ...
    [],nlmefun,[0 0],'REParamsSelect',REParamsSelect,...
    'ErrorModel','Constant','CovPattern',P);
plotResiduals(stats);
```



The upper probability plots are not straight, indicating the residuals are not normally distributed. The bottom histogram plots are fairly close to the superimposed normal density plots.

7 For another comparison, fit the data to a different structural model than the one that created the data:

```
nlmefun2 = @(PHI,t)(PHI(:,1)*5 + PHI(:,2).*t.^4);
[~,~,stats] = nlmefit(x,y,groups, ...
    [],nlmefun2,[0 0],'REParamsSelect',REParamsSelect,...
    'ErrorModel','constant', 'CovPattern',P);
plotResiduals(stats);
```



The upper probability plots are not straight. Also, the histogram plots are quite skewed compared to the superimposed normal density plots. These residuals are not normally distributed, and do not match the model.

Mixed-Effects Models Using nlmefit and nlmefitsa

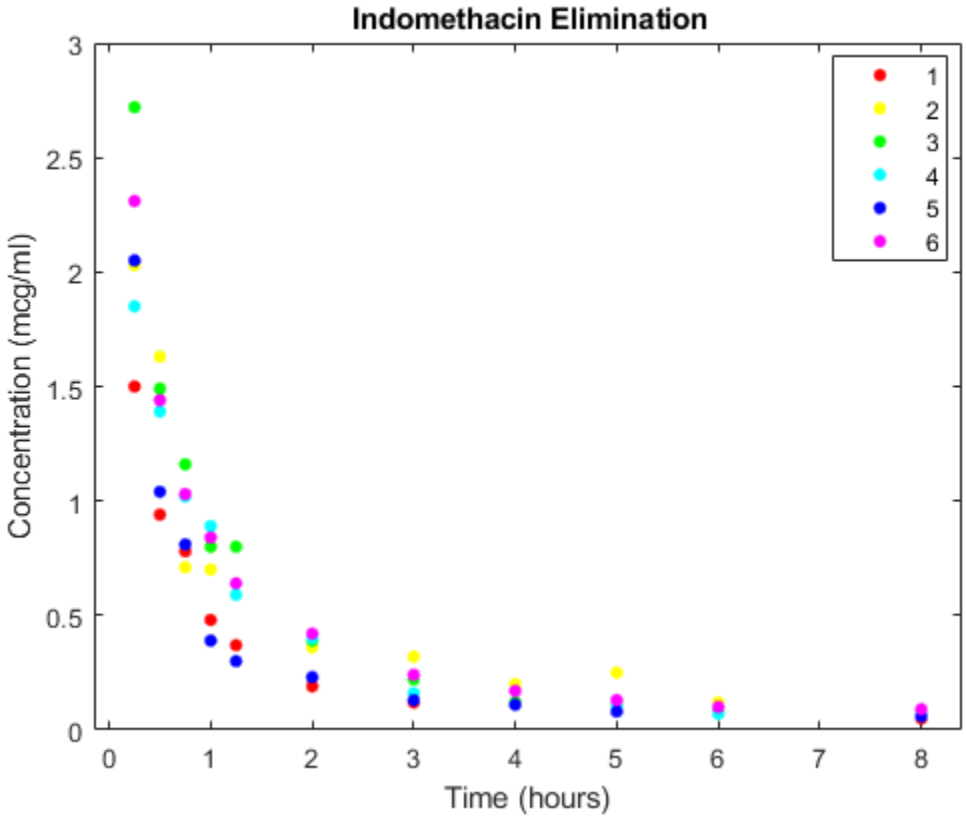
Load the sample data.

```
load indomethacin
```

The data in `indomethacin.mat` records concentrations of the drug indomethacin in the bloodstream of six subjects over eight hours.

Plot the scatter plot of indomethacin in the bloodstream grouped by subject.

```
gscatter(time,concentration,subject)
xlabel('Time (hours)')
ylabel('Concentration (mcg/ml)')
title('{\bf Indomethacin Elimination}')
hold on
```



`Specifying Mixed-Effects Models` page discusses a useful model for this type of data.

Construct the model via an anonymous function.

```
model = @(phi,t)(phi(1)*exp(-exp(phi(2))*t) + ...
                 phi(3)*exp(-exp(phi(4))*t));
```

Use the `nlinfit` function to fit the model to all of the data, ignoring subject-specific effects.

```
phi0 = [1 2 1 1];
[phi,res] = nlinfit(time,concentration,model,phi0);
```

Compute the mean squared error.

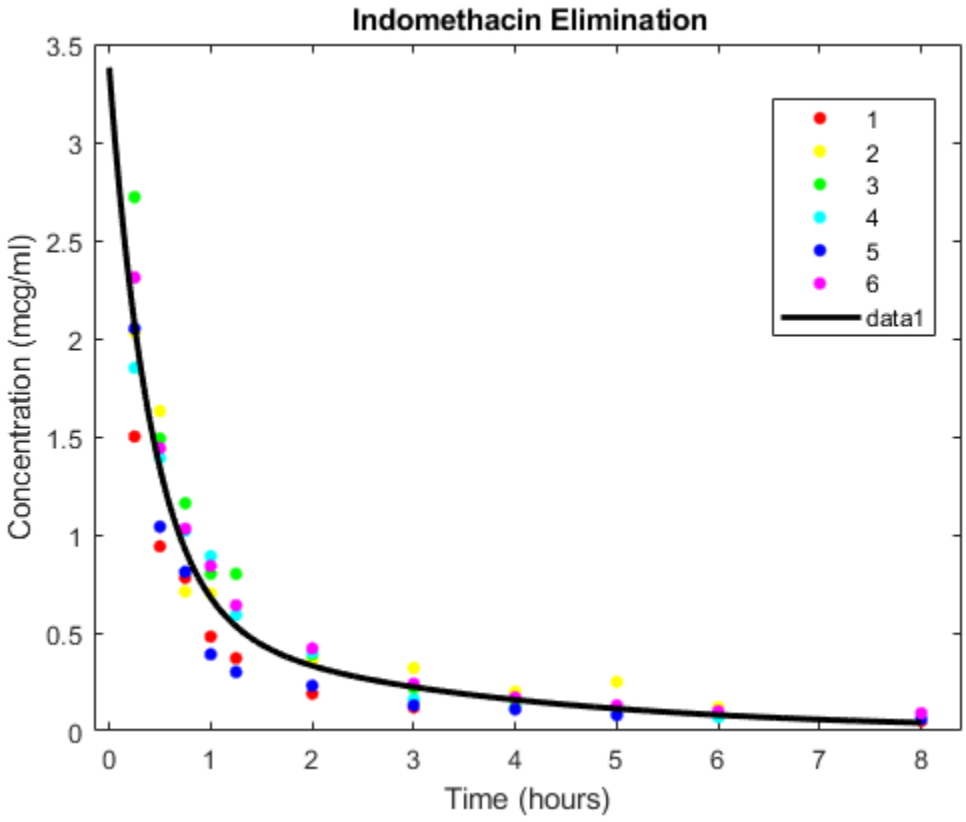
```
numObs = length(time);
numParams = 4;
df = numObs-numParams;
mse = (res'*res)/df
```

```
mse =

    0.0304
```

Super impose the model on the scatter plot of data.

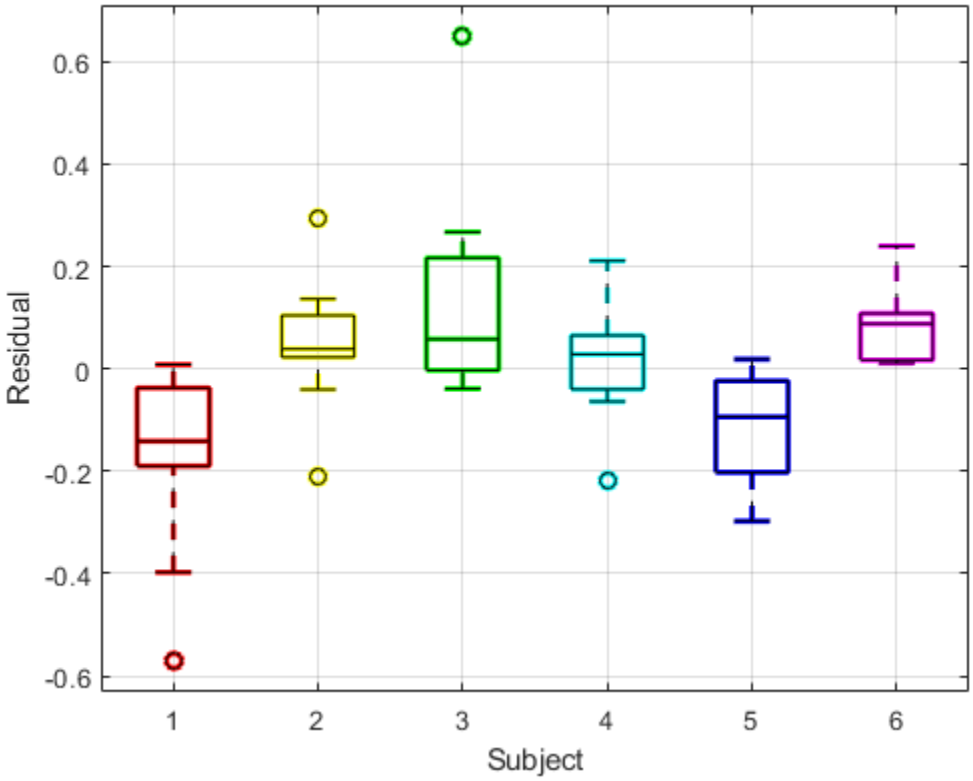
```
tplot = 0:0.01:8;
plot(tplot,model(phi,tplot),'k','LineWidth',2)
hold off
```



Draw the box-plot of residuals by subject.

```
colors = 'rygcbm';
h = boxplot(res,subject,'colors',colors,'symbol','o');
set(h(~isnan(h)),'LineWidth',2)
hold on
boxplot(res,subject,'colors','k','symbol','ko')
grid on
xlabel('Subject')
```

```
ylabel('Residual')
hold off
```



The box plot of residuals by subject shows that the boxes are mostly above or below zero, indicating that the model has failed to account for subject-specific effects.

To account for subject-specific effects, fit the model separately to the data for each subject.

```
phi0 = [1 2 1 1];
PHI = zeros(4,6);
RES = zeros(11,6);
for I = 1:6
    tI = time(subject == I);
    cI = concentration(subject == I);
    [PHI(:,I),RES(:,I)] = nlinfit(tI,cI,model,phi0);
end
PHI
```

```
PHI =

    2.0293    2.8277    5.4683    2.1981    3.5661    3.0023
    0.5794    0.8013    1.7498    0.2423    1.0408    1.0882
    0.1915    0.4989    1.6757    0.2545    0.2915    0.9685
   -1.7878   -1.6354   -0.4122   -1.6026   -1.5069   -0.8731
```

Compute the mean squared error.

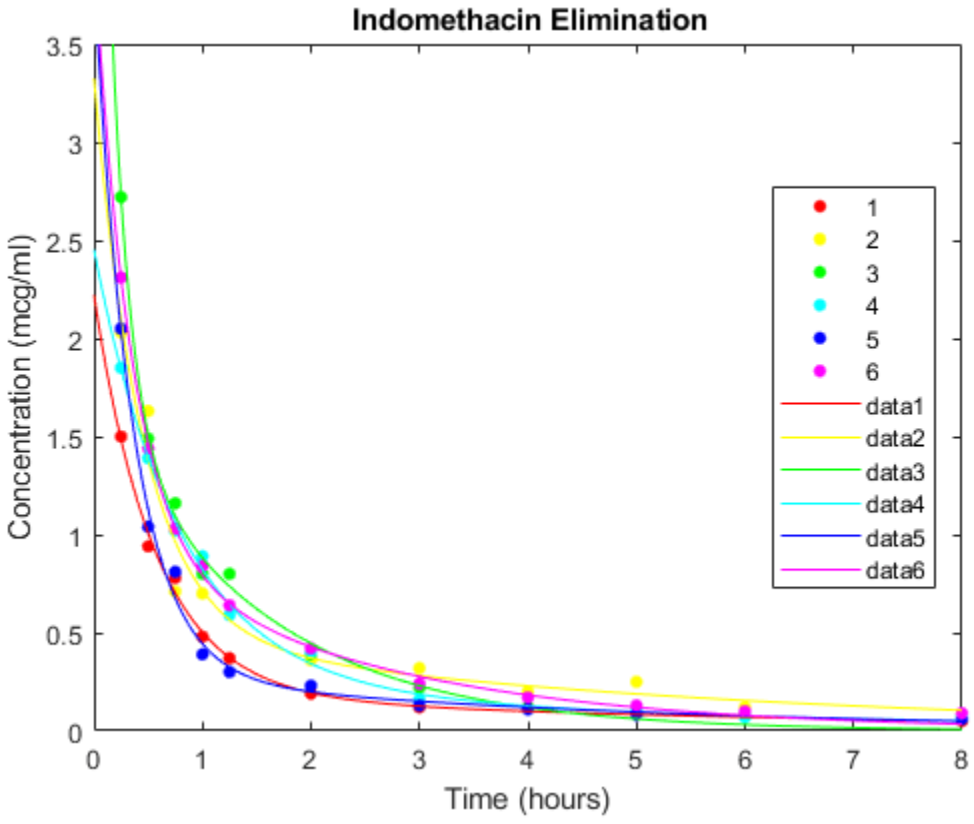
```
numParams = 24;
df = numObs-numParams;
mse = (RES(:)'*RES(:))/df
```

```
mse =

    0.0057
```

Plot the scatter plot of the data and superimpose the model for each subject.

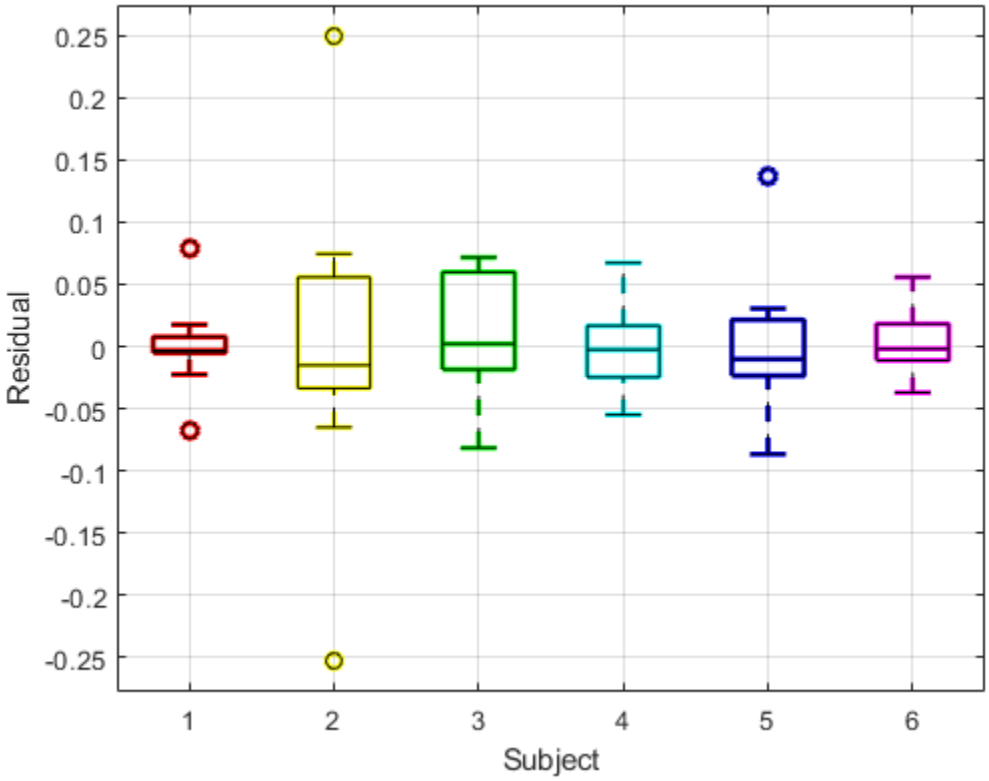
```
gscatter(time,concentration,subject)
xlabel('Time (hours)')
ylabel('Concentration (mcg/ml)')
title('{\bf Indomethacin Elimination}')
hold on
for I = 1:6
    plot(tplot,model(PHI(:,I),tplot),'Color',colors(I))
end
axis([0 8 0 3.5])
hold off
```



`PHI` gives estimates of the four model parameters for each of the six subjects. The estimates vary considerably, but taken as a 24-parameter model of the data, the mean-squared error of 0.0057 is a significant reduction from 0.0304 in the original four-parameter model.

Draw the box plot of residuals by subject.

```
h = boxplot(RES,'colors',colors,'symbol','o');
set(h(~isnan(h)),'LineWidth',2)
hold on
boxplot(RES,'colors','k','symbol','ko')
grid on
xlabel('Subject')
ylabel('Residual')
hold off
```



Now the box plot shows that the larger model accounts for most of the subject-specific effects. The spread of the residuals (the vertical scale of the box plot) is much smaller than in the previous box plot, and the boxes are now mostly centered on zero.

While the 24-parameter model successfully accounts for variations due to the specific subjects in the study, it does not consider the subjects as representatives of a larger population. The sampling distribution from which the subjects are drawn is likely more interesting than the sample itself. The purpose of mixed-effects models is to account for subject-specific variations more broadly, as random effects varying around population means.

Use the `nlmefit` function to fit a mixed-effects model to the data. You can also use `nlmefitsa` in place of `nlmefit` .

The following anonymous function, `nlme_model` , adapts the four-parameter model used by `nlinfit` to the calling syntax of `nlmefit` by allowing separate parameters for each individual. By default, `nlmefit` assigns random effects to all the model parameters. Also by default, `nlmefit` assumes a diagonal covariance matrix (no covariance among the random effects) to avoid overparameterization and related convergence issues.

```
nlme_model = @(PHI,t)(PHI(:,1).*exp(-exp(PHI(:,2)).*t) + ...
                      PHI(:,3).*exp(-exp(PHI(:,4)).*t));
phi0 = [1 2 1 1];
[phi,PSI,stats] = nlmefit(time,concentration,subject, ...
                          [],nlme_model,phi0)

phi =

    2.8277
    0.7729
    0.4606
   -1.3459

PSI =

    0.3264         0         0         0
         0    0.0250         0         0
         0         0    0.0124         0
         0         0         0    0.0000

stats =

  struct with fields:

          dfe: 57
         logl: 54.5882
          mse: 0.0066
         rmse: 0.0787
    errorparam: 0.0815
          aic: -91.1765
          bic: -93.0506
         covb: [4x4 double]
       sebeta: [0.2558 0.1066 0.1092 0.2244]
         ires: [66x1 double]
         pres: [66x1 double]
        iwres: [66x1 double]
        pwres: [66x1 double]
        cwres: [66x1 double]
```

The mean-squared error of 0.0066 is comparable to the 0.0057 of the 24-parameter model without random effects, and significantly better than the 0.0304 of the four-parameter model without random effects.

The estimated covariance matrix `PSI` shows that the variance of the fourth random effect is essentially zero, suggesting that you can remove it to simplify the model. To do this, use the `'REParamsSelect'` name-value pair to specify the indices of the parameters to be modeled with random effects in `nlmefit` .

```
[phi,PSI,stats] = nlmefit(time,concentration,subject, ...
                          [],nlme_model,phi0, ...
                          'REParamsSelect',[1 2 3])

phi =
```

```
    2.8277
    0.7728
    0.4605
   -1.3460

PSI =

    0.3270         0         0
         0    0.0250         0
         0         0    0.0124

stats =

  struct with fields:

          dfe: 58
         logl: 54.5875
          mse: 0.0066
         rmse: 0.0780
    errorparam: 0.0815
          aic: -93.1750
          bic: -94.8410
         covb: [4x4 double]
       sebeta: [0.2560 0.1066 0.1092 0.2244]
         ires: [66x1 double]
         pres: [66x1 double]
        iwres: [66x1 double]
        pwres: [66x1 double]
        cwres: [66x1 double]
```

The log-likelihood `logl` is almost identical to what it was with random effects for all of the parameters, the Akaike information criterion `aic` is reduced from -91.1765 to -93.1750, and the Bayesian information criterion `bic` is reduced from -93.0506 to -94.8410. These measures support the decision to drop the fourth random effect.

Refitting the simplified model with a full covariance matrix allows for identification of correlations among the random effects. To do this, use the `CovPattern` parameter to specify the pattern of nonzero elements in the covariance matrix.

```
[phi,PSI,stats] = nlmefit(time,concentration,subject, ...
                          [],nlme_model,phi0, ...
                          'REParamsSelect',[1 2 3], ...
                          'CovPattern',ones(3))

phi =

    2.8159
    0.8263
    0.5570
   -1.1478

PSI =
```

```
    0.4737    0.1145    0.0491
    0.1145    0.0323    0.0029
    0.0491    0.0029    0.0227

stats =

  struct with fields:

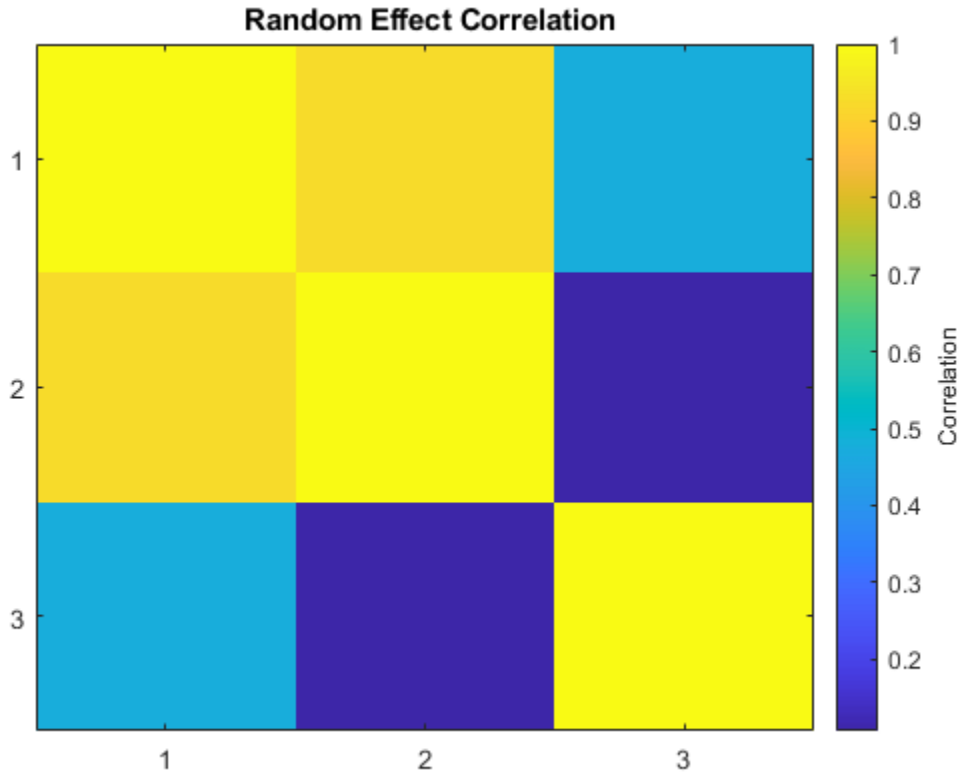
          dfe: 55
         logl: 58.4419
          mse: 0.0061
         rmse: 0.0783
   errorparam: 0.0781
          aic: -94.8838
          bic: -97.1744
         covb: [4x4 double]
       sebeta: [0.3018 0.1104 0.1170 0.1675]
         ires: [66x1 double]
         pres: [66x1 double]
        iwres: [66x1 double]
        pwres: [66x1 double]
        cwres: [66x1 double]
```

The estimated covariance matrix `PSI` shows that the random effects on the first two parameters have a relatively strong correlation, and both have a relatively weak correlation with the last random effect. This structure in the covariance matrix is more apparent if you convert `PSI` to a correlation matrix using `corrcov` .

```
RHO = corrcov(PSI)
clf;
imagesc(RHO)
set(gca,'XTick',[1 2 3],'YTick',[1 2 3])
title('{\bf Random Effect Correlation}')
h = colorbar;
set(get(h,'YLabel'),'String','Correlation');

RHO =

    1.0000    0.9264    0.4735
    0.9264    1.0000    0.1070
    0.4735    0.1070    1.0000
```



Incorporate this structure into the model by changing the specification of the covariance pattern to block-diagonal.

```
P = [1 1 0;1 1 0;0 0 1] % Covariance pattern
[phi,PSI,stats,b] = nlmefit(time,concentration,subject, ...
                            [],nlme_model,phi0, ...
                            'REParamsSelect',[1 2 3], ...
                            'CovPattern',P)
```

```
P =

     1     1     0
     1     1     0

```

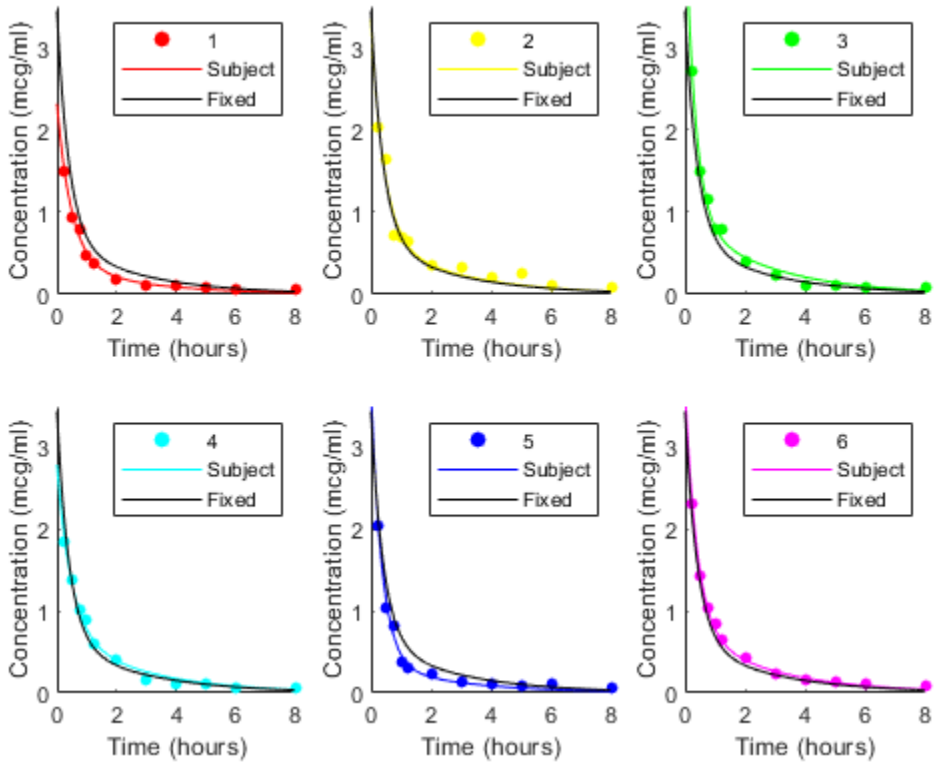
The block-diagonal covariance structure reduces `aic` from -94.9462 to -98.1608 and `bic` from -97.2368 to -100.0350 without significantly affecting the log-likelihood. These measures support the covariance structure used in the final model. The output `b` gives predictions of the three random effects for each of the six subjects. These are combined with the estimates of the fixed effects in `phi` to produce the mixed-effects model.

Plot the mixed-effects model for each of the six subjects. For comparison, the model without random effects is also shown.

```
PHI = repmat(phi,1,6) + ...                 % Fixed effects
      [b(1,:);b(2,:);b(3,:);zeros(1,6)];    % Random effects
RES = zeros(11,6); % Residuals
colors = 'rygcbm';
for I = 1:6
    fitted_model = @(t)(PHI(1,I)*exp(-exp(PHI(2,I))*t) + ...
                        PHI(3,I)*exp(-exp(PHI(4,I))*t));
    tI = time(subject == I);
    cI = concentration(subject == I);
    RES(:,I) = cI - fitted_model(tI);

    subplot(2,3,I)
    scatter(tI,cI,20,colors(I),'filled')
    hold on
    plot(tplot,fitted_model(tplot),'Color',colors(I))
    plot(tplot,model(phi,tplot),'k')
    axis([0 8 0 3.5])
    xlabel('Time (hours)')
```

```
    ylabel('Concentration (mcg/ml)')
    legend(num2str(I),'Subject','Fixed')
end
```



If obvious outliers in the data (visible in previous box plots) are ignored, a normal probability plot of the residuals shows reasonable agreement with model assumptions on the errors.

```
clf; normplot(RES(:))
```

Data

Weighted Nonlinear Regression

This example shows how to fit a nonlinear regression model for data with nonconstant error variance.

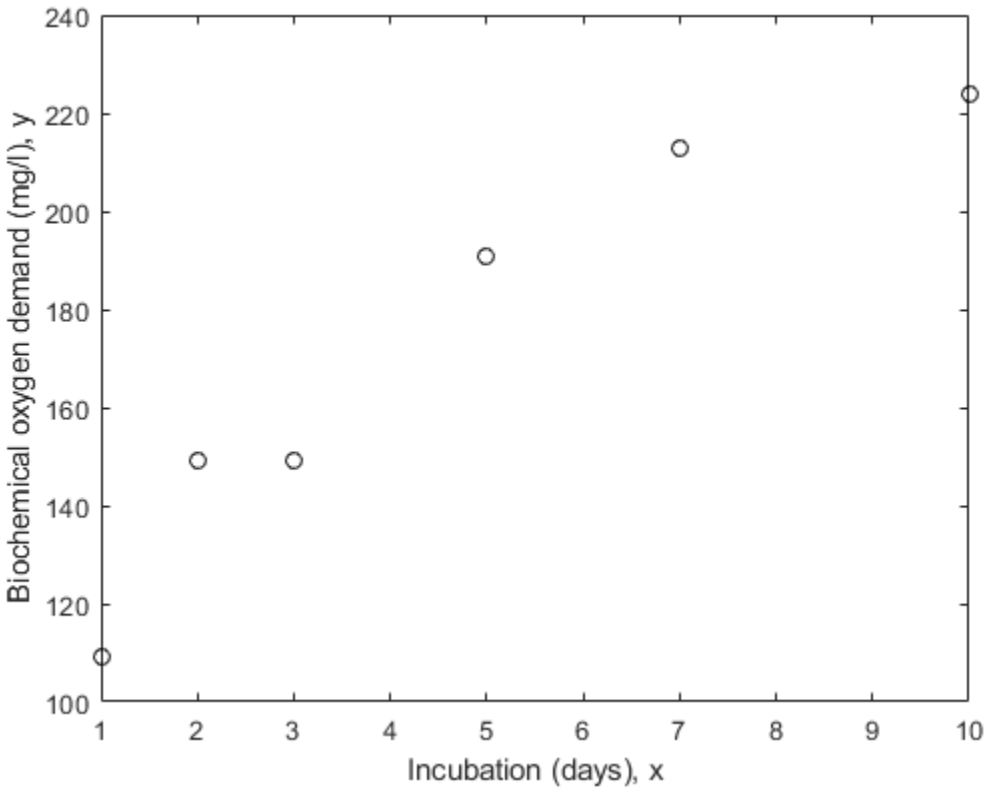
Regular nonlinear least squares algorithms are appropriate when measurement errors all have the same variance. When that assumption is not true, it is appropriate to used a weighted fit. This example shows how to use weights with the `fitnlm` function.

Data and Model for the Fit

We'll use data collected to study water pollution caused by industrial and domestic waste. These data are described in detail in Box, G.P., W.G. Hunter, and J.S. Hunter, Statistics for Experimenters (Wiley, 1978, pp. 483-487). The response variable is biochemical oxygen demand in mg/l, and the predictor variable is incubation time in days.

```
x = [1 2 3 5 7 10]';
y = [109 149 149 191 213 224]';

plot(x,y,'ko');
xlabel('Incubation (days), x'); ylabel('Biochemical oxygen demand (mg/l), y');
```



We'll assume that it is known that the first two observations were made with less precision than the remaining observations. They might, for example, have been made with a different instrument. Another common reason to weight data is that each recorded observation is actually the mean of several measurements taken at the same value of x. In the data here, suppose the first two values represent a single raw measurement, while the remaining four are each the mean of 5 raw

measurements. Then it would be appropriate to weight by the number of measurements that went into each observation.

```
w = [1 1 5 5 5 5]';
```

The model we'll fit to these data is a scaled exponential curve that becomes level as x becomes large.

```
modelFun = @(b,x) b(1).*(1-exp(-b(2).*x));
```

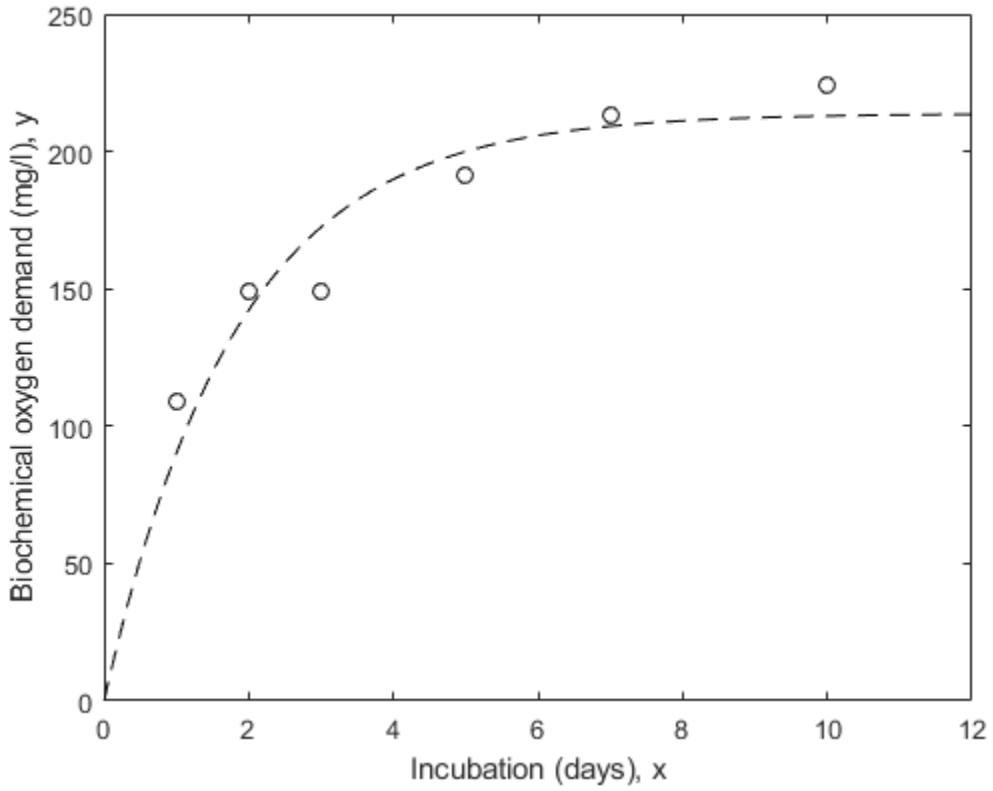
Just based on a rough visual fit, it appears that a curve drawn through the points might level out at a value of around 240 somewhere in the neighborhood of x = 15. So we'll use 240 as the starting value for b1, and since e^(-.5*15) is small compared to 1, we'll use .5 as the starting value for b2.

```
start = [240; .5];
```

Fit the Model without Weights

The danger in ignoring measurement error is that the fit may be overly influenced by imprecise measurements, and may therefore not provide a good fit to measurements that are known precisely. Let's fit the data without weights and compare it to the points.

```
nlm = fitnlm(x,y,modelFun,start);
xx = linspace(0,12)';
line(xx,predict(nlm,xx),'linestyle','--','color','k')
```



Fit the Model with Weights

Notice that the fitted curve is pulled toward the first two points, but seems to miss the trend of the other points. Let's try repeating the fit using weights.

```
wnlm = fitnlm(x,y,modelFun,start,'Weight',w)
line(xx,predict(wnlm,xx),'color','b')
```

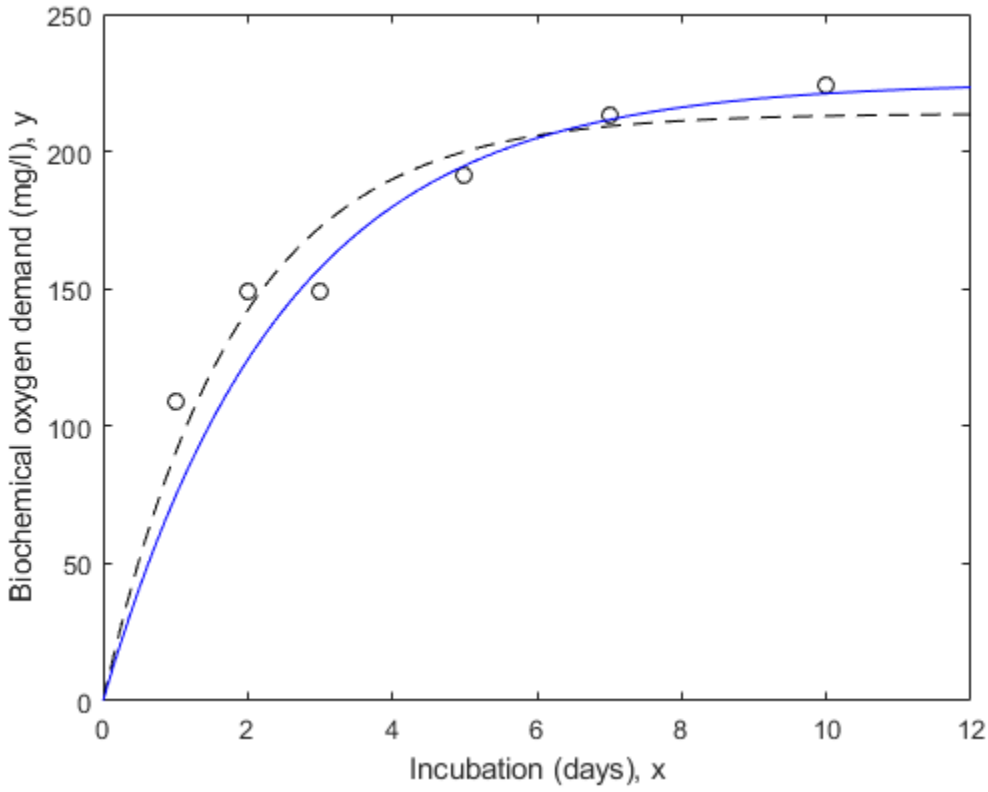
```
wnlm =

Nonlinear regression model:
    y ~ b1*(1 - exp( - b2*x))

Estimated Coefficients:
          Estimate       SE       tStat       pValue
          ________    ________    ______    __________

    b1     225.17         10.7    21.045    3.0134e-05
    b2    0.40078     0.064296    6.2333     0.0033745

Number of observations: 6, Error degrees of freedom: 4
Root Mean Squared Error: 24
R-Squared: 0.908,  Adjusted R-Squared 0.885
F-statistic vs. zero model: 696, p-value = 8.2e-06
```



The estimated population standard deviation in this case describes the average variation for a "standard" observation with a weight, or measurement precision, of 1.

```
wnlm.RMSE
```

```
ans =

   24.0096
```

An important part of any analysis is an estimate of the precision of the model fit. The coefficient display shows standard errors for the parameters, but we can also compute confidence intervals for them.

```
coefCI(wnlm)
```

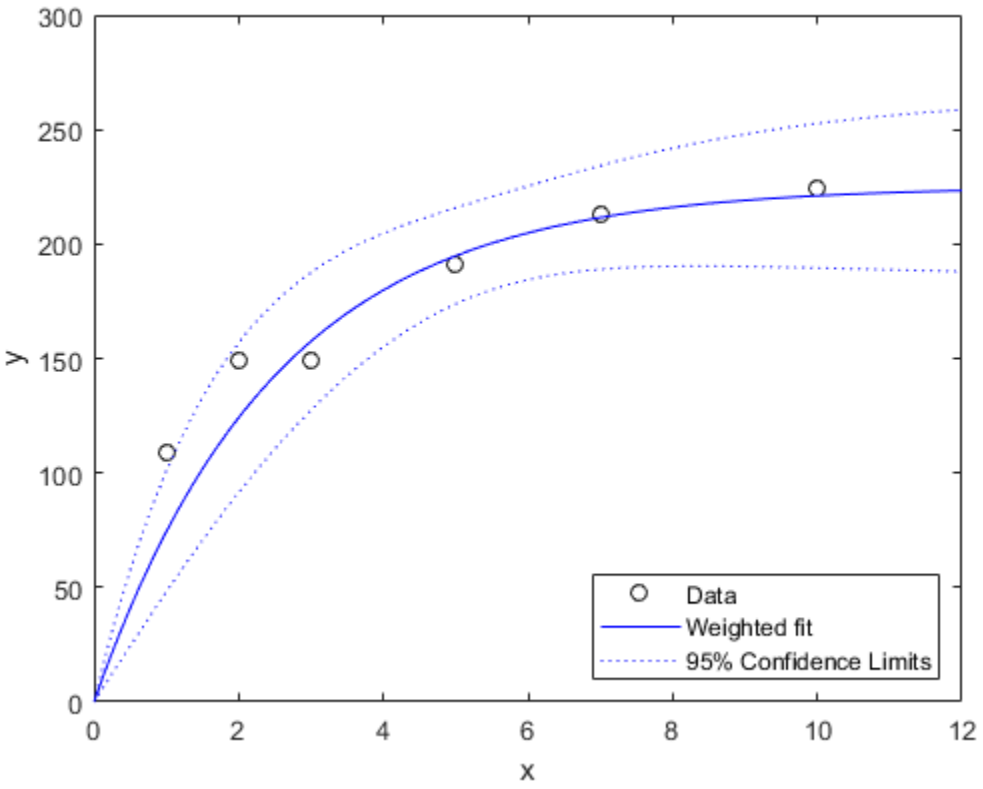
```
ans =

  195.4650  254.8788
    0.2223    0.5793
```

Estimate the Response Curve

Next, we'll compute the fitted response values and confidence intervals for them. By default, those widths are for pointwise confidence bounds for the predicted value, but we will request simultaneous intervals for the entire curve.

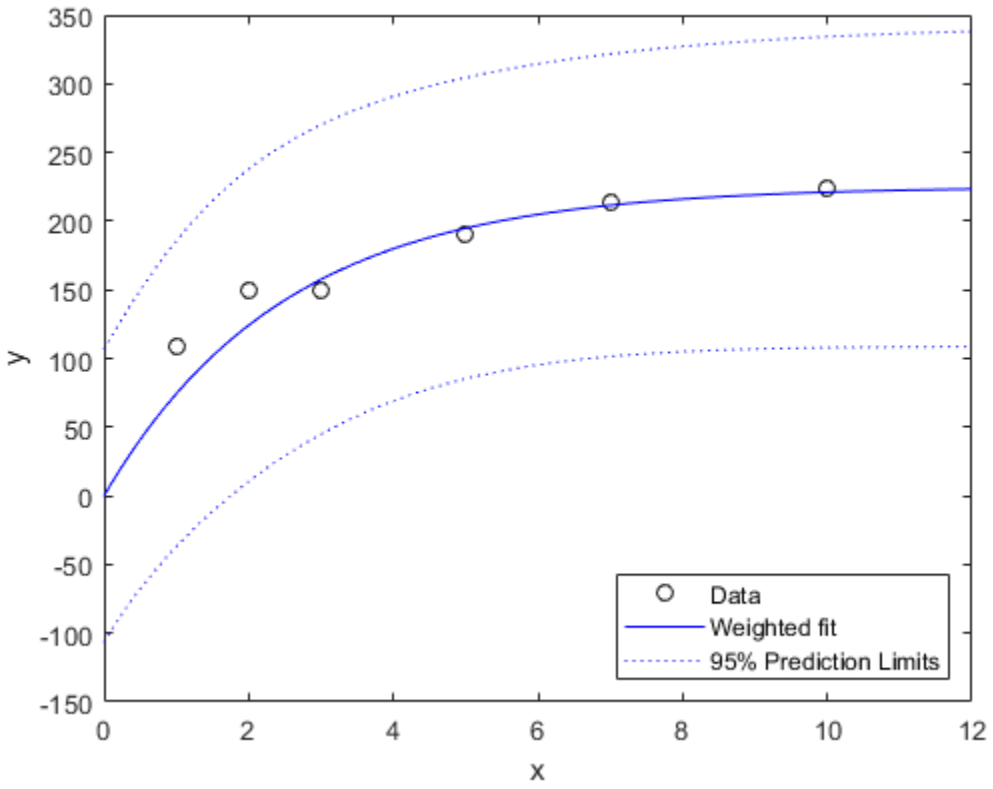
```
[ypred,ypredci] = predict(wnlm,xx,'Simultaneous',true);
plot(x,y,'ko', xx,ypred,'b-', xx,ypredci,'b:');
xlabel('x'); ylabel('y');
legend({'Data', 'Weighted fit', '95% Confidence Limits'},'location','SouthEast');
```



Notice that the two downweighted points are not fit as well by the curve as the remaining points. That's as you would expect for a weighted fit.

It's also possible to estimate prediction intervals for future observations at specified values of x. Those intervals will in effect assume a weight, or measurement precision, of 1.

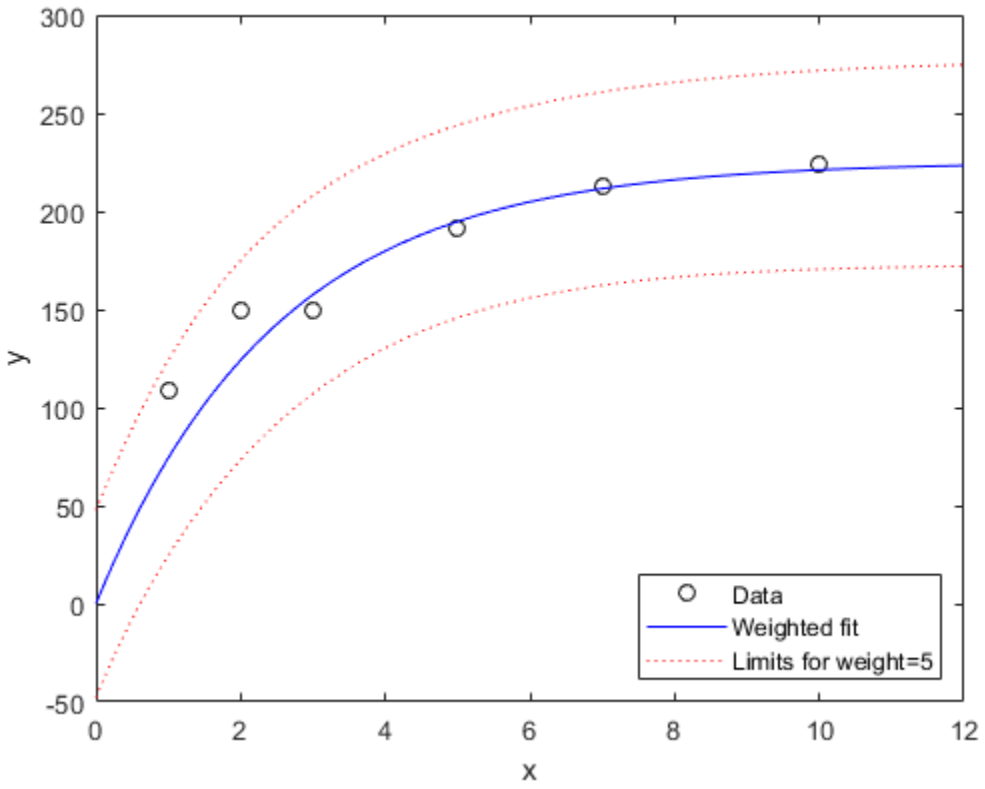
```
[ypred,ypredci] = predict(wnlm,xx,'Simultaneous',true,'Prediction','observation');
plot(x,y,'ko', xx,ypred,'b-', xx,ypredci,'b:');
xlabel('x'); ylabel('y');
legend({'Data', 'Weighted fit', '95% Prediction Limits'},'location','SouthEast');
```



The absolute scale of the weights actually doesn't affect the parameter estimates. Rescaling the weights by any constant would have given us the same estimates. But they do affect the confidence bounds, since the bounds represent an observation with weight 1. Here you can see that the points with higher weight seem too close to the fitted line, compared with the confidence limits.

While the `predict` method doesn't allow us to change the weights, it is possible for us to do some post-processing and investigate how the curve would look for a more precise estimate. Suppose we are interested in a new observation that is based on the average of five measurements, just like the last four points in this plot. We could reduce the width of the intervals by a factor of sqrt(5).

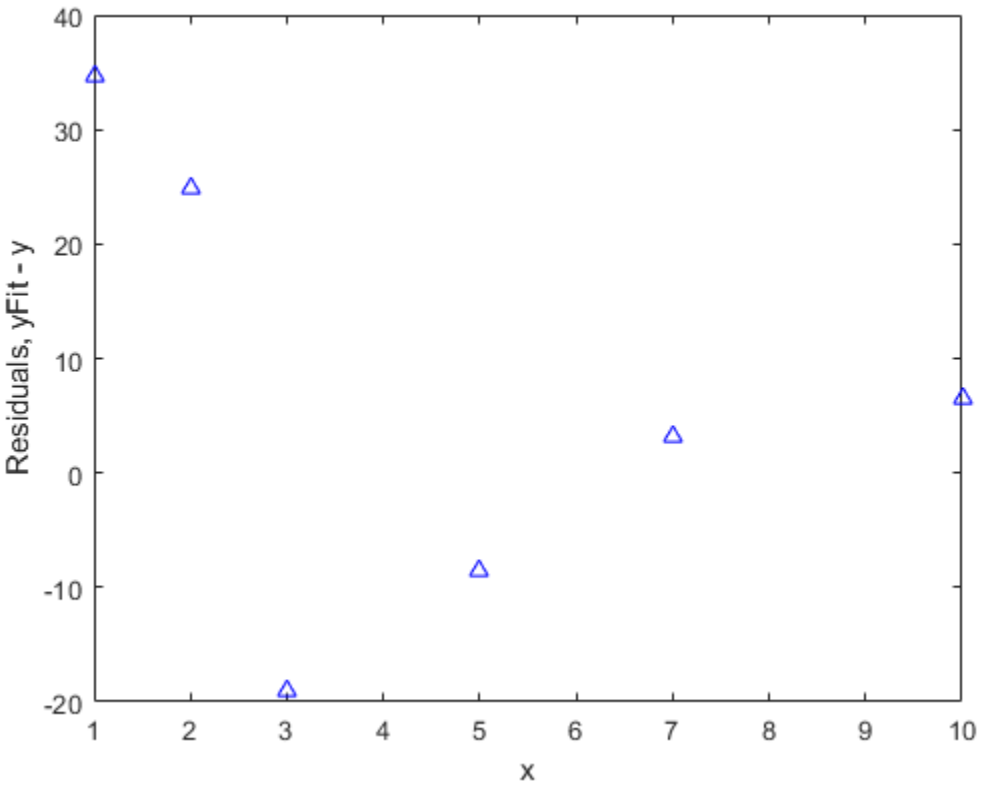
```
halfwidth = ypredci(:,2)-ypred;
newwidth = halfwidth/sqrt(5);
newci = [ypred-newwidth, ypred+newwidth];
plot(x,y,'ko', xx,ypred,'b-', xx,newci,'r:');
xlabel('x'); ylabel('y');
legend({'Data', 'Weighted fit', 'Limits for weight=5'},'location','SouthEast');
```



Residual Analysis

In addition to plotting the data and the fit, we'll plot residuals from a fit against the predictors, to diagnose any problems with the model. The residuals should appear independent and identically distributed but with a variance proportional to the inverse of the weights. We can standardize this variance to make the plot easier to interpret.

```
r = wnlm.Residuals.Raw;
plot(x,r.*sqrt(w),'b^');
xlabel('x'); ylabel('Residuals, yFit - y');
```



There is some evidence of systematic patterns in this residual plot. Notice how the last four residuals have a linear trend, suggesting that the model might not increase fast enough as x increases. Also, the magnitude of the residuals tends to decrease as x increases, suggesting that measurement error may depend on x. These deserve investigation, however, there are so few data points, that it's hard to attach significance to these apparent patterns.

Pitfalls in Fitting Nonlinear Models by Transforming to Linearity

This example shows pitfalls that can occur when fitting a nonlinear model by transforming to linearity. Imagine that we have collected measurements on two variables, x and y, and we want to model y as a function of x. Assume that x is measured exactly, while measurements of y are affected by additive, symmetric, zero-mean errors.

```
x = [5.72 4.22 5.72 3.59 5.04 2.66 5.02 3.11 0.13 2.26 ...
     5.39 2.57 1.20 1.82 3.23 5.46 3.15 1.84 0.21 4.29 ...
     4.61 0.36 3.76 1.59 1.87 3.14 2.45 5.36 3.44 3.41]';
y = [2.66 2.91 0.94 4.28 1.76 4.08 1.11 4.33 8.94 5.25 ...
     0.02 3.88 6.43 4.08 4.90 1.33 3.63 5.49 7.23 0.88 ...
     3.08 8.12 1.22 4.24 6.21 5.48 4.89 2.30 4.13 2.17]';
```

Let's also assume that theory tells us that these data should follow a model of exponential decay, y = p1*exp(p2*x), where p1 is positive and p2 is negative. To fit this model, we could use nonlinear least squares.

```
modelFun = @(p,x) p(1)*exp(p(2)*x);
```

But the nonlinear model can also be transformed to a linear one by taking the log on both sides, to get log(y) = log(p1) + p2*x. That's tempting, because we can fit that linear model by ordinary linear least squares. The coefficients we'd get from a linear least squares would be log(p1) and p2.

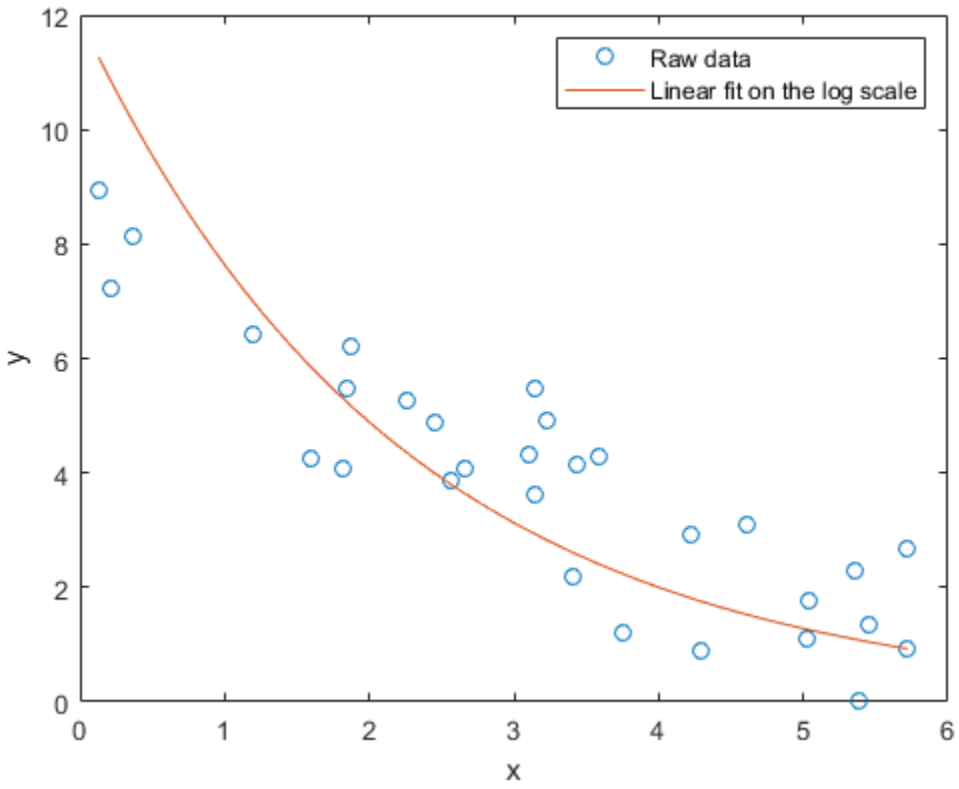
```
paramEstsLin = [ones(size(x)), x] \ log(y);
paramEstsLin(1) = exp(paramEstsLin(1))
```

```
paramEstsLin =

   11.9312
   -0.4462
```

How did we do? We can superimpose the fit on the data to find out.

```
xx = linspace(min(x), max(x));
yyLin = modelFun(paramEstsLin, xx);
plot(x,y,'o', xx,yyLin,'-');
xlabel('x'); ylabel('y');
legend({'Raw data','Linear fit on the log scale'},'location','NE');
```



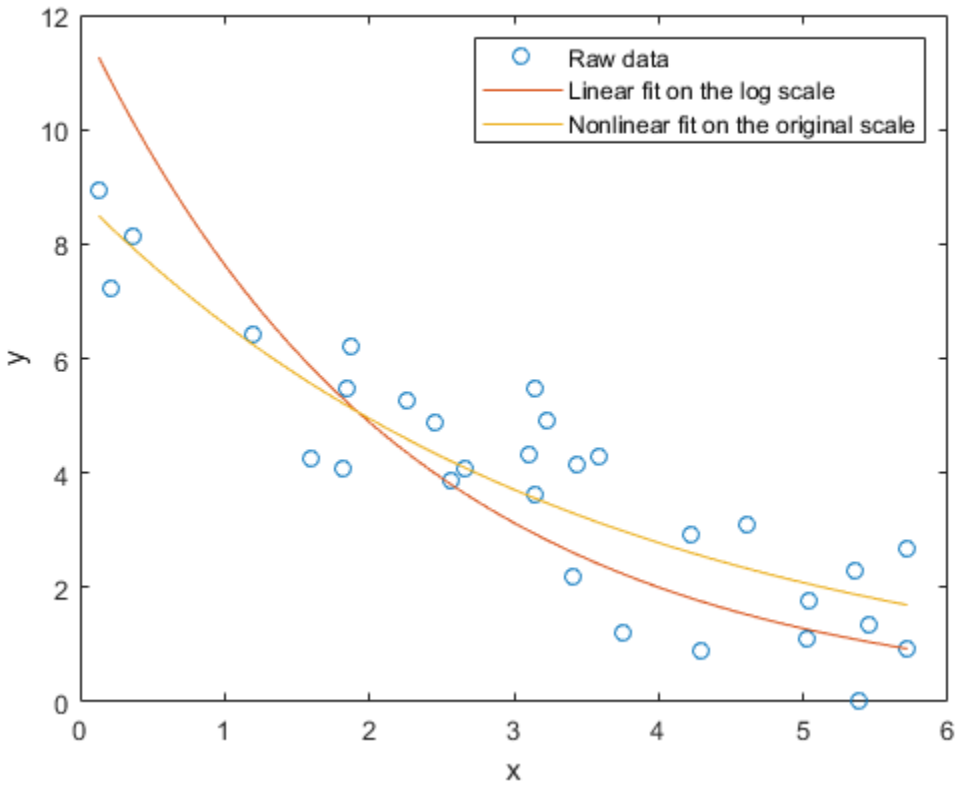
Something seems to have gone wrong, because the fit doesn't really follow the trend that we can see in the raw data. What kind of fit would we get if we used `nlinfit` to do nonlinear least squares instead? We'll use the previous fit as a rough starting point, even though it's not a great fit.

```
paramEsts = nlinfit(x, y, modelFun, paramEstsLin)
```

```
paramEsts =

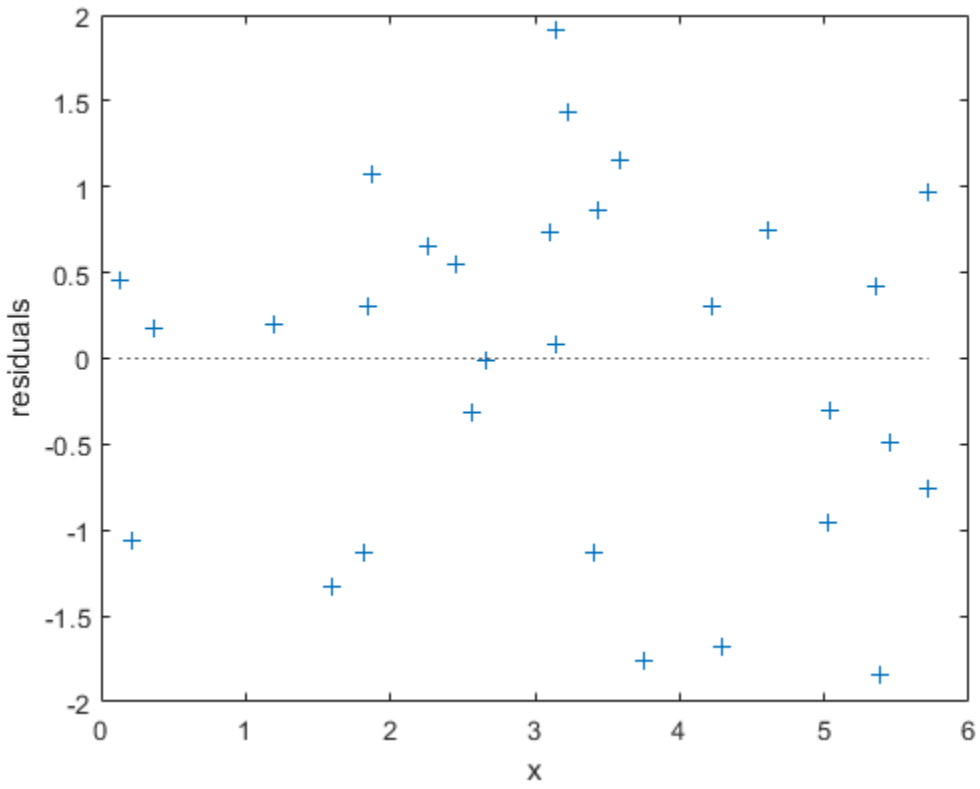
    8.8145
   -0.2885
```

```
yy = modelFun(paramEsts,xx);
plot(x,y,'o', xx,yyLin,'-', xx,yy,'-');
xlabel('x'); ylabel('y');
legend({'Raw data','Linear fit on the log scale',  ...
    'Nonlinear fit on the original scale'},'location','NE');
```



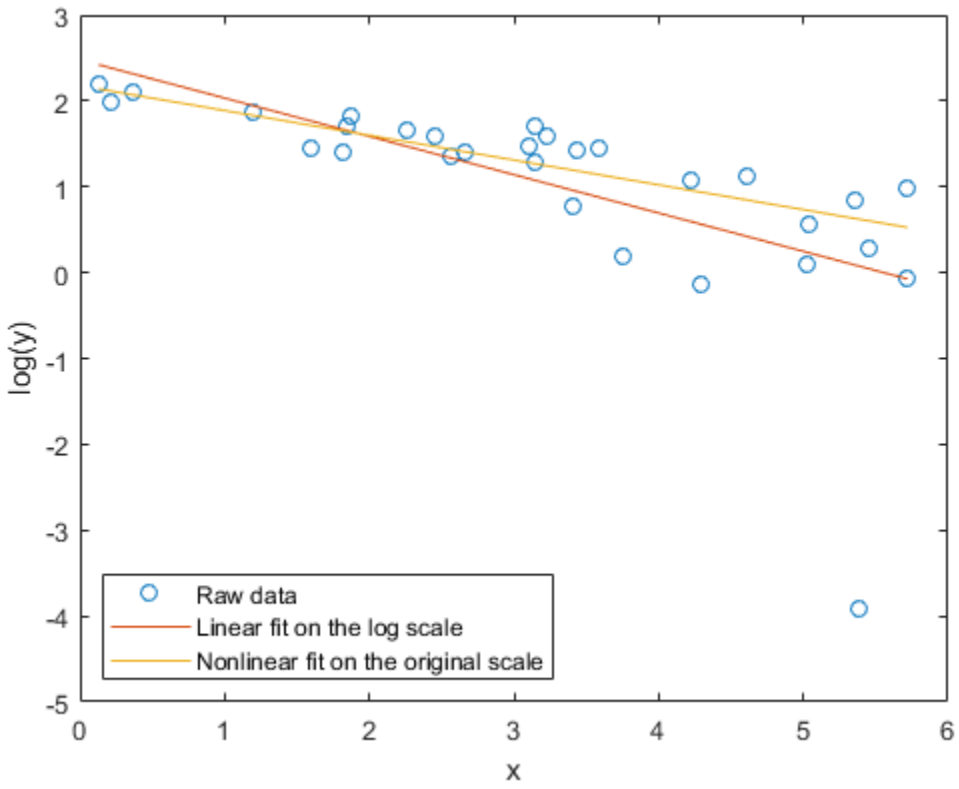
The fit using `nlinfit` more or less passes through the center of the data point scatter. A residual plot shows something approximately like an even scatter about zero.

```
r = y-modelFun(paramEsts,x);
plot(x,r,'+', [min(x) max(x)],[0 0],'k:');
xlabel('x'); ylabel('residuals');
```



So what went wrong with the linear fit? The problem is in log transform. If we plot the data and the two fits on the log scale, we can see that there's an extreme outlier.

```
plot(x,log(y),'o', xx,log(yyLin),'-', xx,log(yy),'-');
xlabel('x'); ylabel('log(y)');
ylim([-5,3]);
legend({'Raw data', 'Linear fit on the log scale',  ...
    'Nonlinear fit on the original scale'},'location','SW');
```



That observation is not an outlier in the original data, so what happened to make it one on the log scale? The log transform is exactly the right thing to straighten out the trend line. But the log is a very nonlinear transform, and so symmetric measurement errors on the original scale have become asymmetric on the log scale. Notice that the outlier had the smallest y value on the original scale -- close to zero. The log transform has "stretched out" that smallest y value more than its neighbors. We made the linear fit on the log scale, and so it is very much affected by that outlier.

Had the measurement at that one point been slightly different, the two fits might have been much more similar. For example,

```
y(11) = 1;
paramEsts = nlinfit(x, y, modelFun, [10;-.3])
```

```
paramEsts =

    8.7618
   -0.2833
```

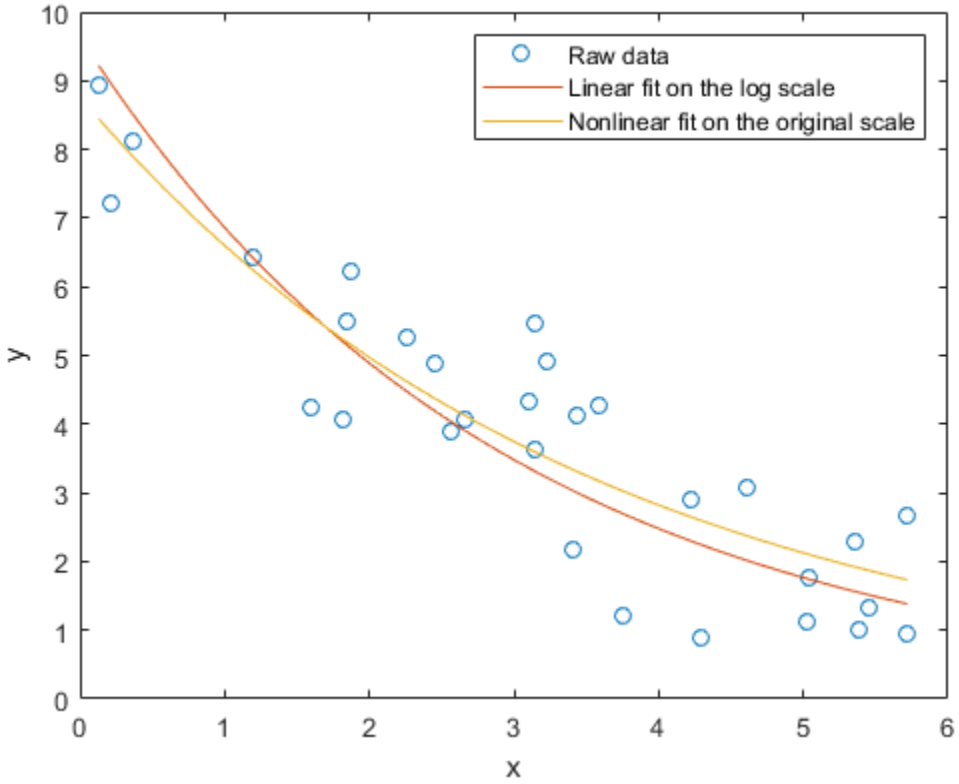
```
paramEstsLin = [ones(size(x)), x] \ log(y);
paramEstsLin(1) = exp(paramEstsLin(1))
```

```
paramEstsLin =

    9.6357
```

```
    -0.3394
```

```
yy = modelFun(paramEsts,xx);
yyLin = modelFun(paramEstsLin, xx);
plot(x,y,'o', xx,yyLin,'-', xx,yy,'-');
xlabel('x'); ylabel('y');
legend({'Raw data', 'Linear fit on the log scale',  ...
    'Nonlinear fit on the original scale'},'location','NE');
```



Still, the two fits are different. Which one is "right"? To answer that, suppose that instead of additive measurement errors, measurements of y were affected by multiplicative errors. These errors would not be symmetric, and least squares on the original scale would not be appropriate. On the other hand, the log transform would make the errors symmetric on the log scale, and the linear least squares fit on that scale is appropriate.

So, which method is "right" depends on what assumptions you are willing to make about your data. In practice, when the noise term is small relative to the trend, the log transform is "locally linear" in the sense that y values near the same x value will not be stretched out too asymmetrically. In that case, the two methods lead to essentially the same fit. But when the noise term is not small, you should consider what assumptions are realistic, and choose an appropriate fitting method.

Nonlinear Logistic Regression

This example shows two ways of fitting a nonlinear logistic regression model. The first method uses maximum likelihood (ML) and the second method uses generalized least squares (GLS) via the function `fitnlm` from Statistics and Machine Learning Toolbox™.

Problem Description

Logistic regression is a special type of regression in which the goal is to model the probability of something as a function of other variables. Consider a set of predictor vectors $x_1, \ldots, x_N$ where N is the number of observations and x_i is a column vector containing the values of the d predictors for the i th observation. The response variable for x_i is Z_i where Z_i represents a Binomial random variable with parameters n, the number of trials, and μ_i, the probability of success for trial i. The normalized response variable is $Y_i = Z_i/n$ - the proportion of successes in n trials for observation i. Assume that responses Y_i are independent for $i = 1, \ldots, N$. For each i:

$$E(Y_i) = \mu_i$$

$$Var(Y_i) = \frac{\mu_i(1-\mu_i)}{n}.$$

Consider modeling μ_i as a function of predictor variables x_i.

In linear logistic regression, you can use the function `fitglm` to model μ_i as a function of x_i as follows:

$$\log\left(\frac{\mu_i}{1-\mu_i}\right) = x_i^T\beta$$

with β representing a set of coefficients multiplying the predictors in x_i. However, suppose you need a nonlinear function on the right-hand-side:

$$\log\left(\frac{\mu_i}{1-\mu_i}\right) = f(x_i, \beta)\,.$$

There are functions in Statistics and Machine Learning Toolbox™ for fitting nonlinear regression models, but not for fitting nonlinear logistic regression models. This example shows how you can use toolbox functions to fit those models.

Direct Maximum Likelihood (ML)

The ML approach maximizes the log likelihood of the observed data. The likelihood is easily computed using the Binomial probability (or density) function as computed by the `binopdf` function.

Generalized Least Squares (GLS)

You can estimate a nonlinear logistic regression model using the function `fitnlm`. This might seem surprising at first since `fitnlm` does not accommodate Binomial distribution or any link functions. However, `fitnlm` can use Generalized Least Squares (GLS) for model estimation if you specify the mean and variance of the response. If GLS converges, then it solves the same set of nonlinear equations for estimating β as solved by ML. You can also use GLS for quasi-likelihood estimation of generalized linear models. In other words, we should get the same or equivalent solutions from GLS

and ML. To implement GLS estimation, provide the nonlinear function to fit, and the variance function for the Binomial distribution.

Mean or model function

The model function describes how μ_i changes with β. For `fitnlm`, the model function is:

$$\mu_i = \frac{1}{1 + \exp\{-f(x_i, \beta)\}}$$

Weight function

`fitnlm` accepts observation weights as a function handle using the `'Weights'` name-value pair argument. When using this option, `fitnlm` assumes the following model:

$$E(Y_i) = \mu_i$$

$$Var(Y_i) = \frac{\sigma^2}{w(\mu_i)}$$

where responses Y_i are assumed to be independent, and w is a custom function handle that accepts μ_i and returns an observation weight. In other words, the weights are inversely proportional to the response variance. For the Binomial distribution used in the logistic regression model, create the weight function as follows:

$$w(\mu_i) = \frac{1}{Var(y_i)} = \frac{n}{\mu_i(1-\mu_i)}$$

`fitnlm` models the variance of the response Y_i as $\sigma^2/w(\mu_i)$ where σ^2 is an extra parameter that is present in GLS estimation, but absent in the logistic regression model. However, this typically does not affect the estimation of β, and it provides a "dispersion parameter" to check on the assumption that the Z_i values have a Binomial distribution.

An advantage of using `fitnlm` over direct ML is that you can perform hypothesis tests and compute confidence intervals on the model coefficients.

Generate Example Data

To illustrate the differences between ML and GLS fitting, generate some example data. Assume that x_i is one dimensional and suppose the true function f in the nonlinear logistic regression model is the Michaelis-Menten model parameterized by a 2×1 vector β:

$$f(x_i, \beta) = \frac{\beta_1 x_i}{\beta_2 + x_i}.$$

```
myf = @(beta,x) beta(1)*x./(beta(2) + x);
```

Create a model function that specifies the relationship between μ_i and β.

```
mymodelfun = @(beta,x) 1./(1 + exp(-myf(beta,x)));
```

Create a vector of one dimensional predictors and the true coefficient vector β.

```
rng(300,'twister');
x    = linspace(-1,1,200)';
beta = [10;2];
```

Compute a vector of μ_i values for each predictor.

```
mu = mymodelfun(beta,x);
```

Generate responses z_i from a Binomial distribution with success probabilities μ_i and number of trials n.

```
n = 50;
z = binornd(n,mu);
```

Normalize the responses.

```
y = z./n;
```

ML Approach

The ML approach defines the negative log likelihood as a function of the β vector, and then minimizes it with an optimization function such as `fminsearch`. Specify `beta0` as the starting value for β.

```
mynegloglik = @(beta) -sum(log(binopdf(z,n,mymodelfun(beta,x))));
beta0 = [3;3];
opts = optimset('fminsearch');
opts.MaxFunEvals = Inf;
opts.MaxIter = 10000;
betaHatML = fminsearch(mynegloglik,beta0,opts)
```

```
betaHatML = 2×1

    9.9259
    1.9720
```

The estimated coefficients in `betaHatML` are close to the true values of `[10;2]`.

GLS Approach

The GLS approach creates a weight function for `fitnlm` previously described.

```
wfun = @(xx) n./(xx.*(1-xx));
```

Call `fitnlm` with custom mean and weight functions. Specify `beta0` as the starting value for β.

```
nlm = fitnlm(x,y,mymodelfun,beta0,'Weights',wfun)
```

```
nlm =
Nonlinear regression model:
    y ~ F(beta,x)

Estimated Coefficients:
          Estimate      SE       tStat       pValue
          ________    _______    ______    __________

    b1     9.926      0.83135     11.94     4.193e-25
    b2     1.972      0.16438    11.996    2.8182e-25
```

```
Number of observations: 200, Error degrees of freedom: 198
Root Mean Squared Error: 1.16
R-Squared: 0.995,  Adjusted R-Squared 0.995
F-statistic vs. zero model: 1.88e+04, p-value = 2.04e-226
```

Get an estimate of β from the fitted `NonLinearModel` object `nlm`.

```
betaHatGLS = nlm.Coefficients.Estimate
```

```
betaHatGLS = 2×1

    9.9260
    1.9720
```

As in the ML method, the estimated coefficients in `betaHatGLS` are close to the true values of `[10;2]`. The small p-values for both β_1 and β_2 indicate that both coefficients are significantly different from 0.

Compare ML and GLS Approaches

Compare estimates of β.

```
max(abs(betaHatML - betaHatGLS))
```

```
ans = 1.1460e-05
```

Compare fitted values using ML and GLS

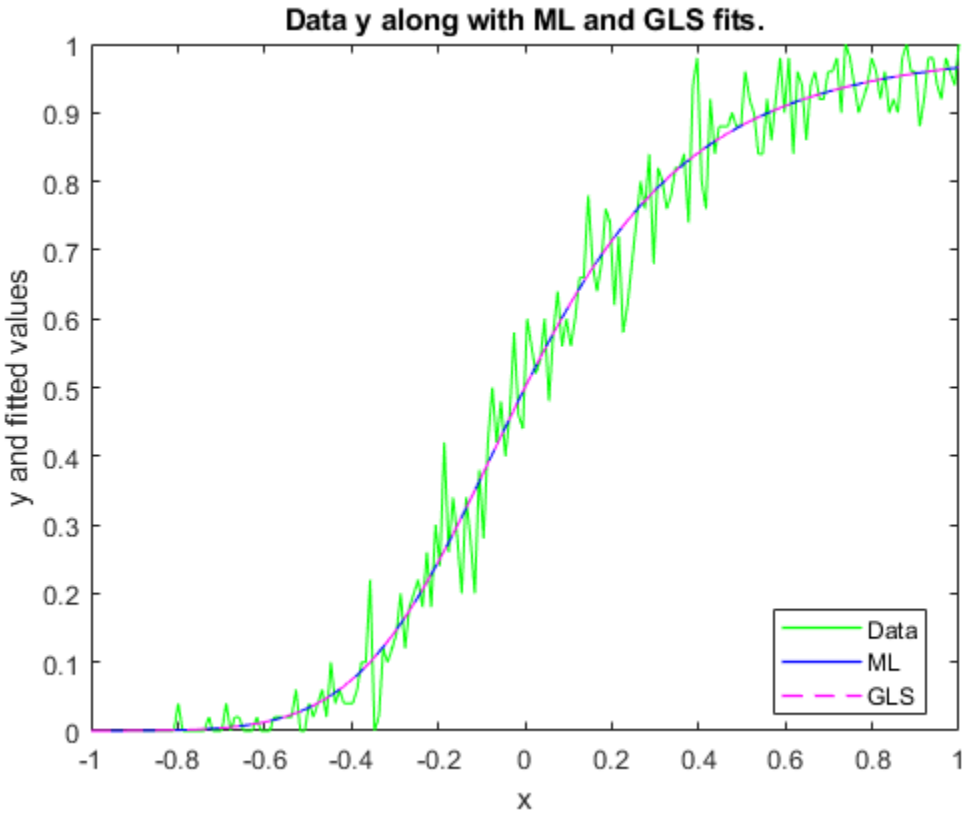
```
yHatML  = mymodelfun(betaHatML ,x);
yHatGLS = mymodelfun(betaHatGLS,x);
max(abs(yHatML - yHatGLS))
```

```
ans = 1.2746e-07
```

ML and GLS approaches produce similar solutions.

Plot fitted values using ML and GLS

```
figure
plot(x,y,'g','LineWidth',1)
hold on
plot(x,yHatML ,'b'  ,'LineWidth',1)
plot(x,yHatGLS,'m--','LineWidth',1)
legend('Data','ML','GLS','Location','Best')
xlabel('x')
ylabel('y and fitted values')
title('Data y along with ML and GLS fits.')
```

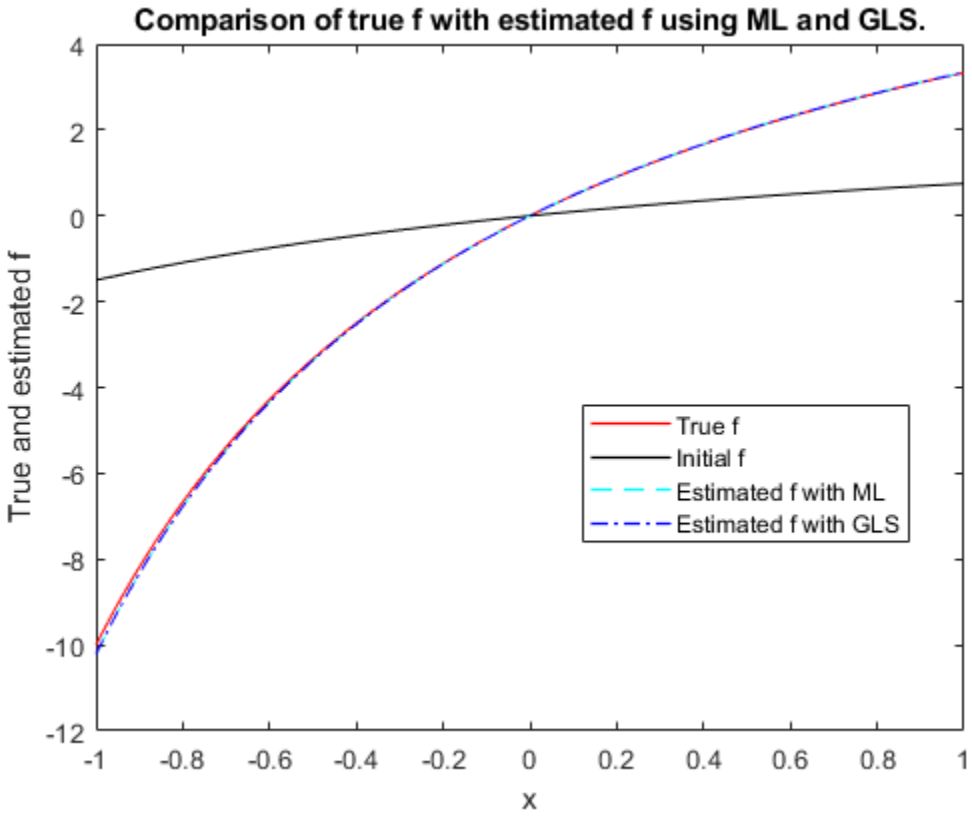


ML and GLS produce similar fitted values.

Plot estimated nonlinear function using ML and GLS

Plot true model for $f(x_i, \beta)$. Add plot for the initial estimate of $f(x_i, \beta)$ using $\beta = \beta_0$ and plots for ML and GLS based estimates of $f(x_i, \beta)$.

```
figure
plot(x,myf(beta,x),'r','LineWidth',1)
hold on
plot(x,myf(beta0,x),'k','LineWidth',1)
plot(x,myf(betaHatML,x),'c--','LineWidth',1)
plot(x,myf(betaHatGLS,x),'b-.','LineWidth',1)
legend('True f','Initial f','Estimated f with ML','Estimated f with GLS','Location','Best')
xlabel('x')
ylabel('True and estimated f')
title('Comparison of true f with estimated f using ML and GLS.')
```



The estimated nonlinear function f using both ML and GLS methods is close to the true nonlinear function f. You can use a similar technique to fit other nonlinear generalized linear models like nonlinear Poisson regression.

Survival Analysis

What Is Survival Analysis?

In this section...

Introduction

Survival analysis is time-to-event analysis, that is, when the outcome of interest is the time until an event occurs. Examples of time-to-events are the time until infection, reoccurrence of a disease, or recovery in health sciences, duration of unemployment in economics, time until the failure of a machine part or lifetime of light bulbs in engineering, and so on. Survival analysis is a part of reliability studies in engineering. In this case, it is usually used to study the lifetime of industrial components. In reliability analyses, survival times are usually called failure times as the variable of interest is how much time a component functions properly before it fails.

Survival analysis consists of parametric, semiparametric, and nonparametric methods. You can use these to estimate the most commonly used measures in survival studies, survivor and hazard functions, compare them for different groups, and assess the relationship of predictor variables to survival time. Some statistical probability distributions describe survival times well. Commonly used distributions are exponential, Weibull, lognormal, Burr, and Birnbaum-Saunders distributions. Statistics and Machine Learning Toolbox functions `ecdf` and `ksdensity` compute the empirical and kernel density estimates of the cdf, cumulative hazard, and survivor functions. `coxphfit` fits the Cox proportional hazards model to the data.

Censoring

One important concept in survival analysis is censoring. The survival times of some individuals might not be fully observed due to different reasons. In life sciences, this might happen when the survival study (e.g., the clinical trial) stops before the full survival times of all individuals can be observed, or a person drops out of a study, or for long-term studies, when the patient is lost to follow up. In the industrial context, not all components might have failed before the end of the reliability study. In such cases, the individual survives beyond the time of the study, and the exact survival time is unknown. This is called right censoring.

During a survival study either the individual is observed to fail at time T, or the observation on that individual ceases at time c. Then the observation is $\min(T,c)$ and an indicator variable I_c shows if the individual is censored or not. The calculations for hazard and survivor functions must be adjusted to account for censoring. Statistics and Machine Learning Toolbox functions such as `ecdf`, `ksdensity`, `coxphfit`, and `mle` account for censoring.

Data

Survival data usually consists of the time until an event of interest occurs and the censoring information for each individual or component. The following table shows the fictitious unemployment time of individuals in a 6-month study. Two individuals are right censored (indicated by a censoring

value of 1). One individual was still unemployed after the 24th week, when the study ended. Contact with the other censored individual was lost at the end of the 21st week.

Unemployment Time (Weeks)	Censoring
14	0
23	0
7	0
21	1
19	0
16	0
24	1
8	0

Survival data might also include the number of failures at a certain time (the number of times a particular survival or failure time was observed). The following table shows the simulated time until a light-emitting diodes drops to 70% of its full light output level, in hours, in an accelerated life test.

Failure Time (hrs)	Frequency
8600	6
15300	19
22000	11
28600	20
35300	17
42000	14
48700	8
55400	2
62100	0
68800	2

Data might also have information on the predictor variables, to use in semi-parametric regression-like methods such as Cox proportional hazards regression.

Time Until Recovery (weeks)	Censoring	Gender	Systolic Blood Pressure	Diastolic Blood Pressure
12	1	Male	124	93
20	0	Female	109	77
7	0	Female	125	83
13	0	Male	117	75
9	1	Male	122	80
15	0	Female	121	70
17	1	Male	130	88

Time Until Recovery (weeks)	Censoring	Gender	Systolic Blood Pressure	Diastolic Blood Pressure
8	0	Female	115	82
14	0	Male	118	86

Survivor Function

The survivor function is the probability of survival as a function of time. It is also called the survival function. It gives the probability that the survival time of an individual exceeds a certain value. Since the cumulative distribution function, $F(t)$, is the probability that the survival time is less than or equal to a given point in time, the survival function for a continuous distribution, $S(t)$, is the complement of the cumulative distribution function:

$S(t) = 1 - F(t)$.

The survivor function is also related to the hazard function on page 14-6. If the data has the hazard function, $h(t)$, then the survivor function is

$$S(t) = \exp\left(-\int_0^t h(u)du\right),$$

which corresponds to

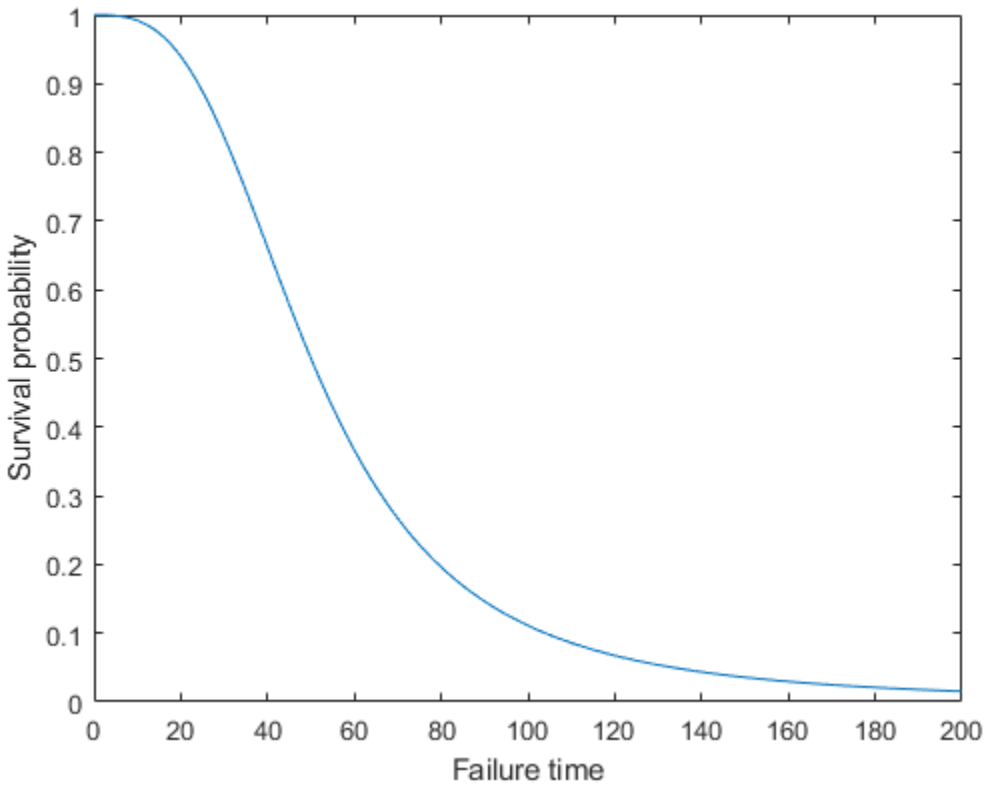
$$S(t) = \exp(-H(t)),$$

where $H(t)$ is the cumulative hazard function.

Burr Distribution Survivor Function

Calculate and plot the survivor function of a Burr distribution with parameters `50`, `3`, and `1`.

```
x = 0:0.1:200;
figure()
plot(x,1-cdf('Burr',x,50,3,1))
xlabel('Failure time');
ylabel('Survival probability');
```



Survivor Function from Data

This example shows how to estimate the survivor function from data.

Load the sample data.

```
load readmissiontimes
```

The column vector `ReadmissionTime` shows the readmission times for 100 patients. The column vector `Censored` has the censorship information for each patient, where 1 indicates censored data, and 0 that indicates the exact readmission times are observed. This data is simulated.

```
[ReadmissionTime Censored]
```

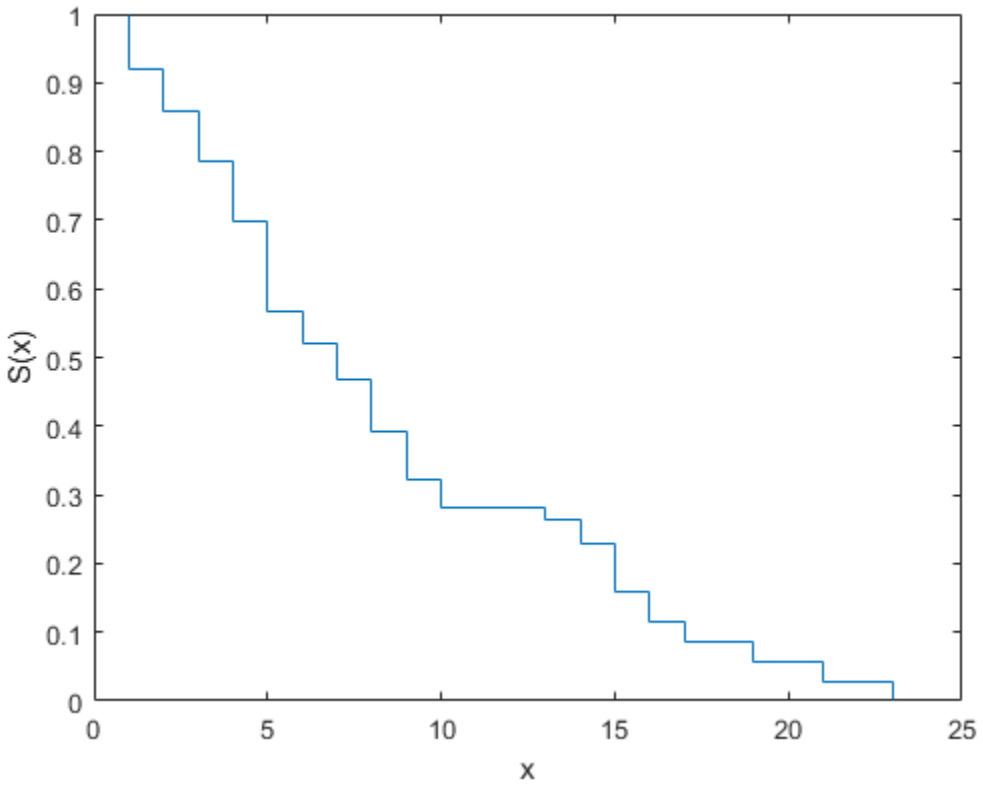
```
ans = 100×2

     5     1
     3     1
    19     0
    17     0
     9     0
    16     0
     4     0
     2     0
     3     0
    15     0
```

The first two readmission times, 5 and 3, are both censored.

Display the empirical survivor function with censoring using `ecdf` with the name-value pair arguments `'function','survivor'` and `'censoring',Censored`.

```
ecdf(ReadmissionTime,'censoring',Censored,'function','survivor')
```



Hazard Function

The hazard function gives the instantaneous failure rate of an individual conditioned on the fact that the individual survived until a given time. That is,

$$h(t) = \lim_{\Delta t \to 0} \frac{P(t \le T < t + \Delta t \,|\, T \ge t)}{\Delta t},$$

where Δt is a very small time interval. The hazard rate, therefore, is sometimes called the conditional failure rate. The hazard function always takes a positive value. However, these values do not correspond to probabilities and might be greater than 1.

The hazard function is related to the probability density function, $f(t)$, cumulative distribution function, $F(t)$, and survivor function, $S(t)$, as follows:

$$h(t) = \frac{f(t)}{S(t)} = \frac{f(t)}{1 - F(t)},$$

which is also equivalent to

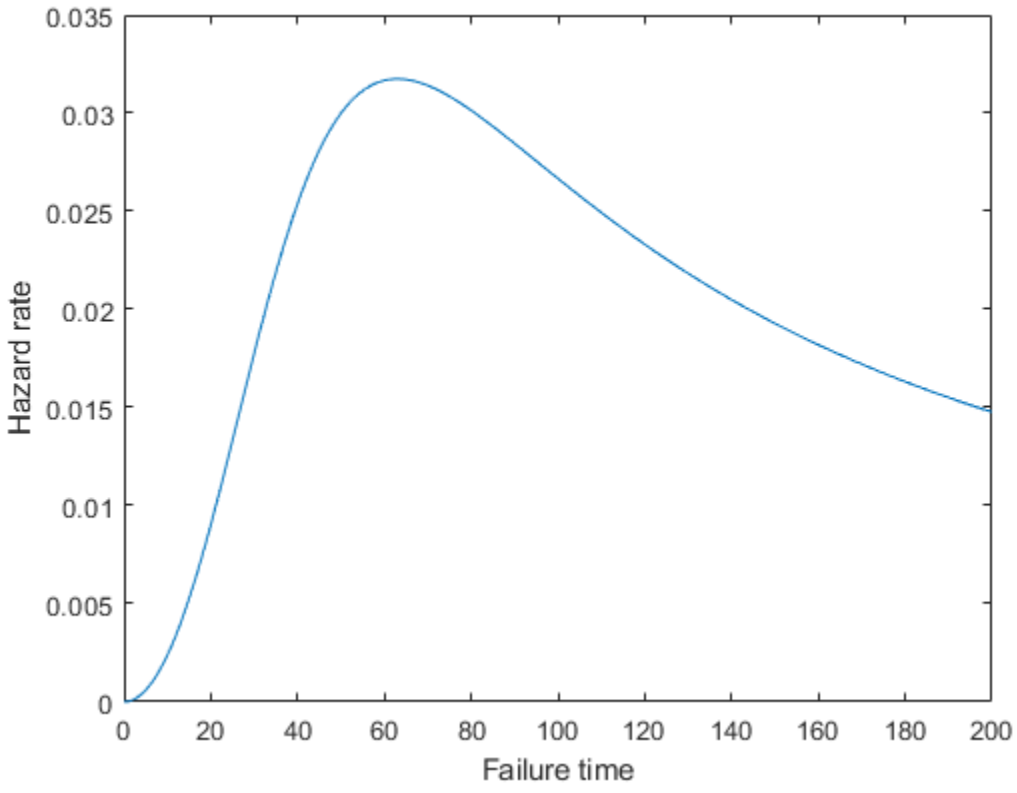
$$h(t) = -\frac{d}{dt}\ln S(t).$$

So, if you know the shape of the survival function, you can also derive the corresponding hazard function.

Burr Distribution Hazard Function

Calculate and plot the hazard function of a Burr distribution with parameters `50`, `3`, and `1`.

```
x = 0:1:200;
Burrhazard = pdf('Burr',x,50,3,1)./(1-cdf('Burr',x,50,3,1));
figure()
plot(x,Burrhazard)
xlabel('Failure time');
ylabel('Hazard rate');
```



Weibull Hazard Functions

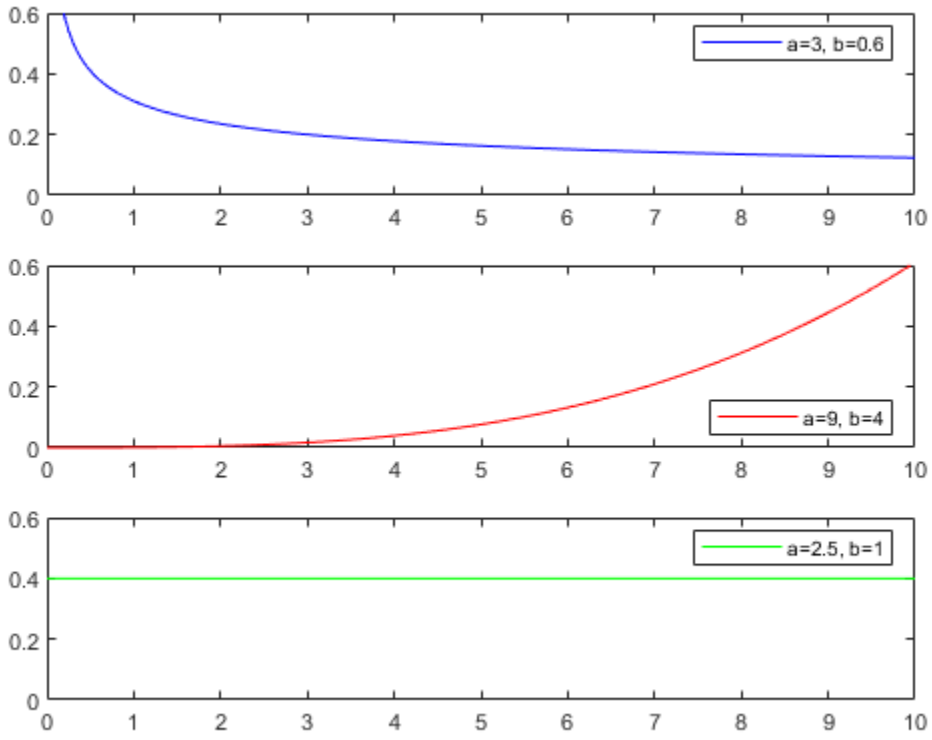
There are different types of hazard functions. The previous figure shows a situation when the hazard rate increases for the early time periods and then gradually decreases. The hazard rate might also be

monotonically decreasing, increasing, or constant over time. The following figure shows examples of different types of hazard functions for data coming from different Weibull distributions.

```
figure
ax1 = subplot(3,1,1);
x1 = 0:0.05:10;
hazard1 = pdf('wbl',x1,3,0.6)./(1-cdf('wbl',x1,3,0.6));
plot(x1,hazard1,'color','b')
set(ax1,'Ylim',[0 0.6]);
legend(ax1,'a=3, b=0.6');

ax2 = subplot(3,1,2);
x2 = 0:0.05:10;
hazard2 = pdf('wbl',x2,9,4)./(1-cdf('wbl',x2,9,4));
plot(x2,hazard2,'color','r')
set(ax2,'Ylim',[0 0.6]);
legend(ax2,'a=9, b=4','location','southeast');

ax3 = subplot(3,1,3);
x3 = 0:0.05:10;
hazard3 = pdf('wbl',x3,2.5,1)./(1-cdf('wbl',x3,2.5,1));
plot(x3,hazard3,'color','g')
set(ax3,'Ylim',[0 0.6]);
legend(ax3,'a=2.5, b=1');
```



In the third case, the Weibull distribution has a shape parameter value of 1, which corresponds to the exponential distribution. The exponential distribution always has a constant hazard rate over time.

Kaplan-Meier Method

The Statistics and Machine Learning Toolbox function `ecdf` produces the empirical cumulative hazard, survivor, and cumulative distribution functions by using the Kaplan-Meier nonparametric method. The Kaplan-Meier estimator for the survivor function is also called the *product-limit estimator*.

The Kaplan-Meier method uses survival data summarized in life tables. Life tables order data according to ascending failure times, but you don't have to enter the failure/survival times in an ordered manner to use `ecdf`.

A life table usually consists of:

- Failure times
- Number of items failed at a time/time period
- Number of items censored at a time/time period
- Number of items at risk at the beginning of a time/time period

The number at risk is the total number of survivors at the beginning of each period. The number at risk at the beginning of the first period is all individuals in the lifetime study. At the beginning of each remaining period, the number at risk is reduced by the number of failures plus individuals censored at the end of the previous period.

This life table shows fictitious survival data. At the beginning of the first failure time, there are seven items at risk. At time 4, three fail. So at the beginning of time 7, there are four items at risk. Only one fails at time 7, so the number at risk at the beginning of time 11 is three. Two fail at time 11, so at the beginning of time 12, the number at risk is one. The remaining item fails at time 12.

Failure Time (t)	Number Failed	Number at Risk
4	3	7
7	1	4
11	2	3
12	1	1

You can estimate the hazard, cumulative hazard, survival, and cumulative distribution functions using the life tables as described next.

Cumulative Hazard Rate (Failure Rate)

The hazard rate at each period is the number of failures in the given period divided by the number of surviving individuals at the beginning of the period (number at risk).

Failure Time (t)	Hazard Rate ($h(t)$)	Cumulative Hazard Rate
0	0	0
t_1	d_1/r_1	d_1/r_1
t_2	d_2/r_2	$h(t_1) + d_2/r_2$
...	...	...
t_n	d_n/r_n	$h(t_{n-1}) + d_n/r_n$

Survival Probability

For each period, the survival probability is the product of the complement of hazard rates. The initial survival probability at the beginning of the first time period is 1. If the hazard rate for the each period is $h(t_i)$, then the survivor probability is as shown.

Time (*t*)	Survival Probability (*S*(*t*))
0	1
t_1	$1*(1 - h(t_1))$
t_2	$S(t_1)*(1 - h(t_2))$
...	...
t_n	$S(t_{n-1})*(1 - h(t_n))$

Cumulative Distribution Function

Because the cumulative distribution function (cdf) and the survivor function are complements of each other, you can find the cdf from the life tables using $F(t) = 1 - S(t)$.

You can compute the cumulative hazard rate, survival rate, and cumulative distribution function for the simulated data in the first table on this page as follows.

t	Number Failed (*d*)	Number at Risk (*r*)	Hazard Rate	Survival Probability	Cumulative Distribution Function
4	3	7	3/7	1 – 3/7 = 4/7 = 0.5714	0.4286
7	1	4	1/4	4/7*(1 – 1/4) = 3/7 = .4286	0.5714
11	2	3	2/3	3/7*(1 – 2/3) = 1/7 = 0.1429	0.8571
12	1	1	1/1	1/7*(1 – 1) = 0	1

This rates in this example are based on the discrete failure times, and hence the calculations do not necessarily follow the derivative-based definition in “What Is Survival Analysis?” on page 14-2

Here is how you can enter the data and calculate these measures using `ecdf`. The data does not necessarily have to be in ascending order. Suppose the failure times are stored in an array `y`.

```
y = [4 7 11 12];
freq = [3 1 2 1];
[f,x] = ecdf(y,'frequency',freq)
```

```
f =

         0
    0.4286
    0.5714
    0.8571
    1.0000
```

```
x =

     4
     4
     7
    11
    12
```

When you have censored data, the life table might look like the following:

Time (*t*)	Number failed (*d*)	Censoring	Number at Risk (*r*)	Hazard Rate	Survival Probability	Cumulative Distribution Function
4	2	1	7	2/7	1 – 2/7 = 0.7143	0.2857
7	1	0	4	1/4	0.7143*(1 – 1/4) = 0.5357	0.4643
11	1	1	3	2/3	0.5357*(1 – 1/3) = 0.3571	0.6429
12	1	0	1	1/1	0.3571*(1 – 1) = 0	1.0000

At any given time, the censored items are also considered in the total of number at risk, and the hazard rate formula is based on the number failed and the total number at risk. While updating the number at risk at the beginning of each period, the total number failed and censored in the previous period is reduced from the number at risk at the beginning of that period.

While using `ecdf`, you must also enter the censoring information using an array of binary variables. Enter 1 for censored data, and enter 0 for exact failure time.

```
y = [4 4 4 7 11 11 12];
cens = [0 1 0 0 1 0 0];
[f,x] = ecdf(y,'censoring',cens)
```

```
f =

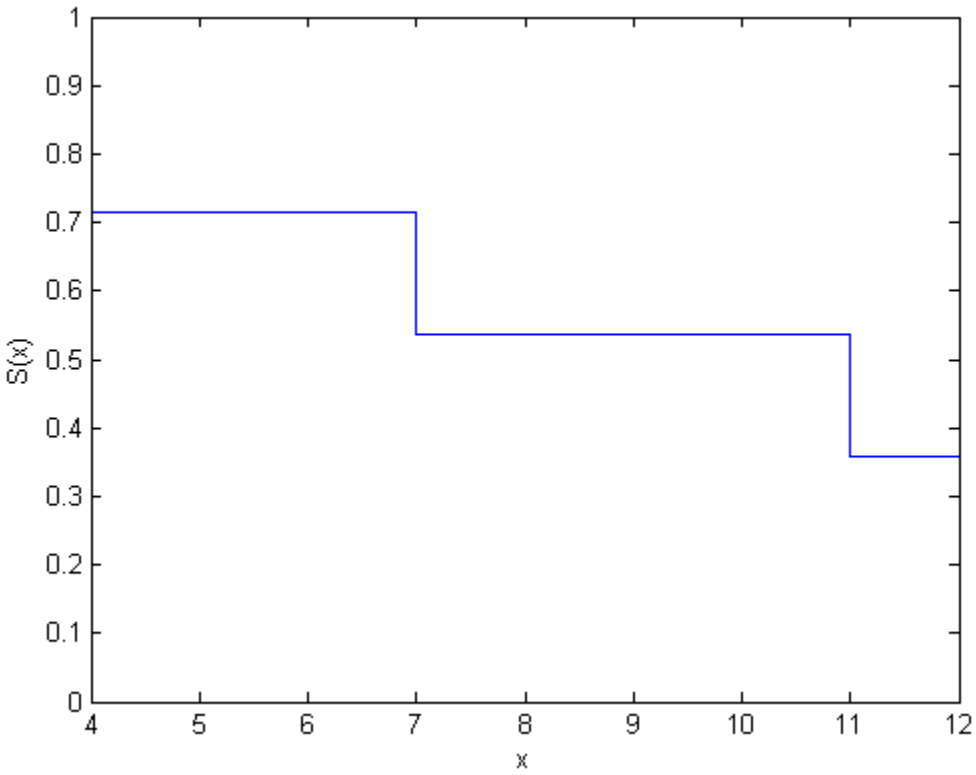
         0
    0.2857
    0.4643
    0.6429
    1.0000

x =

     4
     4
     7
    11
    12
```

`ecdf`, by default, produces the cumulative distribution function values. You have to specify the survivor function or the hazard function using optional name-value pair arguments. You can also plot the results as follows.

```
figure()
ecdf(y,'censoring',cens,'function','survivor');
```



```
figure()
ecdf(y,'censoring',cens,'function','cumulative hazard');
```

Hazard and Survivor Functions for Different Groups

This example shows how to estimate and plot the cumulative hazard and survivor functions for different groups.

Step 1. Load and organize sample data.

Load the sample data.

```
load('readmissiontimes.mat')
```

The data has readmission times of patients with information on their gender, age, weight, smoking status, and censorship. This is simulated data.

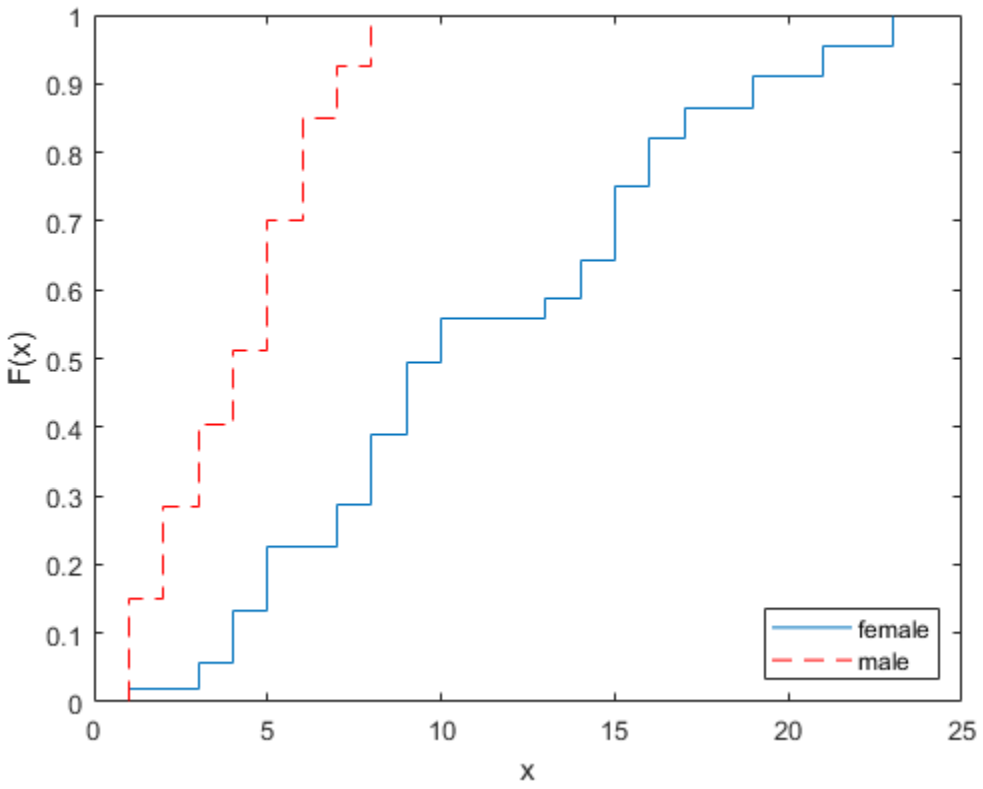
Create a matrix of readmission times and censoring for each gender.

```
female = [ReadmissionTime(Sex==1),Censored(Sex==1)];
male = [ReadmissionTime(Sex==0),Censored(Sex==0)];
```

Step 2. Estimate and plot cumulative distribution function for each gender.

Plot the Kaplan-Meier estimate of the cumulative distribution function for female and male patients.

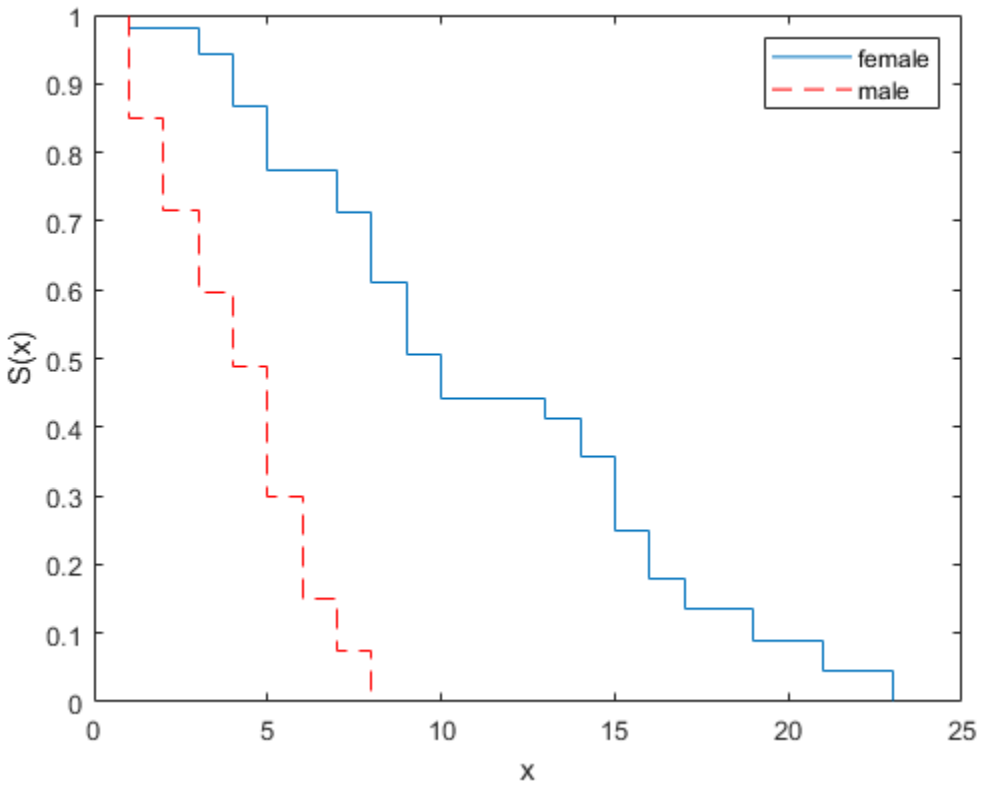
```
figure()
ecdf(gca,female(:,1),'Censoring',female(:,2));
hold on
[f,x] = ecdf(male(:,1),'Censoring',male(:,2));
stairs(x,f,'--r')
hold off
legend('female','male','Location','SouthEast')
```



Step 3. Plot survivor functions.

Compare the survivor functions for female and male patients.

```
figure()
ax1 = gca;
ecdf(ax1,female(:,1),'Censoring',female(:,2),'function','survivor');
hold on
[f,x] = ecdf(male(:,1),'Censoring',male(:,2),'function','survivor');
stairs(x,f,'--r')
legend('female','male')
```



This figure shows that readmission times are shorter for male patients than female patients.

Step 4. Fit Weibull survivor functions.

Fit Weibull distributions to readmission times of female and male patients.

```
pd = fitdist(female(:,1),'wbl','Censoring',female(:,2))
```

```
pd =

  WeibullDistribution

  Weibull distribution
    A = 12.5593   [10.749, 14.6745]
    B = 1.99834   [1.56489, 2.55185]
```

```
pd2 = fitdist(male(:,1),'wbl','Censoring',male(:,2))
```

```
pd2 =

  WeibullDistribution

  Weibull distribution
    A = 4.63991   [3.91039, 5.50551]
    B = 1.94422   [1.48496, 2.54552]
```

```
pd2 = fitdist(male(:,1),'wbl','Censoring',male(:,2))
```

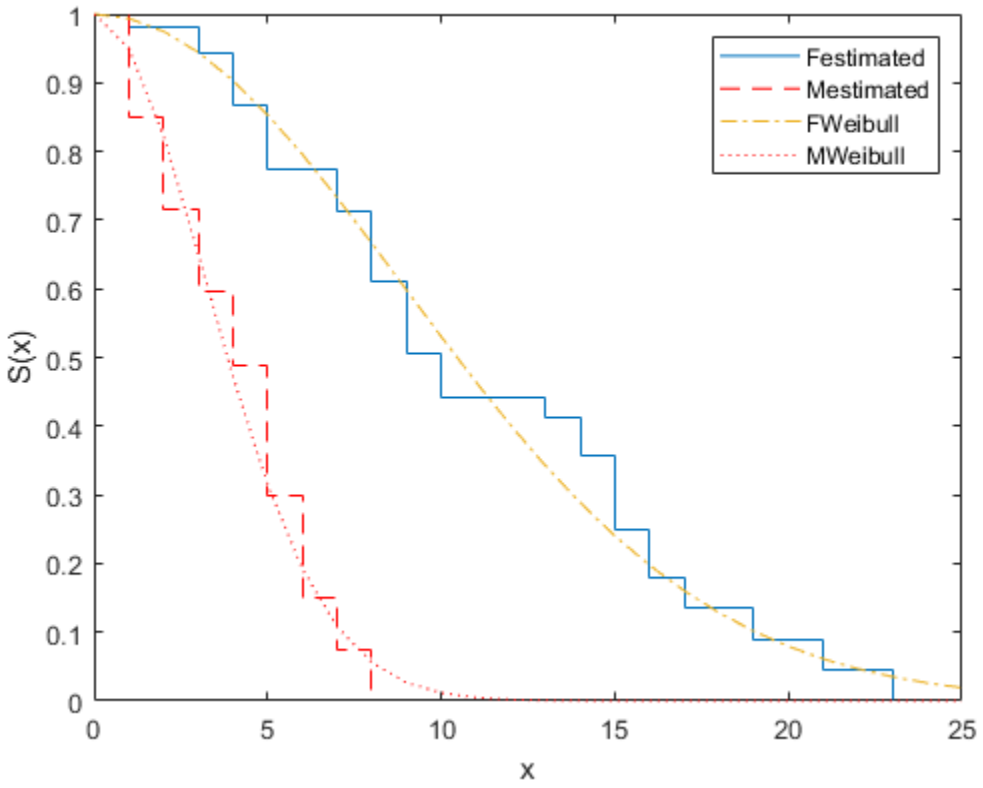
```
pd2 =

  WeibullDistribution

  Weibull distribution
    A = 4.63991   [3.91039, 5.50551]
    B = 1.94422   [1.48496, 2.54552]
```

Plot the Weibull survivor functions for female and male patients on estimated survivor functions.

```
plot(0:1:25,1-cdf('wbl',0:1:25,12.5593,1.99834),'-.')
plot(0:1:25,1-cdf('wbl',0:1:25,4.63991,1.94422),':r')
hold off
legend('Festimated','Mestimated','FWeibull','MWeibull')
```



Weibull distribution provides a good fit for the data.

Step 5. Estimate cumulative hazard and fit Weibull cumulative hazard functions.

Estimate the cumulative hazard function for the genders and fit Weibull cumulative hazard functions.

```
figure()
[f,x] = ecdf(female(:,1),'Censoring',female(:,2),...
'function','cumhazard');
```

```
plot(x,f)
hold on
plot(x,cumsum(pdf(pd,x)./(1-cdf(pd,x))),'-.')
[f,x] = ecdf(male(:,1),'Censoring',male(:,2),...
'function','cumhazard');
plot(x,f,'--r')
plot(x,cumsum(pdf(pd2,x)./(1-cdf(pd2,x))),':r')
legend('Festimated','FWeibull','Mestimated','MWeibull',...
'Location','North')
```

Survivor Functions for Two Groups

This example shows how to find the empirical survivor functions and the parametric survivor functions using the Burr type XII distribution fit to data for two groups.

Step 1. Load and prepare sample data.

Load the sample data.

```
load('lightbulb.mat')
```

The first column of the data has the lifetime (in hours) of two types of light bulbs. The second column has information about the type of light bulb. 0 indicates fluorescent bulbs whereas 1 indicates the incandescent bulb. The third column has censoring information. 1 indicates censored data, and 0 indicates the exact failure time. This is simulated data.

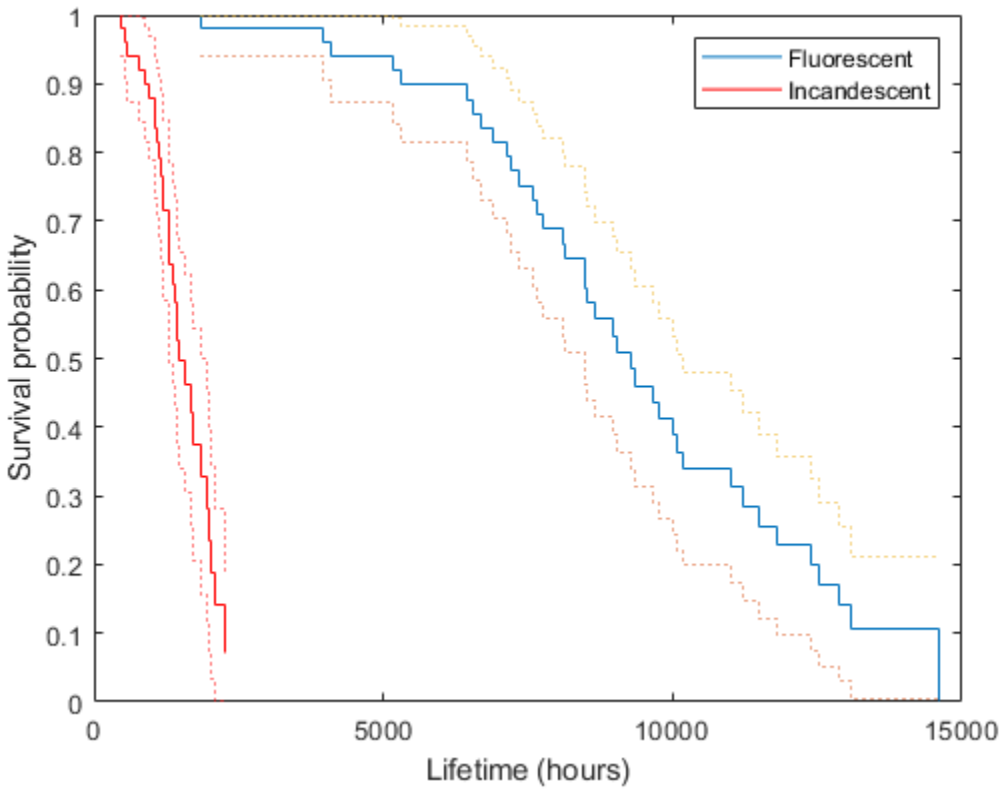
Create a variable for each light bulb type and also include the censorship information.

```
fluo = [lightbulb(lightbulb(:,2)==0,1),...
            lightbulb(lightbulb(:,2)==0,3)];
insc = [lightbulb(lightbulb(:,2)==1,1),...
            lightbulb(lightbulb(:,2)==1,3)];
```

Step 2. Plot estimated survivor functions.

Plot the estimated survivor functions for the two different types of light bulbs.

```
figure()
[f,x,flow,fup] = ecdf(fluo(:,1),'censoring',fluo(:,2),...
                 'function','survivor');
ax1 = stairs(x,f);
hold on
stairs(x,flow,':')
stairs(x,fup,':')
[f,x,flow,fup] = ecdf(insc(:,1),'censoring',insc(:,2),...
                 'function','survivor');
ax2 = stairs(x,f,'color','r');
stairs(x,flow,':r')
stairs(x,fup,':r')
legend([ax1,ax2],{'Fluorescent','Incandescent'})
xlabel('Lifetime (hours)')
ylabel('Survival probability')
```



You can see that the survival probability of incandescent light bulbs is much smaller than that of fluorescent light bulbs.

Step 3. Fit Burr Type XII distribution.

Fit Burr distribution to the lifetime data of fluorescent and incandescent type bulbs.

```
pd = fitdist(fluo(:,1),'burr','Censoring',fluo(:,2))
```

```
pd =
  BurrDistribution

  Burr distribution
    alpha = 29143.4   [0.903922, 9.39617e+08]
        c = 3.44582   [2.13013, 5.57417]
        k = 33.7039   [8.10737e-14, 1.40114e+16]
```

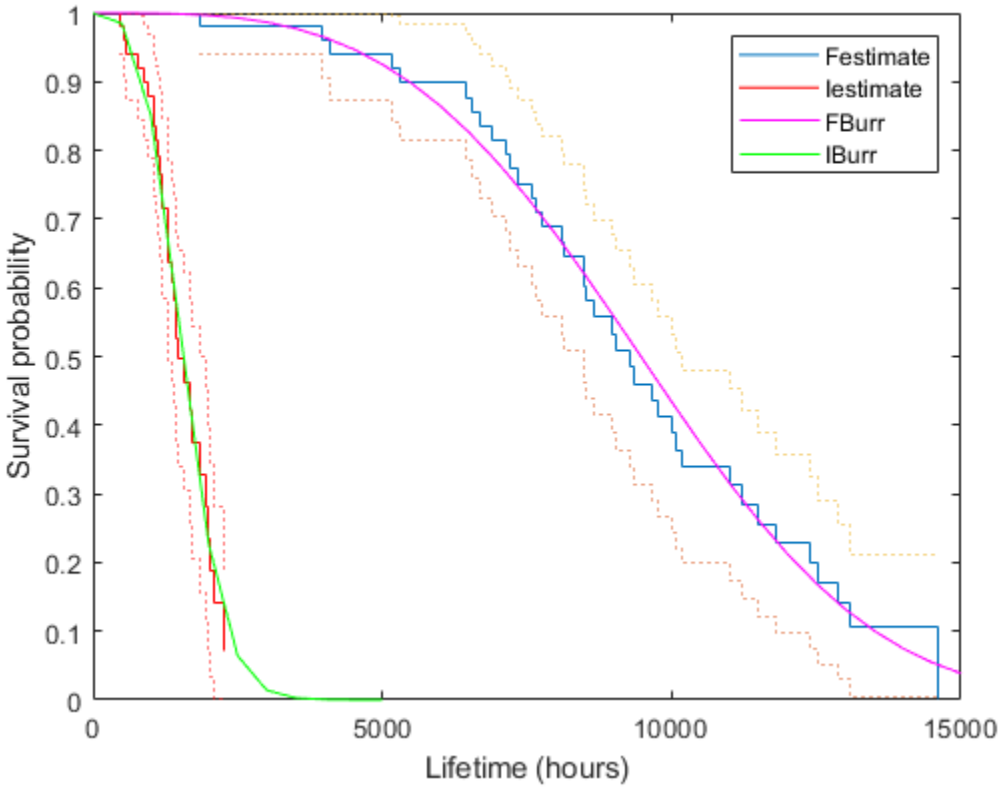
```
pd2 = fitdist(insc(:,1),'burr','Censoring',insc(:,2))
```

```
pd2 =
  BurrDistribution

  Burr distribution
    alpha = 2650.76   [430.773, 16311.4]
        c = 3.41898   [2.16794, 5.39197]
        k =  4.5891   [0.0307809, 684.185]
```

Superimpose Burr type XII survivor functions.

```
ax3 = plot(0:500:15000,1-cdf('burr',0:500:15000,29143.5,...
           3.44582,33.704),'m');
ax4 = plot(0:500:5000,1-cdf('burr',0:500:5000,2650.76,...
           3.41898,4.5891),'g');
legend([ax1;ax2;ax3;ax4],'Festimate','Iestimate','FBurr','IBurr')
```



Burr distribution provides a good fit for the lifetime of light bulbs in this example.

Step 4. Fit a Cox proportional hazards model.

Fit a Cox proportional hazards regression where the type of the bulb is the explanatory variable.

```
[b,logl,H,stats] = coxphfit(lightbulb(:,2),lightbulb(:,1),...
'Censoring',lightbulb(:,3));
stats
```

```
stats = struct with fields:
                 covb: 1.0757
                 beta: 4.7262
                   se: 1.0372
                    z: 4.5568
                    p: 5.1936e-06
               csres: [100x1 double]
              devres: [100x1 double]
             martres: [100x1 double]
              schres: [100x1 double]
```

```
              sschres: [100x1 double]
               scores: [100x1 double]
              sscores: [100x1 double]
    LikelihoodRatioTestP: 0
```

The *p*-value, `p`, indicates that the type of light bulb is statistically significant. The estimate of the hazard ratio is $exp(b) = 112.8646$. This means that the hazard for the incandescent bulbs is 112.86 times the hazard for the fluorescent bulbs.

Cox Proportional Hazards Model

In this section...

Introduction

Cox proportional hazards regression is a semiparametric method for adjusting survival rate estimates to quantify the effect of predictor variables. The method represents the effects of explanatory variables as a multiplier of a common baseline hazard function, $h_0(t)$. The hazard function is the nonparametric part of the Cox proportional hazards regression function, whereas the impact of the predictor variables is a loglinear regression. For a baseline relative to 0, this model corresponds to

$$h(X_i, t) = h_0(t)\exp\left[\sum_{j=1}^{p} x_{ij}b_j\right],$$

where $X_i = (x_{i1}, x_{i2}, \cdots, x_{ip})$ is the predictor variable for the ith subject, $h(X_i,t)$ is the hazard rate at time t for X_i, and $h_0(t)$ is the baseline hazard rate function.

Hazard Ratio

The Cox proportional hazards model relates the hazard rate for individuals or items at the value X_i, to the hazard rate for individuals or items at the baseline value. It produces an estimate for the hazard ratio:

$$HR(X_i) = \frac{h(X_i, t)}{h_0(t)} = \exp\left[\sum_{j=1}^{p} x_{ij}b_j\right].$$

The model is based on the assumption that the baseline hazard function depends on time, t, but the predictor variables do not. This assumption is also called the proportional hazards assumption, which states that the hazard ratio does not change over time for any individual.

The hazard ratio represents the relative risk of instant failure for individuals or items having the predictive variable value X_i compared to the ones having the baseline values. For example, if the predictive variable is smoking status, where nonsmoking is the baseline category, the hazard ratio shows the relative instant failure rate of smokers compared to the baseline category, that is, nonsmokers. For a baseline relative to X^* and the predictor variable value X_i, the hazard ratio is

$$HR(X_i) = \frac{h(X_i, t)}{h(X^*, t)} = \exp\left[\sum_{j=1}^{p} \left(x_{ij} - x_j^*\right)b_j\right].$$

For example, if the baseline is the mean values of the predictor variables (`mean(X)`), then the hazard ratio becomes

$$HR(X_i) = \frac{h(X_i, t)}{h(\bar{X}, t)} = \exp\left[\sum_{j=1}^{p} (x_{ij} - \bar{x}_j) b_j\right].$$

Hazard rates are related to survival rates, such that the survival rate at time t for an individual with the explanatory variable value X_i is

$$S_{X_i}(t) = S_0(t)^{HR(X_i)},$$

where $S_0(t)$ is the survivor function with the baseline hazard rate function $h_0(t)$, and $HR(X_i)$ is the hazard ratio of the predictor variable value X_i relative to the baseline value.

Extension of Cox Proportional Hazards Model

When you have variables that do not satisfy the proportional hazards (PH) assumption, you can consider using two extensions of Cox proportional hazards model: the stratified Cox model and the Cox model with time-dependent variables.

If the variables that do not satisfy the PH assumption are categorizable, use the stratified Cox model:

$$h_s(X_i, t) = h_{0s}(t)\exp\left[\sum_{j=1}^{p} x_{ij} b_j\right],$$

where the subscript s indicates the sth stratum. The stratified Cox model has a different baseline hazard rate function for each stratum but shares coefficients. Therefore, it has the same hazard ratio across all strata if the predictor variable values are the same. You can include stratification variables in `coxphfit` by using the name-value pair `'Strata'`.

If the variables that do not satisfy the PH assumption are time-dependent variables, use the Cox model with time-dependent variables:

$$h(X_i, t) = h_0(t)\exp\left[\sum_{j=1}^{p_1} x_{ij} b_j + \sum_{k=1}^{p_2} x_{ik}(t) c_k\right],$$

where x_{ij} is an element of a time-independent predictor and $x_{ik}(t)$ is an element of a time-dependent predictor. For an example of how to include time-dependent variables in `coxphfit`, see “Cox Proportional Hazards Model with Time-Dependent Covariates” on page 14-35.

Partial Likelihood Function

A point estimate of the effect of each explanatory variable, that is, the estimated hazard ratio for the effect of each explanatory variable is $\exp(b)$, given all other variables are held constant, where b is the coefficient estimate for that variable. The coefficient estimates are found by maximizing the partial likelihood function of the model. The partial likelihood function for the proportional hazards regression model is based on the observed order of events. It is the product of partial likelihoods of failures estimated for each failure time. If there are n failures at n distinct failure times, $t_1 < t_2 < \cdots < t_n$, then the partial likelihood is

$$L = \frac{HR(X_1)}{\sum_{j=1}^{n} HR(X_j)} \times \frac{HR(X_2)}{\sum_{j=2}^{n} HR(X_j)} \times \cdots \times \frac{HR(X_n)}{HR(X_n)} = \prod_{i=1}^{n} \frac{HR(X_i)}{\sum_{j=i}^{n} HR(X_j)}.$$

You can rewrite the partial likelihood by using a risk set R_i:

$$L = \prod_{i=1}^{n} \frac{HR(X_i)}{\sum_{j \in R_i} HR(X_j)},$$

where R_i represents the index set of subjects who are under study but do not experience the event until the ith failure time.

You can use a likelihood ratio test to assess the significance of adding a term or terms in a model. Consider the two models where the first model has p predictive variables and the second model has $p + r$ predictive variables. Then, comparing the two models, $-2*(L_1/L_2)$ has a chi-square distribution with r degrees of freedom (the number of terms being tested).

Partial Likelihood Function for Tied Events

When you have tied events, `coxphfit` approximates the partial likelihood of the model by either Breslow's method (default) or Efron's method, instead of computing the exact partial likelihood. Computing the exact partial likelihood requires a large amount of computation, which involves an entire permutation of the risk sets for the tied event times.

The simplest approximation method is Breslow's method. This method uses the same denominator for each tied set.

$$L = \prod_{i=1}^{d} \prod_{j \in D_i} \frac{HR(X_j)}{\sum_{k \in R_i} HR(X_k)},$$

where d is the number of distinct event times, and D_i is the index set of all subjects whose event time is equal to the ith event time.

Efron's method is more accurate than Breslow's method, yet simple. This method adjusts the denominator of the tied events as follows:

$$L = \prod_{i=1}^{d} \prod_{j \in D_i} \frac{HR(X_j)}{\sum_{k \in R_i} HR(X_k) - \frac{j-1}{d_i} \sum_{k \in D_i} HR(X_k)},$$

where d_i is the number of indexes in D_i.

For an example, assume that the first two events are tied, that is, $t_1 = t_2$ and $t_2 < t_3 < \cdots < t_n$. In Breslow's method, the denominators of the first two terms are the same:

$$L = \frac{HR(X_1)}{\sum_{j=1}^{n} HR(X_j)} \times \frac{HR(X_2)}{\sum_{j=1}^{n} HR(X_j)} \times \frac{HR(X_3)}{\sum_{j=3}^{n} HR(X_j)} \times \frac{HR(X_4)}{\sum_{j=4}^{n} HR(X_j)} \times \cdots \times \frac{HR(X_n)}{HR(X_n)}.$$

Efron's method adjusts the denominator of the second term:

$$L = \frac{HR(X_1)}{\sum_{j=1}^{n} HR(X_j)} \times \frac{HR(X_2)}{0.5HR(X_1) + 0.5HR(X_2) + \sum_{j=3}^{n} HR(X_j)} \times \frac{HR(X_3)}{\sum_{j=3}^{n} HR(X_j)} \times \frac{HR(X_4)}{\sum_{j=4}^{n} HR(X_j)} \times \cdots \times \frac{HR(X_n, t_n)}{HR(X_n, t_n)}.$$

You can specify an approximation method by using the name-value pair `'Ties'` in `coxphfit`.

Frequency or Weights of Observations

The Cox proportional hazards model can incorporate with the frequency or weights of observations. Let w_i be the weight of the ith observation. Then, the partial likelihoods of the Cox model with weights become as follows:

- Partial likelihood with weights

$$L = \prod_{i=1}^{n} \frac{HR_w(X_i)}{\sum_{j \in R_i} w_j HR(X_j)},$$

  where

$$HR_w(X_i) = \exp\left[\sum_{j=1}^{p} w_j x_{ij} b_j\right].$$

- Partial likelihood with weights and Breslow's method

$$L = \prod_{i=1}^{d} \prod_{j \in D_i} \frac{HR_w(X_j)}{\left[\sum_{k \in R_i} w_k HR(X_k)\right]^{\frac{1}{d_i}\sum_{j \in D_i} w_j}}$$

- Partial likelihood with weights and Efron's method

$$L = \prod_{i=1}^{d} \prod_{j \in D_i} \frac{HR_w(X_j)}{\left[\sum_{k \in R_i} w_k HR(X_k) - \frac{j-1}{d_i}\sum_{k \in D_i} w_k HR(X_k)\right]^{\frac{1}{d_i}\sum_{j \in D_i} w_j}}$$

You can specify the frequency or weights of observations by using the name-value pair `'Frequency'` in `coxphfit`.

Cox Proportional Hazards Model for Censored Data

This example shows how to construct a Cox proportional hazards model, and assess the significance of the predictor variables.

Step 1. Load sample data.

Load the sample data.

```
load readmissiontimes
```

The response variable is `ReadmissionTime`, which shows the readmission times for 100 patients. The predictor variables are `Age`, `Sex`, `Weight`, and the smoking status of each patient, `Smoker`. 1 indicates the patient is a smoker, and 0 indicates that the patient does not smoke. The column vector `Censored` has the censorship information for each patient, where 1 indicates censored data, and 0 indicates the exact readmission times are observed. This is simulated data.

Step 2. Fit Cox proportional hazards function.

Fit a Cox proportional hazard function with the variable Sex as the predictor variable, taking the censoring into account.

```
X = Sex;
[b,logl,H,stats] = coxphfit(X,ReadmissionTime,'censoring',Censored);
```

Assess the statistical significance of the term Sex.

```
stats
```

```
stats = struct with fields:
                    covb: 0.1016
                    beta: -1.7642
                      se: 0.3188
                       z: -5.5335
                       p: 3.1392e-08
                   csres: [100x1 double]
                  devres: [100x1 double]
                 martres: [100x1 double]
                  schres: [100x1 double]
                 sschres: [100x1 double]
                  scores: [100x1 double]
                 sscores: [100x1 double]
    LikelihoodRatioTestP: 5.9825e-09
```

The *p*-value, `p`, indicates that the term Sex is statistically significant.

Save the loglikelihood value with a different name. You will use this to assess the significance of the extended models.

```
loglSex = logl
```

```
loglSex = -262.1365
```

Step 3. Add Age and Weight to the model.

Fit a Cox proportional hazards model with the variables Sex, Age, and Weight.

```
X = [Sex Age Weight];
[b,logl,H,stats] = coxphfit(X,ReadmissionTime,'censoring',Censored);
```

Assess the significance of the terms.

```
stats.beta
```

```
ans = 3×1

   -0.5441
    0.0143
    0.0250
```

```
stats.p
```

```
ans = 3×1

    0.4953
    0.3842
    0.0960
```

None of the terms, adjusted for others, is statistically significant.

Assess the significance of the terms using the log likelihood ratio. You can assess the significance of the new model using the likelihood ratio statistic. First find the difference between the log-likelihood statistic of the model without the terms Age and Weight and the log-likelihood of the model with Sex, Age, and Weight.

```
-2*[loglSex - logl]
```

```
ans = 3.6705
```

Now, compute the *p*-value for the likelihood ratio statistic. The likelihood ratio statistic has a Chi-square distribution with a degrees of freedom equal to the number of predictor variables being assessed. In this case, the degrees of freedom is 2.

```
p = 1 - cdf('chi2',3.6705,2)
```

```
p = 0.1596
```

The *p*-value of 0.1596 indicates that the terms Age and Weight are not statistically significant, given the term Sex in the model.

Step 4. Add Smoker to the model.

Fit a Cox proportional hazards model with the variables Sex and Smoker.

```
X = [Sex Smoker];
[b,logl,H,stats] = coxphfit(X,ReadmissionTime,...
'censoring',Censored);
```

Assess the significance of the terms in the model.

```
stats.p
```

```
ans = 2×1
```

```
    0.0000
    0.0148
```

Compare this model to the first model where Sex is the only term.

```
 -2*[loglSex - logl]
```

```
ans = 5.5789
```

Compute the *p*-value for the likelihood ratio statistic. The likelihood ratio statistic has a Chi-square distribution with a degree of freedom of 1.

```
p = 1 - cdf('chi2',5.5789,1)
```

```
p = 0.0182
```

The *p*-value of 0.0182 indicates that Sex and Smoker are statistically significant given the other is in the model. The model with Sex and Smoker is a better fit compared to the model with only Sex.

Request the coefficient estimates.

```
 stats.beta
```

```
ans = 2×1

   -1.7165
    0.6338
```

The default baseline is the mean of X, so the final model for the hazard ratio is

$$HR = \frac{h_X(t)}{h_{\bar{X}}(t)} = \exp\left[\beta_s\left(X_s - \bar{X}_s\right) + \beta_\alpha\left(X_\alpha - \bar{X}_\alpha\right)\right].$$

Fit a Cox proportional hazards model with a baseline of 0.

```
X = [Sex Smoker];
[b,logl,H,stats] = coxphfit(X,ReadmissionTime,...
'censoring',Censored,'baseline',0);
```

The model for the hazard ratio is

$$HR = \frac{h_X(t)}{h_0(t)} = \exp\left[\beta_s X_s + \beta_\alpha X_\alpha\right].$$

Request the coefficient estimates.

```
 stats.beta
```

```
ans = 2×1

   -1.7165
    0.6338
```

The coefficients are not affected, but the hazard rate differs from when the baseline is the mean of X.

Cox Proportional Hazards Model with Time-Dependent Covariates

This example shows how to convert survival data to counting process form and then construct a Cox proportional hazards model with time-dependent covariates.

Step 1. Compare standard layout and counting process form.

A Cox model with time-dependent covariates requires survival data to be in counting process form and not in standard layout. To see the difference between survival data in standard layout and in counting process form, load the following sample data.

```
load simplesurvivaldata
```

This sample data contains two tables: `relapseS` and `relapseCP`. These two tables represent the same simple survival data in standard layout and in counting process form, respectively.

Display the data in standard layout.

```
relapseS
```

```
relapseS=2×5 table
    ID    Time    Censoring    Age    StopTreatment
    __    ____    _________    ___    _____________

    1      5          0        20          NaN
    2     20          1        30           12
```

This data represents two patients whose treatment status changes over time. Patient 1 was not taking treatment for the interval from week 0 to 5 and relapsed at the end of the interval. Patient 2 was taking treatment for the interval from week 0 to 12, but not for the interval from week 12 to 20. Patient 2 did not relapse and left the study after week 20.

Now display the same data in counting process form.

```
relapseCP
```

```
relapseCP=3×6 table
    ID    tStart    tStop    Censoring    Age    TreatmentStatus
    __    ______    _____    _________    ___    _______________

    1       0         5          0        20            0
    2       0        12          1        30            1
    2      12        20          1        30            0
```

In counting process form, each row represents the risk interval `(tStart,tStop]` instead of a single value of an event time. `Censoring` is 0 if the event is observed at the end of the risk interval, and 1 if it is not. `TreatmentStatus` corresponds to a time-dependent covariate, which represents the same information with `StopTreatment` in standard layout. Note that a Cox model assumes time-dependent covariates to be constant in each risk interval.

Step 2. Load sample data.

Next, load sample data to convert.

```
load survivaldatacp
```

This sample data contains a table `labS`, which is simulated survival data including repeated measurement for each patient in standard layout.

Display the simulated survival data in standard layout.

```
labS
```

```
labS=6×7 table
    ID    Time    Censoring    Sex    Lab_0    Lab_50    Lab_100
    __    ____    _________    ___    _____    ______    _______

    1      46         0         1      0.3       NaN       NaN
    2     138         1         0      0.2      0.23      0.39
    3      94         0         1     0.18      0.22       NaN
    4      50         0         0     0.21       0.2       NaN
    5     106         0         0     0.25      0.21      0.42
    6      98         0         0     0.21      0.22       NaN
```

In standard layout, each row of the table shows information for one patient.

- `ID` indicates the ID of a patient. You do not include `ID` as an input of a Cox model. Include `ID` in a data set to confirm that the data set is correctly converted to counting process form.
- `Time` represents time to event in days, which corresponds to a response variable.
- `Censoring` has the censorship information for each patient, where 1 indicates censored data and 0 indicates that the exact time to event is observed at the end of the observation period.
- `Sex` is a time-independent predictor where 1 indicates female, and 0 indicates male.
- `Lab_0`, `Lab_50`, and `Lab_100` represent three consecutive laboratory results measured at day 0, 50, and 100, which correspond to a time-dependent predictor.

Step 3. Convert survival data to counting process form.

To convert the survival data `labS` to counting process form, execute the code below. This code converts `Time` to a risk interval `(tStart,tStop]` and combines three vectors of the time-dependent predictor, `Lab_0`, `Lab_50`, and `Lab_100`, into one vector, `Lab`.

```
mTime = [0 50 100]; % Measurement time
threeLabs = [labS.Lab_0 labS.Lab_50 labS.Lab_100];
nLabMeasure = sum(sum(~isnan(threeLabs))); % Number of lab measurements
data = zeros(nLabMeasure,6); % One row for each observation
oID = 0; % Observation ID
for i = 1 : size(labS,1)
    idx = find(mTime <= labS.Time(i));
    for j = 1 : length(idx)-1
        oID = oID + 1;
        data(oID,:) = [labS.ID(i) mTime(j:j+1) 1 labS.Sex(i) threeLabs(i,j)];
    end
    oID = oID + 1;
    data(oID,:) = [labS.ID(i) mTime(length(idx)) labS.Time(i) ...
            labS.Censoring(i) labS.Sex(i) threeLabs(i,length(idx))];
end
labCP = table(data(:,1),data(:,2),data(:,3),data(:,4),data(:,5),data(:,6), ...
    'VariableNames', {'ID','tStart','tStop','Censoring','Sex','Lab'});
```

Display the survival data in counting process form.

```
labCP
```

```
labCP=13×6 table
    ID    tStart    tStop    Censoring    Sex    Lab
    __    ______    _____    _________    ___    ____

    1        0        46          0         1      0.3
    2        0        50          1         0      0.2
    2       50       100          1         0     0.23
    2      100       138          1         0     0.39
    3        0        50          1         1     0.18
    3       50        94          0         1     0.22
    4        0        50          1         0     0.21
    4       50        50          0         0      0.2
    5        0        50          1         0     0.25
    5       50       100          1         0     0.21
    5      100       106          0         0     0.42
    6        0        50          1         0     0.21
    6       50        98          0         0     0.22
```

In counting process form, each row of table `labCP` shows information of one observation corresponding to one risk interval. Note that a Cox model assumes `Lab` to be constant in the risk interval `(tStart,tStop]`. The value in `Censoring` is 0 if an event is observed at the end of the risk interval, and 1 if an event is not observed.

For example, patient 3 has two laboratory measurements at day 0 and 50, so there are two rows of data for patient 3 in counting process form. A Cox model assumes the lab results 0.18 and 0.22 to be constant in the interval (0,50] and (50,94], respectively. `Censoring` is 1 in (0,50] and 0 in (50,94] because the exact event time of patient 3 is observed at day 94.

Step 4. Adjust zero-length risk interval.

Find a patient who has a zero-length risk interval.

```
idxInvalid = labCP.ID(find(labCP.tStart == labCP.tStop))
```

```
idxInvalid = 4
```

Review the data for patient 4.

```
labCP(find(labCP.ID==idxInvalid),:)
```

```
ans=2×6 table
    ID    tStart    tStop    Censoring    Sex    Lab
    __    ______    _____    _________    ___    ____

    4        0        50          1         0     0.21
    4       50        50          0         0      0.2
```

The time to event of patient 4 coincides with the measurement day 50. However, (50,50] is an invalid risk interval for a Cox model because the model does not accept a zero length interval. Adjust the risk interval to be valid. You can choose any value less than the time unit as an adjustment amount. The choice of an adjustment amount is arbitrary, and it does not change the result.

```
idxAdjust = find(labCP.ID==idxInvalid);
labCP.tStop(idxAdjust(1)) = labCP.tStop(idxAdjust(1))-0.5;
labCP.tStart(idxAdjust(2)) = labCP.tStart(idxAdjust(2))-0.5;
labCP(idxAdjust,:)
```

```
ans=2×6 table
    ID    tStart    tStop    Censoring    Sex    Lab
    __    ______    _____    _________    ___    ____

    4          0     49.5          1         0     0.21
    4       49.5       50          0         0      0.2
```

Step 5. Construct a Cox proportional hazards model.

Fit a Cox proportional hazards model with the time-independent variable `Sex` and time-dependent variable `Lab`.

```
X = [labCP.Sex labCP.Lab];
T = [labCP.tStart labCP.tStop];
b = coxphfit(X,T,'Censoring',labCP.Censoring,'Baseline',0)
```

```
b = 2×1

    2.0054
   29.7530
```

For details on how to assess a Cox proportional hazards model, see “Cox Proportional Hazards Model for Censored Data” on page 14-31.

Cox Proportional Hazards Model Object

This example shows how to fit and analyze a Cox proportional hazards model using a `CoxModel` object. Cox proportional hazards models relate to lifetime or failure time data. For background, see “What Is Survival Analysis?” on page 14-2 and “Cox Proportional Hazards Model” on page 14-26.

Generate the data for three lifetime models with the following types of hazard rates. These models correspond to three stratification levels; see “Extension of Cox Proportional Hazards Model” on page 14-27.

- Bathtub, whose failure rate is high at the beginning, decreases to a low level, then climbs toward a constant level
- Logarithmically increasing: log(x)/10
- Constant 1/4

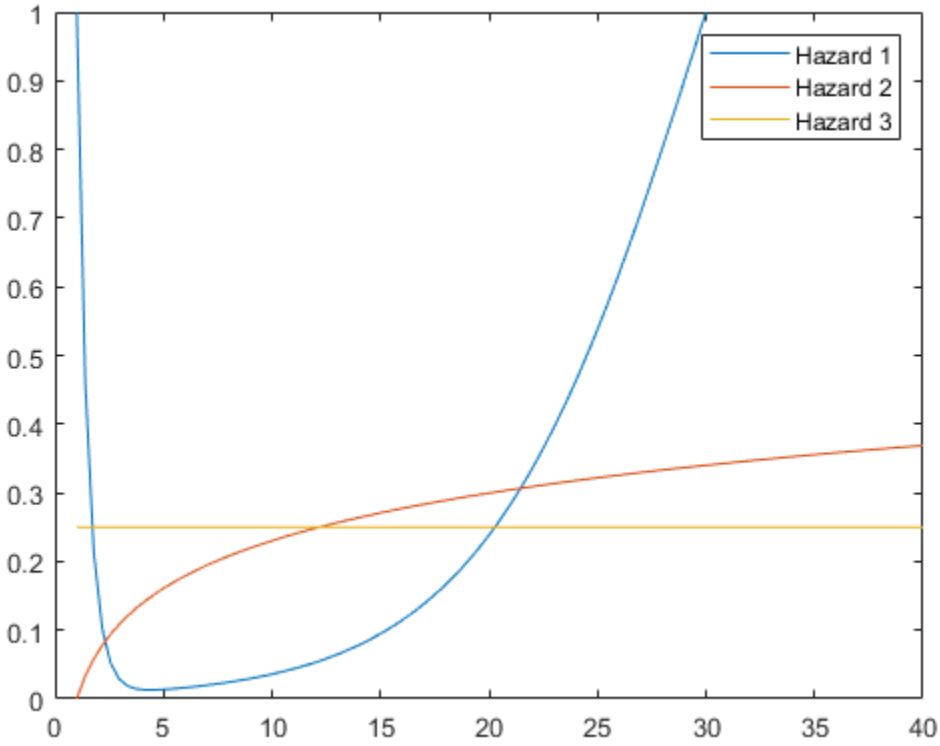
The three models share a predictor with three multipliers for the base hazard rates:

- `1`
- `1/20`
- `1/100`

In total, the data has nine types of population members, one from each stratification level and one from each predictor level. The functions for creating the bathtub and logarithmic hazard rates are in the Helper Functions on page 14-0 section at the end of this example.

Plot the three hazard rates when the predictor value is `1`.

```
t = linspace(1,40);
plot(t,hazard(t),t,log(t)/10,t,1/4*ones(size(t)))
legend('Hazard 1','Hazard 2','Hazard 3','Location','northeast')
ylim([0 1])
```



Create Data for Fitting

Create pseudorandom data for the lifetimes associated with the nine models. Create 9000 samples chosen randomly (about 1000 of each type) by inverting the cumulative distributions. (For details, see Inverse transform sampling).

```
N = 9000;
rng default
mults = [1;1/20;1/100]; % Three predictors
strata = randi(3,N,1); % Three strata
t1 = zeros(N,1);
a0 = randi(3,N,1); % Predictor
a1 = mults(a0);
v1 = rand(N,1);
for i = 1:N
    switch strata(i)
        case 1 % Bathtub
            t1(i) = zeropt(a1(i),v1(i));
        case 2 % Logarithmic
            t1(i) = zeroptold(a1(i),v1(i));
        case 3 % Constant
            t1(i) = 1 + exprnd(4/a1(i));
    end
end
```

Place data into a table.

```
a3 = categorical(a1);
tbldata = table(t1,a3,strata,'VariableNames',["Lifetime" "Predictors" "Strata"]);
```

Fit Cox Model

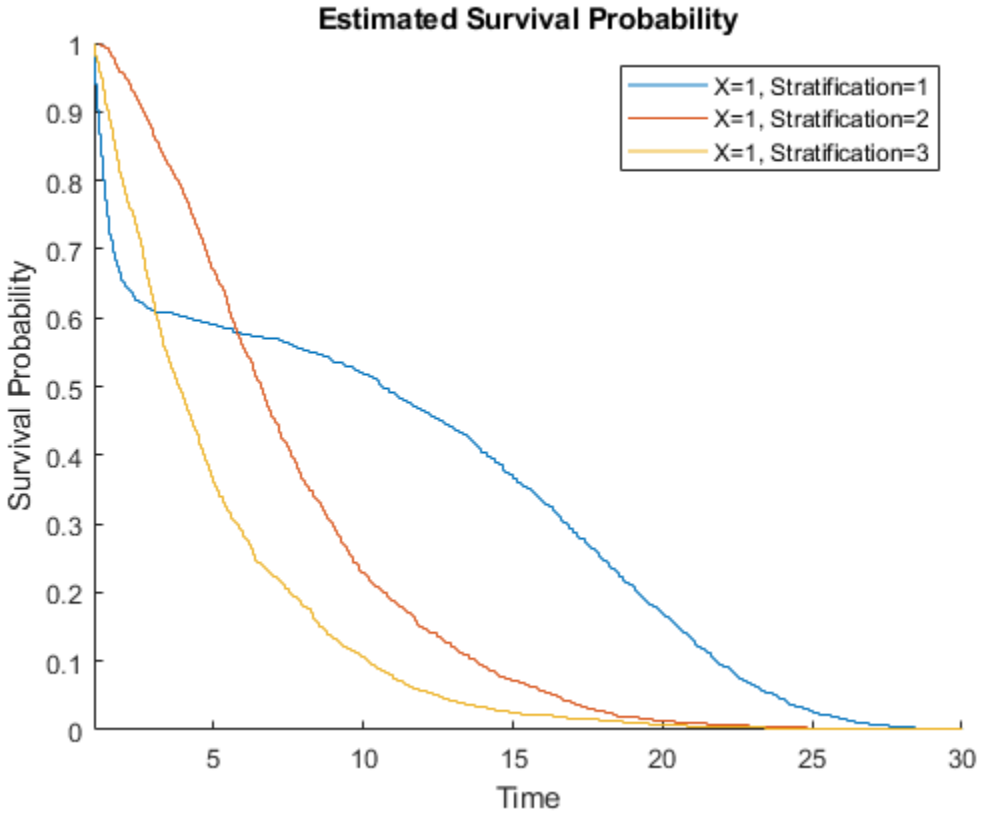
Fit a Cox proportional hazards model to the table data.

```
coxMdl = fitcox(tbldata,'Lifetime ~ Predictors',"Stratification",'Strata');
```

Plot Survival

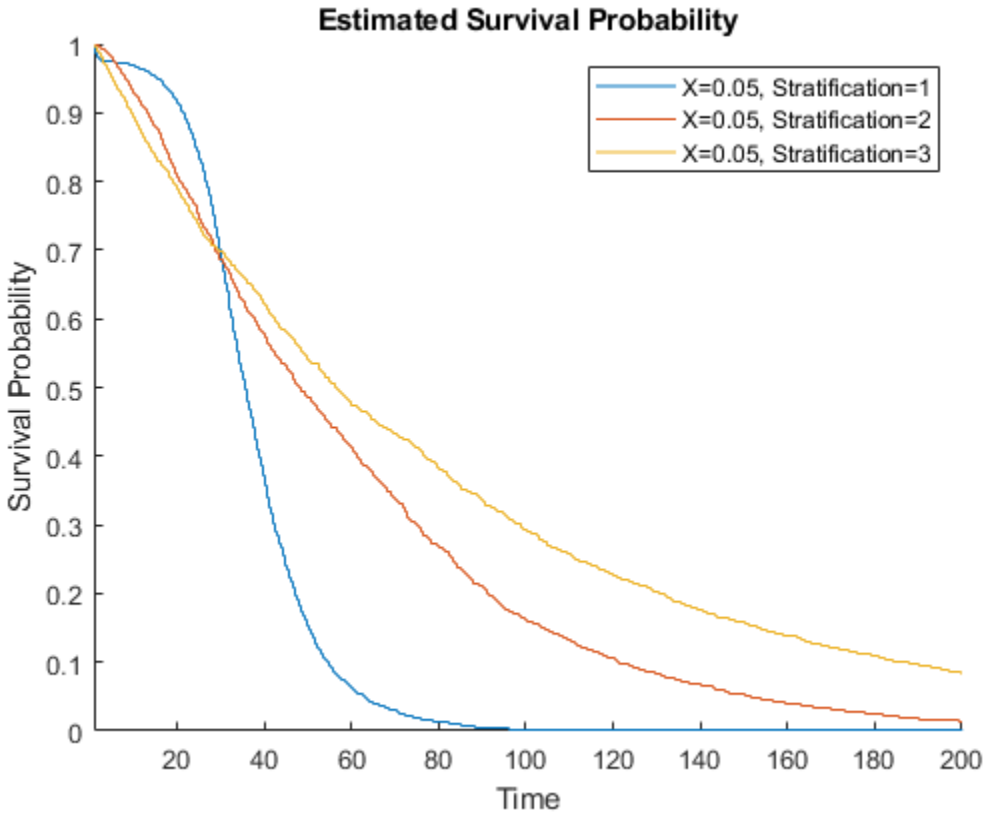
Plot the probability of survival as a function of time for predictor value `1` and the three stratification levels.

```
oo = categorical(1);
plotSurvival(coxMdl,[oo;oo;oo],[1;2;3])
xlim([1,30])
```



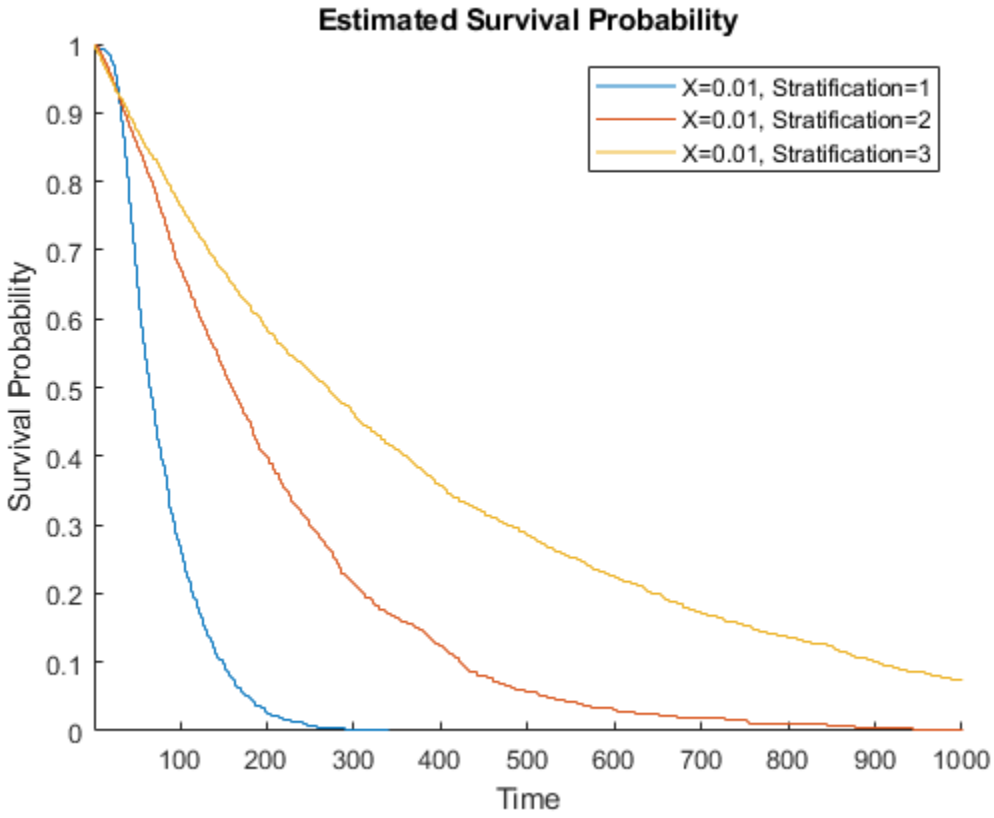
Plot the probability of survival as a function of time for predictor value `1/20` and the three stratification levels.

```
tt = categorical(1/20);
figure
plotSurvival(coxMdl,[tt;tt;tt],[1;2;3])
xlim([1,200])
```



Plot the probability of survival as a function of time for predictor value `1/100` and the three stratification levels.

```
uu = categorical(1/100);
figure
plotSurvival(coxMdl,[uu;uu;uu],[1;2;3])
xlim([1,1000])
```



Even though the hazard rates are proportional for the different predictors, the three survival plots are not proportional.

Analyze Fit

Examine the coefficients of the fitted model.

```
disp(coxMdl.Coefficients)
```

```
                      Beta        SE       zStat     pValue
                    ______    ________    ______    ______

    Predictors_0.05    1.5301    0.031783    48.143      0
    Predictors_1       4.5593    0.052149    87.427      0
```

Notice that the `pValue` entries are `0`, which means that the listed predictor `Beta` values are not zero.

View the confidence intervals for the model coefficients at the 0.01 level of significance.

```
coefci(coxMdl,0.01)
```

```
ans = 2×2

    1.4483    1.6120
    4.4249    4.6936
```

To infer the hazard for the 0.01 level predictor, recall the definition of the Cox model:

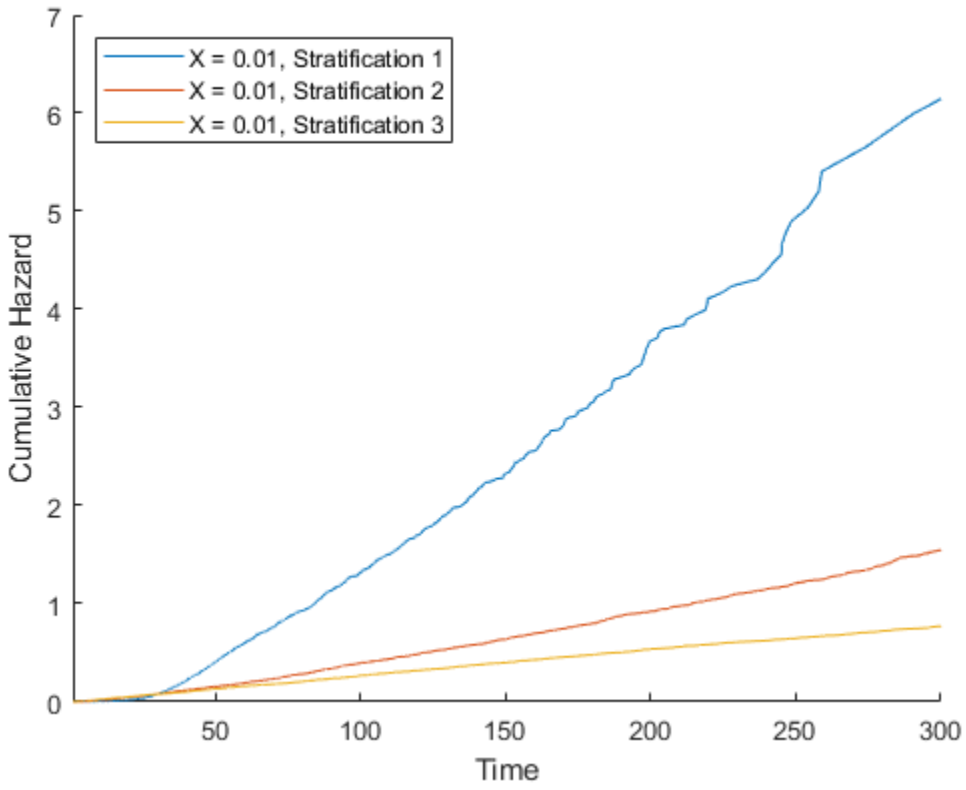
$h(X_i, t) = h_0(t)\exp\left(\sum\ x_{ij}b_j\right)$.

The `fitcox` function uses dummy variables with a reference group to handle categorical data. In this case, the function treats the 0.01 level predictor as the reference group, and encodes the predictor as all 0s when fitting the model. If you enter all 0s into the hazard function, you get

$$h([0,0],t) = h_0(t)\exp(0*b1 + 0*b2) = h_0(t)\exp(0) = h_0(t)\,.$$

$h_0(t)$ is the baseline hazard, which is stored in `coxMdl.Hazard`. Therefore, to get the hazard for the 0.01 level predictor, you can examine `coxMdl.Hazard`. Plot the baseline cumulative hazard for the three stratification levels.

```
figure
hold on
for i = 1:3
    pred3 = find(coxMdl.Hazard(:,3) == i); % Find indices of stratification i
    plot(coxMdl.Hazard(pred3,1),coxMdl.Hazard(pred3,2))
end
xlabel('Time')
ylabel('Cumulative Hazard')
xlim([1 300])
legend('X = 0.01, Stratification 1',...
    'X = 0.01, Stratification 2',...
    'X = 0.01, Stratification 3','Location','northwest')
hold off
```



The cumulative hazard for the other predictor values is exp(Beta) times the baseline cumulative hazard, where Beta is the inferred coefficient.

```
disp(exp(coxMdl.Coefficients.Beta))
```

```
    4.6188
   95.5127
```

These relative hazard values are close to the theoretical values for the data, which was generated with multipliers 1, 1/20, and 1/100. The baseline value corresponds to the 1/100 multiplier, so the theoretical multipliers are 5 and 100.

View the `linhyptest` table.

```
linhyptest(coxMdl)
```

```
ans=2×2 table
         Predictor          pValue
    ____________________    ______

    {'Empty Model'    }       0
    {'Predictors_0.05'}       0
```

Again, the model requires the `1/20` value predictor and the 1 value predictor.

Check whether the data supports the hypothesis that the data is from a Cox proportional hazards model.

```
supports = coxMdl.ProportionalHazardsPValueGlobal
```

```
supports = 0.9730
```

The null hypothesis for this test is that the data is from a Cox proportional hazards model. To reject this hypothesis, `supports` must be less than 0.05 or some other small significance level. The statistic indicates support for the hypothesis that the data is consistent with a Cox model.

Examine Hazard Ratios

Calculate the hazard ratio for the predictor values `1`, `1/20`, and `1/100` compared to a baseline of `0` for the three stratification levels.

```
hazards = hazardratio(coxMdl,...
    categorical([1;1;1;1/20;1/20;1/20;1/100;1/100;1/100]),...
    [1;2;3;1;2;3;1;2;3],'Baseline',0)
```

```
hazards = 9×1

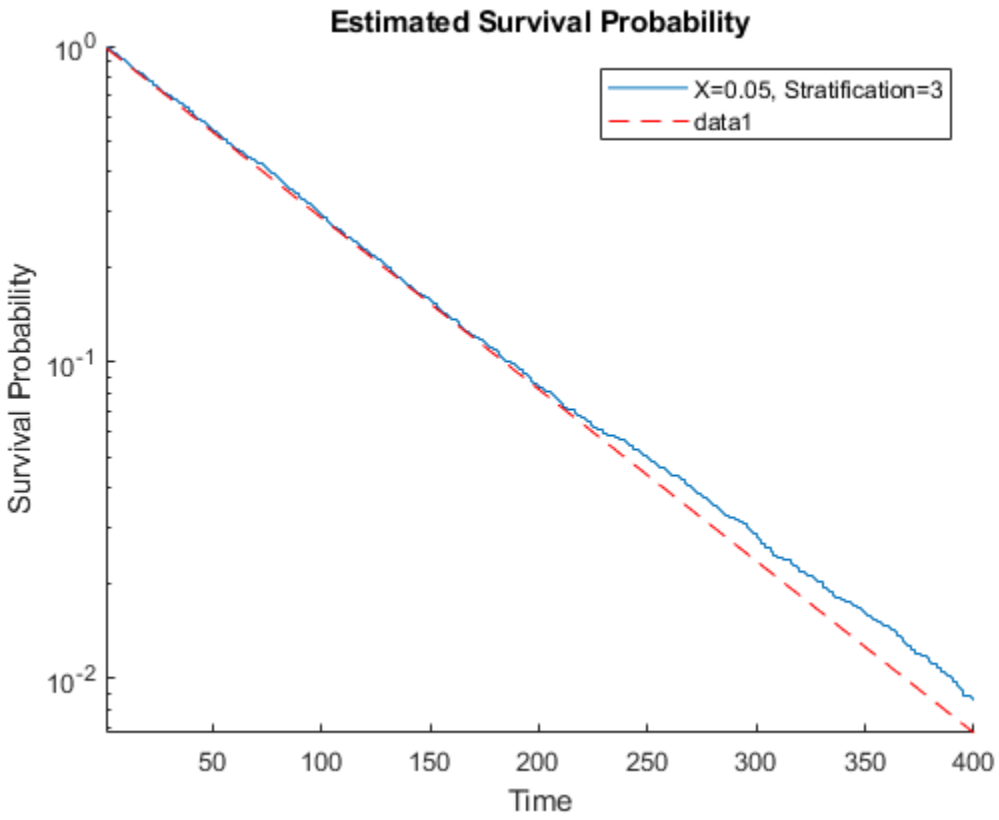
   95.5127
   95.5127
   95.5127
    4.6188
    4.6188
    4.6188
    1.0000
    1.0000
    1.0000
```

The hazard ratios are near their theoretical values of 100, 5, and 1, as explained in the previous section. The hazard ratios do not depend on the stratification level.

How Well Does the Constant Hazard Stratification Level Match Theory?

Stratification level 3 has a constant hazard rate of 1/4. Theoretically, a constant hazard rate means an exponential survival function, whose logarithm is a straight line. Plot the survival of level 3 stratification using the predictor value `1/20`, which leads to an exponential rate of 1/80.

```
tt = categorical(1/20);
h = figure;
axes1 = axes('Parent',h);
plotSurvival(coxMdl,axes1,tt,3);
xlim([1 400]);
axes1.YScale = 'log';
hold on
tms = linspace(1,400);
semilogy(tms,exp(-tms/80),'r--')
hold off
```



The data matches the theoretical line for probabilities well above 1/100.

Helper Functions

This function creates the bathtub hazard rate.

```
function h = hazard(x)
h = exp(-2*(x - 1)) + (1 + tanh(x/10 - 3));
end
```

This function creates the integral of the bathtub hazard rate from `1` to `x`.

```
function eh = exphazard(x)
eh = 1/2 - exp(-2*(x-1))/2;
eh2 = (10*log(cosh(x/10 - 3)) - 10*log(cosh(1/10 - 3)) + x - 1);
eh = eh + eh2;
end
```

This function solves for the root of the cumulative hazard rate with multiplier `a` to level `v`.

```
function zz = zeropt(a,v)
zz = fzero(@(x)(1 - exp(-a*exphazard(x)) - v),[1 100*max(1,1/a)]);
end
```

This function creates the integral of the logarithmic hazard rate with multiplier `1/10` from `1` to `x`.

```
function cr = cumrisk(x)
cr = 1/10*(x.*(log(x) - 1) + 1);
end
```

This function solves for the root of the cumulative hazard rate with multiplier `a` to level `v`.

```
function zz = zeroptold(a,v)
zz = fzero(@(x)(1 - exp(-a*cumrisk(x)) - v),[1 50*max(1,1/a)]);
end
```

Related Examples

- “Analysis of Lifetime Data”

Analyzing Survival or Reliability Data

This example shows how to analyze lifetime data with censoring. In biological or medical applications, this is known as survival analysis, and the times may represent the survival time of an organism or the time until a disease is cured. In engineering applications, this is known as reliability analysis, and the times may represent the time to failure of a piece of equipment.

Our example models the time to failure of a throttle from an automobile fuel injection system.

Special Properties of Lifetime Data

Some features of lifetime data distinguish them other types of data. First, the lifetimes are always positive values, usually representing time. Second, some lifetimes may not be observed exactly, so that they are known only to be larger than some value. Third, the distributions and analysis techniques that are commonly used are fairly specific to lifetime data

Let's simulate the results of testing 100 throttles until failure. We'll generate data that might be observed if most throttles had a fairly long lifetime, but a small percentage tended to fail very early.

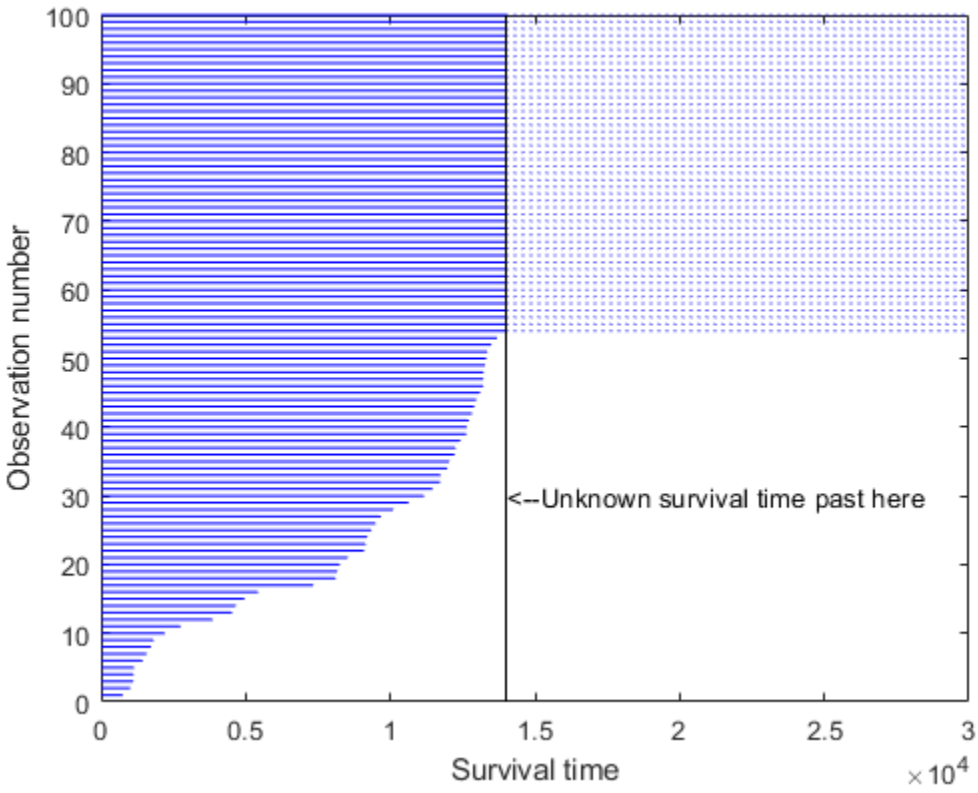
```
rng(2,'twister');
lifetime = [wblrnd(15000,3,90,1); wblrnd(1500,3,10,1)];
```

In this example, assume that we are testing the throttles under stressful conditions, so that each hour of testing is equivalent to 100 hours of actual use in the field. For pragmatic reasons, it's often the case that reliability tests are stopped after a fixed amount of time. For this example, we will use 140 hours, equivalent to a total of 14,000 hours of real service. Some items fail during the test, while others survive the entire 140 hours. In a real test, the times for the latter would be recorded as 14,000, and we mimic this in the simulated data. It is also common practice to sort the failure times.

```
T = 14000;
obstime = sort(min(T, lifetime));
```

We know that any throttles that survive the test will fail eventually, but the test is not long enough to observe their actual time to failure. Their lifetimes are only known to be greater than 14,000 hours. These values are said to be censored. This plot shows that about 40% of our data are censored at 14,000.

```
failed = obstime(obstime<T); nfailed = length(failed);
survived = obstime(obstime==T); nsurvived = length(survived);
censored = (obstime >= T);
plot([zeros(size(obstime)),obstime]', repmat(1:length(obstime),2,1), ...
     'Color','b','LineStyle','-')
line([T;3e4], repmat(nfailed+(1:nsurvived), 2, 1), 'Color','b','LineStyle',':');
line([T;T], [0;nfailed+nsurvived],'Color','k','LineStyle','-')
text(T,30,'<--Unknown survival time past here')
xlabel('Survival time'); ylabel('Observation number')
```



Ways of Looking at Distributions

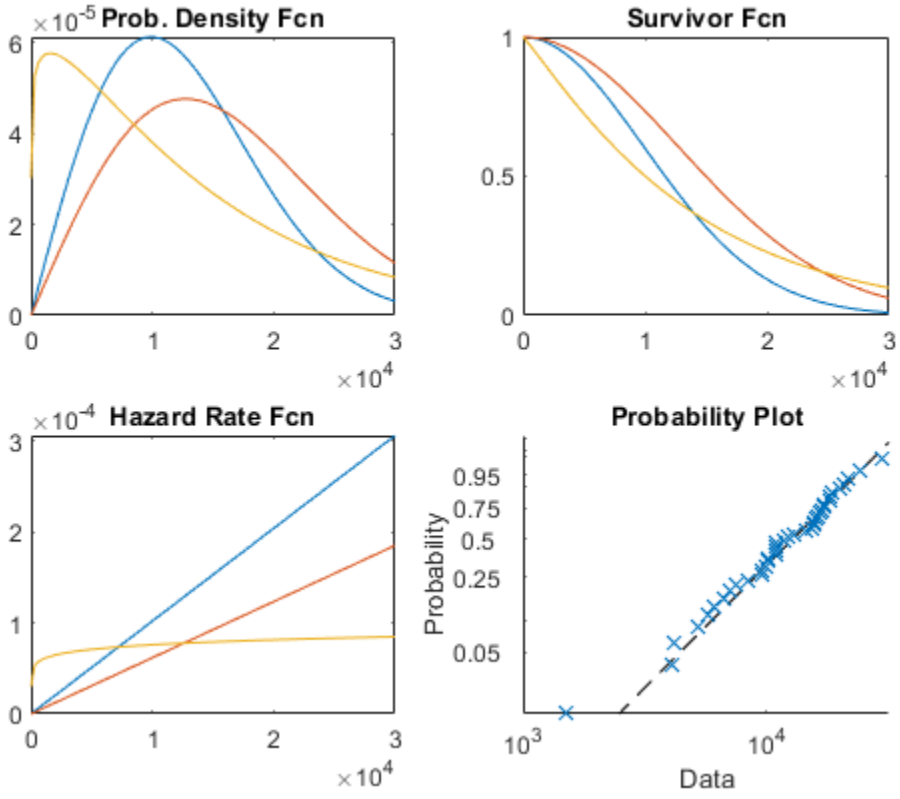
Before we examine the distribution of the data, let's consider different ways of looking at a probability distribution.

- A probability density function (PDF) indicates the relative probability of failure at different times.
- A survivor function gives the probability of survival as a function of time, and is simply one minus the cumulative distribution function (1-CDF).
- The hazard rate gives the instantaneous probability of failure given survival to a given time. It is the PDF divided by the survivor function. In this example the hazard rates turn out to be increasing, meaning the items are more susceptible to failure as time passes (aging).
- A probability plot is a re-scaled CDF, and is used to compare data to a fitted distribution.

Here are examples of those four plot types, using the Weibull distribution to illustrate. The Weibull is a common distribution for modeling lifetime data.

```
x = linspace(1,30000);
subplot(2,2,1);
plot(x,wblpdf(x,14000,2),x,wblpdf(x,18000,2),x,wblpdf(x,14000,1.1))
title('Prob. Density Fcn')
subplot(2,2,2);
plot(x,1-wblcdf(x,14000,2),x,1-wblcdf(x,18000,2),x,1-wblcdf(x,14000,1.1))
title('Survivor Fcn')
subplot(2,2,3);
wblhaz = @(x,a,b) (wblpdf(x,a,b) ./ (1-wblcdf(x,a,b)));
plot(x,wblhaz(x,14000,2),x,wblhaz(x,18000,2),x,wblhaz(x,14000,1.1))
```

```
title('Hazard Rate Fcn')
subplot(2,2,4);
probplot('weibull',wblrnd(14000,2,40,1))
title('Probability Plot')
```



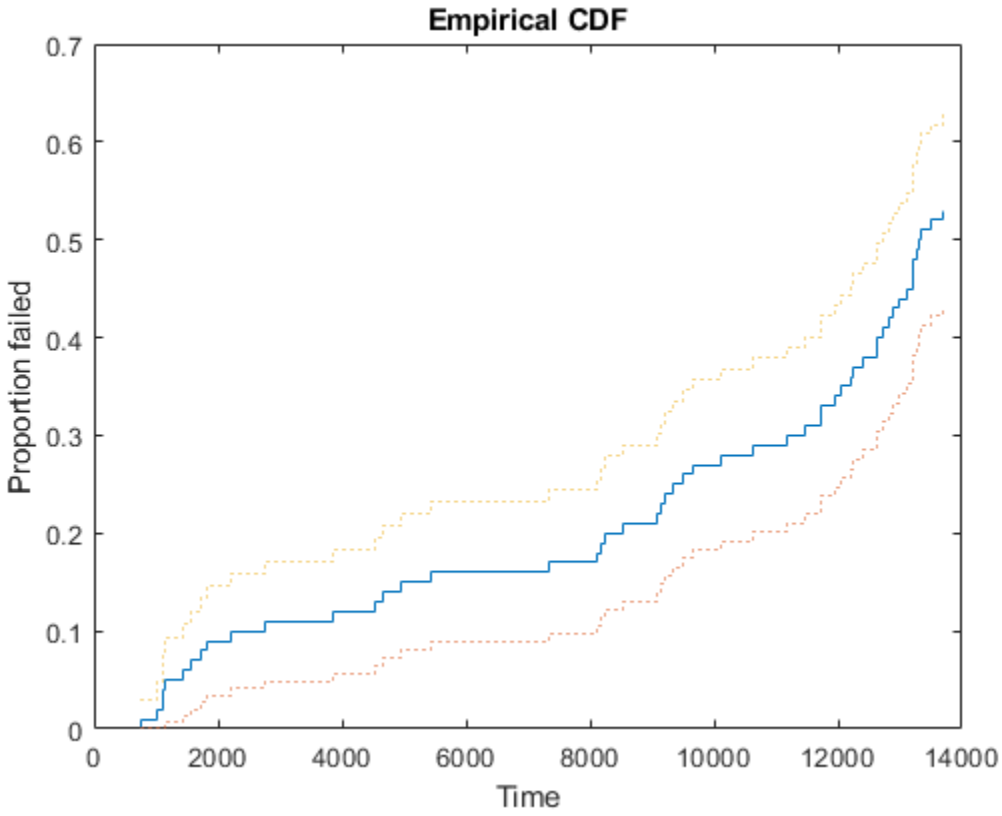
Fitting a Weibull Distribution

The Weibull distribution is a generalization of the exponential distribution. If lifetimes follow an exponential distribution, then they have a constant hazard rate. This means that they do not age, in the sense that the probability of observing a failure in an interval, given survival to the start of that interval, doesn't depend on where the interval starts. A Weibull distribution has a hazard rate that may increase or decrease.

Other distributions used for modeling lifetime data include the lognormal, gamma, and Birnbaum-Saunders distributions.

We will plot the empirical cumulative distribution function of our data, showing the proportion failing up to each possible survival time. The dotted curves give 95% confidence intervals for these probabilities.

```
subplot(1,1,1);
[empF,x,empFlo,empFup] = ecdf(obstime,'censoring',censored);
stairs(x,empF);
hold on;
stairs(x,empFlo,':'); stairs(x,empFup,':');
hold off
xlabel('Time'); ylabel('Proportion failed'); title('Empirical CDF')
```



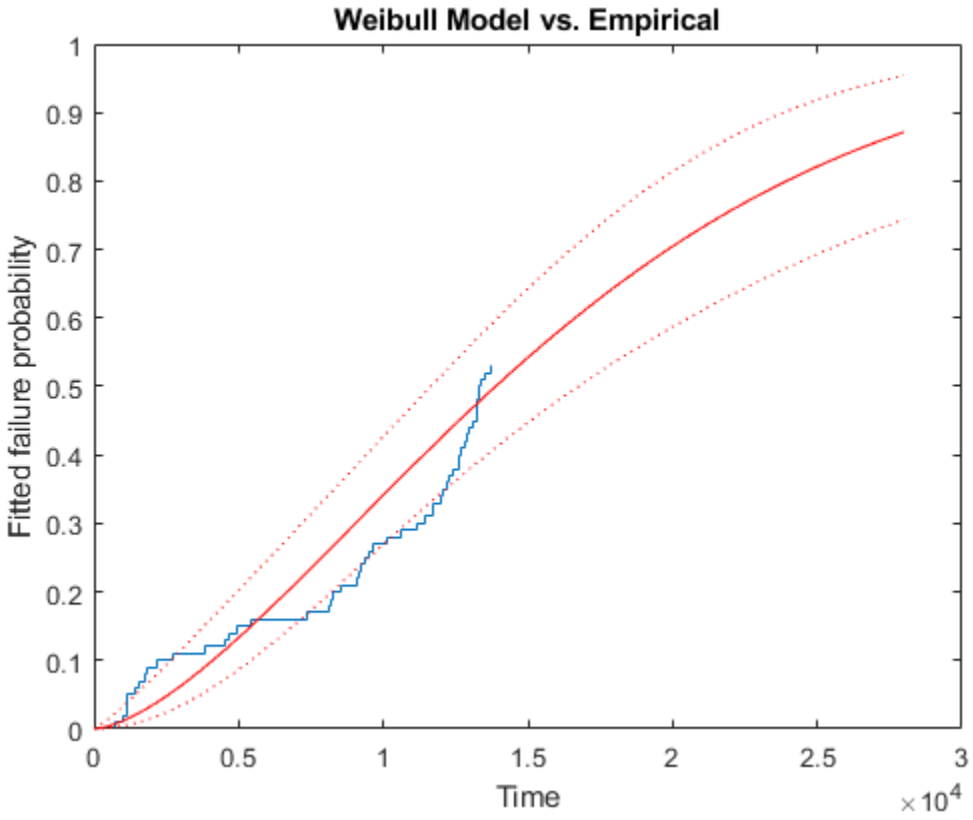
This plot shows, for instance, that the proportion failing by time 4,000 is about 12%, and a 95% confidence bound for the probability of failure by this time is from 6% to 18%. Notice that because our test only ran 14,000 hours, the empirical CDF only allows us to compute failure probabilities out to that limit. Almost half of the data were censored at 14,000, and so the empirical CDF only rises to about 0.53, instead of 1.0.

The Weibull distribution is often a good model for equipment failure. The function `wblfit` fits the Weibull distribution to data, including data with censoring. After computing parameter estimates, we'll evaluate the CDF for the fitted Weibull model, using those estimates. Because the CDF values are based on estimated parameters, we'll compute confidence bounds for them.

```
paramEsts = wblfit(obstime,'censoring',censored);
[nlogl,paramCov] = wbllike(paramEsts,obstime,censored);
xx = linspace(1,2*T,500);
[wblF,wblFlo,wblFup] = wblcdf(xx,paramEsts(1),paramEsts(2),paramCov);
```

We can superimpose plots of the empirical CDF and the fitted CDF, to judge how well the Weibull distribution models the throttle reliability data.

```
stairs(x,empF);
hold on
handles = plot(xx,wblF,'r-',xx,wblFlo,'r:',xx,wblFup,'r:');
hold off
xlabel('Time'); ylabel('Fitted failure probability'); title('Weibull Model vs. Empirical')
```

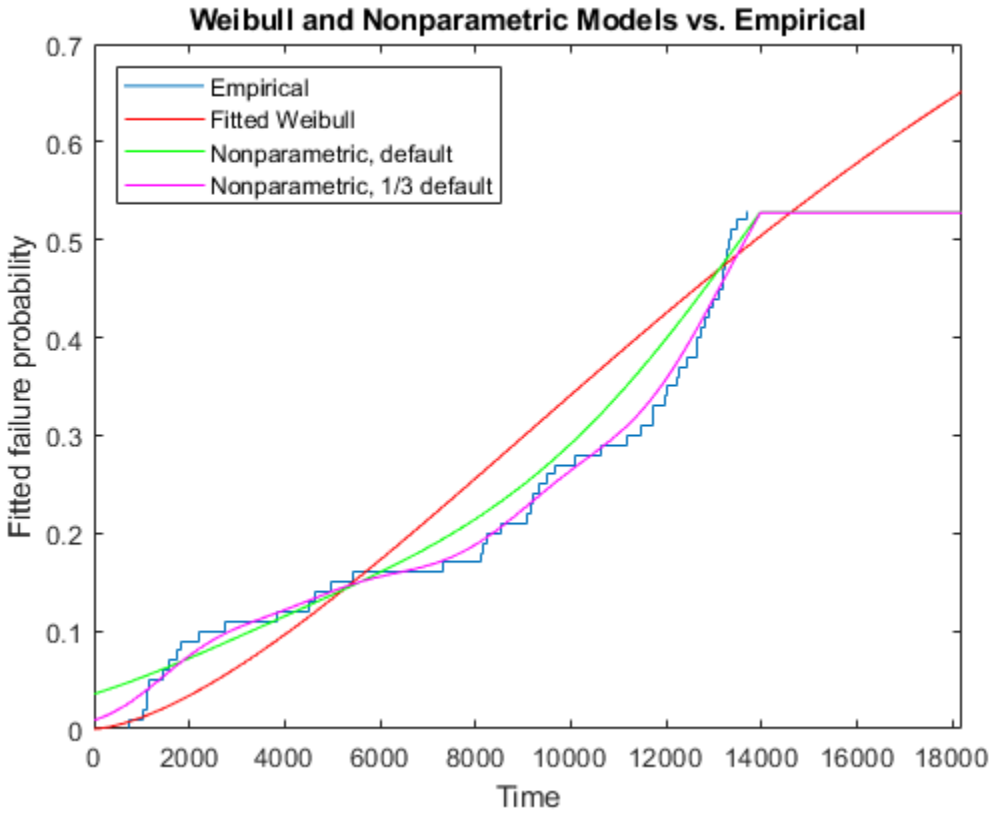


Notice that the Weibull model allows us to project out and compute failure probabilities for times beyond the end of the test. However, it appears the fitted curve does not match our data well. We have too many early failures before time 2,000 compared with what the Weibull model would predict, and as a result, too few for times between about 7,000 and about 13,000. This is not surprising -- recall that we generated data with just this sort of behavior.

Adding a Smooth Nonparametric Estimate

The pre-defined functions provided with the Statistics and Machine Learning Toolbox™ don't include any distributions that have an excess of early failures like this. Instead, we might want to draw a smooth, nonparametric curve through the empirical CDF, using the function `ksdensity`. We'll remove the confidence bands for the Weibull CDF, and add two curves, one with the default smoothing parameter, and one with a smoothing parameter 1/3 the default value. The smaller smoothing parameter makes the curve follow the data more closely.

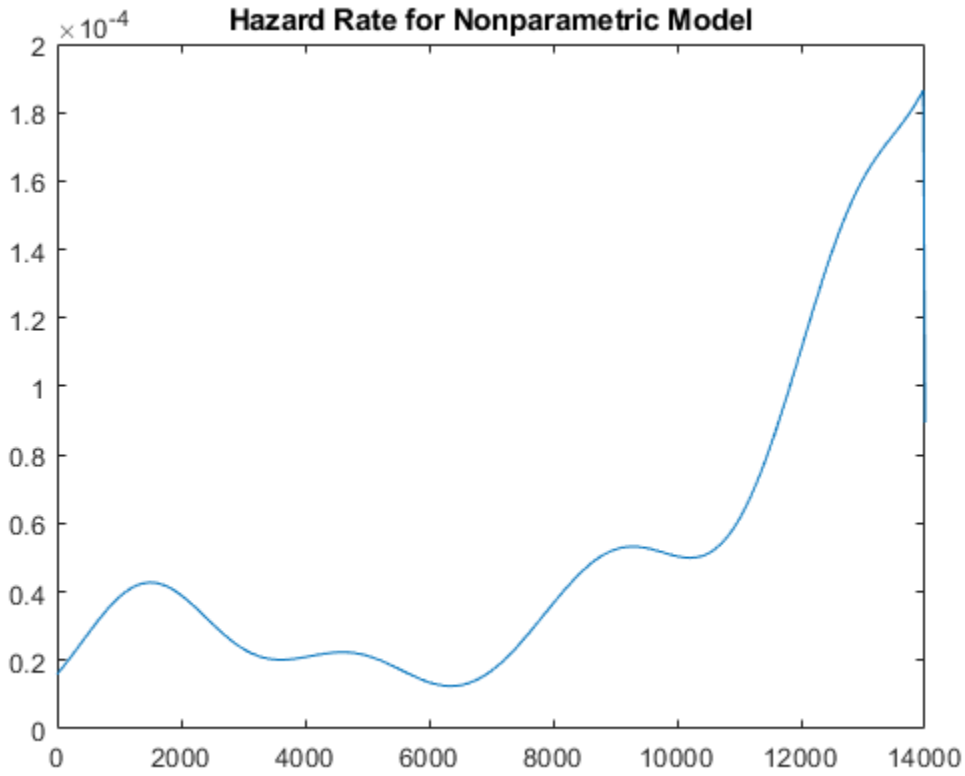
```
delete(handles(2:end))
[npF,ignore,u] = ksdensity(obstime,xx,'cens',censored,'function','cdf');
line(xx,npF,'Color','g');
npF3 = ksdensity(obstime,xx,'cens',censored,'function','cdf','width',u/3);
line(xx,npF3,'Color','m');
xlim([0 1.3*T])
title('Weibull and Nonparametric Models vs. Empirical')
legend('Empirical','Fitted Weibull','Nonparametric, default','Nonparametric, 1/3 default', ...
       'location','northwest');
```



The nonparametric estimate with the smaller smoothing parameter matches the data well. However, just as for the empirical CDF, it is not possible to extrapolate the nonparametric model beyond the end of the test -- the estimated CDF levels off above the last observation.

Let's compute the hazard rate for this nonparametric fit and plot it over the range of the data.

```
hazrate = ksdensity(obstime,xx,'cens',censored,'width',u/3) ./ (1-npF3);
plot(xx,hazrate)
title('Hazard Rate for Nonparametric Model')
xlim([0 T])
```



This curve has a bit of a "bathtub" shape, with a hazard rate that is high near 2,000, drops to lower values, then rises again. This is typical of the hazard rate for a component that is more susceptible to failure early in its life (infant mortality), and again later in its life (aging).

Also notice that the hazard rate cannot be estimated above the largest uncensored observation for the nonparametric model, and the graph drops to zero.

Alternative Models

For the simulated data we've used for this example, we found that a Weibull distribution was not a suitable fit. We were able to fit the data well with a nonparametric fit, but that model was only useful within the range of the data.

One alternative would be to use a different parametric distribution. The Statistics and Machine Learning Toolbox includes functions for other common lifetime distributions such as the lognormal, gamma, and Birnbaum-Saunders, as well as many other distributions that are not commonly used in lifetime models. You can also define and fit custom parametric models to lifetime data, as described in the “Fitting Custom Univariate Distributions, Part 2” on page 5-176 example.

Another alternative would be to use a mixture of two parametric distributions -- one representing early failure and the other representing the rest of the distribution. Fitting mixtures of distributions is described in the “Fitting Custom Univariate Distributions” on page 5-165 example.

Multivariate Methods

Multivariate Linear Regression

In this section...

Introduction to Multivariate Methods

Large, high-dimensional data sets are common in the modern era of computer-based instrumentation and electronic data storage. High-dimensional data present many challenges for statistical visualization, analysis, and modeling.

Data visualization, of course, is impossible beyond a few dimensions. As a result, pattern recognition, data preprocessing, and model selection must rely heavily on numerical methods.

A fundamental challenge in high-dimensional data analysis is the so-called curse of dimensionality. Observations in a high-dimensional space are necessarily sparser and less representative than those in a low-dimensional space. In higher dimensions, data over-represent the edges of a sampling distribution, because regions of higher-dimensional space contain the majority of their volume near the surface. (A d-dimensional spherical shell has a volume, relative to the total volume of the sphere, that approaches 1 as d approaches infinity.) In high dimensions, typical data points at the interior of a distribution are sampled less frequently.

Often, many of the dimensions in a data set—the measured features—are not useful in producing a model. Features may be irrelevant or redundant. Regression and classification algorithms may require large amounts of storage and computation time to process raw data, and even if the algorithms are successful the resulting models may contain an incomprehensible number of terms.

Because of these challenges, multivariate statistical methods often begin with some type of dimension reduction, in which data are approximated by points in a lower-dimensional space. Dimension reduction is the goal of the methods presented in this chapter. Dimension reduction often leads to simpler models and fewer measured variables, with consequent benefits when measurements are expensive and visualization is important.

Multivariate Linear Regression Model

The multivariate linear regression model expresses a d-dimensional continuous response vector as a linear combination of predictor terms plus a vector of error terms with a multivariate normal distribution. Let $\mathbf{y}_i = (y_{i1}, \ldots, y_{id})'$ denote the response vector for observation i, $i = 1,\ldots,n$. In the most general case, given the d-by-K design matrix $\mathbf{X}_i$ and the K-by-1 vector of coefficientsβ, the multivariate linear regression model is

$$\mathbf{y}_i = \mathbf{X}_i\beta + \varepsilon_i,$$

where the d-dimensional vector of error terms follows a multivariate normal distribution,

$$\varepsilon_i \sim MVN_d(\mathbf{0}, \Sigma)\,.$$

The model assumes independence between observations, meaning the error variance-covariance matrix for the n stacked d-dimensional response vectors is

$$\mathbf{I}_n \otimes \Sigma = \begin{pmatrix} \Sigma & & 0 \\ & \ddots & \\ 0 & & \Sigma \end{pmatrix}.$$

If $\mathbf{y}$ denotes the nd-by-1 vector of stacked d-dimensional responses, and $\mathbf{X}$ denotes the nd-by-K matrix of stacked design matrices, then the distribution of the response vector is

$$\mathbf{y} \sim MVN_{nd}(\mathbf{X}\beta, \mathbf{I}_n \otimes \Sigma).$$

Solving Multivariate Regression Problems

To fit multivariate linear regression models of the form

$$\mathbf{y}_i = \mathbf{X}_i\beta + \varepsilon_i, \quad \varepsilon_i \sim MVN_d(\mathbf{0}, \Sigma)$$

in Statistics and Machine Learning Toolbox, use `mvregress`. This function fits multivariate regression models with a diagonal (heteroscedastic) or unstructured (heteroscedastic and correlated) error variance-covariance matrix, Σ, using least squares or maximum likelihood estimation.

Many variations of multivariate regression might not initially appear to be of the form supported by `mvregress`, such as:

- Multivariate general linear model
- Multivariate analysis of variance (MANOVA)
- Longitudinal analysis
- Panel data analysis
- Seemingly unrelated regression (SUR)
- Vector autoregressive (VAR) model

In many cases, you can frame these problems in the form used by `mvregress` (but `mvregress` does not support parameterized error variance-covariance matrices). For the special case of one-way MANOVA, you can alternatively use `manova1`. Econometrics Toolbox™ has functions for VAR estimation.

Note The multivariate linear regression model is distinct from the multiple linear regression model, which models a *univariate* continuous response as a linear combination of exogenous terms plus an independent and identically distributed error term. To fit a multiple linear regression model, use `fitlm`.

Estimation of Multivariate Regression Models

In this section...

Least Squares Estimation

Ordinary Least Squares

When you fit multivariate linear regression models using `mvregress`, you can use the optional name-value pair `'algorithm','cwls'` to choose least squares estimation. In this case, by default, `mvregress` returns ordinary least squares (OLS) estimates using $\Sigma = \mathbf{I}_d$. Alternatively, if you specify a covariance matrix for weighting, you can return covariance-weighted least squares (CWLS) estimates. If you combine OLS and CWLS, you can get feasible generalized least squares (FGLS) estimates.

The OLS estimate for the coefficient vector is the vector $\mathbf{b}$ that minimizes

$$\sum_{i=1}^{n} (\mathbf{y}_i - \mathbf{X}_i\mathbf{b})'(\mathbf{y}_i - \mathbf{X}_i\mathbf{b}).$$

Let $\mathbf{y}$ denote the nd-by-1 vector of stacked d-dimensional responses, and $\mathbf{X}$ denote the nd-by-K matrix of stacked design matrices. The K-by-1 vector of OLS regression coefficient estimates is

$$\mathbf{b}_{OLS} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}.$$

This is the first `mvregress` output.

Given $\Sigma = \mathbf{I}_d$ (the `mvregress` OLS default), the variance-covariance matrix of the OLS estimates is

$$V(\mathbf{b}_{OLS}) = (\mathbf{X}'\mathbf{X})^{-1}.$$

This is the fourth `mvregress` output. The standard errors of the OLS regression coefficients are the square root of the diagonal of this variance-covariance matrix.

If your data is not scaled such that $\Sigma = \sigma^2\mathbf{I}_d$, then you can multiply the `mvregress` variance-covariance matrix by the mean squared error (MSE), an unbiased estimate of σ^2. To compute the MSE, return the n-by-d matrix of residuals, $\mathbf{E}$ (the third `mvregress` output). Then,

$$\text{MSE} = \frac{\sum_{i=1}^{n} \mathbf{e}_i\mathbf{e}_i'}{n-K},$$

where $\mathbf{e}_i = (\mathbf{y}_i - \mathbf{X}_i\beta)'$ is the ith row of $\mathbf{E}$.

Covariance-Weighted Least Squares

For most multivariate problems, an identity error covariance matrix is insufficient, and leads to inefficient or biased standard error estimates. You can specify a matrix for CWLS estimation using the optional name-value pair argument `covar0`, for example, an invertible d-by-d matrix named $\mathbf{C}_0$.

Usually, $\mathbf{C}_0$ is a diagonal matrix such that the inverse matrix $\mathbf{C}_0^{-1}$ contains weights for each dimension to model heteroscedasticity. However, $\mathbf{C}_0$ can also be a nondiagonal matrix that models correlation.

Given $\mathbf{C}_0$, the CWLS solution is the vector $\mathbf{b}$ that minimizes

$$\sum_{i=1}^{n} (\mathbf{y}_i - \mathbf{X}_i\mathbf{b})'\mathbf{C}_0(\mathbf{y}_i - \mathbf{X}_i\mathbf{b}).$$

In this case, the K-by-1 vector of CWLS regression coefficient estimates is

$$\mathbf{b}_{CWLS} = \left(\mathbf{X}'(\mathbf{I}_n \otimes \mathbf{C}_0)^{-1}\mathbf{X}\right)^{-1}\mathbf{X}'(\mathbf{I}_n \otimes \mathbf{C}_0)^{-1}\mathbf{y}.$$

This is the first `mvregress` output.

If $\Sigma = \mathbf{C}_0$, this is the generalized least squares (GLS) solution. The corresponding variance-covariance matrix of the CWLS estimates is

$$V(\mathbf{b}_{CWLS}) = \left(\mathbf{X}'(\mathbf{I}_n \otimes \mathbf{C}_0)^{-1}\mathbf{X}\right)^{-1}.$$

This is the fourth `mvregress` output. The standard errors of the CWLS regression coefficients are the square root of the diagonal of this variance-covariance matrix.

If you only know the error covariance matrix up to a proportion, that is, $\Sigma = \sigma^2\mathbf{C}_0$, you can multiply the `mvregress` variance-covariance matrix by the MSE, as described in “Ordinary Least Squares” on page 15-5.

Error Covariance Estimation

Regardless of which least squares method you use, the estimate for the error variance-covariance matrix is

$$\widehat{\Sigma} = \begin{pmatrix} \widehat{\sigma}_1^2 & \widehat{\sigma}_{12} & \cdots & \widehat{\sigma}_{1d} \\ \widehat{\sigma}_{12} & \widehat{\sigma}_2^2 & \cdots & \widehat{\sigma}_{2d} \\ \vdots & \vdots & \ddots & \vdots \\ \widehat{\sigma}_{1d} & \widehat{\sigma}_{2d} & \cdots & \widehat{\sigma}_d^2 \end{pmatrix} = \frac{\mathbf{E}'\mathbf{E}}{n},$$

where $\mathbf{E}$ is the n-by-d matrix of residuals. The ith row of $\mathbf{E}$ is $\mathbf{e}_i = (\mathbf{y}_i - \mathbf{X}_i\mathbf{b})'$.

The error covariance estimate, $\widehat{\Sigma}$, is the second `mvregress` output, and the matrix of residuals, $\mathbf{E}$, is the third output. If you specify the optional name-value pair `'covtype','diagonal'`, then `mvregress` returns $\widehat{\Sigma}$ with zeros in the off-diagonal entries,

$$\widehat{\Sigma} = \begin{pmatrix} \widehat{\sigma}_1^2 & & 0 \\ & \ddots & \\ 0 & & \widehat{\sigma}_d^2 \end{pmatrix}.$$

Feasible Generalized Least Squares

The generalized least squares estimate is the CWLS estimate with a known covariance matrix. That is, given Σ is known, the GLS solution is

$$\mathbf{b}_{GLS} = \left(\mathbf{X}'(\mathbf{I}_n \otimes \Sigma)^{-1}\mathbf{X}\right)^{-1}\mathbf{X}'(\mathbf{I}_n \otimes \Sigma)^{-1}\mathbf{y},$$

with variance-covariance matrix

$$V(\mathbf{b}_{GLS}) = \left(\mathbf{X}'(\mathbf{I}_n \otimes \Sigma)^{-1}\mathbf{X}\right)^{-1}.$$

In most cases, the error covariance is unknown. The feasible generalized least squares (FGLS) estimate uses $\widehat{\Sigma}$ in place of Σ. You can obtain two-step FGLS estimates as follows:

1. Perform OLS regression, and return an estimate $\widehat{\Sigma}$.
2. Perform CWLS regression, using $\mathbf{C}_0 = \widehat{\Sigma}$.

You can also iterate between these two steps until convergence is reached.

For some data, the OLS estimate $\widehat{\Sigma}$ is positive semidefinite, and has no unique inverse. In this case, you cannot get the FGLS estimate using `mvregress`. As an alternative, you can use `lscov`, which uses a generalized inverse to return weighted least squares solutions for positive semidefinite covariance matrices.

Panel Corrected Standard Errors

An alternative to FGLS is to use OLS coefficient estimates (which are consistent) and make a standard error correction to improve efficiency. One such standard error adjustment—which does not require inversion of the covariance matrix—is panel corrected standard errors (PCSE) [1]. The panel corrected variance-covariance matrix for OLS estimates is

$$V_{pcse}(\mathbf{b}_{OLS}) = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'(\mathbf{I}_n \otimes \Sigma)\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}.$$

The PCSE are the square root of the diagonal of this variance-covariance matrix. “Fixed Effects Panel Model with Concurrent Correlation” on page 15-24 illustrates PCSE computation.

Maximum Likelihood Estimation

Maximum Likelihood Estimates

The default estimation algorithm used by `mvregress` is maximum likelihood estimation (MLE). The loglikelihood function for the multivariate linear regression model is

$$\log L(\beta, \Sigma | \mathbf{y}, \mathbf{X}) = \frac{1}{2} nd \log(2\pi) + \frac{1}{2} n \log(\det(\Sigma)) + \frac{1}{2} \sum_{i=1}^{n} (\mathbf{y}_i - \mathbf{X}_i \beta)' \Sigma^{-1} (\mathbf{y}_i - \mathbf{X}_i \beta).$$

The MLEs for β and Σ are the values that maximize the loglikelihood objective function.

`mvregress` finds the MLEs using an iterative two-stage algorithm. At iteration $m + 1$, the estimates are

$$\mathbf{b}_{MLE}^{(m+1)} = \left(\mathbf{X}' \left(\mathbf{I}_n \otimes \Sigma^{(m)} \right)^{-1} \mathbf{X} \right)^{-1} \mathbf{X}' \left(\mathbf{I}_n \otimes \Sigma^{(m)} \right)^{-1} \mathbf{y}$$

and

$$\widehat{\Sigma}^{(m+1)} = \frac{1}{n} \sum_{i=1}^{n} \left(\mathbf{y}_i - \mathbf{X}_i \mathbf{b}_{MLE}^{(m+1)} \right) \left(\mathbf{y}_i - \mathbf{X}_i \mathbf{b}_{MLE}^{(m+1)} \right)'.$$

The algorithm terminates when the changes in the coefficient estimates and loglikelihood objective function are less than a specified tolerance, or when the specified maximum number of iterations is reached. The optional name-value pair arguments for changing these convergence criteria are `tolbeta`, `tolobj`, and `maxiter`, respectively.

Standard Errors

The variance-covariance matrix of the MLEs is an optional `mvregress` output. By default, `mvregress` returns the variance-covariance matrix for only the regression coefficients, but you can also get the variance-covariance matrix of $\widehat{\Sigma}$ using the optional name-value pair `'vartype','full'`. In this case, `mvregress` returns the variance-covariance matrix for all K regression coefficients, and d or $d(d + 1)/2$ covariance terms (depending on whether the error covariance is diagonal or full).

By default, the variance-covariance matrix is the inverse of the observed Fisher information matrix (the `'hessian'` option). You can request the expected Fisher information matrix using the optional name-value pair `'vartype','fisher'`. Provided there is no missing response data, the observed and expected Fisher information matrices are the same. If response data is missing, the observed Fisher information accounts for the added uncertainty due to the missing values, whereas the expected Fisher information matrix does not.

The variance-covariance matrix for the regression coefficient MLEs is

$$V(\mathbf{b}_{MLE}) = \left(\mathbf{X}' \left(\mathbf{I}_n \otimes \widehat{\Sigma} \right)^{-1} \mathbf{X} \right)^{-1},$$

evaluated at the MLE of the error covariance matrix. This is the fourth `mvregress` output. The standard errors of the MLEs are the square root of the diagonal of this variance-covariance matrix.

For $\widehat{\Sigma}$, let θ denote the vector of parameters in the estimated error variance-covariance matrix. For example, if $d = 2$, then:

- If the estimated covariance matrix is diagonal, then $\theta = (\widehat{\sigma}_1^2, \widehat{\sigma}_2^2)$.
- If the estimated covariance matrix is full, then $\theta = (\widehat{\sigma}_1^2, \widehat{\sigma}_{12}, \widehat{\sigma}_2^2)$.

The Fisher information matrix for θ, $I(\theta)$, has elements

$$I(\theta)_{u,v} = \frac{1}{2} tr\left(\widehat{\Sigma}^{-1}\frac{\partial\widehat{\Sigma}}{\partial\theta_u}\widehat{\Sigma}^{-1}\frac{\partial\widehat{\Sigma}}{\partial\theta_v}\right), \quad u, v = 1, \ldots, n_\theta,$$

where n_θ is the length of θ (either d or $d(d + 1)/2$). The resulting variance-covariance matrix is

$$V(\theta) = I(\theta)^{-1}.$$

When you request the full variance-covariance matrix, `mvregress` returns (as the fourth output) the block diagonal matrix

$$\begin{pmatrix} V(\mathbf{b}_{MLE}) & \mathbf{0} \\ \mathbf{0} & V(\theta) \end{pmatrix}.$$

Missing Response Data

Expectation/Conditional Maximization

If any response values are missing, indicated by `NaN`, `mvregress` uses an expectation/conditional maximization (ECM) algorithm for estimation (if enough data is available). In this case, the algorithm is iterative for both least squares and maximum likelihood estimation. During each iteration, `mvregress` imputes missing response values using their conditional expectation.

Consider organizing the data so that the joint distribution of the missing and observed responses, denoted $\tilde{\mathbf{y}}$ and $\mathbf{y}$ respectively, can be written as

$$\begin{pmatrix} \tilde{\mathbf{y}} \\ \mathbf{y} \end{pmatrix} \sim MVN\left\{\begin{pmatrix} \widetilde{\mathbf{X}}\beta \\ \mathbf{X}\beta \end{pmatrix}, \begin{pmatrix} \Sigma_{\tilde{y}} & \Sigma_{\tilde{y}y} \\ \Sigma_{y\tilde{y}} & \Sigma_y \end{pmatrix}\right\}.$$

Using properties of the multivariate normal distribution, the conditional expectation of the missing responses given the observed responses is

$$\mathrm{E}(\tilde{\mathbf{y}}|\mathbf{y}) = \widetilde{\mathbf{X}}\beta + \Sigma_{\tilde{y}y}\Sigma_y^{-1}(\mathbf{y} - \mathbf{X}\beta).$$

Also, the variance-covariance matrix of the conditional distribution is

$$\mathrm{COV}(\tilde{\mathbf{y}}|\mathbf{y}) = \Sigma_{\tilde{y}} - \Sigma_{\tilde{y}y}\Sigma_y^{-1}\Sigma_{y\tilde{y}}.$$

At each iteration of the ECM algorithm, `mvregress` uses the parameter values from the previous iteration to:

- Update the regression coefficients using the combined vector of observed responses and conditional expectations of missing responses.
- Update the variance-covariance matrix, adjusting for missing responses using the variance-covariance matrix of the conditional distribution.

Finally, the residuals that `mvregress` returns for missing responses are the difference between the conditional expectation and the fitted value, both evaluated at the final parameter estimates.

If you prefer to ignore any observations that have missing response values, use the name-value pair `'algorithm','mvn'`. Note that `mvregress` always ignores observations that have missing predictor values.

Observed Information Matrix

By default, `mvregress` uses the observed Fisher information matrix (the `'hessian'` option) to compute the variance-covariance matrix of the regression parameters. This accounts for the additional uncertainty due to missing response values.

The observed information matrix includes contributions from only the observed responses. That is, the observed Fisher information matrix for the parameters in the error variance-covariance matrix has elements

$$I(\theta)_{u,v} = \frac{1}{2}\sum_{i=1}^{n} tr\left(\widehat{\Sigma}_i^{-1}\frac{\partial\widehat{\Sigma}_i}{\partial\theta_u}\widehat{\Sigma}_i^{-1}\frac{\partial\widehat{\Sigma}_i}{\partial\theta_v}\right),\quad u,v = 1,\ldots,n_\theta,$$

where $\widehat{\Sigma}_i$ is the subset of $\widehat{\Sigma}$ corresponding to the observed responses in $\mathbf{y}_i$.

For example, if $d = 3$, but y_{i2} is missing, then

$$\widehat{\Sigma}_i = \begin{pmatrix} \widehat{\sigma}_1^2 & \widehat{\sigma}_{13} \\ \widehat{\sigma}_{13} & \widehat{\sigma}_3^2 \end{pmatrix}.$$

The observed Fisher information for the regression coefficients has similar contributions from the design and covariance matrices.

Set Up Multivariate Regression Problems

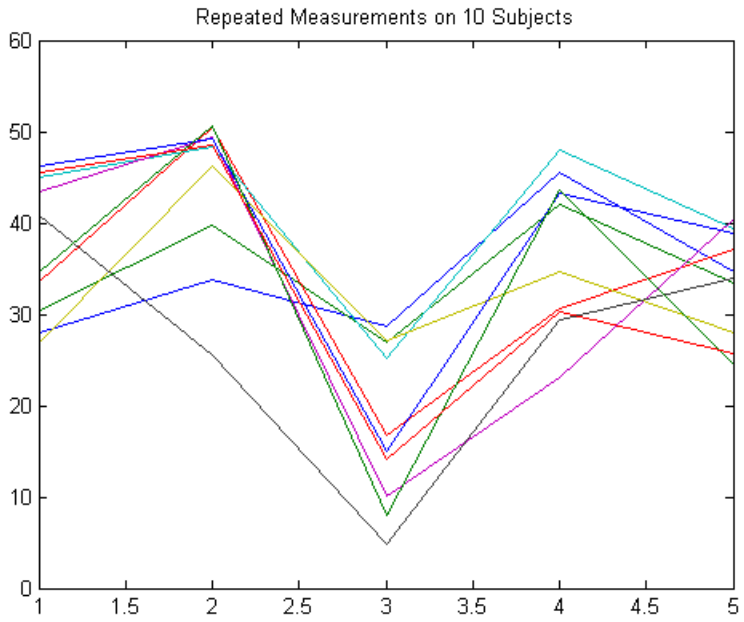
In this section...

Response Matrix

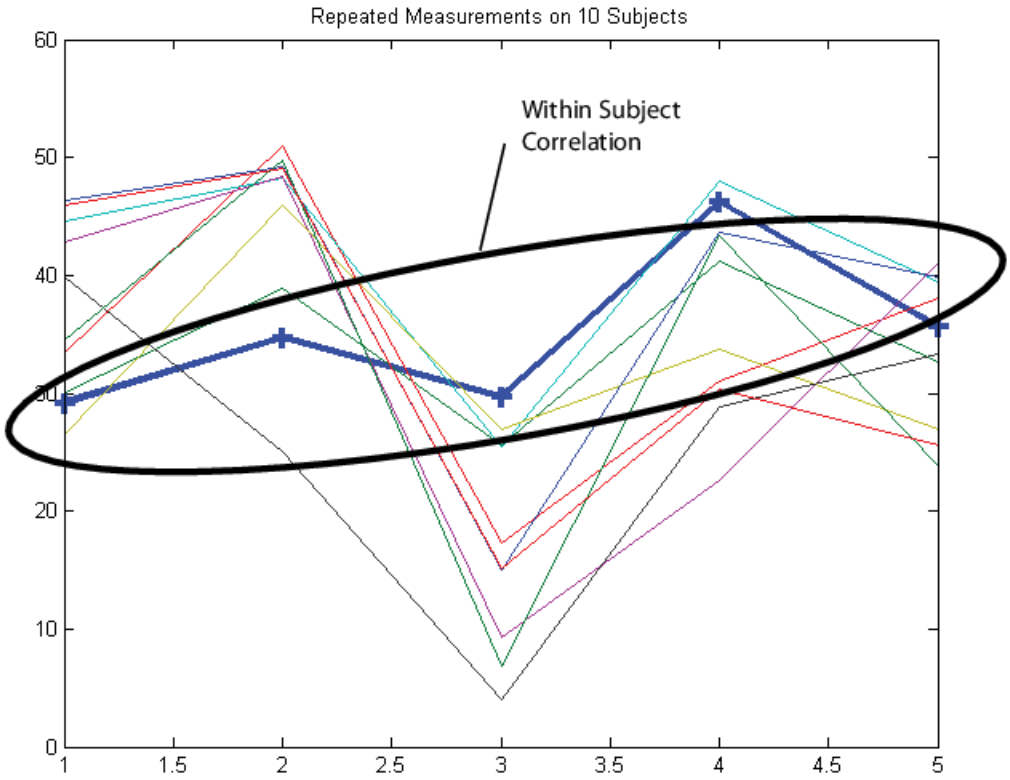
To fit a multivariate linear regression model using `mvregress`, you must set up your response matrix and design matrices in a particular way. Given properly formatted inputs, `mvregress` can handle a variety of multivariate regression problems.

`mvregress` expects the n observations of potentially correlated d-dimensional responses to be in an n-by-d matrix, named `Y`, for example. That is, set up your responses so that the dependency structure is between observations in the same *row*. If you specify `Y` as a vector of length n (either a row or column vector), then `mvregress` assumes that $d = 1$, and treats the elements as n independent observations. It does *not* model the vector as one realization of a correlated series (such as a time series).

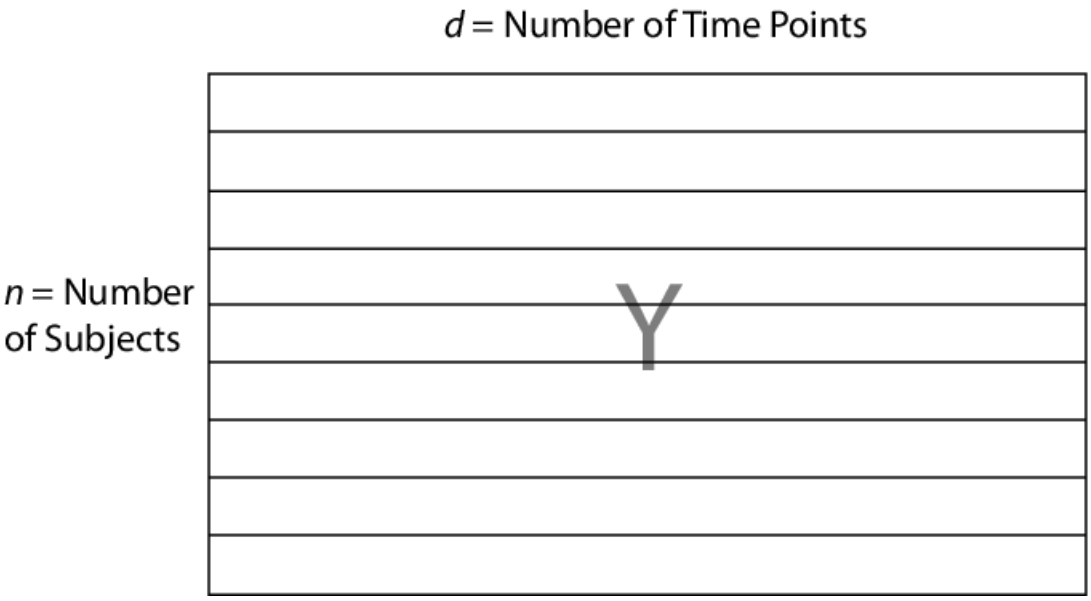
To illustrate how to set up a response matrix, suppose that your multivariate responses are repeated measurements made on subjects at multiple time points, as in the following figure.



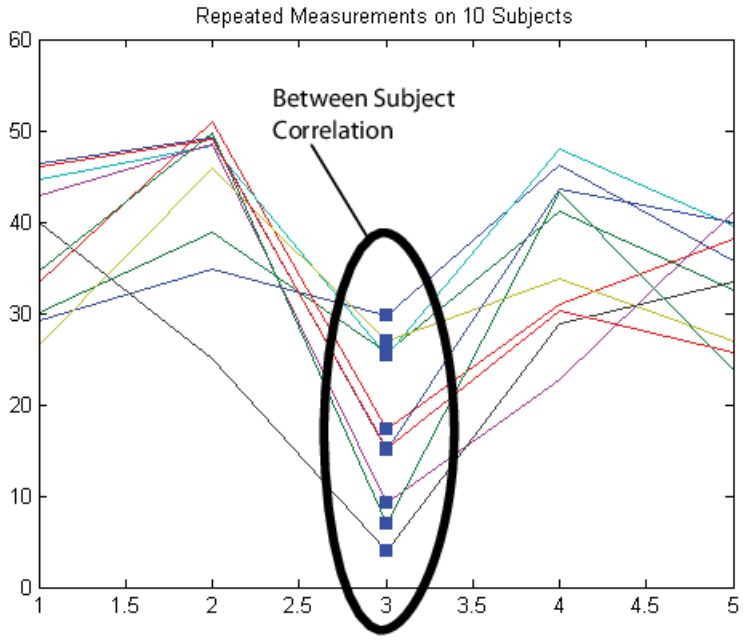
Suppose that observations within a subject are correlated.



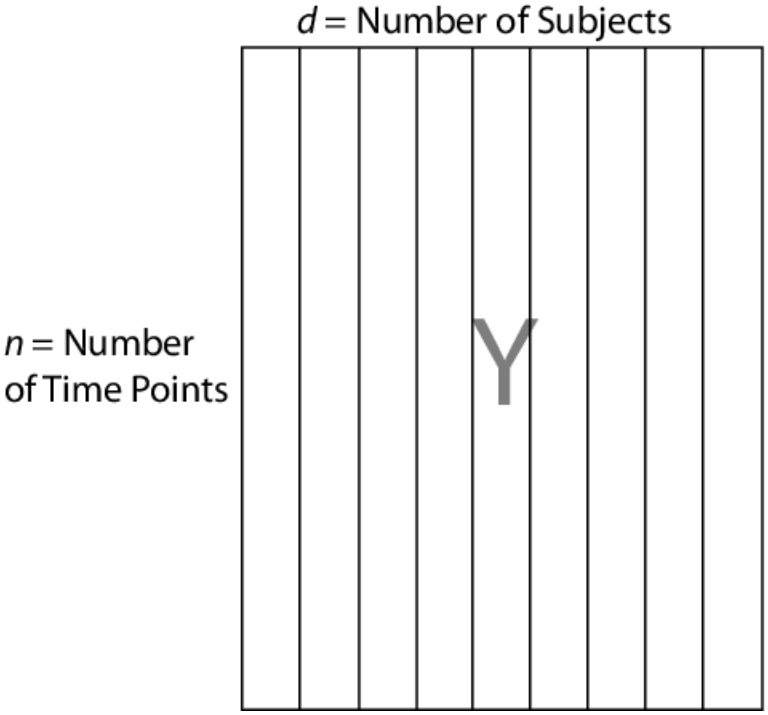
In this case, set up the response matrix Y such that each row corresponds to a subject, and each column corresponds to a time point.



Then again, suppose that observations made on subjects at the same time are correlated (concurrent correlation).



In this case, set up the response matrix Y such that each row corresponds to a time point, and each column corresponds to a subject.



Design Matrices

In the multivariate linear regression model, each d-dimensional response has a corresponding design matrix. Depending on the model, the design matrix might be comprised of exogenous predictor variables, dummy variables, lagged responses, or a combination of these and other covariate terms.

- If $d > 1$ and all d dimensions have the same design matrix, then specify one n-by-p design matrix, where p is the number of predictor variables. To determine an intercept for each dimension, add a column of ones to the design matrix. In this case, `mvregress` applies the design matrix to all d dimensions.
- If $d > 1$ and all d dimensions do not have the same design matrix, then specify the design matrices using a length-n cell array of d-by-K arrays, named `X`, for example. K is the total number of regression coefficients in the model. Note that the rows of the arrays in `X` correspond to the columns of the response matrix, `Y`.

  If all n observations have the same design matrix, you can specify a cell array containing one d-by-K design matrix. In this case, `mvregress` applies the design matrix to all n observations. For example, this situation might arise if the predictors are functions of time, and all observations were measured at the same time points.
- In the special case that $d = 1$, you can specify one n-by-K design matrix (not in a cell array). However, you should consider using `fitlm` to fit regression models to univariate, continuous responses.

The following sections illustrate how to set up the some common multivariate regression problems for estimation using `mvregress`.

Common Multivariate Regression Problems

Multivariate General Linear Model

The multivariate general linear model is of the form

$$\mathbf{Y}_{n\times d} = \mathbf{X}_{n\times (p+1)}\mathbf{B}_{(p+1)\times d} + \mathbf{E}_{n\times d}.$$

In expanded form,

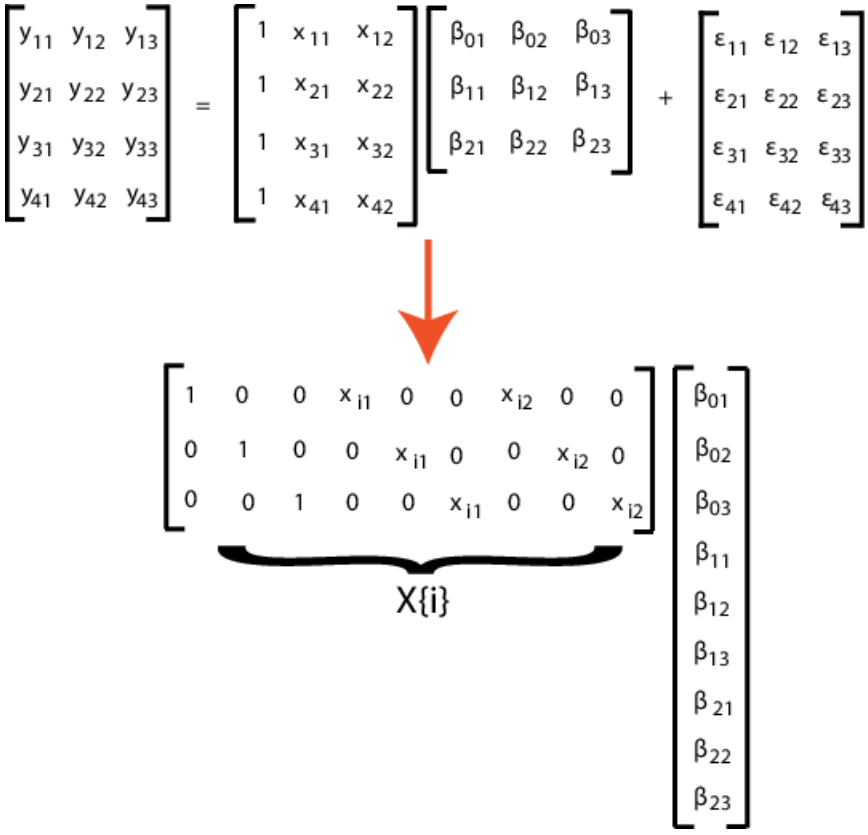
$$\begin{bmatrix} y_{11} & y_{12} & \cdots & y_{1d} \\ y_{21} & y_{22} & \cdots & y_{2d} \\ \vdots & \vdots & \ddots & \vdots \\ y_{n1} & y_{n2} & \cdots & y_{nd} \end{bmatrix} = \begin{bmatrix} 1 & x_{11} & x_{12} & \cdots & x_{1p} \\ 1 & x_{21} & x_{22} & \cdots & x_{2p} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & x_{n1} & x_{n2} & \cdots & x_{np} \end{bmatrix} \begin{bmatrix} \beta_{01} & \beta_{02} & \cdots & \beta_{0d} \\ \beta_{11} & \beta_{12} & \cdots & \beta_{1d} \\ \vdots & \vdots & \ddots & \vdots \\ \beta_{p1} & \beta_{p2} & \cdots & \beta_{pd} \end{bmatrix} + \begin{bmatrix} \varepsilon_{11} & \varepsilon_{12} & \cdots & \varepsilon_{1d} \\ \varepsilon_{21} & \varepsilon_{22} & \cdots & \varepsilon_{2d} \\ \vdots & \vdots & \ddots & \vdots \\ \varepsilon_{n1} & \varepsilon_{n2} & \cdots & \varepsilon_{nd} \end{bmatrix}.$$

That is, each d-dimensional response has an intercept and p predictor variables, and each dimension has its own set of regression coefficients. In this form, the least squares solution is `B = X\Y`. To estimate this model using `mvregress`, use the n-by-d matrix of responses, as above.

If all d dimensions have the same design matrix, use the n-by-(p+1) design matrix, as above. Adding a column of ones to the p predictor variables computes the intercept for each dimension.

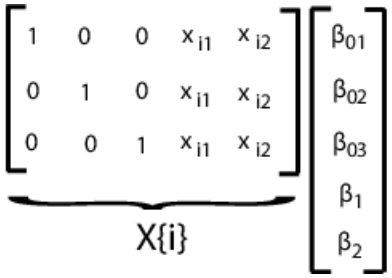
If all d dimensions do not have the same design matrix, reformat the n-by-(p + 1) design matrix into a length-n cell array of d-by-K matrices. Here, $K = (p + 1)d$ for an intercept and slopes for each dimension.

For example, suppose $n = 4$, $d = 3$, and $p = 2$ (two predictor terms in addition to an intercept). This figure shows how to format the ith element in the cell array.



If you prefer, you can reshape the K-by-1 vector of coefficients back into a $(p + 1)$-by-d matrix after estimation.

To put constraints on the model parameters, adjust the design matrix accordingly. For example, suppose that the three dimensions in the previous example have a common slope. That is, $\beta_{11} = \beta_{12} = \beta_{13} = \beta_1$ and $\beta_{21} = \beta_{22} = \beta_{23} = \beta_2$. In this case, each design matrix is 3-by-5, as shown in the following figure.



Longitudinal Analysis

In a longitudinal analysis, you might measure responses on n subjects at d time points, with correlation between observations made on the same subject. For example, suppose that you measure responses y_{ij} at times t_{ij}, $i = 1,...,n$ and $j = 1,...,d$. In addition, suppose that each subject is in one of two groups (such as male or female), specified by the indicator variable G_i. You could model y_{ij} as a function of G_i and t_{ij}, with group-specific intercepts and slopes, as follows:

$$y_{ij} = \beta_0 + \beta_1 G_i + \beta_2 t_{ij} + \beta_3 G_i \times t_{ij} + \varepsilon_{ij}, \;\; i = 1, \ldots, n; \;\; j = 1, \ldots, d,$$

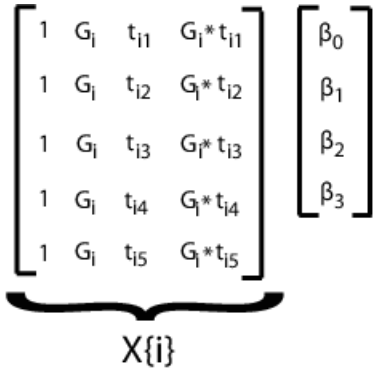
where

$$\varepsilon_i = (\varepsilon_{i1}, \ldots, \varepsilon_{id})' \sim MVN(\mathbf{0}, \Sigma).$$

Most longitudinal models include time as an explicit predictor.

To fit this model using `mvregress`, arrange the responses in an n-by-d matrix, where n is the number of subjects and d is the number of time points. Specify the design matrices in an n-length cell array of d-by-K matrices, where here $K = 4$ for the four regression coefficients.

For example, suppose $d = 5$ (five observations per subject). The ith design matrix and corresponding parameter vector for the specified model are shown in the following figure.



Panel Analysis

In a panel analysis, you might measure responses and covariates on d subjects (such as individuals or countries) at n time points. For example, suppose you measure responses y_{tj} and covariates x_{tj} on subjects $j = 1,...,d$ at times $t = 1,...,n$. A fixed effects panel model, with subject-specific fixed effects, and concurrent correlation might look like:

$$y_{tj} = \alpha_j + \beta x_{tj} + \varepsilon_{tj},$$

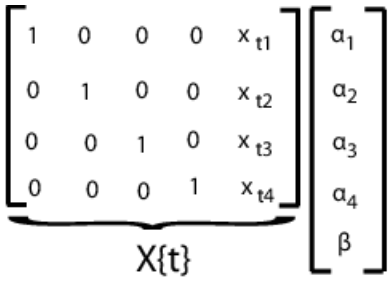
where

$$\varepsilon_t = (\varepsilon_{t1}, \ldots, \varepsilon_{td})' \sim MVN(\mathbf{0}, \Sigma).$$

In contrast to longitudinal models, the panel analysis model typically includes covariates measured at each time point, instead of using time as an explicit predictor.

To fit this model using `mvregress`, arrange the responses in an n-by-d matrix, such that each column corresponds to a subject. Specify the design matrices in an n-length cell array of d-by-K matrices, where here $K = d + 1$ for the d intercepts and a slope term.

For example, suppose $d = 4$ (four subjects). The tth design matrix and corresponding parameter vector are shown in the following figure.



Seemingly Unrelated Regression

In a seemingly unrelated regression (SUR), you model d separate regressions, each with its own intercept and slope, but a common error variance-covariance matrix. For example, suppose you measure responses y_{ij} and covariates x_{ij} for regression models $j = 1,...,d$, with $i = 1,...,n$ observations to fit each regression. The SUR model might look like:

$$y_{ij} = \beta_{0j} + \beta_j x_{ij} + \varepsilon_{ij},$$

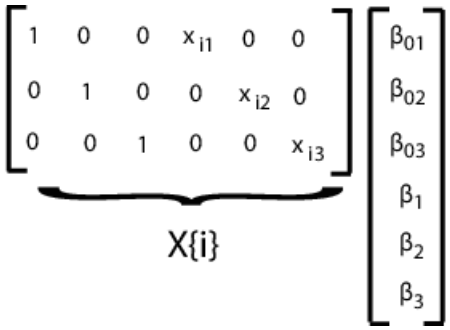
where

$$\varepsilon_i = (\varepsilon_{i1}, \ldots, \varepsilon_{id})' \sim MVN(\mathbf{0}, \Sigma).$$

This model is very similar to the multivariate general linear model, except that it has different covariates for each dimension.

To fit this model using `mvregress`, arrange the responses in an n-by-d matrix, such that each column has the data for the jth regression model. Specify the design matrices in an n-length cell array of d-by-K matrices, where here $K = 2d$ for d intercepts and d slopes.

For example, suppose $d = 3$ (three regressions). The ith design matrix and corresponding parameter vector are shown in the following figure.



Vector Autoregressive Model

The VAR(p) vector autoregressive model expresses d-dimensional time series responses as a linear function of p lagged d-dimensional responses from previous times. For example, suppose you measure responses y_{tj} for time series $j = 1,...,d$ at times $t = 1,...,n$. The VAR(p) model might look like:

$$\begin{bmatrix} y_{t1} \\ y_{t2} \\ \vdots \\ y_{td} \end{bmatrix} = \begin{bmatrix} c_1 \\ c_2 \\ \vdots \\ c_d \end{bmatrix} + \begin{bmatrix} \varphi_{11}^{(1)} & \varphi_{12}^{(1)} & \cdots & \varphi_{1d}^{(1)} \\ \vdots & \vdots & \ddots & \vdots \\ \varphi_{d1}^{(1)} & \varphi_{d2}^{(1)} & \cdots & \varphi_{dd}^{(1)} \end{bmatrix} \begin{bmatrix} y_{t-1,1} \\ y_{t-1,2} \\ \vdots \\ y_{t-1,d} \end{bmatrix} + \cdots + \begin{bmatrix} \varphi_{11}^{(p)} & \varphi_{12}^{(p)} & \cdots & \varphi_{1d}^{(p)} \\ \vdots & \vdots & \ddots & \vdots \\ \varphi_{d1}^{(p)} & \varphi_{d2}^{(p)} & \cdots & \varphi_{dd}^{(p)} \end{bmatrix} \begin{bmatrix} y_{t-p,1} \\ y_{t-p,2} \\ \vdots \\ y_{t-p,d} \end{bmatrix} + \begin{bmatrix} \varepsilon_{t1} \\ \varepsilon_{t2} \\ \vdots \\ \varepsilon_{td} \end{bmatrix},$$

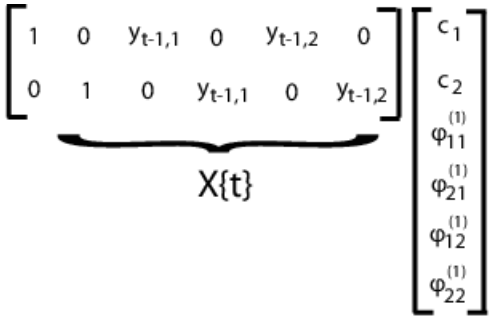
where

$$\varepsilon_t = (\varepsilon_{t1}, \ldots, \varepsilon_{td})' \sim MVN(\mathbf{0}, \Sigma).$$

When estimating vector autoregressive models, you typically need to use the first p observations to initiate the model, or provide some other presample response values.

To fit this model using `mvregress`, arrange the responses in an n-by-d matrix, such that each column corresponds to a time series. Specify the design matrices in an n-length cell array of d-by-K matrices, where here $K = d + pd^2$.

For example, suppose $d = 2$ (two time series) and $p = 1$ (one lag). The tth design matrix and corresponding parameter vector are shown in the following figure.



Alternatively, Econometrics Toolbox has functions for fitting and forecasting VAR(p) models, including the option to specify exogenous predictor variables.

Multivariate General Linear Model

This example shows how to set up a multivariate general linear model for estimation using `mvregress`.

Load sample data.

This data contains measurements on a sample of 205 auto imports from 1985.

Here, model the bivariate response of city and highway MPG (columns 14 and 15).

For predictors, use wheel base (column 3), curb weight (column 7), and fuel type (column 18). The first two predictors are continuous, and for this example are centered and scaled. Fuel type is a categorical variable with two categories (`11` and `20`), so a dummy indicator variable is needed for the regression.

```
load('imports-85')
Y = X(:,14:15);
[n,d] = size(Y);

X1 = zscore(X(:,3));
X2 = zscore(X(:,7));
X3 = X(:,18)==20;

Xmat = [ones(n,1) X1 X2 X3];
```

The variable `X3` is coded to have value `1` for the fuel type 20, and value `0` otherwise.

For convenience, the three predictors (wheel base, curb weight, and fuel type indicator) are combined into one design matrix, with an added intercept term.

Set up design matrices.

Given these predictors, the multivariate general linear model for the bivariate MPG response is

$$\begin{bmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \\ \vdots & \vdots \\ y_{n1} & y_{n2} \end{bmatrix} = \begin{bmatrix} 1 & x_{11} & x_{12} & x_{13} \\ 1 & x_{21} & x_{22} & x_{23} \\ \vdots & \vdots & \vdots & \vdots \\ 1 & x_{n1} & x_{n2} & x_{n3} \end{bmatrix} \begin{bmatrix} \beta_{01} & \beta_{02} \\ \beta_{11} & \beta_{12} \\ \beta_{21} & \beta_{22} \\ \beta_{31} & \beta_{32} \end{bmatrix} + \begin{bmatrix} \epsilon_{11} & \epsilon_{12} \\ \epsilon_{21} & \epsilon_{22} \\ \vdots & \vdots \\ \epsilon_{n1} & \epsilon_{n2} \end{bmatrix},$$

where $\epsilon_i = (\epsilon_{i1}, \epsilon_{i2})' - MVN(0, \Sigma)$. There are $K = 8$ regression coefficients in total.

Create a length $n = 205$ cell array of 2-by-8 (d-by-K) matrices for use with `mvregress`. The ith matrix in the cell array is

$$X(i) = \begin{bmatrix} 1 & 0 & x_{i1} & 0 & x_{i2} & 0 & x_{i3} & 0 \\ 0 & 1 & 0 & x_{i1} & 0 & x_{i2} & 0 & x_{i3} \end{bmatrix}.$$

```
Xcell = cell(1,n);
for i = 1:n
    Xcell{i} = [kron([Xmat(i,:)],eye(d))];
end
```

Given this specification of the design matrices, the corresponding parameter vector is

$$\beta = \begin{bmatrix} \beta_{01} \\ \beta_{02} \\ \beta_{11} \\ \beta_{12} \\ \beta_{21} \\ \beta_{22} \\ \beta_{31} \\ \beta_{32} \end{bmatrix}.$$

Estimate regression coefficients.

Fit the model using maximum likelihood estimation.

```
[beta,sigma,E,V] = mvregress(Xcell,Y);
beta
```

```
beta = 8×1

    0.3950
   -6.3064
   -6.3584
   -9.2284
   -8.6663
```

These coefficient estimates show:

- The expected city and highway MPG for cars of average wheel base, curb weight, and fuel type 11 are `33.5` and `38.6`, respectively. For fuel type 20, the expected city and highway MPG are `33.5476 - 9.2284 = 24.3192` and `38.5720 - 8.6663 = 29.9057`.
- An increase of one standard deviation in curb weight has almost the same effect on expected city and highway MPG. Given all else is equal, the expected MPG decreases by about `6.3` with each one standard deviation increase in curb weight, for both city and highway MPG.
- For each one standard deviation increase in wheel base, the expected city MPG increases `0.972`, while the expected highway MPG increases by only `0.395`, given all else is equal.

Compute standard errors.

The standard errors for the regression coefficients are the square root of the diagonal of the variance-covariance matrix, `V`.

```
se = sqrt(diag(V))
```

```
se = 8×1

    0.7365
    0.7599
    0.3589
    0.3702
    0.3497
```

```
    0.3608
    0.7790
    0.8037
```

Reshape coefficient matrix.

You can easily reshape the regression coefficients into the original 4-by-2 matrix.

```
B = reshape(beta,2,4)'
```

```
B = 4×2

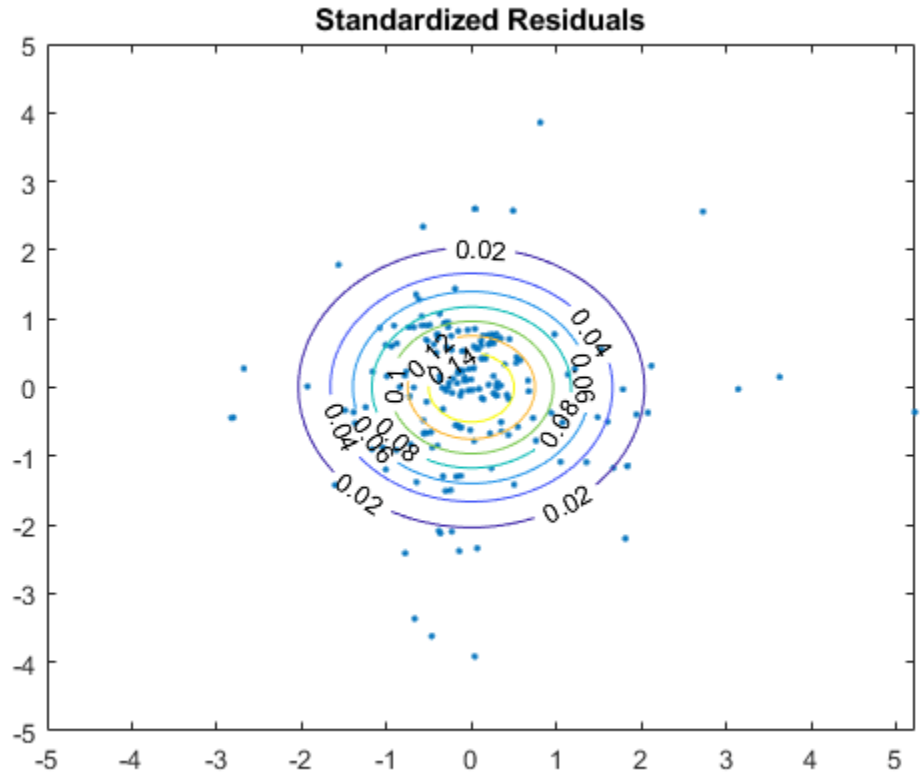
   33.5476   38.5720
    0.9723    0.3950
   -6.3064   -6.3584
   -9.2284   -8.6663
```

Check model assumptions.

Under the model assumptions, $z = \mathbf{E}\Sigma^{-1/2}$ should be independent, with a bivariate standard normal distribution. In this 2-D case, you can assess the validity of this assumption using a scatter plot.

```
z = E/chol(sigma);
figure()
plot(z(:,1),z(:,2),'.')
title('Standardized Residuals')
hold on

% Overlay standard normal contours
z1 = linspace(-5,5);
z2 = linspace(-5,5);
[zx,zy] = meshgrid(z1,z2);
zgrid = [reshape(zx,100^2,1),reshape(zy,100^2,1)];
zn = reshape(mvnpdf(zgrid),100,100);
[c,h] = contour(zx,zy,zn);
clabel(c,h)
```



Several residuals are larger than expected, but overall, there is little evidence against the multivariate normality assumption.

Fixed Effects Panel Model with Concurrent Correlation

This example shows how to perform panel data analysis using `mvregress`. First, a fixed effects model with concurrent correlation is fit by ordinary least squares (OLS) to some panel data. Then, the estimated error covariance matrix is used to get panel corrected standard errors for the regression coefficients.

Load sample data.

Load the sample panel data.

```
load panelData
```

The dataset array, `panelData`, contains yearly observations on eight cities for 6 years. This is simulated data.

Define variables.

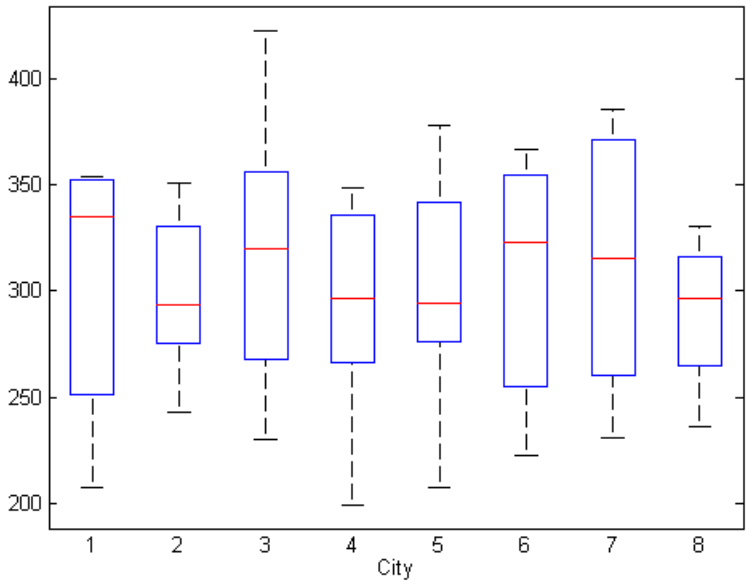
The first variable, `Growth`, measures economic growth (the response variable). The second and third variables are city and year indicators, respectively. The last variable, `Employ`, measures employment (the predictor variable).

```
y = panelData.Growth;
city = panelData.City;
year = panelData.Year;
x = panelData.Employ;
```

Plot data grouped by category.

To look for potential city-specific fixed effects, create a box plot of the response grouped by city.

```
figure()
boxplot(y,city)
xlabel('City')
```

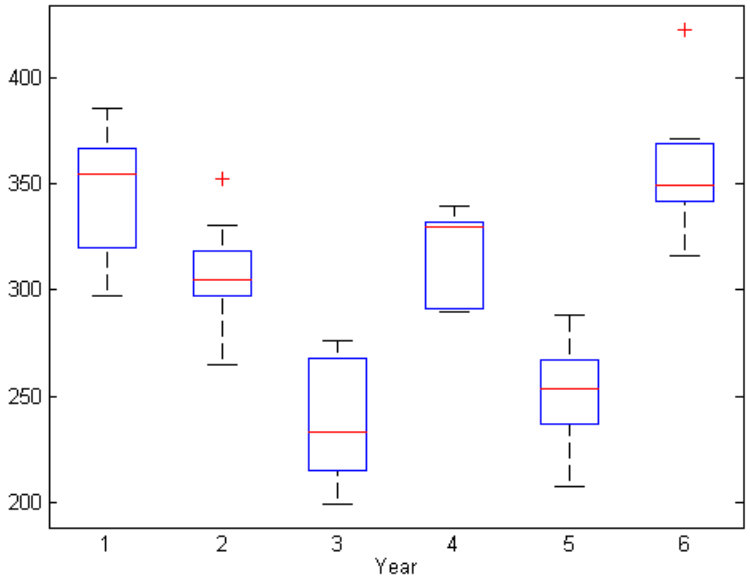


There does not appear to be any systematic differences in the mean response among cities.

Plot data grouped by a different category.

To look for potential year-specific fixed effects, create a box plot of the response grouped by year.

```
figure()
boxplot(y,year)
xlabel('Year')
```



Some evidence of systematic differences in the mean response between years seems to exist.

Format response data.

Let y_{ij} denote the response for city $j = 1,...,d$, in year $i = 1,...,n$. Similarly, x_{ij} is the corresponding value of the predictor variable. In this example, $n = 6$ and $d = 8$.

Consider fitting a year-specific fixed effects model with a constant slope and concurrent correlation among cities in the same year,

$$y_{ij} = \alpha_i + \beta_1 x_{ij} + \varepsilon_{ij}, \quad i = 1, \ldots, n, \; j = 1, \ldots, d,$$

where $\varepsilon_i = (\varepsilon_{i1}, \ldots, \varepsilon_{id})' \sim MVN(\mathbf{0}, \Sigma)$. The concurrent correlation accounts for any unmeasured, time-static factors that might impact growth similarly for some cities. For example, cities with close spatial proximity might be more likely to have similar economic growth.

To fit this model using `mvregress`, reshape the response data into an n-by-d matrix.

```
n = 6; d = 8;
Y = reshape(y,n,d);
```

Format design matrices.

Create a length-n cell array of d-by-K design matrices. For this model, there are $K = 7$ parameters ($d = 6$ intercept terms and a slope).

Suppose the vector of parameters is arranged as

$$\beta = \begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \vdots \\ \alpha_6 \\ \beta_1 \end{pmatrix}.$$

In this case, the first design matrix for year 1 looks like

$$X\left\{1\right\} = \begin{pmatrix} 1 & 0 & \cdots & 0 & x_{11} \\ 1 & 0 & \cdots & 0 & x_{12} \\ \vdots & \vdots & \cdots & 0 & \vdots \\ 1 & 0 & \cdots & 0 & x_{18} \end{pmatrix},$$

and the second design matrix for year 2 looks like

$$X\left\{2\right\} = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 & x_{21} \\ 0 & 1 & 0 & \cdots & 0 & x_{22} \\ \vdots & \vdots & 0 & \cdots & 0 & \vdots \\ 0 & 1 & 0 & \cdots & 0 & x_{28} \end{pmatrix}.$$

The design matrices for the remaining 4 years are similar.

```
K = 7; N = n*d;
X = cell(n,1);
for i = 1:n
    x0 = zeros(d,K-1);
    x0(:,i) = 1;
    X{i} = [x0,x(i:n:N)];
end
```

Fit the model.

Fit the model using ordinary least squares (OLS).

```
[b,sig,E,V] = mvregress(X,Y,'algorithm','cwls');
b
```

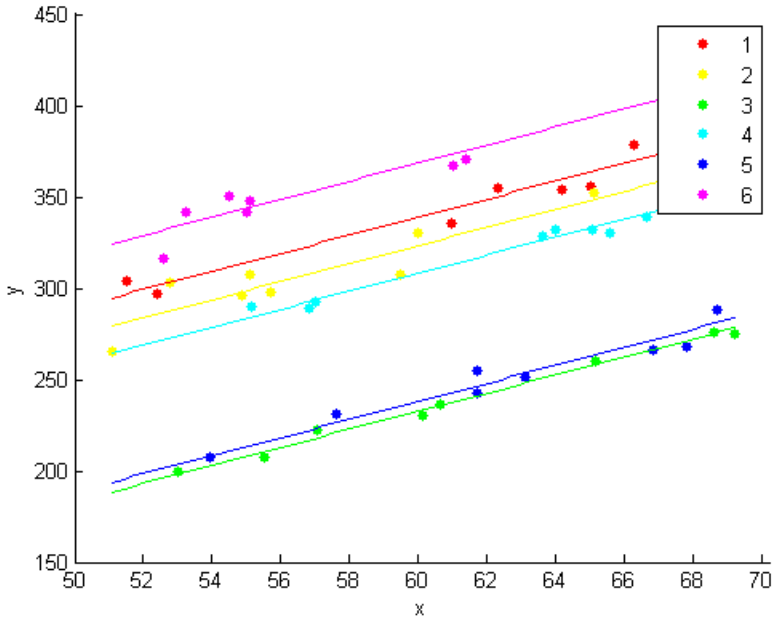
```
b =

   41.6878
   26.1864
  -64.5107
   11.0924
  -59.1872
   71.3313
    4.9525
```

Plot fitted model.

```
xx = linspace(min(x),max(x));
axx = repmat(b(1:K-1),1,length(xx));
bxx = repmat(b(K)*xx,n,1);
yhat =  axx + bxx;

figure()
hPoints = gscatter(x,y,year);
hold on
hLines = plot(xx,yhat);
for i=1:n
   set(hLines(i),'color',get(hPoints(i),'color'));
end
hold off
```

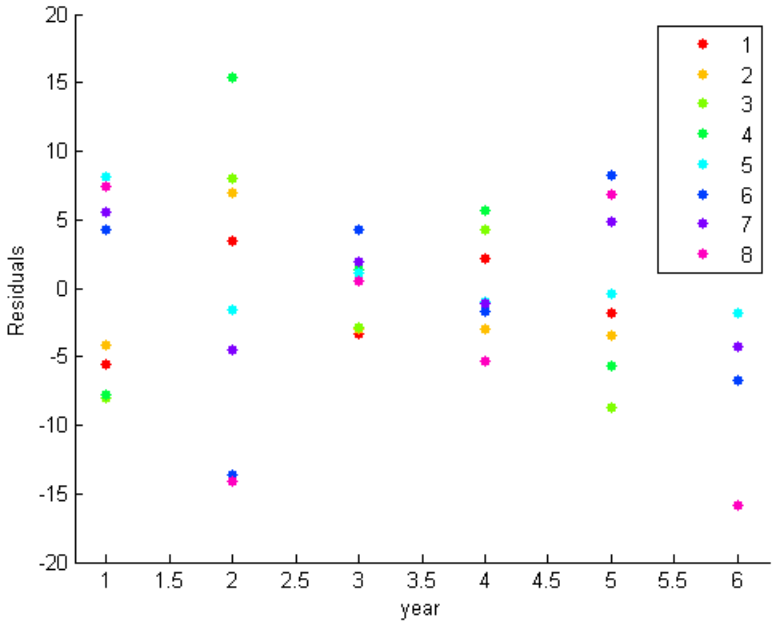


The model with year-specific intercepts and common slope appears to fit the data quite well.

Residual correlation.

Plot the residuals, grouped by year.

```
figure()
gscatter(year,E(:),city)
ylabel('Residuals')
```



The residual plot suggests concurrent correlation is present. For examples, cities 1, 2, 3, and 4 are consistently above or below average as a group in any given year. The same is true for the collection of cities 5, 6, 7, and 8. As seen in the exploratory plots, there are no systematic city-specific effects.

Panel corrected standard errors.

Use the estimated error variance-covariance matrix to compute panel corrected standard errors for the regression coefficients.

```
XX = cell2mat(X);
S = kron(eye(n),sig);
Vpcse = inv(XX'*XX)*XX'*S*XX*inv(XX'*XX);
se = sqrt(diag(Vpcse))
```

```
se =

    9.3750
    8.6698
    9.3406
    9.4286
    9.5729
    8.8207
    0.1527
```

Longitudinal Analysis

This example shows how to perform longitudinal analysis using `mvregress`.

Load sample data.

Load the sample longitudinal data.

```
load longitudinalData
```

The matrix Y contains response data for 16 individuals. The response is the blood level of a drug measured at five time points (t = 0, 2, 4, 6, and 8). Each row of Y corresponds to an individual, and each column corresponds to a time point. The first eight subjects are female, and the second eight subjects are male. This is simulated data.

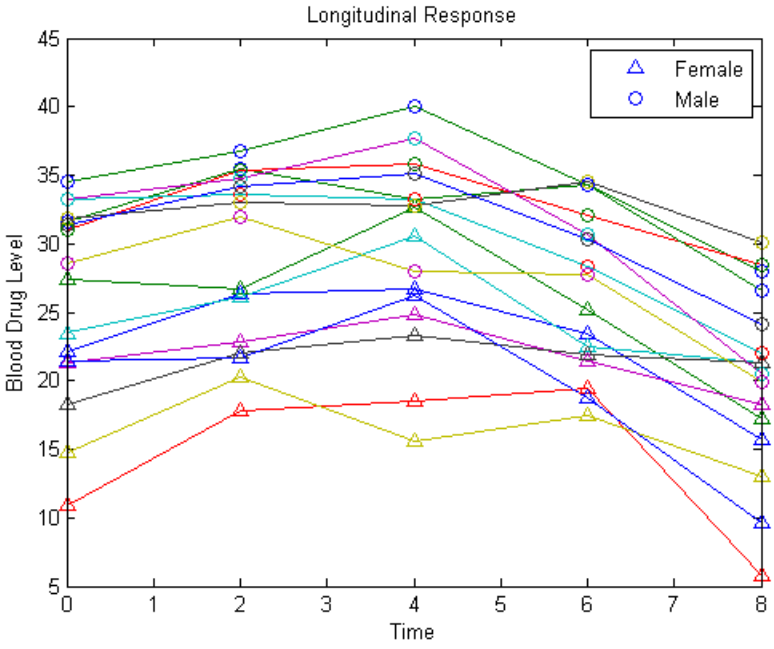
Plot data.

Plot the data for all 16 subjects.

```
figure()
t = [0,2,4,6,8];
plot(t,Y)
hold on

hf = plot(t,Y(1:8,:),'^');
hm = plot(t,Y(9:16,:),'o');
legend([hf(1),hm(1)],'Female','Male','Location','NorthEast')

title('Longitudinal Response')
ylabel('Blood Drug Level')
xlabel('Time')
hold off
```



Define design matrices.

Let y_{ij} denote the response for individual $i = 1,...,n$ measured at times t_{ij}, $j = 1,...,d$. In this example, $n = 16$ and $d = 5$. Let G_i denote the gender of individual i, where $G_i = 1$ for males and 0 for females.

Consider fitting a quadratic longitudinal model, with a separate slope and intercept for each gender,

$$y_{ij} = \beta_0 + \beta_1 G_i + \beta_2 t_{ij} + \beta_3 t_{ij}^2 + \beta_4 G_i \times t_{ij} + \beta_5 G_i \times t_{ij}^2 + \varepsilon_{ij},$$

where $\varepsilon_i = (\varepsilon_{i1}, \ldots, \varepsilon_{id})' \sim MVN(\mathbf{0}, \Sigma)$. The error correlation accounts for clustering within an individual.

To fit this model using `mvregress`, the response data should be in an n-by-d matrix. `Y` is already in the proper format.

Next, create a length-n cell array of d-by-K design matrices. For this model, there are $K = 6$ parameters.

For individual i, the 5-by-6 design matrix is

$$X\left\{i\right\} = \begin{pmatrix} 1 & G_i & t_{i1} & t_{i1}^2 & G_i \times t_{i1} & G_i \times t_{i1}^2 \\ 1 & G_i & t_{i2} & t_{i2}^2 & G_i \times t_{i2} & G_i \times t_{i2}^2 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & G_i & t_{i5} & t_{i5}^2 & G_i \times t_{i5} & G_i \times t_{i5}^2 \end{pmatrix},$$

corresponding to the parameter vector

$$\beta = \begin{pmatrix} \beta_0 \\ \beta_1 \\ \vdots \\ \beta_5 \end{pmatrix}.$$

The matrix `X1` has the design matrix for a female, and `X2` has the design matrix for a male.

Create a cell array of design matrices. The first eight individuals are females, and the second eight are males.

```
X = cell(8,1);
X(1:8) = {X1};
X(9:16) = {X2};
```

Fit the model.

Fit the model using maximum likelihood estimation. Display the estimated coefficients and standard errors.

```
[b,sig,E,V,loglikF] = mvregress(X,Y);
[b sqrt(diag(V))]
```

```
ans =

   18.8619    0.7432
   13.0942    1.0511
```

```
    2.5968    0.2845
   -0.3771    0.0398
   -0.5929    0.4023
    0.0290    0.0563
```

The coefficients on the interaction terms (in the last two rows of `b`) do not appear significant. You can use the value of the loglikelihood objective function for this fit, `loglikF`, to compare this model to one without the interaction terms using a likelihood ratio test.

Plot fitted model.

Plot the fitted lines for females and males.

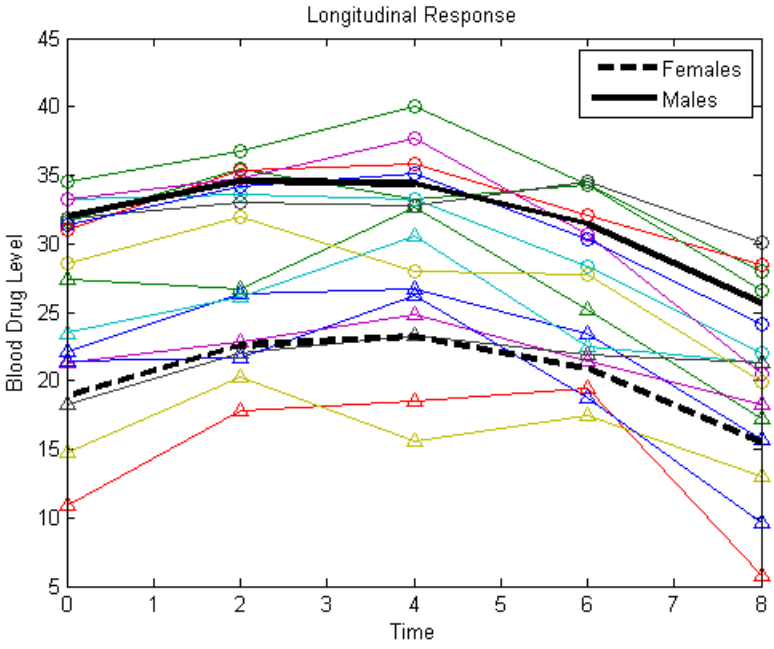
```
Yhatf = X1*b;
Yhatm = X2*b;

figure()
plot(t,Y)
hold on

plot(t,Y(1:8,:),'^',t,Y(9:16,:),'o')

hf = plot(t,Yhatf,'k--','LineWidth',3);
hm = plot(t,Yhatm,'k','LineWidth',3);
legend([hf,hm],'Females','Males','Location','NorthEast')

title('Longitudinal Response')
ylabel('Blood Drug Level')
xlabel('Time')
hold off
```



Define a reduced model.

Fit the model without interaction terms,

$$y_{ij} = \beta_0 + \beta_1 G_i + \beta_2 t_{ij} + \beta_3 t_{ij}^2 + \varepsilon_{ij},$$

where $\varepsilon_i = (\varepsilon_{i1}, \ldots, \varepsilon_{id})' \sim MVN(\mathbf{0}, \Sigma)$.

This model has four coefficients, which correspond to the first four columns of the design matrices `X1` and `X2` (for females and males, respectively).

```
X1R = X1(:,1:4);
X2R = X2(:,1:4);

XR = cell(8,1);
XR(1:8) = {X1R};
XR(9:16) = {X2R};
```

Fit the reduced model.

Fit this model using maximum likelihood estimation. Display the estimated coefficients and their standard errors.

```
[bR,sigR,ER,VR,loglikR] = mvregress(XR,Y);
[bR,sqrt(diag(VR))]
```

```
ans =

   19.3765    0.6898
   12.0936    0.8591
    2.2919    0.2139
   -0.3623    0.0283
```

Conduct a likelihood ratio test.

Compare the two models using a likelihood ratio test. The null hypothesis is that the reduced model is sufficient. The alternative is that the reduced model is inadequate (compared to the full model with the interaction terms).

The likelihood ratio test statistic is compared to a chi-squared distribution with two degrees of freedom (for the two coefficients being dropped).

```
LR = 2*(loglikF-loglikR);
pval = 1 - chi2cdf(LR,2)
```

```
pval =

    0.0803
```

The *p*-value `0.0803` indicates that the null hypothesis is not rejected at the 5% significance level. Therefore, there is insufficient evidence that the extra terms improve the fit.

Multidimensional Scaling

One of the most important goals in visualizing data is to get a sense of how near or far points are from each other. Often, you can do this with a scatter plot. However, for some analyses, the data that you have might not be in the form of points at all, but rather in the form of pairwise similarities or dissimilarities between cases, observations, or subjects. There are no points to plot.

Even if your data are in the form of points rather than pairwise distances, a scatter plot of those data might not be useful. For some kinds of data, the relevant way to measure how near two points are might not be their Euclidean distance. While scatter plots of the raw data make it easy to compare Euclidean distances, they are not always useful when comparing other kinds of inter-point distances, city block distance for example, or even more general dissimilarities. Also, with a large number of variables, it is very difficult to visualize distances unless the data can be represented in a small number of dimensions. Some sort of dimension reduction is usually necessary.

Multidimensional scaling (MDS) is a set of methods that address all these problems. MDS allows you to visualize how near points are to each other for many kinds of distance or dissimilarity metrics and can produce a representation of your data in a small number of dimensions. MDS does not require raw data, but only a matrix of pairwise distances or dissimilarities.

- “Classical Multidimensional Scaling” on page 15-40

Nonclassical and Nonmetric Multidimensional Scaling

In this section...

Perform nonclassical multidimensional scaling using `mdscale`.

Nonclassical Multidimensional Scaling

The function `mdscale` performs nonclassical multidimensional scaling. As with `cmdscale`, you use `mdscale` either to visualize dissimilarity data for which no “locations” exist, or to visualize high-dimensional data by reducing its dimensionality. Both functions take a matrix of dissimilarities as an input and produce a configuration of points. However, `mdscale` offers a choice of different criteria to construct the configuration, and allows missing data and weights.

For example, the cereal data include measurements on 10 variables describing breakfast cereals. You can use `mdscale` to visualize these data in two dimensions. First, load the data. For clarity, this example code selects a subset of 22 of the observations.

```
load cereal.mat
X = [Calories Protein Fat Sodium Fiber ...
    Carbo Sugars Shelf Potass Vitamins];
% Take a subset from a single manufacturer
mfg1 = strcmp('G',cellstr(Mfg));
X = X(mfg1,:);
size(X)
ans =
    22 10
```

Then use `pdist` to transform the 10-dimensional data into dissimilarities. The output from `pdist` is a symmetric dissimilarity matrix, stored as a vector containing only the (23*22/2) elements in its upper triangle.

```
dissimilarities = pdist(zscore(X),'cityblock');
size(dissimilarities)
ans =
     1   231
```

This example code first standardizes the cereal data, and then uses city block distance as a dissimilarity. The choice of transformation to dissimilarities is application-dependent, and the choice here is only for simplicity. In some applications, the original data are already in the form of dissimilarities.

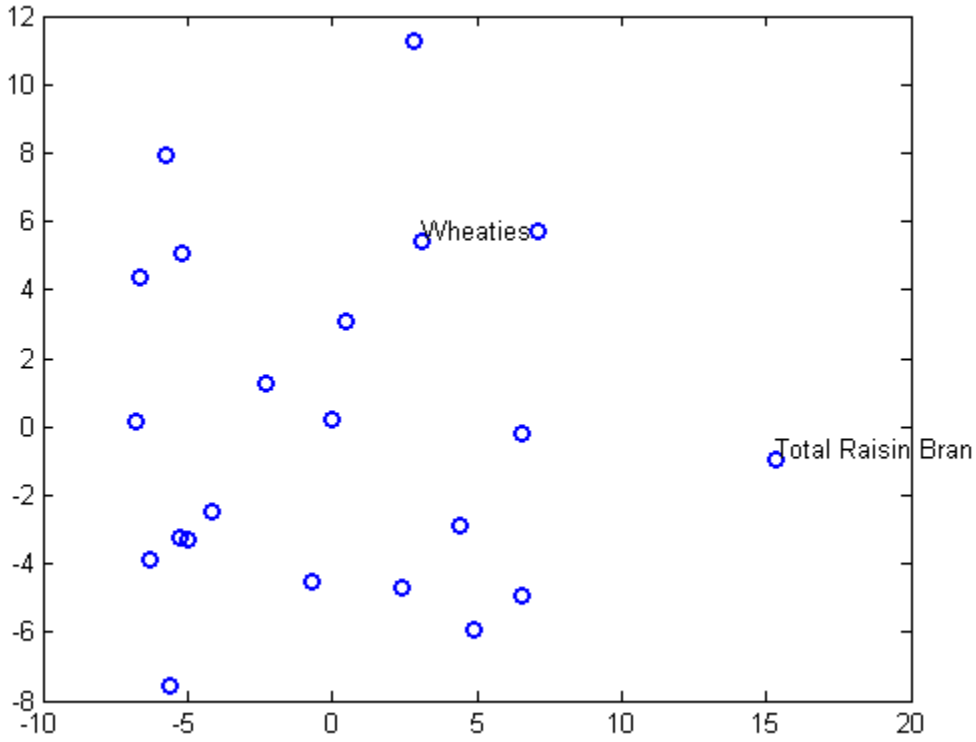
Next, use `mdscale` to perform metric MDS. Unlike `cmdscale`, you must specify the desired number of dimensions, and the method to use to construct the output configuration. For this example, use two dimensions. The metric STRESS criterion is a common method for computing the output; for other choices, see the `mdscale` reference page in the online documentation. The second output from `mdscale` is the value of that criterion evaluated for the output configuration. It measures the how well the inter-point distances of the output configuration approximate the original input dissimilarities:

```
[Y,stress] =...
mdscale(dissimilarities,2,'criterion','metricstress');
```

```
stress
stress =
    0.1856
```

A scatterplot of the output from `mdscale` represents the original 10-dimensional data in two dimensions, and you can use the `gname` function to label selected points:

```
plot(Y(:,1),Y(:,2),'o','LineWidth',2);
gname(Name(mfg1))
```



Nonmetric Multidimensional Scaling

Metric multidimensional scaling creates a configuration of points whose inter-point distances approximate the given dissimilarities. This is sometimes too strict a requirement, and non-metric scaling is designed to relax it a bit. Instead of trying to approximate the dissimilarities themselves, non-metric scaling approximates a nonlinear, but monotonic, transformation of them. Because of the monotonicity, larger or smaller distances on a plot of the output will correspond to larger or smaller dissimilarities, respectively. However, the nonlinearity implies that `mdscale` only attempts to preserve the ordering of dissimilarities. Thus, there may be contractions or expansions of distances at different scales.

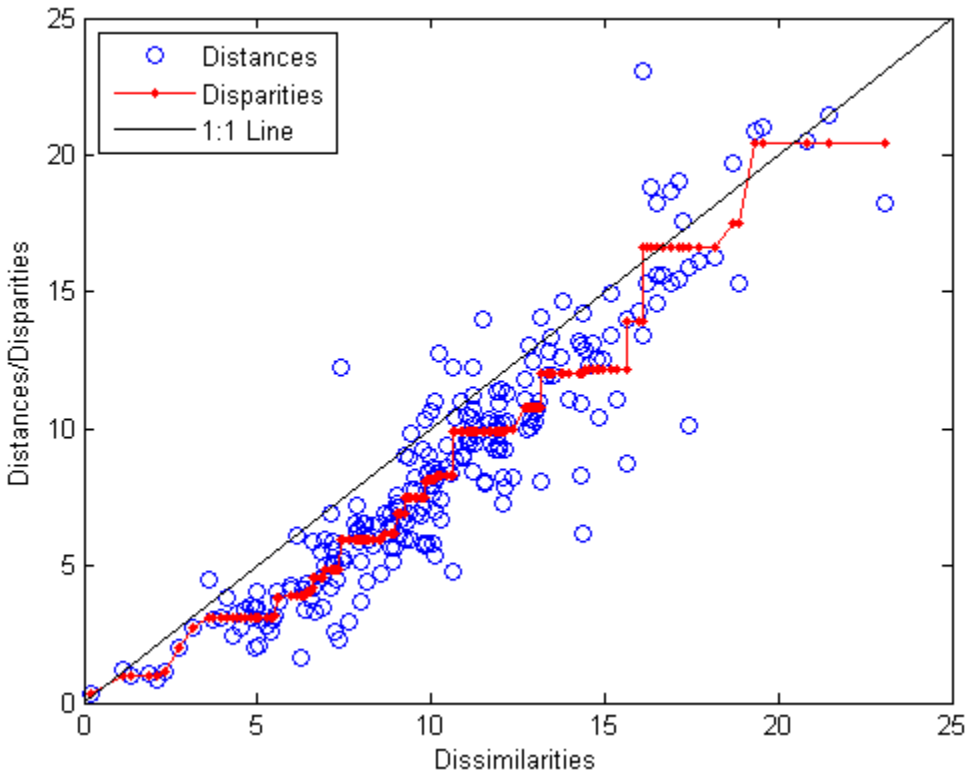
You use `mdscale` to perform nonmetric MDS in much the same way as for metric scaling. The nonmetric STRESS criterion is a common method for computing the output; for more choices, see the `mdscale` reference page in the online documentation. As with metric scaling, the second output from `mdscale` is the value of that criterion evaluated for the output configuration. For nonmetric scaling,

however, it measures the how well the inter-point distances of the output configuration approximate the disparities. The disparities are returned in the third output. They are the transformed values of the original dissimilarities:

```
[Y,stress,disparities] = ...
mdscale(dissimilarities,2,'criterion','stress');
stress
stress =
    0.1562
```

To check the fit of the output configuration to the dissimilarities, and to understand the disparities, it helps to make a Shepard plot:

```
distances = pdist(Y);
[dum,ord] = sortrows([disparities(:) dissimilarities(:)]);
plot(dissimilarities,distances,'bo', ...
     dissimilarities(ord),disparities(ord),'r.-', ...
     [0 25],[0 25],'k-')
xlabel('Dissimilarities')
ylabel('Distances/Disparities')
legend({'Distances' 'Disparities' '1:1 Line'},...
       'Location','NorthWest');
```



This plot shows that `mdscale` has found a configuration of points in two dimensions whose inter-point distances approximates the disparities, which in turn are a nonlinear transformation of the original dissimilarities. The concave shape of the disparities as a function of the dissimilarities indicates that

fit tends to contract small distances relative to the corresponding dissimilarities. This may be perfectly acceptable in practice.

`mdscale` uses an iterative algorithm to find the output configuration, and the results can often depend on the starting point. By default, `mdscale` uses `cmdscale` to construct an initial configuration, and this choice often leads to a globally best solution. However, it is possible for `mdscale` to stop at a configuration that is a local minimum of the criterion. Such cases can be diagnosed and often overcome by running `mdscale` multiple times with different starting points. You can do this using the `'start'` and `'replicates'` name-value pair arguments. The following code runs five replicates of MDS, each starting at a different randomly-chosen initial configuration. The criterion value is printed out for each replication; `mdscale` returns the configuration with the best fit.

```
opts = statset('Display','final');
[Y,stress] =...
mdscale(dissimilarities,2,'criterion','stress',...
'start','random','replicates',5,'Options',opts);

35 iterations, Final stress criterion = 0.156209
31 iterations, Final stress criterion = 0.156209
48 iterations, Final stress criterion = 0.171209
33 iterations, Final stress criterion = 0.175341
32 iterations, Final stress criterion = 0.185881
```

Notice that `mdscale` finds several different local solutions, some of which do not have as low a stress value as the solution found with the `cmdscale` starting point.

Classical Multidimensional Scaling

This example shows how to use `cmdscale` to perform classical (metric) multidimensional scaling, also known as principal coordinates analysis.

`cmdscale` takes as an input a matrix of inter-point distances and creates a configuration of points. Ideally, those points are in two or three dimensions, and the Euclidean distances between them reproduce the original distance matrix. Thus, a scatter plot of the points created by `cmdscale` provides a visual representation of the original distances.

As a very simple example, you can reconstruct a set of points from only their inter-point distances. First, create some four dimensional points with a small component in their fourth coordinate, and reduce them to distances.

```
rng default;  % For reproducibility
X = [normrnd(0,1,10,3),normrnd(0,.1,10,1)];
D = pdist(X,'euclidean');
```

Next, use `cmdscale` to find a configuration with those inter-point distances. `cmdscale` accepts distances as either a square matrix, or, as in this example, in the vector upper-triangular form produced by `pdist`.

```
[Y,eigvals] = cmdscale(D);
```

`cmdscale` produces two outputs. The first output, `Y`, is a matrix containing the reconstructed points. The second output, `eigvals`, is a vector containing the sorted eigenvalues of what is often referred to as the "scalar product matrix," which, in the simplest case, is equal to `Y*Y'`. The relative magnitudes of those eigenvalues indicate the relative contribution of the corresponding columns of `Y` in reproducing the original distance matrix `D` with the reconstructed points.

```
format short g
[eigvals eigvals/max(abs(eigvals))]
```

```
ans = 10×2

        35.41            1
       11.158      0.31511
       1.6894      0.04771
       0.1436    0.0040553
   5.1216e-15   1.4464e-16
   3.4766e-15   9.8181e-17
   1.9662e-15   5.5527e-17
   1.1713e-15   3.3079e-17
  -1.5864e-15    -4.48e-17
  -3.2498e-15  -9.1776e-17
```

If `eigvals` contains only positive and zero (within round-off error) eigenvalues, the columns of `Y` corresponding to the positive eigenvalues provide an exact reconstruction of `D`, in the sense that their inter-point Euclidean distances, computed using `pdist`, for example, are identical (within round-off) to the values in `D`.

```
maxerr4 = max(abs(D - pdist(Y)))   % Exact reconstruction
```

```
maxerr4 =
   2.6645e-15
```

If two or three of the eigenvalues in `eigvals` are much larger than the rest, then the distance matrix based on the corresponding columns of `Y` nearly reproduces the original distance matrix `D`. In this sense, those columns form a lower-dimensional representation that adequately describes the data. However it is not always possible to find a good low-dimensional reconstruction.

```
maxerr3 = max(abs(D - pdist(Y(:,1:3))))  % Good reconstruction in 3D
```

```
maxerr3 =
     0.043142
```

```
maxerr2 = max(abs(D - pdist(Y(:,1:2))))  % Poor reconstruction in 2D
```

```
maxerr2 =
      0.98315
```

The reconstruction in three dimensions reproduces `D` very well, but the reconstruction in two dimensions has errors that are of the same order of magnitude as the largest values in `D`.

```
max(max(D))
```

```
ans =
       5.8974
```

Often, `eigvals` contains some negative eigenvalues, indicating that the distances in `D` cannot be reproduced exactly. That is, there might not be any configuration of points whose inter-point Euclidean distances are given by `D`. If the largest negative eigenvalue is small in magnitude relative to the largest positive eigenvalues, then the configuration returned by `cmdscale` might still reproduce `D` well.

Procrustes Analysis

In this section...

Compare Landmark Data

The `procrustes` function analyzes the distribution of a set of shapes using Procrustes analysis. This analysis method matches landmark data (geometric locations representing significant features in a given shape) to calculate the best shape-preserving Euclidean transformations. These transformations minimize the differences in location between compared landmark data.

Procrustes analysis is also useful in conjunction with multidimensional scaling. In “Construct a Map Using Multidimensional Scaling” on page 33-647 there is an observation that the orientation of the reconstructed points is arbitrary. Two different applications of multidimensional scaling could produce reconstructed points that are very similar in principle, but that look different because they have different orientations. The `procrustes` function transforms one set of points to make them more comparable to the other.

Data Input

The `procrustes` function takes two matrices as input:

- The target shape matrix X has dimension $n \times p$, where n is the number of landmarks in the shape and p is the number of measurements per landmark.
- The comparison shape matrix Y has dimension $n \times q$ with $q \le p$. If there are fewer measurements per landmark for the comparison shape than the target shape ($q < p$), the function adds columns of zeros to Y, yielding an $n \times p$ matrix.

The equation to obtain the transformed shape, Z, is

$$Z = bYT + c \tag{15-1}$$

where:

- b is a scaling factor that stretches ($b > 1$) or shrinks ($b < 1$) the points.
- T is the orthogonal rotation and reflection matrix.
- c is a matrix with constant values in each column, used to shift the points.

The `procrustes` function chooses b, T, and c to minimize the distance between the target shape X and the transformed shape Z as measured by the least squares criterion:

$$\sum_{i=1}^{n}\sum_{j=1}^{p}(X_{ij} - Z_{ij})^2$$

Preprocess Data for Accurate Results

Procrustes analysis is appropriate when all `p` measurement dimensions have similar scales. The analysis would be inaccurate, for example, if the columns of Z had different scales:

- The first column is measured in milliliters ranging from 2,000 to 6,000.
- The second column is measured in degrees Celsius ranging from 10 to 25.
- The third column is measured in kilograms ranging from 50 to 230.

In such cases, standardize your variables by:

1. Subtracting the sample mean from each variable.
2. Dividing each resultant variable by its sample standard deviation.

Use the `zscore` function to perform this standardization.

Compare Handwritten Shapes Using Procrustes Analysis

This example shows how to use Procrustes analysis to compare two handwritten number threes. Visually and analytically explore the effects of forcing size and reflection changes.

Load and Display the Original Data

Input landmark data for two handwritten number threes.

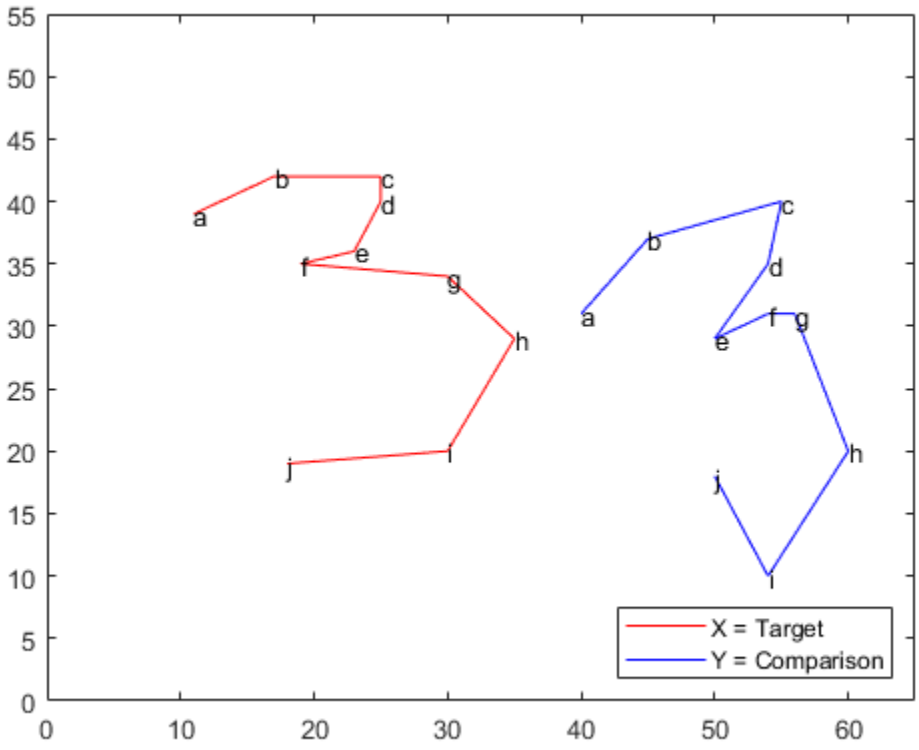
```
A = [11 39;17 42;25 42;25 40;23 36;19 35;30 34;35 29;...
30 20;18 19];
B = [15 31;20 37;30 40;29 35;25 29;29 31;31 31;35 20;...
29 10;25 18];
```

Create X and Y from A and B , moving B to the side to make each shape more visible.

```
X = A;
Y = B + repmat([25 0], 10,1);
```

Plot the shapes, using letters to designate the landmark points. Lines in the figure join the points to indicate the drawing path of each shape.

```
plot(X(:,1), X(:,2),'r-', Y(:,1), Y(:,2),'b-');
text(X(:,1), X(:,2),('abcdefghij')')
text(Y(:,1), Y(:,2),('abcdefghij')')
legend('X = Target','Y = Comparison','location','SE')
xlim([0 65]);
ylim([0 55]);
```



Calculate the Best Transformation

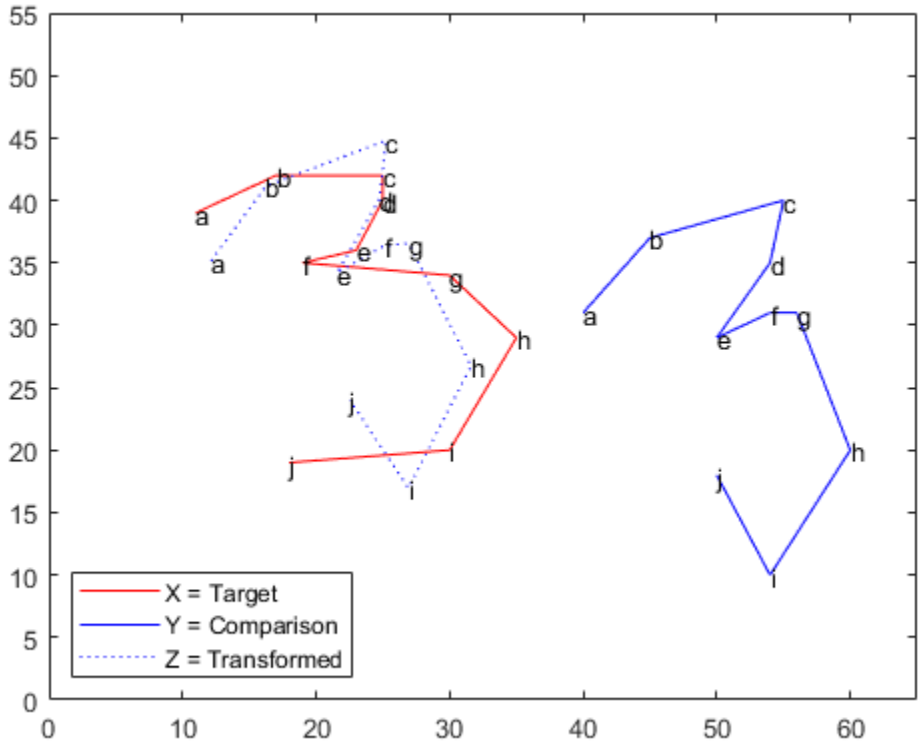
Use Procrustes analysis to find the transformation that minimizes distances between landmark data points.

```
[d,Z,tr] = procrustes(X,Y);
```

The outputs of the function are `d` (a standardized dissimilarity measure), `Z` (a matrix of the transformed landmarks), and `tr` (a structure array of the computed transformation with fields `T` , `b` , and `c` which correspond to the transformation equation).

Visualize the transformed shape, `Z` , using a dashed blue line.

```
plot(X(:,1), X(:,2),'r-', Y(:,1), Y(:,2),'b-',...
Z(:,1),Z(:,2),'b:');
text(X(:,1), X(:,2),('abcdefghij')')
text(Y(:,1), Y(:,2),('abcdefghij')')
text(Z(:,1), Z(:,2),('abcdefghij')')
legend('X = Target','Y = Comparison',...
'Z = Transformed','location','SW')
xlim([0 65]);
ylim([0 55]);
```



Examine the Similarity of the Two Shapes

Use two different numerical values, the dissimilarity measure `d` and the scaling measure `b` , to assess the similarity of the target shape and the transformed shape.

The dissimilarity measure d gives a number between 0 and 1 describing the difference between the target shape and the transformed shape. Values near 0 imply more similar shapes, while values near 1 imply dissimilarity.

```
d
```

```
d = 0.1502
```

The small value of d in this case shows that the two shapes are similar. `procrustes` calculates d by comparing the sum of squared deviations between the set of points with the sum of squared deviations of the original points from their column means.

```
numerator = sum(sum((X-Z).^2))
```

```
numerator = 166.5321
```

```
denominator = sum(sum(bsxfun(@minus,X,mean(X)).^2))
```

```
denominator = 1.1085e+03
```

```
ratio = numerator/denominator
```

```
ratio = 0.1502
```

The resulting measure d is independent of the scale of the size of the shapes and takes into account only the similarity of landmark data.

Examine the size similarity of the shapes.

```
tr.b
```

```
ans = 0.9291
```

The sizes of the target and comparison shapes in the previous figure appear similar. This visual impression is reinforced by the value of b = % 0.93, which implies that the best transformation results in shrinking the comparison shape by a factor .93 (only 7%).

Restrict the Form of the Transformations

Explore the effects of manually adjusting the scaling and reflection coefficients.

Force b to equal 1 (set `'Scaling'` to false) to examine the amount of dissimilarity in size of the target and transformed figures.

```
ds = procrustes(X,Y,'Scaling',false)
```

```
ds = 0.1552
```

In this case, setting `'Scaling'` to false increases the calculated value of d only 0.0049, which further supports the similarity in the size of the two number threes. A larger increase in d would have indicated a greater size discrepancy.

This example requires only a rotation, not a reflection, to align the shapes. You can show this by observing that the determinant of the matrix T is 1 in this analysis.

```
det(tr.T)
```

```
ans = 1.0000
```

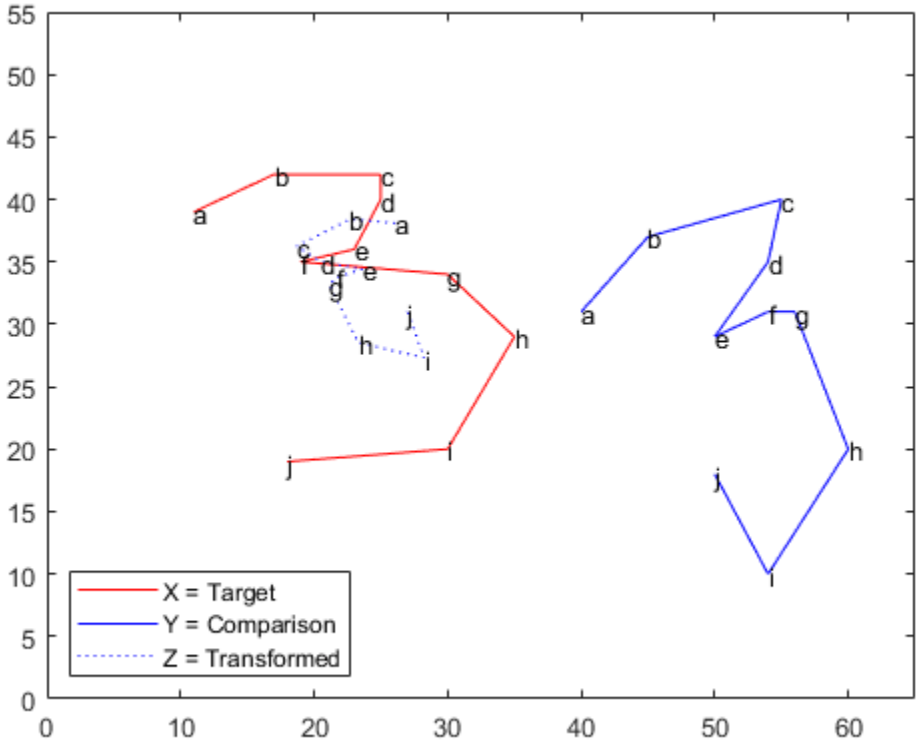
If you need a reflection in the transformation, the determinant of T is -1. You can force a reflection into the transformation as follows.

```
[dr,Zr,trr] = procrustes(X,Y,'Reflection',true);
dr
```

```
dr = 0.8130
```

The d value increases dramatically, indicating that a forced reflection leads to a poor transformation of the landmark points. A plot of the transformed shape shows a similar result.

```
plot(X(:,1), X(:,2),'r-', Y(:,1), Y(:,2),'b-',...
Zr(:,1),Zr(:,2),'b:');
text(X(:,1), X(:,2),('abcdefghij')')
text(Y(:,1), Y(:,2),('abcdefghij')')
text(Zr(:,1), Zr(:,2),('abcdefghij')')
legend('X = Target','Y = Comparison',...
'Z = Transformed','Location','SW')
xlim([0 65]);
ylim([0 55]);
```



The landmark data points are now further away from their target counterparts. The transformed three is now an undesirable mirror image of the target three.

It appears that the shapes might be better matched if you flipped the transformed shape upside down. Flipping the shapes would make the transformation even worse, however, because the

landmark data points would be further away from their target counterparts. From this example, it is clear that manually adjusting the scaling and reflection parameters is generally not optimal.

Introduction to Feature Selection

This topic provides an introduction to feature selection algorithms and describes the feature selection functions available in Statistics and Machine Learning Toolbox.

Feature Selection Algorithms

Feature selection reduces the dimensionality of data by selecting only a subset of measured features (predictor variables) to create a model. Feature selection algorithms search for a subset of predictors that optimally models measured responses, subject to constraints such as required or excluded features and the size of the subset. The main benefits of feature selection are to improve prediction performance, provide faster and more cost-effective predictors, and provide a better understanding of the data generation process [1]. Using too many features can degrade prediction performance even when all features are relevant and contain information about the response variable.

You can categorize feature selection algorithms into three types:

- "Filter Type Feature Selection" on page 15-50 — The filter type feature selection algorithm measures feature importance based on the characteristics of the features, such as feature variance and feature relevance to the response. You select important features as part of a data preprocessing step and then train a model using the selected features. Therefore, filter type feature selection is uncorrelated to the training algorithm.
- "Wrapper Type Feature Selection" on page 15-53 — The wrapper type feature selection algorithm starts training using a subset of features and then adds or removes a feature using a selection criterion. The selection criterion directly measures the change in model performance that results from adding or removing a feature. The algorithm repeats training and improving a model until its stopping criteria are satisfied.
- "Embedded Type Feature Selection" on page 15-54 — The embedded type feature selection algorithm learns feature importance as part of the model learning process. Once you train a model, you obtain the importance of the features in the trained model. This type of algorithm selects features that work well with a particular learning process.

In addition, you can categorize feature selection algorithms according to whether or not an algorithm ranks features sequentially. The minimum redundancy maximum relevance (MRMR) algorithm and stepwise regression are two examples of the sequential feature selection algorithm. For details, see "Sequential Feature Selection" on page 15-61.

You can compare the importance of predictor variables visually by creating partial dependence plots (PDP) and individual conditional expectation (ICE) plots. For details, see `plotPartialDependence`.

For classification problems, after selecting features, you can train two models (for example, a full model and a model trained with a subset of predictors) and compare the accuracies of the models by using the `compareHoldout`, `testcholdout`, or `testckfold` functions.

Feature selection is preferable to feature transformation when the original features and their units are important and the modeling goal is to identify an influential subset. When categorical features are present, and numerical transformations are inappropriate, feature selection becomes the primary means of dimension reduction.

Feature Selection Functions

Statistics and Machine Learning Toolbox offers several functions for feature selection. Choose the appropriate feature selection function based on your problem and the data types of the features.

Filter Type Feature Selection

Function	Supported Problem	Supported Data Type	Description
`fscchi2`	Classification	Categorical and continuous features	Examine whether each predictor variable is independent of a response variable by using individual chi-square tests, and then rank features using the *p*-values of the chi-square test statistics. For examples, see the function reference page `fscchi2`.
`fscmrmr`	Classification	Categorical and continuous features	Rank features sequentially using the "Minimum Redundancy Maximum Relevance (MRMR) Algorithm" on page 33-2482. For examples, see the function reference page `fscmrmr`.
`fscnca*`	Classification	Continuous features	Determine the feature weights by using a diagonal adaptation of neighborhood component analysis (NCA). This algorithm works best for estimating feature importance for distance-based supervised models that use pairwise distances between observations to predict the response. For details, see the function reference page `fscnca` and these topics: • "Neighborhood Component Analysis (NCA) Feature Selection" on page 15-99 • "Tune Regularization Parameter to Detect Features Using NCA for Classification" on page 15-210

Function	Supported Problem	Supported Data Type	Description
`fsrftest`	Regression	Categorical and continuous features	Examine the importance of each predictor individually using an *F*-test, and then rank features using the *p*-values of the *F*-test statistics. Each *F*-test tests the hypothesis that the response values grouped by predictor variable values are drawn from populations with the same mean against the alternative hypothesis that the population means are not all the same. For examples, see the function reference page `fsrftest`.
`fsrnca*`	Regression	Continuous features	Determine the feature weights by using a diagonal adaptation of neighborhood component analysis (NCA). This algorithm works best for estimating feature importance for distance-based supervised models that use pairwise distances between observations to predict the response. For details, see the function reference page `fsrnca` and these topics: • “Neighborhood Component Analysis (NCA) Feature Selection” on page 15-99 • “Robust Feature Selection Using NCA for Regression” on page 15-85
`fsulaplacian`	Unsupervised learning	Continuous features	Rank features using the “Laplacian Score” on page 33-2538. For examples, see the function reference page `fsulaplacian`.

Function	Supported Problem	Supported Data Type	Description
`relieff`	Classification and regression	Either all categorical or all continuous features	Rank features using the “ReliefF” on page 33-5461 algorithm for classification and the “RReliefF” on page 33-5462 algorithm for regression. This algorithm works best for estimating feature importance for distance-based supervised models that use pairwise distances between observations to predict the response. For examples, see the function reference page `relieff`.
`sequentialfs`	Classification and regression	Either all categorical or all continuous features	Select features sequentially using a custom criterion. Define a function that measures the characteristics of data to select features, and pass the function handle to the `sequentialfs` function. You can specify sequential forward selection or sequential backward selection by using the `'Direction'` name-value pair argument. `sequentialfs` evaluates the criterion using cross-validation.

*You can also consider `fscnca` and `fsrnca` as embedded type feature selection functions because they return a trained model object and you can use the object functions `predict` and `loss`. However, you typically use these object functions to tune the regularization parameter of the algorithm. After selecting features using the `fscnca` or `fsrnca` function as part of a data preprocessing step, you can apply another classification or regression algorithm for your problem.

Wrapper Type Feature Selection

Function	Supported Problem	Supported Data Type	Description
`sequentialfs`	Classification and regression	Either all categorical or all continuous features	Select features sequentially using a custom criterion. Define a function that implements a supervised learning algorithm or a function that measures performance of a learning algorithm, and pass the function handle to the `sequentialfs` function. You can specify sequential forward selection or sequential backward selection by using the `'Direction'` name-value pair argument. `sequentialfs` evaluates the criterion using cross-validation. For examples, see the function reference page `sequentialfs` and these topics: • “Select Subset of Features with Comparative Predictive Power” on page 15-61 • “Selecting Features for Classifying High-dimensional Data” on page 15-171

Embedded Type Feature Selection

Function	Supported Problem	Supported Data Type	Description
`DeltaPredictor` property of a `ClassificationDiscriminant` model object	Linear discriminant analysis classification	Continuous features	Create a linear discriminant analysis classifier by using `fitcdiscr`. A trained classifier, returned as `ClassificationDiscriminant`, stores the coefficient magnitude in the `DeltaPredictor` property. You can use the values in `DeltaPredictor` as measures of the predictor importance. This classifier uses the two regularization parameters "Gamma and Delta" on page 33-1124 to identify and remove redundant predictors. You can obtain appropriate values for these parameters by using the `cvshrink` function or the `'OptimizeHyperparameters'` name-value pair argument. For examples, see these topics: • "Regularize Discriminant Analysis Classifier" on page 20-21 • "Optimize Discriminant Analysis Model" on page 33-1574
`fitcecoc` with `templateLinear`	Linear classification for multiclass learning with high-dimensional data	Continuous features	Train a linear classification model by using `fitcecoc` and linear binary learners defined by `templateLinear`. Specify `'Regularization'` of `templatelinear` as `'lasso'` to use lasso regularization. For an example, see "Find Good Lasso Penalty Using Cross-Validation" on page 33-514. This example determines a good lasso-penalty strength by evaluating models with different strength values using `kfoldLoss`. You can also evaluate models using `kfoldEdge`, `kfoldMargin`, `edge`, `loss`, or `margin`.

Function	Supported Problem	Supported Data Type	Description
`fitclinear`	Linear classification for binary learning with high-dimensional data	Continuous features	Train a linear classification model by using `fitclinear`. Specify `'Regularization'` of `fitclinear` as `'lasso'` to use lasso regularization. For an example, see "Find Good Lasso Penalty Using Cross-Validated AUC" on page 33-3286. This example determines a good lasso-penalty strength by evaluating models with different strength values using the AUC values. Compute the cross-validated posterior class probabilities by using `kfoldPredict`, and compute the AUC values by using `perfcurve`. You can also evaluate models using `kfoldEdge`, `kfoldLoss`, `kfoldMargin`, `edge`, `loss`, `margin`, or `predict`.
`fitrgp`	Regression	Categorical and continuous features	Train a Gaussian process regression (GPR) model by using `fitrgp`. Set the `'KernelFunction'` name-value pair argument to use automatic relevance determination (ARD). Available options are `'ardsquaredexponential'`, `'ardexponential'`, `'ardmatern32'`, `'ardmatern52'`, and `'ardrationalquadratic'`. Find the predictor weights by taking the exponential of the negative learned length scales, stored in the `KernelInformation` property. For examples, see these topics: • "Specify Initial Step Size for LBFGS Optimization" on page 33-2151 • "Compare NCA and ARD Feature Selection" on page 33-2507

Function	Supported Problem	Supported Data Type	Description
`fitrlinear`	Linear regression with high-dimensional data	Continuous features	Train a linear regression model by using `fitrlinear`. Specify `'Regularization'` of `fitrlinear` as `'lasso'` to use lasso regularization. For examples, see these topics: • "Find Good Lasso Penalty Using Regression Loss" on page 33-5815 • "Find Good Lasso Penalty Using Cross-Validation" on page 33-2178
`lasso`	Linear regression	Continuous features	Train a linear regression model with "Lasso" on page 33-3431 regularization by using `lasso`. You can specify the weight of lasso versus ridge optimization by using the `'Alpha'` name-value pair argument. For examples, see the function reference page `lasso` and these topics: • "Lasso Regularization" on page 11-120 • "Lasso and Elastic Net with Cross Validation" on page 11-123 • "Wide Data via Lasso and Parallel Computing" on page 11-115
`lassoglm`	Generalized linear regression	Continuous features	Train a generalized linear regression model with "Lasso" on page 33-3446 regularization by using `lassoglm`. You can specify the weight of lasso versus ridge optimization by using the `'Alpha'` name-value pair argument. For details, see the function reference page `lassoglm` and these topics: • "Lasso Regularization of Generalized Linear Models" on page 12-32 • "Regularize Poisson Regression" on page 12-34 • "Regularize Logistic Regression" on page 12-36 • "Regularize Wide Data in Parallel" on page 12-43

Function	Supported Problem	Supported Data Type	Description
`oobPermutedPredictorImportance**` of `ClassificationBaggedEnsemble`	Classification with an ensemble of bagged decision trees (for example, random forest)	Categorical and continuous features	Train a bagged classification ensemble with tree learners by using `fitcensemble` and specifying `'Method'` as `'bag'`. Then, use `oobPermutedPredictorImportance` to compute “Out-of-Bag, Predictor Importance Estimates by Permutation” on page 33-4351. The function measures how influential the predictor variables in the model are at predicting the response. For examples, see the function reference page and the topic `oobPermutedPredictorImportance`.
`oobPermutedPredictorImportance**` of `RegressionBaggedEnsemble`	Regression with an ensemble of bagged decision trees (for example, random forest)	Categorical and continuous features	Train a bagged regression ensemble with tree learners by using `fitrensemble` and specifying `'Method'` as `'bag'`. Then, use `oobPermutedPredictorImportance` to compute “Out-of-Bag, Predictor Importance Estimates by Permutation” on page 33-4358. The function measures how influential the predictor variables in the model are at predicting the response. For examples, see the function reference page `oobPermutedPredictorImportance` and “Select Predictors for Random Forests” on page 18-60.
`predictorImportance**` of `ClassificationEnsemble`	Classification with an ensemble of decision trees	Categorical and continuous features	Train a classification ensemble with tree learners by using `fitcensemble`. Then, use `predictorImportance` to compute estimates of “Predictor Importance” on page 33-5032 for the ensemble by summing changes in the risk due to splits on every predictor and dividing the sum by the number of branch nodes. For examples, see the function reference page `predictorImportance`.

Function	Supported Problem	Supported Data Type	Description
`predictorImportance**` of `ClassificationTree`	Classification with a decision tree	Categorical and continuous features	Train a classification tree by using `fitctree`. Then, use `predictorImportance` to compute estimates of "Predictor Importance" on page 33-5039 for the tree by summing changes in the risk due to splits on every predictor and dividing the sum by the number of branch nodes. For examples, see the function reference page `predictorImportance`.
`predictorImportance**` of `RegressionEnsemble`	Regression with an ensemble of decision trees	Categorical and continuous features	Train a regression ensemble with tree learners by using `fitrensemble`. Then, use `predictorImportance` to compute estimates of "Predictor Importance" on page 33-5044 for the ensemble by summing changes in the risk due to splits on every predictor and dividing the sum by the number of branch nodes. For examples, see the function reference page `predictorImportance`.
`predictorImportance**` of `RegressionTree`	Regression with a decision tree	Categorical and continuous features	Train a regression tree by using `fitrtree`. Then, use `predictorImportance` to compute estimates of "Predictor Importance" on page 33-5049 for the tree by summing changes in the mean squared error (MSE) due to splits on every predictor and dividing the sum by the number of branch nodes. For examples, see the function reference page `predictorImportance`.

Function	Supported Problem	Supported Data Type	Description
`stepwiseglm`***	Generalized linear regression	Categorical and continuous features	Fit a generalized linear regression model using stepwise regression by using `stepwiseglm`. Alternatively, you can fit a linear regression model by using `fitglm` and then adjust the model by using `step`. Stepwise regression is a systematic method for adding and removing terms from the model based on their statistical significance in explaining the response variable. For details, see the function reference page `stepwiseglm` and these topics: • “Generalized Linear Model Using Stepwise Algorithm” on page 33-6004 • “Generalized Linear Models” on page 12-9 • “Generalized Linear Model Workflow” on page 12-28
`stepwiselm`***	Linear regression	Categorical and continuous features	Fit a linear regression model using stepwise regression by using `stepwiselm`. Alternatively, you can fit a linear regression model by using `fitlm` and then adjust the model by using `step`. Stepwise regression is a systematic method for adding and removing terms from the model based on their statistical significance in explaining the response variable. For details, see the function reference page `stepwiselm` and these topics: • “Stepwise Regression” on page 11-99 • “Linear Regression with Interaction Effects” on page 11-44 • “Assess Significance of Regression Coefficients Using t-statistic” on page 11-75

**For a tree-based algorithm, specify `'PredictorSelection'` as `'interaction-curvature'` to use the interaction test for selecting the best split predictor. The interaction test is useful in identifying important variables in the presence of many irrelevant variables. Also, if the training data includes many predictors, then specify `'NumVariablesToSample'` as `'all'` for training.

Otherwise, the software might not select some predictors, underestimating their importance. For details, see `fitctree`, `fitrtree`, and `templateTree`.

***`stepwiseglm` and `stepwiselm` are not wrapper type functions because you cannot use them as a wrapper for another training function. However, these two functions use the wrapper type algorithm to find important features.

Sequential Feature Selection

This topic introduces to sequential feature selection and provides an example that selects features sequentially using a custom criterion and the `sequentialfs` function.

Introduction to Sequential Feature Selection

A common method of Feature Selection on page 15-49 is sequential feature selection. This method has two components:

- An objective function, called the criterion, which the method seeks to minimize over all feasible feature subsets. Common criteria are mean squared error (for regression models) and misclassification rate (for classification models).
- A sequential search algorithm, which adds or removes features from a candidate subset while evaluating the criterion. Since an exhaustive comparison of the criterion value at all 2^n subsets of an n-feature data set is typically infeasible (depending on the size of n and the cost of objective calls), sequential searches move in only one direction, always growing or always shrinking the candidate set.

The method has two variants:

- Sequential forward selection (SFS), in which features are sequentially added to an empty candidate set until the addition of further features does not decrease the criterion.
- Sequential backward selection (SBS), in which features are sequentially removed from a full candidate set until the removal of further features increase the criterion.

Statistics and Machine Learning Toolbox offers several sequential feature selection functions:

- Stepwise regression is a sequential feature selection technique designed specifically for least-squares fitting. The functions `stepwiselm` and `stepwiseglm` use optimizations that are possible only with least-squares criteria. Unlike other sequential feature selection algorithms, stepwise regression can remove features that have been added or add features that have been removed, based on the criterion specified by the `'Criterion'` name-value pair argument.
- `sequentialfs` performs sequential feature selection using a custom criterion. Input arguments include predictor data, response data, and a function handle to a file implementing the criterion function. You can define a criterion function that measures the characteristics of data or the performance of a learning algorithm. Optional inputs allow you to specify SFS or SBS, required or excluded features, and the size of the feature subset. The function calls `cvpartition` and `crossval` to evaluate the criterion at different candidate sets.
- `fscmrmr` ranks features using the minimum redundancy maximum relevance (MRMR) algorithm for classification problems.

Select Subset of Features with Comparative Predictive Power

This example selects a subset of features using a custom criterion that measures predictive power for a generalized linear regression problem.

Consider a data set with 100 observations of 10 predictors. Generate the random data from a logistic model, with a binomial distribution of responses at each set of values for the predictors. Some coefficients are set to zero so that not all of the predictors affect the response.

```
rng(456) % Set the seed for reproducibility
n = 100;
m = 10;
X = rand(n,m);
b = [1 0 0 2 .5 0 0 0.1 0 1];
Xb = X*b';
p = 1./(1+exp(-Xb));
N = 50;
y = binornd(N,p);
```

Fit a logistic model to the data using `fitglm`.

```
Y = [y N*ones(size(y))];
model0 = fitglm(X,Y,'Distribution','binomial')
```

```
model0 =
Generalized linear regression model:
    logit(y) ~ 1 + x1 + x2 + x3 + x4 + x5 + x6 + x7 + x8 + x9 + x10
    Distribution = Binomial

Estimated Coefficients:

    x8              -0.19712    0.17317     -1.1383       0.25498
    x9              -0.20373    0.16796      -1.213       0.22514
    x10              0.99741    0.17247      5.7832    7.3296e-09

100 observations, 89 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 222, p-value = 4.92e-42
```

Display the deviance of the fit.

```
dev0 = model0.Deviance
```

```
dev0 = 101.5648
```

This model is the full model, with all of the features and an initial constant term. Sequential feature selection searches for a subset of the features in the full model with comparative predictive power.

Before performing feature selection, you must specify a criterion for selecting the features. In this case, the criterion is the deviance of the fit (a generalization of the residual sum of squares). The `critfun` function (shown at the end of this example) calls `fitglm` and returns the deviance of the fit.

If you use the live script file for this example, the `critfun` function is already included at the end of the file. Otherwise, you need to create this function at the end of your .m file or add it as a file on the MATLAB path.

Perform feature selection. `sequentialfs` calls the criterion function via a function handle.

```
maxdev = chi2inv(.95,1);
opt = statset('display','iter',...
              'TolFun',maxdev,...
              'TolTypeFun','abs');

inmodel = sequentialfs(@critfun,X,Y,...
                       'cv','none',...
                       'nullmodel',true,...
                       'options',opt,...
                       'direction','forward');
```

```
Start forward sequential feature selection:
Initial columns included:  none
Columns that can not be included:  none
Step 1, used initial columns, criterion value 323.173
Step 2, added column 4, criterion value 184.794
Step 3, added column 10, criterion value 139.176
Step 4, added column 1, criterion value 119.222
Step 5, added column 5, criterion value 107.281
Final columns included:  1 4 5 10
```

The iterative display shows a decrease in the criterion value as each new feature is added to the model. The final result is a reduced model with only four of the original ten features: columns `1`, `4`, `5`, and `10` of `X`, as indicated in the logical vector `inmodel` returned by `sequentialfs`.

The deviance of the reduced model is higher than the deviance of the full model. However, the addition of any other single feature would not decrease the criterion value by more than the absolute tolerance, `maxdev`, set in the options structure. Adding a feature with no effect reduces the deviance by an amount that has a chi-square distribution with one degree of freedom. Adding a significant feature results in a larger change in the deviance. By setting `maxdev` to `chi2inv(.95,1)`, you instruct `sequentialfs` to continue adding features provided that the change in deviance is more than the change expected by random chance.

Create the reduced model with an initial constant term.

```
model = fitglm(X(:,inmodel),Y,'Distribution','binomial')
```

```
model =
Generalized linear regression model:
    logit(y) ~ 1 + x1 + x2 + x3 + x4
    Distribution = Binomial

Estimated Coefficients:
                    Estimate       SE         tStat        pValue
                   __________    _______    _________    __________

    (Intercept)    -0.0052025    0.16772    -0.031018       0.97525
    x1                0.73814    0.16316       4.5241    6.0666e-06
    x2                 2.2139    0.17402       12.722    4.4369e-37
    x3                0.54073     0.1568       3.4485    0.00056361
    x4                 1.0694    0.15916       6.7191    1.8288e-11

100 observations, 95 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 216, p-value = 1.44e-45
```

This code creates the function `critfun`.

```
function dev = critfun(X,Y)
model = fitglm(X,Y,'Distribution','binomial');
dev = model.Deviance;
end
```

Nonnegative Matrix Factorization

Nonnegative matrix factorization (NMF) is a dimension-reduction technique based on a low-rank approximation of the feature space. Besides providing a reduction in the number of features, NMF guarantees that the features are nonnegative, producing additive models that respect, for example, the nonnegativity of physical quantities.

Given a nonnegative m-by-n matrix X and a positive integer $k < \min(m,n)$, NMF finds nonnegative m-by-k and k-by-n matrices W and H, respectively, that minimize the norm of the difference $X – WH$. W and H are thus approximate nonnegative factors of X.

The k columns of W represent transformations of the variables in X; the k rows of H represent the coefficients of the linear combinations of the original n variables in X that produce the transformed variables in W. Since k is generally smaller than the rank of X, the product WH provides a compressed approximation of the data in X. A range of possible values for k is often suggested by the modeling context.

The function `nnmf` carries out nonnegative matrix factorization. `nnmf` uses one of two iterative algorithms that begin with random initial values for W and H. Because the norm of the residual $X – WH$ may have local minima, repeated calls to `nnmf` may yield different factorizations. Sometimes the algorithm converges to a solution of lower rank than k, which may indicate that the result is not optimal.

- “Perform Nonnegative Matrix Factorization” on page 15-66

Perform Nonnegative Matrix Factorization

This example shows how to perform nonnegative matrix factorization.

Load the sample data.

```
load moore
X = moore(:,1:5);
rng('default'); % For reproducibility
```

Compute a rank-two approximation of X using a multiplicative update algorithm that begins from five random initial values for W and H.

```
opt = statset('MaxIter',10,'Display','final');
[W0,H0] = nnmf(X,2,'replicates',5,'options',opt,'algorithm','mult');
```

```
    rep       iteration       rms resid      |delta x|
      1          10         358.296      0.00190554
      2          10         78.3556     0.000351747
      3          10         230.962       0.0172839
      4          10         326.347      0.00739552
      5          10         361.547      0.00705539
Final root mean square residual = 78.3556
```

The `'mult'` algorithm is sensitive to initial values, which makes it a good choice when using `'replicates'` to find W and H from multiple random starting values.

Now perform the factorization using alternating least-squares algorithm, which converges faster and more consistently. Run 100 times more iterations, beginning from the initial W0 and H0 identified above.

```
opt = statset('Maxiter',1000,'Display','final');
[W,H] = nnmf(X,2,'w0',W0,'h0',H0,'options',opt,'algorithm','als');
```

```
    rep       iteration       rms resid      |delta x|
      1           2         77.5315     0.000830334
Final root mean square residual = 77.5315
```

The two columns of W are the transformed predictors. The two rows of H give the relative contributions of each of the five predictors in X to the predictors in W. Display H.

```
H
```

```
H = 2×5

    0.0835    0.0190    0.1782    0.0072    0.9802
    0.0559    0.0250    0.9969    0.0085    0.0497
```

The fifth predictor in X (weight 0.9802) strongly influences the first predictor in W. The third predictor in X (weight 0.9969) strongly influences the second predictor in W.

Visualize the relative contributions of the predictors in X with `biplot`, showing the data and original variables in the column space of W.

```
biplot(H','scores',W,'varlabels',{'','','v3','','v5'});
axis([0 1.1 0 1.1])
```

```
xlabel('Column 1')
ylabel('Column 2')
```

Principal Component Analysis (PCA)

One of the difficulties inherent in multivariate statistics is the problem of visualizing data that has many variables. The function `plot` displays a graph of the relationship between two variables. The `plot3` and `surf` commands display different three-dimensional views. But when there are more than three variables, it is more difficult to visualize their relationships.

Fortunately, in data sets with many variables, groups of variables often move together. One reason for this is that more than one variable might be measuring the same driving principle governing the behavior of the system. In many systems there are only a few such driving forces. But an abundance of instrumentation enables you to measure dozens of system variables. When this happens, you can take advantage of this redundancy of information. You can simplify the problem by replacing a group of variables with a single new variable.

Principal component analysis is a quantitatively rigorous method for achieving this simplification. The method generates a new set of variables, called *principal components*. Each principal component is a linear combination of the original variables. All the principal components are orthogonal to each other, so there is no redundant information. The principal components as a whole form an orthogonal basis for the space of the data.

There are an infinite number of ways to construct an orthogonal basis for several columns of data. What is so special about the principal component basis?

The first principal component is a single axis in space. When you project each observation on that axis, the resulting values form a new variable. And the variance of this variable is the maximum among all possible choices of the first axis.

The second principal component is another axis in space, perpendicular to the first. Projecting the observations on this axis generates another new variable. The variance of this variable is the maximum among all possible choices of this second axis.

The full set of principal components is as large as the original set of variables. But it is commonplace for the sum of the variances of the first few principal components to exceed 80% of the total variance of the original data. By examining plots of these few new variables, researchers often develop a deeper understanding of the driving forces that generated the original data.

You can use the function `pca` to find the principal components. To use `pca`, you need to have the actual measured data you want to analyze. However, if you lack the actual data, but have the sample covariance or correlation matrix for the data, you can still use the function `pcacov` to perform a principal components analysis. See the reference page for `pcacov` for a description of its inputs and outputs.

Related Examples

- “Analyze Quality of Life in U.S. Cities Using PCA” on page 15-69

Analyze Quality of Life in U.S. Cities Using PCA

This example shows how to perform a weighted principal components analysis and interpret the results.

Load sample data.

Load the sample data. The data includes ratings for 9 different indicators of the quality of life in 329 U.S. cities. These are climate, housing, health, crime, transportation, education, arts, recreation, and economics. For each category, a higher rating is better. For example, a higher rating for crime means a lower crime rate.

Display the `categories` variable.

```
load cities
categories
```

```
categories =
   climate
   housing
   health
   crime
   transportation
   education
   arts
   recreation
   economics
```

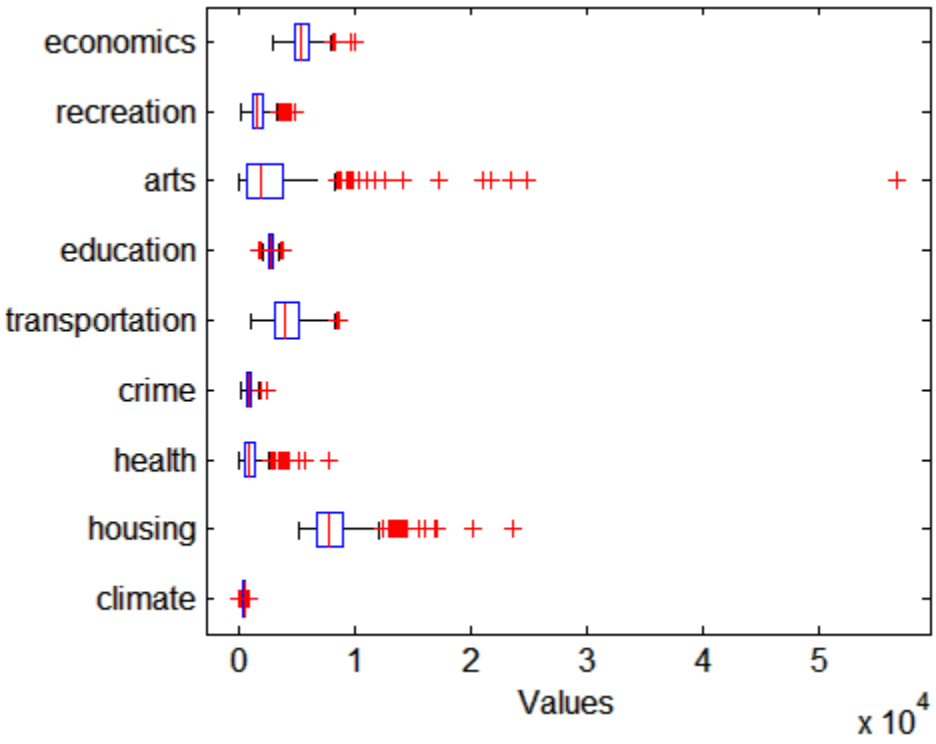
In total, the `cities` data set contains three variables:

- `categories`, a character matrix containing the names of the indices
- `names`, a character matrix containing the 329 city names
- `ratings`, the data matrix with 329 rows and 9 columns

Plot data.

Make a box plot to look at the distribution of the `ratings` data.

```
figure()
boxplot(ratings,'Orientation','horizontal','Labels',categories)
```



There is more variability in the ratings of the arts and housing than in the ratings of crime and climate.

Check pairwise correlation.

Check the pairwise correlation between the variables.

```
C = corr(ratings,ratings);
```

The correlation among some variables is as high as 0.85. Principal components analysis constructs independent new variables which are linear combinations of the original variables.

Compute principal components.

When all variables are in the same unit, it is appropriate to compute principal components for raw data. When the variables are in different units or the difference in the variance of different columns is substantial (as in this case), scaling of the data or use of weights is often preferable.

Perform the principal component analysis by using the inverse variances of the ratings as weights.

```
w = 1./var(ratings);
[wcoeff,score,latent,tsquared,explained] = pca(ratings,...
'VariableWeights',w);
```

Or equivalently:

```
[wcoeff,score,latent,tsquared,explained] = pca(ratings,...
'VariableWeights','variance');
```

The following sections explain the five outputs of `pca`.

Component coefficients.

The first output, `wcoeff`, contains the coefficients of the principal components.

The first three principal component coefficient vectors are:

```
c3 = wcoeff(:,1:3)
```

```
c3 = wcoeff(:,1:3)
c3 =

   1.0e+03 *

    0.0249   -0.0263   -0.0834
    0.8504   -0.5978   -0.4965
    0.4616    0.3004   -0.0073
    0.1005   -0.1269    0.0661
    0.5096    0.2606    0.2124
    0.0883    0.1551    0.0737
    2.1496    0.9043   -0.1229
    0.2649   -0.3106   -0.0411
    0.1469   -0.5111    0.6586
```

These coefficients are weighted, hence the coefficient matrix is not orthonormal.

Transform coefficients.

Transform the coefficients so that they are orthonormal.

```
 coefforth = inv(diag(std(ratings)))*wcoeff;
```

Note that if you use a weights vector, `w`, while conducting the `pca`, then

```
 coefforth = diag(sqrt(w))*wcoeff;
```

Check coefficients are orthonormal.

The transformed coefficients are now orthonormal.

```
I = coefforth'*coefforth;
I(1:3,1:3)
```

```
ans =
    1.0000   -0.0000   -0.0000
   -0.0000    1.0000   -0.0000
   -0.0000   -0.0000    1.0000
```

Component scores.

The second output, `score`, contains the coordinates of the original data in the new coordinate system defined by the principal components. The `score` matrix is the same size as the input data matrix. You can also obtain the component scores using the orthonormal coefficients and the standardized ratings as follows.

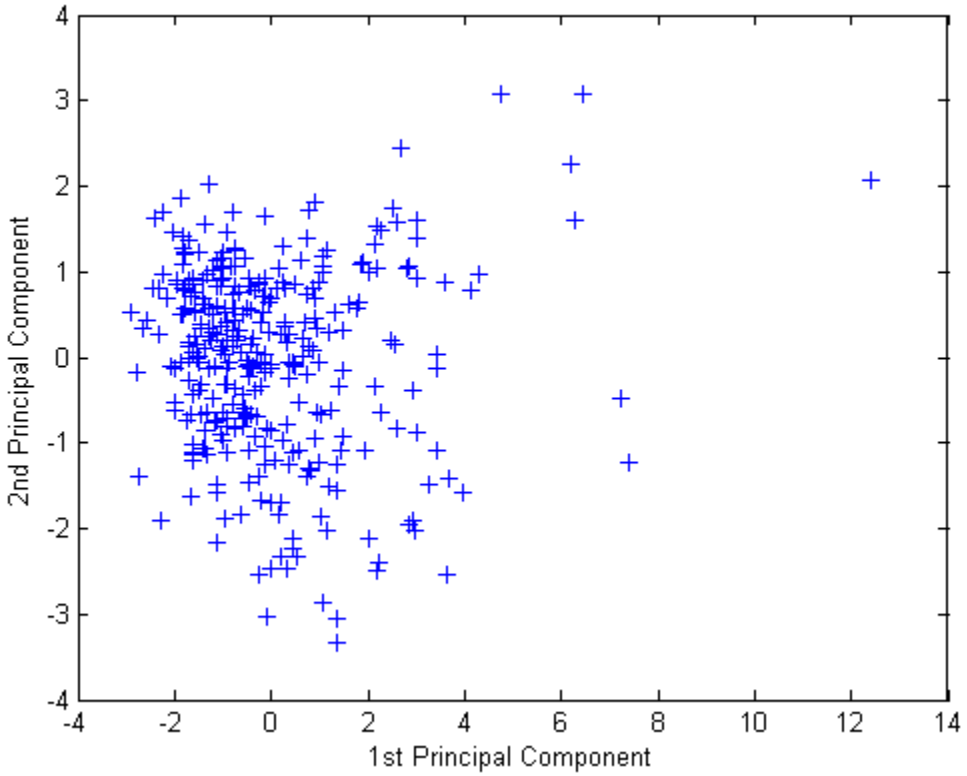
```
cscores = zscore(ratings)*coefforth;
```

`cscores` and `score` are identical matrices.

Plot component scores.

Create a plot of the first two columns of `score`.

```
figure()
plot(score(:,1),score(:,2),'+')
xlabel('1st Principal Component')
ylabel('2nd Principal Component')
```



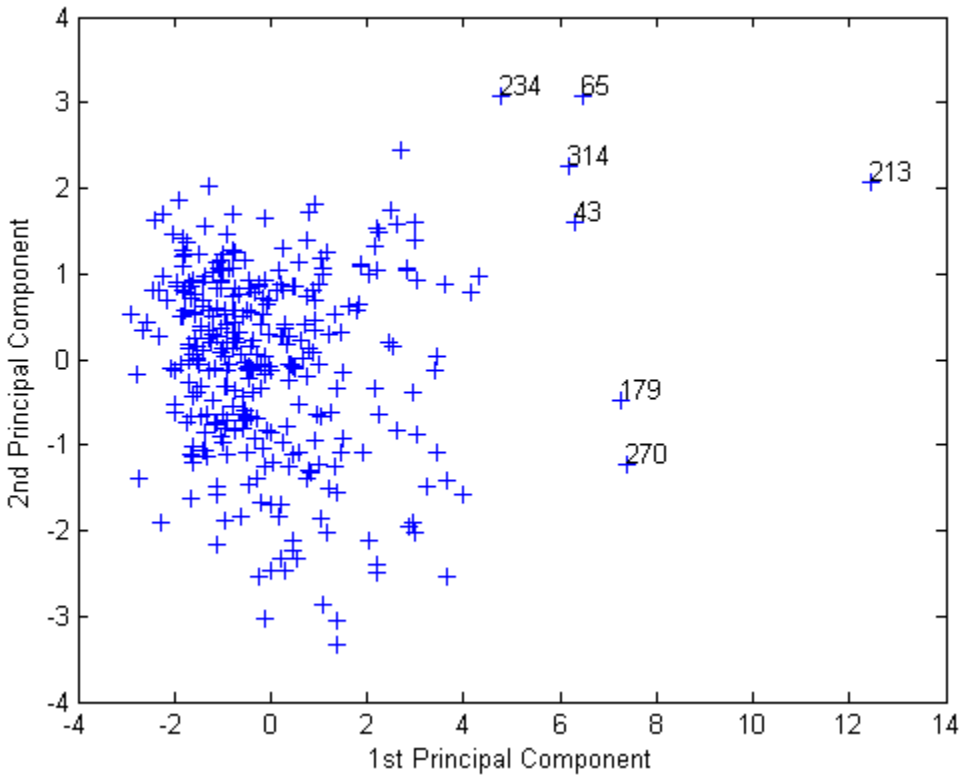
This plot shows the centered and scaled ratings data projected onto the first two principal components. `pca` computes the scores to have mean zero.

Explore plot interactively.

Note the outlying points in the right half of the plot. You can graphically identify these points as follows.

```
gname
```

Move your cursor over the plot and click once near the rightmost seven points. This labels the points by their row numbers as in the following figure.



After labeling points, press **Return**.

Extract observation names.

Create an index variable containing the row numbers of all the cities you chose and get the names of the cities.

```
metro = [43 65 179 213 234 270 314];
names(metro,:)
```

```
ans =
   Boston, MA
   Chicago, IL
   Los Angeles, Long Beach, CA
   New York, NY
   Philadelphia, PA-NJ
   San Francisco, CA
   Washington, DC-MD-VA
```

These labeled cities are some of the biggest population centers in the United States and they appear more extreme than the remainder of the data.

Component variances.

The third output, `latent`, is a vector containing the variance explained by the corresponding principal component. Each column of `score` has a sample variance equal to the corresponding row of `latent`.

```
latent
```

```
latent =

    3.4083
    1.2140
    1.1415
    0.9209
    0.7533
    0.6306
    0.4930
    0.3180
    0.1204
```

Percent variance explained.

The fifth output, `explained`, is a vector containing the percent variance explained by the corresponding principal component.

```
explained
```

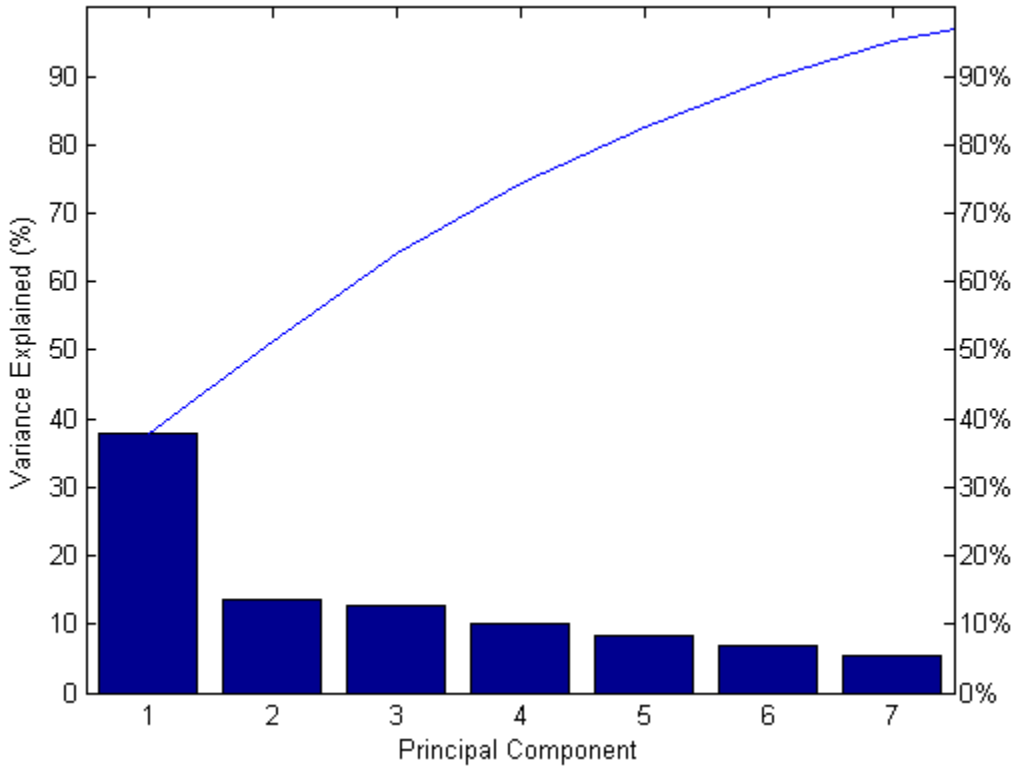
```
explained =

   37.8699
   13.4886
   12.6831
   10.2324
    8.3698
    7.0062
    5.4783
    3.5338
    1.3378
```

Create scree plot.

Make a scree plot of the percent variability explained by each principal component.

```
figure()
pareto(explained)
xlabel('Principal Component')
ylabel('Variance Explained (%)')
```



This scree plot only shows the first seven (instead of the total nine) components that explain 95% of the total variance. The only clear break in the amount of variance accounted for by each component is between the first and second components. However, the first component by itself explains less than 40% of the variance, so more components might be needed. You can see that the first three principal components explain roughly two-thirds of the total variability in the standardized ratings, so that might be a reasonable way to reduce the dimensions.

Hotelling's T-squared statistic.

The last output from `pca` is `tsquared`, which is Hotelling's T^2, a statistical measure of the multivariate distance of each observation from the center of the data set. This is an analytical way to find the most extreme points in the data.

```
[st2,index] = sort(tsquared,'descend'); % sort in descending order
extreme = index(1);
names(extreme,:)
```

```
ans =

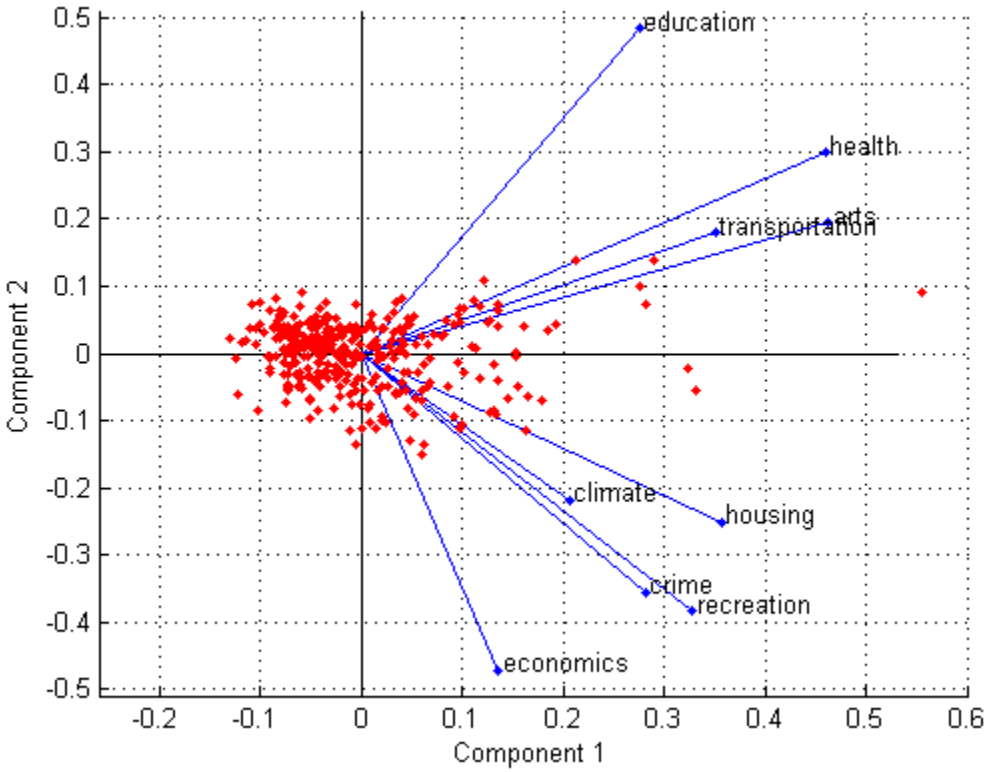
New York, NY
```

The ratings for New York are the furthest from the average U.S. city.

Visualize the results.

Visualize both the orthonormal principal component coefficients for each variable and the principal component scores for each observation in a single plot.

```
biplot(coefforth(:,1:2),'Scores',score(:,1:2),'Varlabels',categories);
axis([-.26 0.6 -.51 .51]);
```



All nine variables are represented in this bi-plot by a vector, and the direction and length of the vector indicate how each variable contributes to the two principal components in the plot. For example, the first principal component, on the horizontal axis, has positive coefficients for all nine variables. That is why the nine vectors are directed into the right half of the plot. The largest coefficients in the first principal component are the third and seventh elements, corresponding to the variables `health` and `arts`.

The second principal component, on the vertical axis, has positive coefficients for the variables `education`, `health`, `arts`, and `transportation`, and negative coefficients for the remaining five variables. This indicates that the second component distinguishes among cities that have high values for the first set of variables and low for the second, and cities that have the opposite.

The variable labels in this figure are somewhat crowded. You can either exclude the `VarLabels` name-value pair argument when making the plot, or select and drag some of the labels to better positions using the Edit Plot tool from the figure window toolbar.

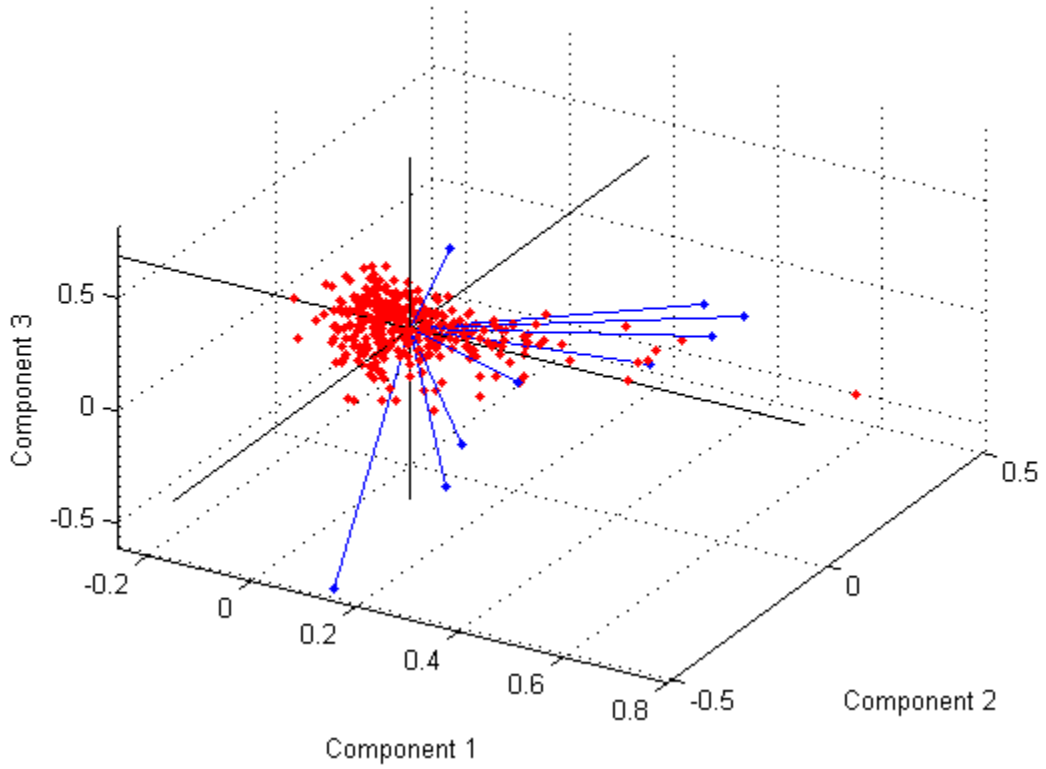
This 2-D bi-plot also includes a point for each of the 329 observations, with coordinates indicating the score of each observation for the two principal components in the plot. For example, points near the left edge of this plot have the lowest scores for the first principal component. The points are scaled with respect to the maximum score value and maximum coefficient length, so only their relative locations can be determined from the plot.

You can identify items in the plot by selecting **Tools>Data Cursor** in the figure window. By clicking a variable (vector), you can read the variable label and coefficients for each principal component. By clicking an observation (point), you can read the observation name and scores for each principal component. You can specify `'Obslabels',names` to show the observation names instead of the observation numbers in the data cursor display.

Create a three-dimensional bi-plot.

You can also make a bi-plot in three dimensions.

```
figure()
biplot(coefforth(:,1:3),'Scores',score(:,1:3),'Obslabels',names);
axis([-.26 0.8 -.51 .51 -.61 .81]);
view([30 40]);
```



This graph is useful if the first two principal coordinates do not explain enough of the variance in your data. You can also rotate the figure to see it from different angles by selecting the**Tools**> `Rotate 3D`.

- “Principal Component Analysis (PCA)” on page 15-68

Factor Analysis

Multivariate data often includes a large number of measured variables, and sometimes those variables overlap, in the sense that groups of them might be dependent. For example, in a decathlon, each athlete competes in 10 events, but several of them can be thought of as speed events, while others can be thought of as strength events, etc. Thus, you can think of a competitor's 10 event scores as largely dependent on a smaller set of three or four types of athletic ability.

Factor analysis is a way to fit a model to multivariate data to estimate just this sort of interdependence. In a factor analysis model, the measured variables depend on a smaller number of unobserved (latent) factors. Because each factor might affect several variables in common, they are known as common factors. Each variable is assumed to be dependent on a linear combination of the common factors, and the coefficients are known as loadings. Each measured variable also includes a component due to independent random variability, known as specific variance because it is specific to one variable.

Specifically, factor analysis assumes that the covariance matrix of your data is of the form

$$\sum_X = \Lambda\Lambda^T + \Psi$$

where Λ is the matrix of loadings, and the elements of the diagonal matrix Ψ are the specific variances. The function `factoran` fits the Factor Analysis model using maximum likelihood.

`factoran`

Related Examples

- “Analyze Stock Prices Using Factor Analysis” on page 15-79

Analyze Stock Prices Using Factor Analysis

This example shows how to analyze if companies within the same sector experience similar week-to-week changes in stock price.

Factor Loadings

Load the sample data.

```
load stockreturns
```

Suppose that over the course of 100 weeks, the percent change in stock prices for ten companies has been recorded. Of the ten companies, the first four can be classified as primarily technology, the next three as financial, and the last three as retail. It seems reasonable that the stock prices for companies that are in the same sector might vary together as economic conditions change. Factor analysis can provide quantitative evidence.

First specify a model fit with three common factors. By default, `factoran` computes rotated estimates of the loadings to try and make their interpretation simpler. But in this example, specify an unrotated solution.

```
[Loadings,specificVar,T,stats] = factoran(stocks,3,'rotate','none');
```

The first two `factoran` output arguments are the estimated loadings and the estimated specific variances. Each row of the loadings matrix represents one of the ten stocks, and each column corresponds to a common factor. With unrotated estimates, interpretation of the factors in this fit is difficult because most of the stocks contain fairly large coefficients for two or more factors.

```
Loadings
```

```
Loadings = 10×3

    0.8885    0.2367   -0.2354
    0.7126    0.3862    0.0034
    0.3351    0.2784   -0.0211
    0.3088    0.1113   -0.1905
    0.6277   -0.6643    0.1478
    0.4726   -0.6383    0.0133
    0.1133   -0.5416    0.0322
    0.6403    0.1669    0.4960
    0.2363    0.5293    0.5770
    0.1105    0.1680    0.5524
```

Factor rotation helps to simplify the structure in the `Loadings` matrix, to make it easier to assign meaningful interpretations to the factors.

From the estimated specific variances, you can see that the model indicates that a particular stock price varies quite a lot beyond the variation due to the common factors. Display estimated specific variances.

```
specificVar
```

```
specificVar = 10×1

    0.0991
    0.3431
```

```
    0.8097
    0.8559
    0.1429
    0.3691
    0.6928
    0.3162
    0.3311
    0.6544
```

A specific variance of 1 would indicate that there is no common factor component in that variable, while a specific variance of 0 would indicate that the variable is entirely determined by common factors. These data seem to fall somewhere in between.

Display the *p*-value.

```
stats.p
```

```
ans = 0.8144
```

The *p*-value returned in the `stats` structure fails to reject the null hypothesis of three common factors, suggesting that this model provides a satisfactory explanation of the covariation in these data.

Fit a model with two common factors to determine whether fewer than three factors can provide an acceptable fit.

```
[Loadings2,specificVar2,T2,stats2] = factoran(stocks, 2,'rotate','none');
```

Display the *p*-value.

```
stats2.p
```

```
ans = 3.5610e-06
```

The *p*-value for this second fit is highly significant, and rejects the hypothesis of two factors, indicating that the simpler model is not sufficient to explain the pattern in these data.

Factor Rotation

As the results illustrate, the estimated loadings from an unrotated factor analysis fit can have a complicated structure. The goal of factor rotation is to find a parameterization in which each variable has only a small number of large loadings. That is, each variable is affected by a small number of factors, preferably only one. This can often make it easier to interpret what the factors represent.

If you think of each row of the loadings matrix as coordinates of a point in M-dimensional space, then each factor corresponds to a coordinate axis. Factor rotation is equivalent to rotating those axes and computing new loadings in the rotated coordinate system. There are various ways to do this. Some methods leave the axes orthogonal, while others are oblique methods that change the angles between them. For this example, you can rotate the estimated loadings by using the promax criterion, a common oblique method.

```
[LoadingsPM,specVarPM] = factoran(stocks,3,'rotate','promax');
LoadingsPM
```

```
LoadingsPM = 10×3
```

```
    0.9452    0.1214   -0.0617
    0.7064   -0.0178    0.2058

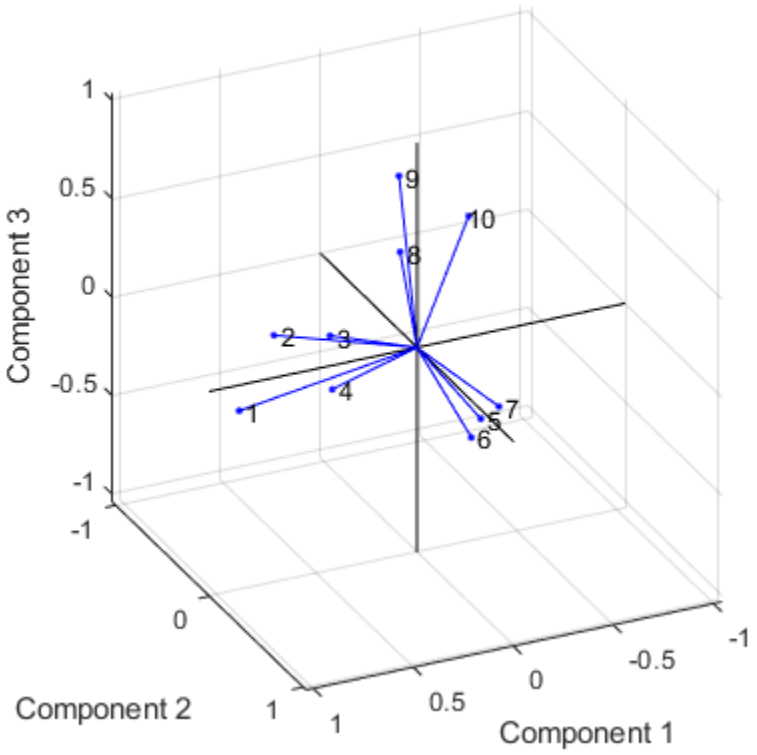
```

Promax rotation creates a simpler structure in the loadings, one in which most of the stocks have a large loading on only one factor. To see this structure more clearly, you can use the biplot function to plot each stock using its factor loadings as coordinates.

```
biplot(LoadingsPM,'varlabels',num2str((1:10)'));
axis square
view(155,27);
```



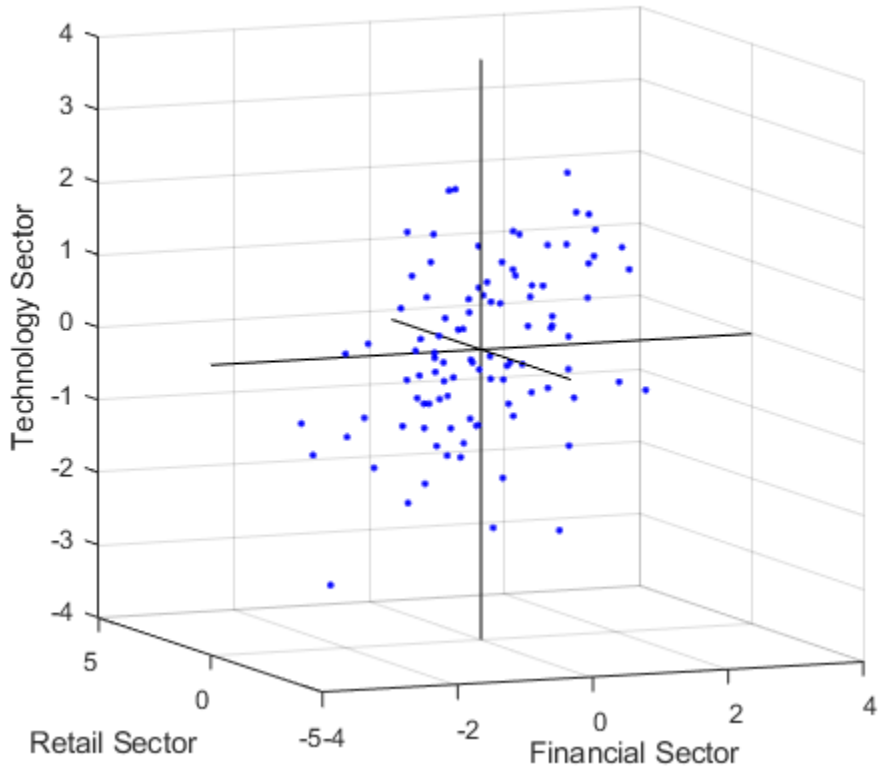
This plot shows that promax has rotated the factor loadings to a simpler structure. Each stock depends primarily on only one factor, and it is possible to describe each factor in terms of the stocks that it affects. Based on which companies are near which axes, you could reasonably conclude that the first factor axis represents the financial sector, the second retail, and the third technology. The original conjecture, that stocks vary primarily within sector, is apparently supported by the data.

Factor Scores

Sometimes, it is useful to be able to classify an observation based on its factor scores. For example, if you accepted the three-factor model and the interpretation of the rotated factors, you might want to categorize each week in terms of how favorable it was for each of the three stock sectors, based on the data from the 10 observed stocks. Because the data in this example are the raw stock price changes, and not just their correlation matrix, you can have `factoran` return estimates of the value of each of the three rotated common factors for each week. You can then plot the estimated scores to see how the different stock sectors were affected during each week.

```
[LoadingsPM,specVarPM,TPM,stats,F] = factoran(stocks, 3,'rotate','promax');

plot3(F(:,1),F(:,2),F(:,3),'b.')
line([-4 4 NaN 0 0 NaN 0 0],[0 0 NaN -4 4 NaN 0 0],[0 0 NaN 0 0 NaN -4 4], 'Color','black')
xlabel('Financial Sector')
ylabel('Retail Sector')
zlabel('Technology Sector')
grid on
axis square
view(-22.5, 8)
```



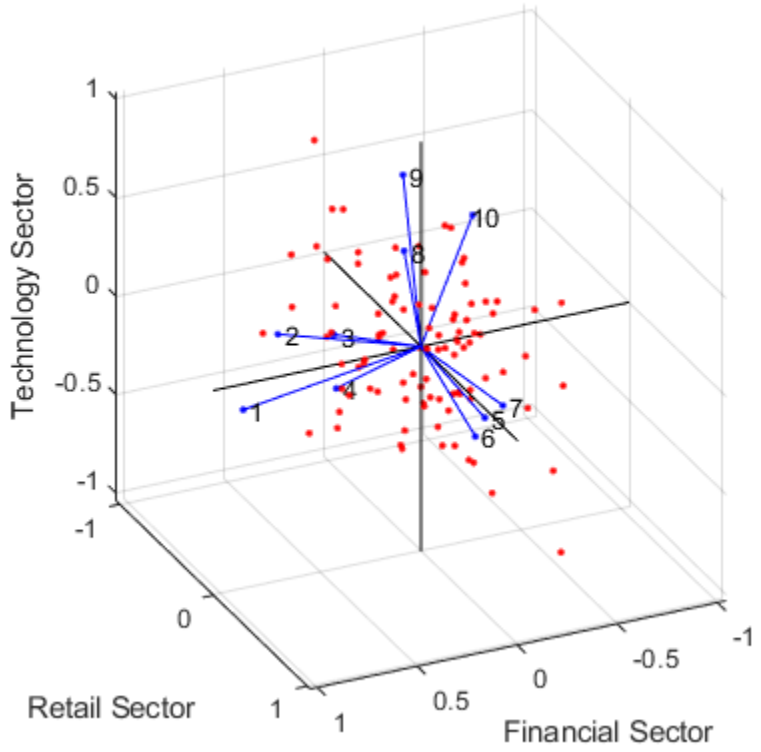
Oblique rotation often creates factors that are correlated. This plot shows some evidence of correlation between the first and third factors, and you can investigate further by computing the estimated factor correlation matrix.

```
inv(TPM'*TPM);
```

Visualize the Results

You can use the biplot function to help visualize both the factor loadings for each variable and the factor scores for each observation in a single plot. For example, the following command plots the results from the factor analysis on the stock data and labels each of the 10 stocks.

```
biplot(LoadingsPM,'scores',F,'varlabels',num2str((1:10)'))
xlabel('Financial Sector')
ylabel('Retail Sector')
zlabel('Technology Sector')
axis square
view(155,27)
```



In this case, the factor analysis includes three factors, and so the biplot is three-dimensional. Each of the 10 stocks is represented in this plot by a vector, and the direction and length of the vector indicates how each stock depends on the underlying factors. For example, you have seen that after promax rotation, the first four stocks have positive loadings on the first factor, and unimportant loadings on the other two factors. That first factor, interpreted as a financial sector effect, is represented in this biplot as one of the horizontal axes. The dependence of those four stocks on that factor corresponds to the four vectors directed approximately along that axis. Similarly, the dependence of stocks 5, 6, and 7 primarily on the second factor, interpreted as a retail sector effect, is represented by vectors directed approximately along that axis.

Each of the 100 observations is represented in this plot by a point, and their locations indicate the score of each observation for the three factors. For example, points near the top of this plot have the

highest scores for the technology sector factor. The points are scaled to fit within the unit square, so only their relative locations can be determined from the plot.

You can use the **Data Cursor** tool from the **Tools** menu in the figure window to identify the items in this plot. By clicking a stock (vector), you can read off that stock's loadings for each factor. By clicking an observation (point), you can read off that observation's scores for each factor.

Robust Feature Selection Using NCA for Regression

Perform feature selection that is robust to outliers using a custom robust loss function in NCA.

Generate data with outliers

Generate sample data for regression where the response depends on three of the predictors, namely predictors 4, 7, and 13.

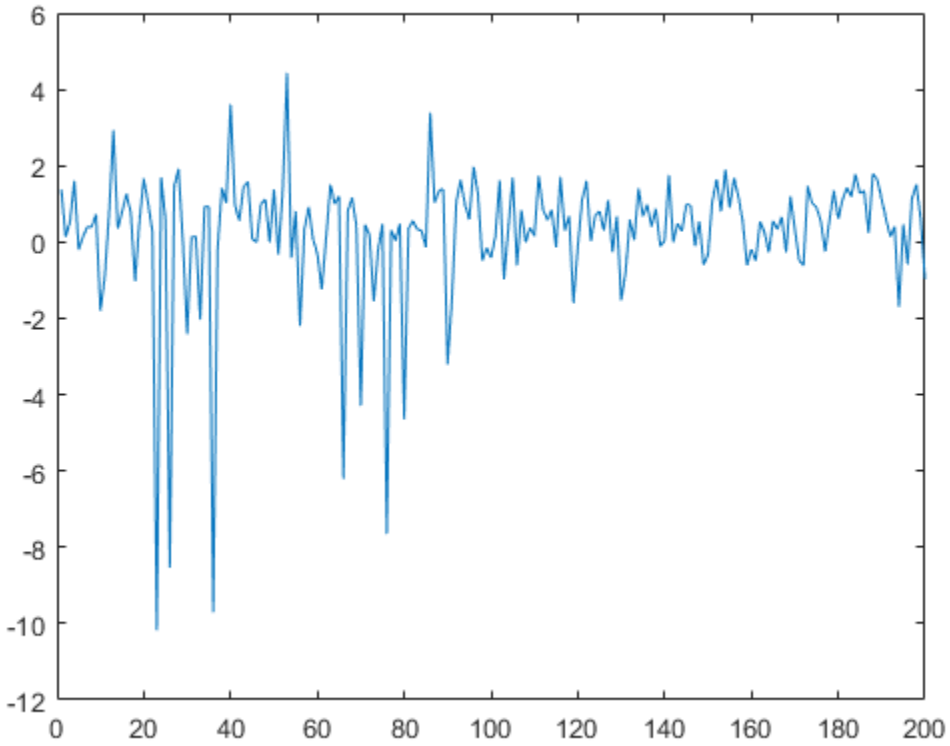
```
rng(123,'twister') % For reproducibility
n = 200;
X = randn(n,20);
y = cos(X(:,7)) + sin(X(:,4).*X(:,13)) + 0.1*randn(n,1);
```

Add outliers to data.

```
numoutliers = 25;
outlieridx = floor(linspace(10,90,numoutliers));
y(outlieridx) = 5*randn(numoutliers,1);
```

Plot the data.

```
figure
plot(y)
```



Use non-robust loss function

The performance of the feature selection algorithm highly depends on the value of the regularization parameter. A good practice is to tune the regularization parameter for the best value to use in feature selection. Tune the regularization parameter using five-fold cross validation. Use the mean squared error (MSE):

$$\mathrm{MSE} = \frac{1}{n}\sum_{i=1}^{n}\left(y_i - y_j\right)^2$$

First, partition the data into five folds. In each fold, the software uses 4/5th of the data for training and 1/5th of the data for validation (testing).

```
cvp = cvpartition(length(y),'kfold',5);
numtestsets = cvp.NumTestSets;
```

Compute the lambda values to test for and create an array to store the loss values.

```
lambdavals = linspace(0,3,50)*std(y)/length(y);
lossvals = zeros(length(lambdavals),numtestsets);
```

Perform NCA and compute the loss for each λ value and each fold.

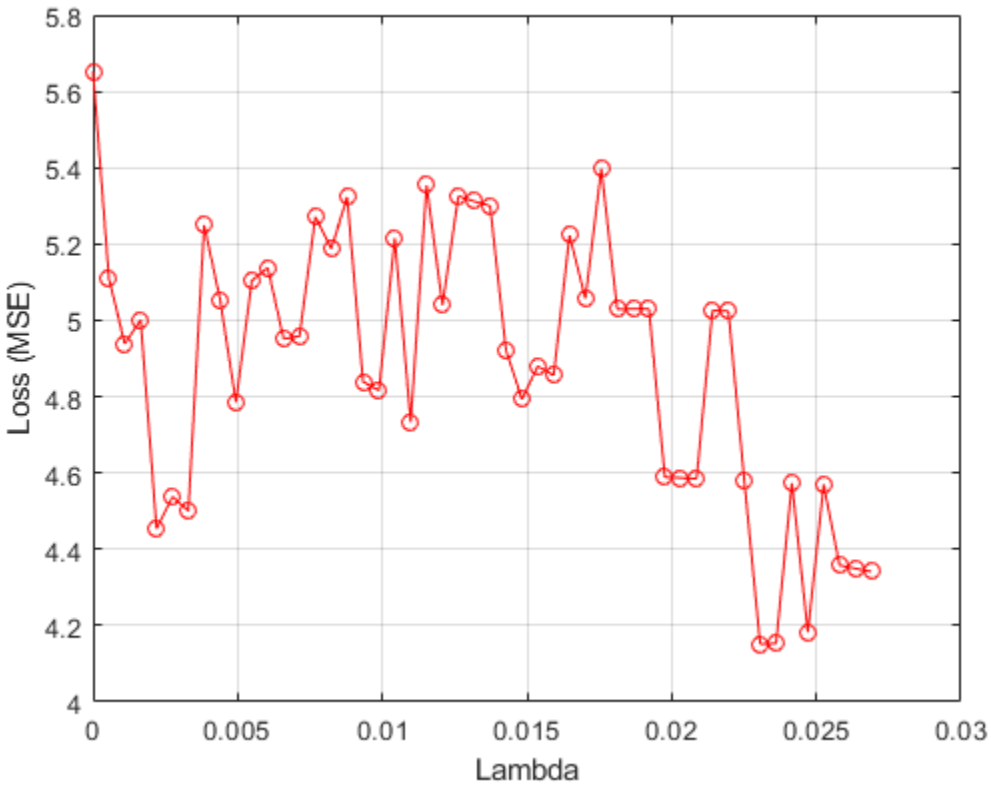
```
for i = 1:length(lambdavals)
    for k = 1:numtestsets
        Xtrain = X(cvp.training(k),:);
        ytrain = y(cvp.training(k),:);
        Xtest = X(cvp.test(k),:);
        ytest = y(cvp.test(k),:);

        nca = fsrnca(Xtrain,ytrain,'FitMethod','exact', ...
            'Solver','lbfgs','Verbose',0,'Lambda',lambdavals(i), ...
            'LossFunction','mse');

        lossvals(i,k) = loss(nca,Xtest,ytest,'LossFunction','mse');
    end
end
```

Plot the mean loss corresponding to each lambda value.

```
figure
meanloss = mean(lossvals,2);
plot(lambdavals,meanloss,'ro-')
xlabel('Lambda')
ylabel('Loss (MSE)')
grid on
```



Find the λ value that produces the minimum average loss.

```
[~,idx] = min(mean(lossvals,2));
bestlambda = lambdavals(idx)
```

```
bestlambda = 0.0231
```

Perform feature selection using the best λ value and MSE.

```
nca = fsrnca(X,y,'FitMethod','exact','Solver','lbfgs', ...
    'Verbose',1,'Lambda',bestlambda,'LossFunction','mse');
```

```
 o Solver = LBFGS, HessianHistorySize = 15, LineSearchMethod = weakwolfe

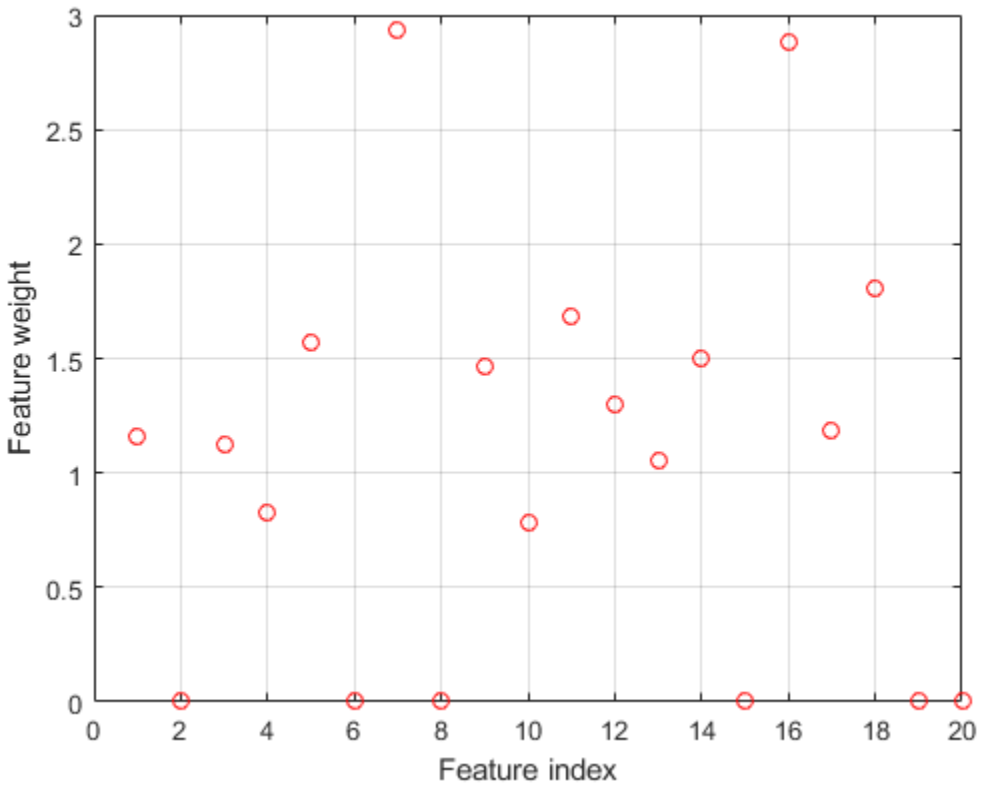
Relative infinity norm of the final gradient = 7.054e-07, TolFun = 1.000e-06
EXIT: Local minimum found.
```

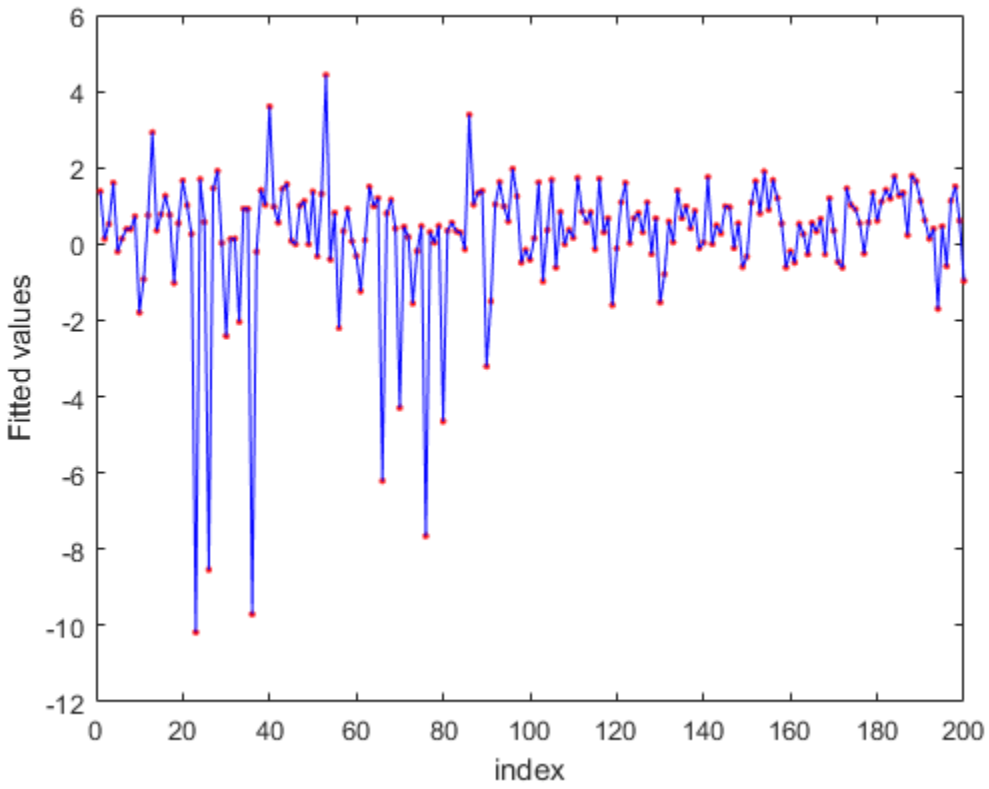
Plot selected features.

```
figure
plot(nca.FeatureWeights,'ro')
grid on
xlabel('Feature index')
ylabel('Feature weight')
```



Predict the response values using the `nca` model and plot the fitted (predicted) response values and the actual response values.

```
figure
fitted = predict(nca,X);
plot(y,'r.')
hold on
plot(fitted,'b-')
xlabel('index')
ylabel('Fitted values')
```



`fsrnca` tries to fit every point in data including the outliers. As a result it assigns nonzero weights to many features besides predictors 4, 7, and 13.

Use built-in robust loss function

Repeat the same process of tuning the regularization parameter, this time using the built-in ϵ-insensitive loss function:

$$l(y_i, y_j) = \max(0, |y_i - y_j| - \epsilon)$$

ϵ-insensitive loss function is more robust to outliers than mean squared error.

```
lambdavals = linspace(0,3,50)*std(y)/length(y);
cvp = cvpartition(length(y),'kfold',5);
numtestsets = cvp.NumTestSets;
lossvals = zeros(length(lambdavals),numtestsets);

for i = 1:length(lambdavals)
    for k = 1:numtestsets
        Xtrain = X(cvp.training(k),:);
        ytrain = y(cvp.training(k),:);
        Xtest = X(cvp.test(k),:);
        ytest = y(cvp.test(k),:);

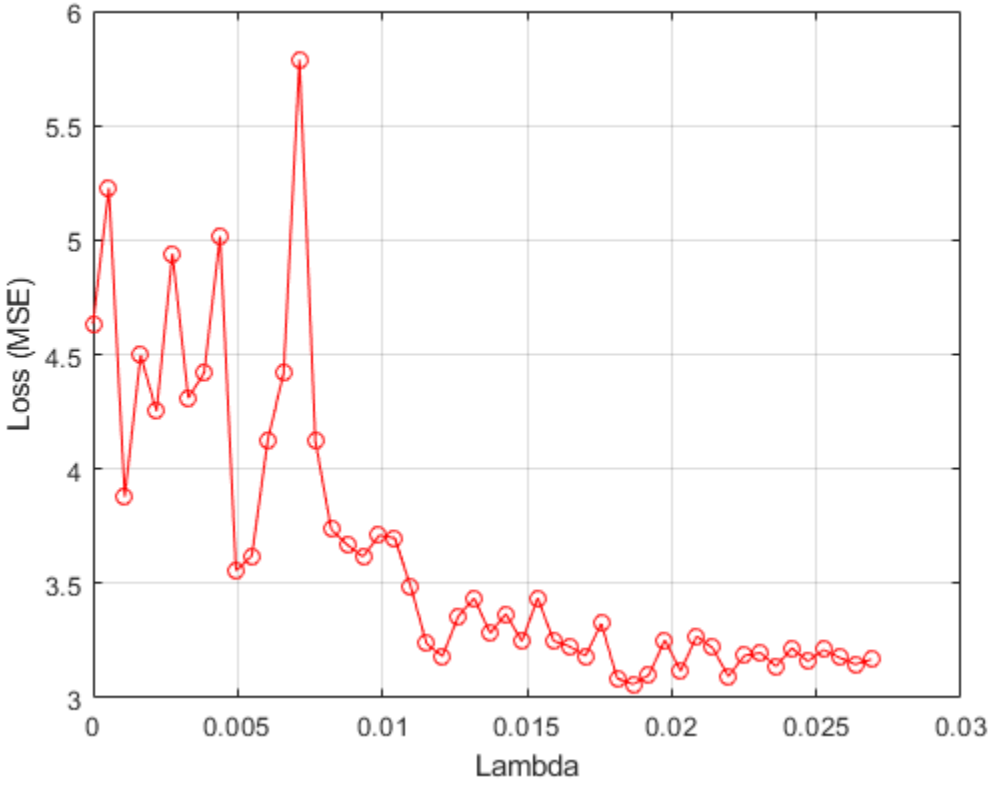
        nca = fsrnca(Xtrain,ytrain,'FitMethod','exact', ...
            'Solver','sgd','Verbose',0,'Lambda',lambdavals(i), ...
            'LossFunction','epsiloninsensitive','Epsilon',0.8);
```

```
        lossvals(i,k) = loss(nca,Xtest,ytest,'LossFunction','mse');
    end
end
```

The ϵ value to use depends on the data and the best value can be determined using cross-validation as well. But choosing the ϵ value is out of scope of this example. The choice of ϵ in this example is mainly for illustrating the robustness of the method.

Plot the mean loss corresponding to each lambda value.

```
figure
meanloss = mean(lossvals,2);
plot(lambdavals,meanloss,'ro-')
xlabel('Lambda')
ylabel('Loss (MSE)')
grid on
```



Find the lambda value that produces the minimum average loss.

```
[~,idx] = min(mean(lossvals,2));
bestlambda = lambdavals(idx)
```

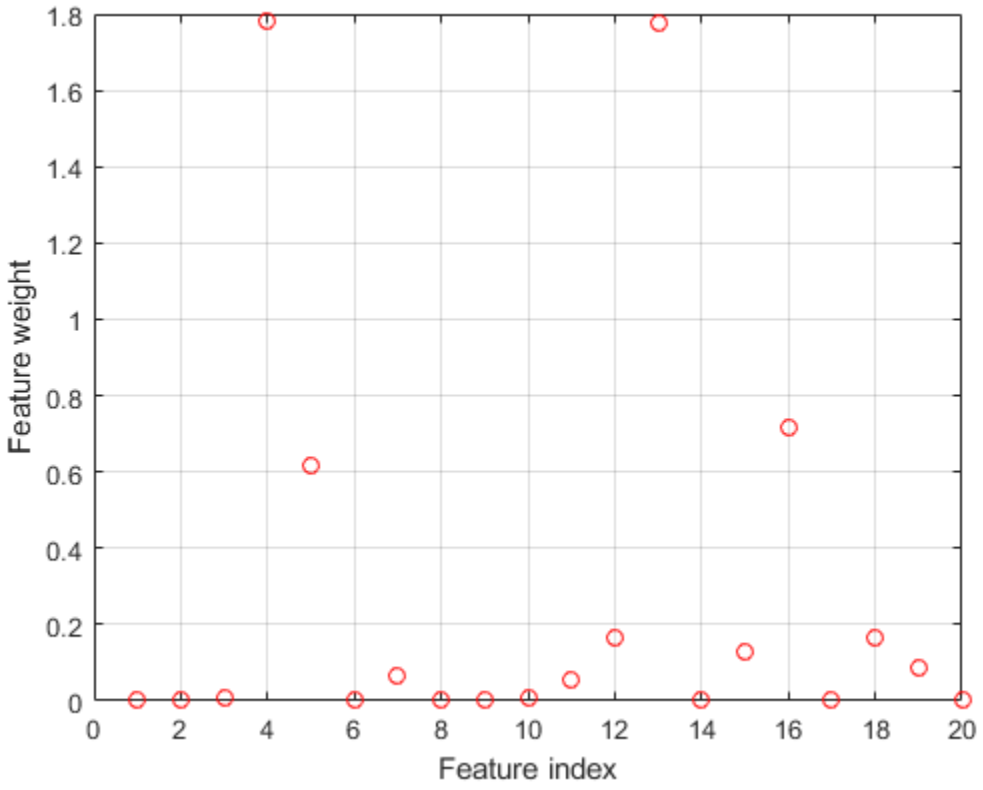
```
bestlambda = 0.0187
```

Fit neighborhood component analysis model using ϵ-insensitive loss function and best lambda value.

```
nca = fsrnca(X,y,'FitMethod','exact','Solver','sgd', ...
    'Lambda',bestlambda,'LossFunction','epsiloninsensitive','Epsilon',0.8);
```

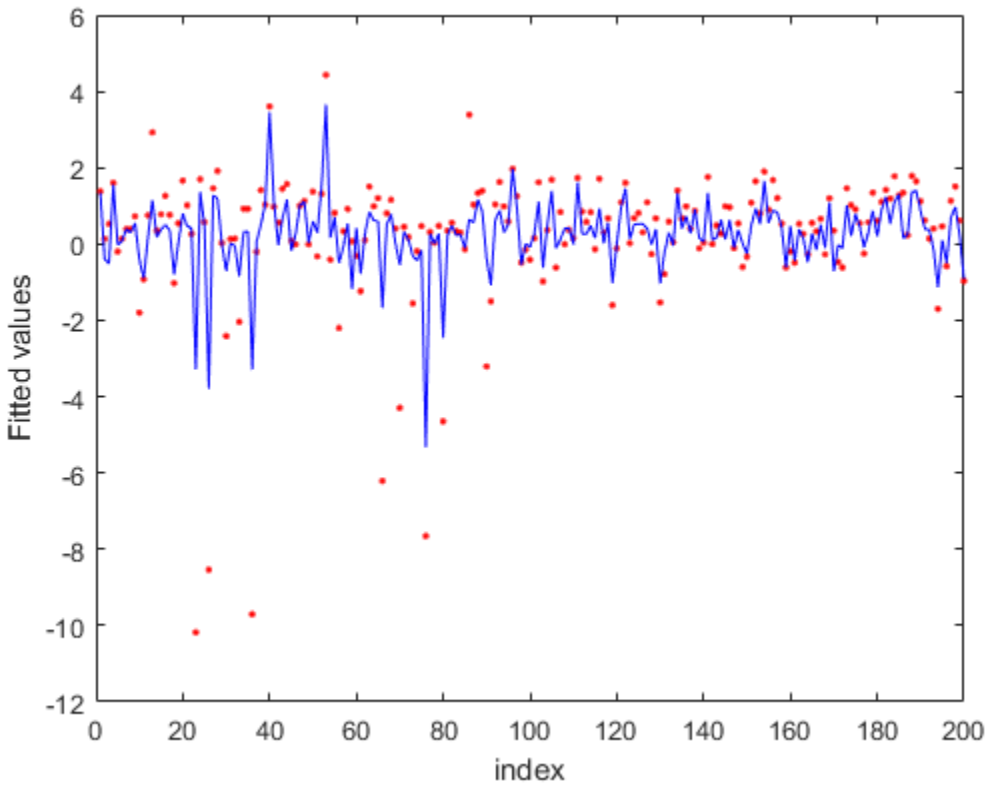
Plot selected features.

```
figure
plot(nca.FeatureWeights,'ro')
grid on
xlabel('Feature index')
ylabel('Feature weight')
```



Plot fitted values.

```
figure
fitted = predict(nca,X);
plot(y,'r.')
hold on
plot(fitted,'b-')
xlabel('index')
ylabel('Fitted values')
```



ϵ-insensitive loss seems more robust to outliers. It identified fewer features than mse as relevant. The fit shows that it is still impacted by some of the outliers.

Use custom robust loss function

Define a custom robust loss function that is robust to outliers to use in feature selection for regression:

$$f(y_i, y_j) = 1 - \exp(-|y_i - y_j|)$$

```
customlossFcn = @(yi,yj) 1 - exp(-abs(yi-yj'));
```

Tune the regularization parameter using the custom-defined robust loss function.

```
lambdavals = linspace(0,3,50)*std(y)/length(y);
cvp = cvpartition(length(y),'kfold',5);
numtestsets = cvp.NumTestSets;
lossvals = zeros(length(lambdavals),numtestsets);

for i = 1:length(lambdavals)
    for k = 1:numtestsets
        Xtrain = X(cvp.training(k),:);
        ytrain = y(cvp.training(k),:);
        Xtest = X(cvp.test(k),:);
        ytest = y(cvp.test(k),:);

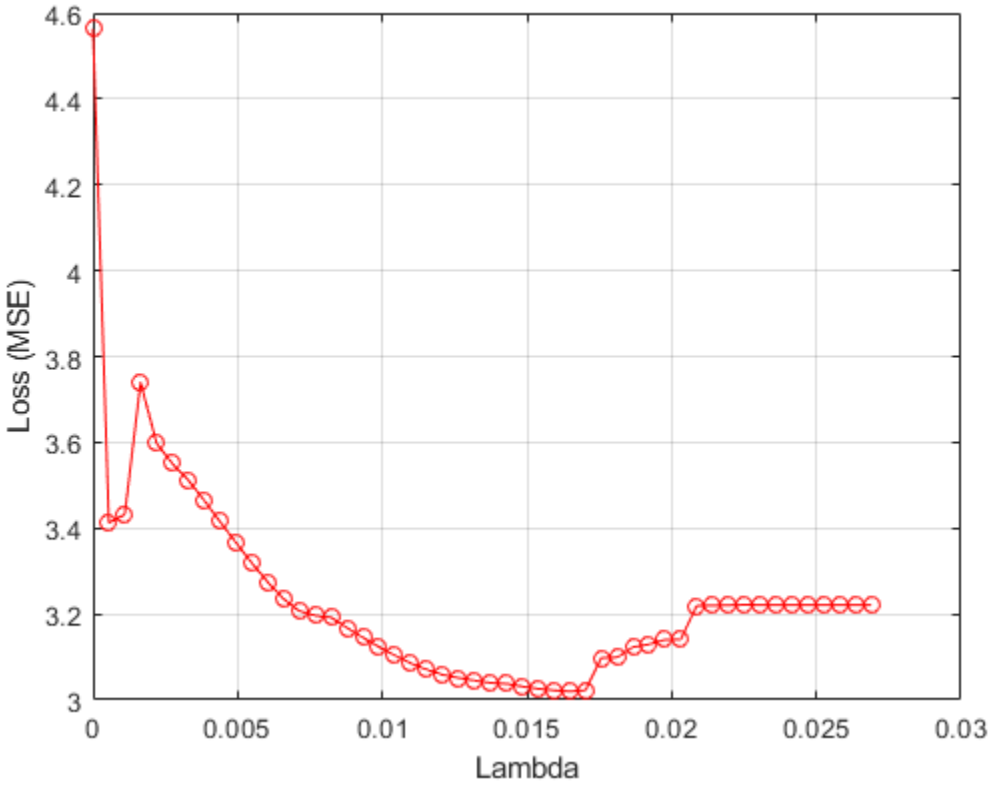
        nca = fsrnca(Xtrain,ytrain,'FitMethod','exact', ...
```

```
            'Solver','lbfgs','Verbose',0,'Lambda',lambdavals(i), ...
            'LossFunction',customlossFcn);

        lossvals(i,k) = loss(nca,Xtest,ytest,'LossFunction','mse');
    end
end
```

Plot the mean loss corresponding to each lambda value.

```
figure
meanloss = mean(lossvals,2);
plot(lambdavals,meanloss,'ro-')
xlabel('Lambda')
ylabel('Loss (MSE)')
grid on
```



Find the λ value that produces the minimum average loss.

```
[~,idx] = min(mean(lossvals,2));
bestlambda = lambdavals(idx)
```

```
bestlambda = 0.0165
```

Perform feature selection using the custom robust loss function and best λ value.

```
nca = fsrnca(X,y,'FitMethod','exact','Solver','lbfgs', ...
    'Verbose',1,'Lambda',bestlambda,'LossFunction',customlossFcn);
```

```
 o Solver = LBFGS, HessianHistorySize = 15, LineSearchMethod = weakwolfe

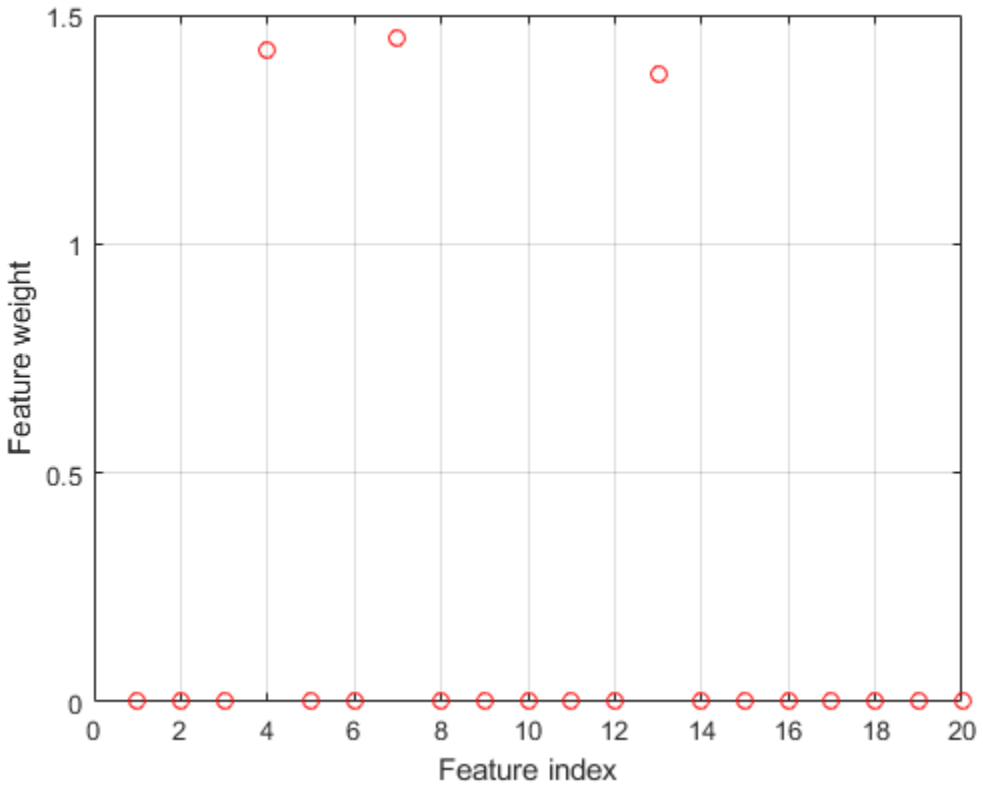
EXIT: Local minimum found.
```

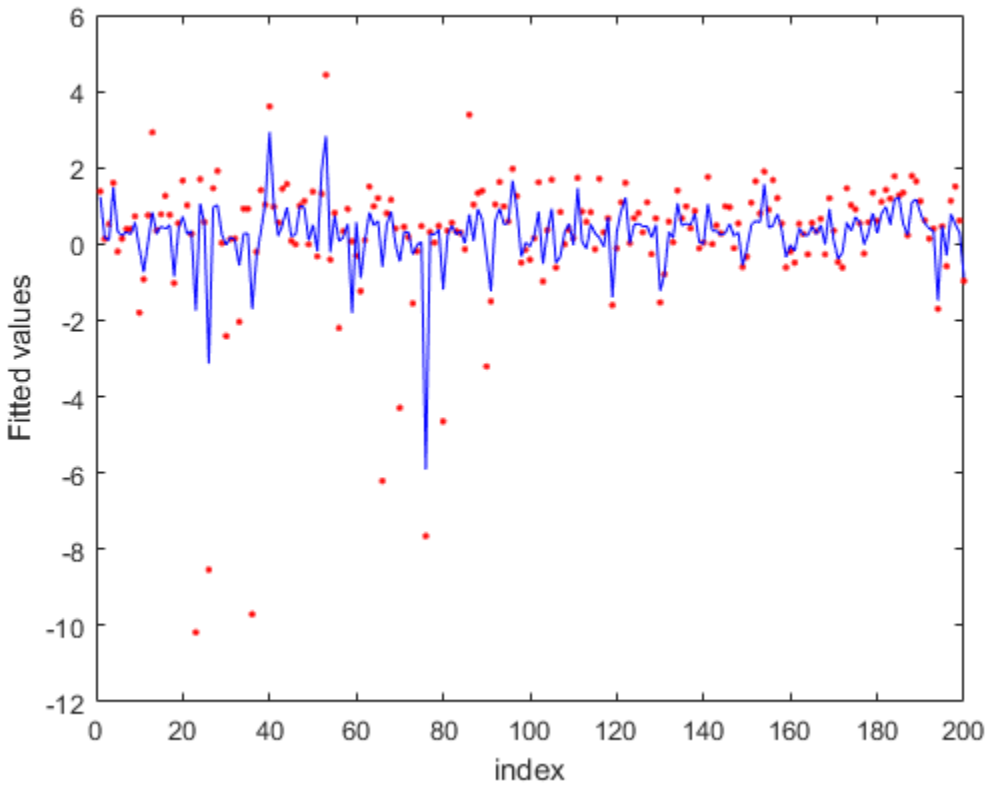
Plot selected features.

```
figure
plot(nca.FeatureWeights,'ro')
grid on
xlabel('Feature index')
ylabel('Feature weight')
```



Plot fitted values.

```
figure
fitted = predict(nca,X);
plot(y,'r.')
hold on
plot(fitted,'b-')
xlabel('index')
ylabel('Fitted values')
```



In this case, the loss is not affected by the outliers and results are based on most of the observation values. `fsrnca` detects the predictors 4, 7, and 13 as relevant features and does not select any other features.

Why does the loss function choice affect the results?

First, compute the loss functions for a series of values for the difference between two observations.

```
deltay = linspace(-10,10,1000)';
```

Compute custom loss function values.

```
customlossvals = customlossFcn(deltay,0);
```

Compute epsilon insensitive loss function and values.

```
epsinsensitive = @(yi,yj,E) max(0,abs(yi-yj')-E);
epsinsenvals = epsinsensitive(deltay,0,0.5);
```

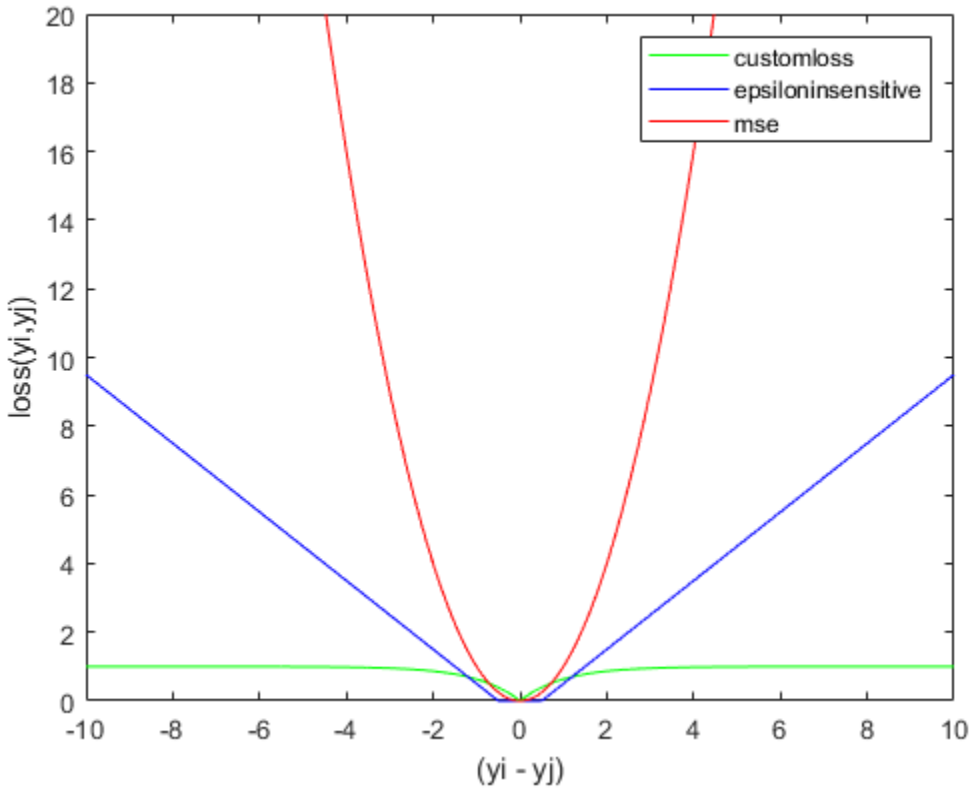
Compute MSE loss function and values.

```
mse = @(yi,yj) (yi-yj').^2;
msevals = mse(deltay,0);
```

Now, plot the loss functions to see their difference and why they affect the results in the way they do.

```
figure
plot(deltay,customlossvals,'g-',deltay,epsinsenvals,'b-',deltay,msevals,'r-')
```

```
xlabel('(yi - yj)')
ylabel('loss(yi,yj)')
legend('customloss','epsiloninsensitive','mse')
ylim([0 20])
```



As the difference between two response values increases, mse increases quadratically, which makes it very sensitive to outliers. As `fsrnca` tries to minimize this loss, it ends up identifying more features as relevant. The epsilon insensitive loss is more resistant to outliers than mse, but eventually it does start to increase linearly as the difference between two observations increase. As the difference between two observations increase, the robust loss function does approach 1 and stays at that value even though the difference between the observations keeps increasing. Out of three, it is the most robust to outliers.

Neighborhood Component Analysis (NCA) Feature Selection

In this section...

Neighborhood component analysis (NCA) is a non-parametric method for selecting features with the goal of maximizing prediction accuracy of regression and classification algorithms. The Statistics and Machine Learning Toolbox functions `fscnca` and `fsrnca` perform NCA feature selection with regularization to learn feature weights for minimization of an objective function that measures the average leave-one-out classification or regression loss over the training data.

NCA Feature Selection for Classification

Consider a multi-class classification problem with a training set containing n observations:

$$S = \{(x_i, y_i), i = 1, 2, ..., n\},$$

where $x_i \in \mathbb{R}^p$ are the feature vectors, $y_i \in \{1, 2, ..., c\}$ are the class labels, and c is the number of classes. The aim is to learn a classifier $f: \mathbb{R}^p \to \{1, 2, ..., c\}$ that accepts a feature vector and makes a prediction $f(x)$ for the true label y of x.

Consider a randomized classifier that:

- Randomly picks a point, Ref(x), from S as the ‘reference point’ for x
- Labels x using the label of the reference point Ref(x).

This scheme is similar to that of a 1-NN classifier where the reference point is chosen to be the nearest neighbor of the new point x. In NCA, the reference point is chosen randomly and all points in S have some probability of being selected as the reference point. The probability $P\left(\text{Ref}(x) = x_j \middle| S\right)$ that point x_j is picked from S as the reference point for x is higher if x_j is closer to x as measured by the distance function d_w, where

$$d_w(x_i, x_j) = \sum_{r=1}^{p} w_r^2 \left| x_{ir} - x_{jr} \right|,$$

and w_r are the feature weights. Assume that

$$P\left(\text{Ref}(x) = x_j \middle| S\right) \propto k\left(d_w\left(x, x_j\right)\right),$$

where k is some kernel or a similarity function that assumes large values when $d_w\left(x, x_j\right)$ is small. Suppose it is

$$k(z) = \exp\left(-\frac{z}{\sigma}\right),$$

as suggested in [1]. The reference point for x is chosen from S, so sum of $P\left(\text{Ref}(x) = x_j \middle| S\right)$ for all j must be equal to 1. Therefore, it is possible to write

$$P\left(\text{Ref}(x) = x_j \middle| S\right) = \frac{k\left(d_w\left(x, x_j\right)\right)}{\sum_{j=1}^{n} k\left(d_w\left(x, x_j\right)\right)}.$$

Now consider the leave-one-out application of this randomized classifier, that is, predicting the label of x_i using the data in S^{-i}, the training set S excluding the point (x_i, y_i). The probability that point x_j is picked as the reference point for x_i is

$$p_{ij} = P\left(\text{Ref}(x_i) = x_j \middle| S^{-i}\right) = \frac{k\left(d_w\left(x_i, x_j\right)\right)}{\sum_{j=1, j\neq i}^{n} k\left(d_w\left(x_i, x_j\right)\right)}.$$

The average leave-one-out probability of correct classification is the probability p_i that the randomized classifier correctly classifies observation i using S^{-i}.

$$p_i = \sum_{j=1, j\neq i}^{n} P\left(\text{Ref}(x_i) = x_j \middle| S^{-i}\right) I\left(y_i = y_j\right) = \sum_{j=1, j\neq i}^{n} p_{ij} y_{ij},$$

where

$$y_{ij} = I\left(y_i = y_j\right) = \begin{cases} 1 & \text{if } y_i = y_j, \\ 0 & \text{otherwise.} \end{cases}$$

The average leave-one-out probability of correct classification using the randomized classifier can be written as

$$F(w) = \frac{1}{n} \sum_{i=1}^{n} p_i.$$

The right hand side of $F(w)$ depends on the weight vector w. The goal of neighborhood component analysis is to maximize $F(w)$ with respect to w. `fscnca` uses the regularized objective function as introduced in [1].

$$\begin{aligned} F(w) &= \frac{1}{n} \sum_{i=1}^{n} p_i - \lambda \sum_{r=1}^{p} w_r^2 \\ &= \frac{1}{n} \sum_{i=1}^{n} \Bigg[\underbrace{\sum_{j=1, j\neq i}^{n} p_{ij} y_{ij}}_{F_i(w)} - \lambda \sum_{r=1}^{p} w_r^2 \Bigg], \\ &= \frac{1}{n} \sum_{i=1}^{n} F_i(w) \end{aligned}$$

where λ is the regularization parameter. The regularization term drives many of the weights in w to 0.

After choosing the kernel parameter σ in p_{ij} as 1, finding the weight vector w can be expressed as the following minimization problem for given λ.

$$\widehat{w} = \underset{w}{\operatorname{argmin}} f(w) = \underset{w}{\operatorname{argmin}} \frac{1}{n} \sum_{i=1}^{n} f_i(w),$$

where $f(w) = -F(w)$ and $f_i(w) = -F_i(w)$.

Note that

$$\frac{1}{n} \sum_{i=1}^{n} \sum_{j=1, j \neq i}^{n} p_{ij} = 1,$$

and the argument of the minimum does not change if you add a constant to an objective function. Therefore, you can rewrite the objective function by adding the constant 1.

$$\begin{aligned}
\widehat{w} &= \underset{w}{\operatorname{argmin}} \{1 + f(w)\} \\
&= \underset{w}{\operatorname{argmin}} \left\{ \frac{1}{n} \sum_{i=1}^{n} \sum_{j=1, j \neq i}^{n} p_{ij} - \frac{1}{n} \sum_{i=1}^{n} \sum_{j=1, j \neq i}^{n} p_{ij} y_{ij} + \lambda \sum_{r=1}^{p} w_r^2 \right\} \\
&= \underset{w}{\operatorname{argmin}} \left\{ \frac{1}{n} \sum_{i=1}^{n} \sum_{j=1, j \neq i}^{n} p_{ij} (1 - y_{ij}) + \lambda \sum_{r=1}^{p} w_r^2 \right\} \\
&= \underset{w}{\operatorname{argmin}} \left\{ \frac{1}{n} \sum_{i=1}^{n} \sum_{j=1, j \neq i}^{n} p_{ij} l(y_i, y_j) + \lambda \sum_{r=1}^{p} w_r^2 \right\},
\end{aligned}$$

where the loss function is defined as

$$l(y_i, y_j) = \begin{cases} 1 & \text{if } y_i \neq y_j, \\ 0 & \text{otherwise.} \end{cases}$$

The argument of the minimum is the weight vector that minimizes the classification error. You can specify a custom loss function using the `LossFunction` name-value pair argument in the call to `fscnca`.

NCA Feature Selection for Regression

The `fsrnca` function performs NCA feature selection modified for regression. Given n observations

$$S = \{(x_i, y_i), i = 1, 2, \ldots, n\},$$

the only difference from the classification problem is that the response values $y_i \in \mathbb{R}$ are continuous. In this case, the aim is to predict the response y given the training set S.

Consider a randomized regression model that:

- Randomly picks a point (Ref(x)) from Sas the 'reference point' for x
- Sets the response value at x equal to the response value of the reference point Ref(x).

Again, the probability $P\left(\text{Ref}(x) = x_j \middle| S\right)$ that point x_j is picked from S as the reference point for x is

$$P\left(\text{Ref}(x) = x_j \middle| S\right) = \frac{k\left(d_w\left(x, x_j\right)\right)}{\sum_{j=1}^{n} k\left(d_w\left(x, x_j\right)\right)}.$$

Now consider the leave-one-out application of this randomized regression model, that is, predicting the response for x_i using the data in S^{-i}, the training set S excluding the point (x_i, y_i). The probability that point x_j is picked as the reference point for x_i is

$$p_{ij} = P\left(\text{Ref}(x_i) = x_j \middle| S^{-i}\right) = \frac{k\left(d_w\left(x_i, x_j\right)\right)}{\sum_{j=1, j\neq i}^{n} k\left(d_w\left(x_i, x_j\right)\right)}.$$

Let $\widehat{y}_i$ be the response value the randomized regression model predicts and y_i be the actual response for x_i. And let $l: \mathbb{R}^2 \to \mathbb{R}$ be a loss function that measures the disagreement between $\widehat{y}_i$ and y_i. Then, the average value of $l(y_i, \widehat{y}_i)$ is

$$l_i = E\left(l(y_i, \widehat{y}_i) \middle| S^{-i}\right) = \sum_{j=1, j\neq i}^{n} p_{ij} l\left(y_i, y_j\right).$$

After adding the regularization term, the objective function for minimization is:

$$f(w) = \frac{1}{n}\sum_{i=1}^{n} l_i + \lambda \sum_{r=1}^{p} w_r^2.$$

The default loss function $l\left(y_i, y_j\right)$ for NCA for regression is mean absolute deviation, but you can specify other loss functions, including a custom one, using the `LossFunction` name-value pair argument in the call to `fsrnca`.

Impact of Standardization

The regularization term derives the weights of irrelevant predictors to zero. In the objective functions for NCA for classification or regression, there is only one regularization parameter λ for all weights. This fact requires the magnitudes of the weights to be comparable to each other. When the feature vectors x_i in S are in different scales, this might result in weights that are in different scales and not meaningful. To avoid this situation, standardize the predictors to have zero mean and unit standard deviation before applying NCA. You can standardize the predictors using the `'Standardize',true` name-value pair argument in the call to `fscnca` or `fsrnca`.

Choosing the Regularization Parameter Value

It is usually necessary to select a value of the regularization parameter by calculating the accuracy of the randomized NCA classifier or regression model on an independent test set. If you use cross-validation instead of a single test set, select the λ value that minimizes the average loss across the cross-validation folds. For examples, see “Tune Regularization Parameter to Detect Features Using NCA for Classification” on page 15-210 and “Tune Regularization Parameter in NCA for Regression” on page 33-2503.

t-SNE

In this section...

What Is t-SNE?

t-SNE (`tsne`) is an algorithm for dimensionality reduction that is well-suited to visualizing high-dimensional data. The name stands for *t*-distributed Stochastic Neighbor Embedding. The idea is to embed high-dimensional points in low dimensions in a way that respects similarities between points. Nearby points in the high-dimensional space correspond to nearby embedded low-dimensional points, and distant points in high-dimensional space correspond to distant embedded low-dimensional points. (Generally, it is impossible to match distances exactly between high-dimensional and low-dimensional spaces.)

The `tsne` function creates a set of low-dimensional points from high-dimensional data. Typically, you visualize the low-dimensional points to see natural clusters in the original high-dimensional data.

The algorithm takes the following general steps to embed the data in low dimensions.

1. Calculate the pairwise distances between the high-dimensional points.
2. Create a standard deviation σ_i for each high-dimensional point i so that the perplexity of each point is at a predetermined level. For the definition of perplexity, see “Compute Distances, Gaussian Variances, and Similarities” on page 15-105.
3. Calculate the similarity matrix. This is the joint probability distribution of X, defined by “Equation 15-2”.
4. Create an initial set of low-dimensional points.
5. Iteratively update the low-dimensional points to minimize the Kullback-Leibler divergence between a Gaussian distribution in the high-dimensional space and a t distribution in the low-dimensional space. This optimization procedure is the most time-consuming part of the algorithm.

See van der Maaten and Hinton [1].

t-SNE Algorithm

The basic t-SNE algorithm performs the following steps.

- “Prepare Data” on page 15-105
- “Compute Distances, Gaussian Variances, and Similarities” on page 15-105
- “Initialize the Embedding and Divergence” on page 15-106
- “Gradient Descent of Kullback-Leibler Divergence” on page 15-106

Prepare Data

`tsne` first removes each row of the input data X that contains any `NaN` values. Then, if the `Standardize` name-value pair is `true`, `tsne` centers X by subtracting the mean of each column, and scales X by dividing its columns by their standard deviations.

The original authors van der Maaten and Hinton [1] recommend reducing the original data X to a lower-dimensional version using “Principal Component Analysis (PCA)” on page 15-68. You can set the `tsne` `NumPCAComponents` name-value pair to the number of dimensions you like, perhaps 50. To exercise more control over this step, preprocess the data using the `pca` function.

Compute Distances, Gaussian Variances, and Similarities

After the preprocessing, `tsne` calculates the distance $d(x_i,x_j)$ between each pair of points x_i and x_j in X. You can choose various distance metrics using the `Distance` name-value pair. By default, `tsne` uses the standard Euclidean metric. `tsne` uses the square of the distance metric in its subsequent calculations.

Then for each row i of X, `tsne` calculates a standard deviation σ_i so that the perplexity of row i is equal to the `Perplexity` name-value pair. The perplexity is defined in terms of a model Gaussian distribution as follows. As van der Maaten and Hinton [1] describe, “The similarity of data point x_j to data point x_i is the conditional probability, $p_{j|i}$, that x_i would pick x_j as its neighbor if neighbors were picked in proportion to their probability density under a Gaussian centered at x_i. For nearby data points, $p_{j|i}$ is relatively high, whereas for widely separated data points, $p_{j|i}$ will be almost infinitesimal (for reasonable values of the variance of the Gaussian, σ_i).”

Define the conditional probability of j given i as

$$p_{j|i} = \frac{\exp\left(-d\left(x_i, x_j\right)^2/\left(2\sigma_i^2\right)\right)}{\sum_{k \neq i} \exp\left(-d\left(x_i, x_k\right)^2/\left(2\sigma_i^2\right)\right)}$$

$$p_{i|i} = 0.$$

Then define the joint probability p_{ij} by symmetrizing the conditional probabilities:

$$p_{ij} = \frac{p_{j|i} + p_{i|j}}{2N}, \tag{15-2}$$

where N is the number of rows of X.

The distributions still do not have their standard deviations σ_i defined in terms of the `Perplexity` name-value pair. Let P_i represents the conditional probability distribution over all other data points given data point x_i. The perplexity of the distribution is

$$\text{perplexity}(P_i) = 2^{H(P_i)},$$

where $H(P_i)$ is the Shannon entropy of P_i:

$$H(P_i) = -\sum_j p_{j|i} \log_2\left(p_{j|i}\right).$$

The perplexity measures the effective number of neighbors of point i. `tsne` performs a binary search over the σ_i to achieve a fixed perplexity for each point i.

Initialize the Embedding and Divergence

To embed the points in X into a low-dimensional space, `tsne` performs an optimization. `tsne` attempts to minimize the Kullback-Leibler divergence between the model Gaussian distribution of the points in X and a Student t distribution of points Y in the low-dimensional space.

The minimization procedure begins with an initial set of points Y. `tsne` create the points by default as random Gaussian-distributed points. You can also create these points yourself and include them in the `'InitialY'` name-value pair for `tsne`. `tsne` then calculates the similarities between each pair of points in Y.

The probability model q_{ij} of the distribution of the distances between points y_i and y_j is

$$q_{ij} = \frac{\left(1 + \|y_i - y_j\|^2\right)^{-1}}{\sum_k \sum_{l \neq k} \left(1 + \|y_k - y_l\|^2\right)^{-1}}$$

$$q_{ii} = 0.$$

Using this definition and the model of distances in X given by “Equation 15-2”, the Kullback-Leibler divergence between the joint distribution P and Q is

$$KL(P||Q) = \sum_j \sum_{i \neq j} p_{ij} \log \frac{p_{ij}}{q_{ij}}.$$

For consequences of this definition, see “Helpful Nonlinear Distortion” on page 15-107.

Gradient Descent of Kullback-Leibler Divergence

To minimize the Kullback-Leibler divergence, the `'exact'` algorithm uses a modified gradient descent procedure. The gradient with respect to the points in Y of the divergence is

$$\frac{\partial KL(P||Q)}{\partial y_i} = 4 \sum_{j \neq i} Z(p_{ij} - q_{ij}) q_{ij} (y_i - y_j),$$

where the normalization term

$$Z = \sum_k \sum_{l \neq k} \left(1 + \|y_k - y_l\|^2\right)^{-1}.$$

The modified gradient descent algorithm uses a few tuning parameters to attempt to reach a good local minimum.

- `'Exaggeration'` — During the first 99 gradient descent steps, `tsne` multiplies the probabilities p_{ij} from “Equation 15-2” by the exaggeration value. This step tends to create more space between clusters in the output Y.
- `'LearnRate'` — `tsne` uses adaptive learning to improve the convergence of the gradient descent iterations. The descent algorithm has iterative steps that are a linear combination of the previous step in the descent and the current gradient. `'LearnRate'` is a multiplier of the current gradient for the linear combination. For details, see Jacobs [3].

Barnes-Hut Variation of t-SNE

To speed the t-SNE algorithm and to cut down on its memory usage, `tsne` offers an approximate optimization scheme. The Barnes-Hut algorithm groups nearby points together to lower the complexity and memory usage of the t-SNE optimization step. The Barnes-Hut algorithm is an approximate optimizer, not an exact optimizer. There is a nonnegative tuning parameter `Theta` that effects a tradeoff between speed and accuracy. Larger values of `'Theta'` give faster but less accurate optimization results. The algorithm is relatively insensitive to `'Theta'` values in the range (0.2,0.8).

The Barnes-Hut algorithm groups nearby points in the low-dimensional space, and performs an approximate gradient descent based on these groups. The idea, originally used in astrophysics, is that the gradient is similar for nearby points, so the computations can be simplified.

See van der Maaten [2].

Characteristics of t-SNE

- “Cannot Use Embedding to Classify New Data” on page 15-107
- “Performance Depends on Data Sizes and Algorithm” on page 15-107
- “Helpful Nonlinear Distortion” on page 15-107

Cannot Use Embedding to Classify New Data

Because t-SNE often separates data clusters well, it can seem that t-SNE can classify new data points. However, t-SNE cannot classify new points. The t-SNE embedding is a nonlinear map that is data-dependent. To embed a new point in the low-dimensional space, you cannot use the previous embedding as a map. Instead, run the entire algorithm again.

Performance Depends on Data Sizes and Algorithm

t-SNE can take a good deal of time to process data. If you have N data points in D dimensions that you want to map to Y dimensions, then

- Exact t-SNE takes of order $D*N^2$ operations.
- Barnes-Hut t-SNE takes of order $D*N\log(N)*\exp(\text{dimension}(Y))$ operations.

So for large data sets, where N is greater than 1000 or so, and where the embedding dimension Y is 2 or 3, the Barnes-Hut algorithm can be faster than the exact algorithm.

Helpful Nonlinear Distortion

T-SNE maps high-dimensional distances to distorted low-dimensional analogues. Because of the fatter tail of the Student t distribution in the low-dimensional space, `tsne` often moves close points closer together, and moves far points farther apart than in the high-dimensional space, as illustrated in the following figure. The figure shows both Gaussian and Student t distributions at the points where the densities are at 0.25 and 0.025. The Gaussian density relates to high-dimensional distances, and the t density relates to low-dimensional distances. The t density corresponds to close points being closer, and far points being farther, compared to the Gaussian density.

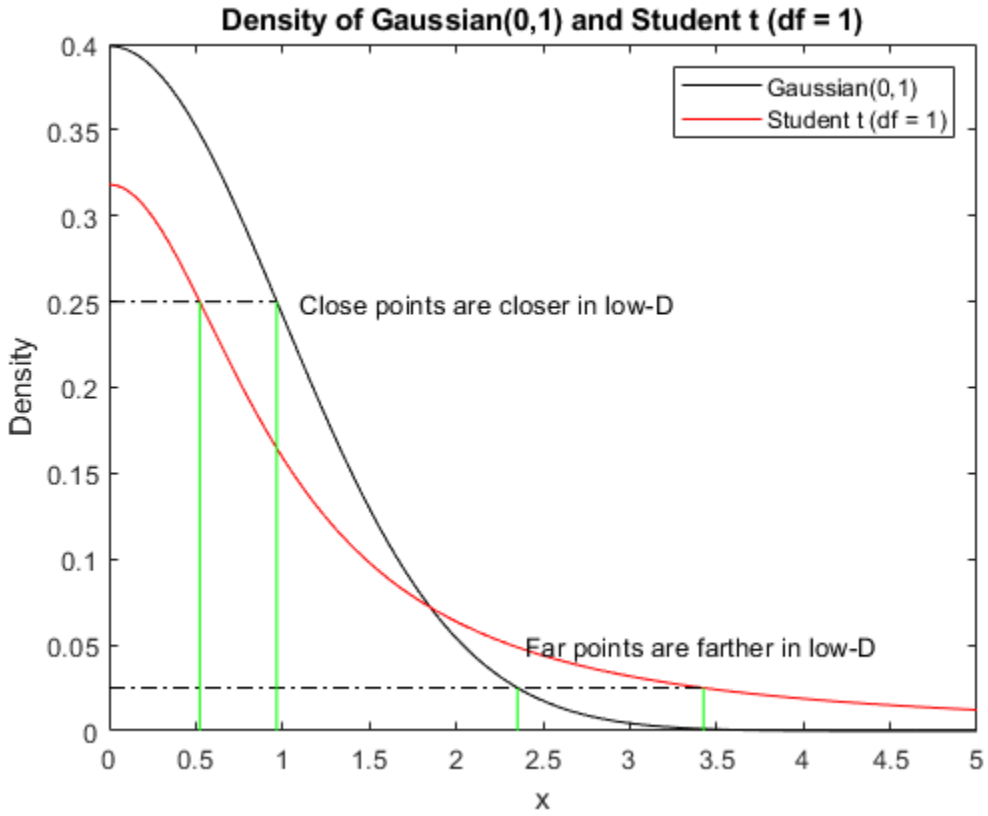
hold off
```



This distortion is helpful when it applies. It does not apply in cases such as when the Gaussian variance is high, which lowers the Gaussian peak and flattens the distribution. In such a case, `tsne` can move close points farther apart than in the original space. To achieve a helpful distortion,

- Set the `'Verbose'` name-value pair to 2.
- Adjust the `'Perplexity'` name-value pair so the reported range of variances is not too far from 1, and the mean variance is near 1.

If you can achieve this range of variances, then the diagram applies, and the `tsne` distortion is helpful.

For effective ways to tune `tsne`, see Wattenberg, Viégas and Johnson [4].

t-SNE Output Function

In this section...

t-SNE Output Function Description

A `tsne` output function is a function that runs after every `NumPrint` optimization iterations of the t-SNE algorithm. An output function can create plots, or log data to a file or to a workspace variable. The function cannot change the progress of the algorithm, but can halt the iterations.

Set output functions using the `Options` name-value pair argument to the `tsne` function. Set `Options` to a structure created using `statset` or `struct`. Set the `'OutputFcn'` field of the `Options` structure to a function handle or cell array of function handles.

For example, to set an output function named `outfun.m`, use the following commands.

```
opts = statset('OutputFcn',@outfun);
Y = tsne(X,'Options',opts);
```

Write an output function using the following syntax.

```
function stop = outfun(optimValues,state)

stop = false; % do not stop by default
switch state
    case 'init'
        % Set up plots or open files
    case 'iter'
        % Draw plots or update variables
    case 'done'
        % Clean up plots or files
end
```

`tsne` passes the `state` and `optimValues` variables to your function. `state` takes on the values `'init'`, `'iter'`, or `'done'` as shown in the code snippet.

tsne optimValues Structure

optimValues Field	Description
`'iteration'`	Iteration number
`'fval'`	Kullback-Leibler divergence, modified by exaggeration during the first 99 iterations
`'grad'`	Gradient of the Kullback-Leibler divergence, modified by exaggeration during the first 99 iterations
`'Exaggeration'`	Value of the exaggeration parameter in use in the current iteration
`'Y'`	Current embedding

t-SNE Custom Output Function

This example shows how to use an output function in `tsne`.

Custom Output Function

The following code is an output function that performs these tasks:

- Keep a history of the Kullback-Leibler divergence and the norm of its gradient in a workspace variable.
- Plot the solution and the history as the iterations proceed.
- Display a `Stop` button on the plot to stop the iterations early without losing any information.

The output function has an extra input variable, `species`, that enables its plots to show the correct classification of the data. For information on including extra parameters such as `species` in a function, see “Parameterizing Functions”.

```
function stop = KLLogging(optimValues,state,species)
persistent h kllog iters stopnow
switch state
    case 'init'
        stopnow = false;
        kllog = [];
        iters = [];
        h = figure;
        c = uicontrol('Style','pushbutton','String','Stop','Position', ...
            [10 10 50 20],'Callback',@stopme);
    case 'iter'
        kllog = [kllog; optimValues.fval,log(norm(optimValues.grad))];
        assignin('base','history',kllog)
        iters = [iters; optimValues.iteration];
        if length(iters) > 1
            figure(h)
            subplot(2,1,2)
            plot(iters,kllog);
            xlabel('Iterations')
            ylabel('Loss and Gradient')
            legend('Divergence','log(norm(gradient))')
            title('Divergence and log(norm(gradient))')
            subplot(2,1,1)
            gscatter(optimValues.Y(:,1),optimValues.Y(:,2),species)
            title('Embedding')
            drawnow
        end
    case 'done'
        % Nothing here
end
stop = stopnow;

function stopme(~,~)
stopnow = true;
end
end
```

Use the Custom Output Function

Plot the Fisher iris data, a 4-D data set, in two dimensions using `tsne`. There is a drop in the Divergence value at iteration 100 because the divergence is scaled by the exaggeration value for earlier iterations. The embedding remains largely unchanged for the last several hundred iterations, so you can save time by clicking the `Stop` button during the iterations.

```
load fisheriris
rng default % for reproducibility
opts = statset('OutputFcn',@(optimValues,state) KLLogging(optimValues,state,species));
Y = tsne(meas,'Options',opts,'Algorithm','exact');
```

- “tsne Settings” on page 15-117

Visualize High-Dimensional Data Using t-SNE

This example shows how to visualize the MNIST data [1], which consists of images of handwritten digits, using the `tsne` function. The images are 28-by-28 pixels in grayscale. Each image has an associated label from 0 through 9, which is the digit that the image represents. `tsne` reduces the dimension of the data from 784 original dimensions to 50 using PCA, and then to two or three using the t-SNE Barnes-Hut algorithm.

Obtain Data

Begin by obtaining image and label data from

http://yann.lecun.com/exdb/mnist/

Unzip the files. For this example, use the `t10k-images` data.

```
imageFileName = 't10k-images.idx3-ubyte';
labelFileName = 't10k-labels.idx1-ubyte';
```

Process the files to load them in the workspace. The code for this processing function appears at the end of this example.

```
[X,L] = processMNISTdata(imageFileName,labelFileName);
```

```
Read MNIST image data...
Number of images in the dataset:  10000 ...
Each image is of 28 by 28 pixels...
The image data is read to a matrix of dimensions:  10000 by  784...
End of reading image data.

Read MNIST label data...
Number of labels in the dataset:  10000 ...
The label data is read to a matrix of dimensions:  10000 by  1...
End of reading label data.
```

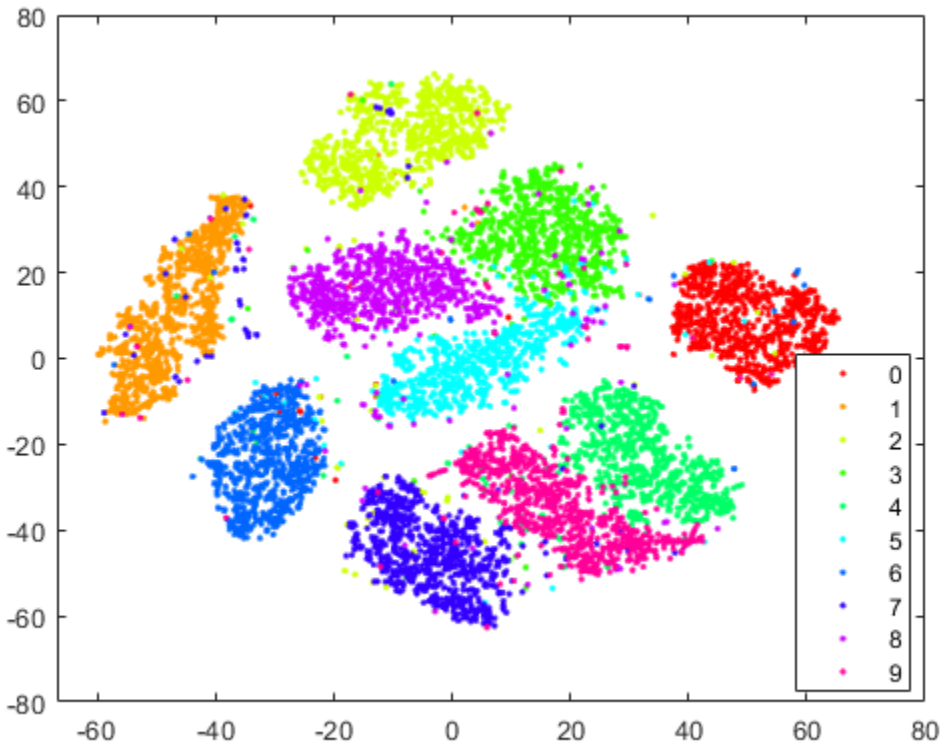
Reduce Dimension of Data to Two

Obtain two-dimensional analogues of the data clusters using t-SNE. Use PCA to reduce the initial dimensionality to 50. Use the Barnes-Hut variant of the t-SNE algorithm to save time on this relatively large data set.

```
rng default % for reproducibility
Y = tsne(X,'Algorithm','barneshut','NumPCAComponents',50);
```

Display the result, colored with the correct labels.

```
figure
gscatter(Y(:,1),Y(:,2),L)
```

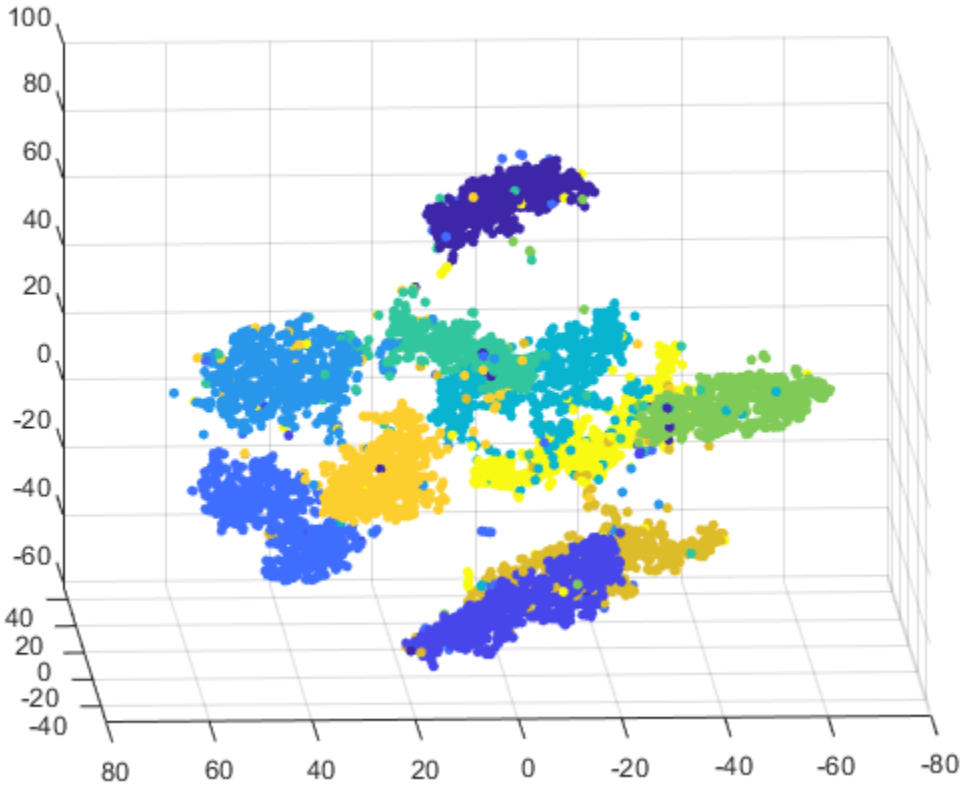


t-SNE creates clusters of points based solely on their relative similarities that correspond closely to the true labels.

Reduce Dimension of Data to Three

t-SNE can also reduce the data to three dimensions. Set the `tsne` `'NumDimensions'` name-value pair to 3.

```
rng default % for fair comparison
Y3 = tsne(X,'Algorithm','barneshut','NumPCAComponents',50,'NumDimensions',3);
figure
scatter3(Y3(:,1),Y3(:,2),Y3(:,3),15,L,'filled');
view(-93,14)
```



Here is the code of the function that reads the data into the workspace.

```
function [X,L] = processMNISTdata(imageFileName,labelFileName)

[fileID,errmsg] = fopen(imageFileName,'r','b');
if fileID < 0
    error(errmsg);
end
%%
% First read the magic number. This number is 2051 for image data, and
% 2049 for label data
magicNum = fread(fileID,1,'int32',0,'b');
if magicNum == 2051
    fprintf('\nRead MNIST image data...\n')
end
%%
% Then read the number of images, number of rows, and number of columns
numImages = fread(fileID,1,'int32',0,'b');
fprintf('Number of images in the dataset: %6d ...\n',numImages);
numRows = fread(fileID,1,'int32',0,'b');
numCols = fread(fileID,1,'int32',0,'b');
fprintf('Each image is of %2d by %2d pixels...\n',numRows,numCols);
%%
% Read the image data
X = fread(fileID,inf,'unsigned char');
%%
```

```
% Reshape the data to array X
X = reshape(X,numCols,numRows,numImages);
X = permute(X,[2 1 3]);
%%
% Then flatten each image data into a 1 by (numRows*numCols) vector, and
% store all the image data into a numImages by (numRows*numCols) array.
X = reshape(X,numRows*numCols,numImages)';
fprintf(['The image data is read to a matrix of dimensions: %6d by %4d...\n',...
    'End of reading image data.\n'],size(X,1),size(X,2));
%%
% Close the file
fclose(fileID);
%%
% Similarly, read the label data.
[fileID,errmsg] = fopen(labelFileName,'r','b');
if fileID < 0
    error(errmsg);
end
magicNum = fread(fileID,1,'int32',0,'b');
if magicNum == 2049
    fprintf('\nRead MNIST label data...\n')
end
numItems = fread(fileID,1,'int32',0,'b');
fprintf('Number of labels in the dataset: %6d ...\n',numItems);

L = fread(fileID,inf,'unsigned char');
fprintf(['The label data is read to a matrix of dimensions: %6d by %2d...\n',...
    'End of reading label data.\n'],size(L,1),size(L,2));
fclose(fileID);
```

tsne Settings

This example shows the effects of various `tsne` settings.

Obtain Data

Begin by obtaining the MNIST [1] image and label data from

http://yann.lecun.com/exdb/mnist/

Unzip the files. For this example, use the `t10k-images` data.

```
imageFileName = 't10k-images.idx3-ubyte';
labelFileName = 't10k-labels.idx1-ubyte';
```

Process the files to load them in the workspace. The code for this processing function appears at the end of this example.

```
[X,L] = processMNISTdata(imageFileName,labelFileName);
```

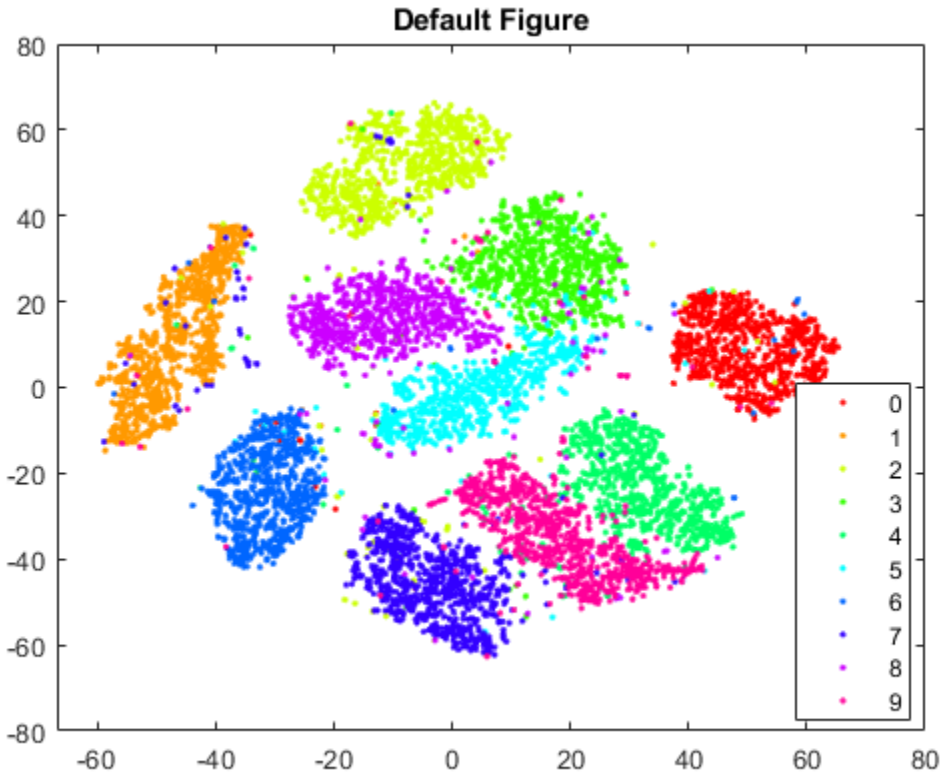
```
Read MNIST image data...
Number of images in the dataset:  10000 ...
Each image is of 28 by 28 pixels...
The image data is read to a matrix of dimensions:  10000 by  784...
End of reading image data.

Read MNIST label data...
Number of labels in the dataset:  10000 ...
The label data is read to a matrix of dimensions:  10000 by  1...
End of reading label data.
```

Process Data Using t-SNE

Obtain two-dimensional analogs of the data clusters using t-SNE. Use the Barnes-Hut algorithm for better performance on this large data set. Use PCA to reduce the initial dimensions from 784 to 50.

```
rng default % for reproducibility
Y = tsne(X,'Algorithm','barneshut','NumPCAComponents',50);
figure
gscatter(Y(:,1),Y(:,2),L)
title('Default Figure')
```



t-SNE creates a figure with well separated clusters and relatively few data points that seem misplaced.

Perplexity

Try altering the perplexity setting to see the effect on the figure.

```
rng default % for fair comparison
Y100 = tsne(X,'Algorithm','barneshut','NumPCAComponents',50,'Perplexity',100);
figure
gscatter(Y100(:,1),Y100(:,2),L)
title('Perplexity 100')

rng default % for fair comparison
Y4 = tsne(X,'Algorithm','barneshut','NumPCAComponents',50,'Perplexity',4);
figure
gscatter(Y4(:,1),Y4(:,2),L)
title('Perplexity 4')
```

Setting the perplexity to 100 yields a figure that is largely similar to the default figure. The clusters are tighter than with the default setting. However, setting the perplexity to 4 gives a figure without well separated clusters. The clusters are looser than with the default setting.

Exaggeration

Try altering the exaggeration setting to see the effect on the figure.

```
rng default % for fair comparison
YEX0 = tsne(X,'Algorithm','barneshut','NumPCAComponents',50,'Exaggeration',20);
figure
gscatter(YEX0(:,1),YEX0(:,2),L)
title('Exaggeration 20')

rng default % for fair comparison
YEx15 = tsne(X,'Algorithm','barneshut','NumPCAComponents',50,'Exaggeration',1.5);
figure
gscatter(YEx15(:,1),YEx15(:,2),L)
title('Exaggeration 1.5')
```

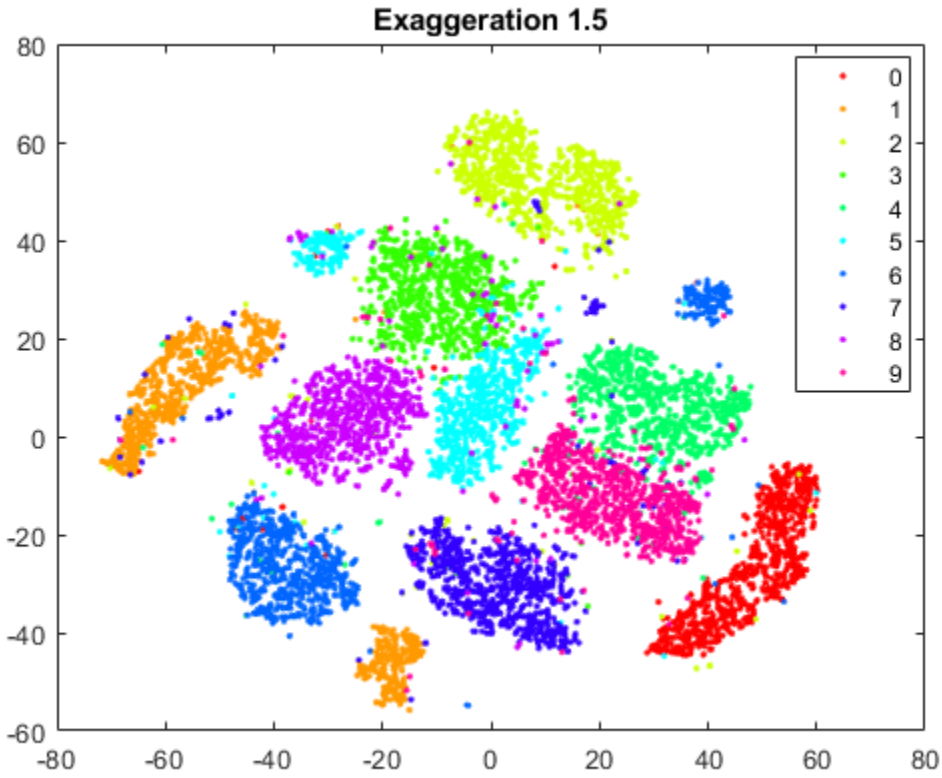
9



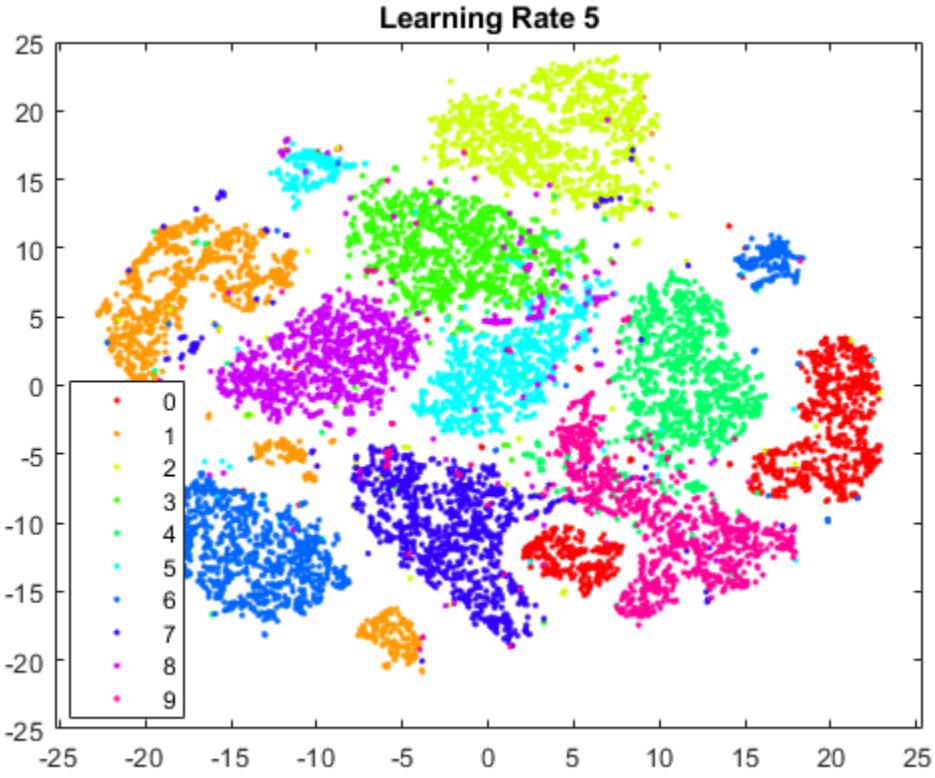
While the exaggeration setting has an effect on the figure, it is not clear whether any nondefault setting gives a better picture than the default setting. The figure with an exaggeration of 20 is similar to the default figure. In general, a larger exaggeration creates more empty space between embedded clusters. An exaggeration of 1.5 causes the groups labeled 1 and 6 to split into two groups each, an undesirable outcome. Exaggerating the values in the joint distribution of X makes the values in the joint distribution of Y smaller. This makes it much easier for the embedded points to move relative to one another. The splitting of clusters 1 and 6 reflects this effect.

Learning Rate

Try altering the learning rate setting to see the effect on the figure.

```
rng default % for fair comparison
YL5 = tsne(X,'Algorithm','barneshut','NumPCAComponents',50,'LearnRate',5);
figure
gscatter(YL5(:,1),YL5(:,2),L)
title('Learning Rate 5')

rng default % for fair comparison
YL2000 = tsne(X,'Algorithm','barneshut','NumPCAComponents',50,'LearnRate',2000);
figure
gscatter(YL2000(:,1),YL2000(:,2),L)
title('Learning Rate 2000')
```



Learning Rate 5

The figure with a learning rate of 5 has several clusters that split into two or more pieces. This shows that if the learning rate is too small, the minimization process can get stuck in a bad local minimum. A learning rate of 2000 gives a figure similar to the default figure.

Initial Behavior with Various Settings

Large learning rates or large exaggeration values can lead to undesirable initial behavior. To see this, set large values of these parameters and set `NumPrint` and `Verbose` to 1 to show all the iterations. Stop the iterations after 10, as the goal of this experiment is simply to look at the initial behavior.

Begin by setting the exaggeration to 200.

```
rng default % for fair comparison
opts = statset('MaxIter',10);
YEX200 = tsne(X,'Algorithm','barneshut','NumPCAComponents',50,'Exaggeration',200,...
    'NumPrint',1,'Verbose',1,'Options',opts);
```

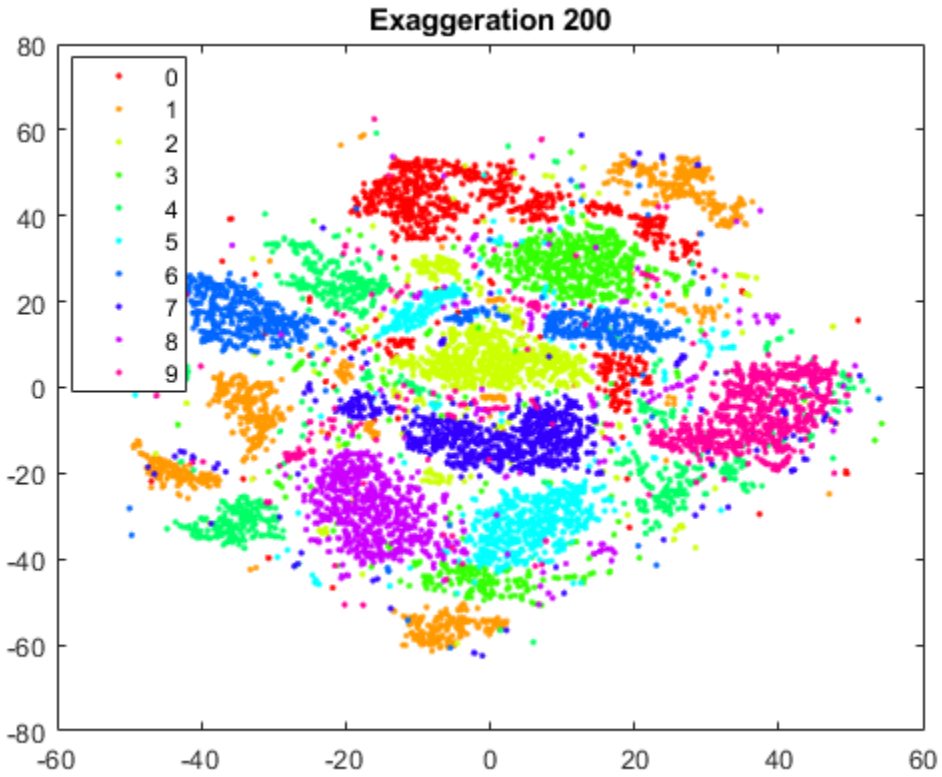
```
|============================================|
|   ITER   | KL DIVERGENCE   | NORM GRAD USING |
|          | FUN VALUE USING | EXAGGERATED DIST|
|          | EXAGGERATED DIST| OF X            |
|          | OF X            |                 |
|============================================|
|        1 |    2.190347e+03 |    6.078667e-05 |
|        2 |    2.190352e+03 |    4.769050e-03 |
|        3 |    2.204061e+03 |    9.423678e-02 |
```

```
|         4 |    2.464585e+03 |    2.113271e-02 |
|         5 |    2.501222e+03 |    2.616407e-02 |
|         6 |    2.529362e+03 |    3.022570e-02 |
|         7 |    2.553233e+03 |    3.108418e-02 |
|         8 |    2.562822e+03 |    3.278873e-02 |
|         9 |    2.538056e+03 |    3.222265e-02 |
|        10 |    2.504932e+03 |    3.671708e-02 |
```

The Kullback-Leibler divergence increases during the first few iterations, and the norm of the gradient increases as well.

To see the final result of the embedding, allow the algorithm to run to completion using the default stopping criteria.

```
rng default % for fair comparison
YEX200 = tsne(X,'Algorithm','barneshut','NumPCAComponents',50,'Exaggeration',200);
figure
gscatter(YEX200(:,1),YEX200(:,2),L)
title('Exaggeration 200')
```



This exaggeration value does not give a clean separation into clusters.

Show the initial behavior when the learning rate is 100,000.

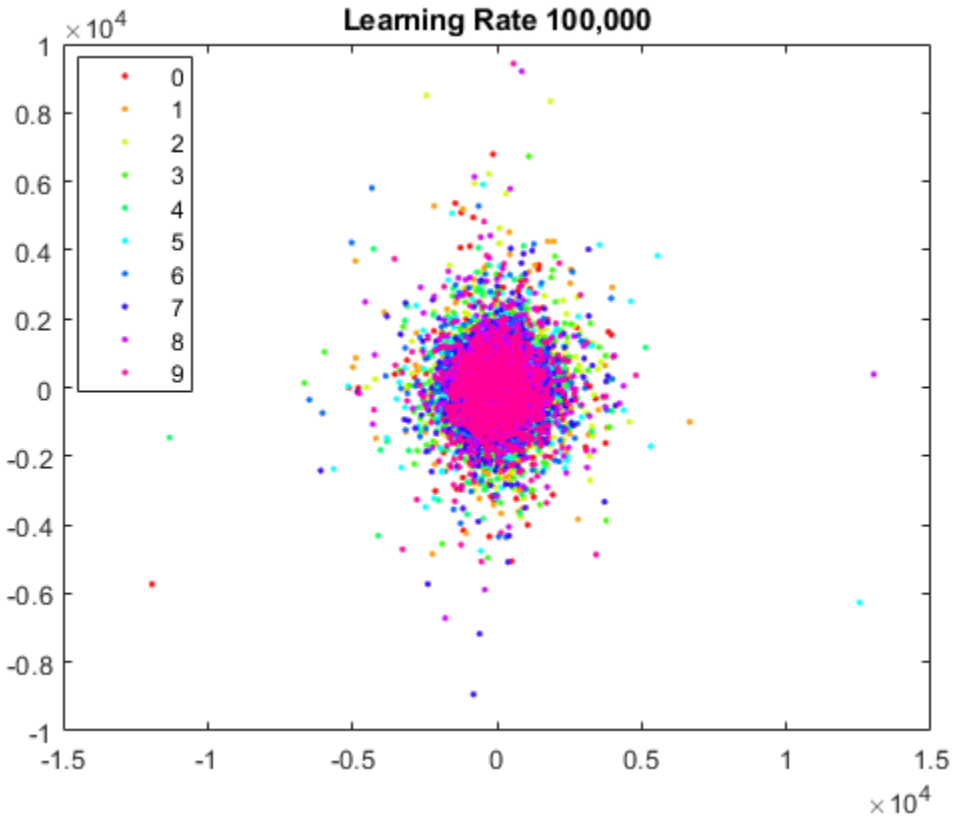
```
rng default % for fair comparison
YL100k = tsne(X,'Algorithm','barneshut','NumPCAComponents',50,'LearnRate',1e5,...
    'NumPrint',1,'Verbose',1,'Options',opts);
```

```
|=============================================|
|   ITER   | KL DIVERGENCE   | NORM GRAD USING |
|          | FUN VALUE USING | EXAGGERATED DIST|
|          | EXAGGERATED DIST| OF X            |
|          | OF X            |                 |
|=============================================|
|        1 |    2.815885e+01 |    1.024049e-06 |
|        2 |    2.816002e+01 |    2.902059e-04 |
|        3 |    3.195873e+01 |    7.355889e-04 |
|        4 |    3.348151e+01 |    3.958901e-04 |
|        5 |    3.365935e+01 |    2.876905e-04 |
|        6 |    3.342462e+01 |    3.906245e-04 |
|        7 |    3.303205e+01 |    4.037983e-04 |
|        8 |    3.263320e+01 |    5.665630e-04 |
|        9 |    3.235384e+01 |    4.319099e-04 |
|       10 |    3.211238e+01 |    4.803526e-04 |
```

Again, the Kullback-Leibler divergence increases during the first few iterations, and the norm of the gradient increases as well.

To see the final result of the embedding, allow the algorithm to run to completion using the default stopping criteria.

```
rng default % for fair comparison
YL100k = tsne(X,'Algorithm','barneshut','NumPCAComponents',50,'LearnRate',1e5);
figure
gscatter(YL100k(:,1),YL100k(:,2),L)
title('Learning Rate 100,000')
```



The learning rate is far too large, and gives no useful embedding.

Conclusion

`tsne` with default settings does a good job of embedding the high-dimensional initial data into two-dimensional points that have well defined clusters. The effects of algorithm settings are difficult to predict. Sometimes they can improve the clustering, but for the most part the default settings seem good. While speed is not part of this investigation, settings can affect the speed of the algorithm. In particular, the Barnes-Hut algorithm is notably faster on this data.

Code to Process MNIST Data

Here is the code of the function that reads the data into the workspace.

```
function [X,L] = processMNISTdata(imageFileName,labelFileName)

[fileID,errmsg] = fopen(imageFileName,'r','b');
if fileID < 0
    error(errmsg);
end
%%
% First read the magic number. This number is 2051 for image data, and
% 2049 for label data
magicNum = fread(fileID,1,'int32',0,'b');
if magicNum == 2051
    fprintf('\nRead MNIST image data...\n')
```

```
end
%%
% Then read the number of images, number of rows, and number of columns
numImages = fread(fileID,1,'int32',0,'b');
fprintf('Number of images in the dataset: %6d ...\n',numImages);
numRows = fread(fileID,1,'int32',0,'b');
numCols = fread(fileID,1,'int32',0,'b');
fprintf('Each image is of %2d by %2d pixels...\n',numRows,numCols);
%%
% Read the image data
X = fread(fileID,inf,'unsigned char');
%%
% Reshape the data to array X
X = reshape(X,numCols,numRows,numImages);
X = permute(X,[2 1 3]);
%%
% Then flatten each image data into a 1 by (numRows*numCols) vector, and
% store all the image data into a numImages by (numRows*numCols) array.
X = reshape(X,numRows*numCols,numImages)';
fprintf(['The image data is read to a matrix of dimensions: %6d by %4d...\n',...
    'End of reading image data.\n'],size(X,1),size(X,2));
%%
% Close the file
fclose(fileID);
%%
% Similarly, read the label data.
[fileID,errmsg] = fopen(labelFileName,'r','b');
if fileID < 0
    error(errmsg);
end
magicNum = fread(fileID,1,'int32',0,'b');
if magicNum == 2049
    fprintf('\nRead MNIST label data...\n')
end
numItems = fread(fileID,1,'int32',0,'b');
fprintf('Number of labels in the dataset: %6d ...\n',numItems);

L = fread(fileID,inf,'unsigned char');
fprintf(['The label data is read to a matrix of dimensions: %6d by %2d...\n',...
    'End of reading label data.\n'],size(L,1),size(L,2));
fclose(fileID);
```

Feature Extraction

In this section...

What Is Feature Extraction?

Feature extraction is a set of methods that map input features to new output features. Many feature extraction methods use unsupervised learning to extract features. Unlike some feature extraction methods such as PCA and NNMF, the methods described in this section can increase dimensionality (and decrease dimensionality). Internally, the methods involve optimizing nonlinear objective functions. For details, see “Sparse Filtering Algorithm” on page 15-130 or “Reconstruction ICA Algorithm” on page 15-132.

One typical use of feature extraction is finding features in images. Using these features can lead to improved classification accuracy. For an example, see “Feature Extraction Workflow” on page 15-135. Another typical use is extracting individual signals from superpositions, which is often termed blind source separation. For an example, see “Extract Mixed Signals” on page 15-164.

There are two feature extraction functions: `rica` and `sparsefilt`. Associated with these functions are the objects that they create: `ReconstructionICA` and `SparseFiltering`.

Sparse Filtering Algorithm

The sparse filtering algorithm begins with a data matrix `X` that has `n` rows and `p` columns. Each row represents one observation and each column represents one measurement. The columns are also called the features or predictors. The algorithm then takes either an initial random `p`-by-`q` weight matrix `W` or uses the weight matrix passed in the `InitialTransformWeights` name-value pair. `q` is the requested number of features that `sparsefilt` computes.

The algorithm attempts to minimize the “Sparse Filtering Objective Function” on page 15-131 by using a standard limited memory Broyden-Fletcher-Goldfarb-Shanno (LBFGS) quasi-Newton optimizer. See Nocedal and Wright [2]. This optimizer takes up to `IterationLimit` iterations. It stops iterating earlier when it takes a step whose norm is less than `StepTolerance`, or when it computes that the norm of the gradient at the current point is less than `GradientTolerance` times a scalar τ, where

$$\tau = \max\left(1, \min\left(|f|, \|g_0\|_\infty\right)\right).$$

$|f|$ is the norm of the objective function, and $\|g_0\|_\infty$ is the infinity norm of the initial gradient.

The objective function attempts to simultaneously obtain few nonzero features for each data point, and for each resulting feature to have nearly equal weight. To understand how the objective function attempts to achieve these goals, see Ngiam, Koh, Chen, Bhaskar, and Ng [1].

Frequently, you obtain good features by setting a relatively small value of `IterationLimit`, from as low as 5 to a few hundred. Allowing the optimizer to continue can result in overtraining, where the extracted features do not generalize well to new data.

After constructing a `SparseFiltering` object, use the `transform` method to map input data to the new output features.

Sparse Filtering Objective Function

To compute an objective function, the sparse filtering algorithm uses the following steps. The objective function depends on the `n`-by-`p` data matrix `X` and a weight matrix `W` that the optimizer varies. The weight matrix `W` has dimensions `p`-by-`q`, where `p` is the number of original features and `q` is the number of requested features.

1. Compute the `n`-by-`q` matrix `X*W`. Apply the approximate absolute value function $\phi(u) = \sqrt{u^2 + 10^{-8}}$ to each element of `X*W` to obtain the matrix `F`. ϕ is a smooth nonnegative symmetric function that closely approximates the absolute value function.
2. Normalize the columns of `F` by the approximate L^2 norm. In other words, define the normalized matrix $\tilde{F}(i, j)$ by

$$\|F(j)\| = \sqrt{\sum_{i=1}^{n} (F(i, j))^2 + 10^{-8}}$$

$$\tilde{F}(i, j) = F(i, j) / \|F(j)\| .$$

3. Normalize the rows of $\tilde{F}(i, j)$ by the approximate L^2 norm. In other words, define the normalized matrix $\widehat{F}(i, j)$ by

$$\left\|\tilde{F}(i)\right\| = \sqrt{\sum_{j=1}^{q} \left(\tilde{F}(i, j)\right)^2 + 10^{-8}}$$

$$\widehat{F}(i, j) = \tilde{F}(i, j) / \left\|\tilde{F}(i)\right\| .$$

   The matrix $\widehat{F}$ is the matrix of converted features in `X`. Once `sparsefilt` finds the weights `W` that minimize the objective function h (see below), which the function stores in the output object `Mdl` in the `Mdl.TransformWeights` property, the `transform` function can follow the same transformation steps to convert new data to output features.

4. Compute the objective function h(`W`) as the 1–norm of the matrix $\widehat{F}(i, j)$, meaning the sum of all the elements in the matrix (which are nonnegative by construction):

$$h(W) = \sum_{j=1}^{q} \sum_{i=1}^{n} \widehat{F}(i, j) .$$

5. If you set the `Lambda` name-value pair to a strictly positive value, `sparsefilt` uses the following modified objective function:

$$h(W) = \sum_{j=1}^{q} \sum_{i=1}^{n} \widehat{F}(i, j) + \lambda \sum_{j=1}^{q} w_j^T w_j .$$

   Here, w_j is the jth column of the matrix `W` and λ is the value of `Lambda`. The effect of this term is to shrink the weights `W`. If you plot the columns of `W` as images, with positive `Lambda` these images appear smooth compared to the same images with zero `Lambda`.

Reconstruction ICA Algorithm

The Reconstruction Independent Component Analysis (RICA) algorithm is based on minimizing an objective function. The algorithm maps input data to output features.

The ICA source model is the following. Each observation x is generated by a random vector s according to

$$x = \mu + As\,.$$

- x is a column vector of length `p`.
- μ is a column vector of length `p` representing a constant term.
- s is a column vector of length `q` whose elements are zero mean, unit variance random variables that are statistically independent of each other.
- A is a mixing matrix of size `p`-by-`q`.

You can use this model in `rica` to estimate A from observations of x. See “Extract Mixed Signals” on page 15-164.

The RICA algorithm begins with a data matrix `X` that has `n` rows and `p` columns consisting of the observations x_i:

$$X = \begin{bmatrix} x_1^T \\ x_2^T \\ \vdots \\ x_n^T \end{bmatrix}.$$

Each row represents one observation and each column represents one measurement. The columns are also called the features or predictors. The algorithm then takes either an initial random `p`-by-`q` weight matrix `W` or uses the weight matrix passed in the `InitialTransformWeights` name-value pair. `q` is the requested number of features that `rica` computes. The weight matrix `W` is composed of columns w_i of size `p`-by-1:

$$W = \begin{bmatrix} w_1 & w_2 & \dots & w_q \end{bmatrix}.$$

The algorithm attempts to minimize the “Reconstruction ICA Objective Function” on page 15-133 by using a standard limited memory Broyden-Fletcher-Goldfarb-Shanno (LBFGS) quasi-Newton optimizer. See Nocedal and Wright [2]. This optimizer takes up to `IterationLimit` iterations. It stops iterating when it takes a step whose norm is less than `StepTolerance`, or when it computes that the norm of the gradient at the current point is less than `GradientTolerance` times a scalar τ, where

$$\tau = \max\left(1, \min\left(|f|, \|g_0\|_\infty\right)\right).$$

$|f|$ is the norm of the objective function, and $\|g_0\|_\infty$ is the infinity norm of the initial gradient.

The objective function attempts to obtain a nearly orthonormal weight matrix that minimizes the sum of elements of $g(\mathtt{XW})$, where g is a function (described below) that is applied elementwise to `XW`. To understand how the objective function attempts to achieve these goals, see Le, Karpenko, Ngiam, and Ng [3].

After constructing a `ReconstructionICA` object, use the `transform` method to map input data to the new output features.

Reconstruction ICA Objective Function

The objective function uses a contrast function, which you specify by using the `ContrastFcn` name-value pair. The contrast function is a smooth convex function that is similar to an absolute value. By default, the contrast function is $g = \frac{1}{2}\log(\cosh(2x))$. For other available contrast functions, see `ContrastFcn`.

For an `n`-by-`p` data matrix `X` and `q` output features, with a regularization parameter λ as the value of the `Lambda` name-value pair, the objective function in terms of the `p`-by-`q` matrix `W` is

$$h = \frac{\lambda}{n}\sum_{i=1}^{n}\left\|WW^{T}x_i - x_i\right\|_2^2 + \frac{1}{n}\sum_{i=1}^{n}\sum_{j=1}^{q}\sigma_j g\left(w_j^{T}x_i\right)$$

The σ_j are known constants that are ±1. When $\sigma_j = +1$, minimizing the objective function h encourages the histogram of $w_j^{T}x_i$ to be sharply peaked at 0 (super Gaussian). When $\sigma_j = -1$, minimizing the objective function h encourages the histogram of $w_j^{T}x_i$ to be flatter near 0 (sub Gaussian). Specify the σ_j values using the `rica` `NonGaussianityIndicator` name-value pair.

The objective function h can have a spurious minimum of zero when λ is zero. Therefore, `rica` minimizes h over W that are normalized to 1. In other words, each column w_j of W is defined in terms of a column vector v_j by

$$w_j = \frac{v_j}{\sqrt{v_j^{T}v_j + 10^{-8}}}.$$

`rica` minimizes over the v_j. The resulting minimal matrix `W` provides the transformation from input data `X` to output features `XW`.

Feature Extraction Workflow

This example shows a complete workflow for feature extraction from image data.

Obtain Data

This example uses the MNIST image data [1], which consists of images of handwritten digits. The images are 28-by-28 pixels in gray scale. Each image has an associated label from 0 through 9, which is the digit that the image represents.

Begin by obtaining image and label data from

http://yann.lecun.com/exdb/mnist/

Unzip the files. For better performance on this long example, use the test data as training data and the training data as test data.

```
imageFileName = 't10k-images.idx3-ubyte';
labelFileName = 't10k-labels.idx1-ubyte';
```

Process the files to load them in the workspace. The code for this processing function appears at the end of this example.

```
[Xtrain,LabelTrain] = processMNISTdata(imageFileName,labelFileName);
```

```
Read MNIST image data...
Number of images in the dataset:  10000 ...
Each image is of 28 by 28 pixels...
The image data is read to a matrix of dimensions:  10000 by  784...
End of reading image data.

Read MNIST label data...
Number of labels in the dataset:  10000 ...
The label data is read to a matrix of dimensions:  10000 by  1...
End of reading label data.
```

View a few of the images.

```
rng('default') % For reproducibility
numrows = size(Xtrain,1);
ims = randi(numrows,4,1);
imgs = Xtrain(ims,:);
for i = 1:4
    pp{i} = reshape(imgs(i,:),28,28);
end
ppf = [pp{1},pp{2};pp{3},pp{4}];
imshow(ppf);
```

Choose New Feature Dimensions

There are several considerations in choosing the number of features to extract:

- More features use more memory and computational time.
- Fewer features can produce a poor classifier.

For this example, choose 100 features.

```
q = 100;
```

Extract Features

There are two feature extraction functions, `sparsefilt` and `rica`. Begin with the `sparsefilt` function. Set the number of iterations to 10 so that the extraction does not take too long.

Typically, you get good results by running the `sparsefilt` algorithm for a few iterations to a few hundred iterations. Running the algorithm for too many iterations can lead to decreased classification accuracy, a type of overfitting problem.

Use `sparsefilt` to obtain the sparse filtering model while using 10 iterations.

```
Mdl = sparsefilt(Xtrain,q,'IterationLimit',10);
```

```
Warning: Solver LBFGS was not able to converge to a solution.
```

`sparsefilt` warns that the internal LBFGS optimizer did not converge. The optimizer did not converge because you set the iteration limit to 10. Nevertheless, you can use the result to train a classifier.

Create Classifier

Transform the original data into the new feature representation.

```
NewX = transform(Mdl,Xtrain);
```

Train a linear classifier based on the transformed data and the correct classification labels in `LabelTrain`. The accuracy of the learned model is sensitive to the `fitcecoc` regularization parameter `Lambda`. Try to find the best value for `Lambda` by using the `OptimizeHyperparameters` name-value pair. Be aware that this optimization takes time. If you have a Parallel Computing Toolbox™ license, use parallel computing for faster execution. If you don't have a parallel license, remove the `UseParallel` calls before running this script.

```
t = templateLinear('Solver','lbfgs');
options = struct('UseParallel',true);
```

```
Cmdl = fitcecoc(NewX,LabelTrain,'Learners',t, ...
    'OptimizeHyperparameters',{'Lambda'}, ...
    'HyperparameterOptimizationOptions',options);

Evaluate Classifier

Check the error of the classifier when applied to test data. First, load the test data.

```
imageFileName = 'train-images.idx3-ubyte';
labelFileName = 'train-labels.idx1-ubyte';
[Xtest,LabelTest] = processMNISTdata(imageFileName,labelFileName);
```

```
Read MNIST image data...
Number of images in the dataset:  60000 ...
Each image is of 28 by 28 pixels...
The image data is read to a matrix of dimensions:  60000 by  784...
End of reading image data.
```

```
Read MNIST label data...
Number of labels in the dataset:  60000 ...
The label data is read to a matrix of dimensions:  60000 by  1...
End of reading label data.
```

Calculate the classification loss when applying the classifier to the test data.

```
TestX = transform(Mdl,Xtest);
Loss = loss(Cmdl,TestX,LabelTest)
```

```
Loss =

    0.1009
```

Did this transformation result in a better classifier than one trained on the original data? Create a classifier based on the original training data and evaluate its loss.

```
Omdl = fitcecoc(Xtrain,LabelTrain,'Learners',t, ...
    'OptimizeHyperparameters',{'Lambda'}, ...
    'HyperparameterOptimizationOptions',options);
Losso = loss(Omdl,Xtest,LabelTest)

The classifier based on sparse filtering has a somewhat higher loss than the classifier based on the original data. However, the classifier uses only 100 features rather than the 784 features in the original data, and is much faster to create. Try to make a better sparse filtering classifier by increasing `q` from 100 to 200, which is still far less than 784.

```
q = 200;
Mdl2 = sparsefilt(Xtrain,q,'IterationLimit',10);
NewX = transform(Mdl2,Xtrain);
TestX = transform(Mdl2,Xtest);
Cmdl = fitcecoc(NewX,LabelTrain,'Learners',t, ...
    'OptimizeHyperparameters',{'Lambda'}, ...
    'HyperparameterOptimizationOptions',options);
Loss2 = loss(Cmdl,TestX,LabelTest)
```

```

This time the classification loss is lower than that of the original data classifier.

Try RICA

Try the other feature extraction function, `rica`. Extract 200 features, create a classifier, and examine its loss on the test data. Use more iterations for the `rica` function, because `rica` can perform better with more iterations than `sparsefilt` uses.

Often prior to feature extraction, you "prewhiten" the input data as a data preprocessing step. The prewhitening step includes two transforms, decorrelation and standardization, which make the predictors have zero mean and identity covariance. `rica` supports only the standardization transform. You use the `Standardize` name-value pair argument to make the predictors have zero

mean and unit variance. Alternatively, you can transform images for contrast normalization individually by applying the `zscore` transformation before calling `sparsefilt` or `rica`.

```
Mdl3 = rica(Xtrain,q,'IterationLimit',400,'Standardize',true);
NewX = transform(Mdl3,Xtrain);
TestX = transform(Mdl3,Xtest);
Cmdl = fitcecoc(NewX,LabelTrain,'Learners',t, ...
    'OptimizeHyperparameters',{'Lambda'}, ...
    'HyperparameterOptimizationOptions',options);
Loss3 = loss(Cmdl,TestX,LabelTest)
```

```

The `rica`-based classifier has somewhat higher test loss compared to the sparse filtering classifier.

Try More Features

The feature extraction functions have few tuning parameters. One parameter that can affect results is the number of requested features. See how well classifiers work when based on 1000 features, rather than the 200 features previously tried, or the 784 features in the original data. Using more features than appear in the original data is called "overcomplete" learning. Conversely, using fewer features is called "undercomplete" learning. Overcomplete learning can lead to increased classification accuracy, while undercomplete learning can save memory and time.

```
q = 1000;
Mdl4 = sparsefilt(Xtrain,q,'IterationLimit',10);
```

```
NewX = transform(Mdl4,Xtrain);
TestX = transform(Mdl4,Xtest);

The classifier based on RICA with 1000 extracted features has a similar test loss to the RICA classifier based on 200 extracted features.

Optimize Hyperparameters by Using `bayesopt`

Feature extraction functions have these tuning parameters:

- Iteration limit
- Function, either `rica` or `sparsefilt`
- Parameter `Lambda`
- Number of learned features `q`

The `fitcecoc` regularization parameter also affects the accuracy of the learned classifier. Include that parameter in the list of hyperparameters as well.

To search among the available parameters effectively, try `bayesopt`. Use the following objective function, which includes parameters passed from the workspace.

```
function objective = filterica(x,Xtrain,Xtest,LabelTrain,LabelTest,winit)

initW = winit(1:size(Xtrain,2),1:x.q);
if char(x.solver) == 'r'
    Mdl = rica(Xtrain,x.q,'Lambda',x.lambda,'IterationLimit',x.iterlim, ...
        'InitialTransformWeights',initW,'Standardize',true);
else
    Mdl = sparsefilt(Xtrain,x.q,'Lambda',x.lambda,'IterationLimit',x.iterlim, ...
        'InitialTransformWeights',initW);
end

NewX = transform(Mdl,Xtrain);
TestX = transform(Mdl,Xtest);
t = templateLinear('Lambda',x.lambdareg,'Solver','lbfgs');
Cmdl = fitcecoc(NewX,LabelTrain,'Learners',t);
objective = loss(Cmdl,TestX,LabelTest);
```

To remove sources of variation, fix an initial transform weight matrix.

```
W = randn(1e4,1e3);
```

Create hyperparameters for the objective function.

```
iterlim = optimizableVariable('iterlim',[5,500],'Type','integer');
lambda = optimizableVariable('lambda',[0,10]);
solver = optimizableVariable('solver',{'r','s'},'Type','categorical');
qvar = optimizableVariable('q',[10,1000],'Type','integer');
lambdareg = optimizableVariable('lambdareg',[1e-6,1],'Transform','log');
vars = [iterlim,lambda,solver,qvar,lambdareg];
```

Run the optimization without the warnings that occur when the internal optimizations do not run to completion. Run for 60 iterations instead of the default 30 to give the optimization a better chance of locating a good value.

```
warning('off','stats:classreg:learning:fsutils:Solver:LBFGSUnableToConverge');
results = bayesopt(@(x) filterica(x,Xtrain,Xtest,LabelTrain,LabelTest,W),vars, ...
    'UseParallel',true,'MaxObjectiveEvaluations',60);
warning('on','stats:classreg:learning:fsutils:Solver:LBFGSUnableToConverge');
```

```

Code for Reading MNIST Data

The code of the function that reads the data into the workspace is:

```
function [X,L] = processMNISTdata(imageFileName,labelFileName)

[fileID,errmsg] = fopen(imageFileName,'r','b');
if fileID < 0
    error(errmsg);
end
%%
% First read the magic number. This number is 2051 for image data, and
```

```
% 2049 for label data
magicNum = fread(fileID,1,'int32',0,'b');
if magicNum == 2051
    fprintf('\nRead MNIST image data...\n')
end
%%
% Then read the number of images, number of rows, and number of columns
numImages = fread(fileID,1,'int32',0,'b');
fprintf('Number of images in the dataset: %6d ...\n',numImages);
numRows = fread(fileID,1,'int32',0,'b');
numCols = fread(fileID,1,'int32',0,'b');
fprintf('Each image is of %2d by %2d pixels...\n',numRows,numCols);
%%
% Read the image data
X = fread(fileID,inf,'unsigned char');
%%
% Reshape the data to array X
X = reshape(X,numCols,numRows,numImages);
X = permute(X,[2 1 3]);
%%
% Then flatten each image data into a 1 by (numRows*numCols) vector, and
% store all the image data into a numImages by (numRows*numCols) array.
X = reshape(X,numRows*numCols,numImages)';
fprintf(['The image data is read to a matrix of dimensions: %6d by %4d...\n',...
    'End of reading image data.\n'],size(X,1),size(X,2));
%%
% Close the file
fclose(fileID);
%%
% Similarly, read the label data.
[fileID,errmsg] = fopen(labelFileName,'r','b');
if fileID < 0
    error(errmsg);
end
magicNum = fread(fileID,1,'int32',0,'b');
if magicNum == 2049
    fprintf('\nRead MNIST label data...\n')
end
numItems = fread(fileID,1,'int32',0,'b');
fprintf('Number of labels in the dataset: %6d ...\n',numItems);

L = fread(fileID,inf,'unsigned char');
fprintf(['The label data is read to a matrix of dimensions: %6d by %2d...\n',...
    'End of reading label data.\n'],size(L,1),size(L,2));
fclose(fileID);
```

Extract Mixed Signals

This example shows how to use `rica` to disentangle mixed audio signals. You can use `rica` to perform independent component analysis (ICA) when prewhitening is included as a preprocessing step. The ICA model is

$$x = \mu + As.$$

Here, x is a p-by-1 vector of mixed signals, μ is a p-by-1 vector of offset values, A is a p-by-q mixing matrix, and s is a q-by-1 vector of original signals. Suppose first that A is a square matrix. If you know μ and A, you can recover an original signal s from the data x:

$$s = A^{-1}(x - \mu).$$

Using the `rica` function, you can perform this recovery even without knowing the mixing matrix A or the mean μ. Given a set of several observations $x(1)$, $x(2)$, ..., `rica` extracts the original signals $s(1)$, $s(2)$, ...

Load Data

Load a set of six audio files, which ship with MATLAB®. Trim each file to 10,000 samples.

```
files = {'chirp.mat'
         'gong.mat'
         'handel.mat'
         'laughter.mat'
         'splat.mat'
         'train.mat'};

S = zeros(10000,6);
for i = 1:6
    test     = load(files{i});
    y        = test.y(1:10000,1);
    S(:,i)   = y;
end
```

Mix Signals

Mix the signals together by using a random mixing matrix and add a random offset.

```
rng default % For reproducibility
mixdata = S*randn(6) + randn(1,6);
```

To listen to the original sounds, execute this code:

```
for i = 1:6
    disp(i);
    sound(S(:,i));
    pause;
end
```

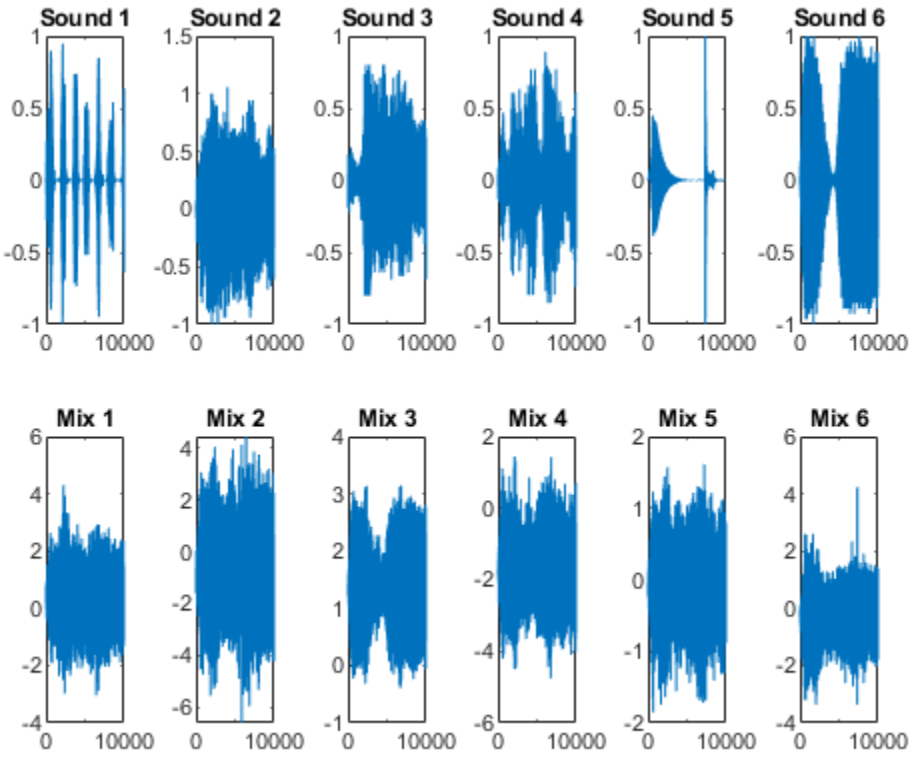
To listen to the mixed sounds, execute this code:

```
for i = 1:6
    disp(i);
```

```
        sound(mixdata(:,i));
        pause;
    end
```

Plot the signals.

```
figure
for i = 1:6
    subplot(2,6,i)
    plot(S(:,i))
    title(['Sound ',num2str(i)])
    subplot(2,6,i+6)
    plot(mixdata(:,i))
    title(['Mix ',num2str(i)])
end
```



The original signals have clear structure. The mixed signals have much less structure.

Prewhiten Mixed Signals

To separate the signals effectively, "prewhiten" the signals by using the `prewhiten` function that appears at the end of this example. This function transforms `mixdata` so that it has zero mean and identity covariance.

The idea is the following. If s is a zero-mean source with statistically independent components, then

$$E(s) = 0$$

$$E(ss^T) = I.$$

Then the mean and covariance of x are

$$E(x) = \mu$$

$$\mathrm{Cov}(x) = AA^T = C.$$

Suppose that you know μ and C. In practice, you would estimate these quantities from the sample mean and covariance of the columns of x. You can solve for s in terms of x by

$$s = A^{-1}(x - \mu) = (A^T A)^{-1} A^T (x - \mu).$$

The latter equation holds even when A is not a square invertible matrix.

Suppose that U is a p-by-q matrix of left eigenvectors of the positive semidefinite matrix C, and Σ is the q-by-q matrix of eigenvalues. Then

$$C = U\Sigma U^T$$

$$U^T U = I.$$

Then

$$AA^T = U\Sigma U^T.$$

There are many mixing matrices A that satisfy this last equation. If W is a q-by-q orthonormal matrix, then

$$W^T W = WW^T = I$$

$$A = U\Sigma^{1/2} W.$$

Substituting into the equation for s,

$$s = W^T \tilde{x}, \text{ where}$$

$$\tilde{x} = \Sigma^{-1/2} U^T (x - \mu).$$

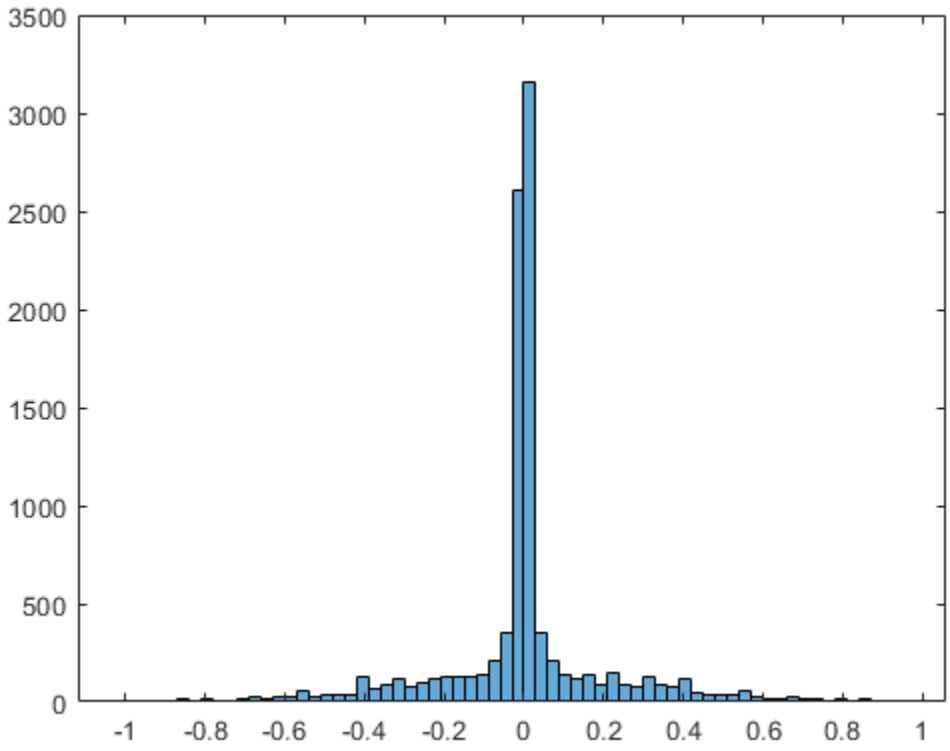
$\tilde{x}$ is the prewhitened data. `rica` computes the unknown matrix W under the assumption that the components of s are as independent as possible.

```
mixdata = prewhiten(mixdata);
```

Separate All Signals

A super-Gaussian source has a sharp peak near zero, such as a histogram of sound 1 shows.

```
figure
histogram(S(:,1))
```



Perform Reconstruction ICA while asking for six features. Indicate that each source is super-Gaussian.

```
q = 6;
Mdl = rica(mixdata,q,'NonGaussianityIndicator',ones(6,1));
```

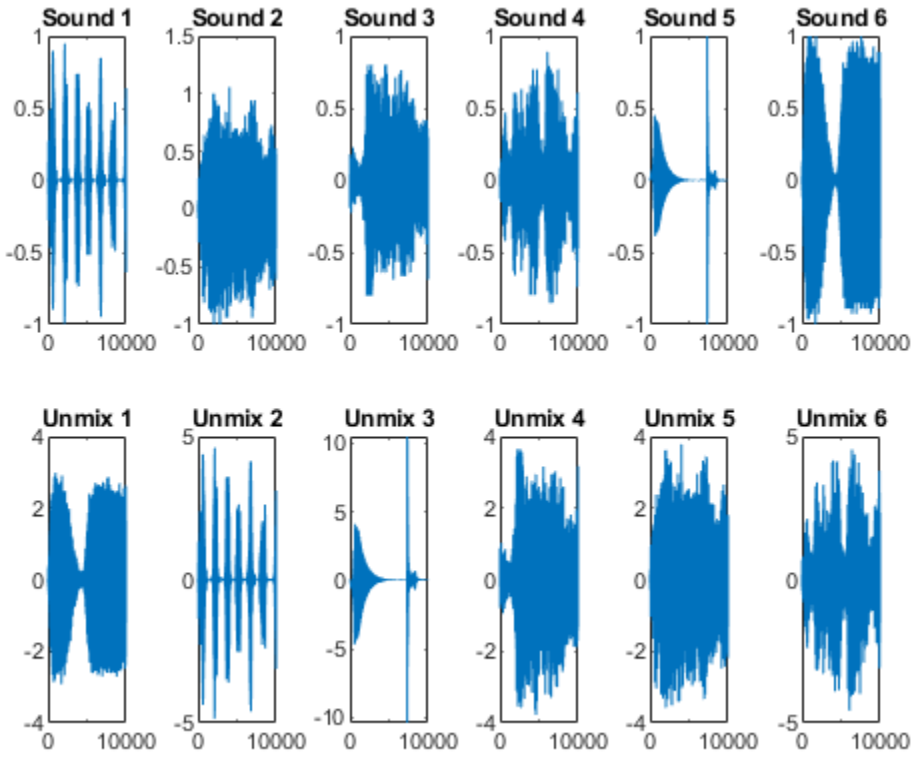
Extract the features. If the unmixing procedure is successful, the features are proportional to the original signals.

```
unmixed = transform(Mdl,mixdata);
```

Compare Unmixed Signals To Original Signals

Plot the original and unmixed signals.

```
figure
for i = 1:6
    subplot(2,6,i)
    plot(S(:,i))
    title(['Sound ',num2str(i)])
    subplot(2,6,i+6)
    plot(unmixed(:,i))
    title(['Unmix ',num2str(i)])
end
```

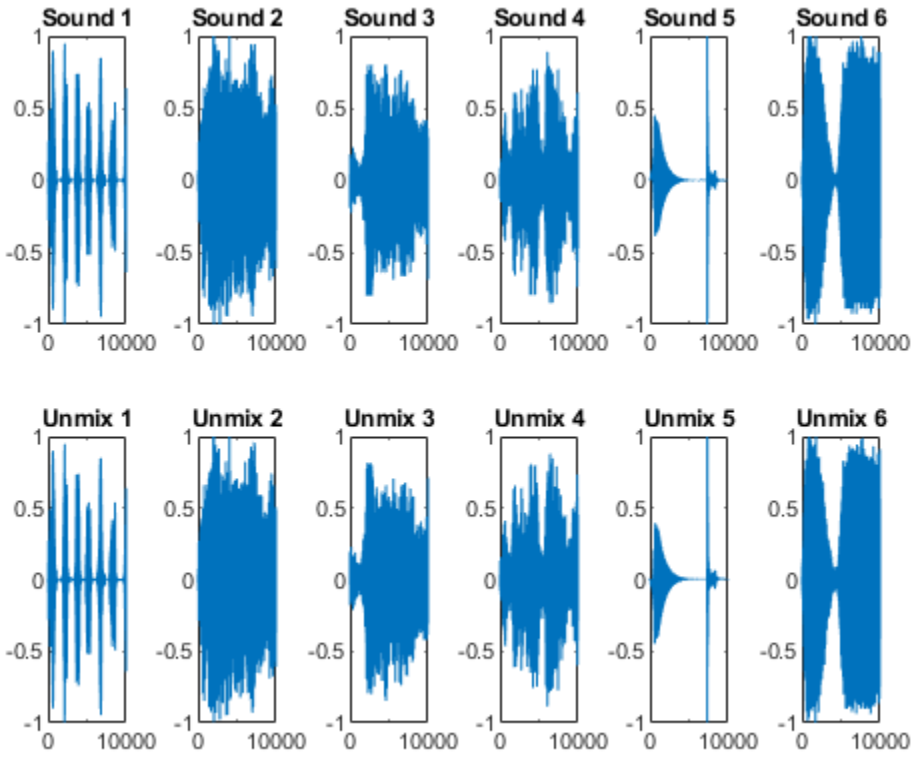


The order of the unmixed signals is different than the original order. Reorder the columns so that the unmixed signals match the corresponding original signals. Scale the unmixed signals to have the same norms as the corresponding original signals. (`rica` cannot identify the scale of the original signals because any scale can lead to the same signal mixture.)

```
unmixed = unmixed(:,[2,5,4,6,3,1]);
for i = 1:6
    unmixed(:,i) = unmixed(:,i)/norm(unmixed(:,i))*norm(S(:,i));
end
```

Plot the original and unmixed signals.

```
figure
for i = 1:6
    subplot(2,6,i)
    plot(S(:,i))
    ylim([-1,1])
    title(['Sound ',num2str(i)])
    subplot(2,6,i+6)
    plot(unmixed(:,i))
    ylim([-1,1])
    title(['Unmix ',num2str(i)])
end
```



The unmixed signals look similar to the original signals. To listen to the unmixed sounds, execute this code.

```
for i = 1:6
    disp(i);
    sound(unmixed(:,i));
    pause;
end
```

Here is the code for the `prewhiten` function.

```
function Z = prewhiten(X)
% X = N-by-P matrix for N observations and P predictors
% Z = N-by-P prewhitened matrix

    % 1. Size of X.
    [N,P] = size(X);
    assert(N >= P);

    % 2. SVD of covariance of X. We could also use svd(X) to proceed but N
    % can be large and so we sacrifice some accuracy for speed.
    [U,Sig] = svd(cov(X));
    Sig     = diag(Sig);
    Sig     = Sig(:)';

    % 3. Figure out which values of Sig are non-zero.
    tol = eps(class(X));
```

```
    idx = (Sig > max(Sig)*tol);
    assert(~all(idx == 0));

    % 4. Get the non-zero elements of Sig and corresponding columns of U.
    Sig = Sig(idx);
    U   = U(:,idx);

    % 5. Compute prewhitened data.
    mu = mean(X,1);
    Z = bsxfun(@minus,X,mu);
    Z = bsxfun(@times,Z*U,1./sqrt(Sig));
end
```

Selecting Features for Classifying High-dimensional Data

This example shows how to select features for classifying high-dimensional data. More specifically, it shows how to perform sequential feature selection, which is one of the most popular feature selection algorithms. It also shows how to use holdout and cross-validation to evaluate the performance of the selected features.

Reducing the number of features (dimensionality) is important in statistical learning. For many data sets with a large number of features and a limited number of observations, such as bioinformatics data, usually many features are not useful for producing a desired learning result and the limited observations may lead the learning algorithm to overfit to the noise. Reducing features can also save storage and computation time and increase comprehensibility.

There are two main approaches to reducing features: feature selection and feature transformation. Feature selection algorithms select a subset of features from the original feature set; feature transformation methods transform data from the original high-dimensional feature space to a new space with reduced dimensionality.

Loading the Data

Serum proteomic pattern diagnostics can be used to differentiate observations from patients with and without disease. Profile patterns are generated using surface-enhanced laser desorption and ionization (SELDI) protein mass spectrometry. These features are ion intensity levels at specific mass/charge values.

This example uses the high-resolution ovarian cancer data set that was generated using the WCX2 protein array. After some pre-processing steps, similar to those shown in the Bioinformatics Toolbox™ example Pre-processing Raw Mass Spectrometry Data, the data set has two variables `obs` and `grp`. The `obs` variable consists 216 observations with 4000 features. Each element in `grp` defines the group to which the corresponding row of `obs` belongs.

```
load ovariancancer;
whos
```

```
  Name        Size                Bytes  Class     Attributes

  grp       216x1                 25056  cell
  obs       216x4000            3456000  single
```

Dividing Data Into a Training Set and a Test Set

Some of the functions used in this example call MATLAB® built-in random number generation functions. To duplicate the exact results shown in this example, execute the command below to set the random number generator to a known state. Otherwise, your results may differ.

```
rng(8000,'twister');
```

The performance on the training data (resubstitution performance) is not a good estimate for a model's performance on an independent test set. Resubstitution performance will usually be over-optimistic. To predict the performance of a selected model, you need to assess its performance on another data set that was not used to build the model. Here, we use `cvpartition` to divide data into a training set of size 160 and a test set of size 56. Both the training set and the test set have roughly the same group proportions as in `grp`. We select features using the training data and judge the performance of the selected features on the test data. This is often called holdout validation. Another

simple and widely-used method for evaluating and selecting a model is cross-validation, which will be illustrated later in this example.

```
holdoutCVP = cvpartition(grp,'holdout',56)
```

```
holdoutCVP =
Hold-out cross validation partition
   NumObservations: 216
       NumTestSets: 1
         TrainSize: 160
          TestSize: 56
```

```
dataTrain = obs(holdoutCVP.training,:);
grpTrain = grp(holdoutCVP.training);
```

The Problem of Classifying Data Using All the Features

Without first reducing the number of features, some classification algorithms would fail on the data set used in this example, since the number of features is much larger than the number of observations. In this example, we use Quadratic Discriminant Analysis (QDA) as the classification algorithm. If we apply QDA on the data using all the features, as shown in the following, we will get an error because there are not enough samples in each group to estimate a covariance matrix.

```
try
   yhat = classify(obs(test(holdoutCVP),:), dataTrain, grpTrain,'quadratic');
catch ME
   display(ME.message);
end
```

```
The covariance matrix of each group in TRAINING must be positive definite.
```

Selecting Features Using a Simple Filter Approach

Our goal is to reduce the dimension of the data by finding a small set of important features which can give good classification performance. Feature selection algorithms can be roughly grouped into two categories: filter methods and wrapper methods. Filter methods rely on general characteristics of the data to evaluate and to select the feature subsets without involving the chosen learning algorithm (QDA in this example). Wrapper methods use the performance of the chosen learning algorithm to evaluate each candidate feature subset. Wrapper methods search for features better fit for the chosen learning algorithm, but they can be significantly slower than filter methods if the learning algorithm takes a long time to run. The concepts of "filters" and "wrappers" are described in John G. Kohavi R. (1997) "Wrappers for feature subset selection", Artificial Intelligence, Vol.97, No.1-2, pp.272-324. This example shows one instance of a filter method and one instance of a wrapper method.

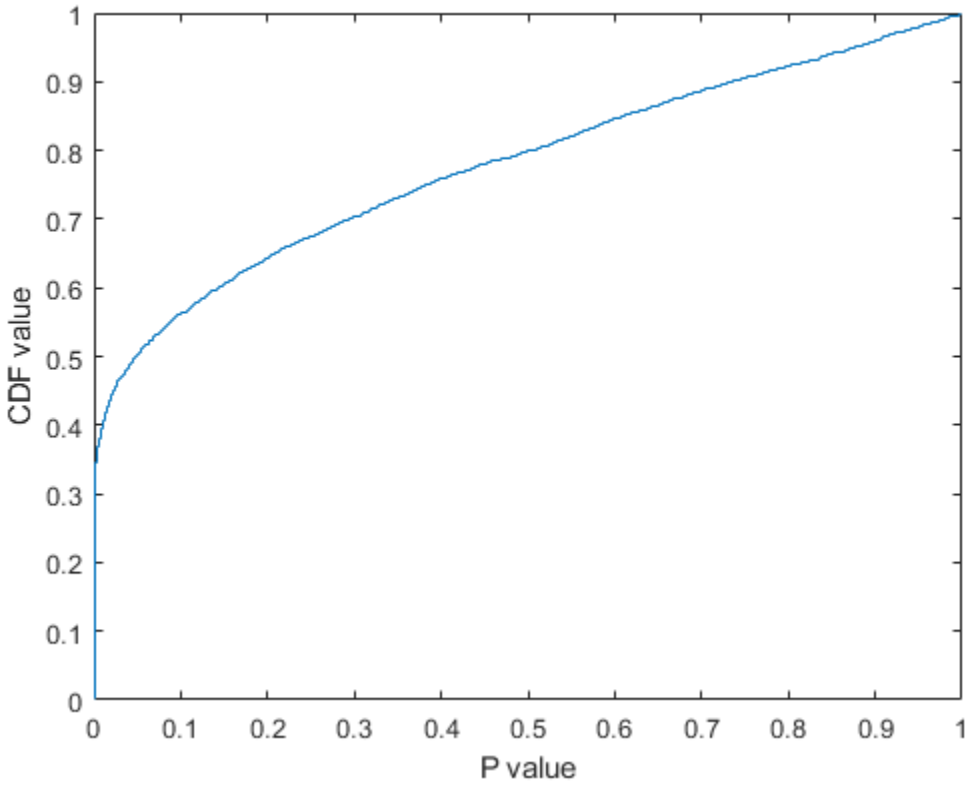
Filters are usually used as a pre-processing step since they are simple and fast. A widely-used filter method for bioinformatics data is to apply a univariate criterion separately on each feature, assuming that there is no interaction between features.

For example, we might apply the *t*-test on each feature and compare *p*-value (or the absolute values of *t*-statistics) for each feature as a measure of how effective it is at separating groups.

```
dataTrainG1 = dataTrain(grp2idx(grpTrain)==1,:);
dataTrainG2 = dataTrain(grp2idx(grpTrain)==2,:);
[h,p,ci,stat] = ttest2(dataTrainG1,dataTrainG2,'Vartype','unequal');
```

In order to get a general idea of how well-separated the two groups are by each feature, we plot the empirical cumulative distribution function (CDF) of the *p*-values:

```
ecdf(p);
xlabel('P value');
ylabel('CDF value')
```



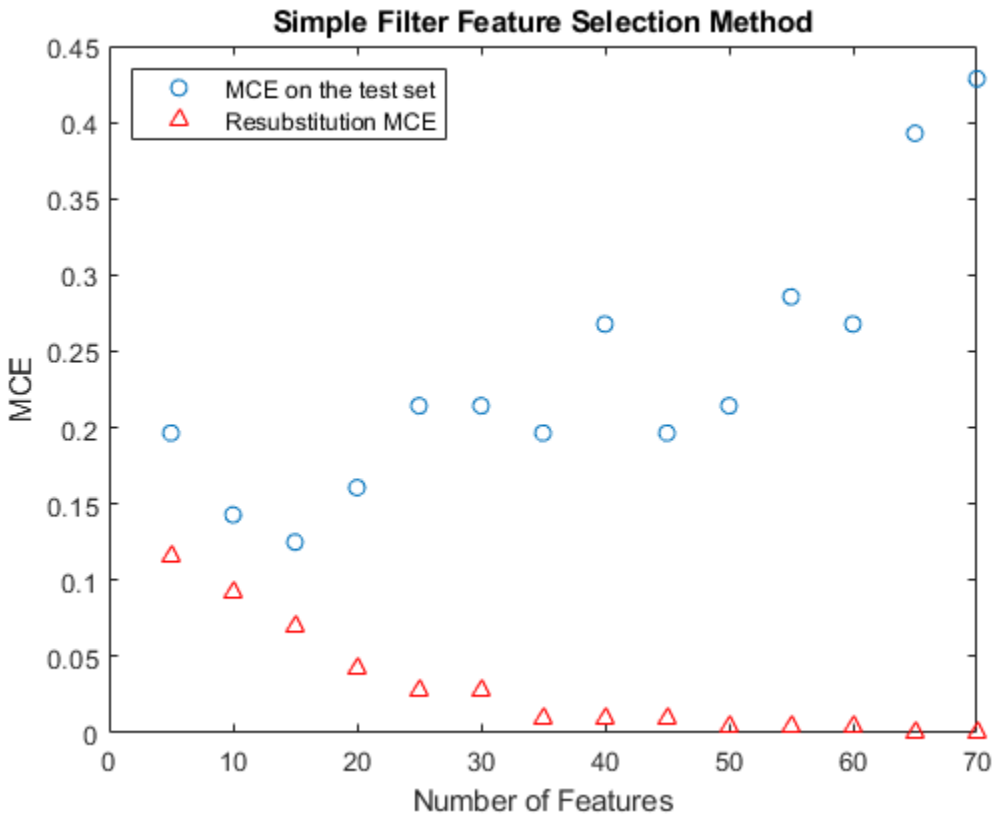
There are about 35% of features having *p*-values close to zero and over 50% of features having *p*-values smaller than 0.05, meaning there are more than 2500 features among the original 5000 features that have strong discrimination power. One can sort these features according to their *p*-values (or the absolute values of the *t*-statistic) and select some features from the sorted list. However, it is usually difficult to decide how many features are needed unless one has some domain knowledge or the maximum number of features that can be considered has been dictated in advance based on outside constraints.

One quick way to decide the number of needed features is to plot the MCE (misclassification error, i.e., the number of misclassified observations divided by the number of observations) on the test set as a function of the number of features. Since there are only 160 observations in the training set, the largest number of features for applying QDA is limited, otherwise, there may not be enough samples in each group to estimate a covariance matrix. Actually, for the data used in this example, the holdout partition and the sizes of two groups dictate that the largest allowable number of features for applying QDA is about 70. Now we compute MCE for various numbers of features between 5 and 70 and show the plot of MCE as a function of the number of features. In order to reasonably estimate the performance of the selected model, it is important to use the 160 training samples to fit the QDA model and compute the MCE on the 56 test observations (blue circular marks in the following plot). To illustrate why resubstitution error is not a good error estimate of the test error, we also show the resubstitution MCE using red triangular marks.

```
[~,featureIdxSortbyP] = sort(p,2); % sort the features
testMCE = zeros(1,14);
resubMCE = zeros(1,14);
nfs = 5:5:70;
classf = @(xtrain,ytrain,xtest,ytest) ...
             sum(~strcmp(ytest,classify(xtest,xtrain,ytrain,'quadratic')));
resubCVP = cvpartition(length(grp),'resubstitution')

resubCVP =
Resubstitution (no partition of data)
   NumObservations: 216
       NumTestSets: 1
         TrainSize: 216
          TestSize: 216

for i = 1:14
   fs = featureIdxSortbyP(1:nfs(i));
   testMCE(i) = crossval(classf,obs(:,fs),grp,'partition',holdoutCVP)...
       /holdoutCVP.TestSize;
   resubMCE(i) = crossval(classf,obs(:,fs),grp,'partition',resubCVP)/...
       resubCVP.TestSize;
end
 plot(nfs, testMCE,'o',nfs,resubMCE,'r^');
 xlabel('Number of Features');
 ylabel('MCE');
 legend({'MCE on the test set' 'Resubstitution MCE'},'location','NW');
 title('Simple Filter Feature Selection Method');
```



For convenience, `classf` is defined as an anonymous function. It fits QDA on the given training set and returns the number of misclassified samples for the given test set. If you were developing your own classification algorithm, you might want to put it in a separate file, as follows:

```
%  function err = classf(xtrain,ytrain,xtest,ytest)
%       yfit = classify(xtest,xtrain,ytrain,'quadratic');
%        err = sum(~strcmp(ytest,yfit));
```

The resubstitution MCE is over-optimistic. It consistently decreases when more features are used and drops to zero when more than 60 features are used. However, if the test error increases while the resubstitution error still decreases, then overfitting may have occurred. This simple filter feature selection method gets the smallest MCE on the test set when 15 features are used. The plot shows overfitting begins to occur when 20 or more features are used. The smallest MCE on the test set is 12.5%:

```
testMCE(3)
```

```
ans = 0.1250
```

These are the first 15 features that achieve the minimum MCE:

```
featureIdxSortbyP(1:15)
```

```
ans = 1×15

        2814        2813        2721        2720        2452        2645        2644        2642
```

Applying Sequential Feature Selection

The above feature selection algorithm does not consider interaction between features; besides, features selected from the list based on their individual ranking may also contain redundant information, so that not all the features are needed. For example, the linear correlation coefficient between the first selected feature (column 2814) and the second selected feature (column 2813) is almost 0.95.

```
corr(dataTrain(:,featureIdxSortbyP(1)),dataTrain(:,featureIdxSortbyP(2)))
```

```
ans = single
    0.9447
```

This kind of simple feature selection procedure is usually used as a pre-processing step since it is fast. More advanced feature selection algorithms improve the performance. Sequential feature selection is one of the most widely used techniques. It selects a subset of features by sequentially adding (forward search) or removing (backward search) until certain stopping conditions are satisfied.

In this example, we use forward sequential feature selection in a wrapper fashion to find important features. More specifically, since the typical goal of classification is to minimize the MCE, the feature selection procedure performs a sequential search using the MCE of the learning algorithm QDA on each candidate feature subset as the performance indicator for that subset. The training set is used to select the features and to fit the QDA model, and the test set is used to evaluate the performance of the finally selected feature. During the feature selection procedure, to evaluate and to compare the performance of the each candidate feature subset, we apply stratified 10-fold cross-validation to the training set. We will illustrate later why applying cross-validation to the training set is important.

First we generate a stratified 10-fold partition for the training set:

```
tenfoldCVP = cvpartition(grpTrain,'kfold',10)
```

```
tenfoldCVP =
K-fold cross validation partition
   NumObservations: 160
       NumTestSets: 10
         TrainSize: 144  144  144  144  144  144  144  144  144  144
          TestSize: 16  16  16  16  16  16  16  16  16  16
```

Then we use the filter results from the previous section as a pre-processing step to select features. For instance, we select 150 features here:

```
fs1 = featureIdxSortbyP(1:150);
```

We apply forward sequential feature selection on these 150 features. The function `sequentialfs` provides a simple way (the default option) to decide how many features are needed. It stops when the first local minimum of the cross-validation MCE is found.

```
 fsLocal = sequentialfs(classf,dataTrain(:,fs1),grpTrain,'cv',tenfoldCVP);
```

The selected features are the following:

```
fs1(fsLocal)
```

```
ans = 1×3

        2337         864        3288
```

To evaluate the performance of the selected model with these three features, we compute the MCE on the 56 test samples.

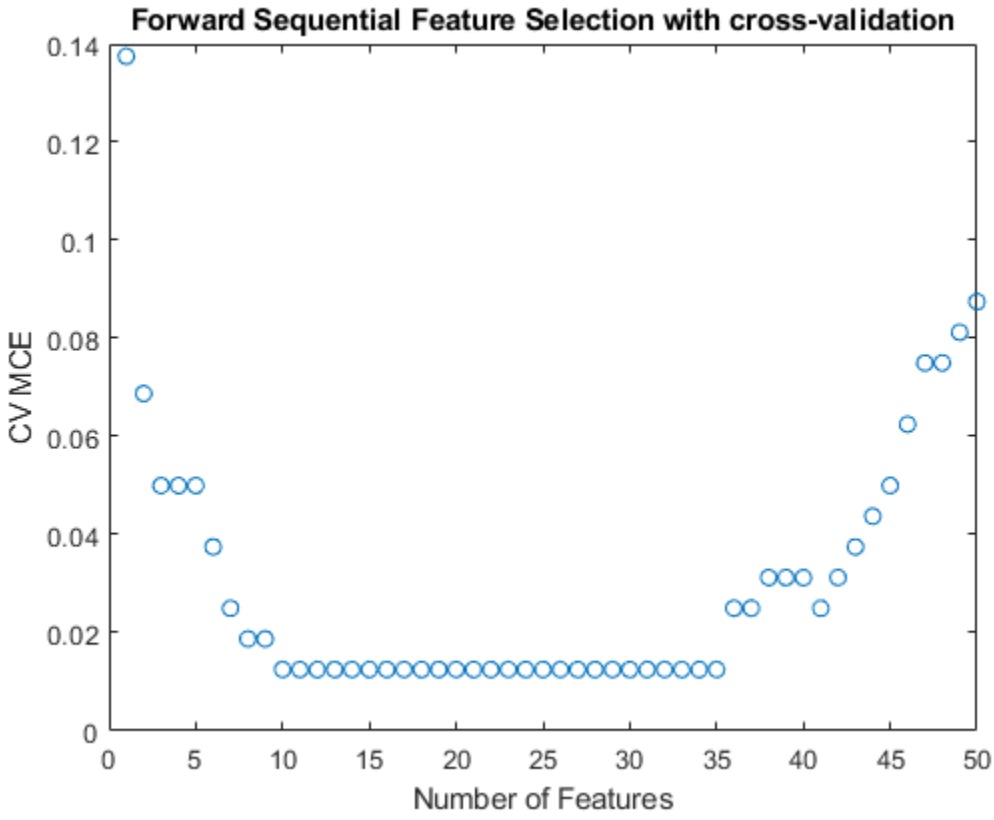
```
testMCELocal = crossval(classf,obs(:,fs1(fsLocal)),grp,'partition',...
    holdoutCVP)/holdoutCVP.TestSize
```

```
testMCELocal = 0.0714
```

With only three features being selected, the MCE is only a little over half of the smallest MCE using the simple filter feature selection method.

The algorithm may have stopped prematurely. Sometimes a smaller MCE is achievable by looking for the minimum of the cross-validation MCE over a reasonable range of number of features. For instance, we draw the plot of the cross-validation MCE as a function of the number of features for up to 50 features.

```
[fsCVfor50,historyCV] = sequentialfs(classf,dataTrain(:,fs1),grpTrain,...
    'cv',tenfoldCVP,'Nf',50);
plot(historyCV.Crit,'o');
xlabel('Number of Features');
ylabel('CV MCE');
title('Forward Sequential Feature Selection with cross-validation');
```



The cross-validation MCE reaches the minimum value when 10 features are used and this curve stays flat over the range from 10 features to 35 features. Also, the curve goes up when more than 35 features are used, which means overfitting occurs there.

It is usually preferable to have fewer features, so here we pick 10 features:

```
fsCVfor10 = fs1(historyCV.In(10,:))
```

```
fsCVfor10 = 1×10

        2814        2721        2720        2452        2650        2731        2337        2658
```

To show these 10 features in the order in which they are selected in the sequential forward procedure, we find the row in which they first become true in the `historyCV` output:

```
[orderlist,ignore] = find( [historyCV.In(1,:); diff(historyCV.In(1:10,:) )]' );
fs1(orderlist)
```

```
ans = 1×10

        2337         864        3288        2721        2814        2658        2452        2731
```

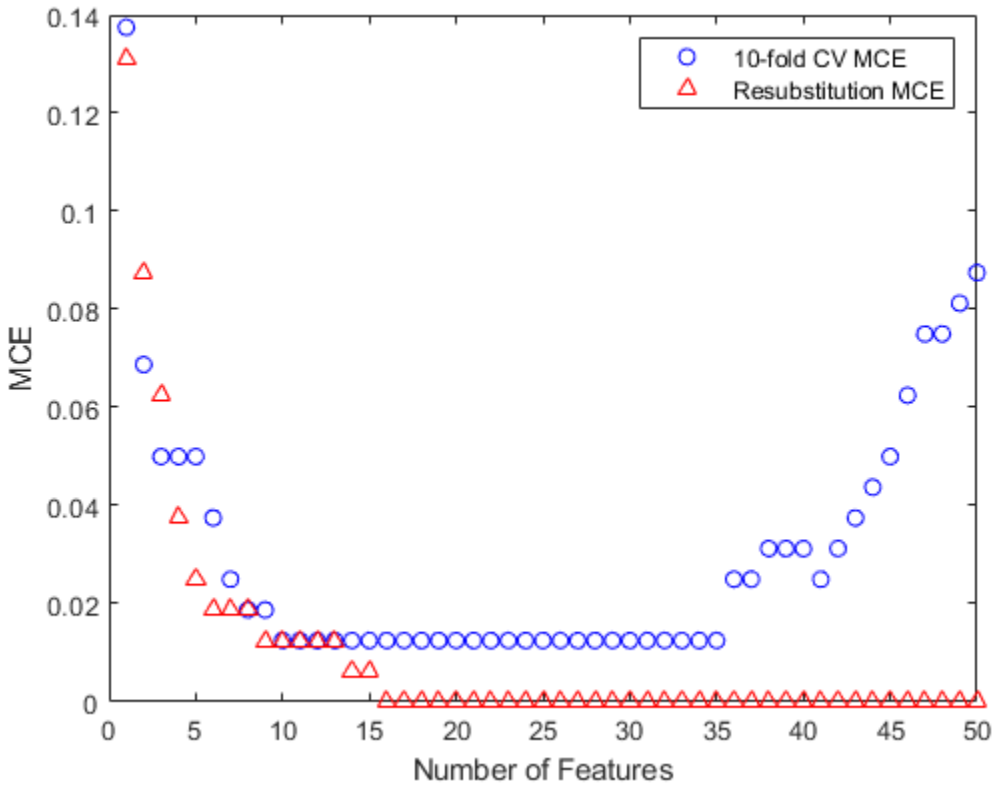
To evaluate these 10 features, we compute their MCE for QDA on the test set. We get the smallest MCE value so far:

```
testMCECVfor10 = crossval(classf,obs(:,fsCVfor10),grp,'partition',...
    holdoutCVP)/holdoutCVP.TestSize
```

```
testMCECVfor10 = 0.0357
```

It is interesting to look at the plot of resubstitution MCE values on the training set (i.e., without performing cross-validation during the feature selection procedure) as a function of the number of features:

```
[fsResubfor50,historyResub] = sequentialfs(classf,dataTrain(:,fs1),...
     grpTrain,'cv','resubstitution','Nf',50);
plot(1:50, historyCV.Crit,'bo',1:50, historyResub.Crit,'r^');
xlabel('Number of Features');
ylabel('MCE');
legend({'10-fold CV MCE' 'Resubstitution MCE'},'location','NE');
```



Again, the resubstitution MCE values are overly optimistic here. Most are smaller than the cross-validation MCE values, and the resubstitution MCE goes to zero when 16 features are used. We can compute the MCE value of these 16 features on the test set to see their real performance:

```
fsResubfor16 = fs1(historyResub.In(16,:));
testMCEResubfor16 = crossval(classf,obs(:,fsResubfor16),grp,'partition',...
    holdoutCVP)/holdoutCVP.TestSize
```

```
testMCEResubfor16 = 0.0714
```

`testMCEResubfor16`, the performance of these 16 features (chosen by resubstitution during the feature selection procedure) on the test set, is about double that for `testMCECVfor10`, the

performance of the 10 features (chosen by 10-fold cross-validation during the feature selection procedure) on the test set. It again indicates that the resubstitution error generally is not a good performance estimate for evaluating and selecting features. We may want to avoid using resubstitution error, not only during the final evaluation step, but also during the feature selection procedure.

Perform Factor Analysis on Exam Grades

This example shows how to perform factor analysis using Statistics and Machine Learning Toolbox™.

Multivariate data often include a large number of measured variables, and sometimes those variables "overlap" in the sense that groups of them may be dependent. For example, in a decathlon, each athlete competes in 10 events, but several of them can be thought of as "speed" events, while others can be thought of as "strength" events, etc. Thus, a competitor's 10 event scores might be thought of as largely dependent on a smaller set of 3 or 4 types of athletic ability.

Factor analysis is a way to fit a model to multivariate data to estimate just this sort of interdependence.

The Factor Analysis Model

In the factor analysis model, the measured variables depend on a smaller number of unobserved (latent) factors. Because each factor may affect several variables in common, they are known as "common factors". Each variable is assumed to depend on a linear combination of the common factors, and the coefficients are known as loadings. Each measured variable also includes a component due to independent random variability, known as "specific variance" because it is specific to one variable.

Specifically, factor analysis assumes that the covariance matrix of your data is of the form

```
SigmaX = Lambda*Lambda' + Psi
```

where Lambda is the matrix of loadings, and the elements of the diagonal matrix Psi are the specific variances. The function `factoran` fits the factor analysis model using maximum likelihood.

Example: Finding Common Factors Affecting Exam Grades

120 students have each taken five exams, the first two covering mathematics, the next two on literature, and a comprehensive fifth exam. It seems reasonable that the five grades for a given student ought to be related. Some students are good at both subjects, some are good at only one, etc. The goal of this analysis is to determine if there is quantitative evidence that the students' grades on the five different exams are largely determined by only two types of ability.

First load the data, then call `factoran` and request a model fit with a single common factor.

```
load examgrades
[Loadings1,specVar1,T,stats] = factoran(grades,1);
```

`factoran`'s first two return arguments are the estimated loadings and the estimated specific variances. From the estimated loadings, you can see that the one common factor in this model puts large positive weight on all five variables, but most weight on the fifth, comprehensive exam.

```
Loadings1
```

```
Loadings1 =

    0.6021
    0.6686
    0.7704
    0.7204
```

```
    0.9153
```

One interpretation of this fit is that a student might be thought of in terms of their "overall ability", for which the comprehensive exam would be the best available measurement. A student's grade on a more subject-specific test would depend on their overall ability, but also on whether or not the student was strong in that area. This would explain the lower loadings for the first four exams.

From the estimated specific variances, you can see that the model indicates that a particular student's grade on a particular test varies quite a lot beyond the variation due to the common factor.

```
specVar1
```

```
specVar1 =

    0.6375
    0.5530
    0.4065
    0.4810
    0.1623
```

A specific variance of 1 would indicate that there is *no* common factor component in that variable, while a specific variance of 0 would indicate that the variable is *entirely* determined by common factors. These exam grades seem to fall somewhere in between, although there is the least amount of specific variation for the comprehensive exam. This is consistent with the interpretation given above of the single common factor in this model.

The p-value returned in the `stats` structure rejects the null hypothesis of a single common factor, so we refit the model.

```
stats.p
```

```
ans =

    0.0332
```

Next, use two common factors to try and better explain the exam scores. With more than one factor, you could rotate the estimated loadings to try and make their interpretation simpler, but for the moment, ask for an unrotated solution.

```
[Loadings2,specVar2,T,stats] = factoran(grades,2,'rotate','none');
```

From the estimated loadings, you can see that the first unrotated factor puts approximately equal weight on all five variables, while the second factor contrasts the first two variables with the second two.

```
Loadings2
```

```
Loadings2 =

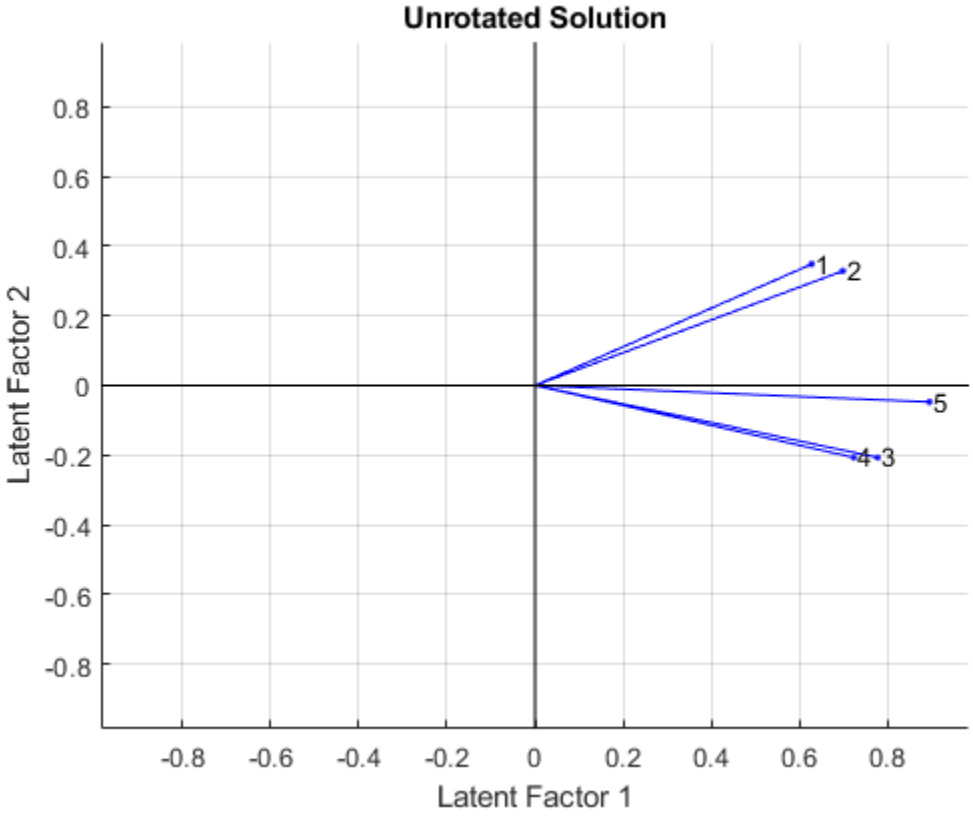
    0.6289    0.3485
    0.6992    0.3287
    0.7785   -0.2069
```

```
    0.7246   -0.2070
    0.8963   -0.0473
```

You might interpret these factors as "overall ability" and "quantitative vs. qualitative ability", extending the interpretation of the one-factor fit made earlier.

A plot of the variables, where each loading is a coordinate along the corresponding factor's axis, illustrates this interpretation graphically. The first two exams have a positive loading on the second factor, suggesting that they depend on "quantitative" ability, while the second two exams apparently depend on the opposite. The fifth exam has only a small loading on this second factor.

```
biplot(Loadings2, 'varlabels',num2str((1:5)'));
title('Unrotated Solution');
xlabel('Latent Factor 1'); ylabel('Latent Factor 2');
```



From the estimated specific variances, you can see that this two-factor model indicates somewhat less variation beyond that due to the common factors than the one-factor model did. Again, the least amount of specific variance occurs for the fifth exam.

```
specVar2
```

```
specVar2 =

    0.4829
    0.4031
```

```
    0.3512
    0.4321
    0.1944
```

The `stats` structure shows that there is only a single degree of freedom in this two-factor model.

```
stats.dfe
```

```
ans =

     1
```

With only five measured variables, you cannot fit a model with more than two factors.

Factor Analysis from a Covariance/Correlation Matrix

You made the fits above using the raw test scores, but sometimes you might only have a sample covariance matrix that summarizes your data. `factoran` accepts either a covariance or correlation matrix, using the `'Xtype'` parameter, and gives an identical result to that from the raw data.

```
Sigma = cov(grades);
[LoadingsCov,specVarCov] = ...
        factoran(Sigma,2,'Xtype','cov','rotate','none');
LoadingsCov
```

```
LoadingsCov =

    0.6289    0.3485
    0.6992    0.3287
    0.7785   -0.2069
    0.7246   -0.2070
    0.8963   -0.0473
```

Factor Rotation

Sometimes, the estimated loadings from a factor analysis model can give a large weight on several factors for some of the measured variables, making it difficult to interpret what those factors represent. The goal of factor rotation is to find a solution for which each variable has only a small number of large loadings, i.e., is affected by a small number of factors, preferably only one.

If you think of each row of the loadings matrix as coordinates of a point in M-dimensional space, then each factor corresponds to a coordinate axis. Factor rotation is equivalent to rotating those axes, and computing new loadings in the rotated coordinate system. There are various ways to do this. Some methods leave the axes orthogonal, while others are oblique methods that change the angles between them.

Varimax is one common criterion for orthogonal rotation. `factoran` performs varimax rotation by default, so you do not need to ask for it explicitly.

```
[LoadingsVM,specVarVM,rotationVM] = factoran(grades,2);
```

A quick check of the varimax rotation matrix returned by `factoran` confirms that it is orthogonal. Varimax, in effect, rotates the factor axes in the figure above, but keeps them at right angles.

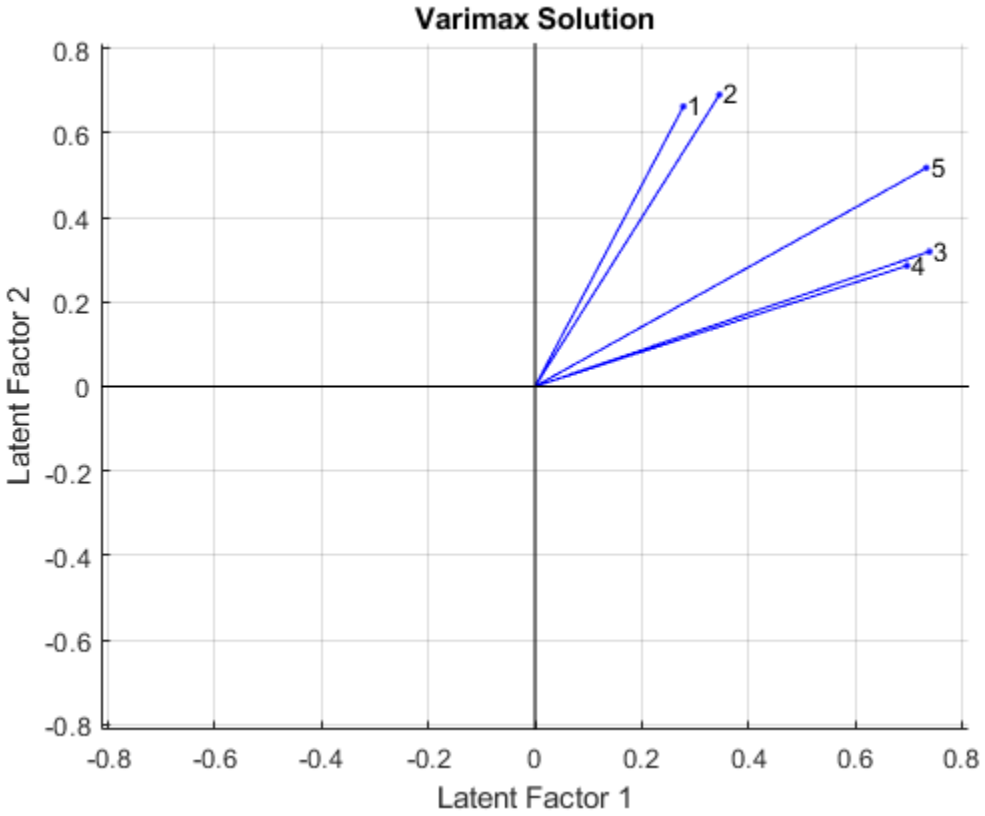
```
rotationVM'*rotationVM

ans =

     1     0
     0     1
```

A biplot of the five variables on the rotated factors shows the effect of varimax rotation.

```
biplot(LoadingsVM, 'varlabels',num2str((1:5)'));
title('Varimax Solution');
xlabel('Latent Factor 1'); ylabel('Latent Factor 2');
```



Varimax has rigidly rotated the axes in an attempt to make all of the loadings close to zero or one. The first two exams are closest to the second factor axis, while the third and fourth are closest to the first axis and the fifth exam is at an intermediate position. These two rotated factors can probably be best interpreted as "quantitative ability" and "qualitative ability". However, because none of the variables are near a factor axis, the biplot shows that orthogonal rotation has not succeeded in providing a simple set of factors.

Because the orthogonal rotation was not entirely satisfactory, you can try using promax, a common oblique rotation criterion.

```
[LoadingsPM,specVarPM,rotationPM] = ...
                factoran(grades,2,'rotate','promax');
```

A check on the promax rotation matrix returned by `factoran` shows that it is not orthogonal. Promax, in effect, rotates the factor axes in the first figure separately, allowing them to have an oblique angle between them.

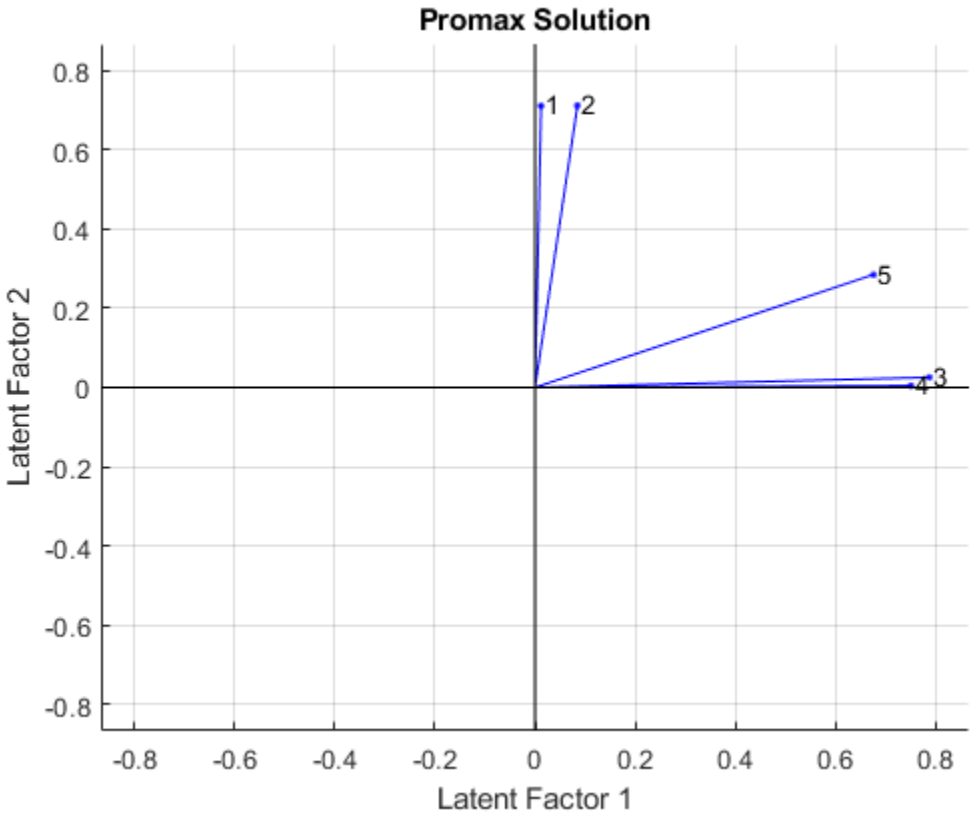
```
rotationPM'*rotationPM
```

```
ans =

    1.9405   -1.3509
   -1.3509    1.9405
```

A biplot of the variables on the new rotated factors shows the effect of promax rotation.

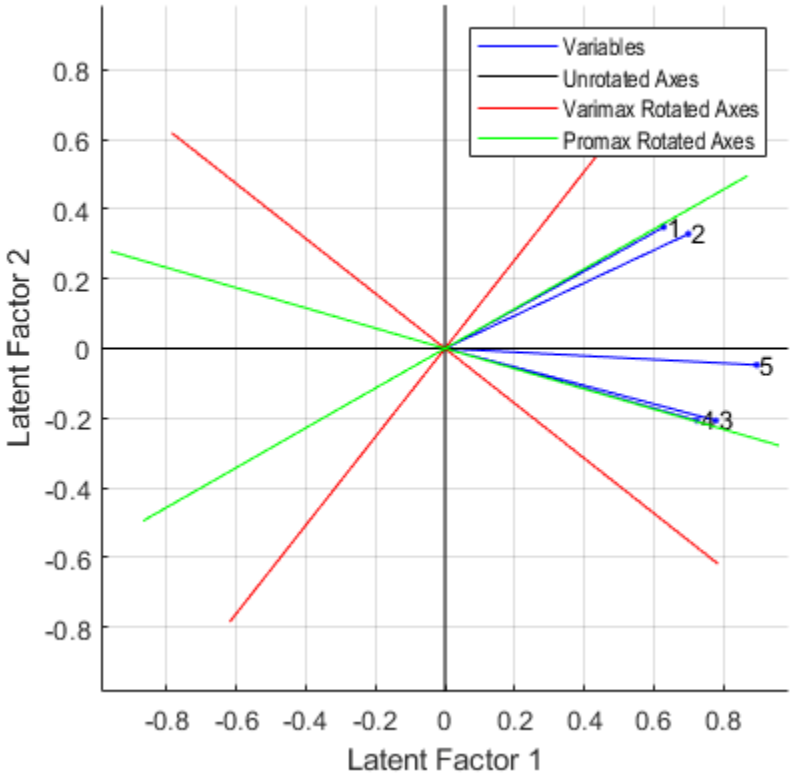
```
biplot(LoadingsPM, 'varlabels',num2str((1:5)'));
title('Promax Solution');
xlabel('Latent Factor 1'); ylabel('Latent Factor 2');
```



Promax has performed a non-rigid rotation of the axes, and has done a much better job than varimax at creating a "simple structure". The first two exams are close to the second factor axis, while the third and fourth are close to the first axis, and the fifth exam is in an intermediate position. This makes an interpretation of these rotated factors as "quantitative ability" and "qualitative ability" more precise.

Instead of plotting the variables on the different sets of rotated axes, it's possible to overlay the rotated axes on an unrotated biplot to get a better idea of how the rotated and unrotated solutions are related.

```
h1 = biplot(Loadings2, 'varlabels',num2str((1:5)'));
xlabel('Latent Factor 1'); ylabel('Latent Factor 2');
hold on
invRotVM = inv(rotationVM);
h2 = line([-invRotVM(1,1) invRotVM(1,1) NaN -invRotVM(2,1) invRotVM(2,1)], ...
          [-invRotVM(1,2) invRotVM(1,2) NaN -invRotVM(2,2) invRotVM(2,2)],'Color',[1 0 0]);
invRotPM = inv(rotationPM);
h3 = line([-invRotPM(1,1) invRotPM(1,1) NaN -invRotPM(2,1) invRotPM(2,1)], ...
          [-invRotPM(1,2) invRotPM(1,2) NaN -invRotPM(2,2) invRotPM(2,2)],'Color',[0 1 0]);
hold off
axis square
lgndHandles = [h1(1) h1(end) h2 h3];
lgndLabels = {'Variables','Unrotated Axes','Varimax Rotated Axes','Promax Rotated Axes'};
legend(lgndHandles, lgndLabels, 'location','northeast', 'fontname','arial narrow');
```



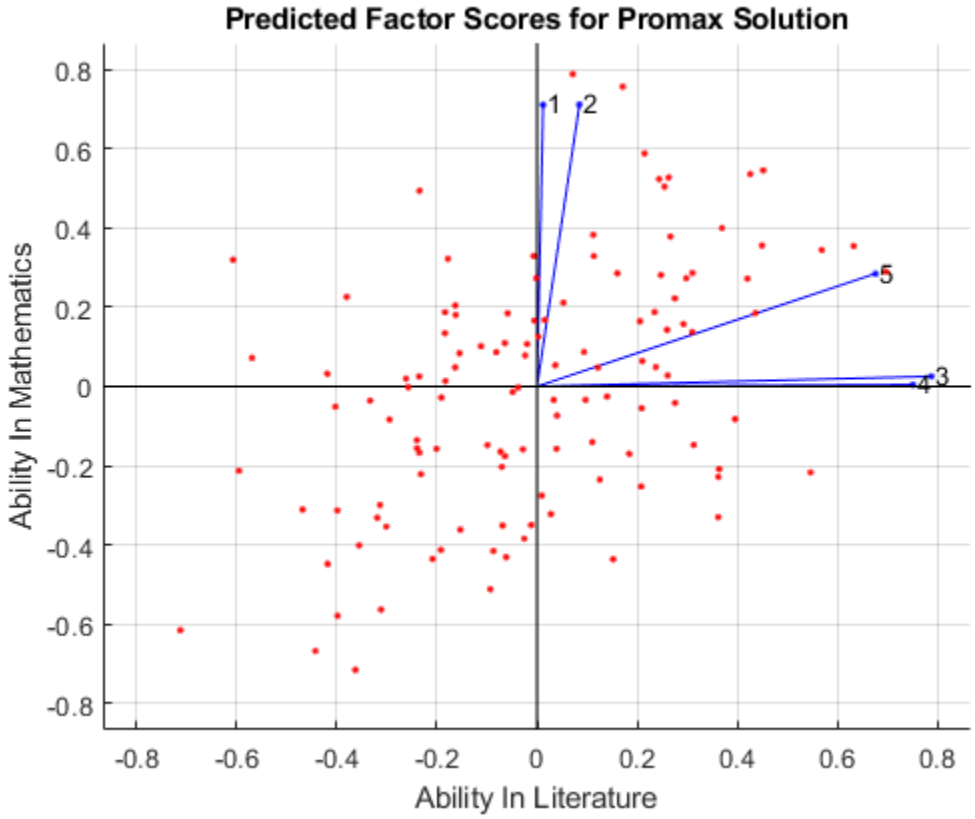
Predicting Factor Scores

Sometimes, it is useful to be able to classify an observation based on its factor scores. For example, if you accepted the two-factor model and the interpretation of the promax rotated factors, you might want to predict how well a student would do on a mathematics exam in the future.

Since the data are the raw exam grades, and not just their covariance matrix, we can have `factoran` return predictions of the value of each of the two rotated common factors for each student.

```
[Loadings,specVar,rotation,stats,preds] = ...
              factoran(grades,2,'rotate','promax','maxit',200);
biplot(Loadings, 'varlabels',num2str((1:5)'), 'Scores',preds);
```

```
title('Predicted Factor Scores for Promax Solution');
xlabel('Ability In Literature'); ylabel('Ability In Mathematics');
```



This plot shows the model fit in terms of both the original variables (vectors) and the predicted scores for each observation (points). The fit suggests that, while some students do well in one subject but not the other (second and fourth quadrants), most students do either well or poorly in both mathematics and literature (first and third quadrants). You can confirm this by looking at the estimated correlation matrix of the two factors.

```
inv(rotation'*rotation)
```

```
ans =

    1.0000    0.6962
    0.6962    1.0000
```

A Comparison of Factor Analysis and Principal Components Analysis

There is a good deal of overlap in terminology and goals between Principal Components Analysis (PCA) and Factor Analysis (FA). Much of the literature on the two methods does not distinguish between them, and some algorithms for fitting the FA model involve PCA. Both are dimension-reduction techniques, in the sense that they can be used to replace a large set of observed variables with a smaller set of new variables. They also often give similar results. However, the two methods are different in their goals and in their underlying models. Roughly speaking, you should use PCA when you simply need to summarize or approximate your data using fewer dimensions (to visualize it,

for example), and you should use FA when you need an explanatory model for the correlations among your data.

Classical Multidimensional Scaling Applied to Nonspatial Distances

This example shows how to perform classical multidimensional scaling using the `cmdscale` function in Statistics and Machine Learning Toolbox™. Classical multidimensional scaling, also known as Principal Coordinates Analysis, takes a matrix of interpoint distances, and creates a configuration of points. Ideally, those points can be constructed in two or three dimensions, and the Euclidean distances between them approximately reproduce the original distance matrix. Thus, a scatter plot of the those points provides a visual representation of the original distances.

This example illustrates applications of multidimensional scaling to dissimilarity measures other than spatial distance, and shows how to construct a configuration of points to visualize those dissimilarities.

This example describes classical multidimensional scaling. The `mdscale` function performs nonclassical MDS, which is sometimes more flexible than the classical method. Nonclassical MDS is described in the “Nonclassical Multidimensional Scaling” on page 15-197 example.

Reconstructing Spatial Locations from Nonspatial Distances

Suppose you have measured the genetic "distance", or dissimilarity, between a number of local subpopulations of a single species of animal. You also know their geographic locations, and would like to know how closely their genetic and spatial distances correspond. If they do, that is evidence that interbreeding between the subpopulations is affected by their geographic locations.

Below are the spatial locations of the subpopulations, and the upper-triangle of the matrix of genetic distances, in the same vector format produced by `pdist`.

```
X = [39.1     18.7;
     40.7     21.2;
     41.5     21.5;
     39.2     21.8;
     38.7     20.6;
     41.7     20.1;
     40.1     22.1;
     39.2     21.6];

D = [4.69 6.79 3.50 3.11 4.46 5.57 3.00 ...
          2.10 2.27 2.65 2.36 1.99 1.74 ...
               3.78 4.53 2.83 2.44 3.79 ...
                    1.98 4.35 2.07 0.53 ...
                         3.80 3.31 1.47 ...
                              4.35 3.82 ...
                                   2.57];
```

Although this vector format for `D` is space-efficient, it's often easier to see the distance relationships if you reformat the distances to a square matrix.

```
squareform(D)
```

```
ans = 8×8

         0    4.6900    6.7900    3.5000    3.1100    4.4600    5.5700    3.0000
    4.6900         0    2.1000    2.2700    2.6500    2.3600    1.9900    1.7400
    6.7900    2.1000         0    3.7800    4.5300    2.8300    2.4400    3.7900
```

```
    3.5000    2.2700    3.7800         0    1.9800    4.3500    2.0700    0.5300
    3.1100    2.6500    4.5300    1.9800         0    3.8000    3.3100    1.4700
    4.4600    2.3600    2.8300    4.3500    3.8000         0    4.3500    3.8200
    5.5700    1.9900    2.4400    2.0700    3.3100    4.3500         0    2.5700
    3.0000    1.7400    3.7900    0.5300    1.4700    3.8200    2.5700         0
```

`cmdscale` recognizes either of the two formats.

```
[Y,eigvals] = cmdscale(D);
```

`cmdscale`'s first output, `Y`, is a matrix of points created to have interpoint distances that reproduce the distances in `D`. With eight species, the points (rows of `Y`) could have as many as eight dimensions (columns of `Y`). Visualization of the genetic distances depends on using points in only two or three dimensions. Fortunately, `cmdscale`'s second output, `eigvals`, is a set of sorted eigenvalues whose relative magnitudes indicate how many dimensions you can safely use. If only the first two or three eigenvalues are large, then only those coordinates of the points in `Y` are needed to accurately reproduce `D`. If more than three eigenvalues are large, then it is not possible to find a good low-dimensional configuration of points, and it will not be easy to visualize the distances.

```
[eigvals eigvals/max(abs(eigvals))]
```

```
ans = 8×2

   29.0371    1.0000
   13.5746    0.4675
    2.0987    0.0723
    0.7418    0.0255
    0.3403    0.0117
    0.0000    0.0000
   -0.4542   -0.0156
   -3.1755   -0.1094
```

Notice that there are only two large positive eigenvalues, so the configuration of points created by `cmdscale` can be plotted in two dimensions. The two negative eigenvalues indicate that the genetic distances are not Euclidean, that is, no configuration of points can reproduce `D` exactly. Fortunately, the negative eigenvalues are small relative to the largest positive ones, and the reduction to the first two columns of `Y` should be fairly accurate. You can check this by looking at the error in the distances between the two-dimensional configuration and the original distances.

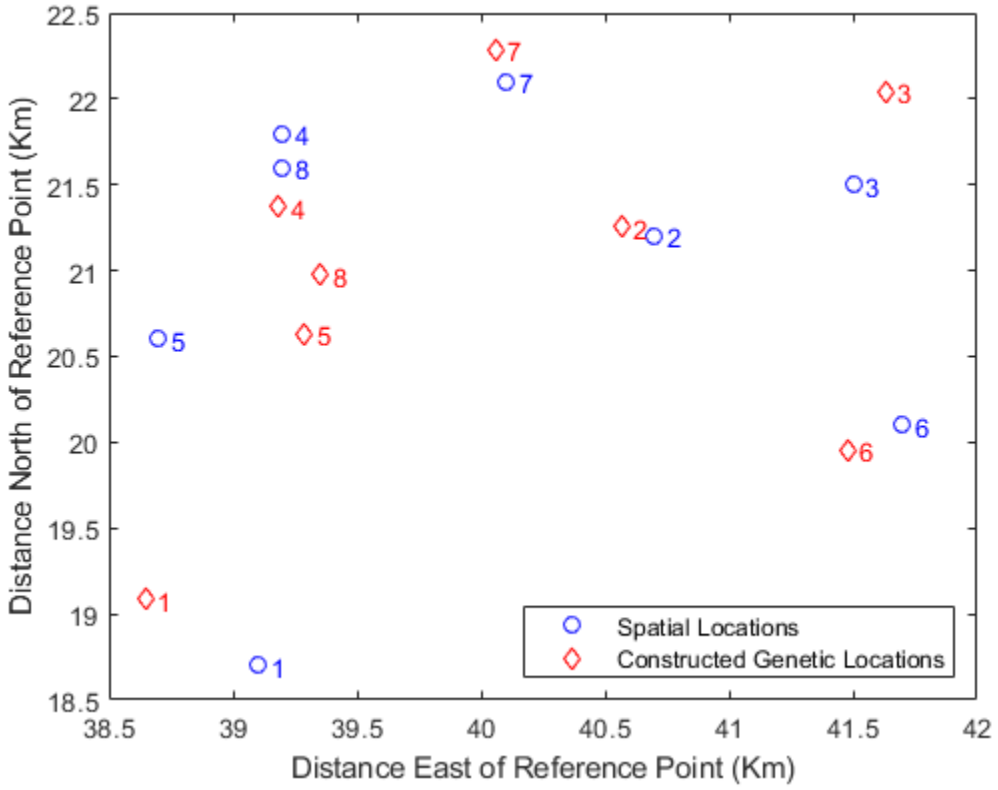
```
maxrelerr = max(abs(D - pdist(Y(:,1:2)))) / max(D)
```

```
maxrelerr = 0.1335
```

Now you can compare the "genetic locations" created by `cmdscale` to the actual geographic locations. Because the configuration returned by `cmdscale` is unique only up to translation, rotation, and reflection, the genetic locations probably won't match the geographic locations. They will also have the wrong scale. But you can use the `procrustes` command to match up the two sets of points best in the least squares sense.

```
[D,Z] = procrustes(X,Y(:,1:2));
plot(X(:,1),X(:,2),'bo',Z(:,1),Z(:,2),'rd');
labels = num2str((1:8)');
text(X(:,1)+.05,X(:,2),labels,'Color','b');
text(Z(:,1)+.05,Z(:,2),labels,'Color','r');
xlabel('Distance East of Reference Point (Km)');
```

```
ylabel('Distance North of Reference Point (Km)');
legend({'Spatial Locations','Constructed Genetic Locations'},'Location','SE');
```



This plot shows the best match of the reconstructed points in the same coordinates as the actual spatial locations. Apparently, the genetic distances do have a close link to the spatial distances between the subpopulations.

Visualizing a Correlation Matrix Using Multidimensional Scaling

Suppose you have computed the following correlation matrix for a set of 10 variables. It's obvious that these variables are all positively correlated, and that there are some very strong pairwise correlations. But with this many variables, it's not easy to get a good feel for the relationships among all 10.

```
Rho = ...
  [1       0.3906  0.3746  0.3318  0.4141  0.4279  0.4216  0.4703  0.4362  0.2066;
   0.3906  1       0.3200  0.3629  0.2211  0.9520  0.9811  0.9052  0.4567  0     ;
   0.3746  0.3200  1       0.8993  0.7999  0.3589  0.3460  0.3333  0.8639  0.6527;
   0.3318  0.3629  0.8993  1       0.7125  0.3959  0.3663  0.3394  0.8719  0.5726;
   0.4141  0.2211  0.7999  0.7125  1       0.2374  0.2079  0.2335  0.7050  0.7469;
   0.4279  0.9520  0.3589  0.3959  0.2374  1       0.9657  0.9363  0.4791  0.0254;
   0.4216  0.9811  0.3460  0.3663  0.2079  0.9657  1       0.9123  0.4554  0.0011;
   0.4703  0.9052  0.3333  0.3394  0.2335  0.9363  0.9123  1       0.4418  0.0099;
   0.4362  0.4567  0.8639  0.8719  0.7050  0.4791  0.4554  0.4418  1       0.5272;
   0.2066  0       0.6527  0.5726  0.7469  0.0254  0.0011  0.0099  0.5272  1     ];
```

Multidimensional scaling is often thought of as a way to (re)construct points using only pairwise distances. But it can also be used with dissimilarity measures that are more general than distance, to spatially visualize things that are not "points in space" in the usual sense. The variables described by Rho are an example, and you can use `cmdscale` to plot a visual representation of their interdependencies.

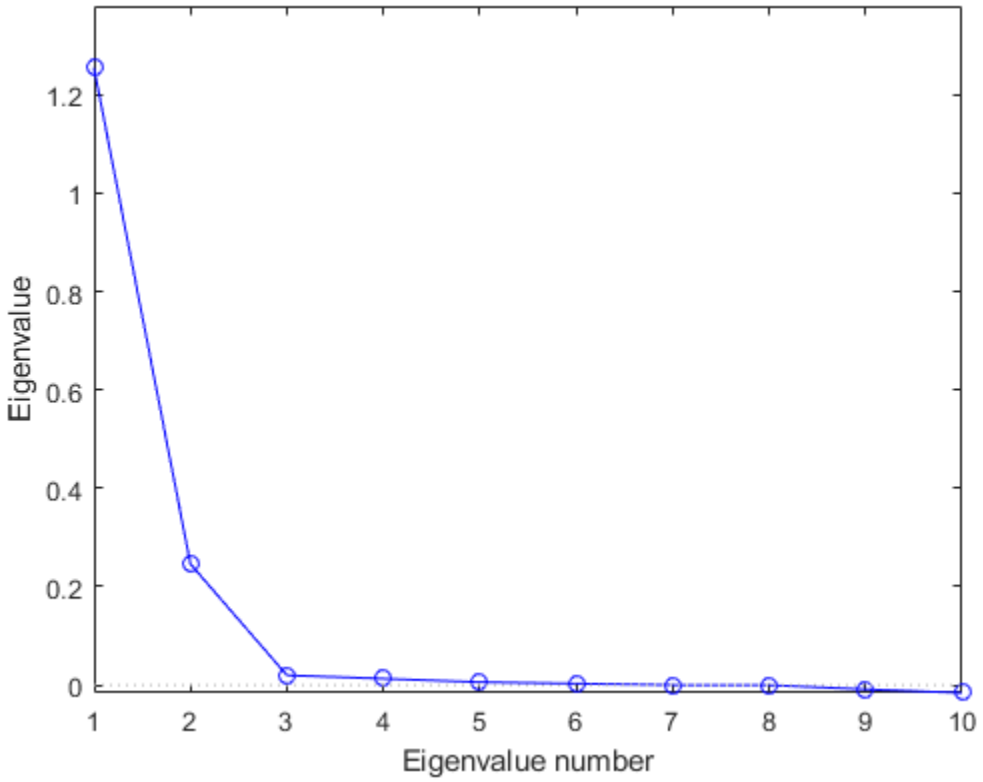
Correlation actually measures similarity, but it is easy to transform it to a measure of dissimilarity. Because all the correlations here are positive, you can simply use

```
D = 1 - Rho;
```

although other choices might also make sense. If `Rho` contained negative correlations, you would have to decide whether, for example, a correlation of -1 indicated more or less of a dissimilarity than a correlation of 0, and choose a transformation accordingly.

It's important to decide whether visualization of the information in the correlation matrix is even possible, that is, whether the number of dimensions can be reduced from ten down to two or three. The eigenvalues returned by `cmdscale` give you a way to decide. In this case, a scree plot of those eigenvalues indicates that two dimensions are enough to represent the variables. (Notice that some of the eigenvalues in the plot below are negative, but small relative to the first two.)

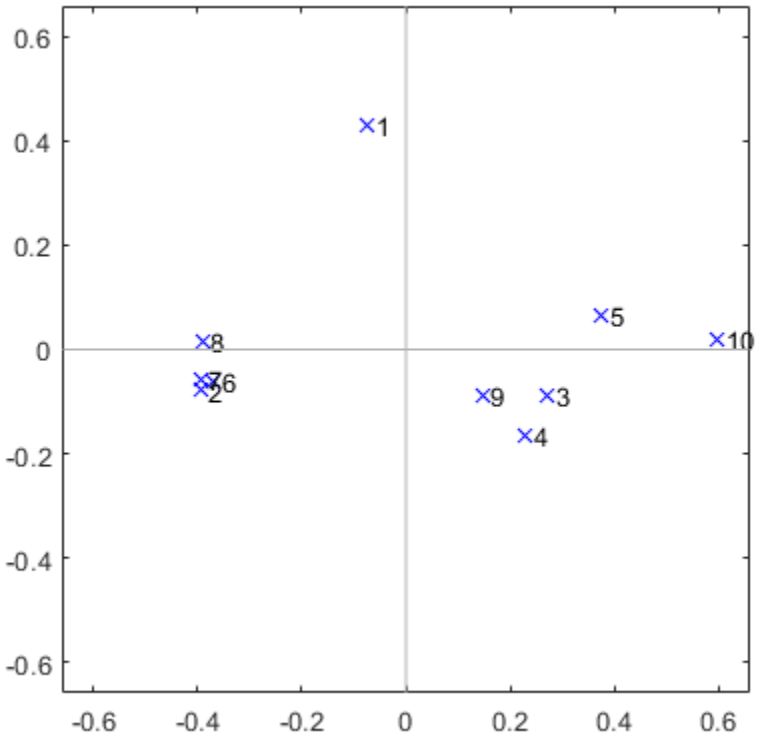
```
[Y,eigvals] = cmdscale(D);
plot(1:length(eigvals),eigvals,'bo-');
line([1,length(eigvals)],[0 0],'LineStyle',':','XLimInclude','off',...
     'Color',[.7 .7 .7])
axis([1,length(eigvals),min(eigvals),max(eigvals)*1.1]);
xlabel('Eigenvalue number');
ylabel('Eigenvalue');
```



In a more independent set of variables, more dimensions might be needed. If more than three variables are needed, the visualization isn't all that useful.

A 2-D plot of the configuration returned by `cmdscale` indicates that there are two subsets of variables that are most closely correlated among themselves, plus a single variable that is more or less on its own. One of the clusters is tight, while the other is relatively loose.

```
labels = {' 1',' 2',' 3',' 4',' 5',' 6',' 7',' 8',' 9',' 10'};
plot(Y(:,1),Y(:,2),'bx');
axis(max(max(abs(Y))) * [-1.1,1.1,-1.1,1.1]); axis('square');
text(Y(:,1),Y(:,2),labels,'HorizontalAlignment','left');
line([-1,1],[0 0],'XLimInclude','off','Color',[.7 .7 .7])
line([0 0],[-1,1],'YLimInclude','off','Color',[.7 .7 .7])
```



On the other hand, the results from `cmdscale` for the following correlation matrix indicates a much different structure: there are no real groups among the variables. Rather, there is a kind of "circular" dependency, where each variable has a pair of "closest neighbors" but is less well correlated with the remaining variables.

```
Rho = ...
  [1       0.7946  0.1760  0.2560  0.7818  0.4496  0.2732  0.3995  0.5305  0.2827;
   0.7946  1       0.1626  0.4227  0.5674  0.6183  0.4004  0.2283  0.3495  0.2777;
   0.1760  0.1626  1       0.2644  0.1864  0.1859  0.4330  0.4656  0.3947  0.8057;
   0.2560  0.4227  0.2644  1       0.1017  0.7426  0.8340  0       0.0499  0.4853;
   0.7818  0.5674  0.1864  0.1017  1       0.2733  0.1484  0.4890  0.6138  0.2025;
   0.4496  0.6183  0.1859  0.7426  0.2733  1       0.6303  0.0648  0.1035  0.3242;

A Comparison of Principal Components Analysis and Classical Multidimensional Scaling

Multidimensional scaling is most often used to visualize data when only their distances or dissimilarities are available. However, when the original data are available, multidimensional scaling can also be used as a dimension reduction method, by reducing the data to a distance matrix, creating a new configuration of points using `cmdscale`, and retaining only the first few dimensions of those points. This application of multidimensional scaling is much like Principal Components Analysis, and in fact, when you call `cmdscale` using the Euclidean distances between the points, the results are identical to PCA, up to a change in sign.

```
n = 10; m = 5;
X = randn(n,m);
D = pdist(X,'Euclidean');
```

```
[Y,eigvals] = cmdscale(D);
[PC,Score,latent] = pca(X);

Y
```

```
Y = 10×5

   -1.4505    1.6602    0.8106    0.5834    0.5952

```

Nonclassical Multidimensional Scaling

This example shows how to visualize dissimilarity data using nonclassical forms of multidimensional scaling (MDS).

Dissimilarity data arises when we have some set of objects, and instead of measuring the characteristics of each object, we can only measure how similar or dissimilar each pair of objects is. For example, instead of knowing the latitude and longitude of a set of cities, we may only know their inter-city distances. However, MDS also works with dissimilarities that are more abstract than physical distance. For example, we may have asked consumers to rate how similar they find several brands of peanut butter.

The typical goal of MDS is to create a configuration of points in one, two, or three dimensions, whose inter-point distances are "close" to the original dissimilarities. The different forms of MDS use different criteria to define "close". These points represent the set of objects, and so a plot of the points can be used as a visual representation of their dissimilarities.

Some applications of "classical" MDS are described in the “Classical Multidimensional Scaling Applied to Nonspatial Distances” on page 15-189 example.

Rothkopf's Morse Code Dataset

To demonstrate MDS, we'll use data collected in an experiment to investigate perception of Morse code (Rothkopf, E.Z., J.Exper.Psych., 53(2):94-101). Subjects in the study listened to two Morse code signals (audible sequences of one or more "dots" and "dashes", representing the 36 alphanumeric characters) played in succession, and were asked whether the signals were the same or different. The subjects did not know Morse code. The dissimilarity between two different characters is the frequency with which those characters were correctly distinguished.

The 36x36 matrix of dissimilarities is stored as a 630-element vector containing the subdiagonal elements of the matrix. You can use the function `squareform` to transform between the vector format and the full matrix form. Here are the first 5 letters and their dissimilarities, reconstructed in matrix form.

```
load morse
morseChars(1:5,:)
```

```
ans = 5x2 cell
    {'A'}    {'.-'  }
    {'B'}    {'-...'}
    {'C'}    {'-.-.'}
    {'D'}    {'-..' }
    {'E'}    {'.'   }
```

```
dissMatrix = squareform(dissimilarities);
dissMatrix(1:5,1:5)
```

```
ans = 5×5

     0   167   169   159   180
   167     0    96    79   163
   169    96     0   141   166
   159    79   141     0   172
   180   163   166   172     0
```

In these data, larger values indicate that more experimental subjects were able to distinguish the two signals, and so the signals were more dissimilar.

Metric Scaling

Metric MDS creates a configuration of points such that their interpoint distances approximate the original dissimilarities. One measure of the goodness of fit of that approximation is known as the "stress", and that's what we'll use initially. To compute the configuration, we provide the `mdscale` function with the dissimilarity data, the number of dimensions in which we want to create the points (two), and the name of the goodness-of-fit criterion we are using.

```
Y1 = mdscale(dissimilarities, 2, 'criterion','metricstress');
size(Y1)
```

```
ans = 1×2

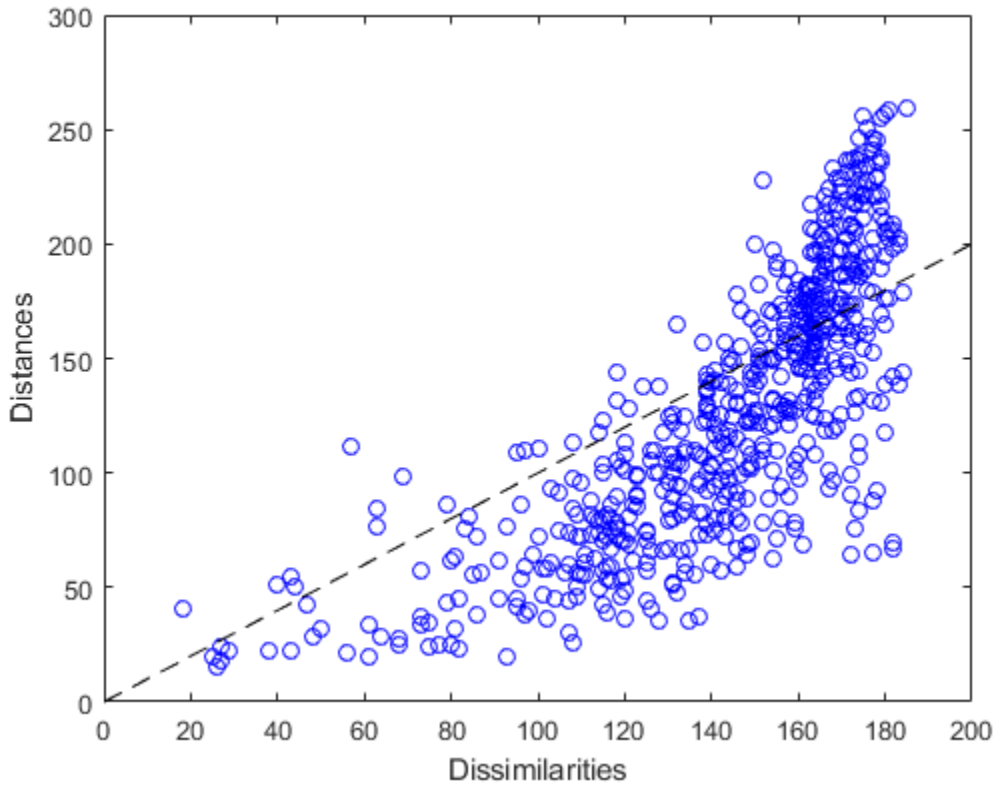
    36     2
```

`mdscale` returns a set of points in, for this example, two dimensions. We could plot them, but before using this solution (i.e. the configuration) to visualize the data, we'll make some plots to help check whether the interpoint distances from this solution recreate the original dissimilarities.

The Shepard Plot

The Shepard plot is a scatterplot of the interpoint distances (there are n(n-1)/2 of them) vs. the original dissimilarities. This can help determine goodness of fit of the MDS solution. If the fit is poor, then visualization could be misleading, because large (small) distances between points might not correspond to large (small) dissimilarities in the data. In the Shepard plot, a narrow scatter around a 1:1 line indicates a good fit of the distances to the dissimilarities, while a large scatter or a nonlinear pattern indicates a lack of fit.

```
distances1 = pdist(Y1);
plot(dissimilarities,distances1,'bo', [0 200],[0 200],'k--');
xlabel('Dissimilarities')
ylabel('Distances')
```



This plot indicates that this metric solution in two dimensions is probably not appropriate, because it shows both a nonlinear pattern and a large scatter. The former implies that many of the largest dissimilarities would tend to be somewhat exaggerated in the visualization, while moderate and small dissimilarities would tend to be understated. The latter implies that distance in the visualization would generally be a poor reflection of dissimilarity. In particular, a good fraction of the large dissimilarities would be badly understated.

Comparing Metric Criteria

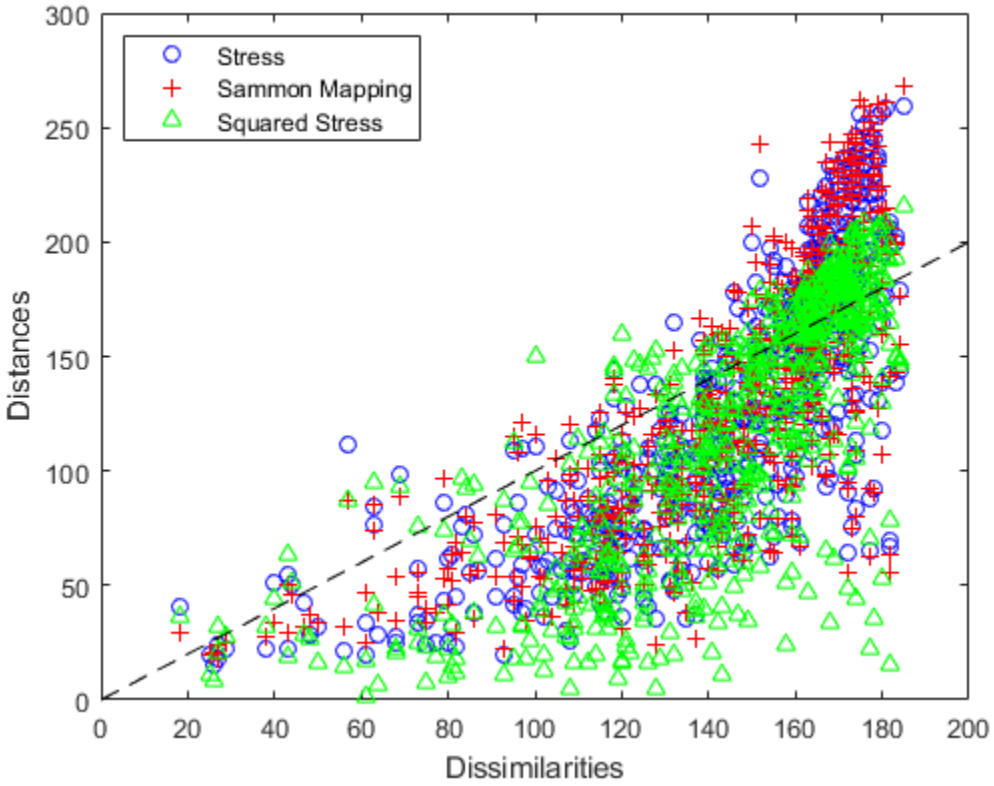
We could try using a third dimension to improve the fidelity of the visualization, because with more degrees of freedom, the fit should improve. We can also try a different criterion. Two other popular metric criteria are known as Sammon Mapping and squared stress ("sstress"). Each leads to a different solution, and one or the other might be more useful in visualizing the original dissimilarities.

```
Y2 = mdscale(dissimilarities,2, 'criterion','sammon');
distances2 = pdist(Y2);
Y3 = mdscale(dissimilarities,2, 'criterion','metricsstress');
distances3 = pdist(Y3);
```

A Shepard plot shows the differences in the three solutions so far.

```
plot(dissimilarities,distances1,'bo', ...
     dissimilarities,distances2,'r+', ...
     dissimilarities,distances3,'g^', ...
     [0 200],[0 200],'k--');
xlabel('Dissimilarities')
```

```
ylabel('Distances')
legend({'Stress', 'Sammon Mapping', 'Squared Stress'}, 'Location','NorthWest');
```



Notice that at the largest dissimilarity values, the scatter for the squared stress criterion tends to be closer to the 1:1 line than for the other two criteria. Thus, for these data, squared stress is somewhat better at preserving the largest dissimilarities, although it badly understates some of those. At smaller dissimilarity values, the scatter for the Sammon Mapping criterion tends to be somewhat closer to the 1:1 line than for the other two criteria. Thus, Sammon Mapping is a little better at preserving small dissimilarities. Stress is somewhere in between. All three criteria show a certain amount of nonlinearity, indicating that metric scaling may not be suitable. However, the choice of criterion depends on the goal of the visualization.

Nonmetric Scaling

Nonmetric scaling is a second form of MDS that has a slightly less ambitious goal than metric scaling. Instead of attempting to create a configuration of points for which the pairwise distances approximate the original dissimilarities, nonmetric MDS attempts only to approximate the *ranks* of the dissimilarities. Another way of saying this is that nonmetric MDS creates a configuration of points whose interpoint distances approximate a *monotonic transformation* of the original dissimilarities.

The practical use of such a construction is that large interpoint distances correspond to large dissimilarities, and small interpoint distances to small dissimilarities. This is often sufficient to convey the relationships among the items or categories being studied.

First, we'll create a configuration of points in 2D. Nonmetric scaling with Kruskal's nonmetric stress criterion is the default for `mdscale`.

```
[Y,stress,disparities] = mdscale(dissimilarities,2);
stress
```

```
stress = 0.1800
```

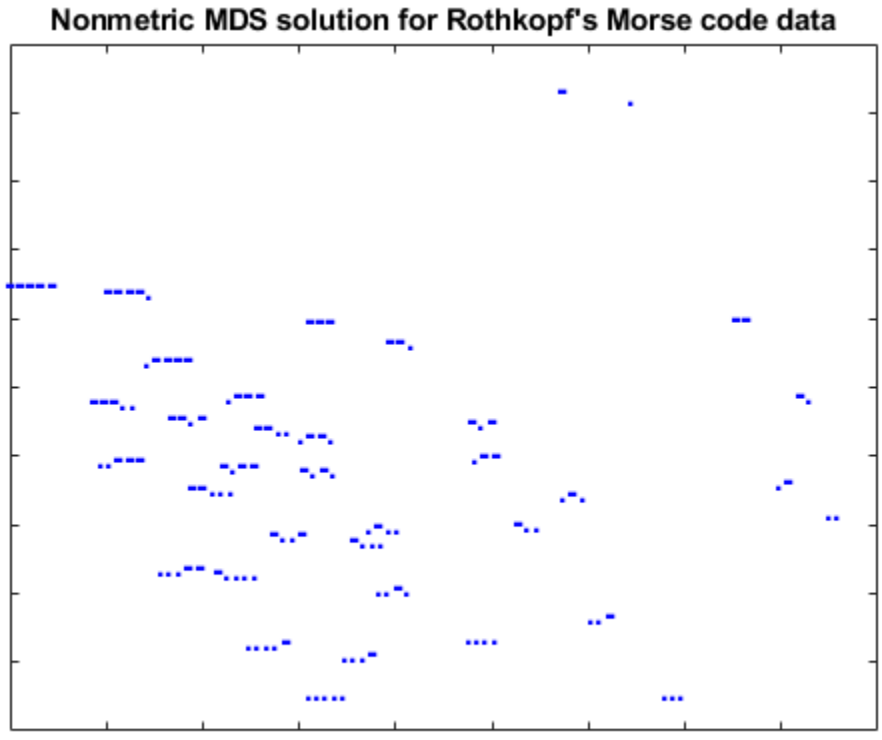
The second output of `mdscale` is the value of the criterion being used, as a measure of how well the solution recreates the dissimilarities. Smaller values indicate a better fit. The stress for this configuration, about 18%, is considered poor to fair for the nonmetric stress criterion. The ranges of acceptable criterion values differ for the different criteria.

The third output of `mdscale` is a vector of what are known as disparities. These are simply the monotonic transformation of the dissimilarities. They will be used in a nonmetric scaling Shepard plot below.

Visualizing the Dissimilarity Data

Although this fit is not as good as we would like, the 2D representation is easiest to visualize. We can plot each signal's dots and dashes to help see why the subjects perceive differences among the characters. The orientation and scale of this configuration is completely arbitrary, so no axis labels or values have been shown.

```
plot(Y(:,1),Y(:,2),'.', 'Marker','none');
text(Y(:,1),Y(:,2),char(morseChars(:,2)), 'Color','b', ...
    'FontSize',12,'FontWeight','bold', 'HorizontalAlignment','center');
h_gca = gca;
h_gca.XTickLabel = [];
h_gca.YTickLabel = [];
title('Nonmetric MDS solution for Rothkopf''s Morse code data');
```

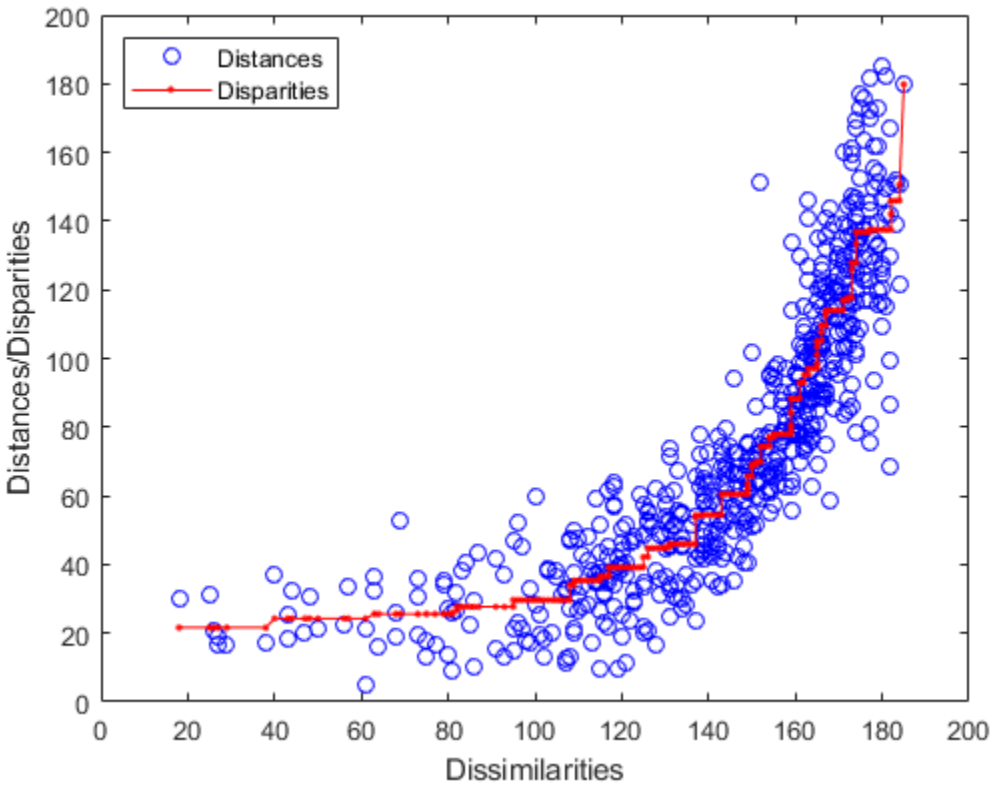


This reconstruction indicates that the characters can be described in terms of two axes: roughly speaking, the northwest/southeast direction discriminates signal length, while the southwest/northeast direction discriminates dots from dashes. The two characters with the shortest signals, 'E' and 'T', are somewhat out of position in that interpretation.

The Nonmetric Shepard Plot

In nonmetric scaling, it is customary to show the disparities as well as the distances in a Shepard plot. This provides a check on how well the distances recreate the disparities, as well as how nonlinear the monotonic transformation from dissimilarities to disparities is.

```
distances = pdist(Y);
[dum,ord] = sortrows([disparities(:) dissimilarities(:)]);
plot(dissimilarities,distances,'bo', ...
     dissimilarities(ord),disparities(ord),'r.-');
xlabel('Dissimilarities')
ylabel('Distances/Disparities')
legend({'Distances' 'Disparities'}, 'Location','NorthWest');
```



This plot shows how the distances in nonmetric scaling approximate the disparities (the scatter of blue circles about the red line), and the disparities reflect the ranks of the dissimilarities (the red line is nonlinear but increasing). Comparing this plot to the Shepard plot from metric scaling shows the difference in the two methods. Nonmetric scaling attempts to recreate not the original dissimilarities, but rather a nonlinear transformation of them (the disparities).

In doing that, nonmetric scaling has made a trade-off: the nonmetric distances recreate the disparities better than the metric distances recreated the dissimilarities -- the scatter in this plot is

smaller that in the metric plot. However, the disparities are quite nonlinear as a function of the dissimilarities. Thus, while we can be more certain that with the nonmetric solution, small distances in the visualization correspond to small dissimilarities in the data, it's important to remember that absolute distances between points in that visualization should not be taken too literally -- only relative distances.

Nonmetric Scaling in 3D

Because the stress in the 2D construction was somewhat high, we can try a 3D configuration.

```
[Y,stress,disparities] = mdscale(dissimilarities,3);
stress
```

```
stress = 0.1189
```

This stress value is quite a bit lower, indicating a better fit. We can plot the configuration in 3 dimensions. A live MATLAB® figure can be rotated interactively; here we will settle for looking from two different angles.

```
plot3(Y(:,1),Y(:,2),Y(:,3),'.', 'Marker','none');
text(Y(:,1),Y(:,2),Y(:,3),char(morseChars(:,2)), 'Color','b', ...
    'FontSize',12,'FontWeight','bold', 'HorizontalAlignment','center');

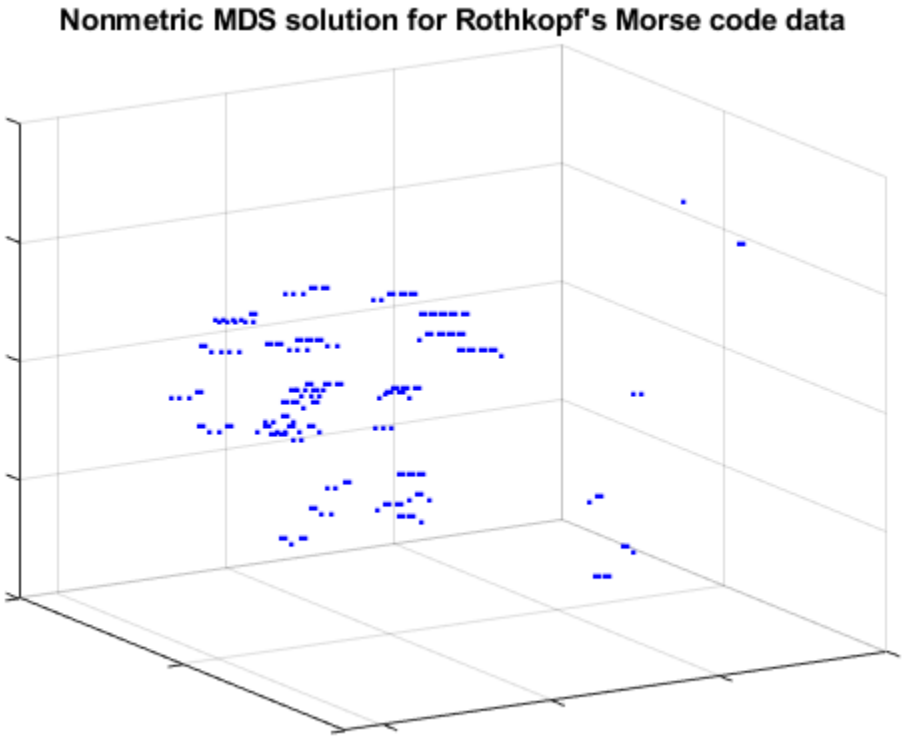
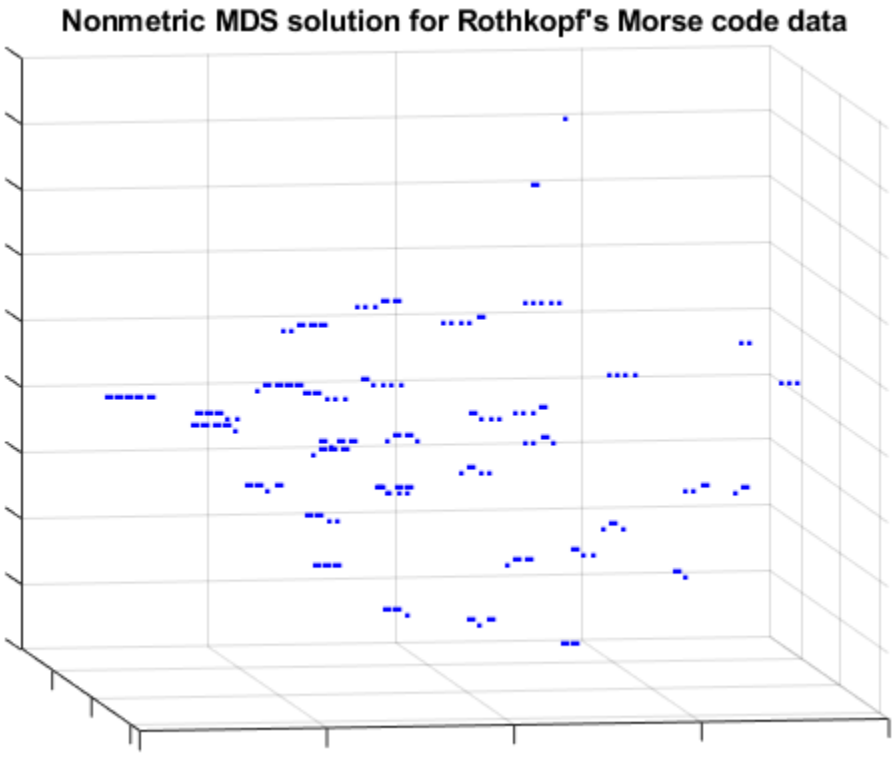
view(59,18);
grid on
```



From this angle, we can see that the characters with one- and two-symbol signals are well-separated from the characters with longer signals, and from each other, because they are the easiest to distinguish. If we rotate the view to a different perspective, we can see that the longer characters can, as in the 2D configuration, roughly be described in terms of the number of symbols and the number of dots or dashes. (From this second angle, some of the shorter characters spuriously appear to be interspersed with the longer ones.)

```
view(-9,8);
```



This 3D configuration reconstructs the distances more accurately than the 2D configuration, however, the message is essentially the same: the subjects perceive the signals primarily in terms of how many symbols they contain, and how many dots vs. dashes. In practice, the 2D configuration might be perfectly acceptable.

Fitting an Orthogonal Regression Using Principal Components Analysis

This example shows how to use Principal Components Analysis (PCA) to fit a linear regression. PCA minimizes the perpendicular distances from the data to the fitted model. This is the linear case of what is known as Orthogonal Regression or Total Least Squares, and is appropriate when there is no natural distinction between predictor and response variables, or when all variables are measured with error. This is in contrast to the usual regression assumption that predictor variables are measured exactly, and only the response variable has an error component.

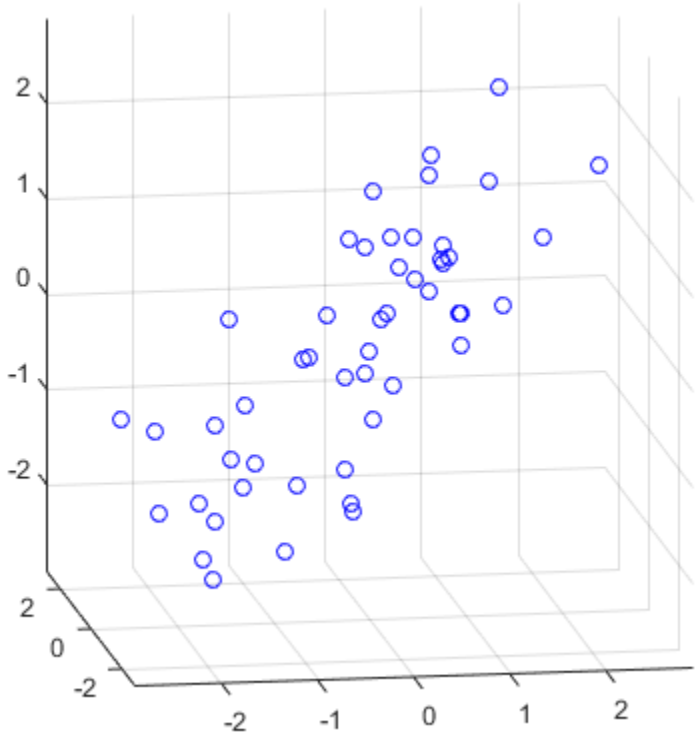
For example, given two data vectors x and y, you can fit a line that minimizes the perpendicular distances from each of the points (x(i), y(i)) to the line. More generally, with p observed variables, you can fit an r-dimensional hyperplane in p-dimensional space (r < p). The choice of r is equivalent to choosing the number of components to retain in PCA. It may be based on prediction error, or it may simply be a pragmatic choice to reduce data to a manageable number of dimensions.

In this example, we fit a plane and a line through some data on three observed variables. It's easy to do the same thing for any number of variables, and for any dimension of model, although visualizing a fit in higher dimensions would obviously not be straightforward.

Fitting a Plane to 3-D Data

First, we generate some trivariate normal data for the example. Two of the variables are fairly strongly correlated.

```
rng(5,'twister');
X = mvnrnd([0 0 0], [1 .2 .7; .2 1 0; .7 0 1],50);
plot3(X(:,1),X(:,2),X(:,3),'bo');
grid on;
maxlim = max(abs(X(:)))*1.1;
axis([-maxlim maxlim -maxlim maxlim -maxlim maxlim]);
axis square
view(-9,12);
```



Next, we fit a plane to the data using PCA. The coefficients for the first two principal components define vectors that form a basis for the plane. The third PC is orthogonal to the first two, and its coefficients define the normal vector of the plane.

```
[coeff,score,roots] = pca(X);
basis = coeff(:,1:2)
```

```
basis = 3×2

    0.6774   -0.0790
    0.2193    0.9707
    0.7022   -0.2269
```

```
normal = coeff(:,3)
```

```
normal = 3×1

    0.7314
   -0.0982
   -0.6749
```

That's all there is to the fit. But let's look closer at the results, and plot the fit along with the data.

Because the first two components explain as much of the variance in the data as is possible with two dimensions, the plane is the best 2-D linear approximation to the data. Equivalently, the third component explains the least amount of variation in the data, and it is the error term in the

regression. The latent roots (or eigenvalues) from the PCA define the amount of explained variance for each component.

```
pctExplained = roots' ./ sum(roots)
```

```
pctExplained = 1×3

    0.6226    0.2976    0.0798
```

The first two coordinates of the principal component scores give the projection of each point onto the plane, in the coordinate system of the plane. To get the coordinates of the fitted points in terms of the original coordinate system, we multiply each PC coefficient vector by the corresponding score, and add back in the mean of the data. The residuals are simply the original data minus the fitted points.

```
[n,p] = size(X);
meanX = mean(X,1);
Xfit = repmat(meanX,n,1) + score(:,1:2)*coeff(:,1:2)';
residuals = X - Xfit;
```

The equation of the fitted plane, satisfied by each of the fitted points in `Xfit`, is `([x1 x2 x3] - meanX)*normal = 0`. The plane passes through the point `meanX`, and its perpendicular distance to the origin is `meanX*normal`. The perpendicular distance from each point in `X` to the plane, i.e., the norm of the residuals, is the dot product of each centered point with the normal to the plane. The fitted plane minimizes the sum of the squared errors.

```
error = abs((X - repmat(meanX,n,1))*normal);
sse = sum(error.^2)
```

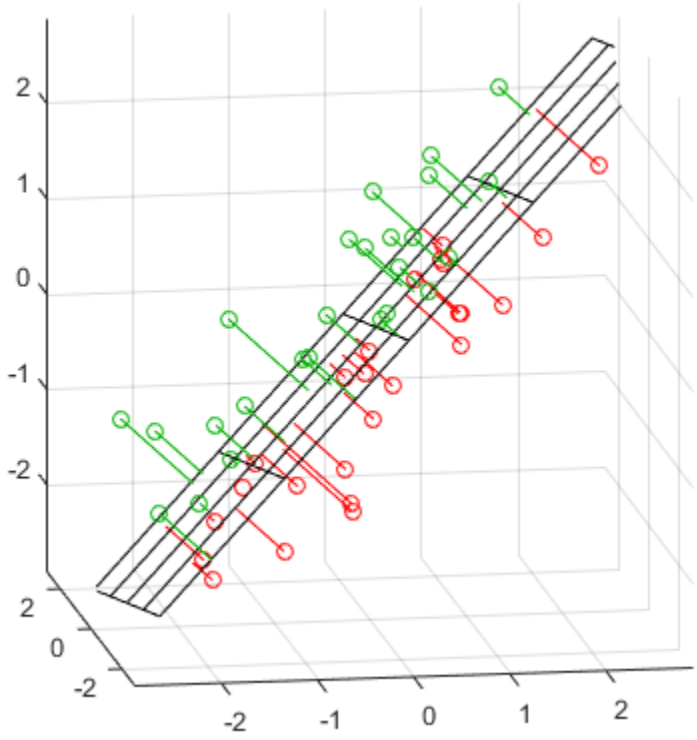
```
sse = 15.5142
```

To visualize the fit, we can plot the plane, the original data, and their projection to the plane.

```
[xgrid,ygrid] = meshgrid(linspace(min(X(:,1)),max(X(:,1)),5), ...
                         linspace(min(X(:,2)),max(X(:,2)),5));
zgrid = (1/normal(3)) .* (meanX*normal - (xgrid.*normal(1) + ygrid.*normal(2)));
h = mesh(xgrid,ygrid,zgrid,'EdgeColor',[0 0 0],'FaceAlpha',0);

hold on
above = (X-repmat(meanX,n,1))*normal < 0;
below = ~above;
nabove = sum(above);
X1 = [X(above,1) Xfit(above,1) nan*ones(nabove,1)];
X2 = [X(above,2) Xfit(above,2) nan*ones(nabove,1)];
X3 = [X(above,3) Xfit(above,3) nan*ones(nabove,1)];
plot3(X1',X2',X3','-', X(above,1),X(above,2),X(above,3),'o', 'Color',[0 .7 0]);
nbelow = sum(below);
X1 = [X(below,1) Xfit(below,1) nan*ones(nbelow,1)];
X2 = [X(below,2) Xfit(below,2) nan*ones(nbelow,1)];
X3 = [X(below,3) Xfit(below,3) nan*ones(nbelow,1)];
plot3(X1',X2',X3','-', X(below,1),X(below,2),X(below,3),'o', 'Color',[1 0 0]);

hold off
maxlim = max(abs(X(:)))*1.1;
axis([-maxlim maxlim -maxlim maxlim -maxlim maxlim]);
axis square
view(-9,12);
```



Green points are above the plane, red points are below.

Fitting a Line to 3-D Data

Fitting a straight line to the data is even simpler, and because of the nesting property of PCA, we can use the components that have already been computed. The direction vector that defines the line is given by the coefficients for the first principal component. The second and third PCs are orthogonal to the first, and their coefficients define directions that are perpendicular to the line. The simplest equation to describe the line is `meanX + t*dirVect`, where `t` parameterizes the position along the line.

```
dirVect = coeff(:,1)
```

```
dirVect = 3×1

    0.6774
    0.2193
    0.7022
```

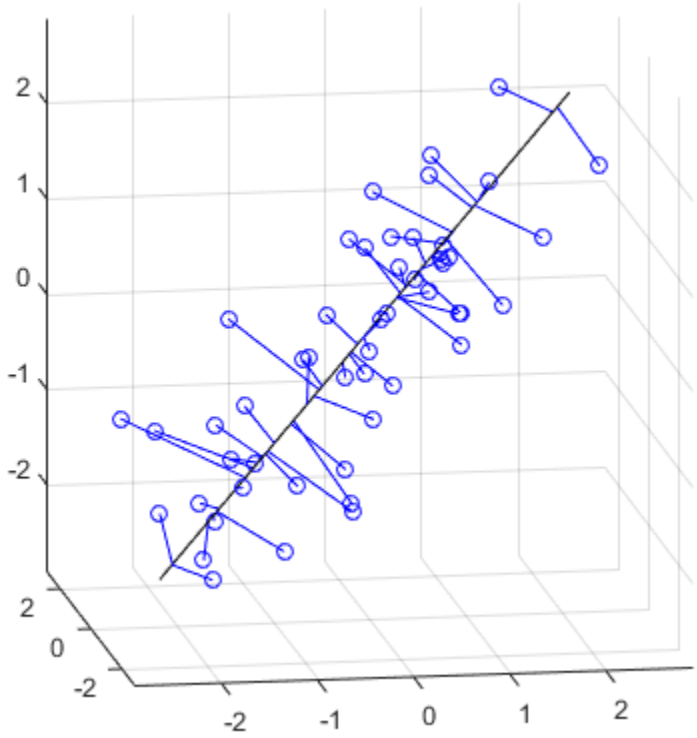
The first coordinate of the principal component scores gives the projection of each point onto the line. As with the 2-D fit, the PC coefficient vectors multiplied by the scores the gives the fitted points in the original coordinate system.

```
Xfit1 = repmat(meanX,n,1) + score(:,1)*coeff(:,1)';
```

Plot the line, the original data, and their projection to the line.

```
t = [min(score(:,1))-.2, max(score(:,1))+.2];
endpts = [meanX + t(1)*dirVect'; meanX + t(2)*dirVect'];
plot3(endpts(:,1),endpts(:,2),endpts(:,3),'k-');

X1 = [X(:,1) Xfit1(:,1) nan*ones(n,1)];
X2 = [X(:,2) Xfit1(:,2) nan*ones(n,1)];
X3 = [X(:,3) Xfit1(:,3) nan*ones(n,1)];
hold on
plot3(X1',X2',X3','b-', X(:,1),X(:,2),X(:,3),'bo');
hold off
maxlim = max(abs(X(:)))*1.1;
axis([-maxlim maxlim -maxlim maxlim -maxlim maxlim]);
axis square
view(-9,12);
grid on
```



While it appears that many of the projections in this plot are not perpendicular to the line, that's just because we're plotting 3-D data in two dimensions. In a live MATLAB® figure window, you could interactively rotate the plot to different perspectives to verify that the projections are indeed perpendicular, and to get a better feel for how the line fits the data.

Tune Regularization Parameter to Detect Features Using NCA for Classification

This example shows how to tune the regularization parameter in `fscnca` using cross-validation. Tuning the regularization parameter helps to correctly detect the relevant features in the data.

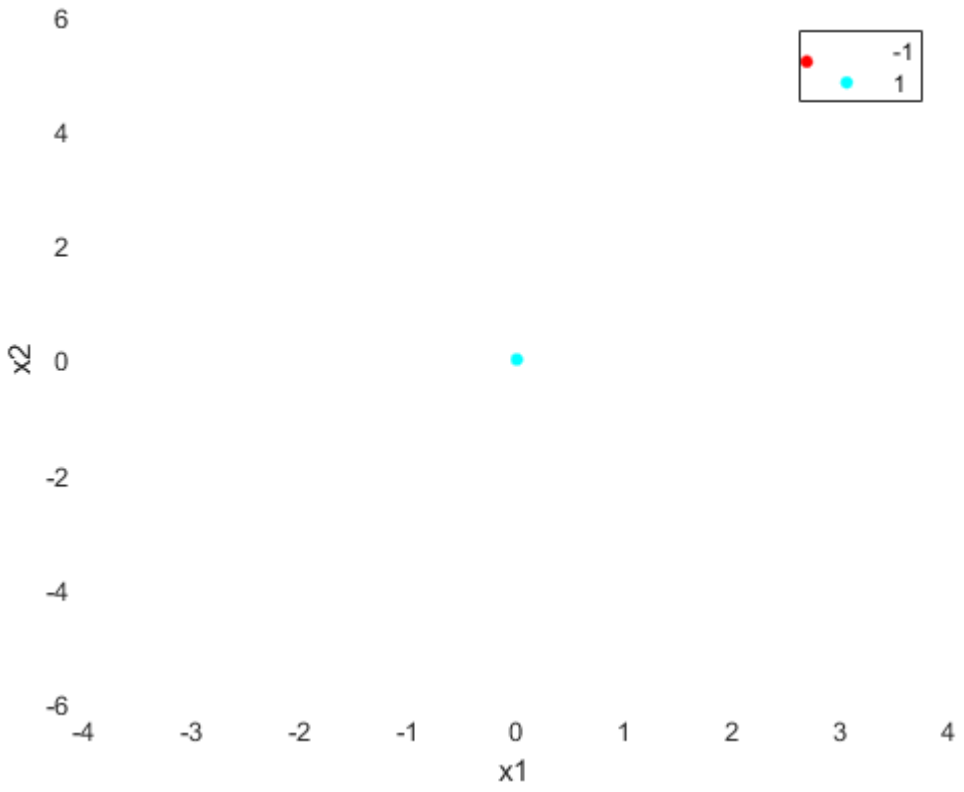
Load the sample data.

```
load('twodimclassdata.mat')
```

This dataset is simulated using the scheme described in [1]. This is a two-class classification problem in two dimensions. Data from the first class are drawn from two bivariate normal distributions $N(\mu_1, \Sigma)$ or $N(\mu_2, \Sigma)$ with equal probability, where $\mu_1 = [-0.75, -1.5]$, $\mu_2 = [0.75, 1.5]$ and $\Sigma = I_2$. Similarly, data from the second class are drawn from two bivariate normal distributions $N(\mu_3, \Sigma)$ or $N(\mu_4, \Sigma)$ with equal probability, where $\mu_3 = [1.5, -1.5]$, $\mu_4 = [-1.5, 1.5]$ and $\Sigma = I_2$. The normal distribution parameters used to create this data set results in tighter clusters in data than the data used in [1].

Create a scatter plot of the data grouped by the class.

```
figure
gscatter(X(:,1),X(:,2),y)
xlabel('x1')
ylabel('x2')
```



Add 100 irrelevant features to X. First generate data from a Normal distribution with a mean of 0 and a variance of 20.

```
n = size(X,1);
rng('default')
XwithBadFeatures = [X,randn(n,100)*sqrt(20)];
```

Normalize the data so that all points are between 0 and 1.

```
XwithBadFeatures = (XwithBadFeatures-min(XwithBadFeatures,[],1))./range(XwithBadFeatures,1);
X = XwithBadFeatures;
```

Fit an nca model to the data using the default `Lambda` (regularization parameter, λ) value. Use the LBFGS solver and display the convergence information.

```
ncaMdl = fscnca(X,y,'FitMethod','exact','Verbose',1, ...
    'Solver','lbfgs');
```

```
 o Solver = LBFGS, HessianHistorySize = 15, LineSearchMethod = weakwolfe

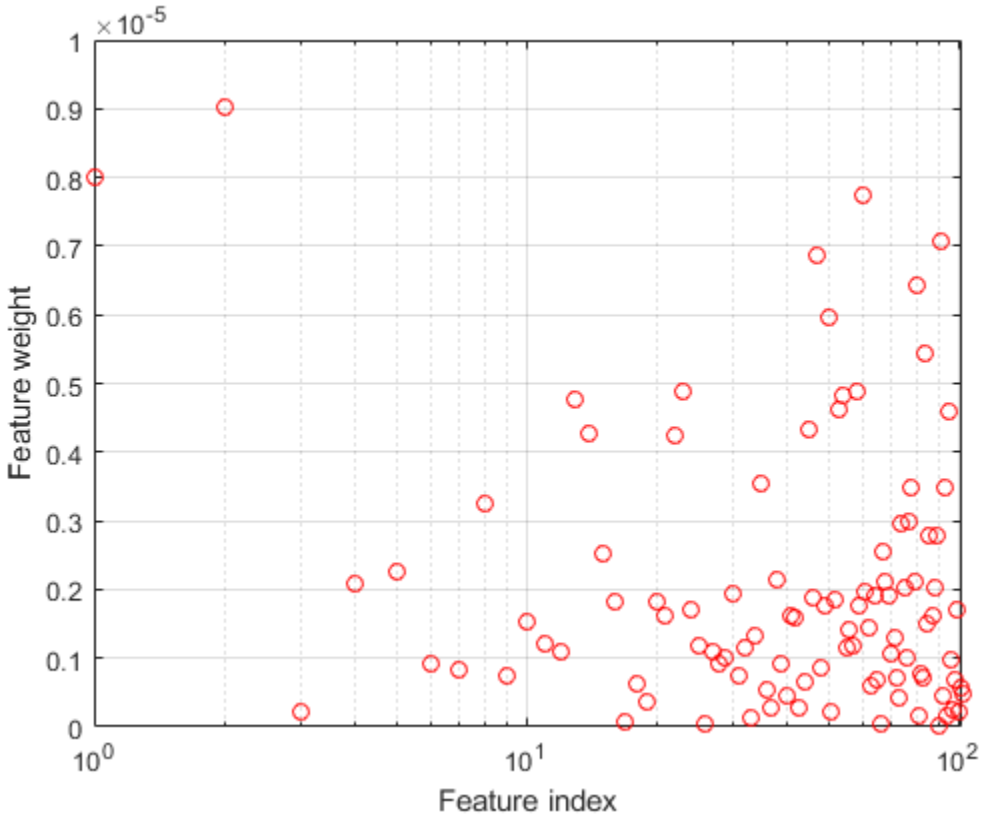
         Infinity norm of the final gradient = 9.404e-08
             Two norm of the final step     = 8.947e-04, TolX   = 1.000e-06
Relative infinity norm of the final gradient = 9.404e-08, TolFun = 1.000e-06
EXIT: Local minimum found.
```

Plot the feature weights. The weights of the irrelevant features should be very close to zero.

```
figure
semilogx(ncaMdl.FeatureWeights,'ro')
xlabel('Feature index')
ylabel('Feature weight')
grid on
```



All weights are very close to zero. This indicates that the value of λ used in training the model is too large. When $\lambda \to \infty$, all features weights approach to zero. Hence, it is important to tune the regularization parameter in most cases to detect the relevant features.

Use five-fold cross-validation to tune λ for feature selection using `fscnca`. Tuning λ means finding the λ value that will produce the minimum classification loss. Here are the steps for tuning λ using cross-validation:

1. First partition the data into five folds. For each fold, `cvpartition` assigns 4/5th of the data as a training set, and 1/5th of the data as a test set.

```
cvp           = cvpartition(y,'kfold',5);
numtestsets   = cvp.NumTestSets;
lambdavalues  = linspace(0,2,20)/length(y);
lossvalues    = zeros(length(lambdavalues),numtestsets);
```

2. Train the neighborhood component analysis (nca) model for each λ value using the training set in each fold.

3. Compute the classification loss for the corresponding test set in the fold using the nca model. Record the loss value.

4. Repeat this for all folds and all λ values.

```
for i = 1:length(lambdavalues)
    for k = 1:numtestsets
```

```
        % Extract the training set from the partition object
        Xtrain = X(cvp.training(k),:);
        ytrain = y(cvp.training(k),:);

        % Extract the test set from the partition object
        Xtest = X(cvp.test(k),:);
        ytest = y(cvp.test(k),:);

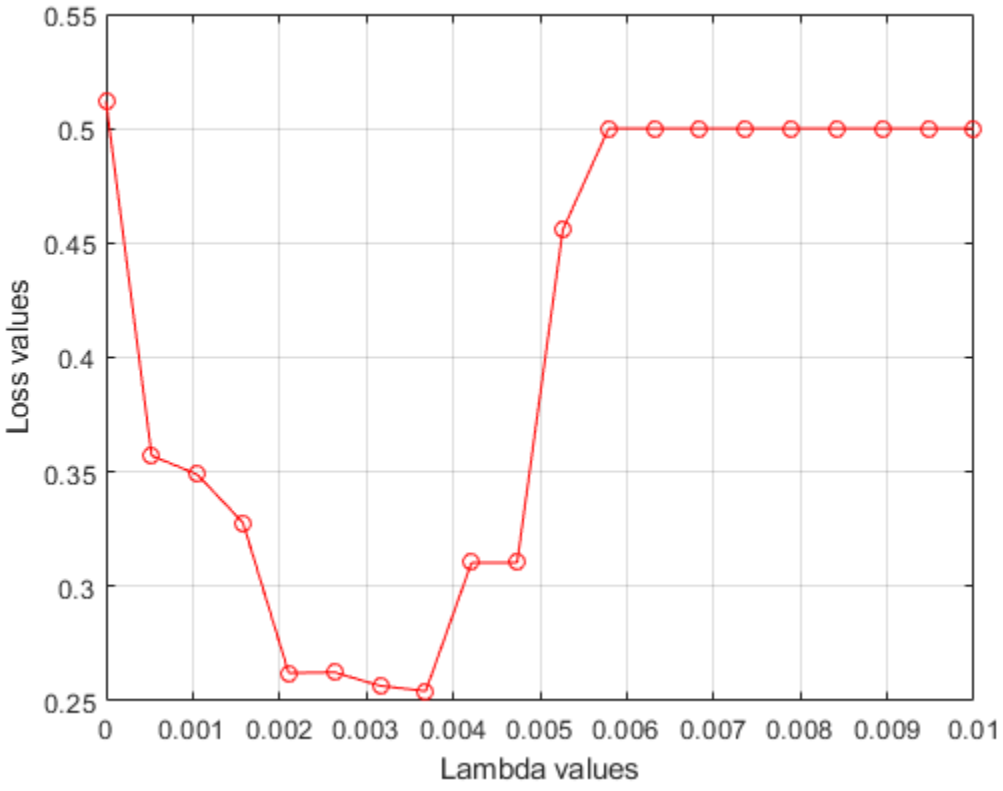
        % Train an nca model for classification using the training set
        ncaMdl = fscnca(Xtrain,ytrain,'FitMethod','exact', ...
            'Solver','lbfgs','Lambda',lambdavalues(i));

        % Compute the classification loss for the test set using the nca
        % model
        lossvalues(i,k) = loss(ncaMdl,Xtest,ytest, ...
            'LossFunction','quadratic');

    end
end
```

Plot the average loss values of the folds versus the λ values.

```
figure
plot(lambdavalues,mean(lossvalues,2),'ro-')
xlabel('Lambda values')
ylabel('Loss values')
grid on
```



Find the λ value that corresponds to the minimum average loss.

```
[~,idx] = min(mean(lossvalues,2)); % Find the index
bestlambda = lambdavalues(idx) % Find the best lambda value
```

```
bestlambda = 0.0037
```

Fit the nca model to all of the data using the best λ value. Use the LBFGS solver and display the convergence information.

```
ncaMdl = fscnca(X,y,'FitMethod','exact','Verbose',1, ...
     'Solver','lbfgs','Lambda',bestlambda);
```

```
 o Solver = LBFGS, HessianHistorySize = 15, LineSearchMethod = weakwolfe

Cluster Analysis

Choose Cluster Analysis Method

This topic provides a brief overview of the available clustering methods in Statistics and Machine Learning Toolbox.

Clustering Methods

Cluster analysis, also called segmentation analysis or taxonomy analysis, is a common unsupervised learning method. Unsupervised learning is used to draw inferences from data sets consisting of input data without labeled responses. For example, you can use cluster analysis for exploratory data analysis to find hidden patterns or groupings in unlabeled data.

Cluster analysis creates groups, or *clusters*, of data. Objects that belong to the same cluster are similar to one another and distinct from objects that belong to different clusters. To quantify "similar" and "distinct," you can use a dissimilarity measure (or distance metric on page 18-12) that is specific to the domain of your application and your data set. Also, depending on your application, you might consider scaling (or standardizing) the variables in your data to give them equal importance during clustering.

Statistics and Machine Learning Toolbox provides functionality for these clustering methods:

- “Hierarchical Clustering” on page 16-2
- “k-Means and k-Medoids Clustering” on page 16-2
- “Density-Based Spatial Clustering of Applications with Noise (DBSCAN)” on page 16-3
- “Gaussian Mixture Model” on page 16-3
- “k-Nearest Neighbor Search and Radius Search” on page 16-3
- “Spectral Clustering” on page 16-3

Hierarchical Clustering

Hierarchical clustering groups data over a variety of scales by creating a cluster tree, or dendrogram. The tree is not a single set of clusters, but rather a multilevel hierarchy, where clusters at one level combine to form clusters at the next level. This multilevel hierarchy allows you to choose the level, or scale, of clustering that is most appropriate for your application. Hierarchical clustering assigns every point in your data to a cluster.

Use `clusterdata` to perform hierarchical clustering on input data. `clusterdata` incorporates the `pdist`, `linkage`, and `cluster` functions, which you can use separately for more detailed analysis. The `dendrogram` function plots the cluster tree. For more information, see “Introduction to Hierarchical Clustering” on page 16-6.

k-Means and k-Medoids Clustering

k-means clustering and *k*-medoids clustering partition data into *k* mutually exclusive clusters. These clustering methods require that you specify the number of clusters *k*. Both *k*-means and *k*-medoids clustering assign every point in your data to a cluster; however, unlike hierarchical clustering, these methods operate on actual observations (rather than dissimilarity measures), and create a single level of clusters. Therefore, *k*-means or *k*-medoids clustering is often more suitable than hierarchical clustering for large amounts of data.

Use `kmeans` and `kmedoids` to implement *k*-means clustering and *k*-medoids clustering, respectively. For more information, see Introduction to *k*-Means Clustering on page 16-33 and *k*-Medoids Clustering on page 33-3345.

Density-Based Spatial Clustering of Applications with Noise (DBSCAN)

DBSCAN is a density-based algorithm that identifies arbitrarily shaped clusters and outliers (noise) in data. During clustering, DBSCAN identifies points that do not belong to any cluster, which makes this method useful for density-based outlier detection. Unlike *k*-means and *k*-medoids clustering, DBSCAN does not require prior knowledge of the number of clusters.

Use `dbscan` to perform clustering on an input data matrix or on pairwise distances between observations. For more information, see “Introduction to DBSCAN” on page 16-19.

Gaussian Mixture Model

A Gaussian mixture model (GMM) forms clusters as a mixture of multivariate normal density components. For a given observation, the GMM assigns posterior probabilities to each component density (or cluster). The posterior probabilities indicate that the observation has some probability of belonging to each cluster. A GMM can perform *hard* clustering by selecting the component that maximizes the posterior probability as the assigned cluster for the observation. You can also use a GMM to perform *soft*, or *fuzzy*, clustering by assigning the observation to multiple clusters based on the scores or posterior probabilities of the observation for the clusters. A GMM can be a more appropriate method than *k*-means clustering when clusters have different sizes and different correlation structures within them.

Use `fitgmdist` to fit a `gmdistribution` object to your data. You can also use `gmdistribution` to create a GMM object by specifying the distribution parameters. When you have a fitted GMM, you can cluster query data by using the `cluster` function. For more information, see “Cluster Using Gaussian Mixture Model” on page 16-39.

k-Nearest Neighbor Search and Radius Search

k-nearest neighbor search finds the *k* closest points in your data to a query point or set of query points. In contrast, radius search finds all points in your data that are within a specified distance from a query point or set of query points. The results of these methods depend on the distance metric on page 18-12 that you specify.

Use the `knnsearch` function to find *k*-nearest neighbors or the `rangesearch` function to find all neighbors within a specified distance of your input data. You can also create a searcher object using a training data set, and pass the object and query data sets to the object functions (`knnsearch` and `rangesearch`). For more information, see “Classification Using Nearest Neighbors” on page 18-12.

Spectral Clustering

Spectral clustering is a graph-based algorithm for finding *k* arbitrarily shaped clusters in data. The technique involves representing the data in a low dimension. In the low dimension, clusters in the data are more widely separated, enabling you to use algorithms such as *k*-means or *k*-medoids clustering. This low dimension is based on eigenvectors of a Laplacian matrix. A Laplacian matrix is one way of representing a similarity graph that models the local neighborhood relationships between data points as an undirected graph.

Use `spectralcluster` to perform spectral clustering on an input data matrix or on a similarity matrix of a similarity graph. `spectralcluster` requires that you specify the number of clusters.

However, the algorithm for spectral clustering also provides a way to estimate the number of clusters in your data. For more information, see “Partition Data Using Spectral Clustering” on page 16-26.

Comparison of Clustering Methods

This table compares the features of available clustering methods in Statistics and Machine Learning Toolbox.

Method	Basis of Algorithm	Input to Algorithm	Requires Specified Number of Clusters	Cluster Shapes Identified	Useful for Outlier Detection
“Hierarchical Clustering” on page 16-6	Distance between objects	Pairwise distances between observations	No	Arbitrarily shaped clusters, depending on the specified `'Linkage'` algorithm	No
“k-Means Clustering” on page 16-33 and k-Medoids Clustering on page 33-3345	Distance between objects and centroids	Actual observations	Yes	Spheroidal clusters with equal diagonal covariance	No
Density-Based Spatial Clustering of Applications with Noise (“DBSCAN” on page 16-19)	Density of regions in the data	Actual observations or pairwise distances between observations	No	Arbitrarily shaped clusters	Yes
“Gaussian Mixture Models”	Mixture of Gaussian distributions	Actual observations	Yes	Spheroidal clusters with different covariance structures	Yes
Nearest Neighbors	Distance between objects	Actual observations	No	Arbitrarily shaped clusters	Yes, depending on the specified number of neighbors
Spectral Clustering (“Partition Data Using Spectral Clustering” on page 16-26)	Graph representing connections between data points	Actual observations or similarity matrix	Yes, but the algorithm also provides a way to estimate the number of clusters	Arbitrarily shaped clusters	No

Hierarchical Clustering

In this section...

Introduction to Hierarchical Clustering

Hierarchical clustering groups data over a variety of scales by creating a cluster tree or dendrogram. The tree is not a single set of clusters, but rather a multilevel hierarchy, where clusters at one level are joined as clusters at the next level. This allows you to decide the level or scale of clustering that is most appropriate for your application. The function `clusterdata` supports agglomerative clustering and performs all of the necessary steps for you. It incorporates the `pdist`, `linkage`, and `cluster` functions, which you can use separately for more detailed analysis. The `dendrogram` function plots the cluster tree.

Algorithm Description

To perform agglomerative hierarchical cluster analysis on a data set using Statistics and Machine Learning Toolbox functions, follow this procedure:

1. **Find the similarity or dissimilarity between every pair of objects in the data set.** In this step, you calculate the *distance* between objects using the `pdist` function. The `pdist` function supports many different ways to compute this measurement. See “Similarity Measures” on page 16-7 for more information.
2. **Group the objects into a binary, hierarchical cluster tree.** In this step, you link pairs of objects that are in close proximity using the `linkage` function. The `linkage` function uses the distance information generated in step 1 to determine the proximity of objects to each other. As objects are paired into binary clusters, the newly formed clusters are grouped into larger clusters until a hierarchical tree is formed. See “Linkages” on page 16-8 for more information.
3. **Determine where to cut the hierarchical tree into clusters.** In this step, you use the `cluster` function to prune branches off the bottom of the hierarchical tree, and assign all the objects below each cut to a single cluster. This creates a partition of the data. The `cluster` function can create these clusters by detecting natural groupings in the hierarchical tree or by cutting off the hierarchical tree at an arbitrary point.

The following sections provide more information about each of these steps.

Note The function `clusterdata` performs all of the necessary steps for you. You do not need to execute the `pdist`, `linkage`, or `cluster` functions separately.

Similarity Measures

You use the `pdist` function to calculate the distance between every pair of objects in a data set. For a data set made up of *m* objects, there are *m**(*m* – 1)/2 pairs in the data set. The result of this computation is commonly known as a distance or dissimilarity matrix.

There are many ways to calculate this distance information. By default, the `pdist` function calculates the Euclidean distance between objects; however, you can specify one of several other options. See `pdist` for more information.

Note You can optionally normalize the values in the data set before calculating the distance information. In a real world data set, variables can be measured against different scales. For example, one variable can measure Intelligence Quotient (IQ) test scores and another variable can measure head circumference. These discrepancies can distort the proximity calculations. Using the `zscore` function, you can convert all the values in the data set to use the same proportional scale. See `zscore` for more information.

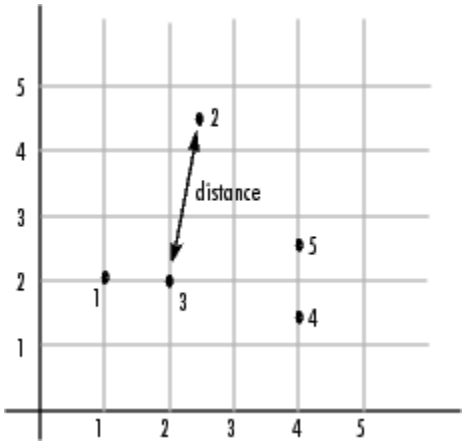
For example, consider a data set, `X`, made up of five objects where each object is a set of *x*,*y* coordinates.

- **Object 1**: 1, 2
- **Object 2**: 2.5, 4.5
- **Object 3**: 2, 2
- **Object 4**: 4, 1.5
- **Object 5**: 4, 2.5

You can define this data set as a matrix

```
rng default;  % For reproducibility
X = [1 2;2.5 4.5;2 2;4 1.5;...
    4 2.5];
```

and pass it to `pdist`. The `pdist` function calculates the distance between object 1 and object 2, object 1 and object 3, and so on until the distances between all the pairs have been calculated. The following figure plots these objects in a graph. The Euclidean distance between object 2 and object 3 is shown to illustrate one interpretation of distance.



Distance Information

The `pdist` function returns this distance information in a vector, `Y`, where each element contains the distance between a pair of objects.

```
Y = pdist(X)
```

```
Y = 1×10

    2.9155    1.0000    3.0414    3.0414    2.5495    3.3541    2.5000    2.0616    2.0616    1.0
```

To make it easier to see the relationship between the distance information generated by `pdist` and the objects in the original data set, you can reformat the distance vector into a matrix using the `squareform` function. In this matrix, element *i*,*j* corresponds to the distance between object *i* and object *j* in the original data set. In the following example, element 1,1 represents the distance between object 1 and itself (which is zero). Element 1,2 represents the distance between object 1 and object 2, and so on.

```
squareform(Y)
```

```
ans = 5×5

         0    2.9155    1.0000    3.0414    3.0414
    2.9155         0    2.5495    3.3541    2.5000
    1.0000    2.5495         0    2.0616    2.0616
    3.0414    3.3541    2.0616         0    1.0000
    3.0414    2.5000    2.0616    1.0000         0
```

Linkages

Once the proximity between objects in the data set has been computed, you can determine how objects in the data set should be grouped into clusters, using the `linkage` function. The `linkage` function takes the distance information generated by `pdist` and links pairs of objects that are close together into binary clusters (clusters made up of two objects). The `linkage` function then links these newly formed clusters to each other and to other objects to create bigger clusters until all the objects in the original data set are linked together in a hierarchical tree.

For example, given the distance vector `Y` generated by `pdist` from the sample data set of *x*- and *y*-coordinates, the `linkage` function generates a hierarchical cluster tree, returning the linkage information in a matrix, `Z`.

```
Z = linkage(Y)
```

```
Z = 4×3

    4.0000    5.0000    1.0000
    1.0000    3.0000    1.0000
    6.0000    7.0000    2.0616
    2.0000    8.0000    2.5000
```

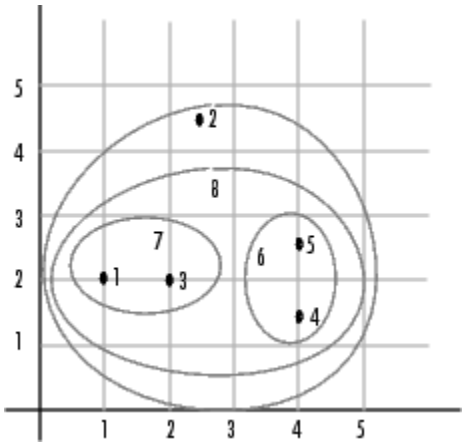
In this output, each row identifies a link between objects or clusters. The first two columns identify the objects that have been linked. The third column contains the distance between these objects. For the sample data set of *x*- and *y*-coordinates, the `linkage` function begins by grouping objects 4

and 5, which have the closest proximity (distance value = 1.0000). The `linkage` function continues by grouping objects 1 and 3, which also have a distance value of 1.0000.

The third row indicates that the `linkage` function grouped objects 6 and 7. If the original sample data set contained only five objects, what are objects 6 and 7? Object 6 is the newly formed binary cluster created by the grouping of objects 4 and 5. When the `linkage` function groups two objects into a new cluster, it must assign the cluster a unique index value, starting with the value *m* + 1, where *m* is the number of objects in the original data set. (Values 1 through *m* are already used by the original data set.) Similarly, object 7 is the cluster formed by grouping objects 1 and 3.

`linkage` uses distances to determine the order in which it clusters objects. The distance vector `Y` contains the distances between the original objects 1 through 5. But linkage must also be able to determine distances involving clusters that it creates, such as objects 6 and 7. By default, `linkage` uses a method known as single linkage. However, there are a number of different methods available. See the `linkage` reference page for more information.

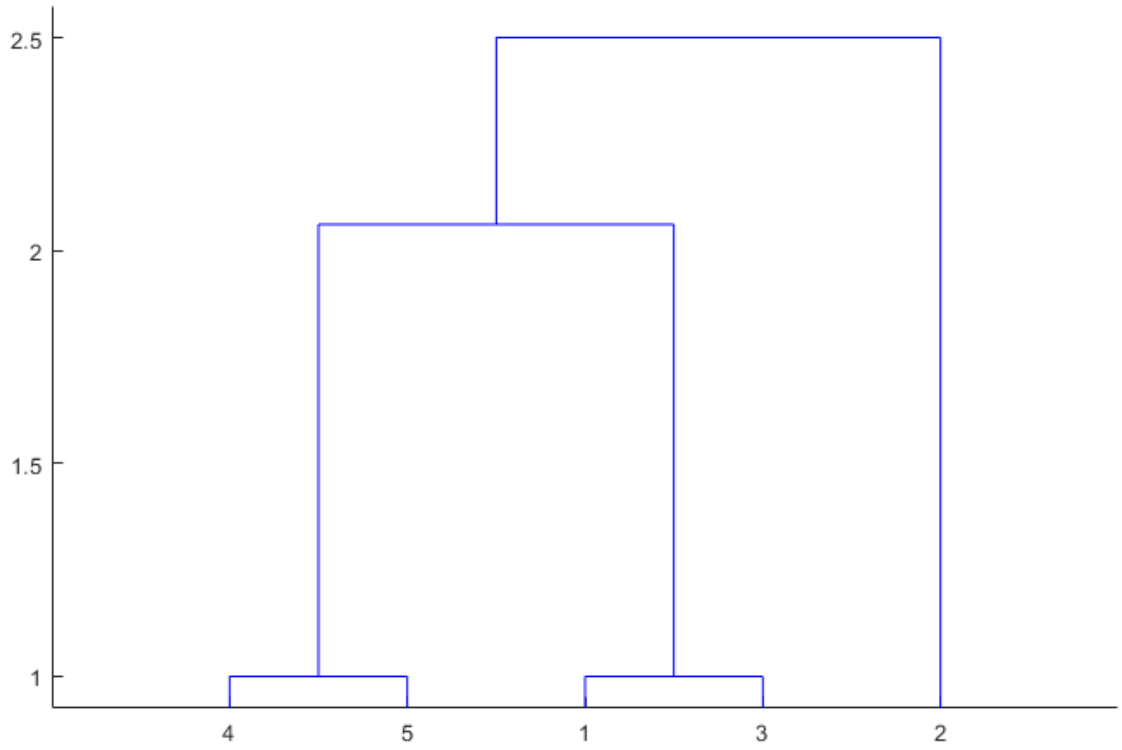
As the final cluster, the `linkage` function grouped object 8, the newly formed cluster made up of objects 6 and 7, with object 2 from the original data set. The following figure graphically illustrates the way `linkage` groups the objects into a hierarchy of clusters.



Dendrograms

The hierarchical, binary cluster tree created by the `linkage` function is most easily understood when viewed graphically. The function `dendrogram` plots the tree as follows.

```
dendrogram(Z)
```



In the figure, the numbers along the horizontal axis represent the indices of the objects in the original data set. The links between objects are represented as upside-down U-shaped lines. The height of the U indicates the distance between the objects. For example, the link representing the cluster containing objects 1 and 3 has a height of 1. The link representing the cluster that groups object 2 together with objects 1, 3, 4, and 5, (which are already clustered as object 8) has a height of 2.5. The height represents the distance `linkage` computes between objects 2 and 8. For more information about creating a dendrogram diagram, see the `dendrogram` reference page.

Verify the Cluster Tree

After linking the objects in a data set into a hierarchical cluster tree, you might want to verify that the distances (that is, heights) in the tree reflect the original distances accurately. In addition, you might want to investigate natural divisions that exist among links between objects. Statistics and Machine Learning Toolbox functions are available for both of these tasks, as described in the following sections.

- “Verify Dissimilarity” on page 16-10
- “Verify Consistency” on page 16-11

Verify Dissimilarity

In a hierarchical cluster tree, any two objects in the original data set are eventually linked together at some level. The height of the link represents the distance between the two clusters that contain those two objects. This height is known as the *cophenetic distance* between the two objects. One way to

measure how well the cluster tree generated by the `linkage` function reflects your data is to compare the cophenetic distances with the original distance data generated by the `pdist` function. If the clustering is valid, the linking of objects in the cluster tree should have a strong correlation with the distances between objects in the distance vector. The `cophenet` function compares these two sets of values and computes their correlation, returning a value called the *cophenetic correlation coefficient*. The closer the value of the cophenetic correlation coefficient is to 1, the more accurately the clustering solution reflects your data.

You can use the cophenetic correlation coefficient to compare the results of clustering the same data set using different distance calculation methods or clustering algorithms. For example, you can use the `cophenet` function to evaluate the clusters created for the sample data set.

```
c = cophenet(Z,Y)
```

```
c = 0.8615
```

`Z` is the matrix output by the `linkage` function and `Y` is the distance vector output by the `pdist` function.

Execute `pdist` again on the same data set, this time specifying the city block metric. After running the `linkage` function on this new `pdist` output using the average linkage method, call `cophenet` to evaluate the clustering solution.

```
Y = pdist(X,'cityblock');
Z = linkage(Y,'average');
c = cophenet(Z,Y)
```

```
c = 0.9047
```

The cophenetic correlation coefficient shows that using a different distance and linkage method creates a tree that represents the original distances slightly better.

Verify Consistency

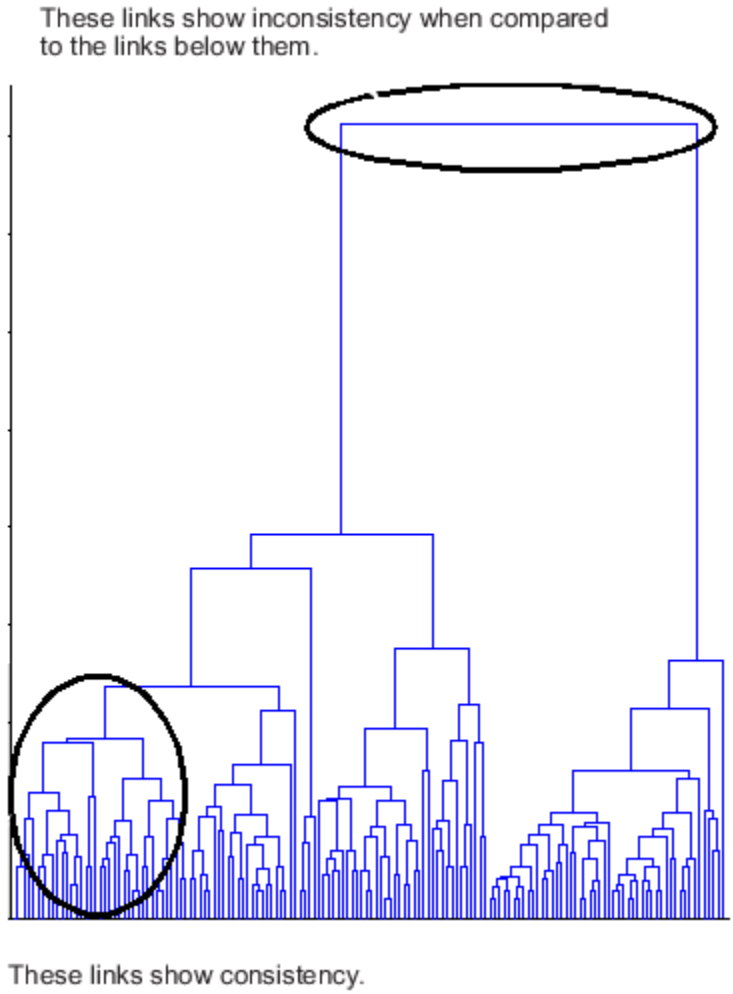
One way to determine the natural cluster divisions in a data set is to compare the height of each link in a cluster tree with the heights of neighboring links below it in the tree.

A link that is approximately the same height as the links below it indicates that there are no distinct divisions between the objects joined at this level of the hierarchy. These links are said to exhibit a high level of consistency, because the distance between the objects being joined is approximately the same as the distances between the objects they contain.

On the other hand, a link whose height differs noticeably from the height of the links below it indicates that the objects joined at this level in the cluster tree are much farther apart from each other than their components were when they were joined. This link is said to be inconsistent with the links below it.

In cluster analysis, inconsistent links can indicate the border of a natural division in a data set. The `cluster` function uses a quantitative measure of inconsistency to determine where to partition your data set into clusters.

The following dendrogram illustrates inconsistent links. Note how the objects in the dendrogram fall into two groups that are connected by links at a much higher level in the tree. These links are inconsistent when compared with the links below them in the hierarchy.



The relative consistency of each link in a hierarchical cluster tree can be quantified and expressed as the *inconsistency coefficient*. This value compares the height of a link in a cluster hierarchy with the average height of links below it. Links that join distinct clusters have a high inconsistency coefficient; links that join indistinct clusters have a low inconsistency coefficient.

To generate a listing of the inconsistency coefficient for each link in the cluster tree, use the `inconsistent` function. By default, the `inconsistent` function compares each link in the cluster hierarchy with adjacent links that are less than two levels below it in the cluster hierarchy. This is called the *depth* of the comparison. You can also specify other depths. The objects at the bottom of the cluster tree, called leaf nodes, that have no further objects below them, have an inconsistency coefficient of zero. Clusters that join two leaves also have a zero inconsistency coefficient.

For example, you can use the `inconsistent` function to calculate the inconsistency values for the links created by the `linkage` function in “Linkages” on page 16-8.

First, recompute the distance and linkage values using the default settings.

```
Y = pdist(X);
Z = linkage(Y);
```

Next, use `inconsistent` to calculate the inconsistency values.

```
I = inconsistent(Z)
```

```
I = 4×4

    1.0000         0    1.0000         0
    1.0000         0    1.0000         0
    1.3539    0.6129    3.0000    1.1547
    2.2808    0.3100    2.0000    0.7071
```

The `inconsistent` function returns data about the links in an (*m*-1)-by-4 matrix, whose columns are described in the following table.

Column	Description
1	Mean of the heights of all the links included in the calculation
2	Standard deviation of all the links included in the calculation
3	Number of links included in the calculation
4	Inconsistency coefficient

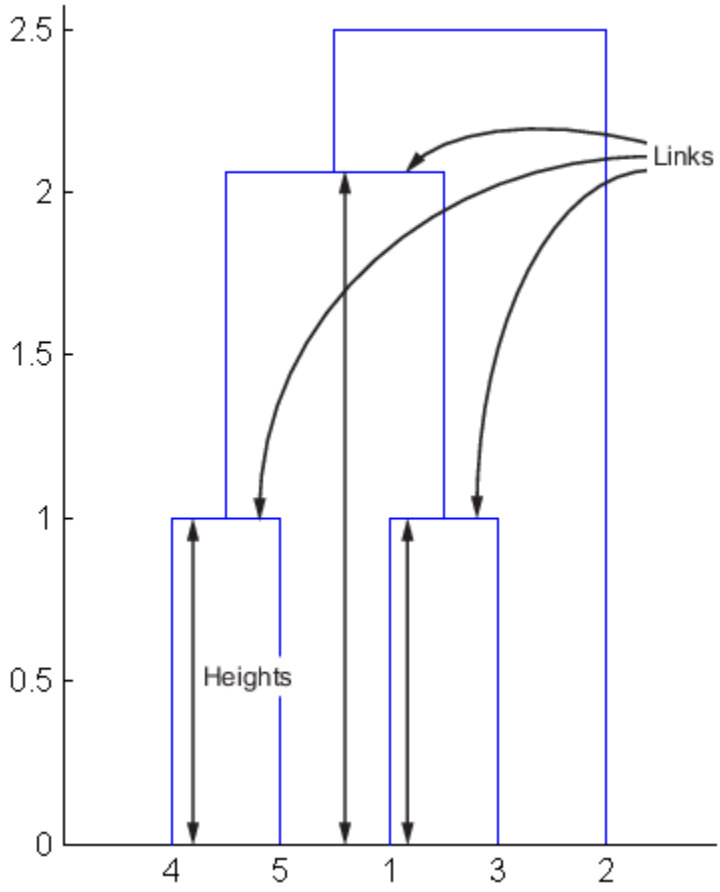
In the sample output, the first row represents the link between objects 4 and 5. This cluster is assigned the index 6 by the `linkage` function. Because both 4 and 5 are leaf nodes, the inconsistency coefficient for the cluster is zero. The second row represents the link between objects 1 and 3, both of which are also leaf nodes. This cluster is assigned the index 7 by the linkage function.

The third row evaluates the link that connects these two clusters, objects 6 and 7. (This new cluster is assigned index 8 in the `linkage` output). Column 3 indicates that three links are considered in the calculation: the link itself and the two links directly below it in the hierarchy. Column 1 represents the mean of the heights of these links. The `inconsistent` function uses the height information output by the `linkage` function to calculate the mean. Column 2 represents the standard deviation between the links. The last column contains the inconsistency value for these links, 1.1547. It is the difference between the current link height and the mean, normalized by the standard deviation.

```
(2.0616 - 1.3539) / .6129
```

```
ans = 1.1547
```

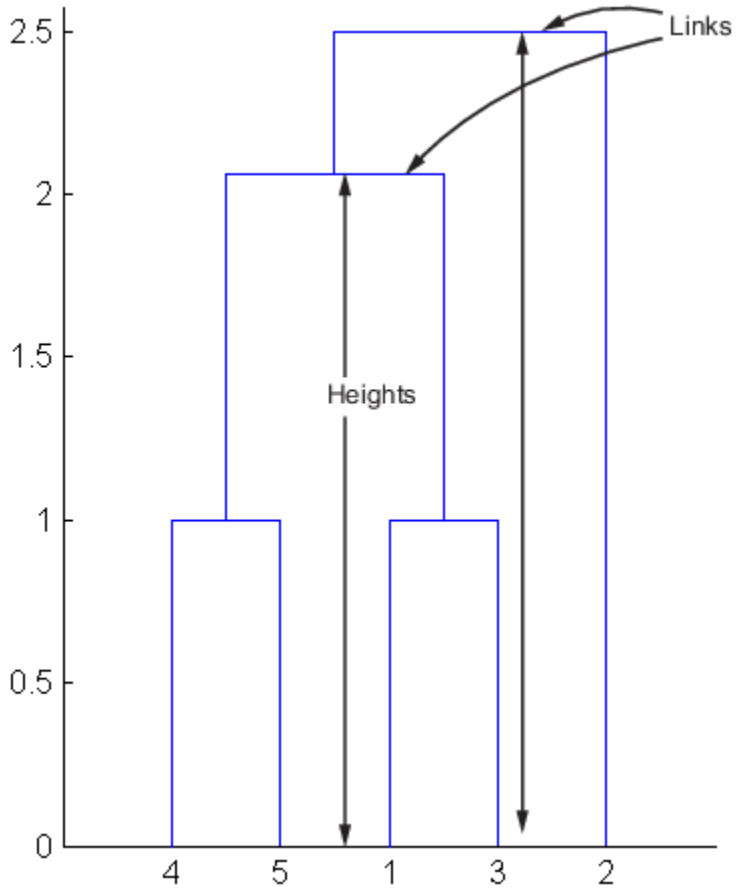
The following figure illustrates the links and heights included in this calculation.



Note In the preceding figure, the lower limit on the *y*-axis is set to `0` to show the heights of the links. To set the lower limit to `0`, select `Axes Properties` from the **Edit** menu, click the **Y Axis** tab, and enter `0` in the field immediately to the right of **Y Limits**.

Row 4 in the output matrix describes the link between object 8 and object 2. Column 3 indicates that two links are included in this calculation: the link itself and the link directly below it in the hierarchy. The inconsistency coefficient for this link is 0.7071.

The following figure illustrates the links and heights included in this calculation.



Create Clusters

After you create the hierarchical tree of binary clusters, you can prune the tree to partition your data into clusters using the `cluster` function. The `cluster` function lets you create clusters in two ways, as discussed in the following sections:

- “Find Natural Divisions in Data” on page 16-15
- “Specify Arbitrary Clusters” on page 16-16

Find Natural Divisions in Data

The hierarchical cluster tree may naturally divide the data into distinct, well-separated clusters. This can be particularly evident in a dendrogram diagram created from data where groups of objects are densely packed in certain areas and not in others. The inconsistency coefficient of the links in the cluster tree can identify these divisions where the similarities between objects change abruptly. (See “Verify the Cluster Tree” on page 16-10 for more information about the inconsistency coefficient.) You can use this value to determine where the `cluster` function creates cluster boundaries.

For example, if you use the `cluster` function to group the sample data set into clusters, specifying an inconsistency coefficient threshold of `1.2` as the value of the `cutoff` argument, the `cluster` function groups all the objects in the sample data set into one cluster. In this case, none of the links in the cluster hierarchy had an inconsistency coefficient greater than `1.2`.

```
T = cluster(Z,'cutoff',1.2)
```

```
T = 5×1

     1
     1
     1
     1
     1
```

The `cluster` function outputs a vector, `T`, that is the same size as the original data set. Each element in this vector contains the number of the cluster into which the corresponding object from the original data set was placed.

If you lower the inconsistency coefficient threshold to `0.8`, the `cluster` function divides the sample data set into three separate clusters.

```
T = cluster(Z,'cutoff',0.8)
```

```
T = 5×1

     3
     2
     3
     1
     1
```

This output indicates that objects 1 and 3 are in one cluster, objects 4 and 5 are in another cluster, and object 2 is in its own cluster.

When clusters are formed in this way, the cutoff value is applied to the inconsistency coefficient. These clusters may, but do not necessarily, correspond to a horizontal slice across the dendrogram at a certain height. If you want clusters corresponding to a horizontal slice of the dendrogram, you can either use the `criterion` option to specify that the cutoff should be based on distance rather than inconsistency, or you can specify the number of clusters directly as described in the following section.

Specify Arbitrary Clusters

Instead of letting the `cluster` function create clusters determined by the natural divisions in the data set, you can specify the number of clusters you want created.

For example, you can specify that you want the `cluster` function to partition the sample data set into two clusters. In this case, the `cluster` function creates one cluster containing objects 1, 3, 4, and 5 and another cluster containing object 2.

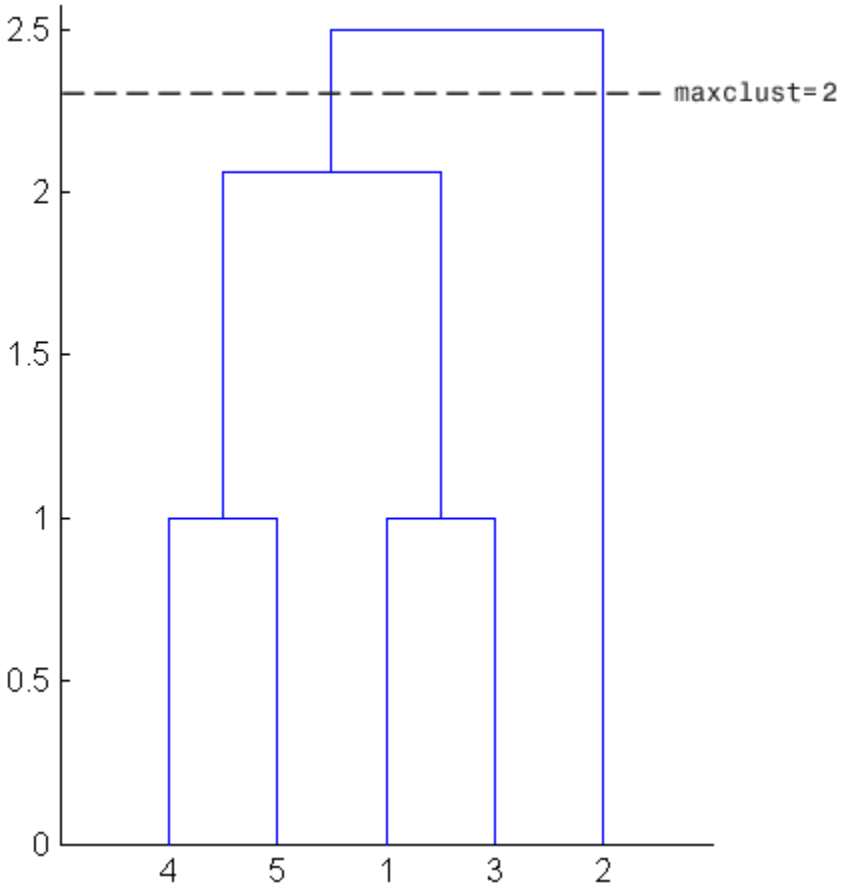
```
T = cluster(Z,'maxclust',2)
```

```
T = 5×1

     2
     1
     2
     2
     2
```

To help you visualize how the `cluster` function determines these clusters, the following figure shows the dendrogram of the hierarchical cluster tree. The horizontal dashed line intersects two lines of the

dendrogram, corresponding to setting `'maxclust'` to 2. These two lines partition the objects into two clusters: the objects below the left-hand line, namely 1, 3, 4, and 5, belong to one cluster, while the object below the right-hand line, namely 2, belongs to the other cluster.



On the other hand, if you set `'maxclust'` to 3, the cluster function groups objects 4 and 5 in one cluster, objects 1 and 3 in a second cluster, and object 2 in a third cluster. The following command illustrates this.

```
T = cluster(Z,'maxclust',3)
```

```
T = 5×1

     2
     3
     2
     1
     1
```

This time, the `cluster` function cuts off the hierarchy at a lower point, corresponding to the horizontal line that intersects three lines of the dendrogram in the following figure.

DBSCAN

In this section...

Introduction to DBSCAN

Density-Based Spatial Clustering of Applications with Noise (DBSCAN) identifies arbitrarily shaped clusters and noise (outliers) in data. The Statistics and Machine Learning Toolbox function `dbscan` performs clustering on an input data matrix or on pairwise distances between observations. `dbscan` returns the cluster indices and a vector indicating the observations that are core points (points inside clusters). Unlike *k*-means clustering, the DBSCAN algorithm does not require prior knowledge of the number of clusters, and clusters are not necessarily spheroidal. DBSCAN is also useful for density-based outlier detection, because it identifies points that do not belong to any cluster.

For a point to be assigned to a cluster, it must satisfy the condition that its epsilon neighborhood (`epsilon`) contains at least a minimum number of neighbors (`minpts`). Or, the point can lie within the epsilon neighborhood of another point that satisfies the `epsilon` and `minpts` conditions. The DBSCAN algorithm identifies three kinds of points:

- Core point — A point in a cluster that has at least `minpts` neighbors in its epsilon neighborhood
- Border point — A point in a cluster that has fewer than `minpts` neighbors in its epsilon neighborhood
- Noise point — An outlier that does not belong to any cluster

DBSCAN works with a wide range of distance metrics on page 33-0 , and you can define a custom distance metric for your particular application. The choice of a distance metric determines the shape of the neighborhood.

Algorithm Description

For specified values of the epsilon neighborhood `epsilon` and the minimum number of neighbors `minpts` required for a core point, the `dbscan` function implements DBSCAN as follows:

1. From the input data set `X`, select the first unlabeled observation x_1 as the current point, and initialize the first cluster label C to 1.
2. Find the set of points within the epsilon neighborhood `epsilon` of the current point. These points are the neighbors.
   a. If the number of neighbors is less than `minpts`, then label the current point as a noise point (or an outlier). Go to step 4.

      Note `dbscan` can reassign noise points to clusters if the noise points later satisfy the constraints set by `epsilon` and `minpts` from some other point in `X`. This process of reassigning points happens for border points of a cluster.

   b. Otherwise, label the current point as a core point belonging to cluster C.

3. Iterate over each neighbor (new current point) and repeat step 2 until no new neighbors are found that can be labeled as belonging to the current cluster *C*.
4. Select the next unlabeled point in X as the current point, and increase the cluster count by 1.
5. Repeat steps 2–4 until all points in X are labeled.

Determine Values for DBSCAN Parameters

This example shows how to select values for the `epsilon` and `minpts` parameters of `dbscan`. The data set is a Lidar scan, stored as a collection of 3-D points, that contains the coordinates of objects surrounding a vehicle.

Load, preprocess, and visualize the data set.

Load the *x*, *y*, *z* coordinates of the objects.

```
load('lidar_subset.mat')
X = lidar_subset;
```

To highlight the environment around the vehicle, set the region of interest to span 20 meters to the left and right of the vehicle, 20 meters in front and back of the vehicle, and the area above the surface of the road.

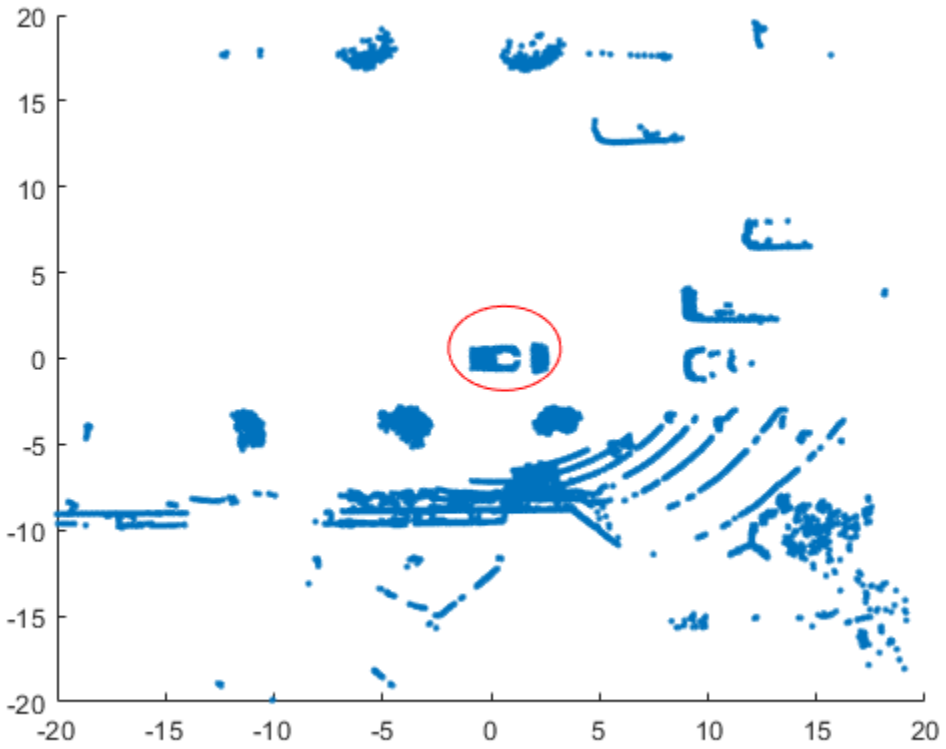
```
xBound  = 20; % in meters
yBound  = 20; % in meters
zLowerBound = 0; % in meters
```

Crop the data to contain only points within the specified region.

```
indices = X(:,1) <= xBound & X(:,1) >= -xBound ...
    & X(:,2) <= yBound & X(:,2) >= -yBound ...
    & X(:,3) > zLowerBound;
X = X(indices,:);
```

Visualize the data as a 2-D scatter plot. Annotate the plot to highlight the vehicle.

```
scatter(X(:,1),X(:,2),'.');
annotation('ellipse',[0.48 0.48 .1 .1],'Color','red')
```



The center of the set of points (circled in red) contains the roof and hood of the vehicle. All other points are obstacles.

Select a value for `minpts`.

To select a value for `minpts`, consider a value greater than or equal to one plus the number of dimensions of the input data [1]. For example, for an `n`-by-`p` matrix `X`, set the value of `'minpts'` greater than or equal to `p+1`.

For the given data set, specify a `minpts` value greater than or equal to 4, specifically the value 50.

```
minpts = 50; % Minimum number of neighbors for a core point
```

Select a value for `epsilon`.

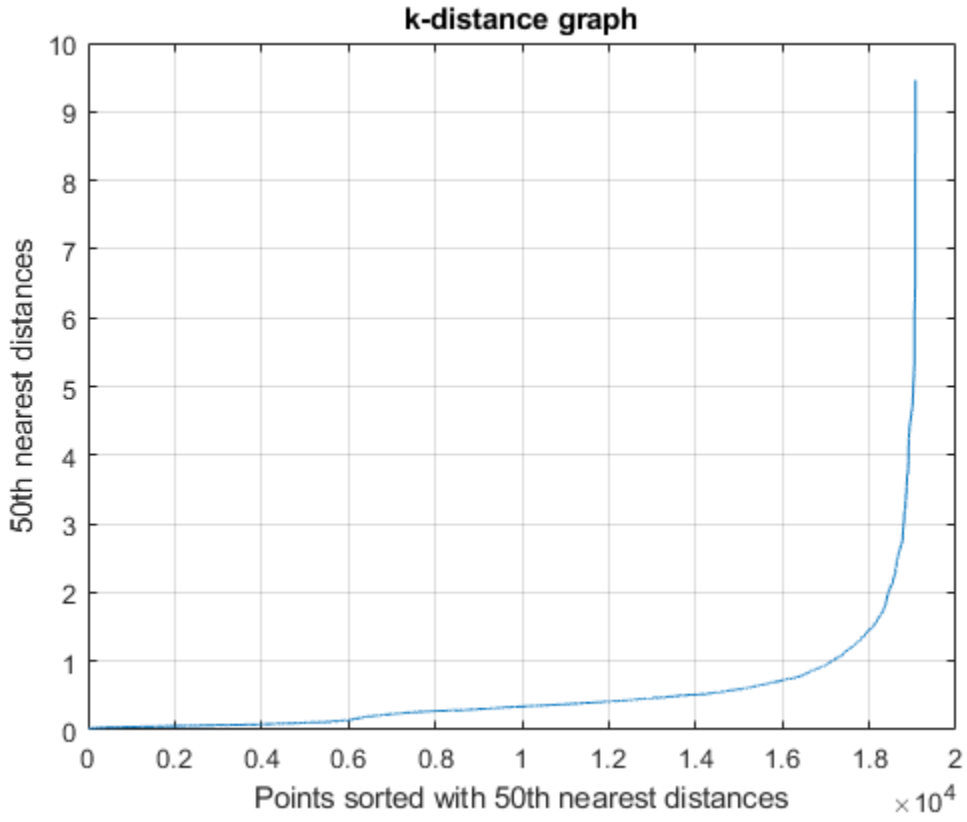
One strategy for estimating a value for `epsilon` is to generate a *k*-distance graph for the input data `X`. For each point in `X`, find the distance to the *k*th nearest point, and plot sorted points against this distance. The graph contains a knee. The distance that corresponds to the knee is generally a good choice for `epsilon`, because it is the region where points start tailing off into outlier (noise) territory [1].

Before plotting the *k*-distance graph, first find the `minpts` smallest pairwise distances for observations in `X`, in ascending order.

```
kD = pdist2(X,X,'euc','Smallest',minpts); % The minpts smallest pairwise distances
```

Plot the *k*-distance graph.

```
plot(sort(kD(end,:)));
title('k-distance graph')
xlabel('Points sorted with 50th nearest distances')
ylabel('50th nearest distances')
grid
```



The knee appears to be around 2; therefore, set the value of `epsilon` to 2.

```
epsilon = 2;
```

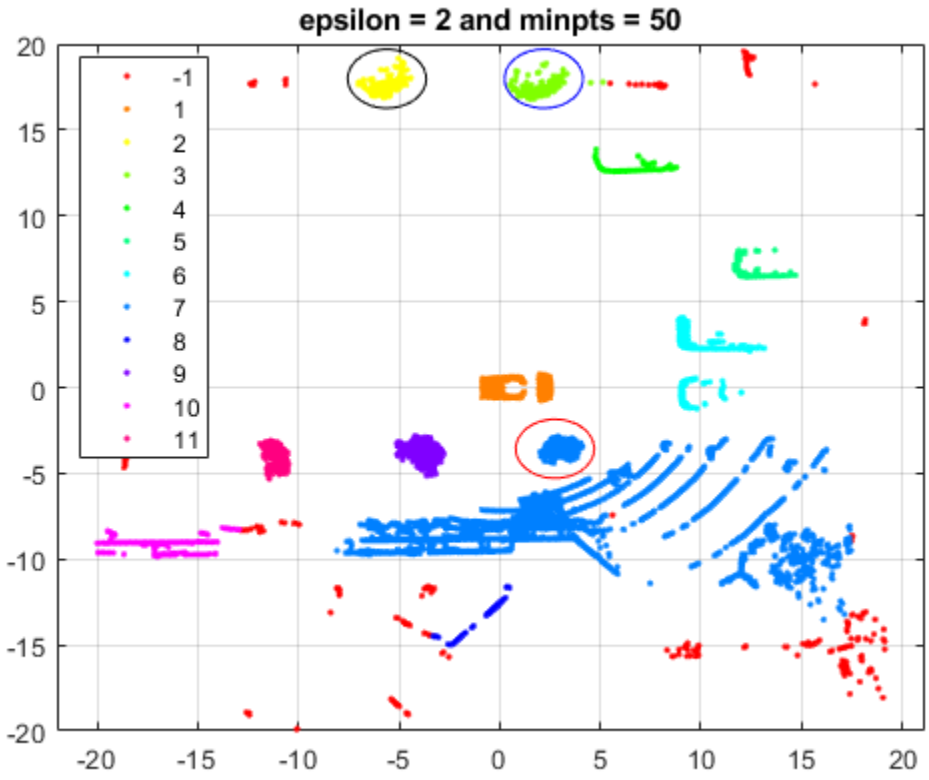
Cluster using dbscan.

Use `dbscan` with the values of `minpts` and `epsilon` that were determined in the previous steps.

```
labels = dbscan(X,epsilon,minpts);
```

Visualize the clustering and annotate the figure to highlight specific clusters.

```
gscatter(X(:,1),X(:,2),labels);
title('epsilon = 2 and minpts = 50')
grid
annotation('ellipse',[0.54 0.41 .07 .07],'Color','red')
annotation('ellipse',[0.53 0.85 .07 .07],'Color','blue')
annotation('ellipse',[0.39 0.85 .07 .07],'Color','black')
```



`dbscan` identifies 11 clusters and a set of noise points. The algorithm also identifies the vehicle at the center of the set of points as a distinct cluster.

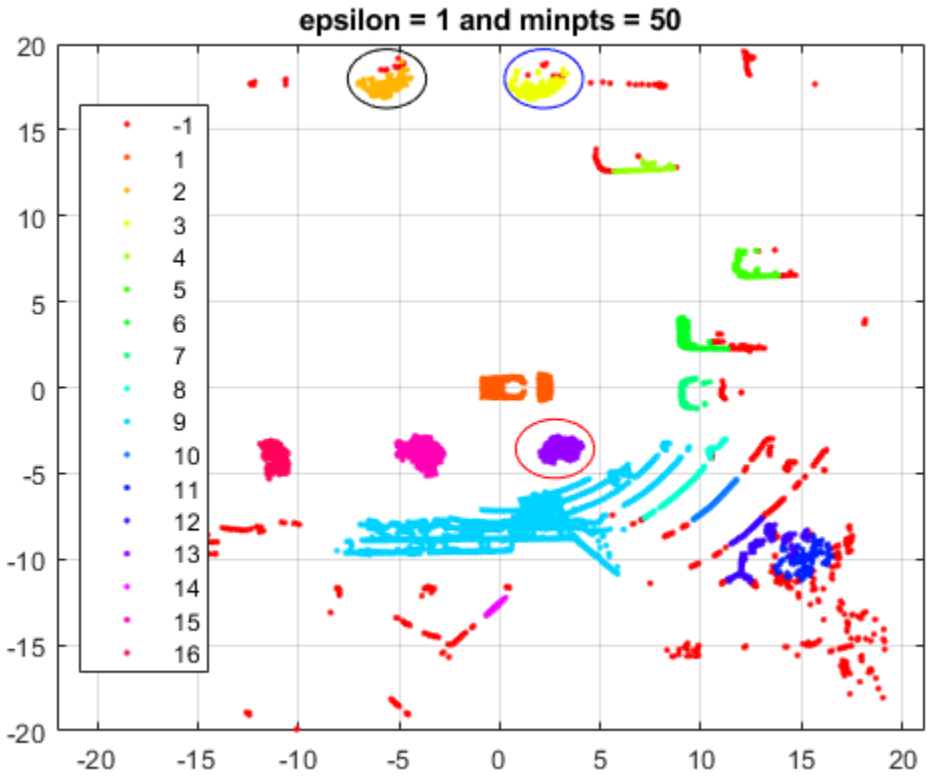
`dbscan` identifies some distinct clusters, such as the cluster circled in black (and centered around (–6,18)) and the cluster circled in blue (and centered around (2.5,18)). The function also assigns the group of points circled in red (and centered around (`3,–4`)) to the same cluster (group 7) as the group of points in the southeast quadrant of the plot. The expectation is that these groups should be in separate clusters.

Use a smaller value for `epsilon` to split up large clusters and further partition the points.

```
epsilon2 = 1;
labels2 = dbscan(X,epsilon2,minpts);
```

Visualize the clustering and annotate the figure to highlight specific clusters.

```
gscatter(X(:,1),X(:,2),labels2);
title('epsilon = 1 and minpts = 50')
grid
annotation('ellipse',[0.54 0.41 .07 .07],'Color','red')
annotation('ellipse',[0.53 0.85 .07 .07],'Color','blue')
annotation('ellipse',[0.39 0.85 .07 .07],'Color','black')
```



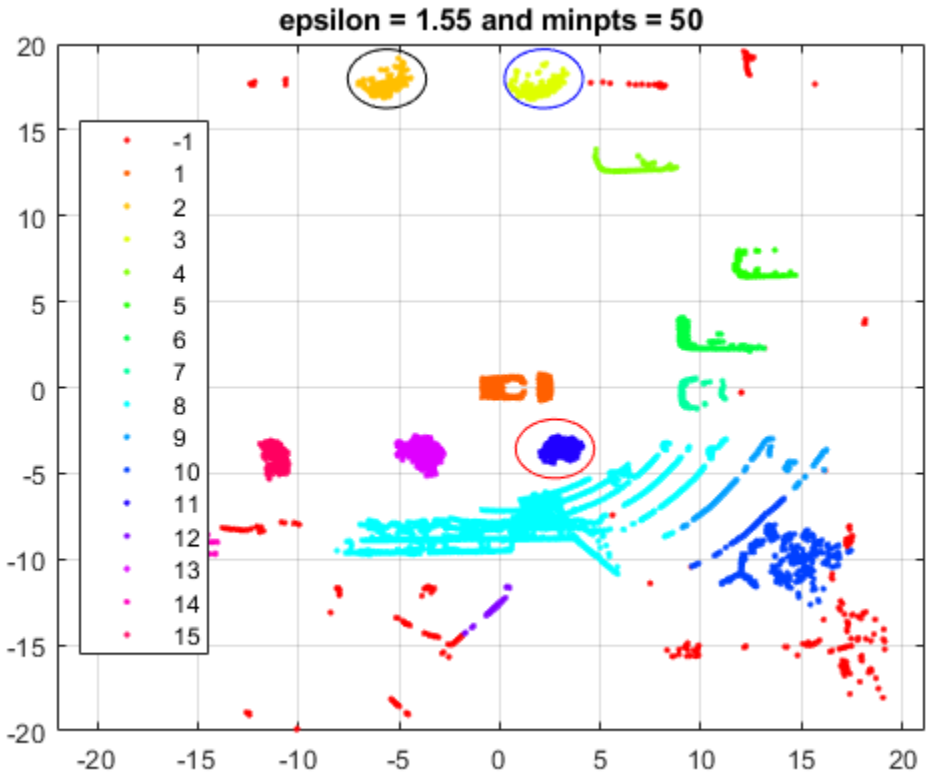
By using a smaller epsilon value, `dbscan` is able to assign the group of points circled in red to a distinct cluster (group 13). However, some clusters that `dbscan` correctly identified before are now split between cluster points and outliers. For example, see cluster group 2 (circled in black) and cluster group 3 (circled in blue). The correct `epsilon` value is somewhere between 1 and 2.

Use an `epsilon` value of `1.55` to cluster the data.

```
epsilon3 = 1.55;
labels3 = dbscan(X,epsilon3,minpts);
```

Visualize the clustering and annotate the figure to highlight specific clusters.

```
gscatter(X(:,1),X(:,2),labels3);
title('epsilon = 1.55 and minpts = 50')
grid
annotation('ellipse',[0.54 0.41 .07 .07],'Color','red')
annotation('ellipse',[0.53 0.85 .07 .07],'Color','blue')
annotation('ellipse',[0.39 0.85 .07 .07],'Color','black')
```



`dbscan` does a better job of identifying the clusters when `epsilon` is set to `1.55`. For example, the function identifies the distinct clusters circled in red, black, and blue (with centers around `(3,–4)`, (–6,18), and (2.5,18), respectively).

Partition Data Using Spectral Clustering

This topic provides an introduction to spectral clustering and an example that estimates the number of clusters and performs spectral clustering.

Introduction to Spectral Clustering

Spectral clustering is a graph-based algorithm for partitioning data points, or observations, into k clusters. The Statistics and Machine Learning Toolbox function `spectralcluster` performs clustering on an input data matrix or on a similarity matrix on page 33-5958 of a similarity graph derived from the data. `spectralcluster` returns the cluster indices, a matrix containing k eigenvectors of the Laplacian matrix on page 33-5959, and a vector of eigenvalues corresponding to the eigenvectors.

`spectralcluster` requires you to specify the number of clusters k. However, you can verify that your estimate for k is correct by using one of these methods:

- Count the number of zero eigenvalues of the Laplacian matrix. The multiplicity of the zero eigenvalues is an indicator of the number of clusters in your data.
- Find the number of connected components in your similarity matrix by using the MATLAB function `conncomp`.

Algorithm Description

Spectral clustering is a graph-based algorithm for finding k arbitrarily shaped clusters in data. The technique involves representing the data in a low dimension. In the low dimension, clusters in the data are more widely separated, enabling you to use algorithms such as k-means or k-medoids clustering. This low dimension is based on the eigenvectors corresponding to the k smallest eigenvalues of a Laplacian matrix. A Laplacian matrix is one way of representing a similarity graph that models the local neighborhood relationships between data points as an undirected graph. The spectral clustering algorithm derives a similarity matrix of a similarity graph from your data, finds the Laplacian matrix, and uses the Laplacian matrix to find k eigenvectors for splitting the similarity graph into k partitions. You can use spectral clustering when you know the number of clusters, but the algorithm also provides a way to estimate the number of clusters in your data.

By default, the algorithm for `spectralcluster` computes the normalized random-walk Laplacian matrix using the method described by Shi-Malik [1]. `spectralcluster` also supports the unnormalized Laplacian matrix and the normalized symmetric Laplacian matrix which uses the Ng-Jordan-Weiss method [2]. The `spectralcluster` function implements clustering as follows:

1. For each data point in `X`, define a local neighborhood using either the radius search method or nearest neighbor method, as specified by the `'SimilarityGraph'` name-value pair argument (see “Similarity Graph” on page 33-5958). Then, find the pairwise distances $Dist_{i,j}$ for all points i and j in the neighborhood.
2. Convert the distances to similarity measures using the kernel transformation $S_{i,j} = \exp\left(-\left(\frac{Dist_{i,j}}{\sigma}\right)^2\right)$. The matrix S is the similarity matrix on page 33-5958, and σ is the scale factor for the kernel, as specified using the `'KernelScale'` name-value pair argument.
3. Calculate the unnormalized Laplacian matrix on page 33-5959 L , the normalized random-walk Laplacian matrix L_{rw}, or the normalized symmetric Laplacian matrix L_s, depending on the value of the `'LaplacianNormalization'` name-value pair argument.

4. Create a matrix $V \in \mathbb{R}^{n \times k}$ containing columns $v_1, ..., v_k$, where the columns are the k eigenvectors that correspond to the k smallest eigenvalues of the Laplacian matrix. If using L_s, normalize each row of V to have unit length.
5. Treating each row of V as a point, cluster the n points using k-means clustering (default) or k-medoids clustering, as specified by the `'ClusterMethod'` name-value pair argument.
6. Assign the original points in `X` to the same clusters as their corresponding rows in V.

Estimate Number of Clusters and Perform Spectral Clustering

This example demonstrates two approaches for performing spectral clustering.

- The first approach estimates the number of clusters using the eigenvalues of the Laplacian matrix and performs spectral clustering on the data set.
- The second approach estimates the number of clusters using the similarity graph and performs spectral clustering on the similarity matrix.

Generate Sample Data

Randomly generate a sample data set with three well-separated clusters, each containing 20 points.

```
rng('default'); % For reproducibility
n = 20;
X = [randn(n,2)*0.5+3;
     randn(n,2)*0.5;
     randn(n,2)*0.5-3];
```

Perform Spectral Clustering on Data

Estimate the number of clusters in the data by using the eigenvalues of the Laplacian matrix, and perform spectral clustering on the data set.

Compute the five smallest eigenvalues (in magnitude) of the Laplacian matrix by using the `spectralcluster` function. By default, the function uses the normalized random-walk Laplacian matrix.

```
[~,V_temp,D_temp] = spectralcluster(X,5)
```

```
V_temp = 60×5

    0.0000    0.2236   -0.0000   -0.1534   -0.0000
    0.0000    0.2236   -0.0000    0.3093    0.0000
    0.0000    0.2236   -0.0000   -0.2225    0.0000
    0.0000    0.2236   -0.0000   -0.1776   -0.0000
    0.0000    0.2236   -0.0000   -0.1331    0.0000
    0.0000    0.2236   -0.0000   -0.2176   -0.0000
    0.0000    0.2236   -0.0000   -0.1967    0.0000
    0.0000    0.2236   -0.0000    0.0088    0.0000
    0.0000    0.2236   -0.0000    0.2844    0.0000
    0.0000    0.2236   -0.0000    0.3275   -0.0000
      ⋮

D_temp = 5×1

   -0.0000
```

```
   -0.0000
   -0.0000
    0.0876
    0.1653
```

Only the first three eigenvalues are approximately zero. The number of zero eigenvalues is a good indicator of the number of connected components in a similarity graph and, therefore, is a good estimate of the number of clusters in your data. So, `k=3` is a good estimate of the number of clusters in `X`.

Perform spectral clustering on observations by using the `spectralcluster` function. Specify `k=3` clusters.

```
k = 3;
[idx1,V,D] = spectralcluster(X,k)
```

```
idx1 = 60×1

     1
     1
     1
     1
     1
     1
     1
     1
     1
     1
      ⋮

V = 60×3

    0.0000   -0.2236    0.0000
    0.0000   -0.2236    0.0000
    0.0000   -0.2236    0.0000
    0.0000   -0.2236    0.0000
    0.0000   -0.2236    0.0000
    0.0000   -0.2236    0.0000
    0.0000   -0.2236    0.0000
    0.0000   -0.2236    0.0000
    0.0000   -0.2236    0.0000
    0.0000   -0.2236    0.0000
      ⋮

D = 3×1
10^-16 ×

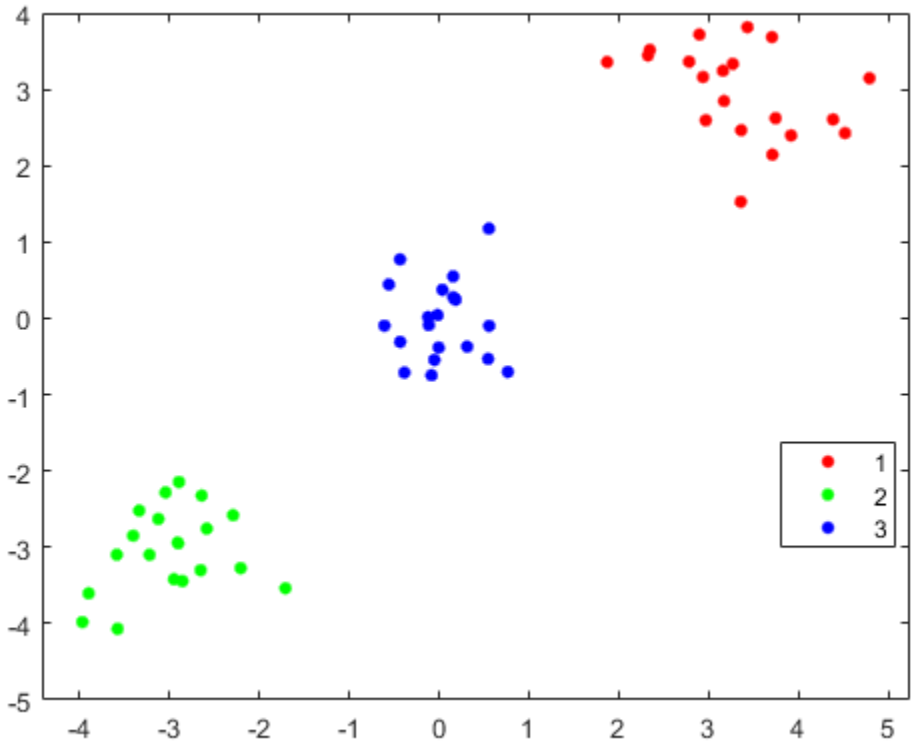
   -0.1031
   -0.1601
   -0.3754
```

Elements of `D` correspond to the three smallest eigenvalues of the Laplacian matrix. The columns of `V` contain the eigenvectors corresponding to the eigenvalues in `D`. For well-separated clusters, the eigenvectors are indicator vectors. The eigenvectors have values of zero (or close to zero) for points

that do not belong to a particular cluster, and nonzero values for points that belong to a particular cluster.

Visualize the result of clustering.

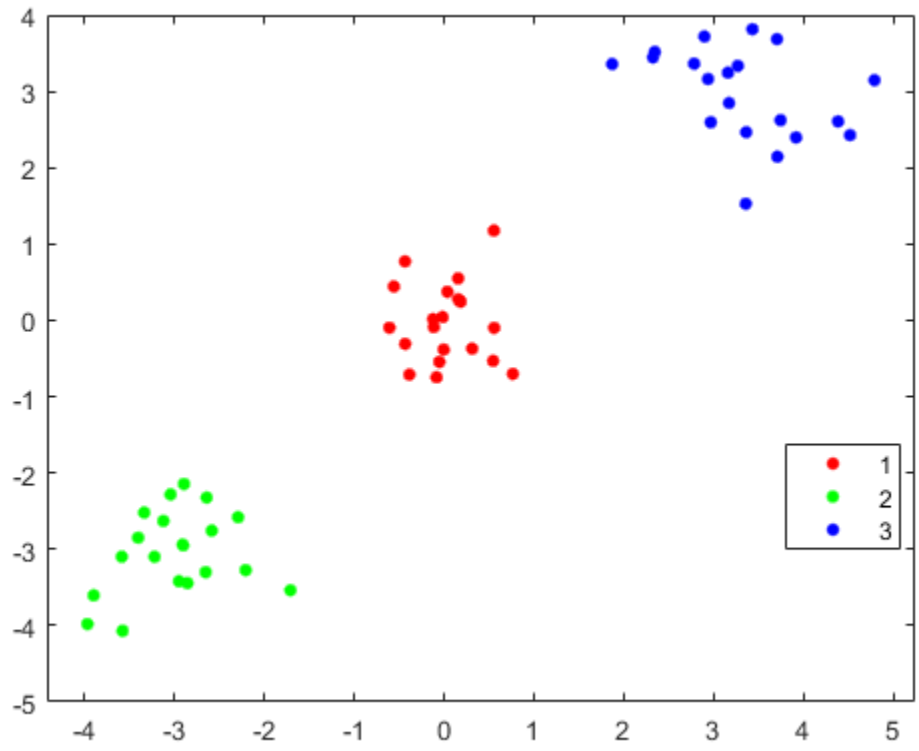
```
gscatter(X(:,1),X(:,2),idx1);
```



The `spectralcluster` function correctly identifies the three clusters in the data set.

Instead of using the `spectralcluster` function again, you can pass `V_temp` to the `kmeans` function to cluster the data points.

```
idx2 = kmeans(V_temp(:,1:3),3);
gscatter(X(:,1),X(:,2),idx2);
```



The order of cluster assignments in `idx1` and `idx2` is different even though the data points are clustered in the same way.

Perform Spectral Clustering on Similarity Matrix

Estimate the number of clusters using the similarity graph and perform spectral clustering on the similarity matrix.

Find the distance between each pair of observations in `X` by using the `pdist` and `squareform` functions with the default Euclidean distance metric.

```
dist_temp = pdist(X);
dist = squareform(dist_temp);
```

Construct the similarity matrix from the pairwise distance and confirm that the similarity matrix is symmetric.

```
S = exp(-dist.^2);
issymmetric(S)
```

```
ans = logical
   1
```

Limit the similarity values to `0.5` so that the similarity graph connects only points whose pairwise distances are smaller than the search radius.

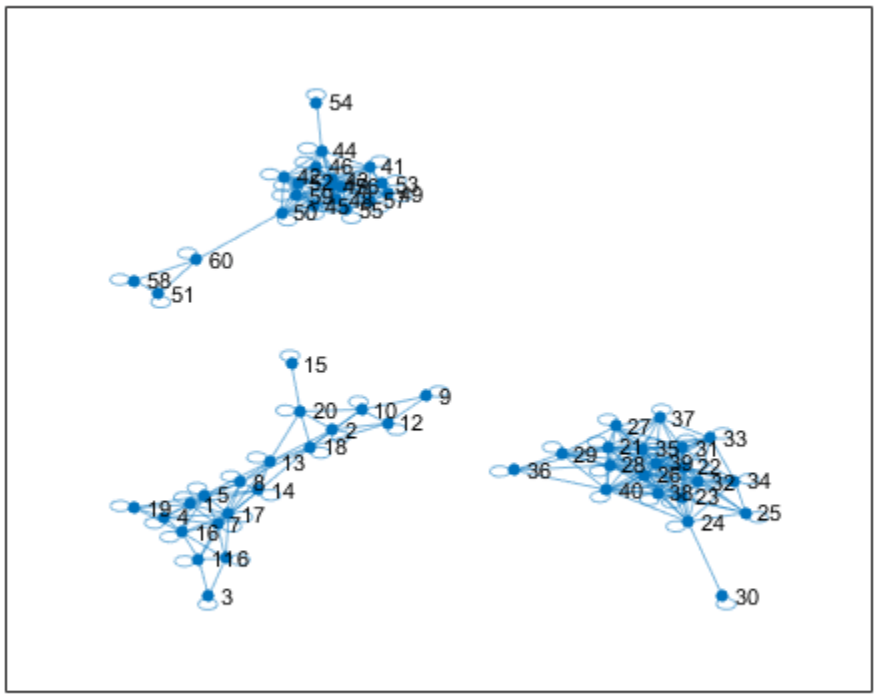
```
S_eps = S;
S_eps(S_eps<0.5) = 0;
```

Create a `graph` object from `S`.

```
G_eps = graph(S_eps);
```

Visualize the similarity graph.

```
plot(G_eps)
```



Identify the number of connected components in graph `G_eps` by using the `unique` and `conncomp` functions.

```
unique(conncomp(G_eps))
```

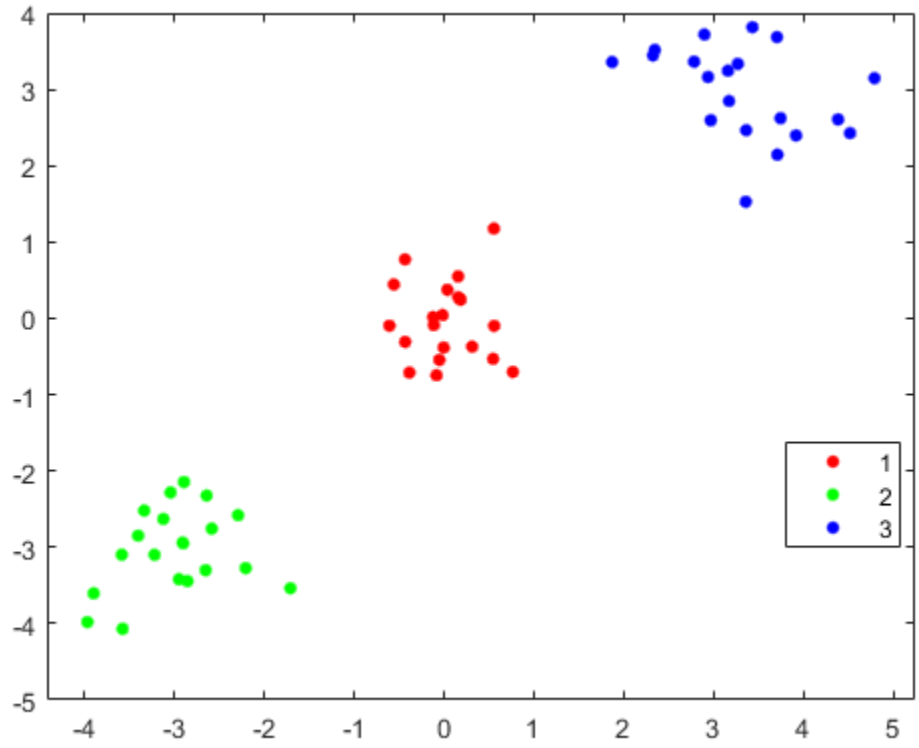
```
ans = 1×3

     1     2     3
```

The similarity graph shows three sets of connected components. The number of connected components in the similarity graph is a good estimate of the number of clusters in your data. Therefore, `k=3` is a good choice for the number of clusters in `X`.

Perform spectral clustering on the similarity matrix derived from the data set `X`.

```
k = 3;
idx3 = spectralcluster(S_eps,k,'Distance','precomputed');
gscatter(X(:,1),X(:,2),idx3);
```



The `spectralcluster` function correctly identifies the three clusters in the data set.

k-Means Clustering

In this section...

This topic provides an introduction to *k*-means clustering and an example that uses the Statistics and Machine Learning Toolbox function `kmeans` to find the best clustering solution for a data set.

Introduction to k-Means Clustering

k-means clustering is a partitioning method. The function `kmeans` partitions data into *k* mutually exclusive clusters and returns the index of the cluster to which it assigns each observation. `kmeans` treats each observation in your data as an object that has a location in space. The function finds a partition in which objects within each cluster are as close to each other as possible, and as far from objects in other clusters as possible. You can choose a distance metric on page 33-0 to use with `kmeans` based on attributes of your data. Like many clustering methods, *k*-means clustering requires you to specify the number of clusters *k* before clustering.

Unlike hierarchical clustering, *k*-means clustering operates on actual observations rather than the dissimilarity between every pair of observations in the data. Also, *k*-means clustering creates a single level of clusters, rather than a multilevel hierarchy of clusters. Therefore, *k*-means clustering is often more suitable than hierarchical clustering for large amounts of data.

Each cluster in a *k*-means partition consists of member objects and a centroid (or center). In each cluster, `kmeans` minimizes the sum of the distances between the centroid and all member objects of the cluster. `kmeans` computes centroid clusters differently for the supported distance metrics. For details, see `'Distance'`.

You can control the details of the minimization using name-value pair arguments available to `kmeans`; for example, you can specify the initial values of the cluster centroids and the maximum number of iterations for the algorithm. By default, `kmeans` uses the *k*-means++ algorithm on page 33-3329 to initialize cluster centroids, and the squared Euclidean distance metric to determine distances.

When performing *k*-means clustering, follow these best practices:

- Compare *k*-means clustering solutions for different values of *k* to determine an optimal number of clusters for your data.
- Evaluate clustering solutions by examining silhouette plots and silhouette values. You can also use the `evalclusters` function to evaluate clustering solutions based on criteria such as gap values, silhouette values, Davies-Bouldin index values, and Calinski-Harabasz index values.
- Replicate clustering from different randomly selected centroids and return the solution with the lowest total sum of distances among all the replicates.

Compare k-Means Clustering Solutions

This example explores *k*-means clustering on a four-dimensional data set. The example shows how to determine the correct number of clusters for the data set by using silhouette plots and values to analyze the results of different *k*-means clustering solutions. The example also shows how to use the `'Replicates'` name-value pair argument to test a specified number of possible solutions and return the one with the lowest total sum of distances.

Load Data Set

Load the `kmeansdata` data set.

```
rng('default')  % For reproducibility
load('kmeansdata.mat')
size(X)
```

```
ans = 1×2

   560     4
```

The data set is four-dimensional and cannot be visualized easily. However, `kmeans` enables you to investigate whether a group structure exists in the data.

Create Clusters and Examine Separation

Partition the data set into three clusters using *k*-means clustering. Specify the city block distance metric, and use the default *k*-means++ algorithm for cluster center initialization. Use the `'Display'` name-value pair argument to print the final sum of distances for the solution.

```
[idx3,C,sumdist3] = kmeans(X,3,'Distance','cityblock','Display','final');
```

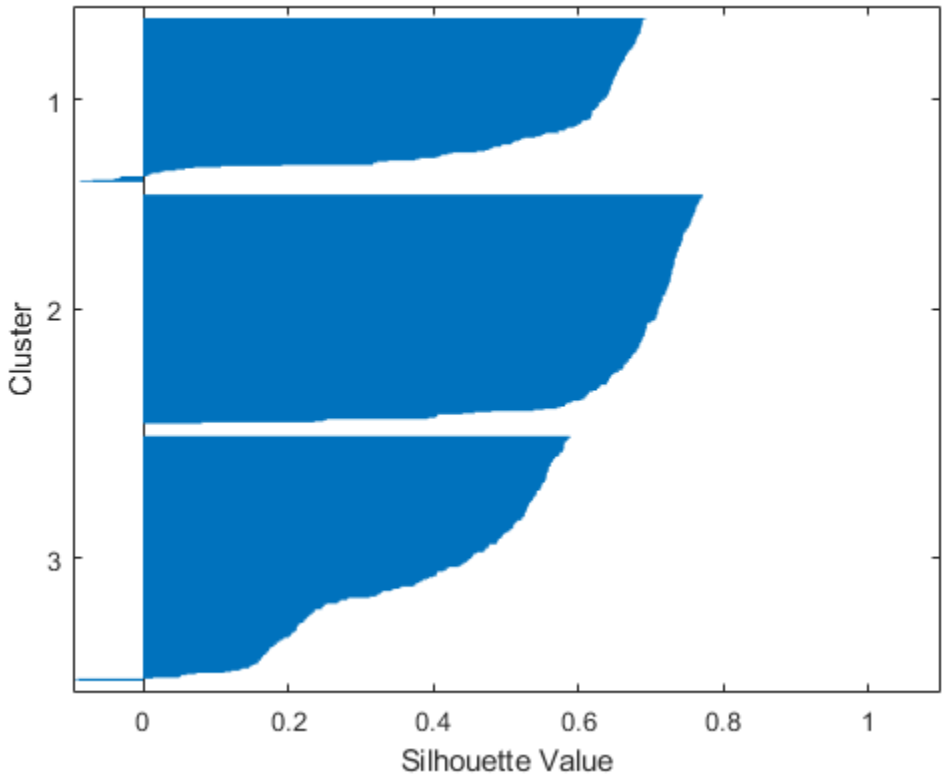
```
Replicate 1, 7 iterations, total sum of distances = 2459.98.
Best total sum of distances = 2459.98
```

`idx3` contains cluster indices that indicate the cluster assignment for each row in `X`. To see if the resulting clusters are well separated, you can create a silhouette plot.

A silhouette plot displays a measure of how close each point in one cluster is to points in the neighboring clusters. This measure ranges from 1 (indicating points that are very distant from neighboring clusters) through 0 (points that are not distinctly in one cluster or another) to –1 (points that are probably assigned to the wrong cluster). `silhouette` returns these values in its first output.

Create a silhouette plot from `idx3`. Specify `'cityblock'` for the distance metric to indicate that the *k*-means clustering is based on the sum of absolute differences.

```
[silh3,h] = silhouette(X,idx3,'cityblock');
xlabel('Silhouette Value')
ylabel('Cluster')
```



The silhouette plot shows that most points in the second cluster have a large silhouette value (greater than 0.6), indicating that the cluster is somewhat separated from neighboring clusters. However, the third cluster contains many points with low silhouette values, and the first and third clusters contain a few points with negative values, indicating that these two clusters are not well separated.

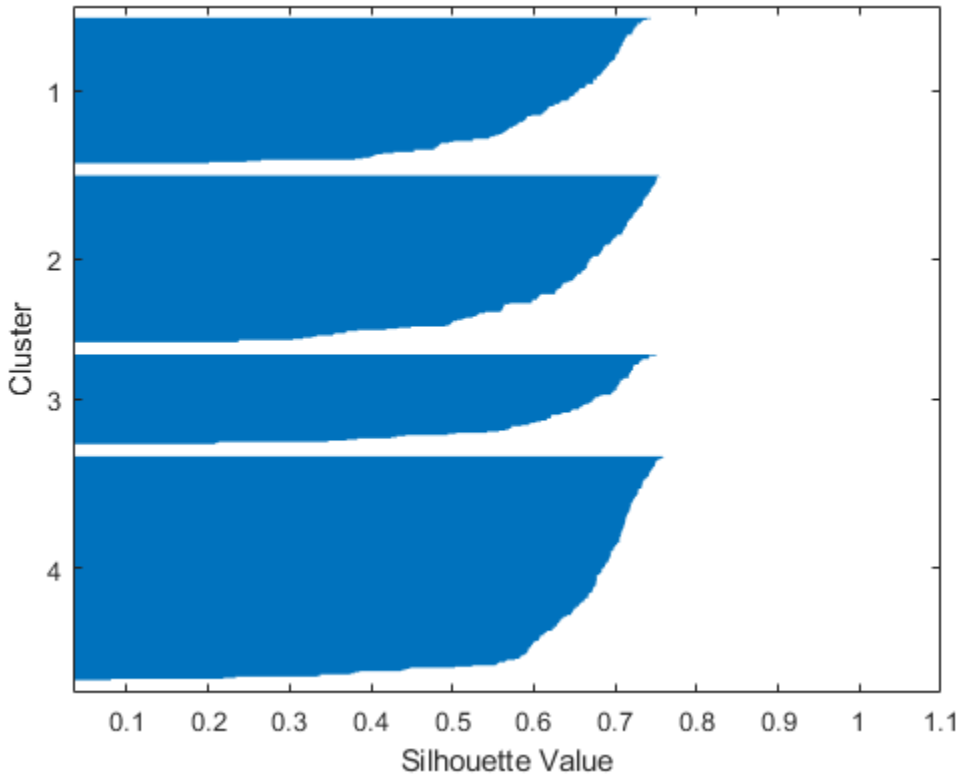
To see if `kmeans` can find a better grouping of the data, increase the number of clusters to four. Print information about each iteration by using the `'Display'` name-value pair argument.

```
idx4 = kmeans(X,4,'Distance','cityblock','Display','iter');
```

```
  iter     phase         num             sum
     1         1         560         1792.72
     2         1           6          1771.1
Best total sum of distances = 1771.1
```

Create a silhouette plot for the four clusters.

```
[silh4,h] = silhouette(X,idx4,'cityblock');
xlabel('Silhouette Value')
ylabel('Cluster')
```



The silhouette plot indicates that these four clusters are better separated than the three clusters in the previous solution. You can take a more quantitative approach to comparing the two solutions by computing the average silhouette values for the two cases.

Compute the average silhouette values.

```
cluster3 = mean(silh3)
```

```
cluster3 = 0.5352
```

```
cluster4 = mean(silh4)
```

```
cluster4 = 0.6400
```

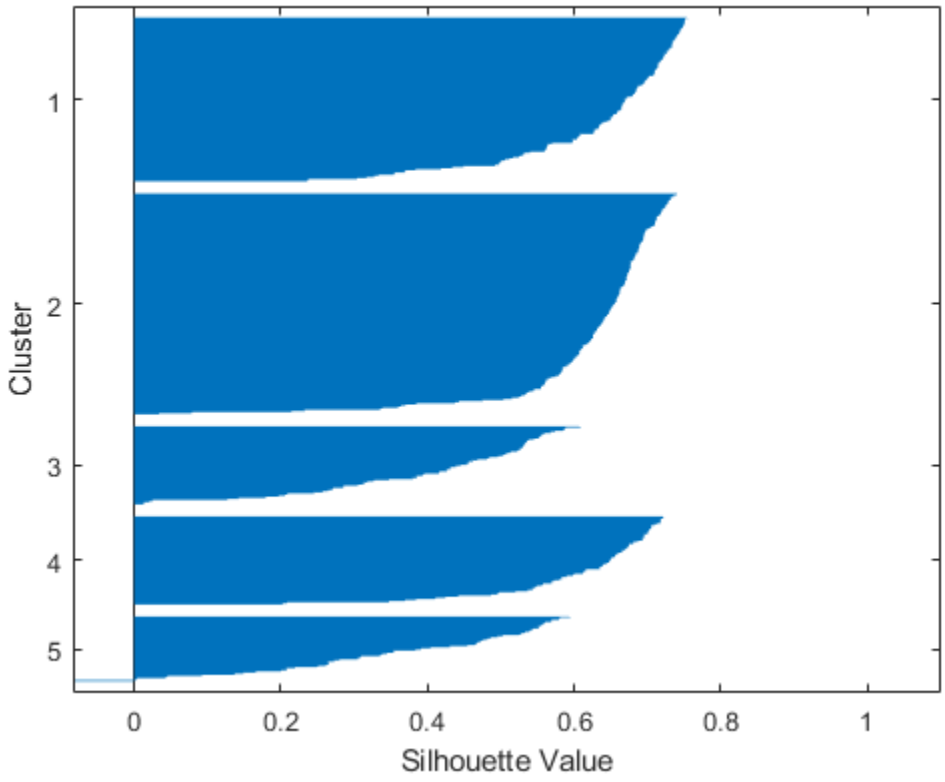
The average silhouette value of the four clusters is higher than the average value of the three clusters. These values support the conclusion represented in the silhouette plots.

Finally, find five clusters in the data. Create a silhouette plot and compute the average silhouette values for the five clusters.

```
idx5 = kmeans(X,5,'Distance','cityblock','Display','final');
```

```
Replicate 1, 7 iterations, total sum of distances = 1647.26.
Best total sum of distances = 1647.26
```

```
[silh5,h] = silhouette(X,idx5,'cityblock');
xlabel('Silhouette Value')
ylabel('Cluster')
```



```
mean(silh5)
```

```
ans = 0.5721
```

The silhouette plot indicates that five is probably not the right number of clusters, because two clusters contain points with mostly low silhouette values, and the fifth cluster contains a few points with negative values. Also, the average silhouette value for the five clusters is lower than the value for the four clusters. Without knowing how many clusters are in the data, it is a good idea to experiment with a range of values for `k`, the number of clusters.

Note that the sum of distances decreases as the number of clusters increases. For example, the sum of distances decreases from `2459.98` to `1771.1` to `1647.26` as the number of clusters increases from 3 to 4 to 5. Therefore, the sum of distances is not useful for determining the optimal number of clusters.

Avoid Local Minima

By default, `kmeans` begins the clustering process using a randomly selected set of initial centroid locations. The `kmeans` algorithm can converge to a solution that is a local (nonglobal) minimum; that is, `kmeans` can partition the data such that moving any single point to a different cluster increases the total sum of distances. However, as with many other types of numerical minimizations, the solution that `kmeans` reaches sometimes depends on the starting points. Therefore, other solutions (local minima) that have lower total sums of distances can exist for the data. You can use the `'Replicates'` name-value pair argument to test different solutions. When you specify more than one replicate, `kmeans` repeats the clustering process starting from different randomly selected

centroids for each replicate, and returns the solution with the lowest total sum of distances among all the replicates.

Find four clusters in the data and replicate the clustering five times. Also, specify the city block distance metric, and use the `'Display'` name-value pair argument to print the final sum of distances for each solution.

```
[idx4,cent4,sumdist] = kmeans(X,4,'Distance','cityblock', ...
                       'Display','final','Replicates',5);
```

```
Replicate 1, 2 iterations, total sum of distances = 1771.1.
Replicate 2, 3 iterations, total sum of distances = 1771.1.
Replicate 3, 3 iterations, total sum of distances = 1771.1.
Replicate 4, 6 iterations, total sum of distances = 2300.23.
Replicate 5, 2 iterations, total sum of distances = 1771.1.
Best total sum of distances = 1771.1
```

In replicate 4, `kmeans` finds a local minimum. Because each replicate begins from a different randomly selected set of initial centroids, `kmeans` sometimes finds more than one local minimum. However, the final solution that `kmeans` returns is the one with the lowest total sum of distances over all replicates.

Find the total of the within-cluster sums of point-to-centroid distances for the final solution returned by `kmeans`.

```
sum(sumdist)
```

```
ans = 1.7711e+03
```

Cluster Using Gaussian Mixture Model

This topic provides an introduction to clustering with a Gaussian mixture model (GMM) using the Statistics and Machine Learning Toolbox function `cluster`, and an example that shows the effects of specifying optional parameters when fitting the GMM model using `fitgmdist`.

How Gaussian Mixture Models Cluster Data

Gaussian mixture models (GMMs) are often used for data clustering. You can use GMMs to perform either *hard* clustering or *soft* clustering on query data.

To perform *hard* clustering, the GMM assigns query data points to the multivariate normal components that maximize the component posterior probability, given the data. That is, given a fitted GMM, `cluster` assigns query data to the component yielding the highest posterior probability. Hard clustering assigns a data point to exactly one cluster. For an example showing how to fit a GMM to data, cluster using the fitted model, and estimate component posterior probabilities, see “Cluster Gaussian Mixture Data Using Hard Clustering” on page 16-46.

Additionally, you can use a GMM to perform a more flexible clustering on data, referred to as *soft* (or *fuzzy*) clustering. Soft clustering methods assign a score to a data point for each cluster. The value of the score indicates the association strength of the data point to the cluster. As opposed to hard clustering methods, soft clustering methods are flexible because they can assign a data point to more than one cluster. When you perform GMM clustering, the score is the posterior probability. For an example of soft clustering with a GMM, see “Cluster Gaussian Mixture Data Using Soft Clustering” on page 16-52.

GMM clustering can accommodate clusters that have different sizes and correlation structures within them. Therefore, in certain applications,, GMM clustering can be more appropriate than methods such as *k*-means clustering. Like many clustering methods, GMM clustering requires you to specify the number of clusters before fitting the model. The number of clusters specifies the number of components in the GMM.

For GMMs, follow these best practices:

- Consider the component covariance structure. You can specify diagonal or full covariance matrices, and whether all components have the same covariance matrix.
- Specify initial conditions. The Expectation-Maximization (EM) algorithm fits the GMM. As in the *k*-means clustering algorithm, EM is sensitive to initial conditions and might converge to a local optimum. You can specify your own starting values for the parameters, specify initial cluster assignments for data points or let them be selected randomly, or specify use of the *k*-means++ algorithm on page 33-1976.
- Implement regularization. For example, if you have more predictors than data points, then you can regularize for estimation stability.

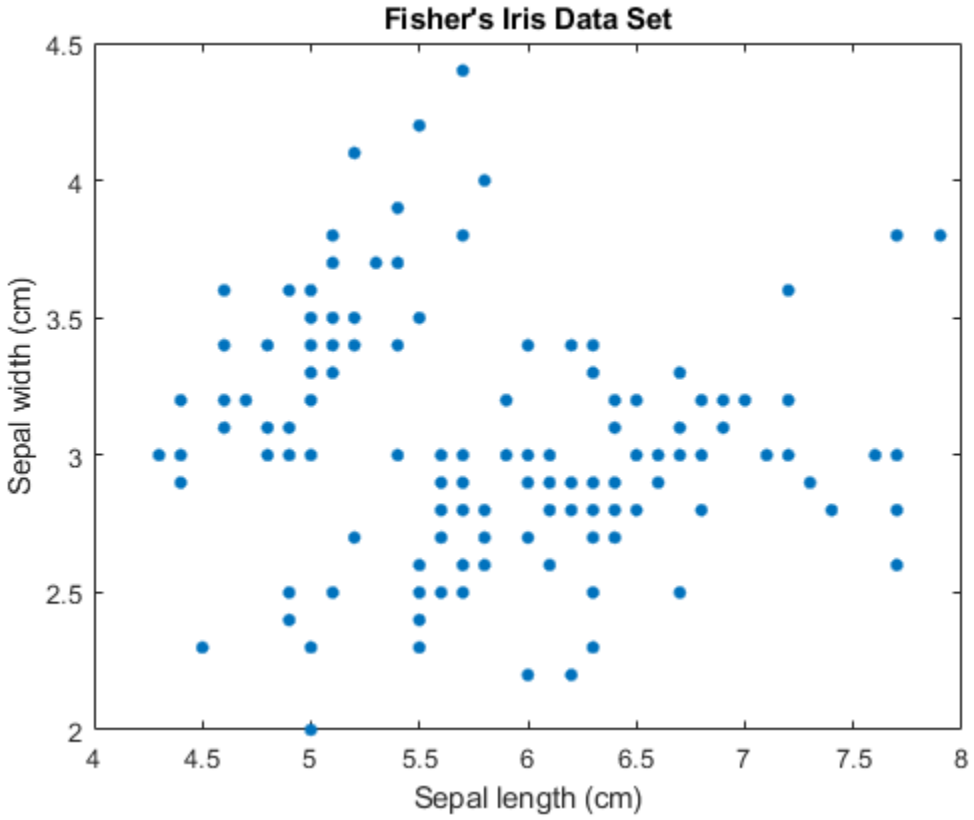
Fit GMM with Different Covariance Options and Initial Conditions

This example explores the effects of specifying different options for covariance structure and initial conditions when you perform GMM clustering.

Load Fisher's iris data set. Consider clustering the sepal measurements, and visualize the data in 2-D using the sepal measurements.

```
load fisheriris;
X = meas(:,1:2);
[n,p] = size(X);

plot(X(:,1),X(:,2),'.','MarkerSize',15);
title('Fisher''s Iris Data Set');
xlabel('Sepal length (cm)');
ylabel('Sepal width (cm)');
```



The number of components k in a GMM determines the number of subpopulations, or clusters. In this figure, it is difficult to determine if two, three, or perhaps more Gaussian components are appropriate. A GMM increases in complexity as k increases.

Specify Different Covariance Structure Options

Each Gaussian component has a covariance matrix. Geometrically, the covariance structure determines the shape of a confidence ellipsoid drawn over a cluster. You can specify whether the covariance matrices for all components are diagonal or full, and whether all components have the same covariance matrix. Each combination of specifications determines the shape and orientation of the ellipsoids.

Specify three GMM components and 1000 maximum iterations for the EM algorithm. For reproducibility, set the random seed.

```
rng(3);
k = 3; % Number of GMM components
options = statset('MaxIter',1000);
```

Specify covariance structure options.

```
Sigma = {'diagonal','full'}; % Options for covariance matrix type
nSigma = numel(Sigma);

SharedCovariance = {true,false}; % Indicator for identical or nonidentical covariance matrices
SCtext = {'true','false'};
nSC = numel(SharedCovariance);
```

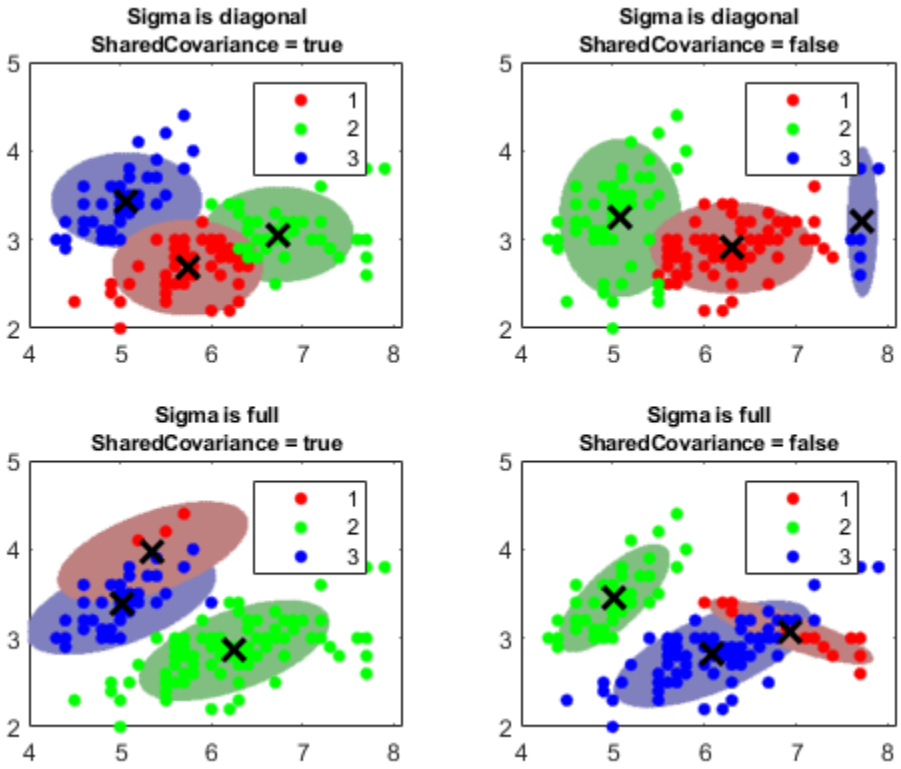
Create a 2-D grid covering the plane composed of extremes of the measurements. You will use this grid later to draw confidence ellipsoids over the clusters.

```
d = 500; % Grid length
x1 = linspace(min(X(:,1))-2, max(X(:,1))+2, d);
x2 = linspace(min(X(:,2))-2, max(X(:,2))+2, d);
[x1grid,x2grid] = meshgrid(x1,x2);
X0 = [x1grid(:) x2grid(:)];
```

Specify the following:

- For all combinations of the covariance structure options, fit a GMM with three components.
- Use the fitted GMM to cluster the 2-D grid.
- Obtain the score that specifies a 99% probability threshold for each confidence region. This specification determines the length of the major and minor axes of the ellipsoids.
- Color each ellipsoid using a similar color as its cluster.

```
threshold = sqrt(chi2inv(0.99,2));
count = 1;
for i = 1:nSigma
    for j = 1:nSC
        gmfit = fitgmdist(X,k,'CovarianceType',Sigma{i}, ...
            'SharedCovariance',SharedCovariance{j},'Options',options); % Fitted GMM
        clusterX = cluster(gmfit,X); % Cluster index
        mahalDist = mahal(gmfit,X0); % Distance from each grid point to each GMM component
        % Draw ellipsoids over each GMM component and show clustering result.
        subplot(2,2,count);
        h1 = gscatter(X(:,1),X(:,2),clusterX);
        hold on
            for m = 1:k
                idx = mahalDist(:,m)<=threshold;
                Color = h1(m).Color*0.75 - 0.5*(h1(m).Color - 1);
                h2 = plot(X0(idx,1),X0(idx,2),'.','Color',Color,'MarkerSize',1);
                uistack(h2,'bottom');
            end
        plot(gmfit.mu(:,1),gmfit.mu(:,2),'kx','LineWidth',2,'MarkerSize',10)
        title(sprintf('Sigma is %s\nSharedCovariance = %s',Sigma{i},SCtext{j}),'FontSize',8)
        legend(h1,{'1','2','3'})
        hold off
        count = count + 1;
    end
end
```



The probability threshold for the confidence region determines the length of the major and minor axes, and the covariance type determines the orientation of the axes. Note the following about options for the covariance matrices:

- **Diagonal covariance matrices** indicate that the predictors are uncorrelated. The major and minor axes of the ellipses are parallel or perpendicular to the x and y axes. This specification increases the total number of parameters by p, the number of predictors, for each component, but is more parsimonious than the full covariance specification.
- **Full covariance matrices** allow for correlated predictors with no restriction to the orientation of the ellipses relative to the x and y axes. Each component increases the total number of parameters by $p(p + 1)/2$, but captures the correlation structure among the predictors. This specification can cause overfitting.
- **Shared covariance matrices** indicate that all components have the same covariance matrix. All ellipses are the same size and have the same orientation. This specification is more parsimonious than the unshared specification because the total number of parameters increases by the number of covariance parameters for one component only.
- **Unshared covariance matrices** indicate that each component has its own covariance matrix. The size and orientation of all ellipses might differ. This specification increases the number of parameters by k times the number of covariance parameters for a component, but can capture covariance differences among components.

The figure also shows that `cluster` does not always preserve cluster order. If you cluster several fitted `gmdistribution` models, `cluster` can assign different cluster labels for similar components.

Specify Different Initial Conditions

The algorithm that fits a GMM to the data can be sensitive to initial conditions. To illustrate this sensitivity, fit four different GMMs as follows:

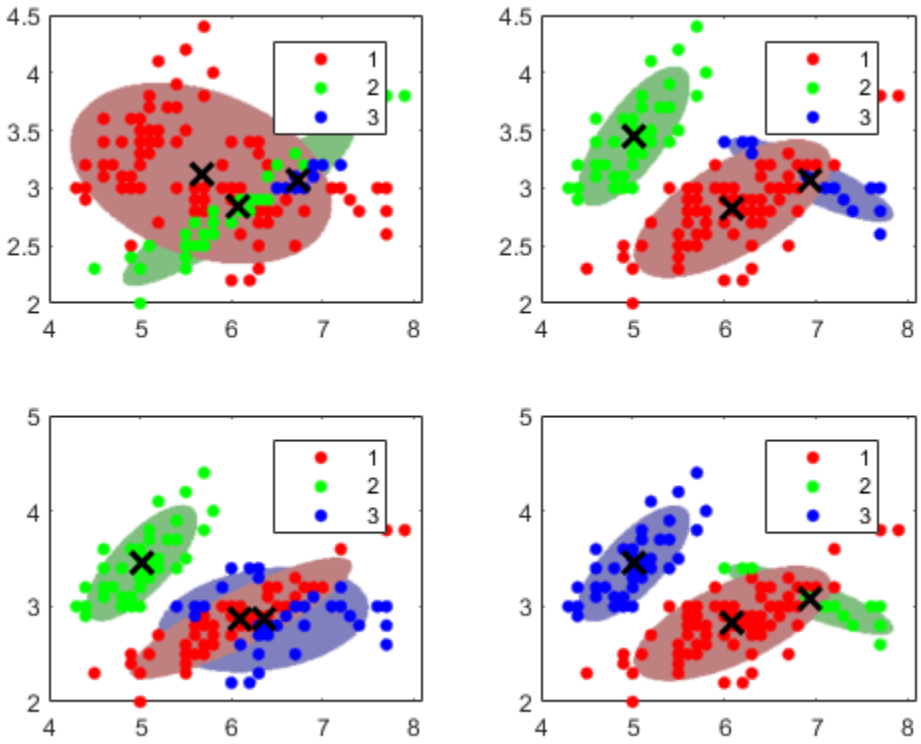
1. For the first GMM, assign most data points to the first cluster.
2. For the second GMM, randomly assign data points to clusters.
3. For the third GMM, make another random assignment of data points to clusters.
4. For the fourth GMM, use *k*-means++ to obtain initial cluster centers.

```
initialCond1 = [ones(n-8,1); [2; 2; 2; 2]; [3; 3; 3; 3]]; % For the first GMM
initialCond2 = randsample(1:k,n,true); % For the second GMM
initialCond3 = randsample(1:k,n,true); % For the third GMM
initialCond4 = 'plus'; % For the fourth GMM
cluster0 = {initialCond1; initialCond2; initialCond3; initialCond4};
```

For all instances, use $k = 3$ components, unshared and full covariance matrices, the same initial mixture proportions, and the same initial covariance matrices. For stability when you try different sets of initial values, increase the number of EM algorithm iterations. Also, draw confidence ellipsoids over the clusters.

```
converged = nan(4,1);

for j = 1:4
    gmfit = fitgmdist(X,k,'CovarianceType','full', ...
        'SharedCovariance',false,'Start',cluster0{j}, ...
        'Options',options);
    clusterX = cluster(gmfit,X); % Cluster index
    mahalDist = mahal(gmfit,X0); % Distance from each grid point to each GMM component
    % Draw ellipsoids over each GMM component and show clustering result.
    subplot(2,2,j);
    h1 = gscatter(X(:,1),X(:,2),clusterX); % Distance from each grid point to each GMM component
    hold on;
    nK = numel(unique(clusterX));
    for m = 1:nK
        idx = mahalDist(:,m)<=threshold;
        Color = h1(m).Color*0.75 + -0.5*(h1(m).Color - 1);
        h2 = plot(X0(idx,1),X0(idx,2),'.','Color',Color,'MarkerSize',1);
        uistack(h2,'bottom');
    end
    plot(gmfit.mu(:,1),gmfit.mu(:,2),'kx','LineWidth',2,'MarkerSize',10)
    legend(h1,{'1','2','3'});
    hold off
    converged(j) = gmfit.Converged; % Indicator for convergence
end
```



```
sum(converged)
```

```
ans = 4
```

All algorithms converged. Each starting cluster assignment for the data points leads to a different, fitted cluster assignment. You can specify a positive integer for the name-value pair argument "'Replicates'" on page 33-0 , which runs the algorithm the specified number of times. Subsequently, `fitgmdist` chooses the fit that yields the largest likelihood.

When to Regularize

Sometimes, during an iteration of the EM algorithm, a fitted covariance matrix can become ill conditioned, which means the likelihood is escaping to infinity. This problem can happen if one or more of the following conditions exist:

- You have more predictors than data points.
- You specify fitting with too many components.
- Variables are highly correlated.

To overcome this problem, you can specify a small, positive number using the `'RegularizationValue'` name-value pair argument. `fitgmdist` adds this number to the diagonal elements of all covariance matrices, which ensures that all matrices are positive definite. Regularizing can reduce the maximal likelihood value.

Model Fit Statistics

In most applications, the number of components k and appropriate covariance structure Σ are unknown. One way you can tune a GMM is by comparing information criteria. Two popular information criteria are the Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC).

Both the AIC and BIC take the optimized, negative loglikelihood and then penalize it with the number of parameters in the model (the model complexity). However, the BIC penalizes for complexity more severely than the AIC. Therefore, the AIC tends to choose more complex models that might overfit, and the BIC tends to choose simpler models that might underfit. A good practice is to look at both criteria when evaluating a model. Lower AIC or BIC values indicate better fitting models. Also, ensure that your choices for k and the covariance matrix structure are appropriate for your application. `fitgmdist` stores the AIC and BIC of fitted `gmdistribution` model objects in the properties AIC and BIC. You can access these properties by using dot notation. For an example showing how to choose the appropriate parameters, see “Tune Gaussian Mixture Models” on page 16-57.

Cluster Gaussian Mixture Data Using Hard Clustering

This example shows how to implement hard clustering on simulated data from a mixture of Gaussian distributions.

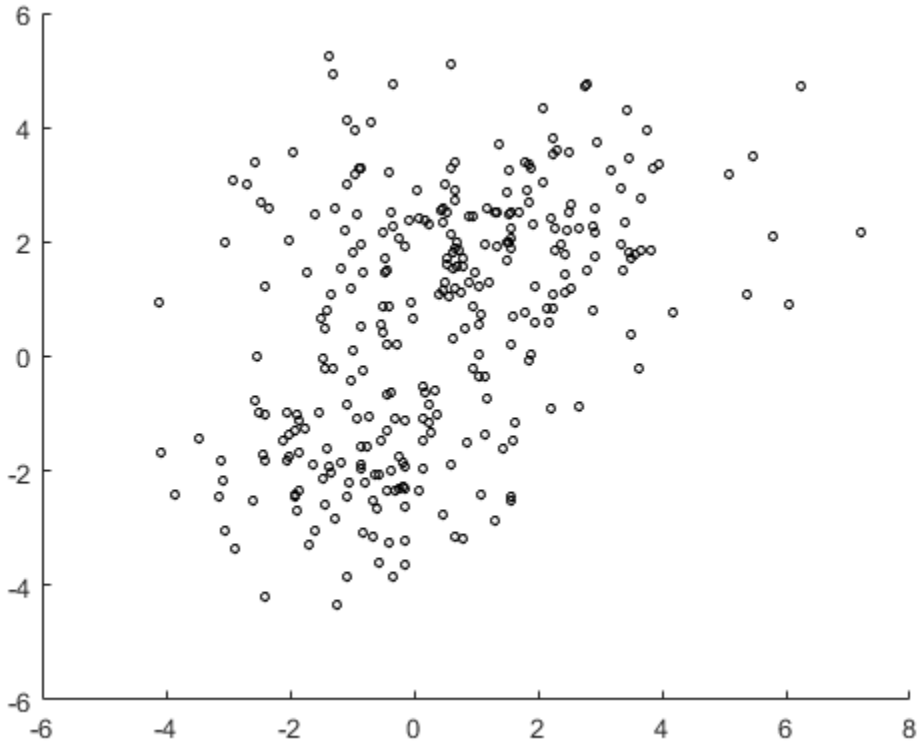
Gaussian mixture models can be used for clustering data, by realizing that the multivariate normal components of the fitted model can represent clusters.

Simulate Data from a Mixture of Gaussian Distributions

Simulate data from a mixture of two bivariate Gaussian distributions using `mvnrnd`.

```
rng('default')  % For reproducibility
mu1 = [1 2];
sigma1 = [3 .2; .2 2];
mu2 = [-1 -2];
sigma2 = [2 0; 0 1];
X = [mvnrnd(mu1,sigma1,200); mvnrnd(mu2,sigma2,100)];
n = size(X,1);

figure
scatter(X(:,1),X(:,2),10,'ko')
```



Fit a Gaussian Mixture Model to the Simulated Data

Fit a two-component Gaussian mixture model (GMM). Here, you know the correct number of components to use. In practice, with real data, this decision would require comparing models with

different numbers of components. Also, request to display the final iteration of the expectation-maximization fitting routine.

```
options = statset('Display','final');
gm = fitgmdist(X,2,'Options',options)
```

```
26 iterations, log-likelihood = -1210.59

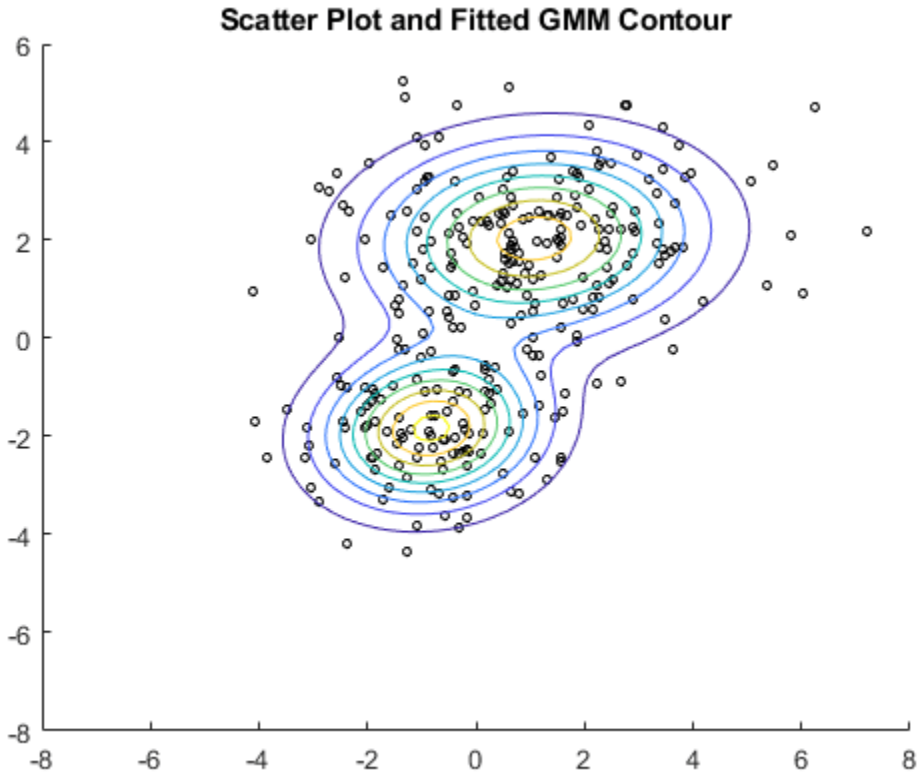
gm =

Gaussian mixture distribution with 2 components in 2 dimensions
Component 1:
Mixing proportion: 0.629514
Mean:    1.0756    2.0421

Component 2:
Mixing proportion: 0.370486
Mean:   -0.8296   -1.8488
```

Plot the estimated probability density contours for the two-component mixture distribution. The two bivariate normal components overlap, but their peaks are distinct. This suggests that the data could reasonably be divided into two clusters.

```
hold on
gmPDF = @(x,y) arrayfun(@(x0,y0) pdf(gm,[x0,y0]),x,y);
fcontour(gmPDF,[-8,6])
title('Scatter Plot and Fitted GMM Contour')
hold off
```



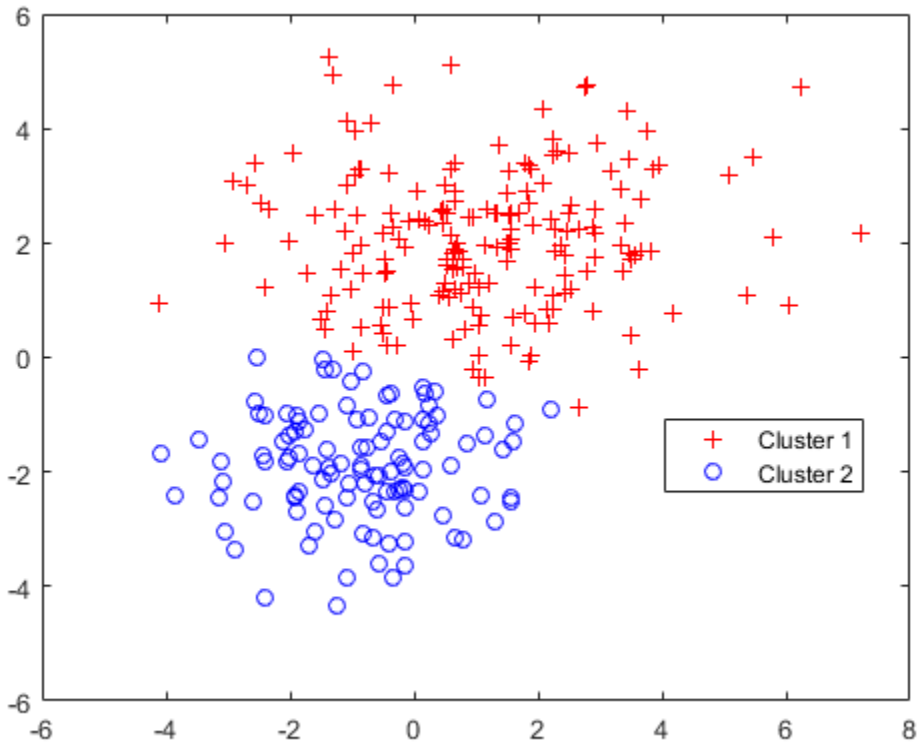
Cluster the Data Using the Fitted GMM

`cluster` implements "hard clustering", a method that assigns each data point to exactly one cluster. For GMM, `cluster` assigns each point to one of the two mixture components in the GMM. The center of each cluster is the corresponding mixture component mean. For details on "soft clustering," see “Cluster Gaussian Mixture Data Using Soft Clustering” on page 16-52.

Partition the data into clusters by passing the fitted GMM and the data to `cluster`.

```
idx = cluster(gm,X);
cluster1 = (idx == 1); % |1| for cluster 1 membership
cluster2 = (idx == 2); % |2| for cluster 2 membership

figure
gscatter(X(:,1),X(:,2),idx,'rb','+o')
legend('Cluster 1','Cluster 2','Location','best')
```



Each cluster corresponds to one of the bivariate normal components in the mixture distribution. `cluster` assigns data to clusters based on a cluster membership score. Each cluster membership scores is the estimated posterior probability that the data point came from the corresponding component. `cluster` assigns each point to the mixture component corresponding to the highest posterior probability.

You can estimate cluster membership posterior probabilities by passing the fitted GMM and data to either:

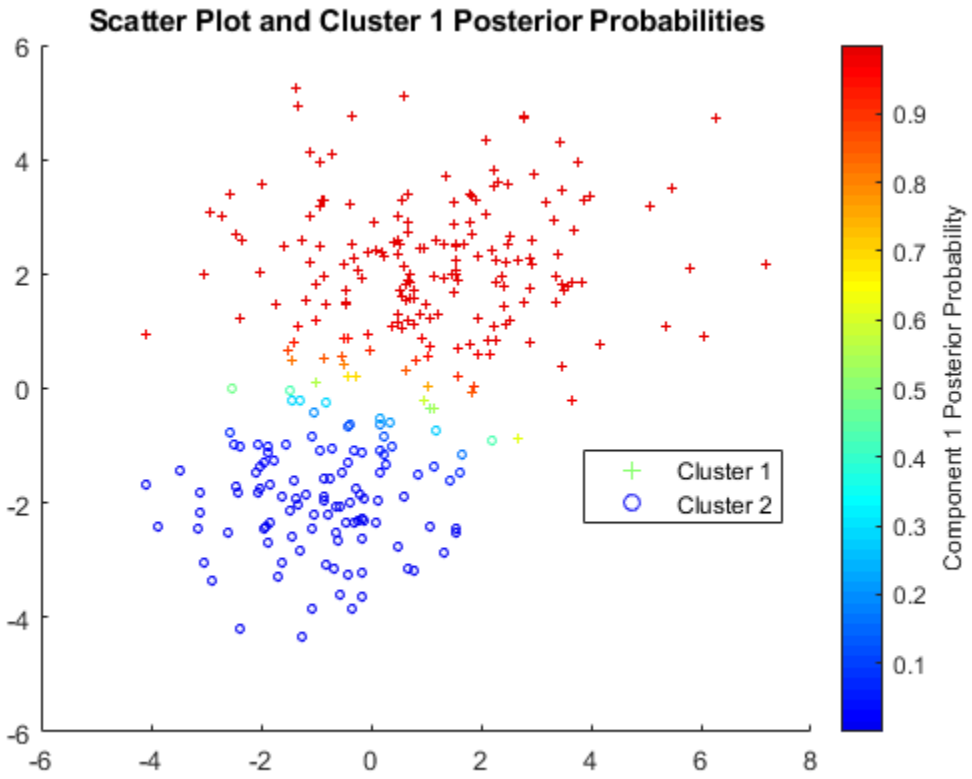
- `posterior`
- `cluster`, and request to return the third output argument

Estimate Cluster Membership Posterior Probabilities

Estimate and plot the posterior probability of the first component for each point.

```
P = posterior(gm,X);

figure
scatter(X(cluster1,1),X(cluster1,2),10,P(cluster1,1),'+')
hold on
scatter(X(cluster2,1),X(cluster2,2),10,P(cluster2,1),'o')
hold off
clrmap = jet(80);
colormap(clrmap(9:72,:))
ylabel(colorbar,'Component 1 Posterior Probability')
legend('Cluster 1','Cluster 2','Location','best')
title('Scatter Plot and Cluster 1 Posterior Probabilities')
```



`P` is an `n`-by-2 matrix of cluster membership posterior probabilities. The first column contains the probabilities for cluster 1 and the second column corresponds to cluster 2.

Assign New Data to Clusters

You can also use the `cluster` method to assign new data points to the mixture components found in the original data.

Simulate new data from a mixture of Gaussian distributions. Rather than using `mvnrnd`, you can create a GMM with the true mixture component means and standard deviations using `gmdistribution`, and then pass the GMM to `random` to simulate data.

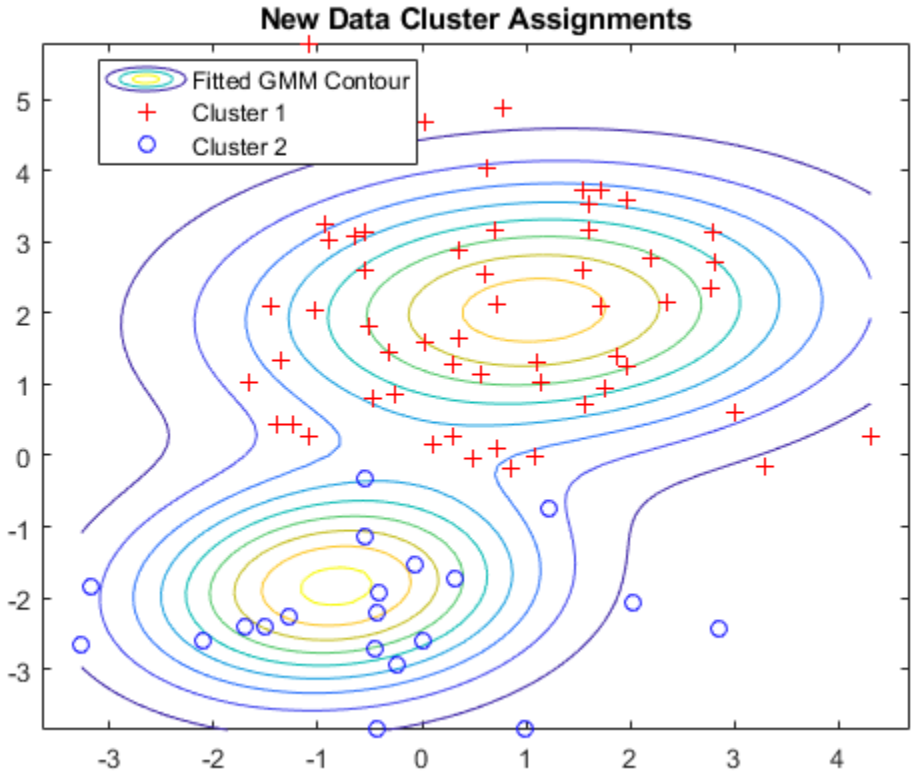
```
Mu = [mu1; mu2];
Sigma = cat(3,sigma1,sigma2);
p = [0.75 0.25]; % Mixing proportions

gmTrue = gmdistribution(Mu,Sigma,p);
X0 = random(gmTrue,75);
```

Assign clusters to the new data by pass the fitted GMM (`gm`) and the new data to `cluster`. Request cluster membership posterior probabilities.

```
[idx0,~,P0] = cluster(gm,X0);

figure
fcontour(gmPDF,[min(X0(:,1)) max(X0(:,1)) min(X0(:,2)) max(X0(:,2))])
hold on
gscatter(X0(:,1),X0(:,2),idx0,'rb','+o')
legend('Fitted GMM Contour','Cluster 1','Cluster 2','Location','best')
title('New Data Cluster Assignments')
hold off
```



For `cluster` to provide meaningful results when clustering new data, `X0` should come from the same population as `X`, the original data used to create the mixture distribution. In particular, when

computing the posterior probabilities for `X0`, `cluster` and `posterior` use the estimated mixing probabilities.

Cluster Gaussian Mixture Data Using Soft Clustering

This example shows how to implement soft clustering on simulated data from a mixture of Gaussian distributions.

`cluster` estimates cluster membership posterior probabilities, and then assigns each point to the cluster corresponding to the maximum posterior probability. Soft clustering is an alternative clustering method that allows some data points to belong to multiple clusters. To implement soft clustering:

1. Assign a cluster membership score to each data point that describes how similar each point is to each cluster's archetype. For a mixture of Gaussian distributions, the cluster archetype is corresponding component mean, and the component can be the estimated cluster membership posterior probability.
2. Rank the points by their cluster membership score.
3. Inspect the scores and determine cluster memberships.

For algorithms that use posterior probabilities as scores, a data point is a member of the cluster corresponding to the maximum posterior probability. However, if there are other clusters with corresponding posterior probabilities that are close to the maximum, then the data point can also be a member of those clusters. It is good practice to determine the threshold on scores that yield multiple cluster memberships before clustering.

This example follows from “Cluster Gaussian Mixture Data Using Hard Clustering” on page 16-46.

Simulate data from a mixture of two bivariate Gaussian distributions.

```
rng(0,'twister')  % For reproducibility
mu1 = [1 2];
sigma1 = [3 .2; .2 2];
mu2 = [-1 -2];
sigma2 = [2 0; 0 1];
X = [mvnrnd(mu1,sigma1,200); mvnrnd(mu2,sigma2,100)];
```

Fit a two-component Gaussian mixture model (GMM). Because there are two components, suppose that any data point with cluster membership posterior probabilities in the interval [0.4,0.6] can be a member of both clusters.

```
gm = fitgmdist(X,2);
threshold = [0.4 0.6];
```

Estimate component-member posterior probabilities for all data points using the fitted GMM `gm`. These represent cluster membership scores.

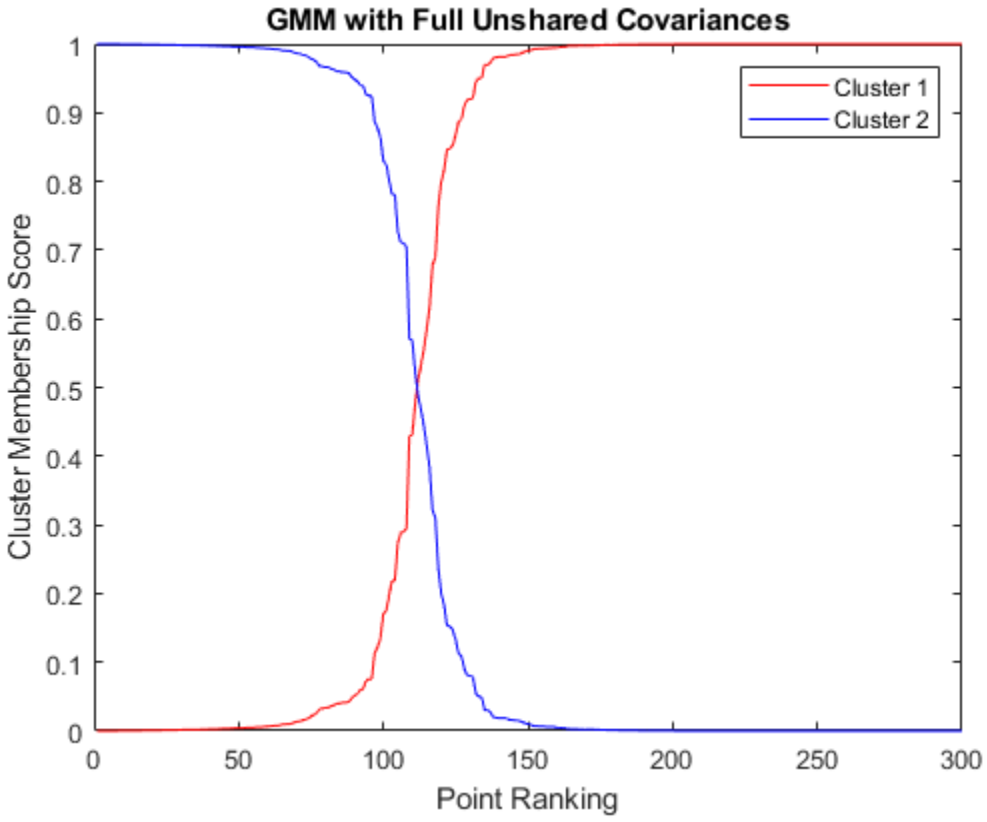
```
P = posterior(gm,X);
```

For each cluster, rank the membership scores for all data points. For each cluster, plot each data points membership score with respect to its ranking relative to all other data points.

```
n = size(X,1);
[~,order] = sort(P(:,1));

figure
plot(1:n,P(order,1),'r-',1:n,P(order,2),'b-')
legend({'Cluster 1', 'Cluster 2'})
```

```
ylabel('Cluster Membership Score')
xlabel('Point Ranking')
title('GMM with Full Unshared Covariances')
```



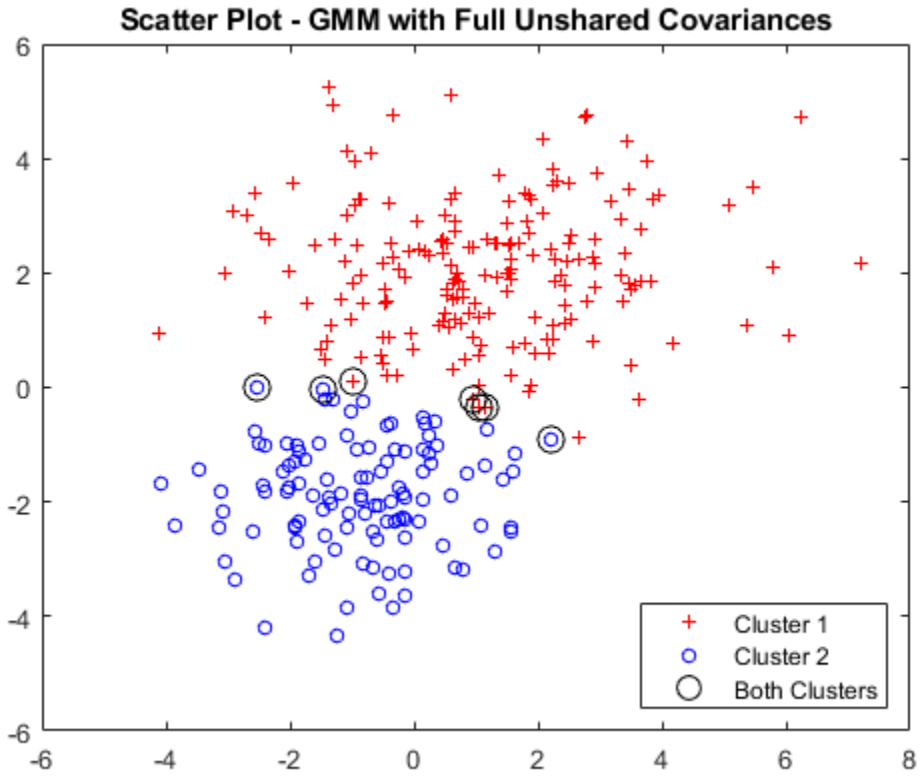
Although a clear separation is hard to see in a scatter plot of the data, plotting the membership scores indicates that the fitted distribution does a good job of separating the data into groups.

Plot the data and assign clusters by maximum posterior probability. Identify points that could be in either cluster.

```
idx = cluster(gm,X);
idxBoth = find(P(:,1)>=threshold(1) & P(:,1)<=threshold(2));
numInBoth = numel(idxBoth)
```

```
numInBoth = 7
```

```
figure
gscatter(X(:,1),X(:,2),idx,'rb','+o',5)
hold on
plot(X(idxBoth,1),X(idxBoth,2),'ko','MarkerSize',10)
legend({'Cluster 1','Cluster 2','Both Clusters'},'Location','SouthEast')
title('Scatter Plot - GMM with Full Unshared Covariances')
hold off
```



Using the score threshold interval, seven data points can be in either cluster.

Soft clustering using a GMM is similar to fuzzy *k*-means clustering, which also assigns each point to each cluster with a membership score. The fuzzy *k*-means algorithm assumes that clusters are roughly spherical in shape, and all of roughly equal size. This is comparable to a Gaussian mixture distribution with a single covariance matrix that is shared across all components, and is a multiple of the identity matrix. In contrast, `gmdistribution` allows you to specify different covariance structures. The default is to estimate a separate, unconstrained covariance matrix for each component. A more restricted option, closer to *k*-means, is to estimate a shared, diagonal covariance matrix.

Fit a GMM to the data, but specify that the components share the same, diagonal covariance matrix. This specification is similar to implementing fuzzy *k*-means clustering, but provides more flexibility by allowing unequal variances for different variables.

```
gmSharedDiag = fitgmdist(X,2,'CovType','Diagonal','SharedCovariance',true');
```

Estimate component-member posterior probabilities for all data points using the fitted GMM `gmSharedDiag`. Estimate soft cluster assignments.

```
[idxSharedDiag,~,PSharedDiag] = cluster(gmSharedDiag,X);
idxBothSharedDiag = find(PSharedDiag(:,1)>=threshold(1) & ...
    PSharedDiag(:,1)<=threshold(2));
numInBoth = numel(idxBothSharedDiag)
```

```
numInBoth = 5
```

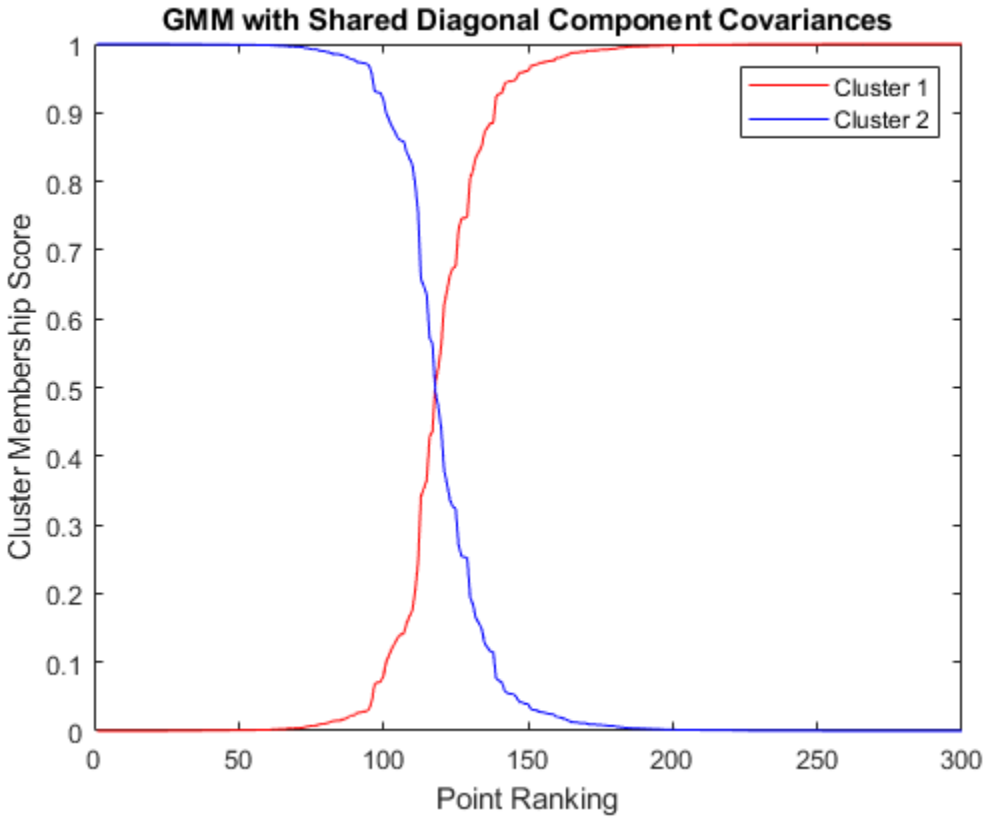
Assuming shared, diagonal covariances among components, five data points could be in either cluster.

For each cluster:

1. Rank the membership scores for all data points.
2. Plot each data points membership score with respect to its ranking relative to all other data points.

```
[~,orderSharedDiag] = sort(PSharedDiag(:,1));

figure
plot(1:n,PSharedDiag(orderSharedDiag,1),'r-',...
    1:n,PSharedDiag(orderSharedDiag,2),'b-')
legend({'Cluster 1' 'Cluster 2'},'Location','NorthEast')
ylabel('Cluster Membership Score')
xlabel('Point Ranking')
title('GMM with Shared Diagonal Component Covariances')
```



Plot the data and identify the hard, clustering assignments from the GMM analysis assuming the shared, diagonal covariances among components. Also, identify those data points that could be in either cluster.

```
figure
gscatter(X(:,1),X(:,2),idxSharedDiag,'rb','+o',5)
hold on
plot(X(idxBothSharedDiag,1),X(idxBothSharedDiag,2),'ko','MarkerSize',10)
legend({'Cluster 1','Cluster 2','Both Clusters'},'Location','SouthEast')
```

```
title('Scatter Plot - GMM with Shared Diagonal Component Covariances')
hold off
```

- “Choose Cluster Analysis Method” on page 16-2

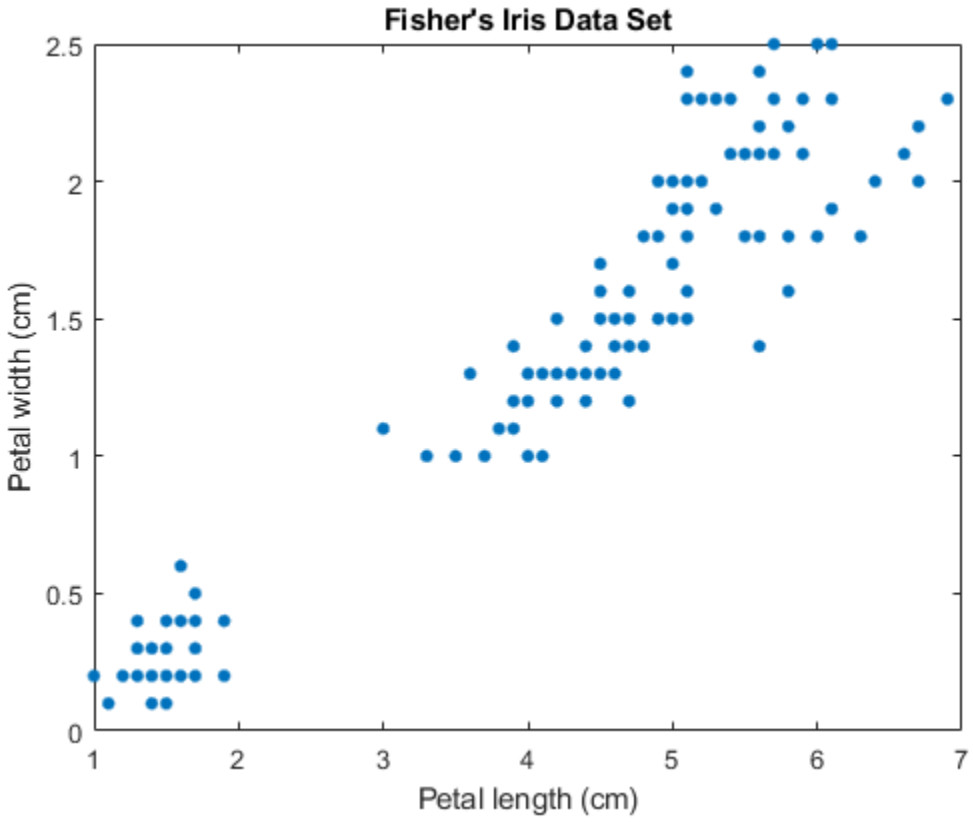
Tune Gaussian Mixture Models

This example shows how to determine the best Gaussian mixture model (GMM) fit by adjusting the number of components and the component covariance matrix structure.

Load Fisher's iris data set. Consider the petal measurements as predictors.

```
load fisheriris;
X = meas(:,3:4);
[n,p] = size(X);
rng(1); % For reproducibility

figure;
plot(X(:,1),X(:,2),'.','MarkerSize',15);
title('Fisher''s Iris Data Set');
xlabel('Petal length (cm)');
ylabel('Petal width (cm)');
```



Suppose k is the number of desired components or clusters, and Σ is the covariance structure for all components. Follow these steps to tune a GMM.

1. Choose a (k, Σ) pair, and then fit a GMM using the chosen parameter specification and the entire data set.
2. Estimate the AIC and BIC.
3. Repeat steps 1 and 2 until you exhaust all (k, Σ) pairs of interest.

4 Choose the fitted GMM that balances low AIC with simplicity.

For this example, choose a grid of values for k that include 2 and 3, and some surrounding numbers. Specify all available choices for covariance structure. If k is too high for the data set, then the estimated component covariances can be badly conditioned. Specify to use regularization to avoid badly conditioned covariance matrices. Increase the number of EM algorithm iterations to 10000.

```
k = 1:5;
nK = numel(k);
Sigma = {'diagonal','full'};
nSigma = numel(Sigma);
SharedCovariance = {true,false};
SCtext = {'true','false'};
nSC = numel(SharedCovariance);
RegularizationValue = 0.01;
options = statset('MaxIter',10000);
```

Fit the GMMs using all parameter combination. Compute the AIC and BIC for each fit. Track the terminal convergence status of each fit.

```
% Preallocation
gm = cell(nK,nSigma,nSC);
aic = zeros(nK,nSigma,nSC);
bic = zeros(nK,nSigma,nSC);
converged = false(nK,nSigma,nSC);

% Fit all models
for m = 1:nSC;
    for j = 1:nSigma;
        for i = 1:nK;
            gm{i,j,m} = fitgmdist(X,k(i),...
                'CovarianceType',Sigma{j},...
                'SharedCovariance',SharedCovariance{m},...
                'RegularizationValue',RegularizationValue,...
                'Options',options);
            aic(i,j,m) = gm{i,j,m}.AIC;
            bic(i,j,m) = gm{i,j,m}.BIC;
            converged(i,j,m) = gm{i,j,m}.Converged;
        end
    end
end

allConverge = (sum(converged(:)) == nK*nSigma*nSC)
```

```
allConverge =

  logical

   1
```

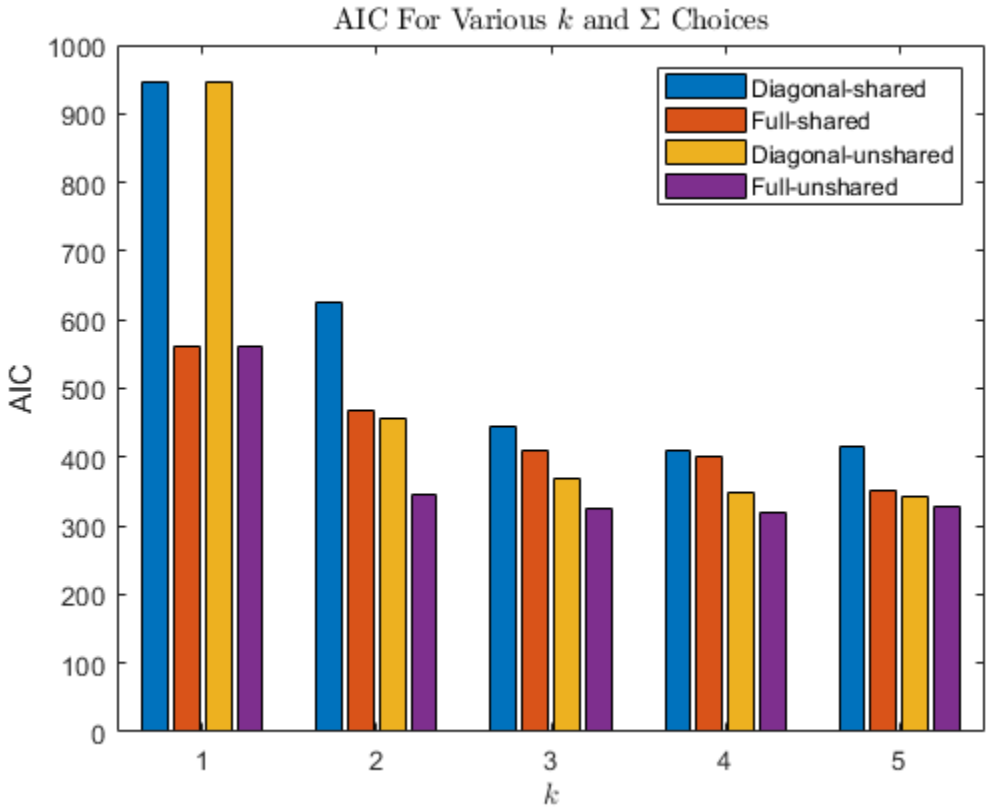
`gm` is a cell array containing all of the fitted `gmdistribution` model objects. All of the fitting instances converged.

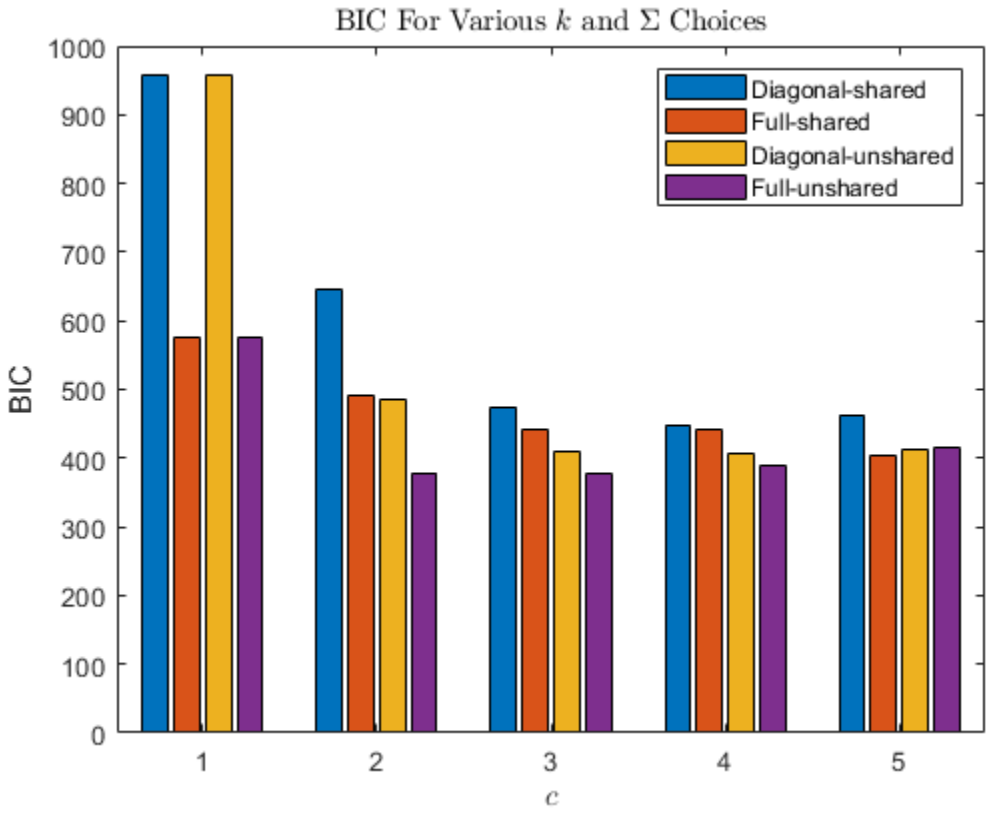
Plot separate bar charts to compare the AIC and BIC among all fits. Group the bars by k.

```
figure;
bar(reshape(aic,nK,nSigma*nSC));
```

```
title('AIC For Various $k$ and $\Sigma$ Choices','Interpreter','latex');
xlabel('$k$','Interpreter','Latex');
ylabel('AIC');
legend({'Diagonal-shared','Full-shared','Diagonal-unshared',...
    'Full-unshared'});

figure;
bar(reshape(bic,nK,nSigma*nSC));
title('BIC For Various $k$ and $\Sigma$ Choices','Interpreter','latex');
xlabel('$c$','Interpreter','Latex');
ylabel('BIC');
legend({'Diagonal-shared','Full-shared','Diagonal-unshared',...
    'Full-unshared'});
```





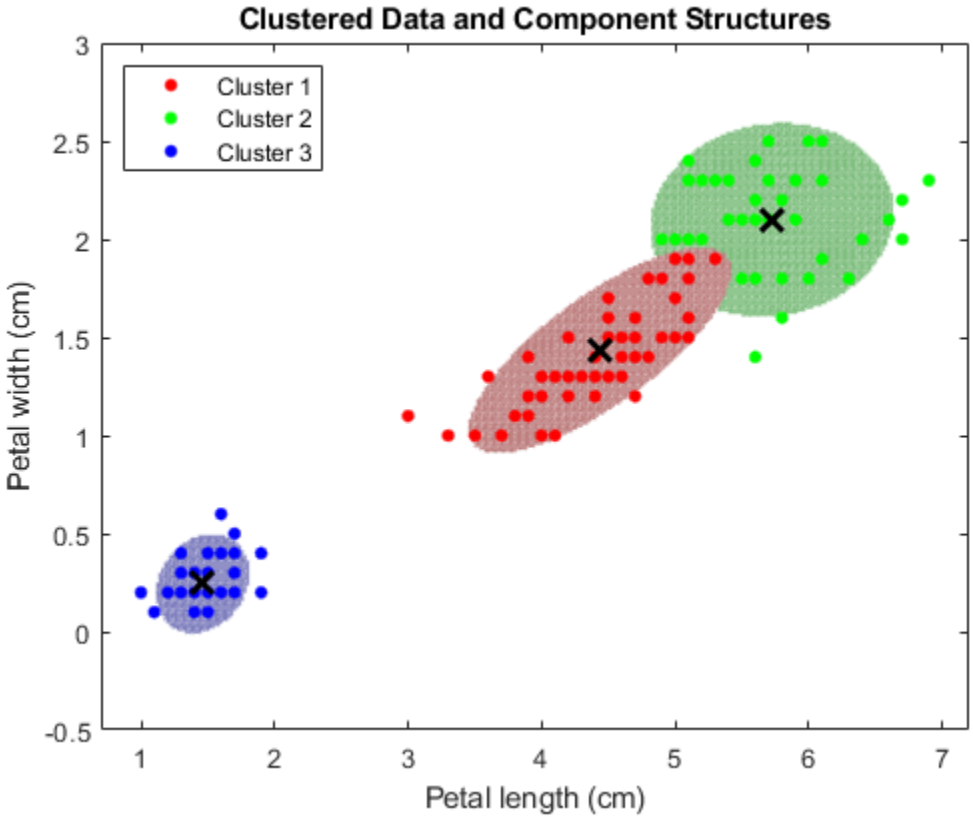
According to the AIC and BIC values, the best model has 3 components and a full, unshared covariance matrix structure.

Cluster the training data using the best fitting model. Plot the clustered data and the component ellipses.

```
gmBest = gm{3,2,2};
clusterX = cluster(gmBest,X);
kGMM = gmBest.NumComponents;
d = 500;
x1 = linspace(min(X(:,1)) - 2,max(X(:,1)) + 2,d);
x2 = linspace(min(X(:,2)) - 2,max(X(:,2)) + 2,d);
[x1grid,x2grid] = meshgrid(x1,x2);
X0 = [x1grid(:) x2grid(:)];
mahalDist = mahal(gmBest,X0);
threshold = sqrt(chi2inv(0.99,2));

figure;
h1 = gscatter(X(:,1),X(:,2),clusterX);
hold on;
for j = 1:kGMM;
    idx = mahalDist(:,j)<=threshold;
    Color = h1(j).Color*0.75 + -0.5*(h1(j).Color - 1);
    h2 = plot(X0(idx,1),X0(idx,2),'.','Color',Color,'MarkerSize',1);
    uistack(h2,'bottom');
end
h3 = plot(gmBest.mu(:,1),gmBest.mu(:,2),'kx','LineWidth',2,'MarkerSize',10);
```

```
title('Clustered Data and Component Structures');
xlabel('Petal length (cm)');
ylabel('Petal width (cm)');
legend(h1,'Cluster 1','Cluster 2','Cluster 3','Location','NorthWest');
hold off
```



This data set includes labels. Determine how well `gmBest` clusters the data by comparing each prediction to the true labels.

```
species = categorical(species);
Y = zeros(n,1);
Y(species == 'versicolor') = 1;
Y(species == 'virginica') = 2;
Y(species == 'setosa') = 3;

miscluster = Y ~= clusterX;
clusterError = sum(miscluster)/n
```

```
clusterError =

    0.0800
```

The best fitting GMM groups 8% of the observations into the wrong cluster.

`cluster` does not always preserve cluster order. That is, if you cluster several fitted `gmdistribution` models, `cluster` might assign different cluster labels for similar components.

Cluster Evaluation

This example shows how to identify clusters in Fisher's iris data.

Load Fisher's iris data set.

```
load fisheriris
X = meas;
y = categorical(species);
```

`X` is a numeric matrix that contains two petal measurements for 150 irises. `Y` is a cell array of character vectors that contains the corresponding iris species.

Evaluate multiple clusters from 1 to 10.

```
eva = evalclusters(X,'kmeans','CalinskiHarabasz','KList',1:10)
```

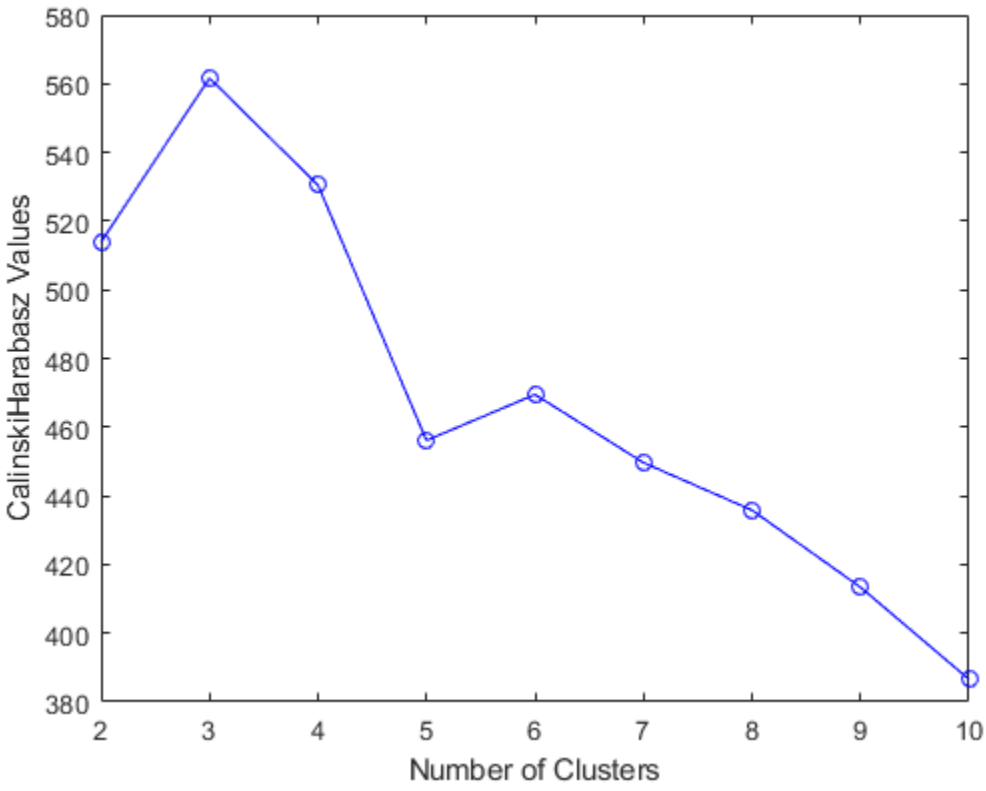
```
eva =
  CalinskiHarabaszEvaluation with properties:

    NumObservations: 150
         InspectedK: [1 2 3 4 5 6 7 8 9 10]
    CriterionValues: [1x10 double]
           OptimalK: 1
```

The `OptimalK` value indicates that, based on the Calinski-Harabasz criterion, the optimal number of clusters is three.

Visualize `eva` to see the results for each number of clusters.

```
plot(eva)
```



Most clustering algorithms need prior knowledge of the number of clusters. When this information is not available, use cluster evaluation techniques to determine the number of clusters present in the data based on a specified metric.

Three clusters is consistent with the three species in the data.

```
categories(y)
```

```
ans = 3x1 cell
    {'setosa'    }
    {'versicolor'}
    {'virginica' }
```

Compute a nonnegative rank-two approximation of the data for visualization purposes.

```
Xred = nnmf(X,2);
```

The original features are reduced to two features. Since none of the features are negative, `nnmf` also guarantees that the features are nonnegative.

Confirm the three clusters visually using a scatter plot.

```
gscatter(Xred(:,1),Xred(:,2),y)
xlabel('Column 1')
ylabel('Column 2')

Cluster Analysis

This example shows how to examine similarities and dissimilarities of observations or objects using cluster analysis in Statistics and Machine Learning Toolbox™. Data often fall naturally into groups (or clusters) of observations, where the characteristics of objects in the same cluster are similar and the characteristics of objects in different clusters are dissimilar.

K-Means and Hierarchical Clustering

The Statistics and Machine Learning Toolbox includes functions to perform K-means clustering and hierarchical clustering.

K-means clustering is a partitioning method that treats observations in your data as objects having locations and distances from each other. It partitions the objects into K mutually exclusive clusters, such that objects within each cluster are as close to each other as possible, and as far from objects in other clusters as possible. Each cluster is characterized by its centroid, or center point. Of course, the distances used in clustering often do not represent spatial distances.

Hierarchical clustering is a way to investigate grouping in your data, simultaneously over a variety of scales of distance, by creating a cluster tree. The tree is not a single set of clusters, as in K-Means, but rather a multi-level hierarchy, where clusters at one level are joined as clusters at the next higher level. This allows you to decide what scale or level of clustering is most appropriate in your application.

Some of the functions used in this example call MATLAB® built-in random number generation functions. To duplicate the exact results shown in this example, you should execute the command below, to set the random number generator to a known state. If you do not set the state, your results may differ in trivial ways, for example, you may see clusters numbered in a different order. There is also a chance that a suboptimal cluster solution may result (the example includes a discussion of suboptimal solutions, including ways to avoid them).

```
rng(6,'twister')
```

Fisher's Iris Data

In the 1920's, botanists collected measurements on the sepal length, sepal width, petal length, and petal width of 150 iris specimens, 50 from each of three species. The measurements became known as Fisher's iris data set.

Each observation in this data set comes from a known species, and so there is already an obvious way to group the data. For the moment, we will ignore the species information and cluster the data using only the raw measurements. When we are done, we can compare the resulting clusters to the actual species, to see if the three types of iris possess distinct characteristics.

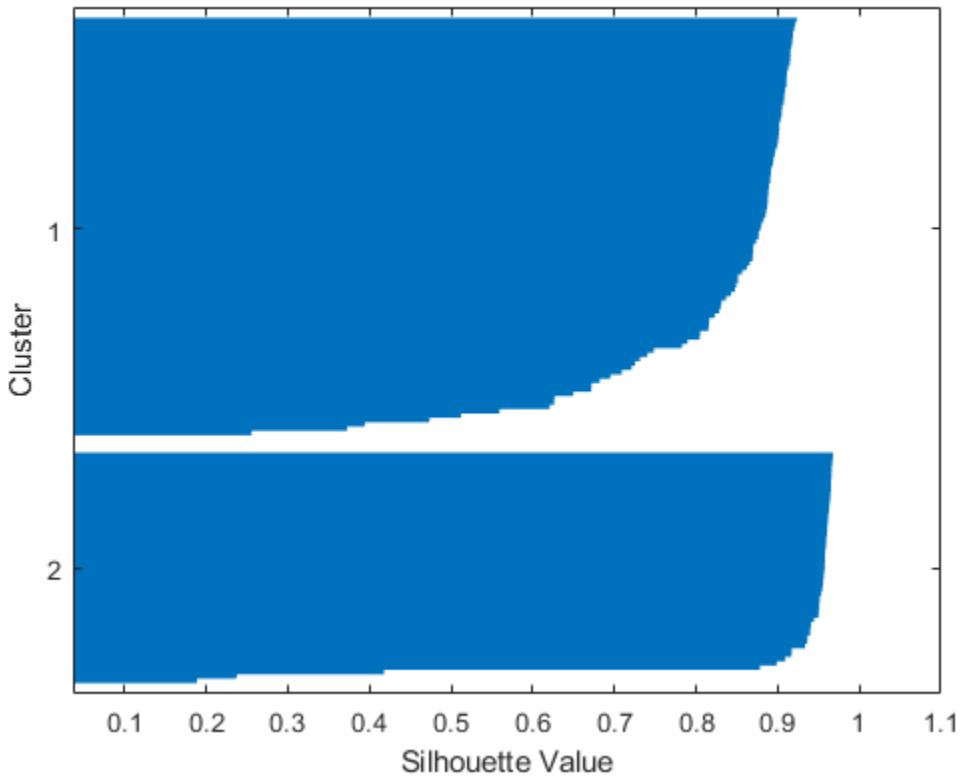
Clustering Fisher's Iris Data Using K-Means Clustering

The function `kmeans` performs K-Means clustering, using an iterative algorithm that assigns objects to clusters so that the sum of distances from each object to its cluster centroid, over all clusters, is a minimum. Used on Fisher's iris data, it will find the natural groupings among iris specimens, based on their sepal and petal measurements. With K-means clustering, you must specify the number of clusters that you want to create.

First, load the data and call `kmeans` with the desired number of clusters set to 2, and using squared Euclidean distance. To get an idea of how well-separated the resulting clusters are, you can make a

silhouette plot. The silhouette plot displays a measure of how close each point in one cluster is to points in the neighboring clusters.

```
load fisheriris
[cidx2,cmeans2] = kmeans(meas,2,'dist','sqeuclidean');
[silh2,h] = silhouette(meas,cidx2,'sqeuclidean');
```

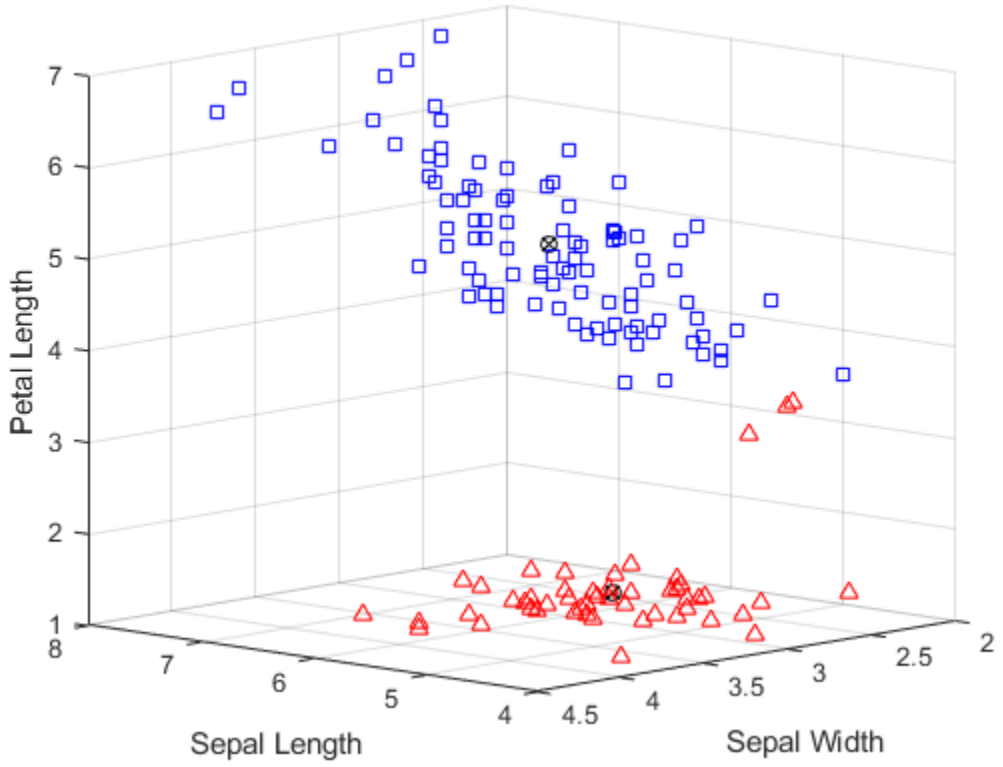


From the silhouette plot, you can see that most points in both clusters have a large silhouette value, greater than 0.8, indicating that those points are well-separated from neighboring clusters. However, each cluster also contains a few points with low silhouette values, indicating that they are nearby to points from other clusters.

It turns out that the fourth measurement in these data, the petal width, is highly correlated with the third measurement, the petal length, and so a 3-D plot of the first three measurements gives a good representation of the data, without resorting to four dimensions. If you plot the data, using different symbols for each cluster created by `kmeans`, you can identify the points with small silhouette values as those points that are close to points from other clusters.

```
ptsymb = {'bs','r^','md','go','c+'};
for i = 1:2
    clust = find(cidx2==i);
    plot3(meas(clust,1),meas(clust,2),meas(clust,3),ptsymb{i});
    hold on
end
plot3(cmeans2(:,1),cmeans2(:,2),cmeans2(:,3),'ko');
plot3(cmeans2(:,1),cmeans2(:,2),cmeans2(:,3),'kx');
hold off
```

```
xlabel('Sepal Length');
ylabel('Sepal Width');
zlabel('Petal Length');
view(-137,10);
grid on
```



The centroids of each cluster are plotted using circled X's. Three of the points from the lower cluster (plotted with triangles) are very close to points from the upper cluster (plotted with squares). Because the upper cluster is so spread out, those three points are closer to the centroid of the lower cluster than to that of the upper cluster, even though the points are separated from the bulk of the points in their own cluster by a gap. Because K-means clustering only considers distances, and not densities, this kind of result can occur.

You can increase the number of clusters to see if `kmeans` can find further grouping structure in the data. This time, use the optional `'Display'` name-value pair argument to print out information about each iteration in the clustering algorithm.

```
[cidx3,cmeans3] = kmeans(meas,3,'Display','iter');
```

```
  iter     phase         num            sum
     1         1         150        146.424
     2         1           5        144.333
     3         1           4        143.924
     4         1           3         143.61
     5         1           1        143.542
     6         1           2        143.414
     7         1           2        143.023
```

```
     8         1           2         142.823
     9         1           1         142.786
    10         1           1         142.754
Best total sum of distances = 142.754
```

At each iteration, the `kmeans` algorithm (see “Algorithms” on page 33-3330) reassigns points among clusters to decrease the sum of point-to-centroid distances, and then recomputes cluster centroids for the new cluster assignments. Notice that the total sum of distances and the number of reassignments decrease at each iteration until the algorithm reaches a minimum. The algorithm used in `kmeans` consists of two phases. In the example here, the second phase of the algorithm did not make any reassignments, indicating that the first phase reached a minimum after only a few iterations.

By default, `kmeans` begins the clustering process using a randomly selected set of initial centroid locations. The `kmeans` algorithm can converge to a solution that is a local minimum; that is, `kmeans` can partition the data such that moving any single point to a different cluster increases the total sum of distances. However, as with many other types of numerical minimizations, the solution that `kmeans` reaches sometimes depends on the starting points. Therefore, other solutions (local minima) that have a lower total sum of distances can exist for the data. You can use the optional `'Replicates'` name-value pair argument to test different solutions. When you specify more than one replicate, `kmeans` repeats the clustering process starting from different randomly selected centroids for each replicate. `kmeans` then returns the solution with the lowest total sum of distances among all the replicates.

```
[cidx3,cmeans3,sumd3] = kmeans(meas,3,'replicates',5,'display','final');
```

```
Replicate 1, 9 iterations, total sum of distances = 78.8557.
Replicate 2, 10 iterations, total sum of distances = 78.8557.
Replicate 3, 8 iterations, total sum of distances = 78.8557.
Replicate 4, 8 iterations, total sum of distances = 78.8557.
Replicate 5, 1 iterations, total sum of distances = 78.8514.
Best total sum of distances = 78.8514
```

The output shows that, even for this relatively simple problem, non-global minima do exist. Each of these five replicates began from a different set of initial centroids. Depending on where it started from, `kmeans` reached one of two different solutions. However, the final solution that `kmeans` returns is the one with the lowest total sum of distances, over all replicates. The third output argument contains the sum of distances within each cluster for that best solution.

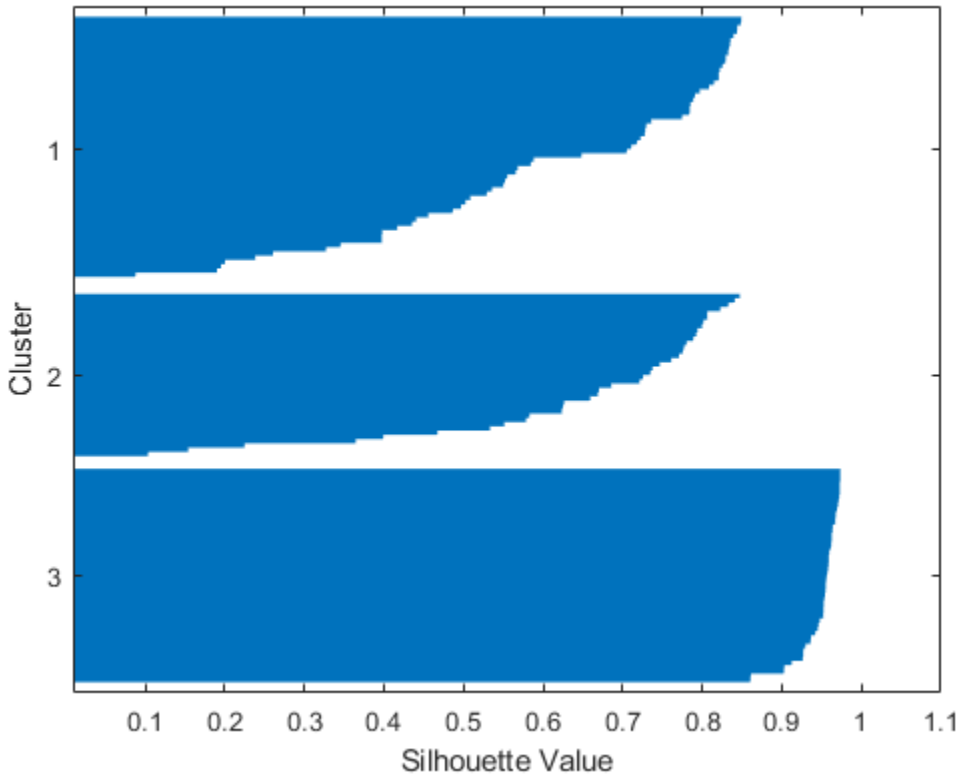
```
sum(sumd3)
```

```
ans =

   78.8514
```

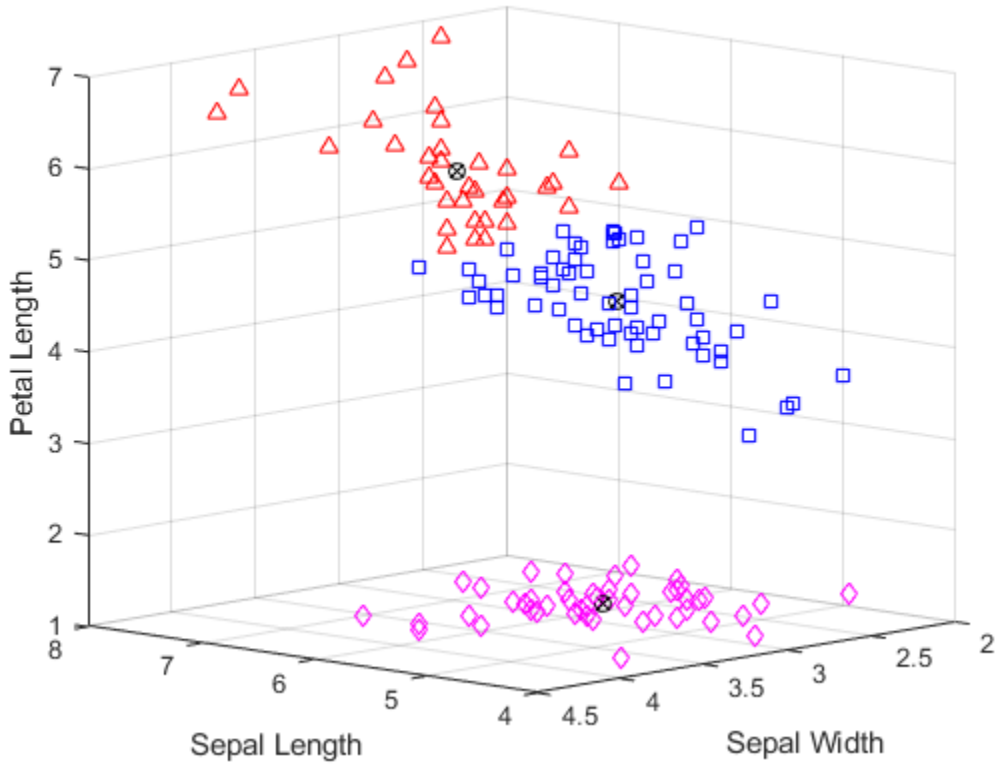
A silhouette plot for this three-cluster solution indicates that there is one cluster that is well-separated, but that the other two clusters are not very distinct.

```
[silh3,h] = silhouette(meas,cidx3,'sqeuclidean');
```



Again, you can plot the raw data to see how `kmeans` has assigned the points to clusters.

```
for i = 1:3
    clust = find(cidx3==i);
    plot3(meas(clust,1),meas(clust,2),meas(clust,3),ptsymb{i});
    hold on
end
plot3(cmeans3(:,1),cmeans3(:,2),cmeans3(:,3),'ko');
plot3(cmeans3(:,1),cmeans3(:,2),cmeans3(:,3),'kx');
hold off
xlabel('Sepal Length');
ylabel('Sepal Width');
zlabel('Petal Length');
view(-137,10);
grid on
```



You can see that `kmeans` has split the upper cluster from the two-cluster solution, and that those two clusters are very close to each other. Depending on what you intend to do with these data after clustering them, this three-cluster solution may be more or less useful than the previous, two-cluster, solution. The first output argument from `silhouette` contains the silhouette values for each point, which you can use to compare the two solutions quantitatively. The average silhouette value was larger for the two-cluster solution, indicating that it is a better answer purely from the point of view of creating distinct clusters.

```
[mean(silh2) mean(silh3)]
```

```
ans =

    0.8504    0.7357
```

You can also cluster these data using a different distance. The cosine distance might make sense for these data because it would ignore absolute sizes of the measurements, and only consider their relative sizes. Thus, two flowers that were different sizes, but which had similarly shaped petals and sepals, might not be close with respect to squared Euclidean distance, but would be close with respect to cosine distance.

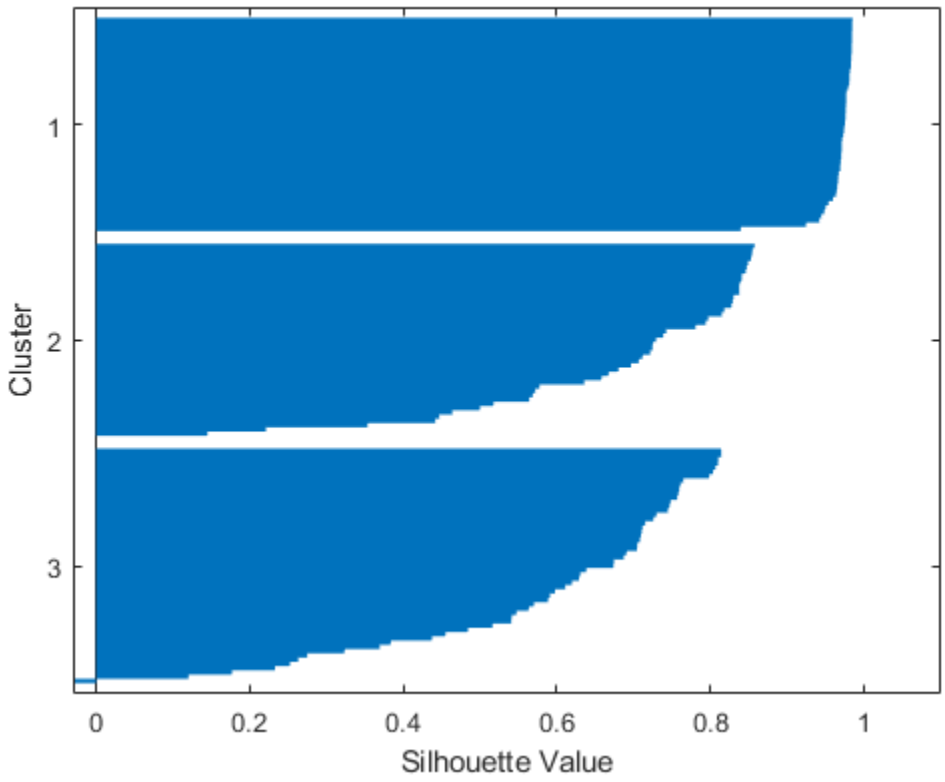
```
[cidxCos,cmeansCos] = kmeans(meas,3,'dist','cos');
```

From the silhouette plot, these clusters appear to be only slightly better separated than those found using squared Euclidean distance.

```
[silhCos,h] = silhouette(meas,cidxCos,'cos');
[mean(silh2) mean(silh3) mean(silhCos)]
```

```
ans =

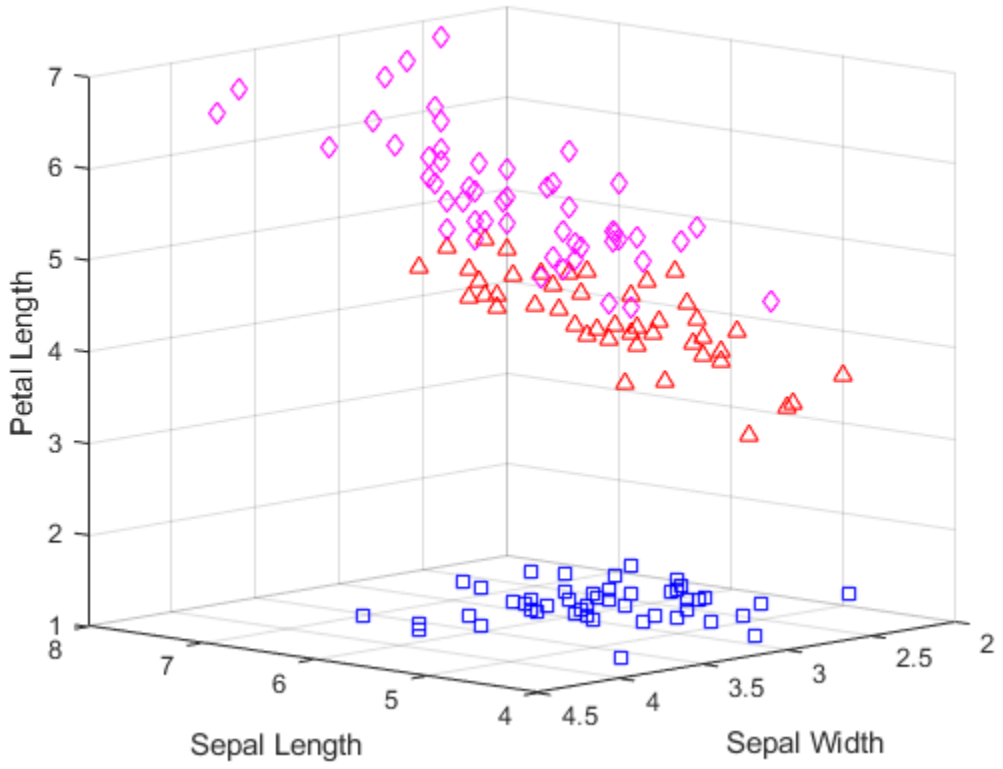
    0.8504    0.7357    0.7491
```



Notice that the order of the clusters is different than in the previous silhouette plot. This is because `kmeans` chooses initial cluster assignments at random.

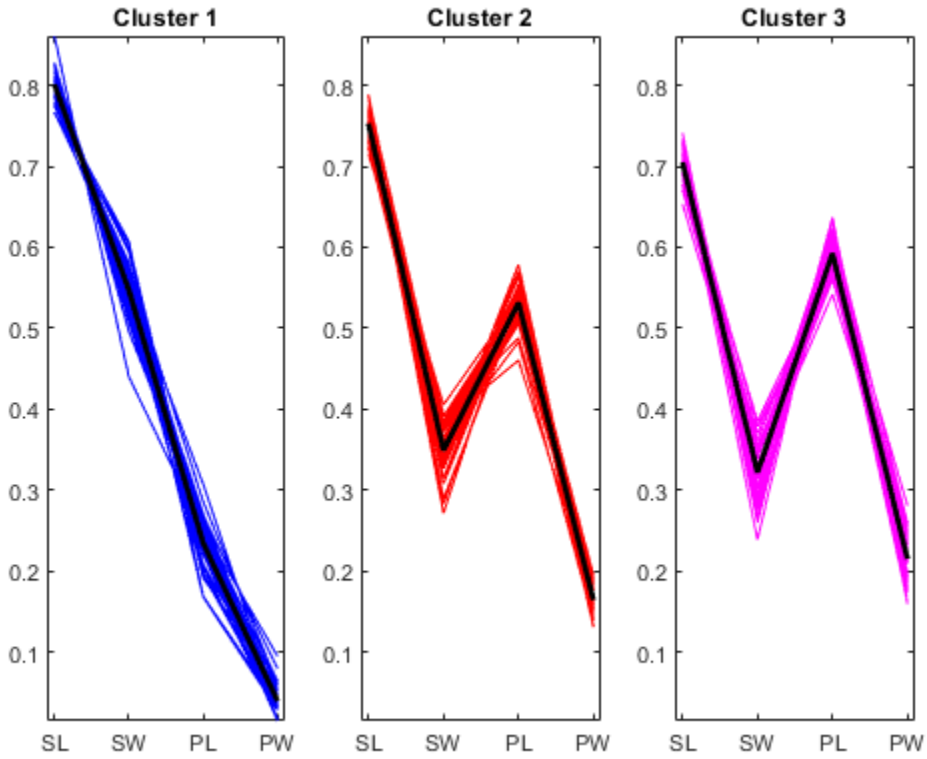
By plotting the raw data, you can see the differences in the cluster shapes created using the two different distances. The two solutions are similar, but the two upper clusters are elongated in the direction of the origin when using cosine distance.

```
for i = 1:3
    clust = find(cidxCos==i);
    plot3(meas(clust,1),meas(clust,2),meas(clust,3),ptsymb{i});
    hold on
end
hold off
xlabel('Sepal Length');
ylabel('Sepal Width');
zlabel('Petal Length');
view(-137,10);
grid on
```



This plot does not include the cluster centroids, because a centroid with respect to the cosine distance corresponds to a half-line from the origin in the space of the raw data. However, you can make a parallel coordinate plot of the normalized data points to visualize the differences between cluster centroids.

```
lnsymb = {'b-','r-','m-'};
names = {'SL','SW','PL','PW'};
meas0 = meas ./ repmat(sqrt(sum(meas.^2,2)),1,4);
ymin = min(min(meas0));
ymax = max(max(meas0));
for i = 1:3
    subplot(1,3,i);
    plot(meas0(cidxCos==i,:)',lnsymb{i});
    hold on;
    plot(cmeansCos(i,:)','k-','LineWidth',2);
    hold off;
    title(sprintf('Cluster %d',i));
    xlim([.9, 4.1]);
    ylim([ymin, ymax]);
    h_gca = gca;
    h_gca.XTick = 1:4;
    h_gca.XTickLabel = names;
end
```

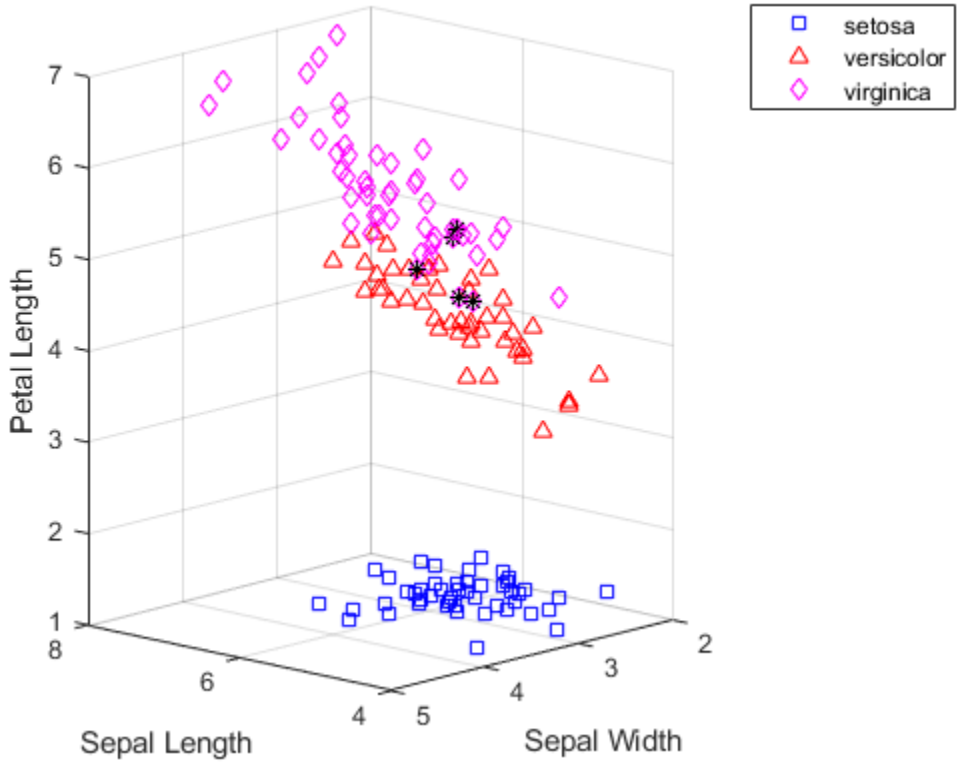


It's clear from this plot that specimens from each of the three clusters have distinctly different relative sizes of petals and sepals on average. The first cluster has petals that are strictly smaller than their sepals. The second two clusters' petals and sepals overlap in size, however, those from the third cluster overlap more than the second. You can also see that the second and third clusters include some specimens which are very similar to each other.

Because we know the species of each observation in the data, you can compare the clusters discovered by `kmeans` to the actual species, to see if the three species have discernibly different physical characteristics. In fact, as the following plot shows, the clusters created using cosine distance differ from the species groups for only five of the flowers. Those five points, plotted with stars, are all near the boundary of the upper two clusters.

```
subplot(1,1,1);
for i = 1:3
    clust = find(cidxCos==i);
    plot3(meas(clust,1),meas(clust,2),meas(clust,3),ptsymb{i});
    hold on
end
xlabel('Sepal Length');
ylabel('Sepal Width');
zlabel('Petal Length');
view(-137,10);
grid on
sidx = grp2idx(species);
miss = find(cidxCos ~= sidx);
plot3(meas(miss,1),meas(miss,2),meas(miss,3),'k*');
```

```
legend({'setosa','versicolor','virginica'});
hold off
```



Clustering Fisher's Iris Data Using Hierarchical Clustering

K-Means clustering produced a single partition of the iris data, but you might also want to investigate different scales of grouping in your data. Hierarchical clustering lets you do just that, by creating a hierarchical tree of clusters.

First, create a cluster tree using distances between observations in the iris data. Begin by using Euclidean distance.

```
eucD = pdist(meas,'euclidean');
clustTreeEuc = linkage(eucD,'average');
```

The cophenetic correlation is one way to verify that the cluster tree is consistent with the original distances. Large values indicate that the tree fits the distances well, in the sense that pairwise linkages between observations correlate with their actual pairwise distances. This tree seems to be a fairly good fit to the distances.

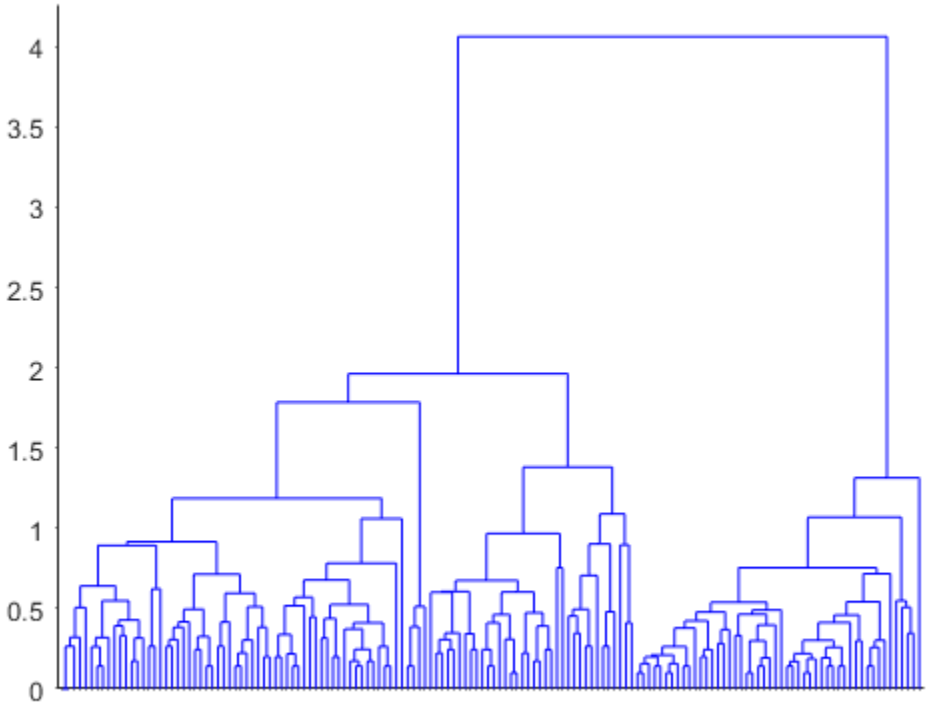
```
cophenet(clustTreeEuc,eucD)
```

```
ans =

    0.8770
```

To visualize the hierarchy of clusters, you can plot a dendrogram.

```
[h,nodes] = dendrogram(clustTreeEuc,0);
h_gca = gca;
h_gca.TickDir = 'out';
h_gca.TickLength = [.002 0];
h_gca.XTickLabel = [];
```



The root node in this tree is much higher than the remaining nodes, confirming what you saw from K-Means clustering: there are two large, distinct groups of observations. Within each of those two groups, you can see that lower levels of groups emerge as you consider smaller and smaller scales in distance. There are many different levels of groups, of different sizes, and at different degrees of distinctness.

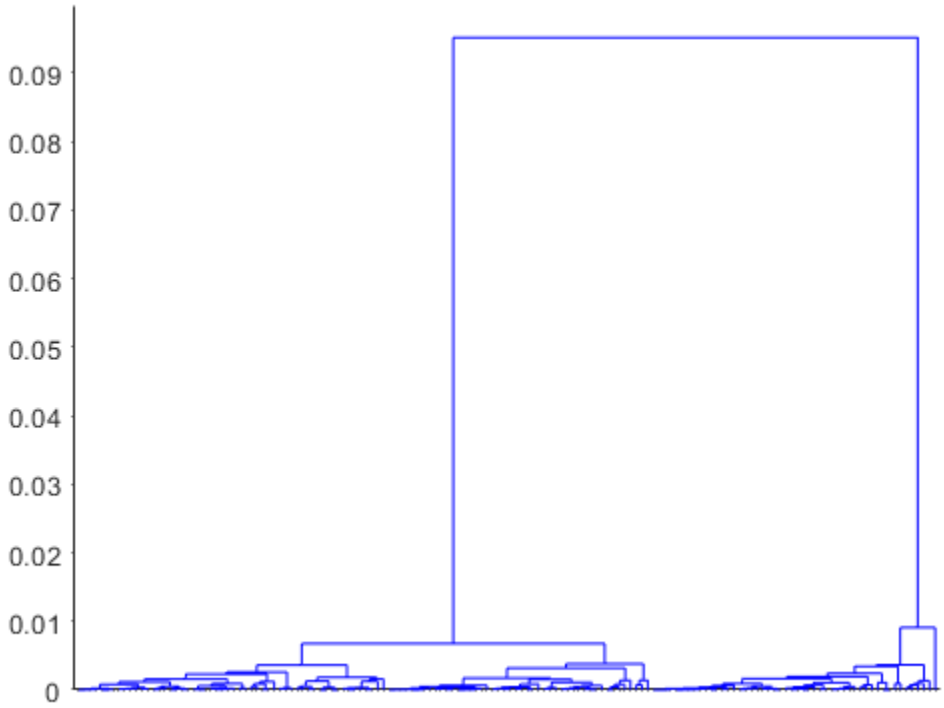
Based on the results from K-Means clustering, cosine might also be a good choice of distance measure. The resulting hierarchical tree is quite different, suggesting a very different way to look at group structure in the iris data.

```
cosD = pdist(meas,'cosine');
clustTreeCos = linkage(cosD,'average');
cophenet(clustTreeCos,cosD)
```

```
ans =

    0.9360
```

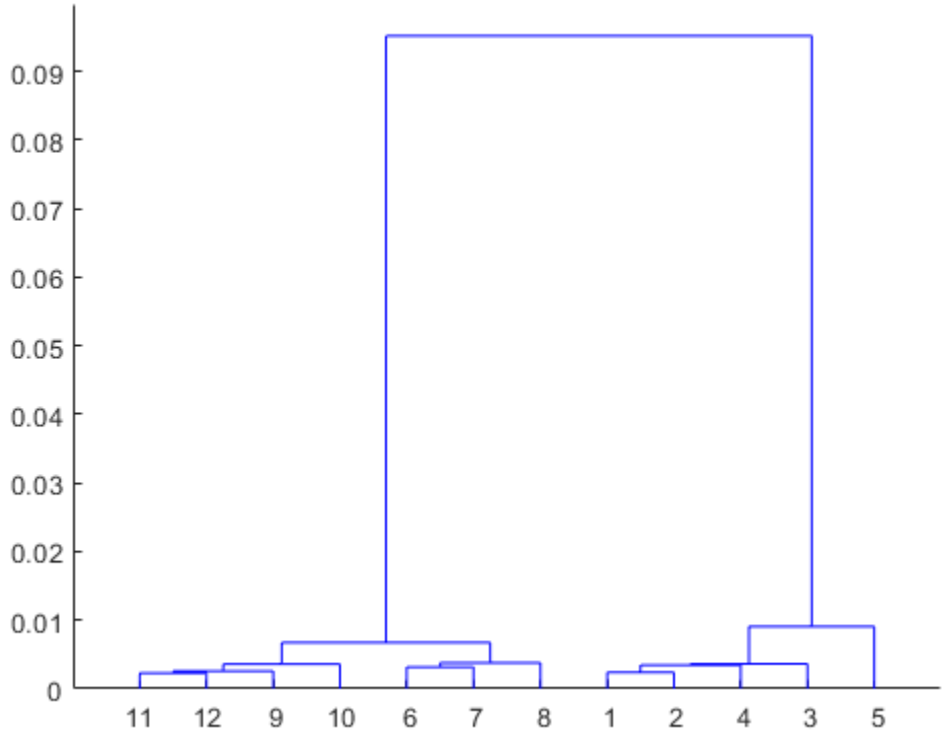
```
[h,nodes] = dendrogram(clustTreeCos,0);
h_gca = gca;
h_gca.TickDir = 'out';
h_gca.TickLength = [.002 0];
h_gca.XTickLabel = [];
```



The highest level of this tree separates iris specimens into two very distinct groups. The dendrogram shows that, with respect to cosine distance, the within-group differences are much smaller relative to the between-group differences than was the case for Euclidean distance. This is exactly what you would expect for these data, since the cosine distance computes a zero pairwise distance for objects that are in the same "direction" from the origin.

With 150 observations, the plot is cluttered, but you can make a simplified dendrogram that does not display the very lowest levels of the tree.

```
[h,nodes] = dendrogram(clustTreeCos,12);
```



The three highest nodes in this tree separate out three equally-sized groups, plus a single specimen (labeled as leaf node 5) that is not near any others.

```
[sum(ismember(nodes,[11 12 9 10])) sum(ismember(nodes,[6 7 8])) ...
                  sum(ismember(nodes,[1 2 4 3])) sum(nodes==5)]
```

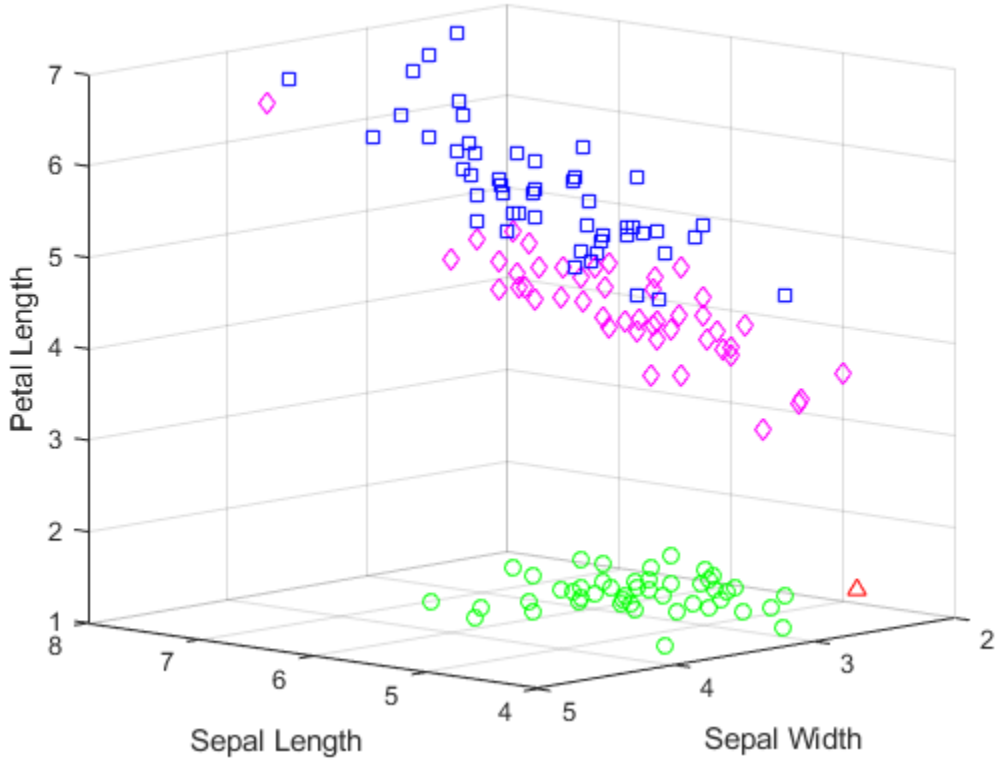
```
ans =

    54    46    49     1
```

For many purposes, the dendrogram might be a sufficient result. However, you can go one step further, and use the `cluster` function to cut the tree and explicitly partition observations into specific clusters, as with K-Means. Using the hierarchy from the cosine distance to create clusters, specify a linkage height that will cut the tree below the three highest nodes, and create four clusters, then plot the clustered raw data.

```
hidx = cluster(clustTreeCos,'criterion','distance','cutoff',.006);
for i = 1:5
    clust = find(hidx==i);
    plot3(meas(clust,1),meas(clust,2),meas(clust,3),ptsymb{i});
    hold on
end
hold off
xlabel('Sepal Length');
ylabel('Sepal Width');
```

```
zlabel('Petal Length');
view(-137,10);
grid on
```



This plot shows that the results from hierarchical clustering with cosine distance are qualitatively similar to results from K-Means, using three clusters. However, creating a hierarchical cluster tree allows you to visualize, all at once, what would require considerable experimentation with different values for K in K-Means clustering.

Hierarchical clustering also allows you to experiment with different linkages. For example, clustering the iris data with single linkage, which tends to link together objects over larger distances than average distance does, gives a very different interpretation of the structure in the data.

```
clustTreeSng = linkage(eucD,'single');
[h,nodes] = dendrogram(clustTreeSng,0);
h_gca = gca;
h_gca.TickDir = 'out';
h_gca.TickLength = [.002 0];
h_gca.XTickLabel = [];
```

Parametric Classification

Parametric Classification

Models of data with a categorical response are called classifiers. A classifier is built from training data, for which classifications are known. The classifier assigns new test data to one of the categorical levels of the response.

Parametric methods, like “Discriminant Analysis Classification” on page 20-2, fit a parametric model to the training data and interpolate to classify test data.

Nonparametric methods, like classification and regression trees, use other means to determine classifications.

Performance Curves

In this section...

Introduction to Performance Curves

After a classification algorithm such as `ClassificationNaiveBayes` or `TreeBagger` has trained on data, you may want to examine the performance of the algorithm on a specific test dataset. One common way of doing this would be to compute a gross measure of performance such as quadratic loss or accuracy, averaged over the entire test dataset.

What are ROC Curves?

You may want to inspect the classifier performance more closely, for example, by plotting a Receiver Operating Characteristic (ROC) curve. By definition, a ROC curve [1,2] shows true positive rate versus false positive rate (equivalently, sensitivity versus 1–specificity) for different thresholds of the classifier output. You can use it, for example, to find the threshold that maximizes the classification accuracy or to assess, in more broad terms, how the classifier performs in the regions of high sensitivity and high specificity.

Evaluate Classifier Performance Using perfcurve

`perfcurve` computes measures for a plot of classifier performance. You can use this utility to evaluate classifier performance on test data after you train the classifier. Various measures such as mean squared error, classification error, or exponential loss can summarize the predictive power of a classifier in a single number. However, a performance curve offers more information as it lets you explore the classifier performance across a range of thresholds on its output.

You can use `perfcurve` with any classifier or, more broadly, with any method that returns a numeric score for an instance of input data. By convention adopted here,

- A high score returned by a classifier for any given instance signifies that the instance is likely from the positive class.
- A low score signifies that the instance is likely from the negative classes.

For some classifiers, you can interpret the score as the posterior probability of observing an instance of the positive class at point `X`. An example of such a score is the fraction of positive observations in a leaf of a decision tree. In this case, scores fall into the range from 0 to 1 and scores from positive and negative classes add up to unity. Other methods can return scores ranging between minus and plus infinity, without any obvious mapping from the score to the posterior class probability.

`perfcurve` does not impose any requirements on the input score range. Because of this lack of normalization, you can use `perfcurve` to process scores returned by any classification, regression, or fit method. `perfcurve` does not make any assumptions about the nature of input scores or relationships between the scores for different classes. As an example, consider a problem with three classes, `A`, `B`, and `C`, and assume that the scores returned by some classifier for two instances are as follows:

	A	B	C
instance 1	0.4	0.5	0.1
instance 2	0.4	0.1	0.5

If you want to compute a performance curve for separation of classes `A` and `B`, with `C` ignored, you need to address the ambiguity in selecting `A` over `B`. You could opt to use the score ratio, `s(A)/s(B)`, or score difference, `s(A)-s(B)`; this choice could depend on the nature of these scores and their normalization. `perfcurve` always takes one score per instance. If you only supply scores for class `A`, `perfcurve` does not distinguish between observations 1 and 2. The performance curve in this case may not be optimal.

`perfcurve` is intended for use with classifiers that return scores, not those that return only predicted classes. As a counter-example, consider a decision tree that returns only hard classification labels, 0 or 1, for data with two classes. In this case, the performance curve reduces to a single point because classified instances can be split into positive and negative categories in one way only.

For input, `perfcurve` takes true class labels for some data and scores assigned by a classifier to these data. By default, this utility computes a Receiver Operating Characteristic (ROC) curve and returns values of 1–specificity, or false positive rate, for `X` and sensitivity, or true positive rate, for `Y`. You can choose other criteria for `X` and `Y` by selecting one out of several provided criteria or specifying an arbitrary criterion through an anonymous function. You can display the computed performance curve using `plot(X,Y)`.

`perfcurve` can compute values for various criteria to plot either on the *x*- or the *y*-axis. All such criteria are described by a 2-by-2 confusion matrix, a 2-by-2 cost matrix, and a 2-by-1 vector of scales applied to class counts.

The `confusionchart` matrix, `C`, is defined as

$$\begin{pmatrix} TP & FN \\ FP & TN \end{pmatrix}$$

where

- *P* stands for "positive".
- *N* stands for "negative".
- *T* stands for "true".
- *F* stands for "false".

For example, the first row of the confusion matrix defines how the classifier identifies instances of the positive class: `C(1,1)` is the count of correctly identified positive instances and `C(1,2)` is the count of positive instances misidentified as negative.

The cost matrix defines the cost of misclassification for each category:

$$\begin{pmatrix} Cost(P|P) & Cost(N|P) \\ Cost(P|N) & Cost(N|N) \end{pmatrix}$$

where `Cost(I|J)` is the cost of assigning an instance of class `J` to class `I`. Usually `Cost(I|J)=0` for `I=J`. For flexibility, `perfcurve` allows you to specify nonzero costs for correct classification as well.

The two scales include prior information about class probabilities. `perfcurve` computes these scales by taking `scale(P)=prior(P)*N` and `scale(N)=prior(N)*P` and normalizing the sum `scale(P)`

+scale(N) to 1. P=TP+FN and N=TN+FP are the total instance counts in the positive and negative class, respectively. The function then applies the scales as multiplicative factors to the counts from the corresponding class: perfcurve multiplies counts from the positive class by scale(P) and counts from the negative class by scale(N). Consider, for example, computation of positive predictive value, PPV = TP/(TP+FP). TP counts come from the positive class and FP counts come from the negative class. Therefore, you need to scale TP by scale(P) and FP by scale(N), and the modified formula for PPV with prior probabilities taken into account is now:

$$PPV = \frac{scale(P)*TP}{scale(P)*TP + scale(N)*FP}$$

If all scores in the data are above a certain threshold, perfcurve classifies all instances as 'positive'. This means that TP is the total number of instances in the positive class and FP is the total number of instances in the negative class. In this case, PPV is simply given by the prior:

$$PPV = \frac{prior(P)}{prior(P) + prior(N)}$$

The perfcurve function returns two vectors, X and Y, of performance measures. Each measure is some function of confusion, cost, and scale values. You can request specific measures by name or provide a function handle to compute a custom measure. The function you provide should take confusion, cost, and scale as its three inputs and return a vector of output values.

The criterion for X must be a monotone function of the positive classification count, or equivalently, threshold for the supplied scores. If perfcurve cannot perform a one-to-one mapping between values of the X criterion and score thresholds, it exits with an error message.

By default, perfcurve computes values of the X and Y criteria for all possible score thresholds. Alternatively, it can compute a reduced number of specific X values supplied as an input argument. In either case, for M requested values, perfcurve computes M+1 values for X and Y. The first value out of these M+1 values is special. perfcurve computes it by setting the TP instance count to zero and setting TN to the total count in the negative class. This value corresponds to the 'reject all' threshold. On a standard ROC curve, this translates into an extra point placed at (0,0).

If there are NaN values among input scores, perfcurve can process them in either of two ways:

- It can discard rows with NaN scores.
- It can add them to false classification counts in the respective class.

That is, for any threshold, instances with NaN scores from the positive class are counted as false negative (FN), and instances with NaN scores from the negative class are counted as false positive (FP). In this case, the first value of X or Y is computed by setting TP to zero and setting TN to the total count minus the NaN count in the negative class. For illustration, consider an example with two rows in the positive and two rows in the negative class, each pair having a NaN score:

Class	Score
Negative	0.2
Negative	NaN
Positive	0.7
Positive	NaN

If you discard rows with NaN scores, then as the score cutoff varies, perfcurve computes performance measures as in the following table. For example, a cutoff of 0.5 corresponds to the middle row where rows 1 and 3 are classified correctly, and rows 2 and 4 are omitted.

TP	FN	FP	TN
0	1	0	1
1	0	0	1
1	0	1	0

If you add rows with NaN scores to the false category in their respective classes, perfcurve computes performance measures as in the following table. For example, a cutoff of 0.5 corresponds to the middle row where now rows 2 and 4 are counted as incorrectly classified. Notice that only the FN and FP columns differ between these two tables.

TP	FN	FP	TN
0	2	1	1
1	1	1	1
1	1	2	0

For data with three or more classes, perfcurve takes one positive class and a list of negative classes for input. The function computes the X and Y values using counts in the positive class to estimate TP and FN, and using counts in all negative classes to estimate TN and FP. perfcurve can optionally compute Y values for each negative class separately and, in addition to Y, return a matrix of size M-by-C, where M is the number of elements in X or Y and C is the number of negative classes. You can use this functionality to monitor components of the negative class contribution. For example, you can plot TP counts on the X-axis and FP counts on the Y-axis. In this case, the returned matrix shows how the FP component is split across negative classes.

You can also use perfcurve to estimate confidence intervals. perfcurve computes confidence bounds using either cross-validation or bootstrap. If you supply cell arrays for labels and scores, perfcurve uses cross-validation and treats elements in the cell arrays as cross-validation folds. If you set input parameter NBoot to a positive integer, perfcurve generates nboot bootstrap replicas to compute pointwise confidence bounds.

perfcurve estimates the confidence bounds using one of two methods:

- Vertical averaging (VA) — estimate confidence bounds on Y and T at fixed values of X. Use the XVals input parameter to use this method for computing confidence bounds.
- Threshold averaging (TA) — estimate confidence bounds for X and Y at fixed thresholds for the positive class score. Use the TVals input parameter to use this method for computing confidence bounds.

To use observation weights instead of observation counts, you can use the 'Weights' parameter in your call to perfcurve. When you use this parameter, to compute X, Y and T or to compute confidence bounds by cross-validation, perfcurve uses your supplied observation weights instead of observation counts. To compute confidence bounds by bootstrap, perfcurve samples N out of N with replacement using your weights as multinomial sampling probabilities.

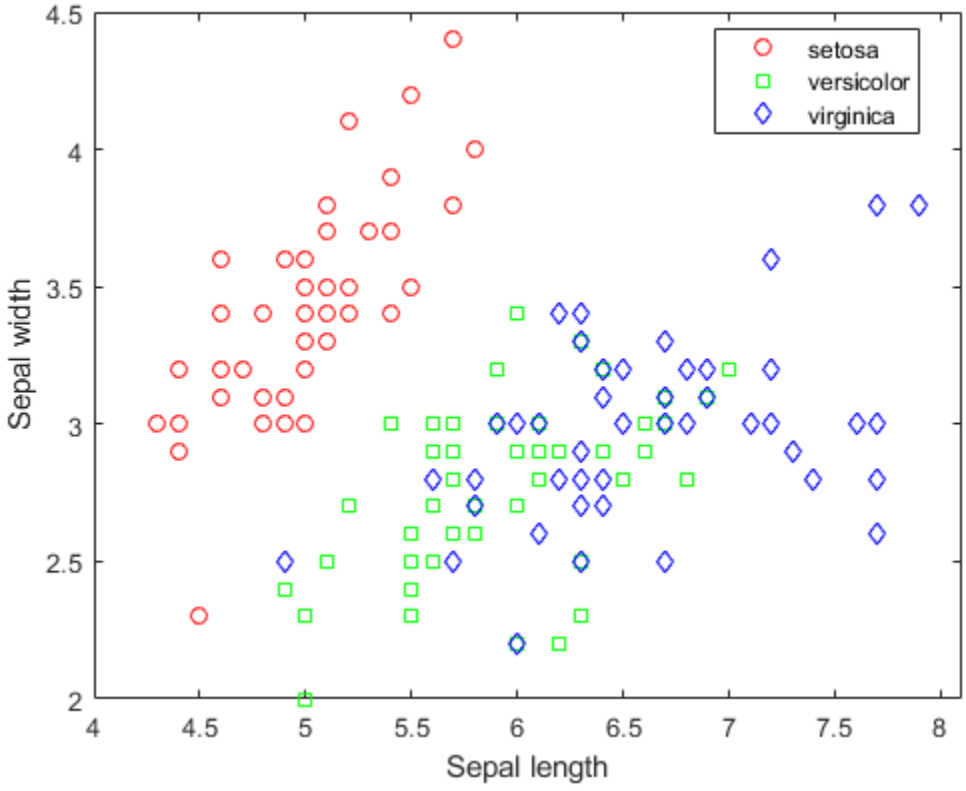
Classification

This example shows how to perform classification using discriminant analysis, naive Bayes classifiers, and decision trees. Suppose you have a data set containing observations with measurements on different variables (called predictors) and their known class labels. If you obtain predictor values for new observations, could you determine to which classes those observations probably belong? This is the problem of classification.

Fisher's Iris Data

Fisher's iris data consists of measurements on the sepal length, sepal width, petal length, and petal width for 150 iris specimens. There are 50 specimens from each of three species. Load the data and see how the sepal measurements differ between species. You can use the two columns containing sepal measurements.

```
load fisheriris
f = figure;
gscatter(meas(:,1), meas(:,2), species,'rgb','osd');
xlabel('Sepal length');
ylabel('Sepal width');
N = size(meas,1);
```



Suppose you measure a sepal and petal from an iris, and you need to determine its species on the basis of those measurements. One approach to solving this problem is known as discriminant analysis.

Linear and Quadratic Discriminant Analysis

The `fitcdiscr` function can perform classification using different types of discriminant analysis. First classify the data using the default linear discriminant analysis (LDA).

```
lda = fitcdiscr(meas(:,1:2),species);
ldaClass = resubPredict(lda);
```

The observations with known class labels are usually called the training data. Now compute the resubstitution error, which is the misclassification error (the proportion of misclassified observations) on the training set.

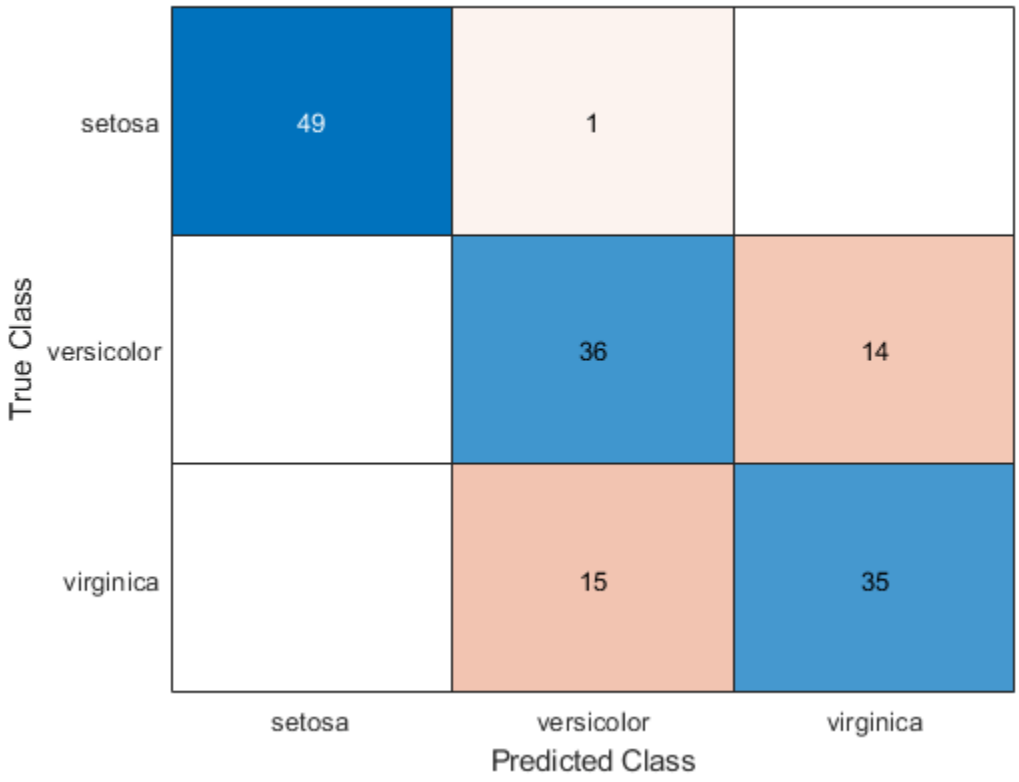
```
ldaResubErr = resubLoss(lda)
```

```
ldaResubErr =

    0.2000
```

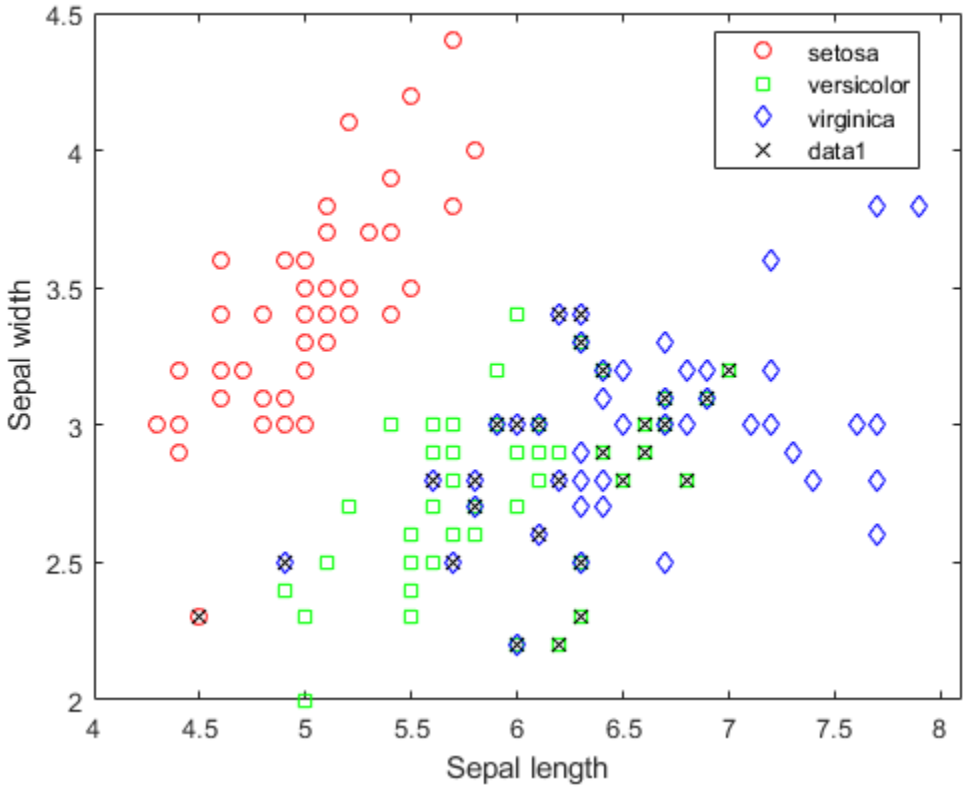
You can also compute the confusion matrix on the training set. A confusion matrix contains information about known class labels and predicted class labels. Generally speaking, the (i,j) element in the confusion matrix is the number of samples whose known class label is class i and whose predicted class is j. The diagonal elements represent correctly classified observations.

```
figure
ldaResubCM = confusionchart(species,ldaClass);
```



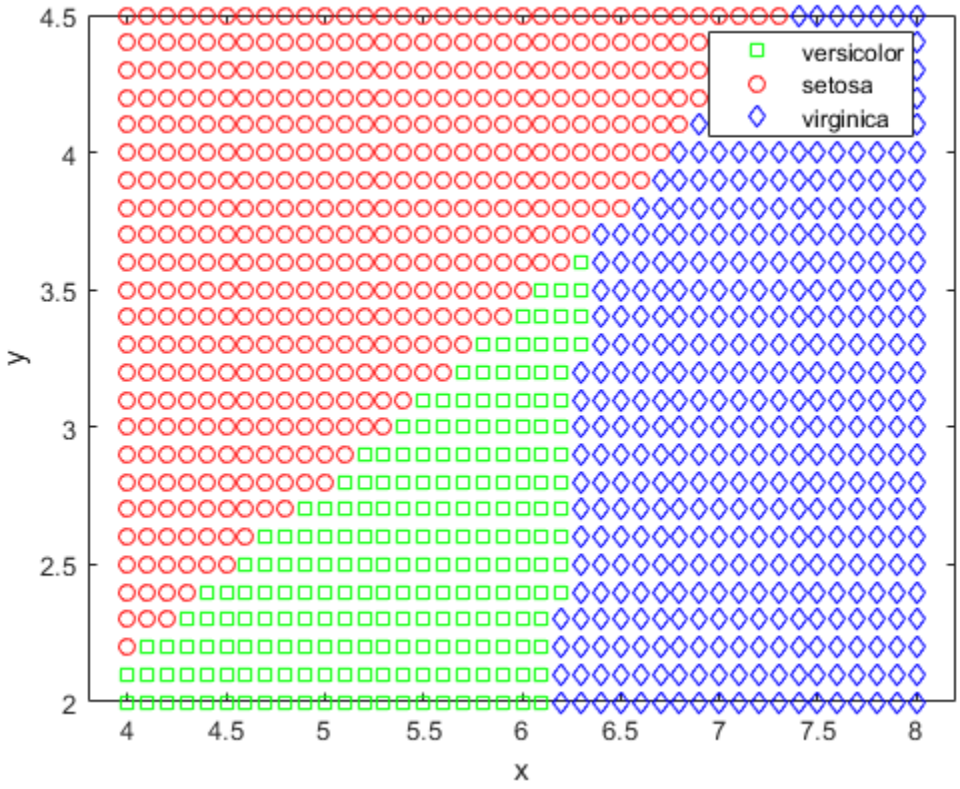
Of the 150 training observations, 20% or 30 observations are misclassified by the linear discriminant function. You can see which ones they are by drawing X through the misclassified points.

```
figure(f)
bad = ~strcmp(ldaClass,species);
hold on;
plot(meas(bad,1), meas(bad,2), 'kx');
hold off;
```



The function has separated the plane into regions divided by lines, and assigned different regions to different species. One way to visualize these regions is to create a grid of (x,y) values and apply the classification function to that grid.

```
[x,y] = meshgrid(4:.1:8,2:.1:4.5);
x = x(:);
y = y(:);
j = classify([x y],meas(:,1:2),species);
gscatter(x,y,j,'grb','sod')
```



For some data sets, the regions for the various classes are not well separated by lines. When that is the case, linear discriminant analysis is not appropriate. Instead, you can try quadratic discriminant analysis (QDA) for our data.

Compute the resubstitution error for quadratic discriminant analysis.

```
qda = fitcdiscr(meas(:,1:2),species,'DiscrimType','quadratic');
qdaResubErr = resubLoss(qda)
```

```
qdaResubErr =

    0.2000
```

You have computed the resubstitution error. Usually people are more interested in the test error (also referred to as generalization error), which is the expected prediction error on an independent set. In fact, the resubstitution error will likely under-estimate the test error.

In this case you don't have another labeled data set, but you can simulate one by doing cross-validation. A stratified 10-fold cross-validation is a popular choice for estimating the test error on classification algorithms. It randomly divides the training set into 10 disjoint subsets. Each subset has roughly equal size and roughly the same class proportions as in the training set. Remove one subset, train the classification model using the other nine subsets, and use the trained model to classify the removed subset. You could repeat this by removing each of the ten subsets one at a time.

Because cross-validation randomly divides data, its outcome depends on the initial random seed. To reproduce the exact results in this example, execute the following command:

```
rng(0,'twister');
```

First use `cvpartition` to generate 10 disjoint stratified subsets.

```
cp = cvpartition(species,'KFold',10)
```

```
cp =

K-fold cross validation partition
   NumObservations: 150
       NumTestSets: 10
         TrainSize: 135  135  135  135  135  135  135  135  135  135
          TestSize: 15  15  15  15  15  15  15  15  15  15
```

The `crossval` and `kfoldLoss` methods can estimate the misclassification error for both LDA and QDA using the given data partition `cp`.

Estimate the true test error for LDA using 10-fold stratified cross-validation.

```
cvlda = crossval(lda,'CVPartition',cp);
ldaCVErr = kfoldLoss(cvlda)
```

```
ldaCVErr =

    0.2000
```

The LDA cross-validation error has the same value as the LDA resubstitution error on this data.

Estimate the true test error for QDA using 10-fold stratified cross-validation.

```
cvqda = crossval(qda,'CVPartition',cp);
qdaCVErr = kfoldLoss(cvqda)
```

```
qdaCVErr =

    0.2200
```

QDA has a slightly larger cross-validation error than LDA. It shows that a simpler model may get comparable, or better performance than a more complicated model.

Naive Bayes Classifiers

The `fitcdiscr` function has other two other types, 'DiagLinear' and 'DiagQuadratic'. They are similar to 'linear' and 'quadratic', but with diagonal covariance matrix estimates. These diagonal choices are specific examples of a naive Bayes classifier, because they assume the variables are conditionally independent given the class label. Naive Bayes classifiers are among the most popular classifiers. While the assumption of class-conditional independence between variables is not true in general, naive Bayes classifiers have been found to work well in practice on many data sets.

The `fitcnb` function can be used to create a more general type of naive Bayes classifier.

First model each variable in each class using a Gaussian distribution. You can compute the resubstitution error and the cross-validation error.

```
nbGau = fitcnb(meas(:,1:2), species);
nbGauResubErr = resubLoss(nbGau)
nbGauCV = crossval(nbGau, 'CVPartition',cp);
nbGauCVErr = kfoldLoss(nbGauCV)

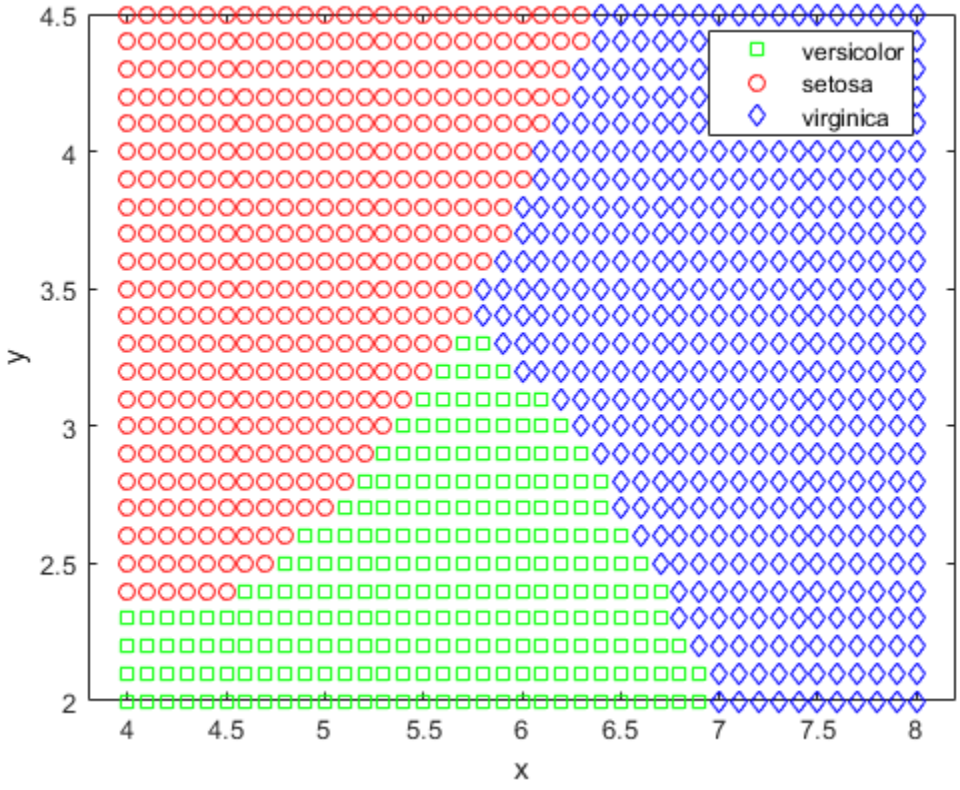
labels = predict(nbGau, [x y]);
gscatter(x,y,labels,'grb','sod')
```

```
nbGauResubErr =

    0.2200

nbGauCVErr =

    0.2200
```



So far you have assumed the variables from each class have a multivariate normal distribution. Often that is a reasonable assumption, but sometimes you may not be willing to make that assumption or you may see clearly that it is not valid. Now try to model each variable in each class using a kernel density estimation, which is a more flexible nonparametric technique. Here we set the kernel to `box`.

```
nbKD = fitcnb(meas(:,1:2), species, 'DistributionNames','kernel', 'Kernel','box');
nbKDResubErr = resubLoss(nbKD)
nbKDCV = crossval(nbKD, 'CVPartition',cp);
nbKDCVErr = kfoldLoss(nbKDCV)

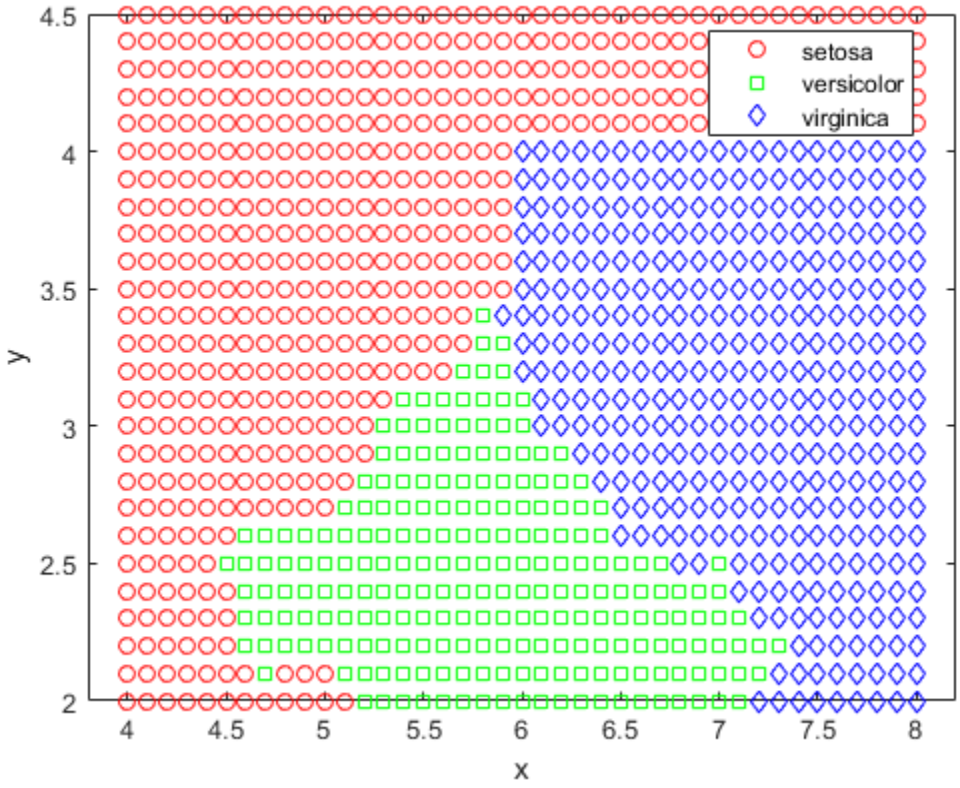
labels = predict(nbKD, [x y]);
gscatter(x,y,labels,'rgb','osd')
```

```
nbKDResubErr =

    0.2067

nbKDCVErr =

    0.2133
```



For this data set, the naive Bayes classifier with kernel density estimation gets smaller resubstitution error and cross-validation error than the naive Bayes classifier with a Gaussian distribution.

Decision Tree

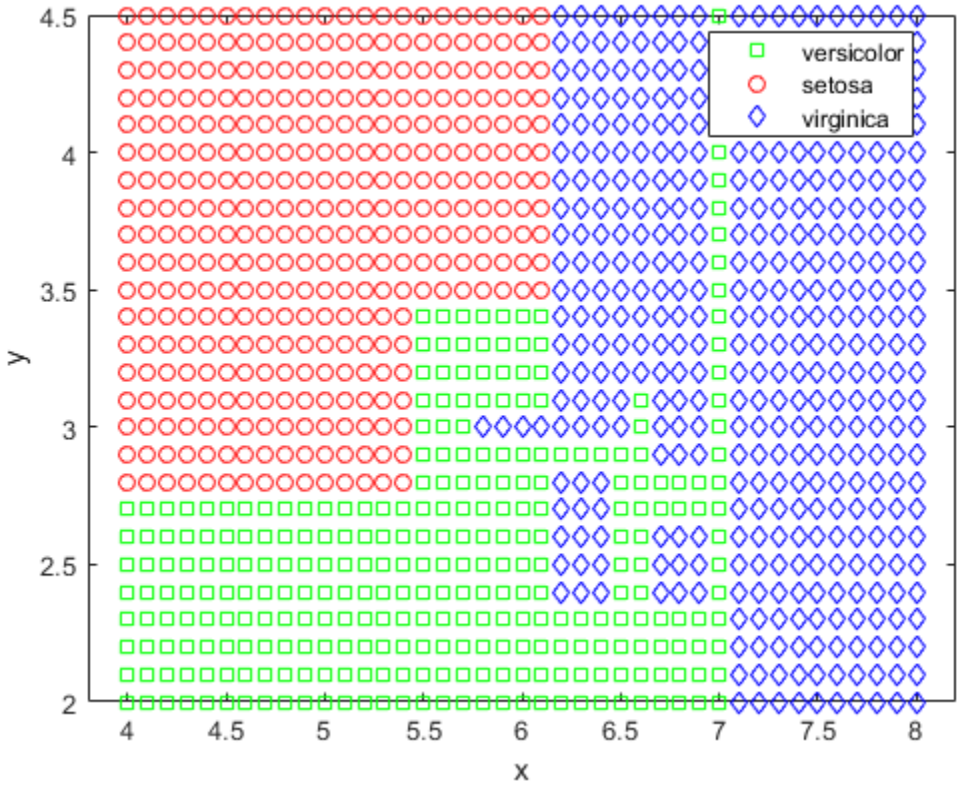
Another classification algorithm is based on a decision tree. A decision tree is a set of simple rules, such as "if the sepal length is less than 5.45, classify the specimen as setosa." Decision trees are also nonparametric because they do not require any assumptions about the distribution of the variables in each class.

The `fitctree` function creates a decision tree. Create a decision tree for the iris data and see how well it classifies the irises into species.

```
t = fitctree(meas(:,1:2), species,'PredictorNames',{'SL' 'SW' });
```

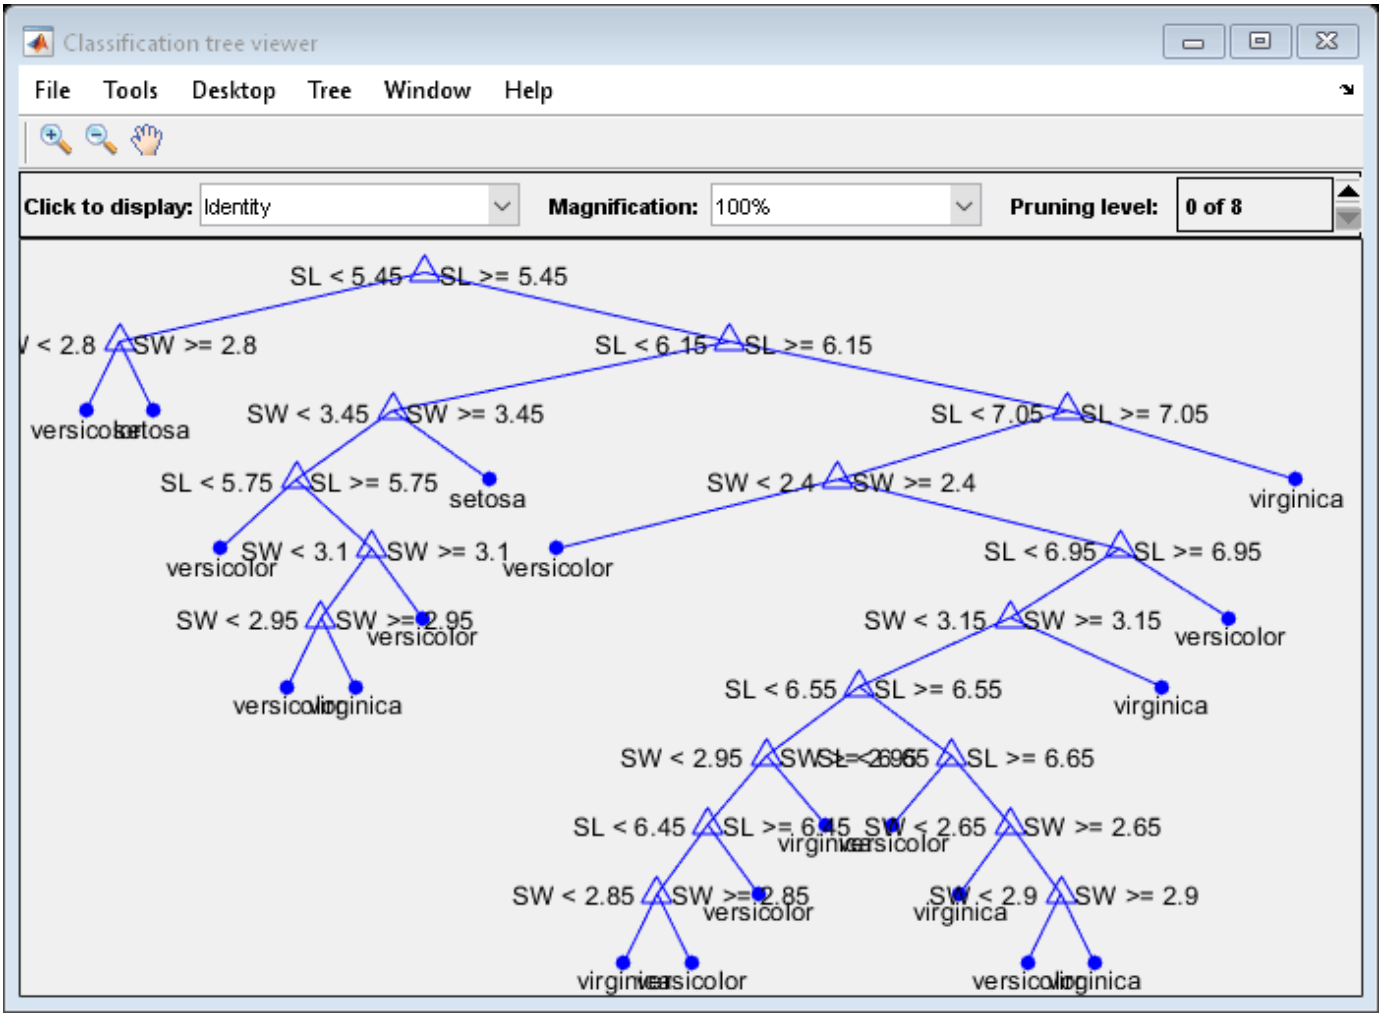
It's interesting to see how the decision tree method divides the plane. Use the same technique as above to visualize the regions assigned to each species.

```
[grpname,node] = predict(t,[x y]);
gscatter(x,y,grpname,'grb','sod')
```



Another way to visualize the decision tree is to draw a diagram of the decision rule and class assignments.

```
view(t,'Mode','graph');
```



This cluttered-looking tree uses a series of rules of the form "SL < 5.45" to classify each specimen into one of 19 terminal nodes. To determine the species assignment for an observation, start at the top node and apply the rule. If the point satisfies the rule you take the left path, and if not you take the right path. Ultimately you reach a terminal node that assigns the observation to one of the three species.

Compute the resubstitution error and the cross-validation error for decision tree.

```
dtResubErr = resubLoss(t)

cvt = crossval(t,'CVPartition',cp);
dtCVErr = kfoldLoss(cvt)
```

```
dtResubErr =

    0.1333

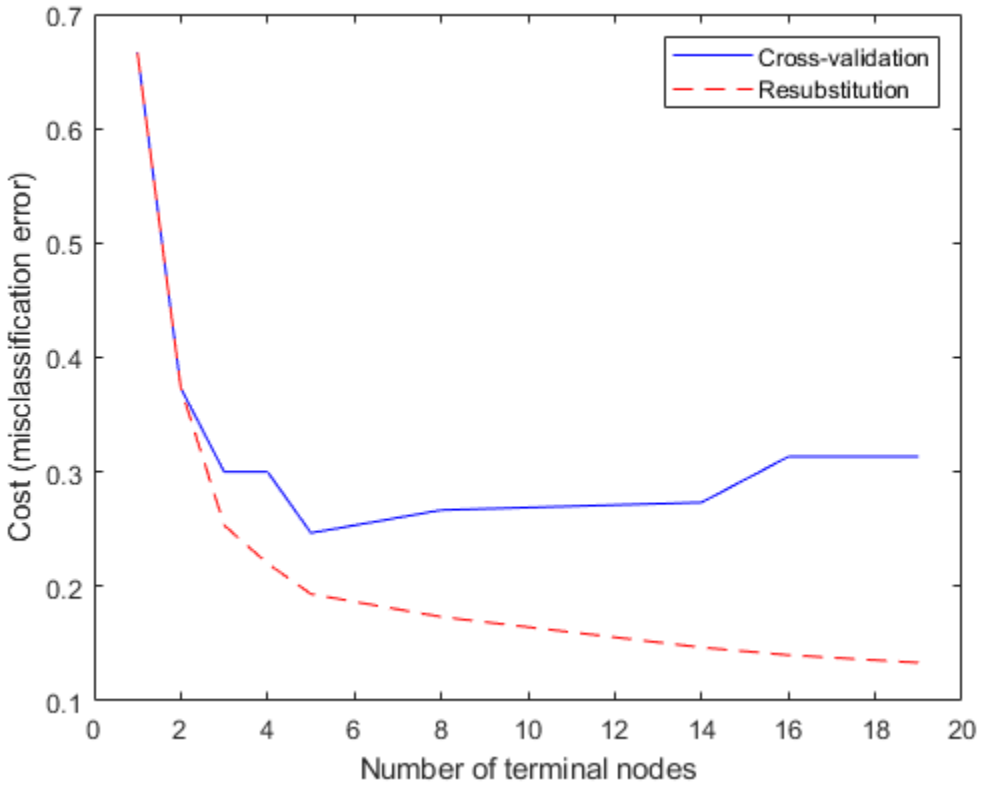
dtCVErr =
```

```
    0.3000
```

For the decision tree algorithm, the cross-validation error estimate is significantly larger than the resubstitution error. This shows that the generated tree overfits the training set. In other words, this is a tree that classifies the original training set well, but the structure of the tree is sensitive to this particular training set so that its performance on new data is likely to degrade. It is often possible to find a simpler tree that performs better than a more complex tree on new data.

Try pruning the tree. First compute the resubstitution error for various subsets of the original tree. Then compute the cross-validation error for these sub-trees. A graph shows that the resubstitution error is overly optimistic. It always decreases as the tree size grows, but beyond a certain point, increasing the tree size increases the cross-validation error rate.

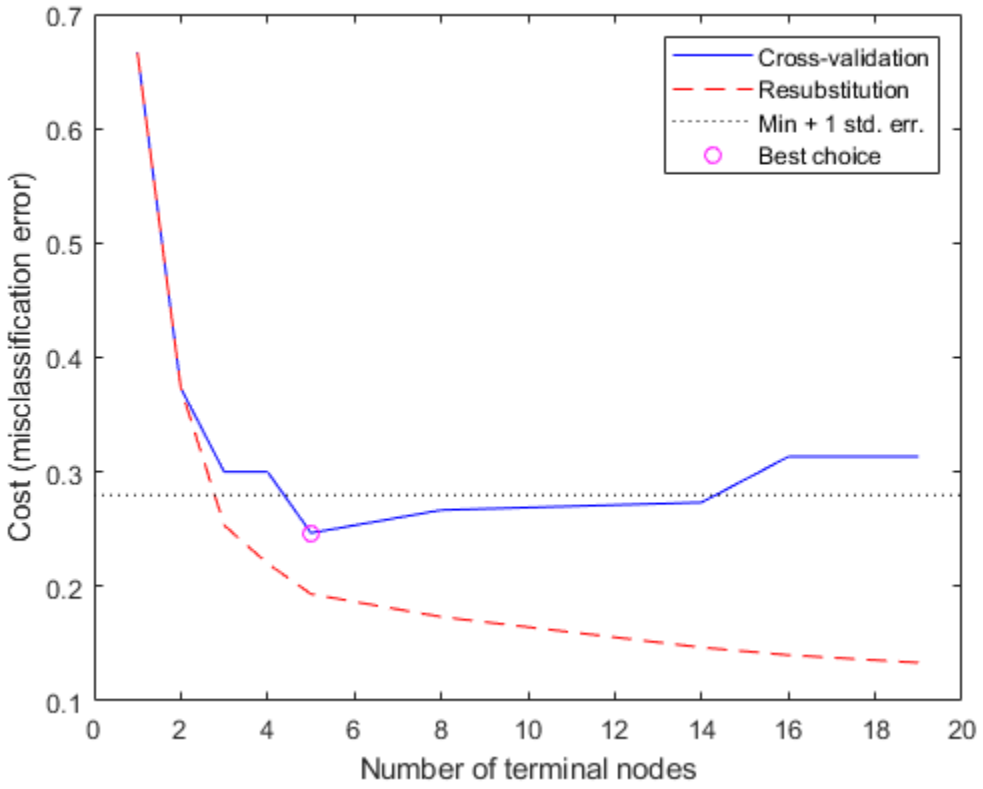
```
resubcost = resubLoss(t,'Subtrees','all');
[cost,secost,ntermnodes,bestlevel] = cvloss(t,'Subtrees','all');
plot(ntermnodes,cost,'b-', ntermnodes,resubcost,'r--')
figure(gcf);
xlabel('Number of terminal nodes');
ylabel('Cost (misclassification error)')
legend('Cross-validation','Resubstitution')
```



Which tree should you choose? A simple rule would be to choose the tree with the smallest cross-validation error. While this may be satisfactory, you might prefer to use a simpler tree if it is roughly as good as a more complex tree. For this example, take the simplest tree that is within one standard error of the minimum. That's the default rule used by the `cvloss` method of `ClassificationTree`.

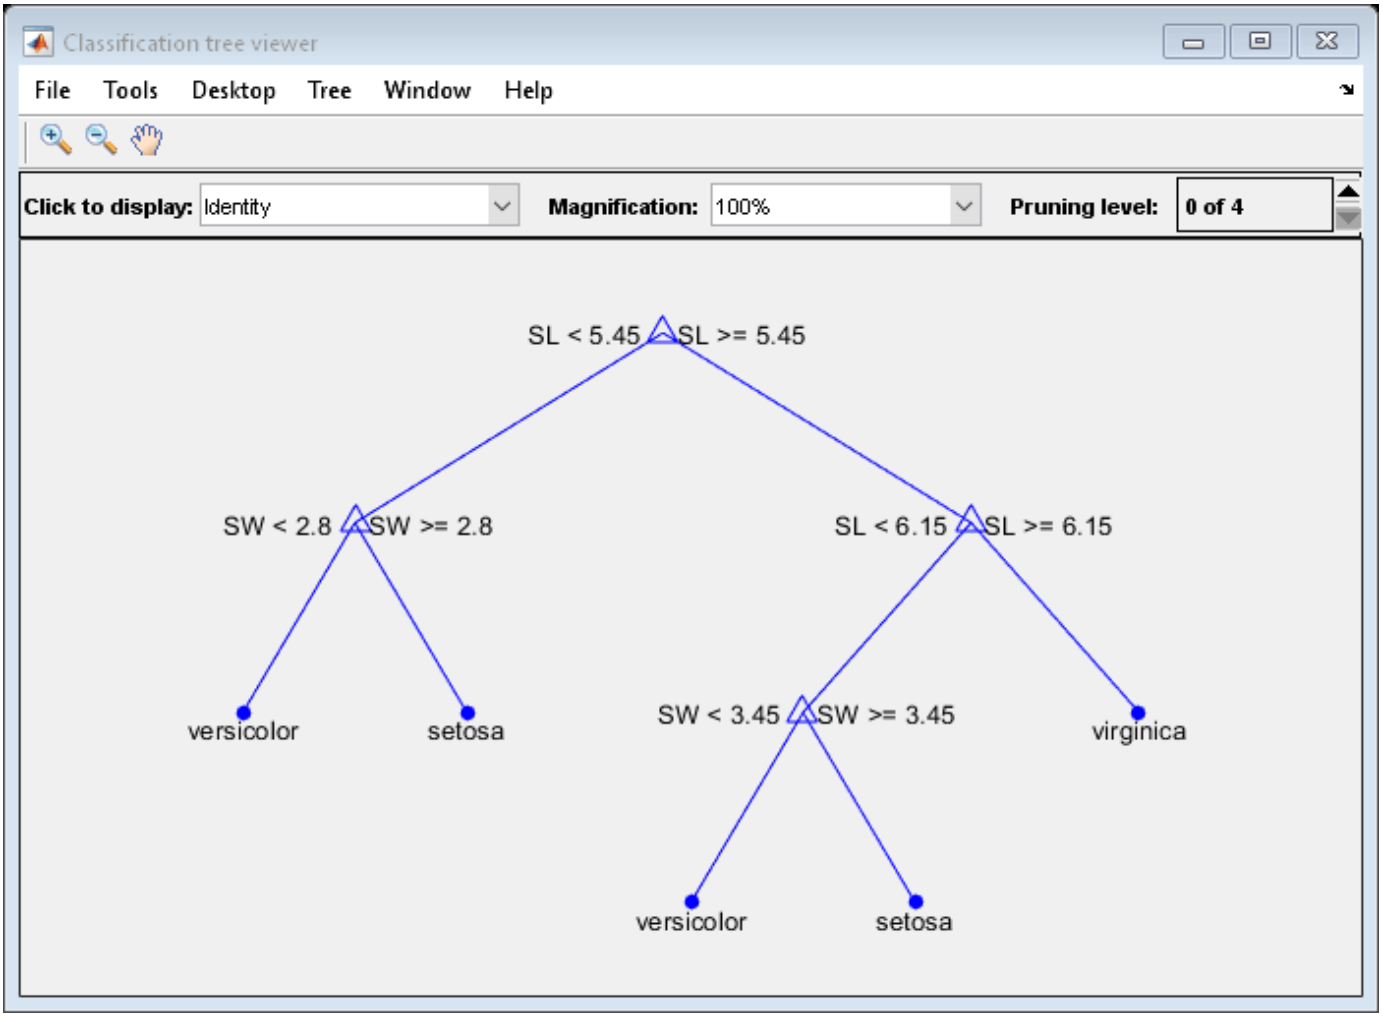
You can show this on the graph by computing a cutoff value that is equal to the minimum cost plus one standard error. The "best" level computed by the `cvloss` method is the smallest tree under this cutoff. (Note that `bestlevel=0` corresponds to the unpruned tree, so you have to add 1 to use it as an index into the vector outputs from `cvloss`.)

```
[mincost,minloc] = min(cost);
cutoff = mincost + secost(minloc);
hold on
plot([0 20], [cutoff cutoff], 'k:')
plot(ntermnodes(bestlevel+1), cost(bestlevel+1), 'mo')
legend('Cross-validation','Resubstitution','Min + 1 std. err.','Best choice')
hold off
```



Finally, you can look at the pruned tree and compute the estimated misclassification error for it.

```
pt = prune(t,'Level',bestlevel);
view(pt,'Mode','graph')
```



```
cost(bestlevel+1)

ans =

    0.2467
```

Conclusions

This example shows how to perform classification in MATLAB® using Statistics and Machine Learning Toolbox™ functions.

This example is not meant to be an ideal analysis of the Fisher iris data, In fact, using the petal measurements instead of, or in addition to, the sepal measurements may lead to better classification. Also, this example is not meant to compare the strengths and weaknesses of different classification algorithms. You may find it instructive to perform the analysis on other data sets and compare different algorithms. There are also Toolbox functions that implement other classification algorithms. For instance, you can use `TreeBagger` to perform bootstrap aggregation for an ensemble of decision trees, as described in the example “Bootstrap Aggregation (Bagging) of Classification Trees Using TreeBagger” on page 18-124.

Nonparametric Supervised Learning

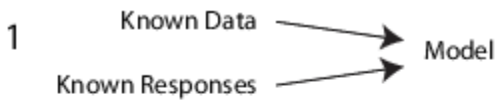
Supervised Learning Workflow and Algorithms

In this section...

What is Supervised Learning?

The aim of supervised, machine learning is to build a model that makes predictions based on evidence in the presence of uncertainty. As adaptive algorithms identify patterns in data, a computer "learns" from the observations. When exposed to more observations, the computer improves its predictive performance.

Specifically, a supervised learning algorithm takes a known set of input data and known responses to the data (output), and trains a model to generate reasonable predictions for the response to new data.



For example, suppose you want to predict whether someone will have a heart attack within a year. You have a set of data on previous patients, including age, weight, height, blood pressure, etc. You know whether the previous patients had heart attacks within a year of their measurements. So, the problem is combining all the existing data into a model that can predict whether a new person will have a heart attack within a year.

You can think of the entire set of input data as a heterogeneous matrix. Rows of the matrix are called observations, examples, or instances, and each contain a set of measurements for a subject (patients in the example). Columns of the matrix are called predictors, attributes, or features, and each are variables representing a measurement taken on every subject (age, weight, height, etc. in the example). You can think of the response data as a column vector where each row contains the output of the corresponding observation in the input data (whether the patient had a heart attack). To fit or train a supervised learning model, choose an appropriate algorithm, and then pass the input and response data to it.

Supervised learning splits into two broad categories: classification and regression.

- In classification, the goal is to assign a class (or label) from a finite set of classes to an observation. That is, responses are categorical variables. Applications include spam filters, advertisement recommendation systems, and image and speech recognition. Predicting whether a patient will have a heart attack within a year is a classification problem, and the possible classes

are `true` and `false`. Classification algorithms usually apply to nominal response values. However, some algorithms can accommodate ordinal classes (see `fitcecoc`).

- In regression, the goal is to predict a continuous measurement for an observation. That is, the responses variables are real numbers. Applications include forecasting stock prices, energy consumption, or disease incidence.

Statistics and Machine Learning Toolbox supervised learning functionalities comprise a stream-lined, object framework. You can efficiently train a variety of algorithms, combine models into an ensemble, assess model performances, cross-validate, and predict responses for new data.

Steps in Supervised Learning

While there are many Statistics and Machine Learning Toolbox algorithms for supervised learning, most use the same basic workflow for obtaining a predictor model. (Detailed instruction on the steps for ensemble learning is in “Framework for Ensemble Learning” on page 18-31.) The steps for supervised learning are:

1. “Prepare Data” on page 18-4
2. “Choose an Algorithm” on page 18-5
3. “Fit a Model” on page 18-5
4. “Choose a Validation Method” on page 18-5
5. “Examine Fit and Update Until Satisfied” on page 18-6
6. “Use Fitted Model for Predictions” on page 18-6

Prepare Data

All supervised learning methods start with an input data matrix, usually called `X` here. Each row of `X` represents one observation. Each column of `X` represents one variable, or predictor. Represent missing entries with `NaN` values in `X`. Statistics and Machine Learning Toolbox supervised learning algorithms can handle `NaN` values, either by ignoring them or by ignoring any row with a `NaN` value.

You can use various data types for response data `Y`. Each element in `Y` represents the response to the corresponding row of `X`. Observations with missing `Y` data are ignored.

- For regression, `Y` must be a numeric vector with the same number of elements as the number of rows of `X`.
- For classification, `Y` can be any of these data types. This table also contains the method of including missing entries.

Data Type	Missing Entry
Numeric vector	`NaN`
Categorical vector	`<undefined>`
Character array	Row of spaces
String array	`<missing>` or `""`
Cell array of character vectors	`''`
Logical vector	(Cannot represent)

Choose an Algorithm

There are tradeoffs between several characteristics of algorithms, such as:

- Speed of training
- Memory usage
- Predictive accuracy on new data
- Transparency or interpretability, meaning how easily you can understand the reasons an algorithm makes its predictions

Details of the algorithms appear in “Characteristics of Classification Algorithms” on page 18-7. More detail about ensemble algorithms is in “Choose an Applicable Ensemble Aggregation Method” on page 18-32.

Fit a Model

The fitting function you use depends on the algorithm you choose.

Algorithm	Fitting Function
Classification Trees	`fitctree`
Regression Trees	`fitrtree`
Discriminant Analysis (classification)	`fitcdiscr`
k-Nearest Neighbors (classification)	`fitcknn`
Naive Bayes (classification)	`fitcnb`
Support Vector Machines (SVM) for classification	`fitcsvm`
SVM for regression	`fitrsvm`
Multiclass models for SVM or other classifiers	`fitcecoc`
Classification Ensembles	`fitcensemble`
Regression Ensembles	`fitrensemble`
Classification or Regression Tree Ensembles (e.g., Random Forests [1])	`TreeBagger`

For a comparison of these algorithms, see “Characteristics of Classification Algorithms” on page 18-7.

Choose a Validation Method

The three main methods to examine the accuracy of the resulting fitted model are:

- Examine the resubstitution error. For examples, see:
  - “Classification Tree Resubstitution Error” on page 19-13
  - “Cross Validate a Regression Tree” on page 19-14
  - “Test Ensemble Quality” on page 18-66
  - “Example: Resubstitution Error of a Discriminant Analysis Classifier” on page 20-16
- Examine the cross-validation error. For examples, see:

- “Cross Validate a Regression Tree” on page 19-14
- “Test Ensemble Quality” on page 18-66
- “Estimate Generalization Error of Boosting Ensemble” on page 33-1653
- “Cross Validating a Discriminant Analysis Classifier” on page 20-17

- Examine the out-of-bag error for bagged decision trees. For examples, see:
  - “Test Ensemble Quality” on page 18-66
  - “Bootstrap Aggregation (Bagging) of Regression Trees Using TreeBagger” on page 18-113
  - “Bootstrap Aggregation (Bagging) of Classification Trees Using TreeBagger” on page 18-124

Examine Fit and Update Until Satisfied

After validating the model, you might want to change it for better accuracy, better speed, or to use less memory.

- Change fitting parameters to try to get a more accurate model. For examples, see:
  - “Tune RobustBoost” on page 18-101
  - “Handle Imbalanced Data or Unequal Misclassification Costs in Classification Ensembles” on page 18-84
  - “Improving Discriminant Analysis Models” on page 20-15
- Change fitting parameters to try to get a smaller model. This sometimes gives a model with more accuracy. For examples, see:
  - “Select Appropriate Tree Depth” on page 19-16
  - “Prune a Classification Tree” on page 19-20
  - “Surrogate Splits” on page 18-91
  - “Ensemble Regularization” on page 18-70
  - “Bootstrap Aggregation (Bagging) of Regression Trees Using TreeBagger” on page 18-113
  - “Bootstrap Aggregation (Bagging) of Classification Trees Using TreeBagger” on page 18-124
- Try a different algorithm. For applicable choices, see:
  - “Characteristics of Classification Algorithms” on page 18-7
  - “Choose an Applicable Ensemble Aggregation Method” on page 18-32

When satisfied with a model of some types, you can trim it using the appropriate `compact` function (`compact` for classification trees, `compact` for regression trees, `compact` for discriminant analysis, `compact` for naive Bayes, `compact` for SVM, `compact` for ECOC models, `compact` for classification ensembles, and `compact` for regression ensembles). `compact` removes training data and other properties not required for prediction, e.g., pruning information for decision trees, from the model to reduce memory consumption. Because *k*NN classification models require all of the training data to predict labels, you cannot reduce the size of a `ClassificationKNN` model.

Use Fitted Model for Predictions

To predict classification or regression response for most fitted models, use the `predict` method:

```
Ypredicted = predict(obj,Xnew)
```

- `obj` is the fitted model or fitted compact model.
- `Xnew` is the new input data.
- `Ypredicted` is the predicted response, either classification or regression.

Characteristics of Classification Algorithms

This table shows typical characteristics of the various supervised learning algorithms. The characteristics in any particular case can vary from the listed ones. Use the table as a guide for your initial choice of algorithms. Decide on the tradeoff you want in speed, memory usage, flexibility, and interpretability.

Tip Try a decision tree or discriminant first, because these classifiers are fast and easy to interpret. If the models are not accurate enough predicting the response, try other classifiers with higher flexibility.

To control flexibility, see the details for each classifier type. To avoid overfitting, look for a model of lower flexibility that provides sufficient accuracy.

Classifier	Multiclass Support	Categorical Predictor Support on page 18-8	Prediction Speed	Memory Usage	Interpretability
"Decision Trees" on page 19-2 — `fitctree`	Yes	Yes	Fast	Small	Easy
Discriminant analysis on page 20-2 — `fitcdiscr`	Yes	No	Fast	Small for linear, large for quadratic	Easy
SVM on page 18-150 — `fitcsvm`	No. Combine multiple binary SVM classifiers using `fitcecoc`.	Yes	Medium for linear. Slow for others.	Medium for linear. All others: medium for multiclass, large for binary.	Easy for linear SVM. Hard for all other kernel types.
Naive Bayes on page 21-2 — `fitcnb`	Yes	Yes	Medium for simple distributions. Slow for kernel distributions or high-dimensional data	Small for simple distributions. Medium for kernel distributions or high-dimensional data	Easy
Nearest neighbor on page 18-12 — `fitcknn`	Yes	Yes	Slow for cubic. Medium for others.	Medium	Hard

Classifier	Multiclass Support	Categorical Predictor Support on page 18-8	Prediction Speed	Memory Usage	Interpretability
Ensembles on page 18-31 — `fitcensemble` and `fitrensemble`	Yes	Yes	Fast to medium depending on choice of algorithm	Low to high depending on choice of algorithm.	Hard

The results in this table are based on an analysis of many data sets. The data sets in the study have up to 7000 observations, 80 predictors, and 50 classes. This list defines the terms in the table.

Speed:

- Fast — 0.01 second
- Medium — 1 second
- Slow — 100 seconds

Memory

- Small — 1MB
- Medium — 4MB
- Large — 100MB

Note The table provides a general guide. Your results depend on your data and the speed of your machine.

Categorical Predictor Support

This table describes the data-type support of predictors for each classifier.

Classifier	All predictors numeric	All predictors categorical	Some categorical, some numeric
Decision Trees	Yes	Yes	Yes
Discriminant Analysis	Yes	No	No
SVM	Yes	Yes	Yes
Naive Bayes	Yes	Yes	Yes
Nearest Neighbor	Euclidean distance only	Hamming distance only	No
Ensembles	Yes	Yes, except subspace ensembles of discriminant analysis classifiers	Yes, except subspace ensembles

Visualize Decision Surfaces of Different Classifiers

This example shows how to plot the decision surface of different classification algorithms.

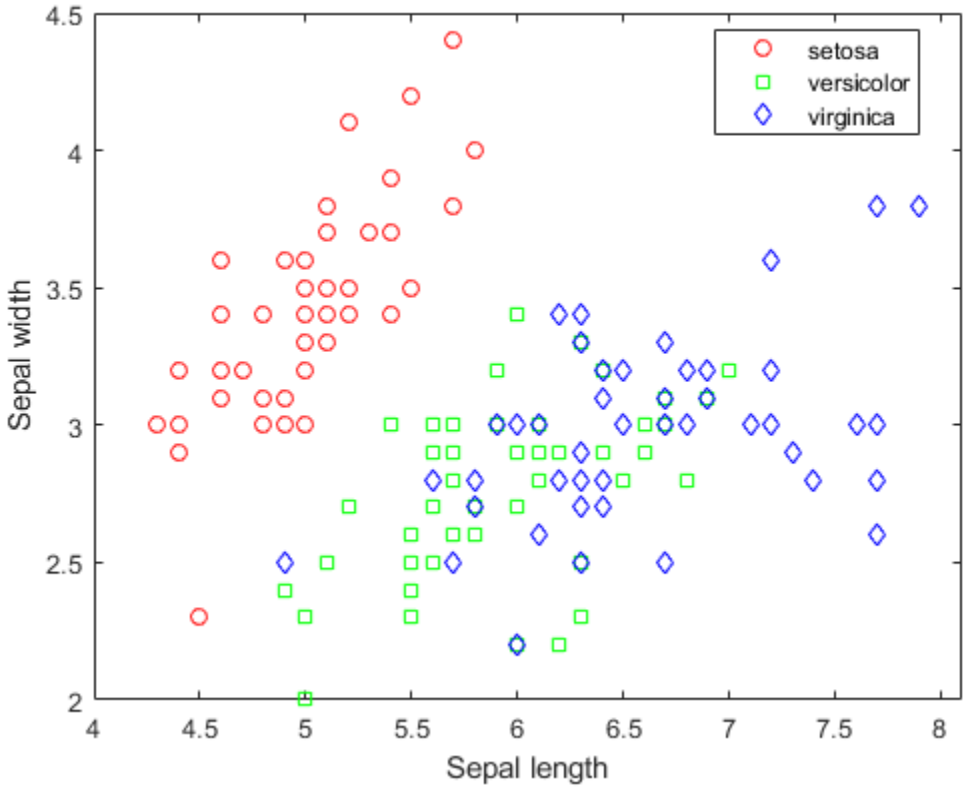
Load Fisher's iris data set.

```
load fisheriris
X = meas(:,1:2);
y = categorical(species);
labels = categories(y);
```

X is a numeric matrix that contains two petal measurements for 150 irises. Y is a cell array of character vectors that contains the corresponding iris species.

Visualize the data using a scatter plot. Group the variables by iris species.

```
gscatter(X(:,1),X(:,2),species,'rgb','osd');
xlabel('Sepal length');
ylabel('Sepal width');
```



Train four different classifiers and store the models in a cell array.

```
classifier_name = {'Naive Bayes','Discriminant Analysis','Classification Tree','Nearest Neighbor
```

Train a naive Bayes model.

```
classifier{1} = fitcnb(X,y);
```

Train a discriminant analysis classifier.

```
classifier{2} = fitcdiscr(X,y);
```

Train a classification decision tree.

```
classifier{3} = fitctree(X,y);
```

Train a *k*-nearest neighbor classifier.

```
classifier{4} = fitcknn(X,y);
```

Create a grid of points spanning the entire space within some bounds of the actual data values.

```
x1range = min(X(:,1)):.01:max(X(:,1));
x2range = min(X(:,2)):.01:max(X(:,2));
[xx1, xx2] = meshgrid(x1range,x2range);
XGrid = [xx1(:) xx2(:)];
```

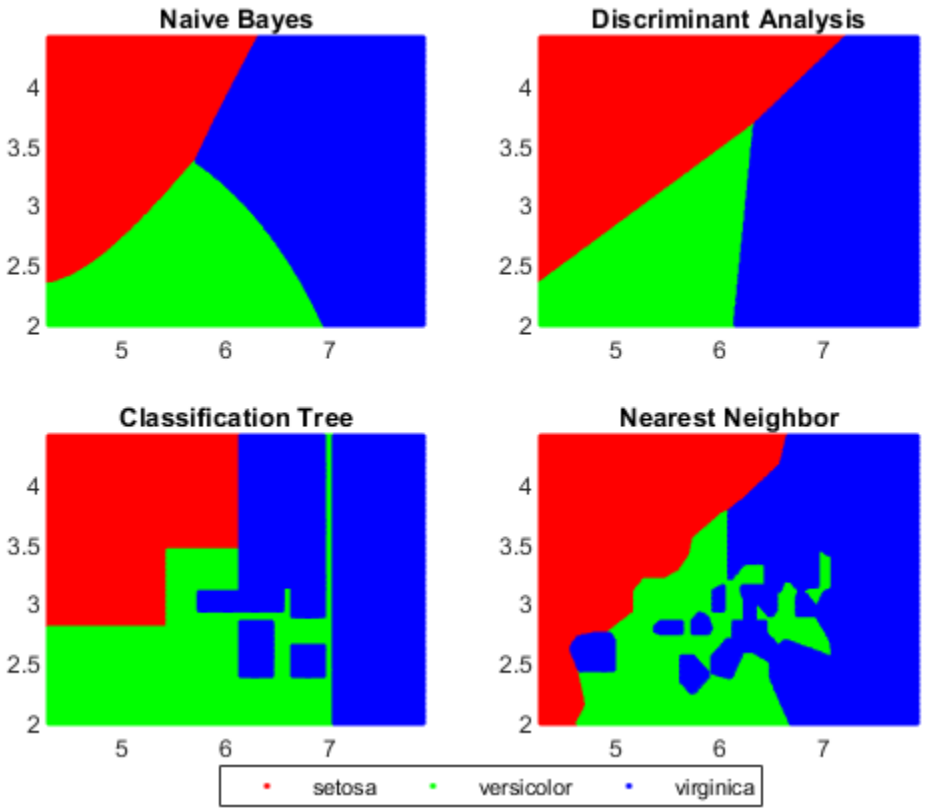
Predict the iris species of each observation in `XGrid` using all classifiers. Plot the a scatter plot of the results.

```
for i = 1:numel(classifier)
   predictedspecies = predict(classifier{i},XGrid);

   subplot(2,2,i);
   gscatter(xx1(:), xx2(:), predictedspecies,'rgb');

   title(classifier_name{i})
   legend off, axis tight
end

legend(labels,'Location',[0.35,0.01,0.35,0.05],'Orientation','Horizontal')
```



Each classification algorithm generates different decision making rules. A decision surface can help you visualize these rules.

Classification Using Nearest Neighbors

In this section...

Pairwise Distance Metrics

Categorizing query points based on their distance to points in a training data set can be a simple yet effective way of classifying new points. You can use various metrics to determine the distance, described next. Use `pdist2` to find the distance between a set of data and query points.

Distance Metrics

Given an mx-by-n data matrix X, which is treated as mx (1-by-n) row vectors x_1, x_2, ..., x_{mx}, and an my-by-n data matrix Y, which is treated as my (1-by-n) row vectors y_1, y_2, ...,y_{my}, the various distances between the vector x_s and y_t are defined as follows:

- Euclidean distance

  $$d_{st}^2 = (x_s - y_t)(x_s - y_t)' .$$

  The Euclidean distance is a special case of the Minkowski distance, where $p = 2$.
- Standardized Euclidean distance

  $$d_{st}^2 = (x_s - y_t)V^{-1}(x_s - y_t)',$$

  where V is the n-by-n diagonal matrix whose jth diagonal element is $(S(j))^2$, where S is a vector of scaling factors for each dimension.
- Mahalanobis distance

  $$d_{st}^2 = (x_s - y_t)C^{-1}(x_s - y_t)',$$

  where C is the covariance matrix.
- City block distance

  $$d_{st} = \sum_{j=1}^{n} \left| x_{sj} - y_{tj} \right| .$$

  The city block distance is a special case of the Minkowski distance, where $p = 1$.

- Minkowski distance

$$d_{st} = \sqrt[p]{\sum_{j=1}^{n} \left|x_{sj} - y_{tj}\right|^p}.$$

For the special case of $p = 1$, the Minkowski distance gives the city block distance. For the special case of $p = 2$, the Minkowski distance gives the Euclidean distance. For the special case of $p = \infty$, the Minkowski distance gives the Chebychev distance.

- Chebychev distance

$$d_{st} = \max_j\left\{\left|x_{sj} - y_{tj}\right|\right\}.$$

The Chebychev distance is a special case of the Minkowski distance, where $p = \infty$.

- Cosine distance

$$d_{st} = \left(1 - \frac{x_s y'_t}{\sqrt{(x_s x'_s)(y_t y'_t)}}\right).$$

- Correlation distance

$$d_{st} = 1 - \frac{(x_s - \bar{x}_s)(y_t - \bar{y}_t)'}{\sqrt{(x_s - \bar{x}_s)(x_s - \bar{x}_s)'}\sqrt{(y_t - \bar{y}_t)(y_t - \bar{y}_t)'}},$$

where

$$\bar{x}_s = \frac{1}{n}\sum_j x_{sj}$$

and

$$\bar{y}_t = \frac{1}{n}\sum_j y_{tj}.$$

- Hamming distance

$$d_{st} = \left(\#\left(x_{sj} \neq y_{tj}\right)/n\right).$$

- Jaccard distance

$$d_{st} = \frac{\#\left[\left(x_{sj} \neq y_{tj}\right) \cap \left(\left(x_{sj} \neq 0\right) \cup \left(y_{tj} \neq 0\right)\right)\right]}{\#\left[\left(x_{sj} \neq 0\right) \cup \left(y_{tj} \neq 0\right)\right]}.$$

- Spearman distance

$$d_{st} = 1 - \frac{(r_s - \bar{r}_s)(r_t - \bar{r}_t)'}{\sqrt{(r_s - \bar{r}_s)(r_s - \bar{r}_s)'}\sqrt{(r_t - \bar{r}_t)(r_t - \bar{r}_t)'}},$$

where

  - r_{sj} is the rank of x_{sj} taken over x_{1j}, x_{2j}, ...$x_{mx,j}$, as computed by `tiedrank`.
  - r_{tj} is the rank of y_{tj} taken over y_{1j}, y_{2j}, ...$y_{my,j}$, as computed by `tiedrank`.
  - r_s and r_t are the coordinate-wise rank vectors of x_s and y_t, that is, $r_s = (r_{s1}, r_{s2}, \ldots r_{sn})$ and $r_t = (r_{t1}, r_{t2}, \ldots r_{tn})$.

- $\bar{r}_s = \frac{1}{n}\sum_j r_{sj} = \frac{(n+1)}{2}$.
- $\bar{r}_t = \frac{1}{n}\sum_j r_{tj} = \frac{(n+1)}{2}$.

k-Nearest Neighbor Search and Radius Search

Given a set X of n points and a distance function, k-nearest neighbor (kNN) search lets you find the k closest points in X to a query point or set of points `Y`. The kNN search technique and kNN-based algorithms are widely used as benchmark learning rules. The relative simplicity of the kNN search technique makes it easy to compare the results from other classification techniques to kNN results. The technique has been used in various areas such as:

- bioinformatics
- image processing and data compression
- document retrieval
- computer vision
- multimedia database
- marketing data analysis

You can use kNN search for other machine learning algorithms, such as:

- kNN classification
- local weighted regression
- missing data imputation and interpolation
- density estimation

You can also use kNN search with many distance-based learning functions, such as K-means clustering.

In contrast, for a positive real value `r`, `rangesearch` finds all points in `X` that are within a distance `r` of each point in `Y`. This fixed-radius search is closely related to kNN search, as it supports the same distance metrics and search classes, and uses the same search algorithms.

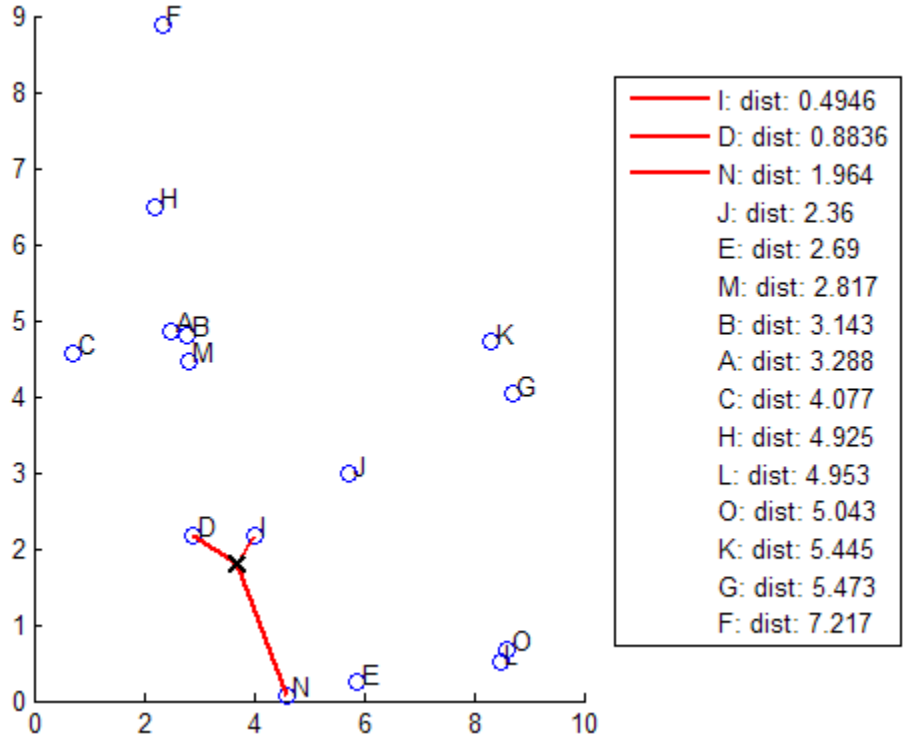
k-Nearest Neighbor Search Using Exhaustive Search

When your input data meets any of the following criteria, `knnsearch` uses the exhaustive search method by default to find the k-nearest neighbors:

- The number of columns of `X` is more than 10.
- `X` is sparse.
- The distance metric is either:
  - `'seuclidean'`
  - `'mahalanobis'`
  - `'cosine'`
  - `'correlation'`
  - `'spearman'`

- `'hamming'`
- `'jaccard'`
- A custom distance function

`knnsearch` also uses the exhaustive search method if your search object is an `ExhaustiveSearcher` model object. The exhaustive search method finds the distance from each query point to every point in `X`, ranks them in ascending order, and returns the k points with the smallest distances. For example, this diagram shows the $k = 3$ nearest neighbors.



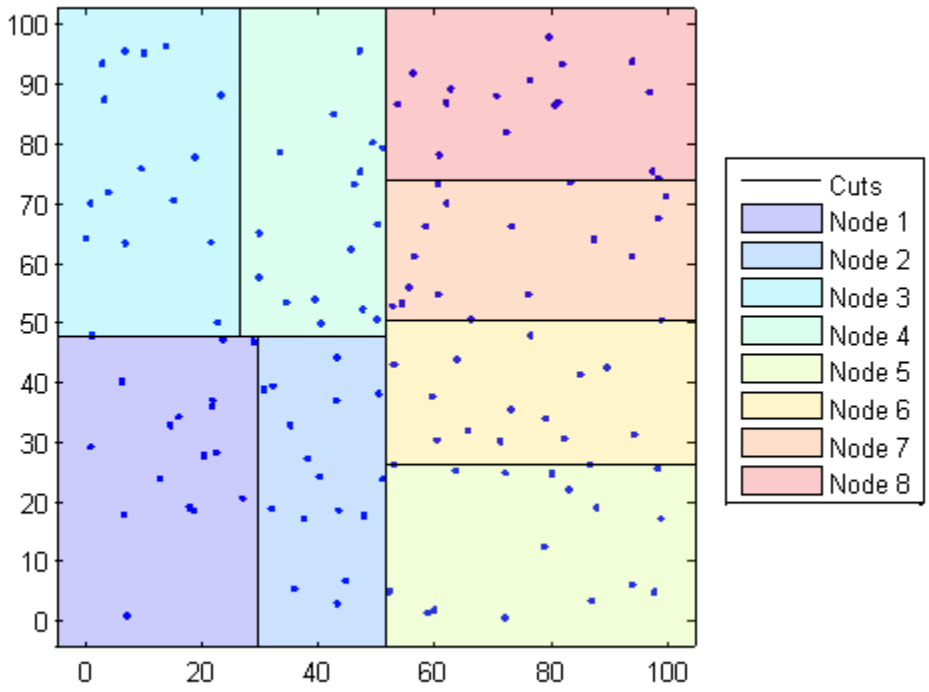
k-Nearest Neighbor Search Using a Kd-Tree

When your input data meets all of the following criteria, `knnsearch` creates a *K*d-tree by default to find the k-nearest neighbors:

- The number of columns of `X` is less than 10.
- `X` is not sparse.
- The distance metric is either:
  - `'euclidean'` (default)
  - `'cityblock'`
  - `'minkowski'`
  - `'chebychev'`

`knnsearch` also uses a *K*d-tree if your search object is a `KDTreeSearcher` model object.

*K*d-trees divide your data into nodes with at most `BucketSize` (default is 50) points per node, based on coordinates (as opposed to categories). The following diagrams illustrate this concept using `patch` objects to color code the different "buckets."



When you want to find the *k*-nearest neighbors to a given query point, `knnsearch` does the following:

1. Determines the node to which the query point belongs. In the following example, the query point (32,90) belongs to Node 4.
2. Finds the closest *k* points within that node and its distance to the query point. In the following example, the points in red circles are equidistant from the query point, and are the closest points to the query point within Node 4.
3. Chooses all other nodes having any area that is within the same distance, in any direction, from the query point to the *k*th closest point. In this example, only Node 3 overlaps the solid black circle centered at the query point with radius equal to the distance to the closest points within Node 4.
4. Searches nodes within that range for any points closer to the query point. In the following example, the point in a red square is slightly closer to the query point than those within Node 4.
